The Molecular Conformation of 1*e*,2*a*,6*e*-Trimethyl-4*e*-phenyl-4*a*-acetoxypiperidine Hydrobomide in the Crystalline State

K. HAYAKAWA AND M. N. G. JAMES

Department of Biochemistry, University of Alberta, Edmonton, Alberta

Received November 2, 1972

The title compound represents one analog of the synthetic 4-phenylpiperidine narcotic analgesics. The crystal structure was determined by the heavy-atom method from data collected on an automated diffractometer. The crystals are monoclinic, space group $P2_1/c$, with unit cell dimensions $a = 11.833$ Å, $b = 11.551$ Å, $c = 14.659$ Å and $\beta = 121° 9'$. The final residual, R, was 0.056. The stereochemistry of the substituents on the piperidine ring as deduced by this structural determination (1*e*,2*a*,6*e*-trimethyl-4*e*-phenyl-4*a*-acetoxypiperidine) confirms the p.m.r. results on the alcohol precursor as *trans* 2-Me/6-Me and *trans* 2-Me/4-Ph. There is a normal length N—H...Br hydrogen bond of 3.234 Å; most intramolecular bond lengths and angles are within the expected ranges but some distortion of the ideal chair conformation of the piperidine ring occurs.

Le composé mentionné dans le titre représente un analogue des analgésiques synthétiques de la série des narcotiques dérivés de la phényl-4 pipéridine. La structure cristalline a été élucidée par la méthode de l'atome lourd à partir de données recueuillies sur un diffractomètre automatique. Les cristaux sont du type monoclinique appartenant au groupe $P2_1$-*c* et possèdent une maille dont les dimensions sont $a = 11.833$ Å, $b = 11.511$ Å, $c = 14.659$ Å et $\beta = 121° 9'$. Le résidu final, R, a été 0.056. La stéréochimie des substituants sur l'anneau pipéridine déduite par l'élucidation de la structure (triméthyl-1*e*,2*a*,6*e* phényl-4*e* acétoxy-4*a* pipéridine) a confirmé les résultats en r.m.n. sur le précurseur alcoolique comme étant *trans* 2-Me/6-Me et *trans* 2-Me/4-Ph. La longueur de la liaison hydrogène N—H...Br est normale et égale à 3.234 Å; la plupart des longueurs de liaison intramoléculaires et des angles se situent à l'intérieur du domaine prévu mais on a noté sur l'anneau pipéridine une certaine déformation comparativement à la conformation du type chaise idéale. [Traduit par le journal]

Can. J. Chem., **51**, 1535 (1973)

Introduction

Various synthetic 4-phenylpiperidine derivatives are in wide clinical use as analgetics; many of these compounds are more potent than the classic analgetic, morphine. The best known and original member of these synthetic analgetics is pethidine (meperidine, **1**), and the crystal structure of its hydrobromide salt has recently been reported (1). A variety of substituents on the piperidine ring and their configurational isomers have been studied with the view to increasing the analgetic potency and at the same time reducing the addiction liability. Little success in the latter direction has been achieved. Replacing the 4-CO_2Et group by 4-OCOEt, giving the so-called reversed esters of pethidine, enhances the analgetic potency in mice by 5–6-fold (2). The positional and configurational isomers of methyl substituents on the piperidine ring have also been widely studied with the view to elucidating the pharmacological determinants of this system. A recent paper by Casy and McErlane (3) presented data relating the pharmacological activity of trimeperidine (γ-promedol, **4**) with the stereochemistry of its other isomers, α and β (**2** and **3** respectively). The most active isomer is the α-promedol (**2**) in the nomenclature suggested by Vlasova and Sheinker (4). Jones *et al.* (5) have corrected the configurational assignments originally described in ref. 3 for the α and β isomers and these have also been confirmed by X-ray structure analysis (6–9) of the α, β, and γ promedol alcohols. Earlier, X-ray studies on alphaprodine (**5**) and betaprodine (**6**) (isomers of 1,3-dimethyl-4-phenyl-4-propionoxypiperidine) showed conclusively that the more potent betaprodine has the 3Me in an axial orientation with a *cis* 3-Me/4-Ph configuration (10,11). This *cis* 3-Me/4-Ph geometry is also observed in the α-promedol (**2**) isomer and suggests it is an important analgetic factor (3). The configuration of the 2-methyl group apparently has little influence on the activity of 4-phenylpiperidine analgetics (3). Although there is little analgetic potency data on the 1,2,6-trimethyl analogs, the details of the stereochem-

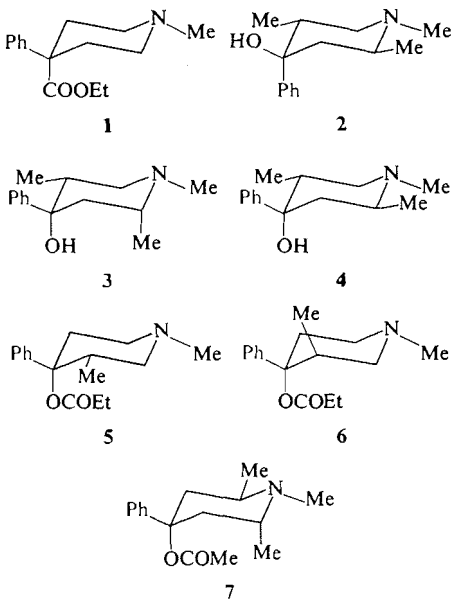
For personal use only.



istry of these compounds is unknown. The isomer used in the present study (7) exhibits twice the analgetic potency in mice as does pethidine (12). With the view to carrying out an independent determination of the molecular configuration (unpublished results by Casy suggests *trans* 2-Me/6-Me and *trans* 2-Me/4-Ph) and in addition, supplying details of the molecular geometry, this structural study of one of the isomers of 1,2,6-trimethyl-4-phenyl-4-acetoxypiperidine hydrobromide was carried out.

Experimental

A sample of 1,2,6-trimethyl-4-phenyl-4-acetoxypiperidine hydrobromide was kindly supplied by Dr. A. F. Casy of the Pharmacy Department, University of Alberta. The sample was recrystallized by vapor diffusion of diethyl ether into a solution of the compound in 50% ethanol, 50% methanol. Crystals of a flat needle habit resulted from this recrystallization and preliminary precession photography showed the space group $P2_1/c$. The density was measured by floatation in a mixture of bromobenzene and chlorobenzene. The crystal data are included in Table 1. The measured density, d_m, the cell volume, V, and a cell content of 4 formula units confirms the molecular weight and the fact there was no solvent of crystallization present in these crystals.

The cell dimensions were determined during the initial alignment of the crystal on a FACS-1 automated diffractometer. The accurately centered angles for 12 reflections were used in a least-squares process (13) that simultaneously refined the cell dimensions and the orientation matrix for the reciprocal lattice parameters with respect to the goniostat. The refined cell dimensions are included in Table 1.

TABLE 1. Crystal data for 1,2,6-trimethyl-4-phenyl-4-acetoxypiperidine hydrobromide

Parameter	Value
Formula	$C_{16}H_{24}NO_2Br$
Molecular weight	342.3 daltons
Space group	$P2_1/c$
Cell dimensions	
a	11.833(2) Å
b	11.551(3) Å
c	14.659(3) Å
β	121° 9′
V	1714.2 Å^3
Density	
d_m	1.333 g cm^{-3}
d_c	1.326 g cm^{-3}
Cell content	
Z	4
Absorption coefficient	
μ (MoK$_\alpha$)	25.4 cm^{-1}
F(000)	712 e

The intensity data were collected from a crystal of dimensions 0.5 × 0.4 × 0.2 mm, mounted with the b axis coincident with the phi shaft of the goniostat. The incident X-radiation used was graphite monochromatized MoK$_{\bar{\alpha}}$ (λ = 0.71069 Å) with the tube at 45 kV and 15 mA. A 2θ scan of 2° per min over a range of 1.8° and two 10 s, fixed position background counts on either side of the peak were used in the data collection. Of the 3020 possible unique reflections within the range $3° < 2\theta < 50°$, 2212 (75%) were classified as observed on the basis that the net peak counts for each reflection be numerically larger than 10% of the total background for the reflection. The intensity data were reduced to structure amplitudes by applying $1/Lp$ corrections including the polarization correction for the graphite monochromator. Observational weights were calculated according to the expression $w^{1/2} = 2F_o/[T + (kI)^2 + B]^{1/2}$ (14) where F_o is the derived structure amplitude, T the total peak count in the scan, I the net counts in the peak after background correction, B the total background, and k is a small constant (0.04) included to allow for minor instrumental inaccuracies (15). Since the main objective of this study was to deduce the configuration of the piperidine ring substituents and not to derive a highly accurate structure, no absorption corrections were applied even though the crystal shape warranted it.

Determination and Refinement of the Structure

The bromide ion coordinates were determined from a $1/Lp$ sharpened Patterson map and used to compute structure factors. The residual ($R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$) using an isotropic temperature factor of B = 3.5 Å^2 for the Br^- in this computation was 0.385. The positions of the other 19 non-hydrogen atoms were determined from a Fourier synthesis with all data included and signs derived from the bromide ion coordinates only. Three cycles of block-diagonal least-squares refinement on the positional parameters and isotropic thermal parameters

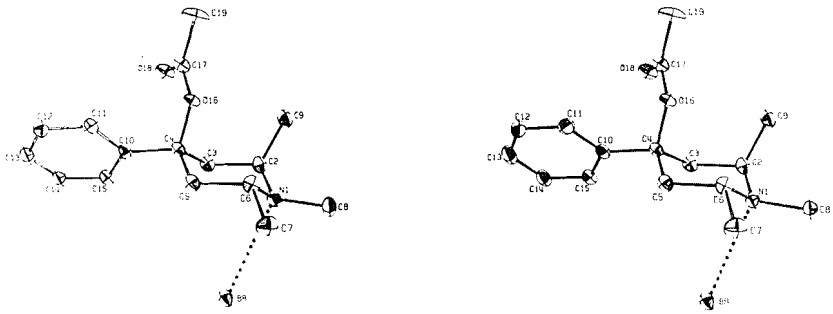

FIG. 1. A stereodrawing of 1,2,6-trimethyl-4-phenyl-4-acetoxypiperidine hydrobromide showing the molecular conformation and the atomic numbering scheme. This drawing and those in Fig. 5(*a*) and 5(*b*) were done using the program ORTEP(25).

of these 20 atoms reduced the *R* factor to 0.119. A difference Fourier synthesis computed at this stage showed positive peaks ranging from 0.3–0.6 e/Å^3 in the regions expected for 21 of the 24 hydrogen atoms in this compound. The three hydrogens of the acetoxy methyl group C(19) (see Fig. 1 for the atom numbering scheme) could not be positioned with certainty. This difference map also indicated anisotropic thermal motion for the majority of atoms.

At this point the bromine scattering curve was corrected for the real and imaginary parts of anomalous dispersion ($\Delta f' = -0.3$ e, $\Delta f'' = -2.7$ e) (16). Least-squares refinement was continued for 6 cycles; the parameters varied were the positional parameters for all atoms and the anisotropic thermal motion parameters for the non hydrogen atoms. The 21 hydrogen atoms were included with isotropic *B* factors of 4.5 Å^2 and these parameters were refined as well. The final *R* factor was 0.056 and the shifts in the parameters were all less than 1/8 of the associated estimated standard deviations. Nine of the most intense low θ reflections showed the effects of secondary extinction and/or absorption and were excluded from these final least-squares cycles. All of the atoms were well behaved during the least-squares refinement, except for one hydrogen atom (H(82)) bonded to C(8). The *B* factor rose to a value of 18.2 Å^2 and positional parameters were shifting by 1/3 of the associated estimated standard deviations. The coordinates for this atom were fixed by an atom positioning program and were not varied in the final cycle. No ordered sites could be found for the hydrogen atoms on C(19) on the final difference Fourier and their coordinates are not reported here.

TABLE 2. Summary of agreement for the observed data only*

Criterion	Number of reflections
$0 < \Delta F/\lvert F_o\rvert < 0.2$	2170
$0.2 < \Delta F/\lvert F_o\rvert < 0.3$	39
$0.3 < \Delta F/\lvert F_o\rvert < 0.4$	3
$0.4 < \Delta F/\lvert F_o\rvert < 0.5$	0

*$\lvert F_o\rvert$, observed structure amplitude; $\lvert F_c\rvert$, calculated structure amplitude based on coordinates in Table 3; ΔF, $\lvert\lvert F_o\rvert - \lvert F_c\rvert\rvert$ differences.

A summary of the agreement for the 2212 observed reflections is included in Table 2; the final atomic coordinates and thermal motion parameters with associated estimated standard deviations are given in Table 3. The scattering factors for the C, N, O, and Br^- atomic species were taken from Cromer (17) and the H curve was that of Mason and Robertson (18). The programs used for this structure analysis were those of Ahmed *et al.* (19) and several programs written in this laboratory for the IBM 360/67. A tabulation of the observed and calculated structure factors for this compound has been submitted to the Depository of Unpublished Data.[1]

Results and Discussion

The molecular conformation and atomic numbering scheme are shown in Fig. 1. The piperidine ring is in the standard chair form with the methyl groups in the following configuration, N(1)—CH_3 equatorial; C(2)—CH_3, axial; C(6)—CH_3, equatorial. The phenyl ring on C(4) is in the equatorial configuration and the reversed acetoxy ester on C(4) is in the axial orientation. This stereochemistry, *trans* 2-Me/6-Me and *trans* 2-Me/4-Ph, confirms the p.m.r. results obtained by Casy (unpublished results) on the 4-OH precursor of the present compound. The configuration of the groups on C(4) is identical to those arrangements in alphaprodine and betaprodine (10, 11) β and γ promedol (6, 7, 9) and pethidine (1). The present compound contains both an axial and an equatorial methyl substituent on the piperidine ring yet exhibits an analgetic potency twice that of pethidine. This indicates that although the enhancement of the activity is small there is some improvement by having these groups present. Unfortunately

†H(82) was positioned and its atomic parameters were not refined.

there is no pharmacological potency data regarding the other congeners of the 1,2,6-trimethyl analgetic and an attempt at drawing conclusions about substitution at the 2 and 6 positions now is premature.

Figure 2 contains the intramolecular bond lengths and bond angles for the non-hydrogen atoms. The bond lengths involving the hydrogen atoms are listed in Table 4. The mean C—C single bond length in the piperidine ring is 1.531 Å and agrees well with the corresponding values found in the similar piperidine rings (7, 8, 10, 11). The three C—N single bond lengths average 1.521 Å and are rather long. The N(1)—C(2) length (1.538(7) Å) is just significantly longer than the other two lengths, a feature that is also observed in the structure of 2-methyl-1-phenethyl-4-phenyl-4-acetoxypiperidine hydrobromide (20). De Camp and Ahmed (7) have noted that protonation of the nitrogen atom of the piperidine ring as occurs in alphaprodine (10) and betaprodine (11), causes an increase in the C—N bond lengths of 0.028 Å from the mean value of 1.471 Å found in the α and γ promedol alcohols. The observed lengthening of these bonds in the present structure is consistent with these observations. The bond lengths in the phenyl group are within the expected limits for aromatic C—C bonds (1.394 Å). The short values for C(12)—C(13) (1.356(9)

Å) and C(13)—C(14) (1.348(9) Å) can be attributed to the relatively large thermal motion of C(13) in the crystals, and is not an uncommon feature of phenyl rings in other crystal structure analyses. Correction of these two bonds for riding motion (21) did not significantly increase their lengths. The bond lengths and angles in the acetoxy group are in close agreement with the analogous moieties of pethidine (1), alphaprodine (10) and betaprodine (11) although in these latter three compounds the axial groups are propionoxy.

The mean plane of the phenyl ring is represented by the equation $0.0701x - 0.6019y - 0.7955z + 3.9309 = 0$ where x, y, and z are referred to the a, b, and c^* axes, respectively. The value of χ^2 for this plane is 3.5 and all six atoms are within 0.006 Å of this plane. Atom C(4) of the piperidine ring is 0.015 Å from this plane; this deviation is not significant ($3\sigma = 0.014$ Å). The mean plane of the piperidine ring has the equation $0.2732x + 0.2481y - 0.9294z + 3.2776 = 0$ and all six atoms are approximately 0.23 Å above and below the plane. The best four atom plane for the piperidine ring is that containing atoms C(2), C(3), C(5), and C(6) with atoms N(1) and C(4) displaced −0.68 Å and +0.66 Å respectively from the plane $-0.0240x + 0.1820y - 0.9830z + 3.7040 = 0$ ($\chi^2 = 1.5$). De Camp and Ahmed (7) have defined the dihedral angle made by the mean plane of the phenyl ring and that of the piperidine ring for (±)-γ-promedol alcohol as 73.7°. The corresponding angle in the present study is 52.5°.

Figure 3 shows several Newman projections along the bond C(4) to the phenyl ring for comparative purposes. Only those structures having equatorial phenyl substituents on the piperidine ring have been included. It can be seen from this figure that the dihedral angles between the mean planes of the phenyl rings and the planes comprising C(4), C(10), and O(16) (numbering scheme for this structure) for these several structures range from 16.0° to 65.1°. Examination of these six structures shows that this angle is determined primarily by the orientation of the bulky axial group on C(4); that is, there is a steric effect between the phenyl ring and the acetoxy group (or propionoxy group in the prodines) that determines not only the direction of the dihedral angle but also its magnitude. In γ-promedol where the axial group is an alcoholic OH the angle is the smallest at 16.0°

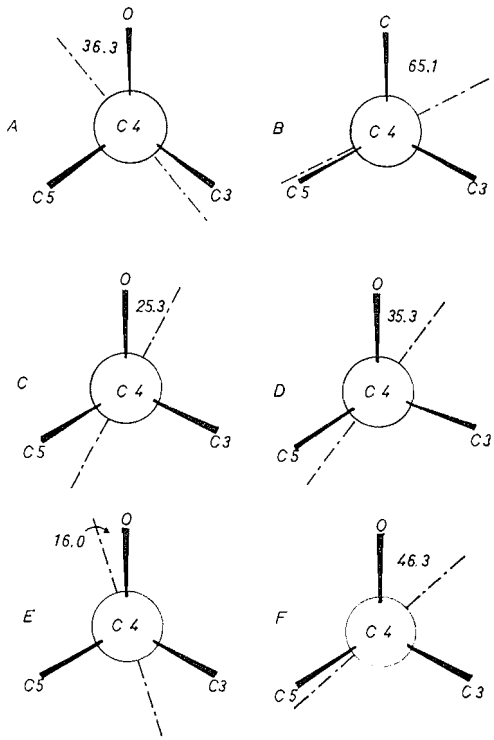

FIG. 3. Newman projection diagrams along the C(4) → phenyl ring bond for the following structures: (*A*) 1,2,6-trimethyl-4-phenyl-4-acetoxypiperidine hydrobromide; (*B*) 1-methyl-4-phenyl-4-carbethoxypiperidine hydrobromide (pethidine) (1); (*C*) 1,3-dimethyl-4-phenyl-4-propionoxypiperidine hydrochloride (*d*, *l*-alphaprodine) (10); (*D*) 1,3-dimethyl-4-phenyl-4-propionoxypiperidine hydrobromide (*d*, *l*-betaprodine) (11); (*E*) 1,2,5-trimethyl-4-phenyl-piperidine-4-ol (γ-promedol) (7); (*F*) 2-methyl-1-phenethyl-4-phenyl-4-acetoxypiperidine hydrobromide (20).

whereas the largest angle, 65.1°, is shown by pethidine which has the propionyl ester in an axial orientation on C(4). This propionyl ester function in pethidine is in the perpendicular orientation (22) thus effecting the largest steric hindrance to the possible position of the phenyl ring. The apparent range of the preferred conformation of the phenyl ring in those compounds with reversed ester groups in the axial position on C(4) is 25° – 46° relative to the axial bond.

The dihedral angles of the piperidine ring are included in Fig. 4. The internal torsion angles in the ring are all less than the perfect chair value of 60° and fall in the range 53.6° to 58.4°. This distortion from ideal chair geometry is a common feature of substituted six-membered pyranose rings (23 and references therein) and

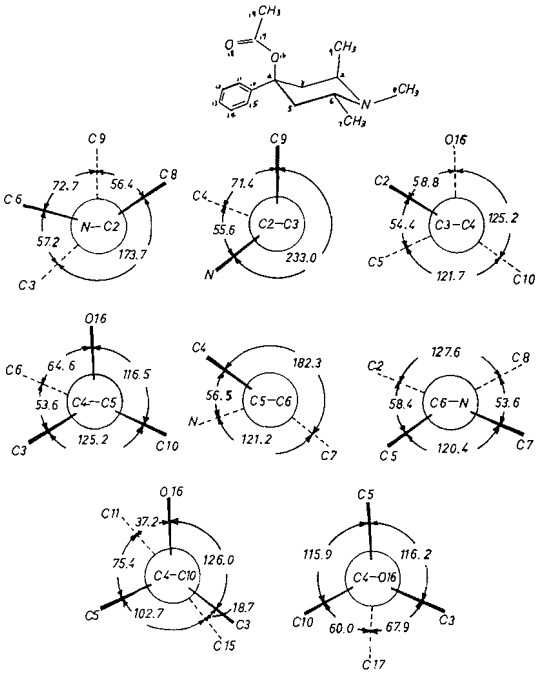

FIG. 4. Torsion angles for 1,2,6-trimethyl-4-phenyl-4-acetoxypiperidine hydrobromide.

cyclohexane rings (24). Several of the external torsion angles also deviate by a large amount from the expected 60.0°. Of particular interest are those angles involving the axial methyl group C(9) which has two torsion angles C(6)—N(1)—C(2)—C(9) = 72.7° and C(9)—C(2)—C(3)—C(4) = 71.4°. These large angles result from the close contact of two axial groups across a six-membered ring, namely C(9) and O(16) of the acetoxy group. The crystal structure of *epi*-inositol (24) has shown that the molecule of inositol containing two axial OH groups on alternate carbon atoms of a cyclohexane ring has comparable exocyclic torsion angles distorted to 65.1 and 69.3°. The internal ring bond angle at the atom bonded to the two carbon atoms containing the axial hydroxyl groups (C(1) in the inositol structure) is distorted to a value of 114.7(2)° (*cf.* the comparable angle at C(3) in the present work of 115.6(4)°). This distortion is also visualized in the two exocyclic bond angles C(3)—C(2)—C(9) = 117.2(4)° and C(3)—C(4)—O(16) = 111.3(4)°. The other external torsion angles which show large deviations from expected values are involved with atom O(16). These deviations result from the bond angle distortion at C(4) from tetrahedral values *viz.* C(3)—C(4)—C(10) = 114.7(4)° and C(5)—C(4)—O(16) = 103.6(4)°. Other piperidine ring bond angles that deviate significantly from the tetrahedral value of 109.5° are C(2)—C(3)—C(4) = 115.6(4)° and C(4)—C(5)—C(6) = 113.3(4)°. These latter two angles are also large in γ-promedol (7), α-promedol (8), and betaprodine (11).

The orientation of the axial acetoxy group on C(4) is seen in the dihedral angle drawing (Fig. 4). The mean plane of the acetoxy group O(16), C(17), O(18), C(19) is given by the equation $-0.9355x + 0.3477y - 0.0622z - 1.3713 = 0$ ($\chi^2 = 0.07$). This plane makes an angle of 3.9° to the plane containing C(4), C(5), O(16) and is *gauche* with respect to both C(3) and C(10). There are two relatively close contacts made to O(18) which could explain the large angle at O(16) of 119.0(4)°. These are C(10)—O(18) = 2.907(7) Å and O(18)—H(32) = 2.36(5) Å. With van der Waals radii of O = 1.40 Å and H = 1.20 Å and the half thickness of a benzene ring of 1.70 Å these distances have expected values of 3.10 Å and 2.60 Å, respectively.

The packing of the molecules in the unit cell is shown in Fig. 5 (*a*) and (*b*). The bromide ion is hydrogen bonded to N(1) and the Br—N(1) distance is 3.234(6) Å. This distance agrees with the corresponding distances in betaprodine hydrobromide (3.209 Å) and pethidine hydrobromide (3.24 Å). The molecules are related across the center of symmetry at the origin by close contact with the acetoxy groups; the distance between O(18) and C(19) across this center is 3.421(9) Å. Contact across the center of symmetry at 1/2,1/2,1/2 brings the methyl groups C(7) bonded to the piperidine ring atom C(6) to a separation of 3.804(8) Å. This is slightly less than 4.0 Å based on a methyl group radius of 2.0 Å. For those molecules related by the *c*-glide plane, there is a close contact between the phenyl ring and the acetoxy methyl carbon atom C(19). The distances from C(19) of the molecule at x, $1/2 - y$, $1/2 + z$ to the atoms of the phenyl ring of the molecule at x, y, z are C(10), 3.715(9) Å; C(11), 3.555(8) Å; C(12), 3.480(8) Å; C(13), 3.568(9) Å; C(14), 3.705(9) Å; C(15), 3.768(9) Å. The contacts to C(11), C(12), and C(13) are therefore approximately 0.2 Å shorter than expected from the van der Waals radii of the groups involved. It is curious that it was the region around C(19) that did not show evi-

Metal Complexes as Antioxidants. I. The Reaction of Zinc Dialkyldithiophosphates and Related Compounds with Peroxy Radicals[1]

J. A. HOWARD, Y. OHKATSU, J. H. B. CHENIER, AND K. U. INGOLD
Division of Chemistry, National Research Council of Canada, Ottawa, Canada K1A 0R9

Received October 6, 1972

The kinetics of the inhibition of the autoxidation of several hydrocarbons by a number of zinc dialkyldithiophosphates and by zinc isopropylxanthate and zinc diethyldithiocarbamate have been studied at 30° and at 50°. The oxidations were generally auto-retarding but initial rate measurements showed that these compounds trapped peroxy radicals and allowed rate constants for this process to be calculated. Rate constants for the reaction of *t*-butylperoxy radicals with these compounds have been measured by a kinetic e.p.r. method in the temperature range 0° to −90°. Extrapolation of the e.p.r. data to the temperatures of the inhibition studies showed that the various experimental procedures yielded results in satisfactory agreement with one another.

It is suggested that the reaction of peroxy radicals with zinc complexes involves reaction at the metal center either by an electron transfer or an S_H2 process.

Les cinétiques d'inhibition de l'auto-oxydation de plusieurs hydrocarbures par un certain nombre de phosphates de dialkyldithio zinc, d'isopropylxanthate de zinc et de diéthyldithiocarbamate de zinc, ont été étudiées à 30° et à 50°. Les oxydations sont généralement auto-retardées mais les mesures de vitesse initiale montrent que ces composés piègent les radicaux peroxy et permettent ainsi le calcul des constantes de vitesse pour ce processus. Les constantes de vitesse pour la réaction des radicaux *t*-butylperoxy sur ces composés ont été mesurées par une méthode cinétique r.p.e. dans l'intervalle de température de 0° à −90°. L'extrapolation des données r.p.e. aux températures d'étude de l'inhibition montre que tous les divers procédés expérimentaux donnent des résultats en accord satisfaisant.

On a suggéré que la réaction des radicaux peroxy sur les complexes de zinc implique une réaction sur le centre métallique soit par un transfert d'électron soit par un processus S_H2.

Introduction

Zinc dialkyldithiophosphates, $[(RO)_2PS_2]_2Zn$, have been widely used as lubricating oil additives. They combine antioxidant properties with an ability to inhibit corrosion and to function as antiwear and as extreme pressure agents for motor oils and automatic transmission fluids. In spite of numerous investigations the detailed mechanism of their antioxidant activity is still uncertain. These compounds, or their decomposition products, have long been known to catalyze the decomposition of hydroperoxides. At low molar ratios of zinc dialkyldithiophosphate to hydroperoxide the products are identical with those formed in an acid catalyzed decomposition, for example, phenol and acetone are produced from cumene hydroperoxide (1).

$$PhC(CH_3)_2OOH \xrightarrow[\text{in catalytic quantities}]{H^+ \text{ or } [(RO)_2PS_2]_2Zn} PhOH + CH_3COCH_3$$

[1]NRCC No. 13088.

Very recently it has been found that when the dithiophosphate and cumene hydroperoxide are present in approximately equimolar amounts the hydroperoxide is reduced almost quantitatively to α,α-dimethylbenzyl alcohol along with traces of acetophenone and α-methylstyrene (1–3). These products are indicative of either a molecular or free-radical induced decomposition of the hydroperoxide.

$$PhC(CH_3)_2OOH \xrightarrow[\text{equimolar quantity}]{[(RO)_2PS_2]_2Zn \text{ in}} PhC(CH_3)_2OH$$

It has been known for some years that zinc dithiophosphates and related compounds do not owe their entire antioxidant action to their ability to destroy hydroperoxides since they are also able to trap certain free radicals (4–15). Although some kinetic studies of this radical trapping antioxidant process have been undertaken, very little quantitative information has been obtained because simple kinetic laws do not appear to have been obeyed. However, a careful

reading of the kinetic papers reveals two important points. In the first place, cumene, tetralin, or ethylbenzene have been employed as the oxidizable substrates. The hydroperoxides derived from these compounds are expected to yield phenols via the catalytic decomposition mentioned above.[2] Since phenols are potent peroxy radical traps, some difficulty in determining the reaction orders and rate constants for the radical–dithiophosphate reaction might be expected. In the second place, in the only detailed kinetic study (6), inhibited oxidation rates were measured under conditions of very short chain lengths ($\nu \sim 1$–3). Meaningful kinetic data on the trapping of the autoxidation chain carrying radicals by the antioxidant cannot be expected to be obtained under such conditions.

The present paper describes a variety of kinetic experiments designed to study the radical trapping antioxidant process for several zinc dialkyldithiophosphates and for a number of related zinc complexes. Rate constants for the peroxy radical – antioxidant reactions have been determined at 50° and at 30° from the rates of inhibited hydrocarbon oxidation and at low temperatures (0° to −90°) by kinetic electron spin resonance spectroscopy. The data obtained by these independent techniques are in satisfactory agreement.

Experimental

Inhibition of Autoxidation

The autoxidation apparatus and general experimental techniques have been adequately described in our earlier papers on inhibition by phenols (16) and amines (17) and on the determination of absolute rate constants for hydrocarbon autoxidation (18). At 50° autoxidations were initiated by the thermal decomposition of α,α′-azo-bis-isobutyronitrile (AIBN) and at 30° they were initiated by the photochemical decomposition of α,α′-azo-bis-cyclohexanecarbonitrile (ACHN). Rates of chain initiation were determined by the usual induction period method (19) using 2,6-di-*t*-butyl-4-methoxyphenol as the inhibitor. The hydrocarbon substrates and the solvents were carefully purified by standard techniques. Adventitious hydroperoxides were the most troublesome impurity and were removed by distillation and/or percolation through basic alumina.

Kinetic E.P.R. Experiments

t-Butylperoxy radicals were generated directly in the cavity of a Varian E-3 e.p.r. spectrometer at temperatures in the range 0° to −90°. The radicals were formed either by the photolysis of 2,2′-azoisobutane (Merck, Sharpe, and Dohme of Canada, Ltd.) in air saturated isopentane,

$$t\text{-BuN=NBu-}t \xrightarrow{h\nu} N_2 + 2t\text{-Bu}^{\cdot} \xrightarrow{O_2} t\text{-BuOO}^{\cdot}$$

or by the photolysis of di-*t*-butyl peroxide in air saturated isobutane.

$$t\text{-BuOOBu-}t \xrightarrow{h\nu} 2t\text{-BuO}^{\cdot} \xrightarrow{t\text{-BuH}} t\text{-Bu}^{\cdot} \xrightarrow{O_2} t\text{-BuOO}^{\cdot}$$

Decays of the radicals upon interruption of the irradiation were followed in the usual way (20). In the absence of a peroxy radical trap *t*-butylperoxy decayed bimolecularly but in the presence of a sufficient concentration of a trap decay was first order. Rate constants for reaction of this peroxy radical with the inhibitor were calculated from the measured rates of radical decay and the concentration of the inhibitor.

Materials

We are indebted to Dr. B. R. Kennedy (Chevron) for generous analytically pure samples of some of the metal complexes used in this work. The few compounds that had to be made in our laboratory were prepared by standard methods and were purified with great care before use.

Results

(a) Kinetics of Inhibited Autoxidations

(1) General

The simplest reaction scheme which can describe the inhibition of the autoxidation of a hydrocarbon, RH, by an antioxidant, A, that traps peroxy radicals can be represented as follows.

Initiation

$$\text{Production of R}^{\cdot} \text{ at a rate} = R_i$$

Propagation

$$R^{\cdot} + O_2 \xrightarrow{\text{fast}} ROO^{\cdot}$$

$$ROO^{\cdot} + RH \xrightarrow{k_p} ROOH + R^{\cdot}$$

(or, for a polymerizable olefin such as styrene (16)

$$ROO^{\cdot} + RH \xrightarrow{k_p} ROO\dot{R}H\ (\equiv R^{\cdot})$$

Termination

$$ROO^{\cdot} + A \xrightarrow{k_{inh}} X$$

$$(n-1)ROO^{\cdot} + X \xrightarrow{\text{fast}} \text{non-radical products}$$

Provided the chain length of the inhibited oxidation, $\nu(= -d[O_2]/dt/R_i)$, is $\geqslant 5$, problems arising from differences in the reactivity of the initiating radical (*i.e.* the radicals from AIBN and ACHN) and the chain propagating radical

[2]Non-alkylaromatic hydrocarbons have, however, been employed in qualitative experiments (4, 5).

TABLE 1. Induction periods and n values for zinc diisopropyldithiophosphate inhibited autoxidations

Substrate	Dithiophosphate concentration $\times$ 10^4 (M)	Induction period $\times$ 10^{-3} (s)	$R_i \times 10^7$ ($M\ s^{-1}$)	n

‖With 10^{-2} M t-butyl hydroperoxide.

can be neglected. The initial rate of oxidation (corrected for oxygen absorption by, and nitrogen evolution from, the initiator) according to this scheme will be independent of the oxygen pressure. It is given by

$$\left[\frac{-\mathrm{d}[O_2]}{\mathrm{d}t}\right]_0 = \frac{k_p[RH]_0 R_i}{nk_{inh}[A]_0}$$

where the subscript 0 refers to the initial concentrations, and n is the number of peroxy radicals trapped by each molecule of A. If the antioxidant behaves in this simple manner, then

$$\frac{[RH]_0 R_i}{[A]_0(-\mathrm{d}[O_2]/\mathrm{d}t)_0} = \frac{nk_{inh}}{k_p}$$

We were unable to confirm previous reports (6, 12) that $n \sim 2.0$ for dithiophosphate antioxidants. Using the usual induction period method (19) we obtained $n \sim 1$ for AIBN initiated oxidations at 50° and $n \sim 3$–4 from photochemically initiated oxidations at 30° (see Table 1). The same n values were obtained with zinc isopropylxanthate and zinc diethyldithiocarbamate. However, there are considerable experimental difficulties in determining n for all these compounds because the induction periods are probably influenced by secondary reactions (*e.g.*, reaction between accumulated hydroperoxide and metal complex). For this reason, we have assumed that $n = 2$ in calculating all the values of k_{inh} quoted in this paper (see, however, section (*b*)).

(2) Thermal Initiation (50°)

Although thermally initiated reactions proved satisfactory for unravelling the mechanism and kinetics of the inhibition of hydrocarbon autoxidation by phenols (16) and aromatic amines (17), this method was much less useful for studying the dithiophosphates. The reason is that the oxygen absorption curves were nonlinear and exhibited pronounced curvature even at quite low extents of oxidation (see below). It was therefore necessary to measure initial oxidation rates, which is not particularly easy in a system that may still be approaching thermal equilibrium. However, our initial studies were made in this type of system using styrene, cyclohexene, and tetralin as substrates. The initial rates were sufficiently reproducible to show that the simple kinetic scheme outlined above was at least approximately obeyed with the zinc dialkyldithiophosphates at 50° (see Table 2 and 3 for examples of the data).

Values of the inhibition rate constants, k_{inh}, at 50° for the five zinc dithiophosphates studied are tabulated in Table 4 together with the k_p values used in the calculations. The similarity in the k_{inh} values obtained with different hydro-

carbon substrates provides additional support for the reaction scheme given above. There can be no doubt that these compounds are moderately efficient traps for peroxy radicals. Unfortunately, because of the difficulties involved in initial rate measurements, the variations in k_{inh} from substrate to substrate and from one antioxidant to another are within the probable experimental errors. The mean value for k_{inh} for a zinc dialkyldithiophosphate at 50° is $4.2 \times 10^3\ M^{-1}\ s^{-1}$.

(3) Photochemical Initiation (30°)

The reaction system was allowed to come to thermal equilibrium in the dark before initiating the oxidation photochemically. This allowed initial rates to be determined with much greater accuracy than in the thermally initiated oxidations. In order to reduce the importance of any thermal self-initiation process the photochemically initiated autoxidations were carried out at 30°. Zinc diisopropyldithiophosphate followed the same simple kinetics as at 50° (see Table 5

for representative data). Inhibition by zinc isopropylxanthate (Table 6) and by zinc diethyldithiocarbamate (Table 7) also obeyed the same kinetics. The calculated inhibition rate constants at 30° are summarized in Table 8. For those substrates for which the oxidation chains are carried by alkylperoxy radicals (*i.e.* styrene, cyclohexene, tetralin, cyclohexa-1,3-diene, and 9,10-dihydroanthracene) the mean values of $k_{inh}^{30°}$ are $3.1 \times 10^2\ M^{-1}\ s^{-1}$ for the dithiophosphate, 41×10^2 for the xanthate, and 5.0×10^2 for the carbamate.

(4) Effect of Hydroperoxide on Inhibited Rates

In general, zinc dithiophosphate inhibited autoxidations were strongly autoretarding. Thus, the rates of oxidation of tetralin (Fig. 1, *I*), 9,10-dihydroanthracene (Fig. 2, *I*), and cyclohexa-1,4-diene (Fig. 2, *II*), decreased markedly after the absorption of as little as $3 \times 10^{-4}\ M$ oxygen. The initial, relatively rapid stage in the inhibited oxidation could be eliminated by pre-oxidizing the hydrocarbon (tetralin, for example, to a hydroperoxide concentration of $\sim 7 \times 10^{-4}\ M$). A similar effect was obtained by adding $\sim 5 \times 10^{-4}\ M$ *t*-butyl hydroperoxide, although in this case the autoxidation was not as slow as when the tetralin was pre-oxidized. Auto-retardation was less pronounced with styrene (which yields principally a polyperoxide, Fig. 2, *III*), cyclohexa-1,3-diene (which yields both hydroperoxide and polyperoxide, Fig, 2, *IV*), and cyclohexene (Fig. 2, *V*), than with the three hydrocarbons mentioned above. Auto-retardation of the inhibited autoxidation of benzaldehyde was slight (Fig. 2, *VI*), but the degree of inhibition by the dithiophosphate was much greater than was found with any of the hydrocarbon substrates.

It would appear that zinc dithiophosphates react with hydroperoxides to produce a more active antioxidant.[3] The more pronounced auto-retardation produced by aralkyl hydroperoxides (*i.e.* those from tetralin and dihydroanthracene) compared with alkyl hydroperoxides, suggests that this reaction is, at least in part, ionic. That is, the aralkyl hydroperoxides can yield phenolic antioxidants (for which $k_{inh} \sim 10^4\ M^{-1}\ s^{-1}$ (16)) in addition to any antioxidants produced from the dithiophosphate itself.

[3]The final products formed by reaction of zinc dithiophosphates with 0.25 mole cumene hydroperoxide (*e.g.* $[(RO)_2PS_2]_6Zn_4O$, see ref. 2) are completely ineffective as antioxidants.

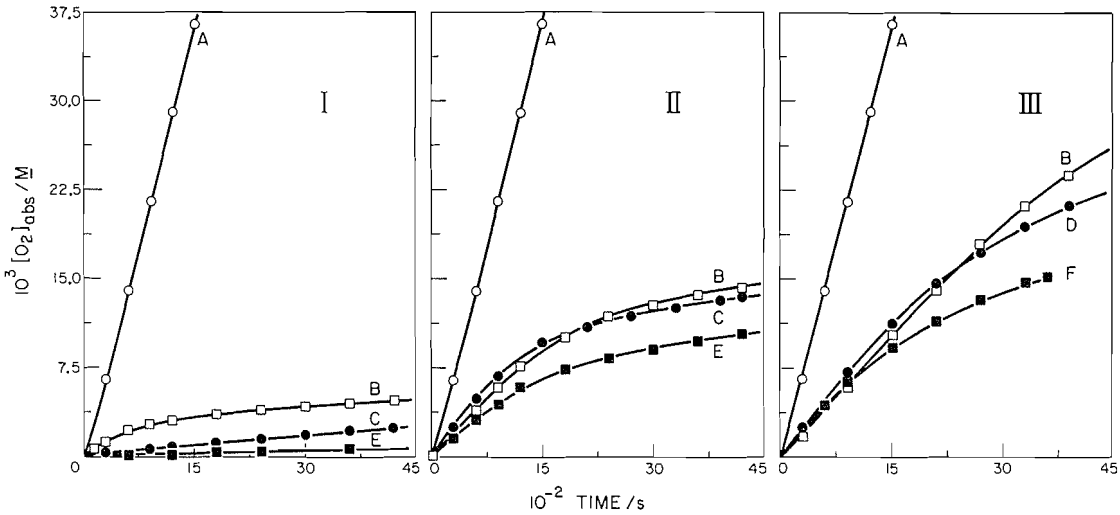

FIG. 1. Oxygen absorption *vs.* time for the photochemically initiated ($R_i = 1.2 \times 10^{-7}$ M s^{-1}) autoxidation of tetralin at 30° inhibited by; *I*, zinc di-isopropyldithiophosphate (0.016M); *II*, zinc isopropylxanthate (0.001 M); and *III*, zinc diethyldithiocarbamate (0.0015 M). *A*, uninhibited; *B*, inhibited, no hydroperoxide present initially; *C*, inhibited, *t*-butyl hydroperoxide (5×10^{-4} M) added; *D*, inhibited, *t*-butyl hydroperoxide (0.01 M) added; *E*, inhibited, tetralin pre-oxidized (to $\sim 7 \times 10^{-4}$ M in hydroperoxide); *F*, inhibited, tetralin hydroperoxide (0.01 M) added.

The effects of hydroperoxides on the initial rates of oxidation of tetralin inhibited by zinc isopropylxanthate (Fig. 1, *II*) and zinc diethyldithiocarbamate (Fig. 1, *III*) are much less than their effects on the dithiophosphate inhibited reaction (Fig. 1, *I*).

It has been reported that zinc dithiophosphates (2, 6, 10) and related compounds (14, 24) *may* exert a pro-oxidant effect on the initial stages of the oxidation of hydrocarbons containing hydroperoxides. We have observed such effects with zinc isopropylxanthate at high hydroperoxide concentrations but not with the dithiophosphate or carbamate. For example, the addition of *t*-butyl hydroperoxide (10^{-2} M) to styrene (7.8 M) containing xanthate (10^{-2} M) that was at thermal equilibrium at 30° caused a rapid, $(-d[O_2]/dt)_0 = 3.7 \times 10^{-7}$ M s^{-1}, but strongly autoretarded absorption of oxygen. No such effect occurred with dithiophosphate or carbamate and, in fact, if *t*-butyl hydroperoxide was added during the course of a dithiophosphate or carbamate inhibited oxidation of styrene, the rate of oxidation was reduced.

(b) Kinetic E.P.R. Spectroscopy

t-Butylperoxy radicals decayed with first order kinetics in the presence of an excess of zinc dialkyldithiophosphates, *i.e.*

$$\frac{-d[t\text{-BuOO}^{\cdot}]}{dt} = nk_{inh}[t\text{-BuOO}^{\cdot}]_0[A]_0$$

The variation with temperature of the k_{inh} values determined by kinetic e.p.r. spectroscopy yielded the Arrhenius parameters listed in Table 9 for the three zinc dialkyldithiophosphates studied in this way. The Arrhenius plot for these inhibitors is shown in Fig. 3 together with the mean k_{inh} values obtained by conventional inhibition studies at 30° and 50°. The agreement in the k_{inh} values obtained by the different methods at different temperatures is satisfactory.

TABLE 9. Arrhenius parameters for the reactions of *t*-butylperoxy radicals with zinc dialkyldithiophosphates and zinc isopropylxanthate as determined by kinetic e.p.r. spectroscopy*

Inhibitor	$\log_{10}(A_{inh}/M^{-1}$ $s^{-1})$	E_{inh} (kcal/mol)
Zinc Dithiophosphates		
Diisopropyl	6.0	4.0
Diisobutyl	6.1	4.1

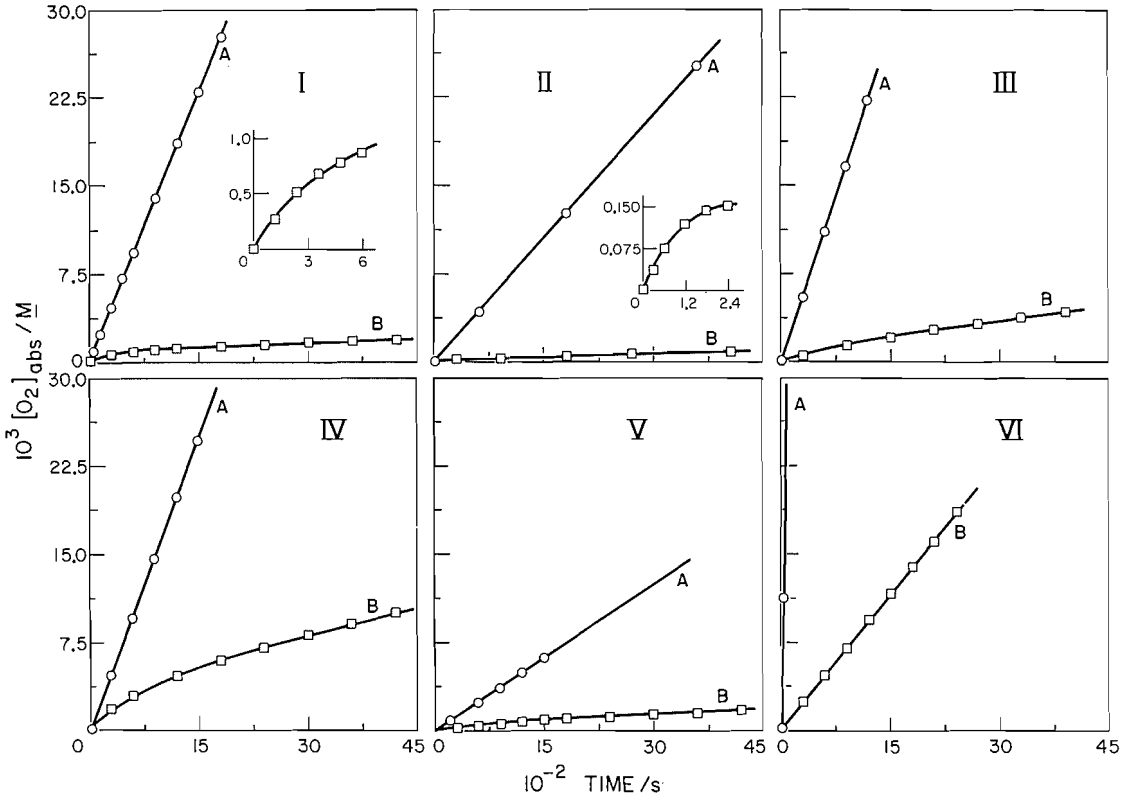

FIG. 2. Oxygen absorption *vs.* time for photochemically initiated ($R_i = 1.2 \times 10^{-7}$ M s^{-1}) autoxidations at 30°; *A*, uninhibited; *B*, inhibited by zinc di-isopropyldithiophosphate (0.016 *M*). *I*, 9,10-dihydroanthracene (0.55 *M* in chlorobenzene); *II*, cyclohexa-1,4-diene (0.42 *M* in chlorobenzene); *III*, styrene (8.7 *M*); *IV*, cyclohexa-1,3-diene (0.42 *M* in chlorobenzene); *V*, cyclohexene (10 *M*); and *VI*, benzaldehyde (0.4 *M* in chlorobenzene).

The decay of *t*-butylperoxy radicals in the presence of zinc isopropylxanthate was also a first order process. The Arrhenius parameters for k_{inh} are listed in Table 9 and the plot is shown in Fig. 3 together with the mean value obtained in the inhibition study at 30°.

Rates of decay of *t*-butylperoxy radicals in the presence of zinc dialkyldithiocarbamates were not reproducible and these experiments were not pursued further.

Discussion

Kinetics of Inhibition

Although several studies have been made of the reactions of peroxy radicals with zinc dialkyldithiophosphates and related compounds (see Introduction), the present work provides the first reliable kinetic data on the inhibition of hydrocarbon oxidation by this process and also the first reliable absolute rate constants for these reactions. The reasonable agreement between the k_{inh} values obtained by conventional inhibition studies and the values calculated by extrapolation of the e.p.r. results provides strong support for the kinetic schemes and for our numerical values of k_{inh}.[4]

The ability of zinc complexes to scavenge peroxy radicals decreases along the series xanthate > dithiophosphate ≥ dithiocarbamate. A similar order in reactivity was obtained from inhibition of the self-initiated oxidation of squalene at 75° (4), for the decomposition of

[4]Ivanov (8) has estimated that for zinc dicyclohexyldithiophosphate k_{inh} is 2.1×10^4 M^{-1} s^{-1} at 80° in ethylbenzene. This value is an order of magnitude greater than our extrapolated e.p.r. data would suggest. A value of k_{inh} which is in better agreement with our work (*viz.* 10^3 M^{-1} s^{-1} at 65°) has been obtained for zinc ditolyldithiophosphate (40).

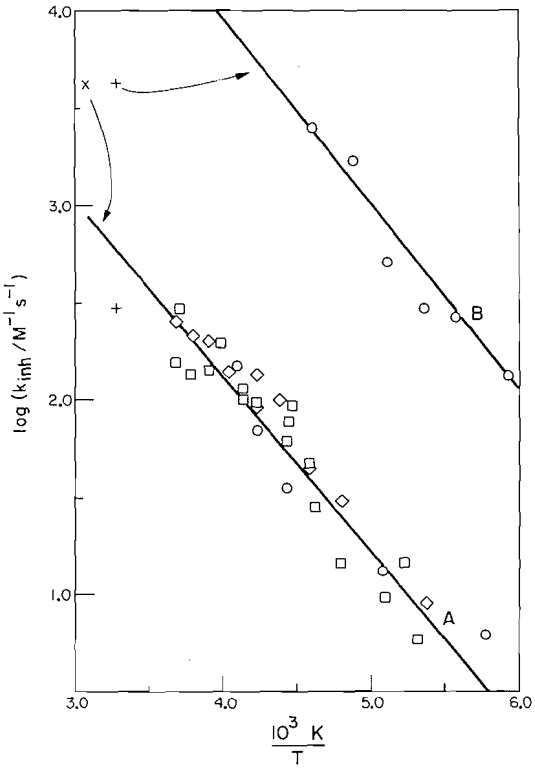

FIG. 3. Plot of log (k_{inh}/M^{-1} s^{-1}) *vs.* the reciprocal of the absolute temperature. The open points refer to values determined by kinetic e.p.r. spectroscopy. The × and + refer to the mean values found by alkylperoxy radicals from oxygen absorption experiments at 50° and 30°, respectively. *A*, reaction with zinc dialkyldithiophosphate (○, diisopropyl-; □, di-*s*-butyl-; and ◇, diisobutyl-). *B*, reaction with zinc isopropylxanthate.

t-butyl hydroperoxide at 20° (4), and (for the first two salts) for the inhibition of the AIBN initiated oxidation of cumene at 60° (5). In contrast, for the inhibition of the AIBN initiated oxidation of squalene at 60°, the order apparently is dithiophosphate > xanthate > dithiocarbamate (4) and for inhibition of the tetralin hydroperoxide catalyzed oxidation of tetralin at 50°, dithiocarbamate > dithiophosphate (24). The difficulties encountered in obtaining reproducible data by conventional methods may be one of the reasons for these conflicting orders in reactivity.

Zinc dithiophosphates are more effective inhibitors in cyclohexa-1,4-diene than in the other hydrocarbons (Table 8). In this compound the oxidation chain is carried by an HOO· radical rather than by an alkylperoxy radical (25). Our results suggest that the HOO· radical is trapped about ten times more readily. Zinc dithiophosphates are even more effective inhibitors in benzaldehyde. The benzoylperoxy radical is known to be between 1000 (26) and 40 000 (27) times as reactive in hydrogen abstraction from hydrocarbons as are alkylperoxy radicals. From the present work it would appear to be about 100 times as reactive towards a dithiophosphate. The high reactivity of benzoylperoxy is because the powerful electron withdrawing carbonyl group immediately adjacent to the peroxy group makes this radical much more electrophilic than an alkylperoxy radical.

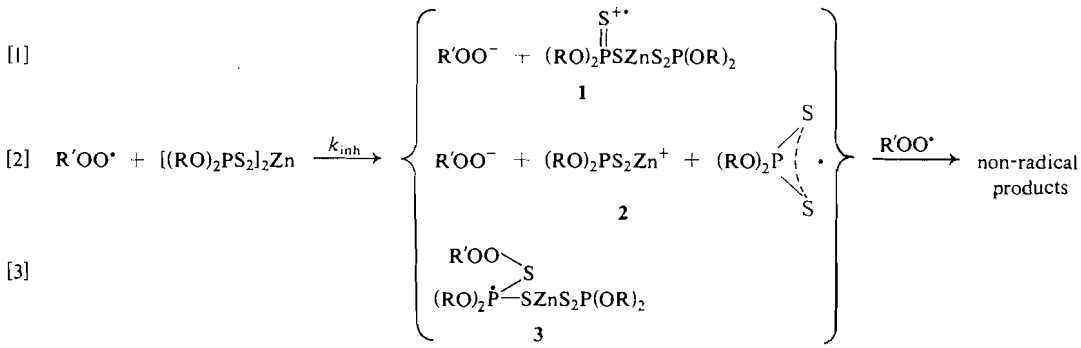
Zinc dithiophosphates and related compounds are particularly effective antioxidants for systems subject to autoxidation at temperatures of 150° and above. Under such conditions their principal function is to decompose hydroperoxides. For this reason there is generally a powerful synergistic effect when they are used in conjunction with conventional peroxy radical trapping agents such as phenols[5] and aromatic amines (31, 32). The contribution from peroxy radical trapping to overall inhibition at high temperatures is difficult to estimate. If we take E_{inh} = 4.0 kcal/mol and $A_{inh} = 10^{6.0}$ M^{-1} s^{-1}, then at 150°, $k_{inh} \sim 10^4$ M^{-1} s^{-1}.[6] However, most commercial inhibitors of the zinc dithiophosphate type are unstable above ~150° (28) and it is therefore unlikely that peroxy radical trapping plays as important a role as is implied by the calculated value of k_{inh}.

Mechanism of Inhibition

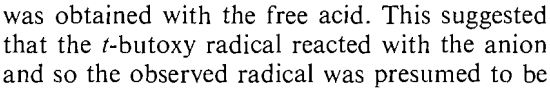
Three mechanisms have been proposed for the reaction of peroxy radicals with zinc dialkyldithiophosphates (4–13). These are

[5]The conversion of dithiophosphates to acidic products by their oxidation or thermal decomposition (28) may be an important contributing factor to the synergistic effect observed with simple phenols since acids can catalyze the dimerization of certain phenoxy radicals (29). If the phenoxy radicals are not destroyed by dimerization they may continue the oxidation chain (30).

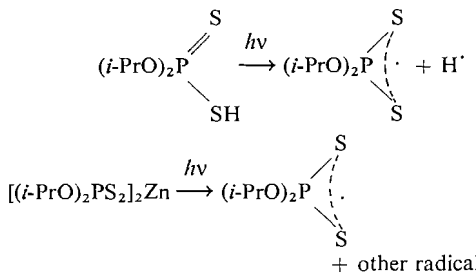
[6]This value is in the general range found for phenolic inhibition at temperatures of 50–80° (16, 23) and expected for phenolic inhibitors at 150° because of the small temperature coefficient for the peroxy radical – phenol reaction (33).



Reactions 1 and 3 have generally been favored in view of Liston, Ingersoll, and Adams (15) work on the *t*-butoxydithiophosphate reaction. These workers reported that photochemically generated *t*-butoxy radicals reacted with zinc dialkyldithiophosphates at 25° to produce a radical with an e.p.r. spectrum that consisted of a simple doublet (a = 24.8–26.7 G, g = 2.0203). The same e.p.r. spectrum was obtained with the diethylammonium salt but no signal was obtained with the free acid. This suggested that the *t*-butoxy radical reacted with the anion and so the observed radical was presumed to be analogous to **1**, or **3**, *i.e.*



We found, however, that photolysis of both zinc diisopropyldithiophosphate and diisopropyldithiophosphoric acid in the *absence* of di-*t*-butyl peroxide gave doublet e.s.r. spectra with hyperfine interactions of 24.7–24.9 G. The intensity of these spectra did not appear to be influenced to any great extent by the addition of di-*t*-butyl peroxide. Although the radical produced in these systems was most probably $(i\text{-PrO})_2PS_2^{\cdot}$,[7] *i.e.*,



[7]It has been suggested (34) that one of the radical species (a_P = 25.5 G) formed during irradiation of dialkyldithiophosphoric acid glasses has the structure $(RO)_2PS_2^{\cdot}$.

we were unable to prove conclusively that reaction of zinc diisopropyldithiophosphate and diisopropyldithiophosphoric acid with *t*-butoxy radicals (and by analogy with alkylperoxy radicals) produced this radical.

There is no experimental evidence to indicate that peroxy radicals react with organosulfur compounds at the sulfur atom (35). Furthermore, the disulfide, $[(i\text{-PrO})_2PS_2]_2$ (5) or esters of the structure $(RO)_2P(S)SR$, *e.g.*, *O,O'*-diisopropyl-*S*-methylthionophosphate do not inhibit autoxidation or react with *t*-butylperoxy radicals at low temperatures (36). It, therefore, seems most probable that reaction of zinc dialkyldithiophosphates and related zinc complexes with peroxy radicals occurs at the metal center rather than at sulfur. Moreover, the small preexponential factors that we have found for this reaction (Table 9) are consistent with attack at a sterically protected central atom. Such a reaction at zinc could take place either by an electron transfer process analogous to [2] or perhaps by an S_H2 process (37),

[4] $$R'OO^{\cdot} + ZnX_2 \rightarrow R'OOZnX + X^{\cdot}$$

where X is $(RO)_2PS_2$, $ROCS_2$, or R_2NCS_2. Thus zinc diisopropyldithiophosphate may react with peroxy radicals to give the diisopropyldithiophosphate radical. It has been suggested (5) that this radical cannot be involved in inhibition because zinc diisopropyldithiophosphate inhibits the oxidation of olefins. In these substrates the zinc complex might be expected to function simply as a chain transfer agent because of the known ability of dialkyldithiophosphate radicals to add to olefins (38, 39).

It has, however, been reported (15), and we have confirmed (36), that dialkyldithiophosphoric acids inhibit hydrocarbon oxidation. For example, diisopropyl- and diethyl-dithiophosphoric acids inhibit the oxidation of cumene,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

styrene, and cyclohexene. These acids also react with *t*-butylperoxy radicals at $-100°$ with bimolecular rate constants of the order of $5 \times 10^2\ M^{-1}\ s^{-1}$. The most probable mechanism for inhibition by these compounds is abstraction of the hydrogen attached to sulfur by a peroxy radical, *i.e.*,

$$(RO)_2P(S)SH + ROO^{\cdot} \rightarrow (RO)_2PS_2^{\cdot} + ROOH$$

with the dialkyldithiophosphate radical being less reactive than a peroxy radical towards propagation.

Although we are reasonably confident that peroxy radicals react with zinc complexes at the metal center, the experimental results presented in this paper do not enable us to distinguish between a rate controlling electron transfer reaction 2 and a displacement reaction 4. Similarly, zinc isopropylxanthate may be a more efficient scavenger of peroxy radicals than zinc diisopropyldithiophosphate because it can donate an electron more readily to an electrophilic species or because the $ROCS_2$ ligand is less tightly bound to zinc than the $(RO)_2PS_2$ ligand.

We wish to thank the Chevron Research Company for financial support in the form of a Fellowship to one of us (Y.O.).

The Chemical Degradation of a Humic Acid[1]

MORRIS SCHNITZER AND MARIA INES ORTIZ DE SERRA[2]
Soil Research Institute, Canada Agriculture, Ottawa, Canada

Received December 1, 1972

A humic acid (HA) extracted from the A_1 horizon of a Brunizem soil was degraded in the unmethylated and methylated form by sequential reaction with oxidants of increasing strength. The HA was first oxidized with alkaline cupric oxide; the products were then further degraded by oxidation with first alkaline $KMnO_4$ and then with H_2O_2 in alkaline solution. Unmethylated HA was also degraded by Na-amalgam reduction. The degradation products were extracted into organic solvents, methylated, and separated by preparative gas chromatography into relatively pure components which were analyzed by mass spectrometry and micro-i.r. spectrophotometry. A matching of the mass and i.r. spectra and gas chromatographic retention times of the isolated components with those of authentic specimens led to their identification.

The experimental data show that the HA contains a relatively easily degradable portion, which comprises guaiacyl and syringyl units and which may be lignin-derived (about 10% of the total weight). This material is degraded by CuO–NaOH oxidation and Na-amalgam reduction. The bulk of the HA structure, however, consists of a more condensed, chemically complex "core", which degrades on more drastic oxidation into complex phenolic and benzenepolycarboxylic acids. It is likely that the "core" originates in part from condensed lignin and in part from products of microbial synthesis. Of the methods investigated, the CuO–NaOH and the $KMnO_4$ oxidation of methylated HA appear most promising for providing information on the chemical structure of the HA.

Un acide humique (HA) extrait du sol de l'horizon A_1 de Brunizem, a été dégradé sous forme non méthylée et méthylée selon une séquence réactionnelle utilisant des oxydants de force croissante. Le HA a d'abord été oxydé par CuO en milieu alcalin; les produits obtenus ont été ensuite degradés par oxydation permanganique et par H_2O_2 en solution alcaline. Le HA non méthylé a été également dégradé par réduction à l'amalgame de Na. Les produits dégradés ont été extraits par des solvants organiques, méthylés puis séparés par chromatographie en phase gazeuse préparative en composés relativement purs qui ont été analysés par spectrométrie de masse et microspectrophotométrie i.r. La comparaison des spectres de masse et i.r. et des temps de rétention de la chromatographie en phase gazeuse des composés isolés avec ceux de specimens authentiques ont suffi à leur identification

Les données expérimentales montrent que le HA comprend une partie relativement facile à degrader qui contient des unités guaiacyle et syringyle, qui peuvent être dérivées de la lignine (environ 10% du poids total). Ce matériel est dégradé par oxydation avec CuO–NaOH et réduction par l'amalgame de Na. Le gros de la structure HA consiste cependant en un noyau plus condensé, chimiquement complexe, qui se dégrade par oxydation plus brutale en phénols complexes et acides benzène polycarboxyliques. Il est probable que ce noyau tire son origine en partie de la lignine condensée et en partie des produits de synthèse microbienne. Parmi les méthodes étudiées, l'oxydation par CuO–NaOH et $KMnO_4$ de HA méthylé est une source d'information pleine de promesse sur la structure chimique de HA.

[Traduit par le journal]

Can. J. Chem., **51**, 1554 (1973)

Introduction

Humic substances are widely distributed in nature and arise from the chemical and biological degradation of plant and animal residues and from synthetic activities of microorganisms. The bulk of the organic matter in most soils and waters consists of humic substances which are amorphous, dark brown or black, hydrophilic, acidic, polydisperse substances of molecular weights ranging from a few hundred to tens of thousands. Based on their solubility in dilute alkali and acid, humic substances are usually subdivided into three main fractions: (*a*) humic acid (HA), which is soluble in dilute alkaline solution but is precipitated by acidification of the alkaline extract; (*b*) fulvic acid (FA), which is that humic fraction which remains in the aqueous acidified solution, *i.e.*, it is soluble in both acid and base; and (*c*) the humic fraction that cannot be extracted by dilute base and acid, which is referred to as humin (1). Important characteristics exhibited by all humic fractions are resistance to microbial degradation, and the ability to form stable water-soluble and water-

insoluble salts and complexes with metal ions and hydrous oxides, and to interact with clay minerals and organic chemicals often added by man, which may be toxic pollutants.

Since quantitatively HA is the most important humic fraction, it is not too surprising that a considerable amount of research has been done on this subject. Yet, in spite of the existence of a voluminous literature, going back more than 200 years (1), very little is known about the synthesis and chemical structure of HA's. The relatively recent availability of powerful and sophisticated analytical tools such as the gas chromatographic–mass spectrometric (g.c.–m.s.) system and the g.c.–m.s.-computer system prompted us to take a new look at this problem in the expectation that significant advances in our knowledge of the chemical structure of HA's, a relatively "old" but neglected problem in chemistry, should now be possible.

Thus, we set out to degrade a HA extracted from a Brunizem soil by oxidative methods of increasing strength. The first method that we used was the relatively mild alkaline cupric oxide (CuO–NaOH) oxidation which had been pioneered by Pearl (2) on lignosulfonates and various lignin preparations. In a second series of experiments we methylated the CuO–NaOH oxidation products and then oxidized these again with alkaline $KMnO_4$ solution at p*H* 10. In a third set of experiments we went one step further and oxidized the CuO–NaOH + $KMnO_4$ oxidation products with H_2O_2 at p*H* 10. This approach was similar to that taken recently by Larsson and Miksche (3), who used a sequence of oxidants of increasing strength on birch lignin. A fourth method that we employed was alkaline $KMnO_4$ oxidation which has been used on coal (4), lignin (5), and humic substances (6). Another approach that we investigated was reduction of the HA with Na-amalgam, a relatively mild method that has been used previously on HA with varying degrees of success (7). Finally, we applied each of the oxidative degradation procedures to HA that was methylated prior to oxidation in order to evaluate the effects of methylation on the quality and quantity of products formed. Following each degradation, the products were methylated, extracted into organic solvents, separated by preparative gas chromatography, and identified by matching their mass and micro-i.r. spectra with those of authentic specimens. Our principal objective was to uncover the method or methods that would provide the most meaningful information on the chemical structure of the HA.

Experimental

HA

The soil sample from which the HA was extracted was taken from the A_1 horizon (0–23 cm) of a Brunizem soil (3.84% C; p*H* = 6.0) from a grassland area in the province of Buenos Aires, Argentina. Methods of extraction, fractionation, and purification were analogous to those described previously (8). Elemental analysis (%) of the purified HA (0.73% ash) showed 54.99 C; 4.38 H; 3.29 N; 0.84 S; 36.50 O; and 1.18 OCH_3. One gram of HA contained 4.75 mequiv CO_2H, 2.36 mequiv phenolic OH, 1.99 mequiv alcoholic OH, and 1.37 mequiv C=O. The ratio of optical densities at 465 and 665 nm (E_4/E_6) was 3.92 and the free radical concentration was 11.73×10^{17} spins/g (8).

(I) CuO–NaOH Oxidation

To 500 mg of HA dissolved in 50 ml of 2 *N* NaOH solution in a 300 ml stainless steel autoclave equipped with a magnetic stirrer, 2.5 g of CuO was added. The system was heated to 170 °C with constant stirring over a period of 1 h and then maintained at that temperature for 2 h. Following cooling to room temperature, suspended CuO was removed by centrifugation and washed with distilled H_2O. The supernatant solution plus washings were saturated with NaCl and extracted successively with 3 × 100 ml aliquots of 2:1 (v/v) chloroform–acetone after acidification to p*H* 6 and 2. When the p*H* was lowered to 2, a fraction of the water-soluble oxidation products became insoluble. The insoluble material, (Ii) was removed by filtration and the clear supernatant solution extracted with chloroform–acetone. The two organic extracts were first dried over anhydrous Na_2SO_4 and then taken to dryness in a rotary evaporator, dissolved in a small volume of CH_3OH, and methylated with an ether solution of diazomethane generated from Diazald. Yields of benzene-soluble, methylated extracts were: 32.3 mg for the extract at p*H* 6, and 27.2 mg for the extract at p*H* 2. The two extracts were combined (fraction I, see Fig. 1). The insoluble fraction (Ii) weighed 150 mg, contained 39.3% ash and, on a dry, ash-free basis, analysis (%) showed 61.62 C; 4.56 H; 2.18 N; 0.68 S; 30.96 O; and 1.19 OCH_3. The major components in fraction I were separated by preparative gas chromatography and identified by mass spectrometry and micro-i.r. spectrophotometry as described below.

(II) CuO–NaOH + $KMnO_4$ Oxidation

The CuO–NaOH oxidation of 500 mg of HA was carried out as described under method I. Fractions I and Ii were methylated with diazomethane and then oxidized with aqueous 4% $KMnO_4$ solution (6). The oxidation products were extracted from acidified aqueous solution with ethyl acetate, remethylated with diazomethane, dissolved in benzene, separated by preparative gas chromatography, and identified by mass spectrometry and micro-i.r. spectrophotometry as described below. Yields of methylated, benzene-soluble fractions II*a* (from I) and II*b* (from Ii) were 20.5 and 65.6 mg, respectively.

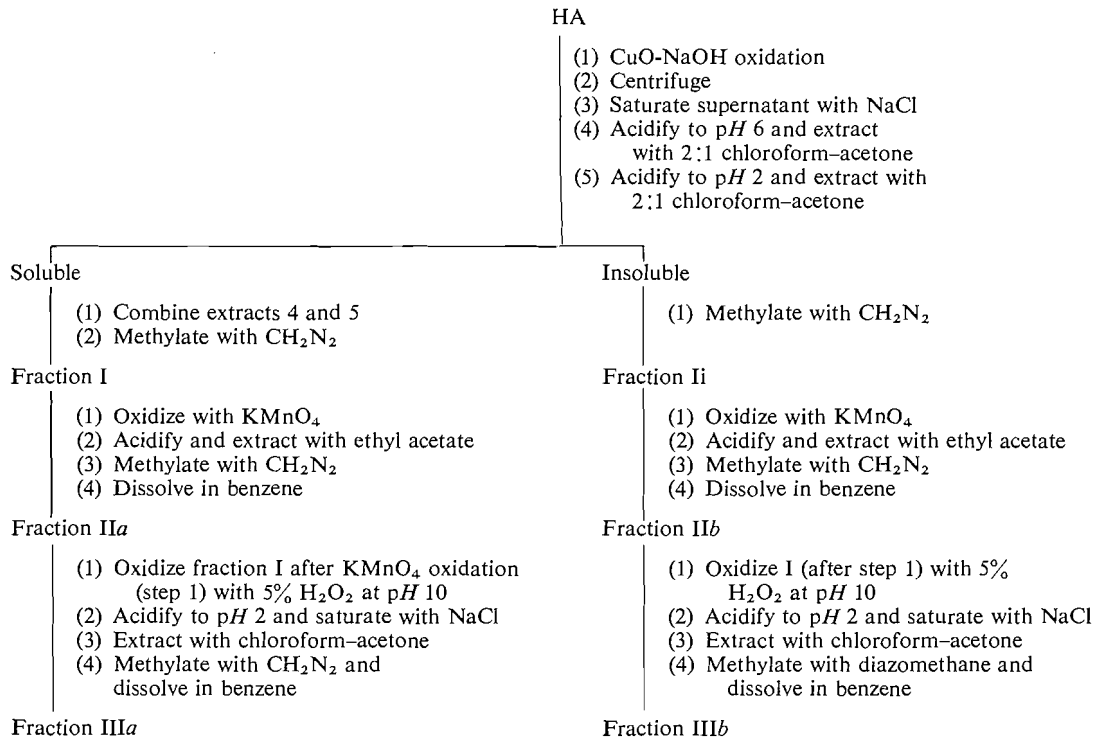

FIG. 1. Oxidation and separation of fractions I, Ii, IIa, IIb, IIIa, and IIIb.

(III) CuO–NaOH + $KMnO_4$ + H_2O_2 Oxidation

Fractions I and Ii were prepared as described above and then oxidized with 4% $KMnO_4$ solution. Water-soluble oxidation products were further oxidized by contact with 5% H_2O_2 solution at p*H* 10 for ½ h at room temperature with intermittent shaking and then warmed briefly to 50 °C. The excess H_2O_2 was destroyed by the addition of a few drops of dilute $KMnO_4$ solution. The resulting solutions were treated briefly with SO_2, acidified to p*H* 2 with 6 *N* H_2SO_4 solution, saturated with NaCl, and extracted three times with 100 ml of 2:1 (v/v) chloroform–acetone. The organic extracts were dried, methylated with diazomethane, dissolved in benzene, and analyzed as described under method I. Yields were as follows: fraction III*a* (from II*a*), 2.1 mg and fraction III*b* (from II*b*), 23.1 mg.

(IV) $KMnO_4$ Oxidation

Five hundred milligrams of HA was refluxed for 8 h with 125 ml of 4% (w/v) aqueous $KMnO_4$ solution (p*H* 10). Following oxidation, the excess $KMnO_4$ was destroyed by careful addition of small volumes of CH_3OH. The insoluble MnO_2 was removed by filtration and washed with small aliquots of hot water. The filtrate plus washings were acidified to p*H* 2, saturated with NaCl, extracted with 3 × 100 ml portions of 2:1 (v/v) chloroform–acetone, dried, methylated, dissolved in benzene, and analyzed as described below. The benzene-soluble, methylated oxidation product (fraction IV) weighed 34.9 mg.

(VI) Na-amalgam reduction

One gram of HA, dissolved in 100 ml of 1% NaOH solution, was refluxed with vigorous stirring under N_2 over 100 g of 5% Na-amalgam (BDH reagent grade) for 3 h. After cooling, the supernatant solution was separated from the insoluble residue by filtration, acidified to p*H* 2, and extracted successively with three 75-ml portions of diethyl ether. The ether extract was dried over anhydrous Na_2SO_4, and then methylated with diazomethane. For additional purification, the methylated reduction products were extracted with three 75-ml portions of benzene to yield fraction VI (39.50 mg). The latter was then separated by preparative gas chromatography and identified as described below.

Oxidation of Methylated HA

Methods I, II, III, and IV were also applied to HA that was methylated with diazomethane (increase in OCH_3 = 14.37%) prior to oxidation. The fractions so obtained are referred to as Im, IIm, IIIm, and IVm (see Table 2 and Fig. 1). Fraction Vm was prepared by oxidizing 500 mg of methylated HA with aqueous 4% $KMnO_4$ solution as described under IV. Water-soluble oxidation products were then further oxidized with 5% H_2O_2 at p*H* 10 as in method III.

Separation and Identification of Degradation Products

Each methylated fraction was first analyzed as a 2.5% solution in benzene by analytical gas chromatography (Hewlett-Packard, Model 402, flame ionization detector,

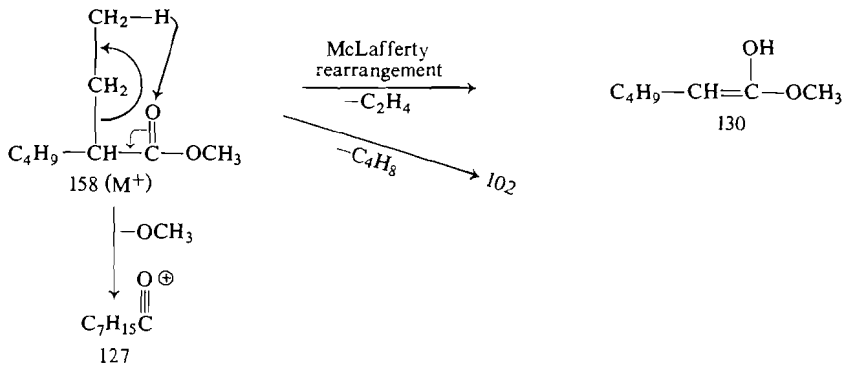

SCHEME 2

1800 × 4 mm glass column packed with 3% OV 17 on Chromosorb W HMDS, 60–80 mesh, programmed from 90–310 °C at a rate of 7.5 °C/min, N_2-flow = 40 ml/min), and then separated as a 10% solution in benzene by preparative gas chromatography under the same conditions. Materials representing the major gas chromatographic peaks were eluted from the gas chromatographic column, collected in capillary tubes, and analyzed by mass spectrometry and by micro-i.r. spectrophotometry as described earlier (9). Mass and i.r. spectra of unknowns were matched with those of standards of known structures. As an additional check, each unknown was co-chromatographed (on the gas chromatograph) with the known compound to which it corresponded. In some instances fractions were analyzed directly on a g.c.–m.s.-computer system. Quantitative estimates of each compound were made by triangulation of peak areas on the gas chromatograms. All solvents were purified by distillation through high-efficiency columns.

The known compounds used as standards for the mass spectrometric and i.r. spectrophotometric identification of the unknowns were either prepared as described earlier (9) or purchased commercially. Each compound was purified by suitable methods. We were unable to obtain appropriate standards for components **27** and **29**, so that the identification of these compounds is tentative only.

Compounds **1** and **5** were identified by g.c.–m.s.-computer (Shrader Analytical and Consulting Laboratories, Detroit, Michigan). The mass spectrum of **1** suggested the fragmentation pattern shown in Scheme 1. The mass spectrum for **5** suggested similarly the fragmentation pattern depicted by Scheme 2. The gas chromatographic separation of fraction Vm is shown in Fig. 2.

Analytical Methods

C and H were determined by dry-combustion, N by the automated Dumas method, S by oxygen-flask combustion, and O was calculated by difference. The OCH_3-content was measured by the Zeisel method.

Results

(A) Degradation of Unmethylated HA

(I) CuO–NaOH Oxidation

Major degradation products resulting from the CuO–NaOH oxidation of the HA are listed in Table 1 under method 1. Since the oxidation products were methylated prior to the gas chromatographic separations, and since the OCH_3-content of the untreated HA was low, it is likely that in the initial HA's the functional group in

the 4-position on the aromatic rings of compounds **10–12** and **15–19** (see Fig. 3) was OH rather than OCH_3. Thus, the major CuO–NaOH oxidation products have guaiacyl and syringyl structures with CHO, $COCH_3$, and CO_2H groups in the 1-position. The weight ratio of guaiacyl (**10–12**) to syringyl (**16–19**) structures was 0.47, indicating a preponderance of syringyl units in the oxidation mixture. Other compounds identified were **20**, which contains both S and N, and about which little is known, and dibutyl phthalate (**24**) which was isolated in relatively large amounts. In view of recent work in this laboratory (10) which showed that HA's can adsorb large amounts of dialkyl phthalates, it is likely that **24** is not a structural HA component but that it is either firmly adsorbed on the HA surface or, less likely, a contaminant.

(II) CuO–NaOH + $KMnO_4$ Oxidation

Further oxidation of methylated fraction I with $KMnO_4$ led to the disappearance of phenolic compounds **10**, **11**, **13**, **15**, **16**, and **17** and to losses of **12** and especially of **19** (Table 1, II*a*). At the same time varying amounts of benzenepolycarboxylic acid methyl esters **8**, **9**, **21–23**, **26**, **30–32**, and **34** were formed, apparently from more complex chemical structures, by the more vigorous oxidation with $KMnO_4$. This was especially so for the CuO–NaOH pretreated material that coagulated at p*H* 2 and that was insoluble in organic solvents. The oxidation ($KMnO_4$) mixture from the latter material (Table 1, II*b*) was free of phenolic compounds but contained relatively large amounts of benzenecarboxylic acid methyl esters, principally the tri-(**21**, **22**), tetra-(**26**) and penta-(**31**) forms. These data indicate the occurrence of more condensed chemical structures in II*b* than in II*a*.

(III) CuO–NaOH + $KMnO_4$ + H_2O_2

Additional oxidation of II*a* with H_2O_2 led to substantial losses of phenolic as well as benzenecarboxylic components (III*a*). In the case of fraction II*b*, H_2O_2 oxidation produced small amounts of C_6C_3-compound **18** and somewhat greater amounts of **19**, but lowered the yields of most benzene – carboxylic acid methyl esters (III*b*, compare with II*b*). It appears that the additional treatment with H_2O_2 in alkaline solution was too drastic.

(IV) $KMnO_4$ Oxidation

The $KMnO_4$ oxidation of the unmethylated HA produced small amounts of benzenecarboxylic acid methyl esters ranging from the di- to the hexa-forms (IV). Especially noteworthy was the formation of relatively large amounts of 1,2,3-benzenetricarboxylic acid trimethyl ester (**21**), accounting for 3.3% of the initial HA. Failure to isolate phenolic compounds under these conditions is not surprising since the pres-

ence of electron-donating OH groups on aromatic rings makes these rings susceptible to attack by electrophilic $KMnO_4$ (4).

(VI) Na-Amalgam Reduction

The major reduction products were phenolic compounds **19**, **18**, and **10** (Table 1, VI). Compound **20** was another major product identified. It was also one of the major components isolated from the mixture resulting from the CuO–NaOH oxidation (I). Thus, the reduction of HA yields both guaiacyl (**10**, **12**) and syringyl (**16–19**) structures, with the latter clearly predominant. Of some interest is the isolation of small amounts of **13**, which is not a "typical" lignin-degradation product.

(B) Degradation of Methylated HA

(Im) CuO–NaOH Oxidation

The CuO–NaOH oxidation of methylated HA (Table 2, Im) yielded the same type of compounds as that of the unmethylated HA (Table 1) but in greater amounts. Again there was a predominance of syringyl (**16–19**) over guaiacyl (**10–12**) moieties. In addition, small amounts of phenolic compound **2** and larger quantities of branched fatty acid methyl esters **1** and **5** were identified in the oxidation mixture. The most abundant products were **20** and **24**. The total weight of oxidation products soluble in organic solvents was about twice that obtained from the CuO–NaOH oxidation of the unmethylated HA. Only about 65% of the oxidation products was identified (Table 2, Im). Most of the compounds that we have so far been unable to identify eluted from the gas chromatographic column at < 200 °C. It is apparent that methylation of the HA prior to CuO–NaOH oxidation increased the yields of oxidation products significantly.

(IIm) CuO–NaOH + $KMnO_4$ Oxidation

Further oxidation with $KMnO_4$ of the products from the CuO–NaOH oxidation that were soluble in chloroform–acetone (IIm*a*) resulted in the virtual disappearance of most of the compounds that eluted at <200 °C and also led to either the disappearance or a reduction in concentration of the phenolic compounds and of **20**. Simultaneously small amounts of benzenecarboxylic acids were formed. The CuO–NaOH pretreated fraction that was insoluble in organic solvents yielded on further oxidation with $KMnO_4$ (IIm*b*), small amounts of aliphatic dicarboxylic acid methyl ester **7**, methylated phenolic acids **12** and **19** and benzenecarboxylic acids, mainly the tetra-**26** and penta-**31** forms.

(IIIm) CuO–NaOH + $KMnO_4$ + H_2O_2

More drastic oxidation of fraction IIm*a* with H_2O_2 produced small amounts of methylated aliphatic dicarboxylic acids (**3**, **4**, **6**, **7**), phenolic compounds (**12**, **18**, and **19**) and benzenecarboxylic acids, some of which contained $OH(OCH_3)$ groups (**25**) (Table 2, IIIm*a*), indicating the occurrence in the HA of complex phenolic structures. Fraction IIIm*b* was similar in composition to IIIm*a*.

(IVm) $KMnO_4$ Oxidation

The permanganate oxidation of methylated HA (Table 2, IVm) yielded small amounts of methylated suberic acid (**7**), complex phenolic acids (**29**, **33**, and **35**) and relatively large amounts of benzenecarboxylic acids, ranging from di- to hexa-types. The most abundant products were the 1,2,3,4-benzenetetra-**26**, the -penta-**31**, and 1,2,4- and 1,2,3-tri-**22** and **-21** benzenecarboxylic acid methyl esters. Of special interest was the isolation of **35**, the only biphenyl compound that we were able to detect.

(Vm) $KMnO_4$ + H_2O_2 Oxidation

Further oxidation of IVm with H_2O_2 yielded fraction Vm which was similar in composition to IVm except that it contained additional small amounts of phenolic compounds **18**, **19**, **25**, **29**, and **30**, aliphatic dicarboxylic acid esters **3**, **4**, **6**, **7**, and **14** but lower concentrations of benzenecarboxylic acid methyl esters. The additional treatment with H_2O_2 appeared to favor, at least to a small extent, the formation of phenolic compounds.

Discussion

The CuO–NaOH oxidation of the unmethylated and methylated HA yields small amounts of guaiacyl and syringyl monomers with up to three C atoms in the aliphatic side chain (Table 1, I; Table 2, Im); in addition, small yields of guaiacyl compounds with a biphenyl structure are obtained by the permanganate oxidation of methylated HA (Table 2, IVm). The CuO–NaOH oxidation of the unmethylated and methylated HA affords phenolic compounds which account for about 3.1 and 6.0% of the weight of the initial HA, respectively. Qualitatively, the compounds identified resemble those isolated by Pearl (2) from products resulting from the CuO–NaOH oxidation of coniferous

and hardwood lignosulfonates. Quantitatively the amounts of phenolics isolated from the HA are low. For example, Pepper and Karapally (11) found average yields (as % of Klason lignin) of 15.1 for **10**, 3.7 for **11**, and 2.0% for **12** (compared to 0.4, 0.4, and 0.2, and 0.3, 0.9, and 1.2%, respectively, from unmethylated and methylated HA, see Table 1, I and Table 2, Im), when they oxidized spruce potolignin with CuO–NaOH. Chang and Allan (12) report that the CuO–NaOH oxidation of spruce lignin yields 15.90 of **10**, and 3.91% of **11**, while that of aspen lignin produces 7.82 of **10**, 1.96 of **11**, 20.0 of **16**, and 5.34% of **17**. On the other hand Greene and Steelink (13) oxidized two HA's with CuO–NaOH and identified 0.57 and 0.01% of **10**, 0.41 and 0.21% of **12** and 0.05% and a trace of **16**, but failed to detect any of the other compounds listed in Table 1, I. Greene and Steelink (13) identified in addition small amounts of *p*-hydroxybenzaldehyde, *m*- and *p*-hydroxybenzoic acid (**2**), and 3,5-dihydroxybenzoic acid (**13**) for a total of 1.43% phenolics for one HA sample and 0.58% for another HA sample. These amounts are lower than those identified in this investigation although they are of the same general magnitude. Reduction of the HA with Na-amalgam (Table 1, VI) affords 1.8% of phenolic compounds, with syringyl units predominating over guaiacyl moieties. Thus, all experimental data point to the occurrence of lignin or lignin-derived material in the HA. Probably the best indication for the presence of lignin-derived units in the HA is the isolation of 0.2% of dehydrodiveratric acid dimethyl ester (**35**) from products resulting from the $KMnO_4$ oxidation of methylated HA (IVm). According to reports in the literature (12), yields of **35** on permanganate oxidation of a variety of methylated lignins, with and without prior alkaline hydrolysis, range from 0.2 to 4.0%. If we accept an average value of 2.0%, the contribution of lignin-derived units to the total weight of the HA as indicated by the isolation of **35** is about 10%.

An objection to the interpretation advanced above arises from recent work in our laboratory (14) which showed that the Na-amalgam reduction of "HA's" synthesized by fungi grown on a glucose–asparagine medium in the laboratory (and which had never been in contact with lignin) also produced small amounts (0.7%) of guaiacyl structures **10** and **12** and syringyl monomers **16–19**. Thus, the isolation of phenolic compound **10–12** and **16–19** is not an unequivocal proof for the presence of lignin-derived units in the HA. It may be relevant at this point to refer to other work that we have done recently (14) in which we investigated the permanganate oxidation of "HA's" synthesized in the laboratory by *Aspergillus niger*, *Epicoccum nigrum* and *Stachybotrys chartarum* grown on a glucose–asparagine medium. The oxidation products of methylated fungal "HA's" produced practically the same types but, per unit weight, relatively greater amounts of aliphatic acids but smaller amounts of phenolic and benzenecarboxylic compounds than those listed in Table 2 under IVm. The only exception was our failure to detect even traces of dehydrodiveratric acid dimethyl ester (**35**), which the fungi were apparently unable to produce. We believe, therefore, that the isolation of **35** is the most reliable indication of the presence of lignin-derived material in HA.

The permanganate oxidation of unmethylated HA (IV) produces 5.6% benzenecarboxylic acids (as esters) which is higher than the yields of 0.1 to 3.8% obtained by Read and Purves (5) from various lignins under the same experimental conditions. It has been postulated that aromatic rings containing oxygen are destroyed by $KMnO_4$ and that benzenecarboxylic acids originate from rings in which ring-C atoms are bonded to other C atoms but not to O atoms. The suggestion has also been made that in the case of lignin, benzenecarboxylic acids are formed from side chains of condensed units having conidendrin-like structures as a result of dehydrogenation (12) or from cyclolignans (3). Whether and to what extent this applies to the HA remains to be investigated.

Larsson and Miksche (3) have recently shown that the permanganate oxidation of methylated birch lignin that had first been pre-oxidized with CuO–NaOH yielded more than three times as much **12** and nine times as much **19** as that of methylated lignin that had not been so pretreated. They ascribe the increased yields to the degradation of structures bonded via phenolic oxygens to other lignin components in addition to structures with free phenolic OH groups (the latter are apparently degraded by $KMnO_4$ oxidation of methylated lignin). When we used this approach on the HA (Table 1, I and III) we were unable to detect even traces of **12** and the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

yield of **19** was reduced to 25% of that obtained with CuO–NaOH alone. Thus, the HA does not appear to contain many "bonded" phenolic oxygens.

Other oxidation products from the methylated HA are small amounts of *p*-methoxy(OH)-benzoic acid methyl ester (**2**), a typical lignin degradation product (2) and somewhat larger amounts of branched butyric acid methyl esters (**1**, **5**) with CH_3- and C_4H_9-groups in the side chains. In addition, small amounts of aliphatic dicarboxylic acid esters, ranging from glutaric ($n = 3$) to sebacic acids ($n = 8$) are formed. Some of the aliphatic compounds may arise from chains that link aromatic or hydroaromatic rings or from the degradation of saturated ring structures. Furthermore, the oxidation of methylated HA produces a number of methoxy-(OH)-benzenecarboxylic acid esters (**25**, **29**, **33**) which are indicative of the occurrence of complex phenols in the HA. The major oxidation products from methylated HA's, however, are benzenecarboxylic acid methyl esters, ranging from the di- to the hexa-forms. For example, the $KMnO_4$ oxidation of the methylated HA (Table 2, IVm) produces 0.1% aliphatic dicarboxylic acid methyl ester, 1.2% phenolic ethers and esters, but 10.6% benzenecarboxylic acid methyl esters. Of the latter 4% are dicarboxylic, 30% tricarboxylic, 47% tetracarboxylic, 15% pentacarboxylic, and 4% hexacarboxylic. Carbon skeletons of possible precursors of the major oxidation products are shown in Fig. 4.

Relatively large amounts of **20** (up to 3.2% of the initial weight) were isolated from the methylated HA. How **20** fits into the chemical structure of HA is not known at this time. Judging from the N content (3.29%), protein could constitute ±20% of the weight of the HA, although a more realistic figure would be 10% (1). In addition, the HA could also contain a few per cent of carbohydrates. Since recent studies (14) have shown that most of the N-compounds and carbohydrates could be removed by hydrolysis with 6 *N* HCl without causing significant changes in analytical and structural characteristics of HA's, it is likely that proteins and carbohydrates are not structural HA components but are adsorbed on the large HA surfaces.

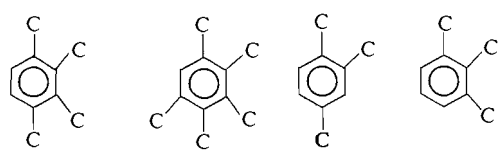

FIG. 4. Carbon skeletons of major products resulting from the $KMnO_4$ oxidation of methylated HA.

The experimental results reported herein show that the HA contains an easily degradable portion which consists of guaiacyl and syringyl units and which may be lignin-derived (about 10% of the total weight). This material is degraded by CuO–NaOH and Na-amalgam. The bulk of the HA-structure, however, consists of a more condensed chemically complex "core" which degrades on more drastic oxidation into complex phenolic and benzenecarboxylic acids. Whether the "core" consists of condensed lignin or whether it is of microbial origin awaits further investigation. It is likely that it is a mixture of the two.

Of the methods that we have examined in this investigation the most promising appear to be: (*a*) the CuO–NaOH oxidation of methylated HA, which produces high yields of products, about half of which elute from the gas chromatographic column at relatively low temperatures (<200 °C), and a substantial portion of which still remains to be identified and (*b*), the permanganate oxidation of methylated HA which provides meaningful information on the chemical structure of the complex "core" of the HA.

We thank S. I. M. Skinner and R. Schaffer of Morgan-Schaffer Corp., Montreal for mass spectrometric analyses, B. Mattson for technical assistance, and G. F. Morris for ultimate analyses.

Isotopic Studies of the Metal–Ligand Bond. Part III. The Far Infrared Spectra of Some Tetragonal Diamine Complexes of Cobalt(II) and Nickel(II): Studies of the Metal–Nitrogen Bond, as a Function of Metal Ion and of Spin State

A. B. P. LEVER AND ELVIO MANTOVANI

Department of Chemistry, York University, Downsview, Ontario M3J 1P3

Received October 17, 1972

The far infrared spectra of 35 complexes of the formula $M(diamine)_2X_2$ are reported where M = Co(II) and Ni(II), X = Cl^-, Br^-, I^-, NO_3^-, SCN^-, ClO_4^-, and AgI_2^- and the diamine is ethylenediamine or its *N,N*-symmetric or antisymmetrically substituted dimethyl or diethyl derivative. Isotopic substitution studies with ^{62}Ni and with ^2H are carried out with eleven characteristic complexes and assignments for the metal–nitrogen modes in both octahedral and square planar complexes so deduced. In most cases the appropriate number of metal–ligand modes, based on symmetry considerations, are observed. The variations in observed M—N frequencies are discussed in terms of the electronic and geometric factors previously utilized for the corresponding copper(II) complexes. In complexes containing the asymmetric ligands, stretching vibrations arising from the two types of metal–nitrogen bond can be separately identified. Isotopic studies of pairs of complexes containing the same ligand and metal ion but with the latter in alternate spin states are reported here for the first time. All of the cobalt(II) complexes and several of the nickel(II) complexes are reported here for the first time.

Les spectres dand l'infrarouge lointain de 35 complexes de formule M $(diamine)_2X_2$ ont été rapportés, avec M = Co(II) et Ni(II), X = Cl^-, Br^-, I^-, NO_3^-, SCN^-, ClO_4^-, et AgI_2^- et la diamine est l'éthylènediamine ou ses dérivés *N,N*-diméthylés ou *N,N*-diéthylés, symétriquement ou antisymétriquement substitués. Les études de substitution isotopique avec ^{62}Ni et ^2H ont été effectuées sur onze complexes caractéristiques et les attributions sur les modes concernant la liaison métal–azote, à la fois pour les complexes octaédral et carré-plan, ont pu être déduites. Dans la plupart des cas, le nombre approprié de modes relatifs au métal–ligand basé sur des considérations de symétrie, a pu être observé. Les variations dans les fréquences M—N observées ont été discutées par rapport aux facteurs électroniques et géométriques précédemment utilisés pour les complexes de cuivre(II) correspondants. Dans les complexes comprenant des ligands asymétriques, les vibrations d'élongation qui sont dues aux deux types de liaison métal–azote ont pu être séparément identifiées. Les études isotopiques portant sur les paires de complexes contenant le même ligand et le même ion métal, ce dernier se trouvant dans des états de spin alternés, ont été rapportées ici pour la première fois. Tous les complexes de cobalt(II) et plusieurs complexes de nickel(II) ont été décrits ici pour la première fois. [Traduit par le journal]

Can. J. Chem., **51**, 1567 (1973)

Introduction

We recently reported the far infrared and electronic spectra of mono- (1) and bis(diamine) (2) complexes of copper(II) and discussed these data in terms of the electronic and geometric structures of the complexes. Subsequent isotopic substitution data (3) generally confirmed the assignments. Novel correlations were observed between the vibrational and electronic spectra and some useful bonding information so derived. This paper deals with corresponding derivatives of cobalt(II) and nickel(II), whose spectra are fairly closely related both to each other and to the copper derivatives. Many of the nickel complexes have been reported previously, whilst the cobalt derivatives are new. The electronic spectra and magnetism of these cobalt complexes will be the subject of a later paper (4).

Whilst there is little doubt that all the previously discussed (2) copper complexes $Cu(diamine)_2X_2$ have a *trans* octahedral configuration, the complexes $Ni(en)_2Cl_2$ and $Ni(en)_2Br_2$ are *cis* dimeric with halogen bridges (5), whilst the isothiocyanate complex $Ni(en)_2(NCS)_2$ has a *trans* monomeric structure (6).

The Ni(*sym*-$Me_2en)_2X_2$ (X = Br, and NO_3) complexes are also *trans* octahedral (7). (See footnotes to Table 1 for abbreviations.) No other X-ray studies of the paramagnetic members of this series appear to have been reported.

The observation of only one ν(CN) stretching frequency in the thiocyanate complexes $M(diamine)_2(NCS)_2$ (especially if the measurement is carried out at liquid nitrogen temperature) (8) provides strong, though probably not unequivocal, support for a *trans* configuration of these complexes.

The criteria used to assign the far infrared

*Previously characterized complexes have been analyzed for at least one element to ensure purity. Previously uncharacterized complexes have been analyzed for several elements to ensure both purity and identity. The octahedral nickel complexes are pale green or pale blue (Table 2) whilst the square derivatives (Table 3) are yellow or yellow orange. The cobalt complexes are generally pink.

†En = ethylenediamine, *sym*-Me_2en = *sym*-*N*,*N*′-dimethylethylenediamine; *asym*-Me_2en = *asym*-*N*,*N*-dimethylethylenediamine; *sym*-Et_2en = *sym*-*N*,*N*′-diethylethylenediamine; *asym*-Et_2en = *asym*-*N*,*N*-diethylethylenediamine; r = required; f = found.

spectra of complexes of this type have been previously discussed (1–3). In the earlier studies (1, 2) many of the complexes were *N*-deuterated by multiple treatment of the complex with D_2O. The metal–nitrogen band decreased in energy as a consequence of resulting increase in the effective reduced mass of the Cu—N bond. Unfortunately it is difficult to carry out similar studies successfully with the cobalt and nickel complexes. In the majority of such experiments the complexes either hydrolyzed or disproportionated to the $M(ligand)_3^{2+}$ species. However two experiments were successful and are included herein. The isotopic substitution technique (3, 9, 10) provides a more definitive guide to the assignment of metal ligand modes.

It is understood that bands identified as "metal–ligand stretching modes" will in general be coupled with other vibrations of the molecule. The description of a band as arising from such a vibration implies that the potential function describing the vibration is predominantly metal–ligand in origin.

The highest copper–nitrogen stretching frequency in the ethylenediamine derivatives occurs (1–3) in the region 350–420 cm^{-1} depending upon the amine, and the axial interaction. For the octahedral complexes of cobalt(II), nickel(II), and copper(II) of nitrogeneous ligands, previous evidence suggests that the highest energy infrared active metal–nitrogen stretching frequency appears to fall in the sequence ν(Cu—N) > ν(Ni—N) > ν(Co—N). This is supported by consideration of the complexes of ammonia, hydrazine (11), and imidazole (12), *viz.* $Cu(NH_3)_4Cl_2$, 420; $Cu(NH_2.NH_2)_2Cl_2$, 440; $Cu(IMZ)_4Cl_2$, 286; $Ni(NH_3)_6Cl_2$, 334; $Ni(NH_2.NH_2)_2Cl_2$, 409; $Ni(IMZ)_6Cl_2$, 262; $Co(NH_3)_6Cl_2$, 318; $Co(NH_2.NH_2)_2Cl_2$, 388; $Co(IMZ)_6Cl_2$, 240 cm^{-1}.

Pyridine complexes also exhibit this trend (13). Unequivocal confirmation of these nitrogen frequencies using isotopic substitution experiments has been obtained by Nakamoto and co-workers (14, 15) who confirm the sequence, at least for 8-hydroxyquinoline derivatives (14). Further, the Ni—N stretching frequency in $Ni(bipy)_3.2ClO_4.2H_2O$ has been unequivocally identified at 292 cm^{-1} (15). Nakamoto and co-workers (16, 17) have also demonstrated by isotopic experiments that the Ni—N stretching frequency lies between 360 and 400 cm^{-1} in complexes of *asym*-dimethylethylenediamine and some mixed nitrogen sulfur bidentate chelating ligands. Thus the metal–nitrogen modes in the *high spin* octahedral cobalt(II) and nickel(II) complexes under discussion are expected below 400 cm^{-1}, the region where the corresponding copper modes are observed.

Having satisfactorily assigned the copper complexes (1–3), assignments for the cobalt(II)

and nickel(II) derivatives should follow readily in those cases where the spectrum of the cobalt or nickel complex is very similar to that of the corresponding copper complex. The intensity of the metal–nitrogen vibration is somewhat variable (18) and whilst it is usually readily identifiable in the copper and nickel spectra, it is frequently very weak in the cobalt spectra. This problem has been partially solved by obtaining low temperature (sample cooled in liquid nitrogen) spectra which are better resolved and in which the band intensities are generally enhanced (19–21).

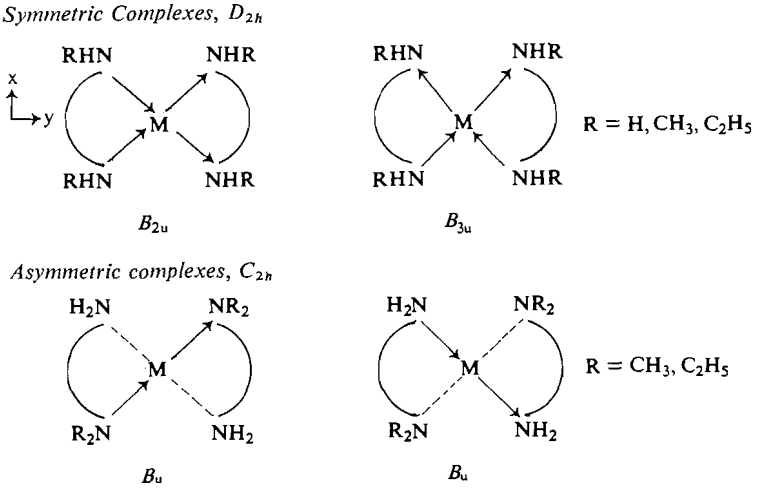
With weakly coordinating anions, or with sterically bulky amines, nickel(II) commonly forms square planar rather than tetragonal octahedral complexes. These complexes are diamagnetic and will have shorter metal–nitrogen bonds than their octahedral analogs. As a consequence the force constant for the nickel–nitrogen vibration should increase and the absorption frequency is expected to occur at a higher energy than in the octahedral complexes; nickel–nitrogen stretching frequencies in diamagnetic nickel complexes have not been well documented. The data were all recorded in the solid state since the species decompose in solution.

Experimental

The far infrared spectra were obtained with a Beckman IR 12 Spectrometer as Nujol mulls supported on polythene. The isotopic data scanned at 1–2 cm^{-1}/min are accurate to ± 0.2 cm^{-1}. The instrument was calibrated with water vapor, in the far infrared region (22), and with polystyrene in the conventional region. Reproducibility from one sample to another was 0.5 cm^{-1} or better, for the sharper bands. Quoted data are the average of at least three scans. Low temperature spectra were obtained with an evacuated VLT-2 Variable Temperature Cell, equipped with NaCl or polypropylene windows. The cold finger was cooled with liquid nitrogen. Equilibrium was achieved after about 40 min beyond which time there were no further changes in the spectra. The exact temperature achieved is not known but is likely to be within about 20° of −196 °C. The complexes studied are listed in Table 1 together with their analytical data and previous references where relevant. New complexes were prepared by the general method of treating the metal salt with the appropriate ligand in stoichiometric proportions in absolute ethanol. For cobalt complexes it was necessary to add triethylorthoformate to the solvent to remove water and to carry out the reaction under a nitrogen atmosphere to preclude oxidation. Many of the cobalt complexes so obtained decomposed slowly in the solid state in the presence of air. Where possible the complexes were recrystallized from the same solvent. The samples were dried at about 80° under vacuum prior to analysis and spectra determination. The isotopically substituted complexes were prepared from ^{62}Ni obtained in 99% isotopic purity from Oak Ridge National Laboratory. The complexes were obtained on a 5 mg (of Ni) scale through the sequence $^{62}Ni \rightarrow {}^{62}NiX_2 \rightarrow$ complex followed by ignition of the complex to recover the nickel as ^{62}NiO and reconversion to $^{62}NiX_2$. Loss of ^{62}Ni could be maintained below 5% per experiment. Deuterated *asym-N,N*-diethylethylenediamine was prepared *in situ* by multiple treatment of $(C_2H_5)_2NCH_2CH_2NH_2$ with D_2O (99.8% D, Stohler Isotope Chemical Co.) acidified by the addition of a small amount of P_2O_5. The product was extracted with chloroform and the extract dried by several applications of anhydrous sodium sulfate and finally by treatment with a small volume of triethylorthoformate. This solution was then added, in excess, to a solution of anhydrous nickel chloride or bromide in a small volume of dimethyl sulfoxide-d^6. The product separated upon shaking for a short period at room temperature. The identity of these products as the *N*-deuterated Ni(*asym*-$Et_2en)_2X_2$ (X = Cl, Br) was assured by comparison of their electronic spectra with the electronic spectra of the hydrogen analogs. Their vibrational spectra showed a very marked decrease in the intensities of the N—H stretching and NH_2 rocking modes, and the appearance of very strong N—D stretching modes near 2300 cm^{-1}. It was not possible to obtain a sample in which the N—H modes were entirely absent and it may be assumed that the complexes $((C_2H_5)_2NCH_2CH_2ND_2)_2NiX_2$ are probably contaminated with some $((C_2H_5)_2NCH_2CH_2NHD)_2NiX_2$ plus a trace (the NH_2 rocking mode was greatly diminished in intensity) of the NH_2 complex.

Results

The discussion follows that developed for the copper(II) complexes of the same general formula (2, 3). However, whilst the axial bonds in the very strongly tetragonally distorted copper complexes did not in general give rise to metal – axial ligand vibrational absorption above 200 cm^{-1}, this will not necessarily be the case in the cobalt(II) and nickel(II) complexes, where the tetragonal distortion may be less marked. Thus in regular octahedral complexes the Co—Cl and Ni—Cl stretching vibrational frequencies are expected (23, 24) near 240 cm^{-1} and the corresponding thiocyanate frequencies (24–26) from about 240 to 300 cm^{-1}. Metal–nitrate vibrations are the subject of some debate but probably lie in the region 250–350 cm^{-1} (16, 17, 27–29). Metal–bromide and iodide bands lie (23) below 200 cm^{-1} and will not be observed in this study. It is evident from the preceeding discussion that no metal (Co(II) or Ni(II)) ligand bands are expected to occur above 400 cm^{-1} in these complexes (except perhaps in the square nickel complexes) and that bands in the region 400–500 cm^{-1} can therefore be safely assigned to



SCHEME 1. Infrared allowed M—N stretching vibrations

ring vibrations (in-plane skeletal vibrations of the ligand back-bone) (1–3). Bending vibrations are unlikely to lie above 225 cm^{-1} (2, 15, 16) in the high spin complexes.

Paramagnetic Complexes

(i) Ethylenediamine derivatives

In view of the *cis* dimeric nature of $Ni(en)_2Cl_2$ and $Ni(en)_2Br_2$ (and on the basis of the similarity of its far infrared spectrum, $Ni(en)_2I_2$), their far infrared spectra differ markedly from the copper complexes of analogous formulation, Since there are no terminal Ni—X bonds, no ν(Ni—X) vibrations will be expected above 200 cm^{-1} (30). The very low symmetry of such complexes should lead to the observation of up to four infrared active metal–nitrogen stretching vibrations. Four bands in the spectrum of natural nickel $Ni(en)_2Cl_2$ shift down by more than 2 cm^{-1} upon substitution with ^{62}Ni. Two strong bands lie at 355.5 and 276 cm^{-1} whilst a weaker double band lies near 300 cm^{-1} (Table 2); these are therefore assigned as ν(Ni—N) vibrations. The bromide and iodide have spectra very similar to each other and to the chloride complex, leading to the facile identification of the four ν(Ni—N) modes in these compounds.

The complex $Ni(en)_2(NCS)_2$, with a *trans* configuration (6), has a very much more simple far infrared spectrum consistent with its higher symmetry. The nitrate $Ni(en)_2(NO_3)_2$ has a similarly simple spectrum and may also be assumed to have a *trans* configuration (note that the ν(NH_2) band is unsplit (31)). Assuming D_{2h} symmetry such complexes should exhibit 2 ν(Ni—N) bands (of B_{2u} and B_{3u} symmetry) and one ν(Ni—X) (B_{1u}) with infrared activity (Scheme 1). In the nitrate complex three bands (at 380, 319, and 292.5 cm^{-1}) shift down in excess of 2 cm^{-1} upon substitution by ^{62}Ni. The band at 380 cm^{-1} is undoubtedly ν(Ni—N). Of the two remaining isotopically sensitive bands that at 319 cm^{-1} is probably ν(Ni—O, NO_3) whilst that at 292.5 cm^{-1} is the remaining ν(Ni—N). This assignment is based on the expected position of ν(Ni—O, NO_3) (16, 17, 27–29), and on its greater sensitivity to isotopic substitution. In the thiocyanate complex, two bands at 305 and 345 cm^{-1} (Table 2) are clearly assignable to ν(Ni—N). Isotopic evidence for some of the substituted thiocyanate complexes presented below suggests that ν(Ni—N, NCS) lies near 240 cm^{-1} in keeping with previous literature (24–26). No such band can be unequivocally identified in this case. Cobalt(II) ethylenediamine complexes are unstable with respect to oxidation and were not studied.

sym-Dimethylethylenediamine Complexes

All these complexes have very similar spectra (Fig. 1) whose gross features are almost independent of change of metal (Co(II), Ni(II), or Cu(II)) or of counter-ion (Cl, Br, I, NCS, or NO_3). The main deviation would appear to be a band observed near 400 cm^{-1} in the copper complexes, probably a ring vibration, which is invariably split into two components in the cobalt and nickel complexes. In these cir-

*Nickel complexes prepared with natural nickel except where indicated; [62], complexes prepared with ^{62}Ni.
†Shoulders cited in parentheses. Data in square brackets indicate effect of liquid nitrogen temperature upon band immediately preceding datum. Note that natural nickel contains mainly ^{58}Ni (68%) and ^{60}Ni (26%). Because of the broadening of the absorption due to ^{60}Ni, the isotopic shifts indicated in these tables will be slightly underestimated.
‡See text for discussion of assignment of this band.

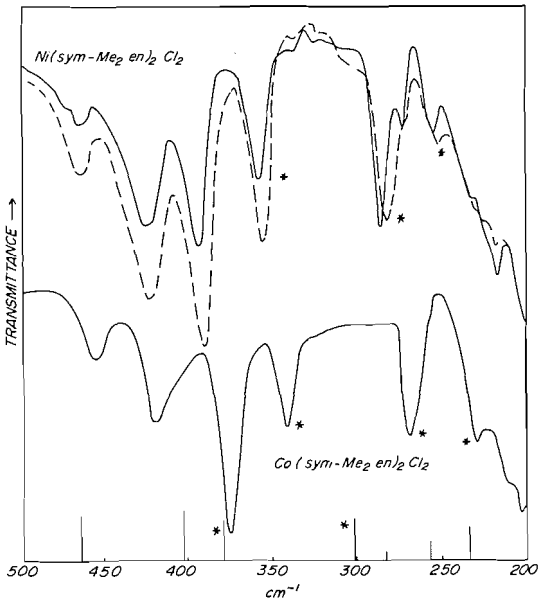

FIG. 1. Representative infrared spectra. Upper: Ni(*sym*-$Me_2en)_2Cl_2$ with natural nickel—, with ^{62}Ni---. Lower: Co(*sym*-$Me_2en)_2Cl_2$. The bars in the bottom of the diagram indicate the positions of the vibrations in Cu(*sym*-$Me_2en)_2Cl_2$ with their height qualitatively proportional to the band intensities.

cumstances a *trans* configuration for all the complexes seems assured. In particular the thiocyanate complexes exhibit a single ν(CN) frequency (at 2104 (Ni) and 2094 (Co) cm^{-1}) which is unsplit when the sample is cooled to −196 °C. Isotopic substitution of Ni(*sym*-$Me_2en)_2Cl_2$ reveals three isotopically sensitive bands at 353, 284, and 251 cm^{-1}. Although in the appropriate region (23, 24) it would be inappropriate to assign the lowest energy band to ν(Ni—Cl) since the band appears in much the same position in all the complexes, *i.e.* is independent of X. In the copper complexes (2, 3) three bands may similarly be identified but the lowest energy band is insensitive to isotopic substitution (3). In the nickel complexes the highest energy band (353 cm^{-1}) is least sensitive. It is probable that these three bands comprise the expected two ν(Ni—N) vibrations plus a ligand vibration of symmetry appropriate for coupling with one of the ν(Ni—N) modes. These three bands are readily picked out in all the complexes of this amine (Table 2); in the case of the cobalt(II) complexes, they are all shifted down, relative to the nickel(II) complexes, by about 15 cm^{-1}. No ν(M—Cl) or ν(M—N, NCS) vibrations can be identified above 200 cm^{-1}. However a band at 303 cm^{-1} in Co(*sym*-$Me_2en)_2(NO_3)_2$ is probably ν(Co—O, NO_3).

asym-Dimethylethylenediamine Complexes

The nickel complexes Ni(*asym*-$Me_2en)_2X_2$ where X = Cl, Br, and NO_3, have been previously discussed by Nakamoto and co-workers (17) with assignments supported by isotopic substitution. These authors assigned a pair of bands near 380 cm^{-1} to ν(Ni—N)(NH_2) and ν(Ni—N)(NMe_2) based on isotopic substitution with ^{62}Ni and ^{2}H. A band near 260 cm^{-1} was assigned to ν(Ni—Cl). Our own data for these complexes were in substantial agreement with this work and are not cited in Table 2. Data for Ni(*asym*-$Me_2en)_2(NCS)_2$ and for some cobalt(II) complexes are however included in Table 2. The spectra are similar to those previously discussed (17) and assignment of the high energy ν(Ni—N) follows readily. However in view of the fairly wide separation of the two ν(Ni—N) vibrations in the copper complexes of this ligand (2, 3), the close spacing of the two ν(Ni—N) modes cited by Nakamoto and co-workers (17) seems anomalous.

Data for *asym*-Et_2en complexes, cited below, suggests that the band at 260 cm^{-1} in Ni(*asym*-$Me_2en)_2Cl_2$ (17) may in fact include *both* ν(Ni—N) and ν(Ni—Cl). Thus the bands near 240 cm^{-1} in the other complexes (indicated in Table 2) may have ν(Ni—N) character, (see discussion below). We note, however, that unlike the symmetric ligand, the spectra of the cobalt and nickel complexes do not bear such a close resemblance to their copper analogs. Moreover broad ν(CN) absorption is noted for the thiocyanate complexes. The possibility of some of these complexes being *cis* rather than *trans* cannot be excluded.

sym-Diethylethylenediamine Complexes

Once again the gross features of the spectra are independent of the metal and of X, providing evidence for a *trans* configuration, and allowing for ease of assignment. The thiocyanate complexes exhibit a single ν(CN) absorption (at 2099 (Ni) and 2090 (Co) cm^{-1}) unsplit at low temperature. Two bands in Ni(*sym*-$Et_2en)_2Cl_2$ at 377 and 287.5 cm^{-1} are sensitive to isotopic substitution and may be assigned as ν(Ni—N) modes. It is inappropriate to assign the 287.5 cm^{-1} band to ν(Ni—Cl) since it is rather too high in energy and a band

of similar energy appears in the spectra of the bromide and iodide complexes. No ν(Ni—Cl) band can be identified. The two bands in the spectra of the other halide complexes, and of the cobalt analogs, are readily identified and similarly assigned. The complex Ni(*sym*-$Et_2en)_2(NCS)_2$ was also isotopically substituted. In this case, anomalously, the higher of the two bands did not shift (see below). However a band at 236 cm^{-1} did show sensitivity and is assigned to ν(Ni—N, NCS).

asym-Diethylethylenediamine Complexes

Once again there is a single ν(CN) absorption in the thiocyanate complexes (at 2098 (Ni) and 2090 (Co) cm^{-1}) unsplit at low temperature, suggesting a *trans* configuration. The cobalt and nickel complexes all have similar spectra suggesting all are *trans*. Isotopic substitution of both Ni(*asym*-$Et_2en)_2Cl_2$ and Ni(*asym*-$Et_2en)_2(NCS)_2$ leads to the identification of two metal sensitive modes near 400 and near 265 cm^{-1}, albeit in the thiocyanate case the sensitivity of the lower energy band is slight. In agreement with the observation of two similarly sensitive bands in the analogous copper(II) complexes (3), these are assigned to the expected ν(Ni—N) modes. By analogy with the *asym*-Me_2en complexes (17) the 265.5 cm^{-1} band in the chloride complex may contain both ν(Ni—N) and ν(Ni—Cl). Comparison with the spectrum of the bromide is not possible since this complex is square planar. It is pertinent that the lower energy ν(Ni—N) mode at 284.5 cm^{-1} in the thiocyanate complex is much weaker than in the chloride complex, and that in addition an isotopically sensitive band occurs in the thiocyanate complex at 242 cm^{-1} and is assigned to ν(Ni—N, NCS).

Unlike the case of the *asym*-Me_2en complexes there is no pair of closely spaced isotopically sensitive bands near 400 cm^{-1}. Accordingly the identification (17) of the bands at 378 and 360 cm^{-1} in Ni(*asym*-$Me_2en)_2Cl_2$ as ν(Ni—N)(M—NH_2), and ν(Ni—N)(M—$N(CH_3)_2$ must be considered unproven.

In the spectrum of the *N*-deuterated Ni(*asym*-$Et_2en)_2Cl_2$ both ν(Ni—N) bands are shifted down, the higher energy band being the most affected.

Diamagnetic Square Planar Complexes

The success of the procedures hitherto applied to the study of the far infrared spectra of metal complexes relies on the fact that bands identified as ν(M—L) have a potential distribution dominated by the M—L normal coordinate. In high spin octahedral and tetrahedral first row transition metal complexes this assumption is generally valid because the metal–ligand interaction, *i.e.* force constant, is sufficiently small, that coupling between the metal–ligand modes, and ligand modes of the same symmetry is minimized. However the apparent absence of some of the ν(M—Cl) and ν(M—N, NCS) modes in the above complexes may reflect coupling with other modes to a sufficient degree that isotopic substitution fails to identify them. It seems more likely however that they are obscured by other absorption. The appearance of three ν(M—N) modes in the *sym*-Me_2en complexes would appear to indicate a situation where coupling with one other mode is important leading to isotopic sensitivity for three, rather than two, bands. Alternatively the observation may arise through correlation coupling in the lattice.

With low spin transition metal derivatives, the metal–ligand interaction and force constant will be larger, and the interaction force constants which couple metal–ligand with ligand modes will also be larger. As a consequence it is expected that the metal–ligand normal coordinate will be spread over a greater number of observed vibrations, *i.e.* more vibrations will show isotopic sensitivity. To further complicate the situation, bending modes involving the lighter ligand atoms may now be expected above 200 cm^{-1}.

Ethylenediamine Complexes

The vibrational spectra of square planar ethylenediamine complexes have been of interest for many years (11, 32). The square planar complex $Cu(en)_2(AgI_2)_2$ (33) exhibits only three reasonably intense bands between 200 and 600 cm^{-1}, at 531, 472, and 414.5 cm^{-1}. Only the last of these is isotopically sensitive (3) and is assigned to ν(Cu—N). In particular the band at 472 cm^{-1} does not shift although a recent normal coordinate analysis (32) assigned this band to a ν(Cu—N) vibration in $Cu(en)_2PtCl_4$. Evidently the assignment is incorrect. However some caution should be exercised since conditions could arise in an *impure* M—L mode whereby isotopic substitution fortuitously leads to no observable shift. Such may be the case in the *sym*-Et_2en complex discussed above.

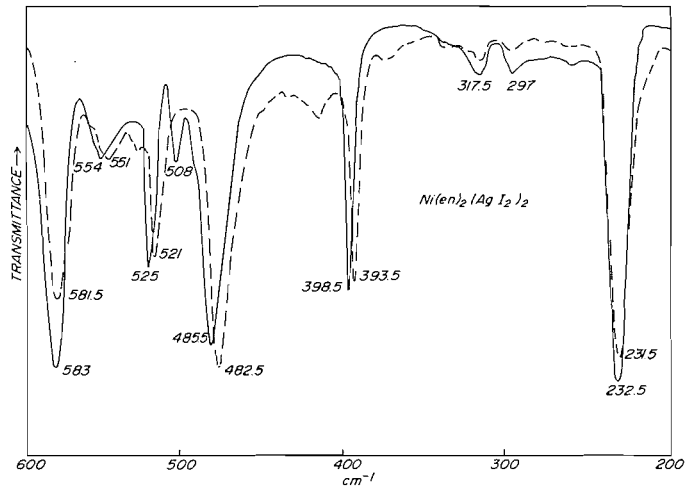

FIG. 2. Vibrational spectrum of $Ni(en)_2(AgI_2)_2$ with natural nickel—, with ^{62}Ni---.

The square planar complex $Ni(en)_2(AgI_2)_2$ (33, 34) on the other hand, has six bands of moderate or high intensity between 230 and 600 cm^{-1} and all are isotopically sensitive (Fig. 2, Table 3). A D_{2h} molecule of this type should have *five* infrared active M—N bending and stretching modes which will all lie above 200 cm^{-1} if the metal–ligand force constant is high enough. Since the Ni—N bond length in a square planar nickel(II) complex, at about 1.8 Å, is about 0.2 Å shorter than in an octahedral nickel(II) amine complex (35), a markedly higher ν(Ni—N) frequency would be expected in the planar ethylenediamine complexes than in the octahedral ones. In this respect the previous assignment (16, 17) of ν(Ni—N) in square planar mercaptoethylamine complexes at frequencies near 380 cm^{-1} comparable to those found in octahedral nickel(II) complexes with ligands of similar type and bulk is anomalous. The ν(Ni—S) vibrations in such square complexes were however assigned at markedly higher frequencies than in the corresponding octahedral complexes. Metal sensitive modes were observed between 500 and 550 cm^{-1} in these square mercaptoethylamine complexes but these were assigned to ring vibrations. In the light of the data presented here, the possibility that these bands contain appreciable ν(Ni—N) character must be considered.

The identification of the 583 cm^{-1} band in $Ni(en)_2(AgI_2)_2$, a band which is almost insensitive to isotopic substitution on a percentage basis, as a ring deformation mode discussed by Omura *et al.* (32) seems secure. Since M—N bending modes are expected to be more intense than stretching modes (16, 17) the weaker bands at 554 and 525 cm^{-1} are tentatively assigned to ν(Ni—N), whilst the stronger bands at 485.5, 398.5, and 232.5 cm^{-1} are tentatively assigned to bending modes (δ(NMN)) coupled with ligand motion. The assignment of the isotopically insensitive 531 cm^{-1} band in the spectrum of $Cu(en)_2(AgI_2)_2$ to a ring vibration must suggest that the bands in the 500–550 cm^{-1} region in the square planar nickel ethylenediamine complexes might also contain some ring vibration coordinate.

asym-Dimethylethylenediamine Complexes

The perchlorate complex has a metal insensitive ring mode at 409 cm^{-1} and four metal sensitive modes at 547, 506, 366, and 263 cm^{-1}. That the two higher energy bands do not differ much in energy from those observed in the ethylenediamine complexes is consistent with their assignment as ν(Ni—N) modes. The apparent decrease in energy of at least two of the bending modes may be a reflection of the increased mass of the ligand. The higher intensity of the stretching vibrations relative to those observed in the unsubstituted ligand probably reflects the lower symmetry of asymmetric ligand.

asym-Diethylethylenediamine Complexes

Further support for these assignments comes from consideration of $Ni(asym\text{-}Et_2en)_2(ClO_4)_2$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

There is a metal insensitive vibration at 440 cm^{-1} assigned as a ring mode, and four metal sensitive modes at 515.5, 371.5, 344.5, and 265.5 cm^{-1}. By analogy to the previous complexes the first two bands are assigned to ν(Ni—N), and the last two to bending modes. The square Ni(*asym*-Et_2en)$_2Br_2$ has a very similar spectrum and is assigned analogously. In the spectrum of the N-deuterated bromide complex the highest energy ν(Ni—N) band shows greatest sensitivity to isotopic substitution with ^2H, whilst the lower energy ν(Ni—N) band is almost insensitive. The bending modes, which all involve flexing of both —NH_2 (—ND_2) and —$N(C_2H_5)_2$ show moderate sensitivity.

Discussion

Reviewing the data presented, certain general observations may be made, namely:

(*i*) In the octahedral complexes the highest energy ν(M—N) mode falls in the general sequence

I NO_3 > halogens > NCS

as far as dependence upon the counter ion is concerned.

(*ii*) In the octahedral complexes with a given counter ion, the highest energy ν(M—N) mode falls in the general sequence

II *asym*-Et_2en > *sym*-Et_2en ~ *asym*-Me_2en > *sym*-Me_2en > en

(with few exceptions).

(*iii*) The energy separation between the highest and lowest energy ν(M—N) mode in octahedral complexes is variable, but is a maximum for complexes of *asym*-Et_2en.

(*iv*) The above statements are true for both nickel(II) and cobalt(II). In many cases the spectra of the cobalt and nickel complexes are very similar. However the ν(Co—N) frequencies are displaced down about 15 cm^{-1} relative to the corresponding ν(Ni—N) frequencies. Other bands are generally less affected, providing further implicit evidence in support of the (M—N) assignments.

(*v*) In the planar diamagnetic complexes, the highest energy ν(Ni—N) falls in the sequence

III en > *asym*-Me_2en > *asym*-Et_2en

(*vi*) In the planar diamagnetic complexes, the energy separation between the highest and lowest energy ν(Ni—N) mode increases in the sequence III.

Data for the corresponding copper complexes (1–3) were interpreted in terms of an increasing in-plane bond strength as (*i*) the base strength of the amine increased, (*ii*) the bulkiness of the amine increased, (iii) the axial Cu—X interaction decreased. In the copper complexes use of bulky amines together with only weakly coordinating anions, such as BF_4^-, lead to the generation of a continuous series of complexes ranging from almost octahedral to four coordinate square. In the cobalt and nickel complexes, the series is not continuous because of the change in spin state which occurs. Nevertheless there is evidence from electronic spectroscopy that with bulky in-plane ligands such as the asymmetric complexes under discussion, the axial and equatorial interaction in a tetragonal complex is diminished through steric hindrance (36–38). There is an important difference between the copper and nickel (or cobalt) complexes in this respect. In the copper complexes use of a bulky in-plane ligand or of a weakly coordinating counter ion always leads to a strengthened in-plane interaction and a weakened (or zero) axial interaction because of the strong tendency for copper(II) complexes to be tetragonally distorted by virtue of their d^9 configuration. In the nickel complexes no such tendency is operating. The difference between the in-plane and axial ligand interactions must be large before a change in spin state occurs and the complex is square planar. Prior to this, increasing the bulkiness of the in-plane ligand or weakening the coordinating ability of the axial ligand will not lead unambiguously to one result as in the copper case. Instead there will be a choice between weakening the axial interaction and/or the in-plane interaction presumably by bond lengthening, as a means of minimizing the steric interaction. The steric hindrance will be most pronounced in the case of *asym*-Et_2en; indeed with many counter ions, nickel bis complexes with this ligand are square planar. In the specific case of octahedral Ni(*asym*-Et_2en)$_2$-$(NO_2)_2$ for which X-ray data are available (39) the in-plane ligand accomodates the steric hindrance by a marked increase in length of the Ni—$N(Et)_2$— bond (2.219 Å) relative to the Ni—NH_2— bond (2.089 Å).

Speculation concerning band shifts is fraught with difficulties, especially as the low temperature data cited here indicate (Table 2) how complex the spectra can become on cooling. In view

For personal use only.

of the possibility of vibrational coupling, it would be better to discuss trends in force constants rather than frequencies. Lacking the former, however, and bearing in mind the previous comments, some speculation is admissible if, as we try to show, trends in the spectra of all the cobalt, nickel, and copper complexes, can be reconciled on the basis of one model of tetragonal distortion.

It is proposed that in the asymmetric ligand complexes the higher energy ν(M—N) vibration corresponds to (M—NH_2—) and the lower energy ν(M—N) to (M—NR_2—). These vibrations are depicted in Scheme 1 together with those of the symmetric ligands. The highest symmetry obtainable for the asymmetric ligand complexes is C_{2h} whilst for the symmetric ligands it is D_{2h}. We note, that in the asymmetric ligand case, C_{2h}, there is no symmetry element connecting the two kinds of Ni—N vibration (Ni—N, NH_2 and Ni—N, NR_2) and therefore they should be independently observable. However it is also noted that they both transform as B_u, thus coupling could invalidate this conclusion. The deuteration data (Tables 2, 3) for the Ni(*asym*-Et_2en)$_2X_2$ complexes, especially the bromide, provide substantive evidence for the conclusions that the ν(Ni—N, NH_2) and ν(Ni—N, $N(C_2H_5)_2$) vibrations may be uniquely identified (by their deuteration sensitivity (17)) and that the higher energy vibration is due to ν(Ni—N, NH_2). There is also independent electronic spectroscopic data in support of this (40). Sequence II is now readily explained in terms of (*i*) the increased base strength of the symmetrically substituted ligands causing an increase in the in-plane bond strength reflected by the Ni—N force constant and hence frequency, and (*ii*) a weakening (lengthening) of the M—NR_2 bonds in the asymmetric complexes leading to an inductive increase in the strength of the remaining M—NH_2 bonds. Sequence I is explained on the basis of the amount of electron density supplied to the metal atom by the axial ligand, and parallels the discussion for the copper complexes (1–3). The very electronegative NO_3 oxygen ligand renders the metal(II) ion more positive, relative to the halogens, and causes an increased in-plane interaction. Evidently the thiocyanate ion is able to donate considerable electron density to the metal thereby weakening the in-plane interaction. The reason for this probably stems from the small size of the thiocyanate group relative to a halogen allowing for closer contact with the metal atom even in the presence of bulky in-plane ligands and perhaps from the π-donor characteristic of this ligand (41). Observation (*iii*) is explained if all *asym*-Et_2en complexes parallel the behavior of the nitrite complex in having a long M—$N(Et)_2$— bond. Such a postulate explains the marked energy separation between the two ν(Ni—N) bands in these complexes. Parallel behavior by the *asym*-Me_2en complexes is indicated *if* the ν(Ni—N) assignment for the band near 260 cm^{-1} is accepted. If the previous assignment (17) is assumed valid, then these complexes do not follow the pattern exhibited by the other complexes (see below).

Molecular models of the planar complexes suggest that steric hindrance, except possibly for the *asym*-Et_2en complexes, is minimized. This does however assume a *trans* configuration with respect to the asymmetrically substituted ligands. A *cis* configuration would be very hindered and is unlikely to occur. Thus there is no reason to believe that in the planar complexes, the Ni—NR_2— bond will be longer than Ni—NH_2—; indeed the converse might be expected in view of the difference in base strength between the two residues. In this case the upper frequency (presumed Ni—NH_2—) runs counter to the order shown by the octahedral complexes (sequence III rather than II). Possibly in this case, the increase in electron density supplied to the nickel atom by the strong Ni—NR_2— bond actually results in a slight decrease in the bond strength of Ni—NH_2—.

The above discussion relies heavily on the correct identification of the band near 300 cm^{-1} in most of the complexes as the second ν(M—N) vibration. Since this contradicts a recent isotopic study of certain of the complexes studied here (17) it is worthwhile summarizing the evidence favoring this re-assignment. If the earlier assignment (17) is accepted then this lower energy metal sensitive band must be assigned to a bending mode, to a metal – axial ligand mode or to a ligand mode coupled with motion of the metal. These possibilities seem excluded since in the octahedral complexes bending modes are not expected at such a high frequency (2, 16, 17) and the lower energy band is insensitive to replacement of the axial ligand. Finally this band is isotopically sensitive in *every* copper *and* nickel complex so studied; if the band in question

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

is always a ligand mode fortuitously coupled with metal motion, metal sensitivity in every case would not be anticipated. One may further note that if the previous assignment is accepted then the *asym*-Et_2en complexes should exhibit two closely spaced, but certainly well resolved bands near 380 cm^{-1} paralleling thereby the behavior of the *asym*-Me_2en complexes studied previously (17). In fact the high energy ν(M—N) band in the isotopically studied *asym*-Et_2en complexes is quite sharp and symmetric. There is a band to lower energy near 330 cm^{-1} but this is quite insensitive to isotopic substitution. In summary it indeed seems possible to distinguish two separate ν(Ni—N) vibrations of asymmetric ligands such as $(C_2H_5)_2NCH_2CH_2NH_2$. Although this would certainly be anticipated on group theoretical grounds extensive coupling might have invalidated its observation experimentally.

This work presents the first isotopic investigation of the spectra of two complexes containing a given ligand with a metal in alternate spin states, *e.g.*: Ni(*asym*-Et_2en)$_2Cl_2$, $S = 1$, and Ni(*asym*-Et_2en)$_2Br_2$, $S = 0$.

The relevant frequencies are:

Spin state	Configuration	Infrared frequencies (cm^{-1}) ν(Ni—N, NH_2)	ν(Ni—N, $N(C_2H_5)_2$)
$S = 1$	Octahedral	401.5	265.5
$S = 0$	Square planar	516	380

The ratios ν(Ni—N), $S = 1$/ν(Ni—N), $S = 0$, are approximately the same (0.78 and 0.70 respectively). The difference probably reflects the longer Ni—$N(C_2H_5)_2$ bond predicted in the octahedral complexes. The ratio will also be influenced by the ring vibration coordinate contribution to the 516 cm^{-1} band. Similar comparisons may be made with the *asym*-Me_2en data.

In view of the close similarity in behavior of all the cobalt, nickel, and copper complexes in these series, and in view of the fact that the gross changes in metal–nitrogen stretching frequencies can be readily explained in terms of a common argument involving changes in tetragonal distortion, the assignments presented here seem justified.

Note added in proof: Further support for the assumption that there are two markedly unequal metal–nitrogen bond lengths in complexes of the asymmetrically substituted amines arises from an X-ray structural analysis of bis-(1,1,1,5,5,5,-hexafluoropentane-2,4-dionato)bis-(*N*,*N*-dimethylethylenediamine)copper(II) (51). In this complex the Cu—NMe_2 distance is 2.064 Å and the Cu—NH_2 distance is 1.989 Å.

We are indebted to the Consiglio Nazionale delle Richerche, Rome, Italy, and the National Research Council of Canada for financial support. We are also indebted to Mrs. M. Rayner Canham for experimental assistance and to Dr. G. Rayner Canham for useful discussions.

Isotopic Studies of the Metal–Ligand Bond. Part IV. Variable Temperature and Isotopic Studies of the Metal–Ligand Vibrations in Substituted Pyridine Metal Dihalides. Complexes of Cobalt(II), Nickel(II), and Copper(II)

A. B. P. LEVER AND BARATHAM S. RAMASWAMY

Department of Chemistry, York University, Downsview, Ontario, M3J 1P3

Received November 9, 1972

The far infrared spectra (500–200 cm^{-1}) of a series of picoline and ethylpyridine derivatives of cobalt(II), nickel(II), and copper(II) are reported. Metal–ligand assignments are based on isotopic substitution experiments with ^{65}Cu and ^{62}Ni. Low temperature data are also reported and it is noted that the energies of metal–ligand modes are much more sensitive to temperature than the energies of purely ligand vibrations. This observation is discussed and it is suggested, with some caution, that the low temperature behavior may be used as a guide to band assignment.

Les spectres dans l'infra rouge lointain (500–200 cm^{-1}) d'une série de dérivés de la picoline et de l'éthylpyridine avec le cobalt(II), nickel(II), et cuivre(II) ont été rapportés. Les attributions concernant le métal ligand ont été faites sur la base des expériences de substitution isotopique avec le ^{65}Cu et le ^{62}Ni. Les données à basse température ont été également présentées et on a noté que les énergies relatives aux modes métal-ligand sont beaucoup plus sensibles à la température que les énergies de vibration du ligand pur. Ce fait a été discuté et a amené à suggérer, avec quelque précaution, que le comportement à basse température pouvait servir de guide dans l'attribution des bandes.

[Traduit par le journal]

Can. J. Chem., **51**, 1582 (1973)

Pyridine metal halides were among the first compounds to be studied by far infrared spectroscopy (1–10) and the general regions of absorption of the first row transition metal halide and metal pyridine vibrations are well established. There is however still some controversy over individual assignments. More recently we have demonstrated (11) by means of vibrational spectroscopy that in complexes of substituted pyridines steric and electronic effects influence the metal–ligand vibrational frequencies markedly. Of particular interest was the observation (11) that in the tetrahedral cobalt(II) complexes, CoL_2X_2 where L is a sterically bulky substituted pyridine, the Co—X bond is weakened when X is a halogen, but the Co—L bond is weakened when X is NCS. The isotopic substitution method (12) provides the only procedure for the unequivocal identification of metal–ligand modes; it has not hitherto been applied to these series of complexes. We now report such data. Only data obtained in the solid state are reported. Most of the compounds are either insufficiently soluble, or decompose in solution, to permit solution measurements to be made. Metal-ligand vibrations are not usually "pure" since coupling with ligand modes of the same symmetry will generally occur. As a consequence the identification of metal–ligand modes in a vibrational spectrum, in the absence of isotopic data, is fraught with difficulty. There is evidence (11, 13–15) that metal–ligand vibrations increase in frequency relative to "pure" ligand vibrations, when the sample is cooled. These observations are further investigated to see if they provide an additional reliable procedure for the identification of metal–ligand modes.

Experimental Section

All the complexes which have been previously described were prepared by the literature methods (references in Table 1) and were analytically pure. The isotopically substituted derivatives were prepared using 99+% pure ^{65}Cu and ^{62}Ni as previously described (16, 17). Infrared data were recorded with a Beckman IR 12 spectrophotometer scanning at 1–2 cm^{-1}/min and using Nujol mulls on a polythene support, and low temperature data were recorded with the aid of a Beckman VLT-2 variable temperature cell employing polyethylene windows, as previously described (17). The temperature achieved by use of this cell is believed to be within 20° of −196 °C. The reproducibility of the spectra from one mull to another is good, and there is no evidence to suggest that the rate of cooling influences the final spectrum. Samples for the low temperature data were prepared either as Nujol mulls held tightly between polythene plates or were made into a polythene matrix. In this latter case the sample was mixed with powdered high density polythene and the mixture converted into a thin translucent disc by application of pressure at about 50 °C; a conventional laboratory (KBr disc) press was utilized. *All data were measured with the natural metal isotope at room temperature except where indicated. Cu-65, data for ^{65}Cu; Ni-62, data for ^{62}Ni; l.t. Nujol mull liquid nitrogen temperature data. The values quoted in parentheses are the shifts from the room temperature data, *e.g.* 424(+2) implies a band observed at 422 cm^{-1} at room temperature and 424 cm^{-1} at liquid nitrogen temperature, *for the same mull*. Slight discrepancies between these data and the data recorded for isotopic comparison may reflect changes in the mull and changes in the operating conditions used to record the spectra; pm.l.t. These data were recorded as polythene matrices.

†Either no band was observed in the room temperature spectrum or it was present only as an ill resolved shoulder.

‡This band is presumably obscured by the Ni—N absorption in the Ni-62 spectrum.

comparison with room temperature Nujol mulls, use of Nujol is preferred. However, the polythene matrix gives a cleaner spectrum. In both cases the mull must be prepared very dilute, since there is a marked apparent increase in intensity on cooling, and the use of a mull of normal strength will cause the recorder pen to go off scale.

Results and Discussion

Isotopic Data

CuL_2X_2 Complexes

Both room temperature and low temperature data for a series of complexes ML_2X_2 with M = Co(II) or Cu(II), X = Cl, Br and L = 2- or 3-methyl or 2-, 3-, or 4-ethyl pyridine are cited in Table 1. Certain of the cobalt data have been published previously (11) but are repeated here for further discussion. In addition ^{65}Cu isotopic studies are reported for a number of copper complexes. Note that the cobalt complexes are pseudo tetrahedral whilst the copper complexes are expected to be *trans* square planar.

These copper complexes generally exhibit two or three isotopically sensitive bands. Data have not been cited above 450 cm^{-1}; the samples were scanned above this wavenumber but no further isotopically sensitive bands were observed, as was anticipated. In square complexes of copper (II), previous data (1–10) suggests that both νCu—Cl and νCu—Br may be expected above 200 cm^{-1}. Such *trans* square planar complexes should exhibit one infrared active νCu–N vibration and one active νCu—X vibration of B_{2u} and B_{3u} symmetry, in the group D_{2h} (assuming the principal axis is z). The experimental observation of more than two

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

markedly isotopically sensitive bands is indicative that this simple treatment is inadequate. Note that application of the Teller-Redlich rule (18) suggests shifts of about 3 cm^{-1} should be observed in the metal–ligand vibrations; the observed shifts of 1.5 to 3 cm^{-1} are indicative of a substantial metal–ligand contribution to the absorption bands in question. The additional bands must arise through some kind of intermolecular interaction in the solid. Indeed X-ray studies of both (2-picoline)$_2$CuCl$_2$ (19) and the corresponding bromide (20) reveal that these square planar units are loosely associated into dimeric arrays with intermolecular Cu—X distances of 3.37 Å (Cl) and 3.87 Å (Br). Whilst the symmetry of the dimeric units themselves is very low (C_i) the deviation from C_{2h} is not very great and it is convenient to discuss the $Cu_2N_4X_4$ sub-unit within this point group. Group theoretical analysis reveals that this dimeric sub-unit will exhibit two infrared active vCu—N of symmetry A_u and B_u and two active vCu—X both of symmetry B_u.

Given that the vCu—Br/vCu—Cl frequency ratio is of the order of 0.77 (2) assignments for the Cu—N and Cu—X modes follow logically; they are reported in Table 1. In general only one Cu—X stretching mode may be identified, near 240 cm^{-1} in the bromides and near 300 cm^{-1} in the chlorides. In two cases two Cu—N modes may be identified in the room temperature spectrum. In the low temperature spectra the Cu—Cl band in Cu(3-picoline)$_2$Cl$_2$ is split by 4 cm^{-1}; these may be the two Cu—Cl modes but the splitting may also arise through correlation coupling or isotopic effects. An additional band appears at 229 cm^{-1} in the low temperature spectrum of Cu(2-picoline)$_2$Cl$_2$; this may be the second Cu—N mode. However in view of the coupling between the B_u Cu—X and Cu—N modes it is somewhat artificial to distinguish between them. Band positions and assignments are similar to those previously proposed (1, 4). The assignment for Cu(2-EtPy)$_2$Br$_2$ differs from that previously cited (1) by assigning the band at 290 cm^{-1} to a Cu—N vibration rather than an internal ligand mode (1). This reassignment is based on the considerable temperature sensitivity of this band (see discussion below).

NiL$_4$X$_2$ Complexes

Isotopic data are also cited in Table 1 for Ni(3-picoline)$_4$Cl$_2$ and Ni(3-picoline)$_4$Br$_2$. The electronic spectra of these complexes (3, 21) (*vide infra*) infer that they are *trans* tetragonal octahedral, as are the congeneric pyridine complexes (22, 23). For the purposes of discussion of their metal–ligand vibrational spectra D_{4h} symmetry may be assumed; one vNi—N and one vNi—X infrared active vibration is anticipated. However the Ni—Br band will appear below 200 cm^{-1} outside the range of the instrument used (2). Isotopic substitution leads to the unequivocal assignment shown in Table 1. Of the two bands in the chloride, the lower is assigned to vNi—Cl since it is the more intense.

Unfortunately the non-availability of appropriate non-radioactive isotopes of cobalt prevents similar studies being carried out with the corresponding tetrahedral and octahedral cobalt(II) derivatives. However the close general similarity between the cobalt spectra and the spectra of the copper and nickel analogs, provides very strong circumstantial evidence for the validity of the Co—L assignments previously made (11). Further support comes from consideration of the low temperature data.

Low Temperature Data

Table 1 and Fig. 1 cite low temperature data for the complexes discussed above and also for some cobalt(II) picoline derivatives and copper(II) *n*-ethylpyridine derivatives. The following observations may be made from these data:

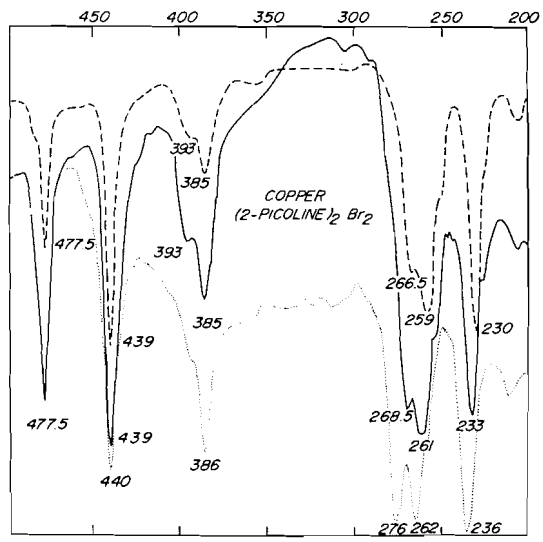

FIG. 1. The vibrational spectrum of Cu(2-Picoline)$_2$-Br$_2$; natural Cu,—; ^{65}Cu,---; natural Cu at liquid nitrogen temperature,....

(*i*) Metal–ligand modes generally increase in energy, sometimes by as much as 11 cm^{-1}, upon cooling the sample to liquid nitrogen temperature. Additional components are frequently resolved in the low temperature spectra. This is particularly true, for example, of the two Co—N modes expected in the C_{2v} CoL_2X_2 pseudotetrahedral complexes. Frequently only one is observed in the room temperature spectrum. It is also of interest that the single νCu—Cl band observed in the room temperature spectrum of $Cu(4\text{-}EtPy)_2Cl_2$ is apparently split by some 17 cm^{-1} upon cooling. An X-ray crystal structural analysis of this compound (24) reveals a *trans* square planar structure with non-bonded Cu—Cl′ contacts of 3.21 Å, actually shorter than in the 2-picoline dimeric array referred to above. Correlation coupling may therefore be responsible for this splitting.

(*ii*) Ligand modes are comparatively insensitive to temperature, shifts of from −1 to +3 cm^{-1} generally can be observed, (see Fig. 1 and Table 1).

It therefore appears that it may be possible to distinguish between ligand modes and metal–ligand modes in the region 450–200 cm^{-1} by their temperature behavior. We note that an increase in energy has also been noted for the asymmetric M—O—M vibration when samples of dimeric oxygen bridged porphyrin derivatives are cooled (14, 15).

Care must be taken in exploiting such data. For example the identity of the sample must not change over the temperature range studied; any phase change or structural change could lead to marked shifts in any or all the bands. Moreover at very low energies, usually below 200 cm^{-1}, lattice vibrations appear, and these may be temperature sensitive (25). Where additional bands are resolved in the low temperature spectrum, the interpretation may be ambiguous.

Mechanism of Band Shift

Cooling of a crystal leads to an overall contraction of the lattice which, in principle, may be isotropic or anisotropic. The cooling process is effectively not very different from the application of high pressure at room temperature. Both procedures may be considered to give rise to compression of the unit cell. It is highly relevant therefore that recent studies of the effects of high pressure upon far infrared spectra (26, 27) also revealed frequency shifts, and changes in intensity. In general these workers observed a much greater effect of pressure upon the metal–ligand modes than upon the pure ligand modes, paralleling thereby the temperature data presented here. It should be noted however that the room temperature high pressure experiments led to considerable broadening of the bands, whilst the low temperature experiments discussed here yielded much sharper and highly resolved spectra.

We assume that either cooling, or high pressure, will result in a decrease in the unit cell volume. Some distortion, albeit slight, of the molecular geometry must occur to accommodate this volume decrease. It is clearly much easier to achieve such distortion by a change in metal–ligand bond length or angle, than by changes in the internal normal coordinates of a polyatomic cyclic ligand such as a picoline. The former will surely be much more adaptable to such changes than the latter. The behavior of the picoline metal halides with temperature change can be rationalized readily on this model. However if a chelate ligand, such as an ethylenediamine is involved, similar arguments would suggest that skeletal vibrations, which occur in this low energy region, might also be temperature sensitive. Experiments with such complexes (ref. 28 and unpublished observations) reveal that such skeletal bands are *slightly* more temperature sensitive than the picoline internal ligand modes. Moreover the M—N stretching modes which will necessarily involve motion of the chelate ring in these complexes are *less* temperature sensitive, in general, than the M—N modes involving monodentate ligands such as the picolines.

It is well known that the electronic spectra of transition metal complexes are also temperature sensitive (29). This is due in part, but not *in toto* (32), to lattice contraction, *presumably* causing a decrease in bond length, and hence an increase in the crystal field strength parameter *Dq*. The electronic spectra of the tetragonal nickel complexes cited in Table 1 are temperature sensitive as anticipated, *viz.* Using the admittedly approximate first order analysis (23, eq. 3) the *Dq*. values are seen to increase with cooling of the sample according to $Ni(3\text{-picoline})_4Cl_2$: *Dq* (picoline) from 1130 to 1160, *Dq* (chloride) from 550 to 570 cm^{-1}; $Ni(3\text{-picoline})_4Br_2$. *Dq* (picoline) from 1080 to 1140, *Dq* (bromide) from 430 to 508 cm^{-1}. The very marked increase in the

νNi—N and νNi—Cl frequencies upon cooling is fully consistent with this approach. It is anticipated that the extent to which a particular M—L vibration is sensitive to such thermal compression will also be a function of the symmetry of the vibration, and also upon whether the compression is isotropic or not. Clearly further work is necessary to learn more about this phenomenon. However it is clear that this procedure adds a valuable new technique to the chemists' repertoire and should lead to a deeper understanding of the steric and electronic factors responsible for molecular geometry.

The authors are indebted to Mrs. G. W. Rayner Canham for experimental assistance, and the National Research Council of Canada for financial support.

Substituent Interactions in Di- and Tri-acyl Derivatives of *cis*- and *trans*-2-Hydrazinocyclopentanol

J. A. CAMPBELL AND DONALD MACKAY

Department of Chemistry, University of Waterloo, Waterloo, Ontario

Received July 17, 1972

The action of thionyl chloride followed by an alkaline work-up quantitatively isomerizes *trans*-1,2-dibenzoyl-1-(2-hydroxylcyclopentyl)hydrazine (**5**) to *cis*-2-benzoyl-1-(2-benzoyloxycyclopentyl)hydrazine (**3**). One equivalent of tosyl chloride in pyridine converts **5** to an intermediate which can be hydrolyzed to a mixture of **3** and **5** or can be transformed to the *N*-tosyl derivative **13** by tosylation and then hydrolysis. Oxazolidine structures are suggested as intermediates for these reactions.

The alcohol **2** can also be isomerized to **3**, using 0.8 *N* aqueous ethanolic hydrochloric acid, to which **5** is inert. The ester **3** is again the major product in the hydrolysis by this acid mixture of the *cis*-tribenzoyl derivative **17**, the *cis*-N_1-*p*-anisoyl derivative **21***a* and the *cis*-N_1-acetyl derivative **21***b*, the amide group being cleaved much more rapidly than the ester, especially in the case of **21***b*. A mechanism involving ester participation by way of an oxazolidinium cation is proposed for these amide hydrolyses, and this is supported by tracer studies.

The *trans*-esters **24***a* and *b* hydrolyze mainly at the ester group with retention of configuration.

Polymorphism is a common phenomenon among the title compounds.

L'action du chlorure de thionyle suivie d'un traitement alcalin isomérise quantitativement le *trans*-dibenzoyl-1,2 (hydroxyl-2 cyclopentyl)-1 hydrazine (**5**) en *cis* benzoyl-2 (benzoyloxy-2 cyclopentyl)-1 hydrazine (**3**). Un équivalent de chlorure de tosyle dans la pyridine transforme **5** en un intermédiaire qui peut être hydrolysé en un mélange de **3** et **5** ou convertit en dérivé *N*-tosyle **13** par tosylation puis hydrolyse. Les structures oxazolidines ont été suggérées comme intermédiaires réactionnels.

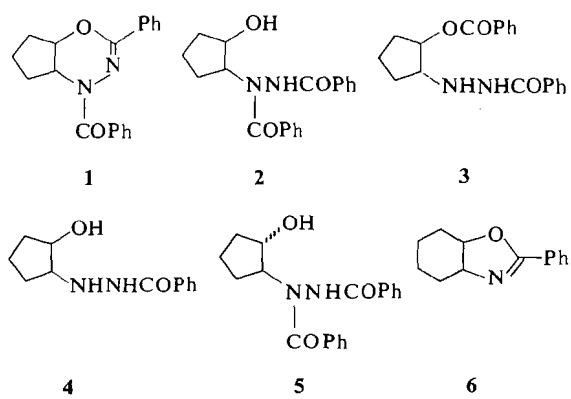
L'isomérisation de l'alcool **2** en **3** est également possible en présence d'une solution aqueuse éthanolique d'acide chlorhydrique 0.8 *N* pour laquelle **5** est inerte. L'ester **3** reste encore le produit majoritaire dans l'hydrolyse par ce mélange acide, du dérivé *cis*-tribenzoyle **17**, du dérivé *cis* N_1-*p*-anisoyle **21***a* et du dérivé cis-N_1-acétyle **21***b*, le groupe amide étant clivé beaucoup plus rapidement que l'ester spécialement dans le cas de **21***b*. Un mécanisme avec participation de l'ester par un cation oxazolidinium a été proposé pour les hydrolyses de ces amides; ce mécanisme a été confirmé par les études par traceur.

Les esters *trans* **24***a* et *b* s'hydrolysent principalement sur le groupe ester avec rétention de configuration. Le polymorphisme est un phénomène commun parmi les composés de cette étude.

[Traduit par le journal]

Can. J. Chem., **51**, 1587 (1973)

In earlier work (1) we used as partial proof of the structure of **1**, the dihydro derivative of the thermal rearrangement product of cyclopentadiene and azodibenzoyl, its ready hydrolysis by acid to *cis*-1,2-dibenzoyl-1-(2-hydroxycyclopentyl)hydrazine (**2**). The alcohol **2** was not itself isolated, but rather its isomer, the ester **3**, and the further hydrolysis product **4**. The intermediacy of **2** was, however, demonstrated by t.l.c., and it was confirmed that under the hydrolysis conditions (0.8 *N* hydrochloric acid in aqueous ethanol) isomerization of **2** to **3** was rapid and efficient. The same ester **3** could also be obtained from the *trans*-isomer **5** of the alcohol **2**, though not under such mild conditions, the use of thionyl chloride or concentrated sulfuric acid being necessary, in which case the yield was quantitative.



We now wish to discuss in more detail these isomerizations and other acid-catalyzed reactions of related derivatives of *cis*- and *trans*-2-hydrazinocyclopentanol.

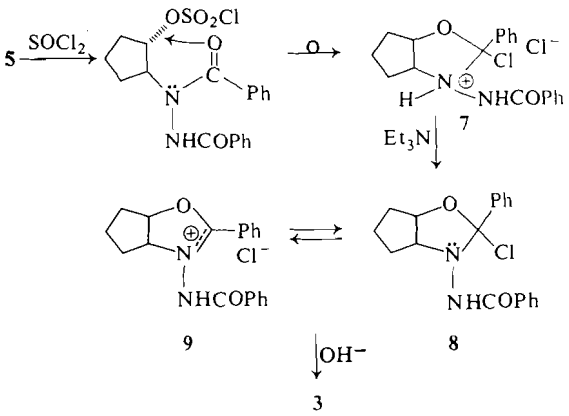
The conversion of **5** into **3** is in fact an example of a well established reaction type in which an α-acylamino alcohol is transformed by acidic reagents (most frequently thionyl chloride) into a derivative of the amino alcohol with inversion at the carbinol carbon (2–11). The key step is the formation of an oxazolinium cation by S_N2 attack of the acylamino oxygen.[1] In the 2-acylaminocycloalkanol series the process has been achieved only for the *trans*-isomers which lead to *cis*-fused oxazolines. These have been isolated as the free bases, (*e.g.* **6** from *trans*-2-benzoylaminocyclohexanol) which are usually stable, or as their salts (3–5, 7–10). Hydrolysis of the oxazolines by acids gives the *cis*-2-acyloxycycloalkylamines (C—N cleavage, overall N → O migration) (2, 4, 7, 8, 10), or, if prolonged, the *cis*-alcohols themselves (3, 5–8, 10), while hydrolysis by basic reagents appears to give *cis*-2-acylaminocycloalkanols (C—O cleavage) (8, 9).

The formation of a neutral oxazoline like **6** is of course possible only with an acylaminocycloalkanol containing a free NH, and cannot occur with **5** which has a benzamido group on the nitrogen.

We have tried to obtain some insight into the mechanism of the thionyl chloride isomerization of **5** using n.m.r. studies. Addition of 1 equiv of thionyl chloride to a solution of **5** in chloroform-*d* caused replacement of the broad absorptions for the *tert*-hydrogens at 5.5 τ by two separate multiplets at 3.95 and 4.60 τ. A broad low field absorption for two hydrogens also appeared at −1.0 τ. The same absorptions were observed when this solution (or one obtained by reacting **5** with a large excess of thionyl chloride[2]) was evaporated, pumped briefly[3] over sodium hydroxide, and the residue redissolved in chloroform-*d*.

We attribute this spectrum to the quaternary compound **7** (Scheme 1), the absorption at −1.0 τ being that of the (exchanging) protons



SCHEME 1

on the nitrogens, while that at 3.95 τ is probably due to the C—H adjacent to N^+. Addition of triethylamine (but not of pyridine) caused the two *tert*-hydrogen absorptions to be replaced by a band at 4.7 τ, which must have been due to the *tert*-hydrogens in either the base **8** or the ion **9** (or a mixture of these in equilibrium), since the process was reversed by addition of hydrogen chloride.[4] Neutralization of **7** by alkali gives **3** (1), as expected, and occurs through attack at the electron deficient carbon in **8** or **9**, as in the parallel reaction of the cyclohexane analog (11).

The formulation **7** was also in agreement with the i.r. spectrum, which showed broad absorption for NH^+ between 2900 and 2300 cm^{-1}, but no other absorption in the region down to 1685 cm^{-1}.

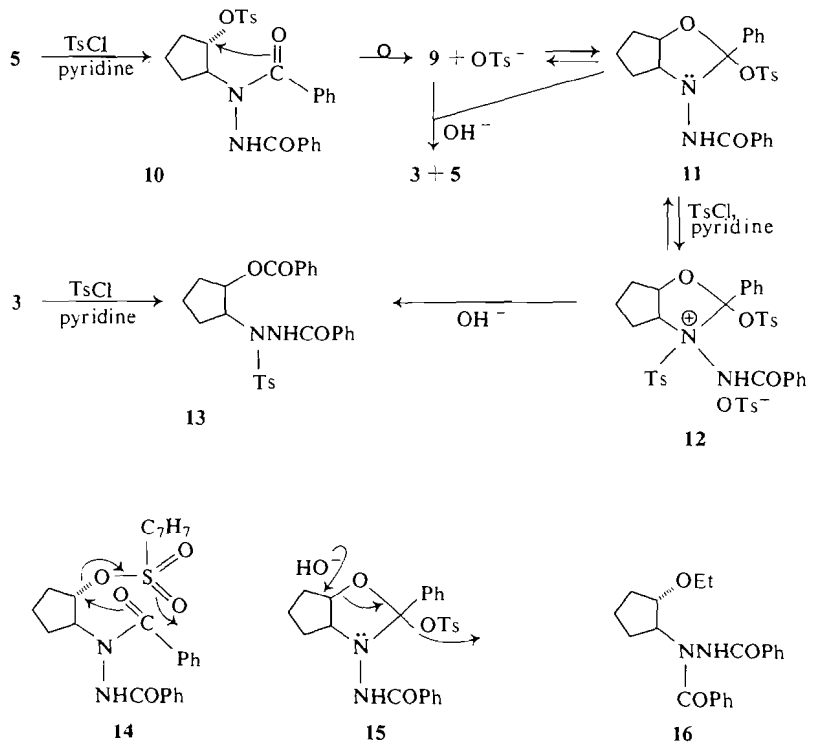
Our original objective in using thionyl chloride was to convert **5** into the chloride of the *cis*-alcohol **2**, a potential precursor to the oxadiazine **1**. As an alternative for the synthesis of **2** we tried to make the tosylate **10** in the expectation that its hydrolysis might occur with inversion. Treatment of **5** with 1 equiv of tosyl chloride in pyridine led to the recovery of 78% of **5** on work-up, and the isolation of 7% of a mono-tosyl derivative. This was not the expected *trans*-*O*-tosyl-*N*-benzoyl compound **10** but rather the *cis*-*O*-benzoyl-*N*-tosyl isomer **13**, its identity being confirmed by its synthesis from **3** with 1 equiv of tosyl chloride in pyridine. With 2

[1]Exceptions have been noted, however, in which stereochemistry is retained (7, 12, 13).

[2]The excess of thionyl chloride may have caused reaction of the *sec*-amide group thus: —NHCOPh → —N=C(Cl)Ph (14). This might cause little change in the appearance of the spectrum and would be of no consequence to the final work-up.

[3]Longer pumping caused the gradual appearance of a broad multiplet at 5.4 τ, which was not discharged by addition of thionyl chloride. It was probably a product of loss of hydrogen chloride, but it was not investigated further.

[4]The ion **9** may be destabilized relative to those derived from acylaminocycloalkanols due to the electron-withdrawing effect of the benzamido group. The neutral form **8** may thus be the dominant species here; it must rank in basicity between pyridine and triethylamine, consistent with the fact that its lone pair is localized.



SCHEME 2

equiv of tosyl chloride, however, **5** gave a 90% yield of **13**. On the basis of these results and a study of the reaction by n.m.r. spectroscopy we propose Scheme 2 to account for these unusual results.

The changes in the n.m.r. spectrum were followed when first one and then a second equivalent of tosyl chloride was added to **5** (0.7 *M*) in chloroform-*d* containing 2.5 equiv of pyridine.[5] The broad peak for the *tert*-hydrogens of **5** at 5.5 τ slowly diminished while absorptions grew at lower field, including ones near 4.0 and 4.6 τ; at the same time the methyl peak of *N*-tosylpyridinium chloride at 7.60 τ[6] was replaced by one at 7.73. The spectrum remained unchanged after about 10 h when the peak at 5.5 τ was about half its original area, and the peak at 7.60 τ had almost disappeared. Addition of D_2O to the sample tube at this point caused most of the methyl peak to disappear into the upper aqueous layer, the spectrum now duplicating that of a mixture of the alcohol **5**, and (on the basis of new peaks formed) smaller amounts of the *N*-tosyl derivative **13** and the ester **3**, the latter being distinguishable by its high field C_1—H absorption at 6.7 τ. As the most soluble of the three products it escaped detection in the original work-up.

Addition of the second equivalent of tosyl chloride resulted in the disappearance over a period of 12 h of the peak at 5.5 τ and all the *tert*-hydrogen absorptions except those at 4.0 and 4.6 τ which continued to grow; the corresponding new methyl peaks formed a broadened line at 7.7 τ. The spectrum remained unchanged over a period of days. Addition of D_2O, however, rapidly produced a quite different spectrum, identical with that of **13** in the same solvent mixture, prepared either from an authentic sample of **13**, or by allowing **3** to react (very rapid reaction) with 1 equiv of tosyl chloride in the presence of the same excess of pyridine. Thus neither **3** nor **13** is at any stage present during the reaction of **5** with 1 or 2 equiv of tosyl chloride.

[5]The reaction was faster with larger amounts of pyridine. The changes in the n.m.r. spectrum were, however, the same as those described here (apart from solvent shifts), even when neat pyridine-d_5 was used.

[6]Control experiment.

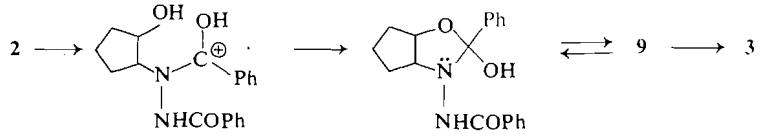

SCHEME 3

The multiplets at 4.0 and 4.6 τ had not only the same chemical shift values as the corresponding ones in **7** but *their splitting patterns were identical* (basically a quartet and a triplet respectively, with added fine structure). We take this as powerful evidence that the intermediate with 2 equiv of tosyl chloride is the quaternary structure **12**. The spectrum after reaction with 1 equiv of tosyl chloride can be interpreted as due to a mixture of a small amount of **12** (the second tosylation step is thus competitive with the first), and the major intermediate, one which is capable both of hydrolysis to **5** and to **3** and of tosylation to **12**. We suggest **11** as the most plausible structure for it.

Two paths to the oxazolidine **11** are possible, either by direct displacement of tosylate to the cation **9** (this has analogy elsewhere (3, 9)), which is neutralized by tosylate anion, or directly, in a concerted mechanism as indicated in **14**. The amounts of **3** formed on work-up are small (n.m.r. analysis indicated 10–15% from the reaction in neat pyridine, but slightly more in chloroform-*d*) and must arise from **11**, in competition with hydrolysis to **5**, or from **9**. We can only speculate on why **11** does not give exclusively **3** by direct displacement of tosylate. Concerted loss of tosylate by attack of hydroxide with inversion at cyclopentyl oxygen, as in **15**, may in this case be sterically preferable. Tosylation of **11** occurs on the ring nitrogen which, like that of **8**, is moderately basic. Alkaline work-up involves attack at the very electrophilic benzylic carbon.

Prolonged evaporation under anhydrous conditions of the solution obtained in the reaction with 1 equiv of tosyl chloride gave a glassy residue. Its n.m.r. spectrum was unchanged, and its i.r. spectrum had NH absorption at 3400 cm^{-1} and a carbonyl doublet at 1685 and 1640 cm^{-1}, reconcilable with structure **11**. The residue was unaffected by treatment with methanol for 12 h at room temperature. Evaporation gave material with the same spectra as before, in particular no trace of methoxy absorption being detectable in the n.m.r. spectrum; work-up gave mainly **5**. Similarly addition of sodium ethoxide in ethanol followed by an aqueous work-up led to **5**. The intervention of the ether **16**, expected by analogy to the hydrolysis to **5**, can be discounted, since an authentic sample of it, prepared from **5** and triethyloxonium fluoroborate, was stable to the work-up conditions.

The ready isomerization of the *cis*-alcohol **2** to the ester **3** under conditions (0.8 *N* acid) to which the *trans*-alcohol was inert, indicated the operation of a different mechanism, probably one in which the alcohol oxygen is retained and adds to the protonated amide to give **9** (Scheme 3). For the *trans*-alcohol this reaction would require formation of the rather strained *trans*-fused isomer of **9**; at the same time the acid concentration is probably too low for protonation of the OH group to an extent favorable for the S_N2 displacement to **9**, similar to that shown in Scheme 1.

To test whether the lability of the benzoyl group on N_1 (the inner nitrogen) under such mild conditions was general for the *cis*-series, or depended specifically on the presence of a free OH group, the *cis*-tribenzoyl derivative **17** was examined. Refluxing of **17** for 19 h and work-up led again to the isolation of the ester **3** (as its hydrochloride) as the major product (36%). The reaction was repeated and monitored by n.m.r. analysis utilizing the areas of the absorptions for C_1—H in both the starting material and the product ester. The ratios of **3**:**17** at 3, 7, and 23 h were 0.18:1, 0.56:1, and 2.3:1 respectively. Further hydrolysis was not extensive, though the monobenzoyl derivative **4** could be detected (C_1—H at 6.78 τ) in the n.m.r. spectrum of the hydrolysate after 23 h. The results can only be reconciled with a rate constant of formation of **3** greater than that of any other product. In a control experiment the ester **3** was recovered in a high yield after refluxing in acid for 17 h.

A more intimate analysis of the reaction path was provided using the *cis*-tribenzoyl derivative ^{14}C labelled at the N_1 carbonyl group, obtained

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

from the ester **3** with ^{14}C-benzoyl chloride in pyridine at 5°. All of the activity was shown to have been incorporated during the benzoylation step,[7] with no further exchange after it, since in a control experiment unlabelled tribenzoyl derivative could not be made active even when refluxed in pyridine with ^{14}C-benzoyl chloride.

Acid hydrolysis of the active tribenzoyl derivative for 21 h followed by work-up and purification gave, as well as unreacted starting material, the expected products **3**, **4**, and benzoic acid.

The percent molar yields[8] and retention of activity of these are shown in Table 1. The ester **3** was isolated as its hydrochloride which was converted into the free base with pyridine and hydrolyzed to the monobenzoyl derivative **4** with alkali. The initially isolated **4**, which was the most troublesome product to purify,[9] was converted with unlabelled benzoyl chloride into the easily purified tribenzoyl derivative. The per cent molar activities of these derivatives are also shown in Table 1.

The ester **3** had only 20% of the molar activity of the starting material and of this about 90% must have been located at the ester carbonyl since the monobenzoyl derivative **4** had only 1.9% retention of activity.

Had the loss of the N_1-benzoyl group occurred exclusively by the sequence of direct ester hydrolysis to **2** followed by benzoyl migration from N → O (Scheme 3) then **3** would have contained all the label. The actual value of 20% cannot be explained in terms of a dilution effect (100 to 20%) through exchange with benzoic acid since the activity of the latter would then have been ⩽20% and not, as observed, much higher.

It thus appears that the hydrolysis of **17** does not go by way of **2** to an extent greater than 20% and that the ratio of tertiary amide cleavage (other than by way of **2**) to ester hydrolysis is at least 0.59 :1 (isolated yield of **3** is 46%; if the remaining 54% undergoes direct ester hydrolysis the ratio is $0.8 \times 0.46 : 0.54 + 0.2 \times 0.46 =$ 0.59 :1). The true value is probably much higher since losses in the work-up of unreacted **17** and **3** would both contribute to lowering the ratio. In addition the previous hydrolysis experiment indicates that loss of tertiary amide (by all mechanisms) is faster than any other process. We conclude, therefore, that amide hydrolysis is faster than ester hydrolysis and presume that it is assisted by the neighboring ester group.[10]

TABLE 1. Hydrolysis of 18 mmol of **17**-^{14}C after 21 h: yields and activities

Compound	Moles	% Yield	Derivative	% Retention of molar activity*
17 (recovered)	6.1			99.6
3 · HCl	5.5	46		19.7
			3	20.2
			4	1.9
4	0.55	4.6		6.3
			12	8.7
$PhCO_2H$	6.6	55		40.8

*Based on starting material with a value of 3.267×10^8 counts min^{-1} mol^{-1}.

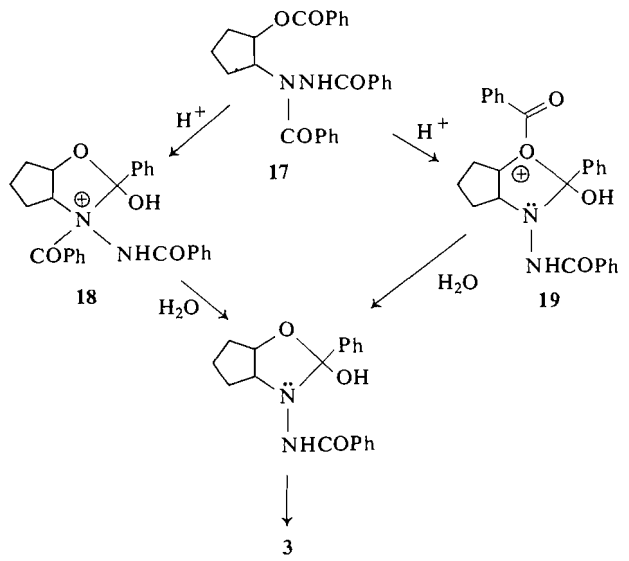
Examples have been described of assisted hydrolysis of amides by carboxyl, amide, amine, hydroxyl (15–19) and, more rarely (20), ester functions; in most of these the assisting group has been in the acyl rather than, as here, the amine moiety. We suggest that the protonated ester group of **17** forms the quaternized cyclol **18** by reaction at N_1 (Scheme 4), thus leading to a faster benzoyl cleavage, and one involving loss of label, than normal hydrolysis. A possible mechanism is also shown in Scheme 4 for ester cleavage, which transfers label directly to the ester position by way of **19**, a less important pathway than through **18** since it puts positive charge on oxygen rather than nitrogen. This is an alternative to the transfer of label by initial hydrolysis to

[7]Scambling during benzoylation, *i.e.* to give label at sites other than at N_1, is considered very unlikely.

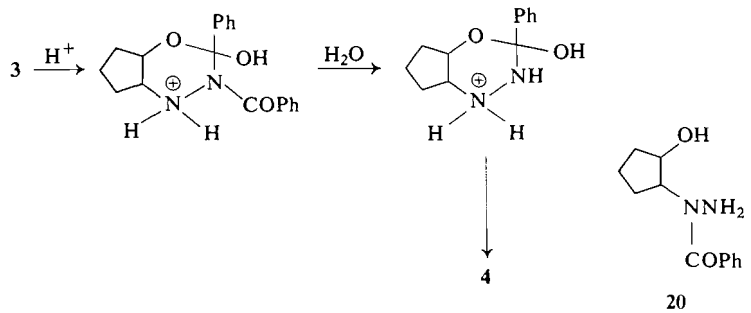
[8]Rigorous purification of the products to constant activity was carried out at the expense of optimization of yields.

[9]The increase in activity after benzoylation shows that it must have been originally contaminated with inactive material.

[10]Some measure of the stability to hydrolysis of the ester and the amide functions in the absence of neighboring group effects can be judged by the hydrolysis of the monosubstituted derivatives cyclopentyl benzoate and 1,2-dibenzoyl-1-cyclopentylhydrazine. After 7 h the ester was 17% hydrolyzed (determined by g.l.c.) and the hydrazide was ⩾20% hydrolyzed (determined gravimetrically). The results from the hydrolysis of **17**, **21***a*, and **21***b* thus show that participation at once assists hydrolysis of the amide and retards that of the ester. The great stability of **3** to these conditions may indeed be due to protection of it as the neutral cyclic structure of Scheme 4 or as its conjugate acid ($3 \cdot H^+$) by protonation on its basic nitrogen.



SCHEME 4



SCHEME 5

the alcohol **2**, followed by the cyclization of Scheme 3. The labelling experiment does not provide a decision between these.

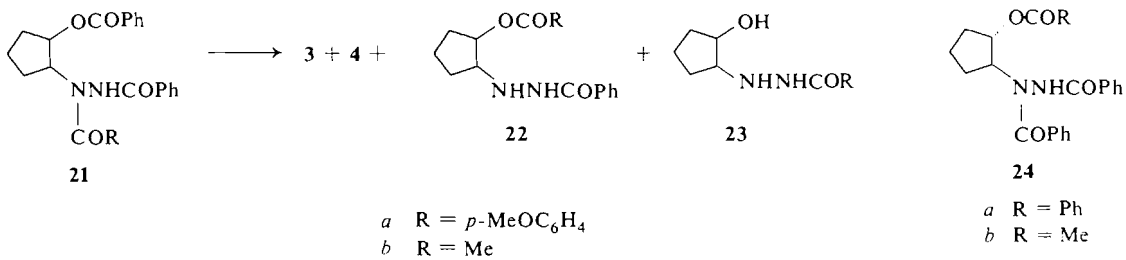
The surprisingly large (~9%) incorporation of label in the isolated monobenzoyl derivative **4** suggests the possibility of acid-catalyzed transfer of benzoyl in **3** from O to N_2 (Scheme 5). We cannot however exclude the possibility that the monobenzoyl derivative **20** is a transient hydrolysis species which isomerizes to **4** and confers activity on it. The isomerization analogous to **20** → **4** in the cyclohexane series has been shown to be efficient in acid, a diaziridine intermediate being proposed to account for it (11).

The hydrolysis of the N_1-*p*-anisoyl derivative **21***a* (Scheme 6) under the same conditions was examined briefly, being followed by n.m.r. analysis, both in the non-acidic hydrolysate by the disappearance of the methoxy singlet relative to the methylene envelope, and in the carboxylic acid fraction by changes in the aromatic region.

After 8 h the products on removal of acid showed a 31% loss of methoxy-containing material (as *p*-anisic acid), the n.m.r. spectrum being readily interpreted through its tertiary proton absorptions as due to starting material, the ester **3**, and probably some **22***a*, with only very little of **23***a*. Work-up of this fraction with cold aqueous methanol gave a 40% recovery of starting material, and by addition of hydrochloric acid to the mother liquor a 33% yield (based on unreacted **21***a*) of the hydrochloride of **3** was isolated. The carboxylic acid fraction had a *p*-anisic – benzoic acid ratio of 2.5 :1. The extent of hydrolysis is thus comparable with that of **17** with cleavage of *tert*-amide again being faster than that of ester.

Hydrolysis of **21***b* was very rapid and occurred

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.



SCHEME 6

almost exclusively at the acetyl group, with 50% hydrolysis after 1 h and 90% after 3.5 h. Work-up at this point led to recovery of 85% of the starting weight after removal of acids. The i.r. and n.m.r. spectra were substantially those of **3** which was isolated pure as its hydrochloride in 50% overall yield. The lability of the acetyl group can be explained if the rate-determining step in amide hydrolysis is typified by the formation of **18** in Scheme 4. The counterpart from **21***b* would be less subject to steric constraints at the quaternized nitrogen than either **18** or the corresponding ion from **21***a*.

The behavior of the *trans*-esters **24***a* and *b* on hydrolysis was examined briefly and found to be more straightforward. The benzoate **24***a* was 40% hydrolyzed in 7 h and 70% in 24 h, the main product being the *trans*-alcohol **5**, identified by t.l.c. At least one minor product was present which was neither the ester **3** nor the alcohol **4** (from the n.m.r. spectrum), the products of inverted stereochemistry. The acetate **24***b* was hydrolyzed much more rapidly, (the differences may be simply steric), again at the ester group, which was completely removed in 7 h. The product was slightly impure **5** (80%). It thus appears that assistance of amide hydrolysis is confined to the *cis*-series.

A number of the di- and tri-substituted *cis*- and *trans*-hydrazinocyclopentanols discussed above showed polymorphism. The *trans*-benzoate **24***a* was typical. From benzene – petroleum ether (b.p. 60–80°) it gave rosettes which melted at 139–139.5°, without prior change in the appearance of the crystals. From aqueous ethanol it gave prisms, the metastable form, which on heating slowly changed appearance; the final m.p. was again 139–139.5°. The i.r. spectra were of course identical in solution but showed differences in the crystalline state, especially so in the NH and CO regions. The stable form had in Nujol NH absorption at 3230 cm^{-1} and CO absorptions at 1715, 1670, and 1652 cm^{-1}. The metastable form had corresponding absorptions at 3320, 1685, and 1664 cm^{-1}. If a sample of the latter was kept at 100° for 10 h, its spectrum changed completely to that of the stable form.

The compounds showing polymorphism are listed in Table 2, polymorph I in each case being the stable form. Included are the solvent from which each polymorph was obtained, and the i.r. absorptions in the OH/NH and CO regions.

The i.r. differences are strongly indicative of differences in hydrogen-bonding types. Models of any of these compounds readily show that free rotation round the sigma bonds of the ester and hydrazine substituents leads to a large number of conformational possibilities with five- or six-membered rings containing hydrogen bonds. The polymorphic pairs presumably correspond to two of these.

Experimental

I.r. spectra were obtained on a Beckman IR 10 spectrophotometer. For the n.m.r. analyses a JEOL C60 or a Varian T60, were used, the τ values quoted being against tetramethylsilane as internal standard.

Thionyl chloride was purified as described by Rigby (21).

The synthesis of compounds **2–5**, **24***a*, and **17** has been described previously (1).

*cis-1-Acetyl-2-benzoyl-1-(2-benzoyloxycyclopentyl)-hydrazine (**21***b*)

A solution of acetyl chloride (1.0 g) and the hydrochloride of **3** (2.0 g, 5.5 mmol) in pyridine (7 ml) was set aside at room temperature for ½ h. Addition of water (100 ml) caused an oil to separate which crystallized overnight (54%). Recrystallization from benzene – petroleum ether (b.p. 60–80°) gave the *N*-acetyl derivative of m.p. 117–118°; ν(CCl_4) 3450, 3380 (NH), 1730, 1707 and 1685 cm^{-1} (ester, *sec*-amide and *tert*-amide C=O); τ($CDCl_3$) 1.5 (NH), 1.9–2.8 (10 phenyl H), 4.50 (C_2—H), 4.90 (C_1—H), 8.00 (Me), 7.3–8.5 p.p.m. (6 methylene H).

	II		aqueous EtOH	3380,3280	1710	1665	1655

*Petroleum ether (b.p. 60–80°).

*trans-1,2-Dibenzoyl-1-(2-acetoxycyclopentyl)hydrazine (**24b**)*

A solution of the *trans*-alcohol **5** (100 mg, 0.30 mmol) and acetic anhydride (0.3 ml) in pyridine (3 ml) was refluxed for ½ h and evaporated to a small volume. Crystallization occurred on addition of water (5 ml), and the acetate (95%) was recrystallized from aqueous ethanol as prisms, m.p. 168.5–169°; ν(CCl_4) 3370 (NH), 1721, 1698 and 1673 cm^{-1} (ester, *sec*-amide and *tert*-amide C=O); τ($CDCl_3$) 1.93 (NH), 2.3–3.1 (10 phenyl H), 4.5–5.7 (2 *tert*-H, overlapping), 7.88 (Me), 7.5–8.7 p.p.m. (6 methylene H).

Anal. Calcd. for $C_{21}H_{22}N_2O_4$: C, 68.84; H, 6.05; N, 7.65. Found: C, 68.59; H, 5.90; N, 7.42.

*cis-1-p-Anisoyl-2-benzoyl-1-(2-benzoyloxycyclopentyl)-hydrazine (**21a**)*

A solution of the hydrochloride of **3** (2.6 g, 7.2 mmol) and *p*-anisoyl chloride (1.0 ml, 7.2 mmol) in pyridine (20 ml) was refluxed for 15 min and then kept at room temperature for 10 h. Addition of water (100 ml) caused precipitation of **21***a* (94%) which after two crystallizations from aqueous methanol had m.p. 182–184°; ν(CCl_4) 3320 (NH), 1728, 1700 and 1670 cm^{-1} (ester, *sec*-amide and *tert*-amide C=O; τ($CDCl_3$) 1.85 (NH), 2.10 (2 methoxyphenyl H, d), 2.3–3.0 (10 phenyl H), 3.30 (2 methoxyphenyl H, d), 4.40 (C_2—H), 5.10 (C_1—H), 6.27 (Me), 7.5–8.9. p.p.m. (6 methylene H).

Anal. Calcd. for $C_{27}H_{26}O_5N_2$: C, 70.73; H, 5.72; N, 6.11. Found: C, 70.43; H, 5.73; N, 6.10.

*trans-1,2-Dibenzoyl-1-(2-ethoxycyclopentyl)hydrazine (**16**)*

The alcohol **5** (0.50 g, 1.6 mmol) was refluxed for 6 h in methylene chloride (10 ml) containing a slight excess of triethyloxonium fluoroborate. The solution was shaken out with aqueous sodium hydrogen carbonate and the organic layer was dried and evaporated, leaving a crystalline residue of high purity (i.r.). Two crystallizations from aqueous methanol gave prisms, m.p. 182–183°; ν(Nujol) 3285 (NH), 1685, 1615 cm^{-1} (*sec*-amide and *tert*-amide C=O); τ($CDCl_3$) 1.3 (NH), 2.2–2.9 (10 phenyl H), 5.60 (C_1—H), 6.00 (C_2—H), 6.53 (OCH_2, J = 8 Hz), 7.8–8.7 (6 methylene H), 8.83 p.p.m. (CH_3).

Anal. Calcd. for $C_{21}H_{24}N_2O_3$: C, 71.57; H, 6.86; N, 7.95. Found: C, 71.91; H, 6.88; N, 8.21.

In a control experiment the ether (20 mg) was kept in a 1 *N*-sodium hydroxide solution of water–ethanol (3:1, 5 ml) for 5 min. The solution was neutralized with acetic acid, the volume reduced, and water added to induce crystallization. The product was analytically pure starting material.

Thionyl Chloride Reactions

*(a) Formation of cis-Ester **3***

Thionyl chloride (50 μl, 0.70 mmol) was added to a suspension of the alcohol (3 ml) at room temperature. The alcohol rapidly dissolved, sulfur dioxide being evolved. After 5 min a solution of sodium hydrogen carbonate (250 mg, 3.0 mmol) in water (10 ml) was added, and the whole was shaken and warmed in a stream of nitrogen to remove the solvent. The gummy residue rapidly crystallized on cooling and scratching (190 mg, 95%), and had the i.r. spectrum and m.p., 86–87.5°, of analytically pure ester without further crystallization.

(b) Nuclear Magnetic Resonance Reactions

Thionyl chloride was added dropwise to a suspension of **5** (100 mg) in chloroform-*d* (0.3 ml) in the sample tube till a clear solution was obtained. The spectrum showed a trace of a broad band at 5.5 τ due to unreacted **5** (C_1— and C_2—H), since it could be intensified by addition of more **5** or removed by addition of more thionyl chloride. The product had τ −1.1 (2H, broad, NH and NH^+), 1.4–2.9 (10 phenyl H), 3.95 (C_1—H, quartet), 4.60 (C_2—H, triplet, the intensities suggesting its origin from two superimposed doublets), 7.0–8.8 p.p.m. (6 methylene H).

Identical spectral patterns were observed for the product with an excess of thionyl chloride, or if thionyl chloride was used as the solvent. In the latter case there were considerable downfield shifts of all absorptions, but the splittings of and the shift between the *tert*-hydrogens were the same.

When the sample from addition of 1 equiv of thionyl chloride was treated with an excess of pyridine there was no effect on the non-aromatic region of the spectrum. Dropwise addition of triethylamine, however, caused

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

disappearance of the *tert*-hydrogen absorptions and formation of a broad band at 4.7 τ. Passage of dry hydrogen chloride regenerated the original spectrum.

(c) Examination of Product

A sample of the product prepared as above from 1 equiv of thionyl chloride had ν($CDCl_3$) 2900–2300 (NH and $NH^{\oplus}$), 1685 cm^{-1} (*sec*-amide C=O).

When a solution prepared from an excess of thionyl chloride in dry methylene chloride (as in section *a*), or in neat thionyl chloride, was evaporated in a stream of dry nitrogen and then pumped over sodium hydroxide (liquid nitrogen trap) the residue frothed but did not crystallize. Redissolved in chloroform-*d* it had the spectrum described above. On prolonged pumping there was a gradual loss of weight from about 1.2 to 1.1 times that of the original alcohol over a period of 3 days. The n.m.r. spectrum of the residue showed a new broad multiplet at 5.4 τ, formed at the expense of the original *tert*-hydrogens. This product was not examined further.

Reactions with p-Toluenesulfonyl Chloride

(a) On cis-Ester 3

The ester (0.20 g, 0.62 mmol) was allowed to react with tosyl chloride (0.12 g, 0.62 mmol) at 5° for 1 day in pyridine (5 ml). Addition of water gave crystalline *cis-1-p-toluenesulfonyl-2-benzoyl-1-(2-benzoyloxycyclopentyl)hydrazine* (**13**) which formed dense prisms (86%), m.p. 153.5–154°, from aqueous methanol; ν(CCl_4) 3410 (NH), 1730, 1708 cm^{-1} (ester, *sec*-amide C=O); τ($CDCl_3$) 1.9–3.0 (14 aromatic H and one H exchangeable with D_2O), 4.45 (C_2—H), 5.45 (C_1—H), 7.68 (Me), 7.4–8.5 p.p.m. (6-methylene H).

Anal. Calcd. for $C_{26}H_{26}N_2O_5S$: N, 5.85. Found: N, 5.93.

(b) On trans-Alcohol 5

The alcohol (0.32 g, 1 mmol) was treated with tosyl chloride (0.19 g, 1 mmol) in pyridine (15 ml) for 17 h at room temperature. Addition of water caused precipitation of a small amount (7%) of the *N*-tosyl derivative **13**. Evaporation of the filtrate and crystallization from aqueous methanol gave the starting alcohol (78%).

Repetition of this reaction on the same scale, but with *2* equiv of tosyl chloride, followed by addition of water gave the *N*-tosyl derivative **13** in 90% yield. Its identity was confirmed by mixed m.p. with the product in section *a*.

(c) Nuclear Magnetic Resonance Reactions

The alcohol **5** (115 mg, 0.35 mmol) was dissolved in chloroform-*d* (5 ml) containing pyridine (0.10 ml, *ca.* 2.5 equiv), and tosyl chloride (67 mg, 0.35 mmol) was added. The volume was reduced to about 0.5 ml by evaporation under dry nitrogen and the solution (0.7 *M*) transferred to a sample tube. The changes in the spectrum till reaction was complete, and thereafter when a second equiv of tosyl chloride was added, are described in the discussion.

The reactions with 1 and 2 equiv of tosyl chloride were also monitored in pyridine-d_5. No significant differences were observed other than solvent shifts.

Addition of D_2O at either stage in the above reactions led to rapid changes in the spectra. The major product from the first stage was the starting alcohol **5** with smaller amounts of the *N*-tosyl derivative **13** and the ester **3**. The yield of the latter from the reaction in pyridine was estimated as 12% by comparison of the area of its C_1—H with that of the total methylene envelope. In the chloroform-*d* reaction the yield appeared to be slightly greater. From the second stage of the reaction the addition of D_2O indicated that **13** was the exclusive product.

Control experiments. To interpret the assignments in the tosylation reactions the spectra of the following compounds or mixtures of reagents were required in chloroform-*d* containing appropriate amounts of pyridine or in pyridine itself: (*i*) tosyl chloride; (*ii*) the ester **3**, alone and with 1 equiv of tosyl chloride; (*iii*) the *N*-tosyl derivative **13**; (*iv*) the alcohol **5**.

(d) Reaction with Methanol and with Sodium Ethoxide

The solution prepared from the alcohol and tosyl chloride (0.50 mmol each) in pyridine (2 ml) was kept for 36 h and then evaporated under reduced pressure (liquid nitrogen trap). The glassy residue was found to have an n.m.r. spectrum the same as that described before; its i.r. spectrum had ν($CDCl_3$) 3400 (NH), 1685 and 1640 cm^{-1} (C=O). The main portion was dissolved in methanol (0.5 ml), kept for 12 h, and pumped down as before. The n.m.r. and i.r. spectra were unchanged. Treatment with aqueous methanol gave a crystalline solid whose i.r. spectrum showed it to be mainly **5**.

To a solution of the complex from 0.30 mmol each of alcohol and tosyl chloride, prepared in pyridine (1.5 ml) and kept 11 h at room temperature, was added a solution of sodium ethoxide (1.0 mmol) in ethanol (1 ml). A flocculent precipitate formed and the whole was briefly warmed to 80° which made it yellow. It was quenched with ice and neutralized with acetic acid. Extraction with methylene chloride gave a residue which crystallized on trituration with a few drops of methanol. The product (80%) was washed with much water and identified as almost pure **5**.

Hydrolysis Reactions

General

The acid solution was prepared by mixing 2 l ethanol, 1 l water, and 200 ml 12 *N* hydrochloric acid. There was a 2.5% shrinkage making the final solution 0.770 *N* in acid. All hydrolyses were done on a scale of 1 mmol in 19.5 ml acid at reflux temperature.

Aliquots were withdrawn at intervals, basified with sodium hydrogen carbonate, evaporated, and shaken with water and methylene chloride. The methylene chloride extraction was repeated four times. The dried extracts were evaporated and the residue analyzed as necessary by i.r. or n.m.r. spectrometry.

Quantitative determinations on the n.m.r. absorptions of protons were carried out at 1 Hz s^{-1} sweep rates in both directions at r.f. power levels low enough to prevent saturation. The traces were photocopied, cut out, and weighed. The absorptions used in individual experiments, the scale and other details follow.

(a) cis-Tribenzoyl Derivative 17 (4 mmol)

C_2—H at 4.3 τ in **17** and C_2—H at 4.7 τ in the product ester **3** were used; they overlapped slightly. In the late stages of the reaction the peak for C_1—H at 6.8 τ in the alcohol **4** was detectable. Ratios of **3**:**17** were, at 3, 7, and 23 h, 0.18:1, 0.56:1, and 2.3:1 respectively.

In a separate experiment **17** (2.3 mmol) was hydrolyzed for 19 h. The residue from the reaction was treated with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

ethanol containing a little hydrochloric acid which precipitated the pure hydrochloride of **3** (36%).

In a control experiment **3** (0.12 mmol) was refluxed for 17 h. On work-up **3** was recovered, contaminated only with a small amount of **4**; it was isolated and identified as its hydrochloride.

*(b) p-Anisoyl Derivative **21a** (4 mmol)*

The area ratio of the methylene envelope to the methoxy singlet was measured in pure **21***a* and its value of 2.35 used in determining the loss of the *p*-anisoyl group during hydrolysis. The sodium hydrogen carbonate solution was acidified and the mixed carboxylic acids extracted with methylene chloride (5 times). Their ratios were determined by n.m.r. analysis by comparing the two high field *p*-anisoyl protons (H_3 and H_5) with the three high field benzoic acid ones (meta and para). At 3, 8, and 19 h the loss of methoxy signal in the non-acidic fraction was 7, 31, and 71% and the ratios of *p*-anisic to benzoic acid at the same times were 2.5:1, 2.5:1, and 0.5:1.

In a separate experiment (1.02 mmol) the hydrolysate was freed from carboxylic acids after 8 h and the non-acidic fraction was crystallized from aqueous methanol. The crystalline product (186 mg, 40%) was identified as starting material. The mother liquor was evaporated and methanolic hydrochloric acid added. An initial crop of crystals was removed, and the soluble fraction worked-up similarly to give a second crop (68 mg in all, 33% based on unrecovered **21***a*); these were combined and identified as the hydrochloride of **3** (superimposable i.r. spectrum). Recrystallization from methanolic hydrochloric acid gave prisms, m.p. 162–164°.

*(c) Acetyl Derivative **21b** (8 mmol)*

The overlapping C_2—H in **21***b* and C_2—H in the product **3** at 4.5 τ were compared with C_1—H in **3** at 6.5 τ. After 1 and 3.5 h the ratios of **3**:**21***b* were 1:1 and 9:1.

After removal of acid, the residue from the reaction (85% by weight of starting material, equivalent to 95% of **3**) had an i.r. spectrum almost identical with that of **3**. Addition of methanol containing 3 *N* hydrochloric acid gave the hydrochloride (50%), m.p. 163–166°, alone or in admixture with an authentic sample.

*(d) trans-Tribenzoyl Derivative **24a** (2 mmol)*

The overlapping C_1—H and C_2—H of **7***d*, between 4.3–5.3 τ, were compared with the sum of the overlapping C_1—H and C_2—H of the product alcohol **5**, between 5.4—6.2τ, and a smaller peak from another product at 6.4 τ. These gave ratios of products: **24***a* of 0.4:1 at 7 h and 1.5:1 at 24 h. T.l.c. on silica gel plates from benzene–ether showed two main spots only, for **24***a* and **5**.

*(e) trans-Acetate **24b** (2 mmol)*

After hydrolysis for 7 h the residue, on removal of acid, was free of an acetyl peak in its n.m.r. spectrum and corresponded to 71% by weight of the starting weight, or a maximum yield of 80% of the *trans*-alcohol **5**. The i.r. spectrum was that of slightly impure alcohol. One crystallization from aqueous methanol gave material of m.p., and mixed m.p. 174–176°.

^{14}C Labeling Experiment

The activity of all compounds was obtained by dissolving a known weight (*ca.* 150 mg) in 20 ml of scintillation fluid and measuring the counts min^{-1} in a Tri-Carb Liquid Scintillation Spectrometer, background count being subtracted. Four determinations were made for each sample. The scintillation fluid consisted of 2,3-diphenyloxazole (PPO, 2.8 g), *p*-bis-[2-(4-methyl-5-phenyloxazolyl)] benzene (dimethyl POPOP, 0.7 g) and Cab-O-Sil (30 g) dissolved in toluene (700 ml) and absolute ethanol (300 ml).

Benzoyl chloride (35 g, 0.25 mol) was made ^{14}C active by heating it at 100° for 2 h with a sample of benzoic acid containing 100 μCi of ^{14}C in the carbonyl group.

The ester **3** as its hydrochloride was converted into the N_1-benzoyl-^{14}C derivative (**17**-^{14}C) with benzoyl chloride-^{14}C in pyridine as described for the synthesis of the unlabelled compound (1). It was crystallized to a constant activity of 3.267×10^8 counts min^{-1} mol^{-1}.

In a control experiment inactive **17** could not be made ^{14}C-active by treatment with benzoyl chloride-^{14}C in refluxing pyridine.

The active ester (18.0 mmol) was hydrolyzed for 21 h. On cooling unreacted ester (6.1 mmol) crystallized out. Concentration of the mother liquor and addition of 3 *N* hydrochloric acid gave the hydrochloride of **3** (5.5 mmol). The remainder of the work-up, as described for the hydrolysis of **1** (1), gave the alcohol **4** (0.37 mmol) and benzoic acid (6.6 mmol).

A portion of the hydochloride of **3** was converted into the free base with pyridine and the remainder was hydrolyzed by heating it at reflux for 3 min in 0.8 *N* sodium hydroxide in aqueous ethanol (1:1). The chilled solution was then extracted thoroughly with ether to give the alcohol **4**.

A portion of the alcohol **4** from the original work-up was converted into the tribenzoyl derivative by treatment with 2 equiv of benzoyl chloride in pyridine at 5° (1).

The percent molar activities of all compounds, based on that of the starting material, are given in Table 1.

We thank the Province of Ontario for a Graduate Fellowship (to J.A.C.) and the National Research Council of Canada for support of this work and for a Scholarship (to J.A.C.).

ortho Diquaternary Aromatic Compounds. IV. Acid-catalyzed Rearrangements of Polyalkyltetralones and Related Ketones

LAWRENCE ROSS COATES BARCLAY, ROBERT HAYWORTH YOUNG, KEIR LEIGH ADAMS, AND HELEN MARY FOOTE

Department of Chemistry, Mount Allison University, Sackville, New Brunswick

Received September 6, 1972

The ketones 1,1,4,4-tetramethyl-2-tetralone (**1***a*), 1,1,4,4,7-pentamethyl-2-tetralone (**1***b*), and 1,1,4,4,6-pentamethyl-2-tetralone (**1***c*) undergo rearrangement on heating with aluminum chloride or ferric chloride in tetrachloroethane or nitromethane into mixtures of their respective isomeric ketones, 1-acetyl-1,3,3-trimethylindane (**2***a*) and 2,2,4,4-tetramethyl-1-tetralone (**3***a*) from **1***a*, 1-acetyl-1,3,3,6-tetramethylindane (**2***b*) and 2,2,4,4,7-pentamethyl-1-tetralone (**3***b*) from **1***b*, and 1-acetyl-1,3,3,5-tetramethylindane (**2***c*) and 2,2,4,4,6-pentamethyl-1-tetralone (**3***c*) from **1***c*. A quantitative study using g.l.c. of the distribution of the ketones with time shows that the sequence of the rearrangement is: $\mathbf{1} \rightleftarrows \mathbf{2} \rightarrow \mathbf{3}$. A methyl group homologously para to the carbonyl (**1***c*) accelerates the rearrangement. The same kind of rearrangement takes place during Friedel–Crafts cyclialkylation with 2,2,5,5-tetramethyltetrahydrofuranone. A unifying reaction mechanism is postulated to account for the rearrangements. This mechanism also accounts for the rearrangement and fragmentation products from treatment of 1,1,4,4-tetramethyl-2,3-dioxotetralin (**9**) with aluminum chloride or sulfuric–acetic acids. The products from **9** include 1-acetyl-1,3,3-trimethyl-2-indanone, 1,1,3-trimethyl-2-indanone, and, from the aluminum chloride – catalyzed rearrangement, 5(or 6)-acetyl-1,1,3-trimethyl-2-indanone.

Les cétones tétraméthyl-1,1,4,4 tétralone-2 (**1***a*) pentaméthyl-1,1,4,4,7 tétralone-2 (**1***b*) et pentaméthyl-1,1,4,4,6 tétralone-2 (**1***c*) se réarrangement par chauffage en présence de chlorure d'aluminium ou chlorure ferrique dans le tétrachloroéthane ou nitrométhane, en mélange de leurs cétones isomères respectivement acétyl-1 triméthyl-1,3,3 indane (**2***a*) et tétraméthyl-2,2,4,4 tétralone-1 (**3***a*) à partir de **1***a*; acétyl-1 tétraméthyl-1,3,3,6 indane (**2***b*) et pentaméthyl-2,2,4,4,7 tétralone-1 (**3***b*) à partir de **1***b* et acétyl-1 tétraméthyl-1,3,3,5 indane (**2***c*) et pentaméthyl-2,2,4,4,6 tétralone-1 (**3***c*) à partir de **1***c*. Une étude quantitative par c.g.l. de la distribution des cétones en fonction du temps, montre que la séquence du réarrangement est: $\mathbf{1} \rightleftarrows \mathbf{2} \rightarrow \mathbf{3}$. Un groupe méthyle homologue en para du carbonyl (**1***c*) accélère le réarrangement. Le même type de réarrangement a lieu lors de la cycloalkylation selon Friedel et Crafts de la tétraméthyl-2, 2,5,5 tétrahydrofuranone. Un mécanisme réactionnel a été postulé pour expliquer ces réarrangements. Ce mécanisme tient compte également des produits de réarrangement et de fragmentation lors du traitement de la tétraméthyl-1,1,4,4 dioxo-2,3 tétraline (**9**) par la chlorure d'aluminium ou le mélange d'acides sulfurique–acétique. Les produits issus de **9** comprennent l'acétyl-1 triméthyl-1,3,3 indanone-2, la triméthyl-1,1,3 indanone-2 et, à partir du réarrangement catalysé par $AlCl_3$, l'acétyl-5 (ou 6) triméthyl-1,1,3 indanone-2. Can. J. Chem., **51**, 1598 (1973)

Introduction

The Friedel–Crafts cyclialkylation of aromatic compounds with 2,2,5,5-tetramethyltetrahydrofuranone is an important synthetic reaction. Since its discovery by Bruson and co-workers in 1958 (1), the reaction has provided intermediates for the synthesis of ortho-di-*t*-butyl-derivatives of benzene (2, 3) and of naphthalene (4). As well as producing the ortho-diquaternary ketone, 1,1,4,4-tetramethyltetralone (**1***a*) this reaction yields isomeric ketones, such as 1-acetyl-1,3,3-trimethylindane (**2***a*) (5) (Scheme 1).

The formation of isomeric ketones, such as **2***a*, placed definite limitations on this cyclialkylation method to produce ortho-di-*t*-butyl-aromatics (6). However, the pathway for formation of **2***a* was not well understood. In view of this and because of our interest in rearrangements of branched condensed ring systems (7), we undertook a study of the acid-catalyzed rearrangements of ketones such as **1***a* and **2***a*. In particular it was desirable to know if rearrangements leading to **2***a* took place before ring closure as was proposed by Grant and coworkers (5) or if rearrangements took place through **1***a*.

Results and Discussion

(1) Rearrangements of 1,1,4,4-Tetramethyltetralone (1a) and 1-Acetyl-1,3,3-trimethylindane (2a)

Initial rearrangement studies carried out on 1,1,4,4-tetramethyltetralone (**1***a*) under various

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

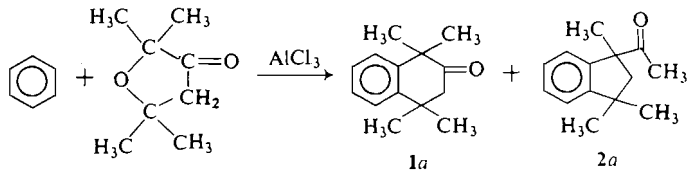
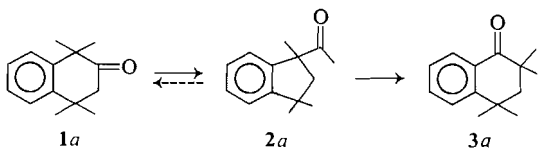


SCHEME 1

conditions are summarized in Table 1. The results show that **1***a* rearranges with different catalysts (aluminum chloride, ferric chloride, hydrogen fluoride) at least partially into 1-acetyl-1,3,3-trimethylindane (**2***a*). A new ketone (**3***a*) was identified in each of the rearrangement experiments. The mass spectrum of **3***a* indicated it to be isomeric with **2***a* and **1***a*. The i.r. and u.v. spectra showed **3***a* to be a conjugated ketone. From these results and its n.m.r. spectrum, the conjugated ketone is assigned the structure 2,2,4,4-tetramethyl-1-tetralone (**3***a*). Results from treatment of 1-acetyl-1,3,3-trimethylindane (**2***a*) with acids (Table 1, nos. 5, 6, and 7) indicate that **3***a* forms from **2***a* (Scheme 2).



SCHEME 2

(2) Studies of Product Distribution with Time in Rearrangements of Polyalkyltetralones

In order to corroborate the evidence that the sequence of the rearrangement is **1** → **2** → **3**, comparative rearrangements were carried out on **1***a*, 1,1,4,4,7-pentamethyl-2-tetralone (**1***b*), and 1,1,4,4,6-pentamethyl-2-tetralone (**1***c*) by measuring the distribution of products with time using gas chromatographic analyses on aliquots from the reactions.

In the rearrangement of **1***a* by aluminum chloride in tetrachloroethane (Table 2, Fig. 1), there was an initial rapid decrease in per cent of **1***a* with a concomitant rapid build up of the primary rearrangement product, **2***a*. The amount of **2***a* then decreased slowly as the new ketone (**3***a*) slowly formed, and after an extended time became the major component present. The formation of **2***a* from **1***a* could also be detected by direct n.m.r. observations of the signal due to the aluminum chloride-complexed methyl keto function. This method gave a less precise indication of the amount of **2***a* but it does show the same trend as found by v.p.c. analysis of aliquots and the n.m.r. method gives direct corroborative evidence for the formation of **2***a* (Fig. 1).

The rearrangement of **1***a* with aluminum chloride in nitromethane (Table 2, Fig. 2) was faster than in tetrachloroethane. In nitromethane the conversion of **1***a* was more complete and the rate of formation of the conjugated ketone (**3***a*) was at least double that observed in tetrachloroethane. This result is surprising in view of the usual mitigating effect of nitromethane on Friedel–Crafts rearrangements. It might be due to the fact that the aluminum chloride – ketone complexes did not appear to be completely soluble in tetrachloroethane, whereas solutions were more readily obtained in nitromethane.

The results for rearrangement of 1,1,4,4,7-pentamethyl-2-tetralone (**1***b*) are summarized in Table 3 (nos. 1–3). This rearrangement yielded 1-acetyl-1,3,3,6-tetramethylindane (**2***b*) and 2,2,4,4,7-pentamethyl-1-tetralone (**3***b*). The data for **1***b* (nos. 1 and 2) are very similar to that observed for rearrangement of **1***a* under comparable conditions (Table 2). In addition the plots of detailed data points for these rearrangements of **1***b* very closely followed the results shown in Figs. 1 and 2 for **1***a*. There was a slight acceleration amounting to 3–4% after 100 min in the formation of the conjugated ketone (**3***b*) compared to **3***a*. Thus a methyl group situated meta[1] with respect to the site of the rearrangement has a slight accelerating effect on the rearrangement. The ketone **1***b* also underwent rearrangement by treatment with ferric chloride in nitromethane (Table 3, no. 3), analogous to the reaction in aluminum chloride – nitromethane.

The rearrangement of ketone **1***c* is of interest because this ketone has an activating methyl group in a position homologously para to the carbonyl group. The results for rearrangement

[1]The methyl groups at position-7 in **1***b* and -6 in **1***c* will be referred to as homologously meta and para respectively to the carbonyl group.

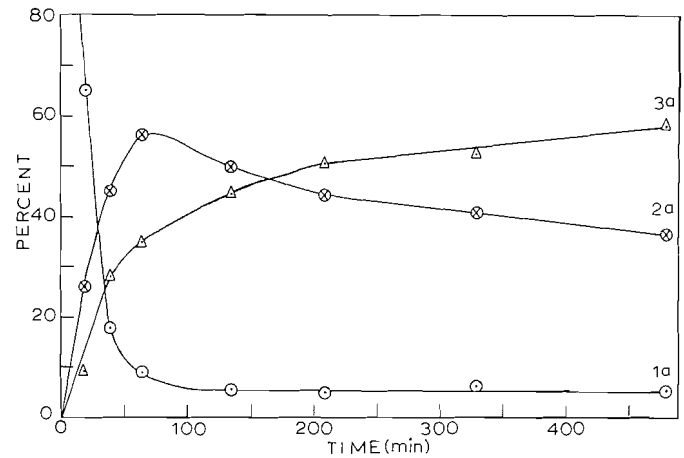

FIG. 2. Progress of rearrangement of 1,1,4,4-tetramethyl-2-tetralone (**1***a*), ⊙, into 1-acetyl-1,3,3-trimethylindane (**2***a*), ⊗, and 2,2,4,4-tetramethyl-1-tetralone (**3***a*), △, with aluminum chloride in nitromethane (90°).

of **1***c* with aluminum chloride in nitromethane are summarized in Table 3 (no. 4) and illustrated in Fig. 3. The methyl group in **1***c* accelerated its rearrangement markedly relative to ketone **1***a* (Fig. 2) or **1***b*. This is especially noticeable in the more rapid formation of the conjugated ketone 2,2,4,4,6-pentamethyl-1-tetralone (**3***c*) with a concomitant rapid decrease in the amount of methyl ketone (**2***c*).

*(3) Rearrangement of 1,1,4,4-Tetramethyl-2,3-dioxotetralin (**9**)*

It was of interest to study the acid-catalyzed rearrangement of the α-diketone **9** under similar conditions to those used for the polyalkyltetralones. The diketone **9** was found to rearrange very rapidly with aluminum chloride. However, by lowering the temperature to 65°, it was possible to follow the course of the rearrangement by v.p.c. analysis of aliquots in the usual way (Table 4 and Fig. 4). The primary product of this rearrangement, 1-acetyl-1,3,3-trimethyl-2-indanone (**10**), formed very rapidly from **9**. The new diketone (**10**) is the result of the same kind of skeletal rearrangement as was observed for the polyalkyltetralones. On the other hand, two other products from the reaction of **9** do not have analogs from previous

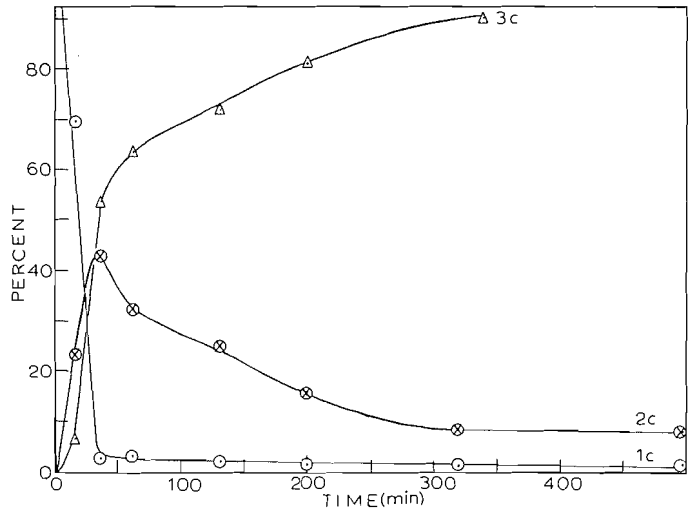

FIG. 3. Progress of rearrangement of 1,1,4,4,6-pentamethyl-2-tetralone (**1***c*), ⊙, into 1-acetyl-1,3,3,5-tetramethylindane (**2***c*), ⊗, and 2,2,4,4,6-pentamethyl-1-tetralone (**3***c*), △, with aluminum chloride in nitromethane (90°).

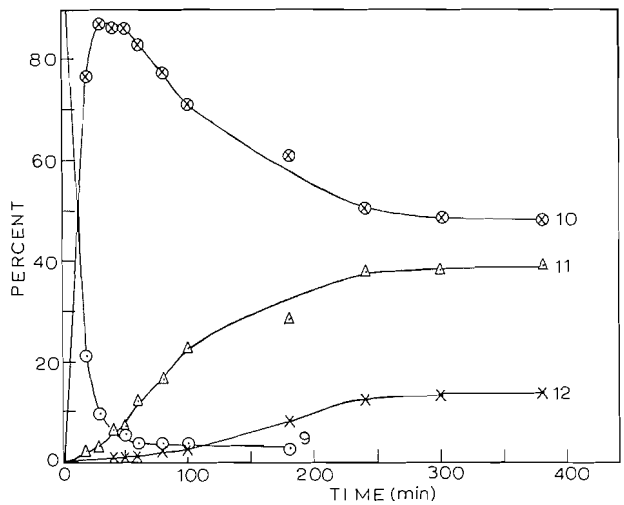

FIG. 4. Progress of rearrangement of 1,1,4,4-tetramethyl-2,3-dioxotetralin (**9**), ⊙, into 1-acetyl-1,3,3-trimethyl-2 indanone (**10**), ⊗, 1,1,3-trimethyl-2-indanone (**11**), △, and 5(or 6)-acetyl-1,1,3-trimethyl-2-indanone (**12**), ×, with aluminum chloride in tetrachloroethane (65°).

rearrangements. One of these was formed in sufficient quantity to be identified as 1,1,3-trimethyl-2-indanone (**11**). The other was formed in later stages of the reaction in relatively small quantities. It is tentatively assigned the structure 5(or 6)-acetyl-1,1,3-trimethyl-2-indanone (**12**) on the basis of spectral evidence.

1,1,4,4-Tetramethyl-2,3-dioxotetralin (**9**) also underwent rearrangement into the diketone **10** and 1,1,3-trimethyl-2-indanone (**11**) on heating with sulfuric acid in acetic acid at 100° (Table 4). There was no evidence of compound **12** from this reaction. The transformation was much slower than the aluminum chloride – catalyzed rearrangement. For example, after 1 h at 100° in the protic acid medium, there remained 80% of the starting diketone (**9**). On the other hand, the aluminum chloride treatment at 65° had transformed all but 4% of **9** in 1 h.

(4) Rearrangements During Cyclialkylation with 2,2,5,5-Tetramethyltetrahydrofuranone

It seemed probable that the sequence of rearrangements **1** ⇄ **2** → **3** would also occur during the Friedel–Crafts cyclialkylations with 2,2,5,5-tetramethyltetrahydrofuranone. This was

TABLE 5. Cyclialkylation of toluene with 2,2,5,5-tetramethyltetrahydrofuranone* (100°)

Time (min)	1,1,4,4,7-Pentamethyl-2-tetralone (%)	1-Acetyl-1,3,3,6-tetramethylindane (%)	2,2,4,4,7-Pentamethyl-1-tetralone (%)
10	70.0	21.0	2.1
20	62.0	27.5	3.1
41	47.3	39.2	6.4
60	40.0	47.0	7.7
92	33.7	55.5	8.1
137	27.8	54.5	11.4
255	16.7	56.6	18.9
1125	13.8	52.7	25.5

*Initial amounts of reagents were toluene (21.1 mmol), 2,2,5,5-tetramethyltetrahydrofuranone (35.2 mmol), and aluminum chloride (70.4 mmol). In addition to the compounds listed, a small amount of a fourth ketone (2–4%) was detected but not identified. Percentages are from v.p.c. analyses of aliquots.

confirmed by a study of the product distribution with time for the cyclialkylation of toluene (Table 5). The results show that there was very rapid cyclialkylation of toluene, under the reaction conditions, to form 1,1,4,4,7-pentamethyl-2-tetralone (**1***b*) as the major compound. Then ketone **1***b* underwent rearrangement into 1-acetyl-1,3,3,6-tetramethylindane (**2***b*) and 2,2,4,4,7-pentamethyl-1-tetralone (**3***b*) in a manner similar to the previous rearrangements.

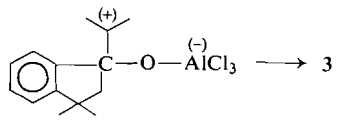
A knowledge of the course of these rearrangements is very useful in preparative reactions with 2,2,5,5-tetramethyltetrahydrofuranone. For example, by quenching the reaction after 10 min, we were able to prepare the ketone **1***b* in 70% yield by cyclialkylation of toluene (6) in the presence of aluminum chloride.

(5) A Reaction Mechanism for the Rearrangements

The rearrangement studies clearly show that the methyl ketones (**2***a–c*) result directly from rearrangement of the polyalkyltetralones (**1***a–c*), either when the latter are initially present in the reaction mixture or when they are formed under cyclialkylation conditions with 2,2,5,5-tetramethyltetrahydrofuranone. These results refute the proposal by Bruson and co-workers (1), supported by Grant and co-workers (5), that the methyl ketone (**2***a*) formed independent of the formation of the tetramethyltetralone (**1***a*), by a pinacol–pinacolone type of rearrangement on the α-ketol-$C_6H_5C(CH_3)_2CH_2COC(CH_3)_2OH$ to form $C_6H_5C(CH_3)_2CH_2COH(CH_3)COCH_3$ followed by ring closure of the latter compound.

The proposed reaction mechanism also has to account for the conversion of the methyl ketones (**2***a–c*) into the conjugated ketones (**3***a–c*). In addition the marked accelerating effect of a methyl group at position-6 (homologously para to the carbonyl group) but not at position-7 must be explained. The various observations can readily be accommodated for by the reaction pathways outlined in Scheme 3. Aluminum chloride forms a complex (**4**) with the carbonyl oxygen. This increases the electron deficiency of the carbonyl carbon. Direct evidence of this was shown in the n.m.r. spectrum of the complex which showed a downfield shift of the adjacent methylene hydrogens of up to 0.7 τ when the ratio of aluminum chloride to **1***a* approached equimolar in tetrachloroethane. A 1,2-methyl shift[2] in **4** yields a carbonium ion **5**, the latter being favored by resonance stabilization with the aromatic ring. Ring contraction by a 1,2-shift in **5** forms **6** which is the complexed form of the methyl ketones (**2**). Eventually the methylketones are irreversibly converted into the conjugated ketones (**3***a–c*). This can be explained by a 1,2-aryl shift in **6** forming the tertiary β-carbonium ion **7**. A 1,2-methyl shift in **7** leads to **8** which is the complexed form of the ketone **3**. A methyl group at position-6 (R_2) is expected to accelerate the rearrangement as observed. This group would stabilize the carbonium ion intermediates **5** and **8**, and presumably the transition states leading to them, and

[2]As pointed out by a referee, this is contrary to the usual trend for an aryl to migrate in preference to a methyl. An initial aryl migration could proceed via



but this is not in agreement with our observation of **2** as an intermediate. In **2** the aryl migration does proceed in preference to a methyl migration.

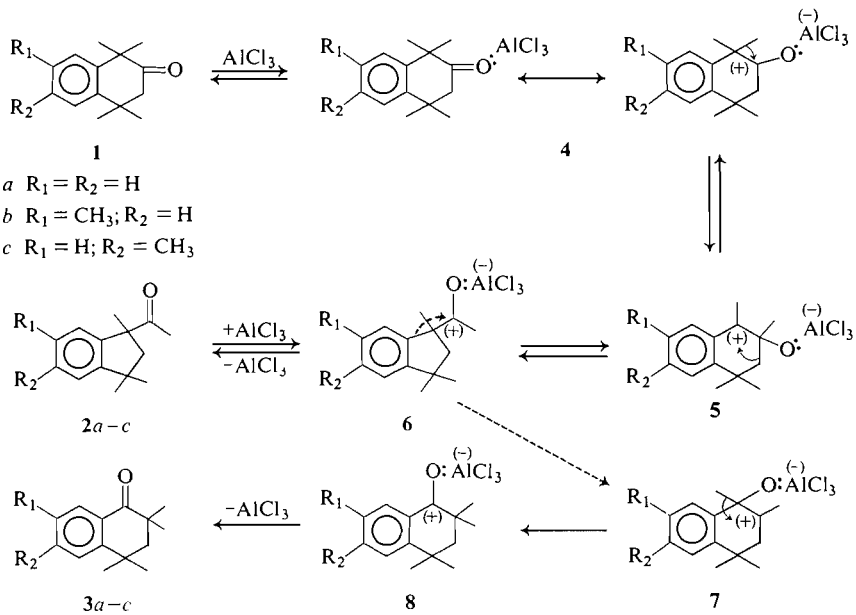
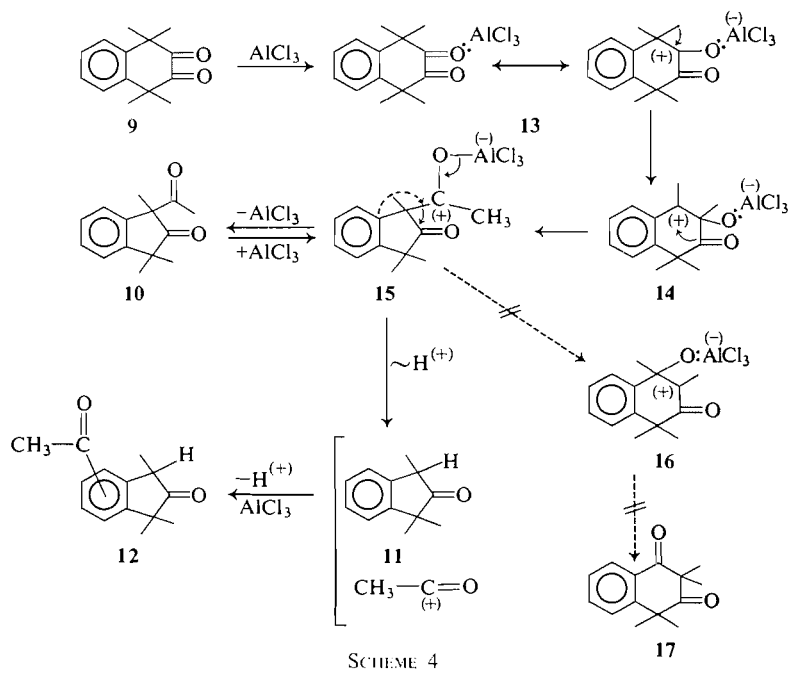


SCHEME 3



SCHEME 4

therefore promote the rearrangements. The reaction pathways are shown by a series of discreet intermediates for convenience in this discussion. It is possible that the 1,2-migrations may take place in concerted mechanisms. Analogous rearrangements have been reported in the literature for acyclic carbonyl compounds. For example, 2-phenyl-2-methylpropanal undergoes acid-catalyzed rearrangement to form 3-phenyl-2-butanone by a 1,2-methyl shift and isobutyrophenone by a 1,2-phenyl shift (8).

The reaction pathways formulated to account for rearrangements of ketones **1** and **2** can readily be adapted to explain the rearrangement

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

of the α-diketone (**9**) (Scheme 4). Thus a 1,2-methyl shift in the complexed ketone (**13**) leads to **14** and ring contraction of **14** results in **15** and the β-diketone (**10**). In this rearrangement, there was no evidence for the formation of a conjugated ketone (**17**) analogous to the final product from rearrangements on the polyalkyltetralones **1***a–c*. The lack of formation of **17** is probably due to the fact that the necessary precursor-carbonium ion **16** is very unfavorable, having the positive charge adjacent to the second electropositive carbonyl group. Alternative reactions take place in this system. Thus cleavage of the β-diketone (**10**) occurs (presumably through an intermediate such as **15**) resulting in 1,1,3-trimethyl-2-indanone (**11**). The acylium ion also produced apparently acylates **11** in the presence of aluminum chloride to form some substitution product **12**. The rearrangement product **10** and fragmentation product **11** can be similarly accounted for from the protic acid treatment of **9** in sulfuric–acetic acids. Under these conditions, the β-diketone (**10**) also undergoes cleavage to **11** but no Friedel–Crafts type acylation of **11** would take place; thus ketone **12** is not formed.

Experimental

G.l.c. analyses were determined by means of an F & M model 500 programmed temperature gas chromatograph equipped with a dual column attachment. The columns were 12 ft × 1/4 in., packed with Apiezon grease (30%) on Chromosorb W. The n.m.r. spectra were recorded on a Varian A-60 NMR Spectrometer using carbon tetrachloride solvent containing tetramethylsilane as internal standard. The i.r. spectra were recorded on a Perkin–Elmer model 337 Grating Spectrophotometer, using potassium bromide pellets for solids and films for liquids. U.v. spectra were recorded on a Beckmann DK-2 Spectrophotometer using spectro-grade cyclohexane as solvent. Melting points were determined on a Thomas Hoover capillary m.p. apparatus and are uncorrected. Elemental analyses were determined by Dr. E. Thommen, Basel, Switzerland and by Dr. C. Daesslé, Montreal, Quebec.

(a) Procedure for Rearrangement Studies

The syntheses and properties of the ketones 1,1,4,4-tetramethyl-2-tetralone (**1***a*), 1,1,4,4,7-pentamethyl-2-tetralone (**1***b*), 1,1,4,4,6-pentamethyl-2-tetralone (**1***c*), and 1,1,4,4-tetramethyl-2,3-dioxotetralone (**9**) were described previously (6, 2). 1-Acetyl-1,3,3-trimethylindane (**2***a*) and 1-acetyl-1,3,3,6-tetramethylindane (**2***b*) were obtained for rearrangement studies by separation and identification from the products of rearrangement of the ketones **1***a* and *b* respectively as described below. The following general procedure was used for rearrangements catalyzed by aluminum chloride in tetrachloroethane or by ferric chloride in nitromethane. The ketone was dissolved in freshly dried and distilled solvent, using 5 ml of solvent per 1 g of ketone. The anhydrous catalyst was added and the reaction mixture heated in a silicone oil bath maintained at the temperature indicated (±0.5°). The reaction was quenched in ice-water and the organic layer extracted with ethyl ether. The ether extracts were washed with water, dried with anhydrous sodium sulfate, and the ether distilled. Gas chromatographic analyses were then made on the residue. Reactions with hydrogen fluoride were carried out in a stainless steel tube (Autoclave Engineers Inc., Testtube Reactor). Otherwise the procedure was the same as before. The results of these rearrangement studies are summarized in Table 1. The procedure for studies of product distributions with time was similar to that outlined above. In these cases, small aliquots were removed from the reaction mixtures with a syringe and worked up for g.l.c. analysis. The results of these studies are given in Tables 2–5. The order of elution of the various isomeric ketones on the g.l.c. Apiezon (30%) columns used was: methyl ketones (**2***a–c*) first, polyalkyltetralones (**1***a–c*) second, and conjugated ketones (**3***a–c*) last. Samples of these ketones for spectral and analytical purposes were obtained by collection of samples from the gas chromatograph. Larger samples of 1-acetyl-1,3,3-trimethylindane (**2***a*) and 1-acetyl-1,3,3,6-tetramethylindane (**2***b*) were obtained in this way and further purified for rearrangement studies through their semicarbazones.

(b) Direct Observations by Nuclear Magnetic Resonance Studies

The interaction of anhydrous aluminum chloride with 1,1,4,4-tetramethyl-2-tetralone (**1***a*) was first studied at the ambient temperature of the n.m.r. probe (approximately 40°). Separate samples of 0.20 g (1.0 mmol) of **1***a* in five n.m.r. tubes containing 0.5 ml of tetrachloroethane were treated with anhydrous aluminum chloride in the amounts: 0.10, 0.35, 0.60, 0.80, and 1.0 mmol. The effect on the chemical shift of the methylene hydrogens of **1***a* is summarized in Table 6.

A plot of the chemical shifts (Δτ) of the methylene hydrogens *vs.* moles of catalyst (from Table 6) showed a linear relationship. The aluminum chloride did not dissolve completely when attempts were made to make measurements with more than 1 mmol present. No rearrangement was observed under these conditions. The acetyl methyl group of 1-acetyl-1,3,3-trimethylindane (**2***a*) underwent a similar downfield chemical shift (Δτ =

TABLE 6. Effect of aluminum chloride complexing with 1,1,4,4-tetramethyl-2-tetralone (**1***a*) on the n.m.r. chemical shift of methylene hydrogens

Ketone (**1***a*) (mmol)	Aluminum chloride (mmol)	Δτ*
1.0	0.10	0.05
1.0	0.35	0.22
1.0	0.60	0.37
1.0	0.80	0.54
1.0	1.0	0.70

*The chemical shift downfield from the methylene hydrogens of **1***a*.

For personal use only.

0.60) when **2***a* was treated with an equimolar amount of anhydrous aluminum chloride in tetrachloroethane.

The direct n.m.r. observation of the rearrangement of **1***a* was carried out by heating **1***a* (0.20 g, 1.0 mmol) with anhydrous aluminum chloride (0.264 g, 2.0 mmol) at 100° in 0.5 ml tetrachloroethane in an n.m.r. tube. The n.m.r. spectrum of the reaction mixture was scanned at various intervals. Formation of 1-acetyl-1,3,3-trimethylindane (**2***a*) was evident from the appearance of a new peak at 7.23 τ assigned to the complexed acetyl methyl group. The amount of **2***a* was estimated by integration of this methyl signal. The results were not very satisfactory because of the complexity of the spectra and the fact that the signal of this methyl group appeared in the same region of the spectrum as part of the quartet due to the methylene hydrogens. The results for the estimation of **2***a* are included in Fig. 1 of the Discussion.

(c) Separation and Identification of New Compounds

1-Acetyl-1,3,3-trimethylindane (2a)

Ketone **2***a* has been described earlier (1, 5). The n.m.r. spectrum of **2***a* also confirmed the structure assigned. This spectrum showed bands at 8.76 and 8.69 (singlets), 8.58 (singlet), 7.84 (quartet, J = 13.5 Hz), 8.05 (singlet), and 2.90 τ (singlet) in the ratio 6:3:3:2:4 and assigned to the $(CH_3)_2C$, the CH_3 at position-1, the acetyl methyl, the methylene group, and the aromatic hydrogens, respectively. The i.r. spectrum showed a strong band at 1710 cm^{-1} (carbonyl) and a strong band at 760 cm^{-1} assigned to an *o*-disubstituted benzene ring. The u.v. spectrum of **2***a* showed bands at 273 (ε 1090), 266.3 (ε 1050) and 261.2 nm (shoulder, ε 753).

1-Acetyl-1,3,3,6-tetramethylindane (2b)

Ketone **2***b* was separated as a colorless liquid by collection from the gas chromatograph as the first component in the mixture from the rearrangement of 1,1,4,4,7-tetramethyl-2-tetralone (**1***b*). The semicarbazone of **2***b* was formed by reaction with an equimolar amount of semicarbazide hydrochloride and sodium acetate in aqueous ethanol. The crystalline product was recrystallized from ethanol followed by sublimation under reduced pressure. The analytical sample melted at 220–225° with some decomposition.

Anal. Calcd. for $C_{16}H_{23}ON_3$: C, 70.29; H, 8.48; N, 15.37. Found: C, 70.36; H, 8.45; N, 15.32.

It was also convenient to separate ketone **2***b* from the other isomeric ketones (**1***b*, **3***b*) due to the fact that ketone **2***b* readily formed a crystalline semicarbazone while the other ketones remained unreacted in solution. The free ketone (**2***b*) was recovered from its semicarbazone by hydrolysis with 1:1 hydrochloric acid – water on the steam cone. The ketone obtained distilled at 74–76°/0.6 mm. It showed a strong i.r. band at 1700 cm^{-1} (carbonyl) and a strong band at 820 cm^{-1} attributed to a 1,2,4-trisubstituted benzene ring. The u.v. spectrum had bands at 278.3 (ε 1410), 271.5 (ε 1274), and 264.2 nm (shoulder, ε 940). N.m.r. bands for **2***b* appeared at 8.77 and 8.73 (singlets), 8.62 (singlet), 8.06 (singlet), 7.87 (quartet, J = 13.5 Hz), 7.72 (singlet), and 3.07 τ (multiplet) in the ratio 6:3:3:2:3:4, assigned to the $(CH_3)_2C$, the CH_3 at position-1, the acetyl methyl, the methylene group, the aryl methyl (position-6), and the aromatic hydrogens, respectively.

1-Acetyl-1,3,3,5-tetramethylindane (2c)

Samples of ketone **2***c* (colorless liquid) for analyses were obtained by collecting the first component from the gas chromatographic separation of the rearrangement products from 1,1,4,4,6-tetramethyl-2-tetralone (**1***c*). The n.m.r. spectrum of **2***c* showed bands at 8.77 and 8.70 (singlets), 8.60 (singlet), 8.06 (singlet), 7.84 (quartet, J = 13.5 Hz), 7.73 (singlet), and 3.03 τ (singlet) in the ratio 6:3:3:2:3:4, assigned to the $(CH_3)_2C$, the CH_3 at position-1, the acetyl methyl, the methylene group, the aryl methyl (position-5), and the aromatic hydrogens, respectively. The u.v. spectrum showed bands at 278.2 (ε 1450) and 271 nm (ε 1255) and a shoulder at 266 nm (ε 870). The mass spectrum of **2***c* indicated a parent mass of 216 (its formula $C_{15}H_{20}O$ requires 216). The base peak appeared at 173 corresponding to the loss of CH_3CO from the parent.

Anal. Calcd. for $C_{15}H_{20}O$: C, 83.29; H, 9.32. Found: C, 82.53; H, 9.15.

2,2,4,4-Tetramethyl-1-tetralone (3a)

Samples of ketone **3***a* were obtained as a colorless liquid for analysis by collecting the third component from the gas chromatographic separation of the rearrangement products of 1,1,4,4-tetramethyl-2-tetralone (**1***a*). The n.m.r. spectrum of **3***a* showed bands at 8.83 (singlet), 8.62 (singlet), 8.11 (singlet), and 2.68–1.98 τ (multiplet and doublet) in the ratio of 6:6:2:4 and assigned to the $(CH_3)_2C$ at position-4, $(CH_3)_2$ at position-2, the methylene hydrogens, and the aromatic hydrogens, respectively. The i.r. spectrum showed strong bands at 1670 (conjugated carbonyl) and 768 cm^{-1} (*o*-disubstituted benzene). The u.v. spectrum showed bands at 286.4 (ε 1630), 241.4 (ε 9440), and 225.4 nm (ε 11 730).

Anal. Calcd. for $C_{14}H_{18}O$ (mol. wt. 202): C, 83.14; H, 8.95. Found (202 (mass spectrum)): C, 83.28; H, 9.01.

The base peak in the mass spectrum appeared at fragment mass 146, attributed to loss of $(CH_3)_2C(\diagup)—CH_2—(\diagdown)$ from the parent ion.

2,2,4,4,7-Pentamethyl-1-tetralone (3b)

Ketone **3***b* was obtained as a colorless liquid from the third component of the gas chromatographic separation of the rearrangement products from 1,1,4,4,7-pentamethyl-2-tetralone (**2***b*). The n.m.r. spectrum of **3***b* showed bands at 8.72 (singlet), 8.65 (singlet), 8.12 (singlet), 7.68 (singlet) and three groups of bands in the aromatic region at 2.82, 2.64, and 2.31 τ, in the ratio 6:6:2:3:3 and assigned to the $(CH_3)_2C$ at position-4, the $(CH_3)_2C$ at position-2, the methylene hydrogens, the aryl methyl (position-7), and the aromatic hydrogens, respectively. The i.r. spectrum of **3***b* showed a strong band at 1680 cm^{-1} (conjugated carbonyl). The u.v. spectrum showed broad bands at 393 (ε 1191) and 248 nm (ε 6050).

Anal. Calcd. for $C_{15}H_{20}O$: C, 83.28; H, 9.32. Found: C, 83.39; H, 9.32.

2,2,4,4,6-Pentamethyl-1-tetralone (3c)

Ketone **3***c* was isolated as a colorless liquid from the gas chromatographic separation of the rearrangement products of 1,1,4,4,6-pentamethyl-2-tetralone (**1***c*) by collecting the third peak. Compound **3***c* showed n.m.r.

bands at 8.85 (singlet), 8.68 (singlet, 8.16 (singlet), 7.66 (singlet), 3.17 (doublet, J = 4 Hz), 2.94 (singlet), 2.25 (doublet, J = 4 Hz) in the ratio 6:6:2:3:1:1:1 and assigned to the $(CH_3)_2C$ at position-4, $(CH_3)_2C$ at position-2, the methylene hydrogens, the aryl methyl at position-6, aryl hydrogen-7, aryl hydrogen-5, aryl hydrogen-8, respectively. (Aryl hydrogens-7,8 absorbed as an AB quartet.)

The u.v. spectrum of **3***c* was typical of a conjugated aromatic ketone, with bands at 293 nm (shoulder, ε 603), 282.5 nm (ε 873) and 250 nm (ε 9000). The mass spectrum of **3***c* showed the expected parent mass of 216. The base peak appeared at fragment mass 160 attributed to loss of $(CH_3)_2\text{—}\overset{|}{\underset{|}{C}}\text{—}CH_2\text{—}$ from the parent ion as in the mass spectrum of **3***a* (above).

Anal. Calcd. for $C_{15}H_{20}O$: C, 83.28; H, 9.32. Found: C, 82.60; H, 9.17.

*1-Acetyl-1,3,3-trimethyl-2-indanone (**10**)*

Ketone **10** was obtained as a colorless liquid by collecting the second component appearing in the gas chromatographic separation of the compounds from rearrangement of 1,1,4,4-tetramethyl-2,3-dioxotetralin (**9**). The n.m.r. spectrum of **10** showed bands at 8.65 and 8.60 (singlets), 8.49 (singlet), 8.07 (singlet) and 2.73 τ (multiplet) in the ratio 6:3:3:4 and assigned to the $(CH_3)_2C$, the methyl at position-1, the acetyl methyl, and the aromatic hydrogens, respectively. The i.r. spectrum of **10** showed bands at 1750 (carbonyl in five-membered ring) and 1715 cm^{-1} (carbonyl in CH_3CO). The u.v. spectrum of **10** had bands at 275 (ε 1054), 268 (ε 1116), 262 (ε 686), and 262.5 nm (shoulder, ε 686).

The semicarbazone derivative of **10** was prepared by treating a 1:1 ethanol–water solution of it with an equimolar amount of semicarbazide hydrochloride in the presence of sodium acetate. The solution was warmed on the steam cone for 5 min, then cooled. Colorless crystals separated. On recrystallization from ethanol the melting point was 209–210°. The carbonyl band in the i.r. at 1750 cm^{-1} for the group in the five-membered ring remained. This showed that the semicarbazone formed only at the acetyl carbonyl.

Anal. Calcd. for $C_{15}H_{19}N_3O_2$: C, 65.93; H, 6.96; N, 15.39. Found: C, 65.49; H, 7.00; N, 15.35.

*1,1,3-Trimethyl-2-indanone (**11**)*

Ketone **11** was collected from the first peak in the gas chromatographic separation of the rearrangement products of **9** as a colorless liquid. The n.m.r. spectrum of **11** had bands at 8.71 (singlet), 8.61 (doublet, J = 7.5 Hz), 6.54 (quartet, J = 7.5 Hz), and 2.81 τ (singlet) in the ratio 6:3:1:4 and assigned to the $(CH_3)_2C$ group, the CH_3— at position-3, the C—H at position-3, and the aromatic hydrogens respectively. The i.r. spectrum of **11** had a strong band at 1750 cm^{-1} due to the carbonyl group in a five-membered ring. The u.v. spectrum of **11** had benzenoid bands at 274, 267, and 261 nm similar to those observed for **10**. The semicarbazone derivative of **11** (prepared as that derivative from **10**) melted at 209–210°.

Anal. Calcd. for $C_{13}H_{17}N_3O$: C, 67.50; H, 7.41. Found: C, 67.73; H, 7.72.

*5(or 6)-Acetyl-1,1,3-trimethyl-2-indanone (**12**)*

Ketone **12** was separated in small quantity as the fourth peak in the gas chromatographic analysis of the rearrangement products from ketone **9**, as a pale yellow solid, m.p. 78–80°. The n.m.r. spectrum of **12** showed bands at 8.69 (singlet) overlapping with a doublet at 8.63 (J = 7.5 Hz), 7.49 (singlet), 6.49 (quartet, J = 7.5 Hz) and an ABC-type multiplet at 2.67 and 2.19 τ. The coupling constants in this multiplet were J_{AB}(ortho) = 8.4, J_{BC}(meta) = 1.8, and J_{AC}(para) = 1.0 Hz. The ratio of peaks was in the order 9:3:1:3 and they were assigned to the $(CH_3)_2C$ at position-1 plus the CH_3— at position-3, the acetyl methyl, the C—H at position-3, and the aromatic hydrogens, respectively. The i.r. spectrum of **12** showed a carbonyl group absorption band at 1750 (five-membered ring) and one at 1680 cm^{-1} (conjugated). The u.v. absorption spectrum was similar to a conjugated aromatic ketone (*e.g.* acetophenone). It showed bands at 292.5 (ε 1967), 282.8 (ε 2417), 274.4 (shoulder, ε 1856), 248 nm (ε 16 611).

Ring–Chain Tautomerism of 5-Oxo-3,5-seco-A-norcholestan-3-ol

JOHN T. EDWARD, MORRIS KAUFMAN, AND RICHARD K. WOJTOWSKI
Department of Chemistry, McGill University, Montreal, Quebec

AND

DESMOND M. S. WHEELER AND THOMAS M. BARRETT
Department of Chemistry, University of Nebraska, Lincoln, Nebraska

Received July 26, 1972

5-Oxo-3,5-*seco*-A-norcholestan-3-ol (**4**) was prepared in four steps from Windaus' keto-acid (**1**; R = H), and found to exist almost completely in the tautomeric hemiketal form **5**. With ethanol and a trace of acid this affords the ethyl ketals **6***a*, **6***b*; under equilibrium conditions the ratio of **6***a*:**6***b* is about 4:1.

Le 5-oxo-3,5-*seco*-A-norcholestan-3-ol (**4**) a été preparé en quatre étapes à partir du céto-acide **1** (R = H) de Windaus, et se présente presque entièrement sous les formes tautomeres **5***a* et *b*. Ces dernières fournissent avec l'éthanol, en presence d'une trace d'acide, les cétals **6***a* et *b*, dans le rapport 4:1 a l'equilibre.

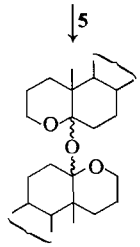
In organic solvents 1-hydroxy-5-hexanone exists to the extent of about 50% as the cylic hemiketal tautomer, but in aqueous-organic solvents the equilibrium is displaced back toward the chain tautomer (1). The latter can exist in many more conformations than the ring tautomer, and hence it can be expected that cyclization will be opposed by unfavorable entropy effects. By comparison, the number of conformations available to the steroidal hydroxyketone **4** (obtained in connection with the synthesis of *gem*-methyl carboxyl compounds (2)) is much reduced, and so would be expected to favor formation of the cyclic hemiketal tautomers (**5***a*, **5***b*). As shown below, this proved to be correct, and in this respect δ-hydroxyketones resemble δ-hydroxyaldehydes previously studied (3).

The hydroxyketone **4** was obtained by the route outlined in Scheme 1 (*cf.* ref. 4). The methyl ester (**1**; R=Me) (5) was converted to the ketal **2**, which was reduced with lithium aluminum hydride to the hydroxy-ketal **3**, and this was hydrolyzed in aqueous dioxane to the hydroxyketone **4**. Attempts to obtain **4** by direct reduction of Windaus' keto-acid **1** (R=H) (6) with diborane (*cf.* ref. 7) gave an intractable mixture.

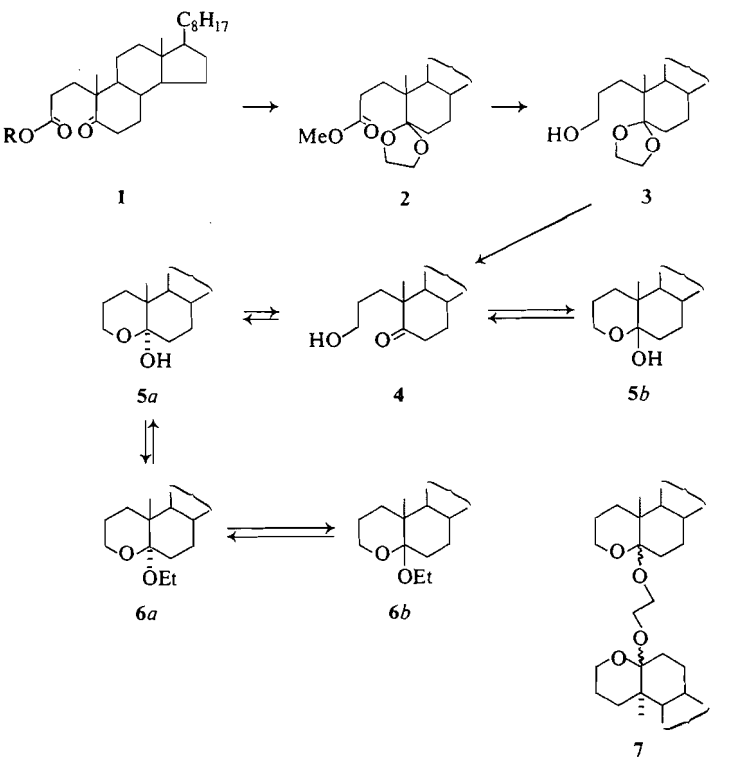
The hydroxy ketone **4** was obtained as an oil which set to a waxy solid, probably composed mostly of **5***a*/**5***b* (as shown below), which melted unsharply at temperatures slightly above room temperature. This compound appeared homogeneous by t.l.c.,[1] and gave the mass spectrum expected for **4**/**5** with a small peak for the parent ion at 390, and prominent peaks at 372 and 357 mass units, perhaps because of the fission sequence depicted in eq. 2.

[1] **4/5** ⇄  **8**



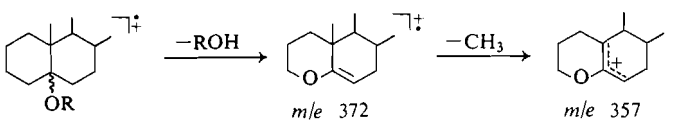
9

[1] An attempt to purify a sample for analysis by distillation at 2 μ and a temperature of 140–150 °C gave a product which appeared from elemental analysis to contain **9** (see eq. 1). The formation of such compound(s) under apparently neutral conditions would find analogy in the formation of a similar ether from a steroidal hydroxy-aldehyde (8), and is probably explained by the presence of acids in ordinary "neutral" solvents or glassware. The extreme facility of such reactions reflects the ease of formation of oxocarbonium intermediates such as **8** which unlike similar intermediates in carbohydrate chemistry are stabilized by inductive effects.



SCHEME 1

[2]



5 R = H
6 R = Et

Because of difficulties in handling the oily **4**/**5**, it was produced *in situ* in hexane solution by hydrolysis of the crystalline ethoxy compound **6***a* (described below) with a few drops of aqueous hydrochloric acid. It was possible to follow the reaction to its completion by t.l.c. This hexane solution showed no u.v. absorption peak at 285 nm, as was shown by 2-methylcyclohexanone (ε 17), which was taken as a reasonable model for **4**. The sensitivity of this method is such that it would have indicated more than 1–2% of **4** in the tautomeric mixture **4**/**5**. The relative absence of **4** in hexane solution was apparent also from the absence of a peak in the circular-dichroism spectrum.

In carbon tetrachloride or chloroform solution the presence of a small amount of the tautomer **4** became apparent from overlapping peaks at 1730 (C=O) and 1700 cm^{-1} (C=O...H—O); the i.r. spectrum also showed a sharp peak at about 3600 (O—H) and a broad peak at 3410 cm^{-1} (bonded O—H). A comparison of the relative areas of the C=O and O—H bands indicates the mixture of **5**/**4** to contain about 8% of **4**, in either solvent, if the intensities of the C=O and O—H bands of **10** and of its 9,11-dihydro derivative (9) in carbon tetrachloride and in chloroform

are accepted as standards. Obviously too many assumptions are involved for much weight to be given to the exact numerical results, but the accumulation of evidence indicates that in organic solvents the tautomeric mixture is more than 90% in the cyclic form **5**. Furthermore, it seems likely, for reasons which will become apparent later, that the cyclic form is made up of the two epimers, **5***a* and *b*, with the former predominating.

In spite of the very great predominance of **5**, the tautomeric mixture reacted with trichloroacetyl isocyanate in deuterochloroform to give a mixture of carbamates containing about 70% of the carbamate derived from **4**, and only about 20% of a carbamate derived from **5** (tentatively assumed to be **5***a*), and 10% of another carbamate derived from **5** (tentatively assumed to be **5***b*). The proportions were deduced from the n.m.r. spectrum of the mixture formed (10). The C-3 protons of the carbamate of **4** would be expected, like the C-3 protons of the carbamate of **3** (2H, at 4.20 δ), to give rise to a triplet, and indeed a triplet (70% of 2H) is observed at 4.24 δ. On the other hand, the C-3 protons of the carbamates of **5***a* and *b* would be expected, like the C-3 protons of **6***a* (2H, at 3.47 δ) and *b* (2H, at 3.49 δ), to give rise to a broad multiplet because of coupling to axial and equatorial protons at C-2, and a broad multiplet (30% of 2H) is observed at 3.71 δ. Singlet N—H peaks are observed at 8.50 δ (70% of 1H, carbamate of **4**), 11.84 δ (20% of 1H, carbamate of **5***a*), and 10.48 δ (10% of 1H, carbamate of **5***b*).

These results require the equilibrium **4** ⇄ **5** in deuterochloroform to be quickly established, perhaps because the trace of DCl resulting from oxidation of deuterochloroform will catalyze both forward and backward reactions (11). The unhindered **4** would then be expected to react with trichloroacetyl isocyanate more rapidly than the hindered **5***a* or *b*, and hence to account for the major part of the trichloroacetyl carbamate formed. As a further example of this effect, chlorosulfonyl isocyanate reacted with the tautomeric mixture **4**/**5** in deuterochloroform to give only the chlorosulfonyl carbamate of **4** (NH singlet, 1H, 9.61 δ; C-3 H_2 triplet, 2H, at 4.27 δ). It seems likely that in this case a trace of chlorosulfonic acid impurity is acting as catalyst, and that the reaction **4** ⇄ **5** has become very fast.

Reaction of the tautomeric mixture **4**/**5** with ethanol containing a trace of hydrogen chloride would be expected to yield the two ethoxy derivatives **6***a* and *b*. Furthermore, because of the presence of angular groups at *both* carbon atoms involved in ring fusion, the two derivatives might be expected to have about the same enthalpy (12), and to be present at equilibrium in roughly equal amounts. In the event, **4**/**5** reacted with acidic ethanol to give a product which appeared from t.l.c. to contain two compounds, but in the proportions of about 4:1. However, crystallization of the product from absolute ethanol gave only one compound, even on further concentration of the other liquors. The structure **6***a* or *b* for this compound (the major product) was supported by elemental analysis, i.r. and n.m.r. spectra, and particularly by its mass spectrum, which showed, beside the peak for the parent ion, prominent peaks at 372 and 357 mass units (see eq. 2). Further analysis of the n.m.r. spectrum (discussed below) indicated the compound to be **6***a*.

The minor compound formed in the reaction is the epimeric **6***b*; the failure to isolate it by concentration of the mother liquors arises from the extraordinary facility of the epimerization **6***b* ⇄ **6***a* (via **8**) in ethanol, and the fact that **6***a* has the smaller solubility and hence crystallizes out first. Similarly, when an attempt was made to crystallize **6***a* from anhydrous methanol, its methoxy analogue (**6***a*; Me in place of Et) was obtained. The later could be obtained readily in a pure state by treatment of **6***a*, **4**/**5**, or **7**A with methanol containing a trace of hydrogen chloride.[2]

The epimerization **6***a* ⇄ **6***b*, and the conversion of **6***a* into its methoxy analog, belong to classes of reactions known to be acid-catalyzed (11), and evidently occur with such facility that they are catalyzed by traces of acids present in ordinary ethanol or methanol. When ethanol was made weakly alkaline with a trace of diethylamine, the interconversion **6***a* ⇄ **6***b* was stopped, and it proved possible to separate **6***a* and **6***b* by chromatography on silica gel which had been made weakly alkaline by exposure to a dilute solution of diethylamine in hexane–benzene.[3]

---

[2]The structure **6***a* (Me in place of Et) is suggested by its rotation ($[\alpha]_D^{25}$ + 55° in ethanol containing a trace of diethylamine), which is the same as that of **6***a*. No attempt was made to isolate **6***b* (Me in place of Et), presumably the minor reaction product.

[3]Chromatography on Merck silica gel which had not been treated with diethylamine resulted in the hydrolysis of **6***a*, **6***b*, or **7**A to **4**/**5**. Very convenient hydrolytic procedures based on this fact are given in the experimental section.

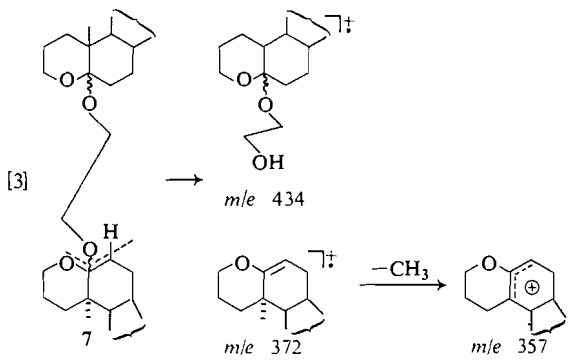
For personal use only.

The structure **6***b* for the second reaction product was indicated by its elemental analysis, its i.r. and mass spectra (which were very similar to those of **6***a*), and, in particular, by its n.m.r. spectrum. Methyl peaks due to the 18-angular methyl group and to the methyl groups of the side chain were observed with about the same chemical shifts as the corresponding methyls of cholestane (13). However, the signal for the 19-methyl group of **6***a* and *b* could be expected to be shifted downfield by the proximity of two oxygen atoms, and furthermore it would be expected that this signal should appear at lower field for **6***b* than for **6***a* (13). In the 220-MHz spectra of the two compounds in carbon tetrachloride, the 19-methyl peak of the predominant epimer appeared at δ 0.83 and of the minor epimer at δ 1.04, so that these are assigned the structures **6***a* and *b* respectively.[4]

At room temperature in untreated ethanol solution both **6***a* and *b* slowly reverted to a mixture of **6***a* and *b*, as could be shown by t.l.c. In the presence of a trace of hydrogen chloride this epimerization became effectively instantaneous, and the rotation of the equilibrium solution ($[\alpha]_D^{25}$ + 45°) was the same whether the starting material was **6***a* ($[\alpha]_D^{25}$ + 55°) or **6***b* ($[\alpha]_D^{25}$ + 5°). This indicates a proportion of 4 : 1 for **6***a* : **6***b* at equilibrium. Approximately the same proportions were obtained by chromatographic separation of **6***a* and *b* from the reaction mixture after interconversion had been quenched by the addition of diethylamine.

Evidently the simple conformational analysis of **6***a* and *b* in terms of *gauche* interactions (12), which indicates structures of equal stability, is in error; it is known that the cyclohexane rings of steroids are somewhat flattened from ideal chair shapes (14). If the *trans* **6***a* is favored over the *cis* **6***b*, it is likely that the *trans* **5***a* is similarly favored over the *cis* **5***b*, and this would explain the unequal formation of the two trichloroacetyl carbamates based on **5**.

While the hydrolysis of the dioxalane **3** was accomplished without difficulty in dioxane–water 2/1 (v/v), unexpected complications were encountered in dioxane–water 98/2 (v/v). The reaction product was shown by t.l.c. to be a mixture, which in hexane solution deposited a small amount of crystalline compound A ($C_{54}H_{94}O_4$). Column chromatography, using hexane–diethyl ether as elutant, gave an isomeric compound B ($C_{54}H_{94}O_4$) as well as 5α-ethoxy-4-oxacholestane (**6***a*), the latter presumably from reaction of **4**/**5** with ethanol, known to be an impurity in the diethyl ether. The structure **7** for both A and B follows from their combustion analyses, molecular weights, and n.m.r. and mass spectra. The high-resolution spectrum of A showed no parent peak, but peaks at 434.376066 ($C_{28}H_{50}O_3$) and 372.339199 mass units ($C_{26}H_{44}O$), as well as a peak at 357 mass units (eq. 3; *cf.* eq. 2). These results indicate the dangers of

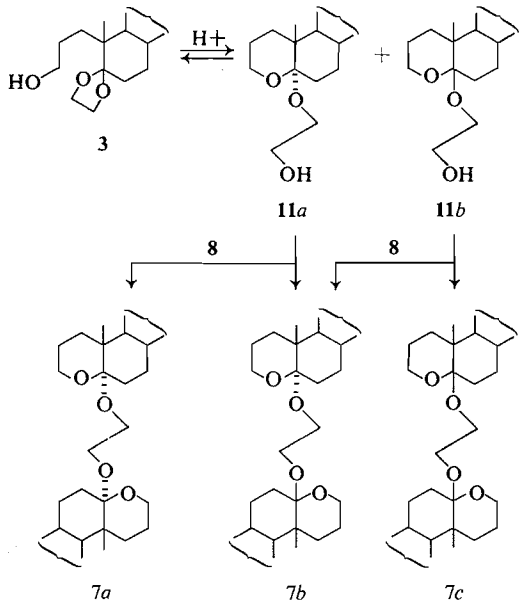


hydrolyzing some ketals (such as **3**) in solutions containing too little water. Under these conditions ketal interchange (**3** → **11**) will predominate over hydrolysis, and this can then be expected to result in formation of the epimers **7***a*, *b*, and *c* (Scheme 2) in proportions depending on the relative stabilities of *trans* and *cis* fusions of the B rings of these compounds. The isolation of **7**A and B in the proportions of about 3 : 1 would indicate the structure **7***a* for **7**A, **7***b* for **7**B,[5] and a 6 : 1 preference for *trans* over *cis* fusion in this series of compounds.[6] This latter figure can only be approximate, because **7**A and B were isolated from a reaction mixture in which reaction had not been quenched by the addition of base.

[4]The 220-MHz spectrum of **6***a* in carbon tetrachloride showed a well-defined CH_3 triplet (δ 1.16) and CH_2 quartet (δ 3.33; J = 7 Hz) due to the ethoxy group. However, the spectrum of **6***b* showed a well-defined triplet (δ 1.19; J = 7 Hz) but a 10-line multiplet for CH_2 centered at δ 3.30. In deuterobenzene at ordinary temperatures the methylene signals of **6***a* showed a similar splitting, and a clean quartet was obtained only when the temperature reached 70°. These effects are being studied further.

[5]As pointed out by a referee, the configurations of **7**A and B should be available from the 220 MHz n.m.r. spectra of the compounds. We hope to confirm these configurations later.

[6]Such a preference would result in the formation of only about 2% of **7***c* in the equilibrium mixture.



SCHEME 2

Experimental

Unless otherwise specified i.r. spectra were run on Perkin–Elmer Instruments 21, 237, and 137 in CH_2Cl_2 solutions; n.m.r. spectra on Varian spectrometers A-60 and T-60 in $CDCl_3$ solution using TMS as an internal reference. Analyses were by Bernhardt, Micro-Tech Laboratories (Skokie, Illinois), and C. Daesslé (Montreal, Quebec).

*5-Oxo-3,5-seco-A-norcholestan-3-oic acid methyl ester (**1**; R=Me)*

The methyl ester (**1**, R=Me), previously obtained (5) by the action of diazomethane on the acid **1** (R=H), was obtained by refluxing a solution of **1** (R=H) in methanol and concentrated sulfuric acid. The ester had b.p. 110–115° at 15 mm, ν_{max} 1783 (s) (ester C=O) and 1703 (s) cm^{-1} (ketone C=O); n.m.r. peaks at δ 3.59 (s, 3, $COOCH_3$) and singlets at 1.05, 0.86, and 0.68 and a doublet at 0.79.

*5,5-Ethylenedioxy-A-nor-3,5-secocholestan-3-oic acid methyl ester (**2**)*

A stirred mixture of A-nor-3,5-secocholestan-5-one-3-oic acid methyl ester (5.70 g), dry benzene (250 ml), ethylene glycol (100 ml), and *p*-toluenesulfonic acid (2.0 g, 11.6 mmol) was refluxed for 40 h in a flask equipped with a reflux condenser and Dean–Stark water separator. When the reaction mixture had cooled to room temperature it was diluted with water (100 ml). The benzene separated, and the aqueous layer was washed with benzene (2 × 75 ml); the combined benzene layers were dried. Evaporation of the solvent gave 5,5-ethylenedioxy-A-nor-3,5-secocholestan-3-oic acid methyl ester as an oil (6.16 g, 97.8%) having b.p. 170–180° at 7 mm: ν_{max} 1735 (s) cm^{-1}; δ 3.92 (s, 4H, OCH_2CH_2O), 3.64 (s, 3H, OCH_3).

Anal. Calcd. for $C_{29}H_{50}O_4$: C, 75.3; H, 10.9; O, 13.8. Found: C, 75.5; H, 11.0; O, 13.7.

*5,5-Ethylenedioxy-A-nor-3,5-secocholestan-3-ol (**3**)*

A solution of 5,5-ethylenedioxy-A-nor-3,4-secocholestan-3-oic acid methyl ester (558 mg, 1.21 mmol) in anhydrous ethyl ether (15 ml) was added over 5 min to a stirred solution of lithium aluminum hydride (366 mg, 9.7 mmol) in ether (5 ml). The reaction mixture was stirred at room temperature for 9 h, poured onto ice, and acidified with hydrochloric acid (20 ml, 5%), and the acidified solution was extracted with ether (3 × 25 ml). The combined ethereal extracts were washed with saturated aqueous sodium chloride (1 × 25 ml), dried, and concentrated under reduced pressure to yield 5,5-ethylenedioxy-A-nor-3,5-secocholestan-3-ol as an oil (534 mg, 1.23 mmol, 100%) having b.p. 160–170° at 15 mm; ν_{max} 3605 cm^{-1}; δ 3.95 (s, 4, OCH_2CH_2O), 3.68–3.37 (m, 2, CH_2O at C-3), 2.99 (s, 1, OH). After addition of trichloroacetyl isocyanate, δ 8.46 (s, 1, NH), 4.0–4.3 (m, 2H, CH_2O at C-3), 3.94 (s, 4H, $O—CH_2CH_2—O$).

*5-Oxo-3,5-seco-A-norcholestan-3-ol (**4**)*

After a mixture of 5,5-ethylenedioxy-A-nor-3,5-secocholestan-3-ol (920 mg, 2.12 mmol), dioxane (20 ml), water (10 ml), and concentrated sulfuric acid (2 ml) had been refluxed 11 h, the solvents were removed under reduced pressure, and the residue was taken-up in acetone. The solution was steam distilled to remove ethylene glycol (600 ml water distilled) and then extracted with ether (2 × 35 ml). The combined ethereal extracts were dried and evaporated under reduced pressure to give an oil (821 mg, 2.11 mmol, 99.5%) having b.p. 140–150° at 2 μ; δ 3.75–3.25 (3, broad, $—CH_2OH$), and indicated by analysis as being an approximately 1:1 mixture of **4** and **9**.

Anal. Calcd. for 50% $C_{26}H_{46}O_2$ + 50% $C_{52}H_{90}O_3$: C, 80.8; H, 11.9; O, 7.2. Found: C, 81.1; H, 11.7; O, 7.6.

1,2-Di(4-oxa-5ξ-cholestanyloxy)ethane (7A and B)

A solution of the hydroxyketal **3** (5.5 g) in purified dioxane (100 ml) containing 7.9% aqueous sulfuric acid (2 ml) was stirred for 2 h at room temperature. The solvent was then removed by rotatory evaporation at 15 mm and the oily residue was extracted with ethyl ether. The ether solution was washed with aqueous bicarbonate and with water, and dried over magnesium sulfate. Evaporation of the ether left an oil (5.2 g) which dissolved in hot hexane. On cooling the hexane solution deposited hexagonal plates (600 mg) of compound A, m.p. 193–195°, δ 3.56 (s, 4H, OCH_2CH_2O), 3.58–3.98 (m, 2H, CH_2O at C-3).

Anal. Calcd. for $C_{54}H_{94}O_4$: (mol. wt. 806) C, 80.3; H, 11.7; O, 7.9. Found: (771 (vapor phase osmometry of CCl_4 solution)) C, 80.5; H, 11.3; O, 8.1.

Chromatographic separation of a portion (2.18 g) of the original oily reaction product on neutral alumina, grade I (500 g), eluting with 4 l of solvent of composition changing by linear gradient from hexane–ether 9:1 to hexane–ether 8:2, yielded the following products: *5α-ethoxy-4-oxacholestane* (**6***a*) (945 mg), a white solid which crystallized from methanol–ethyl ether as glistening flakes, m.p. 96–97°, identical (m.p. and i.r.) with the compound described below.

1,2-Di(4-oxa-5ξ-cholestanyloxy)ethane A (**7**) (319 mg) identical with the material described above; and *1,2-di(4-oxa-5ξ-cholestanyloxy)ethane B* (**7**) (198 mg), crystallizing from methanol–ethyl ether as needles, m.p. 166–167°, δ 3.48–3.90 (m, $—OCH_2CH_2O—$ and CH_2O at C-3).

Anal. Calcd. for $C_{54}H_{94}O_4$ (mol. wt. 806): C, 80.3; H, 11.7; O, 7.9. Found: (734 (vapor phase osmometry of CCl_4 solution)): C, 80.2; H, 11.6; O, 8.1.

Hydrolysis of 1,2-Di(4-oxa-5ξ-cholestanyloxy)ethane A with Silica Gel

Silica gel (20 g) was added to a solution of 7A (1.04 g) which had been dissolved in hexane (100 ml) by warming. The mixture was left at room temperature for 3 days. The silica was removed by filtration and washed with ether (2 × 50 ml). Evaporation of the ether extracts left an oil (924 mg) which solidified on standing, and which was identified as the hydroxyketone **4** by its n.m.r. spectrum (including the changes effected by tricholoroacetyl isocyanate and chlorosulfonyl isocyanate).

5α-Ethoxy-4-oxacholestane (6a)

(a) From 5-Oxo-3,5-seco-A-norcholestan-3-ol (4)

Ethanol containing a trace of hydrogen chloride was prepared by adding 10 drops of acetyl chloride to absolute ethanol (100 ml). In this was dissolved 5-oxo-3,5-*seco*-A-norcholestan-3-ol (70 mg). The solution was left at room temperature overnight, and the ethanol was then removed by evaporation. The residue in hexane was chromatographed on alumina (grade 3) and afforded, after evaporation of the solvent, white crystals of 5α-ethoxy-4-oxacholestane (**6a**) (49 mg, 67%), m.p. 95–96° after one crystallization from ethanol; $[\alpha]_D^{25}$ + 54.6° (in EtOH); n.m.r. δ 3.53 (m, 2H, C-3H_2), 3.41 (q, 2H, —O—CH_2—CH$_3$), 0.62 (s, 3H, C-18H_3).

Anal. Calcd. for $C_{28}H_{50}O_2$ (mol. wt. 418): C, 80.4; H, 11.9; O, 7.6. Found: (426 (vapor phase osmometry in CCl_4)): C, 80.2; H, 11.9; O, 7.6.

Silica gel (10 g) was added to a solution of 5α-ethoxy-4-oxacholestane (100 mg) in hexane (100 ml) and the mixture allowed to stand at room temperature for four days. The silica gel was removed by filtration and extracted by several washings with ethyl ether. Removal of the solvent gave an oil (90 mg), identified by its n.m.r. spectrum as the hydroxyketone **4**.

(b) From 1,2-Di(4-oxa-5ξ-cholestanyloxy)ethane (7A)

Compound 7A (400 mg) was dissolved in ethanol (50 ml) containing a trace of hydrogen chloride by boiling under reflux, and the solution was left overnight at room temperature. It was then worked-up as above to give a 5α-ethoxy-4-oxacholestane (200 mg), identical (m.p., mixture m.p., and i.r.) with the compound described above.

5β-Ethoxy-4-oxacholestance (6b)

(a) From 5α-Ethoxy-4-oxacholestane (6a)

Alkaline silica gel was prepared by adding dropwise 5 ml of freshly-distilled diethylamine in benzene–hexane 1:1 (50 ml) to a stirred suspension of chromatographic silica gel (Merck) (100 g) in benzene–hexane 1:1 (200 ml). The mixture was then stirred for a further 1 h before being transferred to a chromatographic column.

Compound **6a** (590 mg) was dissolved by heating in ethanol (50 ml) containing a trace of hydrogen chloride, and the solution allowed to stand for 30 min. It was then made alkaline with freshly-distilled diethylamine (0.5 ml), and the ethanol removed by evaporation at reduced pressure. The residue in benzene–hexane 1:1 was chromatographed on alkaline silica (60 g). The column was eluted with benzene–hexane 1:1 containing a trace of diethylamine (10 drops/l), and yielded first crystalline 5α-ethoxy-4-oxacholestane (**6a**) (401 mg, 68%), m.p. 95–96°, and then impure 5β-ethoxy-4-oxacholestane (**6b**) (169 mg, 29%), an oil which after some days in the refrigerator solidified to crystals, m.p. 85–87°. These were shown by t.l.c. to be contaminated by small amounts of **6a** and were purified by recrystallization from absolute ethanol containing a trace of diethylamine, followed by a second rapid crystallization (1 h in refrigerator) from absolute ethanol: colorless needless, melting sharply at 89° (m.p. depressed by admixture with **6a**).

Anal. Calcd. for $C_{28}H_{50}O_2$: C, 80.4; H, 11.9. Found: C, 80.5; H, 12.0.

The compound in ethanol solution slowly isomerized to **6a**, as shown by t.l.c.

(b) From 1,2-Di(4-oxa-5ξ-cholestanyloxy)ethane (7A)

Compound 7A (200 mg) was dissolved in hot ethanol (30 ml) containing a trace of hydrogen chloride and the solution left overnight at room temperature. It was then worked-up by the procedure above to give **6a** (120 mg, 67%) and *b* (41 mg, 23%).

(c) From 5-Oxo-3,5-seco-A-norcholestan-3-ol (4)

The tautomeric mixture **4/5** (50 mg) in ethanol (60 ml) containing a trace of hydrogen chloride gave **6a** (35 mg, 70%) and *b* (12 mg, 25%).

5α-Methoxy-4-oxacholestane (6a; Me in place of Et)

(a) From 1,2-Di(4-oxa-5ξ-cholestanyloxy)ethane (7A)

Compound 7A (100 mg) was dissolved by refluxing in anhydrous methanol (60 ml) containing a trace of hydrogen chloride, and the solution left overnight at room temperature. It was concentrated to 5 ml at reduced pressure, and kept in the refrigerator for 48 h. A crystalline solid was removed by filtration and purified by chromatography in hexane on alumina, yielding **6a** (R=Me in place of Et) (75 mg), m.p. 79–82° after crystallization from methanol; $[\alpha]_D^{25}$ + 54.8° (in EtOH with trace of diethylamine), δ 3.23 (s, OCH_3), 3.66 (m, CH_2O at C-3), mass spectral peaks at *m/e* 404 (M^+), 372, and 357.

Anal. Calcd. for $C_{27}H_{48}O_2 \cdot \frac{1}{2}H_2O$: C, 78.4; H, 11.9. Found: C, 78.2; H, 11.9.

(b) From 5-Oxo-3,5-seco-A-norcholestan-3-ol (4)

The hydroxyketone **4** (50 mg), after being boiled for 1 h in anhydrous methanol (40 ml) containing a trace of hydrogen chloride, was worked-up as above to give **6a** (R=Me in place of Et) (30 mg).

Scytalone (3,6,8-Trihydroxytetralone), a Metabolite from a *Scytalidium* Species

J. A. FINDLAY AND D. KWAN

Department of Chemistry, University of New Brunswick, Fredericton, New Brunswick

Received November 17, 1972

A metabolite from culture filtrates of a *Scytalidium* strain is shown by spectroscopic and chemical means to have structure **1***a*. The oxygenation pattern is as anticipated from a polyketide precursor.

La structure **1***a* a été proposée pour un métabolite issu de filtrats de culture de *scytalidium*, par les méthodes spectroscopiques et chimiques. Le modèle d'oxygénation est celui attendu pour un précurseur polycétide. [Traduit par le journal]

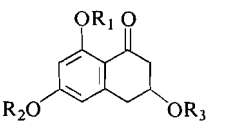
Can. J. Chem., **51**, 1617 (1973)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

In a recent paper Strunz *et al.* (1) reported the isolation of several metabolites from a species of *Scytalidium* FY strain. The structure of one of these was shown to be related to the nonadrides. We wish to report the structure of a new metabolite, scytalone, from the same source.

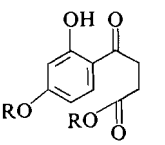
The high resolution mass spectrum of scytalone displays a molecular ion at *m/e* 194.0575 corresponding to $C_{10}H_{10}O_4$. The i.r. spectrum (KBr) shows a broad absorption in the hydroxyl region and a strong band at 1640 cm^{-1} indicative of an α,β-unsaturated β-hydroxy ketone system (2) while the u.v. spectrum (λ_{max} (C_2H_5OH, 95%) 222, 232, 284, 322 nm (log ε 4.18, 3.81, 4.11, 3.83) compares favorably with that of 2,4-dihydroxyacetophenone (3). The 60 MHz n.m.r. spectrum (acetone-d_6) of scytalone shows a sharp one-proton, D_2O exchangeable signal at δ 12.8 p.p.m. ascribed to an intramolecularly bonded proton of an ortho hydroxyphenone system (4). Signals at δ 6.3 (1H, dd, $J = 2$, $J = 1$ Hz) and 6.15 (1H, d, $J = 2$ Hz) p.p.m. are assigned to aromatic protons in a meta relationship (5), one of which is additionally long-range coupled. A complex multiplet at δ 4.3 (2H) p.p.m. which collapses to a simpler one-proton signal after addition of D_2O and complex multiplets δ 3.2–2.7 (4H) p.p.m. are the remaining features of the n.m.r. spectrum.

2,4-Dihydroxybenzoylpropionic acid (**2***a*) was prepared by Friedel–Crafts reaction between resorcinol and succinic anhydride. It displayed similar i.r. (1640 cm^{-1}) and u.v. (λ_{max} (C_2H_5OH, 95%) 213, 231, 276, 313 (log ε 4.18, 3.81, 4.11, 3.83) nm) characteristics to the metabolite. Scytalone and the synthetic compound **2***a* show parallel shifts of all u.v. maxima in basic media. Furthermore the n.m.r. spectrum ($CDCl_3$) of **2***a*



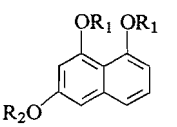
1

a $R_1R_2R_3 = H$
b $R_1R_3 = H$; $R_2 = CH_3$
c $R_1 = H$; $R_2 = CH_3$; $R_3 = Ac$



2

a $R = H$
b $R = CH_3$



3

a $R_1 = Ac$; $R_2 = CH_3$
b $R_1R_2 = Ac$

displays a sharp singlet at δ 12.6 p.p.m. (1H) and aromatic proton signals at δ 6.45 (1H, dd, $J = 8$, $J = 3$ Hz) and 6.35 (1H, d, $J = 3$ Hz) p.p.m. in close correspondance with the features of scytalone. An additional aromatic proton signal δ 7.85 (1H, d, $J = 8$ Hz) p.p.m. in the spectrum of **2***a* confirms the 1,2,4-substitution pattern (5).

Both scytalone and **2***a* were readily converted into monomethyl ethers by treatment with ethereal diazomethane and in both cases n.m.r. data attest to the survival of the intramolecularly-bonded hydroxyl group. Accordingly structure **2***b* is assigned to the product from **2***a*.

Thus the nature of the chromophoric system in scytalone is established as a 2,4-dihydroxyphenone additionally substituted at position-6.

Treatment of scytalone monomethyl ether with acetic anhydride pyridine at 0 °C afforded an impure, labile monomethyl ethermono-

For personal use only.

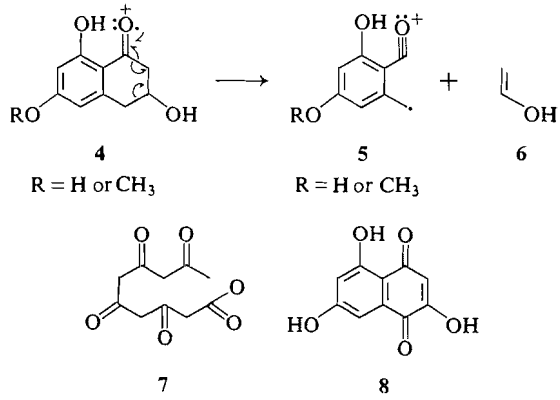
acetate whose 60 MHz n.m.r. spectrum ($CDCl_3$) shows a pentuplet at δ 5.4 (1H) p.p.m. indicative of the presence of a secondary oxygen in the acetate and hence in scytalone. Attempts to purify this acetate by preparative t.l.c. and other means led to decomposition and n.m.r. inspection of recovered material indicated diminution of the acetate methyl signal and appearance of signals in the aromatic region.

By refluxing scytalone monomethyl ether with acetic anhydride – pyridine at 76% yield conversion into a monomethoxynaphthalene diacetate was achieved. The 220 MHz n.m.r. spectrum revealed the existence of either a 1,3,8- or a 1,3,6-substitution pattern (5) in accord with formulation **3***a* for this product. That the product is 1,8-diacetoxy-3-methoxynaphthalene follows from consideration of the established oxygenation pattern of the precursor methyl scytalone and the reasonable assumption that the secondary oxygen is eliminated during the reaction. From scytalone we obtained 1,3,8-triacetoxynaphthalene (**3***b*) in 93% yield by similar acetylation procedure.

Clarification of the remaining structural features of scytalone came from 220 MHz nuclear magnetic double resonance (n.m.d.r.) experiments on methyl scytalone. Irradiation of the multiplet at δ 4.3 p.p.m. caused collapse of the AB part of an ABX pattern δ 2.60 (1H, dd, J = 17, J = 7 Hz), 3.14 (1H, dd, J = 17, J = 3 Hz) p.p.m. to a simple AB system 2.60 (1H, d, J = 17 Hz), 3.14 (1H, d, J = 17 Hz) while a more complex signal centered near δ 2.9 (2H) p.p.m. was substantially decoupled at the same time. Irradiation in the regions δ 2.6, 2.9, or 3.1 p.p.m. caused substantial decoupling in the signal at δ 4.3 p.p.m. Thus the non-D_2O exchangeable portion of the δ 4.3 p.p.m. signal is assigned to a secondary hydroxyl having two α methylene groups. Only structures **1***a*, *b*, and *c*, for scytalone, methyl scytalone, and methyl scytalone acetate respectively are in accord with these results.

Corroboration of these assignments is afforded by the high resolution mass spectra of scytalone **1***a* and scytalone methyl ether **1***b* both of which display base peaks corresponding to loss of C_2H_4O, explained by the fragmentation **4** → **5** + **6**.

It is worthy to note that the oxygenation pattern of scytalone corresponds precisely to that anticipated by cyclization of a polyketide



4 **5** **6** **7** **8**

system such as **7** which has been postulated (6) as a biogenetic precursor for structurally related metabolites such as flaviolin **8**.

Experimental

The i.r. spectra were recorded on a Perkin–Elmer model 237B instrument. High resolution mass spectra were obtained from the Mass Spec Lab, University of Alberta, Edmonton, Alberta. Low resolution mass spectra were obtained with an Hitachi Perkin–Elmer RMU-6D spectrometer. The u.v. spectra were determined on a Perkin–Elmer model 467 spectrophotometer. The 60 MHz n.m.r. spectra were recorded with a Varian T-60 instrument employing tetramethylsilane as internal standard. The 220 MHz spectra were obtained from a Varian HR 220 instrument at the Canadian 220 MHz NMR Centre, Ontario Research Foundation. A Kofler hot stage apparatus was employed to determine melting points which are uncorrected.

Scytalone ***1a***

Culture filtrate medium which had supported growth of *Scytalidium* sp FY strain (1) was washed with chloroform (to remove scytalidin) and subjected to continuous extraction with ether The dried ($MgSO_4$) ether extract yielded a dark brown viscous mass on evaporation. A portion (0.5 g) of this material was chromatographed on a silica gel column. Using 20% ether-in-benzene as eluant, scytalone (0.24 g) was recovered and was recrystallized from ether–benzene giving ivory crystals, homogeneous on t.l.c., m.p. 160–168°, ν_{max} (KBr) 3500 (broad), 1640, 1590 cm^{-1}; λ_{max} (95% ethanol) 222, 232, 284, 322 nm (log ε 4.18, 3.81, 4.11, 3 83); λ_{max} (95% ethanol + OH^-) 210, 253, 334 nm (log ε 4.33, 3.73, 4.5); δ 60 MHz (acetone-d_6) 2.7–3.2 (4H, m), 4.3 (2H, m), 6.15 (1H, d, J = 2 Hz), 6.3 (1H, dd, J = 2, J = 1 Hz), 12.8 (1H, s) p.p.m.; δ 60 MHz (acetone-d_6 + D_2O) 2.7–3.2 (4H, m), 4.3 (1H, m), 6.15 (1H, d, J = 2 Hz), 6.3 (1H, dd, J = 2, J = 1 Hz); *m/e* 194.0575 (M^+), $C_{10}H_{10}O_4$ requires 194.0579; 176.0472, $C_{10}H_8O_3$ requires 176.0474; 150.0312, $C_8H_6O_3$ requires 150.0317

*Scytalone Monomethyl Ether (****1b****)*

Scytalone (0.24 g) in ether was treated with excess ethereal diazomethane for 5 h with stirring at room temperature after which time t.l.c. indicated complete reaction. The solution was filtered and evaporated yielding

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

the product **1***b* (0.21 g, 82%) which was recrystallized from benzene yielding white crystals, homogeneous on t.l.c., m.p. 76–84°, ν_{max} ($CHCl_3$) 3500 (broad), 1626, 1580 cm^{-1}; λ_{max} (95%, ethanol) 222, 231, 237, 281, 316 nm (log ε 3.82, 3.77, 3.69, 3.84, 3.43); λ_{max} (95% ethanol + OH^-) 218, 238, 281, 347 nm (log ε 3.91, 3.93, 3.58, 3.38); δ 60 MHz ($CDCl_3$) 2.7–3.2 (4H, m), 3.8 (3H, s), 4.3 (2H, m), 6.3 (2H, bs), 12.7 (1H, s); *m/e* 208.0741 (M^+), $C_{11}H_{12}O_4$ requires 208.0736; 190 ($M^+ - H_2O$); 164.0483, $C_9H_8O_3$ requires 164.0474.

Methyl Scytalone Acetate (1c)

A mixture of methyl scytalone **1***b* (0.02 g), pyridine (0.4 ml), and acetic anhydride (0.6 ml) was stirred at 0° for 3 h and then evaporated in high vacuum at room temperature. The residual brown viscous liquid (0.024 g) showed δ 60 MHz 2.0 (3H, s), 2.8 (2H, m), 3.1 (2H, m), 3.8 (3H, s), 5.4 (1H, m), 6.35 (2H, s), 12.6 (1H, s). Attempts to purify the material for further characterization led to decomposition.

2,4-Dihydroxybenzoylpropionic Acid (2a)

A mixture of *m*-resorcinol (8.1 g) and succinic anhydride (7.5 g) in nitrobenzene (48.2 ml) was treated with aluminum chloride (18.8 g) for 48 h at room temperature. The resulting green gelatinous mass was treated with ice (75 g) and concentrated HCl (38 ml) and the mixture steam distilled for 4 h. The p*H* of the residue was adjusted to ~8 by addition of solid NaOH and steam distillation continued for 2 h. The residual yellow suspension was filtered, acidified with concentrated HCl, and cooled whence yellow crystalline **2***a* (1.72 g, 11.1%) was obtained, m.p. 196–200, ν_{max} (KBr) 3350 (broad), 1725, 1640, 1620 cm^{-1}; λ_{max} (95% ethanol) 213, 231, 276, 313 nm (log ε 4.18, 3.81, 4.11, 3.83); λ_{max} (95% ethanol + OH^-) 215, 252, 334 nm (log ε 4.1, 3.72, 4.41); δ 60 MHz (acetone-d_6) 2.7 (2H, t, J = 7 Hz), 3.3 (2H, t, J = 7 Hz), 6.35 (1H, d, J = 3 Hz), 6.45 (1H, dd, J = 8, J = 3 Hz), 7.85 (1H, d, J = 8 Hz), 12.6 (1H, s); *m/e* 210 (M^+, $C_{10}H_{10}O_5^+$), 192, 165, 147, 137, 109.

Methyl-(2-hydroxy-4-methoxybenzoyl)propionate (2b)

A solution of 2,4-dihydroxybenzoyl propionate (0.39 g) in ether (10 ml) was treated with excess ethereal diazomethane for 2 h. Evaporation afforded white crystalline **2***b* (0.442 g, 100%), m.p. 73–76°, ν_{max} (KBr) 3400 (broad), 1736, 1640, 1620 cm^{-1}; λ_{max} (95% ethanol) 217, 229, 236 (s), 275, 315 nm (log ε 4.29, 4.10, 4.04, 4.25, 4.00); λ_{max} (95% ethanol + OH^-) 218, 230, 242, 275, 350 nm (log ε 4.22, 4.23, 4.20, 3.94, 4.04); δ 60 MHz ($CDCl_3$) 2.75 (2H, t, 6 Hz), 3.3 (2H, t, J = 6 Hz), 3.7 (3H, s), 3.9 (3H, s), 6.45 (1H, d, J = 3 Hz), 6.5 (1H, dd, J = 10, J = 3 Hz), 7.7 (1H, d, J = 10 Hz), 12.5 (1H, s); *m/e* 238 (M^+, $C_{12}H_{14}O_5^+$), 207, 179, 151, 137, 108, 95.

1,8-Diacetoxy-3-methoxynaphthalene (3a)

A mixture of methyl scytalone (0.044 g), pyridine (0.8 ml), and acetic anhydride (1.2 ml) was refluxed for 2 h and then evaporated in high vacuum yielding a brown solid (0.063 g) which was chromatographed on a silica gel column. Elution with 2% ether in benzene afforded **3***a* (0.044 g, 76%) m.p. 99–101°, ν_{max} 1770, 1635, 1610 cm^{-1}; λ_{max} (ethanol) 212 (s), 231, 267, 279, 290, 319, 333 nm (log ε 4.22, 4.67, 3.52, 3.62, 3.55, 3.12, 3.45); δ 220 MHz (acetone-d_6) 2.94 (3H, s), 2.96 (3H, s), 3.94 (3H, s), 7.0 (1H, d, J = 2.5 Hz), 7.12 (1H, dd, J = 8, J = 1 Hz), 7.39 (1H, d, J = 2.5 Hz), 7.54 (1H, t, J = 8 Hz), 7.84 (1H, dd, J = 8, J = 1 Hz); *m/e* 274 (M^+, $C_{15}H_{14}O_5^+$), 232, 190.

Anal. Calcd. for $C_{15}H_{14}O_5$: C, 65.69; H, 5.11; O, 29.21. Found: C, 65.23; H, 5.28; O, 28.98.

1,3,8-Triacetoxynaphthalene (3b) from Scytalone

A mixture of scytalone (0.065 g), pyridine (0.8 ml), and acetic anhydride (1.2 ml) was refluxed for 2 h and then evaporated *in vacuo* yielding a pinkish brown crystalline solid **3***b* (0.93 g, 93%), m.p. 120–123°, ν_{max} (KBr) 1760 cm^{-1}, λ_{max} (ethanol) 210, 226, 283 (log ε 4.39, 4.81, 3.70); δ (acetone-d_6) 2.3 (3H, s), 2.4 (6H, s), 7.1 (1H, d, J = 2 Hz), 7.2 (1H, dd, J = 8, J = 2 Hz), 7.51 (1H, t, J = 8 Hz), 7.64 (1H, d, J = 2 Hz), 7.82 (1H, dd, J = 8, J = 2 Hz); *m/e* 302 (M^+, $C_{16}H_{14}O_6^+$) 284, 260, 218, 176.

Introduction

The quantitative investigation of the behavior of the pyridine aza group as an aromatic substituent is of current interest. Thus, aza σ values have been obtained for a number of side-chain reactions (1) and these studies have extended to determination of σ_R^0 (2) and σ^0 (3) values, and to the effect of solvent on the aza substituent effect (4). In such reactivity studies it is usual to include the 2-aza substituent since steric effects should be minimal in this case. Because of the similarity between many qualitative aspects of the chemistry of pyridine and nitrobenzene it has been of interest throughout to compare the quantitative effects of the aza and nitro substituents.

As an extension of this investigation to another reaction type, we report here the solvolysis of pyridyldimethylcarbinyl chlorides, and derivation of σ^+ values for the aza substituent. Taylor (5) has previously determined these values from gas phase pyrolysis of pyridylethylacetates and it was of interest to compare his values with those obtained in a reaction where the aza group would be solvated.

Results and Discussion

The kinetics of the solvolysis, in basic conditions, of the three pyridyldimethylcarbinyl chlorides and some other representative carbinyl chlorides were studied both in acetone–water and in methanol solvents. In acetone–water, measurements were made at 25.5° in various solvent compositions, and at 40° in 45% (wt.) acetone–water; reactions in methanol were carried out over the range 0–80°. Non-linear rate plots were encountered with the high temperature runs in methanol with methoxide as base. This trouble was eliminated when triethylamine was used instead and in lower temperature reactions the rates were shown to be independent of the nature of the base. In both solvent systems, the first order rate constants were independent of base concentration.

The kinetic results are listed in Tables 1 and 2. The aza σ^+ values were derived from these results by using the ρ value (−4.82) derived by Brown and co-workers (6) for reaction in methanol at 25°, or from the relative rates of the *m*-bromo and *p*-nitro substituted compounds at 25.5° in 55% acetone–water and 40° in 45% acetone–water. These values and those from the gas phase pyrolysis data of Taylor (5) together with σ values obtained from ester hydrolysis (7) are listed in Table 3.

There is excellent agreement between the σ^+ values of both the 2- and 4-aza substituents for the solvolysis studies in the two different solvent systems, but for the 3-aza substituent the difference between the σ^+ values obtained in the different solvents is greater than would be expected from the precision of the rate constants. For the 3- and 4-aza substituents the σ^+ values obtained in the solvolysis studies are markedly

greater than Taylor's gas-phase values; a difference of 0.2 in σ^+ corresponds to a rate ratio, for solvolysis, of greater than 6. A plausible explanation of this difference in σ^+ values is solvation of the nitrogen in the hydrogen-bonding solvents used. Such solvation would enhance the electron-withdrawing character of the aza substituent, relative to that exhibited in the gas phase. It is surprising, however, that the 2-aza values do not show the same trend since the evidence suggests (4) that this ortho substituent effect is the most sensitive to solvent change.[2]

Like the nitro substituent the aza substituent exhibits electron-withdrawing polar and resonance effects. For such substituents σ^+ and σ values are normally not significantly different and Table 3 shows that this is indeed so for the 2-aza substituent. However for the 4-aza substituent, σ^+ is significantly greater than σ determined from ester hydrolysis. The aza substituent cannot be said to be well-behaved, a conclusion which reinforces the observation of Jaffé and Jones (1) that "the picture (for the application of the Hammett equation to pyridine reactivities) is quite discouraging." The variability of the substituent constants for the aza group is attributable, at least in part, to variation in the extent of its solvation in different reactions.

The enthalpies and entropies of activation point to the importance of solvation in the solvolysis reaction. While variation in ester hydrolysis rates among the pyridyl compounds is primarily enthalpy controlled (9), the thermodynamic parameters in Table 2 indicate that in the solvolysis reaction entropy differences are responsible for the rate differences. Thus the least stable transition state (that for the 4-pyridyl compound) is most heavily solvated because this reduces the electron demand on the pyridyl system. The greater solvation of the transition state for solvolysis of the 4-pyridyl compound is also indicated by the slopes of plots of $-\log k$ for solvolysis in acetone–water at 25.5° against the reciprocal of the dielectric constant of the solvent: 228 for 2-, 158 for 3- and 333 for 4-pyridyldimethylcarbinyl chlorides (reciprocal Debye units). The transition state for solvolysis of the 4-pyridyl compound is evidently the most sensitive to solvent change and that for the 3-pyridyl compound the least sensitive. It is consistent with the expected greater solvation of the pyridyl compounds that all of the above slopes are greater than those calculated from Okamoto and Brown's (10) data for solvolysis of

[2]From the rate of deuteration of 4-aminopyridazine, Katritzky and Pojarlieff (8) have estimated for 4-aza σ^+ = 0.67. This cannot be considered a reliable value.

3-iodo, 3-fluoro, and 4-fluorophenyldimethylcarbinyl chlorides: 134, 143, and 132, respectively.

Experimental

N.m.r. spectra were determined on Varian HA-60-IL and Perkin–Elmer R12A spectrometers with tetramethylsilane as internal standard. Coupling constants and chemical shifts were refined using the computer program UEAITR (11). Mass spectra were determined on a Perkin–Elmer Hitachi RMU-7 spectrometer. Microanalyses were by Microanalysis Laboratories Limited, Toronto 5, Ontario. The p*H*-stat consisted of a Radiometer pH Meter 26, Titrator 11, and Autoburette ABU 11. Melting points are uncorrected.

Pyridyldimethylcarbinyl Chlorides

The three pyridyldimethylcarbinols were prepared by established methods (12).

A solution of thionyl chloride (3 ml) in methylene chloride (30 ml) was added dropwise to a solution of the appropriate pyridyldimethyl carbinol (5 g) in methylene chloride (50 ml) at ambient temperature. The mixture was stirred for 1 h, the solvent and excess thionyl chloride were evaporated under reduced pressure at 40°, and the residue taken up in ethanol (100 ml). Excess anhydrous potassium bicarbonate was added, the mixture filtered, and the solvent evaporated at 40°. The residue was dissolved in methylene chloride (100 ml), the solution dried over magnesium sulfate and the solvent evaporated after filtration. The crude product (4–4.6 g) was a mixture of the desired chloride (26–53%) and the isopropenylpyridine. The olefin and chloride were separated by chromatography on silica at −20° with elution by pentane and ether–pentane mixtures.

2-Pyridyldimethylcarbinyl chloride (1.4 g, 24%) was eluted with 1% ether–pentane; n.m.r. (CCl_4) τ 1.54 (m, 1, 6-*H*), 2.24 (m, 1, 3-*H*), 2.39 (m, 1, 4-*H*), 2.91 (m, 1, 5-*H*), 8.07 p.p.m. (s, 6, CH_3), J_{34} 7.86, J_{35} 1.08, J_{36} 0.89, J_{45} 7.30, J_{46} 1.80, J_{56} 4.66 Hz; mass spectrum (70 eV) *m/e* (relative intensity) 140 (1.4, M − CH_3), 120 (100, M − Cl), 104 (11), 92 (21), 79 (11), 78 (15), 77 (5). 2-Pyridyldimethylcarbinyl chloride hydrochloride had m.p. 75–76°.

Anal. Calcd. for $C_8H_{11}NCl_2$: C, 50.02; H, 5.77; N, 7.29. Found: C, 50.05; H, 6.03; N, 7.13.

3-Pyridyldimethylcarbinyl chloride (2.2 g, 39%) was eluted with 10% ether–pentane; n.m.r. (CCl_4) τ 1.26 (m, 1, 2-*H*), 1.54 (m, 1, 6-*H*), 2.13 (m, 1, 4-*H*), 2.76 (m, 1, 5-*H*), 8.03 p.p.m. (s, 6, CH_3), J_{24} 2.41, J_{25} 0.81, J_{26} 0.3, J_{45} 7.88, J_{46} 1.50, J_{56} 4.65 Hz; mass spectrum (70 eV) *m/e* (relative intensity) 155 (12, M_r ($C_8H_{10}NCl$) = 155), 140 (4.5), 120 (100), 104 (16), 92 (47), 78 (13), 77 (11). 3-Pyridyldimethylcarbinyl chloride hydrochloride had m.p. 126–127°.

Anal. Calcd. for $C_8H_{11}NCl_2$: C, 50.02; H, 5.77; N, 7.29. Found: C, 49.92; H, 5.99; N, 7.38.

4-Pyridyldimethylcarbinyl chloride (1.2 g, 21%) was eluted with 10% ether–pentane; n.m.r. (CCl_4) τ 1.49 (m, 2, 2-*H* and 6-*H*), 2.61 (m, 2, 3-*H* and 5-*H*), 8.10 p.p.m. (s, 6, CH_3), J_{23} and J_{56} 5.2, J_{25} and J_{36} 0.6, J_{26} 0.3, J_{35} 2.0 Hz; mass spectrum (70 eV) *m/e* (relative intensity) 155 (26, M_r ($C_8H_{10}NCl$) = 155), 140 (7), 120 (100), 104 (8), 92 (35), 78 (8), 77 (8). 4-Pyridyldimethylcarbinyl chloride hydrochloride had m.p. 160–161°.

Anal. Calcd. for $C_8H_{11}NCl_2$: C, 50.02; H, 5.77; N, 7.29. Found: C, 50.16; H, 5.91; N, 7.35.

3-Bromophenyldimethylcarbinyl chloride (13) and 4-nitrophenyldimethylcarbinyl chloride (10) were prepared from the corresponding carbinol and styrene, respectively.

Kinetics Studies

Acetone–water

Reactions were followed using a p*H*-stat to maintain the p*H* at 8 as the reaction, which liberated hydrogen chloride, proceeded. The pyridyldimethylcarbinyl chloride (0.015 ml) was added to the acetone–water solvent (100 ml) in a jacketed cell containing a glass and calomel combination electrode and the solution titrated to p*H* 8 with sodium hydroxide solution (0.05 *M*). Water from a thermostatted water bath was circulated through the cell jacket. Carbon dioxide was excluded from the reaction vessel by venting through a solution of concentrated sodium hydroxide. At suitable time intervals the volume of sodium hydroxide which had been added by the autoburette was recorded. The product was shown in each case to be the corresponding pyridyldimethylcarbinol by n.m.r.; no olefin was formed.

Methanol

The carbinylchloride (*ca.* 0.5 ml) was added to basic methanol (100 ml, 0.05 *M* in NaOH or NEt_3) at the appropriate temperature, and under air-free conditions. At appropriate times, 5 ml aliquots were quenched in 50 ml acetone at 0° and titrated immediately with 0.025 *M* hydrochloric acid using methyl red – thymol blue indicator. For the higher temperature reactions the initial mixing was carried out at 0° and 5 ml samples were sealed in tubes before initiating reaction.

First-order rate-constants were evaluated by a least squares fit of the exponential form of the first order rate equation to the titer values. Each data point was given

For personal use only.

unit weighting. Mean rate constants (2–4 runs) are estimated to be precise to ±5%. No variation of rate constant was found in the example of 4-pyridyldimethylcarbinyl chloride, over the p*H* range 6.3–10 in 20% acetone at 40° or with 0.3–0.5 *M* NEt_3 in methanol at 65°.

The precision of 5% in the rate constants results in a precision of better than ±0.02 in the σ^+ values, even in the least favorable cases such as when the latter were obtained using the rates of the *m*-bromo and *p*-nitrophenyldimethylcarbinyl chlorides to determine (in effect) the ρ value. This favorable result is a consequence of the large magnitude of ρ. However, for the rate constants determined at 25.5° the value for 4-pyridyldimethylcarbinyl chloride in 55% acetone–water was obtained by extrapolation from the measured values in 20 and 35% acetone–water assuming [3] a linear relationship between log *k* and D^{-1}. The extrapolation reduces the precision by a factor of five, *i.e.*, the derived rate constant is precise to ±25% and the derived σ^+ value to ±0.1.

[3]Okamoto and Brown (10) showed that for the solvolysis of three halophenyldimethylcarbinyl chlorides in acetone–water log *k* is a linear function of $(D - 1)/(2D + 1)$. However, for the range of dielectric constants of acetone–water mixtures the latter function is linear in D^{-1}, within a precision better than that of the rate constants. Within this same precision *D* is linear in wt. % of the acetone (14). We correlated *D* with wt. % acetone (*w*) over the range 20–70% and found $D = 79.74 - 0.63\ w$ and then correlated log *k* with $(79.74 - 0.63\ w)^{-1}$ to extrapolate the rate constant.

Flash Photolysis Studies of Solute Triplets: an Anomalous Heavy Atom Effect of Xenon[1,2]

DAVID ALAN HEAD,[3] AJIT SINGH,[4] MARGARET GRACE COOK, AND MICHAEL JOHN QUINN

Research Chemistry Branch, Whiteshell Nuclear Research Establishment, Atomic Energy of Canada Limited, Pinawa, Manitoba, R0E 1L0

Received November 15, 1972

Flash photolysis studies show that in solutions of naphthalene in methylcyclohexane the apparent yield of the naphthalene triplet is enhanced ~6% by added krypton and ~50% by added xenon. The effect of xenon on the decay rate of the naphthalene triplet is anomalous; the decay rate decreases instead of increasing. This is attributed to complex formation between singlet excited naphthalene and xenon. We have also investigated the heavy atom effect in solutions of naphthalene in other solvents and in solutions of other solutes. It is anomalous in some of these solutions but to a lesser extent.

Les études par photolyse flash montrent que pour les solutions de naphtalène dans le méthylcyclohexane, le rendement apparent en naphtalène triplet est augmenté de ~6% par addition de krypton et de ~50% par addition de xenon. L'effet du xénon sur la vitesse d'extinction du naphtalène triplet est anormal, celle-ci décroit au lieu de croître. Ce phénomène a été attribué à la formation d'un complexe entre le naphtalène singulet excité et le xenon. L'effet d'un atome lourd dans des solutions de naphtalène avec d'autres solvants et en solution avec d'autres solutés a été également étudié. L'anomalie a été également constatée avec certaines de ces solutions mais à un degré moindre. [Traduit par le journal]

Can. J. Chem., 51, 1624 (1973)

Introduction

Enhancement of forbidden singlet to triplet electronic transitions by the presence of atoms of high atomic number, called the heavy atom effect (h.a.e.) was elegantly demonstrated by Kasha (1). Mixing of the two colorless liquids, ethyl iodide and α-chloronaphthalene, produced a yellow color although no chemical reaction occurred. The observation of an intramolecular h.a.e. in several systems (2–4) prompted Kasha (1) to attribute this yellow color to enhanced ground state singlet to excited triplet electronic transition of α-chloronaphthalene by spin–orbit coupling induced by the external heavy atom (iodine of ethyl iodide). Since then both the theoretical and the experimental aspects of the h.a.e. have been widely studied (5–16).

The h.a.e. results in (10, 13): (*i*) enhanced singlet to triplet absorption, ($S_0 \rightarrow T_1$); (*ii*) enhanced intersystem crossing ($S_1 \rightarrow T_1$); and (*iii*) increased triplet decay rate ($T_1 \rightarrow S_0$). Halogenated solvents have often been used in h.a.e. studies (1, 4, 13). However, halogenated compounds are susceptible to photochemical decomposition (17), particularly those containing bromine or iodine. The overlap of their absorption spectra (18) with that of many of the solutes of interest (aromatic compounds, ketones, etc.) also restricts their usefulness. On the other hand, xenon causes a measurable h.a.e. and although it does undergo photochemical reactions (19–22), its lowest energy level is at 1.332 aJ (8.315 eV, 149 nm), which means that for all practical purposes xenon should be inert in organic solution photochemistry. Hence, xenon has found increasing use in h.a.e. studies (23–27), since it would seem to be an ideal heavy atom (28).

According to one report (12) the magnitude of the heavy atom effect of krypton was about half that of xenon. This investigation was therefore originally undertaken to evaluate the usefulness of krypton as a heavy atom in flash photolysis studies, and to compare it to xenon. At that time krypton was significantly cheaper than xenon (29). However, contrary to expectations, preliminary experiments showed that xenon decreased the decay rate of the naphthalene triplet. The scope of the investigation was then enlarged in an attempt to explain this anomaly.

Our detailed results of the flash photolysis of naphthalene solutions, along with the results of brief investigations of other systems, are reported here. Brief comments are also made on possible h.a.e. in radiolysis and photosensitization studies where xenon or other heavy atoms are present in the system.

Experimental

Chemicals

The following chemicals were used without further purification: camphorquinone (Eastman; white label); anthracene, biphenyl, 9,10-dimethylanthracene, naphthalene, and phenanthrene (James Hinton; zone refined); acetonitrile, benzene, 2-propanol, and methylcyclohexane (Matheson, Coleman, and Bell; Spectroquality); Freon E_4 fluorinated ether, $C_{14}F_{29}HO_4$ (DuPont); and argon and krypton (Matheson, research grade).

Xenon (Matheson, research grade) was stored on a vacuum line in a Pyrex vessel; it was degassed by the freeze–pump–thaw method (at 77 K) before use. The only detectable impurity found by the mass spectroscopic analysis of samples of this xenon gas was air; the gas was 99.85 ± 0.15% Xe, and O_2 was 0.007 ± 0.004 mol%. Water was triply distilled before use (30).

Apparatus and Techniques

The apparatus and techniques have been described previously (31). Additional details and relevant modifications are now reported. The introduction of a Tobe Deutschmann trigger switch (SBG-5) to discharge the capacitors resulted in a light flash width at half-height of 6, 9, and 12 μs with 4.5, 8, and 15 μF capacitors, respectively. The light flash widths at the 90% decay level are about twice these values. Three different tubing materials were used as filters around the Vycor flash lamps: Plexiglass (~380 nm), cellulose acetate butyrate (~310 nm) and Pyrex (~280 nm); the figures in parentheses indicate their low wavelength cut-offs. The photomultipliers used were the Hamamatsu R 166 (260–320 nm), the RCA 7200 and 1P 28 (310–650 nm), and the RCA 7102 and Philips 150 CVP (600–1100 nm).

Solutions to be flash photolyzed were degassed under vacuum in a mercury free system (31). Pressures of added gases (13.3 mPa to 133 kPa [10^{-4} to 1000 Torr]) were measured with an NRC Alphatron gauge mounted on the vacuum line.

Two different samples of xenon, obtained at different times, were used with the same results. Most of the solutions were flash photolyzed by more than one of the experimenters with similar results. After each flash the solutions were shaken and allowed to stand for a short time (~5 min) before being flash photolyzed again. All solutions were flash photolyzed at room temperature (22 °C).

Results

Effect of the Noble Gases

The h.a.e. of argon, krypton, and xenon on the transient absorption, observed on flash photolysis of 10^{-3} mol l^{-1} solutions of naphthalene in methylcyclohexane, was examined. The enhancement of the transient absorption by these gases was: (*i*) $\leq 10^{-2}$ mol l^{-1} Ar: <2%; (*ii*) ~5×10^{-2} mol l^{-1} Kr: ~6%; (*iii*) ~5×10^{-2} mol l^{-1} Xe: ~50%. The only transient observed by absorption spectroscopy in the absence of these gases was the naphthalene triplet. The concentrations of added noble gases were based upon data in refs. 19 and 32. The decay rate of the transient absorption was found to be:

(*i*) unchanged by Ar, (*ii*) slightly decreased (~6%) by Kr, and (*iii*) markedly decreased (≫6%, see later in Table 1 and Fig. 2) by Xe. Since the h.a.e. of both argon and krypton was much smaller than that of xenon, only xenon was used in further work.

Effect of Xenon on Various Solutions

In degassed solutions of the various solutes (Table 1), the solute triplets were the only transients produced, as observed by absorption spectroscopy. The triplet spectra of these solutes are known (31, 33, 34). The observed h.a.e. of xenon on the transient formation in solutions of these solutes is summarized in Table 1. In most of the cases, the results were as one might have predicted on the basis of the intersystem crossing efficiencies, *i.e.* the higher the intersystem crossing efficiency the lower the h.a.e. However, anomalous behavior was observed in a number of instances. In most of the naphthalene solutions, the transient decay rates in the presence of xenon were lower than those in the degassed solutions. The same effect was observed in solutions of phenanthrene in methylcyclohexane. The transient decay rates in biphenyl solutions seemed unaffected by xenon as were those in solutions of phenanthrene in 2-propanol.

In most of the cases, the decay of the triplets was found to follow first order kinetics over the first three half-lives. The decays of the naphthalene triplet in 2-propanol, acetonitrile, the fluoroether, and water, and of the biphenyl triplet in methylcyclohexane showed some deviation from first order kinetics. However, since enhanced second order effects, *i.e.* triplet–triplet annihilation, would enhance decay rates rather than decrease them, and so tend to mask the anomalous behavior, these deviations from first order kinetics do not affect the conclusions being drawn in this paper. Data from a typical experiment, plotted in both a first order and a second order manner, are given in Fig. 1. The

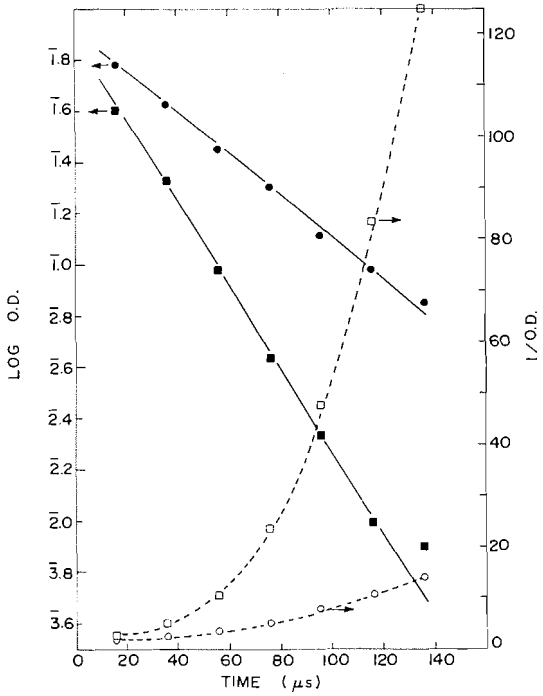

FIG. 1. Decay of transient absorption in a solution of 10^{-3} mol l^{-1} naphthalene in methylcyclohexane (412 nm). Zero time is the start of the flash: □, no xenon present; ○, 0.13 mol l^{-1} xenon.

data show the transient decay to be first order in the presence and in the absence of xenon, in methylcyclohexane solutions.

Since the magnitude of the h.a.e. of xenon was largest and usually anomalous for the naphthalene solutions, these solutions were more thoroughly investigated.

Naphthalene Solutions

(a) Methylcyclohexane Solutions

The effect of xenon concentration on the transient yield and its half-life for 10^{-3} mol l^{-1} solutions of naphthalene in methylcyclohexane is shown in Fig. 2. The data in Fig. 2 represent averages of from four to six determinations, and an estimate of the error in each point is given. Above ~0.04 mol l^{-1} the h.a.e. seems to be independent of the xenon concentration.

The relative transient yields and half-lives were the same whether a 4.5 or a 15 μF capacitor was used. Thus two photon or other bimolecular effects do not contribute to the observed slower transient decay rate in the naphthalene solutions. Changing the analyzing light level by a factor of ~20, by the insertion of neutral density filters in the path of the analyzing beam of light, had no effect on the transient yields or half-lives. Hence the observed effects were not due to photolysis by the analyzing beam of light.

All the above-mentioned results relate to measurements made at the wavelengths of the absorption maxima of the naphthalene triplet. The entire spectral region from 300–1000 nm was also investigated. The observed spectra were in good agreement with the known naphthalene triplet spectrum (33). The shape of the spectral envelope was independent of the presence of xenon through-out this spectral region, with the exception of a very small additional absorption at 380 nm.

To assess the possible role of the naphthalene excimer formation in the h.a.e. of xenon, the relative yield and half-life of the naphthalene triplet in 0.1 mol l^{-1} and 0.4 mol l^{-1} naphthalene solutions were also investigated. In these

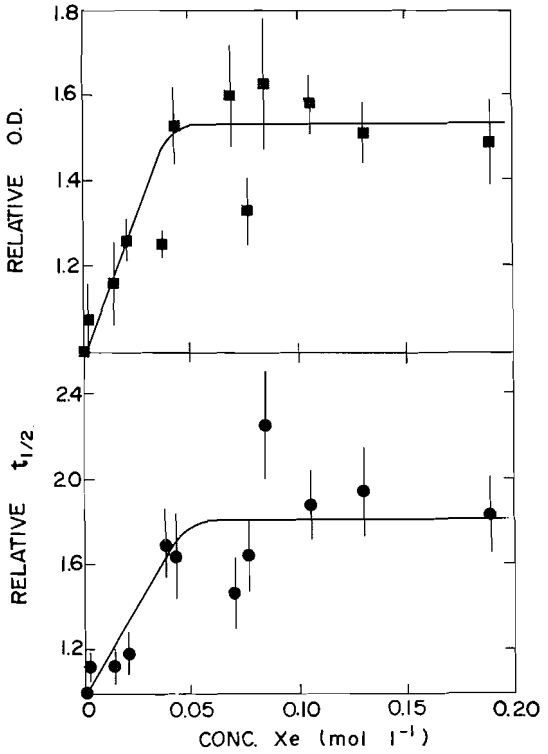

FIG. 2. Effect of xenon on transient yield and half-life in a solution of 10^{-3} mol l^{-1} naphthalene in methylcyclohexane (412 nm). "Relative" indicates the value in the presence of xenon divided by the value in the absence of xenon. Measured at 15 μs after the start of the flash.

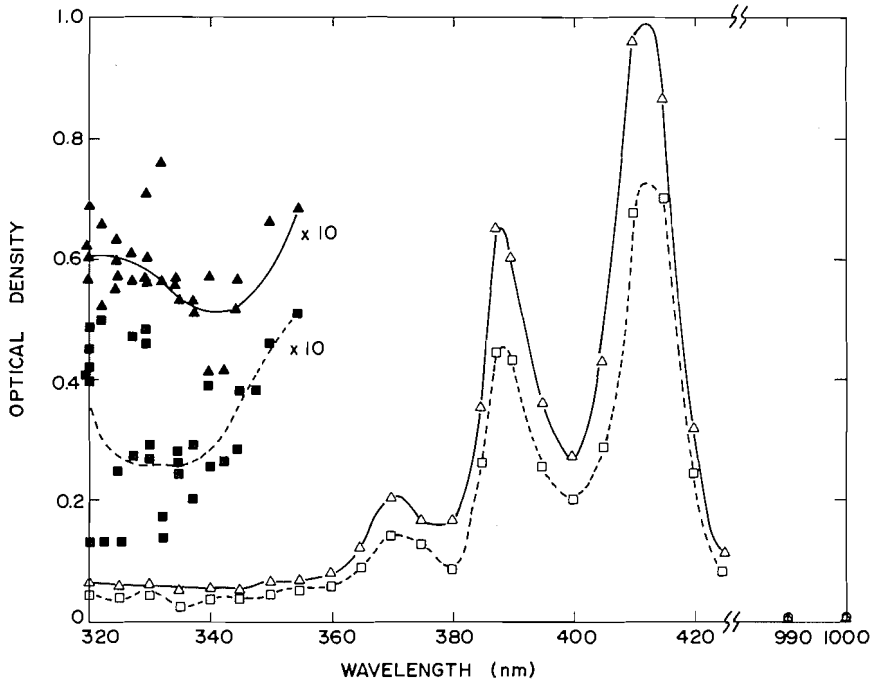

FIG. 3. The transient absorption spectra of a solution of 10^{-3} mol l^{-1} naphthalene in 2-propanol. Measured at 30 μs after the start of the flash: □, no xenon present; △, 160 kPa (1200 Torr) xenon added.

solutions the addition of 0.13 mol l^{-1} xenon enhanced the transient yield by ~20% and increased the half-life by ~15%. Thus, the h.a.e. of xenon was lower at higher naphthalene concentrations.

To determine whether the observed h.a.e. in the naphthalene solutions was due mainly to the interaction of xenon with (*i*) the naphthalene excited singlet, or (*ii*) the naphthalene excited triplet, flash photolysis of solutions containing both phenanthrene and naphthalene was studied, using 310 nm cut-off filters so that phenanthrene would be preferentially excited. The energy level of the lowest excited singlet of phenanthrene is lower than that of naphthalene whereas its triplet energy is greater (Table 1). Therefore only triplet energy transfer from phenanthrene to naphthalene would be expected. This expectation was experimentally substantiated, and it was found that in the presence of xenon the decay rate of the transient so produced, with absorption spectrum indistinguishable from that of the naphthalene triplet, was slightly faster as compared to its decay rate in the absence of xenon (Table 1). This result is in sharp contrast to that obtained by direct flash photolysis of solutions of naphthalene.

Flash photolysis of a solution of xenon in methylcyclohexane and 2-propanol showed no transient absorption.

(b) Other Solutions

In an effort to determine whether ionic transients of naphthalene were involved in the observed h.a.e. of xenon, solutions of naphthalene in solvents with a variety of dielectric constants were flash photolyzed (Table 1). The h.a.e. of xenon was not so marked in the polar solvents. Use of the fluoroether as a solvent (with dielectric constant and viscosity similar to those of methylcyclohexane) also reduced the magnitude of the h.a.e. of xenon.

Transient spectra were measured in solutions of naphthalene in 2-propanol (Fig. 3), acetonitrile (Fig. 4), and water. In general the spectral envelope when xenon was present was indistinguishable from that in the absence of xenon at wavelengths >350 nm. An additional absorption was seen in the 320–340 nm region in the solutions in 2-propanol. The reproducibility of the data was not good in this region due to problems with the equipment. However, each run showed that the absorption in both the presence and the absence of xenon was different in this region. In

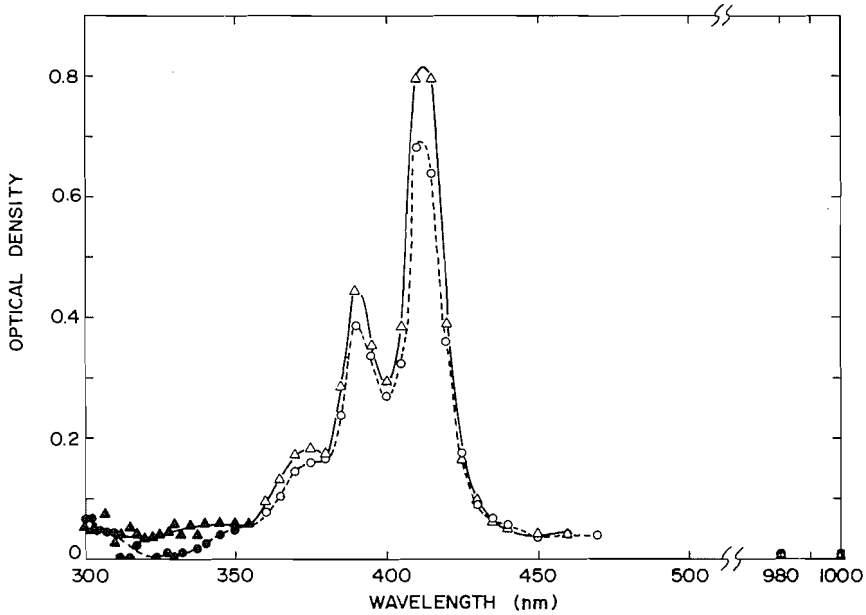

FIG. 4. The transient absorption spectra of a solution of 10^{-3} mol l^{-1} naphthalene in acetonitrile. Measured at 30 μs after the start of the flash (○, △) and 50 μs after the start of the flash (●, ▲): ○, ●, no xenon present; △, ▲, 180 kPa (1350 Torr) xenon added.

acetonitrile solutions, an additional absorption centered at ~325 nm was seen. Within the accuracy of the measurements, no additional absorption was seen in the water solutions. However, no absorption measurements below 370 nm could be made at short times after the flash due to an intense emission. At 80 μs after the start of the flash, no additional absorption was seen in the 300–370 nm region.

To investigate the possibility of the participation of free radicals in the observed h.a.e. of xenon, ethylene was added to 2-propanol solutions of naphthalene in 2-propanol since it is a free radical scavenger (35). Addition of ethylene to a free radical leads to another free radical. Therefore, addition of ethylene would affect the observed results only if the combined effect, due to possible changes in lifetimes and reaction rates, of the new free radicals, and their spectra were different than those of the original ones. Added ethylene (2×10^{-3} mol l^{-1}) had no effect upon the transient life-time or yield in solutions with and without xenon present.

Emission due to fluorescence of naphthalene was found to decrease on the addition of xenon, as expected (5–8, 24).

The effect of varying xenon concentration on the enhancement of the 9,10-dimethylanthracene triplet yield, in solution in methylcyclohexane, was also briefly investigated. The triplet yield was found to increase with the concentration of xenon (≤ 0.13 mol l^{-1}) without reaching a plateau, in contrast to that in the case of naphthalene.

Discussion

Naphthalene Solutions

(a) Heavy Atom Effect on Transient Decay Rate

The observed decrease in the transient decay rate, in the presence of xenon, was totally unexpected. Solute triplet decay rates have not been reported in most of the earlier flash photolysis studies using xenon for h.a.e. (10, 16, 23, 24, 28) although the possibility of increased triplet decay rate as a consequence of h.a.e. has been recognized (10, 11, 28). Indeed, xenon has been found to act as a solute triplet quencher in solutions of benzene and naphthalene at low temperatures (5–8, 11). The decrease in the decay rate of the transient in our studies suggests that either (*i*) a quencher is present in the naphthalene solutions which is rendered ineffective by xenon, or, (*ii*) another transient is formed in solutions containing xenon.

The possibility that the observed decreased

decay rate could be an artifact due to continuous formation of the naphthalene triplet by light absorption from the analyzing beam of light (reaction 1; the superscript prefixes 1 and 3 in this and the subsequent reactions denote the lowest excited singlet and triplet states, respectively) may be discounted, since changes in the

[1] $$N + Xe + h\nu \rightarrow {}^3N + Xe$$

intensity of the analyzing light beam, by insertion of neutral density filters, did not affect the triplet decay rate.

It is possible that the naphthalene solutions contained traces of oxygen or some organic impurities which would quench the naphthalene triplet. Since xenon does not react photochemically with oxygen or with organic compounds at the energies available in our experiments ($\lambda > 280$ nm), (19–22, 36), the removal of these impurities by xenon is most unlikely. Therefore, the change in the transient decay rate does not seem to be related to the presence of impurities.

Free radicals are known to quench triplet excited states (37). If free radicals were to be formed from the naphthalene excited singlet then, on the addition of xenon the yield of the free

[2] $$N + h\nu \rightarrow {}^1N$$

[3] $${}^1N \rightarrow \text{Free radicals}$$

radicals should decrease because of the enhanced intersystem crossing of the naphthalene singlet.

[4] $${}^1N + Xe \rightarrow {}^3N + Xe$$

Thus the observed changes in the transient decay rates will be consistent with quenching by free radicals. However, the energy of the naphthalene singlet is not enough to break any of the bonds in the naphthalene molecule (17) and it is recognized that where free radicals are formed on photolysis of aromatic solutes, the phenomenon is attributable to two photon effects (38) (reactions 2 and 5). In our case, assuming the

[5] $${}^1N + h\nu \rightarrow \text{Free radicals}$$

quenching rate constant for the free radicals to be $\sim 10^{-9}$–10^{10} l mol^{-1} s^{-1} (37), a concentration of free radicals of $\sim 10^{-6}$–10^{-5} mol l^{-1} would be necessary to account for the change in decay rates of the transient. The concentration of the triplet formed, on the basis of the known extinction coefficients (39), is $\sim 3 \times 10^{-6}$ mol l^{-1}. Since the quantum yield for intersystem crossing for naphthalene is ~ 0.8 (40), the yield of the excited singlet would only be $\sim 4 \times 10^{-6}$ mol l^{-1}. Therefore, it is difficult to see how a free radical yield of $\sim 10^{-5}$–10^{-6} mol l^{-1} can be produced from the naphthalene excited singlet by two photon effects. Further, the more commonly accepted mechanism for the formation of free radicals is via photon absorption by the triplet (38). In this case, then, the effect of addition of

[6] $${}^3N + h\nu \rightarrow \text{Free radicals}$$

xenon should be just the opposite, *i.e.* increased decay rate of the transient, since the triplet yield would be increased by added xenon (reaction 4). Thus, the observed decrease in the decay rate of the naphthalene triplet is not attributable to free radicals. This interpretation is also consistent with the observed lack of two photon effect and lack of any effect by added ethylene.

Therefore, the observed decrease in the transient decay rate is most probably due to the formation of transient(s) other than free radicals.

(b) New Transient

The lowest excitation potential of xenon is at 1.332 aJ (8.315 eV, 149 nm) (19). Filters around our flashlamps did not allow the passage of light with $\lambda < 280$ nm, so, direct excitation of xenon in the solutions was most unlikely. The lack of observation of any transient absorption on flash photolysis of solutions of xenon is consistent with this expectation.

The non-involvement of excimer formation and decay in the observed decrease in the transient decay rate was shown by the results in the concentrated solutions of naphthalene. In 0.1 and 0.4 mol l^{-1} solutions of naphthalene the observed h.a.e. was lower than that in 10^{-3} mol l^{-1} solutions. This is reasonable, since in the more concentrated solutions there will be competition between the reaction of the naphthalene excited singlet with xenon (reaction 4), and with naphthalene.

[7] $${}^1N + N \rightarrow {}^1N_2$$

The spectra of ionic transients derived from naphthalene are known (41), and the ionization potentials of both naphthalene and xenon are much higher (42) than the energies of photons available from our flash lamps. Therefore, the formation of ionic transients would not be expected. In the 300–1000 nm region, there was no indication of a spectrum of any charged transient.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

It would then appear that another transient (X) is formed in the solutions containing xenon. It must meet one of the following criteria: (*i*) the transient X has no absorption bands in the 350–1000 nm region, but decays (on μs timescale) to triplet naphthalene; (*ii*) it has an absorption spectrum indistinguishable from that of the naphthalene triplet in the 350–1000 nm region, but decays (on μs timescale) faster than the naphthalene triplet to give the naphthalene triplet; (*iii*) it has an absorption spectrum indistinguishable from that of the naphthalene triplet and decays more slowly than the naphthalene triplet. Each of these criteria leads to an overall half-life of the transient to be greater than that of the naphthalene triplet.

If either (*i*) or (*ii*) were correct, one would expect to see a non-exponential decay of the transient absorption; however, the decay is exponential for more than three half-lives in methylcyclohexane solutions (Fig. 1). We therefore favor the possibility (*iii*) and suggest that the transient absorption in solutions of naphthalene, in the presence of xenon, is predominantly due to a complex formed between excited naphthalene and xenon.

It should be pointed out that complex formation involving noble gases has been suggested before in several systems: (*i*) xenon–benzene and xenon–naphthalene complex formation in low temperature spectroscopic studies (5–9, 11); (*ii*) Xe–CO* complex formation in xenon sensitized fluorescence of CO (43); (*iii*) (Xe–Kr)* complexes in luminescence of their condensed solutions (44), and (*iv*) $Xe–H_2$ and $Xe–D_2$ complex formation in photosensitized exchange studies (45). Complex formation between xenon and an excited aromatic compound in liquid solutions has not been recognized before.

(c) Precursor and Nature of the Complex

Our results show that the transient decay rate is decreased, and the complex is formed, when solutions of naphthalene containing xenon are flash photolyzed. However, when the solutions also contain phenanthrene the naphthalene triplet is formed by energy transfer from the phenanthrene triplet and no naphthalene singlet is formed; in this case the rate of decay of the naphthalene triplet is slightly increased by xenon. These results suggest that it is the naphthalene excited singlet, and not the naphthalene triplet, which enters into a complex with xenon (reaction 8). The half-lives of the known lowest

[8] $$^1N + Xe \rightarrow {}^1NXe$$

excited singlets are <1 μs (40, 46). The half-life of the complex is ~40 μs. It is highly unlikely, therefore, that the complex is in excited singlet state. We suggest that the singlet excited complex undergoes rapid intersystem crossing ($t_{\frac{1}{2}} < 1$ μs) to its triplet, and then decays, radiatively and

[9] $$^1NXe \rightarrow {}^3NXe$$

non-radiatively, to ground state naphthalene and xenon. Siegel and Judeikis (11) observed phosphorescence from such complexes (reaction 10).

[10] $$^3NXe \rightarrow N + Xe + h\nu$$

[11] $$^3NXe \rightarrow N + Xe$$

Their xenon–naphthalene complex may also have been formed from the naphthalene excited singlet (reactions 8 and 9.) In these (11) and other low temperature studies (5–8) the rate of decay of the naphthalene phosphorescence was found to increase in the presence of xenon. However, our results on the decay rates are not directly comparable to theirs (5–8, 11) since (*i*) they used much higher concentrations of xenon (≥ 0.9 *M*) and (*ii*) the h.a.e. of xenon on the radiative transitions of triplets should be greater than on the non-radiative transitions. Triplet decay in liquids is mainly due to the non-radiative transitions.

Since the main bands in the absorption spectra of the naphthalene triplet and the complex are indistinguishable from each other, it appears that xenon perturbs the relevant electronic energy levels of the naphthalene triplet to the same extent. Earlier work by Siegel and Judeikis (11) showed lack of a significant perturbation of the naphthalene triplet phosphorescence by xenon; the phosphorescence spectra of the naphthalene–xenon complexes were very similar to that of the naphthalene triplet. Since xenon does not seem to affect the lowest excited triplet level of naphthalene (11), it is probably reasonable to assume that it does not affect the higher triplet levels either; hence the similarity between the main absorption bands of the naphthalene triplet and the complex is not as surprising as it might seem at first sight. Weak new transient absorption in the 300–350 nm region in solutions in acetonitrile (Fig. 4) and 2-propanol (Fig. 3) might also be attributable to the excited naphthalene–xenon complex. The effect of xenon concentration on the transient yield and half-life

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

(Fig. 2) is not inconsistent with the complex formation. The small decrease in the decay rate of the transient, in solutions of naphthalene, in the presence of krypton is probably also due to complex formation between excited naphthalene and krypton.

(d) Solvent Effect on Heavy Atom Effect

The h.a.e. appears to decrease as the polarity of the solvent increases (Table 1). Molecules in their excited states are more polarizable than in their ground state (40); therefore, as the solvent polarity increases the solvation of the solute excited states would increase (40). Increased solvation is most likely to inhibit h.a.e. of xenon since a solvent layer would tend to reduce complex formation between the solute excited molecule and xenon. Polarity of solvents has no clearly defined effect on the intersystem crossing efficiency of singlet excited states (46), so the solvent effect cannot be attributed to this. Increasing the polarity of solvents tends to increase the fluorescence lifetime of excited molecules (46); this effect would tend to enhance the h.a.e. Other factors which may contribute to the observed solvent effects, but whose contribution in our system is not known, are solvent viscosity and the solubility of xenon. Increasing solvent polarity seems to affect the yield of the complex and its half-life to different extents (Table 1). This suggests that the solvent polarity affects complex formation (reaction 8) more than the xenon enhanced intersystem crossing (reaction 4) and hence possible differences in the solubility of xenon probably play only a minor role in the observed solvent effects.

Heavy Atom Effect in Other Solutions

It is not certain whether the complex formation is peculiar to excited naphthalene or whether it is a more general phenomenon for polyatomic systems. If an increase in the half-life of the triplet in the presence of xenon, or, lack of quenching by xenon (*i.e.* anomalous h.a.e.) were the criteria of complex formation, then it occurs in solutions of phenanthrene and biphenyl as well. Data in Table 1 show that there is no correlation between the solute triplet energies and the lack of increase of transient decay rates in their solutions by added xenon. However, the energies of the singlet states of the three solutes showing anomalous h.a.e. of xenon are the highest among the solutes studied (Table 1). Perhaps there is a dependence of the complex formation on solute singlet energy. This is consistent with the earlier conclusion that xenon is complexing with the naphthalene excited singlet. It also suggests that the interaction between excited solute and xenon might have a charge transfer character, in accordance with previous suggestions on the nature of h.a.e. (6, 7, 13). The excited singlet energy of biphenyl is greater than that of naphthalene. However, the effect of xenon on the rate of the biphenyl triplet decay is smaller than that on the naphthalene triplet, suggesting that other factors, particularly stereochemistry of the excited molecules, also influence the complex formation.

Heavy Atom Effect in Radiolysis and Photosensitization

The h.a.e. of added xenon has been used to aid in determining the roles of solute excited singlet and triplet states (including those of naphthalene) in the pulse radiolysis of liquid solutions (47, 48). No decrease in solute triplet decay rates, in the presence of xenon, has been observed in these studies (47, 48). While this would seem to be at variance with our results, in radiolysis a larger number and variety of transient species are formed (49, 50). The triplet decay rates observed in pulse radiolysis studies are much faster than those in flash photolysis studies (50), due to quenching by these additional transients. We feel that the presence of these other transients in pulse radiolysis probably interferes with the observation of the complex formation. Xenon and other rare gases have also been used as solvents in many radiolysis studies (*e.g.* 51, 52). The h.a.e. of xenon and krypton on the excited molecules formed in these systems seems to have been overlooked (51, 52). In mercury photosensitization studies, also, the h.a.e. on the excited states formed seems to have been overlooked. It has been pointed out that in energy transfer from excited mercury atoms, the overall spin angular momentum should remain unaltered (53, 54). However, if the energy transfer takes place on collision with an acceptor, the h.a.e. might well alter the overall spin angular momentum. For example, on energy transfer from $Hg(6^3P_1)$ to naphthalene, both the naphthalene triplet and the naphthalene excited singlet could result. Observation of acceptor excited singlet states does not seem to have been attempted in mercury photosensitization studies.

Helpful discussions with Dr. B. Henry, Dr. L. Stein, and Mr. M. Tomlinson are gratefully acknowledged. We

should also like to thank Mr. D. Owens and Mr. P. deSouza for technical help with some of the experiments, Mr. D. Bell for the mass spectral analyses of xenon, and Mr. E. E. Wuschke for modifying the flash photolysis system. Award of a post doctoral fellowship by the National Research Council of Canada to one of us (D.A.H.) is gratefully acknowledged.

Mechanistic Studies of Isomerization Reactions of Tetragonal Planar Tertiary Phosphine Complexes of Palladium(II)[1]

DAVID G. COOPER AND JOHN POWELL

Lash Miller Chemical Laboratories, University of Toronto, Toronto 181, Ontario

Received October 19, 1972

The complexes $[PdCl_2(Me_2RP)_2]$ (R = *o*-tolyl; α-napthyl) may be isolated in both *cis* and *trans* forms. In $CHCl_3$ solution *cis–trans* isomerization processes for these complexes are slow and this is ascribed to steric hindrance by the bulky R groups. The *cis–trans* isomerization is catalyzed by a variety of added ligands L. These isomerization processes have been extensively studied for the complexes *cis*- and *trans*-$[PdCl_2(Me_2o\text{-tolylP})_2]$ in $CHCl_3$ solution. The results of variable temperature n.m.r. and u.v. kinetic studies are fully consistent with a consecutive displacement mechanism with an ionic species of the type $[PdCl(Me_2o\text{-tolylP})_2L]^+Cl^-$ as an intermediate. The kinetic characteristics are determined by the nature and relative stability of this ionic intermediate. For L = Me_2o-tolylP the rate of isomerization is zero order in complex and second order in added phosphine concentration. (At 38° $k_{cis\rightarrow trans}$ = 6.2×10^3 l mol^{-1} s^{-1}, $k_{trans\rightarrow cis} = 6.3 \times 10^3$ l mol^{-1} s^{-1}.) For L = PPh_3 the rate of isomerization is considerably slower and first order in both complex and added PPh_3 concentrations ($k_{cis\rightarrow trans}$ = 6.3×10 l mol^{-1} s^{-1}, $k_{trans\rightarrow cis} = 6.7 \times 10$ l mol^{-1} s^{-1}). Isomerization is also effected in neat methanol and the rate is first order in complex concentration. N.m.r. studies of mixtures of *trans*-$[PdI_2(Me_2o\text{-tolylP})_2]$ and *cis*-$[PdCl_2(Me_2o\text{-tolylP})_2]$ in $CHCl_3$ solution show halogen exchange to occur more rapidly than isomerization. However a *cis*-diiodo complex is not observed and instead isomerization to the *trans*-diiodo complex is observed to occur.

Les complexes $[PdCl_2(Me_2RP)_2]$ (R = *o*-tolyl, α-naphtyl) peuvent être isolés sous forme *cis* et *trans*. En solution dans le $CHCl_3$, les processus d'isomérisation *cis–trans* pour ces complexes sont lents et ceci est dû à l'empêchement stérique des groupes R volumineux. L'isomérisation *cis–trans* est catalysée par divers ligands L ajoutés. Les processus d'isomérisation ont été intensivement étudiés pour les complexes $[PdCl_2(Me_2o\text{-tolylP})_2]$ en solution dans le $CHCl_3$. Les résultats des études RMN à température variable et des études cinétiques par l'u.v. sont pleinement compatibles avec un mécanisme de déplacement consécutif avec comme intermédiaire, une espèce ionique du type $[PdCl(Me_2o\text{-tolylP})_2L]^+Cl^-$. Les caractéristiques cinétiques ont été déterminées par la nature et la stabilité relative de l'intermédiaire ionique. Pour L = Me_2o-tolylP, la vitesse d'isomérisation est d'ordre zéro pour le complexe et d'ordre deux pour la concentration de phosphine ajoutée. (à 38°, $k_{cis\rightarrow trans} = 6.2 \times 10^3$ l mol^{-1} s^{-1}, $k_{trans\rightarrow cis} = 6.3 \times 10^3$ l mol^{-1} s^{-1}). Pour L = PPh_3, la vitesse d'isomérisation est beaucoup plus lente et d'ordre un pour le complexe et pour les concentrations en PPh_3 ajouté. ($k_{cis\rightarrow trans}$ = 6.3×10 l mol^{-1} s^{-1}, $k_{trans\rightarrow cis} = 6.7 \times 10$ l mol^{-1} s^{-1}). L'isomérisation a été également effectuée dans le méthanol seul et la vitesse est d'ordre un par rapport au complexe. Les études RMN des mélanges de $[PdI_2(Me_2o\text{-tolylP})_2]$ *trans* et $[PdCl_2(Me_2o\text{-tolylP})_2]$ *cis* en solution dans le $CHCl_3$ montrent un échange d'halogène plus rapide que l'isomérisation. Cependant, le complexe *cis*-diiodo n'a pas été observé, à la place une isomérisation en complexe *trans*-diiodo s'est produite.

[Traduit par le journal]

Can. J. Chem., **51**, 1634 (1973)

Introduction

Whilst *cis-trans* isomerization processes in tetragonal planar nickel(II) complexes have been studied in detail (ref. 1 and references cited therein) the mechanism of *cis-trans* isomerization in tetragonal planar complexes of palladium(II) and platinum(II) have received only limited attention. Dichloro-bis(*t*-phosphine)platinum(II) complexes are generally rather inert to *cis–trans* isomerization. However addition of traces of a tertiary phosphine to such a system catalyzes *cis–trans* isomerization. A consecutive displacement mechanism (2) and a mechanism involving pseudo-rotation of a five coordinate intermediate (3) have been proposed to explain the tertiary phosphine catalyzed isomerization. Recently we obtained ^1H n.m.r. and kinetic evidence from studies of *cis–trans* $[PtI_2(Me_2PhP)_2]$/Me_2PhP systems which favored the consecutive displacement mechanism (*e.g.* eq. 1) (4). A consecutive displacement mechanism has been previously proposed for the amine (am) catalyzed

[1]During the preparation of this manuscript Shaw and co-workers described briefly the preparation of *cis*- and *trans*-$[PdCl_2(Me_2o\text{-tolylP})_2]$ (8).

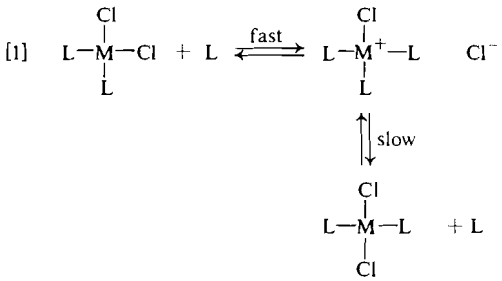
cis–trans isomerization of the palladium complexes $[PdX_2(am)_2]$. (5) We now report the results of a kinetic study of the tertiary phosphine catalyzed *cis–trans* isomerization of $[PdCl_2(Me_2o\text{-tolylP})_2]$ in chloroform solution. The data obtained fully support a consecutive displacement mechanism analogous to that proposed for the $[PtI_2(Me_2PhP)_2]/Me_2PhP$ system (4).



Results and Discussion

The Isolation and Characterization of cis- and trans-$[PdCl_2(Me_2o\text{-tolylP})_2]$ and Related Complexes

The product obtained from the reaction of two Me_2o-tolylP ligands with Li_2PdCl_4 in EtOH consists of a mixture of *cis*- and *trans*-$[PdCl_2Me_2o\text{-tolylP})_2]$. The *cis* isomer may be obtained in a pure form by extraction of the mixture with refluxing ethanol. Extraction of the mixture with refluxing benzene gave the *trans* isomer. The stereochemistry of the *cis* and *trans* isomers in the solid state was confirmed by far infrared and Raman spectroscopy. The *cis* isomer exhibited two νPd—Cl absorptions at 289 and 311 cm^{-1} active in both the i.r. and Raman, whereas the *trans* isomer exhibited one i.r. active and one Raman active νPd—Cl absorption (See Table 1). These stereochemistries are confirmed by n.m.r. studies of the complexes in $CDCl_3$ solution. The ^1H n.m.r. and proton decoupled ^{13}C n.m.r. spectra of the methyl groups of the *trans*-isomer consist of a singlet resonance assignable to the tolyl methyl, together with a 1:2:1 triplet assignable to the phosphine methyls (virtual coupling of two *trans* ^{31}P nuclei (6, 7) (see Table 1). The phosphine methyl resonances of the *cis*-isomer consist of a 1:1 doublet.[1] Slow isomerization of the *cis* isomer or the *trans* isomer to a *ca.* 2:1 *cis–trans* equilibrium occurs in chloroform solution over a period of *ca.* 1–5 d (*e.g.* see Fig. 1*f*). However on addition of a trace amount of a tertiary phosphine (*e.g.* Me_2o-tolylP, Me_2PhP, *n*-Bu_3P, Ph_3P) isomerization is rapid and equilibrium is reached in *ca.* 20 min (34°). The non-lability of $[PdCl_2(Me_2o\text{-tolylP})_2]$ towards *cis–trans* isomerization contrasts markedly with previous studies of dichlorobis(*t*-phosphine)palladium(II) complexes where isomerization has been shown to be extremely facile. (6) Thus for example whilst $[PdCl_2(Me_2PhP)_2]$ may be isolated as the *cis*-isomer in the solid state (9) it very rapidly isomerizes to a *ca.* 2:1 *cis–trans* equilibrium mixture in $CHCl_3$ at *ca.* 34° (6). The Me_2o-tolylP platinum(II) complexes *cis*- and *trans*-$[PtI_2(Me_2o\text{-tolylP})_2]$ are also considerably less labile to ligand substitution and isomerization than their Me_2PhP analogues. As the electronic factors associated with the Me_2o-tolylP and Me_2PhP ligands are very similar, the marked difference in the kinetic lability of these complexes is probably due to a steric effect of the ortho-methyl group of the Me_2o-tolylP ligand. Molecular models indicate that the ortho-methyl group and/or the ortho-hydrogen will tend to impede the approach of a nucleophile along the *z*-axis and hence inhibit S_N2 reactions.

The complex $[PdCl_2(Me_2\alpha\text{-napthylP})_2]$ may also be isolated as *cis* and *trans* isomers which are also non-labile to *cis–trans* isomerization, presumably for similar reasons. However attempts to prepare *cis*-dibromo or *cis*-diiodo derivatives of these complexes by metathetical replacement failed, only the *trans* isomers being isolated.

An unusual feature of the ^1H n.m.r. spectrum of *cis*-$[PdCl_2(Me_2o\text{-tolylP})_2]$ is a high field quartet resonance of relative intensity one (per Me_2o-tolylP) at 6.52δ assignable to an aromatic proton. No anomalous high field aromatic absorptions are observed for the free ligand (Me_2o-tolylP), *trans*-$[PdX_2(Me_2o\text{-tolylP})_2]$ (X = Cl, Br, I), nor *cis*/*trans*-$[PdCl_2(Me_2PhP)_2]$. However the cationic complex $[PdCl(Me_2o\text{-tolylP})_3]^+PF_6^-$ does exhibit a high field aromatic proton resonance of relative intensity one (per Pd atom). It is anticipated that this high field aromatic proton resonance is due to the ortho-hydrogen on the tolyl ring. A 220 MHz ^1H n.m.r. spectrum of *cis*-$[PdCl_2(o\text{-tolyl}Me_2P)_2]$ supported this assignment. Close proximity of the ortho-hydrogen of an aryl phosphine ligand to the central metal atom has been observed in the X-ray diffraction study of *trans*-$[PdI_2(Me_2PhP)_2]$

(10). The only common feature to account for the high field aromatic proton resonances in *cis*-$[PdCl_2(Me_2o\text{-tolylP})_2]$ and $[PdCl(Me_2o\text{-tolylP})_3]^+PF_6^-$ (one high field proton only) is that in both cases the phosphine giving rise to the high field aromatic resonances is *trans* to a chloride ligand. It is anticipated that a P—Pd bond *trans* to Cl will be shorter than one *trans* to P (see ref. 9 and references therein). If the observed high field shift is due to paramagnetic shielding by the d-electrons of the Pd atom, one would expect such shielding to be very sensitive to the Pd–ortho-proton separation and the orientation of the proton relative to the coordination plane (11). An upfield shift would be anticipated if the ortho-proton has a preferred conformation in, or close to the coordination plane. This explanation is not very satisfactory as it implies that the tolyl methyl protons should have a preferred conformation close to the *z*-axis above the coordination plane for which a paramagnetic downfield shift is predicted (11). No downfield shift of the tolyl methyl proton resonances in *cis*-$[PdCl_2(Me_2o\text{-tolylP})_2]$ or $[PdCl(Me_2o\text{-tolylP})_3]^+PF_6^-$ relative to *trans*-$[PdCl_2(Me_2o\text{-tolylP})_2]$ is observed.

The Tertiary Phosphine Catalyzed cis–trans Isomerization of $[PdCl_2(Me_2o\text{-tolylP})_2]$

Because of its relative non-lability we have utilized the complex $[PdCl_2(Me_2o\text{-tolylP})_2]$ to study the mechanism of the tertiary phosphine catalyzed *cis–trans* isomerization of tetragonal planar complexes of palladium(II).[2] The approach used is similar to that previously used to study phosphine catalyzed *cis–trans* isomerization in analogous platinum(II) complexes (4).

^1H *n.m.r. Studies*

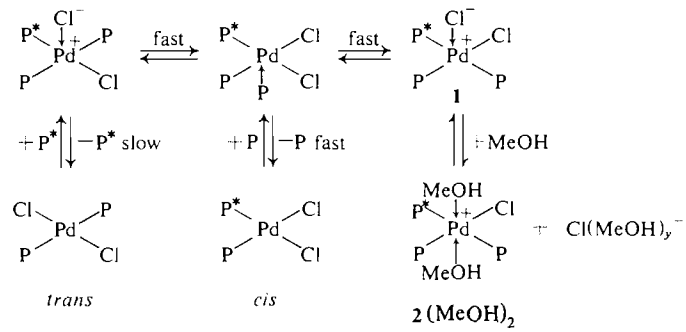
Addition of one Me_2o-tolylP per Pd atom to a $CDCl_3$ solution of $[PdCl_2(Me_2o\text{-tolylP})_2]$ (0.2 *M*) at *ca.* $-10°$ gives a proton n.m.r. spectrum containing a broad 1:2:1 triplet resonance (excluding tolyl methyl protons) assignable to two *trans*-Me_2o-tolylP ligands and a doublet resonance assignable to a *cis*-Me_2o-tolylP ligand (see Table 1 and Fig. 1*a*). No resonances assignable to free Me_2o-tolylP are observed. A similar but better resolved pattern is obtained at 34° in MeOH solution (Fig. 1*b*). The spectra are consistent with the solution species being $[PdCl(Me_2o\text{-tolylP})_3]^+Cl^-$ and on addition of NH_4PF_6 to such solutions the salt $[PdCl(Me_2o\text{-tolylP})_3]^+PF_6^-$ is readily isolated and structurally characterized (see Table 1 for n.m.r. data). The far infrared spectrum of a 0.1 *M* chloroform solution of $[PdCl_2(Me_2o\text{-tolylP})_2]$ in the presence of one Me_2o-tolylP per Pd further confirms the formation of $[PdCl(Me_2o\text{-tolylP})_3]^+Cl^-$ (**1**) (see Table 1). In the range 500–250 cm^{-1} the spectrum contains only one absorption assignable to a νPd—Cl band and is identical to the far infrared spectrum of $[PdCl(Me_2o\text{-tolylP})_3]^+PF_6^-$. Thus in $CDCl_3$ solution in the temperature range $-10°$ to 31° equation 2 lies well to the right hand side.

[2] $[PdCl_2(Me_2o\text{-tolylP})_2] + PMe_2o\text{-tolylP} \underset{\text{equilibrium in } CDCl_3}{\overset{\text{fast}}{\rightleftharpoons}} [PdCl(Me_2o\text{-tolylP})_3]^+Cl^-$

The species $[PdCl(Me_2o\text{-tolylP})_3]^+Cl^-$ may exist either as a contact ion pair with a square pyramidal geometry (**1** in Scheme 1) or alternatively as a completely solvated species (*e.g.* **2**$(MeOH)_2$ in Scheme 1). The relative concentrations of such species will be a function of solvent, salt concentration, and temperature. The completely dissociated ionic species (*e.g.* **2**$(MeOH)_2$) will be favored by polar solvents, low concentrations, and low temperatures.

On addition of Me_2o-tolylP (*ca.* 20% per Pd) to a $CDCl_3$ solution of $[PdCl_2(Me_2o\text{-tolylP})_2]$ at $-20°$ the phosphine methyl (P—Me) ^1H n.m.r. spectrum consists of a broad 1:2:1 triplet and a broad 1:1 doublet assignable to $[PdCl(Me_2o\text{-tolylP})_3]^+Cl^-$ (20%) together with a sharp 1:1 doublet assignable to *cis*-$[PdCl_2(Me_2o\text{-tolylP})_2]$ (80%) (see Fig. 1*c*). (The equilibrium *cis–trans* isomer ratio is temperature dependent (12) and at $-20°$ is >95% *cis*.) The broadness of the salt resonances relative to those of the *cis* complex suggest that intramolecular exchange of *cis* and *trans* phosphines in the salt is faster than intermolecular salt–*cis*-phosphine exchange (13). This is borne out by studies using 1:1 salt – *cis* ratios. On raising the temperature of the system (80% $[PdCl_2(Me_2o\text{-tolylP})_2]$ + 20% $[PdCl(Me_2o\text{-tolylP})_3]^+Cl^-$) to 10° the "P—Me" proton resonances of the salt and *cis* isomer coalesce whilst the 1:2:1 "P—Me" triplet of

[2] $[PdCl_2(Me_2o\text{-tolylP})_2]$ was chosen for this study rather than $[PdCl_2(Me_2\alpha\text{-napthylP})_2]$ as the *cis* and *trans* isomers of the latter are less distinguishable by u.v. spectroscopy, see Table 1.



SCHEME 1. Mechanism proposed to account for rapid intramolecular exchange of P* in salt, and rapid salt–*cis* intermolecular exchange of P*. Axially solvating $CHCl_3$ molecules have been omitted for the sake of simplicity. Each ligand substitution is considered to proceed through a trigonal bipyramidal five coordinate intermediate and thus involves loss of a solvating $CHCl_3$ molecule. P = Me_2*o*-tolylP.

the *trans* isomer remains sharp and well resolved (% *trans* at 10° = *ca.* 10%) (see Fig. 1*d*). This indicates that intermolecular Me_2*o*-tolylP exchange between the salt and the *cis* isomer is *fast* on the n.m.r. time scale whereas *cis–trans* isomerization is *slow* on the n.m.r. time scale. This is more obviously so in Fig. 1*e* where the amount of added Me_2*o*-tolylP has been reduced to 5%. If 20% $[PdCl(Me_2o\text{-tolylP})_3]^+PF_6^-$ is added to $[PdCl_2(Me_2o\text{-tolylP})_2]$ in $CDCl_3$ at 34° no collapse of "P—Me" resonances is observed. Thus the ionic chloride ligand of $[PdCl(Me_2o\text{-tolylP})_3]Cl$ must be involved in the mechanism of Me_2*o*-tolylP exchange. The above observations suggest the mechanism shown in Scheme 1 for Me_2*o*-tolylP exchange in the salt–*cis* system. Addition of methanol to a 1:1 mixture of $[PdCl_2(Me_2o\text{-tolylP})_2]$ and Me_2*o*-tolylP in $CDCl_3$ at 34° slows the ligand exchange. In neat methanol no collapse of the phosphine methyl resonances is observed and the spectrum is consistent with *cis*-$[PdCl_2(Me_2o\text{-tolylP})_2]$ and $[PdCl(Me_2o\text{-tolylP})_3]^+(MeOH)_x$, $Cl^-(MeOH)_y$ being the solution species (*i.e.* solvation of the contact ion pair **1** by MeOH removes the Cl^- ligand from the axial position in **1** and thereby inhibits Me_2*o*-tolylP exchange. See Scheme 1.) These observations parallel the previous studies on $[PtI_2(Me_2PhP)_2]$ + Me_2PhP systems (4) and are consistent with the consecutive displacement mechanism for phosphine ligand exchange shown in Scheme 1.

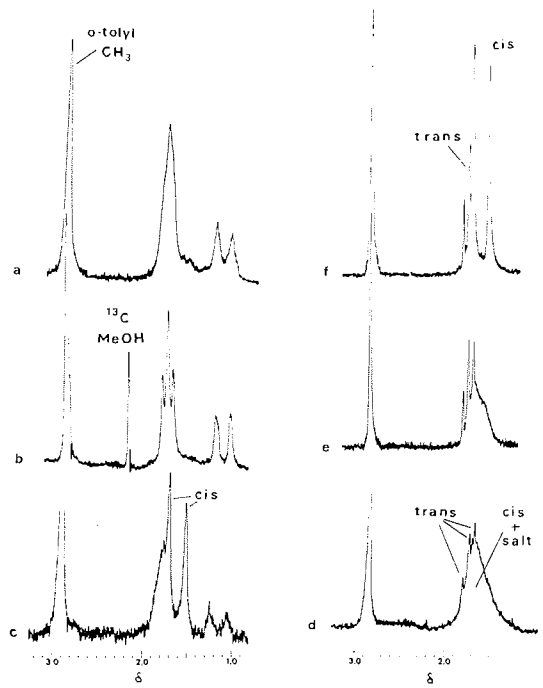


FIG. 1. ^1H n.m.r. spectrum of methylprotons of $[PdCl(Me_2o\text{-tolylP})_3]Cl$ (*a*) in $CDCl_3$ at −10°; (*b*) in MeOH at 34°; (*c,d*) the methyl proton resonance of a *ca* 4:1 mixture of $[PdCl_2(Me_2o\text{-tolylP})_2]$ and $[PdCl(Me_2o\text{-tolylP})_3]Cl$ in $CDCl_3$ solution at −20° (*c*), and +10° (*d*); (*e*) the methyl proton resonance of a *ca.* 19:1 mixture of $[PdCl_2(Me_2o\text{-tolylP})_2]$ and $[PdCl(Me_2o\text{-tolylP})_3]Cl$ in $CDCl_3$ solution at 34°; (*f*) the methyl proton resonance of an equilibrium *cis–trans* mixture of $[PdCl_2(Me_2o\text{-tolylP})_2]$ in $CDCl_3$ at 34°.

Addition of L = Me_2PhP, *n*-Bu_3P, or Me_2-PhAs also collapses the methyl proton resonances of *cis*-$[PdCl_2(Me_2o\text{-tolylP})_2]$ at 34°. At lower temperatures resonances assignable to species of the type $[PdCl(Me_2o\text{-tolylP})_2L]Cl$ similar to **1** are observed. However, whilst collapse of the methyl proton resonances and *cis–trans* isomerization are also promoted by Ph_3P the n.m.r. spectrum of $[PdCl_2(Me_2o\text{-tolylP})_2]$ in $CDCl_3$ in the presence of *ca.* 4 PPh_3 per Pd at −20° exhibits resonances assignable to *cis* (plus a very

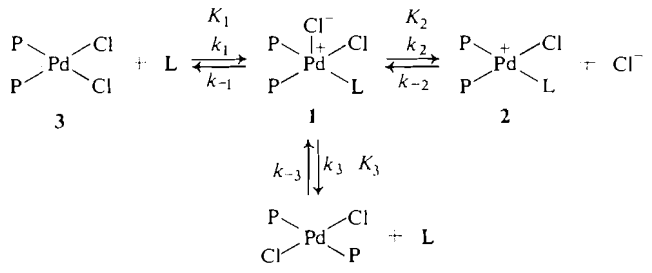

SCHEME 2. Consecutive displacement mechanism of *cis–trans* isomerization for L = P. For L ≠ P the ion-paired species (**1**) (*cis*-[PdClP$_2$L]Cl) must undergo rearrangement to *trans*-[PdClP$_2$L]Cl (of the type shown for P* in Scheme 1) before step 3. Axially solvating $CHCl_3$ molecules have been omitted for the sake of simplicity. Each ligand substitution is considered to proceed through a trigonal bipyramidal five coordinate intermediate and thus involves loss of a solvating $CHCl_3$ molecule.

small amount of *trans*) [PdCl$_2$(Me$_2$*o*-tolylP)$_2$] and free PPh_3. No resonances assignable to a species such as [PdCl(Me$_2$*o*-tolylP)$_2$(PPh_3)]Cl are observed. The relative instability of such a species is further confirmed by far infrared studies. In contrast to the [PdCl$_2$(Me$_2$*o*-tolylP)$_2$] + Me$_2$*o*-tolylP system (see above) the far infrared spectrum (400–250 cm^{-1}) of [PdCl$_2$(Me$_2$*o*-tolylP)$_2$] in the presence of 4 PPh_3 per Pd is the same as that of the equilibrium *cis–trans* mixture.

Ultraviolet Kinetic Studies

The close analogy between the above n.m.r. studies and those previously observed for [PtI$_2$(Me$_2$PhP)$_2$]–Me$_2$PhP systems (4) suggested that the kinetics of the PR_3 catalyzed *cis–trans* isomerization of [PdCl$_2$(Me$_2$*o*-tolylP)$_2$] would probably be similar to those found for the platinum(II) system. Thus the consecutive displacement mechanism shown in Scheme 2 is proposed to account for these isomerization processes. To obtain the fullest consistency with the above n.m.r. data it was decided to test the proposed mechanism by means of a kinetic study of both *cis*-to-*trans* and *trans*-to-*cis* tertiary phosphine catalyzed isomerizations of [PdCl$_2$(Me$_2$*o*-tolylP)$_2$] in chloroform solution at 38°. The above n.m.r. studies and known *trans* effect data indicate that the equilibria K_1 and K_2, involving the *cis* complex **3** (see Scheme 2), L (=PR_3 catalyst), and the ionic species **1** and **2**, are rapidly established and that the interconversion of **1** and the *trans* complex **4** will be rate determining. A *ca.* 10^{-4} *M* solution of [PdCl$_2$(Me$_2$*o*-tolylP)$_2$] in the presence of a *ca.* 5×10^{-6} *M* concentration of added Me$_2$*o*-tolylP catalyst will generate a *ca.* 5×10^{-6} *M* concentration of the ionic species [PdCl(Me$_2$*o*-tolylP)$_3$]$^+$Cl$^-$ which will most probably be in the fully solvated form **2** (*i.e.* [**2**] ≫ [**1**] and [**2**] ≈ [L$_0$] = concentration of L at the instant of addition, prior to formation of **2**).

For *cis* (**3**) to *trans* (**4**) isomerization the rate is represented by eq. 3:

$$[3] \quad \text{Rate} = -\frac{d[\mathbf{3}]}{dt} = \frac{d[\mathbf{4}]}{dt} = k_3[\mathbf{1}] - k_{-3}[\mathbf{4}][L]$$

Assuming the pre-equilibrium approximation and remembering that [**2**] = [Cl$^-$] ≈ [L$_0$] and that [L] ≈ 0 then it follows that

$$[4] \quad K_2 = \frac{[\mathbf{2}][Cl^-]}{[\mathbf{1}]} \approx \frac{[L_0]^2}{[\mathbf{1}]}$$

Initially [**4**] = 0. Substituting eq. 4 into eq. 3 for [**1**] gives the expression:

$$[5] \quad \text{Initial rate } (c \rightarrow t) = \frac{k_3[L_0]^2}{K_2} = k_0[L_0]^2$$

(k_0 = observable second order rate constant.)

For Me$_2$*o*-tolylP catalyzed *trans*-to-*cis* isomerization, the initial rate of formation of **3** is given by

$$[6] \quad \text{Initial rate} = \frac{d[\mathbf{3}]}{dt} = k_{-1}[\mathbf{1}]$$

As equilibria K_1 and K_2 are rapidly established the steady state approximation may be applied, *i.e.*

$$[7] \quad \frac{d[\mathbf{1}]}{dt} = k_1[\mathbf{3}][L] + k_{-2}[\mathbf{2}][Cl^-] + k_{-3}[\mathbf{4}][L] - (k_{-1} + k_2 + k_3)[\mathbf{1}] = 0$$

For conditions applicable to initial stages of reaction, eq. 7 simplifies to

For personal use only.

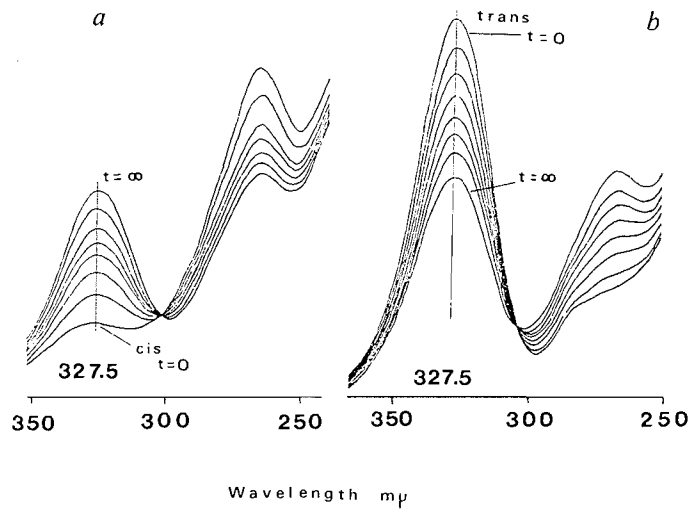

FIG. 2. U.v. spectral changes for PMe_2o-tolyl catalyzed *cis–trans* isomerization of $[PdCl_2(Me_2o\text{-tolylP})_2]$ in $CHCl_3$ at 38°: (*a*) *cis* to equilibrium; (*b*) *trans* to equilibrium.

$$[8] \qquad [\mathbf{1}] = \frac{k_{-2}[L_0]^2}{k_{-1} + k_2 + k_3}$$

Substituting eq. 8 into eq. 6 gives

$$[9] \quad \text{Initial rate } (t \rightarrow c) = \frac{k_{-1}k_{-2}[L_0]^2}{k_{-1} + k_2 + k_3} = k_0[L_0]^2$$

Although K_1 and K_2 are rapidly established it must be remembered that substitution of Cl in **4** by L is the rate determining step. As such an induction period prior to steady state conditions is anticipated for the L catalyzed *trans*-to-*cis* isomerization thereby making the observation of initial rates more difficult (*i.e.* at mixing most of added L is present as free phosphine and has to react with the *trans* isomer to form the salt). On the basis of eqs. 5 and 9, which incorporate the restrictions inferred by the n.m.r. studies, the consecutive displacement mechanism (Scheme 2) predicts that the initial rates of Me_2o-tolylP catalyzed *cis*-to-*trans* and *trans*-to-*cis* (steady state conditions) isomerization will be zero order in complex and second order in the concentration of added Me_2o-tolylP ($[L_0]^2$).

Figure 2 shows the observed changes in the u.v. spectra for *cis* to equilibrium (Fig. 2*a*) and *trans* to equilibrium (Fig. 2*b*) processes studied in 96% chloroform – 4% cyclohexane (by volume) at 38°. The 4% cyclohexane was necessitated by the fact that tertiary phosphines react very slowly with chloroform (14). As a precaution, therefore, standard solutions of the phosphine catalyst were made up in cyclohexane. Using a fixed amount of added Me_2o-tolylP pseudo zero order initial rate plots were obtained, the "initial zeroth order" approximation holding good for *ca.* 50% completion and for a 3-fold range of complex concentration.[3] Plots of the observed pseudo zero order initial rate constants for different concentrations of added Me_2o-tolylP *vs.* the square of the concentration of added Me_2o-tolylP ($[L_0]^2$) gave the linear correlations shown in Fig. 3. The slopes of these plots give the experimentally observed second order rate constants k_0 (see eqs. 5 and 9). Thus the observed kinetics are consistent with the above ^1H n.m.r. studies and the consecutive displacement mechanism when the added phosphine is one that readily generates an ionic species. To further verify the mechanism shown in Scheme 2 we decided to examine the chloride ion dependence of the rate by studying *trans*-to-*cis* isomerization at a fixed Me_2o-tolylP catalyst

[3]For the *trans*-to-*cis* isomerization process an induction period of *ca.* 1 min (during which *trans*-to-*cis* isomerization was rapid) was observed prior to steady state conditions.

The range of complex concentration is limited by experimental difficulties, a particular one being the problem of preparing very dilute ($> 10^{-7}$ *M*) standard solutions of the tertiary phosphine catalyst.

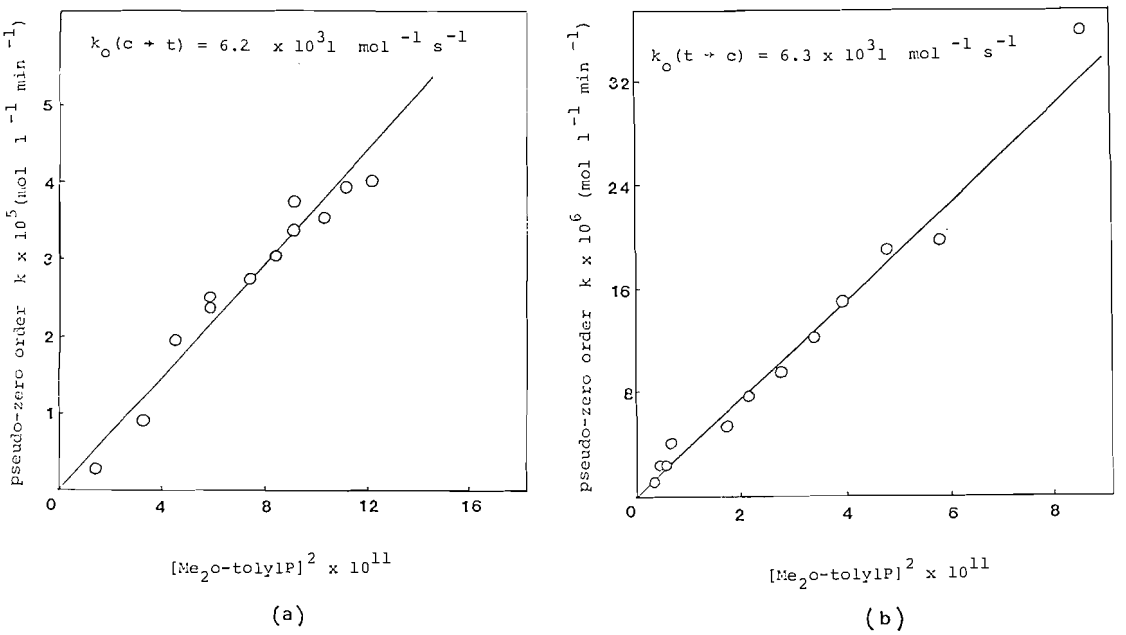

FIG. 3. Plots of the observed pseudo-zero order initial rate constants k *vs.* the square of the concentration of added Me_2o-tolyl catalyst for (*a*) *cis*-to-*trans*, and (*b*) *trans*-to-*cis* isomerization of $[PdCl_2(Me_2o\text{-tolylP})_2]$ in 96% $CHCl_3$ – 4% cyclohexane at 38°. Slope = k_o.

concentration but at varying chloride ion concentrations. Chloride ions were added in the form $[Et_4N]^+Cl^-$. In the presence of a fixed amount of added chloride ion (*ca.* 10^{-2} *M*) a pseudo-zero order reaction was still observed. The observed pseudo zero-order rate constants, although dependent on $[Cl^-]$ did not give a simple first order correlation as initially anticipated. This was found to be due to the fact that the *trans*/*cis* equilibrium constant, $K_{t/c}$, is quite sensitive to the concentration of added $[Et_4N]Cl$ decreasing from 1.06 (38°, no $[Et_4N]Cl$) to 0.56 (38°, 6.9×10^{-2} *M* in $[Et_4N]Cl$). As such we studied the *trans*-to-*cis* isomerization at a fixed concentration of added $[Et_4N]Cl$ (6.9×10^{-2} *M*) and varied the concentration of added Me_2o-tolylP. For the situation where $[Cl^-] \gg [L_0]$ eq. 9 is modified such that

$$\text{Initial rate}_{(t\rightarrow c)} = \frac{k_{-1}k_{-2}[L_0][Cl^-]}{k_{-1} + k_2 + k_3}$$

For fixed concentration of excess "added chloride" a first order dependence on the concentration of added Me_2o-tolylP should be observed. This was indeed found to be the case.

Since ^1H n.m.r. and far infrared studies of the system $[PdCl_2(Me_2o\text{-tolylP})_2] + PPh_3$ have shown that PPh_3 has little tendency to generate an ionic species we decided to carry out a kinetic study of this system in order to see whether or not a consecutive displacement mechanism is still applicable. To be consistent with the mechanism outlined in Scheme 2 and the n.m.r. data, PPh_3 catalyzed isomerization should be slower (more difficult to generate the ionic intermediate). One would also anticipate the following kinetic characteristics:

For L = PPh_3 the n.m.r. data indicates that $[L] \gg [\mathbf{1}]$ and that $[L] \approx [L_0]$. Thus the initial rate of *cis*-to-*trans* isomerization is given by

$$[10] \quad \text{Initial rate}_{(c\rightarrow t)} = k_3[\mathbf{1}] = k_3K_1[\mathbf{3}][L] \approx k_0'\,[\mathbf{3}][L_0]$$

For *trans*-to-*cis* isomerization the initial rate is given by

$$[11] \quad \text{Initial rate}_{(t\rightarrow c)} = k_{-3}\,[\mathbf{4}][L] \approx k_0'\,[\mathbf{4}][L_0]$$

Using a fixed concentration of added PPh_3 (and studying the isomerization in 96% $CHCl_3$ – 4% cyclohexane at 38°) a first order dependence on complex concentration for the initial rates of *cis*-to-*trans* and *trans*-to-*cis* isomerization was observed. A plot of the pseudo first order rate constants *vs.* the concentration of added PPh_3 gave the linear correlations shown in Fig. 4

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

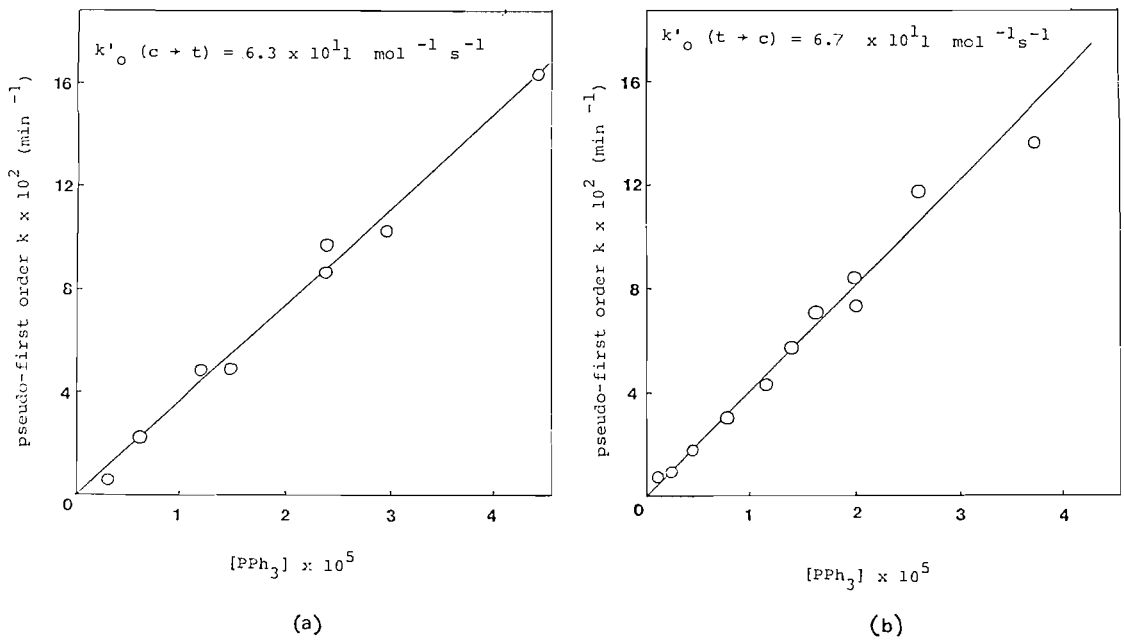

FIG. 4. Plots of the observed pseudo-first order initial rate constants *k vs.* the concentration of added Ph_3P catalyst for (*a*) *cis*-to-*trans*, and (*b*) *trans*-to-*cis* isomerization of $[PdCl_2(Me_2o\text{-tolylP})_2]$ in 96% $CHCl_3$ – 4% cyclohexane at 38°. Slope = k_o'.

from which values of the second order rate constants k_0' are obtained. From eqs. 10 and 11 the ratio $k_0'_{(c\rightarrow t)}/k_0'_{(t\rightarrow c)} = k_3K_1/k_{-3} = K_1K_3 = K_{t/c} = 0.95$. This is in very good agreement with the observed value of the *trans–cis* equilibrium constant, $K_{t/c}$, of 1.06 ± 0.03 ($K_{t/c}$ was calculated from the u.v. spectra of a *ca.* 10^{-4} *M* solution of complex + trace of Me_2o-tolylP, the equilibrium data being obtained after at least $20 \times t_{1/2}$). The experimentally observed kinetics for PPh_3 catalyzed isomerization are clearly consistent with the consecutive displacement. Furthermore, as expected, PPh_3 is a considerably poorer catalyst than Me_2o-tolylP.

The low temperature ^1H n.m.r. spectrum (−20°) of a 1:1 mixture of $[PdCl_2(Me_2o\text{-tolylP})_2]$ and $Me(o\text{-tolyl})_2P$ in $CDCl_3$ exhibits resonances assignable to *at least* two types of ionic species (*ca.* 20%) together with resonances due to *cis*-$[PdCl_2(Me_2o\text{-tolylP})_2]$ (*ca.* 80%) and free $Me(o\text{-tolyl})_2P$. Consistent with this observation, which indicates a situation intermediate between the Me_2o-tolylP and PPh_3 systems, initial rate studies did *not* give linear correlations for plots of the type shown in Figs. 3 and 4. The overall efficiency of tertiary phosphines to promote *cis–trans* isomerization decreases in the order $Me_2PhP \sim {}^nBu_3P \gtrsim Me_2o$-tolylP $\gg$ $Me(o\text{-tolyl})_2P > Ph_3P$.

Methanol Catalyzed trans–cis Isomerization

When *trans*-$[PdCl_2(Me_2o\text{-tolylP})_2]$ is dissolved in methanol complete isomerization to the *cis* isomer is observed at a rate much faster than the spontaneous isomerization observed in chloroform. The kinetics of this isomerization were studied by addition of a solution of the *trans* isomer in 4 parts chloroform to 96 parts methanol at 38°. At a complex concentration of *ca.* 5×10^{-4} *M* reproducible first order kinetics (in complex concentration) were observed which gave a pseudo first order rate constant, $k = 1.7 \times 10^{-4}$ s^{-1}. In more dilute solutions (*ca.* 5×10^{-5} *M*) a competing reaction obscures the kinetics. A new species with a u.v. band at 511 mμ is generated at a rate comparable to isomerization and the color of the solution turns from pale yellow to pink. A large excess of chloride ion (*e.g.* LiCl or $AsPh_4Cl$) eliminates the pink species. Addition of 1 mol of $AgPF_6$ per Pd to $[PdCl_2(Me_2o\text{-tolylP})_2]$ in methanol generates a deep red color (λ_{max} = 511 mμ). Likewise if the dimeric salt $[Pd_2Cl_2(Me_2o\text{-tolylP})_4]^{2+}2BF_4^-$ (pale yellow) is dissolved in methanol; the

For personal use only.

solution turns red within 10 min (λ_{max} = 511 mμ). Although we have been unable to isolate the red species all the above data are consistent with formation of a salt [PdCl(MeOH)(Me_2o-tolylP)$_2$]$^+Cl^-$. It seems likely therefore that the methanol catalyzed *trans*-to-*cis* isomerization also proceeds via the consecutive displacement mechanism (Scheme 2, L = MeOH; concentrations of **1** and **2** are very small).

The role of solvent molecules on the equilibrium energetics of *cis–trans* isomerization for planar palladium(II)–phosphine complexes and their probable role in the isomerization process has been recently discussed by Redfield and Nelson (15).

trans-$PdI_2(Me_2o$-tolylP$)_2$ Catalyzed *cis–trans* Isomerization of $PdCl_2(Me_2o$-tolylP$)_2$

On mixing *trans*-[$PdCl_2(Me_2o$-tolylP$)_2$] with an equimolar quantity of *trans*-[$PdI_2(Me_2o$-tolylP$)_2$] in $CDCl_3$ a statistical equilibrium between the dichloro, the diiodo, and the *trans* chloro-iodo mixed species was observed immediately (<2 min) (*i.e.* Cl_2:ClI:I_2 = 1:2:1).

In another experiment *ca.* 5% *trans*-[PdI_2-(Me_2o-tolylP$)_2$] was added to a 0.2 *M* solution of *trans*-[$PdCl_2(Me_2o$-tolylP$)_2$] in chloroform. Within 1 h resonances assignable to *cis*-[$PdCl_2$-(Me_2o-tolylP$)_2$] were observed and an equilibrium situation was reached in *ca.* 24 h (22°). A control solution initally containing *trans*-[$PdCl_2$-(Me_2o-tolylP$)_2$] only isomerized very slowly and did not reach equilibrium with the *cis* isomer within 5 d. In neither experiments were n.m.r. resonances assignable to the *cis* isomers of [$PdI_2(Me_2o$-tolylP$)_2$] and [PdClI(Me_2o-tolylP$)_2$] observed.

Similar studies were done with solutions of *cis*-[$PdCl_2(Me_2o$-tolylP$)_2$] and *trans*-[$PdI_2(Me_2o$-tolylP$)_2$]. Again no peaks due to *cis*-[$PdI_2(Me_2o$-tolylP$)_2$] or *cis*-[PdClI(Me_2o-tolylP$)_2$] were observed. Again a rapid statistical equilibration between the reactant *trans*-diiodo, *cis*-dichloro complexes and the *trans*-dichloro and mixed *trans*-iodo-chloro products occurred. Likewise the *trans*-diiodo complex catalyzed the *cis–trans* isomerization of the *cis*-dichloro complex. When *ca.* 5% *trans*-[$PdI_2(Me_2o$-tolylP$)_2$] was mixed with *cis*-[$PdCl_2(Me_2o$-tolylP$)_2$] (22°) in chloroform *cis–trans* equilibrium was reached within 4 h (22°). A control sample took more than 24 h to reach equilibrium.

It seems likely that replacement of chloride by the bulkier iodide ligand in the *cis* isomer (and to a lesser extent the *trans* isomer) will introduce considerable steric strain into the molecule. This will facilitate solvolysis of an iodide to give an ionic intermediate such as [$PdI(Me_2o$-tolylP$)_2$-($CHCl_3$)]$^+I^-$ which rapidly rearranges to the *trans* diodide. Rapid Cl–I exchange then gives the *trans* isomer of the dichloride.

Experimental

The Preparation of Compounds

cis- and *trans*-[$PdCl_2(Me_2RP)_2$] (R = *o*-tolyl, α-napthyl) were prepared from Me_2RP and Li_2PdCl_4 using the general method described by Jenkins and Shaw (6). The *trans*-dibromo and *trans*-diiodo complexes were prepared from the corresponding dichloro complex (either *cis* or *trans*) via the method of metathetical replacement. The *cis* or *trans* stereochemistry of the complexes was determined on the basis of ^1H and ^{13}C n.m.r. and vibrational spectroscopy studies (see Table 1 and discussion section). The following new complexes were isolated:

Dichloro-bis(dimethyl-o-tolylphosphine)palladium(II) was obtained initially as a mixture of *cis* and *trans* isomers (yield 60%).

Anal. Calcd. for $C_{18}H_{26}Cl_2P_2Pd$: C, 44.98; H, 5.43. Found: C, 44.9; H, 5.5.

Extraction of the *cis–trans* mixture with refluxing benzene followed by filtration of the combined extracts and evaporation of the filtrate to dryness gave a yellow solid. Recrystallization from chloroform–cyclohexane gave *trans*-dichlorobis(dimethyl-*o*-tolylphosphine)palladium(II) as yellow needles (41%), m.p. 174–191°. (The large melting point range is due to *trans*-to-*cis* isomerization in the melt.)

Extraction of the *cis–trans* mixture with refluxing ethanol followed by a similar work up of the extracts gave a very pale yellow solid. Recrystallization from chloroform–cyclohexane gave *cis*-dichlorobis(dimethyl-*o*-tolylphosphine)palladium(II) as pale yellow plates (60%), m.p. 186–190°.

trans-Dibromobis(dimethyl-o-tolylphosphine)palladium-(II) was isolated as orange prisms (55%), m.p. 205–210°.

Anal. Calcd. for $C_{18}H_{26}Br_2P_2Pd$: C, 37.89; H, 4.56. Found: C, 37.8; H, 4.65.

trans-Diiodobis(dimethyl-o-tolylphosphine)palladium-(II) was isolated as orange-red prisms (60%), m.p. 215–220°.

Anal. Calcd. for $C_{18}H_{26}I_2P_2Pd$: C, 32.53; H, 3.95. Found: C, 32.4; H, 3.9.

Dichlorobis(dimethyl-α-napthylphosphine)palladium(II) was isolated from the reaction of $2Me_2$NapthylP with Li_2PdCl_4 as a mixture of *cis* and *trans* isomers (80%).

Anal. Calcd. for $C_{24}H_{26}Cl_2P_2Pd$: C, 52.05; H, 4.74. Found: C, 52.2; H, 4.8.

Extraction with benzene gave the *trans* isomer as yellow prisms (20%), m.p. 190–195° (melts and recrystallizes as the *cis* isomer which then melts at 230–235°).

Extraction of the *cis–trans* mixture with ethanol gave the *cis* isomer as pale yellow needles (73%), m.p. 231–235°.

trans-Dibromobis(dimethyl-α-napthylphosphine)palladium(II) was isolated as orange prisms (50%), m.p. 205–210°.

Anal. Calcd. for $C_{24}H_{26}Br_2P_2Pd$: C, 44.85; H, 4.09. Found: C, 44.9; H, 4.1.

trans-Diiodobis(dimethyl-α-napthylphosphine)palladium(II) was isolated as red prisms (60%), m.p. 230–235°.

Anal. Calcd. for $C_{24}H_{26}I_2P_2Pd$: C, 39.13; H, 3.56. Found: C, 39.1; H, 3.4.

Chloro-tris(dimethyl-o-tolylphosphine)palladium(II) Hexafluorophosphate. A solution of dichlorobis(dimethyl-*o*-tolylphosphine)palladium(II) (0.53 g) and dimethyl-*o*-tolylphosphine (0.17 g) in dichloromethane (30 ml) was shaken with excess ammonium hexafluorophosphate (0.51 g) for 2 d. Filtration of the reaction mixture and evaporation of the filtrate to dryness gave a yellow solid. Recrystallization from dichloromethane–cyclohexane gave the required product as pale yellow microprisms (60%), m.p. 194–197°.

Anal. Calcd. for $C_{27}H_{39}ClF_6P_4Pd$: C, 43.37; H, 5.29. Found: C, 43.46; H, 5.56.

μ-Dichloro-tetrakis(dimethyl-o-tolylphosphine)dipalladium(II) Bis(tetrafluoroborate). Silver tetrafluoroborate (0.53 g) in acetone (20 ml) was added to a solution of dichlorobis(dimethyl-*o*-tolylphosphine)palladium(II) (0.11 g) in dichloromethane (5 ml). The reaction mixture was filtered to remove AgCl and the filtrate evaporated to dryness under reduced pressure. The resultant solid was recrystallized from dichloromethane–hexane to yield the required product as pale yellow microprisms (80%), decomp. > 160°.

Anal. Calcd. for $C_{36}H_{52}B_2Cl_2F_8P_4Pd_2$: C, 40.18; H, 4.88. Found: C, 40.2; H, 5.1.

Physical Measurements

^1H and ^{13}C n.m.r. spectra were recorded on Varian A56-60D and XL-100 spectrometers respectively. Far-infrared spectra were recorded on a Perkin–Elmer 180 instrument whilst Raman spectra were recorded on a Spex 1401 spectrometer. Ultraviolet spectra were recorded on a Bausch and Lomb spectronic 505 spectrometer.

All u.v. kinetic studies were carried out at $+38° \pm 0.1°$, using A.C.S. grade solvents which had been previously purged with "O_2-free" dry nitrogen for 1–3 h. The *cis* and *trans* isomers of dichloro-bis(dimethyl-*o*-tolylphosphine)palladium(II) were recrystallized three times from dichloromethane–hexane prior to use. Phosphines used as catalysts were handled under nitrogen and distilled (or recrystallized) immediately prior to use. The rates of *cis–trans* isomerization of dichloro-bis(dimethyl-*o*-tolylphosphine)palladium(II) were monitored at 327.5 mμ and a sharp isobestic point at 303 mμ was always observed. Kinetic runs were carried out in chloroform–cyclohexane with chloroform as the bulk solvent. The phosphine catalyst in 1 part cyclohexane at 38° was added to the palladium complex in 19 parts chloroform at 38°. This procedure was adopted as the phosphines used react very slowly with the chloroform.

The authors wish to thank the National Research Council of Canada for financial support of this investigation and one of us (D.G.C.) wishes to thank the Ontario Government for an Ontario Graduate Fellowship.

Bimolecular Reactions of Trapped Ions. VI. Ion–Molecule Reactions Involving CH_5^+ and $C_2H_5^+$ [1]

A. S. BLAIR AND A. G. HARRISON

Department of Chemistry, University of Toronto, Toronto 181, Ontario

Received December 8, 1972

The ion–molecule reactions in mixtures of methane with the polar molecules dimethyl-d_6 ether, ethylene-d_4 oxide, acetaldehyde-d_4, acetone, and acetonitrile have been studied using the trapped-ion technique. The CH_5^+ and $C_2H_5^+$ ions produced by ion–molecule reactions in methane react rapidly (predominantly by proton transfer) with the polar molecules; the rate coefficients range from 1.98×10^{-9} cm^3 molecule^{-1} s^{-1} ($C_2H_5^+ + C_2D_4O$) to 5.26×10^{-9} cm^3 molecule^{-1} s^{-1} ($CH_5^+ + (CH_3)_2CO$). The rate coefficients are much larger than those predicted from ion – induced dipole interactions only indicating that ion–dipole interactions play a large role in the collision process.

Rate coefficients for reaction of CH_3^+ and CH_4^+ with the polar molecules also have been measured. Most of these also are larger than predicted from ion – induced dipole interactions indicating in this case as well substantial effects due to ion–dipole interactions.

Les réactions ion–molécule dans des mélanges de méthane avec des molécules polaires du type diméthyléther-d_6, oxyde d'éthylène-d_4, acétone et acétonitrile, ont été étudiées par la technique de captage ionique. Les ions CH_5^+ et $C_2H_5^+$ issus des réactions ion–molécule dans le méthane réagissent rapidement (surtout par transfert de proton) avec les molécules polaires; l'intervalle des coefficients de vitesse va de 1.98×10^{-9} cm^3 molécule^{-1} s^{-1} ($C_2H_5^+ + C_2D_4O$) à 5.26×10^{-9} cm^3 molécule^{-1} s^{-1} ($CH_5^+ + (CH_3)_2CO$). Les coefficients de vitesse sont beaucoup plus grands que ceux prévus à partir des interactions ion-dipôle induit indiquant que les interactions ion–dipôle jouent un grand rôle dans le processus de collisions.

Les coefficients de vitesse pour la réaction de CH_3^+ et CH_4^+ avec les molécules polaires ont été aussi mesurés. La plupart d'entre eux sont également plus élevés que ceux prévus par les interactions ion–dipôle induit montrant aussi bien dans ce cas, des effets substantiels dûs aux interactions ion–dipôle.

Introduction

Since the pioneering work of Field and Munson (1) chemical ionization mass spectrometry (2) has become an important tool in the identification and structure elucidation of organic molecules. In this technique the ionization of interest results from ion–molecule reactions between the ions produced in the reactant gas at high pressures ($\sim$ 1 Torr) and the neutral additive present at low concentration. The most commonly used reactant gas has been methane, in which at high pressures the dominant ions are CH_5^+ and $C_2H_5^+$. Consequently, there is a large body of information available concerning the products formed when CH_5^+ and $C_2H_5^+$ react with organic molecules (2–4).

On the other hand there is very little quantitative data concerning the rates of reaction of CH_5^+ and $C_2H_5^+$ with polar organic molecules and what data exist often is contradictory (5, 6). The measurement of rate coefficients requires a knowledge of the ion source residence times of the reactant ions, which, at the high pressures used, are determined by ion mobilities and cannot be calculated simply from source dimensions and applied fields. Rather they must be calculated from mobility theory (5–9)[2] and it is known (9) that such calculated values can be substantially in error even for apparently ideal conditions.

The ion-trapping technique developed recently in this laboratory (11) permits variation of the ion source residence times in a known fashion over a wide range. The technique has proven (12, 13) to be particularly suited to the quantitative study of sequential ion–molecule reactions such as those producing and consuming CH_5^+

[1]Presented, in part, at the 20th Annual Conference on Mass Spectrometry, Dallas, Texas, June 1972. The work reported here will constitute part of the Ph.D. Thesis to be submitted to the University of Toronto by A. S. Blair.

[2]An alternative approach is to measure the residence times directly. Such measurements using a pulsed high pressure source have been reported recently by Meisels and co-workers (10).

and $C_2H_5^+$ in mixtures with methane. The present work reports the study of the ionic reactions occurring in mixtures of methane with the polar molecules acetaldehyde-d_4, ethylene-d_4 oxide, dimethyl-d_6 ether, acetone, and acetonitrile.[3] We have obtained rate coefficients and approximate product yields for reaction of CH_5^+ and $C_2H_5^+$ with the organic neutral and, in addition, rate coefficients for reaction of CH_3^+ and CH_4^+ with the organic neutral. With the exception of CH_3CN, the ion–molecule reactions occurring in the one-component polar molecule systems have been studied previously (13) using the ion-trapping technique.

Experimental

All experimental work was carried out using the mass spectrometer and ion trapping technique described previously (11). In this technique ions produced during a short pulse (~ 1 μs) of ionizing electrons of suitable energy are trapped in the negative space charge associated with a continuous electron beam of energy insufficient to cause ionization. A known and variable time after ion formation a positive voltage pulse is applied to the repeller electrode in the ion source to remove the ions for mass analysis. Delay times between the ionizing and withdrawal pulses (and, hence, reaction times) of up to 3.2 ms were used in the present work.

Figure 1 illustrates the results obtained with pure methane at ionizing electron energies sufficient to produce only CH_3^+ and CH_4^+ primary ions. The CH_3^+ and CH_4^+ ions react rapidly with methane to form $C_2H_5^+$ and CH_5^+ respectively (reactions 1 and 2).

[1] $$CH_3^+ + CH_4 \rightarrow C_2H_5^+ + H_2$$

[2] $$CH_4^+ + CH_4 \rightarrow CH_5^+ + CH_3$$

In agreement with previous studies (11, 14, 15) we find that these products do not react further with methane; consequently their relative intensities remain constant from 0.6 to 3.2 ms. When a small amount of a reactive additive is mixed with the methane the CH_5^+ and $C_2H_5^+$ intensities initially increase (reactions 1 and 2); however, they pass through a maximum and then decrease due to reaction with the additive (see, for example, Fig. 2). From the linear portions of the semi-logarithmic plots for the CH_5^+ and $C_2H_5^+$ ions the rate coefficients for reaction with the additive can be determined.

In the present work runs were carried out using CH_4 to additive concentration ratios ranging from 5:1 to 10:1 at approximately 0.5 to 1.0 $\times 10^{13}$ molecule cm^{-3} total source concentration for determination of the rate coefficients. Mixtures were made up accurately by pressure and at least three different mixtures were used to determine the rate data. The error limits quoted represent the mean deviation of the experimental results. Source pressures were not measured directly but were related to the inlet pressure through observation of the rate of reaction 2 in pure methane. All rate data are therefore relative to the established value (16) $k_2 = 1.20 \times 10^{-9}$ cm^3 molecule^{-1} s^{-1}. At the inlet and source pressures used the gas flow from the inlet system to the ion source and the gas flow out of the ion source both are molecular with the result that the gas composition in the ion source is the same as that in the inlet system.

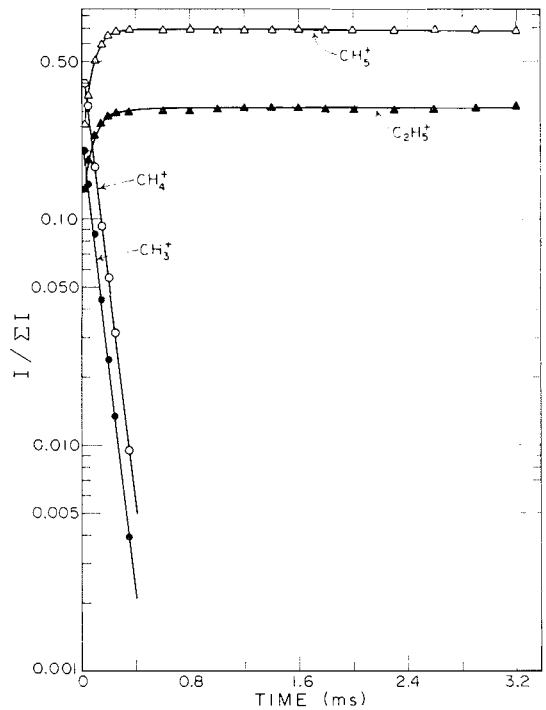

FIG. 1. Methane system $[CH_4] = 9.80 \times 10^{12}$ molecules cm^{-3}.

Additional runs were carried out using approximately 100:1 mixtures at low ionizing energies (CH_4^+ only significant primary ion from methane) to estimate the products formed by reaction of CH_5^+ with the additive. The approximate fractional yields were estimated from the slopes of the plots of the product ion intensities *vs.* $\Delta I_{CH_5^+}$, the CH_5^+ which had reacted, covering the experimental time range beyond 0.5 ms, *i.e.* after the primary methane ions had reacted completely. The yields from reaction of $C_2H_5^+$ were estimated in a similar fashion from runs at higher electron energy after substraction of the CH_5^+ yields.

In the mixtures CH_3^+ and CH_4^+ ions disappear not only by reactions 1 and 2 respectively, but also by reaction with the additive M. Considering reactions 1 and 3 for CH_3^+ we may derive equation 4 for the time dependence of $I_{CH_3^+}$.

[3] $$CH_3^+ + M \rightarrow \text{Products}$$

[4] $$\log I_{CH_3^+} = \frac{-(k_1[CH_4] + k_3[M])t}{2.303} + \text{constant}$$

[3]The deuterated compounds were used in the first three cases to avoid complications due to the $C_2H_5^+$–CHO^+ doublet at *m/e* 29.

*All rate coefficients cm^3 $molecule^{-1}$ s^{-1} × 10^9.
†See text.

From the slope of the plot of log $I_{CH_3^+}$ *vs.* t at constant source concentration we may estimate k_3 since k_1, $[CH_4]$, and [M] are known. A similar equation can be derived for the time dependence of $I_{CH_4^+}$ permitting evaluation of the rate coefficient for reaction of CH_4^+ with M. The value $k_1 = 1.15 \times 10^{-9}$ cm^3 $molecule^{-1}$ s^{-1} (11) was used. In the mixtures used approximately 10–30% of the CH_3^+ or CH_4^+ reacted with the additive, the remainder reacting with methane. Consequently larger errors are possible in the reported rate coefficients for reaction of CH_3^+ and CH_4^+.

All ion intensities in the following are reported as a fraction of the total recorded ion current.

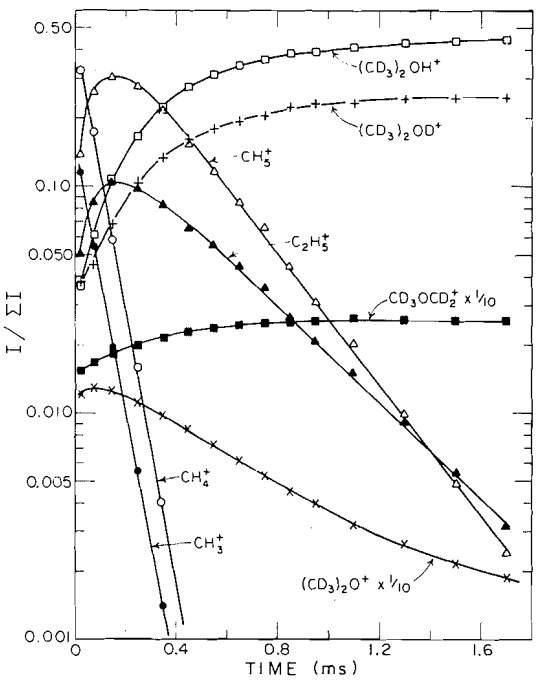

FIG. 2. Methane – dimethyl-d_6 ether system $[CH_4]$ = 9.77 × 10^{12} molecules cm^{-3}, $[(CD_3)_2O]$ = 1.01 × 10^{12} molecules cm^{-3}.

The methane used was Matheson Research grade. Acetaldehyde-d_4, ethylene-d_4 oxide, and dimethyl-d_6 ether were from Merck, Sharp and Dohme, Montreal. Acetonitrile and acetone were commercial samples of high purity. None of the samples showed detectable impurities in their mass spectra.

Results and Discussion

Methane – Dimethyl-d_6 Ether

Typical results obtained in a 9.68:1.00 CH_4–$(CD_3)_2O$ mixture are shown in Fig. 2. The non-linear semi-logarithmic plot for $(CD_3)_2O^+$ at longer times may not be real since this low intensity peak was slightly masked by the large $(CD_3)_2OH^+$ peak, making accurate intensity measurements difficult. Good linear plots for CH_5^+ and $C_2H_5^+$ are observed leading to the average rate coefficients for reaction with $(CD_3)_2O$ recorded in Table 1. The CH_5^+ datum is the average of ten determinations while the $C_2H_5^+$ datum is the average of eight determinations. Five different mixtures were used ranging from 10.21:1.00 to 4.48:1.00 CH_4:$(CD_3)_2O$.

The rate coefficients obtained for reaction of CH_3^+ and CH_4^+ with $(CD_3)_2O$ are presented in Table 2; the former is the average of eight determinations while the latter is the average of thirteen determinations. The previous ion-trapping study (13) of the reactions in $(CH_3)_2O$ has established the reaction

[5] $CH_3^+ + (CH_3)_2O \rightarrow CH_3OCH_2^+ + CH_4$

with a rate coefficient of 2.0 ± 0.3 × 10^{-9} cm^3 $molecule^{-1}$ s^{-1}. The present value for the rate coefficient for the $CH_3^+ + (CD_3)_2O$ reaction is in agreement within the combined experimental error. The increase in $CD_3OCD_2^+$ appears too great to be attributed entirely to reaction of

CH_3^+ and it appears likely that CH_4^+ produces this ion as well as $(CD_3)_2O^+$, which increases at short reaction times, by charge transfer.[4] Proton transfer from CH_4^+ to $(CD_3)_2O$ may also occur. These reactions are all thermochemically permitted,[5] however it is not possible to establish their relative importance.

Figure 3*a* shows the variation of ion intensities with time in a 107:1.0 CH_4–$(CD_3)_2O$ mixture at low ionizing energies (CH_4^+ only primary ion from methane) covering the time range from 0.5 to 2.5 ms. Figure 3*b* shows the product ion intensities plotted *vs.* $\Delta I_{CH_5^+}$, the CH_5^+ which has reacted. $\Delta I_{CH_5^+} = I_{CH_5^+}\ (t = 0.5\text{ ms}) - I_{CH_5^+}\ (t)$. From the slopes of the linear plots in Fig. 3*b* we estimate that 84% of the CH_5^+ reaction produces $(CD_3)_2OH^+$, 7% produces $CD_3OCD_2^+$, and 9% produces $(CD_3)_2O^+$ or some other species which subsequently forms $(CD_3)_2OD^+$.

The first two products presumably are formed by the reaction sequence[6]

[6] $$CH_5^+ + (CD_3)_2O \rightarrow (CD_3)_2OH^+ + CH_4 \qquad \Delta H = -59\text{ kcal mol}^{-1}$$

[7] $$(CD_3)_2OH^+ \rightarrow CD_3OCD_2^+ + HD \qquad \Delta H = +19\text{ kcal mol}^{-1}$$

[4]In the pure ether $CD_3OCD_2^+$ is neither produced nor does it react to a significant extent at the electron energy employed (13).

[5]Thermochemical data are taken from ref. 17 unless otherwise noted. Heats of formation of deuterium containing species are assumed to be identical to the species containing the lighter isotope.

[6]Thermochemical calculations employ $\Delta H_f((CH_3)_2OH^+) = 136$ kcal mol^{-1}, derived from the proton affinity, *PA* ($(CH_3)_2O = 186$ kcal mol^{-1} (18)), $\Delta H_f(CH_3OCH_2^+) = 155$ kcal mol^{-1} (19), and $\Delta H_f(CH_5^+) = 221$ kcal mol^{-1} (20), ($PA(CH_4) = 127$ kcal mol^{-1}).

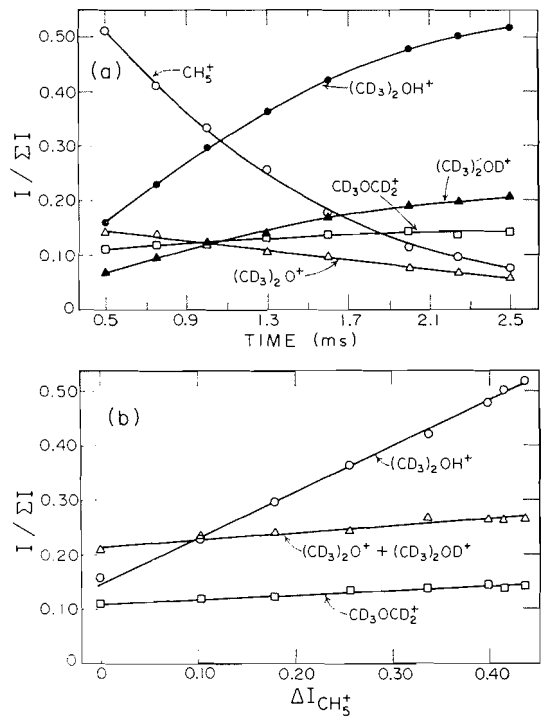

FIG. 3. Methane – dimethyl-d_6 ether system [CH_4]:[$(CD_3)_2O$] = 107:1.0, total source concentration ~2.5 × 10^{13} molecules cm^{-3}. (*a*) Ion intensities *vs.* time. (*b*) Product ion intensities *vs.* $\Delta I_{CH_5^+}$.

The low yield of $CD_3OCD_2^+$ suggests that little of the exothermicity of reaction 6 is retained as internal excitation of the product ion to assist in surmounting the energy barrier for reaction 7.

The increase in the sum $(CD_3)_2O^+ + (CD_3)_2OD^+$, which experimentally is an increase in $(CD_3)_2OD^+$, indicates the formation of a precursor to this ion which must be either $(CD_3)_2O^+$ or CDO^+ (13). Formation of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

$(CD_3)_2O^+$, reaction 8, is quite endothermic and it is probable that at least part of the reaction of CH_5^+ produces CDO^+ by the exothermic reaction 6 followed by reaction 9.

[8] $CH_5^+ + (CD_3)_2O \rightarrow (CD_3)_2O^+ + CH_4 + H$
$\Delta H = +43$ kcal mol^{-1}

[9] $(CD_3)_2OH^+ \rightarrow CDO^+ + HD + CD_4$
$\Delta H = +43$ kcal mol^{-1} [7]

The $C_2H_5^+$ ion reacted with the ether entirely (>95%) by proton transfer at the pressures used in our experiments.

Methane – Ethylene-d_4 Oxide

Figure 4 shows typical results obtained in a 4.84:1.00 CH_4–C_2D_4O mixture. The rate coefficients for reaction of CH_5^+ and $C_2H_5^+$ with the oxide, calculated from the linear portions of the semi-logarithmic plots, are given in Table 1. Each value is the average of five determinations in three different mixtures.

The average rate coefficients determined for reaction of CH_3^+ (four determinations) and CH_4^+ (seven determinations) are summarized in Table 2. The products of the reactions are not clearly established, however $C_2D_3O^+$ and $C_2D_4O^+$ show substantial initial increases in intensity showing that they are products of ion–molecule reactions. Similarly the plot for CDO^+ shows an initial slight increase and curvature consistent with its formation in low yield. It is probable that CH_3^+ reacts with C_2D_4O predominantly by D^- abstraction to produce $C_2D_3O^+$ while CH_4^+ reacts by charge transfer to produce CDO^+ and $C_2D_4O^+$; CH_4^+ may also proton transfer to C_2D_4O. All these reactions are thermochemically permitted.

Figure 5*a* shows the variation of ion intensities with time from 0.5 to 2.0 ms in a 116:1.0 CH_4–C_2D_4O mixture under conditions where CH_4^+ was the only significant primary ion from methane. The plot of product ion intensities *vs.* $\Delta I_{CH_5^+}$ derived from 5*a* is shown in Fig. 5*b*. There is a small but definite increase[8] in $C_2D_4O^+$

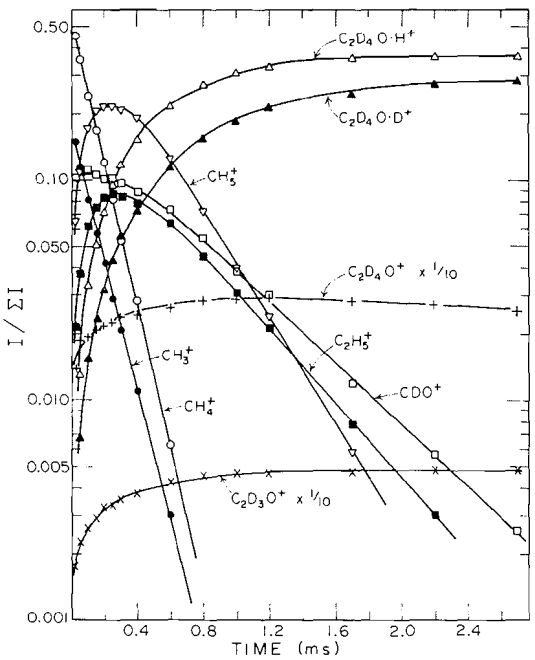

FIG. 4. Methane – ethylene-d_4 oxide system $[CH_4] = 4.50 \times 10^{12}$ molecules cm^{-3}, $[C_2D_4O] = 0.93 \times 10^{12}$ molecules cm^{-3}.

[7]Calculated using $\Delta H_f(CDO^+) = 197$ kcal mol^{-1} (21).

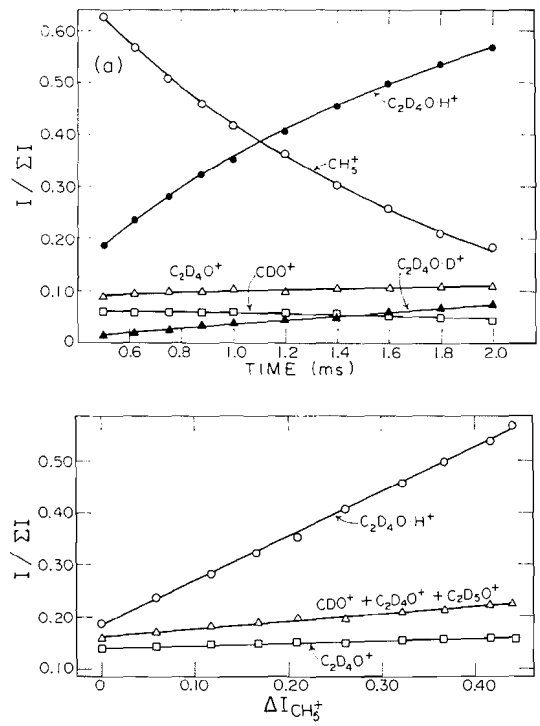

FIG. 5. Methane – ethylene-d_4 oxide system $[CH_4]$: $[C_2D_4O] = 116:1.0$, total source concentration ~2.5 × 10^{13} molecules cm^{-3}. (*a*) Ion intensities *vs* time. (*b*) Product ion intensities *vs.* $\Delta I_{CH_5^+}$.

[8]The increase is detectable because $C_2D_4O^+$ reacts only very slowly with C_2D_4O (13) and, apparently, is unreactive with methane.

(~0.05 fractional yield) even though reaction 10 is strongly endothermic.

[10] $CH_5^+ + C_2D_4O \rightarrow C_2D_4O^+ + CH_4 + H$
$\Delta H = +57$ kcal mol^{-1}

The increase cannot be due to formation of other ions which subsequently react to form $C_2D_4O^+$ since no such reactions were detected in the study of the ionic reactions in ethylene oxide (13). The major product is $C_2D_4O{\cdot}H^+$ (~0.84 fractional yield) with a smaller yield (~0.11 fractional yield) of CDO^+ which reacts rapidly (13) to produce $C_2D_4OD^+$. The $C_2D_4O{\cdot}H^+$ and CDO^+ products are formed by the reaction sequence[9]

[11] $CH_5^+ + C_2D_4O \rightarrow C_2D_4OH^+ + CH_4$
$\Delta H = -56$ kcal mol^{-1}

[12] $C_2D_4OH^+ \rightarrow CDO^+ + CD_3H$
$\Delta H = +9$ kcal mol^{-1}

The $C_2H_5^+$ ion reacts entirely (>95%) by proton transfer under our experimental conditions.

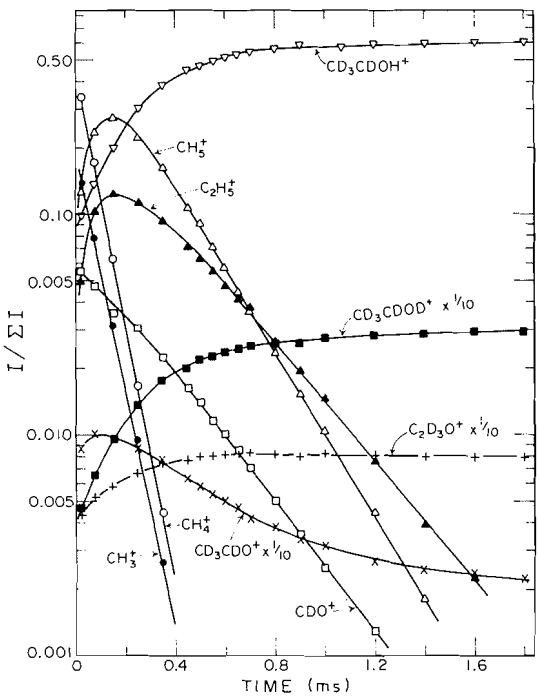

FIG. 6. Methane – acetaldehyde-d_4 system [CH_4] = 9.15×10^{12} molecules cm^{-3}, [CD_3CDO] = 0.99×10^{12} molecules cm^{-3}.

[9]Thermochemical calculations employ $\Delta H_f(C_2H_4O{\cdot}H^+) = 170$ kcal mol^{-1} (18).

Methane – Acetaldehyde-d_4

Typical results obtained in a 9.26:1.00 CH_4–CD_3CDO mixture are shown in Fig. 6. The non-linear semi-logarithmic plot for CD_3CDO^+ at longer reaction times may be an experimental artifact arising from an incorrect estimation of the overlap with the large CD_3CDOH^+ ion signal. Five different mixtures were studied leading to the average rate constants (nine determinations in each case) recorded in Table 1.

The rate coefficients derived for the reactions of CH_3^+ and CH_4^+ with CD_3CDO are recorded in Table 2. The former is the average of three determinations while the latter is the average of eight determinations, each in three different mixtures. Previous trapped-ion experiments (13) have shown that CH_3^+ reacts with CH_3CHO with a rate coefficient of $2.49 \pm 0.05 \times 10^{-9}$ cm^3 molecule^{-1} s^{-1}, predominantly by reaction 13.

[13] $CH_3^+ + CH_3CHO \rightarrow C_2H_3O^+ + CH_4$

The present result for the reaction $CH_3^+ + CD_3CDO$, $k = 3.10 \pm 0.3 \times 10^{-9}$ cm^3 molecule^{-1} s^{-1} is slightly larger but has a large error associated with it. The reaction of CH_4^+ with CD_3CDO produces both CD_3CDO^+ (reaction 14) and possibly CDO^+ (reaction 15) as shown by the initial curved regions of the semi-logarithmic plots for these ions. Proton transfer (reaction 16) is also possible.

[14] $CH_4^+ + CD_3CDO \rightarrow CD_3CDO^+ + CH_4$
$\Delta H = -56$ kcal mol^{-1}

[15] $CH_4^+ + CD_3CDO \rightarrow CDO^+ + CD_3 + CH_4$
$\Delta H = -22$ kcal mol^{-1}

[16] $CH_4^+ + CD_3CDO \rightarrow CD_3CDOH^+ + CH_3$
$\Delta H = -57$ kcal mol^{-1}

Figure 7*a* shows the variation of ion intensities over the time range 0.5 to 2.0 ms in a 125:1.0 CH_4–CD_3CDO mixture at an ionizing electron energy such that CH_3^+ production from methane was negligible. The derived plots of ion intensities *vs.* $\Delta I_{CH_5^+}$ are shown in Fig. 7*b*. From these plots we estimate as fractional yields from the reaction $CH_5^+ + CD_3CDO$: CD_3CDOH^+, 0.94; $C_2D_3O^+$, 0.02_5; CDO^+ or CD_3CDO^+, 0.03_5. (The latter two cannot be distinguished since both react to form CD_3CDOD^+.)

The CD_3CDOH^+ and $C_2D_3O^+$ products probably originate from the reaction sequence

For personal use only.

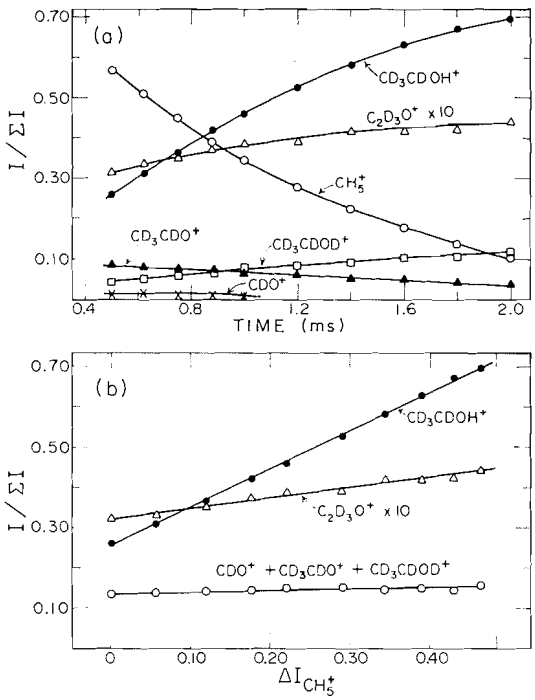

FIG. 7. Methane–acetaldehyde-d_4 system, $[CH_4]$: $[CD_3CDO] = 125:1.0$, total source concentration $\sim 2.5 \times 10^{13}$ molecules cm^{-3}. (*a*) Ion intensities *vs.* time. (*b*) Product ion intensities *vs.* $\Delta I_{CH_5^+}$.

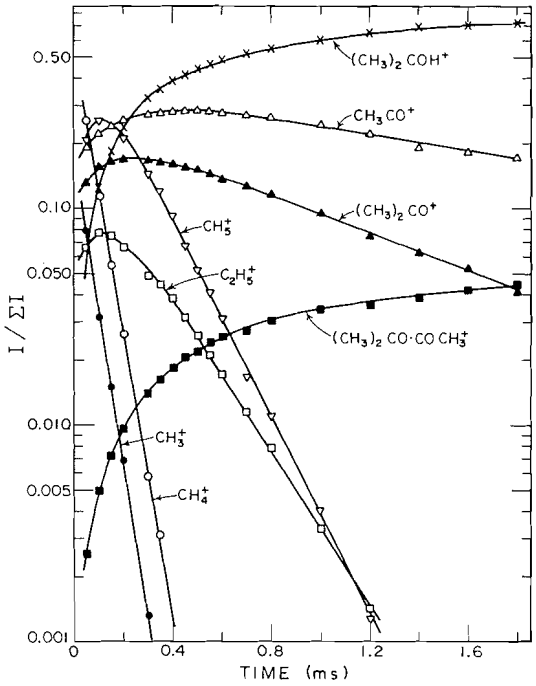

FIG. 8. Methane–acetone system, $[CH_4] = 9.72 \times 10^{12}$ molecules cm^{-3}, $[(CH_3)_2CO] = 1.00 \times 10^{12}$ molecules cm^{-3}.

[17] $CH_5^+ + CD_3CDO \rightarrow CD_3CDOH^+ + CH_4$
$\Delta H = -56$ kcal mol^{-1}

[18] $CD_3CDOH^+ \rightarrow CD_3CO^+ + HD$
$\Delta H = +9$ kcal mol^{-1}

The low yield of $C_2D_3O^+$ again suggests that the ionic product of the proton transfer reaction contains little of the exothermicity of the reaction as internal excitation.

Production of CD_3CDO^+ and CDO^+ cannot be separated since both react rapidly with CD_3CDO to form CD_3CDOD^+ (13).[10] Formation of CD_3CDO^+ by the charge transfer reaction 19 is quite endothermic while formation of CDO^+ by the exothermic reaction 17 followed by reaction 20 is thermochemically possible.

[19] $CH_5^+ + CD_3CDO \rightarrow CD_3CDO^+ + CH_4 + H$
$\Delta H = +49$ kcal mol^{-1}

[20] $CD_3CDOH^+ \rightarrow CDO^+ + CD_3H$
$\Delta H = +36$ kcal mol^{-1}

The $C_2H_5^+$ ion reacts essentially completely (>95%) by proton transfer to CD_3CDO.

Methane–Acetone

Figure 8 illustrates typical results obtained in a 9.72:1.00 CH_4–$(CH_3)_2CO$ mixture. The rate coefficients for reaction of CH_5^+ and $C_2H_5^+$ with acetone determined from the linear portions of the semi-logarithmic plots are recorded in Table 1. Each value is the average of five determinations in three different mixtures.

The rate coefficients estimated for reaction of CH_3^+ and CH_4^+ with acetone are recorded in Table 2. The CH_3^+ result is the average of four determinations while the CH_4^+ result is the average of six determinations both employing three different mixtures. The plots of the CH_3CO^+ and $(CH_3)_2CO^+$ ion intensities both show initial increases indicating that these ions are produced by reaction of CH_3^+ and CH_4^+ while $(CH_3)_2COH^+$ production by proton transfer from CH_4^+ is also possible. The thermochemically permitted reactions are[11]

[10]On the other hand CD_3CO^+ is unreactive with CD_3CDO (13).

[11]Thermochemical calculation employs $\Delta H_f((CH_3)_2COH^+) = 125$ kcal mol^{-1} (22, 23). A value of 111 kcal mol^{-1} has also been reported (24).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

[21] $CH_3^+ + (CH_3)_2CO \rightarrow (CH_3)_2CO^+ + CH_3$
$\Delta H = -4$ kcal mol^{-1}

[22] $CH_4^+ + (CH_3)_2CO \rightarrow (CH_3)_2CO^+ + CH_4$
$\Delta H = -69$ kcal mol^{-1}

[23] $CH_4^+ + (CH_3)_2CO \rightarrow CH_3CO^+ + CH_3 + CH_4$
$\Delta H = -55$ kcal mol^{-1}

[24] $CH_4^+ + (CH_3)_2CO \rightarrow (CH_3)_2COH^+ + CH_3$
$\Delta H = -64$ kcal mol^{-1}

Figure 9*a* shows the variation of ion intensities with time between 0.5 and 2.0 ms in a 157:1.0 CH_4–$(CH_3)_2CO$ mixture where CH_5^+ is the only reactant ion produced from methane. Figure 9*b* shows the plot of product ion intensities *vs.* $\Delta I_{CH_5^+}$ derived from this data. The $(CH_3)_2COH^+$ product accounts for ~98% of the reaction of CH_5^+ while CH_3CO^+ accounts for ~2% of the reaction; in addition there may be a very small yield of $(CH_3)_2CO^+$. The yields of CH_3CO^+ and $(CH_3)_2CO^+$ are lower limits while that for $(CH_3)_2COH^+$ is an upper limit since both $(CH_3)_2CO^+$ and CH_3CO^+ react with acetone to form $(CH_3)_2COH^+$.[12] The reactions definitely occurring are

[25] $CH_5^+ + (CH_3)_2CO \rightarrow (CH_3)_2COH^+ + CH_4$
$\Delta H = -62$ kcal mol^{-1}

[26] $(CH_3)_2COH^+ \rightarrow CH_3CO^+ + CH_4$
$\Delta H = +10$ kcal mol^{-1}

The $C_2H_5^+$ ion reacts with acetone entirely (>95%) by proton transfer at the pressures we have used.

Methane–Acetonitrile

Figure 10 shows typical results obtained in a 9.78:1.00 CH_4–CH_3CN mixture. The rate coefficients for reaction of CH_5^+ and $C_2H_5^+$ derived from the linear portions of the semi-logarithmic plots are given in Table 1. Each value is the average of four determinations in three different mixtures. The only product detected from reaction of either CH_5^+ or $C_2H_5^+$ was protonated acetonitrile, CH_3CNH^+. Since the proton affinity of CH_3CN is 186 kcal mol^{-1} (23) while the proton affinities of CH_4 and C_2H_4 are 127 and 160 kcal mol^{-1}, respectively, these reactions are to be expected.

The rate coefficients determined for reaction of CH_3^+ and CH_4^+ with CH_3CN are given in Table 2. The CH_3^+ result is the average of four determinations while the CH_4^+ result is the average of eight determinations. The only products clearly identified by initial ion intensity increases are CH_2CN^+ and CH_3CNH^+. The former is probably formed by the hydride-transfer reaction 27.

[27] $CH_3^+ + CH_3CN \rightarrow CH_2CN^+ + CH_4$
$\Delta H = -1$ kcal mol^{-1}

There is no initial increase in the CH_3CN^+ intensity and we conclude that this ion cannot be formed to any significant extent by charge transfer from CH_4^+ even though the charge transfer is exothermic. It appears that CH_4^+ reacts entirely by proton transfer to form CH_3CNH^+. The CH_3CN^+ disappears in the mixtures more rapidly than can be accounted for[13] by reaction with CH_3CN and we estimate

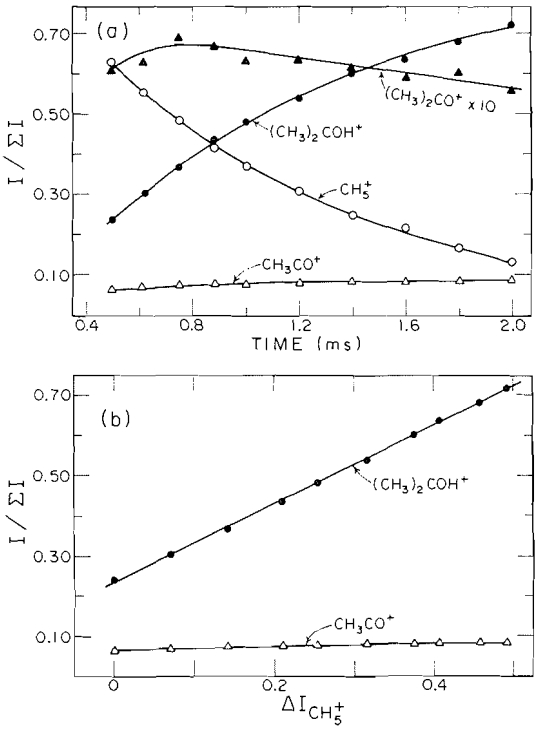

FIG. 9. Methane–acetone system, $[CH_4]:[(CH_3)_2CO] = 157:1.0$, total source concentration ~2.5×10^{13} molecules cm^{-3}. (*a*) Ion intensities *vs.* time. (*b*) Product ion intensities *vs* $\Delta I_{CH_5^+}$.

[12] $(CH_3)_2CO^+$ also reacts (13) with acetone to produce $(CH_3)_2CO{\cdot}COCH_3^+$ which is shown as a product ion in Fig. 8.

[13] In pure CH_3CN we find that CH_3CN^+ reacts with a total rate constant of $1.77 \pm 0.1 \times 10^{-9}$ cm^3 molecule^{-1} s^{-1} predominantly to form CH_3CNH^+. The rate constant is in reasonable agreement with previous values of $1.9_6 \times 10^{-9}$ cm^3 molecule^{-1} s^{-1} (16) and $2.0_1 \times 10^{-9}$ cm^3 molecule^{-1} s^{-1} (25).

For personal use only.

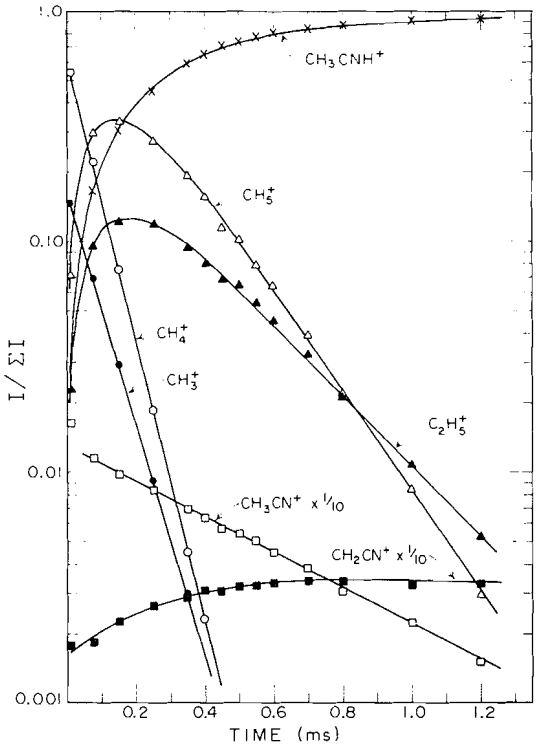

FIG. 10. Methane–acetonitrile system $[CH_4] = 9.59 \times 10^{12}$ molecules cm^{-3}, $[CH_3CN] = 0.98 \times 10^{12}$ molecules cm^{-3}.

for the reaction

[28] $CH_3CN^+ + CH_4 \rightarrow CH_3CNH^+ + CH_3$
$\Delta H = -51$ kcal mol^{-1}

a rate coefficient of $0.3_4 \pm 0.1 \times 10^{-9}$ cm^3 $molecule^{-1}$ s^{-1}.

Comparison of Experiment with Theory

The experimental rate coefficients tabulated in Tables 1 and 2 are, with few exceptions, much larger (at least a factor of two) than the rate coefficients calculated from a collision model which assumes only ion-induced dipole interactions (26). The most noticeable exceptions are the reactions of CH_3^+ with ethylene-d_4 oxide and with acetaldehyde where the experimental results are in reasonable agreement with the values, 1.44×10^{-9} and 1.48×10^{-9} cm^3 $molecule^{-1}$ s^{-1}, respectively, calculated from the ion-induced dipole model.

For the remaining reactions it is clear that ion–dipole interactions must play an important role. This is particularly evident for the proton-transfer results in Table 1 where there is an established trend for the rate coefficient to increase with the dipole moment of the neutral molecule. We have therefore calculated rate coefficients from a model which includes ion–dipole interactions. It has been shown previously (16) that if the dipole "locks-in" as the positive charge approaches the microscopic rate constant $k(g)$ as a function of the relative velocity, g, of the colliding pair is given by

$$[29] \qquad k(g) = 2\pi e\left(\frac{\alpha}{\mu}\right)^{1/2} + \frac{2\pi e\rho}{g\mu}$$

where e is the electronic charge, α the polarizability of the neutral, ρ the dipole moment of the neutral molecule, and μ the reduced mass of the colliding pair. From 29 we may derive (27), for the rate constant $k(E)$ at a relative kinetic energy of the two reactants, E, the expression

$$[30] \qquad k(E) = 2\pi e\left(\frac{\alpha}{\mu}\right)^{1/2} + \pi e\rho\left(\frac{2}{E\mu}\right)^{1/2}$$

Previous experiments (11) have shown that in the ion trapping technique the reactant ions have an average kinetic energy of 0.3 to 0.5 eV (lab scale). This corresponds to an approximate relative kinetic energy (center of mass) of 0.2 eV. Accordingly we have calculated from equation 30 rate coefficients for this value of E. These are listed in Tables 1 and 2 under the heading k(calcd). The calculated values are a factor of two to three higher than those obtained including the ion-induced dipole term only and are, in most cases, in moderately good agreement with the experimental values.

For two reasons this agreement cannot be taken to indicate anything more than the fact that ion–dipole forces are important. First the calculated values depend strongly on E which is not known accurately. Second, the calculations are based on a "locked-in" dipole model which is known (28–30) from trajectory calculations to be a highly simplified and naive model. However, the trajectory calculations have shown that even if the dipole does not "lock-in" ion–dipole interactions can cause a significant increase in the rate coefficients.

Conclusions

The present work has shown that the CH_5^+ and $C_2H_5^+$ ions produced by ion–molecule reactions in methane rapidly proton-transfer to polar organic molecules. The rapidity of these reactions is undoubtedly one of the reasons why chemical ionization mass spectrometry using

methane has been so successful since the rapid reactions will result in a high sensitivity for the technique. The rates of the proton transfer reactions depend on ion–dipole interactions with respect to both the magnitude of the rate constant and the trend among a series of polar molecules.

The above observations concerning ion–dipole effects are in contrast to the conclusions reached by Hellner and Sieck (24). They observed that proton-transfer reactions from $t\text{-}C_4H_9^+$ (produced by photoionization of neopentane) to acetone, ammonia, and various methyl amines all had rate coefficients which could be explained by ion-induced dipole interactions only and they concluded that ion–dipole effects were unimportant. There are a number of differences between our experiments and their's which may be important. Their reactant ions are produced by low energy photons and have thermal kinetic energies, while our reactant ions are produced by exothermic ion–molecule reactions and have $\sim$0.4 eV kinetic energy. In addition the reactions studied by Hellner and Sieck are approximately thermoneutral while those we have studied are strongly exothermic. We are continuing our studies in an effort to elucidate the effects of internal energy, kinetic energy, and reaction exothermicity on the rates of proton transfer reactions involving polar molecules.

The Photolysis of 3,3,3-Trifluoropropyne

D. F. HOWARTH AND A. G. SHERWOOD

Department of Chemistry, Simon Fraser University, Burnaby 2, British Columbia

Received July 13, 1971[1]

The photolysis of 3,3,3-trifluoropropyne has been studied in the 190 nm wavelength region. The primary process is the dissociation of the compound to give ethynyl and trifluoromethyl radicals. In the presence of propane, these radicals undergo abstraction reactions to give fluoroform and acetylene. The presence of nitric oxide also results in the trapping of the CF_3 radical as CF_3NO. Ethynyl radicals are not trapped by NO.

La photolyse du trifluoro-3,3,3 propyne a été étudiée dans la zone de longueur d'onde 190 nm. Le processus primaire est la dissociation du composé en radicaux éthynyle et trifluorométhyle. En présence de propane, ces radicaux arrachent l'hydrogène et conduisent à l'acéthylène et au fluoroforme. La présence de nitroxyde a pour résultat également de piéger le radical CF_3 en CF_3NO. Les radicaux éthynyles ne sont pas piégés par NO. [Traduit par le journal]

Can. J. Chem., 51, 1655 (1973)

Introduction

Investigations of the gas phase photochemistry of alkynes have been almost inclusively confined to studies of acetylene and propyne. It has been suggested that, in the quartz-u.v. region, there are two primary processes, the formation of excited molecules and, as well, the formation of ethynyl radicals and H-atoms (1, 2). The mercury photosensitized decomposition of acetylene has also been studied (3–11) and the same primary products have been suggested although there is some disagreement about the extent of involvement of excited acetylene molecules.

Propyne has been photolyzed at wavelengths near the long wavelength limit of its u.v. absorption (12, 13) and at 147 nm (14). In the former case, propargyl radicals were observed by e.s.r. techniques suggesting the primary process

[1] $$CH_3\text{-}C{\equiv}CH + h\nu \rightarrow H\cdot + \cdot CH_2\text{-}C{\equiv}CH$$

At the shorter wavelength some elimination of molecular hydrogen is indicated.

The mercury photosensitization of propyne was studied by Kebarle (7). The primary product was suggested to be an excited molecule which decomposed to give a propargyl radical and an H-atom as in [1].

There was no indication in either the photosensitized reaction or in the direct photolyses of C—C bond cleavage to give methyl and ethynyl radicals, *i.e.*

[2] $$CH_3{-}C{\equiv}CH \xrightarrow{h\nu \text{ or } Hg(6^3P_1)} \cdot CH_3 + \cdot C{\equiv}CH$$

A study of the photolysis of 3,3,3-trifluoropropyne in the vapor phase was undertaken in order to determine if this type of reaction would take place when the methyl hydrogen atoms were replaced by far less labile fluorine atoms.

Experimental

Materials

Trifluoropropyne, obtained from Peninsular Chemresearch Co., was purified by gas chromatography before use. Nitric oxide, from Matheson of Canada Limited, was distilled prior to use to remove higher oxides of nitrogen. Propane, also from Matheson, was used without further purification. Butadiyne was prepared according to the method of Georgieff and Richard (15). Other chemicals required for calibration of the gas chromatograph were obtained from commercial suppliers.

Apparatus

Irradiations were carried out at 25 ± 2 °C in a Suprasil quartz cell, 10 cm long and 5 cm in diameter. The light source was an unfiltered Hanovia Model 30620 medium pressure mercury arc. Manipulations of reactants and products were done in a conventional high vacuum apparatus. Analysis was done by temperature programmed gas chromatography using a 6 ft × 3/10 in. I.D. Poropak Q column. The chromatograph was fitted with a trapping system so that peaks could be trapped for identification by i.r., n.m.r., and mass spectrometry.

Results and Discussion

Photolysis of Trifluoropropyne

Trifluoropropyne does not absorb at wavelengths greater than about 220 nm. Below this

[3] 
the effective absorption increases to the transmission limit of the cell at about 180 nm. Examination of the emission spectrum of the lamp indicates that the radiation responsible for photolysis is a pair of low intensity lines at 195 and 197 nm. The main product of this reaction is an involatile solid polymer. The only volatile product observed was identified by n.m.r. and by mass spectrometry as the trimer of trifluoropropyne 1,3,5-tris(trifluoromethyl)-benzene. In the absence of an authentic sample of this material, it was not determined quantitatively but the gas chromatographic peak areas indicated that the rates of formation dropped with extent of reaction presumably because of a decrease in the absorbed light intensity as the polymer deposited on the cell.

The origin of this compound is probably the type of reaction which was originally suggested by Cashion and LeRoy (4), *i.e.*, the successive addition of three propyne molecules to a radical followed by cyclization and elimination of the radical (see eq. 3).

The 1,3,5-isomer will be formed whether the initial attack is at the C-1 or -2 position provided only that subsequent attacks are the same as the first one. There was no indication of the formation of other isomers of the benzene so the attack must have been specific in this sense. These observations give no clue to the identity of the initiating radical so the reaction was conducted in the presence of propane as a source of abstractable hydrogen atoms in order to identify the radicals present.

Photolysis of CF_3—C≡CH with Added Propane

A pressure of 2.61 Torr of substrate was photolyzed for 1 h with various pressures of added propane. The propane had the effect of reducing the yield of the benzene while new products, CF_3H, C_2H_2, C_2HF, and 1,1,1,4,4,4-hexafluoro-2-butene were formed.

These results are shown graphically in Fig. 1. Fluoroacetylene is not indicated as its yield is very nearly constant at 0.29 μmol over the pressure of propane used (2). The yield of the trimer is given relative to the yield in the absence of propane.

The CF_3H and C_2H_2 indicate the presence of $CF_3\cdot$ and $C_2H\cdot$ radicals and the following primary process is suggested.

[4] $$CF_3 - C{\equiv}CH + h\nu \rightarrow CF_3\cdot + C_2H\cdot$$

followed by abstraction reactions.

[5] $$CF_3\cdot + C_3H_8 \rightarrow CF_3H + C_3H_7\cdot$$

[6] $$C_2H\cdot + C_3H_8 \rightarrow C_2H_2 + C_3H_7\cdot$$

The decrease in the benzene yield suggests that one of these radicals initiates reaction 3.

The hexafluorobutene must arise from the reaction of CF_3 radicals with substrate to form substituted vinyl radicals which subsequently abstract hydrogen from the propane (eqs. 7 and 8). The CF_3 radical thus adds, in the expected

[7] 
[8] 
anti-Markovnikov fashion, to give a 2-butenyl radical. The product of the subsequent abstraction reaction was shown to be exclusively the

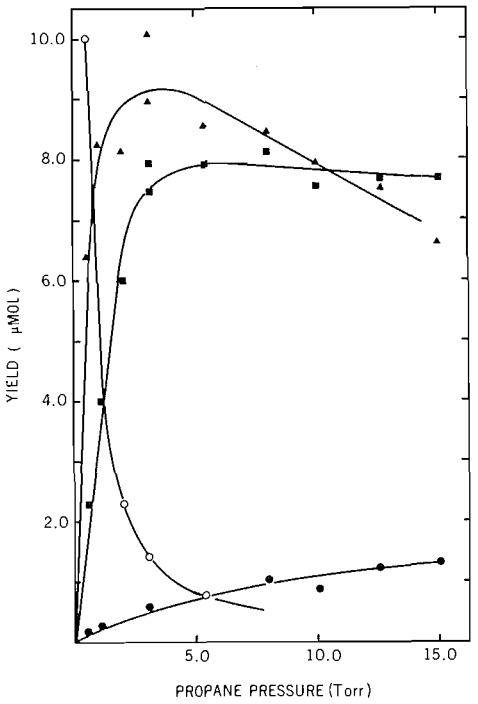

FIG. 1. Product yields as a function of propane pressure: ▲, hexafluoro-2-butene; ●, CF_3H; ■, C_2H_2; ○, 1,3,5-tris(trifluoromethyl) benzene. Pressure of CF_3—C≡CH = 2.61 Torr.

trans-isomer by comparison of its i.r. spectrum with that published by Henne and Nager (16) and by A.P.I. (17). As pointed out by Singer (18), this observation may not be interpreted unambiguously. It may indicate a *trans*-addition of the trifluoromethyl radical followed by abstraction before inversion of the vinyl radical could take place. The other possibility is that the butenyl radical rapidly assumes the more stable *trans*-isomeric form before abstraction takes place.

At pressures of propane greater than 5 Torr, most ethynyl radicals abstract hydrogen to give acetylene while few CF_3 radicals abstract to give CF_3H. Most CF_3 radicals add to substrate to eventually give the hexafluorobutene. This fact makes it possible to calculate a very approximate value of k_5/k_7 from the yields of CF_3H and the butene at low propane pressures. The value obtained is 0.1. Unfortunately there are no values in the literature with which to compare this approximation.

These pressures of propane depress the yield of the trimer to a very small value which suggests that the species which initiates reaction 3 to form the trimer is the ethynyl radical.

The fact that the yield of C_2H_2 is less than the yield of CF_3H + CF_3—CH=CH—CF_3 at intermediate propane pressures suggests that, under those conditions, some low-yield product of ethynyl radical reactions had escaped detection.

Photolysis of CF_3—C≡CH in the Presence of NO

The presence of NO inhibits the formation of the trimer and results in new products: CF_3NO, CF_3CN, butadiyne, and smaller amounts of C_2HF, C_2H_2, N_2O, CO_2, and an unidentified nitroso compound. Yields as a function of NO pressure are indicated in Figs. 2 and 3.

Comparison of emission spectrum of the lamp with the absorption spectrum of NO indicates that photoexcitation of NO had not occurred under the conditions of the experiment. The effect of NO must therefore be explained in terms of its reactions with reactive intermediates. The CF_3NO suggests the presence of CF_3 radicals.

[9] $$CF_3 + NO \rightarrow CF_3NO$$

The yield of this product, identified by its i.r.

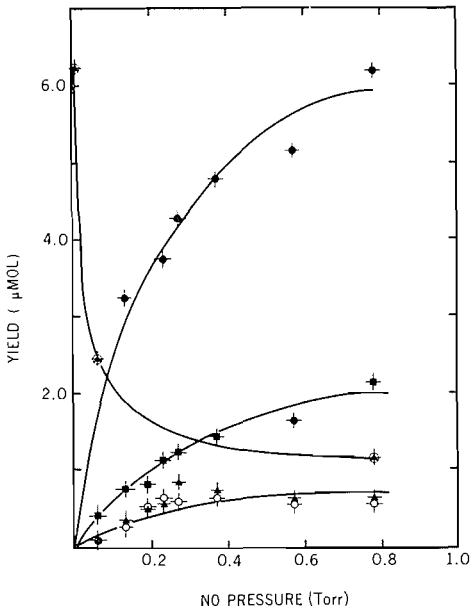

FIG. 2. Product yields as a function of NO pressure: ●, C_4H_2; ◬, 1,3,5-tris(trifluoromethyl) benzene; ■, CF_3CN; ▲, C_2HF; ○, C_2H_2. Pressure of CF_3—C≡CH = 2.61 Torr.

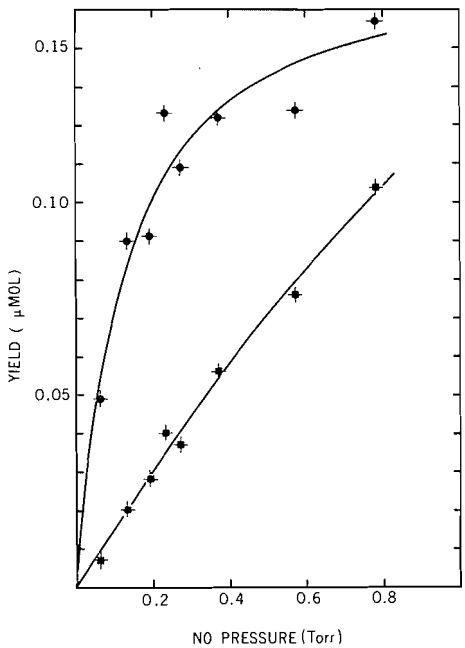

FIG. 3. Product yields as a function of NO pressure: ●, CO_2; ■, N_2O. Pressure of CF_3—C≡CH = 2.61 Torr.

and mass spectra, could not be determined quantitatively by gas chromatography. This difficulty has been encountered previously (19) and is no doubt associated with the formation of the CF_3NO dimer followed by its decomposition which has been shown (20) to yield N_2O and CO_2 which are also products of this reaction.

The vinyl radical formed in reaction 7 is no doubt the source of the nitrile by its reaction with NO in the manner indicated by Sherwood and Gunning (21) (see eq. 10).

[10] 
The fluoral, which would be expected from reaction 10 was not found and tests with an authentic sample indicated that it would not have survived the analytical procedures.

The formation of butadiyne by the reaction of ethynyl radicals with acetylenes in the presence of nitric oxide has been observed previously (21, 22). The absence of butadiyne among the

[11] $HC{\equiv}C\cdot + CF_3{-}C{\equiv}CH \rightarrow HC{\equiv}C{-}C{\equiv}CH + CF_3\cdot$

products of the uninhibited reaction, also observed previously in similar systems (21, 22), may be due to consumption of this product by free radicals or to actual participation of NO in its formation. This aspect of the problem requires further work as does the problem of the origins of the C_2HF and C_2H_2.

In summary, the main primary process seems to be the dissociation of the molecule into ethynyl and trifluoromethyl radicals, each of which initiates polymerization reactions. The propyne trimer has been shown to be a product of a free radical initiated reaction.

Aromatic Substitutions with Carbanion Nucleophiles. II. The Kinetics and Mechanism of the Reaction of 1-Fluoro-2,4-dinitrobenzene with the Diethyl Malonate Anion[1,2]

KENNETH T. LEFFEK AND PAUL H. TREMAINE[3]

Department of Chemistry, Dalhousie University, Halifax, Nova Scotia

Received November 14, 1972

The reaction of fluoro-2,4-dinitrobenzene with the sodium salt of diethyl malonate to form diethyl (2,4-dinitrophenyl)malonate is fast in dimethyl sulfoxide solvent. The stable red color of the reaction solution is due to the anion of the product, although the initially formed unstable intermediate between the substrate and the anion nucleophile is also red and can be observed at times less than 200 ms after mixing.

The rate constants for all the steps in the reaction have been measured and the activation parameters for the three processes involved in the nucleophile substitution have been calculated.

La réaction du fluoro dinitro-2,4 benzène avec le sel de sodium du malonate d'éthyle est rapide dans le diméthyl sulfoxyde et conduit au (dinitro-2,4 phényl) malonate du diéthyle. Quoique l'intermédiaire instable formé initialement entre le substrat et l'anion soit rouge et qu'on puisse l'observé jusqu'à 200 ms après le mélange des réactifs, la couleur rouge stable de la solution réactionnelle est attribuée à l'anion du produit.

Les constantes de vitesse pour chacune des étapes de la réaction ont été mesurées et les paramètres d'activation pour chacun des trois processus impliqués dans une substitution nucléophile ont été calculés.

[Traduit par le journal]

Can. J. Chem., **51**, 1659 (1973)

Introduction

In the reaction of 1-fluoro-2,4-dinitrobenzene with diethyl malonate in the presence of triethylamine, Baudet reported (1) the observation of a stable intermediate **1** as a red material in DMSO solution. Leffek and Tremaine (2) compared this reaction with that of the sodium salt of diethylmalonate on the same substrate and re-interpreted Baudet's observation, assigning the red coloration to the anion of the final product diethyl (2,4-dinitrophenyl)malonate. In addition, Shein and Ivanova (3) disputed Baudet's interpretation and showed by fluorine n.m.r. spectroscopy that the stable red material contained no covalently bound fluorine.

This paper presents a spectrophotometric and kinetic study of the reaction between the diethyl malonate anion and 1-fluoro-2,4-dinitrobenzene in DMSO, which is believed to react as in eq. 1 under the experimental conditions in which the malonate anion is present in large excess.

[1]Reference 2 is considered to be Part I.

Results and Discussion

On mixing 1-fluoro-2,4-dinitrobenzene and the sodium salt of diethyl malonate in DMSO, a stable purple color (λ_{max} 520 nm, $\varepsilon_{apparent}$ 24 000 l mol^{-1} cm^{-1}) was produced immediately. A solution of identical λ_{max} and ε was obtained when the same anion was mixed with 2,4-dinitrophenyl malonate **2** in DMSO. With the concentration of **2** equal to 6×10^{-5} *M* and the anion concentration varying between 1.5×10^{-3} and 1.5×10^{-2} *M*, the absorbance at 520 nm remained approximately constant; thus, this third step of the reaction appears to be in equilibrium predominantly on the side of the deprotonated product **3**. This result is as expected, since the acidity of 2,4-dinitrophenyl malonate **2** is obviously very much greater than that of the sodium salt of diethyl malonate. Also, since the third step is a proton transfer from a moderately strong carbon acid, k_3 should be larger than the other rate constants in the reaction scheme.

A series of kinetic experiments were carried out to determine the pseudo first-order rate constants by light absorption at 520 nm with the anion concentration in large excess over that of the substrate. These rate constants are shown

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

[1]

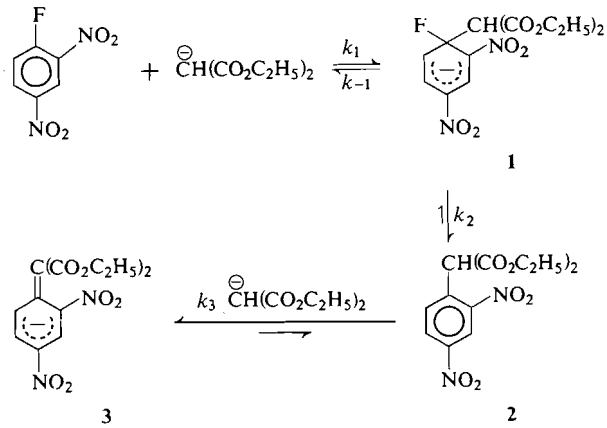

TABLE 1. Pseudo first-order rate constants for the reaction of diethyldinitrophenyl malonate with the sodium salt of diethylmalonate in DMSO at 23.0 °C. Initial concentration of substrate = 5.0×10^{-5} mol l^{-1}

Initial concentration anion $\times 10^3$ (M)	No. of runs	k (s^{-1}) ± std. dev.
1.31	2	32.8 ± 0.3
2.63	5	50.0 ± 1.5
3.94	3	60.5 ± 3.0
4.46	3	69.4 ± 0.4
5.25	3	78.1 ± 0.8
6.56	7	93.3 ± 2.0

in Table 1. Guggenheim plots for these runs had good correlation coefficients, ranging between 0.9950 and 0.9999. A plot of the first-order rate constant against anion concentration has a slope equal to the second order rate constant k_3. The results of Table 1 give a numerical value of 11 500 l mol^{-1} s^{-1} for k_3.

If this step of the reaction in eq. 1 is faster than the two earlier steps, it is possible to use the appearance of this color to study the reaction. Simple kinetics would ensue if the initial attack of the anion on the substrate molecule was the slowest step. However, this does not appear to be the case since the rate of appearance of the purple color from 1-fluoro-2,4-dinitrobenzene and sodiodiethylmalonate, at 520 nm, did not give good first-order rate constants which varied linearly with the anion concentration. There appeared to be an initial rapid reaction which was followed by a slower reaction. If there are two reactions which each give rise to a colored species (*i.e.* **1** and **3**), the absorption spectrum of the reaction mixture should show this, unless these two products have absorption peaks at identical wavelengths. Therefore, a series of absorption scans of the visible spectrum of the reaction mixture was composed at different elapsed times from the time of mixing, using a stopped-flow spectrophotometer. Since the moment of mixing cannot be precisely known, it was arbitrarily set at the origin of the oscilloscope sweep at 2 ms per division of timebase. The absorbance *vs.* time scans were then photographed for a series of different "time-after-mixing" values. In this way visible absorption spectra were obtained for the system at 15 different times-after-mixing, varying between 1 and 2000 ms. Eight of these spectra are shown in Fig. 1, from which it can be seen that there is an initial rapid formation of a peak at 540 nm which is essentially complete after 200 ms, then a slower formation of the product (λ_{max} 520 nm).

The 520 nm peak has been positively identified (2) as the product **3** so the 540 nm peak is assumed to be the intermediate **1**. The only other possibilities are the corresponding intermediates where the diethyl malonate anion is attached at the C-3 or -5 positions. Such intermediates have been postulated for hydrolysis reactions of similar substrates (4) and also have been observed spectroscopically for reactions of methoxide ion with substituted anisoles (5–8). These C-3 and -5 intermediates have been observed to be kinetically favored relative to the C-1 intermediate, but thermodynamically less stable. However, in the present system, it is clear that the intermediate **1** is formed, since the corresponding product is obtained and the u.v. spectra in Fig. 1. show a clear isosbestic point, which indicates the presence of only one species

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

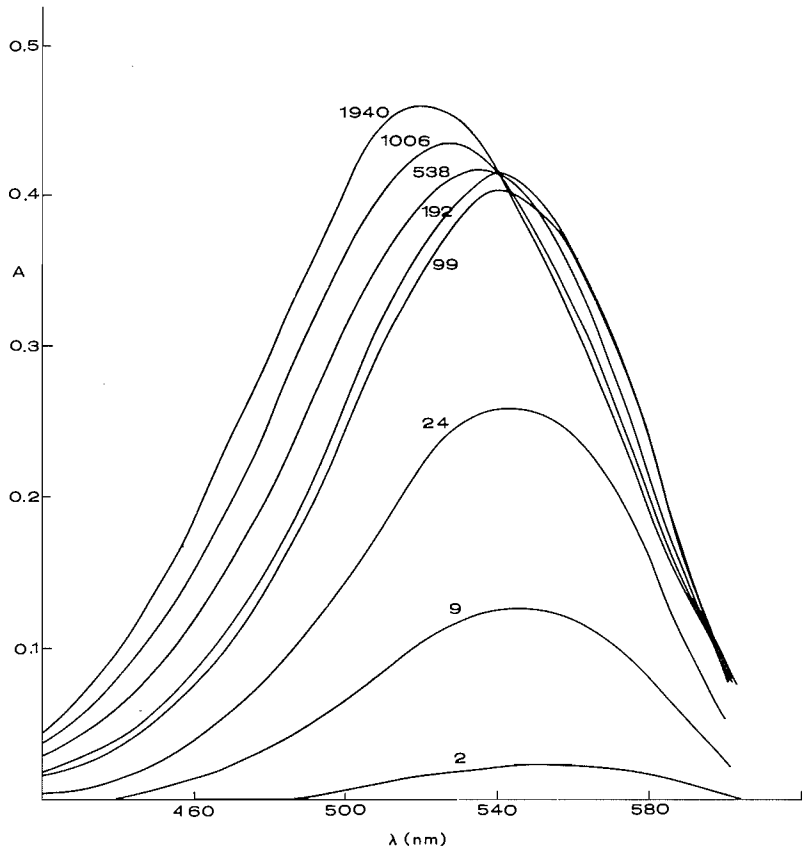

FIG. 1. Visible absorption spectra for the reaction of 1-fluoro-2,4-dinitrobenzene and diethylmalonate anion. The number adjacent to each curve is the "time-after-mixing" in ms.

other than the product. It is concluded, therefore, that if the C-3 or -5 intermediates are formed, they are not kinetically significant.

The kinetic situation is that of a consecutive reaction, for which, if the two steps are sufficiently separated in rate, reasonable approximations to the rate constants might be obtained by carrying out measurements at appropriate wavelengths and time scales. Examples of this type of study of aromatic nucleophilic substitutions have appeared in the literature recently (9, 10).

The first rapid step of the reaction was measured using the wavelength of the isosbestic point. This wavelength varied slightly with reagent concentration; for the conditions under which the kinetic runs were made it was usually higher than 550 nm. If this first step is assumed to be an equilibrium as shown in eq. 1 with the malonate anion in large excess, the kinetic eq. 2 may be derived (11) where x_e and x are the concentrations of the intermediate **1** at equilibrium and at time t, k_1 and k_{-1} are second- and first-order rate constants shown in eq. 1, and b is the concentration of malonate anion. Equation 2 is of the first-order form for which the observed first-order rate constant is equal to $(k_1b + k_{-1})$. The k_{obs} values shown in Table 2 were plotted against anion concentration b and the values of k_1 and k_{-1} thus obtained are shown in Table 3.

$$[2] \quad (x_e - x)/x_e = \exp[-(k_1b + k_{-1})t]$$

The slower second step of the reaction was studied at a lower wavelength, ignoring the first 200 ms of the reaction. This should give a reasonable approximation to k_2, provided k_3 is sufficiently greater than k_2. A series of pseudo first-order rate constants measured at 510 nm at various temperatures are collected in Table 2, from which it can be seen that k_2 is indeed very much less than k_3.

TABLE 3. Forward and reverse rate constants for the reaction of 1-fluoro-2,4-dinitrobenzene with malonate anion to form a σ-bonded complex in DMSO

Temperature (°C)	$k_1(l\ mol^{-1}\ s^{-1})$	$k_{-1}(s^{-1})$
20.5	4680	17.0
25.0	6200	21.8
30.0	8240	29.1
35.0	8690	42.5
40.0	10750	55.4

Thus, from these three sets of values for k_1, k_{-1}, and k_2 at the five temperatures, the activation parameters for this nucleophilic substitution reaction may be calculated. The values of k_2 in Table 2 do not remain constant with reagent concentration but appear to be subject to some catalysis, therefore the k_2 figures used to calculate the activation parameters were those obtained by extrapolation to zero anion concentration. The values of the activation parameters, calculated by the least squares method are given in Table 4. The quoted errors are standard deviations which contain only the random errors of the method. These are rather large, but still do not include systematic errors resulting from the consecutive reaction sequence. Some computations have been made for consecutive reactions with rate constants of the same order of magnitude which have been found in these experiments and it appears that systematic errors in the rate constants as we have derived them are of the order of 5–10%. These result from the assumption in our rate constant calculations that neither step in the reaction sequence interferes with the other. Since the random experimental errors arising in the determination of the rate constants are probably of the same magnitude, these systematic errors are presently acceptable.

TABLE 4. Activation parameters for the nucleophilic substitution of 1-fluoro-2,4-dinitrobenzene by malonate anion in DMSO

Reaction	$\Delta H^{\ddagger}$ ± std. dev. (kcal mol^{-1})	$\Delta S^{\ddagger}$ ± std. dev. (cal mol^{-1} deg^{-1})	$\Delta G^{\ddagger}_{300\,°K}$ (kcal mol^{-1})
Formation of complex (Step 1)	6.9 ± 0.9	−18.2 ± 3.0	12.3
Decomposition of complex to starting materials (Step −1)	10.7 ± 0.4	−16.5 ± 1.4	15.6
Decomposition of complex to substituted products (Step 2)	12.6 ± 0.8	−16.0 ± 2.7	17.4

At 25 °C our rate constants have the values $k_1 = 6200$ l mol^{-1} s^{-1}, $k_{-1} = 22$ s^{-1}, and $k_2 = 1.0$ s^{-1} which may be compared to the corresponding values of 9.01 mol^{-1} s^{-1}, 6.0 s^{-1}, and 0.12 s^{-1} for the attack of hydroxide ion on 1-chloro-2,4,6-trinitrobenzene obtained by Gaboriaud and Schaal (9).

The magnitudes of the activation parameters seem to be reasonable except for the fact that the entropies of activation for the three steps of the reactions are the same within experimental error and are all negative. It was expected that the decomposition of the intermediate to give either reactants or products would have a positive entropy of activation or at least a much less negative one. However, this result is not without precedent, for Bernasconi (12) found negative entropies of activation for the decomposition of the Meisenheimer adduct of methoxide ion and 2,4-dinitroanisole as well as for its formation. Bernasconi interpreted this result in terms of the concentration of negative change on the incipient methoxide ion in the transition state of the decomposition, which enhanced the solvation of the transition state relative to the initial state. A similar explanation may be advanced in the present case with the negative charge concentrating either on the carbon atom of the incipient malonate anion, or on the incipient fluoride ion for decomposition to reactants and products respectively. At present there are insufficient experimental results to develop a detailed theory, but it is clear that the entropies of activation can only be rationalized if solvation changes are making substantial contributions to this parameter.

It has been assumed in the kinetic analysis that the reaction is that shown in eq. 1 with no other side reactions taking place. However, it is possible that an intermediate could be formed from a reaction between the substrate and the anion of DMSO, if that were present in solution. The dimsyl anion is well known (13, 14) and its adduct with 1,3,5-trinitrobenzene has been observed (15). It is known to be formed in DMSO–alkoxide mixtures (16) and is believed to be the active reagent in some proton transfer reactions in such solutions (17).

The dimsyl anion was prepared from sodium hydride and DMSO and reacted with 1-fluoro-2,4-dinitrobenzene. This yielded rapidly two absorption peaks at 431 and 372 nm, clearly different from the absorption spectrum observed with the malonate anion. It is concluded, therefore, that there is no significant amount of attack by dimsyl anion, which probably means that this ion is formed only in very small concentration in solutions of malonate anion in DMSO.

In summary, the activation parameters for each step of this reaction, while not determined with great precision, give the reaction profile quite clearly. It should be possible to find a number of other aromatic nucleophilic substitutions for which the kinetics and activation parameters for the individual steps can be determined.

Experimental

Materials

The sodium salt of diethyl malonate was prepared from sodium hydride and diethyl malonate. Sodium hydride in oil was washed with several portions of dry petroleum ether and then mixed with an equimolar amount of diethyl malonate in petroleum ether solvent. After 1 h the precipitated salt was filtered and washed with petroleum ether, then dried under vacuum at room temperature for 2 h. On a 0.05 mol scale the yield of this reaction is about 90%. The product was assayed by potentiometric titration against standard perchloric acid in isopropyl alcohol which indicated 98 ± 0.5% purity.

Dimethyl sulfoxide solvent was dried over calcium hydride, then fractionally distilled from fresh calcium hydride under nitrogen.

Kinetic Procedure

The rate measurements, and the absorption spectra at times less than 2 s after mixing, were determined with a Durrum stopped-flow spectrophotometer fitted with a 2 mm light-path optical cell. The bath in which the drive syringes of the apparatus were immersed was maintained at the quoted temperatures to ± 0.03 °C. This bath fluid was circulated around the mixing jet and optical cell.

Each run consisted of three consecutive trials, for which the transmittance vs. time traces were superimposed on the Tektronix 564 storage oscilloscope screen. The transmittance readings were read from the photograph of the composite trace, converted to absorbance, and the first-order rate constants were computed by the least squares method using the Guggenheim treatment. Correlation coefficients and standard error calculations were included in the program. Two runs, sometimes more, were carried out for each set of concentrations and temperature at different oscilloscope time bases.

The Importance of Conformation of the Tetrahedral Intermediate in the Hydrolysis of Amides. Selective Cleavage of the Tetrahedral Intermediate Controlled by Orbital Orientation[1]

PIERRE DESLONGCHAMPS,[2] CLAUDE LEBREUX, AND ROLAND TAILLEFER

Laboratoire de Synthèse organique, Département de chimie, Université de Sherbrooke, Sherbrooke, Québec

Received January 24, 1973

The basic hydrolysis of *N*-disubstituted imidate salts proceeds via a hemi-orthoamide tetrahedral intermediate which can in principle give amide–alcohol or ester–amine products. Experimental evidence has been obtained which shows that the specific conformation of the tetrahedral intermediate determines products formation and it is further suggested that the orientation of the lone pair orbitals of the heteroatoms governs this remarkable selective decomposition.

L'hydrolyse basique des sels d'imidate *N*-disubstitués passe par la formation d'un intermédiaire tétrahédrique du type hémi-orthoamide qui peut conduire soit aux produits amide–alcool ou ester–amine. Les résultats expérimentaux obtenus démontrent que la conformation précise de l'intermédiaire tétrahédrique détermine la formation des produits. Il est de plus avancé que l'orientation des orbitales d'électrons non-liés des hétéroatomes contrôle la décomposition sélective de l'intermédiaire tétrahédrique.

Can. J. Chem., **51**, 1665 (1973)

We have recently demonstrated the importance of the conformation of the tetrahedral intermediate (hemi-orthoester) during the hydrolysis or the transesterification of esters (1).

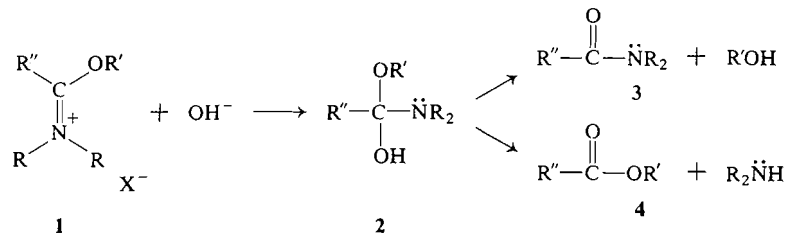
We now wish to report that the conformation of the tetrahedral intermediate (hemi-orthoamide) formed during the hydrolysis of amide and related functions is equally important; specific cleavage of a carbon–oxygen or a carbon–nitrogen bond being allowed only if the other two heteroatoms (oxygen or nitrogen) of the tetrahedral intermediate have each an orbital oriented antiperiplanar to the leaving *O*-alkyl or *N*-alkyl group. In order to verify this stereoelectronic theory, we have selected for study the basic hydrolysis of the *N*-disubstituted imidate salts **1** (2) (Scheme 1), expecting that such salts would react very fast with hydroxide ion to yield a tetrahedral intermediate **2** which can give in principle the amide-alcohol products **3** or the ester–amine products **4**.[3] If the reaction gives the amide-alcohol products **3** via a kinetically controlled reaction, no information on the orbital assisted decomposition of the tetrahedral intermediate can be obtained since the amide–alcohol products **3** are also the thermodynamically favored products of the reaction. However, the formation of the ester–amine products **4** can give useful information on the decomposition of the tetrahedral intermediate **2** since they are clearly the result of a kinetically controlled reaction. Thus, if products **4** are preferentially observed it means that the transition state leading to those products is of lower energy than the one leading to the formation of the much more stable amide-alcohol products **3**. We disclose here experimental evidence which clearly establishes that the preferential formation of the ester–amine products **4** is possible in basic medium and proposed that whenever such products are formed, the low energy transition state is due to the formation of a specific conformation of the tetrahedral intermediate **2** in which the lone pair orbitals of the oxygens are properly oriented to permit the specific cleavage of the carbon–nitrogen bond.

Imidate salts can exist into two different planar conformations, the *anti* (**1***a*) or the *syn* (**1***b*) form. If the *anti* form **1***a* reacts with hydroxide ion (Scheme 2), it should give specifically

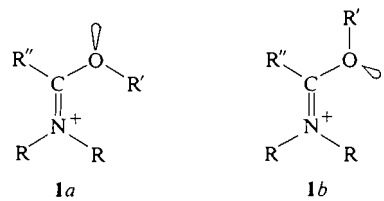
[1]Support for this work by the National Research Council of Canada and by the "Ministère de l'Education" Québec, is gratefully acknowledged.

[2]A. P. Sloan Fellow 1970–1972. To whom inquiries should be addressed.

[3]Study of the decomposition in a basic medium is important in order to prevent the protonation of the basic nitrogen of the intermediate **2**.

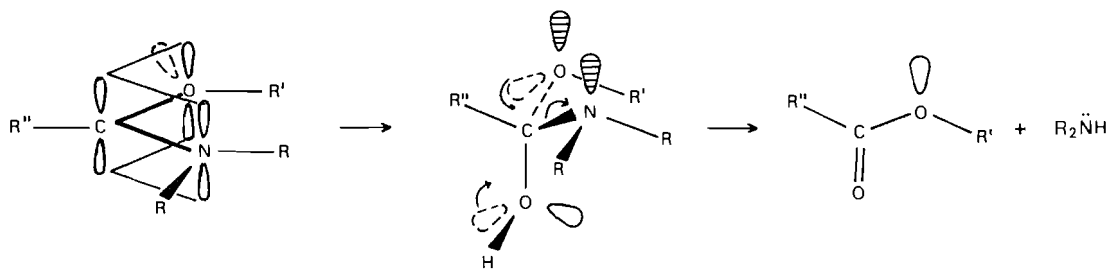


1 2 3 4



1*a* 1*b*

SCHEME 1



1a 2a 4

SCHEME 2

the conformer **2***a* in which the two new lone-pair orbitals on the oxygen of the OR′ group and the nitrogen are both oriented antiperiplanar to the C—OH bond (1). In this tetrahedral intermediate, the oxygens of the OH and the OR′ group each possess an orbital oriented antiperiplanar to the C—N bond so the cleavage of the C—N bond is possible by an orbital assisted mechanism yielding an ester and a secondary amine.[4] The nitrogen atom does not possess an orbital oriented antiperiplanar to the C—OR′ bond, the cleavage of the C—OR′ bond will therefore be a much higher energy process and should not be observed. Thus *anti* imidate salt **1***a* should give specifically the conformer **2***a* which will immediately decompose in one specific direction giving the ester–amine products **4**.

Reaction of hydroxide ion on the *syn* form **1***b* of the imidate (Scheme 3) should give specifically the conformer **2***b*. In conformer **2***b*, the nitrogen does not possess an orbital oriented antiperiplanar to the C—OR′ bond and similarly the OR′ oxygen does not possess an orbital antiperiplanar to the C—N bond. Therefore, we propose that intermediate **2***b* will not decompose before it undergoes rotational changes to give new intermediates such as **2***a* or *c* for example. In conformer **2***c*, the nitrogen atom and the oxygen of the OH group have each an orbital oriented antiperiplanar to the C—OR′ bond, thus **2***c*, once formed should give immediately the amide–alcohol products **3**. Consequently,

[4]The breakdown of the tetrahedral intermediate is certainly subject to complex general acid–base catalysis (3) which implies that the nitrogen will not be ejected as an amide ion but as a secondary amine.

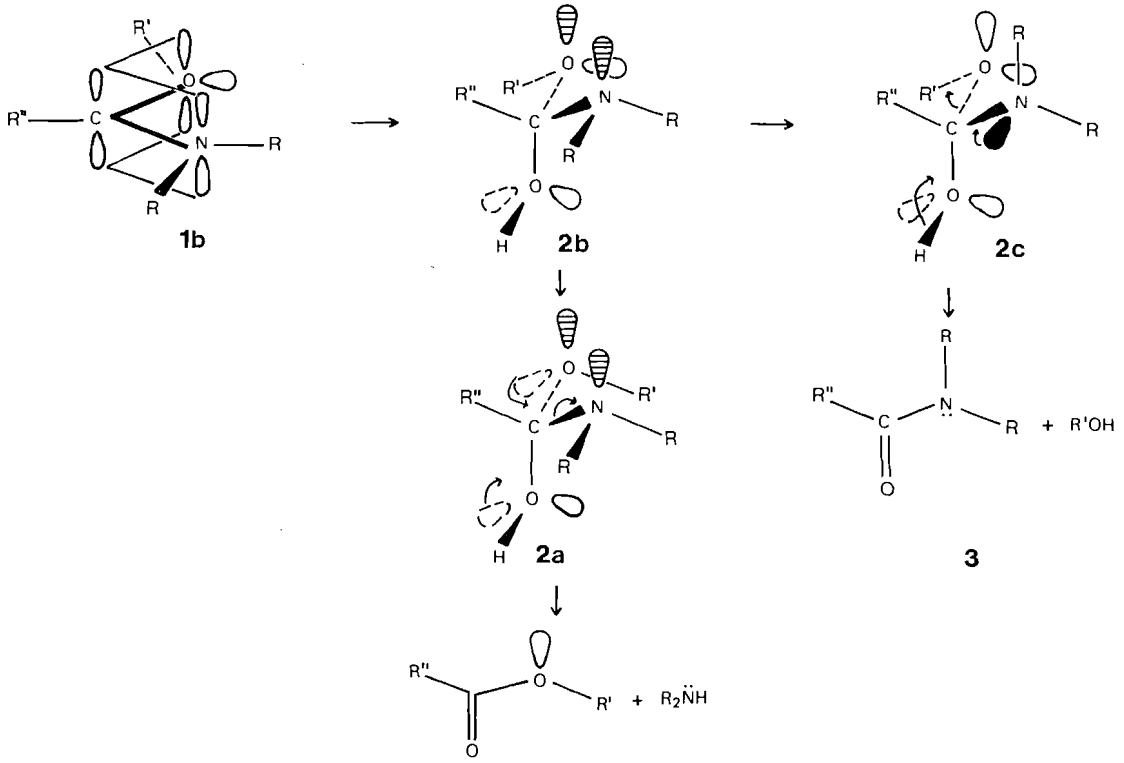

SCHEME 3

basic hydrolysis of *syn* imidate salt **1***b* can in principle give both types of products **3** and/or **4** depending on the new conformers that will be formed by bond rotation of conformer **2***b*.

Hydrolysis[5] of **5**[6] (CD_3CN–D_2O, NaOH, 2 equiv) at room temperature for 2 min gave ≃95% of ester–amine **6** and ≃5% of amide–alcohol **7**. After 30 min, the reaction mixture consisted of **7**[7] only, indicating that **6** is first formed and then converted into **7** under those conditions. Treatment[5] of the ammonium salt **8**[8] under identical basic conditions gave also the ester–amine **6** (≃95% after 2 min) which was completely converted into the amide–alcohol **7**[7] after 30 min. Hydrolysis[5] of **5** utilizing excess sodium carbonate (CD_3CN–D_2O) gave exclusively the ester–amine **6**[9] which was not converted into **7** under these conditions. Similarly, hydrolysis[5] of **9**[10] with sodium carbonate gave exclusively the ester–amine **10**.[9] Hydrolysis of **9** with sodium hydroxide (≃2 min) gave exclusively the amide-alcohol **11**.[7] However, treatment of the ammonium salts **12**[5,8] under similar conditions with sodium hydroxide also gave only the amide–alcohol **11**.[7] This result shows that the transformation of the ester–amine **10** into the amide–alcohol **11** is a very fast reaction in presence of sodium hydroxide. Hydrolysis[5] of **13**[11] with sodium carbonate gave after ≃10 min the ester–amine **14**[9] which is then transformed completely into the amide–alcohol **15**[7] after standing for 1.5 h at room temperature.

It has been reported (8) that the salts **16**, **17**,

18 gave the corresponding ester–amine **19**, **20**, and **21** on basic hydrolysis. Reaction of **22** with water has also been reported recently (9) and the ester–amine **23** was the only product isolated. In those cases (**16**, **17**, **18**, and **22**) two factors direct the specific cleavage of the carbon–nitrogen bond as shown in the intermediate **24**: the orbital orientation factor and a 1,3-diaxial type interaction between the OH group and the pseudo axial methyl group. The importance of this steric compression factor was verified in the following way. Ozonolysis (10, 11) of the acetal **25** gave exclusively the primary ester **26**.[12] During this reaction the intermediate **27** is formed and the orientation of the orbitals favors the opening in both directions equally but the interaction between the OH group and the pseudo axial methyl group in **27** is strong enough to allow a specific cleavage in one direction. The preceding study was carried out with rigid *anti* imidate salts and the experimental results clearly demonstrate that in such case, the ester–amine products are the only products observed under kinetically controlled condition.

We have also studied the basic hydrolysis of the imidate salts **28**[13] (R = H, CH_3, C_6H_{11} (cyclohexyl), $(CH_3)_3C$ and C_6H_5). Such salts can exist in principle in the *anti* (**28***a*) or the *syn* (**28***b*) form. The extent of the electronic interactions in either of these two forms is as yet unknown. There is however a steric repulsion between the R group and the ethyl group in the *syn* form **28***b*. There is also a steric interaction between the ethyl and the methyl groups in the *anti* form **28***a*. Therefore, when R is a small

TABLE 1. Basic hydrolysis of imidate salts **28**

R	% ester*	% amide*
H	50	50
CH_3	81	19
C_6H_{11}	50†	50†
$(CH_3)_3C$	>98	—
C_6H_5	>98	—

*Yields were estimated by p.m.r. spectroscopy analysis.
†Yields were estimated by v.p.c. analysis.

group, one can postulate that the *syn* form **28***b* might be favored and when R is a large group (*t*-butyl and planar C_6H_5), the *anti* form **28***a* would predominate. If this assumption is correct, the stereoelectronic theory predicts that basic hydrolysis of **28** should give a mixture of products **3** and **4** when R is a small group and it should give mainly the ester amine products **4** when R is a large group. Table 1 described results which are in accord with the preceding discussion.

Basic hydrolysis of the cyclic imidate salts **29**[13] and **32**[13] was also studied. Treatment of a solution of **29** in dichloromethane with a large excess of aqueous sodium carbonate at 0 °C for ≃15 s (rapid mixing) gave a mixture of ester–amine **30**[9] (65%) and lactam **31** (35%). A similar experiment with **32** gave also a mixture of ester–amine **33**[9] (83%) and lactam **34** (17%).

Work is now in progress to complete this study with various types of *N*-dialkylated imidate salts.

The Surface Analysis of Nickel Chromia Catalysts by X-Ray Photoelectron Spectroscopy[1]

NORMAN STEWART MCINTYRE, NORMAN HENRY SAGERT, AND RITA MARY LOUISE POUTEAU

Chemistry and Materials Science Division, Atomic Energy of Canada Limited, Whiteshell Nuclear Research Establishment, Pinawa, Manitoba R0E 1L0

AND

WARREN GEORGE PROCTOR

Physical Measurements Applications Instrument Division, Varian Associates, 611 Hansen Way, Palo Alto, California 94303

Received January 25, 1973

The surface composition of a series of nickel–chromia catalysts has been examined by X-ray photoelectron spectroscopy. Correlation of the amount of available surface nickel with the activity of the particular catalyst for hydrogen water deuterium isotope exchange is very good. No significant alterations are observed in the valence band spectra as the surface composition changes.

La composition de la surface d'une série de catalyseurs nickel-chrome a été examinée par spectroscopie photoélectronique obtenue par rayon X. La corrélation de la surface de nickel disponible avec l'activité du catalyseur concernant l'échange isotopique hydrogène–deutérium pour l'eau, est très bonne. Il n'y a pas de changements notables dans les spectres de bande de valence avec les changements de composition de la surface. [Traduit par le journal]

Can. J. Chem., **51**, 1670 (1973)

The use of photoelectron spectroscopy (XPS) for catalyst characterization has been recently reviewed (1). From this, it is clear that the ability of XPS measurements to probe the chemical nature as well as the composition of the first few atomic surface layers is potentially very useful in catalyst research. A number of studies (2–4) have already reported chemical shifts in elemental binding energies and changes in line shapes between "active" and "non-active" catalyst samples. This investigation has concentrated on the XPS of a number of "nickel–chromia" catalysts which are known to catalyze the deuterium isotope exchange between hydrogen and water vapor (5, 6). This particular system was chosen because there is a reasonably well defined optimum concentration of nickel (95%) for which catalytic activity reaches a maximum. It was expected that changes in photoelectron line shapes and intensities would be observable in the region of this maximum.

Catalysts with [Ni]/([Ni] + [Cr]) = 100, 99, 98, 97, 95, 90 and 81% w/w were prepared from 2 *M* solutions of the mixed nickel and chromium nitrates. The carbonates were precipitated by slow addition of $(NH_4)_2CO_3$ and were filtered, dried, crushed, and sieved to 40–60 mesh. The samples were then reduced in purified hydrogen at 300 °C and were stored under high purity nitrogen. Chromium and nickel concentrations were determined by atomic absorption spectrophotometric analysis of the dissolved carbonates.

Core and valence electron spectra of the catalysts were studied using a Varian VIEE-15 electron spectrometer fitted with a high intensity MgKα X-ray source (1253.6 eV). Samples were attached to the probe by cellophane tape and were transferred to the spectrometer, under a nitrogen atmosphere. Energy values reported are those directly obtained from the spectrometer which had been calibrated using the core $4f_{7/2}$ level of deposited gold and a secondary voltage standard. The sample surface charging was noted by measuring the shift of the C (1s) impurity line.

When the intensities of the Ni(3d) and (3s) bands are plotted against bulk nickel composition (see Fig. 1) a maximum occurs at 95% nickel catalyst composition. The Cr(3p) intensity also rises sharply up to the 95% sample, past which little further variation is observed.

The increasing nickel intensity in the composition range 99–95% probably results from the decrease in nickel particle size and the resultant increase in nickel surface area known to occur in

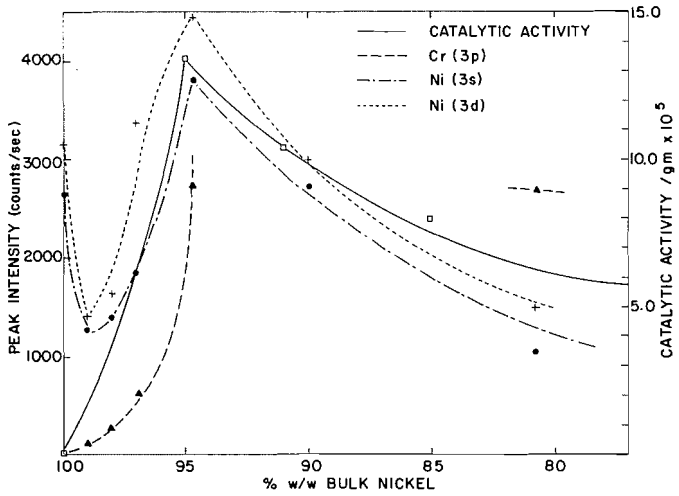

FIG. 1. Elemental surface concentrations and catalytic activity as a function of bulk nickel concentration; □ catalytic activity (see ref. 6); ▲, Cr(3p) line intensity; ● Ni(3s) line intensity; +, Ni(3d) line intensity.

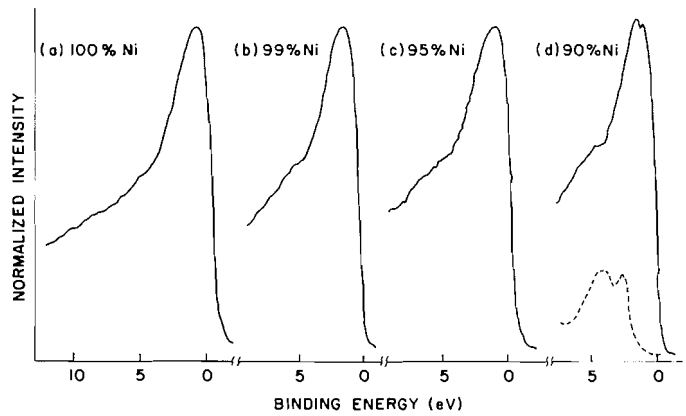

FIG. 2. Nickel valence band shape as a function of bulk nickel composition. Dashed line in (d) indicates the position and shape of the Cr_2O_3 bands.

this composition range (6). It was previously proposed (6) that as chromia is added to the system, it is first deposited in a very thin layer, or possibly a Ni–Cr compound of undetermined structure gives way to a bulk chromia phase at a composition of around 95% nickel. These suggestions are supported by our observation of an initial drop in nickel line intensity at the 99% composition as chromia is first introduced to the system, and by the constant value of the Cr(3p) intensity at compositions lower than 95% nickel.

Catalytic activities for hydrogen–water deuterium exchange are taken from Tarina *et al.* (6). They represent moles of HD formed per g-s at 130 °C. The parallel variation of the Ni(3p) and (3d) line intensities with the reported catalytic activity in the nickel composition range 95–80% suggests that the exchange rate in this range may depend mainly on the availability of surface nickel and is consequently a function of the physical structure. Conclusions regarding a similar correspondence in the composition range 100–95% require further kinetic data for intermediate points in this area.

The Ni(3d) band shapes for four catalyst compositions are shown in Fig. 2. In the pure nickel sample (a), the band maximum occurs at a binding energy 1.4 eV higher than the Fermi level compared with the 1.0 eV found by previous authors (7). This difference and the slightly

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

broader band may be due to the powdered nature of our samples. Superimposed on the pure nickel band shape, two new features gradually appear at binding energies of 0.7 and 4.0 eV above the original band maximum as the chromia content increases. A spectrum of pure Cr_2O_3 in the same energy region (see Fig. 2(*d*)) has two d electron bands whose positions closely match those appearing in the catalyst spectrum using the O(2s) peak as energy reference. Thus the observed changes occurring in the catalyst valence spectra probably result from the presence of Cr_2O_3.

Examination of the $Ni(2p_{3/2})$ line for this catalyst series suggests that some oxygen contamination of the surface occurred during sample transfer. However, the $Ni(3p_{3/2, 1/2})$ line for those samples low in Cr_2O_3 is a clean gaussian singlet with only a small shoulder on the high binding energy side indicating that only a very small fraction of the nickel is present as oxide. The apparent difference in surface composition suggested by the two nickel lines is explained by the fact that escaping Ni(3p) electrons have a kinetic energy of about 1200 eV while those from the 2p level have only an energy of about 400 eV. Recent studies of electron escape depths (8) suggest that 1200 eV electrons have at least twice the escape depth of 400 eV electrons. The Ni(3p) line is thus less sensitive to contamination of the very outermost surface since it samples a somewhat greater depth than the 2p line.

A clear correlation between XPS peak intensity and catalytic activity is shown in the present study, but no indication of electronic promotion is seen in the valence band spectra. It is not clear, at present, whether catalytically significant changes in valence band structure can be resolved by current XPS techniques. However, such interaction obviously does occur, since the available surface nickel in the 100% nickel catalyst (Fig. 1) is almost as great as that in the 95% catalyst yet the former is completely inactive. Electronic differences may be occurring in unoccupied nickel orbitals and thus may be observable in the "shake-up" electron spectrum associated with the Ni(2p) lines (9).

Base-catalyzed Isotopic Exchange of Molecular Hydrogen. II.[1] Rate Dependence on Basicity in the Dimethyl Sulfoxide–Water System[2]

E. ALLAN SYMONS[3] AND ERWIN BUNCEL

Department of Chemistry, Queen's University, Kingston, Ontario

Received November 27, 1972

Isotopic exchange of D_2 has been determined in mixtures of dimethyl sulfoxide and water under catalysis by hydroxide ion. The rate of exchange increases by *ca.* 10^4 as the medium composition is changed from 0% DMSO to 99.6% DMSO at 65 °C. The unusually low sensitivity to medium basicity is reflected in abnormally low slope values for the plots of log k_{obs} *vs.* H_- or J_-. When [Me_4NOH] is varied at a given medium composition, the apparent order with respect to [Me_4NOH] is greater than unity.

These results are discussed in terms of (*1*) rate determining proton transfer from D_2 to OH^- with formation of hydride ion; (*2*) a concerted reaction of OH^-, D_2, and H_2O; (*3*) addition of OH^- to D_2 to yield an intermediate adduct, $[HODD]^-$; (*4*) a 6-centered process involving cation participation and electrophilic assistance by H_2O in the reaction of OH^- with D_2.

L'échange isotopique de D_2 a été étudié dans des mélanges de sulfoxyde de diméthyle et d'eau sous l'effet d'une catalyse par l'ion hydroxyle. Le taux d'échange augmente d'environ 10^4 alors que la composition du milieu change de 0% en DMSO à 99.6% en DMSO à 65 °C. La sensitivité anormalement faible à la basicité du milieu est réflétée par des valeurs anormalement faibles de la pente dans les graphiques du log k_{obs} *vs.* H_- ou J_-. Quand la concentration de Me_4NOH est changée pour une composition donnée du milieu, l'ordre apparent en ce qui a trait à la [Me_4NOH] est plus élevé que l'unité.

On discute de ces résultats en fonction du (*1*) transfert de proton responsable du taux d'échange de D_2 à OH^- avec la formation d'un hydrure; (*2*) d'une réaction concertée de OH, D_2 et H_2O; (*3*) d'addition de OH^- à D_2 pour donner un produit d'addition intermédiaire $[HODD]^-$; (*4*) d'un processus à 6 membres impliquant une participation cationique et une assistance électrophile de l'eau dans la réaction de OH^- avec D_2.

Can. J. Chem., 51, 1673 (1973)

Wirtz and Bonhoeffer reported in 1936 (1) the observation of proton exchange between hydrogen gas and deuterium oxide in the presence of potassium hydroxide. Since then several groups of workers have studied various aspects of this base-catalyzed reaction in aqueous solution (2–10). It has been determined that the hydroxide ion-catalyzed exchange occurs homogeneously in the liquid phase, the rate being approximately proportional to the base concentration up to 1 *M* (3, 6), and to the hydrogen pressure up to at least 100 atm (6). Acids are not effective as catalysts (3–5), while catalysis by water is extremely slow even at several hundred degrees Centigrade (6). Activation energies of 24, 24 ± 2, 29 ± 3 kcal/mol have been reported for the reaction in the region of 100° (3), 115° (6), and 150° (4), respectively.

Isotope exchange results from heterolytic

cleavage of the D—D bond in protic medium. Wilmarth and co-workers (3, 5) suggested that the rate-limiting step involved either transfer of deuterium to OH^-, leaving temporarily a deuteride ion (reaction 1*a*), to be followed by its rapid discharge (reaction 1*b*), or else simultaneous reaction of the D_2, OH^-, and H_2O species (reaction 2) to yield the final products of the exchange, namely HD and DOH. However it was believed that the absence of acid catalysis tends to rule out this latter possibility (3, 5).

$$[1a] \quad HO^- + D{-}D \xrightarrow{\text{slow}} HOD + D^-$$

$$[1b] \quad D^- + HOH \xrightarrow{\text{fast}} DH + OH^-$$

$$[2] \quad HO^- + D{-}D + HOH \rightarrow HOD + DH + OH^-$$

Formation of a free hydride ion (reaction 1*a*) with an appreciable life-time was considered unlikely by Schindewolf (6), since no base-catalyzed reductions or hydrogenations could be detected under the conditions of the exchange measurements. The preferred mechanism (6) was one in which polarization of the hydrogen molecule by hydroxide ion occurred simultaneously with attack by a water molecule:

$$[3] \quad HO^- \cdots \overset{\delta+\ \delta-}{D{-}D} + HOH \rightarrow HO{-}D + D{-}H + OH^-$$

The process in reaction 3, though akin to that given in reaction 2, bears some resemblance to the mechanism discussed below in which association between HO^- and D—D is considered to be complete in an initial stage.

In a theoretical approach to the problem, Ritchie and King (9, 10) have performed non-empirical *ab initio* (l.c.a.o.–m.o.–s.c.f.) calculations of the potential energy surface for the gas phase reaction of water molecule with hydride ion to produce hydroxide ion and hydrogen molecule. These computations point to the formation of an addition complex, $[HODD]^-$, which is stable relative to the reactants and products. Thus a classical activation energy barrier is shown to be absent for the gas phase process. Hence the magnitude of the experimental activation energy for isotopic exchange in solution was ascribed almost entirely to the necessary partial desolvation of the hydroxide ion before it can take part in reaction. On this basis isotopic exchange in solution will take place by the mechanism of reactions 4*a* and 4*b*.

$$[4a] \quad \begin{matrix} HOH{-}{-}{-}O^- \\ \quad\quad\quad | \\ \quad\quad\quad H \end{matrix} + D{-}D \xrightarrow{\text{slow}} HOH + [HO{-}D{-}D]^-$$

$$[4b] \quad [HO{-}D{-}D]^- + HOH \xrightarrow{\text{fast}} HOD + D{-}H + OH^-$$

Somewhat conflicting evidence regarding such an intermediate has appeared recently. Through mass spectrometric measurements, Bohme and co-workers (11) have reported kinetic data for the reaction $H^- + H_2O \rightleftarrows H_2 + OH^-$ in the gas phase at thermal energies. There was no indication of a stable species like $HHOH^-$, though collisional stabilization of transient $HHOH^-$ species would be difficult at the low pressures employed.

The hydroxide ion-catalyzed reaction between D_2 and H_2O is too slow to be of commercial value in an industrial process for the production of heavy water from a hydrogen or water source, despite a favorable separation factor (12). However, it is well known that many base-catalyzed reactions, including those involving proton transfer from carbon, are greatly accelerated when the solvent contains an aprotic component (see for example, refs. 13–16).

The present research was undertaken to examine the effect of adding dimethyl sulfoxide (DMSO) to the aqueous D_2 exchange system. Preliminary exchange rate data measured with tetramethylammonium hydroxide as a function of medium composition from 20.2 to 99.6 mol% DMSO have already been reported (17). We now present the detailed results for the dependence of exchange rate on medium basicity and base concentration. In addition, as part of this work, some solubility data for D_2 have been determined, supplementary to the complete H_2 solubility study recently reported (18).

Experimental

Reagents

Procedures for purification and storage of DMSO and tetramethylammonium hydroxide have been presented previously (18). Deionized distilled water was used throughout the work.

Deuterium gas (Matheson, technical grade) was conveniently stored and purified (removal of traces of O_2) via the uranium deuteride in a narrow cylindrical steel pressure vessel containing uranium turnings (19). The temperature in a furnace surrounding the vessel was raised to 225 °C whenever the latter required recharging, and to 450 °C for gas withdrawal. Some of the later runs in this study were carried out employing C.P. grade

Matheson gas drawn directly from a small cylinder. A comparison of runs under otherwise identical conditions, but performed with the two D_2 sources, indicated no difference in rate constants within experimental error.

Conversion of the experimental vapor phase exchange rate constants to in-solution data required knowledge of the solubility of deuterium gas in the various media studied. Since such data were found to be available only for pure DMSO and only at 25 °C (20), it was necessary to measure the gas solubility in the H_2O–DMSO mixed solvent system.

A gas chromatographic method was chosen (18) because the procedure is simple and fast (21). Since D_2 reacts fairly rapidly in the alkaline media under study, a time-dependent mixture of D_2, HD, and H_2 is always present in solution. Because the thermal conductivities of D_2 and H_2 are quite different (22), consistent solubility results based on D_2 would not be possible by this method. Therefore pure H_2 was employed for most of the solubility measurements, and the data from this investigation have already been reported (18). The conversion to the D_2 data required for the exchange study was accomplished by comparing the D_2 and H_2 solubilities in pure DMSO and water at 25 °C. These D_2 solubilities at 25 °C were determined in the same manner as for H_2 (18).

The solubility results are presented in Table 1, with the corresponding literature data where available. The present data are believed to be accurate within ±2% (18). From the data in Table 1 a factor of 1.05 ± 0.03 is calculated for conversion from H_2 to D_2 solubilities in these media. It has been assumed that this factor is independent of solvent composition and temperature, within the experimental error. It is known that the relative solubilities of H_2 and D_2 do change slightly with temperature in nonpolar solvents (23), but the variation is within the above error limit.

Exchange Run Procedure

The reaction vessel was the same as that employed for the gas solubility measurements (18). Only Pyrex glass and Teflon came into contact with the solutions.

Exchange runs were carried out in the following manner. Stock DMSO was withdrawn under dry nitrogen by calibrated 25 ml volumetric pipet and transferred to the reaction vessel, which was being flushed with nitrogen. The vessel was then stoppered, placed in ice-cold water to chill the DMSO and finally evacuated for several minutes to facilitate degassing. D_2 was admitted to an ambient-temperature pressure so as to yield a partial pressure of one atm at operating temperature. Allowance was made for the change in pressure resulting from subsequent addition of the base solution, and also for the extra water where necessary. The addition of water, when required, was done at this point by syringe. The final solvent composition was calculated from the quantities of DMSO and water used.

The vessel was submerged in a constant temperature bath controlled to better than ± 0.05 °C, and the solution was stirred for 5 min to allow both gas–liquid and temperature equilibration before the base was introduced by syringe. A stirring rate of 700–800 r.p.m. was used, since, within experimental error, the observed rate constant was independent of stirring rate in the range 300–950 r.p.m. for a test series of runs under conditions approaching the fastest exchange rates encountered.

Periodically, 0.5 cc gas samples were withdrawn from the vapor space by means of a 5 cc Becton–Dickinson Plastipak syringe equipped with a two-way valve and 6 in. needle. Normally a total of six or seven such samples, comprising a maximum of 3% of the initial D_2 charge, were taken per run. The samples were transferred to individual evacuated storage tubes constructed from two 2 mm bore stopcocks joined together. One outer end of each tube was fitted with a rubber serum cap, the other end with a ground glass joint for connection to a vacuum rack. Internal volume was approximately 0.8 cc.

The D_2–HD–H_2 molar composition of the samples was determined by mass spectral analysis on a Consolidated Electrodynamics Corporation model 21-130 mass spectrometer connected to a Varian data computer. Accuracy is believed to be ±0.5% absolute and ±0.2% relative per set for the mol% D_2 figures.

Kinetic Analysis

The exchange data were plotted as $\log_{10}$ (mol% D_2) *vs* time, with the best line through the points being obtained by means of least squares computer calculation. For most solvent compositions these first order plots exhibited excellent linearity, whether the particular run was followed for 80 or for just a few percent reaction. The correlation coefficients were consistently 0.998 or better. However in media of compositions above 95 mol% DMSO the exchange rate usually decreased slowly with time, so that only initial rates were measured. The solution color had become pale yellow by the end of these runs, and a strong amine odor could be detected.

It is probable that the tetramethylammonium cation is undergoing hydrolysis under such strongly basic condi-

tions, since quaternary ammonium cations tend to be fairly unstable in basic media (24). The tetramethyl form appears to be the least reactive, but stability decreases when the water content of the solvent is lowered (24). Trimethylamine has been reported (25) as a decomposition product of the pyrolysis of the solid tetramethylammonium hydroxide.

The rate constants measured by the procedure outlined above apply to the vapor phase rate of change of D_2–HD–H_2 composition. In order to obtain the in-solution first order rate constants, which are necessary to assess the true medium effect on the exchange reaction, the vapor phase values must be multiplied by a factor representing the distribution of D_2 between the two phases. This factor is given by: (total moles D_2 in the system)/(moles D_2 dissolved in the liquid phase) (5). The term in the denominator was calculated by combining the H_2 solubilities in the various exchange media at each temperature (18) with the H_2-to-D_2 conversion factor of 1.05 (see above). The term in the numerator was obtained from a knowledge of the partial pressure of the D_2 at ambient temperature, and the internal volume of the reaction vessel, corrected for solution volume. The net rate correction factor ranged between 95 and 180, being greater the lower the temperature. The main contribution arises from the strong dependence of gas solubility on temperature for most of the media. The in-solution rate constants are believed to be accurate within ±5% in the solvent composition range 20–97 mol% DMSO. However, reproducibility was poorer in solvents richer in DMSO, presumably because of a slight variation in water content from one run to the next.

The ratio of exchangeable H to D atoms, arising respectively from the water and DMSO (26, 27) and from the total D_2 in the system, was always greater than 225. Also, a comparison was made between the rate of D_2 exchange, under conditions of both the fastest and slowest rate measured, and the rate of H/D transfer for DMSO–water mixtures as calculated from the data of Stewart and Jones (26). For example, while the rates are comparable in 20 mol% DMSO at 35 °C, in 78 mol% DMSO at this temperature the DMSO–water exchange is estimated to be approximately 1000 times faster. This means that *if*, in media rich in DMSO, formation of HD can arise only through transfer of H from a water molecule, the DMSO protons would be readily available in that form, because of the rapid DMSO–water exchange.

To ensure that catalysis of the D_2 exchange reaction by water was unimportant in these media, runs were performed without added base in 77.9 mol% DMSO at 65 °C and in 96.9 mol% DMSO at 80 °C. In both cases there was negligible reaction after several hours, in comparison to 35 and 90% exchange under the basic conditions normally employed (0.134 and 0.022 *M* base, respectively).

Results and Discussion

Rate Dependence on Medium Composition: Qualitative Observations

The kinetic results of this investigation, as given in Tables 2 and 3, show that the rate of the hydroxide ion catalyzed exchange of D_2 increases markedly as the DMSO content of the medium is increased. This is shown explicitly in Table 3 where the rate data have been reduced to a common hydroxide ion concentration (0.011 *M*) by extrapolation. The overall increase in rate as one proceeds from purely aqueous medium to 99.6 mol% DMSO is thus of the order of 10^4. This rate enhancement, though appreciable in absolute terms, is less than would have been expected relative to other systems (*vide infra*), and is insufficient from the viewpoint of adoption in a technical process for D_2O production (12). It appears likely that the observed rate behavior is tied in some fashion to the mechanism of the exchange process and it is therefore pertinent to consider in some detail the mechanistic implications of the present results.

TABLE 3. Medium dependence of the first order, in-solution rate constants for D_2 exchange at constant [Me_4NOH], (0.011 *M*), at 65.0°*

Mol% DMSO	$10^4 k_{obs}$ (s^{-1})
0.0	0.018
20.2	0.070
40.1	0.20
59.0	0.55
77.9	1.9
87.5	4.3
96.9	30
98.5	81
99.2	83
99.6	147

*Data for the solvent compositions 20.2–96.9 mol% DMSO have been obtained from Table 2 by extrapolation to a common hydroxide concentration, 0.011 *M*. The results for 98.5, 99.2, and 99.6 mol% DMSO are separate measurements carried out at the single value of [Me_4NOH]. The value for 0% DMSO has been calculated from ref. 5. The estimated error on the data is ±10%.

Rate Dependence on Acidity Functions

Useful information concerning reaction mechanism of base catalyzed processes may often be derived from consideration of rate dependence on solution basicity (28). For binary solvent systems consisting of dipolar aprotic–protic solvent mixtures, such as the DMSO–water case of the present study, the medium basicity at constant stoichiometric hydroxide ion concentration does not remain constant but increases dramatically as the proportion of the protic component decreases (29, 30). The increased basicity is generally ascribed (29–32) largely to the progressive desolvation of hydroxide ion as the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

hydroxylic component is replaced by the poorly hydrogen-bonding DMSO.

The acidity functions, first introduced by Hammett (33), provide quantitative measure of the basicity of such solvent systems. Thus the H_- function is applicable to base-induced ionization of a neutral weakly acidic indicator ($HA + OH^- \rightleftarrows A^- + H_2O$) and is defined as $H_- = -\log a_{H^+} f_{A^-}/f_{HA}$ where a_{H^+} is the hydrogen ion activity and f_{A^-}, f_{HA} are activity coefficient terms. J_- is applicable to addition of hydroxide ion to a neutral indicator ($R + OH^- \rightleftarrows ROH^-$) and is given by $J_- = -\log a_{H^+} f_{ROH^-}/a_{H_2O} f_R$. It is seen that the two functions are related by the expression:

$$[5] \quad J_- = H_- + \log a_{H_2O} + \log \frac{f_R f_{A^-}}{f_{ROH^-} f_{HA}}$$

Correlations of reaction rates with acidity functions are theoretically based on a number of assumptions (28, 34) whose validity may be difficult to ascertain in practice. However such correlations often provide an empirical criterion of reaction mechanism, through classification and comparison with reactions of known mechanistic types.

A number of rate–acidity function correlations have been recorded for base-induced reactions over the past few years (28–30, 34–37). The log (rate) *vs.* H_- plots are generally found to be linear, with slopes in the region 0.5–1.0. Similar relationships have been found for the J_- function. The linearity of such plots is usually taken as indicative of constancy of mechanism over the basicity range considered. The magnitude of the slopes of such plots has been interpreted as signifying the degree of proton transfer between substrate and base in the case of H_- correlations (by analogy with Brønsted β values), or with the extent of bond formation between substrate and base for J_- correlations. For example, in the case of proton exchange in the CH_3SOCH_3–OH^-–H_2O system the observed slope of 0.93 in the log (rate) *vs.* H_- plot was interpreted on the basis of essentially complete transfer of the proton from the carbon acid to OH^- in the rate-determining transition state (38). However it has been pointed out (ref. 39 and others cited therein) that the experimentally observed slope of a Brønsted plot may not be an accurate indication of the transition state structure.

The problem at hand is whether it is feasible to differentiate between the alternative mechanisms for the D_2–OH^- exchange via the acidity function approach. From reaction 1 it is seen that the hydride ion mechanism involves essentially rate-limiting proton transfer from D—D to OH^-, so that a rate correlation with H_- may be expected to apply. Now since D_2 is a much weaker acid than H_2O one would predict that in the transition state for reaction 1*a* the proton would be virtually completely transferred to OH^-, as the weaker base compared to D^-.[4] Hence the slope of the log (rate) *vs.* H_- plot would be expected to be near unity. The actual plot of the data (Table 3) is shown in Fig. 1. As is seen, not only is the plot non-linear, but the slopes are considerably below unity. The observed slope values of the curved plot, ranging from 0.23 in near aqueous medium to 0.36 at the DMSO-rich end, appear to be the lowest yet recorded in the literature and are contrary to expectations for the proton transfer mechanism. The concerted type mechanisms given by reactions 2 and 3 would presumably be expected to show similar dependence of rate on medium basicity, *i.e.* a near unit slope in the log (rate) – H_- plot, since the rate limiting proton transfer aspect is retained in these pathways.

The addition complex mechanism (reaction 4) does not involve proton transfer in the rate-limiting transition state, so that one would predict a low sensitivity of rate to medium

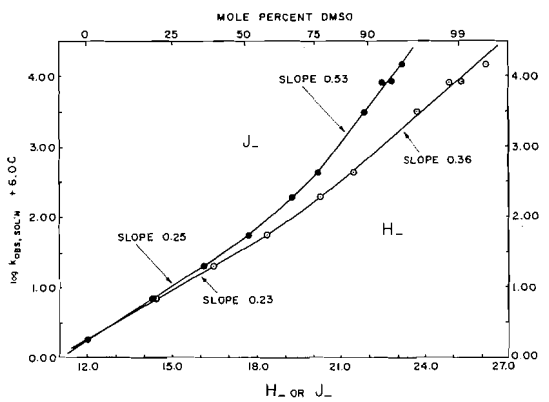

FIG. 1. Plots showing the medium dependence of the first order, in-solution rate constants for D_2 exchange at 65° (s^{-1}) on the H_- and J_- acidity functions.

[4]The pK_a of H_2 is not known with certainty, estimates ranging between 29 and 38 for the value in aqueous medium (40). The pK_a of H_2O (15.7 in aqueous medium) is known to increase in DMSO-containing media (*vide supra* for discussion of solvation of OH^-), reaching the value 26 in 93 mol% DMSO (41).

basicity and hence a small value of the slope in the log k_{obs} – H_- plot, as is in fact observed. On the other hand the slow formation of $DDOH^-$ might have been expected to lead to a satisfactory correlation with the J_- function. As seen in Fig. 1 this plot is also curved and the slopes are still considerably less than unity, though larger than in the H_- plot.[5]

It should be pointed out that quantitative interpretation of the nature of the H_- and J_- plots in the case of D_2 will be tenuous. The necessary condition of similarity in structure between the substrate used in the reaction and the indicators employed to set up the acidity functions, as required for valid interpretation of the rate-acidity function correlations, is probably less well met with D_2 than with any other substrate under investigation. The major problem is that the character of the hydride ion in solution is not known. Intuitively one would have expected H^- to be susceptible to extremely strong solvation by water molecules. However Pearson *et al.* (40) classify it as a *soft* (albeit strong) base and Cotton and Wilkinson (43) consider H^- to be a rather diffuse ion. On the other hand hydroxide ion is generally regarded to be hard. Hence interaction of H^- with the *aprotic* component of the solvent system may in fact be *more extensive*, while solvation by water molecules may be less effective, than occurs with OH^-.

Rate Dependence on Concentration of Tetramethylammonium Hydroxide

The isotopic exchange of D_2 is characterized by an unusual dependence of rate on the concentration of tetramethylammonium hydroxide, as shown by the data in Table 2. Thus for a given DMSO–water medium the plot of the rate constant for exchange (k_{obs}) *vs.* [Me_4NOH] generally exhibits an upward curvature, with slopes greater than unity in the log–log plot at the higher base concentrations. An example is shown in Fig. 2, corresponding to the data for 87.5 mol% DMSO. It appears therefore that the rate of reaction is not simply dependent on the hydroxide ion concentration as in a first order process.

In considering reasons for the apparent deviation from first order dependence on [Me_4NOH], one possibility is that it is caused by deviant H_- behavior, *i.e.* that H_- rises more rapidly than log [OH^-] in a given DMSO–water medium. Unfortunately, literature data on the variation of H_- with [Me_4NOH] are not available for these systems. In principle this factor cannot be excluded, though it would be surprising if such deviation were important for base concentrations of the order of 0.1–0.2 *M*. Significantly, Wilmarth *et al.* (3) observed a similar curvature for D_2 exchange in purely aqueous medium in a region of base concentration where a linear relationship is maintained between H_- and log [OH^-]. It is probable therefore that some other factor(s) are at play in these processes.

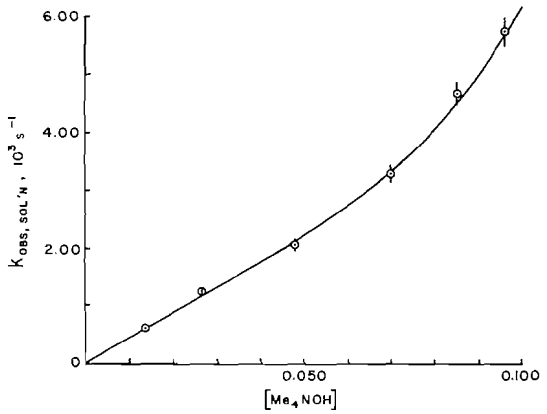

FIG. 2. Illustrative plot to show non-linear dependence of the first order, in-solution rate constants for D_2 exchange at 65° on [Me_4NOH], using the data for 87.5 mol% DMSO.

One general explanation for such behavior was proposed by Prue and co-workers (44), in considering the results of a study of the hydrolysis of diacetone alcohol by various tetraalkylammonium hydroxides. They pointed out that the rate expression will contain the concentrations of substrate and hydroxide ion, multiplied by an activity coefficient factor, $f_A f_{OH^-}/f_{(AOH)^-}{}^{\ddagger}$, where the terms in the numerator refer to reactants and the denominator to the transition state. An increase in the catalytic rate constant would then most likely arise from an increase in the ratio $f_{OH^-}/f_{(AOH)^-}{}^{\ddagger}$, which would be caused by specific short-range interaction of hydroxide ion and/or the transition state with an oppositely charged tetraalkylammonium ion. Similarly, an apparent second order dependence on hydroxide ion concentration was recently ascribed by

[5]The function plotted is $J_- = H_- + \log a_{H_2O}$ according to eq. 5, on the assumption that the activity coefficient ratio cancels (28–30). The a_{H_2O} data for the DMSO–H_2O system are taken from ref. 42.

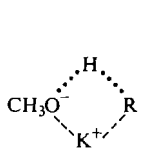
Edwards and co-workers (45) to the operation of a salt effect (see also ref. 46).

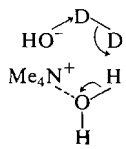
A mechanistic explanation has been given by Kollmeyer and Cram (35) for the observed non-linear dependence of rate on base concentration for hydrogen exchange involving some carbon acids in a medium of DMSO–MeOH containing MeOK. The experimental data were fitted to the following rate equation

$$[6] \qquad \text{rate} = k_2[RH][B] + k_3[RH][B]^2$$

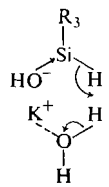
The term second order in base was then ascribed to a pathway involving participation by methoxide ion and potassium ion (via the ion-pairs) in the rate-determining step, as indicated in the structure **1**. In the present system, one may



1



2



3

tentatively propose a reaction route also involving cation participation. The 6-centered process shown in **2** involves participation by the cation as well as by a solvent molecule; the role of the latter would be to provide electrophilic assistance and thereby eliminate the necessity for free hydride ion formation. Sommer *et al.* (47) have put forward an analogous mechanism, shown in **3**, for base induced displacement of hydride from silicon.

It is difficult at the present time to draw definite conclusions concerning the mechanism of the D_2 exchange process. Such caution is dictated by the unusual nature of some of the results recorded here. Further studies on this problem are in progress.

The authors wish to thank Atomic Energy of Canada Ltd. for a research contract and also for a postdoctoral fellowship to E.A.S., 1969–1971. Sincere appreciation is extended to the staff of the Analytical Branch of the Whiteshell Nuclear Research Establishment at Pinawa, Manitoba, for the mass spectral analyses. Discussions with G. G. Strathdee, N. H. Sagert, and M. Tomlinson are gratefully acknowledged.

Photooxidation and Reduction of Ascorbic Acid Studied by E.S.R.

ROBERT D. MCALPINE,[1] MICHAEL COCIVERA, AND HOLGER CHEN
Department of Chemistry, University of Guelph, Guelph, Ontario

Received May 16, 1972[2]

The photooxidation of ascorbic acid in water at p*H* 4.5–11.6 was studied using electron spin resonance spectroscopy. In the presence of oxygen, only one radical is detected and its resonance lines are broad. In the absence of O_2, better resolution is obtained and a second radical is observed. When N_2O or H_2O_2 is added, the second radical disappears while the concentration of first radical is increased. These results are consistent with a primary photochemical step involving ejection of an electron from the monoanion of ascorbic acid to form the ascorbate. The second radical appears to be formed by addition of a hydrated electron to the monoanion of ascorbic acid.

La photooxydation de l'acide ascorbique dans l'eau à des p*H* 4.5–11.6 a été étudiée en utilisant la spectroscopie de résonance du spin électronique. En présence d'oxygène, on a détecté un seul radical et ses bandes de résonance sont larges. En absence d'oxygène, on a obtenu une meilleure résolution en même temps qu'un second radical fut détecté. Lorsque l'on a ajouté du N_2O ou du H_2O_2, le second radical est disparu alors que la concentration du premier radical a augmenté. Ces résultats sont donc compatibles avec la première étape photochimique qui implique l'expulsion d'un électron à partir du monoanion de l'acide ascorbique pour former l'ascorbate. Le second radical semble donc être formé par addition d'un électron hydraté au monoanion de l'acide ascorbique.

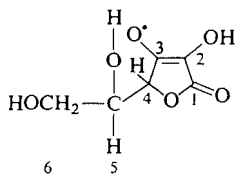
Can. J. Chem., **51**, 1682 (1973)

Introduction

Oxidation–reduction reactions among ascorbic acid, monodehydroascorbic acid radical, and dehydroascorbic acid are believed to play a very important role in a number of biologically essential redox systems (1). Yamazaki, Mason, and Piette (2–4), using electron spin resonance spectroscopy (e.s.r.), have studied the oxidation of ascorbic acid by H_2O_2 and peroxidase. They observed a two line spectrum (one proton with a hyperfine splitting constant of 1.7 G) which they attribute to the monodehydroascorbic acid radical.



I

Later, Förster, Weis, and Staudinger (5) observed the same spectrum under conditions which yielded greater resolution of the fine details of the spectrum. This spectrum, obtained in water solution by mixing ascorbic acid and dehydroascorbic acid, showed six lines which could be interpreted in terms of one proton with a hyperfine constant of 1.7 G (doublet) and two equivalent protons with hyperfine constant of 0.32 G (triplet). As with Yamazaki, Mason, and Piette (2–4), the hyperfine of 1.7 G was assigned to the lone hydrogen on C_4 of the monodehydroascorbic acid radical (5). The triplet splitting due to two magnetically equivalent protons was not specifically assigned other than to suggest that it was due to hydrogens located on the aliphatic side chain.

We have studied the photochemical oxidation of aqueous ascorbic acid, by e.s.r. spectroscopy, in both oxygen saturated and anaerobic solutions. In both cases we observed the same radical detected by previous workers (1–5). For oxygen saturated solutions, the observed linewidths were about the same as those observed by Yamazaki, Mason, and Piette. However the resolution obtained for deoxygenated solutions was better than that obtained by Förster, Weis, and Staudinger. In addition a new radical was observed. Our results are consistent with the formation of the monodehydroascorbic acid radical via electron ejection from an excited state of the monoanion of ascorbic acid. The second radical appears to be formed by the addition of the hydrated electron to the monoanion.

Experimental

Solutions of 10^{-2} *M* L-ascorbic acid (obtained from B.D.H., reagent grade, and Nutritional Biochemical Corporation and used without further purification) were studied at various p*H* values between 4.5 and 11.6 in a continuous closed flow system. A description of this system has been given previously (6). Irradiation was carried out in the microwave cavity of a Varian E-12 e.s.r. spectrometer using the full spectrum (quartz optics) of a 1000 W high pressure Hanovia mercury–xenon lamp. Usually nitrogen gas was bubbled through the solutions. Several experiments were performed with H_2O_2 (Fisher Scientific) added or with N_2O (Canox) replacing the nitrogen gas. In addition a few experiments were carried out using oxygen (Canox) saturated solutions.

5,6-*o*-Isopropylidene-L-ascorbic acid was prepared as reported by Vargha (7). A mixture of 500 ml of acetone, 50 g of $CuSO_4$, and 12 g of L-ascorbic acid was stirred for 24 h. After filtering, the solution was concentrated to one third its volume, and petroleum ether was added to precipitate a white crystalline material. After recrystallization several times and drying, this material melted sharply at 218 °C (uncorrected) compared to 176 °C for ascorbic acid. Mass spectroscopy of this compound showed a strong parent peak at mass 216 whereas a peak due to ascorbic acid could not be detected. The n.m.r. spectrum at 60 MHz indicated a compound containing two methyl groups having a different chemical shift than acetone. Acetone could not be detected.

The Photochemical Oxidation of Ascorbic Acid

The e.s.r. spectrum of an oxygen saturated water solution of ascorbic acid during irradiation is given in Fig. 1*A*. This spectrum (obtained at p*H* 6.3 and ambient temperature) consists of two broad lines (bandwith ~ 0.9 G) about $g = 2.0052$, and is nearly identical to the one obtained by Yamazaki, Mason, and Piette for the enzymatic oxidation of ascorbic acid in water (2–4). When the solution is deoxygenated, the resolution of the spectrum is improved significantly as can be seen from Fig. 1*B*, which was obtained at p*H* 11. Thus, the greater linewidth observed in the presence of molecular oxygen indicates that the oxygen probably is increasing the spin relaxation rate for the radical (**1**). The sweepwidth is the same for Figs. 1*A* and 1*B*; however the linewidth in 1*B* is narrow enough to observe an additional triplet splitting. In addition, the weaker spectrum of another radical (hereafter referred to as **2**) is observed with $g = 2.0045$; this radical has not been reported by previous workers. The spectrum of **2** can be analyzed in terms of two inequivalent hydrogens with hyperfine coupling constants 13.8 and 0.74 G. Regions of the spectrum of **1** and **2** were studied in more detail under conditions of improved instrument resolution (sweepwidth of 4 G, modulation amplitude of 0.02 to 0.06 G and 2 mW of microwave power). The spectrum of **2** showed no further structure (see Fig. 2*A*); however a total of twelve lines was observed in the spectrum of **1** (see Fig. 2*B*). These twelve lines can be ascribed to 4 hydrogens in equivalent sets 2:1:1 with hyperfine coupling constants 0.17, 0.06, and 1.75 G, respectively. To ensure that the 0.06 G splitting is real and not an artifact due to the 100 kHz modulation, the experiment was re-

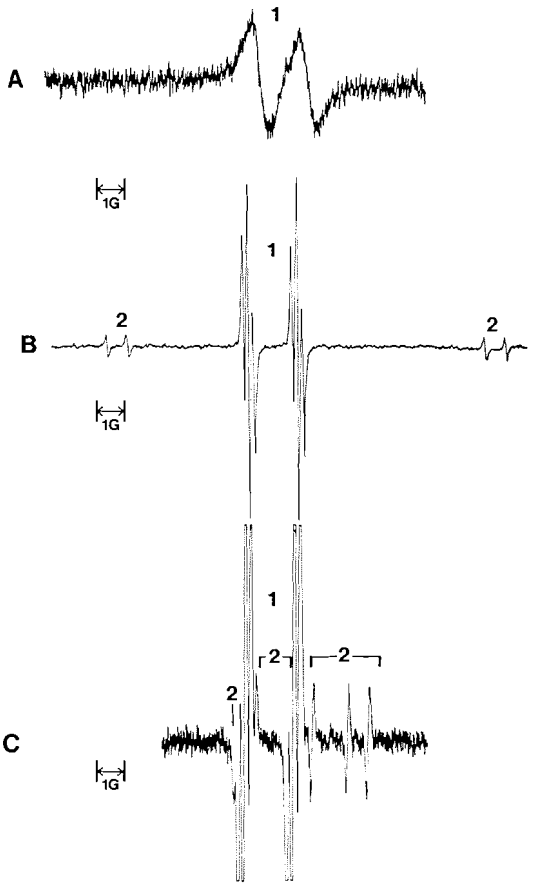

FIG. 1. (*A*) The e.s.r. spectrum of 10^{-2} *M* L-ascorbic acid irradiated in an oxygen saturated aqueous solution at p*H* 6.3. Radical **1** is observed as two broad lines (bandwidth ~ 0.9 G); but radical **2** is not observed. (*B*) The e.s.r. spectrum of a 10^{-2} *M* solution of L-ascorbic acid irradiated in an oxygen free solution of p*H* 11. Radical **1** is seen to sharpen considerably, while a new radical (**2**) is observed with two hyperfine coupling constants of 13.8 and 0.74 G. (*C*) The e.s.r. spectrum of 10^{-2} *M* L-ascorbic acid in D_2O under oxygen-free conditions. Radical **1** is unchanged; however the proton responsible for the 13.8 G splitting in **2** is replaced by a deuterium, yielding a 6 line spectrum for radical **2** with a hydrogen hyperfine of 0.74 G and a deuterium hyperfine of 2.05 G.

For personal use only.

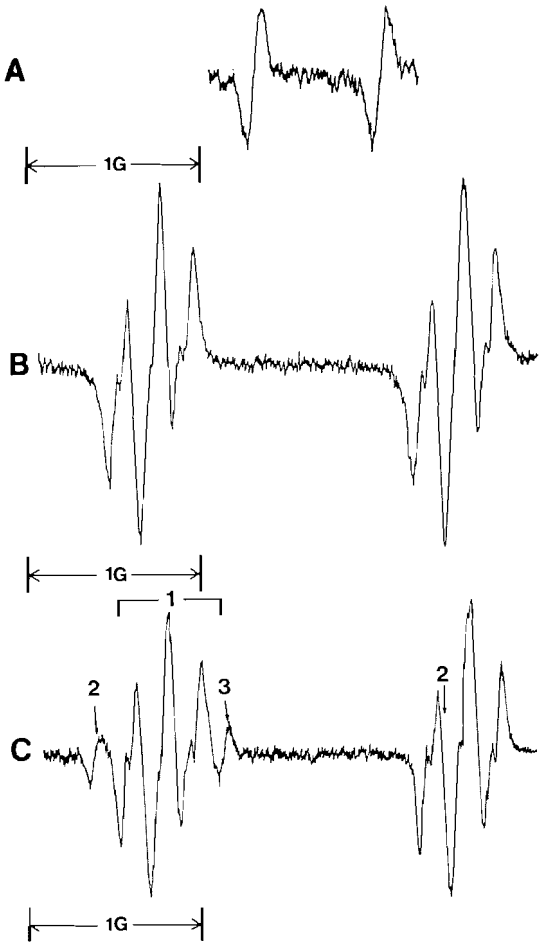

FIG. 2. (*A*) A portion of the e.s.r. spectrum of radical **2** under conditions of high resolution. (*B*) The e.s.r. spectrum of radical **1** under conditions of high resolution. It is evident that radical **1** is a 12 line spectrum which can be ascribed to 4 hydrogens in equivalent sets 2:1:1. The hyperfine coupling constants are 0.17, 0.06, and 1.75 G, respectively. (*C*) The high resolution e.s.r. spectrum of radicals **1** and **2** generated in a D_2O solution. The spectrum of radical **1** is unchanged except for the overlapping of new deuterium lines which arise from radical **2**.

peated using 10 kHz modulation. Under these conditions, the small splitting did not disappear, but on the contrary was somewhat better resolved. Because of the overlap of these lines, a computer simulation was used in this analysis.[3]

In the absence of radiation, radical **1** can still be detected in basic solution but not in acid solution. However, its concentration is about a factor 10 lower than the concentration obtained during irradiation with our light source. Radical **2** is not observed under these conditions. The observation of a small amount of radical **1** in the absence of radiation indicates that a small amount of dehydroascorbic acid is present in the ascorbic acid since radical **1** can be generated in a solution containing ascorbic acid and dehydroascorbic acid (5). The absence of radical **2** under these conditions will be discussed below.

The experiment was repeated using D_2O as a solvent (see Figs. 1*C* and 2*C*). In this case the hydrogen having the coupling constant of 13.8 G in **2** is replaced by a deuterium. This results in the doublet with the 13.8 G splitting becoming a triplet of three equal intensity lines with a splitting of 2.05 G. On the other hand, none of the hydrogens of radical **1** are replaced by deuterium when D_2O is used as a solvent. In Fig. 1*C*, it can be seen clearly that the spectrum of **1** is unchanged except for overlap by the new lines of spectrum **2**. Thus, none of the hydrogens which interact with the unpaired electron of **1** appear to exchange easily with D_2O under basic conditions.

N.m.r. studies (8, 9) indicate that OH-protons of alcohols and acids exchange rapidly in basic media. To determine if any of the CH-protons can readily exchange at the p*H* values employed in the present study, a solution of ascorbic acid in D_2O at p*H* 12 was allowed to sit for several hours at room temperature. Since ascorbic acid decomposes at high p*H* when O_2 is present, the solution was evacuated to 2 μ Hg. Under these conditions, the n.m.r. spectrum obtained indicated that none of the CH-protons had been replaced by deuterium and that no decomposition had occurred. Thus the hydrogen responsible for the 13.8 G coupling constant in **2** probably is hydroxylic in nature, and all of the hydrogens responsible for the observed hyperfine structure in **1** must be attached to carbon atoms.

Structure and Mechanism

The structure of radical **1** has been suggested to be the monodehydroascorbic acid radical (structure **1**) (2–5). Our results are consistent with this structure if the hyperfine coupling constants are assigned as follows: C_4-proton, 1.75 G; C_5-proton, 0.06 G; and C_6-protons, 0.17 G. This assignment requires that the C_6-protons have a somewhat larger electron spin density than the C_5-proton. Since the values are small it is not

[3]Program written by C. S. Johnson, modified by P. J. Black and T. J. Debyer.

impossible that conformational effects might account for this order. However to check the possibility that the spectrum might be due to a different radical having a second ring formed by bonding the C_6-oxygen to C_3, we have obtained the e.p.r. spectrum of an aqueous solution of 5,6-isopropylidene-L-ascorbic acid under the same conditions. Since the C_5 and C_6 oxygens are blocked in this compound, ring formation involving the aliphatic side chain is unlikely. For this compound, the observed spectrum is the same as the one observed for radical **1**. Consequently, this result does not support a two ring structure for radical **1**, and structure **1** seems more reasonable.

(Note added in proof: Recently, the same e.s.r. spectrum has been observed as a result of reaction of OH with ascorbic acid in H_2O, and the same structure has been proposed (17).)

Radical **2** appears to be formed by the addition of the hydrated electron to the monoanion of ascorbic acid. This conclusion is based on the following evidence. This radical is formed only during irradiation, *i.e.* in the absence of irradiation, radical **2** is not detected even though radical **1** can be detected. Under these equilibrium conditions, one would not expect the formation of radical **2** if the hydrated electron is involved. Furthermore, during irradiation in the presence of N_2O, **2** cannot be detected whereas the concentration of **1** is increased by a factor of two. This increase is prevented by the addition of methanol. Since N_2O reacts with the hydrated electron to form the hydroxy radical (10), this result supports the hypothesis that N_2O prevents the formation of **2** by reacting faster with the hydrated electron than does the monoanion of ascorbic acid.

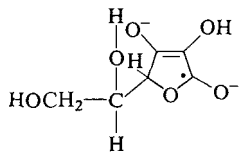
Furthermore, the increase in the concentration of **1** can be explained by a reaction of the hydroxy radical (formed by the reaction of N_2O with the hydrated electron) with the monoanion of ascorbic acid. The effect of H_2O_2 on the concentrations of **1** and **2** is consistent with this conclusion. In the absence of radiation, the concentration of radical **1** is approximately doubled when 3% H_2O_2 is added to a deoxygenated solution of 0.01 *M* ascorbic acid at p*H* 8. Radical **2** is not detected. However during irradiation of solutions containing 0.3 to 3% H_2O_2 at p*H* values between 4.5 and 11.6, the concentration of radical **1** increases by up to a factor of 25, *i.e.* about 5 times larger than the concentration of **1** obtained during irradiation in the absence of H_2O_2. Radical **2** cannot be detected. Addition of methanol at a concentration equal to that for H_2O_2 decreases the intensity of **1** to the value obtained in the absence of H_2O_2, and radical **2** cannot be detected.[4] Some further quenching is observed if more methanol is added. The effect of methanol is consistent with the suggestion that OH is present since methanol scavenges OH (12). Thus, the effect of N_2O on the concentration of **1** is consistent with the suggestion that the hydrated electron is formed during the irradiation of an aqueous solution of ascorbic acid. We suggest the following mechanism. The monoanion of ascorbic acid absorbs light and subsequently forms radical **1** by ejecting an electron while in an excited electronic state. The hydrated electron formed in this manner adds to another ascorbic acid anion in its ground state to form **2**.

The reduction potential of ascorbic acid indicates that the addition of an electron to the monoanion is a possibility. The reduction potentials for ascorbic acid and cinnamic acid are -2.06 and -1.93 V, respectively. These potentials were measured in solution in acetonitrile on a Hg electrode with an Ag/AgCl reference electrode. Cinnamic acid was chosen for comparison because it is somewhat similar in structure to ascorbic acid and its anion reacts with the hydrated electron at a nearly diffusion controlled rate (13). Unfortunately, it was not possible to measure the reduction potentials for the anions of the acids because the reduction could not be performed with water as the solvent. At any rate, the close similarity in the reduction potentials for these acids indicates that the addition of an electron to the monoanion of ascorbic acid probably is not unreasonable.

The structure of **2** cannot be specified with any certainty at this time. The e.p.r. results using D_2O indicate that the hydrogen having the hyperfine coupling constant of 13.8 G exchanges easily. The n.m.r. study using D_2O indicates that the hydrogens bonded to carbon atoms in ascorbic acid do not exchange easily. Consequently it would appear that the exchangeable hydrogen is attached to an oxygen atom. Furthermore, the hydrated electron most likely would add to the carbonyl group at position 1.

[4]Radical **2** might disappear by reacting with H_2O_2; or H_2O_2 could prevent the formation of **2** by reacting with the hydrated electron (11).

By analogy, the hydrated electron appears to add to the CO_2^- group of tyrosine (14). These results would suggest structure **2** with the



2

coupling constants 13.8 and 0.74 G assigned to the OH in position 2 and the CH in position 4, respectively. However, the coupling constant as large as 13.8 G for an OH-proton in liquid solutions is unprecedented. Usually it is much smaller, although values of 12 and 13.9 G have been observed in the solid state (15, 16). Therefore, structure **2** must be regarded as tentative.

The authors wish to thank Dr. R. O. Loutfy for measuring the reduction potentials, and Professor M. Fujimoto for his generosity in making his e.s.r. facilities available to us. This work has been supported in part by DUA grant #64061, DRB grant #953096, and by PRF grant #PR4904.

Temperature Dependence of Activation Volumes of Solvolysis Reactions in Light and Heavy Water

CLAUDE S. DAVIS[1] AND J. B. HYNE
Department of Chemistry, University of Calgary, Calgary, Alberta

Received October 23, 1972

The pressure dependence of the solvolysis rates for benzyl chloride, isopropyl bromide, and methanesulfonyl chloride in H_2O and D_2O have been measured. The temperature dependence of the activation volumes appears to be indicative of the mechanism of solvolyses and the differences in the temperature dependence of the activation volumes for the two solvents are consistent with D_2O being the more structured. The more extensive data in the case of methanesulfonyl chloride deuterolysis indicates extremum behavior in ΔV^* as a function of temperature in the 5–25 °C range.

La relation entre la pression et le taux de solvolyse du chlorure de benzyle, du bromure d'isopropyle et du chlorure de méthane sulfonyle dans l'H_2O et dans le D_2O a été évaluée. La relation entre la température et les volumes d'activation semble être caractéristique du mécanisme des solvolyses. De plus, les différences dans la relation des volumes d'activation et la température pour les deux solvants sont en accord avec le fait selon lequel le D_2O est le mieux structuré. Les données les plus complètes en ce qui a trait à la deutérolyse du chlorure de méthanesulfonyle montrent un comportement extrême du ΔV^* en fonction de la température dans l'intervalle de 5 à 25 °C. [Traduit par le journal]

Can. J. Chem., 51, 1687 (1973)

Introduction

The temperature dependence of the volumes of activation, $d\Delta V^*/dT$, for solvolysis reactions in H_2O have been reported previously (1–7) and for some reactions $d\Delta V^*/dT$ has been dissected into initial and ground state components (1). The behavior of these parameters has been discussed in terms of the differences in polarity of the initial and transition states. It is well known that aqueous binary solvents significantly alter activation parameters (4, 8). This variation in the activation parameters has been discussed largely in terms of the effect that the addition of cosolvent has on the structure of water as well as in terms of the change in polarity of the substrate in the activation process. In view of the analogous structural properties of H_2O and D_2O and the influence temperature has on them, this investigation deals with the temperature dependence of the activation volume in H_2O and D_2O.

Although there is a large amount of kinetic data for solvolysis reactions in heavy water (9, 10) no data have been obtained at pressures other than atmospheric. The present study was undertaken to determine whether or not the difference in structural properties of D_2O and H_2O are significant enough to be reflected in the temperature dependence of the volume of activation for these solvolyses.

Experimental

Materials

Water

House distilled water was passed through a deionizing resin. The specific conductance of the water used was no greater than $8 \times 10^{-7}\ \Omega^{-1}\ cm^{-1}$ at 25 °C.

Heavy Water

99.8 mol% D_2O from Bio-Rad Laboratories was used. The D_2O was redistilled before use. The H_2O content which was checked by n.m.r. never exceeded 0.4 mol%.

Methanesulfonyl Chloride, Benzyl Chloride, and Isopropyl Bromide

These compounds were each twice distilled under reduced pressure and the middle fractions were collected each time. Analysis by gas–liquid chromatography showed less than 0.02% impurity.

Kinetics

The rates of solvolysis of isopropyl bromide and benzyl chloride in H_2O and D_2O were studied at 40.00 and 60.00 °C.

The rates for methanesulfonyl chloride in H_2O were measured at 0.50 and 13.00 °C. The rates in D_2O were determined at 5.00, 8.17, 11.48, 16.20, 21.00 and 26.00 °C. Rates were usually measured over the pressure range 1 to 3402 atm. Temperature control was ±0.01 °C or better and the pressure was maintained within ±14 atm. The reactions were monitored conductimetrically. Details of the high pressure system, conductance bridge and timer have been described previously (11, 12). Graphical analysis of the conductance–time data by the Guggenheim method (13) yielded pseudo first order rate constants.

Results

Solvolytic rate constants obtained as a function of pressure for benzyl chloride and isopropyl bromide are shown in Tables 1 and 2. The errors indicated are average deviations of at least three replicate rate determinations.

The pressure dependence of the solvolysis rate of isopropyl bromide in H_2O has been reported previously (2), but in view of the surprising results obtained, the data were redetermined in these laboratories. Although, as indicated in Table 2, the rate constants at atmospheric pressure compare favorably with the previously reported values (2, 14), the complex rate constant-pressure behavior reported previously (2) was not evident.

The pressure dependence of the rate of solvolysis of methanesulfonyl chloride in both heavy and light water was determined in considerable detail as indicated in Tables 3 and 4. Values at six temperatures were obtained in D_2O and the earlier data of Mackinnon and Hyne (1) in H_2O at two temperatures were expanded to give more complete coverage of the low temperature range.

The rate–pressure data reported in Tables 1–4 were fitted to the equation

$$[1] \qquad \ln k = A + Bp + Cp^2$$

The constants A, B, and C were derived by the least mean squares method using a computer. The volumes of activation and their pressure dependence were calculated using the following relationships (4).

$$[2] \qquad \Delta V^* = -RTB$$

$$[3] \qquad \frac{\partial \Delta V^*}{\partial p} = -2RTC$$

Table 5 lists the values of ΔV^* and $\partial \Delta V^*/\Delta p$ as calculated from the rate–pressure data in Tables 1–4 together with previously published values for light water solvolyses of benzyl chloride (4), and for methanesulfonyl chloride at 5 and 21 °C (1). The activation parameter values presented in Table 5 represent the essential data to be discussed in this paper.

Discussion

Comparison of Hydrolyses

It is interesting to note in Table 5 that at the same temperature there can be small but significant differences in activation volumes for solvolyses reactions in light and heavy water. However, in view of the fact that the structures of H_2O and D_2O vary to different extents as the temperature is altered, we feel that the meaningful parameter to compare is $d\Delta V^*/dT$ in each solvent. Table 6 lists values for $d\Delta V^*/dT$ for the three solvolyses in H_2O and D_2O determined from temperature dependence data in Table 5. In the case of methanesulfonyl chloride the value of 0.00 ± 0.03 merely indicates that the temperature dependence of the volume of activation in this system is small compared with the other

solvolyses. The detailed nature of the temperature dependence of ΔV^* for the sulfonyl chloride will be discussed at a later point in the analysis.

The temperature dependence of the volume of activation can be discussed in terms of its component parts, the temperature dependences of the partial molal volumes of the initial and transition states. The more negative $d\Delta V^*/dT$ values for the

$$\frac{d\Delta V^*}{dT} = \frac{d\bar{V}^t}{dT} - \frac{d\bar{V}^g}{dT} \quad [4]$$

compared with H_2O indicates that the difference in the temperature dependence of the volume of the two states is greater in D_2O than in H_2O. Why should the volumes of the ground and/or transition states in D_2O be relatively more temperature sensitive than in H_2O? The volumes being discussed here are the volumes of the kinetically significant entities which include not only the substrate molecule, but its kinetically important solvent environment. D_2O is known to possess more inherent "structuredness" than H_2O and hence it is reasonable to conclude that a state incorporating the more structured D_2O will in turn have a volume that is more sensitive to thermal disruption. Until some estimate of the values for the thermal expansivity of one or other of the component states are available a more specific analysis of the volume temperature dependence in terms of structure is precluded.

The difference in activation volume temperature dependence between D_2O and H_2O is very significantly less for methanesulfonyl chloride compared with the two alkyl halides. There seems little doubt that the interaction of a highly polar substrate such as methanesulfonyl chloride with a water environment will be significantly different from that in the case of the more hydrophobic and less polar alkyl halides. *The difference* in solute–solvent interaction both between initial and transition states and between light and heavy water will thus be masked in the methanesulfonyl chloride cases and this in turn will be reflected in the greater similarity of the temperature dependences of the volumes. The equal and small $d\Delta V^*/dT$ values (0.00 ± 0.03) for methanesulfonyl chloride support this interpretation.

Available heat capacities of activation in both light and heavy water shown in Table 6 provide further supportive evidence. ΔC_p^* values for methanesulfonyl chloride in the two waters are identical within experimental error in keeping with the postulate that the *difference* between the solute–solvent interaction of both states in both solvents is negligible. On the other hand there is a significant difference between ΔC_p^* values in light and heavy water for isopropyl bromide solvolysis paralleling the behavior observed for the temperature dependence of the activation volume.

The redetermined value of $d\Delta V^*/dT$ for isopropyl bromide hydrolysis deserves comment as it relates to the earlier analysis of Mackinnon and Hyne using the literature rate values (2). Dissection of $d\Delta V^*/dT$ values by these authors for a series of hydrolyses indicated that the $d\bar{V}^t/dT$ component increased in the order:

$$pMe\phi CH_2Cl < MeSO_2Cl < \phi CH_2Cl < \text{allyl Cl} < n\text{BuBr} < \text{isoPrBr}$$

The apparently anomalous position of isopropyl bromide in this sequence required an earlier rationalization based on differences in solvent accessibility to the reaction site. The redetermined $d\Delta V^*/dT$ value for isopropyl bromide *reverses* the order of the two alkyl bromides which is in keeping with the expected larger degree of charge development in the activation process for the secondary halide.

Special Case of Methanesulfonyl Chloride

The gross changes in ΔV^* as a function of temperature for the three solvolyses in light and heavy water have already been discussed. The more extensive data for methanesulfonyl chloride, however, warrant further examination. It must be recognized that the temperature dependence of the volume of activation is a second order derivative of the experimentally measured rate and the inherent uncertainties in such a parameter are expected to be sizeable. Nonetheless, dogmatism excluded, it is considered justifiable to examine the apparent trends in the temperature dependence in both H_2O and D_2O.

The temperature variation of the measured

volumes of activation for the solvolyses of methanesulfonyl chloride in light and heavy water are presented graphically in Fig. 1. The error bars shown indicate the uncertainties in ΔV^* as obtained from the least mean squares fit of the rate–pressure data to eq. [1].

An obvious reason for examining the dependence of the volume of activation on temperature in both light and heavy water in this particular temperature range (0–25 °C) was that both solvents exhibit maximum density behavior in this same range. Since this behavior is known to be related to structural phenomena in the liquids is there a reflection of this solvent structural variation in the volume of activation parameter? Having specifically sought such evidence it will be obvious why care was taken to comment on errors and significance in the preceding paragraph! Despite the error limits, the data in Fig. 1 are considered to indicate such a kinetic reflection of solvent structural variation in the case of D_2O. The same cannot be claimed for the H_2O data. In the latter case, however, it should be recalled that the overall "structuredness" of light water is less than heavy water (17) and hence there will be less overall water structure variation to be reflected in the kinetic parameters. Furthermore, the extremum in the density and hence structural behavior is at 3.984 °C (compare 11.185 °C for D_2O (18)), very close to the lower temperature limit dictated by the freezing point. Hence, in light water, a kinetic manifestation of the density extremum would have to be detected at one end of the accessible temperature range compared with the mid-point location in the D_2O case. Clearly the Fig. 1 data for light water does not provide a definitive answer to this question.

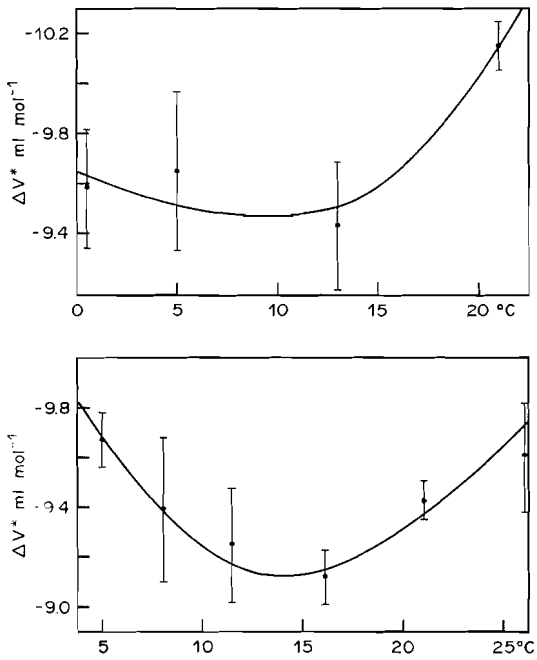

FIG. 1. Variation of volumes of activation for the solvolysis of methanesulfonyl chloride in H_2O and D_2O as a function of temperature.

The heavy water case does suggest an extremum in the temperature dependence of the volume of activation in the 10–20 °C temperature range. Extrema of this kind are commonplace in the dependence of volume of activation on solvent composition for solvolyses in aqueous binary systems, and have been rationalized in terms of the effect of the non-aqueous component on water structure (8). The extremum behavior in ΔV^* for methanesulfonyl chloride in D_2O as a function of temperature can also be rationalized in an analogous manner. The volume of activation for methanesulfonyl chloride is least negative at the extremum. As the temperature is decreased, ΔV^* becomes more negative. This decrease in ΔV^* occurs in the temperature range where the solvent D_2O is becoming increasingly structured. Analogous decreases in ΔV^* are also observed for hydrolyses in aqueous alcohol systems when alcohol is initially added to pure water (8). The effect of the addition of small quantities of alcohol has been asserted to increase the structuredness of the solvent system (19, 20). The extremum in the case of the temperature dependence of ΔV^* for deuterolysis of methanesulfonyl chloride can therefore be due to analogous structural changes induced thermally rather than by adding cosolvent. The extremum is not as marked as in the binary solvent system, but the thermal structural changes in the case of D_2O are likely to be smaller.

Thallium and Tin Electrode Potentials in Fused LiCl–KCl Eutectic

JOSEPH M. SHAFIR AND JAMES A. PLAMBECK
Department of Chemistry, University of Alberta, Edmonton, Alberta
Received December 11, 1973

Electrode potentials of thallium and tin couples were measured in dilute solutions of the ionic species in fused LiCl–KCl eutectic, at 450 °C. Standard molar electrode potentials of the Tl(III)/Tl(I) and Sn(IV)/Sn(II) couples are +0.155 and −0.310 V against a standard molar platinum reference electrode (s.m.p.e.). The standard potentials of the Tl(III)/Tl(0) and Sn(IV)/Sn(0) couples were calculated to be −0.385 and −0.964 V, respectively, *vs.* the s.m.p.e.

Les potentiels d'électrode des couples thallium et étain ont été mesurés en solutions diluées sur les espèces ionisées dans l'eutectique en fusion LiCl–KCl, à 450 °C. Les potentiels d'électrode standard molaire des couples Tl(III)/Tl(I) et Sn(IV)/Sn(II) sont de +0.155 et −0.310 V par rapport à l'électrode standard molaire de référence de platine. Les potentiels standards des couples Tl(III)/Tl(0) et Sn(IV)/Sn(0) ont été calculés et valent −0.385 et −0.964 V respectivement, par rapport à l'électrode standard molaire de platine. Introduction

The standard potentials of the Tl(I)/Tl(0) and Sn(II)/Sn(0) couples have been previously measured in the fused LiCl–KCl eutectic at 450 °C (1). Delarue (2), in a voltammetric study of thallium in the LiCl–KCl eutectic melt, has reported the oxidation of thallium(I) to thallium(III) at a graphite electrode; the half-wave potential of this process was given as +0.2 V. Delarue (2) also carried out the voltammetric oxidation of Sn(II) to Sn(IV) at a graphite electrode and reported the half-wave potential of this process as 0.0 V. In the course of a continuing program of measurement of standard potentials in this solvent (3) it appeared desirable to make equilibrium potential measurements of the Tl(III)/Tl(I) and Sn(IV)/Sn(II) couples.

Experimental

The LiCl–KCl eutectic melt (59 mol % LiCl, (4)) was prepared as previously described (3). Thallium (99.9999%, shot) and tin (99.9999%, wire) were obtained from Alfa Inorganics, Beverly, Massachusetts.

The apparatus and procedure employed have been described (3). The reference electrode employed was the s.m.p.e., as described by Laitinen and Liu (1). Thallium metal as obtained from the manufacturer was covered with a brown-black layer of Tl_2O. Since this compound is soluble in the melt (2), the oxide-coated metal was allowed to remain in contact with the bulk melt for 18 h prior to the commencement of experimental work. This resulted in the dissolution of all oxide and the formation of a bright thallium pool for the coulometric oxidizations. The thallium pool electrode was then transferred into an isolation compartment as previously described (4). The thermoelectric potential between platinum and graphite was found to be 0.004 V (graphite positive), and that between platinum and tungsten was found to be 0.005 V (tungsten positive), both at 450 °C. These thermoelectric potentials were appropriately subtracted from the experimental potentials.

Voltammetric curves were obtained, at slow scan rates, with a Metrohm–Polarecord E261 polarograph; a two-electrode system was employed. Solute concentrations were calculated using 1.648 g/ml as the density of the fused LiCl–KCl eutectic at 450 °C (5).

Results and Discussion

Thallium

For the determination of the standard potential of the Tl(III)/Tl(I) redox couple, a solution of Tl(I) was generated by coulometrically oxidizing a liquid thallium pool. In the course of this generation, ten concentration–potential data points were collected in order to obtain a value of the Tl(I)/Tl(0) standard potential, and to compare it with the value obtained by Laitinen and Liu (1) who electrolytically reduced Tl(I) (added to the melt as anhydrous thallium(I) chloride) at a tungsten electrode. The current density employed in the anodization of the thallium pool was 20 mA/cm^2, and the concentration range of Tl(I) over which data was collected was 2.08×10^{-2} to 0.148 *M*. A plot of the cell electromotive force against the logarithm of Tl(I) concentration was linear and had a slope of 0.140 ± 0.002 V/log unit, in agreement with the theoretical value of 0.143 V/log unit for a one-electron process at 450 °C. The standard molar potential of the Tl(I)/Tl(0) redox couple was calculated to be −1.465 ± 0.002 V. This value, corrected for the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

thermoelectric potential between platinum and tungsten, confirms the value of -1.476 ± 0.002 V determined by Laitinen and Liu (1).

Thallium(I), produced by the coulometric oxidation of elemental thallium, was further oxidized at a graphite electrode after the thallium metal had been removed. The current density employed was 0.6 mA/cm^2. A total of thirty concentration–potential points were taken in two separate experiments in which the concentration ratio of Tl(I)/Tl(III) ranged from 27.57 to 1.222. The solution of Tl(I) was colorless, but turned light green when Tl(III) was generated. A plot of the cell electromotive force as a function of log [Tl(I)]/[Tl(III)] was linear (Fig. 1) and had a slope of 0.074 ± 0.002 V/log unit, in agreement with the theoretical value of 0.072 V/log unit for a two-electron process at 450 °C. The standard potential of the Tl(III)/Tl(I) redox couple was calculated to be 0.155 ± 0.002 V. This value is corrected for the thermoelectric potential between graphite and platinum.

From the standard potentials of the Tl(I)/Tl(0) and Tl(III)/Tl(I) redox couples measured in this study, the standard potential of the Tl(III)/Tl(0) redox couple is calculated to be -0.385 ± 0.003 V, and the equilibrium constant for the reaction $3Tl(I) \rightleftarrows Tl(III) + 2Tl(0)$ is calculated to be 2.55×10^{-23} l^2 mol^{-2}. Thus, thallium metal will quantitatively reduce Tl(III) to Tl(I).

Tin

A liquid tin pool was anodized to prepare a solution of Sn(II) for use in the determination of the standard potential of the Sn(IV)/Sn(II) redox couple. In the course of this anodization, eight concentration–potential data points were collected so that a comparison of the value of the Sn(II)/Sn(0) standard potential could be made against the value (1) obtained by electrolytic reduction of Sn(II) (added to the melt as anhydrous Sn(II) chloride). The current density was approximately 40 mA/cm^2. The concentration range of Sn(II) employed was 1.68×10^{-2} to 0.194 *M*. A plot of log [Sn(II)] against the cell potential had a slope of 0.071 ± 0.002 V/log unit, in agreement with the theoretical value of 0.072 V/log unit for a two-electron process at 450 °C. The standard potential determined for the Sn(II)/Sn(0) couple was -1.079 V, with a standard deviation of less than 1 mV. This value (corrected for the thermoelectric potential between platinum and tungsten) confirms the value of -1.082 ± 0.002 V determined by the procedure of Laitinen and Liu (1).

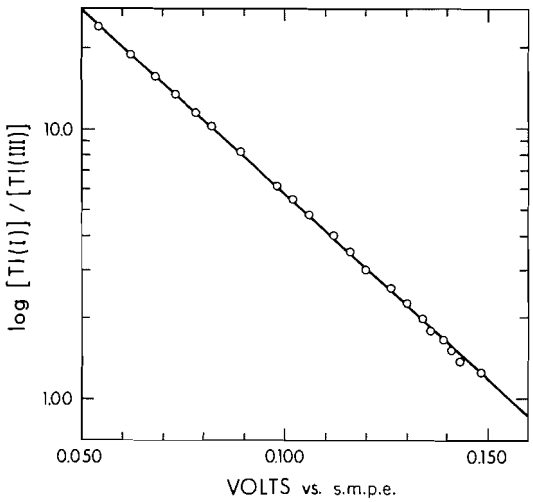

FIG. 1. Nernst plot for the Tl(III)/Tl(I) couple. Potential is corrected for the thermoelectric potential of 0.004 V between graphite and platinum.

The Sn(II) solution was further oxidized to Sn(IV) at a graphite electrode after the tin metal had been removed. The current density was approximately 0.6 mA/cm^2. Few points could be taken in any one experiment because, as the anodization proceeded, the polarization potential steadily drifted to more positive values. In order to maintain the polarization potential below chlorine evolution ($\sim +0.3$ V), the experiment had to be interrupted repeatedly, whereupon the graphite anode was shaken in the melt. This did not completely eliminate the problem, as the amount of current which could be passed between interruptions became steadily smaller; eventually it became impractical to continue the experiment. Careful observation of the graphite electrode did not reveal tin tetrachloride gas evolution. Agitation of the graphite electrode during electrolysis did not reduce the increasing polarization potential, which therefore cannot be attributed solely to concentration polarization of the anode, that is, to depletion of Sn(II) at the surface of the graphite electrode. Although the polarization potential increased, it did not stop at chlorine evolution but went several hundred mV beyond that potential. Normally, anodization of a graphite electrode in the fused LiCl–KCl eutectic results in chlorine evolution, and at low current densities this process occurs at a constant potential of about

TABLE 1. Standard potentials of thallium and tin couples at 450 °C

Couple	E_M^0	E_m^0	E_X^0	Standard deviation
Tl(I)/Tl(0)	−1.465	−1.449	−1.359	0.002
Tl(I)/Tl(0)*	−1.476	−1.460	−1.370	0.002
Tl(III)/Tl(I)	+0.155	+0.139	+0.049	0.002
Tl(III)/Tl(0)†	−0.385	−0.390	−0.420	0.003

†Calculated from experimental free energies.

+0.3 V. These observations can be explained on the basis that the $SnCl_4(g)$ formed in the anodization of Sn(II) is absorbed onto or into the graphite electrode; it is nonconductive so that a greater potential is required. After current cessation, stirring of the graphite anode resulted in the return of its potential to a steady value well within the potential range of the melt. The $SnCl_4(g)$ adsorbed onto or into the graphite anode during Sn(II) oxidation must dissolve in the melt during this time. Fourteen data points were thus collected in three separate experiments; the concentration ratio of Sn(II)/Sn(IV) varied from 6.86 to 3.58. A plot of log [Sn(II)]/[Sn(IV)] against the observed cell potential was linear and had a slope of 0.063 ± 0.005 V/log unit, in fair agreement with the theoretical value of 0.072 V/log unit for a two-electron process at 450 °C. It is not surprising that the slope of the Nernst plot is low, as Sn(IV) volatilized slowly from the solution as $SnCl_4(g)$. This was evidenced by the slight presence of white fumes when the tin compartment was exposed to the atmosphere at the end of the experiment. Loss of Sn(IV) by volatilization of $SnCl_4(g)$ was not serious, as the potential of the graphite electrode remained constant (maximum drift 4 mV/30 min) after cessation of Sn(IV) generation and stirring. The standard state of Sn(IV) was taken as Sn(IV) in solution. The standard potential of the Sn(IV)/Sn(II) redox couple was determined to be −0.310 ± 0.003 V; this value has been corrected for the thermoelectric potential of +0.004 V between platinum and graphite at 450 °C. In view of the adsorption of $SnCl_4(g)$ onto the graphite electrode, and the possibility that not all $SnCl_4(g)$ was desorbed, the standard deviation of ±0.003 V must be taken to represent only the lower limit of uncertainty in the standard potential of the Sn(IV)/Sn(II) couple.

Delarue (2) reported the half-wave potential of 0.0 V for the voltammetric oxidation of Sn(II) to Sn(IV) at a graphite electrode. Because his half-wave potential value does not correspond to the standard potential determined in this work, the voltammetric study was repeated. A sharpened graphite rod dipping 1–2 mm into the melt was used as the indicating electrode. Scanning anodically, only one wave was observed, and the half-wave potential of this wave was found to be −0.31 V, in excellent agreement with the standard potential of the Sn(IV)/Sn(II) redox couple determined in the present study. Reduction of Sn(II) at the graphite microelectrode gave rise to large, ill-defined waves as expected, due to the large concentration of Sn(II) present. The voltammetric wave crossed the zero current axis at −1.1 V, in good agreement with the standard potential of the Sn(II)/Sn(0) couple. The difference between Delarue's value (2) of the half-wave potential for the oxidation of Sn(II) to Sn(IV) and that obtained in this study can be explained as follows. If Delarue employed large current densities in the oxidation of Sn(II) to Sn(IV), then absorption of $SnCl_4(g)$ into the graphite anode would have taken place and a significant shift of the half-wave potential in the positive direction would have occurred. Also, Delarue (2) did not purify his melt, nor was his cell kept under an inert atmosphere, so contamination by traces of water may also account for the discrepancy.

Reversibility of the Sn(IV)/Sn(II) couple was determined by a micropolarization technique. Small amounts of current were passed in either direction through the graphite electrode and it

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

was observed that the open circuit potential recovered its initial value within 30 s after current cessation.

From the standard potentials of the Sn(II)/Sn(0) and Sn(IV)/Sn(II) redox couples measured in this study, the standard potential of the Sn(IV)/Sn(0) couple is calculated to be -0.694 ± 0.003 V, and the equilibrium constant for the reaction $2Sn(II) \rightleftarrows Sn(0) + Sn(IV)$ is calculated to be 1.88×10^{-11} l mol^{-1}. Thus Sn(0) and Sn(IV) will react quantitatively to produce Sn(II).

The standard potentials of thallium and tin are reported in Table 1 on the molar (M), molal (m), and mole fraction (X) concentration scales.

Conclusion

The stable oxidation states of thallium in the LiCl–KCl eutectic melt are Tl(0), Tl(I), and Tl(III), and those of tin are Sn(0), Sn(II), and Sn(IV). The standard potentials of the redox couples between these states have been determined.

The authors are grateful to the National Research Council of Canada for support of this research through an Operating Grant (to J.A.P.) and a NRCC Scholarship (to J.M.S.). The paper is taken in part from the thesis of one of the authors (J.M.S.) submitted to the Faculty of Graduate Studies and Research, University of Alberta, Edmonton, Alberta, in partial fulfillment of the requirements for the Ph.D. degree.

Models for the Interaction of Nitrogen with Transition Metals. Part III. Preparation and Properties of some Cationic Arylazo Complexes of Iron[1]

D. R. FISHER AND D. SUTTON[2]

Department of Chemistry, Simon Fraser University, Burnaby 2, British Columbia

Received November 10, 1972

$Fe(CO)_3(PPh_3)_2$ reacts with *p*-substituted aryl diazonium tetrafluoroborates to yield the compounds $[Fe(CO)_2(PPh_3)_2(N_2C_6H_4X)]BF_4$ (where X = F, Cl, Br, H, NO_2, OCH_3, and OH but not NEt_2). The complex cation displays properties consistent with replacement of an equatorial CO ligand in $Fe(CO)_3(PPh_3)_2$ by the more effective π-acceptor ligand $[N_2C_6H_4X]^+$ analogous to NO^+. A very strong band at *ca.* 1720 cm^{-1} in the i.r. spectrum due to $\nu(N_2)$ has been identified by ^{15}N isotopic substitution. This value is much higher than for most other arylazo complexes yet prepared and the azo group resists catalytic hydrogenation. A number of spectroscopic measurements are reported, including unusually small quadrupole splitting effects in the Mössbauer spectra.

Le $Fe(CO)_3(PPh_3)_2$ réagit avec des tétrafluoroborates de diazonium aryle substitué en position para pour donner des composés du type $[Fe(CO)_2(PPh_3)_2(N_2C_6H_4X)]BF_4$ (où X = F, Cl, Br, H, NO_2, OCH_3, et OH mais jamais NEt_2). Le cation du complexe révèle des propriétés en accord avec la substitution du coordinat CO équatorial dans $Fe(CO)_3(PPh_3)_2$ par le coordinat meilleur accepteur d'électrons $[N_2C_6H_4X]^+$ analogue à NO^+. Une bande très forte à environ 1720 cm^{-1} en infra rouge causée par le $\nu(N_2)$ a été identifiée à l'aide d'une substitution isotopique (^{15}N). Cette valeur est de beaucoup supérieure à celle obtenue avec d'autres complexes arylazo déjà obtenus, de plus le groupe azo résiste à l'hydrogénation catalytique. Un grand nombre de mesures spectroscopiques sont rapportées en incluant des effets de dédoublement quadrupolaire faibles de façon inhabituelle dans les spectres Mössbauer.

Introduction

The chemistry governing the interaction of unsaturated nitrogen ligands such as the diazonium ion $Ar—N\equiv N^+$ with the metals iron and molybdenum is largely unexplored. Yet it is potentially a rich area for study, since these metals are present in the nitrogen fixing enzyme *nitrogenase* and either (or both) have been implicated as sites for binding dinitrogen during the fixation process (1). Both metals have been shown capable of forming synthetic dinitrogen complexes. Of the two, only molybdenum has, till now, been found to complex with the diazonium ion (2–6). This paper reports the first arylazo complexes of iron, a series of cationic complexes $[Fe(CO)_2(PPh_3)_2(N_2C_6H_4X)]^+$. Previous attempts by King to prepare arylazo derivatives of $NaFe(C_5H_5)(CO)_2$ were unsuccessful (2).

Results and Discussion

A benzene solution of $Fe(CO)_3(PPh_3)_2$ reacts with acetone solutions of a range of *p*-substituted diazonium salts to give products containing the complex carbonyl cation $[Fe(CO)_2(PPh_3)_2(N_2C_6H_4X)]^+$ according to the reaction

$$p\text{-}XC_6H_4N_2BF_4 + Fe(CO)_3(PPh_3)_2 \rightarrow [Fe(CO)_2(PPh_3)_2(N_2C_6H_4X)]BF_4 + CO$$

The quantitative evolution of the one mole of carbon monoxide per mole of $Fe(CO)_3(PPh_3)_2$ consumed was confirmed volumetrically. Analytical data are listed in Table 1. The molar electrical conductance values obtained (Table 1) are similar to those expected for 1:1 electrolytes. Molecular weight determinations carried out on a 10^{-2} *M* acetone solution of the *p*-bromo compound (having an expected molecular weight of 907) gave an apparent molecular weight of 498 $\pm$ 3 consistent with 82% dissociation as a 1:1 electrolyte at this concentration. The compounds are stable in air, soluble in polar organic solvents such as alcohols, acetone, acetonitrile, nitromethane, dichloromethane, and chloroform, but are insoluble in water and common non-polar solvents.

The stereochemistry of the complex cation is expected to be closely related to that of $Fe(CO)_3(PPh_3)_2$, that is, to possess approximately trigonal bipyramidal geometry, with apical

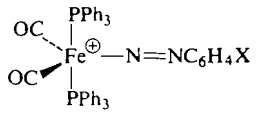
phosphine ligands and one of the three equatorial sites occupied by the coordinated diazonium group as in **1**.[3]

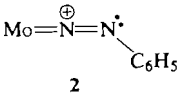


1

All compounds exhibit infrared spectra in which two bands appear in the ν(CO) region (Table 2) consistent with *cis*-carbonyl groups; further, the relative intensities are in agreement with results for other dicarbonyl complexes having two equatorial carbonyl groups in a trigonal bipyramidal geometry (7). A further very strong i.r. band occurs at ~1720 cm^{-1} which we initially suspected from its position to be due to bridging CO, but which was subsequently identified by isotopic substitution as ν(N_2).

The ^1H n.m.r. spectrum of the methyl protons in $[Fe(CO)_2(PPh_2Me)_2(N_2C_6H_4Cl)]BF_4$ (acetone-d_6 solution) appears as a 1:1 doublet of separation 8.9 Hz centered at 7.42 τ separated by a broad unresolved resonance having approximately the same integrated intensity as the outer doublet. Thus, the spectrum is typical of intermediate phosphorus–phosphorus coupling (8) and $|J_{P-H} + J'_{P'-H}| = 8.9$ Hz. No firm stereochemical information may be drawn from this result alone, but it should be noted that $Fe(CO)_3(PPh_2Me)_2$ gives an exactly similar spectrum. We were unable to observe ^{31}P spectra for comparison owing to low solubility in appropriate solvents.

A major feature of interest in the complex cation is the mode of coordination of the diazonium group and the effect of ligation upon the stretching frequency of the N—N bond. Coupled with this is the question of what changes in the geometry of the diazonium are brought about by coordination. Rather little structural or spectroscopic information is available on coordinated diazonium groups and only a few examples are carbonyl complexes. The X-ray structure of hydrotris(1-pyrazolyl) boratobenzenediazodicarbonyl molybdenum ($HB(pz)_3Mo(CO)_2(N_2C_6H_5)$) shows that, in this molecule, coordination of the diazonium group results in a near linear Mo—N—N configuration, but that the N—N—C angle is close to 121°, suggesting the presence of a lone-pair of electrons on the uncoordinated nitrogen (6). This, coupled with the bond lengths Mo—N (1.825(4) Å) and N—N (1.211(6) Å) indicates considerable π-bonding between molybdenum and the coordinating nitrogen atom, which may be described in conventional terms either by back-bonding from molybdenum filled 4d orbitals into the π* system of $[N_2C_6H_5]^+$ or by the valence-bond formalism **2**.



2

Trofimenko assigned a band at 1620 cm^{-1} in these compounds either to ν(N_2) or to an aromatic mode, and in general ν(N_2) has been weak and difficult to assign in those few known

[3]This stereochemistry has now been established by X-ray crystallography by B. J. Haymore and J. A. Ibers (private communication).

carbonylazo compounds. Where assignments have been attempted, $\nu(N_2)$ has generally been placed in the region of 1440–1620 cm^{-1} in these compounds (2–4, 11).

The complexes presently described, then, are remarkable in that $\nu(N_2)$ occurs unambiguously as a very strong band at a much higher frequency, in the region of 1720 cm^{-1} (Table 2). Its intensity is similar to that of the stronger ν(CO) bands.[4] However, $\nu(N_2)$ gives only very weak Raman emission, in distinct contrast to $Rh(N_2Ar)Cl_2(PPh_3)_2$ complexes (9) where $\nu(N_2)$ is a prominent feature of the Raman spectrum.

The assignment of $\nu(N_2)$ was confirmed by ^{15}N substitution; for example, it occurs at 1721 cm^{-1} in $[Fe(CO)_2(PPh_3)_2(^{14}N{=}^{14}NC_6H_4Br)]BF_4$ but shifts to 1691 cm^{-1} in $[Fe(CO)_2(PPh_3)_2(^{15}N{=}^{14}NC_6H_4Br)]BF_4$. The high $\nu(N_2)$ values may be partly accounted for by the fact that the complex is a cation. If it is assumed that the metal atom is largely the site of positive charge this would result in a lower degree of back bonding to the diazonium group compared with the neutral compounds. In agreement, ν(CO) occurs 40–60 cm^{-1} higher than in the neutral complexes $LMo(CO)_2(N_2Ar)$ (L = $HB(pz)_3$ or C_5H_5) (2,4) and generally, higher than in a range of isostructural neutral complexes, $Fe(CO)_2(PR_3)_3$ (7). A somewhat parallel situation exists in the related isostructural nitrosyl complex $[Fe(CO)_2(PPh_3)_2(NO)]^+$ where it is observed (10) that both the ν(CO) and ν(NO) are up to 100 cm^{-1} higher than in the isoelectronic neutral complex $Mn(CO)_2(NO)(PPh_3)_2$.

When the cations $[Fe(CO)_2(PPh_3)_2NO]^+$ and $[Fe(CO)_2(PPh_3)_2(N_2C_6H_4X)]^+$ are compared it is seen that ν(CO) bands are both about 20 cm^{-1} lower in the azo complex, and $\nu(N_2)$ about 70 cm^{-1} lower than ν(NO). However, the general similarity of the spectra suggests that the coordination of the diazonium and nitrosyl groups toward iron in these compounds is closely similar and that in the azo compound the diazonium group may be considered formally to be either a 3-electron donor toward Fe^I or coordinated to Fe^0 as the 2-electron donor cation $XC_6H_4N{\equiv}N^+$. The latter view seems to be particularly consistent with $\nu(N_2)$ values. The actual values appear to be almost independent of X or to show, at best, a small decrease as the electron withdrawing properties of X increase. When compared with $\nu(N_2)$ for the free diazonium ion in each case the ratios (ν/ν_0 in Table 2) decrease in the order OH, OCH_3 > Br > H, Cl > F > NO_2 as expected if the diazonium group withdraws electrons from the iron atom by acting as a π-acceptor. This may be contrasted with the constant values of ν/ν_0 observed for the complexes $Rh(N_2C_6H_4X)Cl_2(PPh_3)_2$ (9). In accordance, ν(CO) values increase in the reverse sequence indicating that the diazonium group competes effectively with CO ligands for metal d_π-electrons. Further, a comparison of (ν/ν_0) for these compounds with ν/ν_0 for $[Fe(CO)_2(PPh_3)_2NO]BF_4$ (Table 2) shows that in all cases the relative lowering of $\nu(N_2)$ is greater than that of ν(NO) (from 2280 cm^{-1} to 1790 cm^{-1}), consistent with the diazonium group acting as a rather better π-acceptor than nitrosyl.[5]

The behavior of many arylazo complexes toward hydrogenation under mild conditions has been studied in relation to the use of such complexes as models for the nitrogen-reducing enzyme *nitrogenase* (11). In several cases where $\nu(N_2)$ appears in the region of 1500 cm^{-1} the azo function is hydrogenated at atmospheric pressure and room temperature using an appropriate catalyst (*e.g.* $Pd/BaSO_4$). It is therefore extremely interesting that all of these iron complexes were recovered unchanged after attempts to reduce them catalytically with hydrogen even under more severe conditions.[6] The Mo and W complexes reported by Trofimenko (4) are also resistant to hydrogenation, and we intend to examine further the apparently critical relationship of $\nu(N_2)$ with ease of hydrogenation. In this regard it is perhaps relevant that despite the fact that $\nu(N_2)$ in metal dinitrogen complexes may be lowered as far as 1630 cm^{-1} by attachment of an acceptor atom M′ to the terminal nitrogen atom to form a polynuclear M—N=N—M′ bridge, such compounds have not been found to undergo reduction of the azo-function (12, 13).

The colors of the complexes are orange to

[4] $\nu(N_2)$ has been quoted to occur at *ca.* 1700 cm^{-1} in the arylazo complexes $[Ru(N_2Ar)_2(PPh_3)_2Cl]BF_4$, but no details confirming the assignment were given; ref. 19.

[5] However, ν(CO) values for the nitrosyl complex are consistently higher than ν(CO) for the arylazo complexes, consistent with the opposite view.

[6] The compounds are, however, reduced by $NaBH_4$ in ethanol with apparently cleavage of the N—N bond and the formation of products as yet unidentified.

brown compared with the yellow color of $Fe(CO)_3(PPh_3)_2$. The electronic spectra of solutions in ethanol at room temperature exhibit three main broad bands of high extinction coefficient in the regions 205, 230, and 300 nm respectively (Table 2). The origin of these bands is difficult to assign with the presently available evidence, since charge transfer transitions, as well as transitions in the aromatic, carbonyl, and azo chromophores may all contribute, and it is probable that the spectrum is a feature of the complex as a whole rather than generally assignable to discrete chromophores. Again, the observed band contours may well envelope several composite absorption bands. In an analysis of $Fe(CO)_5$, intense bands at 200 and 240 nm were assigned to M → L charge transfer (14). The assignment of the bands at 204 and 251 nm in $Fe(CO)_3(PPh_3)_2$ and those at about 205 and 230 nm in this series of cations may be similar. The somewhat shorter wavelength for the second band in the cationic complexes is in accord with this, and the relative positions of this band for the *p*-NO_2 and *p*-OMe complexes follow the anticipated shift to longer wavelength in the case of a π-electron withdrawing substituent on L. The band at 300 nm is absent in $Fe(CO)_5$ and $Fe(CO)_3(PPh_3)_2$ and therefore seems to be a feature of the metal–azo group. However, it exhibits shifts contrary to those expected for M → L charge transfer and we tentatively assign it to a $\pi^* \leftarrow \pi$ transition of the azo chromophore.

The ^1H n.m.r. spectra of all $[Fe(CO)_2(PPh_3)_2(N_2C_6H_4X)]^+$ exhibited broad complex absorptions in the aromatic region together with expected absorptions due to any protons on the *p*-substituents. For example, the *p*-Br complex exhibited two main aromatic multiplets at τ 2.62 and τ 2.38 in a 10:24 approximate ratio, possibly due to the six 4-*H* protons of the triphenyl phosphine groups accidentally absorbing at the same frequency as the four protons of the azophenyl group. The ability to observe n.m.r. spectra at first seemed to be consistent with the absence of paramagnetism, as expected in view of the observation that the cation obeys the 18-electron rule. However, measurements of the magnetic susceptibility by the Faraday technique indicate all the compounds to be paramagnetic with magnetic moments ranging from 0.5–2.5 B.M. Consequently, the magnetism in solution was checked by the proton resonance shift method of Evans (15) and good agreement with the solid state values was observed. On the other hand the complexes do not exhibit e.p.r. spectra, or show line broadening of the ^1H n.m.r. spectra. The observed paramagnetism is presumably due to second-order Zeeman effects ("temperature independent paramagnetism"), but some of the values of μ_{eff} seem to be remarkably large.[7] Paramagnetism was also observed for $[Fe(CO)_2(PPh_3)_2NO]BF_4$, $\mu_{eff} = 0.8$ B.M. but $Fe(CO)_3(PPh_3)_2$ was found to be diamagnetic.

The ^{57}Fe Mössbauer spectra of these complexes exhibit interesting features. We find the parent compound $Fe(CO)_3(PPh_3)_2$ to have Mössbauer parameters $\delta = +0.15$ (± 0.01) with respect to sodium nitroprusside and $\Delta = 2.75$ (± 0.01) mm s^{-1} in good agreement with reported values (16), consistent with trigonal bipyramidal Fe^0 stereochemistry. However, $[Fe(CO)_2(PPh_3)_2NO^+]BF_4^-$ ($\delta = +0.17 \pm 0.01$) displays a considerably smaller quadrupole splitting value of $\Delta = 1.85$ mm s^{-1}. The quadrupole splitting is decreased still further in $[Fe(CO)_2(PPh_3)_2(N_2C_6H_4Br)^+]$ where $\delta = +0.18$ (± 0.01) $\Delta = 0.94$ (± 0.01) mm s^{-1}. Other members of the series are similar. Such a Δ-value is highly atypical of most trigonal bipyramidal Fe^0 complexes. The large Δ-values these normally display are due to a considerable electric field gradient which results from the asymmetric (*i.e.*, non-cubic) environment of the metal in these complexes. The replacement of CO by NO^+ and $N_2C_6H_4X^+$ therefore appears to reduce the electric field gradient despite the fact that the ligand environment of the iron atom is rendered more asymmetric by the removal of trigonal symmetry. There is no evidence to support coordination of a sixth ligand (such as would produce a pseudo-octahedral complex) either by BF_4^- coordination, *o*-metallation of an aromatic ring, or by close contact of an *o*-hydrogen atom with the metal. It therefore seems that the explanation for this effect must lie in the electronic properties of the coordinated nitrosyl and arylazo ligands, and may arise from the increased π-acceptor character of these ligands

[7]NOTE ADDED IN PROOF: We have since been informed by J. A. Ibers and B. J. Haymore that they have succeeded in removing paramagnetism from their preparation by careful recrystallisation. While we have observed paramagnetism despite recrystallisation, the magnetic results must nevertheless be viewed with caution.

in comparison to that of the carbonyl group as evidenced in the i.r. data discussed above.

Experimental

$Fe(CO)_3(PPh_3)_2$ and $Fe(CO)_3(PPh_2Me)_2$ were prepared by the reaction of $Fe_3(CO)_{12}$ with the phosphine as described elsewhere (17). Aryldiazonium tetrafluoroborates were prepared by diazotization of the corresponding anilinium tetrafluoroborate. Purity of these starting materials was checked by i.r. spectroscopy and elemental analysis.

Preparation of $[Fe(CO)_2(PR_3)_2(N_2C_6H_4X)]BF_4$

Details are given for $[Fe(CO)_2(PPh_3)_2(N_2C_6H_4Br)]BF_4$; other derivatives were generally prepared similarly. Reactions were carried out under dry, oxygen-free nitrogen using dry, degassed solvents. An almost saturated solution of $BrC_6H_4N_2BF_4$ (1 mmol) in acetone was added dropwise to a stirred, yellow solution of $Fe(CO)_3(PPh_3)_2$ (1 mmol) in benzene (20 ml) at room temperature. Almost immediately the color of the solution became orange, gas was evolved, and an orange precipitate formed. The precipitate was removed after 2 h and recrystallized from acetone–ether (70% yield). Yields of other recrystallized products are listed in Table 1. The amount of CO evolved was determined in the *p*-Br case by performing the reaction *in vacuo*, transferring the evolved gases by Toepler pump into a known volume, and measuring the pressure. A sample was then identified as carbon monoxide by high resolution mass spectrometry. No nitrogen was present. In the typical run 0.10 mmol of $Fe(CO)_3(PPh_3)_2$ produced 0.10 mmol of CO. Confirmation of the presence of two CO groups in the prepared complexes was obtained by oxygen analysis on $[Fe(CO)_2(PPh_3)_2N_2C_6H_4Br]I$ prepared by metathesis from the tetrafluoroborate and NaI in acetone.

Anal. Calcd. O, 3.39. Found: O, 3.61.

Attempts to synthesize complexes with X = *p*-NEt_2 failed. Instead, intensely red crystals resulted of a compound whose analysis corresponded to $[Et_2NC_6H_4N_2PPh_3]^+BF_4^-$. Details of the synthesis and properties of this compound will follow separately. Isotopic substitution by ^{15}N adjacent to iron was achieved (for examination of i.r. and Raman spectral shifts) by repeating the synthesis with $BrC_6H_4{}^{14}N{\equiv}{}^{15}N^+BF_4^-$ prepared by diazotisation of the corresponding anilinium tetrafluoroborate with $Na^{15}NO_2$ (95% ^{15}N) available from Isomet Corporation, New York.

Infrared spectra were recorded on samples pressed in KBr using Perkin–Elmer 457 and Beckman I.R. 12 spectrometers. Raman spectra on solid samples at room temperature were recorded using a Cary 81 spectrometer with unfocussed He–Ne laser excitation from a Spectra-Physics Model 125 laser producing 70 mW at source. Samples decomposed in a focussed beam. Proton n.m.r. spectra were recorded at 60 and 100 MHz using Varian A-60 and HA-100 spectrometers; τ values are relative to $(CH_3)_4Si$ (τ = 10.0) as internal standard. Mössbauer spectra were recorded (by Dr. C. H. W. Jones of this Department) with the absorbers at 80 ± 1 °K and a ^{57}Co/Pd source (New England Nuclear, 10 mCi) at room temperature. A Technical Measurement Corporation constant acceleration spectrometer was used, providing 2 × 200 channel spectra. The spectrometer was calibrated using a N.B.S. Standard absorber; $Na_2[Fe(CN)_5NO]2H_2O$ (Δ = 1.172 mm s^{-1}, $\delta(^{57}Co/Pd)$ = −0.442 mm s^{-1}). Magnetic susceptibility measurements were made at room temperature on a Faraday apparatus calibrated against $HgCo(NCS)_4$, and yielded the following values of μ_{eff} (corrected for diamagnetism) for the series $[Fe(CO)_2(PPh_3)_2(N_2C_6H_4X)]BF_4$: X = *p*-$NO_2$, 2.30, 2.32, 2.16; *p*-OMe, 2.46, 2.09 (±0.10); *p*-F, 0.76, 0.52 (±0.06); *p*-Cl, 1.21, 1.22, 1.28[8] (±0.08); *p*-Br, 0.84, 0.92 (±0.09); *p*-OH, 2.01, 1.83 (±0.10) B.M. The value obtained for $[Fe(CO)_2(PPh_3)_2NO]BF_4$ was 0.84 (±0.09) B.M. The susceptibility for the *p*-NO_2 compound was also determined over the temperature range 85–281 °K using the automatic variable temperature Faraday balance at York University, Ontario. The values of χ_M^{corr} increased (and μ_{eff} decreased) steadily from 2863 × 10^6 c.g.s. (2.54 B.M.) at 281 °K to 6105 × 10^6 (2.04 B.M.) at 85 °K. Finally, the magnetic susceptibilities of solutions of the *p*-Cl and *p*-NO_2 complexes in acetone were determined from the n.m.r. downfield contact shift of the methyl resonance of added *t*-butanol using the method of Evans (15). The observed shifts gave μ_{eff} = 2.09 (±0.10) B.M. for *p*-NO_2 and 1.39 (±0.10) B.M. for *p*-Cl in reasonable agreement with the Faraday method.

Molecular weights were determined from osmometric measurement on acetone solutions using a Perkin–Elmer Hitachi Model 115 calibrated with benzil. Electrical conductances were determined at room temperature for 10^{-4} *M* solutions in acetone and nitromethane using a standard conductivity meter. Elemental analyses for non-metal content were determined by the SFU Microanalytical Laboratory and by A. Bernhard, Germany. Iron was determined by atomic absorption spectroscopy using a Perkin–Elmer Model 305.

Support of this work was through a National Research Council of Canada Operating Grant. We wish to thank Professor J. A. Ibers and B. J. Haymore for communicating the results of their X-ray study before publication, Dr. C. H. W. Jones for making the Mössbauer measurements, Dr. F. G. Herring for e.p.r., and Dr. K. I. Thé for CO determinations. We are also grateful to Dr. G. W. Rayner Canham for variable-temperature magnetic measurements and to Dr. A. B. P. Lever for making this facility available.

Neighboring Group Participation in the Halogenation of Sulfoxides

T. DURST, K.-C. TIN, AND M. J. V. MARCIL
Department of Chemistry, University of Ottawa, Ottawa, Canada K1N 6N5

Received October 5, 1972

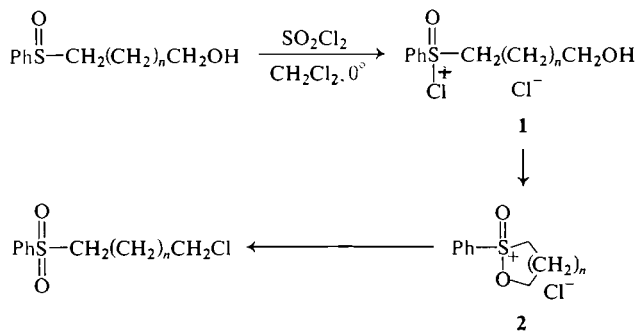
$PhS(O)(CH_2)_nCH_2OH$(n = 1–3) react with sulfuryl chloride at −78° or 0° in methylene chloride to give the corresponding $PhSO_2(CH_2)_nCH_2Cl$. Evidence is presented that cyclic alkoxyoxosulfonium salts are intermediates in these transformations. When n = 4 only chlorination α to the sulfoxide function was observed. The sulfinyl carboxylic acids $PhS(O)(CH_2)_nCO_2H$ (n = 1–3) and amides $PhS(O)(CH_2)_n$-$CONH_2$ (n = 1–3) were also reacted with SO_2Cl_2. α-Chlorination was observed for both compounds when n = 1 or 3. When n = 2 the products were the 3-phenylsulfonylpropionyl chloride and 3-phenylsulfonylpropionitrile respectively.

Le $PhS(O)(CH_2)_nCH_2OH$ (n = 1–3) réagit avec le chlorure de sulfuryle à −78° ou à 0° dans le dichlorométhane pour donner le produit correspondant $PhSO_2(CH_2)_nCH_2Cl$. On a prouvé que les sels cycliques d'alkoxyoxosulfonium sont des intermédiaires dans ces transformations. Quand n = 4 on a observé que seulement la chloration en α du sulfoxyde s'effectuait. Les acides carboxyliques sulfinylés $PhS(O)(CH_2)_nCO_2H$ (n = 1–3) ainsi que les amides $PhS(O)(CH_2)_nCONH_2$ (n = 1–3) ont aussi été mis en réaction avec le SO_2Cl_2. La chloration en α a été observée pour les deux composés quand n égalait 1 ou 3. Quand n égalait 2, les produits furent le chlorure de phényl-3 sulfonylpropionyle et le phényl-3 sulfonylpropionitrile respectivement. [Traduit par le journal]

Can. J. Chem., 51, 1704 (1973)

As part of a study of the mechanism of the halogenation of sulfoxides we recently reported some preliminary results of our investigation of the reaction of several β, γ, and δ-hydroxy sulfoxides with sulfuryl chloride (1). In these reactions we observed no α-chorination (2–5) but obtained in high yield the corresponding β, γ, and δ-chloro sulfones. The formation of these products was rationalized as occurring via ring opening of a cyclic alkoxyoxosulfonium ion **2** which was generated by an intramolecular displacement of chloride ion from the initially formed chloro-oxosulfonium chloride **1** (Scheme 1). We would now like to present further results in this area and also an extension of the work to the chlorination of sulfoxides bearing other remote nucleophilic groups such as $—CO_2H$ and $—CONH_2$.

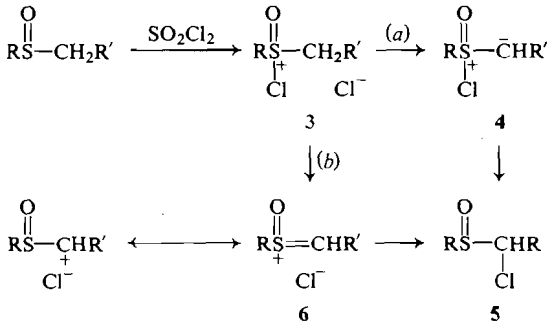
The mechanism of the chlorination of sulfoxides with various chlorinating agents *e.g.* SO_2Cl_2 (2, 3), $PhICl_2$ (4), and *t*-BuOCl (5) is in all likelihood as shown in Scheme 2. A point of disagreement which remains is the manner in which the initially formed chloro-oxosulfonium salt **3** is converted to the α-chlorosulfoxide **5**. Two routes have been suggested: (*a*) Formation of the ylid **4**, followed by intramolecular rearrangement to **5** (4) and (*b*) loss of HCl from **3** to give the oxosulfenium ion **6** which rapidly readds Cl^- to give **5** (1, 6, 7).



n = 0, 1, 2

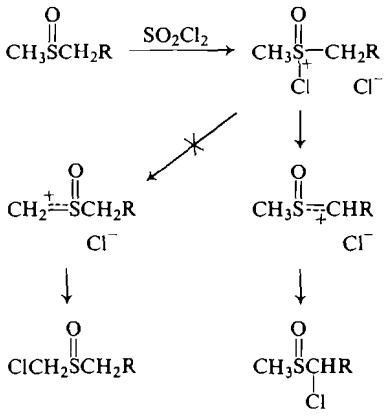
SCHEME 1

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.



SCHEME 2

Mechanism (*b*) is supported by the observation that unsymmetrical sulfoxides are chlorinated preferentially at the more highly substituted carbon (1, 6, 7). An ylid intermediate, mechanism (*a*), would be expected to lead to substitution at the less substituted carbon whereas a positively charged intermediate should give product arising from substitution at the more substituted carbon (Scheme 3).



SCHEME 3

Also supporting mechanism (*b*) are the results obtained by Marquet and co-workers (7) in the chlorination of *cis* and *trans*-4-*t*-butyl-thiane-*S*-oxides. Both isomers gave the same mixture of products **8** and **9**. Their formation was rationalized as a "*trans*" addition of Cl^- (Cl^- and sulfur lone pair are *trans*) to the intermediate oxosulfenium ion **7**, the major product **8** being the result of the preferred *trans*-diaxial addition (Scheme 4).

The chlorination of sulfoxides bearing nucleophilic groups in position β, γ... etc. to the sulfoxide function was undertaken with the hope of observing a reaction between these groups and some of the intermediates suggested in Scheme 2. Depending on the position and nature of the nucleophilic group we observed either α-chlorination, or the interaction of the functional group with the chloro-oxosulfonium ion resulting in the formation of a cyclic intermediate from which substituted sulfones were obtained. We have as yet been unable to trap the oxosulfenium ion **6**.

Hydroxy Sulfoxides

Hydroxy sulfoxides bearing the hydroxyl group in the β, γ, or δ position were converted in high yield to the corresponding chlorosulfones. In contrast, those having the OH at a more remote position gave only α-chloro-ω-hydroxy sulfoxides (eq. 1).

The yield of the chlorosulfones was generally over 75% regardless of whether the hydroxyl group was primary, secondary, or tertiary and β, γ, or δ to the sulfoxide (Table 1).

In the preliminary communication (1) we presented strong evidence which supported the intermediacy of cyclic alkoxyoxosulfonium salts in the conversion of **10** (n = 0–2) to **11**. For example, the formation of the *cis*-chloro sulfone

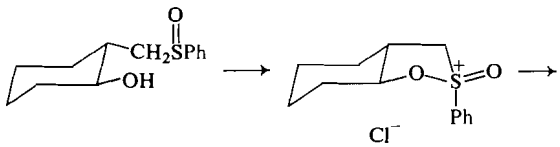
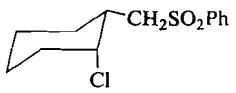
14 from the *trans*-hydroxy sulfoxide **13** verified the required inversion of configuration at the carbon originally bearing the hydroxyl group.



13 **13a**



14

In contrast to **13**, the chlorination of the *trans* sulfoxide **15** gave a complicated mixture of products which we have not been able to separate. Very little, if any, of the *cis*-chloro sulfone **16** appeared to have been formed as determined by examination of the n.m.r. spectrum of the crude product. This result was not unexpected since the formation of **16** would require the intermediacy of **17**, a highly strained *trans* 6,4-ring system.

When bromination of **10** ($n = 1$) with Br_2 was carried out in pyridine, both the bromo sulfone **18** and the pyridinium perbromide sulfone **19** were obtained; these products are probably the

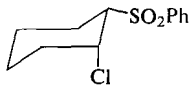
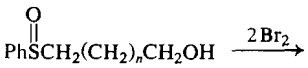
15 17

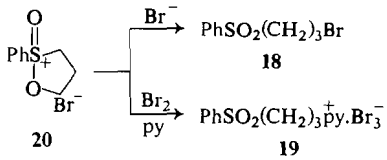


16

result of ring opening of the intermediate **20** by Br^- and pyridine respectively.



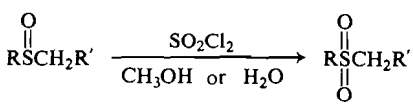
10 ($n = 1$)



20 **18** **19**

The failure of **10** ($n = 3,4$) to give chloro sulfones is understandable in terms of Scheme 1 since the formation of such products in these cases would require the intermediacy of 7- and 8-membered ring alkoxyoxosulfonium salts respectively.

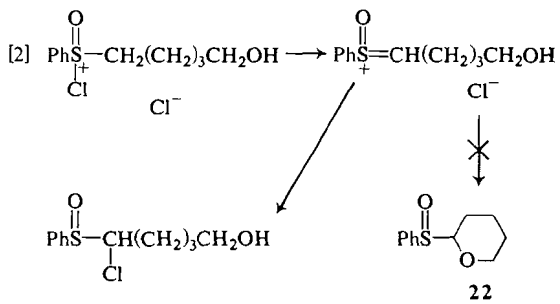
Among the more interesting facets of the above reactions is the ease with which the displacement of Cl^- from the chloro-oxosulfonium ion occurs. Simple sulfoxides, such as phenyl ethyl sulfoxides, are converted in excellent yield to α-chloro derivatives within 5 min at −78° or 0° upon exposure to SO_2Cl_2 (2). The replacement of a β-hydrogen by an OH group however completely suppresses the rapid chlorination reaction by interception of the chloro-oxosulfonion ion intermediate, despite the fact that such a reaction leads to the formation of a 4-membered ring intermediate. Indeed, chloro-oxosulfonium ions can be effectively intercepted by external nucleophiles such as water or methanol; in these cases sulfones are produced (2).



Alkoxyoxosulfonium salts, which can be considered as *O*-alkylated sulfones, have not been previously isolated, presumably because of the ease with which the C—O bond is broken, the cleavage being facilitated by the excellent leaving group characteristics of the $-\overset{+}{O}S(O)R$ function.[1] Particularly impressive, in this connection, is the displacement of the $-\overset{+}{O}S(O)R$ group in **13***a* by Cl^- which occurred in CH_2Cl_2 within minutes at −78°. The closely related aryloxy-oxosulfonium ions, *e.g.* **21**, have been isolated by Whiting and co-workers (8) from the thermal decomposition of aryl diazonium salts in the presence of sulfones. Carbon–oxygen bond cleavage in these species either via an S_N2 or S_N1 process, is not as favorable as for the alkoxyoxosulfonium salts.

21

We had hoped that the reaction of the hydroxy sulfoxides **10** ($n = 3,4$) might provide conclusive evidence that the conversion of the chloro-oxosulfonium ions to α-chloro sulfoxides occurs via an elimination addition sequence, *i.e.* via oxosulfenium ions such as **6**. In the case of **10** ($n = 3$) such an ion could have been trapped intramolecularly by the OH group to produce the tetrahydropyran derivatives **22** (Eq. 2). However no evidence for the formation of **22** could be obtained. We are presently continuing our efforts to prove the intermediacy of oxosulfenium ions in the migration of chlorine from sulfur to carbon.



[2]

22

Sulfinyl Carboxyl Acids and Amides

In the reaction of the acid and amide sulfoxides **23** and **24** with SO_2Cl_2 in CH_2Cl_2, the interception of the intermediate chloro-oxosulfonium salt by the acid or amide function occurred only when a 5-membered ring inter-

[1]Sulfones show extremely low nucleophilicity and are only partially protonated by concentrated sulfuric acid. The pK_a of protonated sulfones is estimated to be about −12 (14, 15).

24 ($n = 1$) **26**

mediate was formed, the products being the acid chloride sulfone **25** (83%) and the nitrile sulfone **26** (95%), respectively. Chlorination of ortho-methylsulfinyl benzoic acid gave a quantitative yield of ortho-methylsulfonyl benzoyl chloride. Again in this example a five-membered ring acyloxyoxosulfonium ion can be formed as an intermediate.

In the compounds **23** and **24** when $n = 0$ or 2 the only isolable products were the α-chloro sulfoxides (Tables 2 and 3). The failure to form four-membered ring intermediates in the reaction of **23** ($n = 0$) and **24** ($n = 0$) may be that such intermediates contain additional angle strain when compared to the analogs derived from the hydroxy sulfoxides due to the presence of an sp^2 hydridized carbon in the 4-membered ring; **27** *vs.* **2** ($n = 0$). The failure to form 6-membered ring intermediates from **23** ($n = 2$) and **24** ($n = 2$) was unexpected.

Experimental

Melting points were determined on a Thomas Hoover apparatus and are not corrected. Infrared spectra were obtained in chloroform solution on a Beckman IR-20 Spectrophotometer. N.m.r. spectra, $CDCl_3$ solution, were obtained using Varian HA-100 or T-60 Spectrometers, peak positions are reported in δ units. Usual workup refers to separation of the mixture into CH_2Cl_2 and water soluble portions, drying the CH_2Cl_2 layer over anhydrous magnesium sulfate and evaporating the solvent

on a rotor evaporator. Unless otherwise stated, yields are based on purified products.

Preparation of β-Hydroxy Sulfoxides by Reaction of Ketones, Aldehydes, and Epoxides with $PhS(O)CH_2Li$

General Procedure

To a solution of methyl phenyl sulfoxide in THF at −78° under N_2 was added 1.2 equivalents of CH_3Li (1.5 *M* in ether, Foote Mineral Co.). The clear yellow solution was stirred for 15 min at −78° and then treated with the appropriate electrophile, neat if liquid, or as a THF solution if solid. The reaction mixture was stirred for several minutes then quenched with water. The usual workup gave the crude products which were generally recrystallized from methylene chloride – pentane. The yields refer to purified products and are given in Table 4. Analytic and n.m.r. data are also given in Table 4.

Reaction of Sulfoxides with SO_2Cl_2

General Procedure

The sulfoxide was dissolved in methylene chloride (approx. 1 g/30 ml) and the reaction mixture was cooled to 0° or −78°. The reaction mixture was protected from moisture. Sulfuryl chloride (1.1–1.2 equiv.) was then introduced and the reaction mixture was stirred for up to 30 min. It was then poured into water and the layers were separated. The aqueous phase was extracted once more with methylene chloride. The methylene chloride fractions were dried and the solvent evaporated. Yields, unless otherwise specified, refer to purified products.

*2-Phenylsulfinylethanol (**10**, n = 0)*

The above sulfoxide (978 mg) and sulfuryl chloride (1.03 g) were allowed to react in 25 ml of CH_2Cl_2 at −78°. The yield of 2-chloroethyl phenyl sulfone, m.p. 54–55°, was 1.14 g (95%). Lit. m.p. 54–55° (9).

*3-Phenylsulfinylpropanol (**10**, n = 1)*

Sulfuryl chloride (810 mg) and sulfoxide (905 mg) in 25 ml of CH_2Cl_2 at −78° gave 1.03 g (96%) of 3-chloropropyl phenyl sulfone (10).

*4-Phenylsulfinylbutanol (**10**, n = 2)*

Reaction of sulfoxide (996 mg) with 810 mg of SO_2Cl_2 at −78° gave 1.01 g (88%) of 4-chlorobutyl phenyl sulfone, m.p. 56° (10).

*5-Phenylsulfinylpentanol (**10**, n = 3)*

Sulfuryl chloride (3.0 mmol) was added to a solution of 565 mg (2.7 mmol) of hydroxy sulfoxide in 20 ml of CH_2Cl_2 at −78°. Workup gave 600 mg of α-chloro-ω-hydroxy sulfoxide **12** (*n* = 3) as a colorless oil. The crude yield was greater than 90%. The spectroscopic properties of this material were: n.m.r. 1.0–2.6 (m, 6H), 3.0 (s, 1H exchangeable with D_2O), 3.4–3.8 (m, 2H), 4.4–4.8 (m, 1H), and 7.3–7.7 (m, 5H); i.r. ($CHCl_3$), 3430 (broad), 1140 (s), 1090 (s), and 1050 (s) cm^{-1}; mass spectrum, M^+ = 246 and 248 (ratio 3:1). The material decomposed slowly at room temperature and was not further purified or analyzed.

*6-Phenylsulfinylhexanol (**10**, n = 4)*

Sulfuryl chloride (9 mmol) was added to a solution of 1.70 g (7.5 mmol) of hydroxy sulfoxide in 25 ml of CH_2Cl_2 at 0°. The yield of crude α-chloro-ω-hydroxy sulfoxide **12** (*n* = 4) was essentially quantitative. The product was purified by silica gel column chromatography using 1:1 ether–pentane as eluent. The n.m.r. spectrum showed peaks from 0.8–2.4 (m, 8H), 2.3 (1H, exchangeable with D_2O), 3.4–3.8 (m, 2H), 4.4–4.7 (m, 1H), and 7.4–7.8 (m, 5H). Infrared bands ($CHCl_3$) occurred at 3440 (broad), 1080 (s) and 1042 (s) cm^{-1}. The mass spectrum showed M^+ at 260 and 262, isotope ratio 3:1. The compound could not be distilled without decomposition.

*β-Hydroxy Sulfoxide **28***

Sulfuryl chloride (470 mg) was added to a solution of 723 mg of **28** in 45 ml of CH_2Cl_2 at −78°. The yield of recrystallized product **29**, m.p. 86°, was 642 mg. The n.m.r. spectrum had peaks at 3.94 (d, *J* = 7.0 Hz, 2H), 5.37 (t, *J* = 7.0 Hz, 1H), 7.25 (s, 5H) and 7.4–7.9 (m, 5H). The sulfone bands occurred at 1320 and 1150 cm^{-1} in the infrared.

Anal. Calcd. for $C_{14}H_{13}ClO_2S$: C, 59.68; H, 4.61. Found: C, 59.97; H, 4.75.

*β-Hydroxy Sulfoxide **30***

Sulfuryl chloride (255 mg) and 375 mg of **30** in 10 ml of CH_2Cl_2 at −78° gave 310 mg (73%) of the β-chloro sulfone **31** m.p. 95–97° (ether–pentane), *m/e* = 272 and 274 (ratio 3:1). The n.m.r. spectrum had peaks at 1.2–2.4 (m, 10H), 3.65 (s, 2H), and 7.5–8.1 (m, 5H). The sulfone bands occurred at 1320 and 1150 cm^{-1}.

The β-chloro sulfone was dehydrochlorinated by passing it through a basic alumina column. The β,γ-unsaturated sulfone thus obtained had m.p. 73–74° and n.m.r. bands at 1.3–2.3 (m, 8H), 3.62 (s, 2H), 5.4 (m, 1H), and 7.4–8.0 (m, 5H).

Anal. Calcd. for $C_{13}H_{16}O_2S$: C, 66.08; H, 6.83. Found: C, 65.68; H, 6.74.

In a second experiment the crude product obtained from the reaction of **30** with SO_2Cl_2 was chromatographed directly. The yield of unsaturated sulfone was 92%.

*β-Hydroxy Sulfoxide **32***

Sulfuryl chloride (400 mg) was added to 350 mg of sulfoxide **32** in 15 ml of CH_2Cl_2. The crude product was separated by preparative t.l.c. The yield of chloro sulfone

33, m.p. 45° (lit. m.p. 44–45° (11)), was 168 mg (41%). In addition, 115 mg (34%) of the unsaturated sulfone **34** (M^+ = 196) was obtained as a colorless oil. N.m.r. peaks occurred at 1.85 (s, 3H), 3.8 (s, 2H), 4.75 (s, 1H), 5.50 (m, 1H), and 7.4–8.1 (m, 5H).

In a second experiment the crude product was chromatographed and gave **34** in 81% yield.

β-Hydroxy Sulfoxide 35

Sulfuryl chloride (230 mg) and sulfoxide **35** (470 mg) in 25 ml of CH_2Cl_2 at −78° gave 417 mg (89%) of the α,β-unsaturated sulfone **36**, m.p. 105–107°; i.r. bands 1320, 1164, and 1150 cm^{-1}; n.m.r. peaks at 6.84 (s, 1H) and 6.9–7.6 (m, 15H).

trans-Hydroxy Sulfoxide 13

(a) Preparation

To a solution of 15.7 mmol of $PhS(O)CH_2Li$ in tetrahydrofuran at −78° was added 1.5 g (15.6 mmol) of cyclohexene oxide. The reaction mixture was warmed to room temperature and then refluxed for 30 min. The usual work-up followed by purification by preparative t.l.c. gave 265 mg (7%) of **13** as colorless needles, m.p. 95–96° (Table 4).

(b) Reaction with SO_2Cl_2

Hydroxy sulfoxide **13** (250 mg) and SO_2Cl_2 (165 mg) were allowed to react in 20 ml of CH_2Cl_2 at −78° for 30 min. The crude product was purified by preparative t.l.c. and gave 224 mg (77%) of the *cis*-chloro sulfone **14** as a colorless oil. The n.m.r. spectrum had peaks at 1.0–2.2 (m, 8H), 2.2–2.7 (m, 1H), 2.8–3.6 (8 line multiplet, J_{gem} = 14.0 Hz, J_{vic} = 5.8 and 6.0 Hz, 2H), 4.53 (m, width at half-height = 7 Hz, 1H) and 7.5–8.1 (m, 5H). The i.r. spectrum had bands at 1150 and 1307 cm^{-1}. The mass spectrum showed the parent ions at m/e = 274 and 272 (ratio 1:3).

Reaction of Sulfinyl Carboxylic Acids with SO_2Cl_2

Phenylsulfinylacetic Acid

Sulfuryl chloride (470 mg) was added to 595 mg of a suspension of acid sulfoxide in 25 ml of CH_2Cl_2 at −78°. The reaction was complete after 30 min as indicated by the formation of a fine powder. The solvent was evaporated under reduced pressure. The yield of α-chloro-α-phenylsulfinylacetic acid, obtained as a mixture of diastereomers was 670 mg (97%). The n.m.r. spectrum of the mixture showed 2 singlets at 5.20 and 5.34 (2:1 ratio, 1H), a singlet at 9.20 (1H) and a multiplet from 7.45–7.95 (5H); i.r. bands occurred at 3500–2300 (broad), 1735, 1200, 1080, and 1032 cm^{-1}.

Anal. Calcd. for $C_8H_7ClO_3S$: C, 43.96; H, 3.20. Found: C, 44.61; H, 3.63.

3-Phenylsulfinylpropionic Acid

Sulfuryl chloride (670 mg) was added to a solution of 905 mg of the above acid in 20 ml of methylene chloride at −78°. The solvent was evaporated after 20 min and the residue recrystallized from ether–pentane to give 882 mg (83%) of 3-phenylsulfonylpropionyl chloride; i.r. 1782, 1312, and 1146 cm^{-1}. Hydrolysis gave 3-phenylsulfonylpropionic acid, m.p. 124–126°. Lit. m.p. 125.5–127° (11).

4-Phenylsulfinylbutyric Acid

To a solution of 610 mg of acid sulfoxide in 20 ml of methylene chloride at −78° was added 475 mg of SO_2Cl_2. The reaction mixture was allowed to warm to room temperature during 30 min. The solvent was evaporated and the product recrystallized from CH_2Cl_2–ether–pentane. The yield of 4-chloro-4-phenylsulfinylbutyric acid, m.p. 111°, was 587 mg (83%). The n.m.r. spectrum showed multiplets from 1.7–2.9 (m, 4H), 4.65–5.0 (m, 1H), 7.4–7.8 (m, 5H) and a singlet at 10.34 (1H); i.r. peaks occurred at 3400–2500 (broad), 1720 (s), and 1040 (s) cm^{-1}.

Anal. Calcd. for $C_{10}H_{11}ClO_3S$: C, 48.68; H, 4.49; Cl, 14.38; S, 12.90. Found: C, 48.49; H, 4.52; Cl, 14.54; S, 12.90.

2-Methylsulfinylbenzoic Acid

Sulfuryl chloride (730 mg) was added to a suspension of 827 mg of acid sulfoxide in 25 ml of CH_2Cl_2 at 25°. The solid "dissolved" within an hour. The solvent was evaporated and gave a quantitative yield of 2-methylsulfonylbenzoyl chloride, m.p. 60°; i.r. 1785, 1320, and

For personal use only.

1150 cm^{-1}; n.m.r. 3.28 (s, 3H) and 7.6–8.3 (m, 4H). Hydrolysis gave 2-methylsulfonylbenzoic acid, m.p. 130–132° (13).

Phenylsulfinylacetamide

To a solution of 250 mg of sulfoxide in 10 ml of CH_2Cl_2 at −78° was added 200 mg of SO_2Cl_2. The reaction mixture was stirred for 2 h. The solvent was evaporated to yield 258 mg of crude product which solidified upon standing. After three recrystallizations ($CHCl_3$–hexane) 2-chloro-2-phenylsulfinylacetamide had m.p. 138–139°. The n.m.r. spectrum (DMSO-d_6) showed 2 singlets at 5.51 and 5.55 in addition to the amide and aromatic hydrogens. The relative ratio of the singlets due to two diastereomeric sulfoxides was about 1:1.

Anal. Calcd. for $C_8H_8ClNO_2S$: C, 44.11, H, 3.71; Cl, 16.28; S, 14.70. Found: C, 44.20; H, 3.71; Cl, 16.52; S, 14.68.

3-Phenylsulfinylpropionamide

To a suspension of 318 mg of amide sulfoxide in 20 ml of CH_2Cl_2 at −78° was added 257 mg of SO_2Cl_2. The reaction mixture was stirred for 2 h and then worked up to give 298 mg (95%) of 3-phenylsulfonylpropionitrile, m.p. 92° (methylene chloride – pentane). N.m.r., 2.6–3.0 (m, 2H), 3.30–3.6 (m, 2H) 7.5–8.1 (m, 5H); i.r., 2230, 1325, and 1145 cm^{-1}.

Anal. Calcd. for $C_9H_9NO_2S$: C, 55.38; H, 4.60. Found: C, 55.19, H, 4.64.

4-Phenylsulfinylbutyramide

Sulfoxide (211 mg) and SO_2Cl_2 (150 mg) were allowed to react in 20 ml of methylene chloride as above. The yield of 4-chloro-4-phenylsulfinylbutyramide was 178 mg (73%). Recrystallization from $CHCl_3$–hexane gave a colorless powder, m.p. 137.5–139.5°.

Anal. Calcd. for $C_{10}H_{12}ClNO_2S$: C, 48.84; H, 4.92; S, 13.05. Found: C, 48.44; H, 4.85; S, 13.23.

Reaction of 3-Phenylsulfinylpropanol with Br_2/Pyridine

Bromine (8.8 mmol) was added to a solution of 1.38 g (7.5 mmol) of sulfoxide and 1.5 g pyridine in 40 ml of carbon tetrachloride at 0°. The reaction mixture was yellow and a considerable amount of precipitate formed within 1 h. After 2 h the precipitate was filtered to give 2.32 g (62%) of the perbromide salt, yellow flakes, m.p. 137° (CH_3OH–H_2O). N.m.r., (DMSO-d_6) 2.1–2.4 (m, 2H), 3.4–3.6 (m, 2H), 4.68 (t, J = 7 Hz, 2H) and 7.6–9.1 (m, 10H).

Anal. Calcd. for $C_{14}H_{16}Br_3NO_2S$: C, 33.48; H, 3.21; N, 2.79; S, 6.49; Br, 47.75. Found: C, 33.46; H, 3.19; N, 2.80; S, 6.51; Br, 47.71.

The filtrate was washed with dilute acid solution and the organic layer was dried and evaporated to give 315 mg (16%) of 3-phenylsulfonylpropyl bromide **18**, m/e = 262 and 264 (1:1 ratio). The n.m.r. and i.r. spectra were as expected.

The Infrared Spectrum of the Hydrogen-Bonded Molecule Dimethyl Ether ... Hydrogen Chloride in the Gas Phase[1]

JOHN E. BERTIE AND M. VICTOR FALK

Department of Chemistry, University of Alberta, Edmonton

Received November 20, 1972

A detailed study of the infrared spectra of $(CH_3)_2O...HCl$ and its isotopic modifications is presented. The hydrogen-bond stretching mode occurs at $119 \pm 4\ cm^{-1}$ in $(CH_3)_2O...HCl$, $(CD_3)_2O...HCl$, and $(CH_3)_2O...DCl$. The O...H—Cl deformation modes yield a band centered at $470\ cm^{-1}$, which is broad and complex. It is interpreted in terms of sum and difference transitions involving the HCl rocking modes, which are deduced to be at about $50\ cm^{-1}$. The O...D—Cl deformation band is centered at $360\ cm^{-1}$. A band at $790\ cm^{-1}$ in $(CH_3)_2O...HCl$ and $600\ cm^{-1}$ in $(CH_3)_2O...DCl$ is assigned to the overtone of the deformation modes. The shapes of the bands due to the ethereal modes in the molecule can not indicate the molecular geometry and do not agree with the shapes calculated from reasonable moments of inertia. The temperature dependence of the band due to the HCl stretching mode indicates that the fundamental transition is at $2480\ cm^{-1}$, not at $2574\ cm^{-1}$ as previously postulated. The DCl stretching band in $(CH_3)_2O...DCl$ has a different shape to that in $(CD_3)_2O...DCl$. The differences are attributed to combination transitions involving the ethereal modes. It is suggested that the DCl and HCl stretching modes interact with the DCl or HCl rocking modes, thus causing shoulders $50\ cm^{-1}$ away from the DCl stretching fundamental, and contributing to the general diffuseness of the HCl stretching band. The relative intensities of the bands due to $(CH_3)_2O...HCl$ are presented.

Une étude détaillée des spectres infra rouge de $(CH_3)_2O...HCl$ et de ses modifications isotopiques a été présentée. L'élongation de la liaison hydrogène est à $119 \pm 4\ cm^{-1}$ dans $(CH_3)_2O...HCl$, $(CD_3)_2O...HCl$, $(CH_3)_2O...DCl$. Les déformations de O...HCl donnent une bande centrée à $470\ cm^{-1}$, large et complexe, interprétée comme étant la somme et la différence des transitions comprenant les modes de balancement de HCl à environ $50\ cm^{-1}$. La bande de déformation O...DCl est centrée à 360 cm^{-1}, la bande à $790\ cm^{-1}$ dans $(CH_3)_2O...HCl$ et à $600\ cm^{-1}$ dans $(CH_3)_2O...DCl$ ont été attribuées aux harmoniques des vibrations de déformation. Les formes des bandes dues aux vibrations de l'éther dans la molécule ne sont ni une indication de la géométrie moléculaire ni compatibles avec les formes calculées à partir des moments d'inertie raisonnablement choisis. La dépendance de la température de la bande due à l'élongation de HCl indique que la transition fondamentale est à $2480\ cm^{-1}$ et non à 2574 cm^{-1} comme il a été postulé antérieurement. L'élongation DCl dans $(CH_3)_2O...DCl$ a une forme différente de celle dans $(CD_3)_2O...DCl$, les différences ont été attribuées à la combinaison des transitions comprenant celles de l'éther. Il a été suggéré que les modes d'élongation de DCl et HCl sont en interaction avec les modes de balancement de DCl et HCl causant ainsi des épaulements de $50\ cm^{-1}$ de part et d'autre de la fréquence fondamentale d'élongation de DCl et explique l'aspect général diffus de la bande d'élongation de HCl. Les intensités relatives des bandes dues à $(CH_3)_2O...HCl$ ont été présentées.

Introduction

The molecule dimethyl ether...hydrogen chloride is one of the simplest hydrogen-bonded molecules that can be studied in the gaseous state. It is, therefore, important that the vibrational spectrum of this molecule be known in as much detail as possible, in order to test the theories of the origins of the vibrational spectra of hydrogen-bonded molecules. This paper presents the results of a detailed study of the infrared spectrum of dimethyl ether...hydrogen chloride, and its isotopically-substituted derivatives, between +35 and −30 °C.

The molecule $(CH_3)_2O...HCl$ has 21 vibrations which are derived from those of the pure ether, plus 6 vibrations of the O---H—Cl part of the molecule which are shown in Fig. 1 along with their designation. The symbols ν_s, ν_b, ν_β, etc. correspond to those of Pimentel and McClellan (1) as closely as possible. It should be noted that in $(CH_3)_2O...HCl$ there are two non-equivalent ν_β modes and that ν_b and ν_t would both correspond to pure rotations of the HCl molecule in the absence of the hydrogen bond, whereas in ref. 1 ν_b would remain the in-plane RAH

[1]This work was presented in part at the International Conference on Hydrogen Bonding, Ottawa, August, 1972.

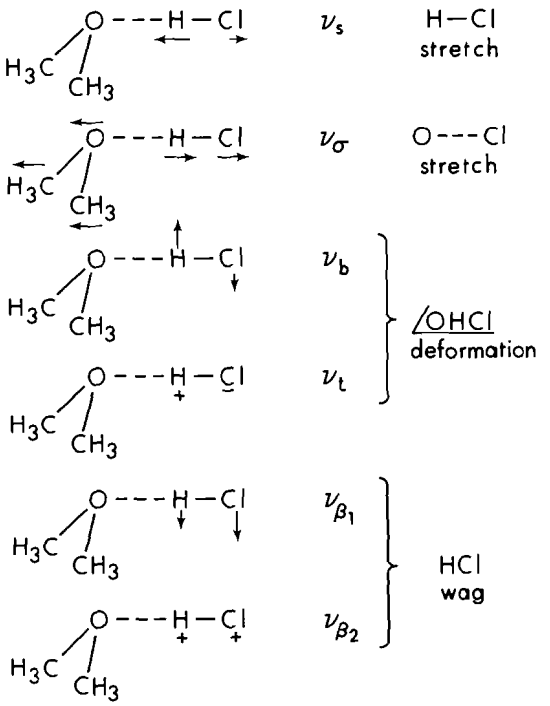

FIG. 1. The six vibrations of the O...H—Cl unit in $(CH_3)_2O$...HCl. The symbols follow those of ref. 1.

bending mode in the absence of the hydrogen bond.

At room temperature the H—Cl stretching mode in $(CH_3)_2O$...HCl yields an absorption at 2574 cm^{-1} which has a halfwidth of about 250 cm^{-1} and consists of a peak and three shoulders separated by 90 to 100 cm^{-1} (2). These main features of the band are quite insensitive to replacement of $(CH_3)_2O$ by some other ether and, in particular, are unchanged if $(CD_3)_2O$ is used (2). Hence they must arise from the O---H—Cl unit and they have been assigned to ν_s and to $\nu_s \pm n\nu_\sigma$, where n is integral (2). The band due to the DCl stretching mode in $(CH_3)_2O$...DCl has been interpreted in the same way and the lower relative intensity of the shoulders in this case has been rationalized (3). One purpose of the present work was to study the temperature dependence of the shape of these bands to test the proposed influence of the difference bands.

The only other mode of Fig. 1 that has been detected is ν_σ which has been reported at 117 ± 3 cm^{-1} in $(CH_3)_2O$...HCl, with some evidence from experiments using a 4:1 HCl:DCl mixture that the isotope shift is small (4). The halfwidth of the band due to ν_σ is about 30 cm^{-1}, which is of the order expected for the rotational envelope in this molecule (2) and found (5) for the bands due to the C—O stretching and methyl rocking modes. A second aim of the present work was to confirm the isotope shift of the 117 cm^{-1} band. Further aims were to locate ν_b, ν_t, and ν_β, and to extend the work of ref. 5 to determine the shapes of the remaining bands due to modes of the ethereal part of $(CH_3)_2O$...HCl.

Experimental

The infrared instrumentation has been described previously (6, 7). The gases were contained in a cylindrical cell with 10 cm pathlength, 1 in. internal diameter and a coaxial cooling jacket. The cylinder containing the gases was made of copper to maximize heat transfer. The cell was capable of holding at least 10 atm pressure and was cooled with cold nitrogen gas. The temperature was controlled to ±1 °C. and was measured to ±1 °C by a calibrated thermometer resting on the copper cell wall in the cooling chamber. The cell windows were potassium chloride, high-density polyethylene, or, for the 300 to 500 cm^{-1} region, cesium iodide coated with a thin layer of paraffin wax to protect it from attack by the hydrogen chloride.

Dimethyl ether-h_6 (Matheson of Canada, Ltd.), dimethyl ether-d_6 and deuterium chloride (Merck, Sharp and Dohme, Montreal), and hydrogen chloride (Matheson of Canada, Ltd., or prepared in vacuum from phosphorus pentachloride and water) were dried in vacuum by repeated distillation from −80 °C. No impurities were detected except for carbon dioxide in some samples, and hydrogen chloride in the deuterium chloride. In spite of extensive pre-deuteration of the vacuum lines and cells, there always was 10 to 20% of HCl in the DCl used. The high-pressure samples were handled in a stainless steel vacuum manifold, and the pressures were measured to ±30 Torr by a monel Bourdon Gauge. Pressures below atmospheric were measured by a mercury manometer to ±1 Torr. All gas pressures quoted were measured at room temperature (22 °C).

Results and Discussion

The ν_σ, ν_β, ν_b, *and* ν_t *Modes*

The far infrared spectra of mixtures of 325 Torr of ether and of acid showed that a band due to the hydrogen-bonded molecule occurs at about 120 cm^{-1}, not only for $(CH_3)_2O$...HCl (4), but also for $(CH_3)_2O$...DCl and $(CD_3)_2O$...HCl. $(CD_3)_2O$...DCl was not studied in this region. The band grows in intensity as the temperature is lowered to the onset of condensation, is independent of whether ether or the acid is in excess and has a halfwidth of about 30 cm^{-1}. The maximum of the band was not clearly observed, due to an overlapping

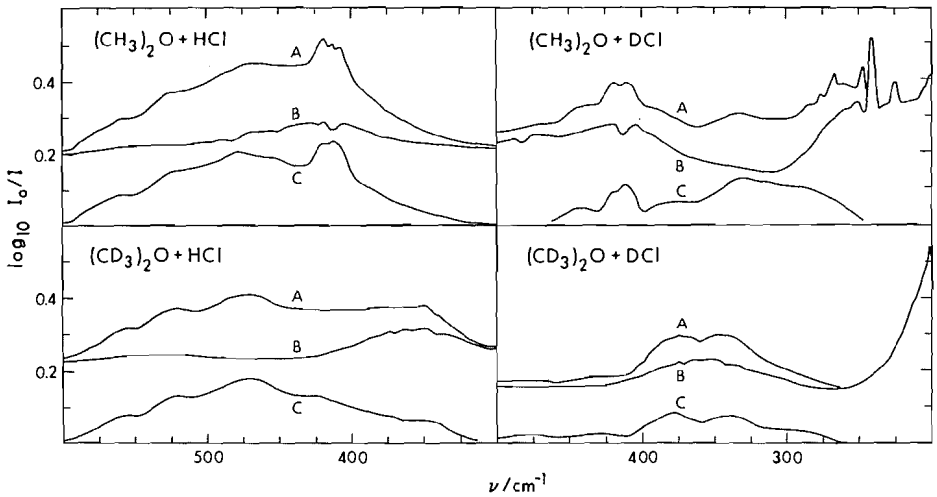

FIG. 2. Curves *A*: infrared absorption by mixtures of 110 Torr of $(CH_3)_2O$ or $(CD_3)_2O$ plus 880 Torr of HCl or DCl, as indicated, at −30 °C. Curves *B*: infrared absorption by 110 Torr of $(CH_3)_2O$ or $(CD_3)_2O$ at −30 °C. 10 cm pathlength. In each box curve *C* was obtained by subtracting curve *B* from curve *A*, and represents the absorption by the appropriate isotopic modification of $(CH_3)_2O...HCl$.

HCl or DCl line, but unless the band is grossly asymmetric the maximum is at 119 ± 4 cm^{-1} in all cases. The isotope shift of this band is consistent with its assignment to ν_σ or to one or both of the ν_β modes. Evidence is given below to suggest that ν_β lies at about 50 cm^{-1}, so the band at 119 cm^{-1} is assigned to ν_σ, in agreement with ref. 4.

Figure 2 shows the absorption by $(CH_3)_2O...HCl$ and $(CD_3)_2O...HCl$ between 300 and 600 cm^{-1} and that by $(CH_3)_2O...DCl$ and $(CD_3)_2O...DCl$ between 200 and 500 cm^{-1}. In each case curve *C* shows the absorption by the hydrogen-bonded molecule, obtained by subtracting that due to the same pressure of pure ether as was put into the mixture (curve *B*) from the spectrum of the mixture (curve *A*). In all cases where the absorption by the free ether was subtracted (Figs. 2, 5, and 6), it was shown that the ether absorption is unaffected by pressure-broadening by nitrogen or argon, and is unchanged by cooling from +35 to −30 °C. There is, however, an uncertainty in how much absorption to subtract (either manually or by putting a cell containing ether in the reference beam of the spectrometer). Three effects of this uncertainty are fairly obvious in Fig. 2: the doublet character of the peak between 410 and 420 cm^{-1} in the spectra of the $(CH_3)_2O$ complexes may not be real, and for $(CH_3)_2O...HCl$ the frequency of the peak at 480 cm^{-1} is slightly higher than it should be, and the weak feature at 450 cm^{-1} is probably spurious. Less obvious is some uncertainty in the correct shape of the band below 300 cm^{-1} for the DCl complexes and in the existence of the shoulder at 425 cm^{-1} for $(CD_3)_2O...HCl$.

The absorption attributed to the hydrogen-bonded molecule increased in intensity as the temperature was lowered to the condensation point, and no changes in the relative intensities of its various features were detected between +30 and −30 °C, or when the ether:acid ratio was changed from 1:2 to 1:8. Therefore it can be assigned to the 1:1 hydrogen-bonded complex, and is clearly due to one, or both, of ν_b and ν_t, and to the C—O—C deformation mode in the complex. For the HCl complexes it is clear that the features at about 570, 525, and 470 cm^{-1} are due to the O...H—Cl part of the molecule, while that between 420 and 410 cm^{-1} in the spectrum of $(CH_3)_2O...HCl$ is due to the C—O—C deformation mode. For $(CD_3)_2O...HCl$, the feature at 425 cm^{-1} can be assigned to the O...H—Cl part of the molecule while that at about 340 cm^{-1} is probably due to the C—O—C deformation mode. The situation is less clear for the DCl complexes. In the spectrum of $(CH_3)_2O...DCl$ the feature between 410 and 420 cm^{-1} is clearly due to the C—O—C deformation mode, and other features occur at 440, 375, 330, and, probably, 280 cm^{-1}. For

$(CD_3)_2O...DCl$ the relative intensities are quite different but features occur at 430, 380, 340, and, probably 290 cm^{-1}, very nearly coincident with those in $(CH_3)_2O...DCl$. We therefore conclude that all of these features in the spectrum of $(CD_3)_2O...DCl$ are due to the O...D—Cl part of the molecule, but the ethereal modes clearly influence their relative intensities and, to a lesser extent, their frequencies.

From the general assignment presented above, the bands due to the O---H—Cl and O---DCl deformation modes, ν_b and/or ν_t, have many of the characteristics of those due to the H—Cl and D—Cl stretching modes. The bands are broad, with a halfwidth of about 150 cm^{-1} for the HCl complexes, and complex, with four features observed for each case. By analogy with the interaction between ν_s and ν_σ (2), it is probable that the breadth and complexity of these bands arise from interaction of ν_b and/or ν_t with the appropriate ν_β, HCl rocking mode. The observed features are assigned, therefore, to transitions of the type ν_b, or ν_t, $\pm n\nu_\beta$, where n is zero or integral. From the separation of the features the fundamental frequency of the ν_β modes must be about 50 cm^{-1}. The observed constancy of the bandshape with temperature was not sufficiently precise to contradict this assignment provided that the difference transitions originate in energy levels that are less than about 100 cm^{-1} above the ground state.

Before the assignment of these features is discussed in more detail, the spectra shown in Fig. 3 must be presented. A weak absorption occurs at 790 cm^{-1} in $(CH_3)_2O...HCl$. Its intensity increases, reversibly, as the temperature is lowered, and is the same for $(CH_3)_2O$:HCl ratios of 1:2 and 2:1 (curves *A* and *B*). The integrated intensity of this absorption is about one sixth of that of the absorption centered at 470 cm^{-1}. The band is not present in $(CH_3)_2$-O...DCl (the weak feature seen in curve *C* undoubtedly arises from the HCl impurity in the DCl used) or in the spectra of pure ether (curve *D*) or HCl (curve *E*). This band could not be studied in $(CD_3)_2O...HCl$ because the symmetric CO stretching mode overlaps this region. In the spectra of $(CH_3)_2O...DCl$ a very weak absorption was detected between 550 and 630 cm^{-1}. This absorption was reproduceable but very near to our detection limit, and rapid formation of methyl chloride prevented the use of higher gas pressures to improve its observation. We tentatively conclude that the 790 cm^{-1} feature does shift to about 600 cm^{-1} in the DCl complex. Only two assignments appear to be possible for this feature. Either it is due to the second O...H—Cl (or O...D—Cl) deformation mode, ν_b or ν_t, or to the first overtone of ν_b or ν_t. Intuitively it seems improbable that one of the deformation modes would be near to 470 cm^{-1} while the other is at 790 cm^{-1} and that one would absorb six times more strongly than the other one; their proposed relative frequencies and intensities in $(CH_3)_2O...HF$ (8) seem far more reasonable. Therefore we assign this feature to the first overtone of ν_b or ν_t.

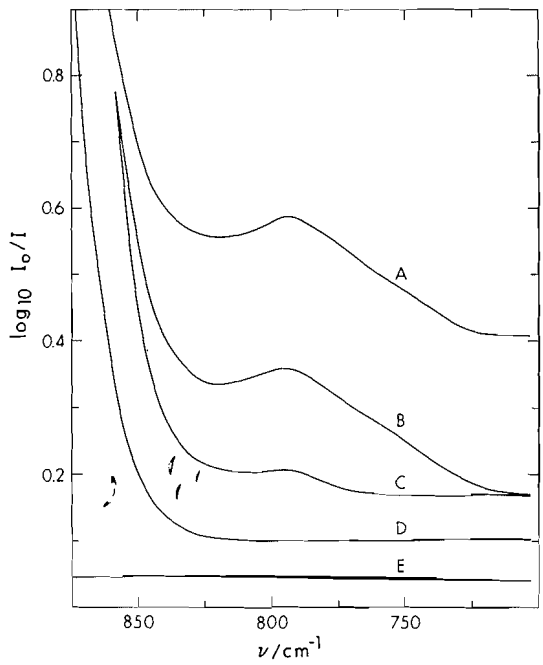

FIG. 3. Infrared absorption in 10 cm pathlength at +35 °C by: *A*, 1 atm of $(CH_3)_2O$ mixed with 2 atm of HCl; *B*, 2 atm of $(CH_3)_2O$ mixed with 1 atm of HCl; *C*, 2 atm of $(CH_3)_2O$ mixed with 1 atm of DCl; *D*, 1 atm of $(CH_3)_2O$; *E*, 1 atm of HCl. The curves have been offset for clarity, but *B* is positioned relative to *C* as observed.

The ν_b and ν_t fundamentals can not be assigned definitively from this evidence. They were assigned at 750 and 660 cm^{-1} for $(CH_3)_2O...HF$ and at 550 and 490 cm^{-1} for $(CH_3)_2O...DF$ (8), although it is not known whether ν_b or ν_t has the higher frequency. If the ratio ν_b/ν_t is the same for the HCl and DCl complexes as for the HF and DF ones, respectively, then ν_b and ν_t must be separated by about

60 cm^{-1} near to 500 cm^{-1} and by about 40 cm^{-1} near to 360 cm^{-1}. Thus ν_b and ν_t can be assigned at 340 and 380 cm^{-1} for the DCl complexes, and their assignment at 470 and 525 cm^{-1} for the HCl complexes yields an isotopic ratio of 1.38 for both bands, compared to 1.40 under the harmonic approximation, if it is assumed that ν_b is higher (or lower) than ν_t in both isotopic molecules. However this assignment suggests that 790 cm^{-1} is a very low frequency for the first overtone. It is possible that the 790 cm^{-1} feature is at the low-frequency end of a broad overtone absorption, most of which is hidden by the much stronger band above 850 cm^{-1}. It is also possible that, because of the vibrational Franck–Condon effect (9), the most intense transition in the overtone band is not the overtone of the most intense transition in the fundamental band. An alternative assignment which uses this feature is to assign ν_b and ν_t at 470 and 420 cm^{-1} in the HCl complexes and at 340 and 290 cm^{-1} in the DCl complexes. The ratio 470/340 = 1.38 is satisfactory, but the ratio 420/290 = 1.45 is somewhat large.

It is helpful to use these frequencies to calculate ω_e and $\omega_e x_e$, where $\omega_e(v + 1/2) - \omega_e x_e(v + 1/2)^2$ is the assumed vibrational term (10). ω_e and $\omega_e x_e$ for the DCl complex can be obtained from those of the HCl complex by multiplying by ρ and ρ^2, respectively (10), where $\rho^2 = G_D/G_H$, where G_D and G_H are the **G** matrix elements (11) for the O...D—Cl and O...H—Cl deformation coordinates, respectively. If the first assignment above is taken, and 790 cm^{-1} is taken to be the first overtone of 470 cm^{-1}, then ω_e = 620 cm^{-1} and $\omega_e x_e$ = 75 cm^{-1} for $(CH_3)_2O$...HCl and the corresponding frequencies in the DCl complex are calculated to be 660 and 370 cm^{-1}. The weak feature observed in the DCl complexes was definitely to low frequency of 660 cm^{-1}, and the pairing of 470 and 370 cm^{-1} indicates that 520 and 340 cm^{-1} must correspond to the same vibration. Thus, this assignment requires that the anharmonicities be very large indeed, and does not agree well with the overtone frequency for $(CH_3)_2O$...DCl. The second assignment, in which 790 cm^{-1} is taken to be the first overtone of 420 cm^{-1}, yields ω_e = 470 cm^{-1} and $\omega_e x_e$ = 25 cm^{-1} for the HCl complex and predicts the corresponding frequencies for the DCl complex to be 595 and 310 cm^{-1}. 595 cm^{-1} agrees well with the observed overtone absorption in the DCl complex, but 310 cm^{-1} does not correspond to any obvious feature in the observed spectra. Thus, with the present data no unique assignment can be made, although of the two discussed the second one is to be preferred on the basis of the smaller anharmonicity that it implies for this mode.

The Band Contours for the Ethereal Modes, and the Molecular Shape

Figure 4 shows the changes that occur in the bands due to the ethereal modes between 800 and 1500 cm^{-1} when the $(CH_3)_2O$...HCl molecule is formed. The results for the CO stretching and methyl rocking modes, between 900 and 1200 cm^{-1} (12), agree with those of Lascombe and co-workers (5), except that the shoulder at 920 cm^{-1} is less pronounced in our spectra.

The shape of the band at 912 cm^{-1} (Fig. 4) has been used (13) as evidence that the hydrogen chloride bonds to one of the two lone pairs of electrons on the ether, creating a molecule with C_s symmetry, rather than bonding symmetrically between them and creating one with C_{2v} sym-

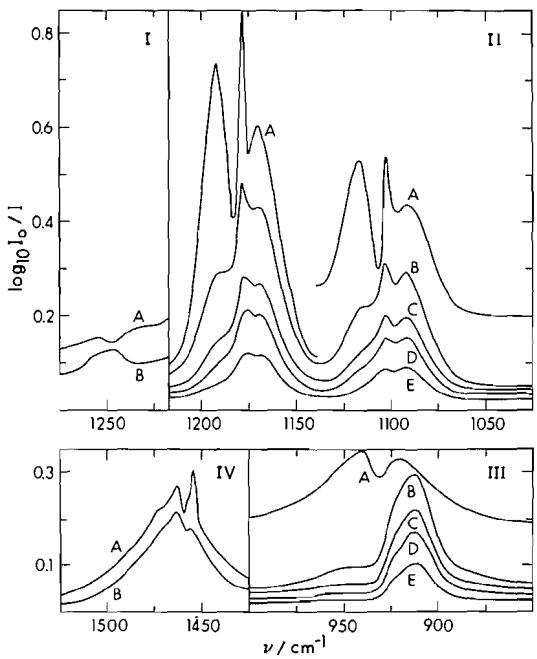

FIG. 4. Infrared absorption in 10 cm pathlength of mixtures of: boxes I and IV, 20 Torr of $(CH_3)_2O$ plus 6000 Torr of Ar (curve *A*) or plus 6000 Torr of HCl (curve *B*), at 0 °C; boxes II and III, 10 Torr of $(CH_3)_2O$ plus 6000 Torr of Ar at +35 °C (curve *A*) or plus 6000 Torr of HCl at +35 °C (*B*), +10 °C (*C*), 0 °C (*D*) or −10 °C (*E*).

metry. This conclusion seems intuitively correct but calculations based on an O---Cl distance of 3.1 Å, reasonable geometry for the ether, and the work of Ueda and Shimanouchi (14), predicted an A–C hybrid band of type 18 (14) for the C_s model and an A-type band of type 8 (14) for the C_{2v} model, with a halfwidth of about 30 cm^{-1} in each case. The halfwidths agree with the observed one, but both predicted bands show pronounced PQR structure which does not agree with the observed bandshape (Fig. 4) nor, therefore, indicate a preference for either model. The failure to predict the observed band shape must be influenced by the high population of excited states of the ν_β and ν_σ modes at −10 °C if, as is probable, rather large deviations from the equilibrium molecular geometry exist in these states.

Because the calculated and observed bandshapes disagree, the frequencies of the vibrational transitions can not be reported accurately. The centers of intensities of the bands in $(CH_3)_2O$...HCl are at 912, 1097, 1171, 1248, and 1465 cm^{-1}. Bands due to ethereal modes in $(CD_3)_2O$...HCl are centered at 815, 920, 1055, and 1150 cm^{-1}.

The ν_s Mode

The absorption by the H—Cl stretching mode, ν_s, in $(CD_3)_2O$...HCl at +34 and −30 °C is shown in Fig. 5. The spectra shown are corrected for the absorption by free ether (2). At the lower temperature the peak is 8 cm^{-1} lower in frequency, the feature at 2475 cm^{-1} is resolved as a peak and is more intense relative to the maximum, and the entire high-frequency side of the band has lower intensity relative to the maximum, than at +34 °C. These results prove that the feature at 2480 cm^{-1} does not arise from $\nu_s - \nu_\sigma$ (the transition [$\nu_s = 0 \rightarrow 1$, $\nu_\sigma = 1 \rightarrow 0$]) as previously postulated (2), but do not allow a unique reassignment to be made.

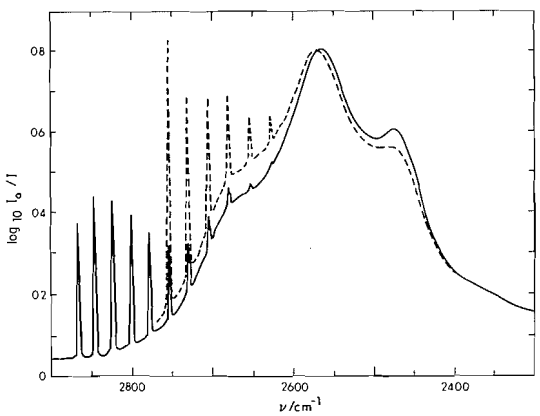

FIG. 5. Infrared absorption in 10 cm pathlength by 250 Torr of $(CD_3)_2O$ mixed with 250 Torr of HCl at +34 °C (dashed line) and by 100 Torr of $(CD_3)_2O$ mixed with 100 Torr of HCl at −30 °C (solid line). In each case the reference beam contained 250 or 100 Torr, as appropriate, of $(CD_3)_2O$ in a 10 cm cell at +34 °C.

The band due to ν_s in $(CH_3)_2O$...HCl was also studied between +34 and −30 °C, and shows the same temperature dependence as that in $(CD_3)_2O$...HCl. The only differences between the two bands are that for $(CH_3)_2O$...HCl the central peak is slightly broader and the 2475 cm^{-1} peak is slightly less well resolved at −30 °C. Lassegues, Huong, and Lascombe (15, 16) have studied the ν_s band of $(CH_3)_2O$...HCl quantitatively between −50 and +90 °C (these workers have also seen the band due to the O..H—Cl deformation mode in $(CH_3)_2O$...HCl (15).) Their results agree with ours between +30 and −30 °C but their spectra above +30 °C showed that $\nu_s - \nu_\sigma$ can be assigned to the shoulder at 2360 cm^{-1}, although the transition [$v_s = 0 \rightarrow 1$, $v_\sigma = 2 \rightarrow 1$] appears to be stronger than [$v_s = 0 \rightarrow 1$, $v_\sigma = 1 \rightarrow 0$]. This allows ν_s to be assigned at 2480 cm^{-1} and $\nu_s + \nu_\sigma$ (the transition [$v_s = 0 \rightarrow 1$, $v_\sigma = 0 \rightarrow 1$]) at 2574 cm^{-1} (at +30 °C). The shoulder at 2680 cm^{-1} is assigned to $\nu_s + 2\nu_\sigma$ and the decrease in intensity on cooling is explained by postulating (15, 16), that, because of the vibrational Franck–Condon effect (9), the transition [$v_s = 0 \rightarrow 1$, $v_\sigma = 2 \rightarrow 4$] is more intense than [$v_s = 0 \rightarrow 1$, $v_\sigma = 0 \rightarrow 2$].

This assignment indicates that the difference between the $v_\sigma = 1$ and $v_\sigma = 0$ states is 95 ± 5 cm^{-1} when $v_s = 1$, compared with 119 cm^{-1} when $v_s = 0$. This implies that although the curve of energy *vs.* O...Cl distance must have a deeper minimum for the $v_s = 1$ state than for the $v_s = 0$ state (9), the minimum must be broader, so that the curvature is smaller, for the $v_s = 1$ state.

This assignment can clearly be applied to the ν_s band of $(CD_3)_2O$...HCl, but it also seems clear that these transitions (16) alone can not account for the entire band unless some special mechanism, such as an abnormally large effect of centrifugal distortion (15), broadens the rotational envelope. Any such effect can only be operative in the $v_s = 1$ state, because the

30 cm^{-1} halfwidth of the bands due to the ethereal modes, for which $v_s = 0$, can be explained without invoking it. It seems probable that hot bands from excited states of ν_β, as well as from ν_σ (16), contribute to the ν_s band and, in view of the results for the deuterium-bonded molecules, it is probable that combination bands between ν_s and ν_β also contribute.

The temperature dependence of the bands due to the DCl stretching mode, ν_s, in $(CH_3)_2O$...DCl and $(CD_3)_2O$...DCl is shown in Fig. 6. The absorption by the free ether has been subtracted from that of the mixture to yield the curves shown. In each case the entire band sharpens as the temperature is lowered and, if allowance is made for the frequency shift of about 5 cm^{-1} between +30 and −30 °C, all features decrease in intensity relative to the peak at 1850 cm^{-1}. The only exception is the shoulder at 1870 cm^{-1} in $(CD_3)_2O$...DCl, which is discussed below.

It has been noted that the ν_s bands of several ether..DCl molecules are similar to those of ether...HCl, with the side bands due to $\nu_s \pm n\nu_\sigma$ weaker for the deuterated acid (3). However, the details of the bands of $(CH_3)_2O$...DCl and $(CD_3)_2O$...DCl can not be entirely explained in this way, and there are differences between these two bands which must be explained. The feature at 1870 cm^{-1} in the spectrum of $(CD_3)_2O$...DCl

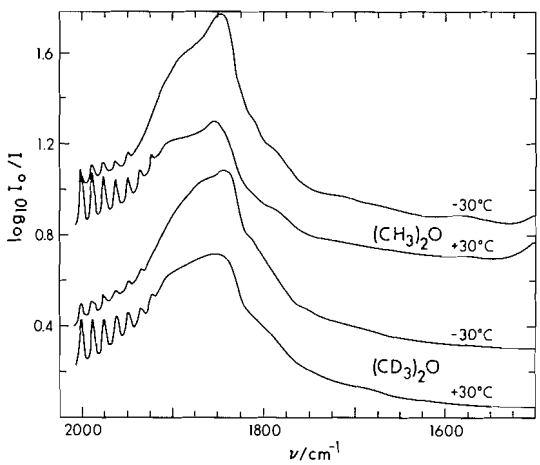

FIG. 6. Infrared absorption in 10 cm pathlength by mixtures of $(CH_3)_2O$ + DCl (upper two curves) and of $(CD_3)_2O$ + DCl (lower two curves). For each pair of curves, the upper one was obtained using 100 Torr of each gas cooled to −30 °C and the lower one required 250 Torr of each gas at +30 °C. In each case the reference beam contained 100 or 250 Torr, as appropriate, of the ether in 10 cm pathlength.

at −30 °C is attributed to the combination transition due to the symmetric CO stretching and CD_3 deformation modes, 815 plus 1055 cm^{-1}. The shoulder at 1800 cm^{-1} in $(CD_3)_2$-O...DCl appears to be a single feature, while in $(CH_3)_2O$...DCl features can be identified at about 1785 and 1810 cm^{-1}, and the additional feature is attributed to the overtone of the symmetric CO stretching mode, 2 × 912 cm^{-1}. The weak feature at 1585 cm^{-1} in the spectrum of $(CH_3)_2O$...DCl is present in that of $(CH_3)_2$-O...HCl and undoubtedly corresponds to a weak feature at this frequency in the pure ether. These features appear to be more intense in the hydrogen-bonded molecules than in the pure ether, in which case they must gain intensity through Fermi resonance with the ν_s mode.

The most prominent features that are common to the ν_s bands of both deuterium-bonded molecules are the central peak at 1850 cm^{-1}, shoulders 50 cm^{-1} away to either side, and much weaker features further away whose frequencies can not be well identified. In view of the deduction that the HCl rocking modes, ν_β, occur at about 50 cm^{-1}, it is logical to assign the fundamental, ν_s, to the peak at 1850 cm^{-1}, and to assign the shoulders 50 cm^{-1} away from the peak to the sum and difference bands $\nu_s + \nu_\beta$, and $\nu_s - \nu_\beta$.

The ratio of the fundamental, ν_s, frequencies for HCl and DCl is 2480/1850 = 1.340, which indicates that the anharmonicity of these modes is greater than that of the OH stretching mode in ice, where the ratio is 1.354 (17), but is not extraordinarily large.

Relative Intensities

In Table 1 the frequencies and approximate relative integrated intensities of the various bands in the spectrum of $(CH_3)_2O$...HCl are presented. The relative intensities of the bands above 850 cm^{-1} should be quite reliable because they were all measured from a single spectrum of a mixture of 20 Torr of $(CH_3)_2O$ plus 8 atm of HCl at 10 °C. The relative intensities of the bands below 850 cm^{-1} must be regarded as approximate. They were determined using an equilibrium constant at 0 °C of 1.13, standard state 1 atm, which was calculated from the mean enthalpy and entropy of formation reported by Govil, Clague, and Bernstein (18). The mean enthalpy of formation was used to determine the temperature dependence of the

TABLE 1. Frequencies and relative intensities of absorption bands in $(CH_3)_2O...HCl$

ν/cm^{-1}	Assignment	Intensity (Arbitrary units)
2675 2574 2480 ~2360	HCl stretch, ν_s	1000
1465	CH_3 deformation	58
1248	CH_3 rock	5
1171 1097	CH_3 rock + asymmetric CO stretch	180 130
912	Symmetric CO stretch	100
790	$2\nu_b$, $2\nu_t$	5
570 525 470	O...H—Cl deformation ν_b, ν_t	30*
415	C—O—C deformation	
119	O---H stretch ν_σ	2.5

*The intensity was measured for $(CD_3)_2O...HCl$.

equilibrium constant. However, the errors on the values of the enthalpy and entropy of formation (18) allow the equilibrium constant at 0 °C to lie between 0.15 and 9.5, standard state 1 atm. Thus the relative intensities quoted may be considerably in error, because widely differing pressures of the component gases were required for the different bands and the intensities obtained markedly reflect the value of the equilibrium constant that was used. It should also be noted that the relative intensity of the O...H—Cl deformation modes was determined for $(CD_3)_2$-O...HCl. The limited part of the band that was observable in $(CH_3)_2O...HCl$ indicated that the intensity was approximately the same in the two systems.

Studies on Lactoperoxidase. VI. Kinetics of the Oxidation of *p*-Cresol by Compound II[1]

R. James Maguire and H. Brian Dunford
Department of Chemistry, University of Alberta, Edmonton 7, Alberta
Received February 1, 1972[2]

The kinetics of the oxidation of *p*-cresol by compound II of lactoperoxidase have been studied over the p*H* range 2.1–11.2 by the stopped-flow technique. The reaction is kinetically first-order with respect to *p*-cresol over the entire p*H* range. Use is made of the diffusion-controlled limit that can be placed on a bimolecular rate constant to show that *p*-cresol reacts in the unionized form. The complexity of the p*H*-rate profile is discussed in terms of acid dissociation constants of groups in the enzyme and the ionization of the substrate.

Les cinétiques de l'oxydation du *p*-crésol par le composé II de la lactoperoxydase ont été étudiées dans l'intervalle de p*H* de 2.1–11.2, par la technique du "flow stop". La réaction est d'ordre un par rapport au *p*-crésol dans tout ce domaine de p*H*. On a utilisé la diffusion contrôlée limite qui peut être inclus dans une constante de vitesse bimoléculaire pour montrer que le *p*-crésol réagit sous forme non ionisée. La complexité du profil de vitesse en fonction du p*H* a été discutée en fonction des constantes de dissociation acide des groupes de l'enzyme et de l'ionisation du substrat. [Traduit par le journal]

Can. J. Chem., 51, 1721 (1973)

Studies on the enzyme lactoperoxidase from this laboratory have been directed toward the elucidation of the structure–activity relationship of the active site of the native enzyme and its compounds formed by reaction with hydrogen peroxide (1–4) and simulation of the action of thyroid peroxidase in the thyroid gland, which is involved in the production of thyroxine through coupling of iodinated tyrosine residues (5). The present study was undertaken with a view of determining the effect of a neutral molecule on the reduction of compound II to the native enzyme. *p*-Cresol was chosen because of the remarkable efficiency of oxidation of phenols by peroxidase systems, and because of its resemblance to the amino acid tyrosine, while having fewer acid–base groups.

Experimental

Lactoperoxidase (LP) was obtained and purified as described previously (5). Practical grade *p*-cresol was obtained from Eastman Organic Chemicals and was purified by sublimation.[3] All other substances were of reagent grade and were used without further purification. Kinetic investigations were carried out using a stopped-flow apparatus described previously (5, 6), with the formation of compound II accomplished as described in the investigation of the kinetics of the reaction between compound II and iodide ion (5). All measurements were made at 25° on solutions of total ionic strength 0.05. The acid dissociation constant of *p*-cresol at this value of ionic strength was determined spectrophotometrically to be 10.11 ± 0.01, in agreement with the value 10.10 obtained by the use of Davies' equation (7) together with the value at zero ionic strength found by Chen and Laidler (8).

The experimental conditions were such that there was a large excess of *p*-cresol over compound II. Thus pseudo first-order conditions were obtained, and the value of the second-order rate constant of the reaction was obtained by dividing the value of the pseudo first-order rate constant by the concentration of *p*-cresol. At p*H* values below 2 and above 11.3, the enzyme denatured. Overlapping buffer systems were used to check for buffer effects on the value of the second-order rate constant, k, but no buffer effects were observed.

Results and Discussion

Values of the apparent second-order rate constant, k, obtained at different p*H* values are shown in Fig. 1. By the use of Dixon's rules of p*H* effects in enzyme kinetics (9), which demonstrate that inflections in such curves are the result of kinetically important ionizations occurring in the reacting species, it is seen that the variation of k with p*H* depends on the acid dissociation of the substrate at p*H* 10 and the ionization of three kinetically important enzyme groups having pK_a values of around 2, 6, and 9.5. The minimum reaction scheme consistent with the data is given by Scheme 1, in which P-II, HP-II, H_2P-II, and H_3P-II are the four

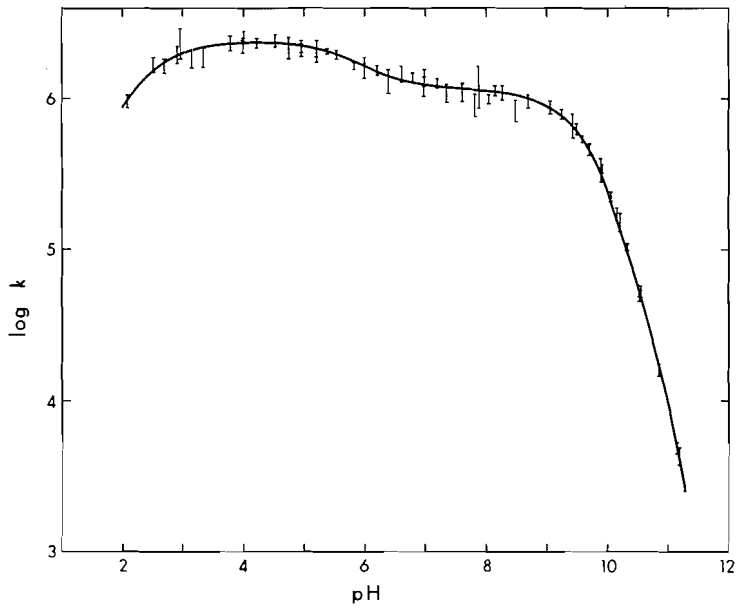

FIG. 1. A plot of log k *vs.* pH for the reaction between LP-II and *p*-cresol. The solid line is a curve calculated by computer for the fitting of the data to eq. 1. The error bars represent standard deviations of the rate constant k, which has units of M^{-1} s^{-1}.

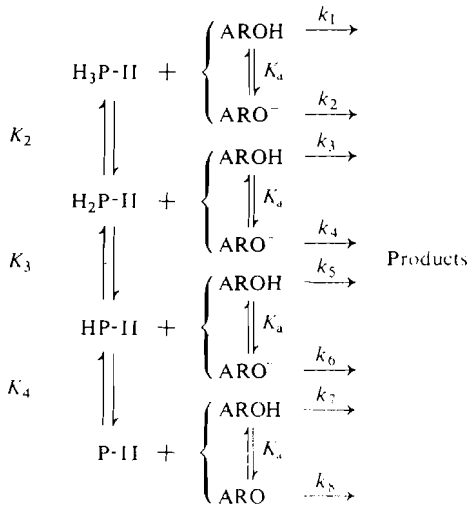

SCHEME 1

kinetically distinct states of protonation of compound II, the K's are molecular or macroscopic acid dissociation constants, and the k's are bimolecular rate constants.

The corresponding kinetic expression is given by eq. 1. The smooth curve in Fig. 1 shows the best fit to eq. 1, and is defined by the parameters of a least squares fit in Table 1. The value of pK_a obtained in this way is different from the spectrophotometric results; however, a second kinetic analysis with a fixed value of pK_a = 10.11 produced only small changes in the other parameters, and a good fit to the experimental data, so that the difference in pK_a values may not be significant.

It is possible to arrive at a conclusion regarding the nature of the reactive form of *p*-cresol. In order to decide which of the kinetically equivalent pathways included in each of the two non-zero rate terms in eq. 1 given in Table 1 is responsible for the reaction rate, it is necessary to make use of the maximum value that can be placed on the rate constant of a bimolecular process, about 10^{10} M^{-1} s^{-1}. Since $K_a/K_2 = 10^{-8}$ and $K_a/K_3 = 3 \times 10^{-5}$, it follows that in order to account for the observed rate the values of k_2 and k_4 would have to exceed 10^{10} M^{-1} s^{-1}, and therefore the predominant pathways are not those denoted by the rate constants k_2 and k_4, but by k_3 and k_5. Thus the protonated forms of lactoperoxidase compound II appear to react with the neutral form of *p*-cresol.

This work can be compared to the reaction between LP-II and iodide ion, in which the second-order rate constant varies with unit

negative slope over the experimental pH range, from 4.2×10^6 M^{-1} s^{-1} at pH 2.9 to 2.6×10^{-1} M^{-1} s^{-1} at pH 10.1 (5). The second-order rate constant for *p*-cresol oxidation by LP-II is appreciably greater than the rate constant for iodide oxidation over most of the pH range, except for the low pH region. The radical difference in the pH-rate profiles for these two substrates (three enzyme pK_a's observed in *p*-cresol oxidation, none in the range 2.9–10.1 for iodide oxidation) may be a result of the lack of steric interactions between iodide ion and LP-II, or the result of the operation of a different mechanism. Since *p*-cresol reacts in its unionized form, electrostatic interactions are not a factor in its oxidation.

A comparison with the pH-rate profile of the reaction of compound II of horseradish peroxidase with *p*-cresol shows several differences in detail (10). The analogous comparisons between lacto- and horseradish peroxidases with respect to (*a*) the compound II reactions with iodide (5, 11) and (*b*) cyanide and fluoride binding to the native enzymes (1, 2, 12) also show marked differences, indicating that generalizations about properties of various peroxidases must be made with caution.

The Synthesis of a 5,6-Dihydropyridazine[1,2]

P. DE MAYO AND M. C. USSELMAN

Photochemistry Unit, Department of Chemistry, The University of Western Ontario, London, Ontario

Received October 10, 1972

The synthesis of 3,6-dimethyl-6-*n*-butyl-5,6-dihydropyridazine, the first 5,6-dihydropyridazine, is described. On heating it undergoes a [1,5] sigmatropic hydrogen rearrangement to give the corresponding 1,6-dihydropyridazine.

On décrit la première synthèse d'une dihydro-5,6 pyridazine, la diméthyl-3,6 butyl-6. Par chauffage, elle se transforme en dihydro-1,6 pyridazine par un réarrangement sigmatropique [1,5] d'hydrogène.

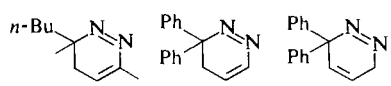
Introduction

In connection with our studies on the mechanism of photoannelation, specifically the addition of cyclic enones to acetylenes (for a general discussion, see ref. 1) we required a 5,6-dihydropyridazine. This paper describes the first synthesis of a member of this class: 3,6-dimethyl-6-*n*-butyl-5,6-dihydropyridazine (**1**); its photochemical properties are discussed in the following paper (17).

At the outset of our investigations the only 5,6-dihydropyridazine mentioned in the literature (2) was a substance tentatively assigned structure **2**. This was prepared by the action of cyclopropene on diphenyldiazomethane. The main basis for the structural designation was the u.v. spectrum (λ_{max} 334 nm) but, as will be seen, this criterion actually eliminates **2** from consideration as a possible structure. The alternative **3**, also considered by the authors, seems at present the more likely candidate. Recently Gorse and Binkley (3) have postulated a member



1 **2** **3**

of the related system, 1,9-dihydrophthalazine, as an intermediate in a complex sequence following the photolysis of benzophenone azine. Thus, although dihydropyridazines with the saturated centers at other than the 5,6 positions were well known there appeared to be no authenticated derivative available for our photochemical study, and a direct synthesis was therefore undertaken.

Gillis and Hagarty (4) have developed a convenient route to α,β-unsaturated azo compounds, but their method is not directly applicable to the synthesis of cyclic analogs. The methods used by Closs and Heyn (5) for the synthesis of the 3*H*-pyrazole system appeared more promising. The sequence depicted in Scheme 1 is illustrative, and consists of the bromination of a 2-pyrazoline followed by base-induced dehydrobromination. The product was a mixture of 3*H*-pyrazoles. In an alternative procedure the 1-*p*-toluenesulfonyl derivative of the pyrazoline on treatment with alkoxide ion eliminated the elements of *p*-toluenesulfonic acid to give essentially the same pyrazole mixture.

The dihydropyridazine selected as the object of synthesis was **1**. With the substitution–elimination procedures outlined in mind the tetrahydropyridazine (**7**) then became the immediate objective. This could be obtained from easily available starting materials.

Condensation of acetonylacetone with hydrazine has been shown to give, instead of the expected dihydropyridazine, a dimeric product **6** (6). Under alkylating or arylating conditions, this substance behaves as would be expected of the monomer (6) indicating a ready reversibility. By the method used (7) for the 6-phenyl substituted analog, but employing lithium butyl (2 equiv), **7** was obtained in 50% yield. The stoichiometry of the reaction suggests that the lithium butyl is instrumental in effecting the dissociation of the dimeric **6**.

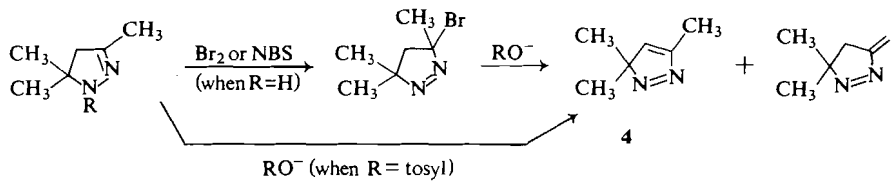
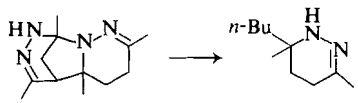


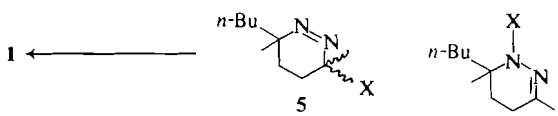
SCHEME 1



6 7

With the tetrahydro derivative **7** available, a number of direct dehydrogenation procedures were attempted. Mild reagents (mercuric oxide, phenanthraquinone at room temperature) led to essentially unchanged starting material, whilst more powerful conditions (chloranil, phenanthraquinone at 150°) led to intractable and uninspiring tars. An attempt to prepare the *N*-tosyl derivative by the method of Closs and Heyn (5) was similarly discouraging, and attention was then turned to the halogenation–dehydrohalogenation procedure.

Halogenation at the 3-position of 2-pyrazolines was achieved by Closs and Heyn (5) using bromine or *N*-bromosuccinimide. For the present reaction the hypohalites proved to be superior reagents. The tetrahydropyridazine (**7**) in benzene solution reacted very rapidly with *tert*-butylhypochlorite to give the two diastereoisomers of 6-*n*-butyl-3-chloro-3,6-dimethyl-3,4-5,6-tetrahydropyridazine (**5***a*). These could be separated by chromatography. The structures of the diastereoisomers (excluding stereochemical assignments) followed from the n.m.r. data. Further, the u.v. absorption spectrum excluded alternative isomeric possibilities, such as **8**, since an azo grouping was clearly present (λ_{max} 390 nm).



5

a X = Cl
b X = Br
c X = OMe

8

The chloro-compounds were solvolytically stable since the n.m.r. of the less polar diastereoisomers in deuteriochloroform solution showed no change after 48 h at 80°, thus precluding the interconversion of the diastereoisomers. Further, the substances were resistant to dehydrochlorination when treated with an equimolar amount of sodium methoxide in refluxing methanol. The base did not induce interconversion of the diastereoisomers when a pure diastereoisomer was used.

The lack of reactivity of **5***a* to mild dehydrohalogenating conditions suggested the preparation of **5***b*. This was readily achieved under similar conditions using *tert*-butyl hypobromite. The reaction was facile and the spectral properties of the isolated **5***b* closely resembled those of **5***a*. There was, however, a marked difference in stability, and the mixture decomposed rapidly in air. For this reason it was always prepared immediately before use.

A number of dehydrohalogenating agents were used without success (silver oxide in pyridine, sodium hydride, potassium *tert*-butoxide in dimethylsulfoxide) and a study of the complex mixture obtained showed no initial accumulation of any one substance, and adumbrated the instability of **1**. Dehydrohalogenating agents which could also act as nucleophiles led to overall substitution. For instance, reaction of **5***b* with sodium methoxide in refluxing methanol gave **5***c* in good yield,[3] whilst silver acetate in benzene gave a mixture in which the acetate moiety had been incorporated.

Conversion of **5***b* to **1** was ultimately achieved in reasonable yield (15–20%) using 1,5-diazabicyclononene (DABN). Reaction in an excess (1.3 mol) of DABN in tetrahydrofuran at room temperature gave **1** as the only major initial product, but the yield was strongly dependent on reaction time. A maximum was reached after 8–10 h under these conditions, after which the yield declined. At maximum yield some 30% of the starting material remained unchanged. The absence of the exomethylene isomer of **1** is

[3]The substance appeared to be homogeneous, but may well have been the expected mixture of diastereoisomers having closely similar physical properties.

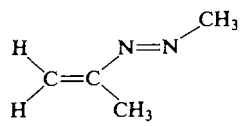
surprising, but may be due to its further reaction and transformation to intractable material.

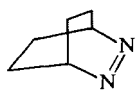
The n.m.r. spectrum of **1** in deuteriochloroform showed a high field methyl signal at 1.18 p.p.m. There was also a three-proton signal for a vinyl methyl group (2.27 p.p.m.) and a single vinyl proton at 5.2 p.p.m. Double irradiation revealed that the vinyl proton and the vinyl methyl protons were both coupled to the two allylic protons as well as to each other. The mass spectrum showed the expected molecular ion, but the spectrum could only be interpreted in terms of the thermal rearrangement described below, and so only indirectly supported the structural allocation.

The u.v. spectrum justifies a brief discussion. The absorption maximum of what is presumably the $\pi \rightarrow \pi^*$ transition at 268 nm is of the same intensity and of slightly lower energy than the corresponding transition in **4** (257 nm). Analogy with the carbocyclic equivalents would have led, perhaps, to the expectation of a somewhat larger shift in the same direction. The $n \rightarrow \pi^*$ transition at 447 nm, however, appears at much longer wavelength than the apparently corresponding transition in **4** which is at 350 nm. Both these values are to be compared with that found (386 nm) for the open-chain substance **9** (4). In fact the only relevant azo substance known to us absorbing at such long wavelengths is *cis*-azo-



9

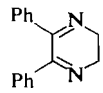
10



11

2-methyl-2-propane (8) which has a low intensity absorption band at 447 nm. Since *cis*-azomethane absorbs at 353 nm (9) and **10** and **11** have λ_{max} at 342 (10) and 378 nm (11), respectively, the difference in the case of the first substance for lack of a better interpretation would seem to be attributed to the distortion from planarity induced by the bulky groups. It is difficult to see any relevance of this phenomenon to our present problem since both **1** and **4** should be close to planar. Little change can be expected in the energy of the non-bonding electrons and such change as occurs should surely be lowered in the geometry defined by **1** rather than **4** by something like 0.75 eV.[4]

An alternative possiblity is that the bands do not represent the same transition, and that relevant bands may be submerged under the other absorption, or be of very low intensity.[5] The observation by Arnold and his co-workers (13) in a study of five-, six- and seven-membered cyclic 1,4-diaza-1,3-dienes of abnormal spectral changes may be relevant. They found that the long wavelength absorption maximum (normally attributed to an $n \rightarrow \pi^*$ transition) of 2,3-diphenyl-5,6-dihydropyrazine (**12**) to be at significantly longer wavelength than either of the related five- or seven-membered equivalents.

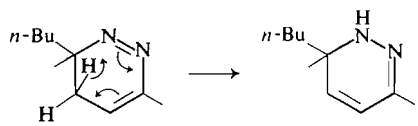


12

These authors have attributed this long wavelength absorption not to an $n \rightarrow \pi^*$ transition, but to a transition between the ground state 5,6-dihydropyrazine and an electronic excited state of the ring-opened enediimine, a transition not available to the other ring systems.

Thermal Rearrangement

When **1** is dissolved in benzene or *n*-hexane, the solution degassed by the freeze–pump–thaw cycle, and heated to 125°, it undergoes a smooth sigmatropic rearrangement to give **13** quantita-



1 **13**

tively. This substance, a 1,6-dihydropyridazine is also unstable to air and the structure assigned to it rests essentially on spectroscopic data and on its presumed mode of genesis.

The n.m.r. spectrum shows absorption for the

[4]Subsequent to the submission of this paper, calculations by Baird *et al.* have established a correlation between the angle subtended by an azo group and the energy of the $^1(n,\pi^*)$ transition (18). On the basis of this correlation, the "anomalous" long wavelength absorptions of **1** and *cis*-azo-2-methyl-2-propane may be attributed, not to out-of-plane distortion, but to in-plane distortion, and a consistent pattern of $n \rightarrow \pi^*$ azo transitions results.

[5]For a discussion of $n \rightarrow \pi^*$ transitions in the azo group, see ref. 12.

For personal use only.

protons of a vinyl methyl group at 2.0 p.p.m. Two vinyl protons were observed at 5.6 and 5.8 p.p.m. with a coupling constant of 10 Hz. The vinyl methyl protons did not appear to be coupled with either of the vinyl protons and appeared as a sharp singlet. The presence of the *cisoid* ethylene moiety implies the transfer of one hydrogen from the allylic methylene group in **1**, and the terminus for its transfer should be the nitrogen in the β position. Indeed NH absorption was visible in the n.m.r. spectrum at approximately 5.7 p.p.m. (broad). In agreement the i.r. spectrum showed strong NH stretching absorption near 3250 cm^{-1} (broad). The character of the u.v. absorption was completely changed, the resolved $\pi \rightarrow \pi^*$ and $n \rightarrow \pi^*$ bands of **1** being replaced by general absorption from 225 nm (ε 2000) extending beyond 350 (ε 50) to 400 nm.

The sigmatropic [1,5] suprafacial hydrogen shift leading from **1** to **13** is thermally allowed and has ample general analogy (14). Rearrangements in six-membered rings appear to be rare, but a [1,5] methyl shift has recently been reported (15).

In the determination of the mass spectrum of **1** it appears that rearrangement, at least in good proportion, must precede fragmentation. The elimination of nitrogen appears to be a minor process as in the formation of methyl acetylene. On the other hand acetonitrile and acetylene formation would seem to be important, as does the formation of valeronitrile (and its further fragmentation products (16)). Cleavage of the C_4 side chain also occurs, and the only significant peak not susceptible to ready interpretation is that at *m/e* 115.

Experimental

Proton spectra were obtained with Varian T-60 and HA-100 spectrometers. I.r. spectra were run on Beckman IR 10 and 20A spectrometers and a Carey 14 was used for obtention of the u.v. spectra. Mass spectra were obtained with a Varian M66 spectrometer.

Unless otherwise stated, all solvents were Fischer Spectranalyzed grade, and were used without further purification.

3,6-Dimethyl-6-n-butyl-2,3,4,5-tetrahydropyridazine (7)

The compound was prepared as previously described (6). It is stable for prolonged periods when stored at 0° under nitrogen. After repeated brief exposures to the atmosphere for withdrawal of samples, the compound assumes a pale yellow color which can be removed by careful redistillation. Upon appearance of the yellow color, the compound is no longer suitable for reaction with the *tert*-butylhypohalites because dark colored impurities are formed. These catalyze the decomposition of the halo products, and make their isolation in pure form exceedingly difficult. The attempted preparation of the *p*-toluenesulfonate derivative by the method of Closs and Heyn (5) gave a complex mixture of products.

3-Chloro-3,6-dimethyl-6-n-butyl-3,4,5,6-tetrahydropyridazine (5a)

To 7 (1.17 g) in benzene (5 ml) at 10° was added dropwise *tert*-butyl hypochlorite (0.77 g, Frinton Laboratories). The solution immediately became bright yellow. After allowing to warm to room temperature the solvent was removed under reduced pressure and the residual mixture separated by chromatography on silica gel (60–120 mesh; 60 g) and elution with ether–benzene (1:19). Two fast-running yellow substances were collected; the first (**A**) in 49% yield (0.7 g) and the second (**B**) in order of elution in 42% (0.6 g) yield. Both gave a positive Beilstein test. The substances were further purified by bulb-to-bulb distillation at 50°/0.2 mm. The substance **A** had ν_{max} ($CHCl_3$) 2960, 2940, 2865, 1460, 1380, and 868 cm^{-1}; δ ($CDCl_3$) 1.90 (3H, s), 1.32 (3H, s), 0.94 (3H, m), 2.20–1.20 (10H, complex); λ_{max} (C_6H_{12}) 385 nm (ε 75).

The substance **B** had ν_{max} ($CHCl_3$) 2970, 2940, 2870, 1450, 1385, and 865 cm^{-1}; δ ($CDCl_3$) 1.98 (3H, s), 1.22 (3H, s), 0.94 (3H, m), 2.20–1.20 (10H, complex); λ_{max} (C_6H_{12}) 390 nm (ε 80).

Anal. mixture of isomers **A** and **B**. Anal. Calcd. for $C_{10}H_{19}N_2Cl$: C, 59.22; H, 9.47; N, 13.81; Cl, 17.50. Found: C, 59.48; H, 9.60; N, 13.82; Cl, 17.40.

The substance **B** was recovered essentially unchanged when refluxed in methanol solution containing 1 equiv of sodium methoxide for 30 min under nitrogen.

3-Bromo-3,6-dimethyl-6-n-butyl-3,4,5,6-tetrahydropyridazine (5b)

The procedure followed was that employed for the chloro-isomers with the substitution of *tert*-butyl hypobromite for the hypochlorite. The combined yield of stereoisomers was 60–70% after bulb-to-bulb distillation, the lower yield being attributed to the greatly increased instability of the bromine-substituted diastereoisomers which precluded the obtention of analytical data.

The faster-running isomer had ν_{max} ($CHCl_3$) 2955, 2935, 2865, 1445, 1380, and 865 cm^{-1}; δ ($CDCl_3$) 2.17 (3H, s), 1.34 (3H, s), 0.94 (3H, m), 2.4–1.2 (10H, complex). The slower-running isomer had ν_{max} ($CHCl_3$) 2955, 2925, 2855, 1440, 1370, and 860 cm^{-1}; δ ($CDCl_3$) 2.19 (3H, s), 1.19 (3H, s), 0.94 (3H, m), 2.4–1.2 (10H, complex).

3,6-Dimethyl-3-methoxy-6-n-butyl-3,4,5,6-tetrahydropyridazine (5c)

To the freshly-prepared slower-running isomer of **5***b* (70 mg) was added an equimolar quantity of sodium methoxide (20 mg) in methanol (2 ml) and the mixture was heated to reflux under nitrogen for 5 h. T.l.c. showed one major product running slower than **5***b* (eluent: ether–benzene, 1:9). On preparative t.l.c. the product was isolated in 60% yield (eluent: ether–benzene, 1:9). It had δ ($CDCl_3$) 3.52 (3H, s), 1.40 (3H, s), 1.27 (3H, s), 0.94 (3H, m), 2.0–1.2 (10H, complex). Under the same conditions the faster-running isomer gave the same product as identified by n.m.r.

The diastereoisomeric mixture when treated with silver acetate in benzene at 45° for 48 h gave three products in poor yield. Two of these contained acetyl groups, as judged by the n.m.r. spectra. They were not further studied.

*3,6-Dimethyl-6-n-butyl-5,6-dihydropyridazine (**1**)*

To a freshly-prepared diastereoisomeric mixture of **5***b* (200 mg) in 2 ml tetrahydrofuran, which had been freshly distilled from sodium borohydride, was added 1,5-diazabicyclononene (200 mg; 1.3 mol equiv) in 2 ml tetrahydrofuran. The mixture was allowed to stand under nitrogen for 10 h during which time the base hydrobromide separated as long needles. The tetrahydrofuran was removed under reduced pressure, the product taken up in benzene and separated by preparative t.l.c. (eluent: ether–benzene, 1:9). In larger scale preparations the product could be isolated by column chromatography on silica gel (60–120 mesh; 60:1) using ether–benzene (1:19) as eluent. The yields after bulb-to-bulb distillation of the product (50°/0.1 mm) were 15–20%. The product had ν_{max} ($CHCl_3$) 2980, 2960, 2885, 1675, 1470, and 1390 cm^{-1}; δ ($CDCl_3$) 5.2 (1H, m), 2.27 (3H, m), 2.0–1.6 (2H, m), 1.6–1.2 (6H, complex), 1.18 (3H, s), 0.94 (3H, m); λ_{max} (C_6H_{12}) 268 nm (ε 2100), 447 nm (ε 150); *m/e* (70 eV) 166 (mol ion) (8.6%), 125 (48), 115 (44), 58 (87), 57 (58), 56 (97), 55 (63), 43 (100), 41 (75), 39 (45).

Anal. Calcd. for $C_{10}H_{18}N_2$: C, 72.24; H, 10.91. Found: C, 72.26; H, 10.96.

*3,6-Dimethyl-6-n-butyl-1,6-dihydropyridazine (**13**)*

The 5,6-dihydropyridazine (30 mg) in C_6D_6 (0.4 ml) with hexamethyldisiloxane as reference was sealed in an n.m.r. tube after degassing. A solution (1 mg/ml) in cyclohexane or hexadecane was similarly sealed in a u.v. cell. The solutions were heated to 125° in the dark for 12 h, at the end of which time conversion to the 1,6-dihydro compound appeared complete. The spectroscopic details are given in the discussion. The compound decomposed rapidly when exposed to the atmosphere, thus precluding analysis.

The Photochemistry of a Dihydropyridazine[1]

P. DE MAYO AND M. C. USSELMAN

Photochemistry Unit, Department of Chemistry, The University of Western Ontario, London, Ontario

Received October 10, 1972

Irradiation of a 5,6-dihydropyridazine in either the n → π* or π → π* absorption bands results in ring-opening to the two isomeric diazatrienes expected of a concerted, electrocyclic process. Population of the triplet state of the dihydropyridazine by sensitization also results in ring-opening, but much less efficiently. The quantum yields of the two processes were found to be 0.40 ± 0.04 and 0.07 ± 0.01, respectively. The primary photoproducts, *cis,cis*- and *cis,trans*-4,5-diazatriene, isomerize thermally at temperatures greater than 20° to the *trans,cis* and *trans,trans* isomers.

L'irradiation de la dihydro-5,6 pyridazine selon les bandes d'absorption n → π* ou π → π* conduit par ouverture du cycle aux deux diazatriènes isomériques prévus par un processus électrocyclique et concerté. La population de l'état triplet de la dihydro-5,6 pyridazine par sensibilisation conduit aussi à l'ouverture du cycle mais avec une efficacité de beaucoup inférieure. Les rendements quantiques des deux processus sont égaux à 0.40 ± 0.04 et 0.07 ± 0.01, respectivement. Les photoproduits primaires, *cis,cis*- et *cis,trans*-diazatriènes-4,5 s'isomérisent thermiquement à des températures plus élevés que 20° pour donner des isomères *trans,cis* et *trans,trans*. [Traduit par le journal]

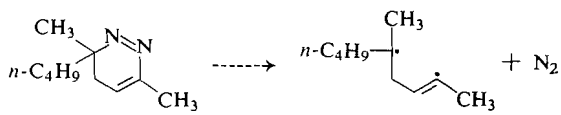
Introduction

A 1,4-biradical (tetramethylene) has frequently been invoked as an intermediate in cyclobutane formation and rupture. In particular it is believed that the addition of triplet enones to olefins involves such an intermediate (for a general discussion, see ref. 1). Indirect information about the fate of such tetramethylenes, formed by photochemical addition, may be obtained from quantum yield data for product formation in systems where such species are believed transients (1–5, and refs. cited therein).

Interpretations drawn from such indirect information rely heavily upon analogy with systems in which tetramethylenes, singlet and triplet, are studied directly. In the case of tetramethylenes, O'Neal and Benson (6) have calculated that cyclization and cleavage (to two ethylene molecules) are approximately isoenergetic. These calculations are supported by both direct (*e.g.* ref. 7) and indirect (4) experiments.

Through studies of the photoannelation of cyclic enones with acetylenes (8) the conclusion was arrived at that a 1,4-biradical possessing a terminal π-bond does not behave significantly differently in its chemistry from a tetramethylene despite hybridization and obvious stereochemical differences. In an effort to obtain more direct information about the behavior of such a biradical we have synthesized a member of the previously unknown 5,6-dihydropyridazine series, specifically 3,6-dimethyl-6-*n*-butyl-5,6-dihydropyridazine (**1**) (9) in the hope that it would, on irradiation or thermolysis, eliminate nitrogen to generate the biradical (**2**).[2] Under none of the conditions employed was this the case however: thermally the molecule underwent a sigmatropic [1,5] hydrogen migration (9) and photochemically it rearranged. The photochemistry of this substance is described in this paper.



1 **2**

Results and Discussion

On direct irradiation into the n → π* band (435 nm), the dihydropyridazine rearranged to form the two aliphatic diazatrienes **3** and **4** which would be the products expected of a concerted electrocyclic process. Irradiation into the higher energy π → π* envelope (λ_{max} 267 nm) gave the same products at approximately the same rate.

[1]Publication No. 61 from the Photochemistry Unit, The University of Western Ontario, London, Ontario. Photochemical Synthesis, Part 46.

[2]Recently, the irradiation of a series of 1*H*-2,3-benzodiazepines has been reported (39). No nitrogen elimination was observed; rather, each of the diazepines was converted quantitatively to its tricyclic valence tantomer.

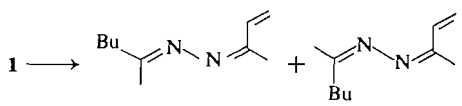
C_1—H_t	5.55 or 5.54	5.54 or 5.55	5.57	5.57
$J_{H_{cis}}$	= 11.0 Hz			
$J_{H_{trans}}$	= 18.0 Hz			
$J_{H_{gem}}$	= 1.0 Hz			

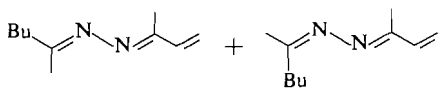
*Chemical shifts (δ) are given in p.p.m. relative to hexamethyldisiloxane, which absorbs 6.38 Hz downfield from TMS.
†C_n refers to the carbon to which the absorbing species is attached. H_c refers to the hydrogen on C_1 which is *cis* to the hydrogen on C_2 and H_t refers to the hydrogen on C_1 *trans* to that on C_2.

The diazatrienes **3** and **4** were produced (435 nm) when any of benzene, chloroform, or cyclohexane was used as the solvent. These trienes, although stable in degassed solutions at temperatures below 20°, on exposure to atmospheric oxygen were rapidly destroyed. Consequently their structural determinations rest largely on spectroscopic data.



3 **4**

At temperatures above 20° isomerization occurred about the imine functions to give the two further isomers **5** and **6**. At equilibrium one isomer constituted more than 90% of the triene mixture. The assignments of stereochemistry rest



5 **6**

on the assumption that the *trans,trans* isomer is the most stable and is that favored in the equilibrium mixture. The 100 MHz n.m.r. data are summarized in Table 1.

Isomers **3** and **4** have absorptions for the C-2 proton at considerably lower fields than those for the isomers **5** and **6** which contain the central unsaturation in the *trans* configuration. The C-2 proton is deshielded by the terminal imine, an effect which has analogy in the related shift of the γ proton in α,β-unsaturated esters. However, the allylic methyl protons do not show a net deshielding due to a proximate imine, but appear at higher field when attached to a *cis* imine. Thus the C-6 methyl signals in **3** and **5** occur at about 0.2 p.p.m. to higher field than in **4** and **6** and the C-3 methyl is at higher field in **5** and **6** than in **3** and **4**. Similar chemical shift changes have been observed by Baldwin and Krueger (11) in their determination of stereochemistry of the four isomeric 3-methyl-7-isopropylhexatrienes.[3,4]

The coupling constants between the protons of the vinyl group are consistent with those expected of such a grouping (12) and are identical for all four isomers.

The n.m.r. data are consonant with the gross structures and define the stereochemistry. The gross structure is also supported by such u.v. absorption data as were obtained in the following way.

A solution of **1** in cyclohexane was irradiated in a sealed degassed quartz cell under conditions where complete conversion to **3** and **4** occurs. The mixture then showed intense end absorption with a shoulder at 235 nm (ε 12 000), and tailing to 375 nm. Thermal conversion to **6** resulted in only minor modification of the spectrum. Although a model is not available, acetone azine has absorption at 205 (ε 18 000) and 287 nm (ε 105). Addition of a *transoid* ethylenic linkage to many dienic systems frequently leads to a red shift of some 30 nm of the main ($\pi \rightarrow \pi^*$) absorption in agreement with the shift here observed with respect to the azine. The effect on a component of the $n \rightarrow \pi^*$ transition is harder to assess, and the $n \rightarrow \pi^*$ transition here,

[3]We are grateful to Professor Baldwin for copies of his spectra of these trienes.

[4]The absorptions of these vinyl methyls are unlike those observed in β,β-dimethylmethacrylate in which the methyl *cis* to the carbonyl group (10) is deshielded.

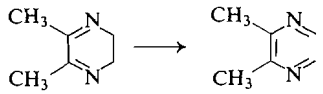
although not resolved, is probably contributing to the long wavelength absorption.

Evidently the most satisfactory proof of gross structure would be by synthesis, but attempts in this direction were unsuccessful. It was, however, possible to substantiate the gross structure of the diazatrienes chemically, as follows.

2,4-Dinitrophenylhydrazine in diglyme was added anaerobically to a solution of **3** and **4** and the mixture heated. From this reaction mixture it was then possible to isolate, and in high yield, the 2,4-dinitrophenylhydrazone of 2-hexanone.[5] It was, unfortunately, not possible to identify the other product of exchange, but we take the accumulated chemical and physical evidence for the structural designations as conclusive.

The photochemically-induced ring opening of substituted cyclohexadienes is a long-known and well-studied reaction in large part because of its occurrence in vitamin D photochemistry. The stereochemistry of ring opening in simple substituted cyclohexadienes has recently been studied by Baldwin and Krueger (11) and by Spangler and Hennis (13), and the reaction has been extended to 5,6-dihydropyrazines such as **7**.

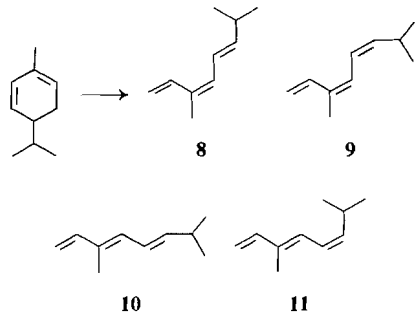


7

The photochemical behavior of the latter chromophore has recently been summarized by Arnold *et al.* (14). Such dienes are predicted by symmetry considerations (and in historical fact were the stimulus for such considerations) to open photochemically in a concerted conrotatory process. A molecule such as α-phellandrene should provide only two of the four possible isomers, and Baldwin and Krueger (11) have shown this to be true: the remaining pair was formed later by secondary absorption. By lowering the temperature to −196°, **8** became favored over **9** (29:1 low temperature; 3:1 room temperature) and it was postulated that the photochemical product ratios reflected the ground state conformation populations of α-phellandrene. We shall return to this point later.

Irradiation of **1** ($n \rightarrow \pi^*$) at 10° gave a ratio of **3**:**4** of 2.6:1.0. Since the products do not

[5]Model studies had previously shown the hydrazone exchange procedure to be applicable to an azine.



8 **9**

10 **11**

absorb at 435 nm the final product ratio should represent the initial product ratio unless energy may be transferred to **3** and **4** by some other excited molecule. The constancy of this ratio during reaction shows that this process is not occurring. No change in the obtained ratio was observed when the reaction temperature was lowered to −45°, and indeed if the Baldwin view be correct, none should be observed since conformational population changes should be small. The product ratio of *cis,trans* to *cis,cis* observed is intermediate to that obtained by Spangler and Hennis (13) for methyl- and isopropyl-5-substituted cyclohexadienes. Since an *n*-butyl group may be expected to be intermediate in its steric demand between those of a methyl and isopropyl group, a consistent pattern is obtained.

It is not necessarily true, however, that the ratio of conrotatory opening processes reflects directly the ground state conformational equilibrium. Such a conclusion is valid only if ring opening occurs from the geometry produced in the excited state by the Franck–Condon transition, *i.e.* before any vibrational relaxation by collision with solvent molecules. If this be not so, there will then be vibrational cascade to the lowest vibrational levels of the excited state. The energy surface of the excited state should exhibit two minima corresponding to two different conformations. The energy difference between the excited state conformations should be equal to or less than that of the ground state conformers (since steric demands of substituents should be equal or less) and the conformational population in the excited state would be temperature dependent. Thus the conformational population of that state need not necessarily parallel that of the ground state.

Ring opening could follow immediately upon Franck–Condon excitation if the energy surfaces of the excited diene and product triene intersect.

It has been suggested by Arnold *et al.* (14) in connection with the u.v. absorption spectrum of the dihydropyrazines that the excited state of the dienes actually lies on the same surface as the spectroscopic transition from the triene: that is, the excited state of the diene *is* the excited state of the triene at an appropriate vibrational level. Such seems essentially to have been the view of Woodward when rationalizing the difference in λ_{max} between homoannular dienes contained in five-, six-, and seven-membered rings (15).

The electrocyclic opening of homoannular conjugated dienes is normally understood to proceed in a stereospecific manner because, with the retention of a C_2 axis of symmetry, the first singly excited state of the diene correlates with the first singly excited state of the triene (for discussions in general and also with regards the route to ground state products, see ref. 16–19). In the present case the situation is more complex, since the excited state engendered is one not present in the carbocyclic series. It was shown, in fact, that irradiation into the shorter wavelength absorption band gave the same products at about the same rate when corrected for light intensity as irradiation into the longer wavelength absorption band, strongly suggesting that internal conversion to the n,π^* manifold competes successfully with reaction in the π,π^* state. However, with but one substituted center only analogy suggests that the ring opening be a concerted singlet process at all. Experiments were therefore undertaken to ascertain whether there could be reaction from the triplet if generated, and whether under the conditions of direct irradiation it was the singlet which was reacting.

Firstly, attempts were made to quench the direct reaction. A problem immediately arises in that no experimental evidence exists to indicate the triplet energy of such a molecule. A crude assessment may be made in the following way. If we take the onset of the n,π^* absorption band as the O–O singlet energy of **1** a value of about 53 kcal/mol is obtained. In non-conjugated azo compounds the singlet–triplet splitting has been assessed as being of the order of 15–20 kcal/mol (20, 21) whilst experimental values determined (from emission data) for diazabicycloheptene (22) and diazabicyclooctene (23, 24) indicate a splitting of near 20 kcal/mol. Such values suggest that the triplet energy of **1** may be of the order of 35 kcal/mol. A suitable quencher must have an energy at or below this value and, further, have a singlet energy above 53 kcal/mol to prevent singlet energy transfer. In addition since the lifetime of the triplet may be expected to be short, the quencher must have adequate solubility and exceedingly low absorption in the region of excitation of **1** (~435 nm). As a further requirement, the substance should not have signals in the n.m.r. which would prevent the monitoring of the reaction progress or which decompose to do this. The quencher selected was cyclooctatetraene (COT) despite the fact that its triplet energy, though low, appears not to be known. Present evidence indicates that it is below 40 kcal/mol (25). The result obtained therefore has still an element of doubt. It was found that with concentrations of COT ranging up to 0.19 *M* the rate of conversion, up to 100% conversion, for all samples was the same, nor was there any evidence of extraneous product formation. Since some quenching, even if not diffusion controlled, would have been expected even with 2 kcal/mol endothermicity we conclude that either COT has a triplet energy between 38–40 kcal, or that the triplet of **1**, if formed, has a lifetime too short for detectable quenching at the concentration of COT used. The second alternative requires a triplet lifetime of below 10^{-9} s.

But we are inclined to interpret this evidence as, in fact, indicating that reaction is proceeding through the singlet. Our argument is as follows. If the triplet of **1** were generated the diazatrienes would then exist in the presence of triplet **1**. Since, clearly, the triplet energies of the trienes must be below that of the dienes diffusion controlled quenching would be expected. It has been observed that azo compounds in the triplet state isomerize (26, 27), and such behavior is, of course, well established for dienes, trienes, and higher polyenes (28, 29). Under such circumstances, variation of the composition of the irradiation mixture with time would be expected, and the appearance of the second pair of isomers, **5**, and **6**; such was not the case. Furthermore the generation of triplet **1** by direct irradiation, *i.e.* intersystem crossing, would be a phenomenon that so far has not received support in the literature (23, 30), and, in fact, Allred and Smith (31) have observed a spin-correlation effect in the direct and sensitized decomposition of 5-methoxydiazabicycloheptene. The slowness of intersystem crossing in trienes is well-known,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

but is not acceptable as a model because of the absence of any n,π* state, and, in fact, the question of intersystem crossing in azo compounds cannot be regarded as completely clarified.

The discussion presented above raised the question of what in fact would occur if the triplet of **1** were generated. Unlike aliphatic azo compounds, which either isomerize or decay to the ground state, cyclic compounds such as diazabicycloheptene and diazobicyclooctene (32, 23) when excited to the triplet state (by sensitization) decompose with the evolution of nitrogen.

The generation of triplet **1** was undertaken using benzophenone (E_T 69 kcal/mol) and Michler's ketone (E_T 61 kcal/mol). Both absorb at 366 nm where **1** has a very low extinction coefficient. Both have high intersystem crossing rates, such that quenching of their singlets has not been observed in solution under normal conditions. When a sample of **1** was irradiated in deuteriobenzene in the presence of benzophenone such that the benzophenone absorbed more than 94% of the incident light, a mixture of **3**–**6** was obtained, wherein most probably **5** and **6** arose from **3** and **4** by isomerization. A similar result was obtained when Michler's ketone was used such that the ketone absorbed more than 99.5% of the incident light.

At this stage quantum yields were not available, and though the sensitized reaction appeared to be slow the degree was uncertain, and it was possible that the reaction was induced by the small amount of light absorbed directly. The experiments were then repeated with samples in which the concentration of Michler's ketone was such as to absorb 98.0 and 99.5% of the incident light. The rate of isomerization, measured by n.m.r., was the same for both samples despite the factor of four in the amount of light absorbed directly.

Since exchange singlet energy transfer may be discounted there remain but three possibilities. These are resonance singlet energy transfer, reaction from the triplet, and reaction from a high vibrational level of the ground state generated by intersystem crossing from the triplet.

Although the singlet emission spectrum (not visible) of the ketone would overlap with the absorption n,π* band of the azo compound, the intensities of these transitions are too low for efficient transfer, and we therefore discount resonance transfer as a possibility. We have noted that **1** quenches the room temperature phosphorescence of benzophenone in carbon tetrachloride at or near a diffusion controlled rate but have not been able to measure lifetimes.

We are presently unable to distinguish between the other two processes for the reaction pathway, although the generally high rapidity of vibrational quenching in solutions leads us to prefer the first.

The fact that both a singlet and a triplet mechanism leading to the same type of products appeared to be available made the determination of quantum yields of some importance, since, if the reaction even on direct irradiation, proceeded via the triplet, then the latter pathway should proceed in higher quantum yield.

The only method of analysis available was that employing n.m.r., and so resort was had to irradiation in transparent n.m.r. tubes. The accuracy of such determinations is thus limited. For this purpose we have employed the Jasco spectroirradiator Model CRM-FA which has a holder well-adapted for holding such tubes. The light intensity may be calibrated using a ferrioxalate actinomer, but errors due to reflection may be large.

In an effort to estimate this error, the quantum yield of the ferrioxalate actinometer was determined in a clear n.m.r. tube at 278 (a quartz tube), 362, and 404 nm. Although the values obtained at each individual wavelength were reproducible to within 5%, the percentage of light reflected from the cylindrical tubes varied from 51 to 59% over the three wavelengths. Thus rates and quantum yields determined by this method must contain a similar error, *i.e.* ±5%. Since proton integration as a measure of product yield could contribute a further ±5% error (which we feel is a maximum), we have set error limits of ±10% for the quantum yields reported below.

By this method we were able to determine the approximate quantum yields of diazatriene formation both at 278 and 447 nm as being 0.40 ± 0.04. Using Michler's ketone as sensitizer and assuming efficient energy transfer, the quantum yield is 0.07 ± 0.01. The diazatriene also competes with **1** for the ketone triplet, but at maximum conversion (20%) **1** is still in excess by a factor of four, and both quenching processes are presumably proceeding at the same rate. It would thus seem that making all allow-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

ances the quantum yield of the triplet reaction is significantly lower than that of the singlet and appears to indicate that there are two pathways to the same product.

The systems under discussion may not be treated by the consideration of state correlation diagrams since the involvement of the n,π* state removes significant symmetry.

Fukui (33, 34) has considered the reaction of α,β-unsaturated ketones as taking place with the conversion of an n,π* triplet to a π,π* triplet. Such a process does not appear energetically available to the singlet. It may be relevant, however, that of the two important interactions considered by Fukui, SO–LU and SO′–HO, the former exists in the present system, whilst the latter is nil since in the azo compounds the n and π orbitals are orthogonal. When, however, the molecule begins to react, twisting will occur about the π-bonds, and the resultant modification of orbitals is not predictable in the absence of detailed calculations. It may be that the SO–LU interaction dominates the course of the reaction, and so a concerted electrocyclic process may be simulated, even in the case of the triplet.

Experimental

General procedures are as described in the preceding paper.

All sensitization and quenching studies, relative rate and quantum yield determinations, are the average, at least, of two determinations, and agreement of individual determinations within ±5%.

The JASCO Spectroirradiator Model CRM-FA used for rate measurements and quantum yields consists essentially of a 2000 W Xenon lamp whose emitted light is passed through a grating and dispersed onto a curved cell holder. The wavelength of the light incident upon the cell holder varies from 689 to 222 nm with a dispersion of 1.5 nm/mm. Openings in the cell holder are spaced 18 mm apart and may be varied from 1 to 10 mm in width. The radiant energy incident upon one cell may be accumulated with a thermopile and calibrated against the integrated value of light of 850 nm as collected and totalled with a connected integrator. The instrument enables one to irradiate simultaneously a number of samples at different wavelengths, and to calculate the amount of incident light on each cell.

Irradiation of Dihydropyridazine (1): General Procedure

Freshly prepared pure **1** was dissolved in the appropriate solvent (deuteriobenzene or deuteriochloroform for the longer wavelengths and deuteriocyclohexane for the shorter wavelengths) and placed in a vessel to which a clear quartz or Pyrex n.m.r. tube had been attached, hexamethyldisiloxane (HMDS) being used as an internal reference. The solutions (0.3 *M*) were degassed with the solution in the main receptacle to a pressure of 5×10^{-5} mm by the freeze–pump–thaw method. The degassed solution was then run into the attached n.m.r. tube which was sealed off and detached.

For the irradiation at 10° the sample was immersed in a water-bath held at that temperature by a water-cooled copper coil. For the experiment at −45° the sample was immersed in a chlorobenzene – Dry Ice bath.

Irradiations at 435 nm were performed using the relevant line of a Hanovia 450 W lamp isolated by passage of the light through Corning filters 3–73 and 7–59. Corning filters 7–60 and 0–52 were used to isolate the 366 nm line. The irradiations in the 278 nm region were performed on a JASCO Spectroirradiator Model CRM-FA with the entrance slit at 2 nm and the cell slits at 4 mm. Rate measurements were also performed on this apparatus. For quantum yields the radiation counter in the apparatus was calibrated at 850 nm against the ferrioxalate actinometer. The relative intensities at 447, 362, and 278 ± 3 nm were then determined with a thermopile supplied with the instrument. The samples were held at 10° by placing the n.m.r. tubes during the irradiation in a water-cooled block.

Preparation of the Isomeric Diazatrienes (3–6)

A solution of **1** (0.3 *M*) in deuteriobenzene was irradiated at 435 nm and at 10° until the nmr spectrum showed the complete disappearance of starting material (2–3 h). Two products (**3** and **4**) in a ratio of 2.1:1.0 accounted for all the signals in the spectrum. Upon warming to 45° for 0.5 h the two initial sets of signals decreased and two new sets, assigned to **5** and **6**, appeared in a ratio of 4:1, respectively. After 12 h at 45° the signals attributed to **5** outweighed the combined signals of the other three isomers by 10:1, as determined by proton integration, and continued heating, even to 80°, brought about no further change in the spectrum. Irradiation in $CDCl_3$ at 10° and at −45° gave product mixtures identical with those obtained in C_6D_6 at 10°.

For the obtention of the u.v. spectrum of the products **1** was irradiated in a quartz u.v. cell in cyclohexane (6×10^{-5} *M*) at 10° until continued irradiation produced no further changes in the spectrum. After the recording of the u.v. spectrum the solution was heated to 60° for 12 h, and the absorption spectrum redetermined.

The Reaction of Diazatrienes 3 and 4 with 2,4-Dinitrophenylhydrazine

Into one bulb of a reaction vessel to which two bulbs and a clear n.m.r. tube had been attached was placed 5 ml (10^{-3} mol) of Shine's reagent (35). Into the attached n.m.r. tube was added 63 mg (4×10^{-4} mol) of the dihydropyridazine **1** in 0.5 ml benzene. The two solutions were then degassed, and that containing the dihydropyridazine irradiated for 12 h at 435 nm. This time was more than three times longer than that generally required for complete conversion of **1**. The solutions were then mixed in the second bulb which was sealed and detached. The contents were heated at 60° for 10 h after which the container was opened and the solvent removed under reduced pressure. The residue was analyzed by t.l.c. (solvent: ether–benzene, 1:4). A spot was detected with R_F corresponding to that shown by the 2,4-dinitrophenylhydrazone of 2-hexanone, but none was visible where expected for the derivative of methyl vinyl ketone. The substance responsible for the spot in the position of the 2-hexanone

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

derivative was isolated by preparative t.l.c., the crude product (87 mg, 82%) then being crystallized from ethanol when it had m.p. 105–106°, which was undepressed on admixture with an authentic specimen of the 2-hexanone derivative of the same m.p.

Attempted Quenching of the Phototransformation of **1**

Into each of the four n.m.r. tubes was placed 0.4 ml. of a 0.3 *M* solution of **1** in $CDCl_3$. Cyclooctatetraene was added to three tubes so as to achieve the concentrations 0.00, 0.048, 0.096, and 0.192 *M*, respectively. The solutions were degassed, sealed and placed side by side in a bath held at 10°. They were then simultaneously irradiated at 435 nm. The reaction progress was monitored by n.m.r. Product formation proceeded at an equal rate in all four samples up to 100% conversion.

Irradiation near 278 nm

Identical samples of **1** were prepared, one with $CDCl_3$ solvent in a clear n.m.r. tube, and the other with C_6D_{12} as solvent in a clear quartz nmr tube. Both samples were irradiated in the spectroirradiator, one at 447 nm and the C_6D_{12} solution at 278 nm. The concentrations of **1** were such that all incident light was absorbed at both wavelengths ($A > 20$ in a path length of 4 mm). The rate of product formation was followed to 30% conversion and, after correction for differences in light intensity, were found to be identical within the accuracy of proton integration (±5%).

Sensitized Phototransformation of Dihydropyridazine **1**

To one of three identical solutions of **1** in C_6D_6 (0.3 *M*) was added sufficient benzophenone (28 mg) so as to absorb >94% (calculated at the incident wavelength) of the incident light at 366 nm. To a second was added Michler's ketone (0.5 mg) so as to absorb >98% of the light, and to the third Michler's ketone (4.1 mg) so as to absorb >99.5% of the light. The samples, placed side-by-side in a water-cooled bath, were simultaneously irradiated (366 nm; 10°) with a 450 W medium pressure mercury lamp and the transformation followed by n.m.r. spectroscopy. The rates of the reactions appeared to be identical within ±5% up to complete conversion. A mixture of all four stereoisomers (**3–6**) was obtained in all cases.

Phosphorescence Quenching of Benzophenone by Dihydropyridazine **1**

A solution of benzophenone (8.0×10^{-4} *M*) in carbon tetrachloride containing the pyridazine **1** (1.0×10^{-4} *M*) was prepared and the room-temperature phosphorescence compared with an identical solution not containing **1**. The concentration of the quencher **1** was chosen such that, under the assumptions of diffusion controlled quenching and a room-temperature triplet lifetime of benzophenone in carbon tetrachloride as 10^{-4} s (36) *ca.* 98% of the emission would be quenched. The emission of both samples was recorded, under identical conditions, on a spectrophosphorimeter (37).

The intensity of the emission of the solution containing the quencher was reduced by 88 ± 10% as compared with that which did not. The partially-quenched emission was not shifted nor altered in shape from that of the unquenched emission.

Quantum Yields

After calibration of the JASCO Spectroirradiator apparatus against the ferrioxalate actinometer it was found that equivalent irradiation in an n.m.r. tube resulted in large light losses by reflection. Irradiation of a 0.15 *M* solution of ferrioxalate actinometer in an n.m.r. tube yielded quantum yields of 0.64 ± .03, 0.50 ± .01 and 0.50 ± .02 at 278, 362 and 404 nm, respectively. The accepted values (38) at these wavelengths are 1.25, 1.22, and 1.14, which represent corresponding light losses of 51, 59, and 56%. Thus, quantum yields of product formation so obtained are subject to a high error even when corrected.

A solution of **1** in C_6D_{12} in a quartz n.m.r. tube (0.3 *M*) was irradiated near 278 nm simultaneously with irradiation of similar solutions in $CDCl_3$ near 446 nm and in C_6D_6 near 362 nm, the latter containing sufficient Michler's ketone (0.044M) to absorb >99.6% (calculated by integration of the absorption curves of the absorbing species over the band width of the incident light) of the incident light. The samples were irradiated to 20% conversion and the transformation measured by integration of the nmr spectrum. The quantum yields obtained were, respectively, 0.40 ± .04, 0.40 ± .04, and 0.07 ± 0.01.

Iridoids of *Mentzelia decapetala* (Pursh). II. Decaloside[1]

TERRY JOHN DANIELSON AND EDWARD MILES HAWES
College of Pharmacy, University of Saskatchewan, Saskatoon, Saskatchewan

AND

CARMAN ARTHUR BLISS
College of Pharmacy, University of New Mexico, Albuquerque, New Mexico

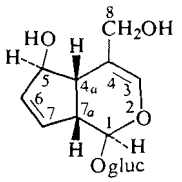
Received July 31, 1972

Decaloside (**1**), a minor component of *Mentzelia decapetala* (Loasaceae) has been isolated and characterized as *1S,4aS,5R,7aR*-1-*O*-β-D-glucosyl-5-hydroxy-1,4*a*,5,7*a*-tetrahydro-4-hydroxymethylcyclopenta(*c*)pyran.

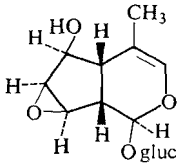
Le décaloside (**1**), un composé mineur de la *Mentzelia decapetala* (Loasaceae) a été isolé et caractérisé comme étant le β-D-glucosyl-1-*O* hydroxy-5 tétrahydro-1,4*a*,5,7*a* hydroxyméthyl-4 cyclopenta(*c*) pyranne-*1S,4aS,5R,7aR*. [Traduit par le journal]

Can. J. Chem., **51**, 1737 (1973)

A previous study (1) on *Mentzelia decapetala* reported the isolation and elucidation of the relative stereochemistry of an iridoid, mentzeloside (**2**). We report here the determination of the absolute stereochemistry of a second isolated iridoid, decaloside (**1**). **1** was isolated by column



1



2

chromatography of the methanolic extract of *M. decapetala* after elution of **2**. The optically active product was unstable and a satisfactory elemental analysis could not be obtained. Its mass spectrum showed a weak molecular ion at *m/e* 346, and a relatively strong $(M - 162)^+$ ion at *m/e* 184 indicated loss of glucose. This fragmentation of an unstable glycoside to produce a stable aglycone molecular ion has been found to be a prominent feature of the spectra of iridoids (2). A molecular formula of $C_{15}H_{22}O_9$ was indicated.

The iridoid character of **1** was also indicated by formation of a black polymer on acid hydrolysis, and the enol ether function by a peak of 1658 cm^{-1} in the i.r. spectrum. A band at 204 nm in the u.v. spectrum was attributed to a $\pi \rightarrow \pi^*$ transition of an enol ether double bond in which the β-carbon does not bear a carbonyl substituent. These assignments were confirmed by the 100 MHz (^1H) n.m.r. spectrum. A broadened one-proton signal at 6.34 p.p.m. was designated as the α-proton of an enol ether, and the lack of any large coupling indicated that C-4 was substituted.

Examination of the n.m.r. spectrum was hampered by its complex nature, but a few other features were informative. A slightly broadened two-proton singlet at 5.83 p.p.m. was assigned to two olefinic protons on the basis of chemical shift comparisons (3) with olefinic protons in similar systems such as aucubin (**3**). The lack of any visible couplings between these olefinic protons can be attributed to an A_2 system as $\Delta\nu/J \rightarrow 0$ (4). Two one-proton doublets at 4.50 and 4.62 p.p.m. were assigned to the acetal protons on C-1′ of the sugar moiety and C-1 of the aglycone respectively. The magnitude of the coupling of the former with C-2′ ($J = 7$ Hz) indicated a β-glucoside linkage as in **2** (1). The coupling of the C-1 proton with the C-7*a* proton at 2.72 p.p.m. ($J = 7$ Hz) was suggestive of a *trans*-interaction between these protons. No signal comparable to the allylic methyl of **2** was present so a hydroxymethyl group at C-4 was suspected, although poor resolution did not permit an actual assignment at this stage.

Enzymatic hydrolysis of **1** with emulsin yielded an aglycone and glucose as demonstrated by paper chromatography. The use of various spray reagents indicated the reducing properties of the aglycone. All attempts to isolate or prepare aglycone derivatives failed.

4

When decaloside was allowed to react with acetic anhydride a crystalline hexaacetate (**4**) was obtained. The i.r. and n.m.r. spectra did not display any bands assignable to hydroxyl functions, thereby eliminating the possibility of tertiary alcohol protons in the starting material. All nine oxygen atoms of **1** could now be assigned. Six must be present as primary or secondary alcohol functions, four in the glucose moiety and two in the aglycone, while the remaining three could be assigned as the ethereal and acetal oxygens about C-1 and -1′.

The 100 MHz n.m.r. spectrum of **4** (Fig. 1) was well resolved and enabled assignment of the hitherto undetermined features of **1**. A low-field one-proton multiplet at 6.37 p.p.m. was assigned to the proton on C-3. This displayed long-range coupling into two one-proton quartets at 4.69 (J = 0.5 Hz) and 4.33 (J = 0.5 Hz) p.p.m. These latter protons were presumed to be geminally coupled methylene protons (J = 12 Hz) of an acetylated primary alcohol at C-4. These assignments were substantiated by deoxydodidrovaltrate, an iridoid with a C-4 methylene group. Here the proton on C-3 is reported to appear at 6.42 p.p.m. while the allylic methylene protons at C-4 resonate at 4.63 and 4.39 (J = 12 Hz) p.p.m. (5).

The bridgehead protons on C-4*a* and -7*a* appeared as complex signals at 2.79 and 3.07 p.p.m. respectively. The interaction between these protons (J = 8 Hz) was similar to that observed in **2** (J = 7.5 Hz) (1) and indicated a similar *cis*-ring fusion. The proton on C-7*a* was also coupled with a downfield proton, which was hidden beneath the broad glucosyl proton signal at 5.58–4.75 p.p.m. This hidden signal was assigned to the C-1 acetal proton. The magnitude of the coupling (J = 7 Hz) was suggestive of a *trans*-interaction between the protons on C-1 and -7*a*. Comparison with aucubin (J = 7.5 Hz) confirmed this steric assignment (3).

Two vicinally coupled olefinic protons appeared as a quartet at 6.02 and as an octet at 5.89 p.p.m. The magnitude of the coupling constant (J = 6 Hz) was suggestive of a *cis*-olefinic coupling in a five-membered ring (4). This olefinic function could be assigned as either a Δ^5 or Δ^6 bond. In Δ^5-iridoids the olefinic proton on C-5 appears between 6.1 and 6.3 while the C-6 proton appears between 5.6 and 5.7 p.p.m. (6, 7). In Δ^6-iridoids the C-6 proton appears close to 5.90 p.p.m., as for example, aucubin 5.87 (3), scandoside 5.85 (8), and melittoside 5.91 p.p.m. (3). Although the validity of this comparison is open to question due to the model compounds having substituents on C-7, a Δ^6-iridoid assignment for **1** is indicated. No chemical shift comparisons are possible for the proton on C-7 as no Δ^6-iridoids without a C-7 substituent are reported in the literature.

This assignment was confirmed by mass spectrometry. A prominent feature in the spectra of Δ^5-iridoids involves cleavage of the C_1—C_2 and C_{4a}—C_{7a} bonds, via a retro-Diels–Alder reaction, followed by cleavage of the C_6—C_7 bond. In the mass spectrum of **1** these expected ions at *m/e* 111 and 73 were of low intensity. This feature is compatible with a Δ^6 bond (2).

In view of the Δ^6-iridoid assignment a multiplet at 5.53 p.p.m. was attributed to an allylic acetate methine at C-5. The C-4*a* proton displayed coupling (J = 4 Hz) with this signal. Steyn and Sable (9) reported that in substituted cyclopentenes couplings are in the range 2–5.5 Hz for *trans*- and 6.2–7.4 Hz for *cis*-vicinal protons, while Stevens and Fletcher (10) noted that a coupling of less than about 4 Hz was indicative of a *trans*-vicinal interaction in cyclopentane systems. Thus a *trans*-interaction between protons on C-4*a* and -5 in **4**, and by analogy in **1**, is indicated.

The absolute configuration of **1**, and by similar techniques **4**, may be assigned by measurement of their optical rotatory powers. Mills (11) showed that cyclohexyl allylic alcohols derived from structural unit **5** were more laevorotatory than those derived from the epimeric unit **6**, and that these differences were greatly enhanced by esterification. Brewster (12) also demonstrated that cyclopenten-3-ols corresponding to **5** were laevorotatory while those corresponding to **6** were dextrorotatory.

These principles (11, 12) should be applicable

Daphylloside hexaacetate†		+51 (EtOH)	+335

*Reference 14.
†Reference 15.

to iridoid glucosides since it has been shown that acetylation of α- or β-methyl-D-glucosides does not significantly alter their molecular rotations (13). Values for **1** and its acetate derivative, and for reference compounds are recorded in Table 1.

Compound **3** (14) which contains structural unit **5** displays laevorotatory powers, while daphylloside (15) which contains **6** displays dextrorotatory powers. **1** was found to become more laevorotatory upon acetylation, and thus the absolute stereochemistry about C-5 must be the same as in **3**. This allows only two possible structures, varying only in the absolute stereochemistry of the dihydropyran ring. **1** must be as shown on the basis of three features. Firstly, this structure contains a *trans*-relationship between protons on C-4*a* and -5, as indicated by the n.m.r. of **4**. Secondly, the C-5 hydroxyl group possesses the same relative stereochemistry as the analogous C-5 hydroxyl in **2**. Finally, the assign-

ment as shown is the same as that found for all other iridoids for which absolute stereochemistries have been determined.

Experimental

The general experimental procedures were as previously described (1). Paper chromatograms were run on Whatman No. 1 filter paper using a *n*-butanol, acetic acid, and water (63:10:27) solvent system. R_f values were measured to the front of the compound spots. Compounds were detected with either vanillin (1 g) and concentrated hydrochloric acid (3 ml) in methanol (150 ml) and heating for 2 min at 100 °C or with Tollen's ammoniacal silver nitrate reagent.

Extraction and Isolation of Decaloside (1)

The preparation of the crude iridoid fraction and its preliminary separation on a Florisil column was described earlier (1). The crude mentzeloside (**2**) fraction was followed on further elution with benzene–methanol (3:1) by a second iridoid containing fraction (1900–3000 ml). Repeated chromatography of this fraction on Florisil with benzene–methanol (3:1) and crystallization from ethyl acetate yielded decaloside (**1**) as colorless crystals (0.300 g): m.p. 193°; R_f 0.37 (red with vanillin reagent, negative with Tollen's); $[\alpha]_D^{23}$ −137.9° (*c* 0.475, CH_3OH); u.v. max 204 nm (log ε 3.68); i.r. 1658 (C=C—O) and 3390 cm^{-1} (O—H); n.m.r. (DMSO-d_6) δ 6.34 (m, 1, C_3—*H*), 5.83 (S*, 2, C_6—*H* and C_7—*H*), 4.62 (d, 1, $J_{1,7a}$ = 7 Hz, C_1—*H*), 4.50 (d, 1, $J_{1',2'}$ = 7 Hz, glucose), and 2.72 p.p.m. (ddd*, 1, $J_{7a,1}$ = 7 and $J_{7a,4a}$ = 8 Hz, C_{7a}—*H*); mass spectrum *m/e* (relative intensity) 346 (0.2), 184 (8), 120 (42), 91 (42), 45 (45) and 43 (100).

Anal. Calcd. for $C_{15}H_{22}O_9$: C, 52.02; H, 6.40. Found: C, 51.10; H, 6.10.

Enzymatic Hydrolysis of Decaloside

To a solution of decaloside (0.013 g) in water (3 ml) was added β-glucosidase (0.010 g). After 12 h at room temperature the mixture was examined by paper chromatography. Three compounds were shown to be present: the aglycone, R_f 0.68 (red with vanillin reagent, black with Tollen's); decaloside, R_f 0.37 (reference 0.37) (red with vanillin reagent, negative with Tollen's); and glucose R_f 0.17 (reference 0.17–0.18) (negative with vanillin reagent, black with Tollen's). All attempts to isolate the aglycone gave only intractable tars.

Decaloside Hexaacetate (4)

To a solution of **1** (0.025 g) in pyridine (5 ml) was added acetic anhydride (0.5 ml). After heating under reflux (2 h) the reaction mixture was poured into cold water and filtered. Crystallization from ethanol yielded **4** (0.030 g, 70%) as colorless crystals: m.p. 162–164°; $[\alpha]_D^{24}$ −127.62 (*c* 1.144, $CHCl_3$); i.r. 1661 (C=C—O) and 1740 cm^{-1} (ester C=O); n.m.r. ($CDCl_3$) δ 6.37 (m, 1, $J_{3,8}$ = 0.5 Hz, C_3—*H*), 6.02 (dd, 1, *J* = 6 and 2 Hz, C_6—*H* or C_7—*H*), 5.89 (ddd, 1, *J* = 6, 2 and 1.5 Hz, C_6—*H* or C_7—*H*), 5.53 (m, 1, C_5—*H*), 5.58–4.75 (c, 5, C_1—*H*, and glucose 4*H*), 4.69 (dd, 1, $J_{8,8'}$ = 12 and $J_{8,3}$ = 0.5 Hz, C_8—*H*), 4.33 (dd, 1, $J_{8',8}$ = 12 and $J_{8',3}$ = 0.5 Hz, C_8—*H'*), 4.13 (c, 2, glucose 2*H*), 3.65 (m, 1, glucose 1*H*), 3.07 (ddd, 1, $J_{7a,1}$ = 7, $J_{7a,4a}$ = 8, and J_x = 2 Hz, C_{7a}—*H*), 2.79 (ddd, 1, $J_{4a,7a}$ = 8, $J_{4a,5}$ = 4, and $J_{4a,3}$ = 0.5 Hz, C_{4a}—*H*), and 1.98 p.p.m. (c, 18, 6 CH_3COO—).

Anal. Calcd. for $C_{27}H_{34}O_{15}$: C, 54.18; H, 5.69. Found: C, 54.04; H, 5.78.

Isothiazolopyridines. I. Synthesis and Spectra of Isothiazolo[3,4-*b*]-, 3-Aminoisothiazolo[4,3-*b*]-, Isothiazolo[5,4-*b*]-, and 3-Methylisothiazolo[5,4-*c*]pyridines. Preparation and Spectra of Some 2,3- and 3,4-Disubstituted Pyridines[1]

ALFRED TAURINS AND VIRGINIA TAN KHOUW[2]

Department of Chemistry, McGill University, Montreal, Quebec

Received September 20, 1972

Isothiazolo[3,4-*b*]pyridine was synthesized from 2-aminonicotinonitrile in three steps: by the reaction with ammonia and hydrogen sulfide to produce 2-aminothionicotinamide; oxidative cyclization with hydrogen peroxide to give 3-aminoisothiazolo[3,4-*b*]pyridine, followed by diazotization and reduction with hypophosphorous acid. 3-Aminoisothiazolo[4,3-*b*]pyridine was prepared in a similar way from 3-aminopicolinonitrile via 3-aminothiopicolinamide. Isothiazolo[5,4-*b*]pyridine was synthesized from 2-chloronicotinonitrile in three steps: by the reduction with formic acid in the presence of Raney nickel to obtain 2-chloronicotinaldehyde; transformation of the latter into 2-thiocyanonicotinaldehyde; and finally cyclization with ammonia to obtain isothiazolo[5,4-*b*]pyridine. 3-Methylisothiazolo[5,4-*c*]pyridine was prepared by cyclization of 4-acetyl-3-thiocyanopyridine with ammonia. N.m.r. and u.v. spectra of the isothiazolopyridines, their derivatives, and the pyridine intermediates were recorded and interpreted.

L'isothiazolo pyridine-[3,4-*b*] a été synthétisée à partir de l'amino-2 nicotinonitrile en trois étapes: par la réaction avec de l'ammoniac et de l'hydrogène sulfuré pour donner l'amino-2 thionicotinamide: par la cyclisation par voie oxydante avec de l'eau oxygénée pour donner l'amino-3 isothiazolo pyridine-[3,4-*b*] suivie par une diazotisation et par une réduction avec de l'acide hypophosphoreux. L'amino-3 isothiazolo pyridine-[4,3-*b*] a été préparée en suivant un procédé similaire à partir de l'amino-3 picolinonitrile en passant par l'amino-3 thiopicolinamide. L'isothiazolo pyridine-[5,4-*b*] a été synthétisée à partir du chloro-2 nicotinonitrile en trois étapes: par réduction avec l'acide formique en présence de nickel de Raney pour obtenir la chloro-2 nicotinaldehyde; par la transformation de ce dernier produit en thiocyano-2 nicotinaldehyde; et finalement par la cyclisation en présence d'ammoniac pour obtenir l'isothiazolo pyridine-[5,4-*b*]. La méthyl-3 isothiazolo pyridine-[5,4-*c*] a été préparée par cyclisation de l'acétyl-4 thiocyano-3 pyridine avec de l'ammoniac. Les spectres r.m.n. et u.v. des isothiazolo pyridines, de leurs dérivés ainsi que des intermédiaires des pyridines ont été enregistrés et interprétés.

[Traduit par le journal]

Can. J. Chem., 51, 1741 (1973)

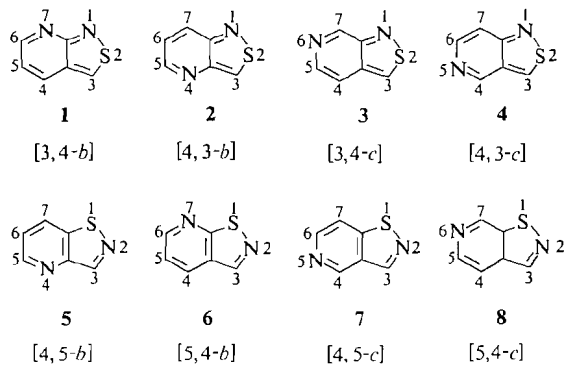
Introduction

Isothiazolopyridines (**1**–**8**) form a new class of heteroaromatic compounds, four of which possess ortho-quinoid structures (**1**–**4**) while the other four, benzenoid (**5**–**8**). Since isothiazolopyridines have remained hitherto an unknown class of compounds, it seemed to be of significance to synthesize and study them and their derivatives. In this work the preparation and spectra of isothiazolo[3,4-*b*]-, -[4,3-*b*]-, -[5,4-*b*]-, and -[5,4-*c*]pyridines were investigated.

Discussion

The first derivatives of isothiazolo[3,4-*b*]- (**1**) and -[4,3-*b*]pyridine (**2**) prepared were the 3-amino compounds **11** and **18**, respectively

Isothiazolopyridines



(Schemes 1 and 2). They were obtained by a general method involving the oxidative cyclization of the appropriate pyridine *o*-aminothiocarboxamides. The precursor of 3-aminoisothiazolo[3,4-*b*]pyridine (**11**) was 2-aminonicotinonitrile (**9**) (1) which was transformed into 2-aminothionicotinamide (**10**) by the addition of

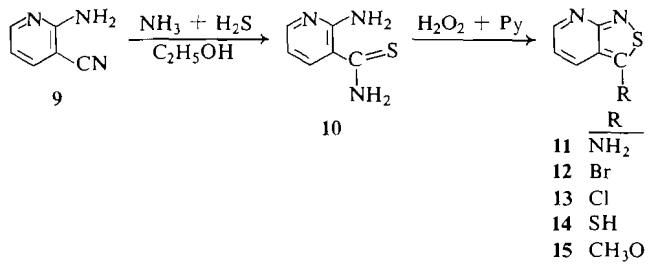
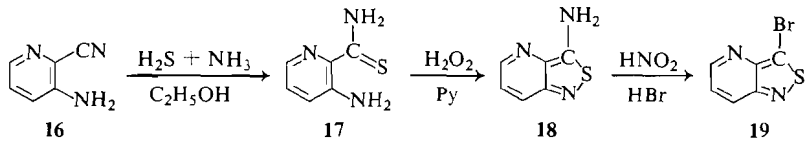


SCHEME 1



SCHEME 2

hydrogen sulfide to the cyano group. Oxidation of 2-aminothionicotinamide (**10**) with 30% hydrogen peroxide in pyridine produced 3-aminoisothiazolo[3,4-*b*]pyridine (**11**) (Scheme 1).

The mechanism of the oxidative cyclization of the aromatic and heterocyclic thioamides with hydrogen peroxide in pyridine is not known. However, it has been suggested by Davis (2) that the intermediates in such reactions could be *S*-oxides, in analogy to the *S*-oxides formed from aliphatic thioamides and hydrogen peroxide (3).

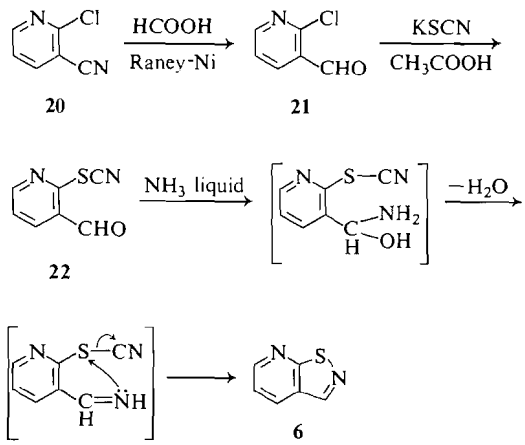
3-Aminoisothiazolo[3,4-*b*]pyridine (**11**) was diazotized in a mixture of 70% nitric and 85% orthophosphoric acid (1:4) and the diazonium salt reduced with 30% hypophosphorous acid to obtain the new parent compound, isothiazolo-[3,4-*b*]pyridine (**1**).

3-Bromiosothiazolo[3,4-*b*]pyridine (**12**) was prepared by the diazotization of **11** in 48% fuming hydrobromic acid.

3-Chloroisothiazolo[3,4-*b*]pyridine (**13**) was obtained by the Gattermann reaction of **11**. 3-Mercapto- (**14**) and 3-methoxyisothiazolo-[3,4-*b*]pyridine (**15**) were prepared by a nucleophilic substitution of the chlorine atom in **13** (Scheme 1). The red color of the compound **14** indicates that its dominating tautomeric form may be a thione.

In the isothiazolo[4,3-*b*]pyridine series, the starting material was 3-aminopicolinonitrile (**16**) which was transformed into 3-aminopicolinonitrile (**17**) with hydrogen sulfide. 3-Aminoisothiazolo[4,3-*b*]pyridine (**18**) was obtained by the oxidative cyclization of **17** with 30% hydrogen peroxide in pyridine solution (Scheme 2). The presence of the amino group in the 3-position in **18** was proved by the i.r. spectrum and replacement of the amino group by a bromo atom when **18** was diazotized in 48% hydrobromic acid. The efforts to deaminate **18** in order to obtain unsubstituted isothiazolo[4,3-*b*]pyridine (**2**) were unsuccessful.

The general method for the synthesis of isothiazolo[5,4-*b*]pyridine (**6**) (Scheme 3) and 3-



SCHEME 3

methylisothiazolo[5,4-*c*]pyridine (**25**), a derivative of **8**, (Scheme 4) was based on the reaction of *o*-thiocyano-formyl- or *o*-thiocyano-acetyl-pyridine with ammonia. The starting material for the preparation of **6** was 2-chloronicotinonitrile (**20**) (1) which was reduced with formic acid – Raney nickel to obtain 2-chloronicotinaldehyde (**21**). 2-Thiocyanonicotinaldehyde (**22**) was prepared by the treatment of **21** with potassium thio-

cyanate in glacial acetic acid in nitrogen atmosphere. Cyclization of 2-thiocyanonicotinaldehyde (**22**) with a large excess of liquid ammonia at −50° for 4 h produced isothiazolo[5,4-*b*]pyridine (**6**).

The synthesis of 3-methylisothiazolo[5,4-*c*]-pyridine (**25**) was based on a principle similar to one applied in the case of **6** (Scheme 4). 4-Acetyl-3-aminopyridine (**23**) was diazotized and the diazonium salt was treated with potassium thiocyanate to obtain 4-acetyl-3-thiocyanopyridine (**24**) which was cyclized into **25** either with liquid ammonia at −50° for 5 h, or with ammonia in a pressure bomb at about 130° for 15 h.

Spectra

Nuclear Magnetic Resonance Spectra

The n.m.r. spectra of the 2,3-disubstituted pyridines (Table 1) **10**, **17**, **21**, and **22** display three sets of well resolved quartets of the AMX type (protons 3, 4, and 6). The three coupling constants $J_{4,5}$, $J_{4,6}$, and $J_{5,6}$ can be measured directly from the spectra. The spectra of the 3,4-disubstituted pyridines **23** and **24** exhibit a singlet for H-2 and a pair of doublets for H-5 and -6, consequently, there is no observable coupling between H-2 and other ring protons.

The three pyridine ring protons of isothiazolo-[3,4-*b*]pyridine (**1**) and its derivatives **11**–**15**, isothiazolo[5,4-*b*]pyridine (**6**), and 3-aminoisothiazolo[4,3-*b*]pyridine (**18**) also show three sets of quartets of the AMX type (Table 2). If we compare the chemical shifts of protons 2, 3, and 4 in 1,5- and 1,6-naphthyridine (4) (Scheme 5), we notice a similarity between **1** and **6** on one hand, and the two naphthyridines on the other hand.

Ultraviolet Spectra

The u.v. absorption data of 2,3- (**10**, **17**, **21**, **22**, and **26**) and 3,4-disubstituted pyridines (**23** and **24**) are given in Table 3. All of these compounds show three main bands designated as the α-, p- and β-bands (5). In the 2,3-substituted amino-

*Solvent: 95% ethanol.
†Solvent: absolute methanol.

pyridinethioamides **10** and **17**, the bathochromic shift of the α-band is considerably larger than in the 3,4-substituted isomer, 4-aminothionicotinamide (**26**). This is in conformity with the u.v. absorption of the three isomeric aminopyridines: 2- and 3-aminopyridines absorb at 287 and 288 nm, respectively, as compared with the absorption by 4-aminopyridine at 268(sh) nm (6). In the u.v. spectrum of 4-acetyl-3-thiocyanopyridine (**23**) the α-band is displaced more toward the longer wavelength than in the spectrum of 4-acetyl-3-thiocyanopyridine (**24**) due to the conjugation of acetyl and amino groups.

The u.v. spectra of isothiazolo[3,4-*b*]- (**1**) (Table 4) and -[5,4-*b*]pyridine (**6**) (Table 5) consist of only two absorption bands each. The long wavelength bands at 296 and 298 nm, respectively, actually are not pure α-bands, but are overlapping with the p-bands due to the large bathochromic shift of the latter. The u.v. bands of **1** and **6** at 213 and 228 nm, respectively, are the β-bands, comparable to those present in the spectra of thiazolo[4,4-*c*]pyridine (7) and benzo[*b*]thiophene (8) at 216 and 227 nm, respectively. The u.v. spectra of **1** and **6** are also similar to those of 1,6- and 1,7-naphthyridine (9), but not to any other naphthyridines. The spectra of the halogen derivatives **12**, **13**, and **19**, and of 3-methylisothiazolo[5,4-*c*]pyridine (**25**) display only two bands.

Experimental

The melting points were determined on a Gallenkamp melting point apparatus and are corrected. N.m.r. spectra were obtained on a Varian high resolution n.m.r. model HA-100 spectrometer. Solvents used were deuterio-

*Solvent: 95% ethanol.

chloroform and dimethyl sulfoxide-d_6 and concentrations of solutions were 10–40 mg of solute per 0.5 ml of solvent. Tetramethylsilane was used as an internal reference. The u.v. spectra were recorded on a Unicam model SP-800 spectrophotometer and absolute ethanol and methanol were used as solvents. The i.r. spectra were taken in potassium bromide pellets on a Perkin–Elmer model 521 grating spectrometer. The mass spectra were obtained on an AEI-MS-902 double focusing mass spectrometer. The low resolution mass spectra were used to check the purity of compounds. The high resolution mass spectra served the purpose to prove the empirical formulas of unstable compounds, or when a small amount of material was available.

The elemental analyses were carried out by Dr. C. Daesslé, Montreal, and by A. Bernhardt, Germany.

*2-Aminothionicotinamide (**10**)*

Alcoholic ammonia (65 ml) containing 5 g of NH_3 (five-fold excess) was added to 2-aminonicotinonitrile (**9**) (7.0 g, 58.8 mmol) dissolved in absolute ethanol (16 ml) and triethylamine (5.9 g, 58.8 mmol). The reaction mixture was stirred magnetically and saturated with hydrogen sulfide for 1½–2 h. A yellow crystalline compound precipitated in less than an hour. The flask was loosely stoppered and allowed to stand at room temperature for 2 days to complete the reaction. Then the solution was poured onto crushed ice and the yellow substance was collected by suction filtration and dried at 60–70°. By this procedure 6.9 g of 2-aminothionicotinamide (**10**) was obtained. A further 0.6 g of the product was recovered by concentrating the filtrate under reduced pressure, pouring the solution on crushed ice, and filtering. 2-Aminothionicotinamide (**10**) was obtained in a nearly pure form (yield 7.5 g, 83%). Recrystallization from benzene gave yellow prisms, m.p. 132–133°. I.r. (KBr): 3420, 3310, 3180 cm^{-1} (NH_2).

Anal. Calcd. for $C_6H_7N_3S$ (mol. wt. 153.15): C, 47.0; H, 4.6; N, 27.4; S, 20.9. Found: C, 47.1; H, 4.7; N, 27.5; S, 20.8. *M/e*: 153 (P); 155 (P + 2).

*3-Aminoisothiazolo(3,4-b)pyridine (**11**)*

2-Aminothionicotinamide (**10**) (4.6 g, 0.03 mol) was dissolved in pyridine (10 ml) and warmed at 35° with stirring. Hydrogen peroxide (30%) (3.6 ml) was added very slowly to the reaction mixture. After the addition was completed, a yellow solid precipitated. The solution was further stirred at 35° for 10 min and let stand at room temperature for 16 h. The resulting precipitate was filtered off, washed with water, and dried. Crystallization

from ethanol gave 3.67 g (80% yield) of fine needles of 3-aminoisothiazolo(3,4-*b*)pyridine, m.p. 203.5–204.5°. I.r. (KBr): 1620, 3297–3258 (broad), 3100 cm^{-1} (NH_2).

Anal. Calcd. for $C_6H_5N_3S$ (mol. wt. 151.13): C, 47.7; H, 3.3; N, 27.8; S, 21.2. Found: C, 47.8; H, 3.2; N, 27.8; S, 21.3. *M/e*: 151 (P); 153 (P + 2).

*Isothiazolo[3,4-b]pyridine (**1**)*

3-Aminoisothiazolo[3,4-*b*]pyridine (**11**) (2.7 g, 17.9 mmol) was dissolved in 85% phosphoric acid (120 ml) and 70% nitric acid (30 ml) was added. The resulting solution was cooled to −5 to −2° and sodium nitrite (1.32 g, 19.1 mmol) in water (12 ml) was added with stirring over a period of 30 min. The reaction mixture was stirred for another 10 min at this temperature and then was added in portions to a stirred 30% hypophosphorous acid (50 ml) at 25–35°, to which a small amount of cuprous oxide has been added. The reaction mixture was stirred for 1 h at room temperature. It was then made alkaline with 20% sodium hydroxide solution with cooling. The mixture was extracted thrice with 400 ml portions of ether. The ethereal extract was washed with water, dried over sodium sulfate, and evaporated to dryness under reduced pressure. Crystallization from *n*-hexane produced 0.59 g (24% yield) of pure isothiazolo[3,4-*b*]pyridine (**1**) as short colorless needles, m.p. 58.5°.

M/e: 136 (P); 138 (P + 2). Calcd. mass from the exact mass measurement: 136.008933. Calcd. mass for $C_6H_4N_2S$: 136.009519. Delta mass: 0.000585.

*3-Bromoisothiazolo[3,4-b]pyridine (**12**)*

3-Aminoisothiazolo[3,4-*b*]pyridine (**11**) (0.97 g, 6.4 mmol) was suspended in 48% fuming hydrobromic acid (25 ml). Sodium nitrite (0.7 g, 10 mmol) was added in small portions over a period of 20 min with stirring. The temperature of the mixture was kept at −4° to −20°. When the addition was completed, the mixture was stirred at 0° for a further 30 min and let stand overnight at room temperature. It was poured slowly onto 200 g of crushed ice and made strongly alkaline with 20% sodium hydroxide. The solution was extracted thrice with 150 ml portions of ether and the combined ethereal extract was dried over sodium sulfate. The solvent was evaporated under reduced pressure leaving 0.84 g of a crude yellow substance. Chromatography followed by crystallization from ethyl acetate gave 0.52 g (38% yield) of pure 3-bromoisothiazolo[3,4-*b*]pyridine (**12**) as yellow prisms m.p. 158–159°.

Anal. Calcd. for $C_6H_3N_2SBr$ (mol. wt. 215.12): C, 33.5; H, 1.4; N, 13.0; S, 14.9; Br, 37.2. Found: C, 33.4; H, 1.6; N, 13.3; S, 14.8; Br, 37.5. *M/e*: 214 (P); 216 (P + 2).

*3-Chloroisothiazolo[3,4-b]pyridine (**13**)*

Cuprous chloride was prepared from 3.0 g of cupric sulfate, 0.66 g of sodium chloride, 0.5 g of sodium hydrogen sulfite, and 0.36 g of sodium hydroxide and was dissolved in 10 ml of concentrated hydrochloric acid.

3-Aminoisothiazolo[3,4-*b*]pyridine (**11**) (0.9 g, 6 mmol) was dissolved in a mixture of 40 ml of 80% phosphoric acid and 10 ml of 70% nitric acid. The acid mixture was cooled to −5 to −2° (acetone – Dry Ice bath) and stirred magnetically. Sodium nitrite (0.44 g, 6.5 mmol) in water (4.0 ml) was added dropwise to the cooled stirred solution. The resulting diazonium solution was stirred for another 20 min at −5° and subsequently added slowly with stirring to the pre-cooled cuprous chloride solution at −5 to −2°. The reaction mixture was stirred at this temperature for 20 min and at room temperature for another hour. It was then made alkaline with 20% sodium hydroxide solution. The mixture was extracted with three 150 ml portions of ether. The combined ethereal extract was washed with water, dried over sodium sulfate, and evaporated to dryness under reduced pressure leaving 0.71 g of a crude yellow solid. Crystallization from *n*-hexane gave 0.46 g (45% yield) of pure 3-chloroisothiazolo[3,4-*b*]pyridine (**13**) as pale yellow needles, m.p. 96–97°. I.r. (KBr): 1003 cm^{-1} (strong) (Cl).

Anal. Calcd. for $C_6H_3N_2SCl$ (mol. wt. 170.56): C, 42.4; H, 1.8; N, 16.4; S, 18.8; Cl, 20.8. Found: C, 42.3; H, 1.6; S, 18.9; Cl, 20.7. *M/e*: 170 (P); 172 (P + 2).

*3-Mercaptoisothiazolo[3,4-b]pyridine (**14**)*

A solution of 3-chloroisothiazolo[3,4-*b*]pyridine (0.3 g, 1.8 mmol) and thiourea (0.2 g, 2.6 mmol) in 20 ml of absolute ethanol was refluxed for 3 h. The crystalline precipitate was dissolved in 40 ml of 1 *N* sodium hydroxide solution and filtered. Acidification of the filtrate with acetic acid produced a flocculent precipitate which was filtered off, washed with water, and dried to obtain 0.16 g (56% yield) of 3-mercaptoisothiazolo[3,4-*b*]pyridine (**14**). Crystallization from ethanol produced **14** in the form of fine dark purple needles, m.p. 188–189°.

M/e: 168 (P); 170 (P + 2). Calcd. mass from the exact mass measurement: 167.981477. Calcd. mass for $C_6H_4N_2S_2$: 167.981592. Delta mass: 0.000114.

*3-Methoxyisothiazolo[3,4-b]pyridine (**15**)*

3-Chloroisothiazolo[3,4-*b*]pyridine (0.3 g, 1.8 mmol) was dissolved in 30 ml of absolute methanol and a solution of sodium methoxide, prepared from 0.1 g of sodium and 5 ml of methanol, was added. The yellow solution was neutralized with dilute acetic acid and diluted with 50 ml of water. The precipite was filtered off, washed with water and dried. Chromatography and crystallization from methanol gave 0.12 g (41% yield) of **15**, m.p. 104–105°.

M/e: 166 (P); 168 (P + 2). Calcd. mass from the exact mass measurement: 166.027814. Calcd. mass for $C_7H_6N_2SO$: 166.021082. Delta mass: 0.006732.

*3-Aminothiopicolinamide (**17**)*

Alcoholic ammonia (58 ml) was added to 3-aminopicolinonitrile (**16**) (6.3 g, 0.54 mol) dissolved in a mixture of 14.5 ml of absolute ethanol and 53.1 g (0.054 mol) of triethylamine. The solution was stirred and saturated with hydrogen sulfide for 90 min; a yellow substance precipitated. The flask was loosely stoppered and let stand at room temperature for 2 days. The solution was poured onto crushed ice and the yellow product filtered off. Crystallization from benzene gave 2.95 g (36% yield) of 3-aminothiopicolinamide (**17**), m.p. 161–162°.

Anal. Calcd. for $C_6H_7N_3S$ (mol. wt. 153.15): C, 47.0; H, 4.6; N, 27.4; S, 20.93. Found: C, 47.0; H, 4.8; N, 27.6; S, 20.8. *M/e*: 153 (P); 155 (P + 2).

*3-Aminoisothiazolo[4,3-b]pyridine (**18**)*

3-Aminothiopicolinamide (**17**) (0.42 g, 2.7 mmol) was dissolved in 1.7 ml of pyridine by heating at 35° with stirring. Hydrogen peroxide (30%, 1.0 ml) was added dropwise to the reaction mixture to maintain the temperature below 35°. The flask was stoppered and let stand at room temperature for 16 h. It was then poured onto a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

small amount of crushed ice and the yellow product filtered off. Crystallization from benzene produced 0.124 g (30% yield) of 3-aminoisothiazolo[4,3-*b*]pyridine (**18**) as fine yellow needles, m.p. 195–196°. I.r. (KBr): 1652, 3310, 3250, 3080 cm^{-1} (NH_2).

Anal. Calcd. for $C_6H_5N_3S$ (mol. wt. 151.13): C, 47.7; H, 3.3; N, 27.8; S, 21.2. Found: C, 47.4; H, 3.4; N, 28.0; S, 21.0. *M/e*: 151 (P); 153 (P + 2).

*3-Bromoisothiazolo[4,3-b]pyridine (**19**)*

3-Aminoisothiazolo[4,3-*b*]pyridine (**18**) (90 mg, 0.59 mmol) was suspended in 5 ml of 48% hydrobromic acid. Sodium nitrite (70 mg, 1.0 mmol) was added in small portions over a period of 3 min with constant stirring at −4 to 0°. The mixture was stirred for 30 min at 0° and let stand at room temperature overnight. Crushed ice was added and the solution was made strongly alkaline with 20% sodium hydroxide solution. The mixture was extracted continuously with ether in liquid–liquid extractor. The ethereal extract was dried over sodium sulfate and the solvent evaporated to dryness leaving 53 mg of a brown substance. Chromatography and crystallization from benzene gave 28 mg (21% yield) of 3-bromoisothiazolo[4,3-*b*]pyridine (**19**) as yellow needles, m.p. 145–156°.

M/e: 214 (P); 216 (P + 2). Calcd. mass from the exact mass measurement: 215.916945. Calcd. mass for $C_6H_3z_2SBr$: 215.916411. Delta mass: 0.000543.

*2-Chloronicotinaldehyde (**21**)*

Raney nickel alloy (50–50; 30 g) was stirred with 3 l of 2 *N* sodium hydroxide solution for 30–40 min, the temperature being allowed to rise. The alkaline solution was decanted and the Raney nickel was washed twice with distilled water. A solution of 2-chloronicotinonitrile (**20**) (20.0 g, 0.141 mol) in 300 ml of 98% formic acid was added to the moist Raney nickel catalyst and the mixture was stirred for 30 min at 45–80°. The mixture was diluted with 280 ml of ethanol–water (2:1, v/v), filtered, and the catalyst washed twice with 50 ml of warm ethanol. The filtrate together with the ethanol washings was diluted with water and extracted several times with ether. The ethereal extract was washed with dilute sodium bicarbonate solution and water, and dried over sodium sulfate. The solvent was evaporated leaving 14.5 g of an oily brown substance which on distillation at 66–70°/5 mm Hg produced 11.8 g (58% yield) of a colorless oil which solidified immediately on cooling. Crystallization from ether–chloroform gave a pure 2-chloronicotinaldehyde (**21**) as colorless needles, m.p. 42–43°. I.r. (KBr): 2280 (—C*H*O) and 1688 cm^{-1} (—CH*O*).

M/e: 141 (P); 143 (P + 2). Calcd. mass from the exact mass measurement: 140.998452. Calcd. mass for C_6H_4NOCl: 140.998139. Delta mass: 0.000313.

*2-Thiocyanonicotinaldehyde (**22**)*

Potassium thiocyanate (7.4 g, 0.0754 mol) was added to 2-chloronicotinaldehyde (**21**) (6.0 g, 0.0427 mol) in glacial acetic acid (60 ml). The reaction mixture was stirred at room temperature and was kept under nitrogen atmosphere overnight. The solution was poured onto crushed ice and the yellow precipitate was collected by suction after a few hours. Crystallization from ethyl acetate yielded 4.6 g (65%) of 2-thiocyanonicotinaldehyde (**22**) as long yellow needles m.p. 143–144°. I.r. (KBr): 2163 cm^{-1} (SCN).

M/e: 164 (P); 166 (P + 2). Calcd. mass from the exact mass measurement: 164.004568. Calcd. mass for $C_7H_4N_2OS$: 164.004433. Delta mass: −0.000135.

*Isothiazolo[5,4-b]pyridine (**6**)*

Liquid ammonia in a large excess was added over a 3 h period to 2-thiocyanonicotinaldehyde (**22**) (4.1 g, 0.025 mol) placed in a 300 ml two-necked flask equipped with a magnetic stirrer and immersed in an ethanol – Dry Ice bath kept below 50°. The mixture was kept at this temperature with constant stirring for 5 h. Ammonia was allowed to evaporate slowly at room temperature leaving 3.06 g of a tan solid. Crystallization from *n*-hexane gave 1.3 g (38% yield) of isothiazolo[5,4-*b*]pyridine (**6**) in the form of fine colorless needles, m.p. 54.5–55.5°.

M/e: 136 (P); 138 (P + 2). Calcd. mass from the exact mass measurement: 136.009204. Calcd. mass for $C_6H_4N_2S$: 136.009519. Delta mass: 0.000315.

*4-Acetyl-3-thiocyanopyridine (**24**)*

4-Acetyl-3-aminopyridine (**23**) (1.08 g, 7.2 mmol) was dissolved in concentrated sulfuric acid (2.5 g) and water (5 ml), cooled to −4 to −2°, and diazotized with a solution of 0.58 g (8.2 mmol) of sodium nitrite in 2.5 ml of water. The resulting diazonium salt solution was stirred at this temperature for 10 min and then added dropwise with stirring to a solution of 0.88 g of potassium thiocyanate (9.0 mmol) in 2.5 ml of aqueous cuprous thiocyanate (prepared from 0.2 g of cupric sulfate, 0.88 g of potassium thiocyanate and 0.35 g of ferrous sulfate) was added to the mixture which was further stirred at room temperature for another hour. The reaction mixture was poured onto a small amount of crushed ice and neutralized with solid sodium bicarbonate. The brown precipitate was filtered off, dried, and crystallized from *n*-hexane to obtain 0.86 g (45% yield) of a pure 4-acetyl-3-thiocyanopyridine (**24**) as long colorless needles, m.p. 83–84°. I.r. (KBr): 2158 cm^{-1} (SCN).

M/e: 178 (P); 180 (P + 2).

Anal. Calcd. for $C_8H_6N_2SO$: C, 53.9; H, 3.4; N, 15.7; S, 17.99. Found: C, 53.2; H, 3.6; N, 15.6; S, 18.1.

*(a) Cyclization of 4-Acetyl-3-thiocyanopyridine (**24**) with Ammonium Hydroxide Under High Pressure*

A mixture of 1.78 g (0.01 mol) of 4-acetyl-3-thiocyanopyridine (**24**) and 100 ml of concentrated ammonium hydroxide was placed in a glass-liner within a stainless steel pressure bomb equipped with a magnetic stirrer and heated in a silicon oil bath at 130° for 5 h. The reaction mixture was evaporated to dryness leaving a brown solid substance. Chromatography and crystallization of the product from *n*-hexane gave 0.31 g (20% yield) of 3-methylisothiozolo[5,4-*c*]pyridine (**25**) as pale orange prisms, m.p. 57–58°.

M/e: 150 (P); 152 (P + 2); mol. wt. 150.13. Calcd. mass from the exact mass measurement M: 150.02448. Delta mass: 0.00042. Calcd. mass for $C_7H_6N_2S$: M 150.0249. Delta mass: 0.00042.

*(b) Cyclization of 4-Acetyl-3-thiocyanopyridine (**24**) with Liquid Ammonia*

Liquid ammonia was added in a large excess over a 3 h period to 1.0 g (6.7 mmol) of 4-acetyl-3-thiocyanopyridine (**24**) placed in a 200 ml two-neck flask equipped with a magnetic stirrer and immersed in an ethanol – Dry Ice bath kept below −50°. The reaction mixture was further stirred for another 5 h and then ammonia was allowed to

evaporate slowly at room temperature leaving a brown solid substance. Crystallization of the product from *n*-hexane gave 0.185 g (22% yield) of 3-methylisothiozolo-[5,4-*c*]pyridine (**25**), m.p. 57–58°.

The n.m.r. and mass spectra of this compound were exactly the same as for **25** prepared by the procedure *a*.

*4-Aminothionicotinamide (**26**)*

This compound was prepared from 4-aminonicotinonitrile (**27**) by the procedure used in preparing 2-aminothionicotinamide (**10**). From 0.7 g (5.9 mmol) of **27**, 0.56 g (62% yield) of **26** was obtained as fine pale yellow needles, m.p. 157–158°.

The Vibrational Analysis of Cyclopentanone[1]

V. B. KARTHA,[2] H. H. MANTSCH,[3] AND R. N. JONES

Division of Chemistry, National Research Council of Canada, Ottawa, Canada K1A 0R6

Received May 2, 1972[4]

The infrared and Raman spectra of cyclopentanone, $\alpha\alpha\alpha'\alpha'$-$d_4$-cyclopentanone, $\beta\beta\beta'\beta'$-d_4-cyclopentanone and d_8-cyclopentanone have been measured and a normal co-ordinate analysis performed based on a twisted C_2 conformation. The 36 normal vibrations were computed using a selective valence force field comprising 16 diagonal and 16 off-diagonal force constants. The 4 isotopic species provided 144 frequencies to refine 15 diagonal force constants. The initial values of the constants were transferred from a force field for cyclohexanone computed in this laboratory. The infrared and Raman spectra were analyzed in terms of the potential energy distribution coefficients categorized as group frequencies, zone frequencies, and delocalized frequencies.

Les spectres infrarouge et Raman de la cyclopentanone, de la cyclopentanone $\alpha\alpha\alpha'\alpha'$-$d_4$, de la cyclopentanone $\beta\beta\beta'\beta'$-d_4 et de la cyclopentanone-d_8 ont été étudiés et une analyse (en coordonnées normales) a été effectuée en se basant sur une conformation C_2 croisée. Les 36 vibrations normales ont été evaluées en utilisant un champ de force valentielle sélectif qui comprend 16 constantes de force diagonales et 16 autres non-diagonales. Les 4 espèces isotopiques ont engendré 144 fréquences qui ont aidé à déterminer 15 constantes de force diagonales. Les valeurs initiales des constantes ont été obtenues d'un champ de force pour la cyclohexanone calculé dans ce laboratoire. Les spectres infrarouge et Raman ont été analysés en fonction des coefficients de distribution d'énergie potentielle classés selon des fréquences de groupe, des fréquences de zone et des fréquences délocalisées.

Can. J. Chem., 51, 1749 (1973)

Introduction

This paper is concerned with a vibrational analysis of cyclopentanone and three deuterium substituted species (**1**–**4**); it supplements earlier work on cyclohexanone (1). These studies are being made to assess the capabilities and limitations of a simplified normal co-ordinate treatment to aid in the interpretation of the vibrational spectra of molecules of low symmetry related to natural products with particular reference to steroids.

Several conformations varying from planar (C_{2v}) to lower symmetries (C_2, C_s, C_1) have been

proposed for cyclopentanone; they have been reviewed by Howard-Lock and King (2). The ground state geometry assumed in this work (Fig. 1) is based on a least squares fit of the bond parameters (Table 1) to the rotational constants of **1**, **2**, **4**, and two conformers of α-*d*-cyclopentanone (**5**, **6**). The rotational constants were taken from microwave data in the literature (3–7). Calculations were performed with the twisted C_2 and the bent C_3 structures.[5] All 9 parameters were allowed to adjust until the sum of the squares of the differences between the reported and computed rotational constants was minimal. The only restraint was that the C_2—C_3 and C_3—C_4 bond

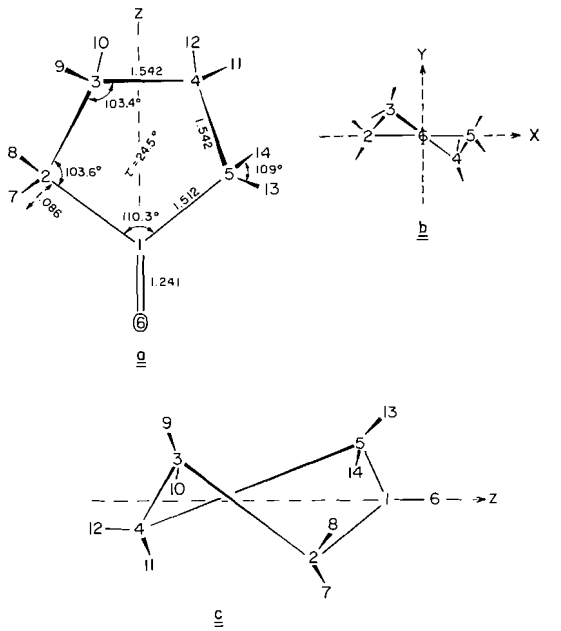

FIG. 1. Atom numeration and geometric parameters in the skew configuration.

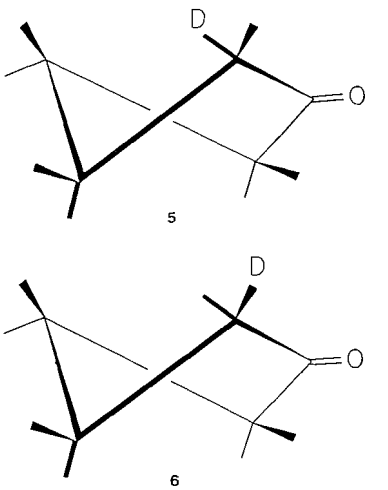
9	Twist angle	24.519°

[5]See Fig. 2 of ref. 2.



lengths remained equal and the calculations were considered self-consistant when the variations in the bond lengths were less than 0.001 Å.[6] The C_2 conformation in which the ring is twisted in a skew configuration gave much the better fit. Such a C_2 ground state is consistent with similar calculations[7] of Kim and Gwinn (7) and Howard-Lock and King (2) and with more recent far infrared studies of Ikeda and Lord (8), and electron diffraction measurements of Geise and Mijlhoff (9).

The Cartesian co-ordinates of the equilibrium positions of the atoms were computed with respect to an origin centered at the mid-point of the C_2—C_5 axis (Table 2). The 47 selected internal valance co-ordinates are identified[8] in Figs. 2 and 3. Under C_2 symmetry the 36 normal vibrations divide into 18 type A (Raman polarized) and 18 type B (Raman depolarized), and all are infrared and Raman active. The 47 internal co-ordinates were combined into 47 non-normalized symmetry co-ordinates (Table 3). As there are 36 normal modes 11 symmetry co-ordinates are redundant. The local redun-

[6]All molecular dimensions are reported in Å (1 Å = 10^{-10} m).

[7]The refined bond parameters in Table 1 differ slightly from those reported in refs. 2 and 7. Our twist angle (24.5°) is close to that of Kim and Gwinn (24°) but Howard-Lock and King obtained 33°. Our differences from Kim and Gwinn's bond lengths are probably due to the fact that they held the C—H and C=O bond lengths and the CH_2 angles fixed during refinement while we allowed them to adjust.

[8]Figure 1 exhibits the true projections of the non-planar ring but the projection diagrams appearing elsewhere have been distorted to permit more space to portray the bond and angle motions within the ring.

dancies at the 5 carbon atoms are easily recognized and the remaining 6 are eliminated during normalization by the GMAT program (1, 10).

Experimental

1 and **4** are commercially available compounds while **2** and **3** were prepared by exchange reactions at the active α positions.

Cyclopentanone (1)

An Eastman Organic Chemical reagent grade sample was distilled under reduced pressure in a Nester–Faust spinning band column.

αα′α′-d_4-Cyclopentanone (2)

Cyclopentanone (30 ml), purified as above, was stirred with D_2O (99.7%, 60 ml) and Na_2CO_3 (600 mg) at room temperature for 24 h in a sealed glass tube. The product was extracted with ether, dried ($MgSO_4$), the ether removed, and the residue distilled under reduced pressure (55–60 Torr). The product was twice recycled under the same conditions. In the final distillation the first fraction (3.5 ml) was discarded and the next 5 ml collected. The infrared spectrum showed negligible H_2O or D_2O absorption and indicated almost complete α-deuteration. Mass spectrum analysis, when extrapolated to zero ionization voltage, indicate a d_4 content in excess of 90%.

ββ′β′-d_3-Cyclopentanone (3)

d_8-Cyclopentanone (1 ml) was stirred with H_2O (3 ml) and Na_2CO_3 (30 mg) in an all-glass system for 24 h at room temperature. The product was extracted with ether, the ether removed by evaporation at room temperature, and the residue again treated for 24 h with H_2O (2 ml)

For personal use only.

and Na_2CO_3 (200 mg). The product was extracted three times with 4 ml portions of ether and the bulked extracts dried with freshly regenerated molecular sieve type 4A. The ether was removed by distillation and the residue distilled under reduced pressure for the infrared and Raman measurements.

d_8-Cyclopentanone (4)

This material was purchased from Merck, Sharpe, and Dohme (Canada) Ltd. and used as received.

The infrared spectra of the pure liquids and solutions were measured in a Perkin–Elmer Model 521 infrared spectrophotometer. The digitally recorded spectra were processed as described elsewhere (1, 11). The same operating conditions, spectral slit widths, and solvent ranges were used as for cyclohexanone (1).

The Raman spectra were obtained with the 4880 Å excitation of a Spectra-Physics induction ion laser and a Spex 1400 recording spectrometer. The samples were distilled into quartz capillary tubes and sealed under helium at a pressure of 100–200 Torr. Under these conditions good Raman spectra could be obtained and reliable polarization measurements could be made.[9] The infrared spectra are shown in Fig. 4, and the Raman spectra in Fig. 5. The positions of the peaks of both the infrared and Raman bands are listed in Table 4*a–d*. Averaged values of the infrared and Raman peak positions were used in the computations except for the C=O stretch bands for which infrared values were employed.

Discussion

Factors influencing the choice of the initial set of force constants have been discussed in connection with cyclohexanone (1). Theoretically there are 1128 quadratic force constants. An initial set of 16 diagonal and 60 off-diagonal constants was used. During the refinement many of the interaction constants were eliminated and a satisfactory force field was achieved with the 16 diagonal and 16 off-axis constants listed in Table 5. Initially the starting constants were transferred from literature data for acetone and the generalized alicyclic hydrocarbon as was done for cyclohexanone (1). Subsequently the refined values obtained for cyclohexanone were used as starting values for cyclopentanone. Both computations converged to a similar force field but convergence from the cyclohexanone input data was much faster and only these values will be reported.[10]

The same systematic trend towards the differentiation of the force constants associated with the α and β carbon atoms was observed as with cyclohexanone *viz*:

$$K_{d(\alpha)} > K_{d(\beta)}$$
$$K_{r(\alpha)} > K_{r(\beta,\gamma)}$$
$$H_{\gamma(\alpha)} < H_{\gamma(\beta)}$$
$$H_{\omega(\alpha)} > H_{\omega(\beta)}$$
$$H_{\delta(\alpha)} < H_{\delta(\beta)}$$
$$H_{\chi} > H_{\iota}$$
$$H_{\tau(\alpha)} < H_{(\beta,\gamma)}$$

The stretch constant ($K_{r(\beta,\gamma)}$) and the corresponding C—C torsion ($H_{\tau(\beta,\gamma)}$) (internal coordinates 14, 45) were kept fixed in the sense that values for the β and γ positions were not allowed to differ. All the interaction constants were kept fixed during the refinement. A total of 144 experimental frequencies, derived from the four isotopic species, were used to refine 15 adjustable diagonal force constants. The force constants associated with the alicyclic part of the molecule are all well determined, but force constant No. 12 (H_χ) proved to be strongly correlated with force constant No. 3 (K_ν) and had to be kept fixed during the refinement.

The analysis of the 36 normal modes is based on the potential energy distribution coefficients (E_p) and the normal vibrations are classified as GF, ZF, or DF (1). These are listed in Table 4*a–d* together with the observed and calculated frequency data. Only the four largest E_p coefficients are listed, and these only if they exceed unity. In the vibrational diagrams only motions associated with $E_p > 10$ are indicated.

The C—C—C Skeletal Vibrations

The six normal modes below 600 cm^{-1} are listed in Table 6; they can be traced through the isotopic series by the E_p coefficients. The lowest band is a ring pucker (τ_α, τ_β); it has been described as a pseudo-rotation of the ring (2, 12) and has been recently investigated in detail by Ikeda and Lord (8). We observe it in the Raman spectra of **1** and **2**. The next higher fundamental at 239 cm^{-1} in **1** is an out-of-plane ring distortion with symmetric twists of the β and γ C—C bonds (τ_β, τ_γ) and closure of the β CCC angles (ω_β). Bands III and IV of Table 6 involve deformations of the C_α—CO—C_α group (ρ, ε) and will be discussed with the carbonyl vibrations.

The two in-plane ring vibrations V and VI

[9]We wish to thank Dr. W. F. Murphy for making these measurements for us.

[10]The detailed numerical calculations for the refinement from the cyclohexanone input data will be found in ref. 10 where they are used as illustrative examples in the description of the computer programs.

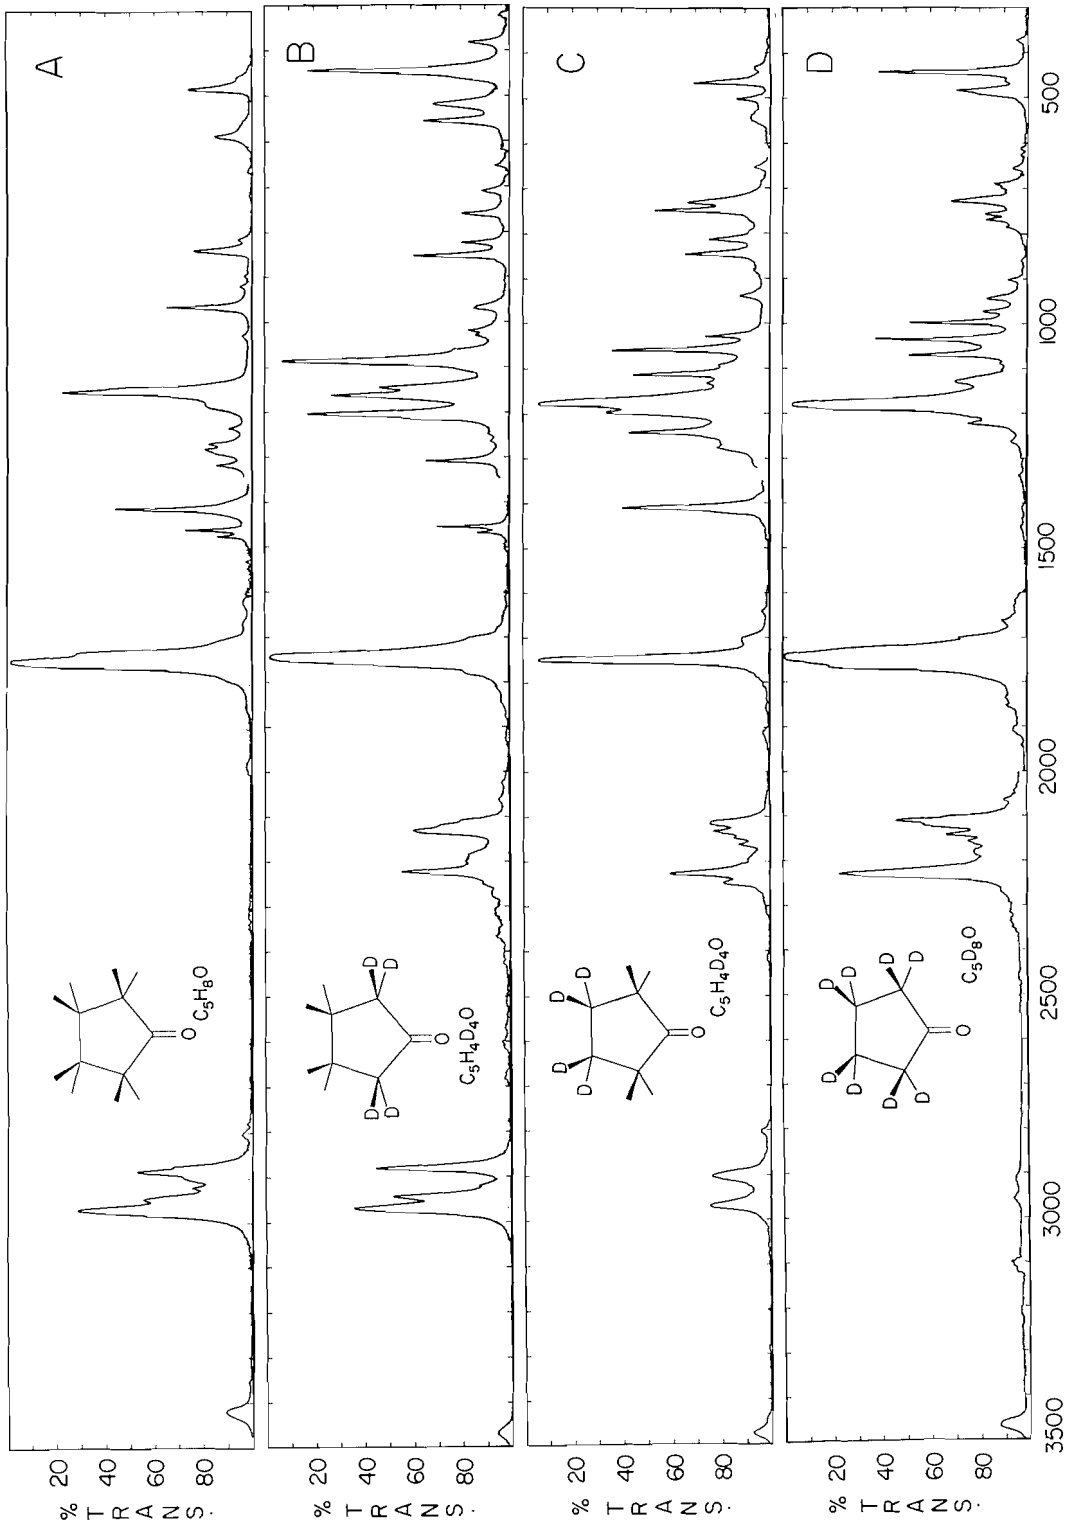

FIG. 4. Infrared spectra in solution. Solvent CCl_4 (4000–1380/630–240 cm^{-1}); CS_2 (1380–630 cm^{-1}). Path length 1 mm.

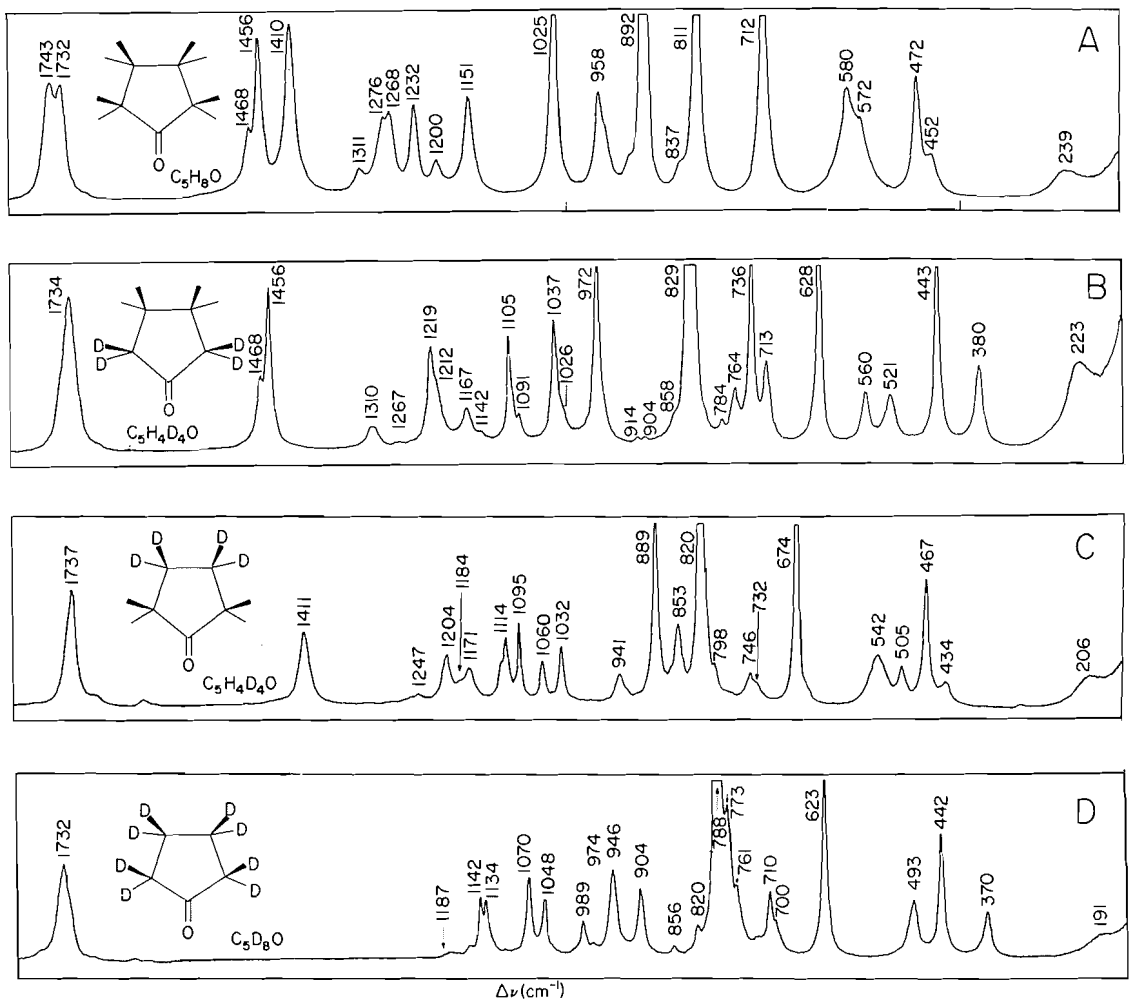

FIG. 5. Raman spectra of the pure liquids measured without polarizers; excitation with 4880 Å argon ion source. The region $\Delta\nu$ = 4600–1800 cm^{-1} is not shown, but the peak positions are listed in Table 12.

overlap near 570 cm^{-1} in **1** and near 490 cm^{-1} in **4**; they are well separated in **2** and **3**. The C_α—CO—C_α angle (χ) and the α C—C—C angle (ω_α) participate in V which is sensitive to α-deuteration. Both V and VI are highly delocalized. Mode VI emphasizes the effect of deuterium substitution on the mixing of the internal co-ordinates (Table 7*a*); on β-deuteration a large contribution to the energy of this mode is injected from the β D—C—C angle bend (γ_β). Above 600 cm^{-1} contributions from H—C—C and D—C—C bend motions predominate and the C—C stretch motions in this region are discussed with the C—H and C—D deformations.

The Carbonyl Group

Linear stretch of the C=O bond (ν) contributes only about 80% to the mode energy of the "C=O stretching group vibration" (Table 8) and the remaining energy is localized mainly in the α C—C stretch (r_α) and the C_α—CO—C_α bend (χ). In **1** the position of the C=O stretch vibration is strongly affected by Fermi resonance.[11] This has not been considered in these calculations since the displacement effect is small, especially for the pure liquid. Of potentially greater significance is the large downward shift in the C=O stretch frequency in passing from

the vapor to the liquid state (~30 cm^{-1}). The liquid state values were used in this work.[12]

The in-plane C=O deformation (ε) is easily identified as a strong band in both the infrared and Raman spectra at 471, 456, 467, and 442 cm^{-1} in **1**–**4** respectively. It is highly localized with E_p 71–75. The out-of-plane C=O vibration (ρ) is the lowest of the three carbonyl frequencies at 451, 379, 434, 369 cm^{-1}; it is a medium-strong depolarized Raman band, strongly affected by α-deuteration, and in all four isotopic species accounts for 65–75% of the mode energy. This contrasts with cyclohexanone in which it is highly delocalized.

Bending Vibrations Involving CH and CD Bonds

There are 21 normal vibrations between 600 and 1500 cm^{-1} that involve HCH, HCC, DCD, and DCC angle deformations. Rigorous classification of these as methylene wag, twist, or rock vibrations is impractical since the normal modes are too complex and many couple strongly with C—C stretch co-ordinates.

The CH_2 scissors motions are all good group frequencies (E_p 70–77) with the residual energy localized mainly in the rock/twist motions on the same carbon atom. For the CD_2 scissor the E_p range is 62–74 which brings one of them down into the marginal group frequency range ($E_p < 66$).[13] At each of the C_α and C_β atoms the scissors motion may be in-phase or out-of-phase with its partner across the ring. The calculated wavenumber differences between such pairs are in the range 4–12 cm^{-1} but not all are separated in the measured spectra (Table 9). The empirically well known displacement of the C_α methylene motion to lower wavenumber is confirmed by the calculations. The corresponding effect on the $H_{\gamma(\alpha)}$ force constant has been noted (see Discussion section). Only a few of the other methylene deformation motions can be clearly identified as rocks, wags, or twists[14] (Table 10).

[12]In one computation the observed "carbonyl stretch" frequency was changed to a vapor phase value of 1771 cm^{-1} for all four species with all other experimental frequencies and all input force constants unchanged. Only three of the refined force constants were altered (Table 5), and these were marginal except for the C=O stretch; there were no significant changes in the E_p coefficients (Table 8). It follows that the vibrational modes are not substantially affected by the use of the condensed state experimental frequencies and even less so by the much smaller Fermi resonance displacement in **1**.

[13]This is band 17 in **2** (Fig. 4*b*).

[14]The differentiation between a wag and a twist or between a scissor and a rock depends on the relative signs of the appropriate eigenvectors. These are not included in Table 4*a*–*d* but are recorded in the eigenvector matrices which are listed in ref. 10.

*The force constant units and symbolism are described in ref. 1. The superscripts on the bend–bend interaction constants are qt (quasi *trans*), qg (quasi *gauche*), qc (quasi *cis*).
†The initial values for the force constants were taken from the refined force field established for cyclohexanone (see Table 3 of ref. 1).
‡The values in parentheses are obtained if an observed C=O stretch frequency of 1771 cm^{-1} is used, corresponding to a vapor state measurement. No other force constants change significantly.

C—C Stretch Vibrations

The bands identifiable as C—C in-plane stretch group frequencies are listed in Table 11. Most notable are the 1166 cm^{-1} (calcd) band in **2** and the bands at 1167 and 1157 cm^{-1} (calcd) in **4**. These motions are illustrated in **7–9** respectively. The intense band at 891 cm^{-1} in **1** is strongly polarized in the Raman spectrum and has been attributed to a ring breathing motion (2) and the E_ρ coefficients support this (Table 7*b*). However, in the deuterated species the "corresponding" bands as judged by the Raman intensity and polarization are readily assigned at 827, 817, 787 cm^{-1} in **2–4** respectively, but the E_ρ data in Table 7*b* suggest that with α-deuteration the energy in the $r_{\beta,\gamma}$ co-ordinate is greatly reduced and much of it transferred to the γ_α and γ_β angle bends. If this is so these modes can no longer be classified as ring breathing motions in **3** and **4** where the $r_{\beta,\gamma}$

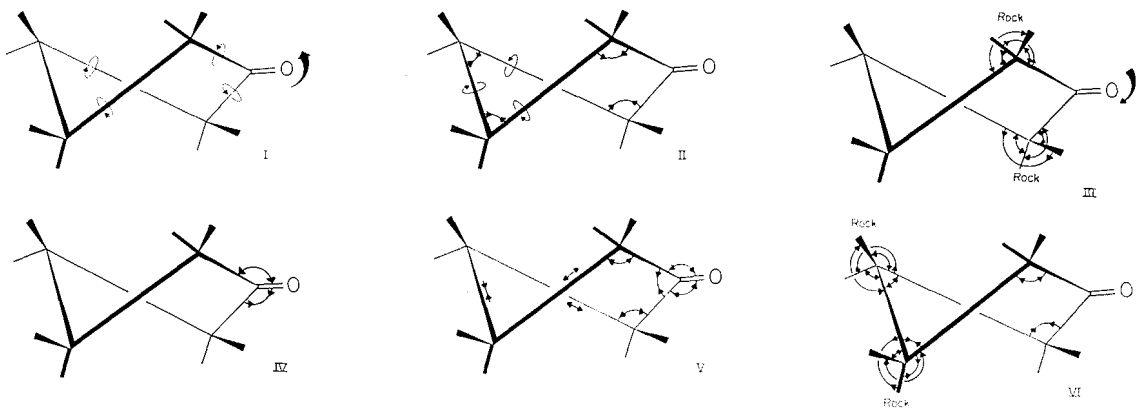
*ν_{calcd} is given first followed by ν_{obs} in parentheses; the observed postions are the mean of the infrared and Raman measurements. Ring vibrations are as follows:



co-ordinates contribute less than 30% of the mode energy. One must bear in mind however that it is in this 800–1100 cm^{-1} region that the computations are most sensitive to small changes in the force field and over-simplified normal co-ordinate analyses are most prone to error.

C—H and C—D Stretch Vibrations

There are 8 calculated frequencies for each isotopic species in the C—H, C—D stretching region (Table 12). The wavenumber differences (1–8 cm^{-1}) calculated for the pairs of in-phase and out-of-phase motions at the C_α and C_β positions correlate with bands in the observed spectra and are reflected in the corresponding force constants. The C—H stretch modes are all good group frequencies with over 90% of the potential energy localized in the C—H bonds. This is true also of most of the corresponding C—D modes except for the symmetric C—D

stretch in **4** where there is appreciable coupling between the C_α and C_β atoms.

Concluding Remarks

One may anticipate that these empirical force fields for cyclohexanone and cyclopentanone should aid in setting up similar computations on more complex molecules such as the β-decalones (with and without methyl substituents at the ring junctions) and the corresponding hydrindanones which would be closer analogs of steroids and other cyclic terpenoids. The replacement of C=O by N—H would open a route via piperidine and pyrrolidine to a set of potentially transferable force field parameters applicable to related *N*-heterocyclic systems. As a wider variety of molecular structures is investigated one may expect that a body of practical lore will evolve based on the co-ordination of the work of the various investigators who are taking this approach (14–16). At an earlier period most of the characteristic vibrational group frequencies of complex mole-

*ν_{calcd} is given first followed by ν_{obs} averaged for infrared and Raman in parentheses.

cules were established in just such a fashion and, in many cases, it was only later that these were rationalized in terms of more formal vibrational theory. In retrospect the sequence of these events tends to be forgotten.

Molecular spectroscopists who are conditioned to the elegant vibrational analysis that can be made for small molecules of high symmetry may be disconcerted by such drastic simplification of the force fields, but this situation is not uncommon when theoretical concepts developed on the basis of simpler model systems are extended to a more general body of scientific data. The caution which must be exercised in applying normal co-ordinate analysis to polymers has been aptly summarized in eight aphorisms by Zerbi[15] and these are also relevant to molecules of the type considered here.

Reductive Cleavage of Carbohydrate *p*-Toluenesulfonates with Sodium Naphthalene

H. C. JARRELL, R. G. S. RITCHIE, W. A. SZAREK, AND J. K. N. JONES

Department of Chemistry, Queen's University, Kingston, Ontario

Received December 8, 1972

Carbohydrate *p*-toluenesulfonates are desulfonylated rapidly and in high yield, by treatment with sodium naphthalene in tetrahydrofuran, to regenerate the original hydroxyl groups. The method has been applied to carbohydrates containing up to three *p*-toluenesulfonate groups, to unsaturated sugars, and to a nucleoside derivative.

Les carbohydrates *p*-toluènesulfonés sont désulfonés rapidement et avec un bon rendement, par traitement avec le naphtalène sodium dans le tétrahydrofurane pour régénérer les groupes hydroxyles originaux. La méthode a été appliquée aux carbohydrates contenant jusqu'à trois groupes *p*-toluènesulfonates, aux sucres insaturés et au dérivé nucléoside. [Traduit par le journal]

The importance of *p*-toluenesulfonic esters of carbohydrates in sugar synthesis has been well established (1, 2). Not only are the *p*-toluenesulfonates useful substrates for a wide variety of nucleophilic displacement reactions, but also the sulfonyl group has been extensively employed as a protecting group. Removal of an *O*-*p*-tolylsulfonyl group, without inversion, to regenerate the original sugar or sugar derivative can be effected in several ways. Reductive desulfonylation has been achieved by the use of sodium amalgam (3), Raney nickel (4), lithium aluminum hydride (5), or sodium in liquid ammonia (6). However, in the reaction with sodium amalgam or Raney nickel, anhydride formation has been observed to be a competing reaction if an unsubstituted hydroxyl group is sterically available. Lithium aluminum hydride operates, on secondary sulfonates, principally by oxygen–sulfur fission, but, on primary sulfonates, with carbon–oxygen fission; thus, with the latter derivatives, reduction mainly to the hydrocarbon stage occurs. The sulfonic esters of carbohydrates are also removable, with retention of configuration, by bases (7); however, anhydro-ring formation, if possible, frequently occurs. Moreover, alkaline conditions can occasionally lead to ring-contracted products (8) or unsaturated derivatives (9, 10). An effective, mild procedure for removal of *O*-*p*-tolylsulfonyl groups is by photolysis of the ester in methanolic solution, in the presence of an equimolar proportion of sodium methoxide (11). The present report describes a new method for reductive desulfonylation of carbohydrate *p*-toluenesulfonates, namely, with sodium naphthalene.

Closson *et al.* (12) have reported previously the use of sodium naphthalene anion radical in tetrahydrofuran solution for the conversion of alkyl mono-*p*-toluenesulfonates into the corresponding alcohols (S—O bond cleavage). The method has been applied to several carbohydrate derivatives; the results are summarized in Table 1. The reactions were performed in a Dry Ice – acetone bath, and the products were isolated at room temperature. In all cases the structures of the products were confirmed by comparison of their t.l.c. mobilities, optical rotations, and melting points (where applicable) with those of authentic samples. It appears that a variety of functional groups (benzylidene and isopropylidene acetals, hydroxyl, alkenyl, and aglycon) in sugar molecules are compatible with the reaction conditions. Moreover, the method is applicable to derivatives containing "isolated" or "non-isolated", primary or secondary *p*-tolylsulfonyloxy groups. The desulfonylation of methyl 4,6-*O*-benzylidene-2-*O*-*p*-tolylsulfonyl-α-D-glucopyranoside is particularly noteworthy, since treatment, with alkaline reagents, of a derivative having an hydroxyl group adjacent and configurationally *trans* to a sulfonyloxy group usually results in the formation of an epoxide ring. The desulfonylation, with retention of configuration, of the compounds having contiguous *p*-tolylsulfonyloxy groups is also significant. With each of the substrates listed in Table 1, t.l.c. examination of the reaction mixture

revealed the formation of only one carbohydrate component; usually, reaction times of 10 min were employed. A disadvantage of the method is that, with large-scale reactions, technical difficulties may be encountered, as regards the separation of a pure product alcohol from the naphthalene and other hydrocarbons which may be formed by the reaction (22) of naphthalene anion radical with water during processing of the reaction mixture.

Experimental

General Method

An approximately 0.5 *M* solution of sodium naphthalene in tetrahydrofuran was prepared by stirring (using a glass-covered stirring bar) a mixture of sodium (2.88 g, 0.125 mol) and naphthalene (17.00 g, 0.133 mol) in dry tetrahydrofuran (250 ml) under an atmosphere of nitrogen for approximately 2.5 h at room temperature. The dark green solution was "standardized"[1] by adding a measured aliquot to water and titrating the aqueous mixture with hydrochloric acid using phenolphthalein as the indicator.

TABLE 1. Desulfonylation of carbohydrate *p*-toluenesulfonates with sodium naphthalene

Substrate	Reference	Equivalents of sodium naphthalene	Method of isolation*	Product	Isolated yield (%)
	13	3	A	1,2:5,6-Di-*O*-isopropylidene-α-D-glucofuranose	78
	14	3	B	1,2-*O*-Isopropylidene-β-D-arabinofuranose	80
	15	3	A	Methyl 4,6-*O*-benzylidene-α-D-glucopyranoside	65
	16	3	A	5,6-Dideoxy-1,2-*O*-isopropylidene-α-D-*xylo*-hex-5-enose	67
	17	6	B	Methyl 5,6-dideoxy-α-L-*arabino*-hex-5-enoside	87
	18	6	A	Methyl 4,6-*O*-benzylidene-α-D-galactopyranoside	50
	19	12	C	Methyl β-D-ribofuranoside	66

*See Experimental.

A solution of the *p*-toluenesulfonate (1–3g) in a minimum volume of dry tetrahydrofuran was added rapidly to a stirred reagent solution (diluted with tetrahydrofuran to approximately 0.3 *M*), containing usually 3 equiv of sodium naphthalene per *p*-tolylsulfonyloxy group, under nitrogen in a Dry Ice – acetone bath. The progress of the reaction was monitored by t.l.c.; usually, reaction times of 10 min were employed. A few drops of water were added to the reaction mixture, and the product was isolated at room temperature by an appropriate procedure.

Isolation of Desulfonylated Products

(A) Chloroform-soluble Alcohols

The reaction mixture was neutralized with Rexyn-101 (H form) resin and then filtered, and the filtrate was evaporated to dryness. The residue was partitioned between chloroform and water, and the chloroform solution was dried (sodium sulfate), decolorized with charcoal, and then evaporated. The residue was fractionated on alumina, with petroleum ether (b.p. 60–80°) as the first eluant to remove the hydrocarbons, followed by methanol to obtain the product alcohol. The product was further purified by standard procedures.

(B) Chloroform- and Water-soluble Alcohols

The reaction mixture was neutralized and evaporated as in isolation procedure A. The residue was partitioned between chloroform and water to remove the hydrocarbons. The aqueous solution was saturated with sodium chloride and then extracted continuously with chloroform until the presence of the product alcohol in the aqueous solution could no longer be detected by t.l.c. The dried (sodium sulfate) chloroform solution was decolorized with charcoal and then evaporated to give the product, which was further purified.

(C) Water-soluble Alcohols

The reaction mixture was deionized with cation and anion exchange resins and then filtered, and the filtrate was evaporated to dryness. The residue was partitioned between chloroform and water. The aqueous solution was evaporated to give the product alcohol, which was further purified.

Chemisorption of Ammonia on Silica

G. A. BLOMFIELD AND L. H. LITTLE

Department of Physical and Inorganic Chemistry, The University of Western Australia, Nedlands, Western Australia, 6009

Received August 31, 1972

The interaction of ammonia with silicas prepared by a variety of methods was studied to resolve conflicting reports of the mode of ammonia adsorption and to determine the role of chlorine impurities (present in the silica) in the adsorption process. Results for the adsorption of water on silica assisted in making band assignments and competition between ammonia and water for silica adsorption sites was observed. It was concluded that dehydroxylated silicas contain sites which dissociate ammonia to form Si—NH_2 groups having infrared bands at 3540, 3450, and 1550 cm^{-1} (the surface amine groups are not displaced by added water). The presence of chlorine in the silica is not a prerequisite for chemisorption of ammonia.

L'interaction de l'ammoniac avec des silices préparées selon plusieurs méthodes a été étudiée afin d'élucider les problèmes issus du mode d'adsorption de l'ammoniac et afin de déterminer le rôle des impuretés du type chlore (présentes dans la silice) dans le processus d'adsorption. Les résultats obtenus lors de l'adsorption de l'eau sur la silice ont contribué à l'attribution des bandes et la compétition entre l'adsorption de l'eau et celle de l'ammoniac sur les sites de la silice a été étudiée. Il a été conclu que les silices déhydroxylées contiennent des sites susceptibles de dissocier l'ammoniac ce qui entrainent la formation de groupes Si—NH_2 possédant en infra-rouge des bandes à 3540, 3450, et 1550 cm^{-1} (les groupes amines en surface ne sont pas déplacés lorsque l'on additionne de l'eau). La présence du chlore dans la silice n'est pas une condition nécessaire à la chémisorption de l'ammoniac. [Traduit par le journal]

Can. J. Chem., 51, 1771 (1973)

Mapes and Eischens (1) reported that ammonia was only physically adsorbed to pure silica and that no chemisorption occurred. Later reports for silicas evacuated at temperatures of 200–800 °C confirmed these results (2–6). Bands which appear at 3400, 3320, and 1625 cm^{-1} in the infrared spectrum have been assigned to ammonia hydrogen bonded to hydroxyl groups on the silica surface (2, 4, 6).

More recently, extra bands at approximately 3525, 3440, and 1555 cm^{-1} have been reported in the spectrum of ammonia adsorbed on silica and these have been assigned to vibrations of a Si—NH_2 group formed by chemisorption of ammonia to the silica (8–10). However, other workers using similar samples and similar pretreatment temperatures still found no evidence for chemisorption (6, 11, 12).

In one case for which chemisorption was reported (8), the silica was prepared by a method involving the use of hydrochloric acid solution and it was found that the band intensities of chemisorbed groups were enhanced by pretreatment of the silica with chlorine or carbon tetrachloride vapors. The other reports of chemisorption considered adsorption onto Cab-O-Sil (10) or Aerosil (9) silicas and we have found that these powders contain traces of chlorine or chloride impurities. Folman (13) had previously reported the formation of Si—NH_2 groups when ammonia was adsorbed on chlorinated porous silica glass. It is possible that the presence of chlorine in silica samples is necessary for chemisorption of ammonia. The formation of Si—NH_2 groups has been reported for ammonia adsorbed on unchlorinated porous silica glass (14) but the existence of such groups was questioned (15) in view of the many reports which suggest that ammonia is not chemisorbed to silica.

In order to resolve the question of chemisorption of ammonia on silica and the role of chlorine and to distinguish between primary amine and secondary amine groups for ammonia adsorbed on porous silica glass (14, 16), the adsorption of ammonia onto silicas prepared by a variety of methods was investigated using infrared spectroscopy. It was concluded that dehydroxylated silicas contain sites which dissociate ammonia to form Si—NH_2 groups. The presence of chlorine in the silicas is not a prerequisite for chemisorption of ammonia.

Experimental

A variety of silica powders was studied. Cab-O-Sil HS-5 and Cab-O-Sil M-5 silicas were supplied by Godfrey L. Cabot Corporation, Boston, Massachusetts. Aerosil silica is manufactured by Degussa, Frankfurt am

Main, Germany. These silicas are prepared by the flame hydrolysis of silicon tetrachloride. A silica powder prepared by precipitation from sodium silicate was obtained (17).

Ludox SM silica was supplied by Dupont, Wilmington, Delaware, as an aqueous sol. Freeze-drying this suspension (initially diluted ten times with distilled, de-ionized water) produced a fluffy white powder. A modified silica was prepared by adding dilute hydrochloric acid to the sol before freeze-drying. The resulting flocculation led to a decrease in the surface area of the chlorinated powder so obtained.

A silica powder was prepared by the hydrolysis of ethyl ortho-silicate. Approximately 10 g of ethyl ortho-silicate was added to 250 ml of distilled, de-ionized water in a polythene beaker and the solution was stirred continuously for 4 days at 20 °C. The resulting silica suspension was freeze-dried.

A chloride-free (as determined by X-ray fluorescence spectroscopy) silica powder was prepared by refluxing approximately 3 g of Cab-O-Sil HS-5 silica for 6 h in concentrated nitric acid. This silica was then washed repeatedly in distilled, de-ionized water, dried at 100 °C and crushed to a fine powder.

Each of these powders was compressed under a pressure of 10 tons/sq in. to form rectangular pellets of 10–35 mg/cm^2. Samples were heated to 400 °C in oxygen before use to remove hydrocarbon impurities.

Pellets of Aerosil silica were suspended in refluxing thionyl chloride for 7 days to induce the exchange of hydroxyl groups on the silica surface by chloride groups. A similar method has been used to chlorinate porous silica glass (13).

The possible effect of iron impurities introduced onto the silica through compression in the steel pellet presses was investigated. Samples of silica – ferric oxide were prepared by soaking pellets of Cab-O-Sil HS-5 silica in a solution of 0.1 *M* ferric chloride in 2 *M* hydrochloric acid. These were then heated in flowing oxygen at 400 °C for 10–12 h to decompose the ferric chloride.

For adsorption onto all samples, anhydrous ammonia obtained from Matheson Company Inc., was used. Surface areas were determined by the B.E.T. method using nitrogen as the adsorbate. The relative chlorine concentrations in each type of silica was determined by X-ray fluorescence spectroscopy using a "Geigerflex X-ray Spectrometer" model KG – 3/5 manufactured by Rigaku–Denki Company Ltd., Tokyo, Japan.

Infrared spectra were recorded on a Perkin–Elmer 521 spectrophotometer in the region 4000 to 1300 cm^{-1}. The spectral slit width was approximately 4 at 3800 cm^{-1} and approximately 2 cm^{-1} in the 1600 cm^{-1} region. A modified windlass cell (16) with a Kanthal wound, silica furnace section permitted evacuation of samples at temperatures up to 900 °C. All spectra were recorded at room temperature and usually a second silica pellet was placed in the reference beam of the spectrometer to compensate for absorption bands due to Si—O vibrations in spectra below 2000 cm^{-1}. Weak bands in the region 3800–3600 cm^{-1} and 1800–1500 cm^{-1} are due to uncompensated water vapor.

Results and Discussion

Spectra of a typical sample of Cab-O-Sil HS-5 silica recorded before and after the addition of ammonia are shown in Fig. 1. Approximately 5 Torr of ammonia was admitted to a sample which had been evacuated at 450 °C (Fig. 1*a*) and bands appeared in the spectrum at 3400, 3320, 3250, 2980, 1625, and 1550 cm^{-1} (Fig. 1*b*). The bands at 3400, 3320, and 1625 cm^{-1} have been assigned to the N—H vibrations of ammonia hydrogen bonded to surface hydroxyl groups (2, 4), and the band at 2980 cm^{-1} is due to the O—H stretching vibration of these hydrogen bonded groups (4). A broad weak band at 3250 cm^{-1} (Fig. 1*b*) is probably due to the first overtone of the N—H deformation fundamental at 1625 cm^{-1}.

Condensing the gas into a liquid air cooled side-arm on the cell removes all the bands due to this hydrogen bonded ammonia from the spectrum and only bands at 3450 and 1550 cm^{-1} remain (Fig. 1*c*). If a larger pressure of gas is admitted to the sample and then condensed the intensities of these bands increase and an additional band appears at 3520 cm^{-1} (Fig. 1*d*). The thickness of samples used in this study was greater than for previous studies in which these bands were undetected (4). These three bands remain in the spectrum of the sample after evacuation at 450 °C and must be produced by one or more species which are chemisorbed to the silica. Folman (13) assigned bands at 3520 and 3540 cm^{-1} to Si—NH_2 groups when ammonia was adsorbed on chlorinated porous silica glass and others have found similar bands for ammonia on dehydroxylated silicas (8–10). All previous reports of ammonia adsorbed on pure silica evacuated at temperatures below 600 °C have concluded that only physical adsorption occurs but the results above indicate that chemisorbed groups are formed as well. It is likely that the smaller gas pressures, the thinner samples, and shorter times of standing used in these former studies produced only low concentrations of chemisorbed species and these were not detected.

The spectrum of Cab-O-Sil HS-5 silica after evacuation at 850 °C (Fig. 1*e*) contains a very sharp peak at 3747 cm^{-1} due to the isolated hydroxyl groups on the silica surface. Admission of approximately 5 Torr of ammonia to this sample produces the spectrum shown in Fig. 1*f*. The bands at 3420, 3337, 3320, 3050, and 1625 cm^{-1} which disappear when the gas is condensed (Fig. 1*g*) are similar to those for ammonia physically adsorbed to Cab-O-Sil evacuated at 450 °C (Fig. 1*b*) except that the band corre-

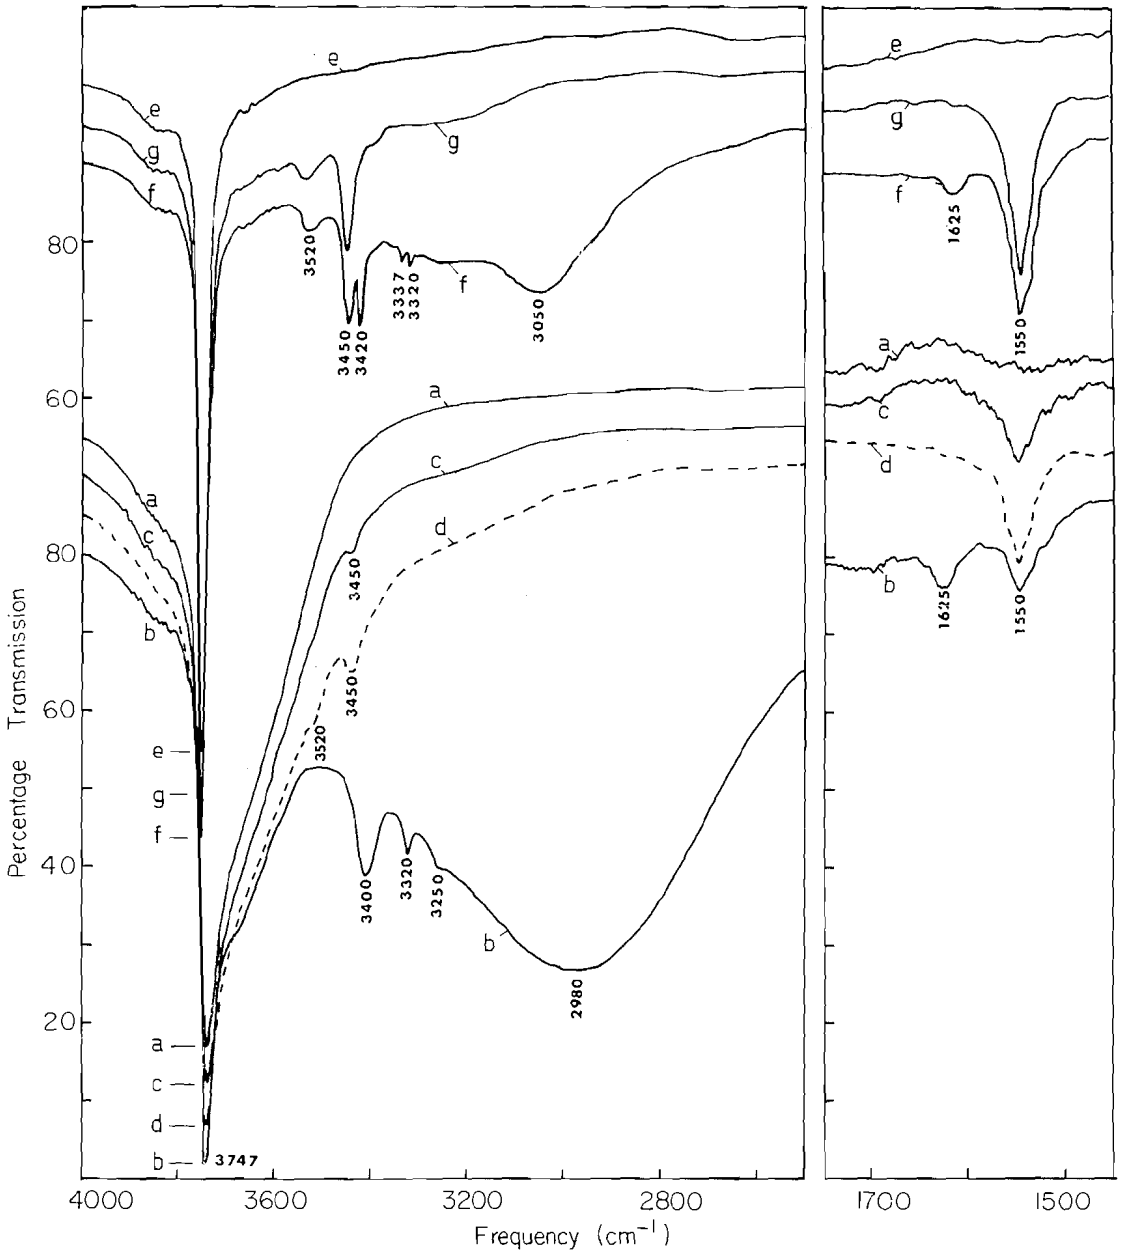

FIG. 1. The infrared spectrum of a sample of Cab-O-Sil HS-5 silica: *a*, after evacuation for 3 h at 450 °C; *b*, after the addition of approximately 5 Torr of ammonia; *c*, after condensing the gas; *d*, after adding 150 Torr of ammonia and condensing the gas; *e*, after evacuation for 5 h at 850 °C; *f*, after adding approximately 5 Torr of ammonia; *g*, after condensing the gas.

sponding to the asymmetric N—H stretching vibration of these hydrogen bonded ammonia molecules has shifted from 3400 to 3420 cm^{-1} and the half-width has decreased. This band is now very sharp suggesting that, unlike the case for Cab-O-Sil evacuated at 450 °C (Fig. 1*b*), the ammonia molecules, hydrogen bonded to single isolated hydroxyl groups are also isolated from one another and from nearby hydroxyl groups and there is no interaction between adjacent groups. Similar sharpening of bands of co-ordinated ammonia were reported on high temperature

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

evacuated porous glass (16). The O—H stretching vibration of these $OH\cdots NH_3$ groups has shifted from 2980 cm^{-1} (Fig. 1*b*) to 3050 cm^{-1} (Fig. 1*f*) indicating that the hydrogen bonds between the ammonia and the hydroxyl groups are weaker for ammonia adsorbed on the more dehydrated sample. The band at 3337 cm^{-1} is due to the symmetric N—H stretching vibration of gaseous ammonia.

The bands at 3520, 3450, and 1550 cm^{-1} which remain in the spectrum after the gas has been condensed (Fig. 1*g*) are similar to those found by other workers (8–10). The bands at 3450 and 1550 cm^{-1} arise from the symmetric stretching and the asymmetric deformation modes respectively of the species Si—NH_2. It will be shown later that the asymmetric stretching mode of this group has a band at 3540 cm^{-1} and that the three bands at 3540, 3450, and 1550 cm^{-1} arise from a single Si—NH_2 species which remains on the sample after evacuation at 400 °C or above. These assignments are confirmed by deuteration studies with ND_3 adsorbed on deuterated silica. The corresponding Si—ND_2 stretching bands occur at 2630 and 2526 cm^{-1}. It is possible that a hydroxyl species formed during the reaction of ammonia with the silica, has a band at 3520 cm^{-1} which overlaps this 3540 cm^{-1} band for spectra of samples after the gas is condensed (Fig. 1*g*).

In addition, a weak shoulder at 3400 cm^{-1} which was not reported in previous studies (8–10) was present in the spectrum of ammonia chemisorbed to dehydrated silica (Fig. 1*g*), and this band disappears after evacuation of the sample at 100–150 °C. The assignment of this band to strongly physically adsorbed ammonia will be considered in a later section.

Similar results were obtained for ammonia chemisorbed to Cab-O-Sil M-5 and Aerosil silicas, although the concentration of chemisorbed species was less than for Cab-O-Sil HS-5 which has a larger surface area. Samples were dehydrated at either 450, 650, or 800 °C before admission of ammonia and for each type of silica, the concentration of the chemisorbed species was greatest for samples which had been evacuated at 800 °C. The intensities of these amine bands also increased if larger ammonia gas pressures were admitted, if the sample was left to stand in the gas for longer periods (12 h) or if the sample was heated in the gas. No further increase was observed when the evacuated sample was immersed in liquid ammonia.

Pellets prepared from the Ludox silica did not transmit infrared radiation as readily as the other silicas and their spectra have a steeply sloping background due to scattering losses. When 100 Torr of ammonia was admitted to a sample which has been evacuated at 450 °C, bands appeared in the spectrum at 3450, 3400, 3320, and 1550 cm^{-1} after the gas was condensed. Heating the sample at 450 °C in ammonia gas increased the concentration of the chemisorbed species and a band appeared at 3520 cm^{-1}. The bands at 3400 and 3320 cm^{-1} were not affected by the heat treatment and remain after evacuation at 20 °C but disappear after evacuation at 150 °C.

The concentration of the chemisorbed species formed on the Ludox sample evacuated at 600 °C after treatment with ammonia is greater than after the 450 °C evacuation. However a similar concentration of Si—NH_2 groups results from heating the sample in the gas. The bands at 3400 and 3320 cm^{-1} are present and disappear after evacuation at 150 °C. Gross sintering of the Ludox silica occurs after evacuation at 800 °C and no chemisorption of ammonia was detected then.

Samples of the silica prepared from sodium silicate (17) were more transparent to infrared radiation than the Ludox silica. Similar spectra were obtained after admission and evacuation of ammonia to pellets dehydrated at 450 or 800 °C. As well as bands due to Si—NH_2 groups, the infrared spectrum contained bands at 3400 and 3320 cm^{-1} which could be removed by evacuating the sample at 150 °C.

For the Cab-O-Sil and Aerosil silicas, admission of ammonia after evacuation at 600–800 °C produced a band at 3400 cm^{-1} in the spectrum and this remained after evacuation of the sample at 20 °C (Fig. 1*g*) but disappeared after evacuation at 150–200 °C. This band was not present in the spectra of samples which had been dehydrated at only 450 °C before ammonia was added (Fig. 1*d*). It is probable that a second band at 3320 cm^{-1} accompanies this 3400 cm^{-1} band but it is very weak and its presence is often difficult to detect. No band at 1625 cm^{-1} was found after evacuation of the ammonia at 20 °C for any of the silicas studied.

It appears that some residual ammonia physically adsorbed to the silica remains after evacuation at 20 °C to produce the bands at 3400 and 3320 cm^{-1}. The Ludox silica and the silica precipitated from sodium silicate (both

TABLE 1. Relative chlorine contents and surface areas of various silicas

prepared from solution) will probably consist of particles containing fine pores in which hydrogen bonded ammonia molecules might be more strongly held. For the Cab-O-Sil and Aerosil silicas (prepared at over 1000 °C) it is only after evacuation at temperatures above 600 °C with some loss of surface area, that sufficient ammonia remains after evacuation at 20 °C to produce weak bands at 3400 and 3320 cm^{-1} in the spectrum. The fact that the band due to the asymmetric stretching vibration of these ammonia molecules appears at 3400 cm^{-1} and not 3420 cm^{-1} (Fig. 1*f*, *g*) suggests that these molecules exist in a more perturbing environment.

Griffiths *et al.* (18) reported bands at 3350 and 3280 cm^{-1} when ammonia was adsorbed on silica-supported platinum or on pure silica samples. They assign these bands to ammonia chemisorbed to platinum sites (Pt—NH_3 groups) in the first instance and ammonia bound to siloxane groups $\left(NH_3—O\begin{matrix}Si\\Si\end{matrix}\right)$ in the second. They did not evacuate the gaseous ammonia from the samples to verify that these chemisorbed ammonia groups were in fact chemically bound to the adsorbent.

In the present investigation, much higher resolution of bands could be obtained and no bands at these frequencies were observed for any of the ammonia–silica systems we have studied. Bands at 3360 and 3260 cm^{-1} were observed for ammonia on silica supported oxides in the presence of gaseous ammonia (19). These bands were ascribed to physically adsorbed ammonia molecules. In view of the poor resolution for the spectra in the study of Griffiths *et al.* (18) and the lack of corroborative evidence to support their assignments (1–6, 8–16) it seems unlikely that chemically bound NH_3 groups are adsorbed onto silica adsorbents. However, the assignment of bands to Pt—NH_3 groups may still apply.

Pellets of silica prepared from ethyl orthosilicate were very opaque and infrared transmission was less than 2% at 4000 cm^{-1}, even for very thin pellets. However, after attenuation of the reference beam, infrared spectra could be recorded. Bands at 3450 and 1550 cm^{-1} were present in the spectra of samples dehydrated at 450 and 800 °C after adsorption and subsequent evacuation of ammonia. It appears that this silica chemisorbs ammonia to form Si—NH_2 groups.

Analysis of a pellet of Cab-O-Sil HS-5 by X-ray fluorescence spectroscopy revealed that for the elemental range sodium to tungsten, small concentrations of iron and chlorine atoms were present as well as the silicon atoms. The iron impurity possibly resulted from the steel press used to prepare the pellets, while the chlorine impurity was possibly derived from the silicon tetrachloride used in the manufacture of the Cab-O-Sil, although pellets of Cab-O-Sil M-5 contained no detectable chlorine. Each type of silica was analyzed for chlorine and the results are shown in Table 1. The result for a standard silicate rock (U.S. Geological Survey, ref. G-2 (20)) containing 108 p.p.m. chlorine, is included for comparison.

Cab-O-Sil M-5 silica containing no detectable chlorine will form Si—NH_2 groups after reac-

[1] $\geq Si—Cl + NH_3 \longrightarrow \geq Si—NH_2 + H—Cl$

tion with ammonia. It appears therefore that the chemisorption of ammonia on silica does not depend upon the presence of chlorine in the silica. The possibility still exists that chlorine impurities will react according to the following equation to produce more Si—NH_2 groups as postulated by Folman (13).

To test this possibility, a sample of Cab-O-Sil HS-5 powder was treated with nitric acid to remove chlorine (Table 1). This chlorine-free silica still reacted with ammonia and in spite of a slight reduction in surface area (Table 1), the intensities of the Si—NH_2 bands in the spectrum of the sample were similar to those for ammonia adsorbed on untreated Cab-O-Sil HS-5. It appears that surface chlorine does not play a prominent role in the production of surface amine groups for the silicas studied.

Several pellets of Aerosil silica were treated with thionyl chloride to exchange the surface hydroxyl groups by chlorine. Only partial chlorination of these samples was achieved since their spectra still contained a strong band due to SiOH groups. Folman (13) reported the exchange of 90% of the hydroxyls on porous silica glass for samples which had been treated with thionyl chloride for 14 days. Boehm (21) has found it was possible to react only 50% of the hydroxyls on Aerosil with thionyl chloride.

After evacuation of these chlorinated samples at 450 or 800 °C, ammonia was admitted to the cell. In each case the intensities of Si—NH_2 bands produced by reaction with the ammonia were no greater than for those formed on untreated Aerosil. Weak bands at 3150, 3050, and 2805 cm^{-1} due to NH_4Cl (13) were formed but there seemed to be no relationship between the concentration of NH_4Cl produced and the intensity of the Si—NH_2 bands. A side reaction 1 between ammonia and adsorbed chlorine atoms may have occurred but this was not the major reaction for the formation of Si—NH_2 groups. Analysis of one of these chlorinated pellets indicated a marked increase in chlorine content (Table 1).

Presumably these chlorine groups, replacing hydroxyls on the Aerosil pellets, were covalently bound to silicon atoms. A sample of Ludox silica which had been treated with hydrochloric acid solution before drying also contained an increased concentration of chlorine (Table 1), probably in an ionic form on the silica surface. In this case, results for reaction with ammonia were identical with those results obtained using the untreated Ludox silica. Thus it can be seen that the ability for silica to chemisorb ammonia is independent of the presence of chlorine or chloride and is a property of the silica itself.

It is possible that traces of iron introduced into the silica samples during compression in the steel pellet press and detected by X-ray fluorescence analysis, may have affected the adsorption of ammonia onto the silica. Any iron in the silica samples would most likely be present as ferric oxide since the pellets were heated in oxygen before they were placed in the spectral cell. Consequently the adsorption of ammonia onto samples of ferric oxide supported in Cab-O-Sil was investigated and these results have been presented elsewhere (22). After admission of ammonia, bands at 3450 and 1550 cm^{-1} were present in the spectra of the silica–ferric oxide samples and more intense bands (assigned to Fe—NH_3 groups) appeared at 3380, 3290, and 1605 cm^{-1}. If the bands at 3520, 3450, and 1550 cm^{-1} observed in the spectra of ammonia chemisorbed to silica (Fig. 1) were due to ammonia chemisorbed to iron impurities, additional (and more intense) bands due to Fe—NH_3 groups should also have been detected. This was not the case and it appears that the possible iron impurities in the silica samples were not responsible for the chemisorption of ammonia to produce bands in the spectrum at 3520, 3450, and 1550 cm^{-1} (Fig. 1).

It has been proposed that the Si—NH_2 groups on the silica surface are formed by the reaction of ammonia with "highly strained" or ionic siloxane bridges (8).

[2] $\begin{matrix} & O & \\ Si & & Si \end{matrix} + NH_3 \rightarrow Si—NH_2 + SiOH$

When ammonia is adsorbed on almost completely dehydroxylated porous silica glass, bands at 3747 and 3704 cm^{-1} due to isolated SiOH and BOH groups respectively, appear at the same time as bands due to amine groups (16). Ammonia reacts with the B—O—B sites on the porous glass more readily than with the siloxane sites.

Attempts to completely dehydroxylate a silica pellet were not successful. A pellet of Cab-O-Sil which has been evacuated for 5 d at 800 °C retained 75% of the free hydroxyl groups that were present after only 8 h evacuation at 800 °C (measured by comparison of the optical densities

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

of the band at 3747 cm^{-1}). When ammonia was added to this sample, bands due to Si—NH_2 groups appeared in the spectrum but no apparent increase in the intensity of the hydroxyl band was observed.

If the strained siloxane sites on dehydrated silica can abstract a hydrogen from ammonia by the mechanism above, it is possible that an adjacent site might react with the Si—NH_2 groups formed and a secondary amine group would result. By comparison with spectra of various silazanes and disilazanes, such groups should have an N—H stretching vibration in the region 3350—3370 cm^{-1} (23) although it is possible that this vibration may occur at a higher frequency and overlap one of the bands due to the Si—NH_2 groups. Low *et al.* (14) reported that a band at 3455 cm^{-1} (which has been assigned to a secondary B—NH—B group on porous glass (14, 15)) was obscured by the Si—NH_2 band at 3459 cm^{-1}. In order to investigate the possible formation of secondary amine groups when ammonia is added to silica, a careful study was made of the desorption of chemisorbed ammonia. Samples of Cab-O-Sil HS-5 silica evacuated at 800 °C were exposed to 250 Torr of ammonia gas and evacuated for 2 h periods at 100 °C intervals. After each evacuation, a spectrum of the sample plus adsorbed species was recorded. The intensity changes of the N—H vibrations were similar for all the samples studied and a typical sequence of spectra is shown in Fig. 2. After evacuation at 100 °C (Fig. 2*a*) the band due to the asymmetric N—H stretching vibration is broad and is centered at 3520–3540 cm^{-1}. After evacuation at 300 °C (Fig. 2*b*), this band has become quite sharp and is now centered at 3540 cm^{-1}. For evacuation at temperatures up to 400 °C, the optical density of this band decreases more rapidly than the optical densities of the bands at 3450 and 1550 cm^{-1} but above this temperature all three bands decrease at similar rates.

These observations suggest that as well as Si—NH_2 groups, a species having a band at 3520 cm^{-1} is formed by the chemisorption of ammonia onto silica and this is removed after evacuation at 300 °C. The bands due to the NH_2 groups are relatively stable at this temperature and it would be expected that a secondary amine group should be equally stable. Therefore it is unlikely that the species producing the 3520 cm^{-1} band is an amine group.

It has been shown (19) that one of the perturbed hydroxyl groups which exist on mildly evacuated silica and rehydrated silica has a band at 3520 cm^{-1} which disappears from the spectrum of the sample after evacuation at 300 °C. It is possible that the SiOH groups formed by the reaction of ammonia with the silica surface (reaction 2) will be in a strongly perturbed environment such that their O—H stretching frequency occurs at 3520 cm^{-1}. These groups are removed by evacuation at 300 °C. The rigorously dehydrated porous silica glass sample investigated previously (16) contained no surface groups before the admission of ammonia and the majority of the hydroxyl groups formed by reaction with ammonia would exist in an unperturbed environment and given rise to the 3747 cm^{-1} band rather than the 3520 cm^{-1} band discussed above. For the band to occur at 3747 cm^{-1}, there must be no hydrogen bonding between the OH and NH_2 groups shown in eq. 2.

An alternative explanation for the high rate of decrease of the 3520–3540 cm^{-1} band with evacuation at temperatures up to 400 °C may be provided by the observation that often species at very low coverages show an abnormally low intensity for the band due to the asymmetric stretching vibration compared to that for the symmetric stretch. Only at higher coverages does the asymmetric stretching band become appreciably intense. This phenomenon has been observed for many systems: *e.g.* ethylene polymers on Ziegler type catalysts where the band due to the asymmetric CH_2 stretching vibration is weak compared to the symmetric stretch at low coverage (24); also for the asymmetric stretching vibration of co-ordinated ammonia on silica – boric oxide and porous silica glass (16). No explanation can be given for these unusual intensity changes, although it must be appreciated that the band due to the asymmetric stretching vibration of gaseous ammonia is weak and only becomes appreciable when intermolecular interactions occur in condensed states.

For desorption of the chemisorbed species from silica at temperatures above 400 °C, the three bands at 3540, 3450, and 1550 cm^{-1} decrease at approximately equal rates suggesting that a single species produces all three bands. Consequently these bands are assigned to the asymmetric stretching, the symmetric stretching, and the asymmetric deformation modes, respec-

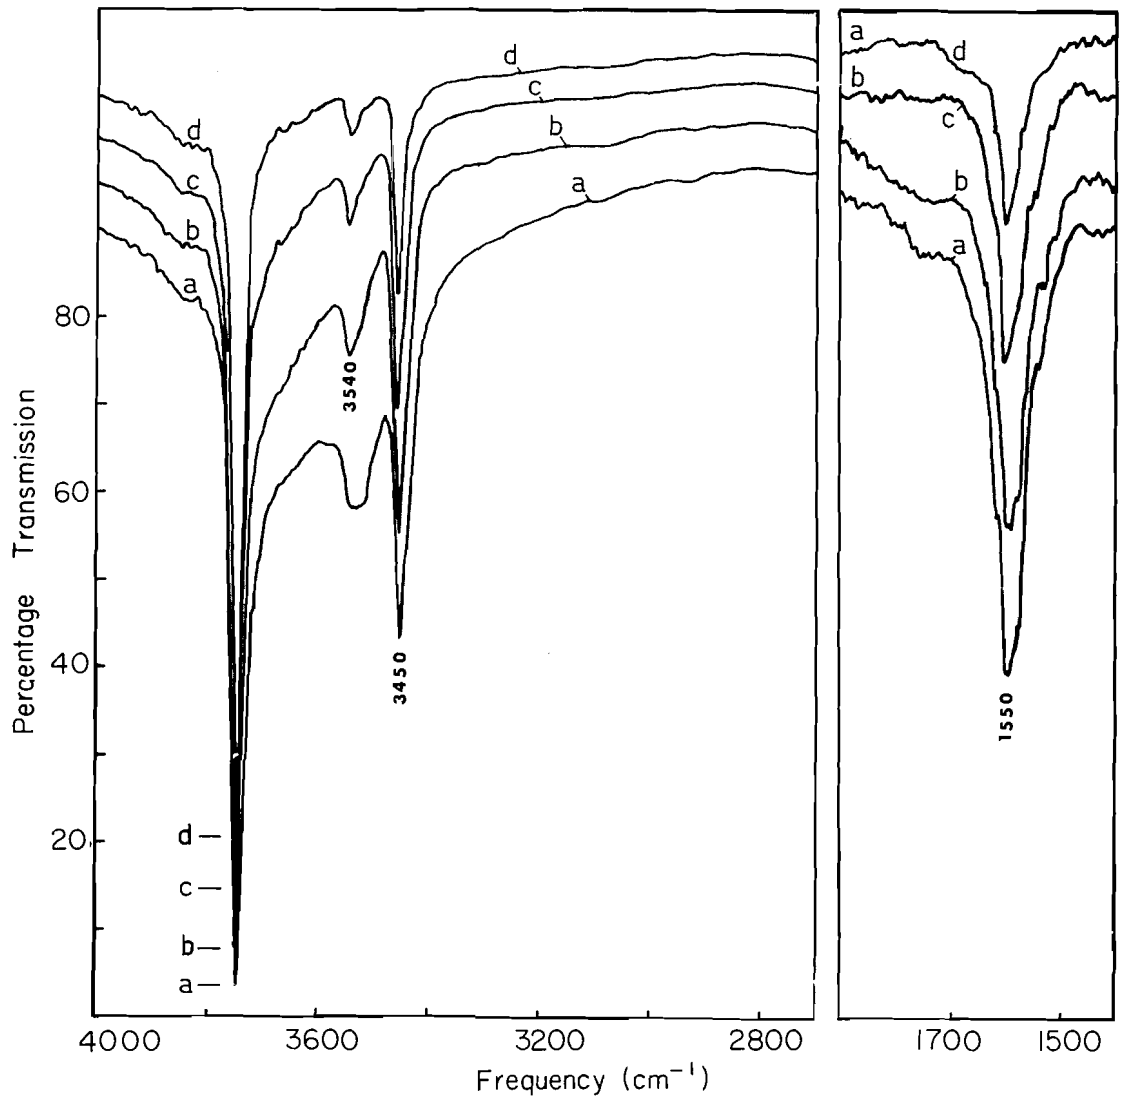

FIG. 2. A sample of Cab-O-Sil HS-5 was evacuated for 10 h at 800 °C and after cooling, 250 Torr of ammonia was admitted. Spectra were recorded: *a*, after subsequent evacuation for 2 h at 100 °C; *b*, after evacuation for 2 h at 300 °C; *c*, after evacuation for 2 h at 500 °C; *d*, after evacuation for 2 h at 700 °C.

tively, of the N—H vibrations of Si—NH_2 groups. These stretching frequencies are approximately 50 cm^{-1} higher than the corresponding frequencies for aminosilanes (23) but the deformation frequency at 1550 cm^{-1} agrees very closely.

It appears that no secondary amine groups are formed by the chemisorption of ammonia on silica. It has been proposed (14, 15) that the band at 3450–3455 cm^{-1} which appears in the spectrum of ammonia chemisorbed to porous silica glass is due to a secondary $\rangle$B—NH— species and this is overlapped by the bands due to the Si—NH_2 groups (14). For the Si—NH_2 groups discussed above, the intensity of the band at 3540 cm^{-1} is less than one-fifth of the intensity of the band at 3450 cm^{-1}. Therefore it is probable that the band at 3450–3455 cm^{-1} reported in the porous silica glass studies (14, 15) is in fact the symmetric stretching vibration of Si—NH_2 groups. The accompanying band at

3540 cm^{-1} is very weak and cannot be distinguished from the 3568 cm^{-1} band due to B—NH_2 groups. Thus it seems doubtful whether secondary amine groups exist on either ammonia – porous glass or ammonia–silica systems.

For each type of silica examined, no chemisorption of ammonia was found until the sample had been evacuated at a temperature of 400 °C or higher. The concentration of the Si—NH_2 groups produced by reaction with ammonia increased as the temperature of dehydration was increased above this temperature. A sample of Cab-O-Sil M-5 silica was evacuated at successively higher temperatures and after each evacuation, 70 Torr of ammonia was admitted. Spectra for this sample after evacuation at 200, 400, 600, and 750 °C are shown in Fig. 3. Fine structure due to gaseous ammonia was evident in the spectra when ammonia was standing over the sample.

After evacuation at 200 °C (Fig. 3*a*) the sample retained most of the weakly hydrogen bonded hydroxyls (having an infrared band at 3650 cm^{-1} (7)) and possibly some of the strongly hydrogen bonded groups having a band at 3520 cm^{-1} (7). This sample did not chemically react with ammonia since no N—H bands remained after evacuation of gaseous ammonia (Fig. 3*c*). After evacuation at 400 °C, only groups having a band at 3747 cm^{-1} with a shoulder at approximately 3650 cm^{-1} remained (Fig. 3*d*). A weak band now appeared at 3450 cm^{-1} in the spectrum of the sample after treatment with ammonia (Fig. 3*f*). Evacuation at 600 °C removed most of the hydrogen bonded hydroxyls from the silica and the band at 3650 cm^{-1} had almost disappeared (Fig. 3*g*). Bands due to Si—NH_2 groups formed by reaction with ammonia were now quite strong (Fig. 3*i*). The concentration of these chemisorbed groups was greater still (Fig. 3*l*) on a sample which had been evacuated at 750 °C before treatment with ammonia (Fig. 3*j*).

It appears that the ammonia chemisorption sites are formed when those hydroxyl groups which produce a band at 3650 cm^{-1} in the infrared spectrum are removed by evacuation at 400 °C and above. The greater the dehydroxylation of the silica surface, the greater the number of chemisorption sites that are formed.

It is considered that ammonia is physically adsorbed to the free hydroxyl groups on the silica surface in preference to hydroxyl groups which are hydrogen bonded to one another (4).

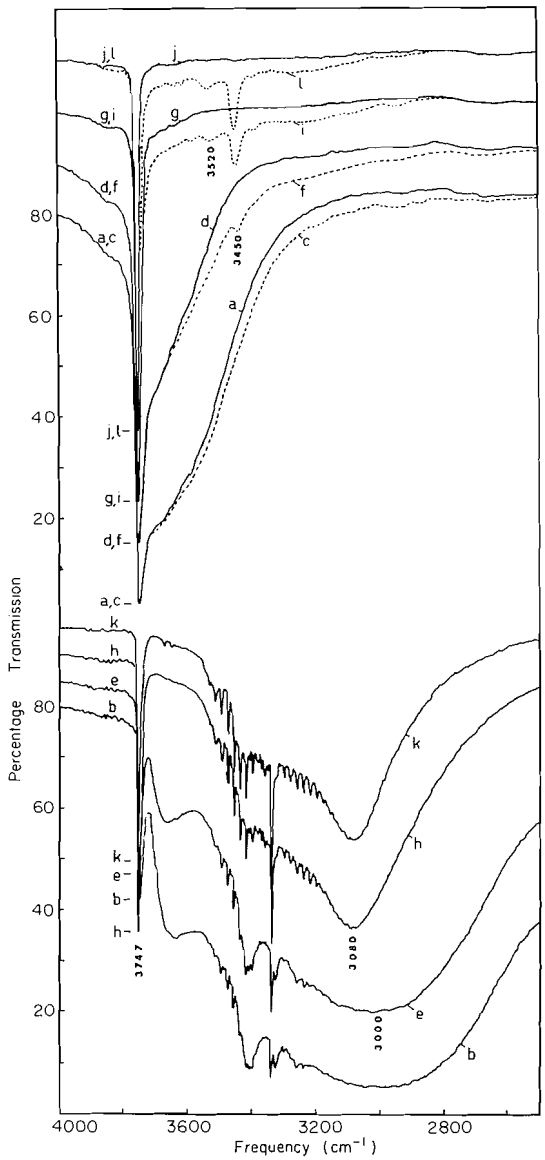

FIG. 3. The infrared spectrum of Cab-O-Sil M-5 silica: *a*, evacuated at 200 °C; *b*, after the addition of 70 Torr of ammonia; *c*, after evacuation at 20 °C; *d*, sample evacuated at 400 °C; *e*, after addition of 70 Torr of ammonia; *f*, after evacuation at 20 °C; *g*, sample evacuated at 600 °C; *h*, after addition of 70 Torr of ammonia; *i*, after evacuation at 20 °C; *j*, sample evacuated at 750 °C; *k*, after addition of 70 Torr of ammonia; *l*, after evacuation at 20 °C.

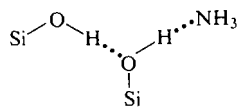
For temperatures of evacuation up to 600 °C, the intensity of the band at 3747 cm^{-1} in the spectrum of a silica sample is almost constant (Fig. 3*a*, *d*, *g*) suggesting that the number of sites for physical adsorption of ammonia mole-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

cules should be approximately the same after evacuation at any temperature in this range. However, when 70 Torr of ammonia was admitted to a sample of silica which had been dried at 200, 400, or 600 °C (Fig. 3*b*, *e*, *h*), the concentration of physically adsorbed ammonia decreased as the evacuation pre-treatment temperature increased. On a sample evacuated at 200 °C (Fig. 3*b*) bands at 3400 and 3320 cm^{-1} due to N—H vibrations and at approximately 2980 cm^{-1} due to O—H vibrations of the O—H···NH_3 groups are very intense. The corresponding decrease in the intensity of the isolated hydroxyl band is also large. The low frequency of the O—H stretching band at 2980 cm^{-1} suggests that the average strength of hydrogen bonds which are formed is large.

There was less adsorption when 70 Torr of ammonia was admitted to the same sample after evacuation at 400 °C and the hydrogen bonded O—H stretching frequency increased to 3000 cm^{-1}. After evacuation at 600 °C, the sample physically adsorbed even less ammonia (Fig. 3*h*) and these adsorbed molecules were less strongly held (the O—H stretching frequency shifted to 3080 cm^{-1}). The band at 3747 cm^{-1}, due to free hydroxyls not interacting with ammonia, was greater than after ammonia adsorption on the sample evacuated at lower temperatures. Many of the hydroxyl groups which adsorbed ammonia molecules in these previous cases will no longer act as physical adsorption sites. The adsorption of ammonia on the sample after evacuation at 750 °C (Fig. 3*k*) was even less but the initial concentration of free hydroxyl groups had also decreased (Fig. 3*j*).

These results suggest that the preferred site for the physical adsorption of ammonia is the hydroxyl group which is illustrated in **1**. A similar conclusion has been reached previously (24).



1

This is a group which is free to bond to ammonia molecules but is also involved in bonding to adjacent groups. The O—H bond will vibrate freely so will have a stretching frequency at approximately 3747 cm^{-1} but the oxygen of the group is bound to an adjacent hydroxyl group (which would have an O—H stretching frequency at 3650 cm^{-1}). The free hydrogen on this group may be expected to be somewhat more electropositive than that on a completely isolated hydroxyl group. The adjacent hydrogen bond (**1**) would induce the removal of electron density from the free hydrogen, although possibly not sufficiently to greatly alter the O—H stretching frequency (McDonald reported that a weakly perturbed hydroxyl having a stretching frequency at 3740 cm^{-1} existed on the surface of evacuated Cab-O-Sil). Ammonia molecules adsorbed to such a hydrogen would be somewhat more strongly held than molecules on completely isolated hydroxyls.

The concentration of these electropositive groups is reduced as the temperature of evacuation of the silica is increased and very few of these groups exist after evacuation at 600 °C (the shoulder at 3650 cm^{-1} is very weak for the spectrum of silica evacuated at this temperature (Fig. 3*g*)). The only hydroxyl adsorption site which remains is one which is completely isolated from its neighbors and not subject to perturbation by adjacent hydroxyl groups. Ammonia adsorbed to such a group will be less strongly bound and the O—H stretching frequency for the O—H···NH_3 group shifts to 3080 cm^{-1}.

The intensity changes of the band due to the free hydroxyl groups which remain at 3747 cm^{-1} after adsorption of ammonia (compare Figs. 3*b*, *e*, and *h*) suggests that less of the free hydroxyls on the silica act as adsorption sites when the sample has been evacuated at 600 °C than after evacuation at 400 °C and 200 °C when many of these groups would have been weakly perturbed, existing as hydroxyl pairs (**1**).

To a sample of silica evacuated at 800 °C, 20 Torr of water vapor was added and then evacuated at 20 °C. When ammonia was admitted to this sample, the gas was physically adsorbed to the surface hydroxyl groups but could be all removed by evacuation at 20 °C and the spectrum returned to its original contour. The rehydroxylated silica surface no longer contained sites which could chemisorb ammonia. However, when water vapor was added to a sample of silica having Si—NH_2 groups on its surface (Fig. 1*g*), the water was chemisorbed to form the hydroxyl groups with bands at 3720 and 3520 cm^{-1} and the adsorbed water did not displace any of the Si—NH_2 groups. Evacuation at 300 °C removed most of the newly

formed hydroxyl groups, leaving in the spectrum a band due to the weakly hydrogen bonded hydroxyls at 3650 cm^{-1} as well as bands due to Si—NH_2 groups and isolated hydroxyl groups. Thus the adsorption of water can still take place in the presence of amine groups on the silica surface whereas chemisorption of ammonia as Si—NH_2 groups is blocked by pre-adsorption of water vapor. It is probable that both water and ammonia react with the same type of sites of dehydroxylated silica but water can also react with sites which are not involved in chemisorption of ammonia.

Thanks are due to Mr. P. Bannister of the Department of Geology for the X-ray fluorescence analyses. Financial assistance from the Australian Research Grants Committee is gratefully acknowledged.

Received October 23, 1972

The carbon-13 magnetic resonance spectra of the diastereoisomers of 1,2-dimethyl- (**1**) and 1,3-dimethyl-4-phenylpiperidin-4-ol (**2**), their esters and corresponding hydrochlorides have been determined. The observed chemical shifts can be ascribed to charge polarization or steric effects. The latter is particularly important in establishing the *axial* configuration of the 4-phenyl group and 3-methyl group in the preferred conformations of α-**1** and β-**2**, respectively, and consequently the stereochemistry of these systems. Substituent additivity effects are similar to those in the piperidones and cyclohexanes. Solvent effects on ^{13}C resonances remove the ambiguities of conformational change suggested in earlier proton studies.

Le spectres de résonance magnétique du ^{13}C sur les diastéréoisomères du diméthyl-1,2 (**1**) et diméthyl-1,3 phényl-4 pipéridinol-4 (**2**), leurs esters et les chlorhydrates correspondants ont été mesurés. Les déplacements chimiques observés peuvent être imputés à la polarisation de charge et aux effets stériques. Ce dernier est particulièrement important dans l'attribution de la configuration *axiale* du groupe phényl-4 et du groupe méthyl-3 des conformations préférentielles de l'α-**1** et β-**2** respectivement et par conséquent, de la stéréochimie de ces systèmes. Les effets d'additivité des substituants sont semblables à ceux des pipéridones et cyclohexanes. Les effets de solvant sur les résonances du ^{13}C lèvent les ambiguités sur le changement conformationel suggéré par les études antérieures concernant le proton.

Can. J. Chem., **51**, 1782 (1973)

Several recent studies (1–7) have demonstrated the value of carbon-13 magnetic resonance (c.m.r.) as a tool in conformational analysis. The empirical substituent parameters derived in carbocyclic (1, 2) and heterocyclic (3–7) systems provide a mechanism to study not only substitution effects but also details of stereochemistry. In the present work the emphasis is placed on the application of the c.m.r. method in the structural analysis of a series of 4-phenyl-piperidine derivatives, some of which are pharmacologically active.

The potential of the c.m.r. method for stereochemical analysis of pharmacologically active molecules has been outlined in a study of synthetic precursors, the *N*-alkyl-4-piperidones (6). The derivatives, 1,2-dimethyl-4-phenyl-piperidin-4-ol (**1**) and 1,3-dimethyl-4-phenylpiperidin-4-ol (the prodinols, **2***a*) and their corresponding propionate esters (the prodines **2***b*) are the subject of the present work. There are two racemic diastereoisomers of **1** and **2**, which have been designated α- and β-isomers.[3] The stereochemistry of the alcohols **1** (8) and **2**a (9) and corresponding propionate esters (8, 10) has been the subject of considerable investigation and is well established (8–10). The present carbon-13 results confirm the assigned stereochemistry in most cases, though there are interesting discrepancies where solvent effects are considered. From the data it is possible

to derive fundamental parameters relating to conformation, configuration, and solvation effects. Further applications of these data in the trimeperidine (or promedol, **3**) series are described in the paper to follow.

Experimental

Carbon-13 spectra were determined at 22.63 MHz in the Fourier mode using a Bruker HFX-90 spectrometer in conjunction with a Nicolet-1085, 20K memory, computer. The spectrometer features a deuterium lock system, a BSV-2 random noise (800 Hz bandwidth) proton decoupler, and a BSV-2 pulse-generator-amplifier. The majority of compounds studied were freshly prepared by methods previously described (8–10). Spectra of all the bases and their corresponding hydrochlorides were determined for solutions in deuterochloroform (which also provided the lock signal) with 2–5% TMS added as internal reference. In the study of solvent effects or where solubility inhibited the use of $CDCl_3$, dimethylsulfoxide-d_6 and/or heavy water were used as solvents. In these cases a mixture containing dioxane and TMS was added as reference. All samples were contained in precision ground 10 mm, o.d., tubes (Wilmad Glass Co.). The spectrometer was used in the cross-coil configuration. On average a 30 μs pulse, corresponding to an approximate tilt angle of 45°, was employed. For the average spectral width of 5000 Hz the delay between pulses was 70 μs. Acquisition times averaged 1–2 h over 8K data points for concentrations of the order of 0.1–0.5 *M*. For off-resonance or coupled spectra this time was approximately doubled.

Results

The conventional labelling system for the piperidine ring (see **1**) is employed throughout this work. Carbon atoms in substituents are identified by a prime symbol on the number appropriate to the position of substitution on the piperidine ring. Phenyl ring carbons are labelled C-q, -*o*, -*m*, and -*p* to indicate the positions C-1, -2,6, -3,5, and -4 on the phenyl ring, respectively. The carbon-13 shifts of the series of α- and β-isomers and their hydrochlorides are given in Tables 1 and 2, respectively. Supporting data on 1-methyl-, 1-methyl-4-phenylpiperidine, 1-methyl-4-phenyl- and 1,2,6-trimethyl-4-phenylpiperidin-4-ol are given in Table 3. The procedure for assigning individual resonances to the appropriate carbon atom has been described in detail elsewhere (6, 11). In most cases assignments were made in a relatively routine and straightforward manner, though ambiguities do remain in the distinction between the ortho- and meta-carbons in all cases. The constant trends observed in the carbon-13 resonances on protonation (6) also served to confirm some of the piperidine ring carbon assignments.

Discussion

It is well established that most simple piperidines undergo rapid chair-to-chair interconversion involving nitrogen inversion (12). The carbon-13 chemical shifts must, therefore, be recognized as weighted averages of these interconverting forms. It is probable that the relatively bulky 4-phenyl substituent in most of the compounds studied in the present work will provide a barrier to this interconversion. We are, therefore, primarily concerned with the measurement of the carbon-13 shifts of the predominant conformer. Previous p.m.r. studies (9, 10) on some of the 4-phenylpiperidine derivatives considered here have suggested that the solvent may induce changes not only in the equilibrium of the interconversion but also give rise to conformational change. We have also investigated these solvent effects. For convenience we first consider the chemical shift effects induced by changes in substituents and their configuration and later the solvent effects.

Chemical Shift Additivity

Figure 1 summarizes schematically the carbon-13 chemical shifts of the piperidine ring carbon atoms in some of the bases studied for solutions in deuterochloroform. Substituent parameters for the directly bonded carbon atom C_α and subsequent carbons C_β, C_γ are summarized in Table 4. As shown in the studies on the *N*-alkyl-4-piperidones (6) these parameters are attenuated relative to those of the cyclohexanes (1, 2). Differences in the effects of equatorial compared with axial substituents are similar to those noted in the cyclohexanes (1, 2). The significance of the γ-parameter is clearly important in cases where 1,3-*syn*-axial interactions occur, otherwise most of the effects can be ascribed to charge polarization (13). The γ-effect at C-5 (7.9 p.p.m. upfield) in the β-1,3-dimethyl isomer (β-prodinol) establishes its configuration compared with the α-form. In contrast, the lower field shift of the C-3′ methyl resonances in the β-isomers (16 p.p.m., compared with 12 p.p.m. in the α-isomers) is attributed to the deshielding effect of the nitrogen lone pair or that of the hydroxyl group (compare the oxygen effect for an axial C-5 substituent in the 1,3-dioxanes (4)) which overides the γ-effect with C-5.

In 1,2,6 - trimethyl - 4 - phenylpiperidin - 4 - ol (Table 3) either the 2- or 6-methyl group must be axial. There is a sharp contrast between the equatorial (19.9 p.p.m.) and axial (13.5 p.p.m.)

methyl shifts in this compound. Further, the γ-effect of the axial C-2′ methyl group is evidenced at C-6 (upfield 4.4 p.p.m.). There is, however, a surprising downfield shift (3.3 p.p.m.) at C-4, compared with 1-methyl-4-phenylpiperidin-4-ol. In the 1,2-dimethyl- α- and β-compounds, relatively small shift differences are observed. In particular, the C-2′ methyl shifts (19.5 and 20.3 p.p.m.) indicate this group is equatorial in both isomers. Further, the shifts at the γ-positions C-4 and -6 are relatively unchanged. These observations suggest that the configurational differences between the 1,2-dimethyl isomers must occur at C-4. The high field shift of the phenyl ring carbon C-q in the α-isomer (upfield 3.8 p.p.m. relative to the β-isomer) is taken as indicative of the axial configuration for the phenyl group. The absence of appreciable γ-shifts at C-2 or -6 in the α-, compared to the β-isomer, suggests distortion of the ring to accommodate the bulky phenyl group at the C-4 position. These results are in agreement with the conformations determined from p.m.r. measurements (8). The importance of steric effects are also evidenced in the ortho-tolyl derivative (Table 1) in which the ring carbons C-3,5 are shifted upfield (2.3 p.p.m.) compared with α-1,3-dimethyl-4-phenylpiperidin-4-ol or the corresponding *p*-tolyl derivative (Table 1).

As indicated in Fig. 1 the steric effects at C-5 in the active analgesic β-prodine (Table 2) are similar (upfield 10.2 p.p.m. compared with 1-methyl-4-phenylpiperidin-4-ol) to those in the corresponding alcohol (7.9 p.p.m.). However, the contrast at C-5 between the α- and β-isomer is still evident, though less marked, in the esters since the ester function does induce a significant upfield shift (8.9 p.p.m.) at this position in α-prodine, compared with α-prodinol. From inspection of Dreiding models it is apparent that the shift at C-5 will be determined by the orientation of the ester and phenyl groups in these systems. In the α-ester the carbonyl double bond orientation is most favored when this group is equidistant from C-5 and -q, which corresponds to a shielding zone for these carbon atoms. The phenyl ring is also at an approximate right angle to the plane of the piperidine ring. In the β-ester an alternative orientation of the ester and phenyl groups is indicated since the steric interaction of the phenyl ring with the C-3 methyl group is removed thus permitting rotation of the phenyl ring into the plane of the piperidine system. That the upfield shifts at C-5 and -q are not steric in origin is indicated by the similar shift of the carbonyl groups (172.3 and 172.6 p.p.m.) in the α- and β-ester isomers, respectively. With the exception of C-4 (β-substituent effect downfield 9.7 p.p.m., compared with the corresponding alcohols) all other ring carbons shift upfield in the esters. The magnitude of these shifts is, in general, larger in the α- than in the β-isomer, a feature which is tentatively attributed to greater steric interactions or shielding effects arising from the C-4 substituent groups and the ring carbons in the less flexible α-isomer.

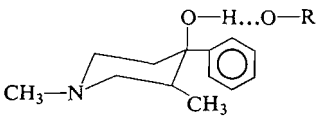
The shifts induced on protonation of the nitrogen correlate reasonably well with those expected on the basis of additivity effects (6). Average α-, β-, and γ-protonation parameters derived for deuterochloroform solutions are given in Table 4. An additional parameter, which we designate $RNH_{C-\delta}{}^{+}$, was derived from the upfield shift at C-q in the phenyl ring and has a value 2.5 p.p.m. It is assumed this shift may be attributed to an electric field contribution analogous to that at C-4 (6), though its magnitude is larger than expected on the basis of a simple r^{-3} dependence.[4]

[4]NOTE ADDED IN PROOF: The recent report of Morishima *et al.* (16) leads us to suggest that C—C or C—H bond polarization might account for these long-range protonation effects.

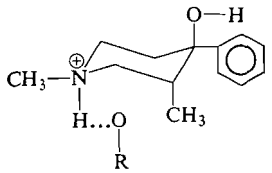
Solvent Effects

Earlier p.m.r. studies (9, 10) on the α- and β-1,3-dimethyl-4-phenylpiperidin-4-ols, their esters and corresponding hydrochlorides indicated that the solvent could determine the conformational preference of the axial 3-methyl conformer in the β-hydrochlorides. High skew-boat populations were postulated for the β-hydrochlorides in polar media in order that the 1,3-*syn*-axial interactions between the $CH_3—\overset{\oplus}{N}—H$ and 3-methyl group be minimized (9, 10). The carbon-13 shifts determined under similar conditions are insufficiently consistent to enable generalizations concerning induced solvent shifts to be made. However, it is reasonably clear that the more polar solvent does induce some ring distortion in β-prodinol hydrochloride but the shifts do not appear to demand contributions from skew-boat conformations.[5]

The shifts induced on changing solvent from deuterochloroform to one more polar are significantly upfield (*ca.* 1.0 p.p.m.) at C-2, -4, -6, and -1′ in α-prodinol, at C-5 in β-prodinol, at C-5 and -3′ in β-prodinol hydrochloride, and at C-3 and -3′ in β-prodine hydrochloride. All other shifts do not change substantially outside the usually accepted solvent effect limit (0.5 p.p.m.) (4, 6). It is probable that the shifts in α-prodinol may be accounted for in terms of a collision complex of the type **4**, which is stabilized by hydrogen-bonding with the solvent (6, 14). The increased steric bulk of the group about C-4 will



4



5

[5]It is anticipated that skew-boat or boat conformations would induce upfield shifts, in particular at C-1′ and -4, the consequence of "flagpole" interactions. To the authors' knowledge no parameter for this effect has been determined but it is intuitively expected to be of similar order to that of the 1,3-*syn*-axial term.

result in greater steric-compression at C-2 and -6. It is not clear why a similar effect is not observed in β-prodinol, but in the α-ester derivatives this type (**4**) of H-bonding is not possible. The shifts observed in the β-isomers, however, may be explained by a change in the center of solvation as indicated in **5**. The increased steric-bulk of the solvent-associated nitrogen center increases the steric-compression at C-3, -3′, and -5 and consequently upfield shifts are observed at these sites. Similarly, in the α-hydrochloride we suggest the nitrogen atom as the center of solvation, thus removing the C-4 effects noted for the bases.

We hesitate to draw generalizations based on the above evidence. However, we do suggest, in contrast with the proton data, that in the β-hydrochlorides some distortions from the regular chair conformations (in $CDCl_3$) are probable in polar media but that contributions from skew-boat conformers are negligible.

Conclusions

The empirical substituent parameters derived in the present work add to the generalization that carbon-13 substituent shifts are reasonably transferable from the cyclohexanes to other more complex systems. The determination of stereochemistry is clearly within the reach of carbon-13 magnetic resonance measurements even where solvent effects may induce distortions in the regular conformation.

Received November 22, 1972

The carbon-13 magnetic resonance spectra of three diastereoisomers of 1,2,5-trimethyl-4-phenylpiperidin-4-ol and their esters and corresponding hydrochlorides have been determined in deuterochloroform and/or dimethylsulfoxide-d_6. Chemical shifts observed support the configurations *t*-2-Me, *c*-5-Me (γ), *c*-2-Me, *t*-5-Me (β), and *c*-2-Me, *c*-5-Me, *r*-4-OH (α) for the isomers specified in parentheses. Chair conformations are preferred for γ (eq-Ph) and β (ax-Ph) piperidinols while the α-form favors a skew-boat. Evidence is presented for conformational changes in the α- and β-forms after *N*-protonation. The γ- and β-esters have conformations similar to the parent 4-piperidinols while the α-acetate base and hydrochloride prefer chair conformations but with different 4-phenyl orientations (base ax-Ph, HCl eq-Ph).

On a déterminé dans le deutérochloroforme et/ou dans le sulfoxyde de diméthyle les spectres en résonance magnétique du carbone-13 de trois diastéréoisomères du triméthyl-1,2,5, phényl-4 piperidinol-4 ainsi que les esters et les chlorhydrates correspondants. Les déplacements chimiques observés ont confirmé les configurations Me-2-*t*, Me-5-*c* (γ), Me-2-*c*, Me-5-*t* (β), et Me-2-*c*, Me-5-*c*, OH-4-*r* (α) pour les isomères indiqués entre les parenthèses. Les pipéridinols γ (Ph-eq) et β (Ph-ax) possèdent préférentiellement une conformation du type chaise alors que la forme α possède une conformation du type bateau-croisé. Les changements conformationnels dans les formes α et β après protonation de l'azote ont été mis en évidence. Les esters γ et β possèdent des conformations similaires aux pipéridinols-4 parents alors que la base et le chlorhydrate de l'α-acétate préfèrent une conformation du type chaise mais avec des orientations différentes du groupe phényl-4 (base Ph-ax, HCl Ph-eq).

Stereochemical studies on narcotic analgesics have been primarily concerned with the determination of stereostructural–activity relationships in order to provide greater insight into the nature of analgesic–receptor interaction. (1) In previous papers (2–4) we have illustrated the potential of the carbon-13 magnetic resonance technique as a tool in the determination of stereochemistry in analgesics. Empirical substituent parameters have been derived from carbon-13 studies of a series of substituted 4-piperidones (2) and 4-phenylpiperidines (3, 4) of pharmacological interest. The parameters have been related to charge polarization (5) or steric (6) effects and correlate reasonably well with the known stereochemistry of the systems. The most valuable of these fundamental parameters is that arising from the steric compression caused by 1,3-*syn*-axial interactions (the γ-effect) (6). In the prodinols (**1***a*) and prodines (**1***b*) this factor was particularly evident in the observed upfield shift of C-5 in the β-isomers in which the C-3′ methyl group is axial, and enabled confirmation of the stereochemistry of these systems suggested by other techniques (7).

Conflicting evidence about the stereochemistry of the narcotic analgesic trimeperidine (promedol **2***a*) and its isomers, in addition to their precursor 1,2,5-trimethyl-4-phenylpiperidin-4-ols (**2***b*) (8–13) prompted the present study.[3] A preliminary account of some of the results has been presented (3). However, in the present paper we describe a modified stereochemistry for the α-alcohol isomer which enables total reconciliation with earlier p.m.r. studies (12). In addi-

tion, the carbon-13 shifts of the stereoisomeric esters are described.

Experimental

Carbon-13 spectra were determined in the Fourier mode using a Bruker HFX-90 spectrometer as described in the preceding paper (4). All compounds were prepared and purified by methods previously described (12, 13), and were dissolved in deuterochloroform. Tetramethylsilane was used as internal reference. For the epimeric hydrochlorides the solvent was changed to dimethylsulfoxide-d_6 in which dioxane–TMS was used as reference.

Results

The numbering system employed and assignment techniques have been described previously (4). Table 1 provides a summary of the carbon-13 chemical shifts of the promedol alcohol isomers (**2***b*) and their hydrochlorides. Similar data for their corresponding esters (promedols, **2***a*) is given in Table 2. For the α-isomer of the latter both the propionate and acetate esters were studied. The difference in shifts induced by these substituents was negligible except at the position of substitution and consequently acetate and propionate esters are compared together. Figure 1 summarizes these data.

It should be noted that the hydrochlorides of the β-isomers provide an epimeric mixture. These mixtures were investigated by changing solvent and temperature conditions in order to resolve an appropriate assignment as given in the tables.

Discussion

Evidence of configuration and solute conformation of the isomers (**2**) is based upon an analysis of their carbon-13 spectra aided by data from the previously studied 3-methyl analogs (**1**) of established stereochemistry (4). Thus, since it has been shown that the piperidine ring adopts a chair conformation with the 4-phenyl substituent equatorial in α- and β-prodinol (**1**) (4), we initially adopt this configuration in the promedol series (**2**). Similarly the characteristic carbon-13 shifts determined for equatorial and axial C-2′ (19.9 and 13.5 p.p.m., respectively) (4) and C-3′ (or C-5′) (12.3 and 16.3 p.p.m., respectively) (4) methyl carbons may be used to help determine the orientation of the methyl substituents in the present compounds. It is convenient to analyze the present data for (*a*) the alcohols (**2***b*), Table 1; (*b*) the corresponding esters (**2***a*), Table 2; and (*c*) their salts, Tables 1 and 2.

(a) The Alcohols

In the most abundant γ-isomer of 1,2,5-trimethyl-4-phenylpiperidin-4-ol (γ-**2***b*), the methyl carbon shifts (20.2 and 12.0 p.p.m.) are characteristic of equatorial methyl groups at C-2 and -5 respectively. The phenyl ring carbon shifts, in particular at C-q and -4, are characteristic of a C-3 (or C-5) substituted piperidine ring with the phenyl group equatorial (compare α-prodinol) (4). All other carbon shifts in this isomer agree with the configuration *t*-2-Me, *c*-5-Me, *r*-4-OH,

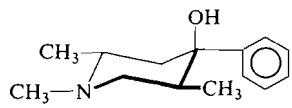
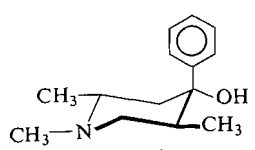
and the preferred conformation (**3**) for the solution of γ-**2***b* in deuterochloroform, also assigned on the basis of the p.m.r. results (12). The same stereochemistry has been shown to be true for γ-**2***b* in the solid state (14).



3

The methyl carbon shifts in the spectrum of the β-**2***b* isomer (20.7 and 14.5 p.p.m.) might lead to the suggestion that C-2′ is equatorial and C-5′ axial (or near axial, compare the characteristic C-3′ axial shift 16.3 p.p.m.) (4). However, no concomitant γ-effects are noted at sites across the piperidine ring at C-3. The carbon shifts at C-3 (42.6 p.p.m.) and -6 (60.5 p.p.m.) are very similar to those noted in the γ-**2***b* isomer (42.8 and 60.1 p.p.m.) and suggest that both the C-2 and -5 methyl groups are equatorial in β-**2***b*. Consequently it is the orientation of the phenyl ring which must change. The shift at C-q (144.9 p.p.m.) in β-**2***b* is similar to that in the α-isomer of 1,2-dimethyl-4-phenylpiperidin-4-ol (145.1 p.p.m.) in which the phenyl group is established as having the axial configuration (4). This shift is also upfield (2.4 p.p.m.), compared to that in the γ- or α-**2***b* isomers. The absence of appreciable 1,3-*syn*-axial effects at C-2 and -6 in β-**2***b* was also noted in the α-isomer of 1,2-dimethyl-4-phenylpiperidin-4-ol (4). These observations emphasize that the steric interaction of the axial phenyl group is minimal at C-2 and -6 (15). It is probable that the orientation of the axial phenyl group determines the deshielding shifts at C-5 and -5′, (*ca.* 3 p.p.m.) compared with those in the γ-isomer. Similar deshielding effects at the 5′-methyl group are apparent in the p.m.r. spectrum of β-**2***b* (12). The conformation **4** is thus preferred by the β-**2***b* isomer in deuterochloroform solution. This stereochemistry is also found in the solid state (14).

The assignment of the preferred conformation in the α-**2***b* isomer rests primarily on the presence



4

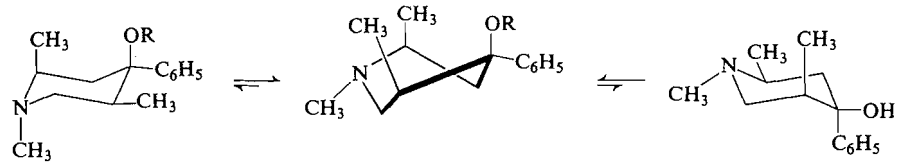
For personal use only.



5 6 7

or absence of upfield shifts induced by potential 1,3-*syn*-axial interactions. The proton and carbon-13 data must be reconciled in this case. The methyl resonances in α-**2***b* are observed at 13.0 and 15.0 p.p.m. The higher field line of this pair must be assigned to an axial methyl group at C-2, since not only is the shift similar to that of the analogous carbon in 1,2,6-trimethyl-4-phenylpiperidin-4-ol (13.5 p.p.m.) (4), but also a concomitant *syn*-axial effect is observed at C-6 (upfield 5.5 p.p.m.), compared with the γ-**2***b* isomer. Surprisingly no major *syn*-axial effect is observed at C-4. In contrast, the equatorial configuration may be tentatively assigned to the methyl group at C-5 since no appreciable *syn*-axial effects are evidenced at C-3. The low field shift of this carbon (15.0 p.p.m.) does suggest a deshielding effect similar to that for the analogous position in β-**2***b*. The similarity in shifts for the phenyl ring carbons in γ- and α-**2***b* provides evidence for the equatorial configuration of the phenyl group in these isomers. Most significant is the upfield shift of the *N*-methyl group C-1′ (4.0 p.p.m.), compared with γ-**2***b*. It is possible to account for this upfield shift if the *N*-methyl group adopts the axial configuration, though no appreciable 1,3-*syn*-axial effects are noted at C-3 or -5.[4] The above data suggest that a contributing form to the structure of α-**2***b* is that shown in **5** (R = H). However, this structure does not account for the deshielding effect noted at C-5′ in the carbon-13 spectrum or the larger of the two $^3J_{HH}$ coupling constants of the 3-methylene protons (4.5 and 6.0 Hz, $CDCl_3$) (12). The conformation that best accommodates these data is the skew-boat **6** (R = H). The C-5′ methyl group in this case would be deshielded by the nitrogen lone pair, while the $^3J_{HH}$ value is appropriately increased from the low value expected in the perfect chair conformer **5**. A third conformation **7** (R = H) cannot be excluded as a contributor to this equilibrium, though the carbon-13 data do suggest that the preferred conformation of α-**2***b* in deuterochloroform solution is **6** (R = H) with high contributions from the form **5** (R = H). It should be noted that the carbon-13 data on the hydrochloride of α-**2***b* suggest the chair conformer **5** (protonated) as the most preferred, the C-q and -5′ shifts being typical of equatorial and the C-2′ shift being typical of axial environments. The high field C-1′ shift (41.9 p.p.m.) supports contributions from the axial configuration of this group.

(b) The Esters

The introduction of the relatively bulky ester function to the C-4 position of the piperidine ring might be expected to alter the relative proportions of the two major contributing chair conformations in the esters, compared with their precursor alcohols. However, if it is assumed that the free energy values for the OH and OCOR groups in the present systems are similar (16) then it is expected that the esters will adopt the same preferred conformation as that of the corresponding alcohol. The validity of this assumption was verified for the propionate esters of α- and β-prodinol described in the preceding paper (4). It was noted (4) that the ring carbon shifts in the esters were strongly influenced by the orientation of the ester and phenyl functions. Thus the complexity of possible factors contributing to the carbon-13 shifts of the esters make it extremely difficult to analyze the data in detail. However, the shifts apparently confirm the general premise that the esters adopt similar preferred conformations to those of the corresponding alcohols.

As in the case of the α- and β-prodines (4) substantial changes are noted at most carbon sites in the esters (**2***a*) compared with their corresponding alcohols (**2***b*). The downfield shift at C-4 in all the esters, compared with the alcohols, is attributed to the β-ester substituent effect (9.7 p.p.m. for propionate (4) and 6.7 p.p.m. for acetate). Comparison of acetates and pro-

[4]Inversion at the nitrogen center is usually considered to remove the possibility of the axial configuration in *N*-alkyl piperidines. However, similar high field shifts of *N*-methyl carbons are noted for the axial *N*-methyl group in the frozen conformation of tropinone (−100°) (A. J. Jones, to be published).

8

pionates in all other respects is considered reasonable since shifts in these esters of α-**2***a* are within 0.1 to 0.3 p.p.m. at all ring carbons sites. Based on earlier p.m.r. studies (13) a structural analogy is expected between the ester γ-**2***a* and α-prodine (**1***b*) (4). With the exception of C-5 (upfield 1.8 p.p.m.) the shifts in γ-**2***a* and α-**1***b*, compared with their corresponding alcohols, are of the same order though they differ in magnitude. It seems probable that the complex shielding contributions at C-5 in α-**1***b* (4) could change to deshielding by simple rotations of the groups at C-4 in γ-**2***a*. However, that these shift effects are induced by the equatorial 2-methyl substituent in γ-**2***a*, compared with α-**1***b* is difficult to reconcile. The lower magnitude of the shift at C-q (upfield 5.3 p.p.m.) in γ-**2***a*, compared with α-**1***b* (upfield 8.0 p.p.m.) might be the result of a rotation of the carbonyl function away from C-q towards C-5, thus changing the position of C-5 from a shielded to a deshielded zone. Further studies are necessary to establish these effects.

The ester β-**2***a* also exhibits some unexpected shifts. The high field shift at C-q (139.5 p.p.m.) in β-**2***a*, compared with γ-**2***a* (C-q 141.9 p.p.m.), suggests retention of the axial configuration for the phenyl group on esterification. The ester function, therefore, is equatorial. Similar ester induced shielding effects to those in α-prodine (4) are observed at C-q (upfield 5.4 p.p.m.) and -3 (analogous to C-5) (upfield 1.6 p.p.m. at C-3 or 5.7 at C-5) in β-**2***a*, compared to β-**2***b*. However, it is apparent that in order to reconcile the upfield shifts at C-2′ (5.0 p.p.m.) and -6 (5.8 p.p.m.) contributions from the alternative chair or skew-boat conformers as in **8** (R = COMe) must be considered. That is, an analogy with the effects observed in the α-**2***b* alcohol is expected. It seems probable, therefore, that the preferred conformation of the β-ester (**2***a*) is best represented by the equilibrium shown in **8**, which is weighted towards the left hand side and, therefore, has a similar conformational equilibrium to that of the corresponding alcohol.

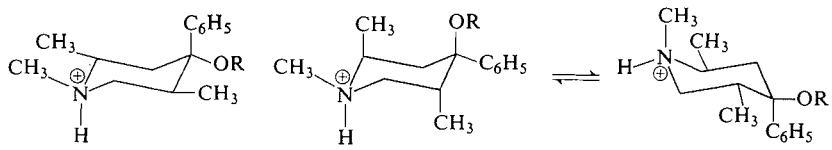
Introduction of the bulky ester substituent to the alcohol α-**2***b* might be expected to shift the equilibrium represented by **5**, **6**, and **7** towards **7** (R = COMe), in order to avoid the steric interaction between the axial C-2 methyl and C-4 ester groups in **5**. The similarity in the quaternary carbon shift in α-**2***a* and that in β-**2***a* is indicative of contributions from an axial phenyl configuration. In addition, the upfield shift of the methyl resonance attributable to C-5′ (3.0 p.p.m., compared with the alcohol) suggests contributions from an axial configuration for this group. Thus, the preferred conformation of the α-**2***a* ester is most satisfactorily represented by an average of the conformers **6** and **7** (R = COMe), weighted towards the conformer **7**, as also suggested by the p.m.r. data (13).

Detailed analysis of the carbon-13 shifts in the ester (**2***a*) derivatives is clearly marred by the difficulty in abstracting the effects induced by substitution of the ester function. A knowledge of the conformation of the precursor alcohols can clearly assist in the interpretation of data for the esters. In addition, the similarities observed on protonation (Section *c* to follow) of the alcohols and the esters provides further indication of conformational similarities. However, the assumption that the free energy values for OH and OCOR groups are similar is not completely valid in the present cases. Clearly, further studies of the complex shielding contributions to carbon-13 chemical shifts induced by such anisotropic groups as the ester function are desirable.

(c) The Hydrochlorides

Protonation of the nitrogen atom in the alcohols and esters (Tables 1 and 2) results in upfield shifts at all piperidine ring carbons with the exception of C-2 which as predicted (2) shifts downfield. Average α-, β-, γ-, and δ- (4) protonation parameters are reasonably close to those observed in earlier studies (2, 4). Of particular significance is the fact that the β-isomers produce epimeric mixtures. The shifts of the epimers were assigned from studies of the compositional changes induced on changing the solvent from deuterochloroform to dimethylsulfoxide-d_6. The structures **9** and **10** are suggested for the major and minor β-epimers in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.



9 10*a* 10*b*

DMSO-d_6 solvent, respectively. The structure of the major epimer **9** is established by the expected upfield shifts induced by protonation of the β-alcohol and ester bases. The equilibrium suggested in **10** is required for the minor isomer in order to account for the typical equatorial phenyl C-q shift 145.1 p.p.m., compared with 145 p.p.m. in the γ- and α-**2***b* hydrochlorides. The large upfield shift at C-1′ (12.3 p.p.m.) in the minor isomer, compared with the base, is attributed to 1,3-*syn*-axial contributions in the conformer **10***b*. Further, the additional upfield shift at C-2′ in the minor epimer, compared to the major, must arise from the 1,3-*syn*-axial interaction with C-6 in **10***a*, while the downfield shift (1.5 p.p.m.) at C-5′ in the minor isomer must be the result of possible deshielding by the phenyl ring in **10***b* (*cf.* α-**2***b*). Similar shift effects are observed in the epimeric hydrochlorides of the β-ester (**2***a*) thus confirming the conformational similarity of this isomer with that of the corresponding alcohol.

It is particularly noteworthy that the conformations of the alcohols and esters which we have established as having an axial phenyl group, including α-1,2-dimethyl-4-phenylpiperidin-4-ol (4), produce an epimeric mixture on protonation. This observation suggests that the conformational strain induced by the axial phenyl substituent is such that a conformational change is readily induced on protonation. The formation of an epimeric mixture of hydrochlorides might, therefore, be considered indicative of the axial phenyl configuration in the preferred conformation of the basic forms of piperidine derivatives.

From the p.m.r. studies (12, 13) there is clear evidence that the ester α-**2***a* changes its preferred conformation on protonation. The carbon-13 data similarly reflect a change in the equilibrium suggested in **5**, **6**, and **7** (R = COMe). In particular, the shifts at the phenyl ring carbon C-q (139.4 p.p.m.) and the C-5′ methyl group (11.3 p.p.m.) are also identical with those in the γ-**2***a* hydrochloride, 139.1 and 11.6 p.p.m., respectively. The equatorial configuration is, therefore, favored for these two groups. Consequently the weighting of the conformation (**5**) is highly favored in the hydrochloride of α-**2***a*.

In conclusion, the carbon-13 chemical shifts have provided an excellent mechanism for determining details of structure in this series of relatively complex stereoisomers in solution. It is clear that the analysis of stereostructural–activity relationship in analgesics will gain much from the use of this spectroscopic technique.

We thank the National and Medical Research Councils of Canada for support.

^1H and ^{13}C Nuclear Magnetic Resonance Spectroscopy of Some Derivatives of Nitro Sugars

N. GURUDATA AND F. J. M. RAJABALEE[1]

Department of Chemistry, Sir George Williams University, Montreal 107, Quebec

Received November 27, 1972

Eight 2,3-dideoxy-2-amino-3-nitrosugar derivatives have been obtained by an elimination–addition reaction on the α and β anomers of methyl-4,6-*O*-benzylidene-3-deoxy-3-nitro-glucopyranoside-2-acetate. P.m.r. is used to show that the compounds exist in the CE conformation. ^{13}C.m.r. data are presented for three anomeric pairs. Trends in the C-13 chemical shifts are found to be similar to those reported in other studies of carbohydrates. Exceptions in direction and magnitude of chemical shift differences are discussed.

Huit dérivés de didéoxy-2,3 amino-2 nitro-3 sucres ont été obtenus par une réaction d'addition-élimination sur les anomères α et β de l'*O*-benzylidène-4,6 déoxy-3 nitro-3 glucopyranoside acétate-2 de méthyle. La r.m.n. a été utilisée pour montrer que les composés existent sous la conformation CE. Les données de la r.m.n. du ^{13}C ont été présentées pour trois couples d'anomères. Les tendances dans les déplacements chimiques du ^{13}C ont été trouvées comparables à celles rapportées par les autres études sur les hydrates de carbone. Les exceptions sur le sens et l'amplitude des différences dans les déplacements chimiques ont été discutées. [Traduit par le journal]

Can. J. Chem., 51, 1797 (1973)

Introduction

While direct interest in nitro sugars has intensified since the discovery of evernitrose (1), much of the investigation of these compounds has centered on their value as synthetic intermediates (2). In the present study, a number of 2,3-dideoxy-2-amino-3-nitrosugar derivatives have been obtained by a modification of the procedure reported by Baer and coworkers (3). First-order analysis of the p.m.r. parameters of the compounds is used to establish their configurations and conformations and trends in the C-13 spectral data are discussed.

Experimental

Compounds **2**–**5** and **7**–**10** were obtained by an elimination–addition reaction on the corresponding nitroacetates **1** and **6**. The procedure followed and the physical properties of the compounds are given elsewhere (4).

Nuclear Magnetic Resonance Spectroscopy

Proton n.m.r. spectra were obtained from 0.2 *M* solutions in $CDCl_3$ using a Varian HA-100 spectrometer in the "frequency sweep" mode. Carbon-13 spectra were obtained from 0.5 *M* solutions in $CDCl_3$ using a Varian XL-100 spectrometer in the FT mode with an external deuterium lock (D_2O) and with tetramethylsilane as internal reference. Spectra were obtained both in the "noise-decoupled" and "off-resonance decoupled" modes. Values for the ^{13}C chemical shifts are derived from the "noise-decoupled" spectra and the precision is estimated to be better than ±0.05 p.p.m.

Results and Discussion

Table I summarizes the first order p.m.r. data for the compounds. The size of the H-1, H-2 splitting in the α-series (2.90–3.75 Hz) shows that H-2 must be axial since H-1 is equatorial (5). The range 7.75–8.00 Hz for $J_{1,2}$ in the β-series is also consistent with H-2 (and H-1) in an axial orientation (6). The ratio of the axial–axial to the axial–equatorial splitting is in the

*± 0.05 Hz.
†n.a. = not assigned.

range 2–3 expected for a chair conformation. Both $J_{2,3}$ (10.25–11.60 Hz) and $J_{3,4}$ (9.56–10.50 Hz) are of the magnitude characteristic of axial–axial couplings and show that H-3 and -4 are axial. (In the α-series, $J_{2,3}$ and $J_{3,4}$ have been assigned on the basis that little change is expected on anomerization. For example, in the β-anomer, **10**, $J_{2,3}$ = 11.00 and $J_{3,4}$ = 10.50 Hz; for the α-anomer, values of 11.50 and 9.75 Hz are obtained. Since the former is closer to 11.00, it is assigned to $J_{2,3}$; $J_{3,4}$ is then 9.75 Hz. It should be noted that any ambiguity in the assignment of $J_{2,3}$ and $J_{3,4}$ does not affect the arguments presented.)

Taken together, the data indicate that the nitrosugar derivatives have the *gluco* configuration at C-2 and -3 and that the pyranose ring is in the CE conformation. This is consistent with the previous report (5) that the pyranoid part of methyl-4,6-*O*-benzylidene-α-D-aldopyranosides exists exclusively in the C1(D) conformation.

The absorption of the aromatic protons (δ = 7.33–7.35) appears insensitive to both changes of the substituent at C-2 and anomerization at C-1. With the exception of that of the β piperidinyl compound, **9**, all the benzylidene proton resonances lie in the range 5.51–5.52 p.p.m. from TMS. According to the recent observations of Baer and Rank (7), this is good evidence that there is no change of configuration at C-2 and -3 in the series of compounds examined. The deviation seen in **9** may be due to conformational changes necessitated by the steric requirements of the piperidine ring.

Axial *O*-methyl groups (δ = 3.38–3.43) absorb at higher field than the corresponding equatorial groups (δ = 3.49–3.54). The chemical shift difference shows some dependence on the C-2 substituent, being 0.09 p.p.m. for the pyrrolidinyl compounds and 0.15 p.p.m. for the piperidinyl analogues. Contributions to these substituent effects may arise from conformational changes (8) caused by the spatial requirements of the substituent as well as from direct intramolecular screening (magnetic, electrical, and van der Waals shieldings) (9). The relative shifts of the anomeric protons also depend on the C-2 substituent, Δδ varying from 0.32 to 0.53 p.p.m.

Assignment of C-13 Resonances

The aromatic quaternary carbon atom, C-1′, is easily recognized since it appears at lowest field (136.27–136.43 p.p.m. from TMS; see Table 2) and is a singlet in both the noise decoupled and off-resonance decoupled spectra. The other aromatic resonances are assigned on the basis of well established substituent shifts (10). Examination of the data reveals little sensitivity to either anomerization or to the substituent at C-2.

Comparison with literature data (11) for the parent amines allows assignment of the signals for the C-2 substituents (Table 3). Anomerization has little effect on these resonances.

Of the "sugar" resonances (Table 4), those of the methoxyl groups appear as quartets in the off-resonance decoupled spectra. In all cases, the axial OMe carbon absorbs at higher field. The chemical shift difference between the axial and equatorial groups at C-1 depends on the substituent at C-2. It is largest for the secondary amine group (**2**, **7**) while being of similar size for the two tertiary amine groups (**3**, **8**; **4**, **9**) examined.

Perlin and co-workers (12) found that, in methyl-D-glucopyranosides, the C-6 carbon of the α anomer absorbs at 0.2 p.p.m. *higher* field than that of the β anomer. In the present data, $\Delta\delta_{ae}$[2] is in the range 0.32–0.40 p.p.m. with the resonance for the α anomer consistently at *lower* field.

Evaluation of substituent effects in the cyclohexane system (13) showed that replacement of a hydroxyl group by a nitro group deshields the attached carbon atom by 14.6 p.p.m. Combining this with a chemical shift of 75.75 p.p.m. for C-3 in methyl-α-D-glucopyranoside (14) gives the basis for assigning the signals in the region of 90 p.p.m. to C-3 of the nitrosugar derivatives. Differences from the predicted value reflect the effects of the acetal ring and the C-2 substituent. The magnitude of $\Delta\delta_{ae}$ (1.43–2.94 p.p.m.) is similar to that obtained for the simple glycopyranosides (12). There is a clear dependence on the C-2 substituent since the observed value (12) for methyl-D-glucopyranosides is 1.6 p.p.m. with C-3 of the α anomer absorbing at higher field.

Neither the chemical shift values for C-5 (Table 4) nor the effect of anomerization (4.21–4.29 p.p.m. with the signal for the α anomer at higher field) shows much dependence on the C-2

[2]$\Delta\delta_{ae}$ is the difference between the chemical shifts of a particular carbon atom in two anomeric compounds.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

substituent. The size of $\Delta\delta_{ae}$ is similar to that obtained (12) for methyl-D-glucopyranoside.

Jones and co-workers (15) found that in *cis*-2-phenyl-4,6-dimethyl-1,3-dioxan, C-4 absorbs at 72.83 p.p.m. An oxygen substituent on the adjacent carbon (C-5) is expected to deshield C-4 by about 5 p.p.m. (13). These considerations lead to the assignment of the C-4 resonances given in Table 4. While previous work (12) showed no systematic anomerization effect at C-4, the present data show that the resonance of the β anomer is consistently at higher field.

Since C-1 and -7 are each attached to two oxygen atoms, the lowest field non-aromatic resonances are attributed to these carbon atoms. The assignments shown in Table 4 are consistent with earlier reports (11, 12, 14, 16) on C-13 chemical shifts of carbohydrates. They are also in accord with present (Table 1) and previous (3) p.m.r. data which indicate that the benzylidene proton is insensitive to the configuration at C-1. In addition, the magnitude of $\Delta\delta_{ae}$ follows the same trend as that of the carbon resonances of the methoxyl group, being largest (6.27 p.p.m.) with the secondary amino group at C-2 and smaller (3.12 and 3.81 p.p.m.) when the C-2 substituent has a tertiary amino group. Alternative assignments of the low field non-aromatic resonances are in principle possible, but suggest anomerization effects at C-7 which are of the same size as those at C-1. These alternatives are, therefore, unlikely.

The authors thank Professor J. B. Stothers of the University of Western Ontario for C-13 spectra on a Varian XL-100 system.

Financial support by the National Research Council of Canada is gratefully acknowledged.

Cyclizations of Dialdehydes with Nitromethane. XV. Synthesis of Four Stereoisomeric Deoxynitroinositol Monomethyl Ethers[1]

JAN KOVÁŘ AND HANS H. BAER

Department of Chemistry, University of Ottawa, Ottawa, Canada K1N 6N5

Received January 4, 1973

Methylation of 1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose (**1**) followed by hydrolysis of the 5,6-ketal group and periodate oxidation gave 1,2-*O*-isopropylidene-3-*O*-methyl-α-D-*xylo*-pentodialdo-1,4-furanose (**4**). Addition of nitromethane to **4** afforded a mixture of 6-deoxy-1,2-*O*-isopropylidene-3-*O*-methyl-6-nitro-α-D-glucofuranose (**5**) and -β-L-idofuranose (**6**). Removal of the 1,2-ketal group led to a mixture of 6-deoxy-3-*O*-methyl-6-nitro-D-glucose (**7**) and -L-idose (**8**) from which the crystalline β-anomer of **7** could be isolated. Cyclization of the nitro hexoses by internal Henry reaction furnished four stereoisomeric deoxynitroinositol monomethyl ethers which were obtained in crystalline condition, in part directly and in part via acetone and acetyl derivatives. The *scyllo* (**9**), DL-*myo*-1 (**10**), *muco*-3 (**14**), and *epi*-3 (**16**) configurations were assigned to the products by n.m.r. spectroscopy.

La méthylation du di-*O*-isopropylidène-1,2:5,6-α-D-glucofuranose (**1**) suivie de l'hydrolyse du groupe cétal-5,6 et de l'oxydation périodique, conduit à l'*O*-isopropylidène-1,2-*O*-méthyl-3-α-D-*xylo*-pentodialdofuranose-1,4 (**4**). L'addition de nitrométhane à **4** conduit à un mélange de déoxy-6-*O*-isopropylidène-1,2-*O*-méthyl-3 nitro-6-α-D-glucofuranose (**5**) et de -β-L-idofuranose (**6**). L'enlèvement du groupe cétal-1,2 conduit au mélange de déoxy-6-*O*-méthyl-3 nitro-6-D-glucose (**7**) et de -L-idose (**8**) à partir duquel l'anomère β cristallin de **7** a pu être isolé. La cyclisation des nitrohexoses par une réaction de Henry interne fournit quatre éthers déoxynitroinositolmonométhylés diastéréoisomères qui ont été obtenus cristallisés soit par voie directe, soit par les dérivés acétone et acétyle. Les configurations *scyllo* (**9**), DL-*myo*-1 (**10**), *muco*-3 (**14**), et *épi*-3 (**16**) ont été attribuées aux produits par spectroscopie r.m.n.

Can. J. Chem., 51, 1801 (1973)

Several recent articles from this laboratory dealt with non-bonded interactions between hydroxyl groups and nitro groups in vicinal position on pyranoside rings, with special reference to the formation and stability of glycoside nitronates. Conformational preferences and configurational equilibrations in such glycosides were correlated with such interactions, and the studies led to new insights into chemical reactivities and mechanisms in this field (2–5). It became desirable to seek, along similar lines, a better understanding of certain aspects of the formation and mutual interconversion of stereoisomeric deoxynitroinositols (6–10), and it now seemed profitable to apply the newly developed concepts and methods of study to this related group of compounds.

It was reasoned that the planned investigations might be facilitated if there were available a number of stereoisomeric deoxynitroinositols that carry an *O*-methyl group in opposition to the nitro function. The methyl group, it was hoped, should render the isomers more readily distinguishable by n.m.r. spectroscopy and thus aid in the analysis of product mixtures while at the same time this functionality would be distant from, and not interfere with, the nitrodiol moiety whose chemistry was to be examined. Consequently we synthesized such methyl ethers as will be reported here, and studied mechanistic aspects of their formation and epimerization as will be communicated elsewhere (11).

The synthesis was to be patterned after the Fischer–Grosheintz nitroinositol synthesis (6, 12) which involves a stepwise nitromethane cyclization of a partially blocked pentodialdose. It was therefore necessary, first, to synthesize 1,2-*O*-isopropylidene-3-*O*-methyl-α-D-*xylo*-pentodialdo-1,4-furanose (**4**) and thence 6-deoxy-3-*O*-methyl-6-nitro-D-glucose (**7**) and (or) its L-*ido* isomer (**8**). The pathway that led to the crystalline β-anomer of **7**, and also to a mixture of **7** and **8** which could not be separated, is delineated in Scheme 1. 1,2:5,6-Di-*O*-isopropylidene-α-D-glucofuranose (**1**) was methylated by the Kuhn method (13), which proved simple and furnished the 3-*O*-methyl derivative **2** in 83% yield. Partial hydrolysis to give 1,2-*O*-isopropylidene-3-*O*-methyl-α-D-glucofuranose (**3**) was readily achieved with 90% acetic acid. The product

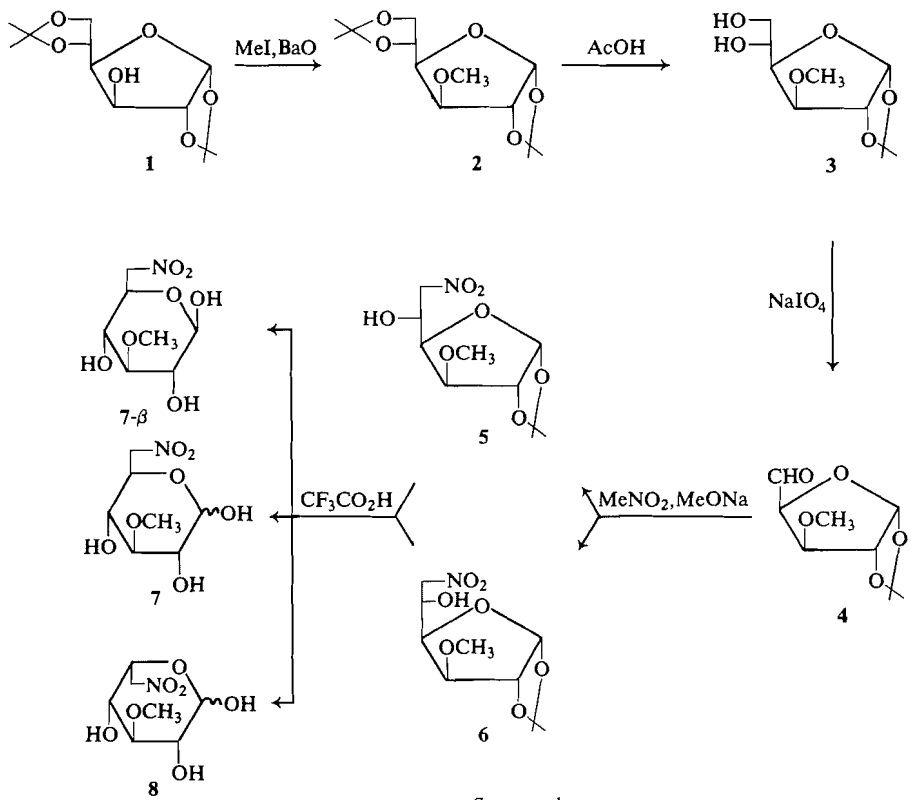

SCHEME 1

could be purified with advantage by chromatography on silica gel instead of distillation as was practiced earlier (14). However, crude **3** was satisfactory for immediate use in the subsequent step. Its periodate oxidation smoothly afforded the partially blocked dialdose **4** as a chloroform-soluble syrup. Because of its apparent sensitivity, purification of **4** for elemental analysis was not pursued, but the n.m.r. spectrum proved its structure beyond doubt. The data (see Experimental) also gave an indication of the conformation of **4** and its precursors **2** and **3**. At 1000 Hz sweep width the signals of H-2 and -3 appeared as doublets due to coupling with H-1 and -4, respectively; the observed splittings were 2.5–4 Hz, and coupling between H-2 and -3 was too small to be observable. These features showed that the furanose ring in these compounds exhibits the same conformational preference as that in 1,2-*O*-isopropylidene-α-D-glucofuranose and related derivatives (15–17). Originally the $^3T_2$ twist conformation had been proposed (15) for this system, but more recent studies indicate (17) that it may better be described by the segment $^3T_4 \rightleftarrows E_4 \rightleftarrows {}^0T_4$ of the cycle of furanose conformers. Another noteworthy signal in the spectrum of **4** was a low-field doublet (δ 9.66, J = 1.5 Hz) whose intensity corresponded to 80% of one proton and tended to decrease when attempts were made to purify the product by repeated distribution between chloroform and water. The signal was assigned to the aldehydic H-5, and the implication is that the compound as prepared under our conditions exists largely as the free aldehyde depicted (**4**) but is prone to undergo hydration and perhaps dimerization. The 3-*O*-benzyl analog of **4** has been regarded as a free aldehyde, whereas the 3-hydroxy analog is known to form, reversibly, a dimeric product (18–20).

The aldehyde **4** was combined with nitromethane in the presence of sodium methoxide in the usual manner. After acidification, the addition product was purified chromatographically to give analytically pure nitro sugar as a syrup which, although exhibiting a single spot on t.l.c., was revealed by its n.m.r. spectrum to be a 2:1 mixture of two components (**5** and **6**). In the

expected resonance position of H-1 a slightly asymmetric, apparent triplet consisting of two partially overlapping doublets was found (δ 5.79 and 5.90; $J_{1,2}$ = 4–5 Hz). The outer lines had an intensity ratio 2:1, and the stronger signal could be attributed to 6-deoxy-1,2-*O*-isopropylidene-3-*O*-methyl-6-nitro-α-D-glucofuranose (**5**) when, at a later stage, pure **5** became available for comparison. The second component was judged to be the β-L-*ido* isomer (**6**). The configurational assignments were supported by circular dichroism data (see later).

The preponderance of the D-*gluco* epimer **5** in the expected formation of two epimers from **4** deserves comment since the 3-*O*-benzyl analog of **4** has been shown to react with Grignard reagents to give preponderantly L-*ido* derivatives, with the degree of stereoselectivity being influenced by the solvent (19, 20). It has been suggested that the transition state in those Grignard reactions may involve coordination between the magnesium and the carbonyl and ring oxygen atoms (21). It can be seen in a molecular model that such a cyclic complex requires the aldehyde group to be so oriented as to expose its *si* face to the less hindered, rear side of the molecule, and attack from that direction will generate the *S* configuration at C-5 and therefore produce L-*ido* derivatives. In our reaction, which is characterized by methanenitronate ion preferentially attacking the *re* face to produce the *R* configuration at C-5, the rotameric orientation of the aldehyde group is not constrained by complexing. A preferred arrangement of the carbonyl double bond antiperiplanar to the C_4—O bond, plausible on grounds of dipole considerations, would be able to account for the result.

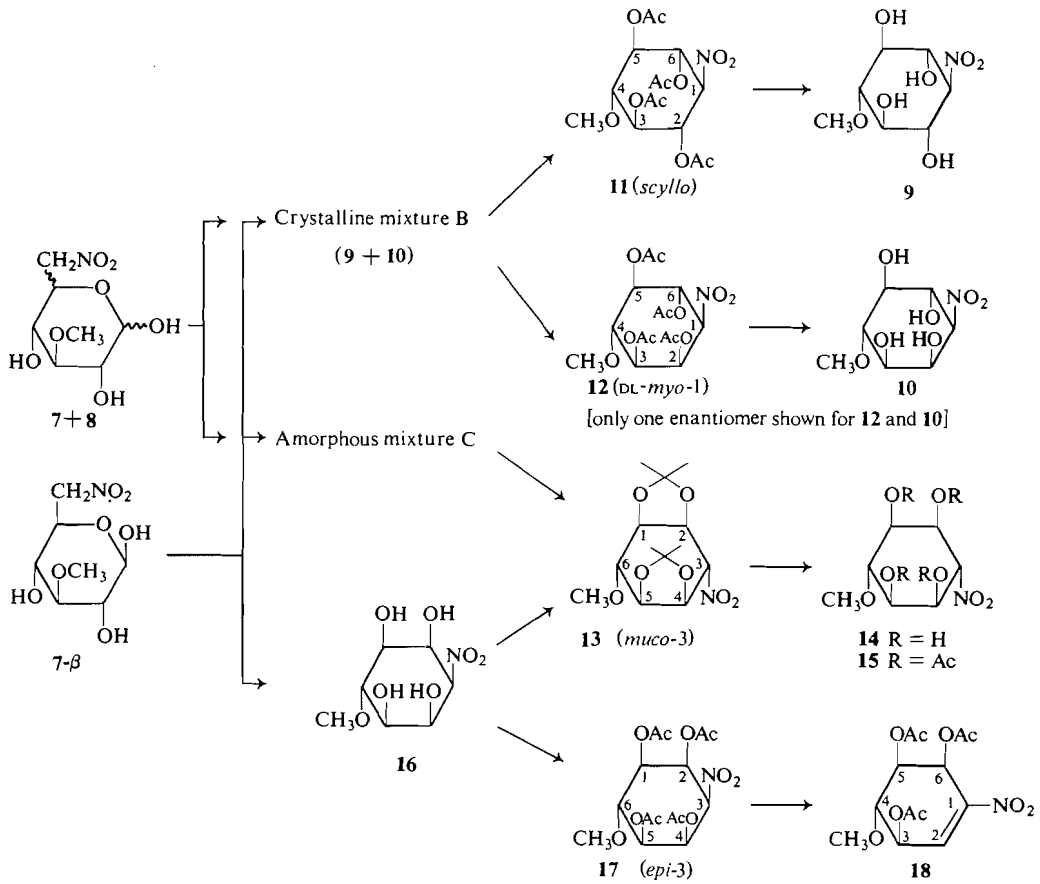
The mixture of **5** and **6** was hydrolyzed with 90% trifluoroacetic acid for removal of the isopropylidene group. One of the products was obtained in crystalline form in 49% yield. It exhibited a negative Cotton effect, indicative of the *R* configuration at C-5, the asymmetric carbon atom next to the nitromethyl group (22), and was thereby revealed to be the D-*gluco* derivative **7**. The crystalline substance (termed **7**-β) was assigned the β-anomeric configuration as it exhibited upward mutarotation. The mother liquor of the reaction yielded an additional 32% of product as a non-mutarotating syrup which showed a positive Cotton effect such as would accord with a mixture containing preponderantly the L-*ido* isomer **8** along with some **7**. The syrup could be used in the subsequent reactions so that the practical, over-all yield in nitro sugars based on **1** was about 45%.

When crystalline **7**-β was reacetonated, syrupy but analytically pure **5** was obtained. It showed the n.m.r. doublet for H-1 at δ 5.90 and exhibited a negative Cotton effect. Similar reacetonation of the mother liquor mixture **8** + **7** gave a mixture of **5** and **6** similar to that described above, except that the intensity ratio of the H-1 doublets was reversed, indicating a 2:1 preponderance of **6**. This mixture showed a positive Cotton effect.

Cyclization of the nitro hexoses **7** and **8** to furnish inositol derivatives was performed in a manner similar to the cyclization of the non-methylated analogs (6). Two procedures were used, namely, reaction in aqueous barium hydroxide solution, and reaction in a mixture of methanol and nitromethane in the presence of sodium methoxide. The first-mentioned procedure gave better yields and was more convenient in work-up; the results shown in Scheme 2 and to be discussed in detail first refer to it. The results of the second procedure, to be mentioned briefly afterwards, were qualitatively similar although there were some minor differences.

When amorphous mixtures of **7** and **8**[2] were employed for cyclization, a partly crystalline mixture of isomeric inositols arose. The smaller, crystalline part (21–30%) of the product melted above 200°, was sparingly soluble in ethanol, and was shown by chromatography to consist of of two compounds (**9** and **10**). They could not be separated directly but gave separable tetraacetates (**11** and **12**) whose acid-catalyzed methanolysis then furnished pure **9** and **10**. The tetraacetates arose in yields of, for instance, 58 (**11**) and 32% (**12**), and presumably **9** and **10** had constituted the crystalline part of that particular cyclization mixture in a similar ratio. The *scyllo* and *myo*-1 configurations were assigned to these isomers on evidence to be given below. The larger, non-crystalline part (36–56%) of the cyclization mixture contained, besides colored impurities, very little of **9** or **10** but consisted chiefly of at least one other isomer.

[2]This refers to both the mother liquor material (richer in **8**) remaining after isolation of crystalline **7**-β, and to the total mixture (richer in **7**) as obtained prior to such isolation.



SCHEME 2

Acetonation of this part led to a di-*O*-isopropylidene derivative (**13**) whose deacetonation afforded the crystalline *muco*-3 isomer **14**. For further characterization, **14** was acetylated to its tetraacetate **15**. From the isolated amount of diacetone derivative **13**, one might have concluded that the mixture subjected to acetonation had contained at least 31% of **14**. This was not the case, however. Compound **14** can be distinguished readily by n.m.r. spectroscopy (see later), and it was found that only small proportions of **14** (never more than 10%) were present in the mixture prior to acetonation. The bulk of **13** must therefore have originated from a secondary reaction, the nature of which will be disclosed later on.

Use of crystalline **7**-β in the barium hydroxide-induced cyclization again furnished a partly crystalline product. However, fractional recrystallization of the crystalline portion not only yielded mixtures of **9** and **10** as before, though in somewhat smaller amounts (18–19%), but gave in addition a fourth isomer (m.p. 165–167°) as the chief component (27–45%). The amorphous portion of the reaction product (29–41%) had similar characteristics as in the previous experiment; although it contained little, if any, of the *muco*-3 isomer **14**, it was acetonated to produce the diacetone derivative **13**. The crystalline, fourth nitroinositol isomer just mentioned was allocated the *epi*-3 configuration (**16**). Acetylation gave a crystalline tetraacetate (**17**) that was characterized by n.m.r. spectroscopy but proved too unstable for purification for elemental analysis. In attempted recrystallization from ethanol a sample deteriorated due to dehydroacetylation. This became evident by the appearance of a low-field n.m.r. signal (δ 7.25) attributable to an olefinic proton, and eventually a small amount of the nitroolefin [3,5,6/4]-3,5,6-

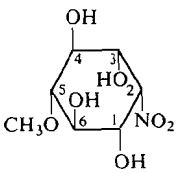
triacetoxy-4-methoxy-1-nitrocyclohexene (**18**) was isolated.[3]

An unexpected observation was made when the *epi*-3 isomer **16** was acetonated. A di-*O*-isopropylidene derivative was formed, but the isolated product (yield, 36%) evidently had undergone epimerization during work-up or chromatography on silica gel and proved identical with **13**. This was verified by acid-catalyzed methanolysis which did not regenerate **16** but gave **14** instead. The epimerization is reminiscent of the facile conversion of 3-deoxy-1,2:5,6-di-*O*-isopropylidene-3-nitro-α-D-glucofuranose into its D-*allo* isomer (16).

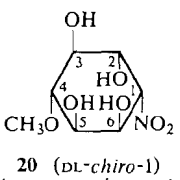
Cyclization of crystalline **7**-β in a methanol–nitromethane solvent containing sodium methoxide furnished a crystalline mixture of **9** and **10** (16%), crystalline **14** (8%), and an amorphous material (61%) that appeared similar in composition to that obtained in the barium hydroxide-promoted reactions.

Configurational Assignments

In the cyclization of the 6-deoxy-6-nitrohexoses considered here, two centers of prochirality (C-1 and -6) are directly involved in producing two new chiral centers in the products. A third chiral center affecting the number of possible epimers stems from chiral C-5 in the hexoses. Due to possibilities of over-all symmetry, however, only six stereoisomeric deoxynitroinositols can thus arise, namely, four meso forms (with the *scyllo*, *myo*-2, *muco*-3, and *epi*-3 configurations) and two racemic forms (with the *myo*-1 and *chiro*-1 configurations). Of these, the *myo*-2 (**19**) and *chiro*-1 (**20**) isomers seemed unlikely to arise under the present conditions because of conformational energy considerations, and the remaining four have all been encountered in this work.



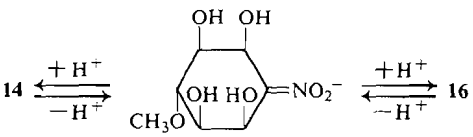
19 (*myo*-2)



20 (DL-*chiro*-1)
[only one enantiomer shown]

[3]It is interesting to note in this connection that the stereoisomeric tetraacetates **11** and **15** were completely stable, whereas **12** was somewhat prone to decomposition if much less so than **17**.

The two isomers that gave a diisopropylidene derivative (in a non-forcing procedure of acetonation) must each possess two *cis*-glycol groupings, a condition met only by **14** and **16**. The fact that the diisopropylidene derivative of one isomer was converted during work-up into that of the other isomer, shows that they were epimeric at the carbon bearing the nitro group where epimerization through the common nitronate ion can occur. Confirming this, the n.m.r. spectra given by **14** and **16** in the presence of excess sodium deuteroxide in D_2O were identical, in accord with the existence of one common nitronate (**21**).



21

Finally, unambiguous allocation of formulas **14** and **16**, and of **9** and **10** to the other two isomers, was possible by analysis of n.m.r. spectra of their tetraacetates in chloroform-*d* (Table 1).[4] The *muco*-3 and *epi*-3 tetraacetates (**15** and **17**) each exhibited in order of decreasing field a one-proton signal for H-6, a one-proton signal for H-3, and two two-proton signals for the enantiotopic pairs H-1, H-5 and H-2, H-4. Two pairs of enantiotopic acetyl groups gave two 6-proton singlets in each compound, and the methoxy group gave a three-proton singlet. Compound **17** showed large coupling in the triplet for H-6 ($J_{1,6} = J_{5,6} = 10$ Hz), indicating a 1,6,5-triaxial proton arrangement and therefore equatorial substituents in these positions. The coupling $J_{1,2}$ ($= J_{4,5}$) was small, requiring the substituents at C-2 and -4 to be axial and hence *cis* to those at C-1 and -5, in accord with the chemical evidence of facile acetonation. The triplet for H-3 showed small coupling (3 Hz), but this feature, even though it was consistent with an equatorial nitro group flanked by two axial acetoxyls as depicted in Table 1, did not disprove an axial nitro group. The *epi*-3 configuration could nevertheless be allocated to **17** with certainty since inversion at C-3 would result in the *muco*-3 configuration which, it was found, must be reserved for compound **15** for the

[4]The spectra of the free nitroinositols in aqueous trifluoroacetic acid were in complete agreement; see Experimental.

following reason. Compound **15** exhibited large splitting in its triplet of H-3 ($J_{2,3} = J_{3,4} = 11$ Hz), clearly requiring a 2,3,4-triequatorial substituent arrangement. This condition is realized only in one conformer, namely that of the *muco*-3 epimer shown in Table 1. The remaining coupling constants, all small, were in harmony with substituent orientations as depicted. It is noteworthy that the non-acetylated *muco*-3 isomer **14** in aqueous solution also adopts the same conformation, with an equatorial nitro group and an axial methoxyl group, as was revealed by analogous n.m.r. data (see Experimental). Evidently when **21**, the nitronate common to **14** and **16**, is protonated, the rule of equatorial nitro group preference (2) is obeyed for both products. In **14**, the methoxyl proton signal is found markedly upfield (by 0.15–0.2 p.p.m.) from the corresponding signals of its three isomers, rendering **14** easily recognizable.

Assignment of the *scyllo* and *myo*-1 configurations to the tetraacetates **11** and **12**, respectively, was straightforward. Thus **11** (and also its parent compound **9**) revealed molecular symmetry by the presence of two pairs of enantiotopic hydrogen atoms (H-2, H-6 and H-3, H-5) which each gave rise to a two-proton signal. All the coupling constants were large (9.5–10.5 Hz), indicating the all-*trans* substituent orientation. By contrast compound **12** and its parent **10**, which lack molecular symmetry, exhibited six individual one-proton signals for their ring hydrogen atoms. The observed multiplicities and splittings demanded the formula depicted. The data of Table 1 also rule out the *myo*-2 (**19**) and *chiro*-1 (**20**) configurations for any of the products obtained.

Experimental

Melting points were determined in capillaries in an electrically heated aluminum block. The n.m.r. data (100 MHz) were obtained on a Varian HA-100 instrument. Optical rotations were measured at room temperature in a Perkin–Elmer automatic polarimeter, Model 141. Circular dichroism was determined with a Jasco ORD/UV-5 instrument. I.r. spectra of new nitro compounds were compatible with the assigned structures.

1,2:5,6-Di-O-isopropylidene-3-O-methyl-α-D-glucofuranose (2)

A mixture of diacetone glucose **1** (8.0 g), methyl iodide (11.4 g), barium oxide (10.0 g) and *N,N*-dimethylformamide (80 ml) in a stoppered flask was vigorously shaken for 67 h at ambient temperature (29°). The mixture was filtered with suction through a layer of Celite and the residue washed successively with ether (100 ml) and water (125 ml). The phases of the filtrate were separated and the water layer was extracted twice with ether which was combined with the organic phase. The latter was washed twice with water, dried ($MgSO_4$), and evaporated to furnish a pale yellow oil (8.2 g; $[\alpha]_D$ −32° in ethanol). The oil was distilled *in vacuo*; following a forerun (0.4 g) the main fraction was collected at 85° (bath temperature) and 0.1 Torr. Compound **2** was thus obtained as a colorless oil (7.0 g, 83%); $[\alpha]_D$ −33° (*c*, 0.4 in ethanol); lit. (23), b.p. (0.3 Torr) 105°, $[\alpha]_D$ −34° in ethanol.

The n.m.r. data (in $CDCl_3$; TMS): δ 5.88 (1H d, H-1, $J_{1,2} = 4$ Hz), 4.57 (1H d, H-2, $J_{1,2} = 4$ Hz), 3.9–4.3 (4H m, H-4, -5, -6, -6′), 3.78 (1H d, H-3, $J_{3,4} = 2.5$ Hz), 3.47 (3H s, OCH_3), 1.50, 1.43, 1.37, 1.33 (four 3H s, isopropylidene methyl groups). The undistilled crude product gave virtually the same spectrum, with additional weak signals due to DMF (δ 2.80, 2.72).

1,2-O-Isopropylidene-3-O-methyl-α-D-glucofuranose (3)

A solution of **2** (7.0 g) in acetic acid (70 ml) and water (7 ml) was kept at 40° for 1.5 h and then evaporated under reduced pressure. Added toluene and benzene were successively evaporated from the residue which was a colorless, viscous oil. The material contained some unreacted **2** (*ca.* 1.1 g) which was removed by two extractions with ether (25 and 10 ml) from an aqueous solution (25 ml) of the crude **3**. The aqueous solution then contained about 5.0 g of **3** and could be used directly for the preparation of **4**.

A sample of crude **3** (553 mg, from a similar experiment) was purified by column chromatography on silica gel (E. Merck AG., 15 g, with 10% of water added). Elution with benzene (180 ml) and benzene containing 2% of ethanol (150 ml) gave a material (45 mg) that was discarded, and further elution with benzene containing 5% of ethanol (120 ml) then gave pure **3** (466 mg, 84%), $[\alpha]_D$ −52.4° (*c*, 0.4 in chloroform); lit. (24) $[\alpha]_D$ −54° (*c*, 3.1 in chloroform). The n.m.r. data (in $CDCl_3$; TMS): δ 5.93 (1H d, H-1, $J_{1,2} = 4$ Hz), 4.62 (1H d, H-2, $J_{1,2} = 4$ Hz), 3.7–4.1 (5H m), 3.49 (3H s, OCH_3), 1.50, 1.33 (two 3H s, isopropylidene methyl groups). The hydroxyl protons were removed by deuterium exchange.

1,2-O-Isopropylidene-3-O-methyl-α-D-xylo-pentodialdo-1,4-furanose (4)

To a cooled (0°) solution of **3** (463 mg) in water (2.7 ml) was added sodium metaperiodate (463 mg) in two portions with a 20-min interval. After 2 h, a few drops of ethylene glycol were added and the reaction mixture was filtered. The filter residue was washed with chloroform and the aqueous filtrate was extracted with the same solvent. The combined chloroform solution was dried ($MgSO_4$) and evaporated to furnish a pale yellow oil which was dried *in vacuo*. The yield was 333 mg (83%); $[\alpha]_D$ −139° (*c*, 0.3 in $CHCl_3$). The n.m.r. data (in $CDCl_3$; TMS): δ 9.66 (1H d, $J_{4,5} = 1.5$ Hz, H-5); 6.10 (1H d, $J_{1,2} = 3.8$ Hz, H-1); 4.67 (1H d, $J_{1,2} = 3.8$ Hz, H-2); 4.57 (1H q, $J_{3,4} = 4$ and $J_{4,5} = 1.5$ Hz, H-4); 4.17 (1H d, $J_{3,4} = 4$ Hz, H-3); 3.37 (3H s, OCH_3); 1.47, 1.33 (two 3H s, $C(CH_3)_2$).

For use in subsequent experiments it was practical to prepare compound **4** as an alcoholic solution on a larger scale. Thus, a solution of **3** (5.62 g, 24 mmol) in water (35 ml) was stirred with ice cooling, and sodium metaperiodate (6.0 g, 28 mmol) was added in portions during

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

½ h, the temperature of the reaction mixture being maintained at 8–11°. Stirring was continued without cooling for another 90 min whereby the temperature gradually rose to 25°. The mixture was then cooled again and 0.2 ml of ethylene glycol followed by 25 ml of ethanol were added. The inorganic precipitate was filtered off and washed thoroughly with ethanol. The filtrate was evaporated to dryness and the residue was taken up in ethanol (10 ml). The solution was filtered from undissolved material which was washed with ethanol (5 ml). The filtrate so obtained (15 ml) was used directly for reaction with nitromethane.

6-Deoxy-1,2-O-isopropylidene-3-O-methyl-6-nitro-α-D-glucofuranose (5) and -β-L-idofuranose (6)

(a) Mixture of 5 and 6 from 4

A solution of oily aldehyde **4** (2.94 g) in nitromethane (4 ml) and methanol (8 ml) was rendered alkaline by the addition of 2.7 *N* sodium methoxide in methanol (6 ml) and stored for 18 h at room temperature, in a pure nitrogen atmosphere. The mixture was then cooled with Dry Ice, glacial acetic acid (1 ml) was added with stirring, and after removal from the cold bath it was shaken briefly with added chloroform (10 ml) and water (10 ml). Upon phase separation the aqueous layer was extracted twice with chloroform, which was combined with the organic layer. The latter was washed five times with 5 ml of water, dried over anhydrous $MgSO_4$, and evaporated to give a brown oil (3.70 g). The oil was chromatographed on silica gel (E. Merck AG; with 10% of water added). The column was eluted first with benzene (500 ml) and then with benzene containing 2% ethanol (900 ml). The last third of the second eluant produced a colorless syrup (3.27 g) of **5** and **6** in a yield of 85%. The t.l.c. with ethyl acetate – chloroform (1:1) showed a single spot, R_f 0.67. Optical rotations: $[\alpha]_{578}$ −48.8, $[\alpha]_{536}$ −56.2, $[\alpha]_{436}$ −102, $[\alpha]_{365}$ −213° (*c*, 0.6, methanol). The n.m.r. spectrum ($CDCl_3$) showed two overlapping H-1 doublets (an apparent triplet), δ 5.98 and 5.90 (J = 4–5 Hz), with an intensity ratio 1:2, indicating that **5** preponderated. The remaining part of the spectrum was identical with that of pure **5** (see below).

Alternatively, an ethanolic solution of **4** (obtained without isolation from 24 mmol of **3**, see earlier) was mixed under nitrogen with nitromethane (7.5 ml) and 3.25 *N* sodium methoxide in methanol (8.25 ml). After 18 h the mixture was cooled, neutralized with glacial acetic acid (1.65 ml, to p*H* 6), and worked-up by dilution with chloroform (25 ml) and addition of water (75 ml). The water layer was extracted four times with chloroform and the combined chloroform extracts were washed four times with 10 ml of water, each water portion being extracted again with chloroform. Drying of the combined chloroform solution ($MgSO_4$) and evaporation furnished a reddish-brown oil (6.62 g) which, according to t.l.c. and n.m.r. analysis, appeared to consist largely of **5** and **6**. Part of the oil (5.1 g) was chromatographed on silica gel as described and gave 4.1 g (84% based on **3**) of a colorless, n.m.r. spectroscopically pure mixture of **5** and **6**.

(b) Pure 5 from 7-β

Crystalline nitro sugar **7-β** (84 mg) was dissolved with Dry-Ice cooling in acetone (4 ml) containing concentrated sulfuric acid (0.08 ml) and then stirred with anhydrous cupric sulfate (0.2 g) for 2 h without further cooling. The mixture was thereafter cooled again, neutralized by addition of concentrated aqueous ammonia (0.33 ml), and filtered through a layer of Dowex 1 × 2 (acetate form; prewashed with acetone) and through a layer of Celite. The filtrate was evaporated to a residue which was taken up in chloroform. The filtered, dried ($MgSO_4$), and evaporated chloroform solution furnished **5** in quantitative yield (100 mg) as a colorless syrup (uniform on t.l.c., R_F 0.67 as in *a* above); $[\alpha]_D$ −34.0, $[\alpha]_{578}$ −35.9, $[\alpha]_{546}$ −41.5, $[\alpha]_{436}$ −88.5, $[\alpha]_{365}$ −256° (in methanol, *c*, 0.7). Circular dichroism (*c*, 0.5 in methanol): $[\theta]_{281}$ −1885. The n.m.r. data (in $CDCl_3$): δ 5.90 (1H d, H-1, $J_{1,2}$ = 4 Hz), 4.4–4.8 (4H m, H-2, -6, -6′, -4 or -5), 4.0–4.2 (1H m, H-4 or -5), 3.88 (d, H-3, J = 3.5 Hz), δ 3.49 (3H s, OCH_3), 1.48 and 1.33 (two 3H s, $C(CH_3)_2$).

Anal. Calcd. for $C_{10}H_{17}NO_7$ (mol. wt. 263.2): C, 45.62; H, 6.51; N, 5.32. Found: C, 45.44; H, 6.38; N, 5.24.

(c) Mixture of 5 and 6 from 7 and 8

An amorphous mixture of **7** and **8** (from which crystalline **7-β** had been collected, see later) was acetonated as described under section *b*. The syrupy product (yield, 87%) gave an n.m.r. spectrum identical with that of the product described under section *a* except that the intensity ratio of the H-1 doublets at δ 5.98 and 5.90 was 3:2, indicating that **6** preponderated. Circular dichroism (*c*, 0.5 in methanol): $[\theta]_{310}$ +260. Assuming a 3:2 ratio for **6** and **5**, and using the [θ] value for pure **5**, the value for **6** may be extrapolated to +1700.

6-Deoxy-3-O-methyl-6-nitrohexoses 7 and 8

(a) Crystalline β-D-gluco Isomer (7-β)

A chromatographically purified mixture of isopropylidene derivatives **5** and **6** (1.56 g, ratio approximately 2:1) was dissolved in trifluoroacetic acid (5.5 ml), water (0.5 ml) was slowly added, and the reaction mixture was stirred for 45 min at room temperature and then evaporated *in vacuo*. From the syrupy residue a few milliliters of added water and subsequently some ethyl acetate were evaporated. The dried syrup (1.7 g) was then triturated with fresh ethyl acetate whereby it partially crystallized on scratching. The crystals (607 mg, 46%) were collected and washed with chloroform; m.p. 149–152°. An analytical sample was recrystallized from ethyl acetate – chloroform; m.p. 152–154°; homogeneous on t.l.c. in ethyl acetate (R_F 0.4) or 2:1 acetone–chloroform (R_F 0.65). The product exhibited upward mutarotation: $[\alpha]_D$ −4 (2 min) → +46° (24 h, final), $[\alpha]_{578}$ −4.3 → +47°, $[\alpha]_{546}$ −5.3 → +51°, $[\alpha]_{436}$ −31 → +61°, $[\alpha]_{365}$ −190 → −48°, in methanol; $[\alpha]_D$ and $[\alpha]_{578}$ +7 (2 min) → +40° (4 h, final), $[\alpha]_{546}$ +6 → +41°, $[\alpha]_{436}$ −10 → +49°, $[\alpha]_{365}$ −141 → −40°, in water.

Circular dichroism (*c*, 0.25 in 2.5 × 10^{-3} *N* acetic acid at anomeric equilibrium): $[\theta]_{319}$ −830, $[\theta]_{275}$ −2050.

The n.m.r. data (in 2 *N* CF_3CO_2D–D_2O with acetone reference): δ 3.0–1.8 (4H m), 1.43 (3H s, OCH_3), 1.4–1.1 (3H m).

Anal. Calcd. for $C_7H_{13}NO_7$ (mol. wt. 223.2): C, 37.66; H, 5.87; N, 6.28. Found: C, 37.90; H, 5.91; N, 6.23.

(b) Mixture of the D-gluco (7) and L-ido (8) Isomers

The ethyl acetate mother liquor obtained upon collection of crude **7-β** was concentrated and deposited an additional 53 mg of less pure **7-β**, which was removed.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Further evaporation gave a syrup (634 mg) which was partitioned between chloroform and water. The chloroform phase yielded a small amount of what appeared on t.l.c. to be impure starting material; it was discarded. The aqueous phase was decolorized by treatment with 0.5 ml of Dowex 1 × 2 (acetate) and evaporated. The remaining colorless syrup (420 mg, dried *in vacuo*) was a mixture of **7** and **8** (yield, 32%), R_F 0.4, 0.6 and 0.65, 0.8 (t.l.c. as described under section *a*). The material showed no mutarotation; $[\alpha]_{578}$ +9.7, $[\alpha]_{546}$ +11.3, $[\alpha]_{436}$ +23.3, $[\alpha]_{365}$ +68 (*c*, 0.52 in methanol); $[\alpha]_{578}$ +0.6, $[\alpha]_{546}$ +3.0, $[\alpha]_{436}$ +12, $[\alpha]_{365}$ +75° (*c*, 0.2 in water).

Circular dichroism (as for pure **7**): $[\theta]_{319}$ +170, $[\theta]_{272}$ −400. Assuming 40% **7** in the mixture, the ellipticities of **8** may be extrapolated to $[\theta]_{319}$ +840, $[\theta]_{272}$ +700.

The complex n.m.r. spectrum of the mixture showed prominent OCH_3 signals at δ 1.43 and 1.32.

Cyclization of Nitro Hexoses with Aqueous Barium Hydroxide

A suspension of crystalline **7**-β (1.76 g, 7.88 mmol) in 0.0025 *N* acetic acid (8 ml) was stirred in an ice water bath in a nitrogen atmosphere, and a saturated solution of barium hydroxide (16 ml, approximately 0.5 *N*) was added in rapid flow. The mixture was stirred at 0° for 2.5 h and then kept at ambient temperature for 18 h. The dark solution was cooled again and acidified to p*H* 4–5 by dropwise introduction into ice cold, *N* acetic acid (20 ml). It was then passed sequentially through columns containing 5 ml of Dowex 1 × 2 (acetate) and 20 ml of Rexyn 101 (H^+), respectively, each column being washed with water (18 ml). Evaporation of the colorless effluent and drying of the residue *in vacuo* gave the nitroinositol mixture as a white semicrystalline mass (1.78 g).

Reactions using noncrystalline mixtures[3] of **7** and **8** were performed in the same fashion.

The reaction product (1.78 g, from **7**-β) was triturated with absolute ethanol (5 ml). Upon storing overnight at 0°, a crop of crystals (1.30 g, m.p. 156–158°) was isolated. This material was not homogeneous but furnished, upon recrystallizations (once from methanol and three times from 95% ethanol), a pure product designated A (95 mg, m.p. 165–167°). Systematic fractional crystallization of the mother liquor materials gave another 145 mg of pure A and 234 mg of less pure A (m.p. 160–167°), the total yield being 27%. In addition, the procedure yielded 333 mg (19%) of a high-melting material designated B, (m.p. 185–205°, dec.), 97 mg (6%) of a mixture which melted in between (at 173–175°) and was dealt with no further, and finally there remained 731 mg (41%) of an amorphous foam designated C. It will be noted that a total of 904 mg of crystals was eventually isolated and the amount of noncrystallizable material remaining after the various recrystallizations was larger than the amount that did not crystallize in the first place. The relative amounts of products depended upon the number of recrystallizations performed, with amorphous C increasing with that number. Thus, an identical cyclization experiment furnished 45% of A (m.p. 165–166°), 18% of B (m.p. 209–215°), and 29% of C.

The semicrystalline reaction product (3.21 g) obtained from a mixture (3.89 g) of **7** and **8** was triturated with cold ethanol (7 ml) to give inhomogeneous crystals (1.77 g, m.p. 199–205° dec.) and an amorphous material (1.32 g). After fractional crystallizations using methanol and ethanol there was obtained 1.18 g (30%) of B (m.p. 205–222°), a total of 0.43 g (11%) of unresolved mixtures melting anywhere between 100 and 175°, and 1.40 g (36%) of amorphous C. No pure A could be isolated. A similar experiment yielded 21% of B and 56% of C.

*3-Deoxy-6-O-methyl-3-nitro-epi-inositol (**16**)*

The crystalline product A, m.p. 165–167° (see above) represented compound **16**. The n.m.r. data (in 2.1 *N* CF_3CO_2D–D_2O with acetone standard): δ 2.62–2.57 (2H m, H-2, -4), 2.47 (1H t, J = 3 Hz, H-3), 1.47–1.44 (3H m, H-1, -5, -6), 1.42 (3H s, OCH_3).

Anal. Calcd. for $C_7H_{13}NO_7$ (mol. wt. 223.2): C, 37.66; H, 5.87; N, 6.28. Found: C, 37.55; H, 5.71; N, 6.40.

*1,2,4,5-Tetra-O-acetyl-3-deoxy-6-O-methyl-3-nitro-epi-inositol (**17**) and (3,5,6/4)-3,5,6-Triacetoxy-4-methoxy-1-nitrocyclohexene (**18**)*

An ice-cooled suspension of **16** (126 mg) in acetic anhydride (1.3 ml) was stirred for 6 h after addition of 2 drops of boron trifluoride etherate. The inositol dissolved when the catalyst was added, and crystalline **17** began to precipitate soon afterwards. It was collected and washed with ethanol (3 × 0.2 ml); yield, 104 mg; m.p. 172–182°. For the n.m.r. data see Table 1.

The product decomposed on attempted recrystallization from ethanol, becoming extremely soluble in the solvent and developing a low-field, olefinic proton signal which was not present in its original n.m.r. spectrum. A small amount of the nitroalkene **18**, m.p. 120–122°, was eventually isolated by crystallization from ether and ether–ligroin. For the n.m.r. data see Table 1.

Anal. Calcd. for $C_{13}H_{17}NO_9$ (mol. wt. 331.3): C, 47.13; H, 5.17; N, 4.23. Found: C, 47.31; H, 5.32; N, 4.18.

*2,3,5,6-Tetra-O-acetyl-1-deoxy-4-O-methyl-1-nitro-scyllo-inositol (**11**)*

The high-melting crystalline cyclization products previously designated B represented mixtures of the *scyllo* and *myo*-1 isomers **9** and **10**. Such a mixture (0.85 g) was acetylated with acetic anhydride (8.5 ml) in the presence of BF_3 etherate (12 drops) by stirring for 10 h at 0° and another 10 h at room temperature. The reaction mixture was then cooled again (0°) and filtered through sintered glass. The crystals (**11**) were washed with 5 ml of cold ethanol in three portions and dried *in vacuo*, and the combined filtrates containing isomeric acetate **12** were set aside. The crystals (0.87 g, 58.5%) were pure according to their n.m.r. spectrum (Table 1). The m.p. of 257–258° observed at this stage did not appear to be reproducible, as higher (270–272°) or lower (230–232°) values were found on occasion in similar preparations which exhibited, nevertheless, exactly the same well-defined n.m.r. spectrum. Recrystallization of a sample (0.47 g) from glacial acetic acid (3 ml) containing acetic anhydride (0.15 ml) gave translucent prisms (0.43 g) of m.p. 220–222°, whereas recrystallization from methanol (44 mg in 4 ml) gave long needles (35 mg) of m.p. 214–216°. The recrystallized samples gave n.m.r. spectra superimposable on those of the original product, and both gave correct microanalyses.

Anal. Calcd. for $C_{15}H_{21}NO_{11}$ (mol. wt. 391.3): C, 46.03; H, 5.41; N, 3.58. Found: C, 45.90; H, 5.46; N, 3.59. C, 45.92; H, 5.47; N, 3.73.

*2,3,5,6-Tetra-O-acetyl-1-deoxy-4-O-methyl-1-nitro-*D,L*-myo-inositol (**12**)*

To the filtrate of the acetylation mixture, from which crystalline **11** had been collected (see preceding section), was added excess ethanol; after decomposition of the remaining acetic anhydride the solution was evaporated, and two portions of added ethanol were evaporated from the residue which after drying weighed 0.64 g and consisted of at least 80% of **12** (n.m.r.). After two crystallizations from small volumes of hot ethanol (performed rapidly without prolonged heating, lest losses due to formation of low-melting, unsaturated products occurred), 475 mg (32%) of the tetraacetate **12** was obtained, m.p. 139–140°. Further recrystallization did not change the n.m.r. spectrum (Table 1) although variations in m.p. from 135–136° to 140–142° were observed.

Anal. Calcd. for $C_{15}H_{21}NO_{11}$ (mol. wt. 391.3): C, 46.03; H, 5.41; N, 3.58. Found: C, 45.95; H, 5.44; N, 3.67.

*1-Deoxy-4-O-methyl-1-nitro-scyllo-inositol (**9**)*

A suspension of tetraacetate **11** (430 mg) in anhydrous methanol (25 ml) containing methyl *p*-toluenesulfonate (0.5 ml) was boiled in a flask fitted with a Vigreux column. Distillation was maintained at a slow rate so that 15 ml of distillate was collected in 5 h. Fresh methanol was introduced during the operation so as to approximately maintain the original volume. The solid gradually dissolved, and the resulting solution was subsequently refluxed for another 20 h and then evaporated. Trituration of the residue with ethanol produced a white powder (277 mg) which was recrystallized from 90% ethanol (7 ml) to give **9** (202 mg, 83%) as needles, m.p. 258–260° (dec.). Recrystallization of a sample from water gave large grains that melted with decomposition at 248–249° (with apparent change in crystal structure from 220°). The n.m.r. data (in 2.1 *N* CF_3CO_2D–D_2O, with acetone as reference): δ 2.39 (1H t, H-1, J = 10.5 Hz), 1.81 (2H t, H-2 and -6, J = 10.5 Hz), 1.41 (3H s, OCH_3), 1.35 (2H t, H-3 and -5, J = 9.5 Hz), 1.02 (1H t, H-4, J = 9.5 Hz).

Anal. Calcd. for $C_7H_{13}NO_7$ (mol. wt. 223.2): C, 37.66; H, 5.87; N, 6.28. Found: C, 37.58; H, 5.82; N, 6.44.

*1-Deoxy-4-O-methyl-1-nitro-*D,L*-myo-inositol (**10**)*

The tetraacetate **12** (315 mg) was methanolyzed as described for **11**. The residue obtained upon evaporation of the reaction solution was dissolved in 1–2 ml of ethanol, and addition of benzene caused crystallization of **10** (178 mg, 99%) which was collected and washed with benzene; m.p. 198–203°. Recrystallization from ethanol–benzene gave very fine needles (150 mg, 83%), m.p. 203–205°. The n.m.r. data (in 2.1 *N* CF_3CO_2D–D_2O, with acetone reference): δ 2.49 (1H q, H-1, $J_{1,2}$ = 2.5, $J_{1,6}$ = 10 Hz), 2.30 (1H t, H-2, J = 2.5 Hz), 2.13 (1H, quartet of narrow doublets, H-6, $J_{1,6}$ = 10, $J_{5,6}$ = 9 Hz, and a 1.5 Hz splitting, presumably due to long-range coupling), 1.6–1.2 (3H m, H-3, -4, -5), 1.39 (3H s, OCH_3).

Anal. Calcd. for $C_7H_{13}NO_7$ (mol. wt. 223.2): C, 37.66; H, 5.87; N, 6.28. Found: C, 37.56; H, 5.85; N, 6.34.

*3-Deoxy-1,2;4,5-di-O-isopropylidene-6-O-methyl-3-nitro-muco-inositol (**13**)*

(a) From Amorphous Cyclization Product C

A sample (372 mg) of the product C (see a previous section) was dissolved in acetone (10 ml) containing concentrated sulfuric acid (0.2 ml). (The reagent was freshly prepared under cooling with Dry Ice.) The mixture was stirred with anhydrous cupric sulfate (120 mg) for 2.5 h at room temperature, then cooled with Dry Ice and neutralized by adding concentrated aqueous ammonia (0.6 ml). The voluminous inorganic precipitate was filtered off and the solution passed through small columns of acetone – prewashed ion exchange resins (1 ml each) Dowex 1 × 2 (acetate) and Amberlite IR-120 (H^+). The columns were rinsed with acetone and methanol (10 ml each). Evaporation of the filtrate gave a syrup (387 mg) which upon extraction with chloroform (3.8 ml) left behind a dark mass (85 mg). The extract was chromatographed on Merck silica gel (10 g, with 1 ml of water added), whereby elution with chloroform furnished a crop (119 mg, 24%) of crystalline **13**, m.p. 160–162°, in the second 10 ml fraction. Further elution with chloroform (50 ml) followed by acetone (30 ml) produced syrups that were combined with the aforementioned insoluble material and acetonated again as described. In this way, a second crop of **13** (36 mg) was obtained (total yield, 31%). Recrystallization from ligroin raised the m.p. to 169–170°. The n.m.r. data (in $CDCl_3$, with TMS): δ 4.6–4.5 (3H m, H-2, -3, -4), 4.24 (2H q, H-1 and -5, $J_{1,6} = J_{5,6}$ = 8, $J_{1,2} = J_{4,5}$ = 5.5 Hz), 3.58 (3H s, OCH_3), 3.41 (1H t, H-6, $J_{5,6} = J_{1,6}$ = 8 Hz), 1.54 and 1.34 (two 6H s, for two isopropylidene groups).

Anal. Calcd. for $C_{13}H_{21}NO_7$ (mol. wt. 303.3): C, 51.48; H, 6.98; N, 4.62. Found: C, 51.34; H, 6.79; N, 4.74.

*(b) From the epi-3 Isomer **16***

A 268-mg sample of pure **16** (free from isomers according to n.m.r. spectrum) was acetonated by the method described in section *a*. By chromatography on silica gel 131 mg (36%) of pure **13**, m.p. 168.5–169.5°, was obtained. Its spectrum was superimposable on that of the previous product.

*3-Deoxy-6-O-methyl-3-nitro-muco-inositol (**14**)*

The compound **13** (93 mg) was deacetonated by treatment with trifluoroacetic acid (0.30 ml) containing water (1 drop) for 30 min at room temperature. Evaporation of the solution followed by crystallization of the residue from ethyl acetate gave **14** (66 mg, 96%) as large colorless prisms or flat rectangular plates, m.p. 161–163°. The n.m.r. data (in 2.1 *N* CF_3CO_2D–D_2O, with acetone as reference): δ 2.75 (1H t, H-3, $J_{2,3} = J_{3,4}$ = 10 Hz), 2.07 (2H q, H-2 and -4, $J_{2,3} = J_{3,4}$ = 10, $J_{1,2} = J_{4,5}$ = 3 Hz), 2.01 (2H t, H-1 and -5, $J_{1,2} = J_{1,6} = J_{4,5} = J_{5,6}$ = 3 Hz), 1.58 (1H t, H-6, $J_{1,6} = J_{5,6}$ = 3 Hz), 1.25 (3H s, OCH_3).

Anal. Calcd. for $C_7H_{13}NO_7$ (mol. wt. 223.2): C, 37.66; H, 5.87; N, 6.28. Found: C, 37.54; H, 6.00; N, 6.47.

*1,2,4,5-Tetra-O-acetyl-3-deoxy-6-O-methyl-3-nitro-muco-inositol (**15**)*

Compound **14** (66 mg) was treated with acetic anhydride (0.66 ml) and 1 drop of BF_3–etherate for 1 h at 0°. Ethanol (0.4 ml) was then added, and the tetraacetate **15** (101 mg, 88%) crystallized in part directly and in part upon evaporation of the solution. It was washed with a small amount of ethanol and melted at 187–188°. Recrystallization lowered the melting point: 170–172° (from ethanol), 175–176° (from ethyl acetate – ligroin). How-

ever, the n.m.r. spectra of the crude and recrystallized samples were indistinguishable (data see Table 1).

Anal. Calcd. for $C_{15}H_{21}NO_{11}$ (mol. wt. 391.3): C, 46.03; H, 5.41; N, 3.58. Found: C, 46.18; H, 5.54; N, 3.70.

Cyclization of Nitro Hexoses with Sodium Methoxide

To a suspension of crystalline 7-β (645 mg) in methanol (2 ml) and nitromethane (2.9 ml) was added 0.96 ml of a 3.25 *N* solution of sodium methoxide in methanol. The addition, which was performed at room temperature under nitrogen, caused 7-β to dissolve, and a new solid began to precipitate immediately afterwards. The reaction mixture was allowed to stand in a closed vessel for 4 days, then cooled with Dry Ice, and acidified with glacial acetic acid (0.3 ml). The solution was passed consecutively through short columns containing 5 ml of Dowex 1 × 2 (acetate) and 10 ml of Rexyn 101 (H^+), respectively. The columns were rinsed with methanol and then with water, the former eluant furnishing upon evaporation 418 mg of a brown syrup, and the latter, 246 mg of a yellow semicrystalline mass. Trituration of the products with ethanol and fractional crystallization gave 102 mg (16%) of a mixture of **9** and **10** (m.p. 190–210°), 52 mg (8%) of what according to an n.m.r. spectrum consisted mainly of **14** (although it melted over the range 102–145° and therefore was not pure), and 395 mg (61%) of an amorphous foam similar in composition to the amorphous material C encountered in the barium hydroxide-induced cyclizations.

A similar experiment starting with a noncrystalline mixture (670 mg) of **7** and **8** furnished, after a reaction time of 1 day, 173 mg (26%) of **9** + **10** (m.p. 200–220°) and 429 mg (64%) of amorphous material.

The amorphous products obtained from these cyclizations were acetonated and yielded pure **13** in yields of 30–35%.

Support of this work by the National Research Council of Canada is gratefully acknowledged.

The Synthesis of Nitro and Dimeric Nitroso Sugars by Peracid Oxidation of Amino Sugars[1]

HANS H. BAER AND SHUET-HING LEE CHIU

Department of Chemistry, University of Ottawa, Ottawa, Canada K1N 6N5

Received January 19, 1973

A number of methyl 3-amino-3-deoxyaldopyranosides were oxidized with *m*-chloroperbenzoic acid. The reaction, which had been previously applied to steroidal amines (6), has provided a new route to nitro sugars and at the same time furnished hitherto unknown nitroso sugar derivatives, namely, dimeric methyl 3-deoxy-3-nitrosoaldopyranosides. Oxidation of a model compound, *trans*-2-aminocyclohexanol, likewise gave the corresponding nitro and dimeric nitroso alcohols. The combined yields of oxidation products ranged from 40 to 95%.

Plusieurs méthyl amino-3 déoxy-3 aldopyranosides ont été oxydés en utilisant l'acide *m*-chloroperbenzoique. Ayant déjà été appliquée aux amines stéroïdales (6), la réaction a ainsi permis une nouvelle approche pour l'obtention de sucres comportant des groupes nitro et ainsi fournir des dérivés de sucres comportant des groupes nitroso jusqu'alors inconnus, à savoir des méthyl deoxy-3 nitroso-3 aldopyranosides dimériques. L'oxydation d'un composé modèle, le *trans*-amino-2 cyclohexanol, a produit tel qu'envisagé les alcools correspondants possèdant un groupe nitro et un groupe nitroso typique du composé dimérique. Les rendements combinés des produits d'oxydation se situent dans l'intervalle de 40 à 95%.
[Traduit par le journal]

Can. J. Chem., 51, 1812 (1973)

In order to complement existing methods for the synthesis of nitro sugars (1), we considered the possibility of oxidizing amino sugar derivatives. Whereas permanganate oxidation is limited to tertiary carbinamines (2) and therefore is not apt to become a general method for the purpose stated, peracid oxidation offered itself as a potential alternative. Aliphatic amines have been oxidized to the corresponding nitro compounds by means of peracetic acid (3, 4), perbenzoic acid (5), and *m*-chloroperbenzoic acid (6). Trifluoroperacetic acid has been stated (3) to be unsuitable for oxidation of amines although it is capable of converting oximes to nitro compounds (7, 8); applications to carbohydrate oximes were reported (9) while the present work was in progress. Of the reagents mentioned, *m*-chloroperbenzoic acid appeared to promise the most convenient and hazard-free use. This stable, commercially available compound is widely employed for various oxidative processes even though use for amine oxidation has been made infrequently.

We now report that certain amino glycosides can indeed be converted into nitro glycosides by treatment with *m*-chloroperbenzoic acid. The reaction proved complicated, however, by the formation of varying proportions of nitroso derivatives along with the desired nitro compounds. Similar observations have been made in previous peracid oxidations (6, 10). The nitroso compounds arise as intermediates and, depending on circumstances, tend to form stable dimers that are oxidized no further. In fact, a dimeric nitroso compound may occasionally be the sole product as was the case in one of our examples and, earlier, in the oxidation of cyclohexylamine with peracetic acid (10). Table I shows the results obtained with five amino glycosides and with *trans*-2-aminocyclohexanol which was included as a model compound. In general, the reactions proceeded quite smoothly in mixtures of chloroform and methanol at reflux temperature, and the combined yields of oxidation products were good.

Even though the original purpose of this enterprise was the search for an alternative route to nitro sugars, the isolation of nitroso carbohydrates was actually of equal interest since very few accounts of such derivatives exist in the literature. Serfontein and coworkers (11) obtained 2-nitrosoglycosyl chlorides by the action of nitrosyl chloride upon glycals. Lemieux and his associates (12) studied the same reaction,

[1]Abstracted from the Ph.D. thesis of S. H. Lee Chiu, University of Ottawa, Ottawa, Canada, 1971, and reported at the 8th International Symposium on the Chemistry of Natural Products (IUPAC), New Delhi, India, February, 1972.

TABLE 1. Yields of oxidation products (%)

Amine	Products	
	Nitro compound	Nitroso dimer
trans-2-Aminocyclohexanol	16	28
Methyl 3-amino-3,6-dideoxy-2,4-di-*O*-methyl-α-L-glucopyranoside	53	0
α-D-glucopyranoside	44*	43*
	51†	33†
	26‡	69‡
	0§	75§
Methyl 3-amino-3-deoxy-β-D-galactopyranoside	28	47
α-D-mannopyranoside	38	32
β-D-xylopyranoside	0	40

*Amine added to oxidant (6.67 mol equiv) over period of 30 min, with final medium being approximately 3:1 chloroform–methanol (v/v); see Experimental.
†Similar to *, with 2:1 chloroform–methanol as final medium.
‡Similar to *, with addition period of 7 min.
§Amine added to oxidant (3 mol equiv) at once, with medium consisting of chloroform only; reaction time, 1 h at reflux temperature.

extended it to include the use of dinitrogentetraoxide which afforded 2-nitrosoglycosyl nitrates, established the dimeric structure of these nitroso sugars, and subjected them to some reactions of mechanistic interest and synthetic promise. But apart from these important studies nothing is known about nitroso sugars, and their availability by simple oxidation of amino sugars should stimulate further exploration of their properties and potential usefulness.

Oxidation of *trans*-2-aminocyclohexanol produced known (13) *trans*-2-nitrocyclohexanol together with dimeric *trans*-2-nitrosocyclohexanol (**1**) which apparently has not yet been described. Its structure followed from spectral data. The compound displayed intense u.v. absorption with λ_{max} 296 nm resembling that reported (10) for dimeric nitrosocyclohexane, λ_{max} 290 nm. Broad i.r. absorption in the 3400 cm^{-1} region indicated hydrogen-bonded hydroxyl, and a strong band near 1200 cm^{-1} was due to the N → O stretching vibration of the dimeric nitroso moiety. Complete lack of absorption between 2800 and 1500 cm^{-1} revealed absence of carbonyl, nitro, amino, and (monomeric) nitroso groups. Similar u.v. and i.r. data were found for our dimeric nitroso glycosides, and according to the literature (14) they suggest *trans*-geometry of the azodioxy bridge. Of further interest were the n.m.r. spectra of **1** and 2-nitrocyclohexanol. In the nitro alcohol, the nitromethine and carbinol protons had similar chemical shifts causing overlapping multiplets near δ 4.2. In **1**, only the carbinol proton (H-1) resonated in that region while H-2 was shifted downfield to δ 5.2 (in $CDCl_3$). The strong deshielding effect of the azodioxy group has been noted previously (12, 15).

Independent work in this laboratory (16) had furnished methyl 3,6-dideoxy-2,4-di-*O*-methyl-3-nitro-α-L-glucopyranoside (**2**) and, by catalytic hydrogenation, the corresponding amino glycoside (**3**). The latter has now been reconverted to the former by oxidation. No nitroso derivative was found in this one case.[2]

When methyl 3-amino-3,6-dideoxy-α-D-glucopyranoside (**4**) was oxidized for 1 h with 3 mol equiv of oxidant in refluxing chloroform, the nitroso dimer **5** was isolated in 75% yield as the sole product, although complete absence of nitro compound **6** was not ascertained. An increased amount of oxidant (4.25 mol equiv) gave rise to a mixture of **5** and **6** in which, according to an estimate from the n.m.r. spectrum, the nitroso

[2]It will be noted (Table 1) that **3** was the only amine thus far examined that does not bear a free hydroxyl group vicinal to the nitrogen. Perhaps this feature favors further oxidation of the nitroso intermediate whose dimer, lacking internal hydrogen bond stabilization, would in this case be less stable than in the others. However, in order to validate such an explanation one ought to reexamine the oxidation of cyclohexylamine (10) under our conditions. An alternative explanation might be steric hindrance to dimerization of the nitroso intermediate. Although a strain-free model of the dimer can be constructed, the two methoxyl groups in positions 2 and 4 could nevertheless have a retarding effect upon the rate of dimerization.

compound still preponderated about 1.5-fold. Best results in terms of oxidation to the nitro stage were achieved when the amine was added gradually to a larger excess (6–7 equiv) of oxidant in refluxing chloroform–methanol mixtures. While relatively rapid addition gave predominantly **5**, slow addition changed the product ratio in favor of **6**. An increase in methanol concentration in the reaction medium likewise operated in this direction (Table 1). One may probably conclude from these observations that rapid oxidation of the amine to monomeric nitroso intermediate is followed by slow oxidation of the latter to the nitro compound in competition with dimerization. Thus, if the concentration of the monomeric nitroso derivative is allowed to build up due to a high initial amine concentration and the presence of only a moderate excess of oxidant, dimerization and hence protection from further oxidation is favored. But when the nitroso monomer concentration is kept low by slow introduction of the amine into the reaction medium, and when a larger excess of oxidant is available, then complete oxidation

wins over dimerization. The effect of added methanol may consist of opposing dimerization by increasing solvation of the monomer and (or) interfering with internal hydrogen bond stabilization in the dimer.

The nitro glycoside **6**, whose 2,4-diacetate **7** was also prepared for further characterization, was identified by comparison with its known L-enantiomer (17, 18). The nitroso dimer **5** showed spectral characteristics similar to **1**, namely, a high-intensity u.v. band with λ_{max} 298 nm and a strong i.r. band at 1190 cm^{-1}. The n.m.r. spectra of **5** and **6** were similar to each other in most respects (see Experimental) but differed significantly by a downfield shift experienced by the H-3 signal of **5**. Its chemical shift of *ca.* δ 6.0 compared well with data recorded (12) for protons at carbon bearing the azodioxy bridge in dimeric nitroso sugars (δ 5.38–5.53).

Oxidation of methyl 3-amino-3-deoxy-β-D-galactopyranoside (**8**) and its α-D-*manno* isomer (**11**) afforded the corresponding nitro glycosides **9** and **12** as well as the dimeric nitroso glycosides **10** and **13**. Like the preceding products the nitro sugars were identified by comparison with authentic samples, and the new nitroso derivatives were structurally elucidated through their spectral properties. Limited attempts to change the product ratios from those listed in Table 1 were to no avail.

The course of oxidation of methyl 3-amino-3-deoxy-β-D-xylopyranoside (**14**) differed from the aforedescribed experiments insofar as a crystalline product separated directly from the reaction medium during the reflux period. It was sparingly soluble in all solvents tried, including water and dimethyl sulfoxide. For this reason no n.m.r. spectrum could be obtained. The product was different from known (19) methyl 3-deoxy-3-nitro-β-D-xylopyranoside, and its u.v. and i.r. data suggested that it was the nitroso dimer **15**. It seems that the high degree of insolubility of the dimer caused the monomer to be removed from solution so rapidly that it failed to be oxidized to the nitro stage.

Experimental

All reactions were monitored by t.l.c. on 7.5-cm silica gel G plates. The spots were made visible by use of 1% ceric sulfate in 10% sulfuric acid as a spray reagent, and heating. Column chromatography was performed with silica gel 7734 (0.05–0.20 mm) of E. Merck AG, Darmstadt, Germany. I.r. spectra were taken on a Beckman IR-20 spectrometer and refer to Nujol mulls unless otherwise stated; only the most prominent bands are listed for characterization of compounds. Optical rotations were measured with a Perkin–Elmer Model 141 automatic polarimeter at room temperature. Chemical shifts in n.m.r. spectra taken in $CDCl_3$ refer to the tetramethylsilane signal, and in those taken in D_2O, to the DOH signal. U.v. spectra were recorded on a Perkin–Elmer Model 202 spectrophotometer.

Materials

trans-2-Aminocyclohexanol

The amino alcohol was prepared according to Brunnel (20) by reaction of cyclohexene oxide (5.3 ml) in methanol (50 ml) with liquid ammonia (40 ml) in a sealed tube for 2 h at 80° and 12 h at room temperature. The product was purified by sublimation at 45° and 2 Torr. It was obtained as colorless needles, m.p. 67–69°, in 63% yield; lit. (20), m.p. 67–68°. I.r. and n.m.r. spectra were in agreement with the structure. Treatment with ethanolic hydrochloric acid furnished the *hydrochloride* which upon recrystallization from 95% ethanol melted at 178.5–180°; lit. (20), m.p. 175°, 176–177°.

*Amino Glycosides **3**, **4**, **8**, and **14***

The known compounds **8** (21, 22) and **14** (23, 24) were on hand from earlier work in this laboratory. Compound **3** (dec. 263–265°, $[\alpha]_D$ −133° in chloroform) was kindly provided by Dr. Chung-Wai Chiu who had synthesized it from known, crystalline methyl 3,6-dideoxy-3-nitro-α-L-glucopyranoside (25, 17) by an unpublished procedure (16). The known compound **4** (26) was obtained by a new synthesis to be described elsewhere (27).

*Methyl 3-Amino-3-deoxy-α-D-mannopyranoside (**11**)*

The free amino glycoside **11**, which has not been described previously, was made from its known hydrochloride (28). A solution of the latter (0.33 g) in 95% ethanol (25 ml) was passed through a column containing 10 g of dry Dowex 1X2 (OH^-) anion exchange resin. The effluent was evaporated to give **11** which was recrystallized from ethanol; m.p. 160–162°, $[\alpha]_D$ +70 (*c*, 1 in H_2O) and +91° (*c*, 1 in methanol). The yield was 0.24 g (86%).

Anal. Calcd. for $C_7H_{15}NO_5$ (mol. wt. 193.2): C, 43.51; H, 7.83; N, 7.25. Found: C, 43.48; H, 7.80; N, 7.21.

Oxidations with m-Chloroperbenzoic Acid. General Procedure

m-Chloroperbenzoic acid (MCPA) was supplied by Aldrich Chemical Co. According to specifications its degree of purity was 85%; the amounts given in the following have been calculated to represent pure MCPA. A solution of the reagent in chloroform (unless otherwise indicated) was heated to reflux, with efficient magnetic stirring, in a vessel equipped with condenser and dropping funnel. A solution (or partial suspension) of the amine to be oxidized, in chloroform or chloroform–methanol mixture as indicated, was admitted slowly over the period of time stated in parentheses. Refluxing was then continued for another period of time, and the reaction mixture was subsequently cooled and worked-up as described.

Oxidation of trans-2-Aminocyclohexanol

trans-2-Nitrocyclohexanol

The amino alcohol (100 mg, 0.865 mmol) in chloroform (8 ml) was added (5 min) to MCPA (450 mg, 2.6

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

mmol) in chloroform (5 ml). The reaction was stopped after 1 h, at which time t.l.c. (10% ethyl acetate in benzene) showed two new spots, R_f 0.6 and 0.3. The solution was cooled in a refrigerator, filtered, washed with ice cold sodium bicarbonate solution, dried (Na_2SO_4), and evaporated. The semi-solid material so obtained was chromatographed on a column of silica gel (5 g). Elution was performed with benzene containing, respectively, 5% ethyl acetate (20 ml), 10 and 25% of the same (20 ml each), and 20% ethyl acetate plus 10% ethanol (40 ml). The faster-moving product, isolated from early fractions that showed a single spot on t.l.c., was a yellow oil which crystallized on trituration with benzene–pentane and cooling. The needles (20 mg, 16%) melted at 46–47°. Recorded (13) for *trans*-2-nitrocyclohexanol, m.p. 46–48°. I.r. absorption was at 3340 (broad; OH), 2930, 2860, 1545, 1450, 1370, 1065, 970, 860, and 735 cm^{-1} (from liquid film). N.m.r. (100 MHz, $CDCl_3$): 2-proton multiplet centered near δ 4.2 (H-1 and -2); 2.74 (s, 1H, exchangeable with D_2O; hydroxy proton); 2.50–0.9 (unresolved, intensity 8H; methylene protons).

*trans-2-Nitrosocyclohexanol Dimer (**1**)*

The fractions containing the slow-moving product from the column mentioned above were evaporated to give a white solid, m.p. 118–122°. Recrystallization from ethyl acetate – petroleum ether (b.p. 60–80°) afforded **1** (31 mg, 28%) as fine needles, m.p. 130–132°. U.v. absorption in methanol: λ_{max} 296 nm (ε 7500). I.r. bands: 3400 (broad), 1195, 1175, 1065, 690 cm^{-1}. N.m.r. (60 MHz, $CDCl_3$): δ 5.2 (m, 1H, H-2); 4.1 (m, 1H, H-1); 3.43 (hydroxyl proton); 2.5–1.0 (unresolved, intensity 8H; methylene protons).

Anal. Calcd. for $C_{12}H_{22}N_2O_4$ (mol. wt. 258.3): C, 55.79; H, 8.59; O, 24.78. Found: C, 55.54; H, 8.38; O, 24.95.

Oxidation of *trans*-2-aminocyclohexanol hydrochloride gave similar results.

*Methyl 3,6-Dideoxy-2,4-di-O-methyl-3-nitro-α-L-glucopyranoside (**2**)*

The amino glycoside hydrochloride **3** (50 mg, 0.21 mmol) in methanol (3 ml) and chloroform (8 ml) was added (20 min) to MCPA (312 mg, 1.81 mmol) in chloroform (10 ml). Although only a trace of **3** remained 5 min later, boiling was continued for another 20 min. One major product spot (R_f 0.70) and a faint shadow just above the baseline were then seen on t.l.c. (15% ethyl acetate in benzene). The reaction mixture was evaporated to dryness and the residue was carefully triturated with chloroform (10 ml) to give a suspension which was strongly cooled (−19°) for some time and then filtered. The filtrate on evaporation gave a material which was chromatographed on silica gel (17 g) using 15% ethyl acetate in benzene (150 ml) as the eluant. The fractions containing the major reaction product yielded a semi-solid mixture of **2** and aromatic acid. Passage of this mixture through a small column (1.5 × 2.0 cm) of aluminum oxide (Woelm, neutral), with benzene as eluant, gave pure **2** as a syrup (26 mg, 53%) from early fractions. The product showed $[\alpha]_D$ −144.3° (*c*, 0.6 in $CHCl_3$), and its spectral data were in agreement with those of an independently synthesized sample (16) which showed $[\alpha]_D$ −141.3° (*c*, 1.6 in $CHCl_3$). Liquid film i.r. absorptions were at 2930, 2840, 1560, 1100, 1050, and 995 cm^{-1}. N.m.r. (60 MHz in $CDCl_3$): δ 4.9–4.8 (2H, d and t overlapping; H-1 and -3 with $J_{1,2} = 3.5$ and $J_{2,3} = J_{3,4} = 10.5$ Hz); 3.82 (1H, q, H-2, with $J_{1,2} = 3.5$ and $J_{2,3} = 10.5$ Hz); 3.65–3.25 (overlapping signals of H-4 and -5, and prominent singlets at 3.47 and 3.42 due to three OCH_3 groups; total intensity 11 H); 1.31 (3H, d, $J_{5,6} = 6$ Hz; C—CH_3).

*Oxidation of Methyl 3-Amino-3,6-dideoxy-α-D-glucopyranoside (**4**)*

The typical procedure described yielded approximately equal amounts of **5** and **6**. Reactions performed in the same general fashion but with variations as specified in Table 1 led to the different yields there recorded.

*Methyl 3,6-Dideoxy-3-nitroso-α-D-glucopyranoside Dimer (**5**)*

Compound **4** (169 mg, 0.95 mmol) in a mixture of methanol (7 ml) and chloroform (10 ml) was added (30 min) to MCPA (1.35 g, 6.67 mmol) in chloroform (12 ml). Ten minutes after the addition, **4** had completely disappeared and two products (R_f 0.23 and 0.1) were formed according to t.l.c. with 5% ethanol in benzene. Another 45 min of refluxing was allowed before the solvent was evaporated. The residue was extracted with water (4 × 5 ml). The material that remained undissolved was mainly aromatic acid and was discarded. Evaporation of the aqueous extract gave a solid (212 mg after drying) which by means of chloroform containing 5% of methanol was passed through a column of 5 g of aluminum oxide (Woelm, neutral, activity grade III). The effluent furnished the nitrogenous sugars still contaminated with aromatic acid. Good separation was then achieved by chromatography on silica gel (9 g) by use of 8 and 10% ethanol in benzene (120 and 50 ml, respectively). The product eluted first (R_f 0.23) was the nitro sugar **6** (see the next section). The fractions that contained the more slowly moving product only were evaporated to give colorless crystals of **5** (78 mg, 43%), m.p. 148–152°. Recrystallization from a small amount of ethyl acetate containing a few drops of absolute ethanol was achieved by adding a few drops of petroleum ether and cooling overnight. The fine prisms then melted at 154–156°, with the melt turning red and decomposing at 165°; $[\alpha]_D$ +152° (*c*, 0.4 in water). U.v. absorption in water, λ_{max} 298 nm (ε 7600). I.r. bands: 3440–3360 (broad), 1295, 1193, 1130, 1095, 1053, 1035, and 960 cm^{-1}. N.m.r. (60 MHz, D_2O): downfield from DOH, 1.25 (t, 1H, $J_{2,3} = J_{3,4} = 10$ Hz; H-3) and 0.20 p.p.m. (d, 1H, $J_{1,2} = 3.7$ Hz; H-1); upfield from DOH, 0.55 p.p.m. (q, 1H, $J_{1,2} = 3.7$, $J_{2,3} = 10$ Hz; H-2); 0.8–1.1 (m, 2H; H-4 and -5); 1.18 (s, 3H; OCH_3); 3.36 (d, 3H, $J_{5,6} = 6$ Hz; C—CH_3).

Anal. Calcd. for $C_{14}H_{26}N_2O_{10}$ (mol. wt. 382.4): C, 43.97; H, 6.85; O, 41.85. Found: C, 43.85; H, 6.70; O, 41.87.

*Methyl 3,6-Dideoxy-3-nitro-α-D-glucopyranoside (**6**)*

The chromatographic fractions containing the faster-moving product (see the preceding section) were evaporated to give a syrup which crystallized on drying *in vacuo* (87 mg, 44%). Recrystallization from chloroform – petroleum ether (b.p. 60–80°) afforded **6** as long needles, m.p. 140–141° and $[\alpha]_D$ +160° (*c*, 1 in water). Data reported (17) for the L-enantiomer: m.p. 136–139°, 141–143°, 142–145°; $[\alpha]_D$ −164.5°, −162°. Compound **6** gave an i.r. spectrum superimposable on that of the enantiomer, and its n.m.r. data agreed completely with those published (25) for the enantiomer.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Methyl 2,4-Di-O-acetyl-3,6-dideoxy-3-nitro-α-D-glucopyranoside (7)

A sample of **6** (35 mg) was acetylated (0°, 30 min) with acetic anhydride (1 ml) and ethereal boron trifluoride (2 drops). Excess anhydride was decomposed with ice-water and the product extracted with chloroform from which, on evaporation with added toluene, a dry syrup was obtained. The syrup crystallized on trituration with petroleum ether, and recrystallization from ethyl acetate – petroleum ether gave colorless needles (40 mg, 81%) showing m.p. 108–110° and $[\alpha]_D$ +154° (*c*, 0.3 in $CHCl_3$). Reported for the L-enantiomer: m.p. 109–110° and $[\alpha]_D$ −154° (18); m.p. 113–113.5° and $[\alpha]_D$ −155.3° (16). I.r. spectra of **7** and its enantiomer were identical.

Oxidation of Methyl 3-Amino-3-deoxy-β-D-galactopyranoside (8)

Methyl 3-Deoxy-3-nitro-β-D-galactopyranoside (9)

The amino glycoside **8** (193 mg, 1.0 mmol) in a 1:1 methanol–chloroform mixture (8 ml) was added (20 min) to MCPA (1.28 g, 6.32 mmol) in the same solvent (19 ml). Refluxing was continued for another 20 min. Complete consumption of **8** and formation of two products, R_f 0.5 and 0.25, was revealed by t.l.c. (20% methanol in chloroform). The white residue obtained upon evaporation of the reaction mixture was extracted with ether (2 × 10 ml). The part that remained undissolved was dealt with as described later on. The ether extract, which contained part of **9** and aromatic acid, was washed with water (3 × 5 ml) which upon evaporation gave a semi-solid material (89 mg). Passage of this material by means of chloroform containing 5% of methanol through a small silica gel column (5 g) yielded syrupy **9** that crystallized from acetone–chloroform. The colorless product (36 mg) exhibited $[\alpha]_D$ +32.5° (*c*, 0.5 in water) and melted at 80–82° (air dried) and at 125–128° (dried for 12 h *in vacuo* at 56°); lit. (21): $[\alpha]_D$ +32.6°; m.p. 87–89 and 131–132°, respectively. Identity of the product with previously prepared **9** (21) was confirmed by i.r. spectra. The n.m.r. spectrum (100 MHz in D_2O) was in accord with the β-D-*galacto* configuration: downfield from DOH, 0.22 p.p.m. (q, 1H, $J_{2,3}$ = 10, $J_{3,4}$ = 3.5 Hz; H-3); upfield from DOH, 0.21 (d, 1H, $J_{1,2}$ = 8 Hz; H-1), 0.55 (q, 1H, $J_{1,2}$ = 8, $J_{2,3}$ = 10 Hz; H-2), 1.07 p.p.m. (s, 3H; OCH_3).

The ether-insoluble residue mentioned above was suspended in methanol (5 ml) whereby it partly dissolved, leaving behind 80 mg of chromatographically pure nitroso dimer **10** (see the next section). The methanolic solution contained both **9** and **10** (t.l.c.). Evaporation followed by chromatography on silica gel (8 g) with chloroform containing increasing amounts of methanol furnished 26 mg of **9** and 17 mg of **10**, thus raising the total yields to 62 (28%) and 97 mg (47%), respectively.

Methyl 3-Deoxy-3-nitroso-β-D-galactopyranoside Dimer (10)

Compound **10** isolated as just described was recrystallized from methanol–water to form colorless needles; m.p. 141–143°, $[\alpha]_D$ +165° (*c*, 0.6 in water); λ_{max} 295 nm (ε 7500, in water). I.r. bands were at 3300 (broad), 1190, 1160, 1130, 1055, 1020, and 980 cm^{-1}. Most of the n.m.r. signals (60 MHz, D_2O) were poorly resolved, but the signal at lowest field (0.69 p.p.m. downfield from DOH) was a clear quartet assignable to H-3 ($J_{2,3}$ = 10, $J_{3,4}$ = 3 Hz). The OCH_3 singlet occurred 1.08 p.p.m. upfield from DOH.

Anal. Calcd. for $C_{14}H_{26}N_2O_{10}$ (mol. wt. 414.4): C, 40.58; H, 6.42; O, 46.34. Found: C, 40.64; H, 6.42; O, 46.26; mol. wt., 423 (osmometrically in water).

Oxidation of Methyl 3-Amino-3-deoxy-α-D-mannopyranoside (11)

Methyl 3-Deoxy-3-nitro-α-D-mannopyranoside (12)

The amino glycoside **11** (110 mg, 0.57 mmol) in a mixture of methanol (9 ml) and chloroform (4 ml) was added (20 min) to MCPA (800 mg, 3.94 mmol) in chloroform (8 ml). After continued refluxing for another 20 min all **11** had been consumed and two products (R_f 0.6 and 0.23, with 3:1 benzene–ethanol) were seen. The residue obtained on solvent evaporation was extracted with ether (4 × 10 ml) and set aside for further use (see below). The ethereal extract was shaken four times with 5 ml of 50% aqueous tetrahydrofuran. The water phase that separated contained part of **12** along with some aromatic acid. The latter could be removed by chromatography of the solute on silica gel (5 g) using chloroform with increasing proportions of methanol (0, 5, 10, 15%) as eluant. The colorless syrup of **12** obtained from the eluate crystallized from ethyl acetate and petroleum ether after prolonged cooling, forming rosettes of large crystals (23 mg), m.p. 120–120.5° $[\alpha]_D$ +37.2° (*c*, 0.6 in water). The i.r. spectrum was identical with that of authentic **12**; lit. (29): m.p. 113–115° (from tetrahydrofuran–ether); $[\alpha]_D$ + 44.5°.

The crude reaction residue that had been extracted with ether (see above) was fractionated on a silica gel column (8 g) with chloroform–methanol as described. An additional 26 mg of the faster-moving nitro sugar **12** was thereby obtained in crystalline form, raising its yield to 49 mg (38.5%). Later fractions contained the nitroso dimer **13**.

Methyl 3-Deoxy-3-nitroso-α-D-mannopyranoside Dimer (13)

Evaporations of the fractions just mentioned gave **13** as a foam which was dried *in vacuo* to a white, hygroscopic powder (40 mg, 34%) melting at 93–96° and exhibiting $[\alpha]_D$ −14° (*c*, 0.2, in water). All attempts at recrystallization failed. The product showed λ_{max} 293 nm (ε 4000, in water) and i.r. bands at 3300 (broad), 1195, 1140, 1060 (broad), and 975 cm^{-1}. Most of the n.m.r. signals (100 MHz in D_2O) were poorly resolved, but the signal at lowest-field (0.69 p.p.m. downfield from DOH) was a well-separated quartet assignable to H-3 ($J_{2,3}$ = 3, $J_{3,4}$ = 10.5 Hz). The OCH_3 singlet occurred at 1.29 p.p.m. upfield from DOH.

Oxidation of Methyl 3-Amino-3-deoxy-β-D-xylopyranoside (14)

A solution of amino glycoside **14** (26.5 mg, 0.16 mmol) in methanol (2 ml) and chloroform (4 ml) was added (10 min) to MCPA (200 mg, 1.16 mmol) in chloroform (6 ml). The initially clear reaction mixture became turbid during this period due to the separation of crystals, and this condition persisted even when more methanol was added. It was seen on t.l.c. that all the starting glycoside had reacted shortly after its introduction, and only one new spot was detected (R_f 0.27). The crystals (11 mg) were collected after cooling of the solution and recrystallized from hot methanol–water. The fine colorless needles melted at 168–170°, turning dark red in the process. The product was assumed to be methyl 3-deoxy-3-nitroso-β-D-

xylopyranoside dimer (**15**) on grounds of its spectral data, low R_f-value, and poor solubility even in water and DMSO. It displayed λ_{max} 300 nm (ε 7000 in water) and i.r. bands at 3400 (broad), 1295, 1215, 1195, 1150, 1120, 1090, 1060, 1020, 985, and 875 cm^{-1}. No NO_2 vibration was present in the 1550 cm^{-1} region. The product was clearly different in all these characteristics from known methyl 3-deoxy-3-nitro-β-D-xylopyranoside (19) which melts at 186–187°, shows greater solubility, and gives a nitro band in the i.r. but no high-intensity u.v. absorption in the 300 nm region.

The Structure of the Capsular Polysaccharide of Klebsiella K-type 24

YUEN-MIN CHOY, GUY G. S. DUTTON, AND ALBERTO M. ZANLUNGO[1]

Department of Chemistry, The University of British Columbia, Vancouver, British Columbia

Received December 11, 1972

Methylation, periodate oxidation, and partial hydrolysis studies on the capsular polysaccharide, and on the carboxyl reduced polymer, of *Klebsiella* K24 show the structure to consist of a repeating unit

$$\begin{array}{l} \overset{2}{\text{—}}\ \text{D-GlcA}p\ \dfrac{1\ 3}{\alpha}\ \text{D-Man}p\ \dfrac{1\ 2}{\alpha}\ \text{D-Man}p\ \dfrac{1\ 3}{\alpha}\ \text{D-Glc}p\ \dfrac{1}{\beta} \\ \quad\ \beta\Big|{}^{4}_{1} \\ \quad\ \text{D-Man}p \end{array}$$

The anomeric linkages were determined in isolated oligosaccharides by p.m.r. spectroscopy which also showed the presence in the polysaccharide of one *O*-acetyl group per seven or eight sugar residues. The *O*-acetyl is tentatively assigned to one of the D-mannose units.

Les méthodes de méthylation, oxydation periodique, et hydrolyse partielle portées au polysaccharide capsulaire, et au polymère avec le groupe carboxyle réduit, de *Klebsiella* K24 ont démontré que la structure se compose d'une unité qui se répéte.

$$\begin{array}{l} \overset{2}{\text{—}}\ \text{D-GlcA}p\ \dfrac{1\ 3}{\alpha}\ \text{D-Man}p\ \dfrac{1\ 2}{\alpha}\ \text{D-Man}p\ \dfrac{1\ 3}{\alpha}\ \text{D-Glc}p\ \dfrac{1}{\beta} \\ \quad\ \beta\Big|{}^{4}_{1} \\ \quad\ \text{D-Man}p \end{array}$$

Les liaisons anomères ont été distinguées chez des oligosaccharides par la spectroscopie r.m.n. qui a aussi mis en évidence dans le polysaccharide la présence d'un groupe *O*-acétyl par rapport à sept ou huit sucres. On pense que le groupe *O*-acétyle est lié à un des restes de D-mannose.

Can. J. Chem., **51**, 1819 (1973)

Qualitative analyses of the capsular polysaccharides of the 80 serotypes of *Klebsiella* bacteria have been provided by Nimmich (1, 2). In continuation of our work (3) on the structure of these materials, we now report studies on the capsular polysaccharide from *Klebsiella* K-type 24.

The polysaccharide, purified by precipitation with Cetavlon, moved as a single band on electrophoresis on cellulose acetate and had $[\alpha]_D^{27}$ +79° and an equivalent weight (by titration) of 786. The p.m.r. spectrum of a 2% solution of the sodium salt of the polysaccharide in D_2O run at 95° showed a sharp singlet at τ 7.8 characteristic of *O*-acetyl and the absence of pyruvate (4, 5). The anomeric region of the spectrum suggested that the repeat unit consists of five sugar units of which three are linked by α-D- and two by β-D-glycosidic bonds (5). Integration of the anomeric and acetate signals indicated one acetyl group to seven or eight sugar units. The presence of *O*-acetyl groups was also confirmed by formation of the hydroxamic ester (6).

Acid hydrolysis of the polysaccharide showed the rapid liberation of D-mannose and after 4 h D-mannose and D-glucose were proved to be the only neutral sugars present, in the ratio of 2.7:1. This analysis was carried out on the derived alditol acetates, samples of which were collected by g.l.c., and measurement of their c.d. spectra confirmed the assignment of the D-configuration to both sugars (7).

Partial hydrolysis of the polysaccharide gave a series of acidic oligosaccharides which were separated from the neutral sugars by ion-exchange resins and individual components were obtained by paper chromatography. These were shown to be an aldobiouronic acid together with related aldotri- and aldotetra-uronic acids. The structures of these oligosaccharides (as their alditols) are given in Table 1 together with the chemical shift of the anomeric proton(s) which

*Spectra run in D_2O with external tetramethylsilane (τ = 10) at 100 MHz.

enables the nature of the glycosidic linkages to be determined. The structures given were determined by (*a*) hydrolysis after conversion to the alditol, (*b*) hydrolysis after carboxyl reduction, and (*c*) methylation, as described in the Experimental. The aldobiouronic acid 3-*O*-(α-D-glucopyranosyluronic acid)-D-mannose has been found in *Klebsiella* K2 and K21 and elsewhere (3).

When a sample of the fully methylated (8, 9) polysaccharide was hydrolyzed and the neutral sugars were examined 2,3,4,6-tetra- and 3,4,6-tri-*O*-methyl-D-mannose and 2,4,6-tri-*O*-methyl-D-glucose were found together with a small quantity of 2,4,6-tri-*O*-methyl-D-mannose. An attempt to analyze this mixture quantitatively as alditol acetates was not satisfactory since on columns of ECNSS-M and butanediol succinate the 2,4,6- and 3,4,6-trimethylhexoses were not resolved. On a column of OS 138 these components gave two major peaks poorly resolved and a minor one (*ca.* 9% of the trimethyl fraction) which was identified by its retention time and mass spec rum as 2,4,6-tri-*O*-methyl-D-mannose. A good separation of the main components was obtained by chromatographing the trimethylsilyl derivatives (10) of the methylated sugars. This was done using three different columns and authentic standards as shown in Table 2. Under these conditions 2,3,4,6-tetra-*O*-methyl-D-mannose was clearly distinguished from the D-glucose isomer but it was not possible to estimate accurately the small amount of 2,4,6-tri-*O*-methyl-D-mannose. The ratio of 2,3,4,6-tetra-*O*-methyl-D-mannose : 3,4,6-tri-*O*-methyl-D-mannose : 2,4,6-tri-*O*-methyl-D-glucose was 1.1 : 1 : 1.

Alternatively it has been found (11) that methylated sugars may be separated conveniently as their acetates. When this method was employed here three main groups of peaks (A; B_1, B_2; C_1, C_2) in approximately equal proportions were obtained; B_2 was present in very small amount and was not examined further. Samples were collected of the other components, deacetylated, and examined on paper. Further samples were reduced, acetylated, and examined by g.l.c.–m.s. and each of the main components thus obtained was demethylated and converted to the hexitol peracetate. All of these results were

TABLE 2. Per(trimethylsilyl) derivatives of methylated sugars from *Klebsiella* K24 capsular polysaccharide

Compounds	Retention time (min) for columns: (a) ECNSS-M	(b) BDS	(c) SE-52
Methylated aldoses of K24	14.4 19.8 21.4	4.6 7.8 11.3	17.6 24.1 16.6
3,4,6-Me_3-Man	14.4	4.6	17.6
2,4,6-Me_3-Glc	19.8	7.8	24.1
2,3,4,6-Me_4-Man	21.4	11.3	16.6
2,3,4,6-Me_4-Glc	15.4 (20%) 17.0 (80%)	7.4 (15%) 8.2 (85%)	

consistent with the assignment of peaks A, B, and C as 2,3,4,6-tetra-*O*-methyl-D-mannose (A), 3,4,6-tri-*O*-methyl-D-mannose (B_1), and 2,4,6-tri-*O*-methyl-D-glucose (C_1 and C_2). The methylated alditol acetate obtained from B_1 showed an additional minor peak whereas both components C_1 and C_2 gave the same single alditol acetate. This indicates that C_1 and C_2 are the two anomers of the trimethylglucose and suggests that the small amount of 2,4,6-tri-*O*-methyl-D-mannose has a similar retention time to the 3,4,6-isomer. It may be noted that in this instance the mannose ethers have shorter retention times than the glucose compound but for the 2,3,6-tri-*O*-methyl derivatives the situation is reversed (11).

These results show the presence of a D-mannose unit substituted at position 2 and a D-glucose unit substituted at position 3 together with a D-mannose residue present as a side chain. The small amount of 2,4,6-tri-*O*-methyl-D-mannose undoubtedly arose by partial cleavage of the aldobiouronic acid linkage.

Another sample of the fully methylated polysaccharide was reduced with lithium borohydride and hydrolyzed. In addition to the methylated sugars described above a new component having the mobility on paper of 3- or 4-*O*-methyl-D-glucose was obtained. The mixture of methylated sugars was reduced with sodium borodeuteride (12) and the new component was isolated by g.l.c. of the alditol acetates. The mass spectrum clearly identified this component as a 3-*O*-methyl hexitol. Furthermore the c.d. spectrum of the alditol acetate was identical in sign (negative) with that obtained from authentic 3-*O*-methyl-D-glucose. This establishes the D-configuration of the glucuronic acid in this polysaccharide (7).

In order to determine the position of attachment of the pendant D-mannose units to the main chain, a sample of the original polysaccharide was subjected to mild hydrolysis and the recovered polymeric material was methylated, reduced with lithium borohydride, and hydrolyzed. Examination of the hydrolyzate by paper chromatography showed, in addition to the compounds previously obtained, a component having the mobility of 3,4-di-*O*-methyl-D-glucose. This was confirmed by g.l.c. separation of the alditol acetates and mass spectrometry of the dimethyl fraction together with demethylation and acetylation to give D-glucitol hexaacetate. The ratio of the tri- to dimethyl fraction was 3.2:1. This indicates that the D-mannose side chains are joined to position 4 of D-glucuronic acid which, in turn, must be linked through position 2 in the main chain.

The methylation data in conjunction with the results of analysis of the acidic oligosaccharides enable the repeat unit of *Klebsiella* K24 capsular polysaccharide to be written thus:

$$\begin{array}{l} \overset{2}{\text{—}}\ \text{D-GlcA}p\ \overset{1\,3}{\alpha}\ \text{D-Man}p\ \overset{1\,2}{\alpha}\ \text{D-Man}p\ \overset{1\,3}{\alpha}\ \text{D-Glc}p\ \overset{1}{\beta} \\ \qquad\quad \beta\Big|{}^{4}_{1} \\ \qquad\quad \text{D-Man}p \end{array}$$

Confirmation of this structure was sought by the Smith degradation procedure (13). Deacetylated polysaccharide was oxidized with periodate when 0.66 mol per hexose unit was consumed. After reduction, the derived polyalcohol was partially hydrolyzed by trifluoroacetic acid at room temperature to give a mixture of glycerol and an oligosaccharide which was then reduced with sodium borohydride. The latter compound

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

was methylated, reduced, and hydrolyzed to give 2,3,4,6-tetra- and 3,4-di-*O*-methyl-D-glucose and 2,4,6-tri-*O*-methyl-D-mannose as expected from the proposed structure; the methylated glycerol derivative was not sought.

An attempt was made to locate the position of the *O*-acetyl group using the procedure of de Belder and Norrman (14). The polysaccharide was dissolved in methyl sulfoxide and reacted overnight with methyl vinyl ether. Excess ether was removed *in vacuo* and the polysaccharide was treated directly with dimethsulfinyl anion and methyl iodide. When the product was hydrolyzed and the components were examined by paper chromatography a major spot for monosaccharide was obtained together with a faint spot with an R_f greater than all monomethylglucose derivatives and which was therefore assumed to be a monomethylmannose. Analysis by g.l.c. of the hydrolyzate, as alditol acetates, suggested that there might be two monomethyl mannoses present. Even if the experiment was to be repeated on a larger scale to allow characterization of the monomethyl sugars their identification as mannose derivatives would still not permit any deduction as to which of the three structurally different mannose residues was acetylated in the original polysaccharide. For this reason and because of the low yields obtained, this aspect of the structure was not pursued further. The use of methyl vinyl ether as a reagent in locating *O*-acetyl groups has been applied successfully to lipopolysaccharides (15) which appear to have lower molecular weights than the capsular polysaccharides of *Klebsiella* (mol. wt. $5–9 \times 10^5$). This difference in molecular weight may account for the low yield obtained in the present instance; similar difficulties have been experienced with other capsular polysaccharides from *Klebsiella* (16). There is good evidence that these capsular polysaccharides have a true repeating unit and also that where a sugar residue is in the form of a pyruvic acid ketal (1-carboxyethylidene derivative) this feature similarly repeats regularly (5). In the case of partial acetylation the substitution pattern appears to be less well defined.

The evidence presented shows clearly that the structure of the capsular polysaccharide of *Klebsiella* K-type 24 is as given above with the tentative assignment of some *O*-acetyl groups on certain of the mannose residues.

Experimental

General methods are as previously described (3).

Isolation and Properties of K24 Capsular Polysaccharide

Klebsiella K24 was grown in the medium (3) as for K21 and the harvested capsular polysaccharide and cells (1½ l) were diluted five-fold and centrifuged at 27 000 r.p.m. at 20° for 45 min. The supernatant was collected and freeze-dried. A 1% aqueous solution of the product (1 vol) was added with stirring to ethanol (6–7 vol). The polysaccharide was collected, washed with acetone, and air dried; yield *ca.* 12 g. The crude product was purified through precipitation with Cetavlon, giving 7 g of pure acidic polysaccharide having $[\alpha]_D^{25}$ +90° (*c* 0.54, water) as Na^+ salt; $[\alpha]_D^{27}$ +79° (*c* 0.68, water) after deionization with Amberlite IR 120. Equivalent weight by titration with 0.03 *N* sodium hydroxide (phenolphthalein) was 786. Addition of excess sodium hydroxide and back titration with hydrochloric acid after stirring under nitrogen for 50 min showed the presence of *ca.* 4% *O*-acetyl. Electrophoresis at p*H* 3 and 8.8 showed the polysaccharide moved as a single component.

Anal.: N, 0; ash, 0%.

A sample of polysaccharide was exactly neutralized and the solution was lyophilized. The residue was dissolved in D_2O and exchanged twice by lyophilization. The p.m.r. spectrum of the solution (*ca.* 2% in D_2O) was run at 95° and showed a sharp peak at τ 7.8 and five protons in the range τ 4.5–5.5 (see Table 1).

The presence of acetate was also confirmed by methanolysis of the polysaccharide and identification of methyl acetate using the hydroxylamine – ferric chloride reagent (6, 16, 17).

Hydrolysis of the Polysaccharide

Polysaccharide (25 mg) was dissolved in sulfuric acid (2.5 ml, *N*) at room temperature (30 min) and the solution was heated on a steam bath for 4 h. The solution was neutralized ($BaCO_3$) and the filtrate was evaporated. On paper chromatography in solvents A and B spots corresponding to D-glucose, D-mannose, and D-glucuronic acid were observed. The hydrolyzate was separated into neutral and acidic fractions using ion-exchange resins and the neutral fraction was found to contain D-mannose and D-glucose in an approximate ratio of 2.7:1 as determined by the g.l.c. of the alditol acetates (column a); D-mannitol hexaacetate had m.p. and mixed m.p. 121.5–122° and D-glucitol hexaacetate had m.p. and mixed m.p. 98.5–99°.

Partial Hydrolysis of the Polysaccharide

The polysaccharide (1.0 g) was dissolved in trifluoroacetic acid (TFA, 100 ml, 2 *M*) and the solution was heated on a steam bath for 4 h. The solution was evaporated, dissolved in 5 ml of water, and evaporated again. The resulting syrup was separated by ion-exchange resins into neutral and acidic (eluted with 4 *M* HOAc) fractions.

The latter was concentrated (300 mg) and chromatography in solvent A showed four components: (*a*) D-glucuronic acid, (*b*) aldobiouronic acid ($R_{glucose}$ 0.43), (*c*) aldotriouronic acid ($R_{glucose}$ 0.13), and (*d*) aldotetrauronic acid ($R_{glucose}$ 0.04). The syrup was separated by preparative paper chromatography on Whatman 3 MM paper in solvent C for 80 h. Yields: (*a*) aldobiouronic

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

acid, 130 mg; (*b*) aldotriouronic acid 50 mg; (*c*) aldotetrauronic acid 25 mg.

Structural Analysis of Aldobiouronic Acid

(a) Anomeric Linkage

A sample of aldobiouronic acid (25 mg) was dissolved in water (1 ml) and reduced with sodium borohydride (25 mg) for 8 h. After work-up and removal of borate, the syrup was dissolved in D_2O (2 ml) and freeze-dried. P.m.r. of this product (in D_2O) showed a doublet at τ 4.85, $J \sim 3.5$ Hz, indicating an α-linkage in the disaccharide.

(b) Reducing End

A portion of the above reduced aldobiouronic acid was hydrolyzed with trifluoroacetic acid (2 *M*) at 100° for 1 h. Uronic acids were removed with anion exchange resin and the neutral fraction was concentrated and acetylated. G.l.c. (column a) gave mannitol hexaacetate m.p. 122°.

(c) Carboxyl Reduction and Hydrolysis of the Disaccharide

Aldobiouronic acid (20 mg) was dissolved in anhydrous methanol (15 ml) containing 1% hydrogen chloride and the solution was left 12 h at room temperature. The solution was neutralized (Ag_2CO_3), centrifuged, and evaporated. The resulting syrup was dissolved in the minimum amount of water, followed by the addition of methanol and the solution was added dropwise over 1 h to a stirred solution of sodium borohydride (25 mg) in a mixture of water (0.5 ml) and methanol (2 ml). The solution was left 12 h at room temperature and was then carefully neutralized and stirred with Amberlite IR-120 (H^+) resin until the solution was free of Na^+. A portion of the syrup, after removal of borate, was hydrolyzed with trifluoroacetic acid (2 *M*) at 100° for 1 h and was shown (solvent A) to give D-glucose and D-mannose.

(d) Methylation

Aldobiouronic acid (12 mg) was methylated according to the procedure of Hakomori and was hydrolyzed (HCl, 3.5 *N*) to give 2,4,6-tri-*O*-methyl-D-mannose (R_f 0.55, solvent D) and 2,3,4-tri-*O*-methyl-D-glucuronic acid (R_f 0.22, solvent E). The former compound was also confirmed by g.l.c.–m.s. of the alditol acetate.

Structure of Aldotriouronic Acid

(a) Anomeric Linkage

A sample of aldotriouronic acid (20 mg) was reduced and dissolved in D_2O. The signals at τ 4.7, $J = 3.5$ Hz (from D-glucuronic acid) and τ 5.0, $J = 1.5$ Hz indicate α-linkages (Table 1).

(b) Reducing End

Hydrolysis of the reduced aldotriouronic acid showed D-mannitol (paper, solvent B and g.l.c.) and the same aldobiouronic acid (paper, solvents A and C).

(c) Methylation

The methyl ester methylglycoside (10 mg) was methylated and on hydrolysis showed (solvent D) two overlapping spots corresponding to 3,4,6- and 2,4,6-tri-*O*-methyl-D-mannose (R_f 0.58 and 0.55, respectively). G.l.c. of the trimethylsilyl derivatives on column a at 135° and on column b at 120° confirmed these assignments and showed them to be present in approximately equimolecular amounts.

Structure of Aldotetrauronic Acid

(a) Anomeric Linkage

A portion of the aldotetrauronic acid (15 mg) was reduced as for the aldobiouronic acid. The p.m.r. spectrum in D_2O showed the following signals: τ 4.70, $J = 3.5$ Hz and τ 4.73, $J = 3.0$ Hz (2H); τ 4.95, $J = 1.5$ Hz (1H).

(b) Reducing End

A portion of the reduced aldotetrauronic acid was hydrolyzed and paper chromatography (solvent B) showed D-glucitol, confirmed by g.l.c. of the alditol acetate. Also produced were the same aldobi- and aldotriouronic acids (solvent C) described above.

Methylation

Dry polysaccharide (1.7 g) was dissolved in anhydrous methyl sulfoxide (300 ml) under nitrogen (8, 9). To this solution methyl sulfoxide anion (26 ml, 2 *M*) was added and the mixture was stirred for 9 h under nitrogen. Methyl iodide (15 ml) was added at such a rate to keep the temperature below 20° and the resulting clear solution was stirred for 10 h. The solution was dialyzed against running water for 2 days and concentrated to a syrup which was methylated eight times with Purdie's reagents to give a product showing no absorption at 3600 cm^{-1}, $[\alpha]_D^{20}$ +64.5° (*c* 1.2, chloroform), OMe, 43.2%. Purification on a silica gel column using chloroform–methanol (95:5) raised the methoxyl content to 44.3%.

Methylated polysaccharide (60 mg) was dissolved in trifluoroacetic acid (2 *M*) and the solution was refluxed for 5 h. Separation on ion-exchange resins gave a neutral fraction which showed on paper chromatography (solvent D) three major components corresponding to 2,3,4,6-tetra- and 3,4,6-tri-*O*-methyl-D-mannose, 2,4,6-tri-*O*-methyl-D-glucose (R_f values 0.80, 0.58, and 0.50) and a minor component 2,4,6-tri-*O*-methyl-D-mannose (R_f 0.55). A portion (10 mg) of the neutral fraction was reduced, acetylated, and examined on column a programmed from 170–194° at 2°/min. Two peaks in the ratio of 1:1.8 were observed at 25.1 and 36.6 min. The faster component was tentatively identified by its retention time and mass spectrum as 2,3,4,6-tetra-*O*-methyl-D-mannose. The mass spectrum of the slower material showed it to be a mixture of 2,4,6- and 3,4,6-trimethylhexoses which also did not resolve on column b. On a column of OS-138 15% on Gas Chrom Q, operated isothermally at 240°, the slower moving fraction was shown to contain one minor and two major components. The minor component crystallized, m.p. 63–66° (3), and was further identified as 2,4,6-tri-*O*-methyl-D-mannitol triacetate by mass spectrometry; the main peaks were not sufficiently well resolved to permit identification.

Resolution of the trimethylhexose fraction was obtained when the trimethylsilyl derivatives of the neutral sugars were run on columns a, b, and c (samples injected in hexane, see Table 2).

When a portion (40 mg) of the neutral methylated sugars was acetylated (pyridine – acetic anhydride 1:1, 100°, 15 min), extracted with chloroform, and injected onto column a at 170° the following peaks were obtained: A (5.8 min); B_1 (8.8), B_2 (10.5); C_1 (16.2), C_2 (17.6). The component B_2 was present in only small amount and this, together with a minor component with a retention time of 7.5 min, was not examined further. Individual fractions

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

were deacetylated (NaOMe, 1 *N* in MeOH, 25°, 30 min), deionized, and examined on paper in solvent D. Components A, B_1, C_1, and C_2 had R_f values of 0.79, 0.57, 0.49, and 0.49. Samples of the individual fractions were also reduced with sodium borohydride, acetylated, and examined on column b at 175°. Components A′, B_1′, C_1′, and C_2′ were eluted at 7.8, 14.6, 15.8, and 15.8 min, each was examined by mass spectrometry and each was demethylated and the product acetylated. D-Mannitol hexaacetate m.p. 120–122° was obtained from A′ and B_1′ while C_1′ and C_2′ yielded D-glucitol hexaacetate m.p. 96–97°.

Reduced Methylated Polysaccharide

Part (100 mg) of the fully methylated polysaccharide was reduced overnight with lithium borohydride in tetrahydrofuran and the product was hydrolyzed by refluxing for 2 h with trifluoroacetic acid (2 *M*). Paper chromatography in solvent D revealed the presence of an extra sugar having the mobility (R_f 0.08) of a monomethylhexose which was shown in solvent E to have the same characteristics as 3- or 4-*O*-methyl-D-glucose. A portion (30 mg) of the hydrolyzate was reduced with sodium borodeuteride, acetylated, and separated on column b. Mass spectrometry of the component having a retention time of 38 min showed it to be a 3-*O*-methylhexitol and the c.d. spectrum was identical with that from 3-*O*-methyl-D-glucitol pentaacetate ($\Delta\varepsilon_{213}^{MeCN} - 0.29$).

Methylated Degraded Polysaccharide

Capsular polysaccharide (1 g) was hydrolyzed overnight at 95° with trifluoroacetic acid (0.4 *M*) using the apparatus of Galanos and co-workers (18). The recovered polysaccharide (200 mg) was methylated, reduced ($LiBH_4$) and hydrolyzed (TFA, 2 *M*). Paper chromatography showed the presence of a new sugar having the mobility of 3,4-di-*O*-methyl-D-glucose (R_f 0.26, solvent D; 0.51, solvent E). This was confirmed by the mass spectrum of the dimethyl fraction, separated as alditol acetates on column a, and by conversion of this fraction to D-glucitol hexaacetate m.p. 98°. The c.d. curve of 3,4-di-*O*-methyl-D-glucitol tetraacetate is weakly negative.

Smith Degradation

Capsular polysaccharide was deacetylated with aqueous sodium hydroxide, dialyzed, and lyophilized. The product (130 mg) was dissolved in sodium metaperiodate (20 ml, 0.05 *M*) and after 3 days in the dark at 4° 0.66 mol of periodate had been consumed per sugar unit. Following the addition of ethylene glycol, dialysis, reduction with sodium borohydride, dialysis, deionization, lyophilization and removal of borate the product was hydrolyzed (TFA, 0.5 *M*) at room temperature for 8 h. Paper chromatography in solvent A showed mainly glycerol and an oligosaccharide with traces of glucose. A part of the hydrolyzate was acetylated and gave a peak corresponding to glycerol triacetate (4 min) on column b at 150°. The majority of the hydrolyzate was reduced ($NaBH_4$) and paper chromatography (solvent A) showed one component having $R_{galactose}$ 0.37 and glycerol.

The mixture containing the oligosaccharide was methylated (8, 9), reduced and hydrolyzed to give (solvent D) components equivalent to 2,3,4,6-tetra- and 3,4-di-*O*-methyl-D-glucose (R_f 0.80, 0.28) and 2,4,6-tri-*O*-methyl-D-mannose (R_f 0.56). This result was confirmed by g.l.c.–m.s. of the alditol acetates (column a, 160-200° at 2°/min) which had retention times of 14.5, 30, and 21 min, respectively.

Attempted Location of O-Acetyl Group

Capsular polysaccharide (80 mg) was dissolved in methyl sulfoxide (20 ml) and anhydrous *p*-toluene sulfonic acid (*ca.* 20 mg) was added. Methyl vinyl ether was passed into the solution until it turned yellow and the reaction was left overnight. Excess methyl vinyl ether was removed on a rotary evaporator and methyl sulfoxide anion was added directly without isolation of the polysaccharide. The solution was shaken for 20 h, methyl iodide (5 ml) was added and the shaking continued for 3 h. The solution was dialyzed against running water, polymeric material formed from methyl vinyl ether was extracted with chloroform, and the aqueous portion was lyophilyzed. Hydrolysis (TFA, 2 *M*, 100°) showed (solvent E) a major spot for monosaccharides together with a faint spot moving faster than all monomethylglucose derivatives (R_f 0.35). G.l.c. of the alditol acetates gave two small peaks at 21 and 23 min (column b, 190°) in addition to hexitol acetates.

We are indebted to Dr. I. Ørskov, Copenhagen, for the gift of an authentic culture of *Klebsiella* K24 (1680/49), to Dr. P. J. Salisbury of this Department for growing the bacteria, to Dr. J. J. R. Campbell and Dr. J. B. Hudson of the Department of Microbiology, University of British Columbia, for the use of their centrifuges, and to Dr. C. T. Bishop for an authentic sample of 3,4,6-tri-*O*-methyl-D-mannose.

The financial support of the National Research Council of Canada and the award of a Killam Fellowship to Y.M.C. are gratefully acknowledged.

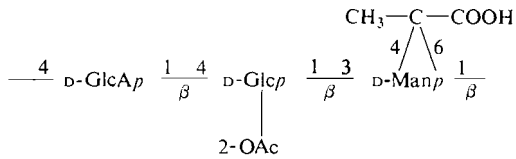
The Structure of the Capsular Polysaccharide of *Klebsiella* K-type 5

GUY G. S. DUTTON AND MO-TAI YANG

Department of Chemistry, The University of British Columbia, Vancouver, British Columbia

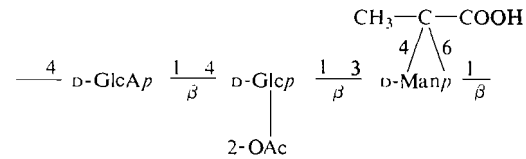
Received December 18, 1972

Methylation, periodate oxidation and partial hydrolysis studies on the capsular polysaccharide, and on the carboxyl reduced polymer of *Klebsiella* K5 show the structure to consist of a repeating unit:



The polysaccharide has a molecular weight (by gel filtration) of 9×10^5 and is the first *Klebsiella* capsule to be found lacking a carbohydrate side chain. The proportion of *O*-acetyl and pyruvate groups was determined by p.m.r. spectroscopy.

Les méthodes de méthylation, oxydation periodique, et hydrolyse partielle portées au polysaccharide capsulaire, et au polymère avec le groupe carboxyle réduit, de *Klebsiella* K5 ont démontré que la structure se compose d'une unité qui se répète.



Le polyoside possède un poids moléculaire (par chromatographie sur gel) de 9×10^5 et cette capsule de *Klebsiella* est la première d'être trouvée sans une chaîne latérale de sucre. Le rapport entre les groupes *O*-acétyles, pyruviques et sucres a été dosé par spectroscopie r.m.n.

Can. J. Chem., **51**, 1826 (1973)

Bacteria of the genus *Klebsiella* elaborate a capsular polysaccharide which is antigenic. Approximately 80 different serotypes are recognized and Nimmich (1, 2) has provided qualitative analyses of these capsular materials. In continuation of our studies (3, 4) on the structure of these polysaccharides we now report on the capsule from *Klebsiella* K-type 5. This polysaccharide differs from those previously described in this genus by lacking any carbohydrate side chain. The polysaccharide is also unusual in affording the first example of a 4,6-*O*-(1-carboxyethylidene)-D-mannose unit in a natural product. This aspect of the structure has been discussed briefly (5).

The crude polysaccharide from *Klebsiella* K5 (E5051) was extremely viscous and it was convenient to purify the material by centrifugation and precipitation with Cetavlon only in small batches. Purified material migrated as a single band on electrophoresis on cellulose acetate and had $[\alpha]_D$ −45.2°, an equivalent weight of 233, and a molecular weight, by gel filtration, of 9×10^5. Acid hydrolysis of the polysaccharide gave D-glucose, D-mannose, D-glucurone, and acidic components. The first two compounds were identified as their crystalline alditol hexaacetates and found to be present in the ratio of 3:5. When a portion of the hydrolyzate was saponified to hydrolyze any lactone, reduced, rehydrolyzed, and processed to avoid contamination of the neutral sugars by lactones, D-glucose and D-mannose were found in the ratio of 1:1. In the case of a sample of the polysaccharide which was methanolyzed, the uronic ester was reduced and the product was hydrolyzed to give D-glucose and D-mannose in the ratio of 2:1.

The glucose and mannose were shown to be of D-configuration by the circular dichroism (c.d.) curve of the alditol acetates; D-glucuronic acid was similarly authenticated by the c.d. of glucurone and of 2,3-di-*O*-methylglucitol acetate

obtained in the methylation study (6). The presence of pyruvic acid in the acid hydrolyzates was demonstrated by paper chromatography (7) and by preparation of the 2,4-dinitrophenylhydrazone (8). When the polysaccharide was subjected to methanolysis both acetate and pyruvate were detected on paper by the ferric chloride–hydroxamic ester test (9). The presence of these two groups was clearly demonstrated by the p.m.r. spectrum of the polysaccharide (10, 11) run in D_2O at 90°. The chemical shift of the anomeric protons indicated three sugars each β-linked in the repeat unit (3) and the integrals showed one acetyl and one pyruvic acid group per repeat unit.

The p.m.r. spectrum of the fully methylated polysaccharide showed the absence of acetate but confirmed the presence of pyruvate in the ratio of one per three sugars. The neutral crystalline sugars obtained on hydrolysis were identified as 2,3,6-tri-*O*-methyl-D-glucose (12) and 2-*O*-methyl-D-mannose (13) and were present in approximately equal amounts. The acidic component on reduction and hydrolysis gave 2,3-di- and 2,3,6-tri-*O*-methyl-D-glucose. These results were confirmed by reduction of the methylated polysaccharide before hydrolysis.

Autohydrolysis of the original capsular polysaccharide removed the pyruvic acid ketal and methylation of the recovered polymeric material followed by hydrolysis gave 2,4,6-tri-*O*-methyl-D-mannose in place of the 2-methyl ether thus demonstrating the linkage of pyruvic acid to positions 4 and 6 of mannose.

Partial hydrolysis of the original polysaccharide yielded a neutral oligosaccharide (N_3) and a series of acidic oligosaccharides (A_{1-6}). The compound N_3 crystallized and was identified as 3-*O*-(β-D-glucopyranosyl)-D-mannose by hydrolysis of the corresponding alditol and by methylation. The compound A_1 was found by titration to be an aldobiouronic acid and was shown to be cellobiouronic acid. Compound A_2 analyzed as an aldotriouronic acid which was characterized as 3-*O*-(β-D-cellobiosyluronic acid)-D-mannose. The higher acidic oligosaccharides were not examined but were assumed to be aldotetra-, penta-, and hexauronic acids.

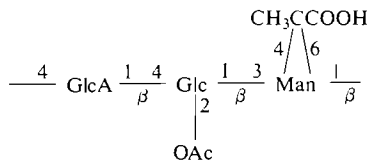
Periodate oxidation of the original capsular polysaccharide resulted in the consumption of 0.35 mol of periodate per sugar residue and the derived polyalcohol gave D-glucose on hydrolysis. Oxidation of de-*O*-acetylated capsular polysaccharide resulted in the initial uptake of 0.35 mol of periodate per sugar residue but when the polyaldehyde was reduced and the product was again treated with periodate further reaction took place to give a total consumption of 0.65 mol of periodate per sugar residue. Oxidation of carboxyl-reduced and de-*O*-acetylated polysaccharide consumed 0.60 mol of periodate per sugar unit. Hydrolysis of the last two polyalcohols failed to reveal the presence of D-glucose. The results are readily interpreted in the light of work by Painter and colleagues (14, 15). These authors have shown that in polysaccharides containing 1,4-linkages inter-residue hemiacetal linkages may be formed readily. Such linkages inhibit the consumption of the theoretical amount of periodate until they are destroyed by reduction. In all oxidized polysaccharides an equilibrium exists between the acyclic aldehyde and the cyclic hemiacetal (14). In the present example the presence of the uronic acid appears to favor the cyclic structure whereas in the reduced polysaccharide oxidation is not inhibited. Sloneker and co-workers (16) have also commented on similar anomalous oxidations.

The polyaldehyde arising from the complete oxidation of de-*O*-acetylated polysaccharide was reduced and hydrolyzed. Paper chromatography in solvent *A* indicated the presence of components having the mobilities of D-mannose, erythritol, D-erythronolactone, and pyruvic acid. The material having the mobility of erythritol was eluted (fraction 3) and appeared homogeneous in solvent *A*. However, when this fraction was chromatographed in solvent *B* prior to development in solvent *A* two components were detected one of which moved slower than erythritol and gave a positive response for lactone (9) while the other appeared to be erythritol. Hydrolysis of fraction 3 gave D-mannose, erythritol, L-erythronolactone, and pyruvic acid. These results indicate that this fraction contains 3-*O*-[4,6-*O*-(1-carboxyethylidene)-D-mannopyranosyl]-L-erythronolactone which, coincidentally, has the same mobility as erythritol in solvent *A*. The formation of this lactone is to be expected on periodate oxidation of a polysaccharide having the structure proposed below.

The results of methylation, partial hydrolysis, and periodate oxidation are consistent with the proposed repeating unit and the only feature not yet accounted for is the position of the *O*-acetyl group. This was located using the methyl vinyl

ether method of de Belder and Norrman (17). Methylation and hydrolysis of the substituted polysaccharide showed on paper chromatography a small spot corresponding to monomethyl hexose in addition to a large quantity of D-glucose and D-mannose. G.l.c. of the hydrolyzate in the form of alditol acetates gave a monomethyl fraction which crystallized and which was identified as 2-*O*-methyl-D-glucitol pentaacetate by mixed m.p. with an authentic sample (6). Low yields of methylated sugars have been obtained using this method on other capsular polysaccharides (4) presumably on account of their high molecular weight.

The structure of the capsular polysaccharide of *Klebsiella* K5 may therefore be represented by the repeat unit:



The characteristic p.m.r. signal at about τ 8.5 of the CH_3—C of the pyruvate ketal and its derivatives persists with only slight change in chemical shift through the typical transformations of methylation, carboxyl reduction, and periodate oxidation and is thus a convenient means of checking that no inadvertent loss of this group occurs at any stage during the structural investigation of the polysaccharide.

The presence of a cellobiouronic acid residue in the structure of K5 polysaccharide suggests that there should be a cross reaction with pneumococcal III and VIII antisera (18) and such reactions have been found (19). The reaction is stronger with anti-III than with anti-VIII consistent with the cellobiouronic acid being linked to position three of the next residue in *Pneumococcus* type III rather than to position four as in *Pneumococcus* type VIII (18).

Experimental

General Methods

These were as previously described (3) except as noted. The columns used for g.l.c. were (*a*) 3% ECNSS-M on Gas Chrom Q (4 ft × 3/16 in.), (*b*) 5% butanediol succinate on Diatoport S (4 ft × 1/4 in.), (*c*) 20% SF-96 on Diatoport S (8 ft × 1/4 in.). An additional solvent for paper chromatography was (*F*) phenol–water (4:1). Melting points were recorded on a Fisher–Johns apparatus and are uncorrected. I.r. spectra were recorded on a Perkin–Elmer model 457 spectrophotometer.

Preparation and Properties of K5 Capsular Polysaccharide

A culture of *Klebsiella* K5 (E5051) was obtained from Dr. I. Ørskov, Copenhagen, and grown on 3% sucrose – yeast-extract agar (30 g sucrose, 2 g Bacto yeast-extract, 15 g agar, 1 l H_2O, 2 g NaCl, 1 g KH_2PO_4, 0.25 g $MgSO_4 \cdot 7H_2O$, and 0.5 g $CaSO_4$) at room temperature for 3–4 days. The growth was scraped off the plates to give 600 ml of slime from 1 l of agar medium. The slime was worked-up in portions in the following manner: each 50 ml portion of the slime was diluted six-fold with water containing 1% phenol, then centrifuged at 65 000 × gravity for 1 h to obtain a clear, slightly yellow solution which was freeze-dried for storage or to which was added 45 ml of 3% hexadecyltrimethylammonium bromide (Cetavlon). The acidic polysaccharide which precipitated was dissolved in sodium chloride (35 ml, 2 *N*) and precipitated with five volumes of ethanol. The precipitate, collected by centrifugation, was dissolved in water, treated with Amberlite resin IR-120 (H^+), dialyzed against distilled water for 24 h, then freeze-dried to give 0.65 g of capsular polysaccharide per 50 ml of slime. This material had $[\alpha]_D$ −45.2° (*c* 0.44, water), an equivalent weight of 233, a molecular weight of 9×10^5, and migrated 3.8 cm on electrophoresis for 30 min at p*H* 8.8 and 300 V. Ash content nil; nitrogen nil.

The supernatant from the precipitation of the acidic polysaccharide with hexadecyltrimethylammonium bromide was dialyzed against tap water for 48 h and freeze-dried, yield 0.1 g. This material was not further examined.

To a portion of the Cetavlon purified acidic polysaccharide (0.89 g) in water (50 ml) was added sodium hydroxide (50 ml, 2 *N*) and the solution was allowed to stand at room temperature for 24 h. The alkaline solution was dialyzed against tap water for 24 h, passed through Amberlite resin IR-120 (H^+), dialyzed against distilled water, and freeze-dried, to give deacetylated polysaccharide (0.8 g).

Total Hydrolysis of the Acidic Polysaccharide

The polysaccharide was heated in sulfuric acid (1 *N*) at 98° for 8 h (or with trifluoroacetic acid, 2 *N*, 98°, 10 h). The cooled solution was neutralized ($BaCO_3$), centrifuged, and decationized. Paper chromatography using solvent *B* (8 h), then solvent *A* (10 h) revealed two major spots for D-mannose and D-glucose, along with a small fast moving spot with the same mobility as D-glucuronolactone and two small slow moving spots corresponding to D-glucuronic acid and an aldobiouronic acid.

Acidic components were removed by passage through a column of Duolite A-4 (OH^-) anion exchange resin and the filtrate was concentrated and reduced with sodium borohydride. Borate was removed by passage through Amberlite IR-120 (H^+) and distillation with methanol.

The alditols were dissolved in a 1:1 mixture of acetic anhydride and pyridine and heated at 100° for 20 min. The acetylation reagents were evaporated with the addition of several portions of ethanol. The alditol acetates, injected in chloroform onto column *a* programmed from 185–210° at 1°/min, with a helium flow rate of 60 ml/min, gave peaks identical to authentic standards of the hexaacetates of D-mannitol (20 min) and D-glucitol (24 min) in a ratio of 5:3. Samples were collected and the m.p. and mixed m.p. of D-mannitol hexaacetate was 121–123°, and that of D-glucitol hexaacetate was 93–95°. The c.d. curves of both hexaacetates were positive (6).

The glucuronic acid from several hydrolyzates was separated on paper and evaporated with the addition of hydrochloric acid. The c.d. curves of authentic D-glucurone and the isolated material were both positive.

In a second experiment the hydrolyzate was processed to obtain complete hydrolysis of the aldobiouronic acid and to avoid contamination of the neutral sugars by D-glucurone. The hydrolyzate was treated with sodium hydroxide (0.5 *N*) then with sodium borohydride. The reaction mixture was allowed to stand at room temperature for 1 h then hydrochloric acid was added to a concentration of 2 *N* and the solution was heated at 100° for 4 h. The hydrolyzate was evaporated to dryness, distilled three times with methanol, made alkaline with sodium hydroxide (0.5 *N*), and reduced with sodium borohydride. The solution was passed successively through columns of Amberlite IR-120 (H^+) and Duolite A-4 (OH^-) to remove the sodium ion and the L-gulonic acid. The neutral effluent was evaporated to dryness, acidified with acetic acid, and distilled with methanol. The ratio of D-mannitol to D-glucitol as hexaacetates was found to be 1:1.

K5 polysaccharide (10 mg) was heated in a sealed test tube with methanolic hydrogen chloride (4%, 1 ml) for 10 h. After neutralization with silver carbonate and centrifugation, the clear supernatant was treated with sodium borohydride (10 mg) for 24 h. Borate was removed and the residue was hydrolyzed with trifluoroacetic acid (2 *N*) at 100° for 8 h. Analysis gave the ratio of D-mannitol hexaacetate (m.p. and mixed m.p. 120–122°) to D-glucitol hexaacetate (m.p. and mixed m.p. 93–95°) as 1:2.

Characterization of Pyruvic and Acetic Acids

Polysaccharide (30 mg) was hydrolyzed with hydrochloric acid (2 ml, 1 *N*) and paper chromatography (solvent *A*) showed a spot with the mobility of pyruvic acid (R_f 0.7) and having the characteristic fluorescence under u.v. (7). The hydrolyzate was extracted with ether (3 × 15 ml), the extract was neutralized with sodium hydroxide and evaporated to dryness. The 2,4-dinitrophenylhydrazone prepared from the residue had the same mobility (R_f 0.41) on t.l.c. (toluene – acetic acid – water, 4:3:1) as that from authentic pyruvic acid.

Polysaccharide (20 mg) was refluxed for 2 h with methanolic hydrogen chloride (1 ml, 4%), the solution was neutralized (Ag_2CO_3), concentrated, and treated with methanolic hydroxylamine hydrochloride (1.5 ml, 1 *N*) and methanolic sodium hydroxide (1.5 ml, 1 *N*). After centrifugation the supernatant was concentrated to 25% of the volume and examined by paper chromatography in 1-butanol – acetic acid – water (4:1:5). The chromatogram was sprayed with 1% ferric chloride and showed the presence of acetic acid (R_f 0.56), pyruvic acid (0.61 and 0.74), and D-glucurone (0.16 and 0.22) by comparison with standards (acetate from D-glucose pentaacetate).

Proton Magnetic Resonance Spectra of Original and De-O-acetylated Polysaccharides

Capsular polysaccharide (*ca.* 20 mg) was dissolved in D_2O and freeze-dried. After two further treatments, the 100 MHz spectrum (10, 11) was run at 90° and showed sharp singlets at τ 8.50 (pyruvate) and 7.93 (acetate) together with signals at τ 5.15 (1H) and 5.50 (2H). The spectrum of deacetylated material was similar with the absence of the peak at τ 7.93.

Methylation of Original Capsular Polysaccharide

Vacuum-dried polysaccharide (400 mg) was methylated by the method of Hakomori and the product was dialyzed against running water for 24 h. Extraction with chloroform (2 × 30 ml) gave 100 mg of material showing no hydroxyl absorption in the i.r. The aqueous layer was lyophilized and subjected to three methylations with Purdie's reagents to give a fully methylated product which was combined with the chloroform extract. The p.m.r. spectrum ($CDCl_3$) showed τ 8.5 (3H), 6–7 (40 H, calcd. 43H), and 5.44 and 5.55 (3H).

Methylated polysaccharide (300 mg) was dissolved in sulfuric acid (3 ml, 72%) and after 2 h at 0° the solution was diluted with water (24 ml) and refluxed for 4 h. Neutralization ($BaCO_3$) and separation on ion exchange resins gave an acidic fraction (60 mg, eluted with 10% formic acid) and neutral sugars (178 mg). The latter showed two components, one (R_f 0.55, solvent D) corresponding to a trimethylhexose and a second (R_f 0.07) equivalent to a monomethyl hexose. Elution of the paper yielded 2,3,6-tri-*O*-methyl-D-glucose (58 mg), m.p. and mixed m.p. 117–119° (from ethyl ether (12)), and 2-*O*-methyl-D-mannose (40 mg), m.p. and mixed m.p. 138–140° (from ethanol (13)). Examination of a portion of the neutral sugars as alditol acetates on column *a* at 180° gave a peak at 6.4 min corresponding to that obtained from authentic 2,3,6-tri-*O*-methyl-D-glucose and a second peak at 18 min. The two peaks were in the ratio of 1:1.2 and the mass spectra of the two compounds were consistent with 2,3,6-tri- and 2-*O*-methyl hexitol acetates. C.d. for 2,3,6-tri-*O*-methyl-D-glucitol acetate $\Delta\varepsilon_{213}^{CH_3CN}$ +0.3 and for 2-*O*-methyl-D-mannitol acetate +0.42.

A portion (5 mg) of the acidic fraction was methanolyzed and examined on column *b* at 170° and gave peaks corresponding to methyl 2,3,6-tri-*O*-methyl-D-glucopyranoside (4.4 min (m), 6.0 min (s)) and methyl 2,3-di-*O*-methyl-D-glucuronic acid methyl ester (11.5 min (m) and 13.5 min (s)).

A second portion (5 mg) was methanolyzed, reduced, and hydrolyzed to show on paper (solvent *D*) components corresponding to 2,3,6-tri-*O*-methyl-D-glucose (R_f 0.56) and 2,3-di-*O*-methyl-D-glucose (0.28). This was confirmed by g.l.c. of the alditol acetates on column *a* at 200° to give two components eluting at 6.1 and 11.9 min and by their mass spectra. The c.d. curves of the isolated 2,3-di-*O*-methyl-D-glucitol tetraacetate and that of a standard (20) were positive ($\Delta\varepsilon_{213}^{CH_3CN}$ +0.1 and +0.08, respectively).

Reduced Methylated Polysaccharide

Fully methylated polysaccharide (170 mg) in tetrahydrofuran (20 ml) was reduced with lithium aluminum hydride (300 mg) in tetrahydrofuran (30 ml) for 18 h. The reduced product (130 mg) showed ($CDCl_3$) a sharp peak at τ 8.6 (CH_3 of hydroxyisopropylidene) and the absence of two peaks in the range τ 6.2–6.4 assumed due to methyl esters.

A part (56 mg) of the reduced product was hydrolyzed (TFA, 6 ml, 2 *N*) and on paper chromatography (solvent *D*) showed three components with R_f values of 0.10, 0.30, and 0.58. The majority of the hydrolyzate (36 mg) was separated on paper to yield 2-*O*-methyl-D-mannose (6 mg), m.p. and mixed m.p. 137–139° (ethanol), and 2,3,6-tri-*O*-methyl-D-glucose (10 mg), m.p. and mixed m.p. 113–115° (ether). The fraction (10 mg) with R_f 0.30 was indis-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

tinguishable from 2,3-di-*O*-methyl-D-glucose but could not be obtained crystalline. The rest of the hydrolyzate (10 mg) was reduced, acetylated, and examined on column *a* programmed from 160–190° at 2°/min. Three peaks were obtained at 16.0, 22.4, and 26.1 min corresponding to 2,3,6-tri-, 2,3-di-*O*-methyl-D-glucose, and 2-*O*-methyl-D-mannose, each of which was present in equivalent amounts.

Methylation of Polysaccharide Recovered from Autohydrolysis

Capsular polysaccharide (0.5 g) dissolved in water (60 ml, initial p*H* 2.5) was heated on a steam bath for 20 h. The solution was dialyzed and the polysaccharide (0.25 g) was recovered by freeze drying. This sample did not show a p.m.r. signal at τ 8.5. Degraded polysaccharide (200 mg) was methylated and the product (170 mg) was subjected to two treatments with Purdie's reagents. A portion (30 mg) was hydrolyzed (TFA, 8 ml, 2 *N*) and the neutral sugars showed (solvent *D*) a major spot (R_f 0.55) corresponding to trimethylhexoses and a faint spot at R_f 0.78. The sugar having R_f 0.10 was absent. The hydrolyzate was reduced, acetylated, and examined on column *a* programmed from 170–200° at 2°/min. A minor peak at 9.3 min (2,3,4,6-tetra-*O*-methyl-D-glucose) was followed by two strong peaks at 16.1 and 18.8 min corresponding to 2,4,6-tri-*O*-methyl-D-mannose and 2,3,6-tri-*O*-methyl-D-glucose. The 1,3,5-tri-*O*-acetyl-2,4,6-tri-*O*-methyl-D-mannitol was recrystallized from petroleum ether (30–60°) and had m.p. and mixed m.p. 64–66° (21).

Partial Hydrolysis of Capsular Polysaccharide

Acidic polysaccharide (3.5 g) was dissolved in water (300 ml, initial p*H* 2.7), heated on a steam bath for 12 h, and the solution was dialyzed against distilled water (2 × 600 ml). The non-dialyzable material was rehydrolyzed and the dialyzates were combined and concentrated. Only a small amount of product was obtained and chromatography in solvent *A* revealed pyruvic acid (R_f 0.7), D-glucose, D-mannose, and two components having R_{Man} 1.2 and 1.7 with traces of other compounds.

The solution containing the non-dialyzable material was concentrated to 150 ml, heated on the steam bath for 24 h, and dialyzed against distilled water (2 × 500 ml). The process was repeated for a total of 148 h heating with periodic concentration to keep the volume below 300 ml. The dialyzates were combined, concentrated, and passed successively through cation and anion exchange resins. The neutral components were fractionated on paper in solvent *B* to give N_1, N_2, and N_3 and the acidic components (eluted with 10% formic acid) were separated in solvent *C* to give A_1–A_6.

The neutral compounds N_1 and N_2 were chromatographically identical to D-mannose and D-glucose and were not further examined. Compound N_3 crystallized from water and had m.p. 164–166°, $[\alpha]_D$ −7.3° (*c* 2.18, water) which agrees with the value (m.p. 165°) given for 3-*O*-β-D-glucopyranosyl-D-mannose (22). Hydrolysis of N_3 gave D-glucose and D-mannose (solvent *B*) and of reduced N_3 gave D-glucose and D-mannitol (solvent *F*). Methylation of N_3 and examination of the hydrolyzate in solvent *D* showed components equivalent to 2,3,4,6-tetra-*O*-methyl-D-glucose (R_f 0.78) and 2,4,6-tri-*O*-methyl-D-mannose (0.56). The alditol acetates gave, on column *a* at 185°, peaks at 6.5 and 13.1 min in agreement with this assignment. The p.m.r. spectrum of the original N_3 in D_2O showed signals at τ 5.46, ($J_{1,2}$ = 6.0 Hz, 1H), τ 5.16 (0.3H) and 4.81, ($J_{1,2}$ = 1 Hz, 0.7H).

Compound A_1 (58 mg, R_{Glc} 0.23, solvent *A*) had an equivalent weight of 394 and $[\alpha]_D$ +9.1° (*c* 0.8, water) in agreement with the value given (23) for cellobiouronic acid of $[\alpha]_D$ +7° (*c* 2.0, water). Hydrolysis of A_1 gave D-glucose and D-glucuronic acid (solvent *A*). Compound A_1 (6 mg) was dissolved in methanol (1 ml), esterified with diazomethane, reduced with sodium borohydride in methanol, and hydrolyzed. Examination in solvent *F* showed D-glucose and D-glucitol which was confirmed by g.l.c. of the trimethylsilyl derivatives on column *c* programmed from 160–220° at 1°/min (D-glucose 23.3 min (w), 27.6 min (s) and D-glucitol (25.6 min)). Methylation and methanolysis of A_1 showed (column *b*, 150°) peaks characteristic of methyl 2,3,6-tri-*O*-methyl-D-glucopyranosides (10.3 min (w), 13.8 min (s)) and methyl 2,3,4-tri-*O*-methyl-D-glucuronic acid methyl ester (15.2 min (w), 21.2 min (s)). Reduction of the methyl glycosides in methanol followed by hydrolysis and examination in solvent *D* showed components corresponding to 2,3,4- and 2,3,6-tri-*O*-methyl-D-glucose (R_f 0.51 and 0.58 respectively).

Compound A_1 (22 mg) was dissolved in methanol (5 ml) and esterified with diazomethane. The syrupy product was dissolved in acetic anhydride (3.5 ml) containing zinc chloride (0.2 g) and the solution held at 60° for 90 min. The crude product was purified on paper (solvent *D*) and hepta-*O*-acetyl-(β-D-glucopyranosyluronic acid methyl ester)-α-D-glucopyranose recrystallized from ethanol had m.p. 248°, $[\alpha]_D$ +31.5° (*c* 0.1, chloroform), lit. (24) m.p. 252°, $[\alpha]_D$ +44° (*c* 1.2, chloroform). The p.m.r. spectrum of A_1 in D_2O showed τ 5.44, ($J_{1,2}$ = 7.5 Hz, 1H), 5.31, ($J_{1,2}$ = 7.9 Hz) and 4.78, ($J_{1,2}$ = 3.3 Hz, 1H combined).

Compound A_2 had an equivalent weight of 559 and $[\alpha]_D$ −24.2° (*c* 3.1, water). Development of a paper chromatogram of a hydrolyzate for 8 h in solvent *B* followed by 28 h in solvent *A* showed D-mannose, D-glucose, D-glucuronic acid and A_1. When A_2 was reduced and hydrolyzed development in solvent *F* showed (ether wash before dipping) cellobiouronic acid (R_{Glc} 0.34), D-glucuronic acid (0.45), D-glucose, and D-mannitol (1.2). Methylation of A_2 (8 mg) showed by paper chromatography of the hydrolyzate (solvent *D*) an acidic compound at the origin and one spot at R_f 0.57 since this solvent does not resolve 2,3,6-tri-*O*-methyl-D-glucose and 2,4,6-tri-*O*-methyl-D-mannose. Reduction of the hydrolyzate and separation of the neutral compounds as alditol acetates on column *a* showed the presence of these two components and their mass spectra were consistent with this assignment. The p.m.r. spectrum of A_2 in D_2O showed signals at τ 4.88 ($J_{1,2}$ = 1.7 Hz, 0.6H), 5.23 ($J_{1,2}$ = 1.2 Hz, 0.4H), 5.43 ($J_{1,2}$ = 7.5 Hz, 1H), 5.47 ($J_{1,2}$ = 7.3 Hz, 1H).

Carboxyl Reduction of K5 Polysaccharide

Polysaccharide (0.8 g) was converted in turn to the propionate (0.83 g), methyl ester (0.89 g) and reduced as previously described (25) to give the carboxyl reduced polysaccharide (0.4 g). The p.m.r. spectrum showed a peak at τ 8.60 but the integral suggested that some of the ketal grouping had been lost during reduction. Hydrolysis

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

gave D-glucose and D-mannose confirmed by separation of the alditol acetates on column *a* programmed from 180–220° at 1°/min; D-glucitol hexaacetate (37.5 min) m.p. and mixed m.p. 93–95° and D-mannitol hexaacctate (31.4 min) m.p. and mixed m.p. 119–121°, ratio 2:1.

Methylation and hydrolysis of reduced polysaccharide gave, as alditol acetates on column *a* programmed from 160–190° at 2°/min, 2,3,6-tri-*O*-methyl-D-glucose (16 min) and 2-*O*-methyl-D-mannose (26 min) in the ratio 2:1.

Periodate Oxidation

Capsular polysaccharide (0.12 g) was oxidized in the dark at 1° with sodium metaperiodate (40 ml, 0.05 *M*) and the consumption, measured spectrophotometrically, became constant at 0.35 mol of periodate per hexose residue after 288 h. Addition of ethylene glycol, dialysis and reduction with sodium borohydride gave the polyalcohol (92 mg). The p.m.r. spectrum in D_2O showed the presence of one pyruvate group to 18 sugar protons, excluding anomeric (theory 3:20). Total hydrolysis of the polyalcohol showed (solvent *A*) components corresponding to D-mannose, D-glucose, erythritol (R_{Man} 2.0), and D-erythronolactone (R_{Man} 3.3; standard obtained from D-glucose by lead tetraacetate oxidation); pyruvic acid was not sought. The lactone was distinguished by the hydroxylamine – ferric chloride spray (9). Reduction and acetylation of the hydrolyzate gave (column *a* programmed from 170–220° at 1°/min) the peracetates of erythritol (7.6 min), D-mannitol (36.1 min), and D-glucitol (40.9 min) in the ratio of 2:2.7:1. Each fraction crystallized and yielded erythritol tetraacetate, m.p. 81–83°, D-mannitol hexaacetate, m.p. 119–121°, and D-glucitol hexaacetate, m.p. 93–95°, undepressed by authentic samples.

Capsular polysaccharide which had been de-*O*-acetylated (0.665 g) was oxidized at 1° in the dark with sodium metaperiodate (200 ml, 0.05 *M*) with a constant uptake of 0.35 mol of periodate per sugar unit after 288 h. After the addition of ethylene glycol, dialysis, borohydride reduction, deionization and removal of boric acid the polyalcohol was recovered by lyophilization. This material was dissolved in sodium metaperiodate solution (100 ml, 0.05 *M*) and consumed a further 0.3 mol of periodate per sugar residue in 120 h. The polyalcohol (0.45 g) was isolated and a portion was hydrolyzed (HCl, 2 *N*, 4 h) to give (solvent *A*) mannose, erythritol, erythronolactone, and a faint spot for pyruvic acid (R_{Man} 4.6). Examination by g.l.c. as before showed the peracetates of erythritol and D-mannitol.

The majority of the polyalcohol (*ca.* 0.4 g) was examined (without hydrolysis) in solvent *C* and showed three main fractions: 1 ($R_{erythritol}$ 1.4), 36.7 mg; 2 ($R_{erythritol}$ 1.2), 23 mg; 3 ($R_{erythritol}$ 1.0), 72 mg. Although fraction 3 had the same mobility as erythritol it gave a pink color with the hydroxylamine – ferric chloride spray. This fraction was therefore examined by running duplicate papers for 8 h in solvent *B* followed by 8 h in solvent *A*. Development of one paper with silver nitrate showed a component with the mobility of erythritol and a slower moving component which streaked somewhat. Development of the duplicate paper with the lactone spray revealed only the slower moving component. *A* portion of fraction 3 was therefore hydrolyzed (HCl, 2 *N*, 4 h) and examined in solvent *A*. Components with the mobilities of D-mannose, erythritol, D-erythronolactone, and pyruvic acid were detected. The p.m.r. spectrum of fraction 3 showed clearly the pyruvate signal at τ 8.5, the anomeric proton at 5.12, and that they were present in the ratio of 3H:1H.

Carboxyl reduced polysaccharide (11.2 mg) consumed 0.60 mol of periodate per sugar residue in 40 h at 1°. Total hydrolysis of the polyalcohol and examination in solvent *A* showed two major components with the mobilities of D-mannose and erythritol with only traces of D-glucose. Partial hydrolysis (H_2SO_4, 1 *N*, 20°) of the polyalcohol for either 4 or 26 h showed (solvent *A*) erythritol and a non-reducing compound with R_{Man} 0.48 assumed to be 2-*O*-β-D-mannopyranosyl-D-erythritol.

Location of O-Acetyl Group

Capsular polysaccharide (30 mg) in methyl sulfoxide (5 ml) was reacted with methyl vinyl ether (5 g) and *p*-toluenesulfonic acid at a temperature not exceeding 20° for 40 min. The reaction mixture was poured into dry acetone (200 ml) and left overnight. The white precipitate was collected by centrifugation and the supernatant was concentrated and added to a column (3 × 22 cm) of Sephadex LH 20 which was eluted with dry acetone. The acetalated polysaccharide was methylated and hydrolyzed. A chromatogram in solvent *B* showed much D-glucose and D-mannose with a small amount of faster moving material. G.l.c. of the reduced hydrolyzate (as column *a* but 8 ft × 1/4 in. at 210°) gave a component which crystallized and had m.p. 54–55° undepressed with an authentic sample (6) of 2-*O*-methyl-D-glucitol pentaacetate m.p. 56–57°

We are indebted to Dr. I. Ørskov, Copenhagen, for a sample of *Klebsiella* K5 (E5051), to Dr. P. J. Salisbury for growing the bacteria, and to Dr. G. H. N. Towers for the use of his centrifuge. We thank Dr. S. C. Churms for the gel chromatography and Dr. E. G. Gros for a sample of 2-*O*-methyl-D-mannose.

The continued financial support of the National Research Council of Canada is gratefully acknowledged.

Acenaphthene III. Coupling Reactions. The Preparation of 4,4′-Dinaphthalic Anhydride and 4′,1-Naphthylnaphthalic Anhydride[1]

LOUIS A. JONES[2] AND RONALD WATSON
Department of Chemistry, North Carolina State University, Raleigh, N.C. 27607

Received October 31, 1972

The syntheses of the previously unknown 4,4′-dinaphthalic anhydride (**4**) and 4′,1-naphthylnaphthalic anhydride (**5**) is reported. The vinylic bromination of 5-(1,-3,4-dihydronaphthyl)acenaphthene (**11**) is also described.

On décrit la synthèse des anhydrides dinaphtalique-4,4′(**4**) et (naphtyl-1)-4 naphtalique (**5**) inconnus jusqu'à maintenant. On rapporte aussi les résultats obtenus lors de la bromination vinylique du (dihydro-3,4 naphtyl-1)-5 acénaphtène (**11**). [Traduit par le journal]

Recent investigations (1, 2) have resulted in the preparation of 4,5-diaminonaphthalic anhydride (**1**) and 3,4-diaminonaphthalic anhydride (**2**). As part of a continuing study in the chemistry of acenaphthene (**3**) and its derivatives, we now report the syntheses of 4,4′-dinaphthalic anhydride (**4**) and 4′,1-naphthylnaphthalic anhydride (**5**).

6

Thallium bromide (**1**) has been used as a reagent for the syntheses of biaryls from aromatic Grignard reagents (3). Consequently, 5-acenaphthyl magnesium bromide, prepared from 5-bromoacenaphthene (4), was treated with thallium bromide to give 5,5′-diacenaphthene (**6**) in low yield. Alternatively it was found that the same product could be obtained in far better yield by utilizing the coupling technique of Kharasch and Fields (5) in which cobalt chloride is used as a catalyst. The fact that coupling has indeed taken place in the *peri*-position was established from consideration of its n.m.r. spectrum. The bridgehead protons gave a sharp singlet at τ 6.57 as did the aromatic protons 6,6′, 7,7′, and 8,8′ at τ 2.74. The remaining protons exhibited an AB quartet with a *J* value of 7.3 Hz. Oxidation to the dianhydride **4** was achieved by treatment of the product with sodium dichromate in glacial acetic acid.

Garvey and his co-workers (6) have previously reported the synthesis of 5,5′-diacenaphthene by a different procedure, but no experimental details or spectral data were given.

When the dimer **6** was treated with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ) dehydrogenation took place to give 5,5′-diacenaphthylene (**7**) which readily consumed 2 mol of bromine to give the tetrabromo-compound **8**. Also, oxidation with sodium dichromate again gave the dianhydride **4**.

When the Grignard reagent from 5-bromoacenaphthene was treated with α-tetralone in tetrahydrofuran, the expected coupled product **9** was only obtained in low yield. Rather, we obtained acenaphthene and the aldol condensation product **10** of α-tetralone which was identified by its elemental analysis and by preparation of its 2,4-dinitrophenylhydrazone. This same product has previously been isolated (7) from the reaction of α-tetralone with cyclohexyl magnesium bromide. Consequently, treatment of α-tetralone with 5-lithio-acenaphthene (from 5-

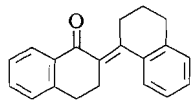
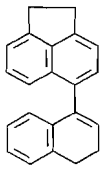
9

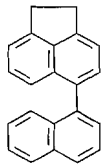


10

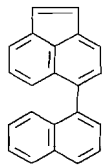
bromo acenaphthene and *n*-butyl-lithium) resulted in the isolation of the hydroxy compound **9** in far better yield. Dehydration to 5-(1,-3,4-dihydronaphthyl)acenaphthene (**11**) was readily effected by treatment with polyphosphoric acid. This product was subsequently dehydrogenated by 10% palladium-on-charcoal to 5′,1-naphthylacenaphthene (**12**) or by DDQ which gave 5′,1-naphthylacenaphthylene acenaphthylene (**13**). Treatment of either compound **12** or **13** with sodium dichromate in glacial acetic acid resulted in oxidation to 4′,1-naphthylnaphthalic anhydride (**5**).



11

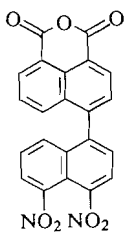


12



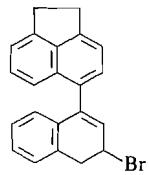
13

Nitration of this anhydride resulted in the isolation of a yellow solid. Consideration of its elemental analysis and mass spectrum indicated the presence of two nitro-groups. Although the positions of these nitro-groups have not as yet been unambiguously assigned, previous experience (8) in this laboratory has shown that, in the case of nitration of 1,1′-binaphthyl the *peri*-positions are more susceptible to nitration. Consequently we propose that this dinitro-compound has the structure **14**. Further, its n.m.r. spectrum exhibits two aromatic multiplets in the ratio of 4:6 which is the pattern one would expect for this structure.

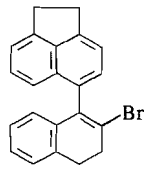


14

The possibility of introducing a bromine atom in the 3′-position of the system **11** and then dehydrobromination as an alternate route to naphthyl acenaphthene (**12**) led us to attempt allylic bromination utilizing *N*-bromosuccinimide (NBS) in carbon tetrachloride as the brominating media (9). This resulted in an inseparable mixture of isomers. When dimethylformamide (DMF) was used as solvent, the reaction proceeded smoothly to give a good yield of a mono-brominated product. This product, however, did not appear to be the required allylically brominated system **15** since it gave no precipitate with alcoholic silver nitrate at room temperature. Consideration of its n.m.r. spectrum revealed that bromination had in fact taken place in the vinyl-2′-position to give compound **16**, the main feature of the spectrum being the disappearance of the triplet at τ 4.0 in the starting material and the appearance of a singlet for the 3′ and 4′-protons. The structure has been unambiguously confirmed by a single crystal X-ray analysis (10).

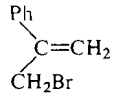


15

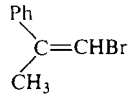


16

Although rare, instances of vinylic bromination in NBS reactions are not altogether unique (11, 12). Pines and his co-workers (13) found that bromination of α-methylstyrene with NBS in carbon tetrachloride gave, as well as the expected 2-phenylallyl bromide (**17**), 1-methyl-1-phenylvinyl bromide (**18**), in a ratio of 3:1. In an earlier study, Roberts and Trumbell (14) found that the reaction of camphene with NBS in carbon tetrachloride gave a 35% yield of mono-brominated



17



18

products, of which 65% proved to be the vinylic substituted product 8-bromocamphene. In each case a free radical mechanism is proposed.

In our hands, the reaction of α-methylstyrene with NBS in DMF gave 56% of mono-brominated products. From g.l.c. studies of the crude

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

mixture and the pure isomers it was shown that the mixture consisted of 80% of **17** and 29% of **18**. The same proportions were obtained from consideration of the n.m.r. spectra of both the crude mixture and the pure compounds. It had previously been reported (*9b*) that NBS was inactive towards styrene and that no monobrominated products were obtained. However, reaction of styrene with NBS in DMF as the solvent was found to produce a 30% yield of dibromostyrene. This would seem to indicate, therefore, that in DMF the addition of bromine to the double bond takes preference over substitution, although in the case of α-methylstyrene, no dibromo-substituted products were detected. This was confirmed by the fact that when the reaction of compound **11** with NBS in DMF was carried out in the dark, the same product, **16**, was obtained in identical yield as had been obtained previously. Further, addition of bromine to the dihydro system **11** again gave the vinylic brominated product **16**, also in the same yield. The mechanism for the formation of **16** therefore, evidently involves an initial addition of bromine to the double bond to form a dibromo-intermediate, which then spontaneously dehydrobrominates to give the product **16**.

This is consistent with the findings of Horner and Winkelmann (*9d*) that with increasing polarity of the solvent used in the bromination reaction of NBS the allylic bromination activity disappears and the addition of bromine to the double bond becomes the main reaction.

Experimental[3]

5,5'-Diacenaphthene (6)

5-Bromoacenaphthene (10.0 g) in anhydrous tetrahydrofuran (100 ml) was added to magnesium turnings (1.98 g) in tetrahydrofuran (100 ml) and the mixture heated to reflux under nitrogen for 16 h. The resulting solution of 5-acenaphthyl magnesium bromide was added to 5-bromoacenaphthene (10.08 g) and anhydrous cobalt chloride (9.5 g) in anhydrous tetrahydrofuran (100 ml) and the mixture heated to reflux for a further 16 h. The mixture was then poured on ice, acidified (diluted HCl), and extracted with methylene chloride. The organic layer was separated, washed, dried, and evaporated to leave a brown semi-solid which was chromatographed on alumina. Elution with hexane gave unreacted bromoacenaphthene and some acenaphthene followed by the product **6** (3.2 g, 49%) which was recrystallized from methylene chloride – hexane to give pale yellow needles, m.p. 176–178°, $\nu_{C=C}$ 1610 cm^{-1} (Nujol); τ ($CDCl_3$) 2.46–2.72 (4H, AB quartet, J = 7.3 Hz, Ar), 2.74 (6H, s, Ar), and 6.57 (8H, s, CH_2).

Anal. Calcd. for $C_{24}H_{18}$: C, 94.1; H, 5.8. Found: C, 94.2; H, 5.9.

4,4-Dinaphthalic Anhydride (4)

Diacenaphthene (3.3 g), sodium dichromate (27 g), and glacial acetic acid (500 ml) were refluxed overnight, cooled, and added to water (600 ml). The precipitated solid was collected and recrystallized from dimethylformamide to give **4** (3.2 g, 71%) as a yellow amorphous solid m.p. 362° (dec.), ν_{max} (Nujol) 1780, 1730 (C=O) and 1595 cm^{-1} (C=C).

Anal. Calcd. for $C_{24}H_{10}O_6$: C, 73.10; H, 3.45%. Found: C, 72.85; H, 3.15.

5,5'-Diacenaphthylene (7)

Diacenaphthene (1.73 g), DDQ (3.12 g), and benzene (40 ml) were heated at reflux overnight; the mixture was cooled, diluted with hexane (200 ml) and the hydroquinone, which had formed during the reaction, was removed by filtration. The filtrate was chromatographed on alumina. Hexane eluted **7** (1.17 g, 70%), yellow plates, m.p. 164–165% (from ethanol), τ ($CDCl_3$) 2.34–2.76 (10H, m, Ar), and 3.02 (4H, s, methine).

Anal. Calcd. for $C_{24}H_{14}$: C, 95.35; H, 4.65. Found: C, 95.25; H, 4.5.

1,1',2,2'-Tetrabromo-5,5'-diacenaphthene (8)

To diacenaphthylene (1.5 g) in hexane (130 ml), a solution of bromine (1.6 g) in hexane (20 ml) was added dropwise and the mixture stirred for 8 h at 20%. The mixture was concentrated and the precipitated solid separated by filtration and recrystallized to give **8** (1.64 g, 50%), as a yellow amorphous solid, m.p. 218–219° (dec.) (from benzene).

Anal. Calcd. for $C_{24}H_{14}Br_4$: C, 46.3; H, 2.25; Br, 51.45. Found: C, 46.45; H, 2.10; Br, 51.35.

Reaction of 5-Acenaphthyl Magnesium Bromide with α-Tetralone

A solution of α-tetralone (6 g) in anhydrous tetrahydrofuran (50 ml) was added to the Grignard solution obtained from 5-bromoacenaphthene (10 g), magnesium turnings (1.08 g), and anhydrous tetrahydrofuran (100 ml) and the mixture refluxed under nitrogen for 3 days; it was then poured onto ice, acidified (dilute HCl), and extracted with methylene chloride. The extract was washed ($NaHCO_3$ then water) and dried (Na_2SO_4), to give a residue which was chromatographed on Florisil. Hexane eluted acenaphthene (3 g, 45%) and further elution with ether gave a brown gum. Trituration of this gum with ether gave **10** (1.9 g, 32%), pale yellow crystals, m.p. 132–133° (from methylene chloride – hexane) (lit. (7) m.p. 132–133°). Evaporation of the filtrate gave the required product **9** (2.5 g, 19%) as a pale brown amorphous solid, m.p. 112–114° (from methylene chloride – hexane), ν_{max} (Nujol) 3450 (OH), 1612 cm^{-1} (C=C).

Anal. Calcd. for C, 88.0; H, 6.65. Found: C, 88.25; H, 6.5.

[3]Melting points were determined on a Thomas–Hoover capillary melting point apparatus and elemental analyses performed by Galbraith Laboratories, Inc., Knoxville, Tennessee. I.r. spectra were measured on a Beckman I.R.-33 i.r. spectrophotometer and n.m.r. spectra were obtained from a Varian HA-100 spectrometer.

*1-Hydroxy-1,2,3,4-tetrahydro-5',1-naphthylacenaphthene (**9**)*

5-Bromoacenaphthene (50 g) in ether (300 ml) and a hexane solution of *n*-butyl-lithium were mixed at 20° and stirred at this temperature under nitrogen for 20 min. α-Tetralone (31 g) in ether (150 ml) was then added and the mixture was stirred for a further 15 h at 20°. The mixture was then poured onto ice and acidified (dilute HCl). The ether layer was separated off, washed, dried, and evaporated to leave a light brown semi-solid. This was triturated with hexane and the residue crystallized from methylene chloride–hexane. The product **9** (40 g 63%) formed a fawn-colored semi-crystalline solid, m.p. 112–114°.

*5-(1,-3,4-Dihydronaphthyl)acenaphthene (**11**)*

The preceding product (30 g) was added with stirring to polyphosphoric acid (500 g) and the mixture was stirred at 60° for 5 h; it was then poured into ice-cold water (1000 ml) and extracted with ether. The extract was washed with aqueous sodium bicarbonate solution and then with water, dried (Na_2SO_4), and evaporated. The dehydrated product **11** (27 g, 95%) formed light brown crystals, m.p. 112° (from methylene chloride–hexane), $\nu_{C=C}$ (Nujol) 1595 and 1610 cm^{-1}; τ ($CDCl_3$) 2.64–3.50 (9H, m, Ar), 4.0 (1H, t, 2'-H), 6.76 (4H, s, 1-H and 2-H), 7.04–7.32 (2H, m, CH_2), and 7.5–7.8 (2H, m, CH_2).

Anal. Calcd. for $C_{22}H_{18}$: C, 93.6; H, 6.4. Found: C, 93.4; H, 6.2.

*5',1-Naphthylacenaphthene (**12**)*

The dihydro-compound **11** (16.5 g) and 10% palladium-on-charcoal (5 g) in α-methylnaphthalene (250 ml) were heated to reflux under nitrogen for 25 h; the mixture was cooled, filtered, the α-methylnaphthalene distilled off under reduced pressure, and the residue chromatographed on alumina. Hexane–benzene (1:1) eluted the product (14.5 g, 89%) as pale yellow crystals, m.p. 103–104° (from hexane), τ ($CDCl_3$) 2.02–2.84 (12H, m, Ar), and 6.59 (4H, s, 1-H and 2-H).

Anal. Calcd. for $C_{22}H_{16}$: C, 94.3; H, 5.7. Found: C, 94.1; H, 5.8.

*5',1-Naphthylacenaphthylene (**13**)*

The dihydro-compound **11** (22 g), DDQ (37 g), and benzene (300 ml) were heated to reflux overnight and then worked-up as for diacenaphthylene. The dehydrogenated product (12 g, 55%) afforded yellow crystals, m.p. 112–114° (from ethanol), τ ($CDCl_3$) 2.1–2.9 (12H, m, Ar), and 3.0 (2H, s, 1-H and 2-H).

Anal. Calcd. for $C_{22}H_{14}$: C, 94.95; H, 5.05. Found: C, 94.7; H, 5.1.

*4',1-Naphthylnaphthalic Anhydride (**5**)*

The preceding product (11.7 g), sodium dichromate (40 g) and glacial acetic acid (500 ml) were heated to reflux overnight, cooled, and added to water (1000 ml). The precipitated solid was collected and recrystallized to give **5** (10 g, 74%) as dark yellow crystals, m.p. 250–252° (from aqueous acetic acid), ν_{CO} (Nujol) 1770, 1730 cm^{-1}; τ ($CDCl_3$) 1.24–1.47 (2H, m, Ar), and 1.95–2.84 (10H, m, Ar).

Anal. Calcd. for $C_{22}H_{12}O_3$: C, 81.5; H, 3.75. Found: C, 81.25; H, 3.75.

Nitration of 4',1-Naphthylnaphthalic Anhydride

To a stirred solution of compound **5** (1.4 g) in methylene dichloride (150 ml), 90% nitric acid (15 ml) was added dropwise and the mixture heated to reflux for 60 h; it was then poured into water (300 ml), the organic layer separated, washed ($NaHCO_3$, then water), dried ($MgSO_4$), and evaporated to give a pale yellow solid. This was dissolved in methylene dichloride and addition of hexane gave the product **14** (0.6 g, 32%) as an amorphous yellow solid, (*m/e* 413) m.p. 280° (dec.) (from acetic acid), ν_{max} (Nujol) 1775, 1730 $\nu_{C=O}$, 1530, and 1355 cm^{-1} (NO_2); τ ($(CD_3)_2SO$) 1.15–1.56 (4H, m, Ar), and 1.69–2.26 (6H, m, Ar).

Anal. Calcd. for $C_{22}H_{10}N_2O_7$: C, 63.75, H, 2.4; N, 6.75. Found: C, 63.75; H, 2.3; N, 6.65.

*2-Bromo-3,4-dihydro-5',1-naphthylacenaphthene (**16**)*

(*a*) To compound **11** (3 g) in dimethylformamide (100 ml) a solution of NBS (1.89 g) also in dimethylformamide (50 ml) was added and the mixture stirred overnight at 20°; it was then poured into water (700 ml) and extracted with ether. The extract was washed with water, dried ($MgSO_4$), and evaporated to give a pale yellow gum which was chromatographed on Florisil. Hexane eluted the product **16** (2 g, 55%), which gave yellow crystals, m.p. 150–152° (from methylene chloride–hexane), $\nu_{C=C}$ (Nujol) 1604, 1585 cm^{-1}; τ ($CDCl_3$) 2.68–3.66 (9H, m, Ar), 6.74 (4H, s, 1-H and 2-H), and 7.07 (4H, s, 3'-H and 4'-H).

Anal. Calcd. for $C_{22}H_{17}Br$: C, 73.15; H, 4.7; Br, 22.15. Found: C, 72.95; H, 4.5; Br, 22.3.

(*b*) To compound **11** (6 g) in carbon tetrachloride (100 ml) a solution of bromine (3.5 g) in carbon tetrachloride (20 ml) was added dropwise and the mixture stirred at room temperature for 30 min; evaporation of the solvent gave **16** (4.3 g, 56%) as light brown crystals, m.p. 150–152° (from methylene chloride–hexane).

Styrene with N-Bromo Succinimide

A solution of NBS (50 g) in dimethylformamide (80 ml) was added to styrene (100 ml) in dimethylformamide (20 ml). After the initial exothermic reaction had subsided, the mixture was stirred overnight at 20°. The solvent and excess styrene were removed under reduced pressure and the residue chromatographed on silicic acid. Hexane eluted dibromostyrene (21.3 g, 30%) as white needles m.p. 70–72° (lit. (15) 72–73°) (from aqueous ethanol).

α-Methylstyrene with N-Bromosuccinimide

A solution of NBS (100 g) in dimethylformamide (250 ml) was added to α-methylstyrene (200 ml). After the initial exothermic reaction had subsided the mixture was stirred overnight at room temperature, poured into water, and extracted with methylene chloride. The extract was washed with water, dried ($MgSO_4$), and evaporated to give a dark brown liquid. Excess α-methylstyrene was removed under reduced pressure and vacuum distillation of the residue gave the mono-brominated products (61.6 g, 56%), b.p. 95–105°/11 mm, a yellow liquid containing a mixture of isomers. The mixture (13 g) was chromatographed on silicic acid and eluted with hexane. The first fractions were composed of pure 1-methyl-1-phenylvinyl bromide (**18**) while the end fractions were composed

of pure 2-phenylallyl bromide (17) (11). From g.l.c. studies of the pure isomers it was calculated that the crude mixture of bromides was composed of 80% of **17**, τ ($CDCl_3$) 2.4–2.76 (5H, m, Ar), 4.49 (1H, s, vinyl-H), 4.56 (1H, s, vinyl-H) and 5.68 (2H, s, CH_2); and 20% of **18** τ ($CDCl_3$) 2.69 (5H, s, Ar), 3.57 (1H, m, vinyl-H), and 7.83 (3H, s, CH_3).

Sur la conformation des *tert*-butylcyclohexanes substitués en position 2

JEAN CLAUDE RICHER ET CHRISTIAN FREPPEL
Département de Chimie, Université de Montréal, B.P. 6128, Montréal, Québec
ET
ALAIN TCHAPLA ET ZOLTAN WELVART
Groupe de Laboratoires du CNRS, 94320 Thiais, France
Reçu le 2 juin 1971[1]

L'examen des pK (dans le méthyl-cellosolve à 80%: pK_{MCS}) d'aminoalcools et d'amines dérivés du *tert*-butylcyclohexane montre que l'introduction d'un groupement *tert*-butyle en position 2 d'un groupement hydroxyle provoque par rapport au cyclohexanol non substitué un aplatissement de cette partie du cycle lorsque l'hydroxyle et le *tert*-butyle sont *trans*; elle provoque un redressement lorsque ces groupements sont *cis*.

Examination of the pK_{MCS} (80% methylcellosolve) of amino alcohols and amines derived from *tert*-butylcyclohexane shows that introduction of a tertiary butyl group in the adjacent position to a hydroxyl leads, by comparison to the non-substituted cyclohexanol, to a flattening of this portion of the ring when the hydroxyl and *tert*-butyl groups are *trans*; when the groups are *cis* a straightening occurs.

Can. J. Chem., **51**, 1838 (1973)

Introduction

Il est admis (1) que l'introduction d'un groupement *tert*-butyle équatorial ne modifie que peu la géométrie d'un noyau cyclohexanique. L'influence de ce groupe est cependant inattendue dans le cas des *tert*-butyl-2 cyclohexanols où l'isomère *trans* (diéquatorial) est moins stable que l'isomère *cis* (axial-équatorial) (2). Cette anomalie n'a toutefois pas été attribuée à la déformation acceptée précédemment (3) dans le cas de la *tert*-butyl-2 cyclohexanone[2] mais plutôt à la conformation de rotation du groupement *tert*-butyle (2, 4). Cette rotation de 17° du groupement *tert*-butyle par rapport à la position parfaitement décalée qui avait été proposée à la suite d'un calcul (4) a été confirmée récemment (5) lors de la détermination par rayons-X de la structure du toluènesulfonate du di-*tert*-butyl-2,5 cyclohexanol-*cis*, *trans*. Cette étude a démontré de plus que la géométrie du cycle est relativement peu affectée malgré l'asymétrie introduite dans le cycle par la rotation du groupement *tert*-butyle qui rend différent les angles de torsion des deux côtés du cycle (4, 5). Il est à noter toutefois que la déformation asymétrique du cycle n'apparait pas pour le *p*-bromobenzoate du *tert*-butyl-4 cyclohexanol-*trans* dont l'étude aux rayons-X a montré que le cycle est légèrement redressé par rapport au cyclohexane non substitué (6).[3]

Il apparait donc que l'influence du groupement *tert*-butyle sur la géométrie d'un noyau cyclohexanique est généralement faible et qu'elle dépende en partie de la nature et de la position des autres substituants. Afin de vérifier si le groupement *tert*-butyle modifie suffisamment la flexibilité du noyau cyclohexanique pour influencer les diverses propriétés de composés cyclohexaniques (7) nous avons fait appel à la détermination des pK (8) de diverses *tert*-butylcyclohexylamines ainsi que d'amino-alcools correspondants; le choix de cette dernière classe de composés est justifié par le fait que des liaisons hydrogènes peuvent s'établir de façon intramoléculaire (9) et que de telles liaisons peuvent amener une déformation supplémentaire du noyau cyclohexanique.

Resultat et Discussion

L'étude des pK_{MCS} est une méthode qui permet de préciser la géométrie relative des substituants des différents isomères d'aminoalcools. Cette

[1]Revision reçue le 27 novembre 1972.

[2]Un calcul d'Allinger effectué dans ce cas montre que la répulsion entre l'oxygène de la cétone et le groupement *tert*-butyle voisin est suffisamment importante pour que cette cyclohexanone adopte une conformation croisée.

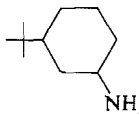
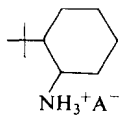
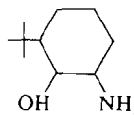
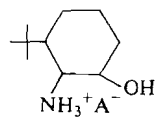
TABLEAU 1. pK_{MCS} de divers *tert*-butylcyclohexylamines et aminoalcools*

Stéréochimie	Isomère					
						








$NH_3^+A^-$ axial	9.37	8.68	OH_a	8.45	OH_a	7.82
			OH_e	8.85	OH_e	8.00
$NH_3^+A^-$ équatorial	9.54	9.01	OH_a	9.04	OH_a	8.66
			OH_e	8.96	OH_e	8.34

*Valeurs déterminées à 25.0 ± 0.5 °C avec une précision de ±0.01 unité de pK. A^- = picrates; dans tous les autres cas A^- = Cl^-.

méthode proposée par Sicher et coll. (8) consiste à examiner le ΔpK, c'est à dire la différence entre les pK_{MCS} de l'aminoalcool considéré et de l'amine correspondante.

On sait que l'introduction d'un groupement OH vicinal diminue notablement la basicité d'une fonction amine par effet inductif (10). Cependant l'abaissement de la basicité peut être compensé lorsque l'angle dièdre entre les deux fonction diminue, c'est à dire lorsque celles-ci deviennent de plus en plus coplanaires: le ΔpK passe de 0.90 pour un aminoalcool cyclohexanique où les substituants sont diaxiaux (angle dièdre de 180°) à 0.18 pour l'aminoalcool ayant ses deux fonctions dans une conformation *cis* bateau (angle dièdre de 0°) (8).

Ainsi, bien que la signification énergétique précise du ΔpK soit complexe[4] sa diminution peut signifier l'aplatissement du noyau cyclohexanique de l'aminoalcool par rapport au noyau de la cyclohexylamine correspondante.

[4]Le ΔpK est en fait la différence de deux différences d'énergies libres:

$$[\Delta E_{(\text{ammonium—amine})} - \Delta E_{(\text{ammonium alcool—amino alcool})}]$$

Nous pouvons penser que divers facteurs conformationnels importants pour une molécule isolée (par exemple le nombre différent de conformations de rotation d'une fonction axiale ou équatoriale) n'ont dans notre cas que peu d'importance pour la molécule en solution dans un solvant hydroxylé. En effet les fonctions amine et hydroxyle adoptent, dans l'amine libre comme dans l'ammonium, la conformation la plus favorable pour la solvatation. D'après le modèle de Prélog et Hafliger (11) qui est le plus conforme aux divers résultats observés jusqu'à maintenant, une stabilisation de l'ion ammonium interviendrait par l'intermédiaire d'une molécule d'eau et au moyen d'une liaison hydrogène avec le groupement hydroxyle. C'est cette stabilisation qui déterminerait la valeur observée pour le ΔpK.

Dans le tableau 1 nous rapportons le pK_{MCS} (12) de quelques amines et aminoalcools dérivés du *tert*-butylcyclohexane dont la synthèse a déjà été décrite (13). La méthode de mesure employée est celle décrite précédemment par Svoboda et coll. (14).

Dans le tableau 2 sont consignés dans les deux premières colonnes les ΔpK déterminés par Sicher et coll. (8) pour les quatre aminoalcools isomères de chaque série **1** et **2** et dans les troisième et quatrième colonnes les ΔpK calculés à partir des résultats du tableau 1. Considérant d'une part que nous avons dosé les sels d'ammonium par l'hydroxyde de tétraméthylammonium alors que Sicher (8) a dosé les bases libres et d'autre part que les différences de ΔpK obtenues sont faibles, nous nous sommes assurés avec plusieurs amines de référence que nos résultats étaient comparables à ceux de Sicher; nous avons obtenu sensiblement les mêmes résultats à 0.01 unité de pK_{MCS} près. Dans le seul cas de la *tert*-butyl-3 cyclohexylamine nous avons un écart maximum de 0.05 unité.

L'examen du tableau 2 conduit aux considérations suivantes pour les isomères de position **1**, **2**, et **3** (le cas des isomères **4** sera discuté à part).

(*1*) Lorsque les deux substituants NH_2 et OH sont axiaux (premier cas) on observe une valeur moyenne de ΔpK de 0.90 ce qui correspond d'après Sicher et coll. (8) à l'abaissement du pK par l'effet inductif.

(*2*) Lorsque l'hydroxyle est équatorial et le groupement amine soit axial soit équatorial (deuxième cas) les valeurs de pK trouvées sont comprises entre 0.65 et 0.68. Le fait que le ΔpK soit plus petit que celui noté précédemment est en faveur d'une diminution de l'angle dièdre entre les deux fonctions. Mais la constance du

TABLEAU 2. ΔpK des divers amino-alcools

Stéréochimie relative		Isomère 1* 	Isomère 2* 	Isomère 3 	Isomère 4 1° cas	NH_{2_a} OH_a	0.88	0.90	0.86	0.92
2° cas	NH_{2_a} OH_e	0.65	0.67	0.68	0.52
	NH_{2_e} OH_e	0.67	0.66	0.67	0.58
3° cas	NH_{2_e} OH_a	0.43	0.40	0.35	0.50

*Sicher et coll. (8).

ΔpK pour ces deux types de composés montre que l'introduction d'un groupement OH équatorial ne doit pas modifier sensiblement la géométrie du cycle de la cyclohexylamine correspondante et ce quelle que soit sa configuration initiale (axiale ou équatoriale).

(*3*) Lorsque l'hydroxyde est axial et le groupement amine équatorial (troisième cas) les valeurs de ΔpK sont nettement plus faibles environ 0.40 ce qui signifie une diminution de l'angle dièdre entre les deux fonctions voisines (aplatissement du cycle). Ceci est en bon accord avec les résultats précédents qui montrent qu'un seul groupement OH axial peut déjà déformer le noyau cyclohexanique (15) substitué par un *tert*-butyle.[5]

(*4*) La position du groupement amine intervient également. En effet la comparaison des valeurs des pK de **1** et **3** (ΔpK = 0.43 et 0.35) montre que l'aplatissement provoqué par l'introduction d'un OH axial est plus important lorsque la fonction amine est en position 2 que lorsqu'elle est en position 4. On voit donc que la répulsion vicinale NH_2-équatorial/*tert*-butyl-équatorial facilite l'aplatissement des carbones 1 et 2 du cycle.

(*5*) Dans les isomères de la série **4** on constate (sauf pour le premier cas) que les valeurs de ΔpK sont différentes de celles des isomères des séries **1**, **2**, ou **3** correspondantes. Ainsi un hydroxyle équatorial en position 2 (deuxième cas) favorise l'aplatissement du cycle puisque les ΔpK sont respectivement de 0.58 et 0.52 au lieu de la valeur moyenne de 0.67 trouvée pour les isomères des séries **1**, **2**, et **3**. Par ailleurs un hydroxyle axial en position 2 (troisième cas) tend à redresser le cycle puisque dans ce cas le ΔpK est de 0.50 au lieu de 0.40 pour les isomères correspondants des séries **1**, **2**, et **3**.

On peut enfin mentionner qu'il est probable que les interactions NH_2 *tert*-butyle provoquent des déformations de cycle semblables à celles dues aux interactions OH/*tert*-butyle; toutefois le pK des amines nous servant de référence, nous ne pouvons les mettre en évidence.

En admettant que la déformation observée par la mesure de ΔpK n'est pas liés à la présence de la fonction amine, mais dépend principalement de la flexibilité du système cyclohexanique, nous pouvons raisonner uniquement sur le motif du *tert*-butyle 2 cyclohexanol. Les figures du schéma I montrent que, lorsque le groupment *tert*-butyle est parfaitement décalé, et que la conformation du cycle est chaise, l'énergie d'interaction *tert*-butyle/OH est la même pour l'isomère *cis* que pour l'isomère *trans*. Or, pour les aminoalcools nos résultats suggèrent l'existence d'un aplatissement du cycle lorsque l'hydroxyle est équatorial et un redressement lorsqu'il est axial. Nous pouvons donc penser que la minimisation de l'énergie d'interaction *tert*-butyle/OH résulte non seulement de la rotation du groupement *tert*-butyle (1, 4, et 5) et d'un resserrement du "parapluie" sur lui même (6 et 16), mais aussi de la modification différente de la géométrie du cycle pour les deux isomères. L'observation des

[5]Un des arbitres nous a demandé de préciser la signification de la déformation: comme la différence entre les valeurs extrêmes des ΔpK est faible (0.72 unité correspond à un changement d'angle dièdre H_2N—C—OH de 180° (8)) une diminution de 0.25 à 0.30 unité de ΔpK indique un changement notable de cet angle dièdre. Or, il nous parait évident que ce n'est possible que si les autres angles dièdres et notamment les angles dièdres correspondants à l'intérieur du cycle (C_1—C_2—C_3 et C_2—C_3—C_4) changent également.

SCHÉMA 1

modèles montre que les interactions OH/*tert*-butyle peuvent se minimiser aussi par la rotation autour de la liaison C_1—C_2. Pour que cette rotation éloigne le groupement hydroxyle du groupement *tert*-butyle, elle doit provoquer pour l'isomère *cis* un redressement et pour l'isomère *trans* un aplatissement du cycle.[6]

Une autre explication a été suggérée par un des arbitres. L'effet stérique proposé par Pasto et Rao (2) permettrait d'expliquer seul l'ensemble des résultats: à savoir que le groupement *tert*-butyle pousse ensemble les groupements fonctionnels, davantage lorsque le groupement fixé en 2 est équatorial que lorsqu'il est axial. De ce fait la liaison hydrogène est favorisée, ce qui diminue le ΔpK. Il ne fait pas de doute que ce facteur intervient, mais il ne peut pas expliquer la différence de ΔpK entre le composé **4** (OH axial – NH_2 équatorial, $\Delta pK = 0.50$) et les composés **3** (OH axial – NH_2 équatorial $\Delta pK = 0.35$ et OH équatorial – NH_2 équatorial $\Delta pK = 0.67$). Or, si le changement de ΔpK est dû à une modification de la géométrie du cycle, il n'est pas étonnant que ces ΔpK deviennent différents.

Finalement, le présent travail montre en outre que la mesure de pK méthode extrêmement simple introduite par Sicher et coll. (14) pour l'étude de la géométrie des cycles permet de mettre en évidence des changements géométriques correspondants même à des faibles variations énergétiques.

[6]Pour l'isomère *trans* la déformation du cyclohexane chaise en conformation croisée (indiquée par les flèches) éloigne l'hydroxyle du *tert*-butyle d'une manière semblable à celle proposée par Allinger et coll. (3) pour la *tert*-butyl-2 cyclohexanone. Il y a diminution notable des interactions pour cette conformation. Pour l'isomère *cis* le passage de la forme chaise à la forme croisée amène l'hydroxyle entre deux méthyles du groupement *tert*-butyle. La diminution des interactions avec un des méthyles est compensée par l'augmentation des interactions avec l'autre méthyle. Les interactions sont donc peu modifiées par cette déformation du cycle. Nous sommes donc amenés à concevoir que la diminution des interactions se fait par la rotation du groupement *tert*-butyle et une rotation autour de la liaison C_1—C_2.

En comparant ces résultats à ceux des divers calculs (3 et 4) et des études au rayons-X (5 et 6) effectués sur divers composés cyclohexaniques substitués par un groupement *tert*-butyle nous pouvons conclure que l'énergie d'interaction du groupement *tert*-butyle avec les substituants du noyau cyclohexanique peut se minimiser de diverses manières. De ce fait les modifications géométriques peuvent être différentes dans l'état cristallin et en solution.

Partie expérimentale

Les pK_{MCS} ont été déterminés en utilisant un ensemble de titration automatique "Radiometer". Les titrages ont été effectués dans les conditions définies par Simon et coll. (12). Les valeurs indiquées dans les tableaux 1 et 2 sont, selon les produits, la moyenne arithmétique de 4 à 7 courbes de titrage indépendante. La méthode des moindres carrés appliquée aux déviations

$$\sqrt{\frac{\sum \Delta^2}{n(n-1)}}$$

est plus petite que 0.018 en unité de pK_{MCS} dans tous les cas considérés.

Nous remercions vivement les Professeurs Altona (Leiden) et Kagan (Orsay) pour leurs diverses remarques sur ce travail, et d'avoir bien voulu faire part de leurs résultats avant leur publication.

Nous remercions également un des arbitres pour ses critiques constructives.

Les auteurs remercient aussi le CNRS et le CNRC pour l'aide financière apportée sous forme d'octrois et de bourses.

Received December 7, 1972

Using parameters derived from the component mononucleotides, β-NMN, 5′-AMP, and 5′-ADP, the ^{31}P n.m.r. spectra of oxidized pyridine coenzymes, recorded in the presence of coupling from the ribose protons, are analyzed with the use of extensive computer simulations. It is shown that the spectra are compatible only with *gauche–gauche* conformation about the $C_{5'}$—$O_{5'}$ bonds on both the adenine and nicotinamide ends of oxidized pyridine coenzymes. The ^{1}H and ^{1}H–{^{31}P} Fourier transformed 16K n.m.r. spectra of 5′-AMP and 5′-ADP are reported and their full analysis given, and it is shown that the nucleotides exist predominantly in the *gauche–gauche* conformation about the $C_{4'}$—$C_{5'}$ and $C_{5'}$—$O_{5'}$ bonds.

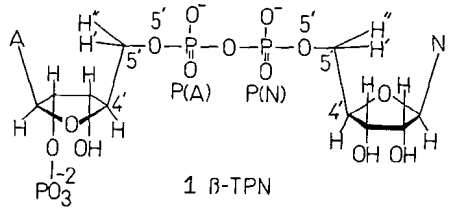
Les spectres r.m.n. ^{31}P des coenzymes oxydées de la pyridine, enregistrés en présence de couplage provenant des protons de la ribose, ont été analysés en utilisant des paramètres obtenus des mononucléotides qui les composent et avec l'aide de nombreuses simulations opérées par l'ordinateur. Il a été montré que les spectres sont seulement en accord avec une conformation *gauche–gauche*, en ce qui a trait aux liens $C_{5'}$—$O_{5'}$ des deux terminaisons adénine et nicotinamide des coenzymes oxydées de la pyridine. Les transformées de Fourier ^{1}H et ^{1}H–{^{31}P} des spectres 16K r.m.n. du 5′-AMP et du 5′-ADP sont décrites ainsi que leurs analyses complètes; il a aussi été montré que les nucléotides existent préférentiellement dans une conformation *gauche–gauche* en ce qui a trait aux liens $C_{4'}$—$C_{5'}$ et $C_{5'}$—$O_{5'}$.

[Traduit par le journal]

Can. J. Chem., **51**, 1843 (1973)

Introduction

An important question about the stereochemistry of pyridine coenzymes **1–4** is the geometric orientation of the pyrophosphate backbone. The three-bond coupling constant data involving ^{31}P nuclei and the 5′-hydrogens ($^{3}J_{PH}$) should provide some information regarding its geometry. Hall and Malcolm (1) demonstrated a



1 β-TPN

2 = TPNH (where N in **1** above is dihydronicotinamide)
3 = DPN (where the PO_3^{2-} in **1** above is OH)
4 = DPNH (where the N in **3** is dihydronicotinamide)

strong stereochemical dependence of vicinal $^{3}J_{PH}$ in H—C—O—P fragments. This was subsequently confirmed by other investigators (2–5). *The gauche $^{3}J_{PH}$ in H—C—O—P fragments have been found to be small and in the range 3 ± 2 Hz whereas the trans $^{3}J_{PH}$ lie in the range of 25 ± 3 Hz.* This information has been used by Schleich *et al.* (6) to determine the conformation of 3′-phosphate in 3′-UMP, by Schweizer and Robins (7) to determine the phosphate conformation of 5′,3′-cyclic AMP and by Sarma and Mynott (8, 9) to determine the preferred conformation constrained to the $C_{5'}$—$O_{5'}$ bonds in β-NMN and β-NMNH.

7

The determination of the conformation (**5**–**7**) about the $C_{5'}$—$O_{5'}$ bonds of the pyridine dinucleotides is complicated by the presence of two phosphate groups, each carrying a ribose unit, making it necessary to define the stereochemistry about two $C_{5'}$—$O_{5'}$ bonds. An obvious way to investigate this problem is to carry out ^1H and ^{31}P n.m.r. studies to determine the four coupling constants, $J_{P(A)5'(A)}$, $J_{P(A)5''(A)}$, $J_{P(N)5'(N)}$, $J_{P(N)5''(N)}$, the letters A and N standing for the adenine and nicotinamide ends of the dinucleotide respectively, and analyze these as for the mononucleotides (8, 9). Unfortunately one cannot obtain these coupling constants *directly* from the ^1H or from the ^{31}P spectra of pyridine coenzymes. In the present investigations, we have examined the ^{31}P n.m.r. spectra of pyridine coenzymes in the presence of coupling from ribose protons at 40.5 MHz and wish to report here that *while the exact* J_{POCH} *coupling constants cannot be determined, the spectrum is consistent only with all the* $^3J_{POCH}$ *coupling constants being in the range for gauche coupling, indicating that the structure is predominantly gauche–gauche about the* $C_{5'}$—$O_{5'}$ *bonds.* Since n.m.r. data from the corresponding mononucleotides were employed during the computer simulations, we have also recorded and fully analysed ^1H n.m.r. spectra of 5′-AMP and 5′-ADP.

Experimental

Instrumentation

The n.m.r. spectra were recorded on a Varian HA-100D spectrometer interfaced to a Digilab FTS-3 NMR-3 Fourier transform data system. The frequencies for the fluorine (lock) channel and proton and phosphorus frequencies (observing or decoupling) were derived from a Digilab 10-94 frequency synthesizer. Hexafluorobenzene in a 1 mm capillary provided the ^{19}F lock signal. The sample temperature was 30.5°, unless otherwise stated. A Digilab 400-2 pulser with a 410-H plug-in unit supplied the proton frequency pulses (100 MHz). Those spectra where the phosphorus nuclei were decoupled were recorded with irradiation derived from a Digilab 50-80 PD plug-in amplifier. The ^{31}P spectra were recorded at 40.48 MHz. The radiofrequency pulses for the observing channel were obtained from a Digilab 400-2 pulser with a 410-P plug-in unit. No internal reference was used for the ^{31}P spectra since the chemical shifts relative to 85% H_3PO_4 had already been determined under similar conditions in the continuous-wave mode in which proton decoupling had been used (10, 11).

Materials

The nucleotides and coenzymes were commercial preparations. The samples were lyophilized three times from 99.8% D_2O and the ^1H spectra were taken in commercial "100%" D_2O. A typical concentration of the internal standard $(CH_3)_4NCl$ was 0.004 *M* for 0.1 *M* solutions. The p*H* values reported are p*H* meter readings from a Leeds and Northrop or a Fischer Accument model 320 p*H* meter. ^{31}P measurements were made in H_2O solutions containing 0.001 *M* EDTA. For solvent perturbation studies, 0.1 *M* sodium salt of the coenzyme (p*H* 8.0 in H_2O) was made up in 50% (v/v) methanol/water mixture.

Results and Discussion

(1) ^1H Fast Fourier Transformed Nuclear Magnetic Resonance Spectra of 5′-AMP and 5′-ADP

In order to determine approximate values of $J_{P(A)5'(A)}$ and $J_{P(A)5''(A)}$ for the dinucleotides we have completely analyzed the ribose region of 5′-AMP and 5′-ADP. The p*H* of the medium was selected such that 5′-AMP would remain as the monophosphate dianion and 5′-ADP as the diphosphate dianion. This situation is most nearly compatible with the ionic state of the phosphates in the pyridine dinucleotides at biological p*H* values. Figure 1*a* shows the ribose region of the ^1H n.m.r. spectrum of 5′-AMP taken in the Fourier mode using a 16K transform. We are primarily interested in the coupling between the ^{31}P nuclei and the 5′-geminal protons. To determine these coupling constants as accurately as possible we have also recorded the ^1H–$\{^{31}P\}$ spectrum of 5′-AMP (Fig. 1*c*). The ribose region of the ^1H and ^1H–$\{^{31}P\}$ n.m.r.[2] spectra of 5′-AMP and 5′-ADP was analyzed with the aid of the computer program LAME. The computer simulated spectra are shown in Fig. 1 and the data are summarized in Table 1.

At this point, it is appropriate to draw some conclusions regarding the favored conformations of 5′-AMP and 5′-ADP from the data in Table 1. The observed sum, $J_{P5'} + J_{P5''}$, strongly suggests (12, 13) that the rotamer constrained to

[2] ^{31}P–$\{^1H\}$ n.m.r. stands for ^{31}P n.m.r. measurements taken under conditions in which the protons are decoupled.

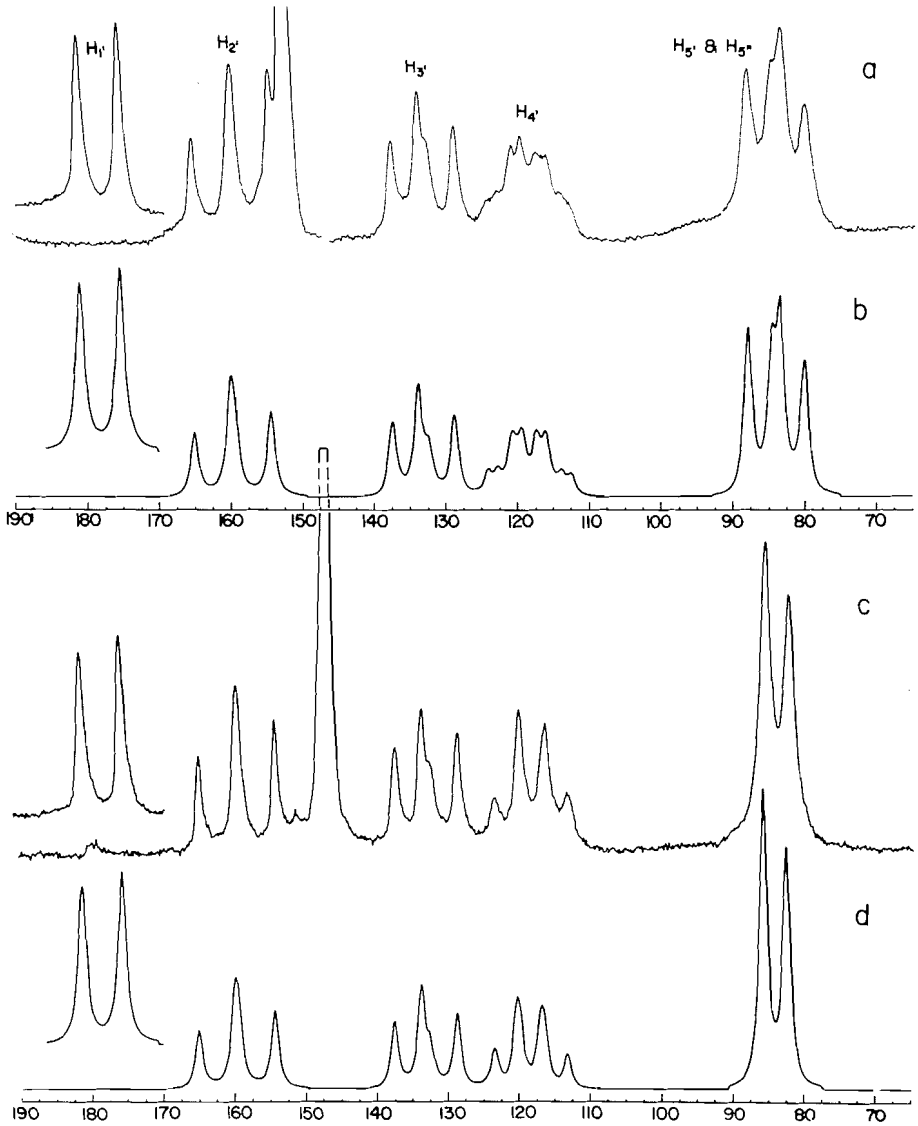

FIG. 1. (*a*), Fourier transformed ^{1}H n.m.r. spectrum of a 0.1 *M* solution of 5′-AMP in 10^{-3} *M* EDTA in 100% D_2O. p*H* = 8.2; number of pulses = 500; pulse width = 50 μs; sampling frequency = 2000 Hz; number of input points = 16 384; delay time = 0.0 s. The scale for (*a*), (*b*), (*c*), and (*d*) is in Hz downfield from internal tetramethylammonium chloride (TMA). (*b*), Simulated spectrum of Fig. 1*a*. Data are given in Table 1. (*c*), Fourier transformed ^{1}H n.m.r. spectrum of the sample as in Fig. 1*a*, but with decoupling of the phosphorus atom. All the parameters are the same as for (*a*), except that the number of pulses = 400. The decoupling caused slight warming up of the sample as is evidenced from the position of the HDO peak. No cooling by N_2 was used because the movement of the HDO resonance was used to uncover the peaks due to 2′ which were partially obscured in (*a*). The slight change in temperature did not affect the chemical shifts or coupling constants to any significant extent. (*d*), Simulated spectrum for the spectrum in Fig. 1*c*.

the $C_{5'}$—$O_{5'}$ is predominantly *gauche–gauche* **5** in both 5′-AMP and 5′-ADP (both 0.1 *M*) at p*H* values 8.2 and 5.2, respectively. Approximate calculations of rotamer populations, using the equations developed in refs. 14 and 15 show that the rotamers constrained to the $C_{4'}$—$C_{5'}$ linkage (**8**–**10**) in 5′-AMP (0.1 *M*) and 5′-ADP (0.1 *M*) at p*H* values 8.2 and 5.2 respectively, are predominantly *gauche–gauche* (**8**), *i.e.* over 65%. We have examined the ^{1}H and ^{1}H–$\{^{31}P\}$ spectra

TABLE 1. ^{1}H chemical shifts and coupling constants of 5′-AMP (pH = 8.2) and 5′-ADP (pH = 5.2), concentrations 0.1 M, temperature 30.5°. Chemical shifts are in p.p.m. downfield from tetramethylammonium chloride

†Only the sum significant. (14, 15).
‡This is an arbitrary value. The experimentally observed values for 5′ UMP and 6-*aza*-5′-UMP are −13.5 and −11.3 Hz. In dUMP, the 2′ and 2″ were strongly coupled and no experimental value could be obtained. In fact, during simulations we have used values from −10 to −13; no change in spectrum appearance was observed.

of 5′-AMP, pH 8.2, in the concentration range of 0.4–0.001 M and have been unable to detect any significant change in the value of $J_{4'5'} + J_{4'5''}$ and $J_{POCH(5')} + J_{POCH(5'')}$ with dilution, indicating that in 5′AMP the predominant rotamer constrained to the $C_{4'}$—$C_{5'}$ and $C_{5'}$—$O_{5'}$ bonds are both *gauche–gauche* (**5** and **8**) in the whole of the concentration range presently accessible. The observed four-bond coupling (16) $^4J_{P4'}$ of about 1.4 Hz (Table 1) may be further evidence for an all-*trans* (W) spatial relationship between phosphorus and the 4′-hydrogen encountered when the molecule is oriented *gauche–gauche* about both $C_{4'}$—$C_{5'}$ and $C_{5'}$—$O_{5'}$ bonds (**11**). Hall and coworkers (1) have presented clear evidence that H–P coupling in H—C—

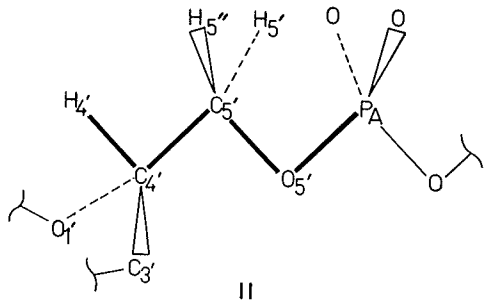
C—O—P fragments is maximal (*ca.* 2.5 Hz) when the all-*trans* arrangement is assumed and decreases (probably to zero) for less favorable arrangements.



11

Detailed discussion of the use of Karplus equation for elucidating the nature of the furanose ring pucker has appeared in the literature (9, 13, 15). In this work we attempt no indepth analysis of the ribose vicinal $J_{1'2'}$, $J_{2'3'}$, and $J_{3'4'}$ coupling constants. We deem it necessary to indicate that the observed data for 5′-AMP and 5′-ADP (Table 1) are consistent with a flexible ring system undergoing pseudorotational motion proposed by Kilpatrick *et al.* (17)

for cyclopentane, and by Hall *et al.* (18) and Sundaralingam (19) for the ribofuranose ring.[3]

(2) ^{31}P Pulsed Fast Fourier Transformed Nuclear Magnetic Resonance Spectra of Oxidized Pyridine Dinocleotides

^{31}P–{^{1}H} spectra of oxidized pyridine dinucleotides (11, 20) show that the two ^{31}P nuclei of the pyrophosphate backbone appear as a *well resolved* AB quartet, $|^{2}J_{POP}|$ being 20.3 Hz and $\nu_0\delta \simeq$ 0.3 p.p.m. Figure 2 shows the ^{31}P fast Fourier transformed 40.48 MHz spectrum of β-TPN, *in which the ribose protons were not decoupled* (β-DPN also gave a similar spectrum). Only the pyrophosphate region is shown. The conditions under which the spectrum was taken are detailed in the caption of Fig. 2. This spectrum has no fine features, and appears as a broad central peak flanked by broad satellites. The 89 MHz ^{31}P n.m.r. spectrum of oxidized pyridine coenzymes (20) also consists of broad resonances in which the central peaks are resolved but there are few defined features. The difference in appearance between the ^{31}P and ^{31}P–{^{1}H} n.m.r. spectra must be due to the coupling of the two ^{31}P nuclei with the neighboring protons (5′, 5″, 4′) of the backbone, but clearly these coupling constants, required to delineate the backbone geometry, cannot be obtained *directly* from either the ^{1}H or the ^{31}P spectrum. However, *it can be shown easily that these coupling constants must fall into the range of gauche* $^{3}J_{POCH}$ *coupling to be able to produce the observed spectrum.*

(3) Computer Simulation of ^{31}P Nuclear Magnetic Resonance Spectra for Possible Backbone Geometries

The observed ^{31}P spectrum of the dinucleotide may arise from any of the nine cases presented in Table 2 or weighted averages of several cases.

[3]X-ray data on a large number of nucleosides and nucleotides indicate that the ribose moiety exists either in the C-3′ *endo* or in the C-2′ *endo* mode. The present n.m.r. data is consistent with a situation in which ribose exist as an equilibrium mixture of the above modes undergoing rapid interconversion. It has been reported (22–24) that the value of $J_{1'2'}$ for 5′-AMP increases slightly as the concentration is reduced. We have examined the H^{1}–{^{31}P} spectra of 5′-AMP in the range 0.4–0.001 *M* and have also observed this increase in $J_{1'2'}$ with dilution; in addition $J_{3'4'}$ shows a corresponding decrease with dilution. These data are consistent with the view that in these concentration ranges 5′-AMP exists as a dynamic equilibrium of 2′-*endo* ⇌ 3′-*endo* with a small shift in population towards 2′-*endo* at lower concentrations.

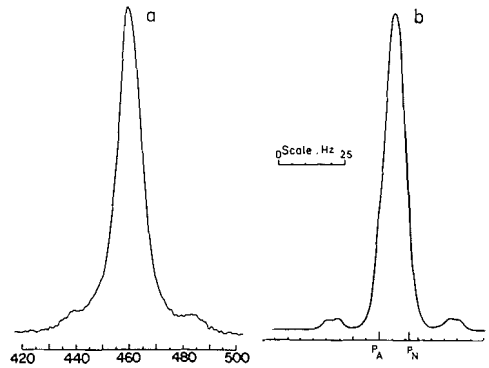

FIG. 2. (*a*) Fourier transformed ^{31}P n.m.r. spectrum of 0.25 *M* aqueous solution of β-TPN in 3×10^{-3} *M* EDTA, p*H* = 7.8. Number of pulses = 15 030; pulse width = 30 μs; sampling frequency = 2000 Hz; number of input points = 2048; delay time = 0.0 s. Scales are given in Hz upfield from external 85% orthophosphoric acid. Observing channel frequency = 40.48 MHz. The spectra illustrated were computed using triangular apodization; the envelope width at half height = 10.5 Hz. Spectra computed from the same FID without apodization were practically identical in shape and had an envelope width at half height of 10.3 Hz. (*b*) Case 1 simulation after refinement and adjustment of parameters. The data used were as follows: *chemical shifts*: P(A) = 11.2; P(N) = 11.5 (both in p.p.m. upfield from external 85% orthophosphoric acid): 4′(A) = 1.20; 5′(A) = 1.07; 5″(A) = 1.07; 4′(N) = 1.20; 5′(N) = 1.01; 5″ (N) = 0.84 (all in p.p.m. downfield from internal TMA). *coupling constants* (in Hz): $J_{P(A)P(N)} = 20.3$; $J_{P(A)4'(N)} = 0.8$; $J_{P(A)4'(A)} = 1.4$; $J_{P(A)5'(A)} = 4.7$; $J_{P(N)4'(N)} = 1.4$; $J_{P(N)4'(A)} = 0.8$; $J_{P(N)5'(N)} = 4.3$; $J_{P(N)5''(N)} = 4.5$; $J_{4'(N)5''(N)} = 2.0$; $J_{4'(N)5'(N)} = 2.6$; $J_{4'(A)5'(A)} = 2.6$; $J_{4'(A)5''(A)} = 2.0$; $J_{5'(A)5''(A)} = 12.1$; $J_{5'(N)5''(N)} = 12.1$.

*The letters (A) and (N) stand for the adenine and nicotinamide ends of the pyridine dinucleotide respectively. The line width at half height used for the lineshape program was 2.3 Hz; this was a representative value from $^{31}P-\{^1H\}$ spectra of the same compound.
†In p.p.m. to higher field than external 85% H_3PO_4.
‡In p.p.m. to lower field than internal tetramethylammonium chloride.

As a starting point in the simulations, we have assumed that one can use the $^3J_{POCH}$ values from the ^1H n.m.r. data of the component mononucleotides, *viz.*, β-NMN, 5'-AMP, and 5'ADP. Data for the last two compounds were taken from Table 1; data for β-NMN were taken from the analysis of spectra recorded at p*H* 8.0 in the Fourier mode by Sarma and Mynott (8, 9). The parameters selected to carry out the simulations of the nine cases are given in Table 3. An absolute spectral assignment of the 5'-, 5''-hydrogens cannot be made at present and thus a distinction between the *gauche–trans* and *trans–gauche* rotamers (about $C_{4'}—C_{5'}$ or $C_{5'}—O_{5'}$ of a particular mononucleotide moiety) should not be made. Thus the nine cases (Table 2), with this limitation, must be grouped into four types: (*a*) the all-*gauche* conformation (case 1); (*b*) the adenine component is *gauche–gauche*, the nicotinamide component *gauche* and *trans* (cases 2 and 3); (*c*) the adenine component *gauche* and *trans*, nicotinamide *gauche–gauche* (cases 4 and 5); (*d*) adenine and nicotinamide components both *gauche* and *trans* (cases 6–9). The approach is thus limited to an evaluation of the contribution from the *gauche–gauche* and the *combined contribution* from the *gauche–trans* and *trans–gauche* conformations of the individual mononucleotides. Representative cases (1, 2, 4, 6) were chosen from each type. The computer simulated spectra, using the parameters in Table 3, are shown in Fig. 3. Also illustrated in the simulations for case 2 is the spectrum to be expected if $^3J_{POCH}$ (*trans*) has the opposite sign from $^3J_{POCH}$ (*gauche*). These preliminary calculations show that *only case 1* or a rapidly exchanging mixture, predominantly of case 1, could possibly give the observed ^{31}P n.m.r. spectrum (compare Fig. 2*a* with case 1 in Fig. 3*a*). The final calculated spectrum for case 1 is shown in Fig. 2*b*, and the line width is 9 Hz. In the experimental spectrum, the band width was found to be 10.3 Hz. The agreement between the calculated (Fig. 2*b*) and experimental (Fig. 2*a*) spectra is reasonable. The various final parameters are listed in the legend for Fig. 2*b*.

(4) Effect of Inter- and Intra-molecular Interactions on the Conformation Constrained to $C_{5'}—O_{5'}$ Bonds

Recent studies (24, 25) have shown that the *chemical shifts* of the adenine and certain ribose protons of pyridine coenzymes show concentration dependence indicating the formation of dimers in which the adenine moieties interact. It is therefore relevant to consider to what extent the conclusions of the previous sections may be invalidated by intermolecular interactions, especially since the concentration employed for recording the ^{31}P n.m.r. spectra (protons not decoupled) were rather high, in order to obtain the wings of the spectral envelope within a reasonable time. Previous studies have shown that intermolecular interactions are much weaker at concentrations of 0.05 *M* (25) and therefore the undecoupled ^{31}P n.m.r. spectra were also examined at this concentration; no significant change in envelope form or width was detected. A concentration below 0.05 *M* was not employed because the compounds are too unstable to last the time required for data collection in the ^{31}P mode. The conclusion about the geometry

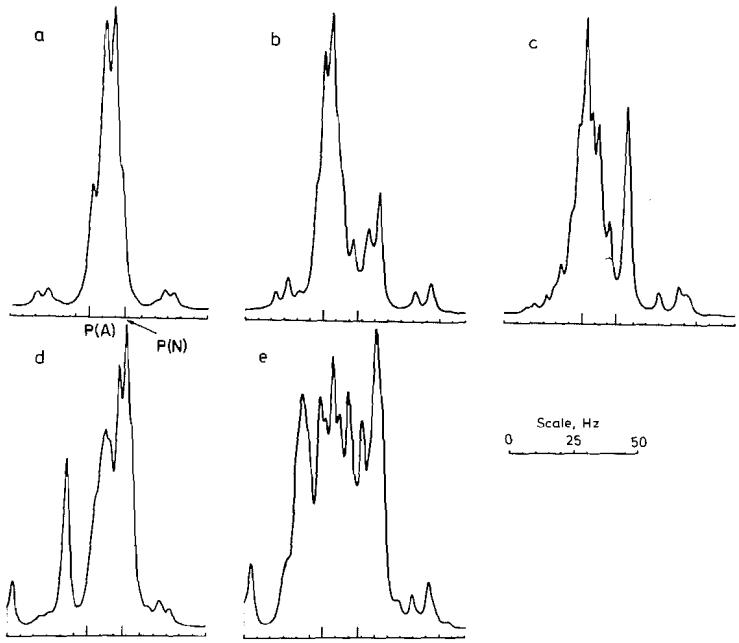

FIG. 3. Simulated ^{31}P n.m.r. spectrum of cases 1, 2, 4, and 6 from Table 1. The parameters used are given in Table 3. (*a*), Case 1; A-$C_{5'}$—$O_{5'}$ *gauche–gauche*-N-$C_{5'}$—$O_{5'}$ *gauche–gauche*. (*b*), Case 2A. A-$C_{5'}$—$O_{5'}$ *gauche–gauche*-N-$C_{5'}$—$O_{5'}$ *gauche–trans*. (*c*), Case 2B. As for (*b*) except that $J_{P(A)5'(A)}$ has been given the opposite sign. (*d*), Case 4. A-$C_{5'}$—$O_{5'}$ *gauche–trans*-N-$C_{5'}$—$O_{5'}$ *gauche–gauche*. (*e*) Case 6. A-$C_{5'}$—$O_{5'}$ *gauche–trans*-N-$C_{5'}$—$O_{5'}$ *gauche–trans*.

constrained to the $C_{5'}$—$O_{5'}$ bonds therefore appears valid in the presence of intermolecular attractions. We have also previously examined the ^{1}H n.m.r. spectra of oxidized pyridine coenzymes in the concentration range 0.4–0.001 *M*. While we have not attempted a full analysis of the ribose proton region, it is clear that there is no significant change in the coupling constants of the ribose region, although there are some minor changes in the spectrum attributable to changes in chemical shift resulting from intermolecular stacking; most certainly a concentration-dependent change in conformation about either $C_{5'}$—$O_{5'}$ bond and introduction of a $^{3}J_{POCH}$ *trans* coupling (25 Hz) would be revealed by a large change in the spectrum in this region.

There is considerable spectrocopic evidence, recently reviewed (10), to show that at biological p*H* and temperature in D_2O or H_2O solutions, pyridine coenzymes exist, on a time-average, in a folded conformation. Sarma and Mynott (25) have shown that the preferred geometry of the folded species is probably an internally stacked right-handed helix. It has not been established whether the system undergoes a dynamic exchange between a folded, several partially folded, and extended forms (21, 24) or whether there is a simple two-state equilibrium (26, 27). However, it is generally agreed that as the temperature is raised, or when organic solvents such as methanol are introduced, the coenzyme becomes more extended (26, 28, 29).

To examine whether unfolding the coenzyme would affect the $C_{5'}$—$O_{5'}$ rotamers, we have studied the effect of temperature on the undecoupled ^{31}P spectrum of oxidized pyridine coenzymes. The range of temperature employed was 8–50°. The concentration of 0.25 *M* enabled the simultaneous monitoring of the effect of both inter- and intramolecular destacking on the backbone geometry. A temperature-induced change in the $C_{5'}$—$O_{5'}$ rotamer population would definitely be manifested in the ^{31}P n.m.r. spectrum, but no such change was observed.[4] In fact, no significant change in the spectrum envelope and width at half height was observed at 8 or 50°, indicating that J_{POCH} was insensi-

[4]Examination of the ^{31}P-{^{1}H} spectra as a function of temperature (8–50°) showed the following results. $^{2}J_{POP}$ was independent of temperature. The difference in chemical shifts between the two ^{31}P nuclei remained the same. However, the center of the AB quartet, as well as the two individual ^{31}P chemical shifts moved to higher fields by 5 Hz (H_3PO_4, 85%, external reference).

tive to temperature-induced perturbations. We have also examined the undecoupled ^{31}P n.m.r. spectrum of a 0.1 *M* solution of β-TPN in a 1:1 methanol–water mixture. As expected from temperature studies, the general form of the spectrum envelope was unchanged; however there was a slight narrowing of the central band, which, from $^{31}P-\{^1H\}$ spectrum, is accounted for by a small reduction in $\nu_0\delta$.

(5) Possible Limitations in the Present Approach

The protons of the ribose region and the phosphorus nuclei of the backbone strictly constitute a 14-spin system, but our analysis has been simplified to that of an 8-spin system. This is entirely reasonable since the possibility of virtual coupling of the 1′-, 2′-, or 3′-protons on either ribose to the ^{31}P nuclei cannot be significant. The $^{31}P-\{^1H\}$ n.m.r. spectra of oxidized pyridine coenzymes are strongly coupled AB quartets at 40.5 MHz ($J/\nu_0\delta = 1.7$) and it would be advantageous to record the undecoupled ^{31}P spectra (in order to extract the J_{POCH} couplings) at *very much* higher fields to produce first order spectra. Nevertheless, we feel that the ^{31}P n.m.r. spectra at 40.5 MHz are sensitive enough to variations of $^3J_{POCH}$ to be able to come to reasonable conclusions about the backbone geometry. This is simply because $^3J_{POCH(gauche)} = 3 \pm 2$ and $^3J_{POCH(trans)} = 25 \pm 3$ Hz. The spectra are strongly second order at 89 MHz ($J/\nu_0\delta = 0.78$ for β-TPN, but they can be a useful check of the conclusions reported here. We have compared the published ^{31}P n.m.r. spectrum of β-DPN at 89 MHz (20) with a simulation carried out by us in the way described previously (only changing $\nu_0\delta$) and found this to be consistent with an all *gauche* conformation for the backbone. It could be argued that it is not reasonable to use $^3J_{POCH}$ (*i.e.* $J_{P5'}$) coupling constants from the mononucleotides (to computer-simulate the ^{31}P spectra of dinucleotides) since this is in effect assumes that the mononucleotides can be considered as *entirely gauche–gauche* about the $C_{5'}—O_{5'}$ bonds. However, we have no more reasonable estimates for the *gauche* couplings, and these still fall within the observed range of 3 ± 2 Hz for $^3J_{POCH(gauche)}$ (1–5). One may argue that we cannot assume that the relative chemical shifts of 4′-, 5′-, and 5″-protons of the nicotinamide and adenine ends of the dinucleotide as identical to those of the mononucleotides, as we have done in our simulations. However, examination of the ^1H 220 MHz and the $^1H-\{^{31}P\}$ 100 MHz spectra of the dinucleotides indicates that these chemical shifts fall in the range we have used, though the complex overlap of the transitions does not allow us to determine them exactly. One may further notice that we have attempted to simulate an envelope comprised of hundreds of closely spaced lines (this is especially so in the case of the backbone when both $C_{5'}—O_{5'}$ bonds are *gauche–gauche*) and that we may not be able to obtain the exact values of $^3J_{POCH}$. Similar types of envelope simulations have been successfully done by Chan and Krieshman (30) who obtained the approximate *J* values for the ribose–phosphate backbone in poly U. In the present paper *we wish to make it clear that we have attempted to obtain* the approximate magnitudes of $^3J_{POCH}$ to see whether any of $J_{P(A)5'(A)}$, $J_{P(A)5''(A)}$, $J_{P(N)5'(N)}$ and $J_{P(N)5''(N)}$ can lie in the range for *trans* coupling (*i.e.* 25 Hz). The important conclusion that emerges from the present study is that the rotamers constrained to the $C_{5'}—O_{5'}$ bonds of both the adenine and nicotinamide ends of oxidized pyridine coenzymes are predominantly *gauche–gauche* (**5**) and that this conclusion is valid irrespective of inter- or intra-molecular interactions.

Our conclusion that the favored conformation about both the $C_{5'}–O_{5'}$ bonds of the backbone of oxidized pyridine coenzymes is *gauche–gauche* is consistent with the observation for nucleotides in the solid state. Thus *gauche–gauche* conformation appears overwhelmingly favored for 5′-mononucleotides (31), appears in the dimers UpA (32) as well as in poly A, RNA, and DNA (33, 34).

This research was supported in part by grants from the National Cancer Institute of NIH (CA 12462-01 and CA 12462-02) and the National Science Foundation (GB 28015), the National Research Council of Canada (CI1544, A6434) and the Research Corporation of New York. The Faculty of Graduate Studies of the University of Manitoba are thanked for a postdoctoral fellowship to D.J.W. The fast Fourier transform system was bought by funds kindly furnished by the National Science Foundation (GP28061) and the State University of New York. The authors are greatly indebted to all these agencies for their support of basic research.

Recently, there has been considerable theoretical interest in the mechanism of radiationless transitions in aromatic molecules and, in particular, the effect of various substituent groups on the rate of these transitions (1). In this regard, it has been popular to determine experimentally the triplet lifetimes of specifically deuterated compounds and to correlate the results with theoretically calculated values. In particular, we wished to carry out such a study utilizing the deuterated derivatives of anthracene listed in Table 1.

Of the derivatives listed, only anthracene-9,10-d_2 (**1**) has been mentioned previously in the literature. It was first synthesized by treating anthracene with D_2SO_4. However, the procedure also gave mono and other polydeuterated products from which **1** was inseparable (2). **1** can be synthesized specifically by hydrolyzing the corresponding dimagnesium derivative with D_2O (99.8%) but preparation of the Grignard is difficult (3, 4). The most successful synthetic method involves preparation of the dilithio derivative followed by hydrolysis with D_2O. Using this method, Petukhov *et al.* originally reported synthesizing **1** in 72% isotopic purity (5). However, Pawliczek and Günther reported isotopic purities of greater than 97% using essentially the same method (6).

Two main synthetic routes are possible for the remaining derivatives in Table 1. Either the deuterium can be introduced after the carbon skeleton is constructed or the molecule can be prepared from suitably deuterated precursors. In the former method metalation and D_2O hydrolysis of the aromatic halides has been one of the more popular methods of approach. However, problems are often encountered in preparing the organometallic derivatives and the isotopic purity of the product is variable (3).

TABLE 1. Isotopic composition of deuterated anthracenes synthesized

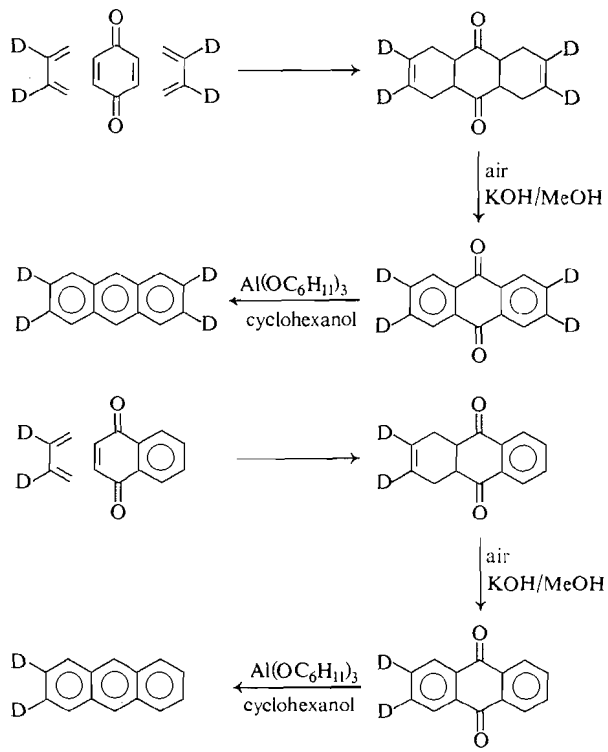
Anthracene	Purity (%)*		
9,10-d_2 (**1**)	7.0 d_1†	85.0 d_2	7.0 d_3
	11.6 d_1‡	88.0 d_2	
2,3-d_2 (**2**)	4.2 d_0	9.5 d_1	86.0 d_2
1,4-d_2 (**3**)	5.1 d_0	3.8 d_1	91.2 d_2
1,4,5,8-d_4 (**4**)	1.1 d_2	3.6 d_3	95.3 d_4
2,3,6,7-d_4 (**5**)	7.6 d_2	17.0 d_3	74.0 d_4
1,2,3,4-d_4 (**6**)	3.7 d_0	7.0 d_3	88.0 d_4

*Mol. % isotopic composition. Values are precise to only ±2%.
†Method *b*; see Experimental.
‡Method *a*; see Experimental.

The best published method for the preparation of perdeuterated anthracene is that of Dinh-Nguyên and Stenhagen (7) using D_2O_2 and a catalyst. The perdeutero compound can also be prepared by base or acid catalyzed deuterium exchange and the latter method is also suitable for specific deuteration if the rates of exchange are sufficiently position dependent. (8, 9, 2). Synthesis of the deuterated aromatics from deuterated precursors can be successful if a high yield procedure, which utilizes relatively simple starting materials, is available.

Results and Discussion

Anthracene-9,10-d_2 was synthesized both by the method of Petukhov *et al.* (5) and by acid-catalyzed deuterium–hydrogen exchange. The former method involved treating 9,10-dibromoanthracene with *n*-butyl lithium in benzene to prepare the 9,10-dilithioanthracene. This was subsequently hydrolyzed with D_2O yielding the dideutero derivative. This reaction was carried out several times and the isotopic purity (mol % dideutero) was never higher than 90% (the remaining 10% being monodeutero). As an alternative procedure we considered a mild



SCHEME 1

acid-catalyzed exchange reaction as the 9,10 positions in anthracene should exchange more rapidly. Since it had already been reported that D_2SO_4 gave a mixture of both mono and polydeuterated material a weaker acid was sought. *p*-Toluenesulfonic acid-*d* was chosen both because of its higher pK_a and its solubility in organic solvents. The acid was prepared *in situ* by adding D_2O to a mixture of anthracene and *p*-toluenesulfonyl chloride in benzene. The exchange occurred rapidly in refluxing benzene after an induction period of up to 48 h. This led us to believe that the hydrolysis of the acid chloride was rate limiting and probably autocatalytic. Although the method used was satisfactory it would probably be more expedient to hydrolyze the sulfonylchloride in a separate step. The product was isolated by stirring the mixture with saturated aqueous bicarbonate overnight and extracting with benzene. The isotopic composition was 85% d_2, 7% d_3, and 7% d_1 (mol %).

After considering the various possibilities for synthesis of the remaining anthracene derivatives we concluded that a scheme based on the Diels–Alder adducts of deuterated butadienes with *p*-benzoquinone or 1,4-naphthoquinone was best. Two representative examples are illustrated in Scheme 1. The basic procedure had been successfully carried out on the nondeuterated analogs by Alder and Stein (10) and by Diels and Alder (11).

In order to utilize the diene synthesis it was necessary to prepare specifically deuterated butadienes. These were prepared using known literature procedures or modifications of these procedures. Perdeutero-1,3-butadiene was synthesized from perchlorobutadiene using zinc and D_2O as described by Craig and Fowler (12). The yields varied from run to run but were generally around 50%. The syntheses of 1,3-butadiene-1,1,4,4-d_4 and -2,3-d_2 are outlined in Scheme 2.

The 3-sulfolenes were prepared from the corresponding butadienes and SO_2 by the method of Grummitt *et al.* (13) and the base-catalyzed exchange accomplished as described by Cope *et al.* (14). The deuterated butadienes were subsequently recovered by pyrolyzing the sulfolenes at 130–160 °C under a slow stream of nitrogen. The Diels–Alder adducts of the

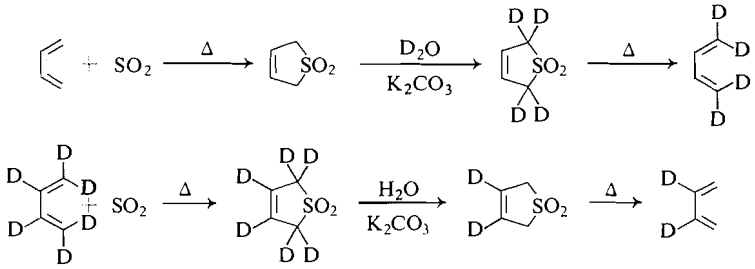

SCHEME 2

deuterated butadienes and *p*-benzoquinone (or 1,4-naphthoquinone) were formed by heating the quinone in an excess of the butadiene at 125 °C for 24 h in a sealed evacuated tube. The yields were quantitative in most cases.

The method of Alder and Stein was also used for the oxidation of the octahydroanthraquinones to the quinones (10). However, it was noted that this base-catalyzed oxidation (air and ethanolic KOH) led to some isotope exchange, especially in the 2,3,6,7-d_4 derivative. This was probably due to a base-catalyzed exchange in the partially oxidized material although it was surprising that it was more severe in the 2,3,6,7-d_4 derivative than in the 1,4,5,8-d_4 derivative. Presumably an alternate oxidation method would eliminate this problem but no other method was attempted in this study.

The reduction of the anthraquinone was achieved using aluminum tricyclohexyloxide in cyclohexanol (15). Although the yields of purified anthracene were very low, this generally reflects extensive purification by chromatography and recrystallization rather than inefficiency in the reduction step.

Table 1 lists the anthracenes synthesized and their isotopic purities as determined by low voltage mass spectrometry (8 eV).

Experimental

Mass spectra were recorded on a Finnigan 1015 mass spectrometer at an ionization energy of 8 eV. Mass ratios were calculated from peak heights and are precise only to ±2%. N.m.r. spectra were recorded on a Varian A56-60 spectrometer and chemical shifts are recorded in p.p.m. downfield from tetramethylsilane. $CDCl_3$ was the solvent used unless otherwise specified.

*Anthracene-9,10-d_2 (**1**)*

(*a*) Butyl lithium (0.01 mol in 3 ml benzene) was added to a solution of 9,10-dibromoanthracene (1.0 g, 0.003 mol) in benzene (35 ml) under nitrogen.

After refluxing 40 min and cooling, D_2O (2 ml) was added and the solution stirred 5 min. The benzene was then washed three times with water, dried ($MgSO_4$) and evaporated to leave a yellow crystalline residue. Ten recrystallizations from chloroform followed by treatment with Norit in chloroform gave 50 mg of blue fluorescent plates.

Mass spectrum: *m/e* (relative intensity) 178(4.9), 180(32), 181(5.0).

(*b*) Anthracene (0.78 g, Baker sensitizer grade) was refluxed in benzene (100 ml) containing *p*-toluene sulfonyl chloride (10 g) and D_2O (2 ml). Progress of the exchange reaction was followed by mass spectrometry. After 30 h the reaction mixture was diluted with benzene (100 ml) and extracted with aqueous sodium bicarbonate (5%). The benzene fraction was evaporated to dryness and the residue heated on a steam bath for 15 h with 100 ml of saturated aqueous sodium bicarbonate. Extraction with $CHCl_3$, drying ($MgSO_4$), and evaporation yielded the crude anthracene-9,10-d_2. This was recrystallized from $CHCl_3$, with treatment with charcoal, to yield blue fluorescent crystals.

Mass spectrum: *m/e* (relative intensity) 179(3.5), 180(42), 181(10.1). N.m.r.: δ 7.46 (m, 4H), 8.03 (m, 4H).

1,3-Butadiene-d_6

The method of Craig and Fowler (12) was used with slight modification. Zinc dust (98 g) and anhydrous dioxane (114 g) were placed in a 500 ml round-bottomed flask fitted with a nitrogen inlet, dropping funnel, condenser, and stirrer. The condenser was connected to a Dry Ice trap. After flushing with nitrogen, NaI (0.8 g), anhydrous CuCl (4.8 g) and D_2O (26.4 g) were added. The mixture was refluxed with stirring and hexachlorobutadiene (52 g) was added over 1 h. The yield of crude product was 7.25 ml (44%).

Mass spectrum: *m/e* (relative intensity) 59(8.7), 60(59.9), 61(3.1).

3-Sulfolene-d_6

The method of Grummitt *et al.* (13) was used with slight modification. 1,3-Butadiene-d_6 (12 ml), sulfur dioxide (13.5 ml), and hydroquinone (0.10 g) were sealed in a thick-walled glass tube after evacuation at −79 °C to 10^{-2} mm Hg. The mixture was heated at 100 °C for 12 h. The crude reaction mixture was dissolved in water and filtered. Evaporation of the water *in vacuo* and recrystallization from methanol gave 15.8 g of yellowish-white crystals (84%).

Mass spectrum: *m/e* (relative intensity) 59(11.0), 60(89.2), 61(4.2).

3-Sulfolene-2,2,5,5-d_4

The method of Cope *et al.* (14) was used with slight modification. 3-Sulfolene (10.0 g), potassium carbonate

For personal use only.

(0.11 g), D_2O (10 g), and anhydrous dioxane (10 ml) were stirred at room temperature for 48 h. The solvents were removed *in vacuo* at room temperature, fresh D_2O and dioxane added, and the solution again stirred 48 h. This procedure was repeated seven times and the residue was dried at room temperature under high vacuum. The product was used in the next step without purification.

Mass spectrum: *m/e* (relative intensity) 57(3.9), 58(31.9), 59(1.8).

1,3-Butadiene-1,1,4,4-d_4

The dried sulfolene-d_4 sample from above was placed in a round-bottomed flask fitted with a nitrogen inlet and connected in series through two gas absorption traps (each containing 25 ml of 20% aqueous NaOH) and a drying tube (Drierite) to a Dry Ice trap. Nitrogen gas was slowly passed through the system and the sample heated to 130–160 °C for 1.5 h. Five milliliters (79%) of butadiene was collected.

3-Sulfolene-3,4-d_2

The perdeutero-3-sulfolene (7.12 g) was treated with H_2O in a manner analogous to the treatment of perhydro-3-sulfolene with D_2O (described above) yielding 6.0 g of the 3-sulfolene-3,4-d_2 (87%) (some insoluble material formed during the exchange and was filtered off).

Mass spectrum: *m/e* (relative intensity) 55(2.8), 56(70.0), 57(3.9).

1,3-Butadiene-2,3-d_2

The 3-sulfolene-3,4-d_2 was pyrolyzed as described previously (for 3-sulfolene-2,2,5,5-d_4) to yield 2.2 ml of 1,3-butadiene-2,3-d_2 (59%).

1,3-Butadiene-1,1,4,4-d_4-p-benzoquinone Adduct

The procedure was generally similar to that of Alder and Stein (10). 1,3-Butadiene-1,1,4,4-d_4 (2.0 g) was distilled into a thick-walled glass tube containing *p*-benzoquinone (1.0 g) and benzene (2 ml). The tube was degassed by three freeze–thaw cycles with evacuation to 10^{-2} mm Hg, then sealed and heated at 120 °C for 24 h. After cooling the product separated as white crystals and, after evaporation of the benzene, was used without further purification. Yield was 2.0 g (100%).

Anthraquinone-1,4,5,8-d_4

The anthraquinone was prepared from the octahydroanthraquinone using the method of Alder and Stein (10). The adduct from above (2.0 g) was refluxed in 5% ethanolic KOH (50 ml) with a stream of air passing through the mixture for 1 h. The mixture was diluted with water, neutralized with 1 *N* HCl, and the quinone extracted with $CHCl_3$. The combined extracts were dried ($MgSO_4$) and evaporated to dryness to yield 1.89 g (98%) which was used without further purification.

Anthracene-1,4,5,8-d_4 (4)

Anthraquinone-1,4,5,8-d_4 from above (1.0 g), aluminum tricyclohexyloxide solution (10 ml, see preparation below), and cyclohexanol (5 ml) were refluxed 48 h. The solution was poured into water (50 ml), benzene added (50 ml), and the mixture filtered, washing the residue well with hot benzene. The benzene and water were separated and the water extracted with benzene. The benzene solutions and extracts were combined and evaporated *in vacuo*. The residual cyclohexanol was removed as an azeotrope with water and benzene. The anthracene was chromatographed on alumina (Woelm, GrI; eluant benzene) and recrystallized five times from chloroform. Yield of blue fluorescent crystals, 0.173 g (21%).

Mass spectrum: *m/e* (relative intensity) 181(2.9), 182(91.8), 183(15.3).

N.m.r.: δ 7.46 (s, 2H), 8.42 (s, 4H).

Aluminum Tricyclohexyloxide Solution

Aluminum wire (5 g), cyclohexanol (100 ml, distilled from CaO), mercuric chloride (25 mg), and CCl_4 (1 ml) were refluxed overnight. The solution was used without further treatment.

1,3-Butadiene-1,1,4,4-d_4-1,4-naphthoquinone Adduct

1,3-Butadiene-1,1,4,4-d_4 (5 ml), 1,4-naphthoquinone (11.0 g), and ethanol (5 ml) were heated in an evacuated, sealed heavy-walled glass tube at 100 °C for 3 h. The solvent was removed *in vacuo* and the product used without further purification.

Anthraquinone-1,4-d_2

The crude adduct from above (6.2 g) was oxidized in 5% ethanolic KOH (*ca.* 50 ml) with air as previously described to yield 2.55 g of crude anthraquinone-1,4-d_2.

Anthracene-1,4-d_2 (3)

The crude anthraquinone-1,4-d_2 (2.0 g) was reduced as previously described with aluminum tricyclohexyl oxide (20 ml of prepared solution) to give, after purification, 84.5 mg of anthracene-1,4-d_2 (5%).

Mass spectrum: *m/e* (relative intensity) 178(4.5), 179(3.8), 180(80.0), 181(13.0).

N.m.r.: δ 7.45 (m, 4H), 8.00 (m, 2H), 8.40 (m, 4H).

1,3-Butadiene-2,3-d_2-p-benzoquinone Adduct

1,3-Butadiene-2,3-d_2 (2.2 ml), *p*-benzoquinone (0.65 g), and benzene (2.5 ml) were sealed in an evacuated thick-walled tube and heated to 120 °C for 24 h. The slightly yellow crystalline product (1.17 g) was used without further purification.

Anthraquinone-2,3,6,7-d_4

The adduct from above (1.17 g) was air-oxidized in 5% methanolic KOH (*ca.* 50 ml) as previously described to yield 0.67 (71%) of crude anthraquinone which was not further purified.

Anthracene-2,3,6,7-d_4 (5)

Anthraquinone-2,3,6,7-d_4 (0.64 g) was reduced with aluminum tricyclohexyloxide (12 ml of prepared solution) as previously described to yield 81 mg of purified anthracene-2,3,6,7-d_4 (14.5%).

Mass spectrum: *m/e* (relative intensity) 180(7.4), 181(17.0), 182(72.2), 183(13.8).

N.m.r.: δ 8.01 (s, 2H), 8.44 (s, 2H).

1,3-Butadiene-2,3-d_2-1,4-naphthoquinone Adduct

The adduct was prepared as described above from 1,3-butadiene-2,3-d_2 (0.42 ml) and 1,4-naphthoquinone (1.2 g) in 2 ml ethanol. The crude product (1.56 g, 97%) was used without further purification.

Anthraquinone-2,3-d_2

The adduct from above (1.56 g) was air-oxidized in 5% ethanolic KOH (*ca.* 30 ml) yielding 1.13 g (72%) of the anthraquinone after work-up (see above).

Anthracene-2,3-d_2 (2)

The crude anthraquinone-2,3-d_2 (1.13 g) was reduced with aluminum tricyclohexyloxide (6 ml of prepared solution) in the previously described manner to yield 0.167 g of anthracene-2,3-d_2 (17.2%) after purification.

Mass spectrum: *m/e* (relative intensity) 178(4.0), 179(9.3), 180(8.3), 181(14.1).

N.m.r.: δ 7.46 (m, 2H), 7.98 (m, 4H), 8.43 (s, 2H).

1,3-Butadiene-d_6-1,4-naphthoquinone Adduct

The adduct was prepared, as previously described, from butadiene-d_6 (8 ml) and 1,4-naphthoquinone in 15 ml of ethanol. Work-up yielded 14.2 g (89%) of the crude adduct used without purification.

Anthraquinone-1,2,3,4-d_4

The adduct above (14.2 g) was air-oxidized in 5% ethanolic KOH (*ca.* 100 ml) to yield 13.8 g (100%) of crude anthraquinone-1,2,3,4-d_4.

Anthracene-1,2,3,4-d_4 (6)

The anthraquinone-1,2,3,4-d_4 (5.0 g) was reduced with tricyclohexyloxide (25 ml of the prepared solution) to yield 0.11 g of purified anthracene-1,2,3,4-d_4 (3%)

Mass spectrum: *m/e* (relative intensity) 181(8.3), 182(111.5), 183(17.6).

N.m.r.: δ 7.46 (s, 2H), 8.02 (m, 2H), 8.42 (s, 2H).

An Investigation into the Nature of π-Inductive Effects: π Polarization Effects in Phenylalkanes with Polar or Charged Substituents[1]

W. F. REYNOLDS[2] AND I. R. PEAT[3]

Department of Chemistry, University of Toronto, Toronto 181, Ontario

M. H. FREEDMAN AND J. R. LYERLA, JR.

Faculty of Pharmacy, University of Toronto, Toronto 181, Ontario

Received August 23, 1972

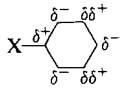
p*H* dependent ^{13}C chemical shifts for phenylglycine, phenylalanine, and phenylalanyl derivatives demonstrate that the electronic distribution of the phenyl group depends upon the distance of charged groups from the phenyl ring. The pattern of chemical shifts and the results of CNDO/2 MO calculations indicate that this is due to polarization of the phenyl π electron system. ^{13}C chemical shifts and CNDO/2 calculations for α- and β-substituted phenylalkanes (substituent = NH_3^+, Cl or Br) provide further evidence for a π polarization effect.

Les déplacements chimiques en ^{13}C reliés au p*H* de la phénylglycine, de la phénylalanine, et des dérivés de la phénylalanine, ont démontré que la distribution électronique du groupe phényle est fonction de la distance entre les groupes chargés et l'anneau phényle. L'arrangement des déplacements chimiques ainsi que les résultats obtenus par des calculs CNDO/2 MO montrent que cette relation est causée par la polarisation du système d'électrons π du phényle. Les déplacements chimiques en ^{13}C et les calculs CNDO/2 pour des phénylalcanes α et β substitués (substituant = NH_3^+, Cl, ou Br) montrent des caractéristiques jouant en faveur de cet effet de polarisation π. [Traduit par le journal]

Can. J. Chem., **51**, 1857 (1973)

Introduction

The nature of π inductive effects is controversial (1). The root of the controversy is largely a question of semantics as the term "π inductive effect" carries different connotations for different groups of investigators. In a recent survey of substituent effects in phenyl derivatives (1), Katritzky and Topsom point out three substituent effects (their effects labeled 4, 5, 6) to which the name π inductive effect has been applied. Effect 4 refers to the redistribution of π electron density as a result of repulsive interactions between a filled orbital on a substituent and the phenyl π electron system (2) (orbital repulsion effect). This effect is illustrated schematically in **1**.



1

Effect 5 is polarization of the π electron system by a polar or charged substituent (3) (π polarization effect) while effect 6 represents changes in the π electron density induced by polarization of the σ electron system (inducto-electromeric effect (4)). These authors point out that theoretical chemists generally consider effects 4 and 5 to be π inductive effects while organic chemists consider effects 5 and 6 to be π inductive effects. Effect 5 is generally considered to be unimportant by both groups of investigators.

We became interested in π inductive effects during an investigation of ^1H and ^{13}C chemical shifts of 4-substituted styrenes (5). Comparison of chemical shifts and valence electron densities estimated by CNDO/2 MO calculations suggested that the phenyl and vinyl π electron systems were polarized by the polar C—X bond. However, a directly bonded substituent can interact with a phenyl group by a variety of mechanisms, making it difficult to separate π polarization effects from other electronic effects. Consequently, since our conclusions were contrary to previous conclusions concerning the importance of π polarization effects (1), it was decided to carry out further investigations of phenyl derivatives. Phenylalkanes with polar or charged substituents in α or β positions were chosen for these investigations. Insulation of the substituent

from the phenyl group by an aliphatic linkage should facilitate the isolation of π polarization effects by minimizing effects which depend upon direct interaction of the substituent with the phenyl ring.

^{13}C chemical shifts were used to monitor changes in the electronic distributions of the phenyl groups. In addition, these electronic distributions were also estimated using all-valence electron (CNDO/2) molecular orbital calculations.

Experimental

^{13}C n.m.r. spectra were determined using a Varian XL-100-15 n.m.r. spectrometer operating in pulsed Fourier transform mode with proton noise-decoupling at 25.16 MHz. Fourier transformations were carried out using a 620 i computer (16 K memory) with standard Varian software. Dioxane was used as an internal ^{13}C reference for aqueous and CF_3COOH solutions while tetramethylsilane was used as a reference for CCl_4 and CD_3OD solutions. Chemical shifts were then expressed relative to $^{13}C_6H_6$ by determining the ^{13}C chemical shift of benzene in the same solvent under the same conditions. D_2O in a concentric tube was used as a lock signal in each case. Repeated measurements under different conditions suggested that chemical shifts were reproducible to 0.04 p.p.m. However, because of low solubility, the chemical shifts of the zwitterionic forms of amino acids and dipeptides as well as the phenylalanyl chemical shifts in polypeptides are probably less accurate (*ca.* 0.10 p.p.m.). Similarly, in some of the phenylalkane derivatives, C-2,6 and -3,5 peaks overlapped, introducing an uncertainty of similar magnitude.

Amino acids, dipeptides and phenylalkane derivatives were obtained commercially and were used without further purification. Commercial bacitracin (Sigma Chemical Co.) was purified by preparative liquid isoelectric focusing (6), using carrier ampholytes covering the range p*H* 5–8. The *15%* uniformly ^{13}C enriched L-phenylalanine was a gift from Dr. J. S. Cohen, the synthetic amino-terminal linear 1–15 peptide of ribonuclease was provided by Dr. I. M. Chaiken, synthetic lysine-vasopressin in the acetate form was obtained from Dr. D. A. J. Ives, while crystalline glucagon was provided by Dr. R. M. Epand. Spectra of these polypeptides were measured in aqueous solution in the p*H* range 5–6 (phenylalanyl chemical shifts were independent of p*H*).

CNDO/2 calculations were carried out on an IBM 370 computer using a standard program (program 141 from the Quantum Chemistry Program Exchange). Bond lengths and angles for CO_2H and CO_2^- groups were identical to those used by Csizmadia and co-workers (7) while standard bond lengths and angles (8) were used for other groups. Conformations used in the calculations are outlined in the Discussion.

Results

^{13}C chemical shifts for L-phenylalanine, DL-phenylglycine, and two dipeptides of phenylalanine are given in Table 1. C-1 and -4 were assigned by intensity measurements and proton-coupled spectra. C-2,6 and -3,5 for phenylalanine were assigned by an observed AB pattern due to direct ^{13}C–^{13}C coupling (*ca.* 56 Hz) between C-4 and -3,5 in a sample of phenylalanine uniformly ^{13}C enriched to 15%. C-2,6 and -3,5 in phenylalanyl derivatives were assigned by analogy to phenylalanine. For phenylglycine, these carbons were assigned by assuming that the titration shifts would be similar in pattern to those for the benzylammonium ion.

^{13}C chemical shifts for phenylalkanes and α and β derivatives of phenylalkanes are given in Table 2. Wherever possible, C-2,6 and -3,5 were assigned by comparing chemical shifts for the compound in question with those for its 4-bromo or chloro derivative. Assuming chemical shift additivity, C-2,6 and -3,5 could then be assigned by comparing the observed shifts with those for 4-halobenzenes relative to benzene (9).

Results of CNDO/2 MO calculations are summarized in Tables 3–7. Only phenyl carbon charge densities are given.

Discussion

(a) Consideration of the Validity of Using ^{13}C Chemical Shifts as a Monitor of Ground State Electronic Distributions in Phenyl groups

The shielding constant for a nucleus can be divided into two terms (10)

$$\sigma = \sigma_d + \sigma_p$$

where σ_d and σ_p respectively represent diamagnetic and paramagnetic contributions to the screening constant. These terms are sometimes further divided into local diamagnetic and paramagnetic contributions and contributions from other atoms (11). It is generally assumed that ^{13}C chemical shift differences are primarily due to changes in σ_p (12) (although it has recently been suggested that variations in σ_d may be larger than previously realized (13)). The magnitude of σ_p depends upon the extent of mixing between ground and excited states and consequently upon the electronic distributions and symmetries of these states as well as the energy separations between the ground state and the various excited states (10). Therefore, it is at first glance surprising that there should be a linear relationship between ^{13}C chemical shifts induced by remote substituents and the ground state charge density of the carbon in question. However, there is

ample experimental evidence for an empirical relationship of this type for aromatic derivatives (5, 9, 14).

Pugmire and Grant have provided a reasonable explanation for this apparent anomaly (15). They showed that the local paramagnetic term, $\sigma_p^{(1)}$, should vary linearly with charge density over a considerable range of charge densities. This relationship arises from changes in the effective nuclear charge parameter and consequent changes in $\langle r^{-3} \rangle$ (where r is the electron-nucleus separation) with charge density. Karplus and Pople also concluded, on the basis of a simpler theoretical treatment, that $\sigma_p^{(1)}$ should vary linearly with charge density (12). Changes in excitation energy and bond orders to adjacent atoms also contribute to σ_p (15). However, these changes should be small for remote substituents, particularly when the substituent is insulated from conjugation with the ring by an aliphatic linkage.

We had originally hoped to compare experimental and calculated substituent-induced ^{13}C chemical shifts in order to determine the factors contributing to these shifts. Consequently the CNDO/2 program was modified to calculate ^{13}C chemical shifts by two previously described methods; σ_p was calculated by both the average energy approximation as formulated by Pugmire and Grant (15) and by the sum-over-states method (16) in which σ_p is summed over all filled and unfilled (corresponding to excited states) molecular orbitals. σ_p was summed over all atoms other than hydrogen. σ_d was evaluated from local charge densities (17).

^{13}C chemical shifts were calculated for several amino acid, phenylalkane, and styrene derivatives using both approaches. Initial results were

*Chemical shift difference between NH_3^+, or Cl, or Br derivative and CH_3 derivative.
†Assignment of C-2,6 and -3,5 not confirmed.
‡Comparison made with phenylpropane rather than phenylbutane. This should introduce negligible error since it involves the δ effect due to a methyl group.

promising since the calculations closely reproduced the p*H*-dependent chemical shifts of the imidazole ring of histidine (*18*) and of the phenyl group in phenylalanine (with an r.m.s. difference of 0.4 p.p.m. between calculated and experimental titration shifts for phenyl carbons). However, while the calculated chemical shifts for phenylalkanes and styrenes were very similar in pattern to the experimental chemical shifts, the former were underestimated by a factor of three to four. Similar discrepancies were noted for the series $C_5H_5^-$, C_6H_6, and $C_7H_7^+$. We suspect that the calculations underestimate the sensitivity of $\sigma_p^{(1)}$ to charge density changes and that the agreement for phenylalanine is fortuitous, *i.e.*, that in this case the above-mentioned error is compensated by an overestimation of the calculated charge densities (see below, part (*c*)).

Recently Ellis *et al.* have formulated an approach to ^{13}C chemical shift calculations based on finite perturbation theory applied to INDO MO wave functions (*19*). These calculations closely reproduce gross chemical shift differences (*e.g.*, CH_4 *vs.* C_2H_4). However, they may also underestimate remote substituent effects since the calculated C-4 chemical shift for toluene (−0.3 p.p.m. relative to benzene) is significantly smaller than the experimental value (−2.9 p.p.m. in CCl_4 (*9*)).

The observations outlined above lead us to conclude that existing models for ^{13}C chemical shift calculations are too imprecise to justify any attempt to give a quantitative account of substituent-induced ^{13}C chemical shifts in terms of variations in σ_d, σ_p, excitation energies, etc. Consequently we prefer at present to discuss ^{13}C

chemical shifts induced by remote substituents in terms of changes in ground state charge densities. There appears to be ample experimental justification as well as some theoretical justification for this approach. It also facilitates a discussion of electronic substituent effects.

The relationship between ^{13}C chemical shifts and electronic substituent effects is more complex when the substituent is three or fewer bonds removed from the carbon of interest. Grant and Paul noted respective chemical shift contributions of +9.1, +9.4, and −2.5 p.p.m. due to α, β, and γ methyl groups in linear alkanes (δ and ε effects were negligible) (20). Similar parameters have been derived for other substituents (21). While the exact origins of these contributions are

still unclear (22), it appears improbable that they will be more than partially reflected by changes in ground state charge density for the carbon of interest. For example, there can be contributions to the two-center paramagnetic term $\sigma_p^{(2)}$ (see eq. 7 of ref. 15), due to replacement of hydrogen by an α substituent. There may also be a contribution to σ_d arising from the electron distribution on the α substituent (13). While the origins of the β effect are uncertain (22), there is good experimental evidence, at least for the methyl group, that the γ effect arises from *gauche* steric

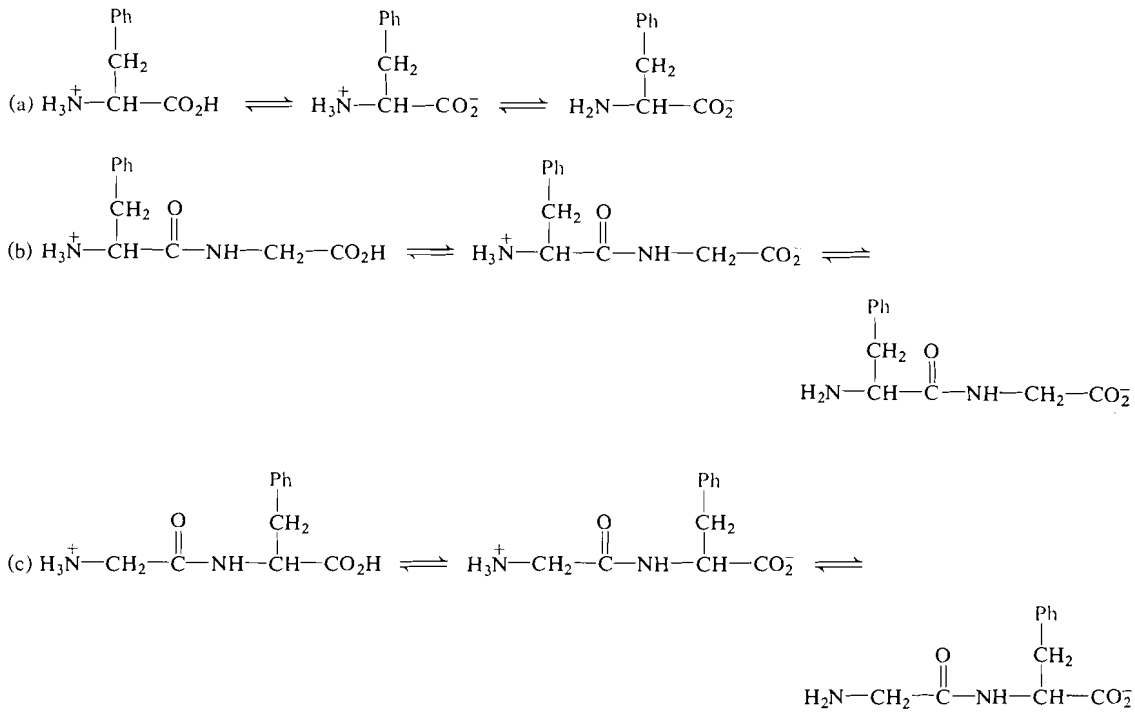

FIG. 1. Structures of ionic forms of (*a*) phenylalanine, (*b*) phenylalanylglycine, and (*c*) glycylphenylalanine.

interactions (17, 22, 23). Substituent-induced changes in excitation energies could also be important, particularly for α or β substituents. Because of α, β, and γ effects, it is essential to choose an appropriate reference compound if one wishes to use ^{13}C chemical shifts to monitor charge density changes due to proximate substituents. This point is further discussed in the following section.

(b) ^{13}C Chemical Shifts of α- and β-Substituted Phenylalkane Derivatives

The first compounds chosen for investigation were the amino acid L-phenylalanine, $C_6H_5CH_2CH(NH_2)CO_2H$, the dipeptides L-glycylphenylalanine (Gly-Phe), and L-phenylalanylglycine (Phe-Gly) (see Fig. 1 for structures), and DL-phenylglycine. These compounds were chosen because it was anticipated that the p*H*-dependent ^{13}C chemical shifts of the phenyl carbons would provide information about changes in the electronic distribution of the phenyl group as the charge on the amino acid function was altered and as the distance of charged functions from the ring was altered.

Two clear trends are apparent from the data presented in Table 1. Firstly, there is a consistent pattern of phenyl carbon chemical shifts on going from the zwitterionic form to either the cationic form (carboxyl titration) or the anionic form (amino titration). In the former case, C-1 shifts to high field with a smaller low field shift for C-4 and very small low field shifts for C-2,6 and -3,5. The ^{13}C chemical shifts associated with the amino titration are similar in pattern but opposite in sign.

Secondly, the magnitudes of the p*H* dependent chemical shifts appear to be closely related to the distance of the charged functions from the ring. For example, if one compares the results for phenylglycine and phenylalanine, the largest shifts are noted for the amino titration of phenylglycine, the shifts for the carboxyl titration of phenylglycine and the amino titration of phenylalanine are almost identical in magnitude while the smallest shift is noted for the carboxyl titration of phenylalanine. These results are exactly what one would expect if the magnitudes of the shifts depend upon the distance of charged functions from the ring since the four titrations

involve gain or loss of protons which are respectively two, three, three, and four bonds removed from the phenyl ring (see Fig. 1).[4]

The distance dependence is even more pronounced in the case of the dipeptides. In Phe-Gly the amino titration shifts (zwitterion to anion) are nearly identical to those for phenylalanine while the carboxyl titration shifts are negligibly small. This pattern is reversed in the case of Gly-Phe. In each case, the group which causes a negligible titration shift is three bonds further removed from the phenyl ring than in phenylalanine, (see Fig. 1) apparently far enough away to have a negligible effect. Similar patterns of p*H*-dependent ^{13}C chemical shifts of phenyl carbons of dipeptides and tripeptides incorporating phenylalanine can be observed in the results of Christl and Roberts (24).

Further information is provided by the chemical shifts of the individual ionic species. In terms of distances of charged groups from the phenyl ring, both cationic and zwitterionic forms of Phe-Gly should resemble the cation of phenylalanine, both the anion of Phe-Gly and the cation of Gly-Phe should resemble neutral phenylalanine while the zwitterion and anion of Gly-Phe should resemble anionic phenylalanine. Neutral phenylalanine does not exist to any extent in aqueous solution. However, incorporation of phenylalanine in the middle of a long chain polypeptide should provide a reasonable electronic facsimile of the neutral species, assuming that the peptide linkages resemble neutral amino and carboxyl functions. Using phenylalanyl residues in polypeptides as models for neutral phenylalanine, the chemical shift data in Table 1 are in good agreement with the predictions outlined above. The chemical shift data in Table 1 also indicate that the C-1 and -4 chemical shifts for the zwitterionic form are intermediate between those for the cationic form and the neutral form (as approximated by phenylalanyl residues).

In view of the consistent pattern of results obtained from the p*H*-dependent ^{13}C chemical shifts of amino acids and dipeptides, it was decided to expand the investigation to include other α- and β-substituted phenylalkanes in non-aqueous solvents to see if the same pattern of results was observed. Derivatives chosen contained either charged, *e.g.* ammonio group or polar, *e.g.* chlorine and bromine, substituents. As mentioned in section (*a*), the choice of proper reference compounds is critical. This can be clearly seen from a consideration of the ^{13}C chemical shift data for phenylalkanes given in Table 2 (similar data have recently been reported by Maciel and co-workers (25)). Both C-4 and -3,5 show similar shifts for all of the phenylalkanes. This is not surprising since the different alkyl groups should have similar electronic effects. However, there are large differences for C-1 and, to a lesser extent, for C-2,6. These chemical shift differences appear to reflect effects similar to the α and β effects for aliphatic derivatives (20) (the γ effect upon C-3,5 should be small since the alkyl group and C-3,5 are *trans* to one another and the γ effect reflects *gauche* interactions (17, 22, 23)). For example, on going from benzene to *n*-propylbenzene, C-1 chemical shifts are +9.0, +6.4, and −1.6 p.p.m. for addition of each succeeding methyl group. These are similar to the α, β, and γ effects for methyl groups in aliphatic derivatives (see section (*a*)).[5]

To the extent that α, β, and γ effects reflect either steric interactions or diamagnetic and paramagnetic contributions associated with the electron distribution on the substituent (see section (*a*)), the best reference substituent for comparison with a polar or charged substituent should be similar in size and isoelectronic with the latter substituent. On this basis, the best reference compound for an ammonio derivative is the corresponding methyl derivative, since the latter is isoelectronic to the ammonio group and similar in size. Since a remote methyl group will have little electronic effect, the chemical shift differences should reflect the effect of the positive charge on the NH_3^+ group. There are no ideal non-polar reference compounds for the halo

[4]The proximity of charged or polar groups to the phenyl ring is discussed in terms of the number of intervening bonds rather than the actual distance, since the latter parameter is difficult to define in a conformationally mobile system. We concede that there are possible conformations where, for example, a β substituent can be as close to the ring as an α substituent. However, inspection of molecular models indicates that these are usually sterically hindered conformations and are unlikely to be significantly populated. Consequently, the weight average distance of a β substituent from the ring should be greater than that for an α substituent, etc.

[5]The phenyl carbons of phenylalanine and related compounds also reflect these effects (particularly C-1). However, gain or loss of a proton during titration should at most cause a small change in the γ effect at C-1. Consequently, comparison of chemical shift differences between different ionic species is justified in these systems.

derivatives. However, the methyl derivatives are probably also the best available references for these compounds. The methyl group is similar in size (van der Waals' radius ≈ 2.0 Å) to chlorine (1.80 Å) and bromine (1.95 Å) and should therefore have similar steric effects. There is unlikely to be a complete cancellation of contributions due to the electronic distribution on the substituent since the methyl group is only crudely similar in electronic structure to the halogens (three σ bonds in lieu of three lone pairs of electrons). This is reflected by gross differences in α effects (respectively +31.2 (21), +20.0 (21), and +9.1 p.p.m. (20) for Cl, Br, and CH_3 groups). However, the β effects (respectively +10.3, +10.6, and +9.4 p.p.m.) and γ effects (−4.6, −3.1, and −2.5 p.p.m.) are similar for the three substituents (the larger γ effect for halogens may reflect the tendency of halopropanes to favor *gauche* conformations (26) while *n*-butane favors the *anti* conformation (27)). Since in the derivatives we have investigated, halogens are either β or γ to the phenyl group, the above discussion suggests that the methyl group is an adequate reference compound for the halo derivatives in these cases.

When ^{13}C chemical shifts of NH_3^+, Cl, or Br derivatives are compared to the chemical shifts for the corresponding methyl derivatives in the same solvent (Table 2), it is seen that there is a consistent pattern of chemical shift changes which is identical to the pattern observed on going from the zwitterionic to the cationic forms of phenylalanine and phenylglycine, *i.e.*, a large negative (high field) chemical shift for C-1, a smaller positive shift for C-4 and very small positive shifts for C-2,6 and -3,5. Furthermore, a similar distance dependence is again noticed since the C-4 chemical shifts decrease regularly (by approximately a factor of two) on going from β to γ to δ substituents. Finally, the magnitudes of the induced chemical shifts by an NH_3^+ group are approximately twice those due to either a Cl or Br substituent for the same phenylalkane. In general, the consistency of the chemical shift patterns in both Table 1 and Table 2 provides further justification for the use of CH_3 derivatives as reference compounds for NH_3^+, Cl, and Br derivatives since it is difficult to believe that such close agreement could be fortuitous.

As can be seen from the above discussion, all of the compounds investigated show very similar patterns of phenyl carbon chemical shifts with the magnitudes of the induced shifts apparently determined by the distance of the substituents from the phenyl groups. Therefore, we felt that it should be possible to account for this consistent pattern of results by a single explanation. It appears highly improbable that it could be accounted for by solvent effects since there is no apparent reason why an effect of this type should depend strongly upon the distance of a substituent from the phenyl group nor why the pattern should be similar for D_2O, CCl_4, and CF_3COOH. The pattern of phenyl carbon chemical shifts is completely inconsistent with a σ inductive effect. Similarly it is inconsistent with a dominant orbital repulsion effect (effect 4, see **1** in Introduction) because in that case C-2,6 should have similar shifts to C-4, with C-3,5 of opposite sign. However, assuming that the ^{13}C chemical shifts are reflecting changes in carbon electron density, the pattern of results is entirely consistent with a π polarization effect in which the phenyl π electrons are polarized towards a positive charge, **2**, and away from a negative charge, **3**. The size of this effect should depend on the distance of the charged function from the ring. A polar $\overset{\delta+}{C}—\overset{\delta-}{X}$ bond should have a similar, but smaller effect, **4**, to a positively charged group.

2 **3** **4**

The field substituent parameter, *F*, of Swain and Lupton (28) should provide a reasonable measure of the polarizing ability of a substituent since it measures the through space field effect of the substituent. In fact the ratio of *F* for $N(CH_3)_3^+$ (which should be similar to NH_3^+) to *F* for the halogens (1.46 to *ca.* 0.70) is almost identical to the ratio of shifts induced by NH_3^+ and the halogens. This explanation can even account for more subtle differences. For example, the zwitterionic form of phenylalanine should show a small π polarization effect similar to **2** since the positive charge is one bond closer to the ring than the negative charge. As pointed out above, the chemical shifts of zwitterionic phenylalanine are intermediate between cationic and neutral phenylalanine. Thus all of the results outlined above can be accounted for in terms of π polarization effects. The only result which is not wholly consistent with this explanation is the observation that there tends to be a larger positive shift for C-2,6 than C-3,5 in the α-halo-

For personal use only.

toluenes. This may indicate the presence of a direct (hyperconjugative) interaction. However, even in these cases, C-4 chemical shifts are substantially larger than C-2,6 chemical shifts, indicating that the π polarization effect is dominant.

(c) CNDO/2 MO Calculations and Phenyl Carbon Charge Densities

While the pattern of substituent-induced ^{13}C chemical shifts can be explained in terms of π polarization effects, this assumes that changes in ^{13}C chemical shifts are paralleled by changes in carbon charge density. Consequently, we carried out all-valence electron (CNDO/2) molecular orbital calculations for many of the phenylalkane derivatives in an attempt to determine whether the pattern of charge density changes was similar to the pattern of chemical shift changes.

All of the compounds included in this investigation can exist in more than one conformational isomer. Conformations of phenylalanine for which calculations were performed are illustrated in Fig. 2. Calculated phenyl carbon charge densities are given in Table 3. There are differences between charge densities for the same ionic species in different conformations, particularly for C-1. However, the pattern of charge densities is consistent from conformation to conformation. Furthermore, there is a consistent pattern of changes in charge densities between different ionic species. Although the calculations suggest that conformation B is least stable, all conformations were equally weighted to arrive at average charge densities (Table 4) since the experimental evidence concerning the conformational preference of phenylalanine in solution is ambiguous (29).

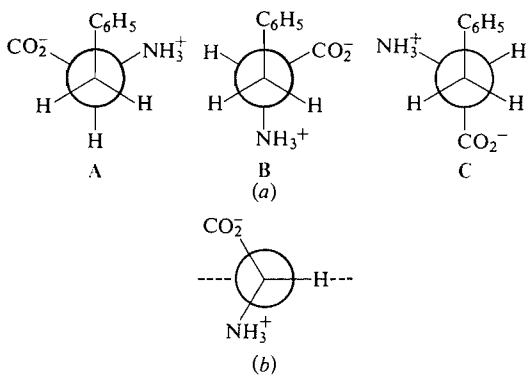

FIG. 2. (*a*) Conformations of phenylalanine used in CNDO/2 calculations (plane of phenyl ring at right angles to C_α—C_β bond). (*b*) Conformation of phenylglycine used in CNDO/2 calculations (dotted line shows the plane of the phenyl ring).

Charge densities for phenylalanine and phenylglycine are summarized in Table 4. The patterns of charge densities for the individual ionic species are not identical to the chemical shift patterns, although the agreement is better for total charge density than for π charge density. The discrepancies may, at least in part, be due to the α, β, and γ effects of the side chain atoms. However, there is much better agreement when chemical shift changes with p*H* are compared with charge density changes. This is not surprising since protonation or deprotonation should at most cause small changes in the γ effect (see footnote 5). In this case, chemical shift trends are almost equally well predicted by total charge density and π charge density,[6] since there are parallel changes in the two parameters, with the π charge densities consistently larger. This apparently arises because changes in π charge density induce smaller changes of opposite sign in σ charge density (a similar phenomenon has been noted in the case of styrene (5) and fluorobenzene (30) derivatives). Consequently, we conclude that changes in total charge density are dominated by changes in π charge density and that the substituent effect primarily involves the π electron system.

These observations are completely inconsistent with an inducto-electromeric effect in which changes in π electron density are induced by changes in σ electron density. However, they are completely consistent with π polarization effects similar to those in **2** and **3**. Furthermore, all of the experimental trends for the two compounds (the signs and relative magnitudes of the chemical shift changes for the different carbons, the relative magnitudes of amino (ΔA) and carboxyl (ΔC) titration shifts, and the relative magnitudes of phenylalanine and phenylglycine shifts) are reflected by corresponding trends in π charge density. The calculations even predict that the chemical shifts for neutral phenylalanine should be intermediate between those for the

[6]Correlation of cation to anion shifts for phenylalanine and phenylglycine with corresponding charge density changes gave a correlation coefficient 0.936 for total charge density and 0.959 for π charge density.

zwitterionic and anionic forms, as observed for C-1 and -4 (Table 1).

CNDO/2 calculations were also carried out for all compounds from Table 2 except the bromo derivatives (the program does not handle third row elements) with results given in Table 5. Calculations for the benzyl derivatives were carried out for a conformation in which the CH_2—CH_3, CH_2—Cl, or CH_2—NH_3^+ bond was at right angles to the plane of the phenyl group. In the case of phenethyl derivatives, calculations were performed for *gauche* and *anti* conformations. The charge densities in Table 4 are averaged (allowing for the two equivalent *gauche* conformations). If charge densities for NH_3^+ or Cl derivatives are compared with those for CH_3 derivatives, the pattern of chemical shift differences is reasonably well reproduced (particularly for phenethyl derivatives) and the distance dependence of the substituent effect is also predicted.

Calculations were also performed for benzene–ammonium ion pairs with the NH_4^+ group in identical positions to the NH_3^+ group in the benzylammonium and phenethylammonium ions. Results are given in Table 6. These calculations were performed in an attempt to determine the mode of transmission of the π polarization effect from the substituent to the phenyl ring. The calculated π electron densities are very similar in pattern to the experimental chemical shift values. However, the electron density changes (relative to benzene) are approximately 40% less than the corresponding electron density changes for the ammonio derivatives of phenylalkanes. This may either reflect enhanced transmission of field effects through the molecular framework of the phenylalkane[7] or partial transmission through the σ electron system. In either case, the calculations suggest that the π polarization effect is predominantly transmitted through space.

While the ^{13}C chemical shift trends are generally well reproduced by the charge density calculations, there are discrepancies in some cases. For example, the calculations for the benzyl derivatives (particularly the chloro derivative) apparently overestimate hyperconjugative effects since C-2,6 and -4 show similar changes in charge density. This discrepancy may be due to the choice of geometry for the calculations. The chosen geometry (with CH_2—X bonds at right angles to the plane of the phenyl group) should maximize direct (hyperconjugative) interactions with the phenyl π system. In actual fact, it is likely that a significant range of conformations is populated. Agreement is much better for the phenethyl derivatives where direct interactions should be much less important.

A more serious discrepancy is revealed by a comparison of the ratio of chemical shifts and charge densities for the different series of compounds. For example, for the C-4 carbon, this ratio is *ca.* 25 p.p.m./π electron for phenylalanine and phenylglycine, *ca.* 60 p.p.m./π electron for the ammonio derivatives of phenylalkanes, and *ca.* 180 p.p.m./π electron for the α- and β-chloro derivatives. Only the latter values are in good agreement with previously accepted values of 160–200 p.p.m./π electron (14*a*, *b*). The discrepancies may partly arise because the calculations correspond to the molecule in the gas phase while chemical shifts are measured in solution. Amino acids were measured in aqueous solutions where the charged groups should be strongly solvated. This should substantially neutralize these charges and consequently reduce π polarization. Ammonio derivatives were measured in CF_3COOH. While the extent of solvation on an NH_3^+ group by CF_3COOH should be small, some ion pairing may occur between the trifluoroacetate counter ion and the NH_3^+ group, causing a decrease in π polarization. There should be much smaller solvation effects for the halo derivatives in CCl_4. However, the differences in scaling factors appear to be too large to be wholly accounted for by this explanation and it is possible that the CNDO/2 calculations inherently overestimate effects of charged groups.

In spite of these apparent quantitative failures of the CNDO/2 calculations, the overall pattern of agreement between chemical shifts and π charge densities provides further strong support for the suggestion that the consistent pattern of p*H*-dependent or substituent-induced chemical shifts noted for the compounds in this investigation arises from π polarization effects.

(d) Consideration of Other Evidence for π Polarization Effects

In addition to the results outlined above, ^1H

[7]CNDO/2 calculations for styrenes and related compounds (5) and for bicyclo[2.2.2]octanecarboxylic acids (31) indicate an enhancement of the field effect of substituents when transmitted through a molecular framework as opposed to through vacuum.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

and ^{13}C chemical shifts and charge densities for 4-substituted styrenes have provided evidence for polarization of both phenyl and vinyl π electron, systems by a polar C—X σ bond (5). In addition, it has recently been reported that ^{13}C chemical shift data and π charge densities for *trans*-1-substituted 1,3-butadienes provide evidence for a similar effect in these compounds (32). This raises the obvious question of why these effects have not previously been considered to be important. As discussed in the Introduction, when a substituent is directly bonded to a phenyl group, any π polarization effect could be masked by other substituent effects (particularly conjugative interactions). However, careful inspection of charge densities for phenyl derivatives (30) provides evidence for the existence of a π polarization effect in these systems. The π charge density for C-4 should be sensitive to any π polarization effects as well as resonance effects. However, the total π charge density, $\sum C_\pi$, only reflects resonance effects (30). Taking $N(CH_3)_2$ as an example of a group with a strong resonance effect and a small field effect (5), the ratio $C\text{-}4_\pi/\sum C_\pi = 0.59$ (30). Other groups with dominant resonance effects show similar ratios. However, the nitro group, which has a dominant field effect (28), has a ratio $C\text{-}4_\pi/\sum C_\pi = 1.75$ (30). Since the field and resonance effects of NO_2 have the same sign (28), any π polarization effect due to the polar C—NO_2 σ bond system (as in **4**) should reinforce the resonance-induced π charge density at C-4. Thus the large ratio $C\text{-}4_\pi/\sum C_\pi$ for NO_2 is consistent with a π polarization effect. Other groups with large *F* effects show similar trends.

In the light of the above results, we decided to attempt to find experimental evidence for π polarization due to a substituent directly bonded to a phenyl group. $N(CH_3)_3^+$ and NH_3^+ are the best substituents for this purpose. $N(CH_3)_3^+$ is isoelectronic with $C(CH_3)_3$, similar in size and is also believed to have a similar (electron-releasing) resonance or mesomeric effect (33). The same relationship should exist between NH_3^+ and CH_3. Consequently, differences in chemical shifts between pairs of compounds in the same solvent should reflect σ and π inductive effects. ^{13}C chemical shifts for *N,N,N*-trimethylanilinium iodide and *t*-butyl benzene in CD_3OD and anilinium trifluoroacetate and toluene in CF_3COOH are given in Table 7, along with results of CNDO/2 MO calculations for these compounds. The chemical shift differences are clearly consistent with π polarization effects, although the magnitudes of C-1 and -2,6 chemical shifts suggest an imperfect cancellation of α and β structural effects. Somewhat surprisingly, C-4 shifts are almost identical to that for the benzylammonium ion. The CNDO/2 calculations for the anilinium and trimethylanilinium ions show clear evidence for π polarization effects, although this trend is partially obscured when comparisons are made between $-NR_3^+$ and $-CR_3$. They also indicate that the change in C-4 charge density for the anilinium ion is nearly identical to that for the benzylammonium ion. Having the substituent directly bonded to the ring may alter the nature of the π polarization effect, accounting for this apparent discrepancy.

Thus a consideration of available evidence leads us to conclude that π polarization similar to that illustrated in **2**, **3**, and **4** is a significant mechanism of transmission of electronic substituent effects in phenyl derivatives and may be the dominant effect in systems where the substituent is insulated from direct conjugative interaction with the phenyl group.

Note added in proof

Taft and co-workers (34) have recently reported the results of ^{19}F measurements for a series of derivatives of the type X—C_6H_4—G—C_6H_4F where G is a variety of linking groups. Correlations of ^{19}F chemical shifts with σ_I and σ_R indicated a substantial π inductive effect which increased when G was a conjugative linkage. We believe that these results are consistent with a π polarization effect of the type discussed above and in ref. 5.

Thiyl Radical Abstraction. A Mechanism for the Free Radical Substitution Reactions of Pentachlorobenzenesulfenyl Chloride

DENNIS D. TANNER, NAOTO WADA,[1] AND BRIAN G. BROWNLEE[2]

Department of Chemistry, University of Alberta, Edmonton, Alberta

Received December 20, 1972

The substitution reactions of pentachlorobenzenesulfenyl chloride with saturated alkanes were found to proceed by a free radical chain mechanism where the pentachlorobenzenethiyl radical is the predominant chain-carrying species. The selectivity of this radical could be determined by the investigation of the photoinitiated reactions of bispentachlorophenyl disulfide with a number of alkanes.

Il a été démontré que les réactions de substitution du chlorure de pentachlorobenzène-sulfényle avec des alcanes saturés se déroulent, selon un mécanisme radicalaire en chaîne où le radical pentachlorobenzène thiyle est l'agent principal de propagation de chaîne. La sélectivité de ce radical peut être déterminée par une étude des réactions de photoinitiées des bisulfures de bis-pentachlorophényle avec plusieurs alcanes.

Can. J. Chem., **51**, 1870 (1973)

Introduction

Homolytic substitution reactions of a number of sulfenyl chlorides (1–5) have been proposed to take place by free radical chain mechanisms where the chain-carrying species could involve the chlorine atom, the thiyl radical, or a mixture of these processes. The choice of the abstracting radical for a particular reagent can be decided on the basis of results obtained from the comparison of the reaction of the reagent with those of the chlorine atom. Product isomer distributions, relative reactivities between substrates (including deuterium isotope effect) and primary:secondary:tertiary (P:S:T) hydrogen selectivities have been used in these comparisons. However, the usefulness of the methods described depends upon the irreversibility of the abstraction (product determining) reaction. The possibility of extensive reversal of thiols formed by thiyl radical abstraction (eq. 1) makes the information obtained from the product studies of these reactions of limited use, since the reversibility of the reaction will mask any kinetically meaningful information that can be obtained.[3]

[1] $$RH + YS\cdot \rightleftarrows R\cdot + YSH$$

If the reactivity of the reagent is different from that of molecular chlorine then one is most likely dealing with a thiyl radical or a mixed chain reaction. It is difficult, however, to determine the true selectivity of the thiyl radical using these methods since the production of thiol which is potentially capable of reversal cannot be ignored.

A typical sulfenyl chloride, pentachlorobenzenesulfenyl chloride (PBSC), was first prepared by Putnam and Sharkey (7). Kharasch and Ariyan found that the reagent underwent reaction with cyclohexane in diffuse sunlight to yield a mixture of products which were qualitatively identified as cyclohexyl chloride, cyclohexyl pentachlorophenyl sulfide, hydrogen chloride, and bispentachlorophenyl disulfide (8). The mechanism of the reaction can potentially yield products via thiyl radical or chlorine atom abstraction or, alternatively, by a mixed chain involving both of these reactive intermediates.

Results

The Photolysis of PBSC with Cyclohexane

The reaction of PBSC with cyclohexane was shown to be a moderately long-chain process since, although not inhibited by *sym*-trinitrobenzene or molecular oxygen, 90% of the material was consumed by initiation with 2 mol % of AIBN (Table 1).

The major products of the photoinitiated reaction of a carbon tetrachloride solution of cyclohexane and PBSC were those which were previously reported. In addition to these four products, hydrogen chloride, bispentachlorophenyl disulfide (**1**), cyclohexyl chloride (**2**), and

[1]University of Alberta, Postdoctoral fellow, 1972.

[2]Taken in part from the M.Sc. dissertation in Chemistry of B. G. Brownlee, University of Alberta, Edmonton, Alberta, 1968.

[3]The kinetic distribution of the radicals initially formed is determined by the selectivity or reactivity of the abstracting radical; however, if a reversible abstraction process is involved in the reaction sequence the rates of reversal of the initially formed radicals will not be necessarily the same as their relative rates of formation. The analysis of the final product distribution of such a sequence of reactions will only give an apparent relative reactivity or selectivity for the abstraction species. For a more detailed discussion of the problem see ref. 6.

cyclohexyl pentachlorophenyl sulfide (**3**), traces of pentachlorothiophenol were found as well as a small amount of hexachlorobenzene. The yields of these materials for reactions run at 40 and 80° constitute a material balance for these reactions and are listed in Table 2. When the photolysis was carried out to 29–100% completion the ratio of the products formed remained unchanged (Table 2, runs 3–7 and 10–12). Reactions run with added pentachlorothiophenol (Table 2, runs 8–9) gave increased yields of **1** and decreased yields of **3**.

The reaction of PBSC (0.32 *M*) with a 1:1 mixture of cyclohexane (1.8 *M*) and perdeuteriocyclohexane (1.8 *M*) was run to completion. The unreacted mixture of cyclohexane and perdeuteriocyclohexane was reisolated by g.l.p.c. and the mixture was subjected to mass spectral analysis. Neither incorporation (< 1%) of deuterium into the cyclohexane nor incorporation of hydrogen into the perdeuteriocyclohexane could be observed.

Photolysis of PBSC with n-Butane and Isobutane

The reactions of these isomeric butanes each gave mixtures of two chlorides and two aryl sulfides. A quantitative determination of the products from each of these reactions is listed in Table 3. Traces (<0.5%) of pentachlorothiophenol were produced in these reactions. From the combination of the yields of the corresponding chloride and sulfide for each of the reactions a relative selectivity/H could be calculated for the reagent of (P:S:T) 1:8:25 at 40°.

The Selectivity of Complexed Molecular Chlorine

The possibility existed that the selectivity observed with the reagent was due to the abstraction reaction of chlorine atoms which had been stabilized by complex formation with PBSC or one of the products of the reaction.

Butane and isobutane were each separately photochlorinated with molecular chlorine at 40° in the presence of 0.1 *M* *n*-butyl pentachlorophenyl sulfide. The P:S:T selectivities calculated from the results of these photochlorinations were 1:2.7:3.5. The results were identical, within experimental error, to the value of 1:2.5:3.2 obtained for chlorination with molecular chlorine alone. Thus the presence of low concentrations of alkyl pentachlorophenyl sulfides did not enhance the selectivity of chlorine atoms. In these photochlorination reactions in the presence of added sulfide the yields of alkyl chlorides were in the order of 50–60% of that expected from the amount of chlorine present. Recovery of the sulfide and analysis by n.m.r. spectroscopy showed that the sulfide itself had undergone substantial chlorination, especially in the α-position. Approximate values for the reactivity of *n*-butyl pentachlorophenyl sulfide relative to the reactivity of butane and isobutane toward chlorine atoms were 17:1 and 27:1 respectively.

PBSC itself was tested as a possible complexing agent by treating isobutane with approximately equimolar amounts of PBSC and molecular chlorine. Reaction conditions and analyses were the same as those used for the PBSC–isobutane reactions. Product yields are quoted in Table 4 along with the selectivities calculated from these yields. The selectivity of the PBSC–chlorine mixture was calculated from the combined yields of the primary chloride and sulfide compared to the yield of the corresponding tertiary substitution products. The values obtained, 1:11 (P:T), can be compared to those predicted, 1:15, for the reaction if the two halogenating reagents reacted independently. Therefore, PBSC could also be eliminated as a complexing agent.

[a]Reaction mixtures contained 50 mmol of isobutane in 10 ml of carbon tetrachloride and 1.00 mmol of Freon 112 as internal standard.
[b]Run 17 was with 1.69 mmol (55 mol %) of PBSC and 1.37 mmol (45 mol %) of chlorine. Run 18 was with 1.60 mmol (54 mol % of PBSC and 1.37 mmol (46 mol %) of chlorine.

chlorophenyl disulfide were carried out with butane and with isobutane and yielded a mixture of the corresponding primary and secondary, or primary and tertiary aryl alkyl sulfides and pentachlorothiophenol. The reaction of the disulfide with isobutane (80°, 50 h with incandescent light, 2 × 200 W) yielded pentachlorothiophenol (80%), *t*-butyl pentachlorophenyl sulfide (**4**) (90%), and *iso*-butyl pentachlorophenyl sulfide (**5**) (2–2.5%). The photoinitiated reaction of butane with bispentachlorophenyl disulfide yielded only pentachlorothiophenol, *sec*-butyl pentachlorophenyl sulfide (**6**), and *n*-butyl pentachlorophenyl sulfide (**7**).

Only apparent selectivities (P:S:T) could be calculated from product ratios obtained in this manner since abstraction reactions which take place in the presence of high concentrations of thiophenols lead to reversal of the abstraction processes. At low conversion of the reactants to products when [ArSH] approaches zero the true selectivities could be estimated. Plots of the ratio of products obtained *vs.* the percentage conversion for the reaction of isobutane and butane are given in Figs. 1 and 2.

When small amounts of pentachlorothiophenol (12 mol %) were added to the mixture of the disulfide and the hydrocarbon, the photolysis, even at low percentage reactions, gave high ratios of secondary/primary (butane) product, 93/7, and tertiary/primary (isobutane) product, 97/3.

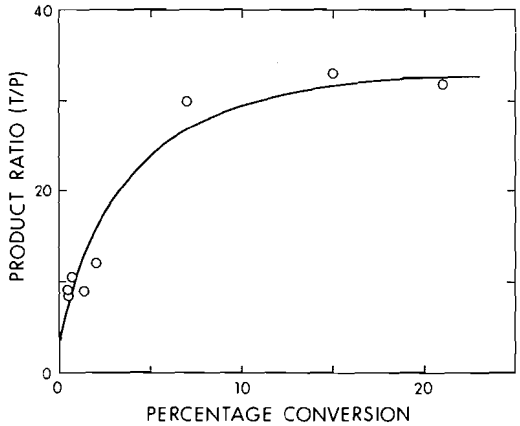

FIG. 1. The ratio of tertiary to primary sulfide formed in the reaction of bispentachlorophenyl disulfide with isobutane *vs.* the % conversion.

The Photolysis of PBSC

The photolysis of PBSC was reported to give bispentachlorophenyl disulfide (8); however, under our reaction conditions (24 h irradiation in carbon tetrachloride) 17% of hexachlorobenzene is obtained (68% of the active halogen, determined by iodometric titration, remained as volatile and nonvolatile products).

Discussion

Several mechanistic schemes can be proposed to rationalize the formation of the products produced in the initiated substitution reactions of PBSC. The observation that the reaction was initiated by small amounts (2%) of AIBN implies a radical chain substitution process of a moderately long chain length (22–45).

Following the initiation step in the light-catalyzed reaction (eq. 2), the chain may be propagated by two distinct and distinguishable sequences of ractions involving abstraction by chlorine atoms or thiyl radicals.

$$\text{[2]} \qquad \text{ArSCl} \xrightarrow{h\nu} \text{ArS}\cdot + \text{Cl}\cdot$$

In order to determine the abstracting species in the chain sequence several control experiments were carried out. If thiyl radical abstraction is proposed as the chain-carrying step in the substitution reaction, and if thiol is only found in trace amounts at the end of the reaction, an efficient reaction is necessary to remove thiol as a reaction product and to produce disulfide in its stead. The reaction of pentachlorothiophenol and PBSC was shown to meet these requirements, eq. 3, since a mixture of these reagents resulted in a very rapid reaction ($k_2 \simeq 2 \times 10^{-2}$ l mol^{-1} s^{-1}) and gave a quantitative yield of bisaryl disulfide. A mixture of hydrogen chloride and

$$\text{[3]} \qquad \text{ArSH} + \text{ArSCl} \xrightarrow{k_2} \text{ArSSAr} + \text{HCl}$$

PBSC was not reactive under the reaction conditions. The third control experiment that allows a determination of the abstracting species in the substitution reaction was one which demonstrates that a reversible abstraction reaction was not involved in the formation of the products. If thiyl radical abstraction is involved in the chain propagation step then the formation of the transfer reagent, ArSH, could lead to reversible abstraction (eq. 4) and to observed radical selectivities which were not the results of the

kinetically determined distribution of the radicals involved.

[4] $ArS\cdot + RH \rightleftarrows ArSH + R\cdot$

The failure to observe any detectable scrambling of protium and deuterium during the reactions of cyclohexane and perdeuteriocyclohexane with PBSC eliminates the possibility that the observed selectivity of the reagent was only an artifact of a combination of abstraction and reversal steps (eq. 4). The absence of this reversal reaction, eq. −4, does not, however, eliminate the possibility that thiol is present during the reaction (traces of this product are found at the completion of the reaction), since the rapid reaction of PBSC with thiol ($k_2 \simeq 2 \times 10^{-2}$ l mol^{-1} s^{-1}, a rate constant which is not incompatible with this suggestion under the concentration conditions of the reaction) could make transfer of an alkyl radical with this reagent a noncompetitive process. The two processes, thiyl radical abstraction and chlorine atom abstraction, are presented in Schemes 1*a* or *b* and 2.

[9] $ArS\cdot + ArSCl \rightarrow ArSSAr + Cl\cdot$

SCHEME 2

The reagent, PBSC, demonstrated a primary:secondary:tertiary selectivity/H of 1:8:25 at 40°. Since the selectivity/H of chlorine atoms, under the reaction conditions, was found to be 1:2.7:3.5 the process depicted by Scheme 2 could not be the sole mechanistic pathway for the formation of the reaction products. The chain process depicted by Scheme 1*a* and *b* or a mixture of the chain reactions, Schemes 1 and 2, could determine the mechanistic course of the reaction. A choice between these two alternatives could be made if the selectivity of the thiyl radical were known. The selectivity of the pentachlorophenylthiyl radicals can be estimated from the plots of the isomer distribution of products *vs.* the percent conversion for the photoinitiated substitution reaction of the aryldisulfide with butane and isobutane (Scheme 3).

$$Ar{-}S{-}S{-}Ar \overset{h\nu}{\rightleftarrows} 2ArS\cdot$$

$$R\cdot + ArS\cdot \rightarrow R{-}S{-}Ar$$

$$ArS = C_6Cl_5S$$

SCHEME 3

The true selectivity of the thiyl radical will be its selectivity in the absence of reversible abstraction, *i.e.* the selectivity obtained at 0% reaction. The extrapolated values of the selectivity obtained for the thiyl radical in the absence of thiol, 0% reaction, were estimated to be 1:8.5:31. These values are not significantly different from the values (1:8:25) obtained from the reaction of PBSC with the same substrates. An interpretation of this observation infers that the radical chain substitution processes of PBSC proceed via a mechanism involving thiyl radical abstraction as the dominant chain carrying step (Scheme 1).

The absence of appreciable numbers of chlorine atoms during the PBSC reaction was attested to by the absence in the reaction mixture of the chlorination products of arylalkyl sulfides. It would be expected that chlorine atoms would favor abstraction from the sulfides rather than the hydrocarbons since the relative reactivity of the sulfides to the hydrocarbons butane and isobutane was found to be from 20–30 in the photochlorination reactions of these substrates with molecular chlorine.

The mechanism of formation of the major substitution product, the sulfide, has been the subject of some speculation for the reaction of a number of sulfenyl chlorides (1–5). A choice between a displacement on the sulfur of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

secondary product, disulfide, or on the sulfenyl chloride itself should, in principle, be able to be made. Since reaction 7 produces a

[6] $R\cdot + ArSSAr \rightarrow ArSR + ArS\cdot$

[7] $R\cdot + ArSCl \rightarrow ArSR + Cl\cdot$

chlorine atom, it would be inconsistent with both the selectivity observed with the reagent and with the absence, as secondary products, of chlorinated arylalkyl sulfide, unless a chlorine destroying process, [8], were also involved. An attempt was made to ascertain the importance of [7] as a major path for the production of sulfide by comparing the ratios of [RCl]/[RSAr] at various percentages of conversion (see Table 2, runs 3–7, 10–12). As the reaction proceeds the sulfenyl chloride to disulfide ratio decreases, and if reactions 7 and 5 are the important product-forming reactions the ratio of [RCl]/[RSAr] should be independent of the percentage of reaction, while if reactions 5 and 6 were the major paths the ratio of products should decrease. The product ratio was found to be, within experimental error, constant; however, it was also observed that at concentrations equivalent to approximately 50% reaction the disulfide began to precipitate from solution. Since the ratio of [ArSCl]/[ArSSAr] would not change as fast under these conditions, no clear choice of reactions could be made for the sulfide-forming reaction.

Hexachlorobenzene was observed as a minor reaction product (1–4% based on PBSC) in all of the reactions run with PBSC. One explanation considered for this was a displacement reaction analogous to that observed by Miller and Walling for displacement of bromine atoms from bromobenzene by chlorine atoms (9), and by Tanner and Van Bostelen for displacement of iodine from iodobenzene by chlorine atoms (10). The yield of hexachlorobenzene did not increase in the reactions using mixtures of chlorine and PBSC, thus discounting the feasibility of proposing a displacement reaction on PBSC by chlorine atoms. A precedent for obtaining hexachlorobenzene as a product during free radical reactions of PBSC was that thermolysis of benzenesulfenyl chloride gave chlorobenzene (60%) plus diphenyl disulfide and sulfur monochloride (11). By analogy a similar mechanism can be suggested for the formation of hexachlorobenzene from the photoinitiated decomposition reaction of PBSC (Scheme 4).

Experimental

Materials

Pentachlorobenzenesulfenyl chloride was prepared by the method of Putnam and Sharkey (7), m.p. 103–104° (lit. (7) m.p. 103–104°).

Anal. Calcd. for C_6Cl_6S: Cl, 67.14. Found: Cl, 67.55.

Iodometric titration showed the material to contain 99.1 ± 0.4% of the theoretically calculated active halogen.

Cyclohexane, butane, and isobutane were Phillips research grade materials and were used without further purification.

Pentachlorothiophenol (Aldrich Chemical Co., technical grade) was purified by crystallization from benzene – carbon tetrachloride, m.p. 238–240° (sealed tube), lit. (12) m.p. 243°.

Fisher spectranalyzed reagent grade carbon tetrachloride was checked for purity by g.l.p.c. prior to use; purified benzene was prepared for analytical work by twice crystallizing reagent grade material and was free from impurities by g.l.p.c. and n.m.r.

Freon 112 (1,2-difluoro-1,1,2,2-tetrachloroethane) was distilled through a 3 ft helices-packed column and had b.p. 89.5–90.0° (700 mm). No impurities were detected by g.l.p.c.

Perdeuteriocyclohexane (99%) was obtained from Merck, Sharp and Dohme (Canada) Ltd.

Bispentachlorophenyl disulfide was prepared by the reaction (80°, 15 min) of a carbon tetrachloride mixture of pentachlorothiophenol (0.25 *M*) and PBSC (0.25 *M*). The disulfide was recrystallized from benzene several times, m.p. 235.5–237° (lit. (8) m.p. 235–236°).

G.l.p.c. Analysis

Analyses were carried out in triplicate. Peak areas were measured by multiplying peak height times peak width at one-half peak height. Calibration curves were used to convert the area ratios of the alkyl chlorides relative to Freon 112 as internal standard or area ratios of the alkyl sulfides relative to added hexachlorobenzene, into molar ratios. Precision of g.l.p.c. analyses was generally 1–3%. Where quoted, the experimental uncertainties are standard deviations from the mean. Retention time comparison and peak enhancement refer to addition of authentic material to a portion of the sample and reanalysis by g.l.p.c.

Initiation and Inhibition Reactions of PBSC with Cyclohexane

Carbon tetrachloride solutions 0.3 *M* in PBSC and 3.7 *M* in hydrocarbon were allowed to react under the conditions indicated in Table 1. The photochemical and AIBN-initiated reactions did not differ in product composition.

Reaction of PBSC with Cyclohexane (Reactions 1–12)

Between 0.47 and 0.50 g of PBSC (1.48–1.56 mmol) was accurately weighed into an ampoule containing

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

3.00 ml of carbon tetrachloride (0.200 *M* in Freon 112 for runs 3–12) and 2.00 ml of cyclohexane. Runs 8 and 9 contained 0.060 g (0.21 mmol) of pentachlorothiophenol. The ampoules were degassed in the absence of light, sealed under vacuum, wrapped in aluminum foil and equilibrated in a water bath at the desired temperature. The foil was then removed and the ampoules irradiated with 2 × 200 W incandescent lamps. At first the reaction mixtures were orange in color. After about 1 h the color had faded to a light yellow and orange solid (**1**) began to crystallize out (except for the 80° runs). After 5–10 h, the reaction mixtures were colorless and crystallization of the solid had apparently been completed. In the reactions containing added pentachlorothiophenol, solid began to crystallize out after 10–15 min.

For the determination of hydrogen chloride (runs 1–2) the ampoules were frozen in liquid nitrogen and broken open under 50–100 ml of water in a stoppered flask. The flask was shaken for 10–15 min. The hydrogen chloride was titrated as iodine liberated after addition of excess potassium iodate and potassium iodide (13).

For the determination of the organic products, the reaction mixtures were first analyzed by g.l.p.c. for cyclohexyl chloride using a 10 ft × 1/4 in. SF-96 column programmed from 75–150°. The material was identified by its isolation and the comparison of retention time and i.r. spectrum with that of an authentic sample. After g.l.p.c. analysis of the supernatant solutions the solid precipitate of orange crystals, bispentachlorophenyl disulfide, was collected by filtration and weighed, m.p. 235–237°. A mixture melting point and i.r. spectrum (Nujol) were identical with those of an authentic sample. The filtrate was evaporated and gave a white solid, m.p. 109.5–112°. The weighed solid was analyzed by g.l.p.c. (5 ft × 1/4 in. SE-30, 15% on 60/80 Chromosorb W at 240°) and showed two components in the ratio 3:97 by area. The first was identical to hexachlorobenzene in retention time, and the mass spectrum of a collected sample was identical to the mass spectrum of an authentic sample of hexachlorobenzene (parent ions at *m/e* 282, 284, 286, and 288 were present with the intensities expected for a molecule containing six chlorine atoms, and were the most intense peaks in the spectrum).

The second component of the mixture was isolated and identified by dissolving the mixture in acetone, filtering the insoluble traces of disulfide and hexachlorobenzene, and crystallizing the soluble portion of the product which consisted of pure cyclohexyl pentachlorophenyl sulfide, m.p. 115–116°, (lit. (8) m.p. 116°); n.m.r. (CCl_4) τ 6.4–7.0 (m, 1H), 7.8–9.0 (m, 10H); i.r. (CS_2) 2935, 2855 (C—H); 1331, 1327, 1309, 1303 (aromatic C=—C) and 687 cm^{-1} (C—Cl). The molar amounts of the sulfide and the hexachlorobenzene determined by isolation were confirmed by the addition of a standard to the admixed material and analysis by g.l.p.c.

The analysis for trace amounts of pentachlorothiophenol was made by acetylation of a portion of the crude reaction mixture, after filtration. The analysis by g.l.p.c. of pentachlorophenyl thiolacetate formed was compared to the amount of hexachlorobenzene (independently calibrated) in the solution. By addition of known amounts of the thiol to the reaction mixture and carrying out the acetylation and analysis an upper limit of 0.2% could be placed on the amount of thiol present in the reaction.

Pentachlorophenyl Thiolacetate

The acetylation was carried out by heating to reflux a carbon tetrachloride solution of the pentachlorothiophenol (0.001–1.0 mmol) with excess acetyl chloride (500 mg, 6.4 mmol). Pyridine (0.5 ml, 6.3 mmol) in 5 ml of carbon tetrachloride was added in small portions through the reflux condenser. After 0.5 h the reaction mixture was cooled and poured onto ice. The carbon tetrachloride layer was separated and washed with ice-cold 3 *N* hydrochloric acid (2 × 30 ml). After drying over anhydrous calcium chloride the solvent was removed to give a >94% yield of pentachlorophenyl thiolacetate, m.p. 116–118° (lit. (14) m.p. 118–119°); i.r. (CS_2) 1722, 1708 (thiolester carbonyl), and 690 cm^{-1} (C—Cl).

The Reaction of PBSC with Cyclohexane and Perdeuteriocyclohexane

A mixture of pentachlorobenzenesulfenyl chloride (0.25 g, 7.9×10^{-4} mol), cyclohexane (0.39 g, 4.5×10^{-3} mol), perdeuteriocyclohexane (0.44 g, 4.6×10^{-3} mol), and carbon tetrachloride (2.4 g) was degassed and sealed in a Pyrex ampoule. The ampoule was irradiated with 2 × 200 W tungsten lamps at 40° for 20 h. Iodometric titration carried out after the irradiation showed the absence of any active halogen. Product analysis carried out in the previously described manner showed the presence of the following: H(D)Cl (74%), chlorocyclohexane (22%), bispentachlorophenyl disulfide (20%), cyclohexyl pentachlorophenyl sulfide (49%), hexachlorobenzene (2%), and pentachlorobenzenethiol (trace).

Mass-spectral analysis of the recovered cyclohexane and perdeuteriocyclohexane was undertaken to compare the ratios of the *m/e* 85 ($C_6H_{11}D$) to 84 (C_6H_{12}), and 95 (C_6HD_{11}) to 96 (C_6D_{12}) intensities with those of the starting mixture of cyclohexane and perdeuteriocyclohexane. The intensity ratios of the *m/e* 85/84 and 95/96 peaks obtained from the analysis were the same, within experimental error $< \pm 1\%$, as those observed from the starting mixture.

A similar experiment without solvent carbon tetrachloride gave the same results.

Synthesis of the Isomeric Butyl Pentachlorophenyl Sulfides, 4–7

The sulfides were prepared by alkylating the sodium salt of pentachlorothiophenol with the appropriate alkyl halide in boiling ethanol (25 ml, 1 h). Compounds **4–7** were isolated by pouring the reaction mixtures onto 100 g of ice. Sulfides **7** and **5** were collected as solids which were crystallized from acetone–ethanol; m.p. of **7** was 38° from methanol–ethanol (lit. (15) m.p. 39–40°). Compound **6** was obtained as a colorless oil which was extracted into benzene. To obtain the *t*-butyl isomer (**4**) free from starting material, the solvent was evaporated and the residue treated with excess 5% sodium hydroxide. The solid remaining was filtered off and crystallized from acetone–ethanol. Analytical samples of **5** and **4** were prepared by sublimation at 110–120° (0.01 mm); m.p. of **5** was 37.5–38°, m.p. of **4** was 122.5–123°. The entire crude yield of **6** was distilled, b.p. 135–145° (0.01 mm), n_D^{20} 1.6124. The analysis was obtained on this material. Table 5 summarizes the details.

The i.r. spectra (CS_2) of all four isomers contained bands for C—H stretching between 2860 and 2980 cm^{-1}. The aromatic C=C stretching appeared as two strong

4	ArS—C(CH_3)—CH_3	8.61 (s, —)

[a]s, singlet; d, doublet; t, triplet; m, multiplet.
[b]Ar = C_6Cl_5 group.

bands (split in **7** and **5**) at 1300–1305 and 1325–1335 cm^{-1}. The C—Cl stretching bands for all four isomers was a strong band between 683 and 686 cm^{-1}.

The n.m.r. data of the four isomers are shown in Table 6.

Reaction of PBSC with Normal Butane (Runs 13 and 14) and Isobutane (Runs 15 and 16)

The reaction mixtures consisted of *ca.* 3 mmol of PBSC (0.95–1.0 g), *ca.* 50 mmol of hydrocarbon (5 ml at −80°), 2.00 mmol of Freon 112, and 10 ml of carbon tetrachloride.

The reaction mixtures were degassed and irradiated at 40° in the same way as the cyclohexane reactions (runs 1–12). Irradiation times of 7–10 h were required for complete reaction as shown by complete disappearance of the orange color of PBSC, and crystallization of the disulfide.

The ampoules were frozen in liquid nitrogen, broken open, and analyzed for alkyl chlorides by g.l.p.c. (20 ft × 1/8 in. SF-96 column 5% on 80/100 Chromosorb W, AW-DMCS at 50°). The chlorides were identified by a comparison of their retention times on two columns with those of authentic samples (20 ft SF-96 and 25 ft × 1/8 in. UCON POLAR, 5% on 80/100 Chromosorb W at 50°).

The disulfide was collected by filtration and was found to be identical with authentic material in mixture m.p. The yield and m.p. of the disulfide obtained in these four runs were: run 13, 0.257 g, m.p. 234–236°; run 14, 0.268 g, m.p. 232–235°; run 15, 0.341 g; run 16, 0.352 g, m.p. 234–236°.

Evaporation of the filtrates gave the crude sulfides. Run 13, 0.775 g; run 14, 0.751 g; run 15, 0.640 g; run 16, 0.664 g.

The isomer ratios were determined by n.m.r. By comparing the ArS—C—H signal of **6** (τ 6.65 multiplet) to the ArS—CH_2— signal of **7** (τ 7.12, triplet) in CCl_4 solvent, the ratio of **6**/**7** was found to be 4.5 for run 13 and 4.1 for run 14. Similarly by comparing the *t*-butyl singlet of **4** (τ 8.82) to the *gem*-dimethyl doublet of **5** (τ 9.14) in benzene solvent, the ratio of **4**/**5** was found to be 2.1 for run 15 and 2.2 for run 16.

The product butyl pentachlorophenyl sulfide had an identical n.m.r. spectrum to that of an authentic sample. Further identification was accomplished by g.l.p.c. retention time comparison with authentic samples of **4**, **5**, **6**, and **7** (5 ft × 1/4 in. SE-30 column at 220–240°). The area ratios were in agreement with the ratios determined from the n.m.r. spectra. Samples were collected by preparative g.l.p.c. for comparison of i.r. spectra and were found to be identical to authentic materials in this respect. Mass spectra were obtained for each of the sulfides collected by g.l.p.c. Each spectrum had a set of parent peaks at *m/e* 336, 338, 340, and 342 in the expected ratios for five chlorine atoms ($C_6{}^{35}Cl_5C_4H_9$ = 336). The base peak for each of the isomers was at *m/e* 57 (C_4H_9).

Hexachlorobenzene (identified by g.l.p.c. retention time and by the mass spectrum of a collected sample) was also present in the mixtures. It comprised about 4% (by peak area) for runs 13 and 14, and 5% for runs 15 and 16.

Pentachlorothiophenol was estimated by the acetylation method previously described. For both run 14 and run 16 none of the thiolacetate could be detected by g.l.p.c. Under the analytical conditions employed the upper limit for the yield of pentachlorothiophenol was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

For personal use only.

0.5%. Run 14 could be analyzed under the g.l.p.c. conditions as used before. Run 16 was analyzed using a 5 ft × 1/8 in. QF-1 column at 200°. A summary of the results for runs 13–16 is listed in Table 3.

Photochlorination of Normal Butane and Isobutane

Butane (2 ml, *ca.* 20 mmol) was photochlorinated at 40° with 2.0 mmol of chlorine in sealed, degassed ampoules with 4.0 ml of carbon tetrachloride as solvent.

Analysis by g.l.p.c. (20 ft × 1/8 in. SF-96 column) gave, for three reactions, *sec*-C_4H_9Cl/*n*-C_4H_9Cl = 1.65 ± 0.07 for a primary:secondary selectivity/H of 1:2.5 ± 0.1.

Similarly photochlorination of 20 mmol of isobutane with 1.7 mmol of chlorine in 4.0 ml of carbon tetrachloride gave, for two reactions, *t*-C_4H_9Cl / *iso*-C_4H_9Cl = 0.358 ± 0.016 for a primary:tertiary ratio of 1:3.2 ± 0.15.

Reaction of Isobutane with PBSC–Chlorine (Runs 17 and 19)

Two reactions were run at 40°. Each reaction mixture consisted of isobutane (5 ml, *ca.* 50 mmol), PBSC (run 17, 0.536 g, 1.69 mmol; run 18, 0.507 g, 1.60 mmol), chlorine (1.37 mmol), Freon 112 (1.00 mmol) and carbon tetrachloride (10.0 ml). Irradiation times of 8–9 h were required for completion of reaction.

The alkyl chlorides were quantitated by g.l.p.c. as before (runs 15 and 16).

The yield, melting point, and mixture melting point (with authentic material) of the disulfide (**1**) were: run 17, 0.116 g, 234–236, 235–237°; run 16, 0.113 g, 235–237°, none.

The yield of crude sulfide was 0.423 g (1.25 mmol) for run 17 and 0.399 g (1.18 mmol) for run 18.

The n.m.r. spectra (CCl_4) of the sulfides were qualitatively identical to those previously obtained for the sulfides from runs 15 and 16. Since the spectra did not contain any signals below τ 7.1 it was concluded that no chlorination of the sulfides had occurred. The ratio (n.m.r.) of **4**/**5** was 1.44 for run 17 and 1.41 for run 18.

Hexachlorobenzene was estimated by g.l.p.c. analysis as before and found to comprise 4–5% (by peak area) of the crude sulfide mixtures. The peak area ratio (g.l.p.c.) of **4**/**5** was about 1.3/1 for both runs.

Photochlorination of Normal Butane (Runs 19 and 20) and Isobutane (Runs 21 and 22) in the Presence of n-Butyl Pentachlorophenyl Sulfide (7)

Each reaction mixture contained 2 ml (20 mmol) of hydrocarbon (3.3 *M*), 1.20 mmol of chlorine (0.20 *M*), 0.60 mmol of **7** (0.10 *M*), 2.00 mmol of Freon 112, and 4.0 ml of carbon tetrachloride. The chlorinations were carried out at 40° and required about 0.25 h of irradiation. The alkyl chlorides were analyzed by g.l.p.c. as before. For runs 19 and 20, the molar ratio *sec*-C_4H_9Cl/*n*-C_4H_9Cl was 1.78 ± 0.06 for a primary:secondary selectivity/H of 1:2.7 ± 0.1. The total yield of alkyl chlorides was 0.72 mmol or about 60% of the theoretical, based on chlorine.

The reaction mixtures from runs 19 and 20 were combined and the solvent removed to give 0.454 g of colorless oil. When the n.m.r. spectrum of this oil was obtained in carbon tetrachloride solution it showed that the sulfide had undergone chlorination. The signal at τ 4.6 (triplet) was assigned to the α-chlorinated product, and the signal at 5.8 was assigned to the β-chlorinated product. The ratio of α-chlorination to β-chlorination was about 2:1. From a comparison of the integrated intensities of the chlorinated sulfides and the unchlorinated starting material it was estimated that about 40% of the sulfide had been chlorinated. Because the α,α-dichlorosulfide could not be observed by n.m.r., it was not known for certain if any dichlorosulfide was produced in the reaction.

Runs 21 and 22 were analyzed in the same way. The ratio *t*-C_4H_9Cl/*iso*-C_4H_9Cl was 0.388 ± 0.023 for a primary:tertiary ratio of 1:3.5 ± 0.2. The total yield of chlorides was 0.60 mmol, about 50% of theoretical. The combined yield of (chlorinated) sulfides was 0.450 g. The n.m.r. spectrum was qualitatively identical to that obtained from the chlorinated sulfides in runs 19 and 20. Again the ratio of α-chlorination to β-chlorination was 2:1. About 50% of the sulfide had been chlorinated.

*Photolysis of Bispentachlorophenyl Disulfide, **1**, in Isobutane – Carbon Tetrachloride*

Mixtures of 0.17 g (3.02×10^{-4} mol) of bispentachlorophenyl disulfide, 3 ml (3.0×10^{-2} mol) of isobutane, and 5 ml of carbon tetrachloride were degassed and sealed in Pyrex ampoules. The ampoules were placed in a thermostat at 80 °C and irradiated with a 200 W tungsten lamp for the appropriate times (0.5–32 h). The ampoules were cooled in liquid nitrogen, opened, and the reaction mixtures were filtrated by suction to remove unreacted bispentachlorophenyl disulfide. Analysis of the filtrates by g.l.p.c. (SE 30, 230°) showed three products which were collected and identified by a comparison of their i.r. spectra with those of authentic samples. The compounds were shown to be pentachlorobenzenethiol, *t*-butyl pentachlorophenyl sulfide, and isobutyl pentachlorophenyl sulfide. The reactions were quantitated by adding known amounts of hexachlorobenzene and determining the yields of the products by the use of standard calibration curves constructed for the products and the standard. Product ratios of *t*-butyl pentachlorophenyl sulfide to isobutyl pentachlorophenyl sulfide were determined by comparison of the corresponding peak areas. Results are given in Fig. 1. In typical runs the products were isolated by g.l.p.c. and the structures were determined by their i.r. and n.m.r. spectra. A control experiment carried out without irradiation resulted in complete recovery of the starting disulfide after 24 h.

The photolysis of bispentachlorophenyl disulfide in isobutane – carbon tetrachloride was carried out with added pentachlorobenzenethiol (12 mol %). The reactions were carried out to 0.1, 2.7, 3.3, and 20.2% conversion and were analyzed in the usual manner. The ratio of **4**/**5** was 96.5 ± 0.5/4 ± 0.5 for these four independent reactions.

Photolysis of Bispentachlorophenyl Disulfide in n-Butane – Carbon Tetrachloride

Mixtures of 0.17 g (3.02×10^{-4} mol) of bispentachlorophenyl disulfide, 3 ml (3.0×10^{-2} mol) of *n*-butane, and 5 ml of carbon tetrachloride were degassed and sealed in Pyrex ampoules. The ampoules were placed in a thermostat at 80° and preheated before irradiation for 3 h. Irradiation with a 200 W tungsten bulb was continued for the appropriate times (1–115 h). G.l.p.c. analysis (SE 30, 230°) of the reaction mixtures showed

three products identified by retention times as pentachlorobenzenethiol, *sec*-butyl pentachlorophenyl sulfide, and *n*-butyl pentachlorophenyl sulfide in the order of elution. In some typical cases products were isolated and their structures determined by comparison of their i.r. (CS_2) and n.m.r. spectra with those of authentic samples. Percent conversion of the disulfide into sulfides and the ratio of *sec*-butyl to *n*-butyl derivatives in each ampoule were determined by g.l.p.c. using calibration curves (standard/hexachlorobenzene). The results of these experiments are given in Fig. 2. A control experiment carried out without irradiation resulted in complete recovery of the starting disulfide.

Photolysis of bispentachlorophenyl disulfide in *n*-butane – carbon tetrachloride was carried out with added pentachlorobenzenethiol (12 mol %). The reactions were carried out and analyzed in the usual manner. Reactions run to 0.7, 1.0, and 2.4% conversion showed ratios of **6**/7 of 93.3 ± 0.3/6.7 ± 0.3.

Photolysis of PBSC in Carbon Tetrachloride

PBSC (0.487 g, 1.54 mmol) was photolyzed at 40° for 24 h in a sealed, degassed ampoule using 5 ml of carbon tetrachloride as solvent. The volatile components were removed by vacuum transfer at room temperature and 0.05 mm. By iodometric titration, 0.10 mmol of active halogen was found in the distillate, and 0.94 mmol was found in the residue. After titration, the organic layer was removed and evaporated leaving a pale yellow solid. Analysis of this solid by g.l.p.c. (SE-30 at 200°) showed hexachlorobenzene as the sole volatile product. By sublimation at 150° and 15 mm, 0.075 g (17%) of hexachlorobenzene was obtained, m.p. 223–226° (sealed tube). After one crystallization from carbon tetrachloride it had m.p. 228–229° (sealed tube) and mixture m.p. with authentic material 228–229° (sealed tube). The i.r. spectrum (Nujol mull) was identical to that of authentic material.

The Rate of the Reaction Between Pentachlorobenzenesulfenyl Chloride and Pentachlorobenzenethiol

The solutions of pentachlorobenzenesulfenyl chloride (1.316 g, 0.052 *M*) in 80 ml of carbon tetrachloride – cyclohexane mixture (5:3 in volume) and pentachlorobenzenethiol (1.174 g, 0.052 *M*) in 80 ml of the same mixture were separately equilibrated at 40° for 10 min and then were mixed together in the dark. The pentachlorobenzenesulfenyl chloride remaining in the solution was monitored by withdrawing aliquot portions of the solution and subjecting them to iodometric titration with standard sodium thiosulfate solution. A second order rate constant of $1.8 \pm 0.2 \times 10^{-2}$ l mol^{-1} s^{-1} was obtained.

The authors wish to thank the National Research Council of Canada and the University of Alberta for their generous support of this work.

The Triplet State of Ketones in Solution: The Role of the Charge Transfer State in the Quenching of Triplet Acetone by Aromatic Molecules[1]

R. O. LOUTFY[2] AND R. W. YIP

Division of Chemistry, National Research Council of Canada, Ottawa, Canada K1A 0R6

Received March 2, 1973

The rate constants for quenching of triplet acetone by a series of halobenzenes have been determined by flash emission technique. Quenching was found to be approximately a hundred times faster than that for triplet benzophenone. For both triplet ketones, quenching did not decrease with the increase in triplet energy difference between ketone and quencher (as expected for normal endothermic triplet energy transfer) and did not correlate with the i.p. of all of the quenchers studied. All of the qualitative features of the quenching results can be simply interpreted in terms of enhanced coupling of the locally excited triplet ketone and quencher states as a result of interaction with the charge transfer state.

Les constantes de vitesse de la désactivation de l'état triplet de l'acétone par une série d'halo-benzenes ont été determinées par la technique de la photolyse éclaire en émission. La désactivation est environ cent fois plus rapide que celle de l'état triplet de la benzophénone. Dans les deux cas (benzophénone et acétone) la vitesse de désactivation ne diminue pas quand la différence entre les énergies triplet de la cétone et du désactivateur augmente (comme attendu dans le cas d'un transfert endothermique d'énergie triplet) et la corrélation entre la vitesse de désactivation et le potentiel d'ionisation du désactivateur n'est pas observée dans tous les cas étudiés. Tous les résultats obtenus peuvent être interprétés qualitativement en postulant une augmentation du couplage entre l'état triplet localement excité de la cétone et les états énergétiques du désactivateur, augmentation dûe à une interaction avec l'état de transfert de charge.

Can. J. Chem., 51, 1881 (1973)

The formation of complexes between triplet excited and ground state molecules (triplet exciplexes) has been of current interest, particularly in connection with the quenching of triplet ketones by amines (1), olefins (2), and substituted benzenes (3, 4). In the case of quenching by amines, both thermodynamic calculations, and a correlation between the quenching rate constants (k_q) and the ionization potentials (i.p.) of the amines, provided substantial evidence for the intermediacy of a charge-transfer (c.t.) complex, (A^-B^+), in which charge is transferred from the quencher (B) to the ketone (A) (1). Apparently such a c.t. complex is not formed in the quenching of triplet benzophenones by electron deficient benzenes. It was reported that k_q did not decrease with increasing i.p. of the quencher as expected for the c.t. complex (A^-B^+) but instead tended to increase with i.p. (4).

As part of our study of triplet ketone reactivity in solution (1, 5–8) by various pulsed techniques (1, 6, 9, 10), we have measured rate constants for the quenching of triplet acetone (6) in order to obtain further information on the interaction between triplet ketones and aromatic molecules.

The decay of triplet acetone in degassed acetonitrile solutions was measured by the flash emission technique described earlier (6). The rate constants for quenching of triplet acetone by a series of aryl halides[3] along with relevant values for quenching of triplet benzophenone[4] (4) are recorded in Table 1. Available triplet energies (E_T) ionization potentials (i.p.), electron

affinities (E_A), and half-wave reduction potentials ($E_{1/2}^{red}$) of the ketones and quenchers are also given. The i.p. values[5] used were those determined by the photoionization method (p.i.).[6]

We note from the results that (*a*) k_q does not decrease with ΔE_T as required by the commonly accepted triplet energy transfer mechanism as applied to endothermic transfer (11); (*b*) contrary to that previously reported for triplet benzophenone (4), we find for both ketones, log k_q does not correlate with the i.p. of all of the quenchers; and (*c*) $k_q^{acetone} > k_q^{benzophenone}$ by ~100 times, in sharp contrast with the amine quenching results where $k_q^{benzophenone} > k_q^{acetone}$ by ~10 times.

Let us consider the possibility of c.t. complex formation in light of the quenching results (*vide supra* point (*b*)) and with regards to the direction of charge transfer. The energy of the zero order (in intermolecular orbital overlap) c.t. state, E(c.t.), is given by

$$[1] \qquad E(\text{c.t.}) = \text{i.p.} - E_A - J$$

where J is the Coulomb integral (12). If it is assumed that J does not differ much for the two possible donor–acceptor pairs, then we have as condition for the pair with the lowest energy, the inequality

$$[2] \qquad (\text{i.p.} + E_A)_{acceptor} > (\text{i.p.} + E_A)_{donor}$$

Calculations based on the relative energies of the zero order c.t. state as applied to both triplet acetone and triplet benzophenone (equation 2) show that the direction of transfer depends very much on the particular substituted benzene. For this reason, we do not expect (nor did we find) that log k_q should correlate with the i.p. of all of the quenchers. Instead, correlations were obtained between log k_q and i.p. for the benzenes forming A^-B^+ complexes (see Fig. 1) and log k_q and $E_{1/2}^{red}$ for the other (more electron-deficient) benzenes (Fig. 2). We note that although the E_A of difluoro- and trifluorobenzene are not known, their $E_{1/2}^{red}$ tend to suggest that these quenchers should act as donors (rather

[5]We thank Dr. F. P. Lossing for valuable discussion in the critical evaluation of i.p. data.

[6]Those determined by electron-impact (e.i.) are consistently higher than the p.i. (~"adiabatic") values. In addition, many earlier e.i. values are now known to be unreliable. Discrepancies of the order of 1 eV can be found. Therefore, from the point of view of reliability and consistency, only p.i. values were used.

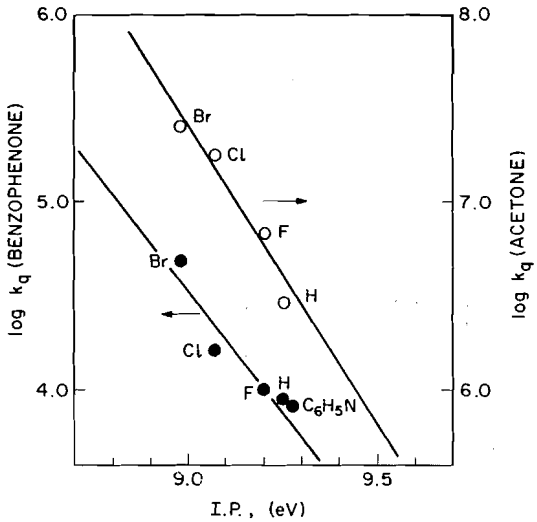

FIG. 1. Plot of log k_q of ketone triplet against the ionization potential of the substituted benzene quenchers. Triplet acetone ○, and triplet benzophenone ●.

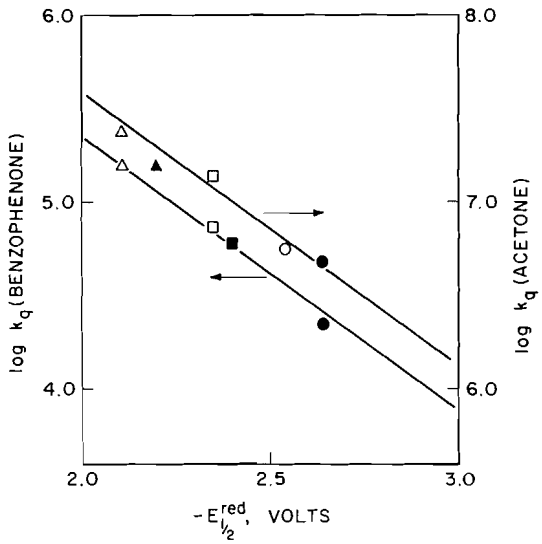

FIG. 2. Plot of log k_q for acetone and benzophenone triplets against the half-wave reduction potential of the quenchers; *m*-$C_6H_4F_2$, ●; $C_6H_5CF_3$, ○; 1,2,4,5-$C_6H_2F_4$, ■; C_6HF_5, □; C_6F_6, △; and C_6H_5CN, ▲.

than acceptors) contrary to experimental results. We believe that for borderline cases like these, the rough guide provided by the energies of the zero order c.t. state is inadequate to explain the direction of charge transfer. When intermolecular overlap is considered, the singlet and triplet c.t. states will be split such that they differ by twice the exchange integral. The possibly larger overlap[7] for $^3(A^+B^-)$ as compared to $^3(A^-B^+)$ could provide the extra stabilization energy needed to alter the direction of charge transfer.

We can view the triplet quenching process in terms of E(c.t.) and its relationship with the energies of the locally excited states ^{3}(*AB) and ^{3}(AB*). Three alternatives exist: (*i*) E(c.t.) > E^3(AB*) > E^3(*AB), (*ii*) E^3(AB*) > E(c.t.) > E^3(*AB), and (*iii*) E^3(AB*) > E^3(*AB) > E(c.t.). Calculations of E(c.t.) using eq. 1, assuming a $J \sim 4$ eV,[8] leads us to favor alternative (*i*). In this case, the main configuration interactions (c.i.) would be (c.t.) $\leftrightarrow\!\!\rightarrow$ ^{3}(AB*) for the benzophenone–benzene complexes, and (c.t.) $\leftrightarrow\!\!\rightarrow$ ^{3}(AB*) > (c.t.) $\leftrightarrow\!\!\rightarrow$ ^{3}(*AB) for the acetone–benzene complexes. As a result of c.i., the ΔE between the locally excited triplet states are reduced, thereby increasing the exchange interactions between these two states and hence the rate of quenching. Since the extent of c.i. depends, in part, on the energy difference between the interacting states, k_q should depend on the energy of the c.t. state, particularly in the case of a closely related series of quenchers. We calculated a decrease in the energy gap between the two locally excited triplets from c.i. with the c.t. states of the order of 0.2–0.3 eV and 0.01–0.08 eV, respectively, for the benzophenone and acetone would account for the observed quenching results. Differences in E(c.t.) between the acetone and the corresponding benzophenone complexes are consistent with larger energy shifts for the benzophenone complexes.

In conclusion, all of the qualitative features of the quenching of triplet acetone (and benzophenone) by substituted benzenes can be simply interpreted in terms of enhanced coupling of the locally excited triplet ketone and quencher states as a result of interaction with the c.t. state. The interpretation neither requires nor

[7]For (A^+B^-) we have overlap of the carbonyl π^* orbital with the π^* orbital of the aromatic ring. For the complex (A^-B^+), the overlap is between the carbonyl n-orbital and the aromatic π orbital (see ref. 13, p. 166).

[8]The value of J taken for the carbonyl–benzene complex is intermediate between the larger naphthalene excimer (3–3.8 eV [12]) and the maximum value assumed by two point charges (4.1–4.8 eV) at similar intermolecular distances. Within the arguments based on the energy of the zero-order c.t. state, our qualitative conclusions are not sensitive to the precise value of J chosen unless the unrealistic assumption is made that J can be represented by two point charges separated by an intermolecular distance $\lesssim$2.8 Å.

excludes the possibility that $E_{binding} > RT$ for the complex.

We wish to thank our colleagues Drs. J. M. Morris and D. F. Williams for discussing with us aspects of charge transfer and for excercising their critical faculties on our manuscript.

Thermal Anomaly in the Temperature Dependence of the Energy–Volume Coefficient of Aqueous KCl Solutions

IKCHOON LEE[1,2] AND J. B. HYNE

Department of Chemistry, University of Calgary, Calgary, Alberta

Received November 3, 1972

The temperature dependence of the energy–volume coefficient of pure water and of aqueous potassium chloride solutions as a function of concentration over the temperature range 10–50 °C has been determined by direct measurement of constant volume thermal–pressure coefficient. The results show that a thermal anomaly exists in the energy–volume coefficient of aqueous solution in the temperature range 30–40 °C and becomes more pronounced as the concentration of solute is increased.

La relation entre la température et le coefficient énergie–volume de l'eau pure et de solutions de chlorure de potassium aqueuses en fonction de la concentration a été déterminée pour l'intervalle de 10–50 °C par la mesure directe du coefficient reliant le volume thermique constant et la pression. Les résultats ont montré qu'il existe une anomalie d'origine thermique dans le coefficient energie–volume de solutions aqueuses pour l'intervalle de 30–40 °C et que cet effet devient plus important à mesure que la concentration en soluté augmente. [Traduit par le journal]

Can. J. Chem. **51**, 1885 (1973)

Introduction

The energy–volume coefficient, $(\partial U/\partial V)_T$, exhibits marked variation as a function of aqueous solution composition (1). These variations have been interpreted in terms of corresponding changes in the intermolecular interactions within the liquid system, commonly, although somewhat imprecisely, called "structural changes" (2). These previous studies have shown that the energy–volume coefficient can be a useful parameter for investigating the structural properties and intercomponent interactions in liquid mixtures.

The structural properties of water have been investigated extensively (3). One recurring phenomenon is the apparent discontinuity in various properties of water as a function of temperature (4–7). Although there is considerable controversy (8) over such discontinuities, the one postulated in the region of 35 °C has been well established in several reports in the literature (4–7). There is a continued interest in the 30–40 °C discontinuity since this could have important biological implications being near body temperature of man. We have used the energy–volume coefficient as a probe and determined the temperature dependence of this quantity for aqueous potassium chloride solutions as well as for pure water over the temperature range 10–50 °C by direct measurement of the constant volume thermal–pressure coefficient, $\gamma_V = (\partial P/\partial T)_V$, of the solution; γ_V is related to the energy–volume coefficient by

$$[1] \qquad (\partial U/\partial V)_T = T\gamma_V - P \simeq T\gamma_V$$

where P is the external pressure and at 1 atm can be neglected.

Experimental

Details of experimental procedure have been reported elsewhere (2). The accuracy claimed for the reported γ_V values is better than $\pm 1\%$. It was found essential for the claimed accuracy to maintain the pressure to within ± 0.5 atm of the contact pressure for over 1 h to permit complete thermal equilibration. The procedure adopted was to maintain the pressure within this limit until the two consecutive readings of the pressure taken at 20 min intervals gave a consistent value.

Aqueous KCl solutions were prepared by dissolving weighed amounts of AR grade KCl in 1 kg of double distilled water at 20.0 °C.

Because of the controversy surrounding the reality of these temperature discontinuities it is particularly important to establish that our observations are not merely experimental artifacts. The temperature dependence of the energy–volume coefficient for pure water has been carefully established by earlier workers and the best values (9) are represented by the curve shown in Fig. 1. The experimental values obtained with the apparatus employed in this work (Table 1) are clearly in excellent agreement with the best literature values providing convincing evidence that the discontinuities observed with the aqueous KCl solutions are not experimental artifacts.

Results and Discussion

Plots of applied pressure (P) against temperature (T) in each determination were linear. The linearity was particularly good if the temperature range was small. The normal range of temperature employed in determination of the gradient, the observed thermal–pressure coefficient, γ_{obs}, was 1 °C. Each γ_{obs} value was then corrected for the finite thermal expansion and compression of the glass vessel containing the aqueous solution. This correction was made using eq. 2

$$[2] \qquad \gamma_V = \gamma_{obs}\left(\frac{\alpha_s}{\gamma_{obs}\beta_g + \alpha_s - \alpha_g}\right)$$

where α_g and β_g are the coefficients of thermal expansion and compressibility of Pyrex glass and α_s is the coefficient of expansion of the liquid under investigation. Instead of taking average values of α_g and β_g for the temperature range studied (10 to 50 °C) (2), we have used interpolated literature values (10, 11) for each temperature. This procedure gave values of γ_V occasionally differing by as much as 1%, from those obtained assuming a single average temperature independent α_g or β_g value.

The α_s values used were similarly determined (12). Results of the thermal–pressure and energy–volume coefficients are summarized in Table 1 for pure water, and in Table 2 for aqueous KCl solutions. These data are presented in graphical form in Fig. 2. Within the temperature range studied, $(\partial U/\partial V)_T$ for pure water increases in a smooth curvilinear manner with temperature. This behavior is opposite to that of non-polar aprotic liquids, *e.g.* methane and carbon tetrachloride (9), and is considered to be characteristic of the highly hydrogen bonded water structure. While the observed behavior for potassium

chloride solutions at various concentrations is generally similar to that for pure water, the smooth curvilinear dependence of $(\partial U/\partial V)_T$ on temperature no longer is observed. Inflections are noted between 30 and 40 °C and these become more marked as concentration of the salt increases. In the case of 1.038 m KCl, curve E, the inflection while still spanning a sizeable temperature range is clearly greater than could be accounted for by experimental error. In this system the inflection, at its deepest point, represents a deviation of some 5% from a smoothed

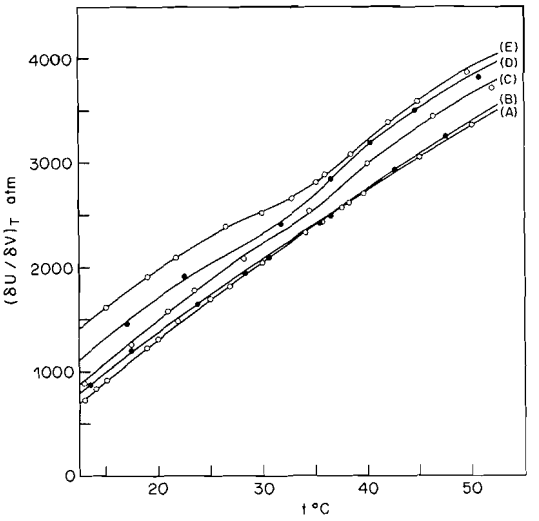

FIG. 2. Plots of the energy–volume coefficient as a function of temperature: (A) pure water; (B) 0.0847 m KCl; (C) 0.284 m KCl; (D) 0.552 m KCl; (E) 1.038 m KCl.

curve of $(\partial U/\partial V)_T$ *vs.* temperature. This deviation is approximately 5 times the experimental error.

In Fig. 3 the interpolated $(\partial U/\partial V)_T$ values from Fig. 2 are presented as a function of concentration. It is interesting to note that at temperatures below 35 °C a straight line correlation holds between $(\partial U/\partial T)_T$ and concentration, while at high temperatures curvilinear behavior is observed.[3] While the somewhat random behavior suggested by the form of presentation in Fig. 2 might lead to a suspicion that the anomalies observed between 30 and 40 °C are experimental artifacts (8), the clearly systematic change in the form of $(\partial U/\partial V)_T$ dependence on concentration as temperature is increased, as shown in Fig. 3, is not likely to be the result of experimental inaccuracies.

The anomalous behavior shown by $(\partial U/\partial V)_T$ at about 35 °C is not unprecedented. Compressibility (4), surface tension (5), viscosity (6), and other (7) properties of water have been reported to exhibit similar behavior in the temperature range 30 to 40 °C. This type of thermal anomaly has been reported both in the properties of aqueous solutions (13) and pure water, and it has been known to be much easier to demonstrate

[3]While statistically tests for linearity or the lack of it are possible the fact that the points in Fig. 3 are interpolated from Fig. 2 data and the limited (five) number of points makes the value of such an analysis arguable.

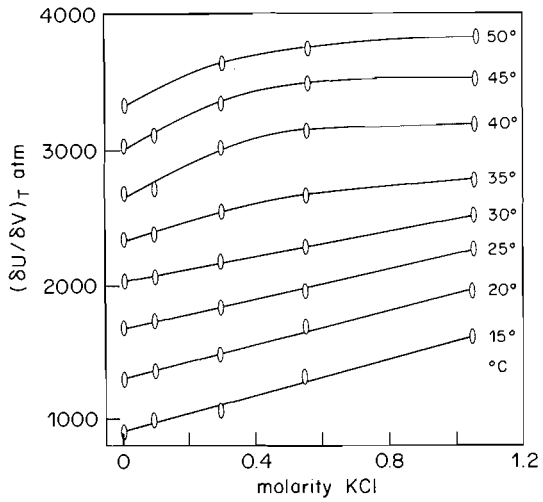

FIG. 3. Plot of the energy–volume coefficient as a function of concentration (*m* KCl).

such an anomaly in solutions than in pure water (13).

Results of the present investigation clearly establish that the thermal anomaly also exists in the energy–volume coefficient of aqueous salt solutions and becomes more pronounced as the concentration of solute is increased.

As noted above the increasing positive $(\partial U/\partial V)_T$ values with temperature are peculiar to extensively hydrogen bonded liquids and in the particular case of water this temperature dependence passes through a maximum at approximately 150 °C (9). The data in Fig. 3 also indicate that increasing concentrations of salt likewise bring about enhancement of $(\partial U/\partial V)_T$ values particularly at lower temperatures. It is tempting to suggest that since increasing temperature and increasing salt concentration both lead to higher energy–volume coefficient values, which have upper limiting values, the reason for the levelling off of $(\partial U/\partial V)_T$ values as a function of salt concentration at high temperatures is that the combined effect of temperature and salt concentration has reached a maximum. Higher temperatures and higher KCl concentrations are both considered to result in water structure disruption and this may well be the phenomenon which is being reflected in the curvature noted in Fig. 3.

The authors are grateful for support of this work by the National Research Council of Canada and in particular for a CIDA-NRC Research Associateship for I.L.

Oligoribonucleotide Synthesis. VI.[1] Selective Deblocking of the 5′-*O*-Triphenylmethoxyacetyl Grouping in Protected Dinucleotides

EVA S. WERSTIUK AND THOMAS NEILSON
Department of Biochemistry, McMaster University, Hamilton, Ontario

Received November 15, 1972

Synthesis and 5′-deblocking of the triphenylmethoxyacetyl grouping in *N*-benzamido-dinucleotide derivatives, UpA, UpC, GpG, GpC, ApU, ApC, CpA, UpAp, and ApUp, are described. Alkaline cleavage behavior of the majority correlated well with the data found for similarly protected parent nucleosides. Those containing adenine residues adjacent to cytosine showed slow de-*O*-esterification and accelerated de-*N*-benzoylation, while those containing 3′-monophosphates showed enhanced de-*O*-esterification.

La synthèse et le déblocage du groupe triphénylméthoxyacétyle en 5′ dans les dérivés du *N*-benzamido-dinucléotide UpA, UpC, GpG, GpC, ApU, ApC, CpA, UpAp, et ApUp, ont été décrits. Le comportement du clivage alcalin de la plupart de ces dérivés correspond bien avec les données trouvées pour les nucléosides parents protégés de la même façon. Ceux qui contiennent des résidus adénine adjacent à la cytosine subissent une *O*-déestérification lente et une *N*-débenzoylation accélérée, tandis que ceux qui ont un groupe monophosphate en 3′ exhibent une *O*-déesterification accélérée.

[Traduit par le journal]

Can. J. Chem., **51**, 1889 (1973)

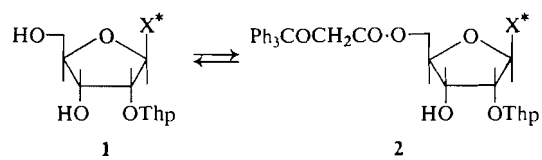
Indirect synthesis of intact transfer RNAs by transcription from synthetic genes consisting of two complementary oligodeoxyribonucleotides is in progress (2). However, to explore specific binding interactions involving transfer RNA, for example aminoacyl synthetase recognition sites, a convenient synthesis of series of oligoribonucleotides of predetermined sequence, say with single nucleotide changes, would be advantageous.

Introduction of a prototype for the first general block synthesis for oligoribonucleotides (3) guaranteed that direct synthesis of biologically interesting fragments of native ribonucleic acids could now be realized. Mononucleotides as their 2′-*O*-tetrahydropyranyl-*N*-benzamides were stepwise coupled together using 3′–5′-phosphotriester linkages (4) to give short protected sequences which in their turn, were coupled together to give much longer sequences, subsequent deblocking of which gave the required free oligoribonucleotides.

The crux of such a synthesis lies in appropriate protection of the 5′-hydroxyl of 5′-terminal nucleotide of each short sequence. Specific deblocking of this 5′-protection is necessary for block synthesis to be realized. The triphenylmethoxyacetyl (trac) (3) grouping was chosen for this important function because of its easy removal by very mild alkaline treatment and its simple detection by ceric sulfate. Successful participation was demonstrated in the synthesis of protected UpApUpA from protected UpA units.

In this communication we describe the synthesis of several representative 5′-triphenylmethoxyacetyl dinucleotide derivatives and discuss comparative specific 5′-deblocking studies of these dinucleotides with those of their parent nucleosides.

Simple selective 5′-esterification of *N*-benzamido-2′-*O*-tetrahydropyranylnucleosides (**1**) by a mixed anhydride method using sodium triphenylmethoxyacetate and triisopropylbenzenesulfonyl chloride (TPS) in pyridine gave the corresponding 5′-triphenylmethoxyacetates (**2**) as crystalline derivatives in >70% yield. Some accompanying disubstituted material was also obtained. Protected nucleosides (**2**) where X = U (3), G^{bz} (1), and A^{bz} (5) have been reported. Preparation of **2** (X = C^{bz}) is described in the Experimental.



1 **2**

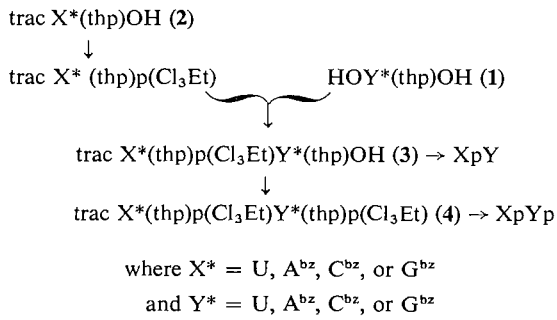
where X* = U, A^{bz}, C^{bz}, or G^{bz}

[1]For part V, see ref. 1.

Syntheses of protected dinucleotide monophosphates, UpA (3), GpG (1), and GpC (1) have already been reported. A summary in the general case is outlined: Phosphorylation of **2** using the pyridinium salt of β,β,β-trichloroethylphosphate (6) and TPS, and subsequent coupling with the higher R_F diastereoisomer of **1** (1, 7, 8) gives the protected dinucleotide XpY[2] (**3**) in yields >50% except when G is involved (*ca.* 30%). "Back tritylation" (4) is routinely carried out to convert any excess nucleoside derivative (**1**) to its more lipophilic 5′-methoxytrityl derivative *and* to convert any 3′–3′ dinucleotide derivative which could arise during coupling, to its more lipophilic 5′-*p*-methoxytrityl derivative. The presence of *p*-methoxytrityl derivatives is easily detected by ceric sulfate spray as an orange coloration on t.l.c. Increase in lipophilicity allows simple chromatographic separation. A typical procedure is illustrated by the synthesis of **3** (X = C^{bz}; Y = A^{bz}) (see Scheme 1). Careful t.l.c. analysis of each XpY derivative (**3**) showed them to be diastereoisomeric mixtures (*ca.* 1 : 1) resulting from phosphotriester chirality (3). In some cases two distinct spots were obtained; however, one elongated spot was more usual. Syntheses of protected dinucleotide diphosphates, UpAp (3), and ApUp (5) have already been reported. Data on all new protected XpY (**3**) and XpYp (**4**) derivatives are summarized in the Experimental. Complete deblocking (4) of **3** and **4** to give free dinucleotides was accomplished in >80% yield. Enzymic analysis (4) of the products confirmed the correct ratio of nucleoside components and checked the fidelity of the 3′–5′ diphosphate linkage.

Comparative studies of the selective deblocking of the 5′-triphenylmethoxyacetyl esters of the four parent nucleosides (**2**) were carried out using dilute methanolic ammonia (0.15 and 0.075 *N*) at room temperature. Conditions of 0.15 *N* smoothly regenerated the 5′-hydroxyl group in *ca.* 2 h in each case. No significant debenzoylation occurred before 2 h. Less concentrated conditions only prolonged the treatment. Stability of *N*-benzamide on heterocyclic bases was found to be C > A > G (Table 1).

Comparative studies of the selective deblocking



SCHEME 1

of the 5′-triphenylmethoxyacetyl esters of protected dinucleotides (**3** and **4**) were also carried out using the same conditions. Data obtained for protected UpA, GpG, GpC, ApU using 0.15 *N* methanolic ammonia showed reasonable correlation with the behavior of their parents. Protected UpC was best deblocked using the milder 0.075 *N* conditions.

Data on alkaline cleavage of protected ApC and CpA were more complex. Apparently the rate of triphenylmethoxyacetyl removal in **3** (X = A^{bz}, Y = C^{bz}) was slower than that for the parent (**2**; X = A^{bz}) and the de-*O*-benzoylation rate was considerably accelerated, so much so, that both rates were almost similar. In the case of **3** (X = C^{bz}, Y = A^{bz}) triphenylmethoxyacetyl removal was slightly faster than the parent (**2**; X = C^{bz}) but de-*N*-benzoylation was again enhanced. Molecular geometry of both protected dinucleotides must be such that, somehow, triphenylmethoxyacetyl cleavage is sterically hindered, and the debenzoylation of the adenine residue is anchimerically assisted (possibly by carbonyl participation from the neighboring heterocyclic base).

Alkaline cleavage rate of the triphenylmethoxyacetyl group in the protected dinucleotide diphosphate derivatives (**4**) showed considerable enhancement over those of the parents (**2**; X = U and X = A^{bz}). Apparently the charged phosphodiester grouping functions as an intra- or intermolecular catalyst.

The above studies indicated that cleavage conditions suitable for protected parent nucleosides (**2**) could not be extended directly to dinucleotide derivatives (**3** and **4**). Chemical operations performed on these sterically crowded multi-functional molecules were subject to unforeseen accelerations and retardations, especially when an adenosine residue was adjacent to a cytidine. Caution would have to be

[2]To condense the large structural formulae necessary to describe protected dinucleotides shown in Scheme 1, a shorthand method suggested by the IUPAC–IUB Commission on Biochemical Nomenclature is adopted (9).

exercised in each case. Further studies on other protected dinucleotides and the use of other hydrolytic conditions would be necessary to rationalize these results.

Prospects for convenient specific 5′-deblocking of protected trinucleotides and longer material consequently are not so bright as once anticipated. Specific 5′-deblocking of protected dinucleotides was accomplished quantitatively in many cases; however, these containing adenine located in the 5′-terminal required chromatographic separation of products and yields for the desired products were around 50% at the best. Perhaps other cleavage conditions may restore selective deblocking.

These present studies *do* show, however, that chemical reactivity of an adenosine residue varies quite markedly depending on its position in a sequence. The biological implications of this discovery are under investigation.

Experimental

The p.m.r. spectra were recorded on a Varian T60 or Varian HA-100 spectrometer in 10–15% (w/v) DMSO-d_6 – D_2O solutions, and line positions are reported in p.p.m. from the reference (TMS).

Silica gel (Baker Analyzed Reagent) was used for column chromatography; and Analtech prescored silica gel plates were employed for t.l.c. The plates were usually developed in 5 or 10% methanol in methylene chloride mixtures. The t.l.c. detection was carried out using a ceric sulfate spray (1 g $H_4Ce(SO_4)_4$ in 10% aqueous sulfuric acid solution) and followed by heating the plates at 300–400 °C. Compounds containing a trityl group develop as yellow spots, while others appear as brown colorations.

Paper chromatography was performed using the descending technique on Whatman No. 1 or 3 MM paper. Analtech pre-coated cellulose plates (Avicel F) were used for t.l.c. of deblocked nucleotides. The solvent systems employed for paper chromatography and t.l.c. on cellulose were ethanol – 1 *M* ammonium acetate, p*H* 7.5 (7:3, v/v), (A); 1-BuOH – glacial HOAc – H_2O (5:3:2, v/v), (B); 2-PrOH – concentrated NH_4OH – H_2O (7:1:2, v/v). (C). A short wave u.v. lamp was used for detection.

It was essential that moisture be excluded from all coupling reactions. After evaporation *in vacuo* of the pyridine solution, normal pressure was restored with dry nitrogen and *not* atmospheric air. All such evaporations were carried out in the temperature range of 30–40 °C.

Emulsion, frequently obtained during methylene chloride extractions of aqueous pyridine solutions, was broken by the addition of a few milliliters of saturated sodium chloride solution.

*N^4-Benzoyl-2′-O-tetrahydropyranyl-5′-O-triphenylmethoxyacetylcytidine (**2**; X = C^{bz})*

Esterification of the low R_F diastereoisomer of N^4-benzoyl-2′-*O*-tetrahydropyranylcytidine (**1**; X = C^{bz}) (7) (0.431 g, 1.0 mmol; R_F 0.52 in 10% CH_3OH–CH_2Cl_2) with sodium triphenylmethoxyacetate (0.674 g, 2.0 mmol) and TPS (0.335 g, 1.1 mmol) (as described earlier for the preparation of **2** (X = U) (3)) gave the desired product (0.520 g, R_F: 0.68 in 10% CH_3OH–CH_2Cl_2) in 72% yield.

An analytically pure sample of **2** (X = C^{bz}) had m.p. 108–110° dec. (from methylene chloride – petroleum ether (30–40°). Its p.m.r. spectrum showed signals (δ TMS) at 8.05–7.75 (4H, multiplet; 6- and 5-protons of C, and *o*-C_6H_5CO protons); 7.6–7.38 (18H, multiplet, trityl aromatic protons, and other C_6H_5CO protons); 5.9 (1H, doublet; $J \simeq 4$ Hz, 1′-anomeric proton); 5.40 (1H, multiplet; 2′-sugar proton); 4.8 (1H, singlet, acetal proton of thp); 3.8 (2H, singlet; —OCH_2CO protons); and 1.6 p.p.m. (6H, broad multiplet; thp protons).

Anal. Calcd. for $C_{42}H_{41}N_3O_9$ (mol. wt. 731.8): N, 5.74. Found: N, 5.61.

N^4-Benzoyl-2′-O-tetrahydropyranyl-5′-O-triphenylmethoxyacetylcytidylyl (3′-β,β,β-trichloroethyl-5′)N^6-benzoyl-2′-O-tetrahydropyranyladenosine (3; X = C^{bz}, Y = A^{bz})

Phosphorylation of the blocked cytidine derivative (as described earlier for blocked uridylate (3)) (**2**; X = C^{bz}) (180 mg, 2.5 mmol; 1 equiv; R_F 0.68 in 10% CH_3OH–CH_2Cl_2) and subsequent coupling with the low R_F diastereoisomer of N^6-benzoyl-2′-O-tetrahydropyranyladenosine (**1**; X = A^{bz}) (7) (172 mg, 3.75 mmol; 1.5 equiv; R_F 0.48 in 10% CH_3OH–CH_2Cl_2) gave the desired product (281 mg, R_F 0.76 and 0.68 in 10% CH_3OH–CH_2Cl_2) in 81% yield as a *ca.* 1:5 mixture of diastereoisomers.

The p.m.r. spectrum of this sample showed signals (δ TMS) at 8.80 and 8.75 (2H, singlets, 2- and 8-protons of A); 8.30–7.20 (27H, multiplet; C_6H_5CO and trityl aromatic protons, and 6- and 5-protons of C); 6.25 and 6.10 (2H, two doublets; superimposed 1′-anomeric protons); 3.80 (2H, singlet; —OCH_2CO protons); and a broad peak centered at *ca.* 1.55 p.p.m. (12H, multiplet; thp protons).

Complete deblocking by the three-step procedure described before (4) gave CpA in 80% yield. (R_{Up} 1.18 in system A, and 1.02 in system C both using paper chromatography, Whatman No. 1). CpA was completely digested by snake venom diesterase to C + pA, and by spleen diesterase to Cp + A. These products were identified with authentic markers using same paper chromatographic systems.

N^6-Benzoyl-2′-O-tetrahydropyranyl-5′-O-triphenylmethoxyacetyladenylyl (3′-β,β,β-trichloroethyl-5′)N^4-benzoyl-2′-O-tetrahydropyranylcytidine (3; X = A^{bz}, Y = C^{bz})

Phosphorylation of the blocked adenosine derivative (5) (**2**; X = A^{bz}) (610 mg, 0.8 mmol; 1 equiv; R_F 0.72 in 10% CH_3OH–CH_2Cl_2) and subsequent coupling with the high R_F diastereoisomer of N^4-benzoyl-2′-O-tetrahydropyranylcytidine (7) (**1**; X = C^{bz}) (520 mg, 1.2 mmol; 1.5 equiv; R_F 0.62 in 10% CH_3OH–CH_2Cl_2) gave the desired product (780 mg, R_F 0.86 and 0.80 in 10% CH_3OH–CH_2Cl_2) in 70% yield as a *ca.* 1:1 mixture of diastereoisomers.

The p.m.r. spectrum showed signals (δ TMS) at 8.65 (2H, broad singlet; 2- and 8-protons of A); 8.25–7.15 (27H, multiplet; C_6H_5CO and trityl aromatic protons and 6- and 5-protons of C); 6.25 and 5.9 (2H, two doublets superimposed; 1′-anomeric protons); 3.8 (2H, singlet; —OCH_2CO protons); and a broad peak centered at *ca.* 1.60 p.p.m. (12H, multiplet; thp protons).

Complete deblocking (4) gave ApC in 86% yield. (R_{Up} 1.24 in system A, and 1.02 in system C both using paper chromatography, Whatman No. 1). ApC was completely digested by snake venom diesterase, to A + pC, and by spleen diesterase to Ap + C. These products were identified with authentic markers using same paper chromatographic systems.

2′-O-Tetrahydropyranyl-5′-O-triphenylmethoxyacetyluridylyl (3′-β,β,β-trichloroethyl-5′)N^4-benzoyl-2′-O-tetrahydropyranylcytidine (3; X = U, Y = C^{bz})

Phosphorylation of the blocked uridine derivative (3) (**2**; X = U) (500 mg, 0.85 mmol; 1 equiv; R_F 0.82 in 10% CH_3OH–CH_2Cl_2) and subsequent coupling with the high R_F diastereoisomer of N^4-benzoyl-2′-O-tetrahydropyranyl-cytidine (7) (**1**; X = C^{bz}) (555 mg, 1.3 mmol; 1.5 equiv; R_F 0.62 in 10% CH_3OH–CH_2Cl_2) gave the desired product (727 mg, R_F 0.40 and 0.31 in 5% CH_3OH–CH_2Cl_2) in 68% yield as a *ca.* 1:1 mixture of diastereoisomers. The p.m.r. spectrum showed signals (δ TMS) at 8.15–7.05 (23H, multiplet C_6H_5CO and trityl aromatic protons; 6- and 5-protons of C, and 6-proton of U); 5.95 and 5.70 (2H, two doublets superimposed; 1′-anomeric protons); 5.45 (1H, doublet, $J \simeq 7$ Hz; 5-proton of U); 3.75 (2H, singlet; —OCH_2CO protons), and a broad peak centered at *ca.* 1.6 p.p.m. (12H, multiplet, thp protons).

Complete deblocking (4) gave UpC in 73% yield. (R_{Up} 1.52 in system A, and 1.1 in system C both using paper chromatography Whatman No. 1). UpC was completely digested by snake venom diesterase, to U + pC; and by spleen diesterase to Up + C. These products were identified with authentic markers using same paper chromatographic systems.

General Method for the Preparation of Protected Dinucleotide Diphosphates (4)

Phosphorylation of protected dinucleotide (**3**) (1 equiv) with the mixed anhydride complex, prepared from the bis-pyridinium salt of mono-β,β,β-trichloroethylphosphate (2 equiv) and TPS (4 equiv), gave desired products (**4**) in *ca.* 80% yield. **4** could be isolated as pyridinium salts from silica gel chromatography on elution with 5–7% methanol – methylene chloride.

Preparation of protected UpAp (**4**; X = U, Y = A^{bz}) using the above method has been reported (3).

*Selective 5′-de-O-Triphenylmethoxyacetylation of **2**, **3**, and **4***

Substrates **2**, **3**, and **4**, (5 mg) were dissolved in methanolic ammonia (0.5 ml) prepared by a 100-fold (0.15 *N*) or 200-fold (0.075 *N*) dilution of concentrated ammonia with methanol. Solutions were sealed and stirred at room temperature. Reaction progress was monitored by t.l.c. in 10% methanol – methylene chloride. Time in hours for disappearance of reactants and appearance of side-products was determined (Table 1).

A large scale experiment of this nature (for protected UpA) has been described (3).

Photoelectron Spectra of Sulfuryl and Thionyl Halides

D. CHADWICK, D. C. FROST, F. G. HERRING, A. KATRIB, C. A. MCDOWELL, AND R. A. N. MCLEAN

Department of Chemistry, The University of British Columbia, Vancouver 8, British Columbia

Received November 30, 1972

The HeI photoelectron spectra of some sulfuryl and thionyl halides have been found, and an attempt has been made to relate the results to the bonding in these molecules.

Le spectre photoélectronique HeI de quelques halogénures de sulfuryle et de thionile a été établi et un essai a été fait pour trouver une corrélation entre les résultats et les liens de ces molécules.

Introduction

There has been considerable interest (*e.g.* 1–5) in the bonding in inorganic sulfur compounds, particularly where the sulfur atom has a formal valence state higher than two and a tendency to form multiple bonds with other atoms. Some of the physical properties of this type of compound, especially bond lengths (2, 3) and vibrational frequencies (6), have been correlated with changes in the π bond orders. As there are a large number of compounds containing sulfur–oxygen bonds available, most of those studies have been carried out on these species.

Photoelectron spectroscopy (p.e.s.) is a direct method for obtaining the orbital energies of molecules and thereby can yield information on multiple bonding involving second row atoms (*e.g.* the halosilanes (7)). However, apart from SO_2 (8) and SO (9) no photoelectron spectra have been published of sulfur–oxygen compounds. In these species considerable changes in molecular structure and properties (particularly S—O stretching vibrations) occur on changing the atom(s) bonded to the sulfur atom, and it is of interest to see if the molecular energy levels obtained from the p.e. spectra reflect these effects. Sulfuryl halides (SO_2X_2) and thionyl halides (SOX_2) are typical examples which show these effects to a large degree. In SO_2F_2, the S—F bond length is reduced only slightly from 1.56 Å in SF_5OF (10) to 1.53 Å in SO_2F_2 (11) whereas the S—O bond length is reduced considerably from 1.64 Å in SF_5OF to 1.405 Å in SO_2F_2. Obviously there must be a considerable increase in the bonding interaction, presumably mainly π bonding (12), in the S—O bond compared to the S—F bond in the latter molecule. This may also be the explanation for the difference in the bond angles. The greater π electron density in the S—O bonds causes greater mutual repulsion than is the case with the S—F bonds, and consequently the OSO angle (124°) is greater than the FŜF angle (96°). A satisfactory bond order – bond length relationship is obtained for S—O bonds in tetra-coordinate sulfur compounds by considering that π bonding involves 2pπ orbitals on the oxygen atoms and only the two d orbitals on the sulfur (2). The shorter SO bond length and wider OSO angle for SO_2F_2 compared to SO_2Cl_2 (1.409 Å and 123° respectively (13)) and SO_2 (1.432 Å and 119° (14)) is most likely caused by the greater contraction of the sulfur d orbitals and hence greater π overlap with the oxygen produced by the more electronegative fluorine atoms. However, it is also possible in this case that the chlorine atoms are more involved in π bonding than the fluorine atoms and this seems to be borne out by the large Cl—S—Cl angle of 100°. It was hoped that the p.e. spectra would give some indication as to the correctness of these views.

Both the p.e. spectrum (8), and recent good SCF calculations (15) on SO_2 indicate that there is a large stabilization of the oxygen pπ orbitals involved in extensive π bonding (a_1, b_1) compared to the other orbitals (a_2, b_2). The corresponding levels in SO_2F_2 may be expected to give evidence for the even stronger π bonding in this molecule.

The bonding in the thionyl halides is complicated by the sulfur "lone pair" electrons, but despite this the X—Ŝ—O and X—Ŝ—X angles are fairly close to those for the analogous sulfuryl compound, *e.g.* in F_2SO, F—Ŝ—O = 107,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

F—Ŝ—F = 93° (16) and in Cl_2SO, Cl—Ŝ—O = 106 and Cl—Ŝ—Cl = 114° (13). All the bond lengths are just significantly longer *e.g.* in F_2SO r(S—F) = 1.585, r(S—O) = 1.412 Å and in Cl_2SO r(S—Cl) = 2.07, r(S—O) = 1.45 Å. As in the sulfuryl compounds, the trends in the thionyl halides have been explained on the basis of a simple LCAO MO treatment (14).

The p.e. spectra of SO_2F_2, SO_2Cl_2, SOF_2, and $SOCl_2$ have been measured and are found to be complex. Despite this the assignment of i.p.'s arising from the mainly halogen "lone pair" orbitals may be made by comparison with the p.e. spectra of a number of the dihalo compounds (17). As we see below, however, the low molecular symmetry in the thionyl compounds makes the interpretation of their p.e. spectra more difficult.

Experimental

The p.e. spectra were recorded using the 584 Å HeI resonance line excited by 2450 MHz microwave discharge. The spectrometer employs a 4 in. radius hemispherical electrostatic analyzer (18) and the resolution (f.w.h.m.) as measured by the argon doublet was 15 mV. The working resolution varied between 20 and 30 mV. Calibration of the spectra was effected by flowing a small quantity of argon or xenon through the spectrometer simultaneously with the sample gas, and because of the reactive nature of these sulfuryl and thionyl halides, the initial spectra were recorded with calibrant present.

The SO_2F_2 sample was obtained from the Matheson Co. and SOF_2 from the Pierce Chemical Co. SO_2Cl_2 and $SOCl_2$ were obtained from B.D.H. Ltd. The purity of the samples was established by i.r. and mass spectrometry.

Some difficulty was experienced in obtaining the p.e. spectra of SO_2Cl_2 and $SOCl_2$ due to sample decomposition. In the case of SO_2Cl_2, the initial few runs produced spectra contaminated with that of SO_2. However, this gradually diminished and finally the spectrum of SO_2Cl_2 was obtained almost completely free of SO_2. In Fig. 2*b*, the strong third band in the spectrum of SO_2 at 16.5 eV is barely visible above the noise level. With $SOCl_2$ the reverse behavior was observed. A quick scan through the spectrum showed that no SO_2 was present. A very slow scan through the spectrum was made, but midway through the scan (~16 eV) the third band in the p.e. spectrum of SO_2 at 16.5–17.0 eV was evident, indicating that now a significant amount of SO_2 was present. It is this spectrum that is reproduced in Fig. 5*b*, though the region above 16 eV is not shown. That very little SO_2 is present in the spectrum below 16 eV can be seen by comparing Fig. 1 with Fig. 5*b*. In particular, the broad second band of SO_2 extends to 14 eV whereas the fifth band in Fig. 5*b* is much sharper and is in the range 13–13.5 eV. Subsequent spectra showed large amounts of SO_2 were present, and finally the spectrum of SO_2 only was observed. After "dosing" the spectrometer with fairly high pressures of $SOCl_2$ the same result was obtained. A glass inlet system was tried without success.

Results and Discussion

The HeI p.e. spectra of SO_2, SO_2F_2, SO_2Cl_2, SOF_2, and $SOCl_2$ are shown in Figs. 1, 2*a* and *b*, 5*a* and *b* respectively. Individual p.e. bands which exhibit resolved vibrational structure are reproduced in Figs. 3, 4 ,and 6 for SO_2F_2, SO_2Cl_2, and SOF_2. Measured vertical ionization potentials (i.p.'s) and vibrational frequencies are given in Tables 1–3. Adiabatic i.p.'s, where appropriate, are reported in the text. The p.e. spectrum of each molecule studied is discussed separately below. For convenience the symmetry elements in the SO_2, SO_2F_2, and SO_2Cl_2 molecules are defined with respect to the SO_2 moiety, which is considered to lie in the *zy* plane. Finally, some general implications concerning the bonding in these molecules are considered.

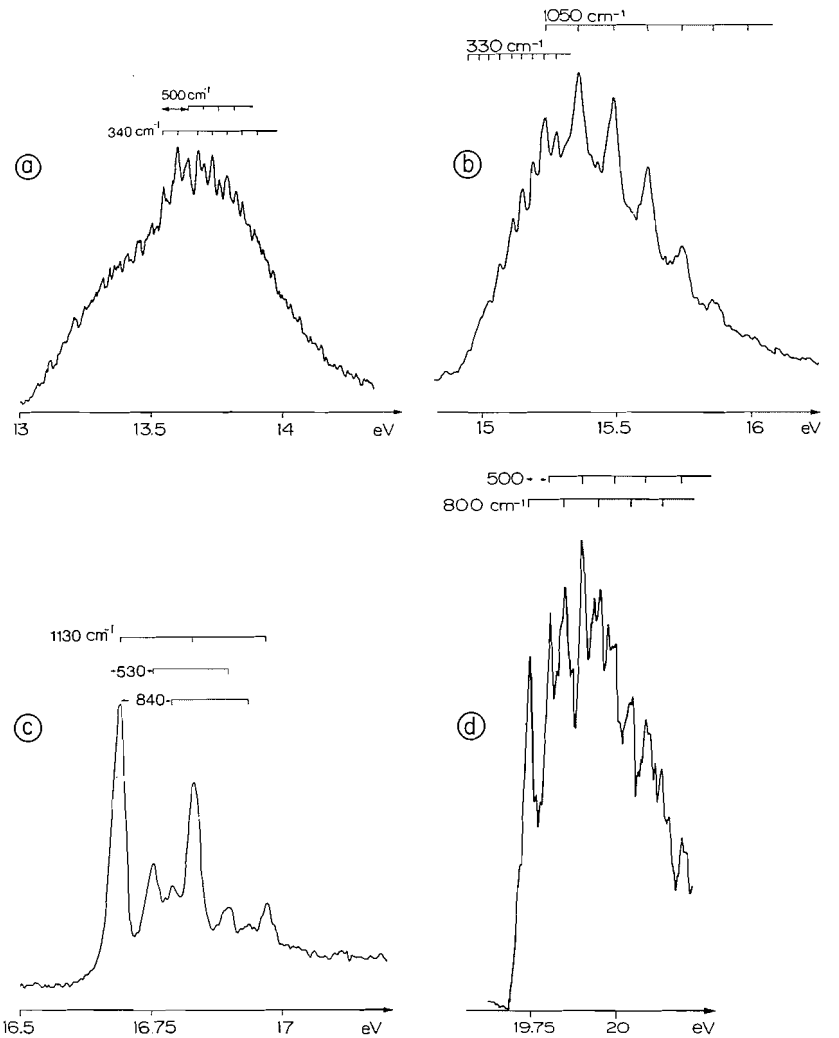

FIG. 3. Individual bands in the HeI photoelectron spectrum of SO_2F_2.

Sulfur Dioxide (SO_2)

To aid the assignment of the sulfuryl species in particular, we first discuss the p.e. spectrum of SO_2 (Fig. 1). The three bands observed below 21 eV have been assigned as follows (8):

(*a*) 12.50 eV band, ionization from the $8a_1$ sulfur "lone pair" orbital.

(*b*) 13–14 eV band, two i.p.'s arising from in-plane ($5b_2$) and out-of-plane ($1a_2$) oxygen non-bonding orbitals.

(*c*) 16–17.5 eV band, at least two ionization processes involving the $7a_1$ and $2b_1$ S—O π bonding orbitals, which may also be regarded as the bonding combinations of oxygen "lone pairs". Possibly a third ionization, from the $4b_2$ S—O σ bonding orbital, occurs in this region.

Recent MO calculations on SO_2 confirm this general pattern, and the separation between the three groups (15). For comparison with the sulfuryl compounds we are particularly interested in the order of the components in the second and third bands. The calculations estimate the separation of the two components of the second band to be 0.6 (15*a*) and 0.9 eV (15*b*) (experimental 0.3 eV) with the a_2 orbital at highest orbital energy. In most species of C_{2v} symmetry containing two equivalent atoms with "lone pairs" the b_2 orbital is at higher energy than the a_2 orbital (16) and, as overlap with sulfur d orbitals would cause greater stabilization of the a_2 orbital (7*b*, 12), this order is surprising. However, a close examination of the band between 13 and 14 eV seems

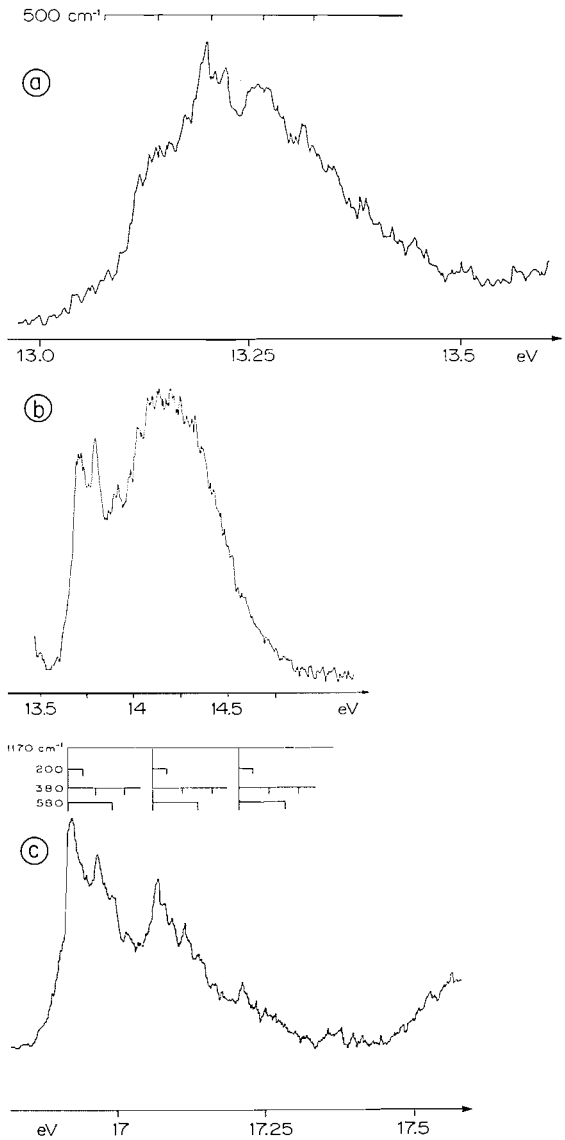

FIG. 4. Individual bands in the HeI photoelectron spectrum of SO_2Cl_2.

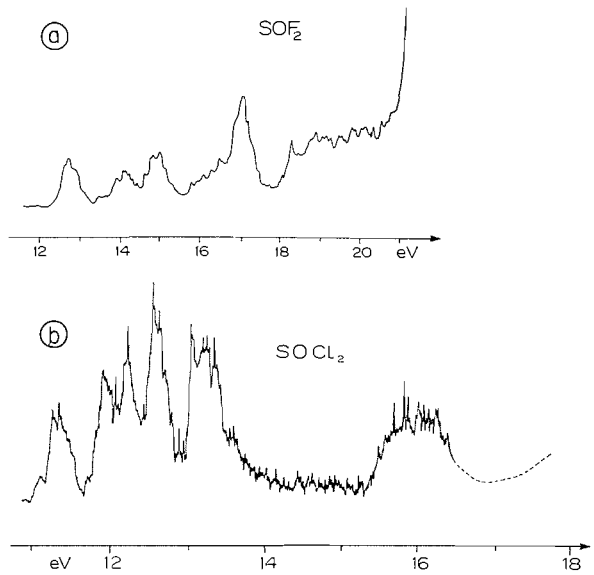

FIG. 5. The HeI photoelectron spectra of (*a*) thionyl fluoride and (*b*) thionyl chloride.

to indicate agreement with the order obtained in the calculations. Our spectrum and analysis of the band is almost identical to that of Eland and Danby (8). It is noted that the first component with adiabatic i.p. 13.01 ± 0.05 eV is narrower in our spectrum and has a vertical i.p. of 13.24 eV. The second component has a vertical i.p. of 13.47 eV but the adiabatic value is not obvious. Eland and Danby prefer to place this at about the same energy as the vertical of the first component (~13.25 eV), but we believe that it may be at least one and possibly up to three vibrational intervals (ν_2) below this. Vibrational analysis of the first component indicated excitation of both the stretching (1100 cm^{-1}) and bending vibrations (~400 cm^{-1}) and of the second, only the bending vibration (~480 cm^{-1}). The following analysis can be made, taking into consideration the oxygen–oxygen antibonding nature of both orbitals involved. The b_2 orbital is a σ type orbital and thus will have considerably more oxygen–oxygen overlap than the a_2 orbital. Therefore, it is likely to cause a larger angle change on ionization and hence a longer progression in the bending vibration. This has been confirmed by calculation (15*b*) and fits well with the b_2 orbital being responsible for the second component of the band. Although normally a decrease in a stretching frequency on ionization indicates a bonding electron has been removed, a decrease in the bending frequency does not necessarily mean this. In other bent triatomics, *e.g.* NO_2 (19) there is always a decrease in the bending vibration on ionization from these orbitals. In NO_2, which has one electron missing from the highest a_1 orbital compared to SO_2 and a bond angle of 134°, the $^3B_2$ and $^1B_2$ states produce similar p.e. bands to the second component referred to above. The decreases in the vibrational spacing from the neutral molecules and the length of the progressions are also simi-

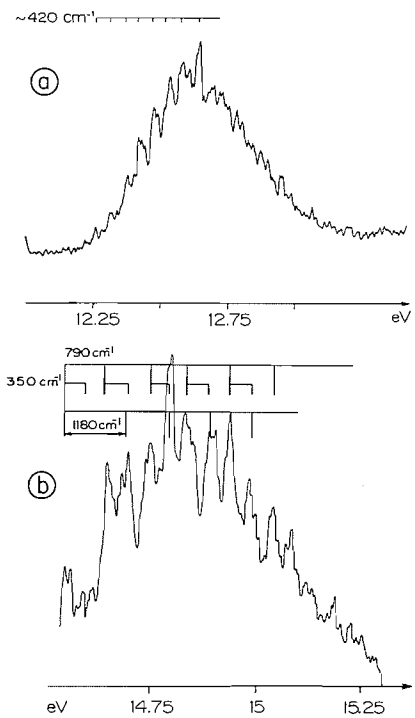

FIG. 6. The first and third bands in the HeI photoelectron spectrum of SOF_2.

lar, indicating that the b_2 orbital is involved in both NO_2 and SO_2. The narrower contour of the first component suggests the more nonbonding a_2 orbital. The excitation of the stretching vibration is consistent with the three times greater p_π–d_π overlap for the a_2 orbital than the b_2. However, similar structure is observed in the $^3A_2$ band of NO_2 where this cannot be the explanation.

In contrast to SO_2 where the b_2 orbital is the third highest in energy, O_3, with the same molecular structure, has the b_2 orbital at highest energy at about the same energy as the a_1 orbital (18, 19). This would indicate a larger "lone pair-lone pair" interaction for the in-plane b_2 orbital probably due to the smaller non-bonded O—O distance. The observed vibrational structure on these states in O_3 is compatible with our assignment of the second band in SO_2, as the i.p. from the b_2 orbital has only a progression on the bending vibration but that arising from the a_2 has progressions involving both the stretching and the bending vibration.

The third band of SO_2 also presents problems in assignment as, although originally it was (8) postulated that there were three components, it has been suggested that only two ionization processes are involved. In fact, Brundle *et al.* (19) assign the ionization from the b_2 σ SO orbital as being at 20.6 eV. Our p.e. spectrum of SO_2, like that of other workers, does not show any obvious structure which could be considered to belong to a third component. The observed structure is well interpreted as belonging to two processes with adiabatic i.p.'s of 15.99 and 16.33 eV and vibrational spacings of 800 and 950 cm^{-1} respectively. If we assign these two components to the $^2A_1$ and $^2B_1$ states of SO_2^+, the order is not obvious. Comparison with the SO_2X_2 species indicates that the $7a_1$ orbital may produce a sharper p.e. band. Therefore, we prefer to assign the higher i.p. (16.33 eV) to the $^2A_1$ state and the

lower (15.99 eV) to the $^2B_1$ state. This is in agreement with the calculated order (15). However, the calculations place the $7a_1$, $2b_1$, and $4b_2$ orbitals close together and in one case (15*b*) the $4b_2$ orbital is predicted to be above the $2b_1$. In our spectrum the third band does appear to be much stronger than the other two, which may be taken as an indication of three components. In this event the 20.6 eV band would correspond to the $6a_1$ orbital.

Sulfuryl Fluoride (SO_2F_2)

By comparison with SO_2 and difluorocompounds, *e.g.* OF_2, CH_2F_2, and SiH_2F_2 (17), one would expect at least eight i.p.'s in the region below 21 eV, corresponding roughly to the four oxygen and four fluorine "lone pair" orbitals. Some of these, of course, will have considerable bonding contributions but the description suffices for the moment. We expect two low i.p.'s from mainly oxygen non-bonding orbitals (a_2, b_2) together at 13–14 eV as in SO_2 (since there will be little interaction of these orbitals with the fluorines) and two higher i.p.'s from sulfur–oxygen π bonding orbitals (a_1, b_1). Similarly, by comparison with F_2O, CH_2F_2, and SiH_2F_2 (17), the two non-bonding fluorine "lone pair" i.p.'s (a_2, b_1) are expected at about 16 eV and there will also be two higher binding energy fluorine "lone pair" i.p.'s (a_1, b_2) which have considerable σ bonding character.

Turning to the p.e. spectrum of SO_2F_2 (Fig. 2*a*) it is noted that there are six distinct bands at (*i*) 13–14 eV; (*ii*) 15–16 eV; (*iii*) 16.7–17 eV; (*iv*) 18–18.5 eV; (*v*) 19.7–20.1 eV; (*vi*) 20.80 eV. The first two bands have an integrated intensity about twice that of the next two and the band contours and vibrational fine structure (see below) indicate the presence of two components in both cases. Bands (*i*) and (*ii*) are then assigned to the non-bonding oxygen and fluorine "lone pairs" respectively in agreement with the above

argument. We now discuss each band separately. The vertical i.p.'s and any resolved ionic vibrational spacings are given in Table 1.

Band (i)

Clearly, this band (Fig. 3*a*) has two components. The first is broad with adiabatic i.p. at *ca.* 13.0 eV and vertical i.p. at *ca.* 13.55 eV. The lack of vibrational structure may indicate the short lifetime of the ion in this state. The second component is much narrower and overlaps the center of the band, and has an adiabatic i.p. apparently at 13.55 eV and a vertical i.p. of 13.61 eV with visible but complex vibrational structure. We tentatively postulate that the principal progression (340 cm^{-1}) is on ν_4 (which is at 384 cm^{-1} in neutral SO_2F_2) and there is another on ν_4 displaced by 500 cm^{-1}, one quantum of ν_3.

The assignment of which of these two components arises from the $2a_2$ (or $6b_2$), mainly oxygen non-bonding orbital is not straightforward. In the second band of SO_2 the higher binding energy component was broader with a progression on the bending frequency but in this case the lower binding energy component is broader and a progression on the OSO bend is not observed. There is little similarity between the vibrational structure on the $^2A_2$ state in SO_2^+ and the second component of this first band in SO_2F_2. Therefore, although on the basis of band shapes it is possible that the assignment of the "non-bonding" oxygen orbitals is reversed compared to SO_2, there is no further confirmation from the observed structure. From qualitative overlap considerations and comparison with other similar "lone pairs" the order should be $6b_2 > 2a_2$, especially if there is considerable d orbital interaction which will be three times as great for the a_2 orbital. This is the order we prefer, as a_2 bands are normally sharper even if there is some d orbital participation (*e.g.* in SiH_2Cl_2 (7)). Also, as the inner a_2 orbital, which is mainly fluorine–fluorine anti-bonding, will be closer than the next highest b_2 orbital, which is fluorine–fluorine bonding, more fluorine character is expected in the $2a_2$ orbital than the $6b_2$ orbital. Thus, excitation of ν_4 is more likely on ionization from the $2a_2$ orbital. However, the order of these two states must remain somewhat speculative.

Band (ii)

This band is plainly made up of two overlapping components each with one main vibrational progression (Fig. 3*b*). The first component has an adiabatic i.p. at 14.89 eV and a regular progression of at least 11 peaks with separation 330 ± 50 cm^{-1}, the tenth peak coinciding with the first peak of the second component. The vibration which is excited must be ν_4, which is 384 cm^{-1} in the neutral species. Using Turner's relationship (20)

$$\text{i.p. (vertical)} - \text{i.p. (adiabatic)} = 1.2\,(\omega_{\text{neutral}}/\omega_{\text{ion}} - 1)$$

and assuming $\omega_{\text{ion}} = 320$ cm^{-1}, the vertical i.p. is at 15.18 eV, which is the most distinct peak. The second component appears to commence at 15.23 eV, *i.e.* coincident with peak 7 of the first component, although it is conceivable that the true adiabatic i.p. is lower at 15.10 eV. Comparing the intensity of the two series we prefer 15.23 eV as the adiabatic value. There is a regular progression of at least seven peaks with a spacing of 1050 ± 50 cm^{-1} which may correspond to ν_1, the symmetric SO stretch, at 1269 cm^{-1} or to ν_2, the symmetric SF stretch at 848 cm^{-1} in neutral SO_2F_2. There is also an indication of weak peaks between the peaks of the main progression, which would correspond to the addition of one quantum of ν_3 (546 cm^{-1} in SO_2F_2). For the second component of this band Turner's relationship gives the vertical i.p. at 15.44 eV, if it is assumed that ν_1 is the excited vibration. This value is between the two peaks at 15.35 eV and 15.48 eV, both of which could be considered as the vertical i.p. for the process; we prefer the value of 15.35 eV.

The progression on ν_4 in the first component of this band is consistent with ionization from a fluorine "lone pair" orbital. This vibrational structure could point to either the $1a_2$ or the $6b_1$ orbital, both of which are antibonding between the two fluorine atoms. There is no obvious preference, however we prefer the assignment $1a_2$ for the following reasons. First, this fits better the assignment of the p.e. spectra of other difluoro-compounds studied (17) and secondly there would be another a_2 orbital fairly close but at higher energy. Finally the F—F σ overlap of the $6b_1$ orbital is more likely to result in extensive excitation of the bending vibration (in the first component) compared to the π overlap of the $1a_2$ orbital.

Band (iii)

This band with an adiabatic i.p. of 16.68 eV

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

is shown in Fig. 3*c* and the observed structure is interpreted in terms of the excitation of three vibrational modes. The principal progression consists of three quanta with spacing 1130 cm^{-1} and corresponds to ν_1, the S—O stretching vibration. One quantum of ν_3 (520 cm^{-1}) and of ν_2 (840 cm^{-1}) is observed. Only ν_1 is significantly decreased from the value in the neutral species (see Table 1). The relative strength of the O—O transition indicates the removal of a non-bonding or weakly bonding electron. The major excitation of the SO stretching vibration and weak excitation of the OSO bending vibration together with the bands in this region in the p.e. spectrum of SO_2 suggest that a sulfur–oxygen π electron is involved. This is further confirmed by the p.e. spectrum of SO_2Cl_2 which has a band with very similar vibrational structure at similar binding energy. By comparison with SO_2 there are two possible assignments corresponding to ionization from either the $11a_1$ or $5b_1$ SO π orbitals. For various reasons we prefer the former. First, there are no a_1 orbitals at higher energy, whereas the mainly fluorine "lone pair" $6b_1$ orbital is just over one eV higher in energy. Secondly, the $5b_1$ orbital is expected to be more strongly S—O π bonding; this occurs at higher binding energy and gives rise to a broader p.e. band than the $11a_1$. The structure on this band certainly does not correspond to that of the fourth i.p. of SO_2, but there are similarities with the fifth i.p. band. The assignment of this i.p. in SO_2 to ionization from the $7a_1$ orbital is in agreement with the calculated order (15). In both SO_2 and SO_2F_2 this orbital will contribute less to SO π bonding than the b_1 SO π orbital because of the difference in the overlap contributions.

Band (iv)

This band has a vertical i.p. at 18.36 eV and adiabatic i.p. apparently at 17.89 eV. We believe that this ionization is most likely to arise from the SO π bonding $5b_1$ orbital. The orbital is then about 2 eV lower in energy than in SO_2 and must be stabilized by the effect of the higher energy F "lone pair" orbital, and by the inductive effect, and probably contributes considerably to producing a stronger SO bond in SO_2F_2 than in SO_2 as discussed in the introduction to this paper.

Band (v)

The first four peaks of this band are well resolved, while the remaining bands are broader and very asymmetric (Fig. 3*d*). This may be due to the instability of these vibrational states, but there is also the possibility that a second ionization process occurs. If the band is assumed to result from only one ionization process, the adiabatic i.p. is 19.70 eV and the vertical i.p. 19.89 eV. The observed structure may be interpreted in terms of a progression with a spacing of 800 cm^{-1} which corresponds to ν_2, the S—F stretching vibration (848 cm^{-1} in neutral SO_2F_2), and a second progression involving ν_2 displaced by 500 cm^{-1}, corresponding to one quantum of ν_3, the OSO bending vibration (544 cm^{-1} in SO_2F_2). In view of the vibrational structure and previous assignments this ionization must be from an orbital with considerable fluorine character. We postulate that this is the $5b_2$ fluorine orbital which will also have some S—O_2 σ bonding character. The $4b_2$ SO σ bonding orbital in SO_2 is thought to be close in energy to the $2b_1$ and $7a_1$ SO_2 π orbitals. It would be expected that the two fluorine atoms would have a greater stabilizing influence on the σ orbital than on the π orbital (perfluoro effect), and we can say that the b_2, SO_2 σ orbital may be stabilized by at least 2 eV from SO_2 to SO_2F_2.

Band (vi)

This band, whose vertical i.p. may not be observed in our spectrum, probably arises from ionization from the $10a_1$ orbital. Summarizing our assignments, the orbital configuration of SO_2F_2 is

$$(6b_2)^2\ (2a_2)^2\ (6b_1)^2\ (1a_2)^2\ (11a_1)^2\ (5b_1)^2\ (5b_2)^2\ (10a_1)^2$$

Sulfuryl Chloride (SO_2Cl_2)

Below 15 eV, in addition to ionization from the two essentially oxygen "lone pair" orbitals (a_2, b_2), we expect i.p.'s arising from the four chlorine "lone pair" orbitals to be in the order b_1, a_2, b_2, a_1 on simple considerations of the overlap contribution; the a_1 orbital is thought to occur at higher binding energy and probably arises from the S—Cl σ bonding orbitals (a_1, b_1). It appears, by comparison with the other Cl_2X species, SO_2 and SO_2F_2, that neglecting any mutual interaction these outer "lone pair" orbitals would be close together. Above 15 eV we anticipate there will be two S—O σ orbitals.

Seven distinct bands are observed in the p.e. spectrum (Fig. 2*b*) and it is likely that an eighth

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

occurs at about 20.1 eV. Only four bands below 15 eV are apparent, but the cross-sections of the first at 12.41 eV and the fourth at 14.2 eV are approximately three times those of the second and third bands. This indicates that the first and fourth bands contain at least two, and possibly three, components. The seventh band at 17.61 eV may also contain two components. We shall now discuss the bands individually.

Band (i)

The experimental intensity ratios quoted above and the fact that we expect at least 11 states below 21.2 eV indicate that this band probably arises from ionization of three orbitals. However, it was not possible to resolve them, thus we place all the vertical i.p.'s at 12.41 eV, the band maximum. The onset of the band is at 12.05 eV.

Assignment of the three possible components requires consideration of all the "lone pair" ionization processes possible in this region. In the unperturbed state, the a_2 and b_2 oxygen "lone pairs" (*e.g.* in SO_2) are at only slightly higher binding energy (13.5 eV) than the chlorine "lone pairs" in other dichloro compounds (*e.g.* 12.8 eV in Cl_2O, 13.2 eV in Cl_2CO (17)). Thus the interaction between the two a_2 orbitals and the two b_2 orbitals is likely to be such that the resultant molecular orbitals would be of intermediate character between pure oxygen or chlorine lone pairs. In addition, this interaction would destabilize one set of the a_2 and b_2 orbitals so that they are of comparable energy to the lowest binding energy chlorine "lone pair" (b_1) orbital. Thus, we believe that the three states in this band are the $^2A_2$, $^2B_2$ and $^2B_1$.

Band (ii)

This band has an adiabatic i.p. of 13.0 eV and a vertical i.p. of 13.20 eV. There is a poorly resolved progression of broad peaks separated by *ca.* 500 cm^{-1} (Fig. 4*a*), which may correspond to either ν_3, the OSO bend, or to ν_2, the S—Cl stretch, at 560 cm^{-1} and 405 cm^{-1} respectively in the neutral molecule (6*b*). In SO_2 and SO_2F_2 the a_2 and b_2 oxygen "lone pair" orbitals occur in this binding energy region. However, in view of the above discussion concerning the first band we expect these orbitals to be stabilized in SO_2Cl_2 by mixing with the corresponding chlorine "lone pair" orbitals. Therefore, we assign this band to ionization from the a_1 chlorine "lone pair" orbital, however, ionization from the inner a_2 (or b_2) orbital remains a possibility.

Bands (iii) and (iv)

These two bands, shown in Fig. 4*b*, overlap in the region 13.5–14.5 eV. The third band has a vertical i.p. of 13.74 eV and consists of two peaks separated by 640 cm^{-1}, any other peaks being obscured by the strong fourth band. The 640 cm^{-1} spacing is assigned to ν_3, the OSO bend which occurs at 560 cm^{-1} in the neutral molecule. This third band probably corresponds to the removal of an electron from either the a_2 or b_2 oxygen "lone pair" orbitals, though we suggest that these may have substantial chlorine character (see above). The increase in ν_3 in the ion points to the b_2 orbital which is more O—O antibonding than the a_2. In this event the b_2 orbital has been stabilized slightly relative to SO_2 and SO_2F_2.

The broad fourth band, because of its high relative intensity, probably contains three components. We attribute these to ionization from the a_2 oxygen "lone pair" and the a_1 and b_1 S—Cl σ bonding orbitals. It was not possible to obtain vertical i.p.'s for any of these processes. The band maximum is 14.2 eV.

Band (v)

The vibrational structure of this band (Fig. 4*c*) with an adiabatic i.p. of 16.93 eV, is very similar to that observed in the 16.68 eV band in SO_2F_2 (Fig. 3*c*). However, in this case all four symmetric vibrations appear to be excited. Excitation of ν_1 at 1170 cm^{-1} and ν_2 at 380 cm^{-1} is beyond doubt. However, the assignment of single quantum excitation of ν_3 (580 cm^{-1}) and ν_4 (200 cm^{-1}) is slightly more speculative. ν_4 does appear to be excited, but the peaks corresponding to ν_3 could be attributed to multiple excitation of ν_4, which may occur as well as excitation of ν_3 thereby causing the poor resolution. The measured vibrational spacings are insignificantly different from the groundstate values (see Table 2). In contrast, in SO_2F_2 there is a significant decrease in ν_1 (from 1269 cm^{-1} to 1130 cm^{-1} in the ion) and this may be an indication of stronger S—O π bonding in this molecule. Another indication of this may be obtained indirectly by considering the greater excitation of halogen-involved vibrations for SO_2Cl_2. This is shown by excitation of the Cl—S—Cl bend whereas excitation of the F—S—F bend is lacking in the corresponding band in SO_2F_2 and, also, by the increased population of levels involving the S—X stretch (ν_2). It follows that if there is more elec-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

tron density in the S—Cl bonds there must be less in the S—O bonds. Despite this, it is interesting to note that this band is at higher binding energy in SO_2Cl_2 than in SO_2F_2. However, this seems to be further support for the assignment to ionization from the a_1 π SO orbital. In SO_2F_2 there are no higher energy a_1 orbitals but there are two a_1 orbitals just lower in energy (the F "lone pair" and a σ bonding orbital). However in SO_2Cl_2 we assign the Cl "lone pair" and σ S—Cl orbitals to be at higher energy. Obviously the opposite influence of these interactions could place the orbital at higher energy in SO_2F_2. The shape of the band for both molecules makes it clear that the a_1 π SO orbital is very much the less bonding of the two SO π orbitals.

Bands (vi) and (vii)

These bands, which have no vibrational structure, have maxima at 17.61 and 18.12 eV, and are assigned to ionization from the b_1 π SO orbital and b_2 σ SO orbital respectively. The order could be reversed but we prefer to have the π orbital higher than the σ orbital. The b_1 orbital is considerably stabilized compared to that in SO_2 (16.5 eV) and as the other b_1 orbitals in SO_2Cl_2 are at much higher energy, it seems that this is caused by greater π interaction between the sulfur and oxygen atoms. The interaction must be even greater in SO_2F_2 as the b_1 orbital moves at least to -18.34 eV.

Thionyl Fluoride (SOF_2)

By comparison with SO_2F_2 and SO_2, at least seven i.p.'s should be expected for SOF_2 below 21.2 eV, corresponding roughly to ionization from the sulfur lone pair, oxygen lone pair, two fluorine lone pairs, sulfur–oxygen π orbital, and two sulfur–fluorine π orbitals in order of increasing binding energy. It is possible that the sulfur–oxygen σ bonding level is above 21 eV.

Unfortunately it was not easy to obtain a good p.e. spectrum of SOF_2 but five ionization processes are clearly visible below 17 eV (Fig. 5*a*) and in the broad band extending from 18 to 20.5 eV there is likely to be more than one component.

Band (i)

This band with an adiabatic i.p. of 12.25 eV and vertical i.p. of 12.60 eV, has a clear vibrational structure up to the position of the vertical i.p. (Fig. 6*a*). The peaks are irregular and there is the possibility of a double progression. The average spacing of the eight peaks is 420 cm^{-1}, with a decrease through the progression except between the seventh and eighth peaks. This vibrational frequency could correspond to two frequencies in the neutral species, the bending of the SO bond relative to the F—S—F plane (326 cm^{-1}) or the F—S—F bending vibration (526 cm^{-1}). Judging from the width of the peaks it is possible that progressions involving both frequencies are present. The loss of structure just above the vertical transition may be due to dissociation of the ion, or to the ion becoming planar. The ionization process producing this band must involve an a′ orbital localized mainly on the sulfur atom (*i.e.* the sulfur "lone pair"). The corresponding vertical i.p. in SO_2, to which SOF_2 can be compared, is 12.50 eV. The CNDO/2 calculations which we have carried out on SOF_2 agree with this assignment. This a′ orbital will almost certainly be antibonding with respect to the oxygen and fluorine atoms, though the larger interaction should be with the next higher a′ orbital which has mostly π S—O character (see below). This suggests that on ionization the S—O wagging vibration is excited, which requires an increase from 326 cm^{-1} in the neutral species to 420 cm^{-1} in the ion. This would only be possible if there was a strong antibonding interaction between sulfur and oxygen. Although the ionic frequency is closer to the F—S—F bending vibration of the neutral (526 cm^{-1}), there seems no ready mechanism for exciting this vibration. Accepting the first assignment, the decrease in the vibrational spacing through the series and the loss of structure could be explained in a similar manner to the corresponding effect in the $^2A_1$ ionic state of H_2S^+ (21). If the ion becomes planar as the energy increases, the vibrational–rotational energy levels would be doubled, which would reduce the spacing between levels to *ca.* 200 cm^{-1}, which was just beyond the resolution of the spectrometer in this case.

Band (ii)

The adiabatic i.p. of the second band is *ca.* 13.4 eV and the vertical i.p. 14.14 eV. There is an indication of a progression of peaks with a separation of *ca.* 1000 cm^{-1}. By comparison with the p.e. spectra of SO_2 and SO_2F_2 we assign this band to ionization from the "non-bonding" oxygen a″ orbital and thus excitation of the S—O stretching frequency (1308 cm^{-1} in SOF_2) is probably involved. It is interesting that, al-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

though the highest energy orbitals in SO_2 and SOF_2 (sulfur "lone pairs") are at the same energy, the oxygen "lone pair" in SOF_2 is stabilized. This is due to the lower symmetry of SOF_2 allowing more SO π character in the oxygen lone pair orbital, as well as the orbital contraction effect mentioned above. It also partly accounts for the stronger SO bond in SOF_2 compared to SO_2.

Band (iii)

The complex structure of the third p.e. band can be seen in Fig. 6*b*. Both the adiabatic (14.55 eV) and vertical (14.80 eV) i.p.'s are well-defined, though the assignments of ionic vibrational frequencies are clearly dependent on the interpretation of the fine structure. Clearly, two or more normal modes are excited in the ion. We suggest that the principal structure is due to strong excitation of an ionic mode of frequency 790 cm^{-1} as shown in Fig. 6*b*. The additional peaks are attributed to weak excitation of ionic modes of frequency 1180 and 350 cm^{-1}. The 1180 cm^{-1} spacing must correspond to ν_1, the S—O stretch, slightly reduced from its value of 1308 cm^{-1} in the ground state molecule. The 790 and 350 cm^{-1} vibrations correspond to ν_2, the S—F stretch, and ν_4 respectively, which are both insignificantly different from the ground state values. The excitation of several ionic modes is not surprising in a molecule with low symmetry since the orbitals are not well-defined. The similarity of the frequencies in the ion and the neutral species indicates that the parent orbital is essentially non-bonding.

By comparison with a number of other difluoro compounds (17), we assign this band to an a″ fluorine "lone pair" orbital. These have the a_2 and b_2 (in C_{2v} symmetry) orbitals (which are antisymmetric with respect to the plane bisecting the F—S—F angle) around 15 eV. In the C_{2v} molecules the a_2 and b_2 orbitals are fairly close in energy (normally within 0.5 eV). In C_s symmetry both of these become a″ orbitals and interaction between these should cause a much larger separation than that between the a_2 and b_2 orbitals in C_{2v} symmetry. No matter which of the next two i.p.'s involves ionization from the other fluorine lone pair a″ orbital, it is seen that the fluorine orbitals are split apart relative to the other difluoro species.

Band (iv)

This band stretching from 15.5 to 17.5 eV has two structureless components. One is extremely broad and its vertical i.p. is difficult to determine but is probably about 16.6 eV. The other has a half width of *ca.* 0.6 eV, is sharper and has a vertical i.p. of 17.0 eV. By comparison with SO_2 and in line with the discussion of the third band above, the orbitals involved must be (*a*) mainly a″ fluorine "lone pair" and (*b*) mainly a′ π S—O. As the band in this region in $SOCl_2$ (see below) is broad, it could be inferred that the first component is the a′ orbital. There could however be other ionizations present in this band in $SOCl_2$ and the corresponding bands in SO_2, SO_2F_2, and SO_2Cl_2 are quite sharp. None of the evidence is conclusive as neither of these orbitals would be expected to produce such a broad band. In contrast to our earlier suggestion, we now prefer to assign the sharp band to the a′ orbital.

There are obviously other bands between 18 and 21 eV but the rising background prevents us from distinguishing them.

Thionyl Chloride

By comparison with the other species ten i.p.'s should be observed for this molecule below 21.2 eV, corresponding roughly to the following orbitals; sulfur "lone pair", four chlorine "lone pairs", oxygen "lone pair", two sulfur–chlorine σ orbitals, a sulfur–oxygen π orbital, and sulfur–oxygen σ. As it was extremely difficult to obtain a spectrum of $SOCl_2$ free of SO_2, no vibrational structure was observed on any of the bands. Therefore, we shall discuss the spectrum as a whole and not the individual bands.

The observed spectrum below 17 eV (Fig. 5*a*) consists of six well-defined bands with maxima 11.3, 11.9, 12.21, 12.55, 13.04, and 16 eV. The intensity of the last three bands could be enhanced by some SO_2 impurity, but this effect is probably small. The most interesting point about the spectrum is the lack of spread of the lower bands. As the symmetry of the molecule is low (C_s) with only two irreducible representations (a′, a″), it might have been thought that there would be some fairly large interactions between orbitals of the same symmetry. The spectrum indicates that assignments of higher symmetry species on the basis of strong interactions between orbitals of the same symmetry may be erroneous.

The first i.p.'s of thionyl fluoride and dimethylsulfoxide at 12.6 and 9.3 eV respectively are both assigned to the removal of electrons from

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

sulfur "lone pair" orbitals. The ionization arising from the corresponding orbital in $SOCl_2$ should fall between these two values, and there are three bands which fit this criterion at 11.3, 11.9, and 12.21 eV. Since the inductive effect of fluorine is considerably greater than that of chlorine, we attribute the first band at 11.3 eV to ionization from an essentially sulfur "lone pair" orbital (a′). Additional evidence for this assignment may be drawn from the fact that ionizations arising from chlorine "lone pair" orbitals are normally in the range 11.5–13 eV and in SO_2Cl_2 the lowest binding energy chlorine i.p. is 12.41 eV.

In $SOCl_2$ it is likely that the main oxygen "lone pair" (a″) orbital will be at higher binding energy than the four chlorine "lone pairs", as SO_2 has its second i.p. in the 13–14 eV range. Simply relating the symmetry of the chlorine "lone pair" orbitals to C_{2v} molecules, the order in $SOCl_2$ should be a″, a″, a′, a′, the in-plane S—Cl_2 a″ orbital being at the lowest binding energy and also having the largest interaction with the oxygen a″ "lone pair". On this basis, we tentatively assign the 11.9 eV band to the in-plane a″ chlorine "lone pair". The intensity of the 12.55 and 13.04 eV bands strongly suggests that they consist of more than one component, and such overlapping of i.p.'s was a feature of the SO_2Cl_2 p.e. spectrum (Fig. 2*b*). The out-of-plane a″ chlorine "lone pair", which corresponds to a_2 in C_{2v} symmetry, should possibly produce a sharp p.e. band and so we assign this to the sharp component of the 12.55 eV band. This corresponds well with the sharpest band in the SO_2Cl_2 spectrum at 12.4 eV. The other component of the 12.55 eV band is then assigned as one of the chlorine "lone pair" a′ orbitals (probably in-plane C—S—Cl) and the other i.p. at 12.21 eV is then assigned to the remaining a′ lone pair orbital. These assignments would fit with most other simple di-chloro compounds. The 13.04 eV band must then have the mainly oxygen "lone pair" orbital (a″) and both sulfur–chlorine σ bonding orbitals. These latter would then be very high in energy. This is not, however, unreasonable when it is considered that the corresponding orbitals in SO_2Cl_2 were assigned at 14.1 eV and the S—Cl bond in SO_2Cl_2 is somewhat stronger on the basis of S—Cl bond lengths: $SOCl_2$, r(S—Cl) = 2.07; SO_2Cl_2, r(S—Cl) = 1.00 Å. The oxygen "lone pair" orbital is almost at the same energy as the non-bonding "lone pairs" in SO_2 (13.3, 13.6 eV) and intermediate between those of $(CH_3)_2SO$ (10.43 eV) and F_2SO (14.14 eV). In dimethylsulfoxide the oxygen "lone pair" is destabilized because of the lower overall charge and the lack of interaction with orbitals on the sulfur atom. The 16 eV band must be assigned to ionization from the a′ SO π orbital. This orbital is the least stable of all the SO π orbitals in the molecules studied here.

Bonding in Sulfuryl and Thionyl Halides

In the introduction we presented the argument, based on π bonding changes, used to explain various properties of the SO bonds in these compounds. Many of these properties have been compared (6) for a large series of sulfur–oxygen compounds and the relevant data for the five compounds studied in this paper are given in Table 4. These data indicate that the SO bond order decreases in the order $SO_2F_2 > SOF_2 > SO_2Cl_2 > SO_2 > SOCl_2$. We now examine the i.p.'s for correlations based mainly on the SO orbitals. Table 5 lists some pertinent average i.p.'s for (A) all the mainly oxygen "π type" orbitals both "lone pair" and SO π, (B) the SO π orbitals, and (C) the low binding energy oxygen "lone pair" orbitals. The energy of the b_1 π SO orbital is also given for the di-oxygen species.

Although none of the averages show exactly the above trend, the overall average of the "π"

†B = average of the SO π bonding orbitals.
‡C = average of the low binding energy oxygen "lone pair" orbitals.

levels (A) is fairly close to it, *i.e.* $SO_2F_2 \approx SOF_2 > SO_2Cl_2 > SO_2 > SOCl_2$. The range of the average SO π levels (B) is 1.5 eV, whereas the range of the oxygen "lone pair" levels (C) is only 0.8 eV and omitting SOF_2 it is only 0.2 eV. It seems reasonable to suppose that a π bonding orbital would be more influenced by effective charge than the virtually non-bonding orbitals on the oxygen atoms. Current bonding theory would, however, indicate that the a_2 and b_2 oxygen lone pair orbitals have some interaction with the sulfur d orbitals and that this should increase with the charge on the sulfur atoms (1). From SO_2 to SO_2F_2 the "lone pairs" (a_2, b_2) are stabilized on the average by only 0.22 eV whereas the π orbitals (a_1, b_1) are stabilized on an average by 0.9 eV. On symmetry grounds, the d orbitals should affect both those averages by about the same amount. This may be taken as an indication that the major contribution to any increased π bonding in SO_2F_2 is not the increased sulfur d orbital contribution, but the increased sulfur orbital contribution. This is especially noticeable in the b_1 π SO orbital which moves from 16.6 eV in SO_2 to 18.34 eV in SO_2F_2.

It must be borne in mind, however, that the assignments of some bands in the p.e. spectra reported here, with the exception of SO_2 and possibly SO_2F_2 are tentative and, therefore, any conclusions concerning bonding in these molecules based on ionization energies are necessarily of a speculative nature.

We thank the National Research Council of Canada for generous financial support. The awards of a N.A.T.O. Fellowship (to D.C.) from the Science Research Council of Great Britain and a Killam Fellowship (to R.A.N.M.) from the University of British Columbia are gratefully acknowledged.

Electric Dipole Moments and Conformations of ortho-, meta-, and para-Fluoroacetophenones and of ortho-, meta-, and para-Trifluoromethylacetophenones

ERNST BOCK, ROBERT WASYLISHEN,[1] AND BERNARD E. GABOURY
Parker Chemistry Laboratory, University of Manitoba, Winnipeg, Manitoba

AND

EDWARD TOMCHUK
Department of Physics, University of Winnipeg, Winnipeg, Manitoba

Received June 30, 1972[2]

The dipole moments of ortho-, meta-, and para-fluoroacetophenone and of ortho-, meta-, and para-trifluoromethylacetophenone were determined in dilute benzene and carbon tetrachloride solutions at 25 °C. In addition the dipole moments and the total energies of the above molecules and of acetophenone, fluorobenzene, and trifluoromethylbenzene were computed for different molecular conformations by the INDO molecular orbital approximation. In some cases there is quantitative agreement between the experimental dipole moments and the INDO computed dipole moments. The most probable conformation for different fluoroacetophenone and trifluoromethylacetophenone molecules is suggested.

Les moments dipolaires de l'ortho-, méta-, et para-fluoroacétophénone et de l'ortho-, méta-, et para-trifluorométhylacétaphénone ont été évalués à 25 °C dans des solutions diluées de tétrachlorure de carbone et de benzène. En plus, les moments dipolaires et les énergies totales de molécules mentionnées et de l'acétophénone, du fluorobenzène, et du trifluorométhylbenzène ont été calculés pour différentes conformations moléculaires par l'approximation des orbitales moléculaires INDO. Dans certains cas, on a noté un accord quantitatif entre les moments dipolaires expérimentaux et les moments dipolaires calculés (INDO). L'on suggère la conformation la plus probable pour différentes molécules de fluoroacétophénone et de trifluorométhylacétophénone. [Traduit par le journal]

Can. J. Chem., 51, 1906 (1973)

Introduction

In a recent publication (1), we reported on the electric dipole moments and conformations of *o*-, *m*-, and *p*-fluorobenzaldehydes. It was shown there that the dipole moment values computed using the INDO molecular orbital approximation (2) were in remarkably good agreement with the experimental dipole values. We thought it interesting to see whether the same close agreement between theory and experiment would prevail in the case of more complicated molecules. To this end, we computed (using the INDO molecular orbital approximation) and measured (in dilute benzene and carbon tetrachloride solution at 25 °C) the electric dipole moments of ortho-, meta-, and para-fluoroacetophenone and ortho-, meta-, and para-trifluoromethylacetophenone, and of acetophenone, fluorobenzene, and trifluoromethylbenzene.

[1]Holder of an NRCC Scholarship, 1971–1972.

[2]Revision received February 23, 1973.

Experimental

Solvent

Fisher certified reagent benzene and Fisher certified reagent carbon tetrachloride were used as solvents. The solvents were dried by repeated shaking with Linde molecular sieve 4A prior to their use.

Solute

The solute molecules were obtained from the PCR Incorporated Chemical Co. and were used without further purification. However, the purity of the solutes was checked by gas chromatography and n.m.r. In all cases the impurities amounted to less than 1 mol %.

Experimental Procedure

The dipole moment apparatus and experimental procedure have been described elsewhere (3). The experimental error in the dipole moment values is estimated to be ± 0.05 D.

The INDO computations were carried out on an IBM 360/65 computer system, using "standard" molecular geometries (2). In each case less than 25 cycles in the self-consistent-fitting procedure were required to obtain convergence in the electronic energy to within 10^{-6} a.u. = 0.6 cal/mol.

Results and Discussion

The solution dipole moments were calculated after the method of Smith (4).

$$[1] \qquad \mu^2 = \frac{27kT}{4\pi N} \frac{M_2}{d_1(\varepsilon_1 + 2)^2} (\alpha - \nu)$$

where μ is the dipole moment of the solute molecule, k the Boltzmann constant, N the Avogadro number, M_2 molecular weight of the solute, d_1 and ε_1 the density and dielectric constant of the pure solvent, α the slope of the curve $\varepsilon_{12} = \varepsilon_1 + \alpha w_2$, where ε_{12} is the dielectric constant of the solution, and w_2 the weight fraction of the solute in solution, and ν is the slope of the curve $n_{12}^2 = n_1^2 + \nu w_2$ where n_{12} and n_1 is the refractive index of the solution and solvent respectively.

The experimental results are presented in Table 1 in terms of α and ν. The dipole moments derived from these data are summarized in Tables 2, 3, and 4. Included in these Tables are the moment values calculated from group moments and using the INDO calculation for different molecular conformations, the energy difference, ΔE, of the various molecular conformations relative to the most stable conformation calculated using the INDO approximation, the mean equilibrium dipole moment, $\mu_{(eq)}$, calculated on the assumption that the two conformers are in equilibrium, and the dipole moment value, $\mu_{(fr)}$, which would result from a free rotation of the acetyl group about the C_1—C_2 bond (see Figs. 1 and 2). The mean equilibrium dipole moment was calculated using the expression shown in eq. 2 (5). Here $\mu_{(cis)}$ and $\mu_{(trans)}$ is

$$[2] \qquad \frac{\mu^2_{(trans)} + \mu^2_{(cis)}\, e^{(\Delta E/-RT)}}{1 + e^{(\Delta E/-RT)}} = \mu_{(eq)}^2$$

the dipole moment of the *O-cis* and *O-trans* conformer respectively estimated from group moments. The latter were obtained from the experimental dipole moments of acetophenone, fluorobenzene, and trifluoromethylbenzene respectively. The angle between the dipole moment and the C_1—C_2 bond direction in

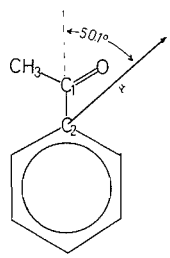

FIG. 1. Direction of the electric dipole moment of acetophenone as calculated by INDO.

acetophenone was computed using the INDO approximation. The angle turned out to be 50.1°. This value is intermediate between the values for this angle given by Smyth (6) and Minkin *et al.* (7); *viz.* 57° and 48° respectively. The values of $\mu_{(fr)}$ resulting from a free rotation of the acetyl group about the C_1—C_2 bond direction were calculated after the method of Fuchs (8).

Fluoroacetophenones

From the entries in Table 2 it is apparent that

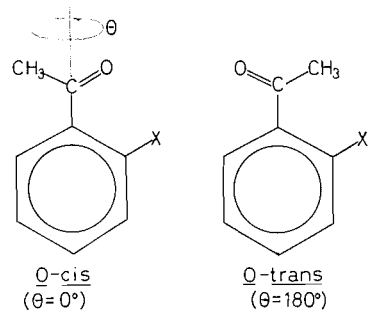

FIG. 2. *O-cis* and *O-trans* conformation of substituted acetophenones. X = F for fluoroacetophenones and X = CF_3 for trifluoromethylacetophenone.

in the case of *o*-fluoroacetophenone the *O-trans* conformer is the more stable conformer. Moreover, it would appear that the energy barrier to free rotation of the acetyl group is at least 1.35 kcal/mol and is high enough to prevent the free rotation of the acetyl group; *o*-fluoroacetophenone exists as an equilibrium mixture of two conformers in the ratio of 9/1 with the *O-trans* conformer predominating. In the case of *m*-fluoroacetophenone the *cis–trans* energy barrier is at least 0.13 kcal/mol and is evidently not high enough to prevent a free rotation of the acetyl group. Thus the dipole moment calculated assuming free rotation, 2.84 D, is in good agreement with the experimental dipole moment measured in dilute benzene solution, *viz.* 2.86 D. It should be noted in this connection that the group moments used in the calculation of $\mu_{(fr)}$ were derived from measurements in benzene solution. These conclusions are not in harmony with the work of Miller *et al.* (9) who investigated

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

the vapor-phase far i.r. spectra of *o*-, *m*-, and *p*-fluoroacetophenone. These workers found that the *cis–trans* energy barrier for *m*-fluoroacetophenone was >3.5 kcal/mol and was higher than the *cis–trans* energy barrier for *o*-fluoroacetophenone, *viz.* ~3.0 kcal/mol. On the other hand our conclusions are in complete agreement with findings of Smith *et al.* (10) who carried out an n.m.r. study of a number of substituted acetophenones, and with the results of our own n.m.r. studies on *o*-, *m*-, and *p*-trifluoromethylacetophenone.[3] Smith *et al.* found that the coupling constant between the methyl and fluorine in *o*-fluoroacetophenone was unusually large (5.1 Hz at room temperature, we found a value of 4.72 ± 0.02 Hz) and exhibited a marked temperature dependence, decreasing with increase in temperature. Moreover, neither the above authors, nor we, could detect any methyl–fluorine coupling in the case of *m*- and *p*-fluoroacetophenone. Smith *et al.* concluded that the large coupling in the case of *o*-fluoroacetophenone resulted from a "through space" coupling mechanism; *i.e.*, the molecule existed in solution mainly in the *O-trans* conformation. Another remarkable feature of Table 2 is the virtually quantitative agreement between the INDO computed dipole moments and the experimental dipole moments in all those cases in which the molecule can exist in one conformation only in solution.

Trifluoromethylacetophenones

From Table 3 it is apparent that the most stable conformation of *o*-trifluoromethylacetophenone is the one in which the acetyl group is at right angles to the plane of the benzene ring. The INDO calculated dipole moment for the 90°-out-of-the-plane conformation is in remarkably good agreement with the experimentally measured dipole moment. The INDO calculations also suggest that the acetyl group executes a rocking motion of some 20° of arc about the 90°-out-of-the-plane position. The above conclusions are supported by the n.m.r. studies of Smith *et al.* (10) who in contrast to *o*-fluoroacetophenone did not detect any methyl-fluorine coupling in *o*-trifluoromethylacetophenone.[4]

In the case of *m*-trifluoromethylacetophenone it is evident that the molecule in solution exists in two conformations of roughly equal proportion and/or there is free rotation of the acetyl group.

Again we note the remarkable agreement between the INDO calculated dipole moment and the experimental dipole moment in the case of *p*-trifluoromethylacetophenone. In this connection it should be noted that the INDO calculations presumably yield gas-phase dipole moment values. Now it is well known that the solution dipole moment values may differ from the gas-phase values by as much as 10% due to the so-called solvent effect (6, 7).

The financial assistance of the National Research Council of Canada and of the Faculty of Graduate Studies and Research of the University of Manitoba are very much appreciated. We thank Dr. T. Schaefer for helpful discussions and the use of the n.m.r. spectrometer.

[4]We found a small coupling of ~0.4 Hz at room temperature between the methyl protons and the fluorines of the trifluoromethyl group.

Synthesis of Tritium Labelled [8-Arginine]-vasopressin[1]

H. Hutch Holton,[2] Luis A. Branda,[3] and Barbara M. Ferrier
Department of Biochemistry, Division of Health Sciences, McMaster University, Hamilton, Ontario
Received January 2, 1973

Ring tritiated phenylalanine has been incorporated into [8-arginine]-vasopressin synthesized by the solid phase method. The peptide produced has levels of biological activities in agreement with those of the highly purified natural hormone.

La phénylalanine tritiée sur le cycle a été incorporée dans l'(Arg-8) vasopressine, synthétisée selon la méthode de la phase solide. Le peptide obtenu possède des degrés d'activité biologique comparables à ceux de l'hormone naturelle hautement purifiée. [Traduit par le journal]

[8-Arginine]-vasopressin, the antidiuretic hormone of man and most mammals, acts on the kidney. This organ in rats has been shown to bind [8-arginine]-vasopressin (1) and it was suggested that the mechanism of the hormone's action involved an exchange between the peptide disulfide and a membrane thiol group. It is now apparent that this is not an exclusive mechanism of action, since synthetic analogs of [8-arginine]-vasopressin which lack a disulfide group have been shown to retain biological activity (2).

There is considerable evidence that polypeptide hormones bind to sites on the outer surface of their target cell membranes (3), and in order to study the binding properties of [8-arginine]-vasopressin to kidney cell membranes we have found it convenient to synthesize radioactive [8-arginine]-vasopressin by incorporating ring-tritiated phenylalanine in position 3 of the peptide chain (Fig. 1). Tritium, rather than radioactive iodine was chosen as the radioisotope, since it was thought that iodination of [8-arginine]-vasopressin could result in a derivative with significantly altered binding properties. This opinion has recently received support by the demonstration that radio-iodinated oxytocin shows no specific binding to kidney or uterine tissue (4).

The solid phase method of synthesis of [8-arginine]-vasopressin described by Meienhofer and coworkers (5) was used for the synthesis of the required protected nonapeptide precursor to the hormone (Fig. 2). Some modifications were

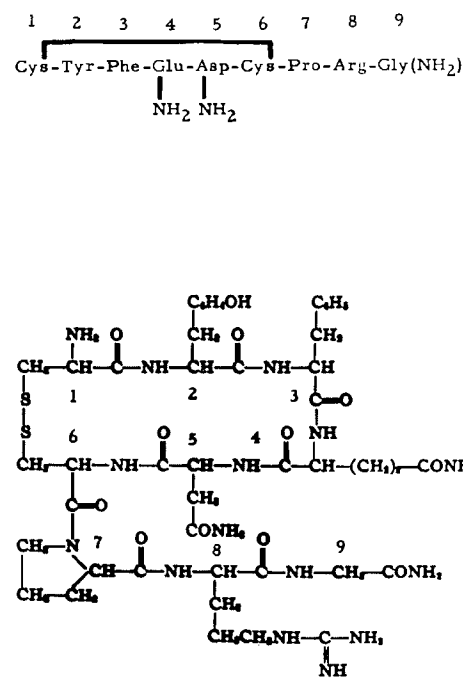

FIG. 1. Structure of [8-arginine]-vasopressin. Numbers indicate amino acid residues.

made in the preparation of the protected amino acids used in the synthesis. The protected nonapeptide derivative was purified by exclusion chromatography on Sephadex LH-20 in *N,N*-dimethylformamide. The protecting groups were removed from the peptide derivative by sodium in liquid ammonia solution and the resultant dithiol compound was oxidatively cyclized using hydrogen peroxide. The [8-arginine]-vasopressin so formed was isolated by sequential exclusion chromatography on Sephadex G-15 in 50% acetic acid, then on Sephadex G-25 in 0.2 *N*

acetic acid. This yielded 11% (based on the starting glycine content) of the peptide, which was found to have 470 ± 50 units per mg of rat antidiuretic activity (6), 24 ± 6 units per mg of "milk-ejecting-like" activity measured on an isolated strip of lactating mouse mammary gland (7) and 2.0×10^6 c.p.m. per mg in dioxane-based scintillation fluid. Amino acid analysis was in agreement with the structure of [8-arginine]-vasopressin.

Before the radioactive amino acid was incorporated, a portion of the protected hexapeptidyl-resin was used to complete the synthesis of cold [8-arginine]-vasopressin. This allowed more accurate estimation of the amount of radioactive amino acid needed, and the yield of radioactive hormone which could be expected. Position 3 was chosen as the one to have the radioactive residue since it was the last position to be filled in a protected heptapeptide intermediate to several projected radioactive analogs of [8-arginine]-vasopressin with modifications in the amino acid residues at positions 1 and 2.

The radioactive [8-arginine]-vasopressin prepared is currently being used in studies on its binding to isolated kidney cell membranes.

Experimental

Materials and Methods

The physical properties of the protected amino acids prepared correspond with those reported by Bayer *et al.* (8). All the protected amino acids were homogenous to t.l.c. (Silica Gel G) in the solvent systems, acetone – acetic acid, 98:2, and chloroform–methanol – acetic acid, 85:10:5. The Merrifield resin was obtained from Schwartz/Mann (Orangeburg, New York), and prepared with a substitution level of 1.0 mmol *tert*-butyloxycarbonyl-glycine (Boc–glycine) per gram of resin according to the procedure of Merrifield (9). Ring tritiated phenylalanine was obtained from Schwartz–Mann (Picker Nuclear Canada, Downsview, Ontario).

Exclusion chromatography was carried out in 1.5 × 90 cm columns (Pharmacia Canada Ltd.), monitored by u.v. absorption at 280 nm using a Beckman DB-GT recording spectrophotometer with a Beckman flow cell. A flow rate of 5 ml/h was used and 1 ml fractions were collected. Peptide materials were collected by pooling fractions corresponding to absorption peaks, concentrating *in vacuo*, and lyophilizing. Scintillation counting was carried out in a dioxane-based cocktail (1000 ml dioxane, 100 g naphthalene, 5 g 2,5-diphenyloxazole) in a Beckman LS-233 scintillation counter. All solvents and reagents were the highest purity commercially available and were used without further purification. Amino acid analyses were carried out using a Beckman 120C amino acid analyzer.

All couplings and washings in the synthesis of the peptide were carried out according to the procedure of Meienhofer *et al.* (5).

Assays for antidiuretic activity were performed on anesthetized, hydrated Sprague–Dawley male rats according to the procedure of Sturmer (6). Milk-ejecting like activity was measured using isolated strips of lactating mouse mammary gland according to the procedure of Fielitz *et al.* (7).

tert-Butyloxycarbonyl Amino Acids

The N^{α}-*tert*-butyloxycarbonyl (Boc) derivatives of glycine, proline, glutamine, and phenylalanine were prepared according to the procedure of Schwyzer *et al.* (10) with the modification that reaction times were extended from 20 to 48 h, the first 24 h at 40–50 °C, the remaining 24 h at 25 °C.

The N^{α}-Boc derivatives of cysteine, asparagine, and tyrosine were prepared according to the same procedure with the modifications that a dioxane–water ratio of 1:1 rather than 2:1 was employed and reaction times were extended to a minimum of 48 h at 40–50 °C.

N^{α}-Boc-arginine

Arginine (3.5 g, 20 mmol) was dissolved in dioxane–water, 1:1, (100 ml) and magnesium oxide (1.6 g, 40 mmol) was added. Boc-azide was then added dropwise (4.3 g, 30 mmol) with stirring. The resultant mixture was stirred 24 h at 45 °C. The suspension was filtered, washed twice with water (50 ml), and extracted three times with diethyl ether (50 ml portions). The aqueous phase was cooled to 0° and the p*H* was adjusted to 2 with 2 *N* hydrochloric acid. The solution was warmed to 25° and saturated with sodium chloride. This produced a fine white precipitate which was recovered by decantation (from excess sodium chloride) and filtration. After drying for 24 h over phosphorous pentoxide *in vacuo*, the product (6.16 g, 99% yield based on Boc-arginine·HCl) melted at 113–115 °C, and was homogenous to t.l.c. on silica gel G (R_f 0.70 using butanol – acetic acid – water, 4:1:5). This material was used without further purification.

N^{α}-Boc-N^{G}-tosyl-arginine

N^{α}-Boc-arginine·HCl (3.12 g, 10 mmol) was dissolved in acetone (50 ml) and water (15 ml), the solution was cooled to 0 °C, the p*H* adjusted to 12.5 with 4 *N* sodium hydroxide, and the suspension was stirred until homogenous (1 h). Tosyl chloride (4.75 g, 25 mmol) in acetone (10 ml) was added dropwise with stirring and sodium hydroxide (4 *N*) was added simultaneously to maintain the p*H* in the range 12.0–12.5. Once the addition was complete the solution was stirred at 0 °C for an additional 3 h, maintaining p*H* 12.5. The p*H* was then adjusted to 7.0 with 1 *N* hydrochloric acid at 0 °C, the acetone was removed *in vacuo*, the solution volume was doubled by the addition of water and the solution was extracted three times with diethyl ether (25 ml portions). The aqueous layer was cooled to 0 °C and the p*H* adjusted to 3.0 with 6 *N* hydrochloric acid. The resultant emulsion was saturated with sodium chloride and extracted 3 times with ethyl acetate (50 ml portions). The organic phase was washed three times with 0.1 *N* hydrochloric acid (15 ml portions), then with water (25 ml portions) until neutral, dried (Na_2SO_4), filtered, and concentrated *in vacuo* to yield 2.8 g (60%) of a white glassy material exhibiting a softening point in the range 95–100 °C. T.l.c. (Silica Gel G, acetone – acetic acid, 98:2) showed the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

majority of the material to have an R_f of 0.42 with minor components at R_f 0.1 and 0.8. These latter components were removable by extraction with diethyl ether and then 0.1 *N* hydrochloric acid. The optical rotation of the purified material, $[\alpha]_D^{25}$ −3.3° (*c* = 4, DMF) corresponds to that reported by Ramachandran and Li (11).

Tritiated N$^{\alpha}$-tert-Butyloxycarbonyl-phenylalanine

A mixture of ring tritiated L-phenylalanine (17 000 mCi/mmol, 2 mCi total) and unlabelled phenylalanine (0.42 mmol) was protected according to the method of Schwyzer *et al.* (10). The resultant ^{3}H-Boc-phenylalanine was found to be greater than 99% pure by radiochromatography on silica gel G using acetone – acetic acid, 98:2.

p-Nitrophenyl Esters

The *p*-nitrophenyl ester of N$^{\alpha}$-Boc-*S*-Bzl-cysteine was prepared according to the procedure of Beyerman *et al.* (12). N$^{\alpha}$-Boc-asparagine *p*-nitrophenyl ester was prepared according to the procedure of Schröder and Klieger (13). N$^{\alpha}$-Boc-glutamine *p*-nitrophenyl ester was prepared according to the procedure of Bodanszky and du Vigneaud (14).

N$^{\alpha}$-Tosyl-S-Bzl-cysteine

N$^{\alpha}$-Tosyl-*S*-Bzl-cysteine was prepared from *S*-Bzl-cysteine (15) according to the procedure of du Vigneaud *et al.* (16).

N$^{\alpha}$-tert-Butyloxycarbonyl-L-glutaminyl-L-asparaginyl-S-benzyl-L-cysteinyl-L-prolyl-N^{G}-tosyl-L-argininyl-glycyl-resin

This Boc-hexapeptide-resin was prepared according to the stepwise procedure of Meienhofer *et al.* (5) from 1.25 g Boc-glycyl-resin (1.25 mmol Boc-glycine) which yielded 2.12 g (88%).

N$^{\alpha}$-Tosyl-S-benzyl-L-cysteinyl-L-tyrosyl-[^{3}H]-L-phenylalanyl-L-glutaminyl-L-asparaginyl-S-benzyl-L-cysteinyl-L-prolyl-N^{G}-tosyl-L-arginylglycyl-resin

This material was prepared from the Boc-hexapeptide resin (0.37 g, 0.21 mmol based on starting Boc-glycine content) by the stepwise procedure according to Meienhofer *et al.* (5), with the exception that ^{3}H-Boc-phenylalanine was incorporated using only a two-fold excess (0.42 mmol). The protected nonapeptide-resin was recovered by filtration after thorough washing with ethanol and ether, which yielded 0.43 g (81%) material.

[8-Arginine]-vasopressin

The protected nonapeptide, *S*-benzyl-N$^{\alpha}$-tosyl-L-cysteinyl-L-tyrosyl-[^{3}H]-phenylalanyl-L-glutaminyl-L-asparaginyl-*S*-benzyl-L-cysteinyl-L-prolyl-N^{G}-tosyl-L-arginyl-glycinamide was separated from the resin by ammonolysis of the peptide resin according to the procedure of Meienhofer *et al.* (5). The oil obtained was purified by chromatography on a column of Sephadex LH-20 (0.9 × 55 cm) in dimethylformamide. The absorbance reading at 280 nm was plotted against the elution volume and the peptide material in the fractions corresponding to the main peak of absorbance (elution volume: 32 ml) was recovered by evaporation *in vacuo*. The oil so obtained was converted to a solid by trituration with ethanol and drying *in vacuo*. This yielded 118 mg (32%) pale yellow powder, optical rotation $[\alpha]_D^{22}$ −26.3° (*c* = 1, DMF).

The solid protected nonapeptide derivative (58 mg) was dissolved in liquid ammonia (100 ml) which had been distilled from sodium. Sodium was added in small quantities to the boiling ammonia solution until a permanent blue color remained for 30 s. The blue color was removed by addition of glacial acetic acid (2 drops) and the ammonia was removed *in vacuo*. The solid product was dissolved in 0.2 *N* acetic acid (150 ml) and the p*H* of the solution adjusted to 8 with concentrated ammonium hydroxide solution, and then hydrogen peroxide solution (30%, 0.5 ml) was added. The solution was stirred for 5 min, then the p*H* was adjusted to 5 with glacial acetic acid, the volume reduced to 50 ml by evaporation *in vacuo*, and evaporation was completed by lyophilization. The resultant solid product was dissolved in 50% acetic acid (4 ml) and purified by chromatography on a column of Sephadex G-15 (1.5 × 90 cm) in 50% acetic acid. The eluent was monitored both by measurement of its u.v. absorption (at 280 nm) and by liquid scintillation counting. A main peak (elution volume: 60 ml) followed by two minor peaks was detected by u.v. absorption measurement while only the main peak was detected by liquid scintillation counting. The fractions corresponding to the leading half and the trailing half of the main peak were pooled and concentrated *in vacuo* to volumes of about 5 ml each, diluted to 50 ml with water and lyophilized to dryness. The material from the trailing half of the main peak was dissolved in 0.2 *N* acetic acid (2.0 ml) and purified by chromatography on a column of Sephadex G-25 superfine (1.5 × 90 cm) in 0.2 *N* acetic acid. The eluent was monitored by u.v. absorption measurement and liquid scintillation counting. The leading and trailing edges of the single peak were discarded and the center portion (elution volume: 123 ml) was concentrated *in vacuo* to a volume of 25 ml and lyophilized to yield 14 mg (11% based on starting glycine) of a solid, white, fluffy material, optical rotation $[\alpha]_D^{22}$ −26.6° (*c* = 0.20, 1 *N* HOAc). The material possessed 470 ± 50 units/mg rat antidiuretic activity, 24 ± 6 units/mg milk-ejecting like activity and 2.0 × 10^6 c.p.m./mg. On re-chromatography on a column of Bio-Rex 70 (0.9 × 60 cm) in 0.5 *M* ammonium acetate, p*H* 6.4, the material was eluted as a single component (elution volume: 20 ml) when monitored by u.v. absorption, scintillation counting and biological assay (milk-ejecting like activity). No change in biological activity and specific radioactivity of the recovered material was observed.

N-Methylamino Acids in Peptide Synthesis. II. A New Synthesis of *N*-Benzyloxycarbonyl,*N*-Methylamino Acids[1]

JOHN R. MCDERMOTT AND N. LEO BENOITON

Department of Biochemistry, University of Ottawa, Ottawa, Canada K1N 6N5

Received December 19, 1972

Reaction of *N*-benzyloxycarbonyl derivatives of aliphatic amino acids, and threonine, aspartic, and glutamic acids whose side-chains were protected with the *t*-butyl group, gave the corresponding *N*-methylamino acid derivatives in good yields. The methionine derivative could be obtained by using only one mol of methyl iodide. Derivatives of threonine, and aspartic and glutamic acids whose side-chains were not protected could not be methylated. Analysis of the crude products of methylation in three cases showed that they contained 0–1% of racemized material.

La réaction des dérivés *N*-benzyloxycarbonyle d'acides aminés aliphatiques, de la thréonine, et des acides aspartique et glutamique dont les chaînes latérales furent bloquées avec le groupe *t*-butyle, a conduit aux dérivés *N*-méthylés correspondants des acides aminés avec d'excellents rendements. Le dérivé de la méthionine a pu être obtenu en utilisant seulement une mole d'iodure de méthyle. Les dérivés de la thréonine et des acides aspartique et glutamique dont les chaînes latérales ne sont pas protégées, n'ont pu être méthylés. L'analyse des produits bruts de la méthylation a montré que dans trois cas, ceux-ci contenaient de 0 à 1% de produits racémisés. [Traduit par le journal]

Can. J. Chem., **51**, 1915 (1973)

The methylation of various *N*-protected amino acids using sodium hydride – methyl iodide in tetrahydrofuran (THF)–dimethylformamide (10:1) under reflux gives the *N*-methylated, methyl ester (1). Similar products have been obtained using silver oxide – methyl iodide in dimethylformamide at room temperature (2). Other methods of *N*-methylation (3–5) used for the permethylation of peptides for sequence analysis by mass spectrometry invariably give methyl esters of the carboxyl functions.

In order to obtain a derivative suitable for peptide synthesis by this approach, it is necessary either to saponify the methyl ester (1, 2) or to remove the amino protecting group (1). It has been shown in this laboratory that saponification of methyl esters of *N*-benzyloxycarbonyl,*N*-methylamino acids or peptides can cause racemization (6). For example, saponification of Z-MeIle-OMe[2] gave 12% of the *allo*-isomer, and saponification of Z-Ala-MeLeu-OMe gave 11% of the L,D-isomer. To circumvent this problem, the methylation step should not esterify the carboxyl group.

In a continuing investigation of the conditions for *N*-methylation, it was found that *N*-benzyloxycarbonylamino acids could be selectively *N*-methylated using sodium hydride (3 mol) and methyl iodide (8 mol) in neat THF at room temperature, without ester formation (8).[3] This observation is supported by the fact that the sodium salt of Z-Ala was esterified only very slowly under these conditions (33% ester formation in 5 days). *N*-Methylation is virtually complete in 24 h; for the sterically hindered Z-*a*lle, only 0.7% of the unreacted amino acid was detected on analysis of the crude product of methylation.

We have prepared several *N*-benzyloxycarbonyl,*N*-methylamino acids by this method. The properties of the crystalline derivatives obtained are given in Table 1. Z-MeAsp and Z-MeGlu were obtained by methylation of the ω-*t*-butyl esters followed by treatment with trifluoroacetic acid since it was found that Z-Asp and Z-Glu were completely resistant to methylation (the reaction was incomplete even

[1]Supported by a grant from the Medical Research Council of Canada. N.L.B. is an Associate of the M.R.C.C., J.R.M. was a Fellow of the M.R.C.C. For the first paper in this series, see ref. 1*b*

[2]The abbreviations for the amino-acid and peptide derivatives are those recommended by the IUPAC–IUB Commission on Biochemical Nomenclature (7). The amino-acid symbols represent the L-isomer.

[3]It was found, in addition, that methylation of Z-Tyr or Z-Tyr(Z) under these conditions gave Z-MeTyr(Me), and that MeTyr could be obtained by methylation of Z-Tyr(Bzl) followed by hydrogenation (8*a*).

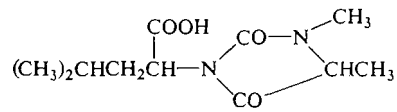
§Literature m.p. 69–70°, $[\alpha]_D^{24}$ −85.8° (9).
‖Literature m.p. 63–64°, $[\alpha]_D^{26}$ −72.4° (10). Analysis of a sample, deprotected by hydrogenation in 80% aqueous acetic acid before crystallization, showed a 1.1% content of MeaIle.
¶Analysis of a sample as above showed no MeIle and a 0.7% content of *a*Ile.

in dimethylformamide). The products obtained from the di-*t*-butyl esters were also pure, but they had lower optical rotations, indicating that partial racemization had occurred. We suggest that the α-carboxyl group when ionized provides some protection against racemization by preventing ionization at the α-carbon atom. Z-Asp(OMe)-OMe after methylation and saponification gave a product with an even lower rotation, probably due to racemization taking place during saponification (6).

Methylation of Z-Thr gave a mixture of *N*-methylated (~60%) and *O*-methylated (~25%) products, together with some unchanged starting material. Z-Thr(Bu^t), however, gave the oily *N*-methylated derivative in good yield, which on hydrogenation gave crystalline MeThr(Bu^t). Methylation of Z-Met gave a water-soluble product, probably the dimethylsulfonium iodide derivative. However, by restricting the amount of methyl iodide to 1 mol (11, 12) it was possible to methylate without sulfonium salt formation, giving Z-MeMet as an oil. Removal of the benzyloxycarbonyl group with hydrogen bromide in acetic acid gave a product containing 3.4% of methionine. Z-Trp gave on methylation the α-*N*,ω-*N*-dimethyl derivative as an oil.

Attempts to crystallize Z-MeAsp(OBu^t), Z-MeGlu(OBu^t), and Z-MeThr(Bu^t) as their dicyclohexylamine salts revealed that these were soluble in light petroleum. This property enabled the removal of small amounts of unreacted benzyloxycarbonylamino acid derivatives from the reaction products as the dicyclohexylamine salts which are insoluble in this solvent. Thus benzyloxycarbonylamino acids with suitably protected carboxylic acid and hydroxyl side-chains can also be *N*-methylated to give directly a derivative suitable for peptide synthesis.

A possible strategy for the synthesis of *N*-methylated peptides is methylation of the *N*-protected peptide (1*a*). The methylation of Z-Ala-Leu gave a 58% yield (by weight) of an oil, whose n.m.r. spectrum showed no peaks for the benzyl group. Formation of the hydantoin **1**



1

would explain this result. This could have arisen from prior ionization of the amide nitrogen followed by cyclization and loss of benzyl alcohol. That this had occurred is supported by the fact that Z-Ala-MeLeu on methylation yielded the *N*,*N*′-dimethyl derivative in good yield.

The method introduced in this laboratory (13) for determination of the optical purity of *N*-methylamino acids has been shown to be invalid, the error having been due to misassignment of the peaks of the amino acid analysis. It transpires that under the conditions described, the L-alanine *N*-carboxyanhydride not only reacts poorly with the *N*-methylleucine but also gives a dipeptide with an unusually low ninhydrin color yield (4.6% of that for alanine, 6.4%

of that for Ala-Leu) making it very difficult to identify the Ala-MeLeu peak among the by-product peaks. A direct test for racemization was possible, however, for the isoleucines. Analysis (after hydrogenation) of the crude products of methylation indicated that Z-MeIle and Z-D-Me*a*Ile contained, respectively, 1.1 and 0.0% of the diastereomer. In an indirect racemization test, *N*-methylleucine from the room-temperature methylation was converted to the benzyl ester *p*-toluenesulfonate (14) and the crude ester was coupled to Z-Ala by the mixed-anhydride method. The neutral product of the coupling was hydrogenated and the resulting dipeptide shown to contain 0.6% of the L,D-diastereomer.[4] Using the same method, it was shown that *N*-methylleucine, prepared by the saponification and subsequent hydrogenation of Z-MeLeu-OMe (1*b*) contained 9.6% of the D-isomer. *N*-Methylthreonine obtained from the crude *t*-butyl derivative had, before recrystallization, an optical rotation close to that reported in the literature. Also, crude MeThr(Bu^t) was homogeneous on t.l.c. and amino-acid analysis, indicating that little racemization had occurred.

It might be expected that amino acids with alkyl side-chains would be less prone to racemize during methylation than amino acids with electron-withdrawing side-chains. The optical integrity of products obtained by the methylation of amino acids of the latter type remains to be established by an unambiguous method.

In view of the racemization occurring during the saponification of *N*-benzyloxycarbonyl,*N*-methylamino-acid esters (6), this method of room temperature methylation should have wide applicability for the preparation of *N*-benzyloxycarbonyl,*N*-methylamino-acid derivatives for peptide synthesis.

Experimental

Materials and Methods

Sodium hydride was obtained from Fluka AG, Buchs, Switzerland, and J. T. Baker Chemical Company, Phillipsburg, New Jersey as 55 and 57% dispersions in oil respectively. Analysis showed the presence of 2–3% by weight of NaOH (15). Methyl iodide and tetrahydrofuran (THF) were products from Fisher Scientific Company, Pittsburgh, Pennsylvania. The THF was purified by distillation from KOH and then from sodium hydride. Amino acids were obtained from General Biochemicals, Chagrin Falls, Ohio, except for D-*allo*-isoleucine which was from ICN Nutritional Biochemicals, Cleveland, Ohio. Benzyloxycarbonylamino acids were prepared by the original procedure as described by Greenstein and Winitz (16). Z-Asp(OBu^t) and Z-Thr(Bu^t) were obtained as their dicyclohexylamine salts and were converted to the free acid using aqueous citric acid. Z-Glu(OBu^t) was obtained from Schwarz-Mann, Orangeburg, New York. Z-Asp-(OBu^t)-OBu^t and Z-Glu(OBu^t)-OBu^t were prepared by the isobutylene method of Anderson and Callahan (17). Z-Asp(OMe)-OMe was the neutral product isolated from the reaction of Z-Asp with diazomethane. Hydrogenations were done in the presence of 10% palladium-on-charcoal catalyst at atmospheric pressure. Light petroleum refers to the 30–60° fraction, from Fisher Scientific Co.

Optical rotations were measured with a Perkin–Elmer model 141 polarimeter using a 1-dm tube. Melting points were taken by the capillary method, and are uncorrected. Elemental analyses were done by Organic Microanalyses, Montreal, on the compounds dried under *vacuo* over P_2O_5. Amino-acid analyses were carried out with a Beckman model 120B amino-acid analyzer with the eluting buffer at half flow rate to allow detection of the *N*-methylamino acids (13).

Proton n.m.r. (Varian T-60) and i.r. (Unicam SP 200) analyses were used routinely to check the product of methylation, using the *N*-methyl singlet at τ 7.0 and the >*N*—H stretch and amide II bands at 3280 and 1520 cm^{-1}, respectively. All products had spectra which were consistent with the assigned structures.

General Methylation Procedure

N-Benzyloxycarbonylamino acid or *t*-butyl derivative (10 mmol) and methyl iodide (5 ml; 80 mmol) were dissolved in THF (30 ml) and the solution was cooled to 0 °C in a flask protected from moisture. Sodium hydride dispersion (1.32 g; 30 mmol) was added cautiously with gentle stirring. The suspension was stirred at room temperature for 24 h. Ethyl acetate (50 ml) was then added (to consume the sodium hydride formed from the excess sodium hydride), followed by water, dropwise, to destroy the excess sodium hydride. The solution was evaporated to dryness, and the oily residue partitioned between ether (30 ml) and water (100 ml). The ether layer was washed with aqueous $NaHCO_3$ (50 ml), and the combined aqueous extracts acidified to p*H* 2 with 5 *N* HCl (for *t*-butyl derivatives, aqueous citric acid was used to p*H* 3). The product was extracted into ethyl acetate (2 × 50 ml), the extract was washed with water (2 × 50 ml), 5% aqueous sodium thiosulfate (2 × 50 ml; to remove iodine), and water (50 ml), dried over $MgSO_4$ and evaporated to give a pale yellow oil.

Z-MeAsp and Z-MeGlu

Z-MeAsp(OBu^t) and Z-MeGlu(OBu^t) were obtained as oils from the corresponding *t*-butyl derivative by the general procedure. The oils were dissolved in ether – light petroleum (1:1), dicyclohexylamine (1 ml) was added, the solutions were left overnight at 0 °C, and the precipitates were filtered off. The filtrates were washed with 5% aqueous citric acid (2×) and water (4×), dried ($MgSO_4$), and evaporated. The purified Z-MeAsp(OBu^t) (86%) and Z-MeGlu(OBu^t) (70%) were left in trifluoroacetic acid (5 ml/g) for 1 h and the solutions were evaporated.

[4]The synthesis of reference compounds and the chromatographic data for the analysis of the various diastereomers will be described in a subsequent paper (6*b*).

MeThr(Bu^t)

Z-MeThr(Bu^t) (0.79 g; 90%) was obtained from Z-Thr(Bu^t) as described for the other *t*-butyl derivatives, including purification through the dicyclohexylamine salt, and was hydrogenated in 65% aqueous ethanol (15 ml) for 4 h. Evaporation of the solution yielded a crystalline product (100% yield) which gave a single peak on amino-acid analysis (long column, p*H* 3.28 buffer). A sample crystallized from water–acetone sublimed at 269–271°, had $[\alpha]_D^{27}$ −53.1° (*c*, 1 in H_2O), and gave only one spot on analysis by t.l.c. The MeThr(Bu^t) was converted to MeThr using trifluoroacetic acid at room temperature for 2 h. The solution was evaporated, the residue dissolved in 1 *N* HCl, and the solution evaporated again. The residue was dissolved in water (5 ml), the solution was stirred with Dowex 50 (H^+ form) resin, and the resin was filtered off and washed with water until the filtrate contained no chloride ions. The product was eluted from the resin with 10 *N* NH_4OH (100 ml), the solution evaporated and the crystalline residue dried over P_2O_5. The product, m.p. 228–236°, $[\alpha]_D^{26}$ −32.0° (*c*, 1 in H_2O), had m.p. 238–240° after recrystallization from methanol, lit. m.p. 244–246°, $[\alpha]_D^{20}$ −35.9° (*c*, 2.3 in H_2O) (18).

Methylation of Z-Asp(OBu^t)-OBu^t, Z-Glu(OBu^t)-OBu^t and Z-Asp(OMe)-OMe

Methylations were carried out by the usual procedure, using 1.5 mol of sodium hydride and 4 mol of methyl iodide. The neutral product was isolated in ether from the ether–water partition, the ether solution was dried ($MgSO_4$) and evaporated to give an oil. N.m.r. and i.r. analyses indicated that complete *N*-methylation had occurred in each case. Deprotection of the *t*-butyl derivatives with trifluoroacetic acid for 2 h gave Z-MeAsp (64% yield, recrystallized) with $[\alpha]_D^{27}$ −21.6° (*c*, 1 in EtOH) and Z-MeGlu (61% yield, recrystallized) with $[\alpha]_D^{27}$ −13.8° (*c*, 1 in EtOH). Saponification of Z-MeAsp-(OMe)-OMe (1.0 g) with 2 *N* NaOH (10 ml) in methanol (10 ml) for 2 h gave Z-MeAsp (0.43 g) with $[\alpha]_D^{26}$ −5.4° (*c*, 1 in EtOH).

Attempted Methylation of Z-Asp, Z-Glu, and Z-Thr

After methylation using 4.5 mol of sodium hydride and 12 mol of methyl iodide, n.m.r. and i.r. analyses of the acidic products indicated that no *N*-methylation of Z-Asp and Z-Glu had taken place. For Z-Thr, n.m.r. analysis showed the presence of *N*-methyl (τ 7.0) and *O*-methyl (τ 6.7) groups with integral values corresponding to 60% *N*-methyl and 25% *O*-methyl. I.r. analysis showed that some >*N*—H was still present.

Methylation of Z-Met

(*a*) When the general procedure was used, the product was lost during the isolation due to its solubility in water.

(*b*) Z-Met (1.34 g; 5 mmol), methyl iodide (0.31 ml; 5 mmol), and sodium hydride dispersion (0.60 g; 15 mmol) were stirred in THF for 18 h. The acidic product was isolated by the general procedure as a pale yellow oil (1.05 g; 71%). N.m.r. and i.r. analyses indicated virtually complete methylation. Analysis of a weighed sample, after deprotection with 2 *N* HBr in acetic acid for 2 h, showed that the sample contained about 3.4% of Z-Met.

Methylation of Z-Trp

N.m.r. analysis of the oily product showed singlets at τ 6.3 and 7.1 in a 1:1 ratio.

Methylation of Z-Ala-Leu

Z-Ala-Leu (19) was methylated by the general procedure using 4.5 mol of sodium hydride and 12 mol of methyl iodide. The acidic product (yield 58% by weight) was an oil whose n.m.r. spectrum showed a singlet at τ 7.0 and no peaks at 2.7 and 4.9 for the benzyl protons. The equivalent weight determined by titration was 294. Required for the hydantoin **1**, 274.

Methylation of Z-Ala-MeLeu

Methylation of Z-Ala-MeLeu[4] by the general procedure gave an oil, 100% yield, with $[\alpha]_D^{19}$ −67.2° (*c*, 2 in EtOH), whose i.r. spectrum showed that no >*N*—H remained.

Racemization Tests

Z-MeLeu was hydrogenated in 80% acetic acid for 4 h and the solution was evaporated giving a white crystalline solid. This compound (0.47 g) was dissolved in benzyl alcohol (20 ml) and benzene (10 ml) containing *p*-toluenesulfonic acid (0.63 g), and the mixture was heated under reflux, the water formed being trapped in a Dean-Stark tube. The benzene was removed by evaporation, the product precipitated with a large volume of ether, and collected by filtration (0.82 g). This MeLeu-OBzl·TosOH (0.106 g) was dissolved in ethyl acetate (1 ml) containing triethylamine (0.035 ml) and the solution was added to the mixed anhydride formed from Z-Ala (0.056 g) and ethyl chloroformate (0.024 ml) in THF (1 ml) at 0 °C by the addition of triethylamine (0.035 ml). The mixture was stirred at 0° for 1 h and at room temperature for 1 h. After removal of the solvent, the total neutral fraction was extracted into ethyl acetate, the solution was dried and evaporated, and the residual oil was hydrogenated in acetic acid containing 2 *N* HCl (0.2 ml) for 8 h to give the free dipeptide. Analysis[4] showed the product to contain 0.6% of the L,D-isomer. A similar experiment using Z-MeLeu prepared by saponification of Z-MeLeu-OMe gave a product containing 9.6% of the L,D-isomer.

Reaction of the Hydrated Electron with HS^-

R. L. EAGER, V. KABACHIA, W. L. WALTZ, R. J. WOODS, AND K. J. MCCALLUM

Department of Chemistry and Chemical Engineering and the Saskatchewan Accelerator Laboratory, University of Saskatchewan, Saskatoon, Saskatchewan

Received December 18, 1972

Evidence is presented to show that the hydrated electron reacts with monohydrogen sulfide ion with a rate constant of $(3.0 \pm 0.4) \times 10^7 M^{-1} s^{-1}$ in contrast to an earlier report that this substrate was unreactive. A comparison of the electron reactivity towards hydrogen sulfides and selenides suggests that the reactivity reflects the ability of the substrate to accommodate the electron as opposed to its ability to donate a proton to the electron.

La réaction de l'électron hydraté sur l'ion hydrogène sulfure a été prouvée et se fait avec une constante de vitesse de $(3.0 \pm 0.4) \times 10^7 M^{-1} s^{-1}$ contrairement à une communication antérieure rapportant la non réactivité de ce substrat. Une comparaison de la réactivité de l'électron avec les sulfures et séléniures d'hydrogène suggère que cette réactivité reflète la capacité du substrat à accepter l'électron opposée à son pouvoir de céder un proton à l'électron. Introduction

An earlier report (1) on the behavior of the hydrated electron, e_{aq}^-, towards H_2S and HS^- indicated that HS^- was unreactive while H_2S was found to be highly reactive ($k_e = 1.1 \times 10^{10} M^{-1} s^{-1}$). In the course of studying the reactions of e_{aq}^- with various sulfur containing materials by pulse radiolysis, we had occasion to observe the behavior of e_{aq}^- in alkaline media in the presence of high concentrations of HS^-. Under these circumstances the disappearance of e_{aq}^- is much more rapid than that of e_{aq}^- in the alkaline matrix itself.

We wish to report here the results of this study which indicate that HS^- can react with e_{aq}^-. These results in conjunction with those reported by others (1–3) on the electron reactivity towards H_2S, H_2Se, and HSe^- lend further credence to the suggestion (4, 5) that electron rate constants for protonic acids reflect the ability of the substrate to incorporate the electron. This situation, shown in reaction 1, is in contrast to a mechanism involving proton transfer, reaction 2. This latter

[1] $$e_{aq}^- + H_nX \rightarrow H_nX^-$$

[2] $$e_{aq}^- + H_nX \rightarrow H_{n-1}X^- + H$$

mechanism has been proposed (6, 7) on the basis that an apparent Bronsted general acid catalysis law has been found to correlate values of k_e for a number of protonic acids with their acid dissociation constants.

Experimental

The pulse radiolysis technique used here is similar to that described elsewhere (8). Deaerated solutions were irradiated in a cyclindrical suprasil quartz cell of 4-cm path length with feeble pulses of *ca.* 17 MeV electrons from the Saskatchewan Linear Accelerator, The behavior of e_{aq}^- was monitored spectrophotometrically at 578 nm using a 200W quartz-tungsten–iodine lamp (GE Q6.6A/T4/CL) as the monitoring light source, a grating monochromator (Bausch-Lomb, 33-86-26-07), and a RCA 931A photomultiplier tube (5 dynodes used). The resulting signals were displayed on a Tektronix oscilloscope (Type 581A) in conjunction with a Type W differential comparator and were photographed on Polaroid Type 107 film. Care was taken to insure that the band width of the electronic circuitry was adequate to display the transient signals.

Triply-distilled water was used to prepare all solutions. Hydrogen sulfide gas (Matheson) was bubbled through saturated Na_2S solutions and then through triply-distilled water. The scrubbed H_2S gas was next passed into water, and the resulting solution diluted to yield solutions of the desired concentrations. The sulfide concentration was determined by standard iodiometric titration. Reagent NaOH was used to adjust the p*H*. The preparation and handling of the deaerated solutions was similar to that described elsewhere (ref. 9 and references therein). All other materials were of reagent quality.

Results and Discussion

The decay of the absorption of e_{aq}^- was measured at 578 nm for both the sodium hydroxide matrices and H_2S solutions in the p*H* range of 10.9 to 12.7 where the total sulfide concentration was greatly in excess of that for e_{aq}^-. The dis-

appearance of e_{aq}^- both in the sulfide solutions and matrices obeyed first order kinetics as shown in Fig. 1. No transitory or stable products were observed under these conditions of low dose.[1] The apparent first order rate constants, k_{obs}, can be expressed by eq. 3

$$[3] \qquad k_{obs} = k_e[S] + k_m$$

where k_e is the second order rate constant for e_{aq}^- reaction with solute and k_m is the first order rate constant for e_{aq}^- decay in the matrix itself. The values of k_e calculated from eq. 3 are shown in Table 1: the corrections for k_m ranged between 5 and 20% of k_{obs}. Clearly the disappearance of e_{aq}^- is first order in total sulfide concentration and essentially independent of pH. The average value for k_e of $(3.0 \pm 0.4) \times 10^7$ M^{-1} s^{-1} obtained using H_2S compares favorably with the value of $(2.6 \pm 1.4) \times 10^7$ M^{-1} s^{-1} obtained in preliminary experiments at pH 11.4 using $Na_2S{\cdot}10H_2O$. Such agreement between different starting materials indicates that the disappearance of e_{aq}^- is not due to its reaction with possible impurities present in the starting materials.

Three species, H_2S, HS^-, and S^{2-}, can exist in aqueous media: the prevailing species depends upon the pH. Under the foregoing pH conditions, the major species is HS^-, and thus we ascribe the disappearance of e_{aq}^- primarily to its reaction with HS^-. It is however important to inquire as to the potential contributions of S^{2-} and H_2S, particularly as the latter reacts rapidly with e_{aq}^- ($k_e = 1.1 \times 10^{10}$ M^{-1} s^{-1}) (1). The amount of unionized H_2S present is determined by the first ionization constant of H_2S which is 9.0×10^{-8} (10). At the lowest pH used (10.9), the concentration of unionized H_2S is calculated to be 1.1×10^{-6} M for a 0.01 M sulfide solution. Approximately 4% of e_{aq}^- will be scavenged by unionized H_2S, and the values of k_e in Table 1 will be about 4% too large, an amount within experimental

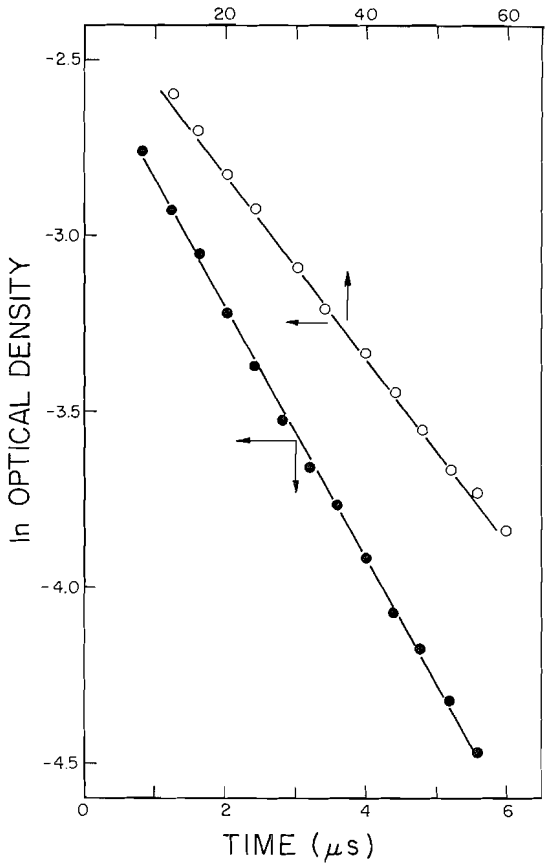

FIG. 1. ln optical density at 578 nm *vs.* time in μs: ○ matrix at pH of 12.6, ●, 0.01 M H_2S at pH of 12.7.

[1]At much higher doses, both intermediates and stable materials were observed at shorter wavelengths; however, so far it has not been possible to positively identify them as to their origin or to their nature.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

error. Unionized H_2S will be of even less significance at higher pH's; however, these solutions will now possibly contain S^{2-} in sufficient quantities to affect the calculated k_e values. The amount of S^{2-} present depends upon the second ionization constant of H_2S. While reported values for this constant range from 10^{-12} to 10^{-14} (10), a recent critical examination of these values has been made (11), and it appears that a value of 1×10^{-14} is appropriate for the present work. For 0.01 M sulfide solutions, the percentage of S^{2-} is calculated to be about 5% at pH 12.6. As HS^- is much less reactive than H_2S, the reactivity of e_{aq}^- towards S^{2-} is anticipated to be less than that of HS^-, and thus the contribution of S^{2-} is expected to be small or negligible. These conclusions appear to be borne out by the independence of k_e on pH, and indicate that e_{aq}^- does react with HS^-. Two situations, as portrayed in reactions 4 and 5

[4] $$e_{aq}^- + HS^- \rightarrow HS^{2-} \rightarrow H + S^{2-}$$

[5] $$e_{aq}^- + HS^- \rightarrow H + S^{2-}$$

can be envisioned as it is likely that H atom is formed by either mechanism (2, 5). Implied in reaction 4 is that k_e reflects the ability of the substrate to accommodate an electron whereas in reaction 5, it reflects proton donation by the substrate. In deciding between these two mechanisms, it is instructive to compare the behavior of the sulfur systems with the analogous selenium systems. The values of k_e for H_2Se and HSe^- are reported (3) to be 1.1×10^{10} and 4.8×10^7 M^{-1} s^{-1} respectively; these are almost identical to those of H_2S and HS^-.

The proton donation mechanism, eq. 5, suggests a relationship between the values of k_e and the appropriate acid dissociation constants. This type of mechanism has found early support in an apparent linear free energy relationship (in the form of a Bronsted Law for general acid catalysis) between k_e for a number of protonic acids and their dissociation constants (6, 7). Such a relationship does not hold for the sulfur and selenium systems as H_2Se and HSe^- are much stronger acids (3) than the corresponding sulfur species (10, 11) yet the similar species react at essentially the same rates. Anbar (4) and Hart and Anbar (5) have also noted additional cases where such a LFER is not fulfilled, and they have suggested that the reactivity of e_{aq}^- with not only protonic acids but also other materials reflects the availability of vacant orbitals on the substrate to accommodate an electron as implied in reaction 4. In this context, the close behavior of sulfur and selenium is understandable in terms of their nearly identical electronegativities (12). The correlation of reactivity and electronegativities probably reflects similar *orbital* electronegativities for the corresponding sulfur and selenium species. This type of explanation also appears consistent with the fact that the dihydrogen forms are much more reactive than the monohydrogen species: the former would be expected to have higher orbital electronegativities than the latter. While differences in overall electrostatic charge may contribute to such disparities in reactivity, it is highly unlikely that they could account for such large differences, as electrostatic effects appear to play a minor role in hydrated electron reactions (4, 5).

We thank the National Research Council of Canada for financial assistance and Messrs. D. Jennings and E. Kozar for technical assistance in operating the linear accelerator.

The Master Equation for the Dissociation of a Dilute Diatomic Gas IX. Rotation–Vibration Relaxation Times

E. KAMARATOS AND H. O. PRITCHARD[1]

Centre for Research in Experimental Space Science, York University, Downsview, Ontario

Received October 25, 1972

The relationships between individual rotational or vibrational transition probabilities and the eigenvalues of the 172nd order relaxation matrix describing the rotation–vibration–dissociation coupling of ortho-hydrogen are explored numerically. The simple proportionality between certain transition probabilities and certain eigenvalues, which was found previously in the vibration–dissociation coupling case, breaks down. However, it is shown that at 2000 °K the second smallest eigenvalue of the relaxation matrix (d_{n-2}), hitherto regarded as determining the "vibrational" relaxation time, is related more to the transition probability assigned to the *largest rotational gap* which lies in the first ($v = 0 \leftrightarrow v = 1$) vibrational gap, *i.e.* to the transition $v = 0, J = 5 \leftrightarrow v = 0, J = 7$, than to anything else; this clearly supports an earlier suggestion that the transient which immediately precedes dissociation in a shock wave has to be regarded as a rotation–vibration relaxation time rather than a vibrational relaxation time. It is suggested that the Lambert–Salter relationships can be rationalized on this assumption.

An analysis is then made of the energy uptake associated with each eigenvalue at three temperatures. At 500 °K, the greatest energy increment is associated with two eigenvalues (d_{n-13} and d_{n-24}) and can be characterized as *essentially* a rotational relaxation: the calculations confirm that the observed rotational relaxation time should first decrease and then increase with increasing temperature, as was recently found to be the case experimentally. At 2000 °K, large energy increments are associated with several eigenvalues between d_{n-2} and d_{n-14}, and at 5000 °K, with most of the eigenvalues d_{n-2} to d_{n-23}; thus, the higher the temperature, the more complex is the (T–VR) rotation–vibration relaxation. Further, relaxation times for the same temperature measured by ultrasonic and shock-wave techniques need not agree.

Les relations entre les probabilités de transition rotationnelle ou vibrationnelle et les valeurs propres d'ordre 172 de la matrice de relaxation décrivant la rotation, vibration, dissociation et couplage de l'hydrogène ortho, ont été explorées par voie numérique. La proportionnalité entre certaines probabilités de transition et certaines valeurs propres qui a été trouvée précédemment pour le cas de la vibration, dissociation et le couplage est rejetée: cependant, on a montré qu'à 2000 °K la seconde valeur propre la plus petite de la matrice de relaxation (d_{n-2}), jusqu'ici considérée comme déterminant le temps de relaxation vibrationnelle, est plus reliée à la probabilité de transition entre l'écart rotationnel le plus grand correspondant à la première intervalle vibrationnelle ($v = 0 \leftrightarrow v = 1$) et la transition $v = 0, J = 5 \leftrightarrow v = 0, J = 7$, qu'a autre chose; ceci confirme de façon claire une suggestion précédente selon laquelle la transition qui précède immédiatement la dissociation dans un choc d'onde, doit être considérée comme un temps de relaxation rotation–vibration plutôt que celui d'une relaxation vibrationnelle. On pense que les relations de Lambert–Salter peuvent être rationnalisées selon cette hypothèse. Une analyse a été ainsi faite sur la dissipation d'énergie associée à chaque valeur propre pour trois températures. A 500 °K, l'incrément d'énergie le plus élevé est associé à deux valeurs propres (d_{n-13} et d_{n-24}) et peut être essentiellement caractérisé par une relaxation rotationnelle: les calculs confirment le fait que le temps de relaxation rotationnelle pourrait décroître dans un premier temps puis croître avec la température comme l'a montré une expérience récente. A 2000 °K, les grands incréments d'énergie sont associés à plusieurs valeurs propres entre d_{n-2} et d_{n-14}; et à 5000 °K, à la plupart des valeurs propres de d_{n-2} à d_{n-23}; ainsi, plus la température croît et plus la relaxation rotation–vibration devient complexe. De plus, les temps de relaxation pour une même température mesurés par les techniques de l'ultra son et du choc d'onde, ne concordent pas nécessairement. [Traduit par le journal]

Can. J. Chem., 51, 1923 (1973)

In the preceding paper in this series,[2] it was found that the second smallest eigenvalue d_{n-2} of the relaxation matrix describing the rotational and vibrational dissociation of hydrogen in the presence of a large excess of inert gas was changed markedly when only *rotational* transition probabilities were altered (1), thus implying that the last transient which immediately precedes the dissociation reaction has a lot of rotational character; hitherto, it had always been tacitly assumed that the last transient was a vibrational relaxation (2, 3). At a macroscopic level, there is strong experimental evidence (3) that at low tempera-

tures, diatomics (especially hydrogen) exhibit relaxations which can be identified clearly as rotational whereas at higher temperatures, a much slower relaxation is found which is "obviously" vibrational in character; recently however, these well established assumptions have been challenged by Dove, Jones, and Teitelbaum (4) who find that they can only explain their shock-wave results for H_2 in the temperature range 1350–3000 °K on the hypothesis that the relaxation is not purely vibrational in character, but is a coupled relaxation involving both rotational and vibrational degrees of freedom. On the other hand, at a microscopic level, detailed studies of individual rotation–vibration levels have now become possible, and it has been found that in the relaxation of the carbon dioxide molecule, in the 500–2000 °K range, each rotational state has its own characteristic vibrational relaxation time (5), showing that one cannot really regard vibrational and rotational relaxation times as separable. The first part of this paper therefore describes the results of some numerical experiments designed to try to find out to which transition probabilities certain key eigenvalues were sensitive. The later part of the paper is concerned with the problem, which arises when the eigenvalue d_{n-2} is not dominant in the sense that $|d_{n-2}{}^{-1}|$ "ordinarily corresponds to the experimental relaxation time" (6), of how does the disturbance (*i.e.* sound wave or shock wave) "know" which eigenvalue to select out of the rather evenly spaced spectrum of eigenvalues?

Numerical Experiments

It was found in our earlier work, in which only vibration–dissociation coupling for H_2 was considered (2), that if the assumed transition probabilities P_{01} and P_{10} were scaled, the eigenvalue d_{n-2} was scaled by exactly the same amount: further, that at temperatures near 2000 °K, the vibrational relaxation time calculated from P_{01} was in fact close to $|d_{n-2}{}^{-1}|$ (the coincidence becoming less marked at higher temperatures because of the obviously increasing complexity of the vibrational relaxation (3)). This direct scaling was surprising, but has been satisfactorily analyzed and explained by Boyd (7), who predicted that this one-to-one relationship would cease to exist if the relaxing levels were too close together and therefore connected by relatively large transition probabilities; this is exactly what we find if we repeat these calculations for molecules having many more bound vibrational states than does H_2.

First, however, an illustration of the kind of difficulties one can encounter using a truncated set of levels to explore the internal relaxation: ortho-hydrogen has 172 rotation–vibration levels (1), so in order to conserve computer time we thought it would surely be satisfactory to examine the relaxation amongst the bottom-most 40 or 50 levels; the disposition of these levels is shown in Fig. 1. No dissociation was allowed so that particles are strictly conserved: therefore the smallest eigenvalue d_{n-1} is identically zero (2) and the required relaxation time is (6) the inverse of $|d_{n-2}|$, which is now the smallest non-zero eigenvalue. Using the set of T–VR transition probabilities prescribed by[2] eq. VIII(16*a*), it was found that at 2000 °K d_{n-2} was, as we had expected, most affected by changes in the transition probability $v = 0, J = 5 \leftrightarrow v = 0, J = 7$, but there was no longer the strict proportionality that we had found in our previous calculations (2, 7): this was true for several truncated sets of levels, with 44, 49, and 50 members in the set; generally, d_{n-2} was scaled by about 20% of the factor used to scale the pair of transition probabilities. Equation VIII(16*a*) assigns the transition probabilities solely on the basis of the energy gap between the two levels involved in the transition (1). However, using eq. VIII(16) which discriminates against larger changes than $\Delta J = 2$, it was found that for the 44-member set d_{n-2} was perturbed the most strongly by changes to the probability for the $v = 0, J = 19 \leftrightarrow v = 0, J = 21$ transition! If a different truncated set was used, *e.g.* the lowest 49 levels, d_{n-2} was most sensitive to the transition probability for $v = 0, J = 5 \leftrightarrow v = 0, J = 7$, and if the lowest 50 levels were used the key transition remained $v = 0, J = 5 \leftrightarrow v = 0, J = 7$. Clearly what is happening (referring now to our 44-level truncated set) is that when large changes in J are penalized and the chain of levels $v = 1, J = 19$; $v = 2, J = 17$; and $v = 3, J = 15$ is deleted, the transitions from $v = 0, J = 21$ to $v = 1, J = 17$ or $v = 2, J = 15$ have quite small probabilities, and therefore relaxation to equilibrium of the $v = 0, J = 21$ state must take place principally through the transition $v = 0, J = 21 \leftrightarrow v = 0, J = 19$ which is slow and rate determining. One can imagine a set of points forming a network, in which most of the points are connected to several other points,

but in which a few of the outlying points lie on branches, each only connected to the main network by a single line passing through all the points on the branch: under these conditions the overall relaxation time will be determined mainly by the characteristic time of the slowest relaxation of any of the branches.[3] This idea was supported by the fact that when, using the 44-member set, the top-most J-sublevels for each v were connected to each other with higher transition probabilities ($\sim 10^{-3}$ per collision), d_{n-2} became most sensitive to the $v = 0$, $J = 5 \leftrightarrow v = 0$, $J = 7$ transition probability with the ΔJ-restricted set of probabilities VIII(16) also, but not to the same extent as with the probabilities VIII(16a) which are solely dependent on the energy gap. Thus, one can regard a dissociating diatomic molecule (as we have suggested previously (1, 8)) as being analogous to a densely interconnected network, and there is only one branch, which in this case is the sequence of levels $v = 0, J = 1$; $v = 0, J = 3$; $v = 0$, $J = 5$; and $v = 0$, $J = 7$ which can then connect either to $v = 0$, $J = 9$ or $v = 1$, $J = 1$. In the energy-dependent case, the latter transition is easy, and so the relaxation time is principally determined by the $J = 5$ to 7 transition of $v = 0$, with $J = 3$ to 5 of $v = 0$ being of lesser importance: in the ΔJ-dependent case however, the sideways transition from $v = 0$, $J = 7$ to $v = 1$, $J = 1$ is much less favorable, and the relaxation becomes sensitive to the probabilities of several of the transitions in this region.

We remark in passing that it is common to perform relaxation calculations using truncated sets of levels; this has probably not led to any spurious conclusions so far, but as calculations become more sophisticated in the future, it will become more important to examine the network properties of the truncated sets of levels and their associated sets of transition probabilities.

So far, we have confined ourselves to the problem of trying to find which single pair of transition probabilities correlates the best with d_{n-2}, the eigenvalue which has previously been identified with the inverse of the observable relaxation time (2, 3, 6). The question then arises, are there any particular eigenvalues in the spectrum which can be identified as being associated with a purely vibrational, or a purely rotational relaxation time, and which are consistent with experimental experience? At 2000 °K (for a mixture consisting of 3.5×10^{19} He atoms per cc and 3.5×10^{16} H_2 molecules per cc), the eigenvalue spectrum[4] for ortho-hydrogen consists of d_{n-1} at about 6×10^{-1} s^{-1} followed by a series of 171 eigenvalues, well spaced, between $d_{n-2} \approx 9 \times 10^6$ s^{-1} and $d_{n-172} \approx 1 \times 10^{11}$ s^{-1}, using the set of probabilities described by eq. VIII(16), and without tunnelling (1); the inclusion of tunnelling only perturbs the larger eigenvalues, which do not concern us here, and the use of the alternative set of transition probabilities, eq. VIII(16a) does not alter any of the qualitative conclusions described in the remainder of this paper. In the first of two experiments, the probability of *every* $J = 1 \leftrightarrow J = 3$ transition, for *all* v, was multiplied by an arbitrary factor of 100, and the eigenvalues compared with the standard set: most of the largest eigenvalues ($10^{10} - 10^{11}$ s^{-1}) remained unchanged down as far as the fourth, fifth, or even sixth decimal place, but most of the smaller ones, from d_{n-2} (d_{170}) $\approx 9 \times 10^6$ s^{-1} to d_{n-44} (d_{128}) $\approx 5 \times 10^8$ s^{-1} were changed by small amounts; it was also possible to identify a few eigenvalues in this group which had been selectively multiplied by larger factors, sometimes approaching 100. Thus at 2000 °K, one cannot identify any single eigenvalue with rotational relaxation; it appears that many eigenvalues, even up to those characterizing the very longest relaxation, have significant rotational character. Incidentally, if *only* the $J = 1 \leftrightarrow J = 3$ transition of $v = 0$ is changed at this temperature, the eigenvalue d_{n-40} (d_{132}) $\approx 4.3 \times 10^8$ s^{-1} is most affected (to the extent of about 20% of the applied perturbation). In the second experiment, *every* $v = 0 \leftrightarrow v = 1$ transition probability, for *all* J, was scaled by a factor of 100, with the result that many eigenvalues changed somewhat, but none of them was obviously scaled by a large amount; likewise,

[3]We would like to thank a referee for pointing out that this statement could be deceptive: starting with a non-equilibrium state in which all the molecules are present in low-lying energy levels, then (as described later in this paper) the amount of energy associated with raising a relatively small number of molecules into the $v = 0$, $J = 21$ state would not be detectable in any macroscopic experiment, and the observed relaxation time would relate to some other process having more energy associated with it; however, if a large fraction of the molecules were initially present in the $v = 0$, $J = 21$ state, the statement would be strictly true.

[4]Note that *all* the eigenvalues are *negative*: however, since no confusion will arise, the minus sign will be dropped, for convenience, from the numerical values of eigenvalues quoted in the descriptive sections of this paper.

when only the $v = 0 \leftrightarrow v = 1$ transition probability for $J = 0$ was scaled, some eigenvalues increased, but no clearly defined effect showed up.

The relaxation effects at 2000 °K are obviously very complex: however, vibrational relaxation should be unimportant at 500 °K, and the rotational relaxation effects at this temperature should therefore be easier to resolve. Again, following the same procedure, individual pairs of transition probabilities P_{ij} and P_{ji} were multiplied by an arbitrary factor of 100, and the results for 500 °K were broadly as follows:

(*a*) When the probability $v = 0, J = 1 \leftrightarrow v = 0, J = 3$ was scaled, eigenvalue d_{119} was scaled by a factor of 98, d_{148} was slightly perturbed (factor of 1.03), and the remainder were virtually unchanged.

(*b*) For higher J-levels, the principal scaling factor was of the order of 30 to 50, with the affected eigenvalues being

$$v = 0, J = 3 \leftrightarrow v = 0, J = 5 \qquad \{d_{148}, d_{119}\}$$
$$v = 0, J = 5 \leftrightarrow v = 0, J = 7 \qquad \{d_{159}, d_{148}\}$$
$$v = 0, J = 7 \leftrightarrow v = 0, J = 9 \qquad \{d_{161}, d_{159}\}$$
$$v = 0, J = 9 \leftrightarrow v = 0, J = 11 \qquad \{d_{164}, d_{161}\}$$

(*c*) Thereafter, more eigenvalues were perturbed by smaller amounts, until at very high J values, there was only a small but still noticeable effect on a single eigenvalue, the remaining change in the trace being dissipated in very small perturbations to other eigenvalues.

(*d*) More interestingly, if for $v = 0$, the probabilities for all the first three transitions $J = 1 \leftrightarrow J = 3$, $J = 3 \leftrightarrow J = 5$, and $J = 5 \leftrightarrow J = 7$ were simultaneously scaled by a factor of 100, then eigenvalues d_{119}, d_{148}, and d_{159} were all scaled by factors between 99.5 and 99.95, with very little other discernible effect on the spectrum. Thus, these three eigenvalues are obviously the principal components of a rotational subset (the vestiges of which still persist in the 2000 °K calculation described above).

(*e*) For transitions among the J-sublevels of $v = 1$, the affected eigenvalues were not the same ones as were changed in (*a*) and (*b*) above for $v = 0$.

(*f*) At 500 °K, unlike the 2000 °K case, d_{170} (d_{n-2}) was sensitive to changes in the probabilities $v = 0, J = 1 \leftrightarrow v = 1, J = 1$, and to a lesser extent $v = 0, J = 3 \leftrightarrow v = 1, J = 3$ (40% and 20% respectively of the imposed perturbation factor); however, at 500 °K, vibrational excitation in H_2 is unimportant.

These calculations therefore suggest that whilst it is possible to define, and presumably observe, a rotational relaxation time at moderately low temperatures, it is not possible to define a vibrational relaxation time, nor observe one, and that the observable quantity that has hitherto been thought to be a vibrational relaxation time possesses considerable rotational character. These conslusions are examined in much more detail later in the paper.[5] The concept is not a foreign one (after all, it is possible to observe pure rotational spectra of molecules, but one cannot observe pure vibrational spectra without superposition of rotational effects). It arises in the present context because whenever vibrational excitation occurs, it has to be arrived at through a whole network of transitions, a few of which may be purely vibrational, some purely rotational together with one rotation–vibration (T–VR) transition, but by far the most of them mixed rotation–vibration transitions. Significantly, the $v = 0, J = 1$ to $v = 0, J = 7$ sequence of levels forms essentially a linear branch (transitions from points on the branch to other points in the network are possible but not probable), and it is the rate-determining properties of this single branch that are the most important factors in

[5]It is well known (3) that if the ultrasonic relaxation times for the halomethanes are plotted against the lowest vibration frequencies of the molecules, the experimental data fall fairly well on two straight lines: molecules with two or more hydrogen atoms fall near one line, and molecules with one or no hydrogen atom near the other; this behavior is usually called the Lambert–Salter relationship. Realizing that a vibrational relaxation time *per se* may have no meaning, and that every observable "vibrational relaxation time" could have a substantial rotational component, we believe that it might be possible to rationalize these data into a single plot, and have made a brief examination of the problem. As far as possible with the data available we have tabulated the rotation–vibrational energy-level spectrum for a number of these molecules, and have looked at two possibilities: one, that the ultrasonic relaxation time will be related to the energy of the largest rotation–vibration spacing in the system, and two, that it will be related to the number of rotational gaps in the lowest vibrational gap; the latter approach seems the more promising at this time. Note that the rotational component implied by this description of the vibrational relaxation process is not the same as that proposed recently by Lambert (15); the same difficulties will arise however in respect of the magnitude of the measured ultrasonic velocity dispersion.

determining the observable relaxation properties of the molecule, at any temperature.

The Mixed Character of Relaxation Times

As we have just seen, there is no single eigenvalue in the spectrum at 2000 °K which can be identified with either a purely rotational or a purely vibrational relaxation time, especially so in the latter case. On the other hand, molecules *do* exhibit well defined and experimentally measureable relaxation times, although in some cases there appear to be double relaxations for more complicated molecules (3). Clearly then, the molecular gas must present to the sound wave or shock wave the appearance of only possessing a few important eigenvalues, and it is obvious that these will be those eigenvalues with which are associated the greatest contributions to the instantaneous heat capacity at the temperature in question. Thus, we now extend our previous analysis to the calculation of the quantity $\Delta\bar{E}(j)$, the amount of energy associated with the jth eigenvalue d_j and which is taken up in the period $|d_j^{-1}|$, *i.e.* the jth relaxation time, given an arbitrary initial distribution: we will in fact only consider the quantity $\Delta\bar{E}_0(j)$ which refers to an initial distribution in which all molecules are in the lowest possible energy level. The following analysis is limited to short times, before any appreciable dissociation takes place (*i.e.* at temperatures where $|d_{n-1}| \ll |d_{n-2}|, |d_{n-3}|$ etc.) and therefore to initial states consisting of only low-lying rotation–vibration states. Thus, eq. III(4) can be approximated to

$$[1] \qquad \dot{\xi} = \mathbf{A}\xi$$

where $\mathbf{A}$ is the transition matrix, ξ is a vector of $n_i/\tilde{n}_i$ (n_i being the instantaneous population of the ith level and $\tilde{n}_i$ being its equilibrium value) and $\dot{\xi}$ is the derivative of ξ with respect to time: the reader is referred to papers I and III of this series (2, 9) for amplification of the precise meaning of symbols, and for clarification of the following derivation. The matrix $\mathbf{A}$, can be symmetrized to a new matrix $\mathbf{B}$ by the transformation $\mathbf{B} = \mathbf{E}\,\mathbf{A}\,\mathbf{E}^{-1}$, and the matrix $\mathbf{B}$ can be diagonalized by the transformation $\mathbf{D} = \tilde{\mathbf{S}}\,\mathbf{B}\,\mathbf{S}$: thus, combining the simplified eqs. III(8a) with III(10), one gets

$$[2] \qquad \tilde{\mathbf{S}}\,\mathbf{E}\,\dot{\xi} = \mathbf{D}\,\tilde{\mathbf{S}}\,\mathbf{E}\,\xi$$

c.f. also ref. 9, eq. I(28). On integration, this becomes

$$[3] \qquad \xi(t) = \mathbf{E}^{-1}\mathbf{S}\,e^{\mathbf{D}t}\,\tilde{\mathbf{S}}\,\mathbf{E}\,\xi(0)$$

whence, writing $\xi = \mathbf{E}^{-2}\mathbf{n}$

$$[4] \qquad \mathbf{n}(t) = \mathbf{E}\,\mathbf{S}\,e^{\mathbf{D}t}\,\tilde{\mathbf{S}}\,\mathbf{E}^{-1}\,\mathbf{n}(0)$$

or, in expanded form, since $(\tilde{\mathbf{S}})_{jk} = (\mathbf{S})_{kj}$, the lth element of the population vector at time t is

$$[4'] \quad n_l(t) = \tilde{n}_l^{1/2} \sum_j S_{lj}\, e^{d_j t} \sum_k S_{kj} \tilde{n}_k^{-1/2} n_k(0)$$

We now abstract from [4'] the component associated with only the jth eigenvalue, yielding

$$[5] \quad n_l(j, t) = \tilde{n}_l^{1/2} S_{lj}\, e^{d_j t} \sum_k S_{kj} \tilde{n}_k^{-1/2} n_k(0)$$

which describes the growth in the population of the lth state which can be ascribed to the jth eigenvalue, from a starting distribution given by $\boldsymbol{n}(0)$; the amount of energy associated with this growth in population is

$$[5e] \quad \varepsilon_l(j, t) = \tilde{n}_l^{1/2} S_{lj}\, e^{d_j t} \sum_k S_{kj} \tilde{n}_k^{-1/2} n_k(0)[\varepsilon_l - \varepsilon_k]$$

where ε_l, ε_k are energy levels. Summation over all l yields the quantity $\Delta E(j, t)$, the total energy increment in the time t associated with the jth relaxation and a given initial distribution. However, the majority of our calculations assumed that all molecules were initially present in the lowest available state ($v = 0, J = 1$), since it was found that the use of two other low-lying initial states ($v = 0$, $J = 3$ or $v = 0$, $J = 5$) gave qualitatively similar results. Thus, apart from a numerical constant, $\boldsymbol{n}(0)$ becomes the vector {1,0,0.....} and we get

$$[6] \quad \Delta E_0(j, t) = \text{constant} \times \sum_l (2J_l+1)^{1/2} \varepsilon_l\, e^{-\varepsilon_l/2kT} S_{lj} S_{0j}\, e^{d_j t}$$

The experimentally important quantity, of course, is the total energy increment associated with the jth relaxation, which is simply

$$[7] \quad \Delta\bar{E}_0(j) = \text{constant} \times S_{0j} \sum_l (2J_l + 1)^{1/2} \varepsilon_l\, e^{-\varepsilon_l/2kT} S_{lj}$$

Alternatively [7] can be regarded as the energy increment taking place in the characteristic period of the relaxation $t = |d_j^{-1}|$.

Use of any of the eqs. 4 to 7 requires the knowledge of the eigenvectors $\mathbf{S}$ of (for ortho-hydrogen) the 172nd order relaxation matrix, and with the

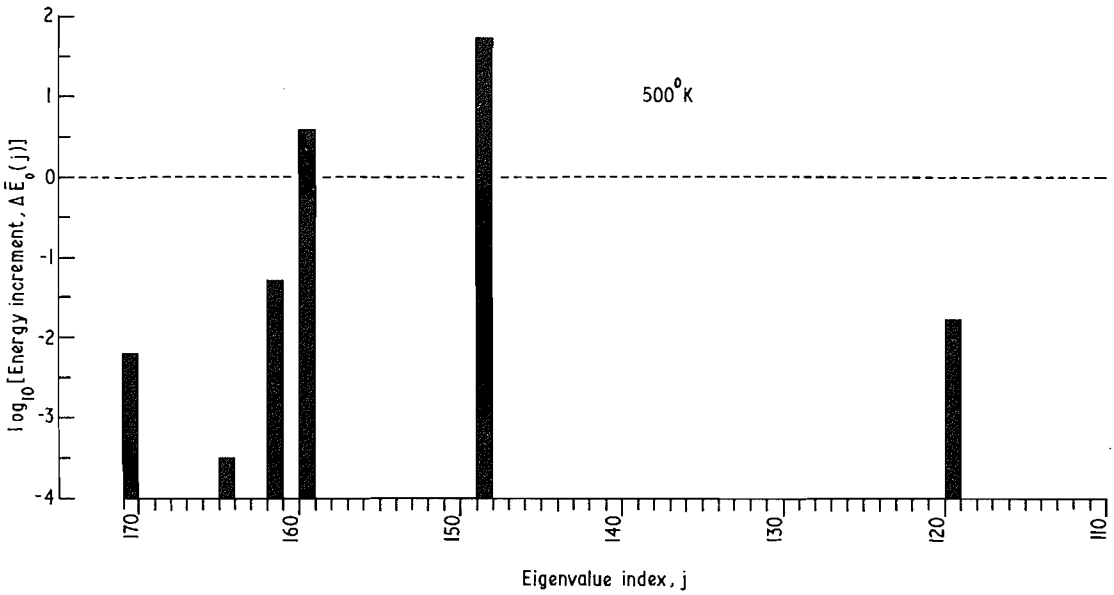

FIG. 2. Logarithmic plot of energy increment $\Delta\bar{E}_0(j)$ against eigenvalue index j for $T = 500\,^{\circ}\mathrm{K}$; the units of $\Delta\bar{E}_0(j)$ are arbitrary.

recent availability of quadruple-length arithmetic on the IBM 370 series of machines, we have been able to calculate most of the vectors of such matrices by existing techniques (9, 10). The eigenvectors we have been unable to find, either because of cancellation or because of overflow difficulties (1), have been those associated with the reaction eigenvalue itself, *i.e.* d_{n-1} especially so at the lower temperatures, and with some of the very large eigenvalues, of the order of 10^{11} s^{-1}: these very rapid processes correspond to equilibrations amongst very highly excited levels, or between these levels and the continuum; hence, it was for these reasons that our derivation and discussion are confined to initial states consisting only of low-lying levels, and to times short compared with the characteristic reaction time.

(i) Rotational Relaxation at 500 °K

It is known that at 500 °K, hydrogen exhibits relaxation properties which can be described with confidence as being rotational in character (3). Thus, in view of the conclusions from the numerical experiments described above, it would seem that one could expect to find the application of eq. 7 to be fairly uncomplicated at this temperature. The energy increment associated with each eigenvalue in its characteristic relaxation time was calculated using the standard set of transition probabilities through eq. 7, and the results are shown graphically in Fig. 2. It can be seen that apart from the three eigenvalues d_{119}, d_{148}, and d_{159}, there is very little other contribution to the energy increment, and taken together with the results of the numerical experiment (*d*) described in the preceding section, clearly identifies these three eigenvalues as being the ones associated with the rotational relaxation at this temperature. Only d_{161}, d_{164}, and d_{170} make any other discernible contribution: d_{161} is closely related to the $v = 0, J = 7 \leftrightarrow v = 0, J = 9$ transition, d_{164} likewise to $v = 0, J = 9 \leftrightarrow v = 0, J = 11$; and d_{170} is related principally to the $v = 0, J = 1 \leftrightarrow v = 1, J = 1$ transition *i.e.* the pure vibrational transition, which is not significantly excited at this temperature.

Then, as a final check on the close connection of the three eigenvalues d_{119}, d_{148}, and d_{159} with the transitions $J = 1 \leftrightarrow J = 3$, $J = 3 \leftrightarrow J = 5$, and $J = 5 \leftrightarrow J = 7$, respectively, of $v = 0$ and their association with an observable relaxation phenomenon, each of these transition probabilities was scaled, in turn, by a small amount (a factor of 2, so as not to upset the relaxation pattern very seriously), and it was found in each case that a large energy increment continued to be associated with the eigenvalue which was moved by this perturbation.

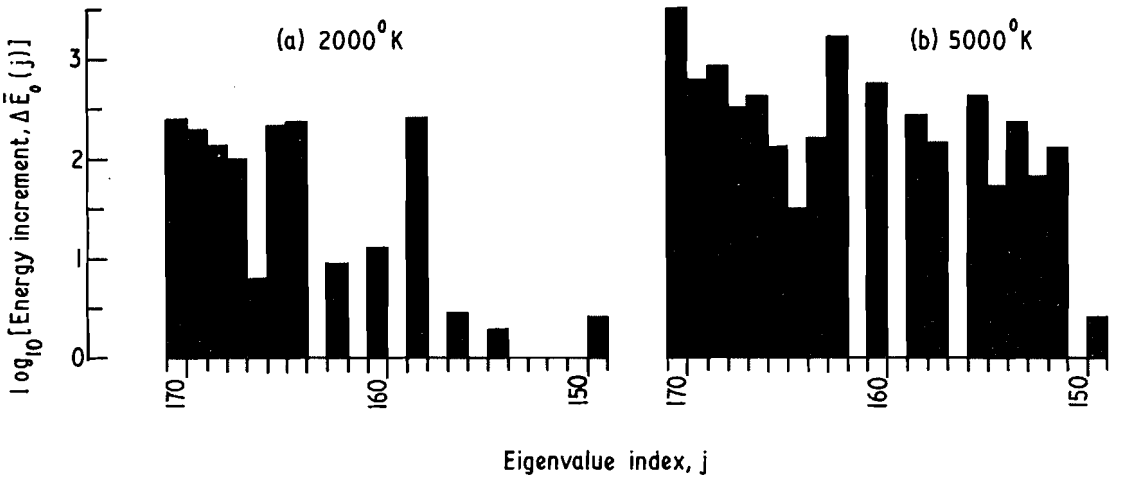

FIG. 3. Logarithmic plot of energy increment $\Delta\bar{E}_0(j)$ against eigenvalue index j: (*a*) for $T = 2000$ °K; (*b*) for $T = 5000$ °K. Note that the units of $\Delta\bar{E}_0(j)$ are arbitrary, but that the constant in eq. 7 is comparable between Figs. 2, 3*a* and 3*b*; thus, only the portion of Fig. 2 above the dotted line is to be compared with Figs. 3*a* and 3*b*.

(ii) Mixed Relaxations at 2000 and 5000 °K

As we noted earlier in the paper, it was not possible to deduce any close connection between individual vibrational transition probabilities and certain eigenvalues for the temperature 2000 °K. Many eigenvalues changed by small amounts as the result of changing one pair of transition probabilities, as expected from the analysis of Boyd (7), and at 5000 °K, the perturbations of the eigenvalues resulting from a single perturbation in a pair of transition probabilities were even more diffuse. Thus, the only analysis of the situation we could perform was an examination of the energy increment associated with each eigenvalue according to eq. 7; only 22 eigenvalues were examined in detail, and the results are shown in Fig. 3. At 2000 °K, about a dozen eigenvalues are associated with significant energy increments, with d_{170}, d_{169}, d_{168}, d_{167}, d_{165}, d_{164}, and d_{158} dominating; the corresponding relaxation times are 10.9, 5.9, 3.8, 2.9, 2.0, 1.7, and 0.7×10^{-8} s, respectively. This implies that the last transient preceding chemical reaction is not a simple relaxation determined by the eigenvalue d_{n-2} (d_{170}), but is rather a complex one which will only approach to a simple exponential decay at the tail end of the relaxation: it would probably be very difficult experimentally to resolve such a complex relaxation into its components (6), but there have been suggestions that, both in N_2 and H_2, the approach to equilibrium is not a pure exponential (11, 12); on the other hand, at low temperatures, one could hope that either ultrasonic or shock-wave relaxation experiments would resolve the kind of behavior depicted in Fig. 2 where the important eigenvalues are very well spaced out in time. At 5000 °K, almost every one of the first 22 eigenvalues makes a significant contribution to the instantaneous heat capacity, as also do several others beyond the 22nd: however, since the interpretation of Fig. 3 can only be extremely qualitative in nature at the present time, we do not reproduce these unnecessary data. It should be noticed that the results depicted in Fig. 3 are *quantitatively* quite sensitive to the assumed sets of transition probabilities. The ones shown were calculated using the ΔJ-dependent probabilities, eq. VIII(16); use of the probabilities eq. VIII(16a) which allow large changes in J to take place if the energy separation is small, appears to simplify the relaxation slightly, in the sense that rather fewer eigenvalues have associated large energy increments; this is consistent with the results found in the numerical experiments described earlier in the paper, but again, we do not reproduce this data since its importance is only qualitative.

Conclusions

The following picture of the relaxation properties of a diatomic gas in a large excess of inert diluent emerges from these calculations; these statements are made in the context of our calcula-

tion using ortho-hydrogen which only possesses odd rotational levels, but are clearly extendable to the general case of a molecule having both odd and even levels (with due regard for the size of the rotational spacings compared with kT). At very low temperatures, say 300 °K, so low that only the $v = 0, J = 1 \leftrightarrow v = 0, J = 3$ transition can be significantly excited, the molecule will exhibit a fairly simple rotational relaxation. Because of computational difficulties (1) we have not been able to locate which eigenvalue this is, but in view of the earlier work on this problem (2, 7), this is certain to be the case; since our assumed transition probabilities increase slowly with increasing temperature, the eigenvalue in question at 300 °K will be close to, but slightly lower (*i.e.* slower) than, the corresponding eigenvalue d_{119} at 500 °K which is 1.1×10^8 s^{-1} *i.e.* $\tau \approx 9.4 \times 10^{-9}$ s. As the temperature increases, this relaxation will speed up slightly because the $J = 1 \leftrightarrow J = 3$ transition probability increases with temperature. However, by 500 °K, three eigenvalues and three processes are important. These are d_{119} (1.1×10^8 s^{-1}), d_{148} (3.3×10^7 s^{-1}), and d_{159} (1.4×10^7 s^{-1}), with the latter two having larger contributions to the energy increment than does the simple $J = 1 \leftrightarrow J = 3$ relaxation with which d_{119} is principally associated. Thus, although the relaxation is still essentially rotational, this increasing complexity brings with it a *lengthening* of the relaxation time, in our case to somewhere of the order of 5×10^{-8} s. It is precisely the beginning of this behavior that has been observed recently in shock-wave measurements of the rotational relaxation times for hydrogen (12); that our predicted effect is more severe than the observed one is almost certainly attributable to imperfections in our assumed set of transition probabilities (1). At this temperature also, it is possible to identify *theoretically* a vibrational relaxation time, but its associated instantaneous heat capacity is negligible and the relaxation would not be observable in any coarse-grained experiment. Then as the temperature increases, the vibrational character of the excitation becomes more important, and the relaxation time will continue to increase rather slowly until at 2000 °K, Fig. 3*a* would suggest a value close to $|d_{n-2}{}^{-1}|$ (1.1×10^{-7} s) or $|d_{n-3}{}^{-1}|$ (5.9×10^{-8} s), probably around 1×10^{-7} s. Further increase in temperature then increases the complexity of the relaxation still further, but the dominant factor is the general increase in transition probabilities with increasing temperature, leading to a gradual *shortening* of the relaxation time again, to about 3 or 4×10^{-8} s at 5000 °K in our calculation: as we have noted before the actual times and temperatures are quoted for illustrative purposes only, the precise magnitudes being dependent on the initial choice of the set of transition probabilities (1); it could be that the apparent turning point in the "vibrational" relaxation time of NO near 500 °K is an example of this (13, 14), although there are alternative satisfactory explanations.

Thus there are basically four regimes in the internal relaxation of the gaseous molecule, as shown schematically in Fig. 4: (*a*) at low temperature, there is the almost pure $J = 1 \leftrightarrow J = 3$ (more generally $J = 0 \leftrightarrow J = 1$ for most molecules) rotational relaxation (T–R); (*b*) then at intermediate temperatures, there is a mixed rotational relaxation, of somewhat longer duration because of the participation of additional excited rotational levels in the equilibration process (T–*n*R); (*c*) then, at somewhat higher temperatures, this merges into a mixed rotation–vibration relaxation (T–VR), which (*d*) becomes more and more complex in nature (T–*n*VR) with increasing temperature, and whose duration is determined by the network properties of the

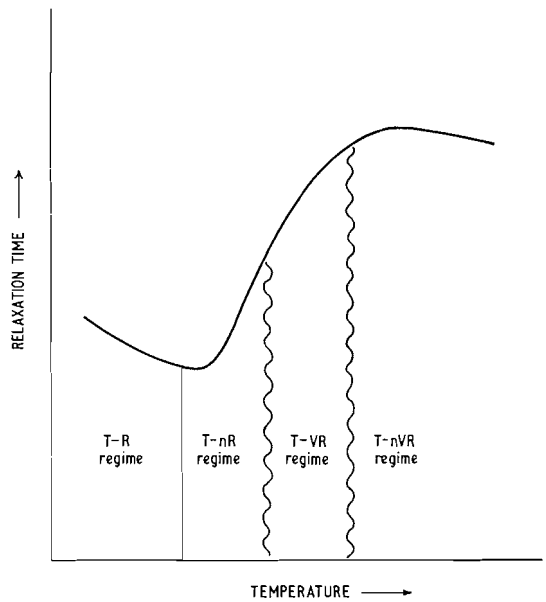

FIG. 4. Schematic diagram of the variation of internal relaxation time with temperature.

larger rotational gaps which interleave the lowest steps on the vibrational ladder.

Thus, whilst to a fair degree of approximation, one can define a rotational relaxation time, it would appear that there is no such thing as a vibrational relaxation time, only a rotation–vibration (T–VR) relaxation time. One should also note that the eigenvalues having large associated energy increments may be dependent on the initial population distribution (*c.f.* eq. 5*e*); thus, it does not necessarily follow that the relaxation time measured for H_2 at 1000 °K in an ultrasonic dispersion experiment needs to be the same as that measured in a shock-wave experiment where the initial temperature is 300 °K and the final temperature is 1000 °K (*c.f.* Fig. 3 of ref. 12).

We would like to express our thanks to Sean McElwain for many helpful discussions, and to Tom Ashton and Gail McCart for programming advice and assistance respectively.

Aqueous Nonelectrolyte Solutions. Part XII. Enthalpies of Mixing of Water and Deuterium Oxide with Tetrahydrofuran[1]

DAVID N. GLEW AND HARRY WATTS

Exploratory Research Laboratory, Dow Chemical of Canada, Limited, Sarnia, Ontario

Received July 21, 1972

Calorimetric enthalpies of mixing have been measured over the whole composition range for the water–tetrahydrofuran and the deuterium oxide – tetrahydrofuran systems at 10.00 and 25.00 °C. The experimental S-shaped, enthalpy of mixing – composition curves are interpreted in terms of changes of the water hydrogen bonding in solution. At low tetrahydrofuran mole fractions the deuterium oxide systems are more exothermal and at high tetrahydrofuran mole fractions more endothermal than the corresponding water systems. A good correlation is found between the enthalpy of mixing and the water proton magnetic resonance chemical shift for solutions with greater than 0.55 mole fraction of tetrahydrofuran.

Les enthalpies calorimétriques de mélange ont été mesurées pour tout l'intervalle de composition des systèmes eau–tétrahydrofuranne et oxyde de deutérium-tétrahydrofuranne à 10.00 et 25.00 °C. Les courbes expérimentales en forme de S, enthalpie de mélange – composition, sont interprétées en fonction des changements dans l'enchainement par liaison hydrogène de l'eau dans la solution. Pour des fractions molaires faibles en tétrahydrofuranne, les systèmes contenant de l'oxyde de deutérium sont plus exothermiques que les systèmes contenant de l'eau similaires; de même pour des fractions molaires élevées en tétrahydrofuranne, les systèmes contenant de l'oxyde de deutérium sont plus endothermiques. On a pu établir une bonne relation entre les enthalpies de mélange et le déplacement chimique en résonance magnétique du proton de l'eau, pour des solutions ayant des fractions molaires en tétrahydrofuranne supérieures à 0.55. [Traduit par le journal]

Can J. Chem., 51, 1933 (1973)

Introduction

Recently we reported measurements of the enthalpies of mixing of water and deuterium oxide with ethylene oxide, EO (1). In that study the S-shaped, enthalpy of mixing – composition curves were interpreted in terms of solution H-bonding changes, with particular reference to the H-bonding of water. We found a good correlation between the enthalpy of mixing and the water proton magnetic resonance (p.m.r.) chemical shift for solutions with mole fraction of EO greater than 0.55. Now we report a continuation of that study in which the enthalpies of mixing of water and deuterium oxide with tetrahydrofuran (THF) have been measured. The behavior of these systems is similar to those containing EO, hence the introduction to that work, and the general comments on the nature of liquid water and aqueous solutions should be read in conjunction with this paper.

Some measurements of the enthalpy of mixing of water with THF at 15 and 25 °C have been reported graphically by Erva (2). However, his study was not so complete as ours.

[1]Contribution No. 196.

Experimental

Materials

The water and deuterium oxide were as used previously (1). Fisher certified grade tetrahydrofuran (THF) was refluxed over lithium aluminum hydride overnight under dry nitrogen and distilled. The distillate was transferred immediately, under an atmosphere of nitrogen, to the calorimeter filling system and freeze-outgassed.

Calorimetry

The calorimeter and its operation have been fully described previously (1, 3). The first system studied with this calorimeter was *n*-hexane–cyclohexane (3), and these measurements have, with others, become embodied in the recommendation that this system be regarded as a standard for testing mixing calorimeters (4). Hence no further comment on the accuracy of the calorimeter is required. All measurements on the water–THF systems were made at 1 atm total pressure.

Results

Enthalpy of mixing measurements at 10.0 and 25.0 °C were made over the complete composition range for both the H_2O–THF and D_2O–THF systems. Tables 1–4 record the weight of H_2O or D_2O and of THF taken in each experiment, together with the temperature of the experiment and the observed heat change. The fifth and sixth columns give the water mole frac-

						$\sigma(\Delta_m h) = 1.8$

tion, x_1, and the enthalpy change per mole of mixture formed, $\Delta_m h$, corrected to the reference temperature of the table.

The experimental results for each system were fitted by the method of least squares to the equation

$$[1] \quad \Delta_m h(\text{J/mol}) = x_1(1 - x_1) \sum_{k=0}^{k=m} B_k(1 - 2x_1)^k$$

with regression coefficients B_k. To fit the S-shaped distribution of results adequately for these systems required up to twelve regression coefficients. When the exothermal and endothermal results were fitted separately the number of regression coefficients was six for each region. The final column in Tables 1–4 gives the residual, $\delta(\Delta_m h(\text{obs}) - \Delta_m h(\text{calc}))$, between the observed enthalpy of mixing and the value calculated from [1]. At the bottom of each table $\sigma(\Delta_m h)$ gives the standard error on a single enthalpy of mixing measurement, assessed from the fit of [1]. Over all measurements $\sigma(\Delta_m h)$ has a value of 4.4 J/mol; when the exothermal results alone are fitted $\sigma(\Delta_m h)$ is increased to 5.0, while the endothermal results alone show $\sigma(\Delta_m h)$ significantly reduced to 2.3 J/mol. This properly reflects the greater calorimetric accuracy of the endothermal measurements, as found previously for the EO systems.

Table 5 gives smoothed $\Delta_m h$ values with standard errors σ evaluated from [1] at regular mole fraction intervals.[2] Values of the regression coefficients for [1] for the four sets of measurements are given in Table 6. In Fig. 1 are shown typical S-shaped enthalpy of mixing curves for the H_2O–THF system at 10.00 and 25.00 °C. Increase of temperature leads to increase in $\Delta_m h$ at all compositions. This is consistent with what is commonly observed in aqueous systems in which strong interaction occurs between the components being mixed (5–7).

In Fig. 2 are shown the enthalpy of mixing curves for the H_2O–THF and D_2O–THF systems at 25.00 °C. At low THF concentrations $\Delta_m h$ values with D_2O lie below those with H_2O but at high THF concentrations they lie above, as previously reported for H_2O with EO (1).

Discussion

Interpretation of the Enthalpy of Mixing Curves

The S-shaped composition dependence curve for $\Delta_m h$, shown in Figs. 1 and 2, is similar to that observed for many aqueous nonelectrolyte systems (5–9) and in particular to those we observed recently with water and EO (1). As before, we divide our discussion into three sections.

Water-rich Region (100–80% Water)

A qualitative explanation only of the effects observed in this region can be offered. As before (1), we envisage the exothermal mixing of small amounts of THF with water as being due partly to H-bond formation between THF and the small amount of non-H-bonded O—H groups present, partly to the reorientation of water molecules around the template of a THF molecule, and partly to the central van der Waals attractive forces between THF and adjacent water (1, 10–13). The water reorientation relieves strain in the bent H-bonded water network, allowing the water–water–water H-bonds to assume angles closer to the regular tetrahedral angle (10, 13) with consequent strengthening of the H-bonds (11) and lowering of the enthalpy. The central attractive forces between THF and its adjacent water further lower the enthalpy and enhance the water reorientation; the enthalpy is lowered because water interactions with second-nearest water neighbors over the solid angle π are replaced by stronger van der Waals interactions with the closer THF. As more THF is added competition of the THF oxygen atoms for H-bond formation leads to replacement of network water–water H-bonds by water–THF H-bonds with increase of enthalpy, which is responsible for the observed minimum.

The behavior of the H_2O–THF and D_2O–THF systems is similar. However, reference to the smoothed data in Table 5 and to Fig. 2 shows

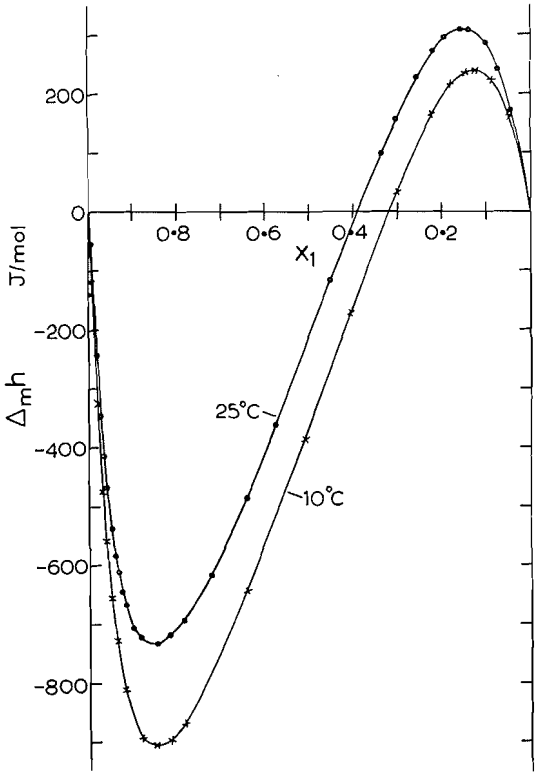

FIG. 1. Molar enthalpy of mixing $\Delta_m h$ dependence on water mole fraction x_1 for the H_2O–THF system at 10.00 and 25.00 °C.

that the D_2O curve lies below the H_2O curve at THF mole fractions less than 0.15 and 0.20 at 10.00 and 25.00 °C, respectively. At higher THF mole fractions the D_2O curve lies above the H_2O curve. A similar effect was observed with EO with the cross-over occurring at lower mole fractions (1). This implies greater strengthening of the three-dimensionally bonded network in D_2O solution than in H_2O solution, and/or stronger THF bonds with D_2O.

The observed minima with THF occur at larger $-\Delta_m h$ values than with EO. This means that THF acts as a better attractive template for reorientation of water molecules than does EO. This is consistent with both the larger downfield water p.m.r. chemical shift observed with THF and the larger excess partial molar volume for water in solution with THF (10) than observed with EO (12).

Intermediate Region (80–20% Water)

A linear dependence of $\Delta_m h$ with composition is observed in the range 0.4–0.7 mole fraction THF. We envisage this as being due to replacement of H-bonds between water molecules by H-bonds between water and THF. This replacement must occur in a perfectly regular manner to cause this long linear region, which has been observed in other aqueous systems (1, 2, 5–9). The water p.m.r. chemical shifts (15) in this linear region show a nearly constant number of water–THF H-bonds per mole of solution with the number of water–water H-bonds decreasing linearly with x_1. This means that the linear increase of $\Delta_m h$ with THF mole fraction directly reflects the linear decrease of the number of water–water H-bonds per mole of solution.

A linear composition dependence of $\Delta_m h$ is also observed with D_2O, but $\Delta_m h$ increases slightly more rapidly for the D_2O systems (Table 5). This implies that the enthalpy difference between a D-bond with D_2O and a D-bond with THF is greater than the corresponding difference for the H_2O–THF system. Thus the breakdown of stronger bonds in the D_2O system leads to larger endothermal enthalpies in this composition region.

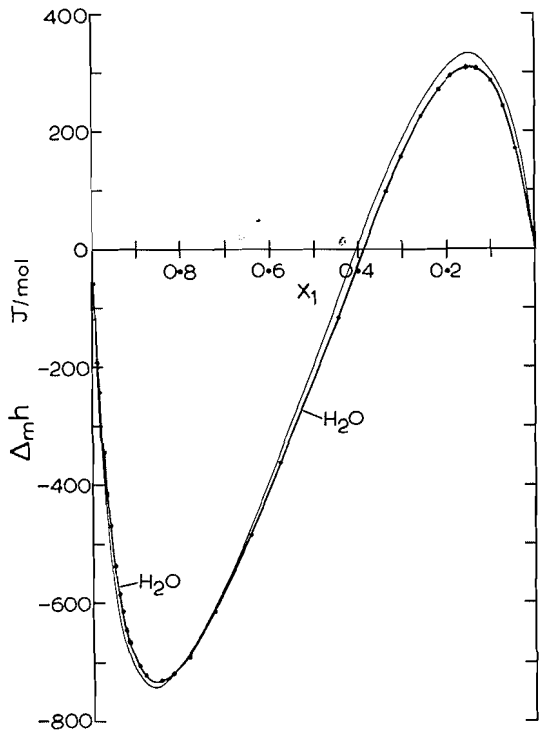

FIG. 2. Comparison of enthalpy of mixing for THF with water (heavy curve showing data points) and with deuterium oxide (fine curve) at 25.00 °C.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

The difference between $\Delta_m h$ values of THF in D_2O and H_2O is smaller than the corresponding difference for EO in D_2O and H_2O over the linear region. Moreover, this difference remains the same within experimental error for the THF systems but decreases with decreasing D_2O (H_2O) mole fraction for the EO systems.

Correlation of Enthalpy of Mixing with Water Proton Magnetic Resonance Chemical Shift

In solutions richer than 0.55 mole fraction THF it is found again that the enthalpy of mixing can be accurately related to the proton magnetic resonance (p.m.r.) chemical shift of the water protons, as found for the aqueous EO systems (1). All symbols are as defined in that earlier work. Due to the relatively large excess of oxygen bonding sites (ether oxygen atoms and water lone pairs) over the water protons we can safely assume that all water protons are H-bonded either to THF oxygen atoms or to water lone pairs, with a negligible fraction as unbonded O—H groups. The lack of detectable unbonded O—H groups for dilute water in THF has already been shown in infrared studies at 0 and 30 °C (10, 14). Thus the water p.m.r. chemical shift in this THF-rich region gives a direct measure of the fraction f_1 of water protons H-bonded to water and of the fraction $(1 - f_1)$ H-bonded to THF (1, 12).

The p.m.r. chemical shifts at 60 MHz have been determined for aqueous THF over the whole composition range at 0 and 25 °C and will be reported elsewhere (15). Some results have already been shown for the water-rich region of aqueous THF at 0 °C (10, 11). The water protons chemical shift relative to the THF α-protons at 25 °C gives $\nu_1 = 60.6$ Hz in pure water (water signal to low field of α-protons signal is defined as positive, and to high field negative) and $\nu_2 = -70.6$ Hz in pure THF. Corresponding linearly interpolated values for 10 °C are $\nu_1 = 69.7$ Hz and $\nu_2 = -65.0$ Hz. In solutions with ideal averaging f_1 values would be expected to be equal to x_1, but in all H_2O–THF solutions measured the f_1 value invariably exceeded x_1, showing that the water protons always formed more than the ideal fraction of H-bonds with water lone pairs and fewer than the ideal fraction with the ether oxygen atom of THF. This was to be expected since water H-bonds with water are on the average stronger, using p.m.r. chemical shift and infrared spectral shift (14) as criteria, than those with THF.

For both the H_2O–THF and D_2O–THF systems at 10.00 and 25.00 °C at THF mole fractions greater than 0.55 the $\Delta_m h$ values were fitted by the two-constant equation

$$[2] \quad \Delta_m h = x_1(1 - x_1)f_1 b_{11} + x_1(1 - x_1)(1 - f_1)b_{12}$$

using the method of least squares, assuming constant enthalpy errors and error-free x_1 and f_1. The f_1 values were interpolated from the p.m.r. chemical shifts for the H_2O–THF system (15). Table 7 shows typical results for the representation of $\Delta_m h$ measurements for H_2O–THF at 25.00 °C by [2] with $b_{11} = -2892$ J/mol and $b_{12} = 5021$ J/mol. The standard error on a single enthalpy determination $\sigma(\Delta_m h)$, assessed from the fit of [2], is 5.1 J/mol, which is larger than that 3.3 J/mol assessed from the fit of the endothermal results by [1] with six regression coefficients.

Table 8 presents the best b_{11} and b_{12} parameters with their standard errors derived from the fit of [2] for the THF-rich regions of the H_2O–THF and D_2O–THF systems. The final column gives the $\sigma(\Delta_m h)$ values assessed from the fits.

The b_{12} values show that the molar transfer of pure water or deuterium oxide to infinite dilution in THF is attended by an enthalpy increase of about 5000 J/mol, with values becoming larger at higher temperatures. This means that the two water H-bonds with THF are each about 2500 J/mol weaker, using enthalpy as a criterion, than the two water H-bonds to water in pure

			$\sigma(\Delta_m h) = 5.1$	

TABLE 8. Regression coefficients for eq. 2

System	Temperature (°C)	b_{11} (J/mol)	b_{12} (J/mol)	$\sigma(\Delta_m h)$ (J/mol)
H_2O–C_4H_8O	10.00	-3426 ± 62	4652 ± 38	4.7
H_2O–C_4H_8O	25.00	-2892 ± 35	5021 ± 30	5.1
D_2O–C_4H_8O	10.00	-3336 ± 55	4885 ± 31	3.8
D_2O–C_4H_8O	25.00	-2887 ± 22	5219 ± 18	3.0

water. Further, the increase of b_{12} values with temperature shows that the water H-bonds with THF weaken more rapidly at higher temperature than do those in liquid water.

The b_{12} values for the D_2O–THF system are significantly larger than those for the H_2O–THF system at the same temperature, the differences with standard errors are 233 ± 49 J/mol at 10.00 °C and 198 ± 35 J/mol at 25.00 °C; these differences at each temperature are the same within experimental error. If it is assumed that THF bonds with D_2O at infinite dilution are not weaker than THF bonds with H_2O, it is found that D-bonds in liquid D_2O are on a minimum estimate at least 108 J/mol stronger than H-bonds in liquid H_2O over the 10–25 °C range.

The b_{12} values for the H_2O–EO system (1) are considerably larger than those for the H_2O–THF system at the same temperature, the differences with standard errors are 2208 ± 60 J/mol at 10.00 °C and 2259 ± 55 J/mol at 25.00 °C; these differences at each temperature are the same within experimental error. This means that water H-bonds with THF are as a maximum estimate 1117 J/mol stronger than water H-bonds with EO at the same temperature. However, this value is an upper limit because in the definition of b_{12} (1) it also includes enthalpies from changes of the non-H-bonded van der Waals interactions. Such van der Waals interactions are expected to be stronger between H_2O and THF than between H_2O and EO, both on general theoretical grounds (16) and from the 10 000 J/mol enthalpy change calculated for water transfer from liquid heptane (17) to the lower molecular weight liquid propane (18). Thus the real enthalpy difference between the water H-bonds to THF and to EO will be some value smaller than 1117 J/mol.

Similarly the difference of b_{12} values for the D_2O–EO and D_2O–THF systems are 2335 ± 61 J/mol at 10.00 °C and 2448 ± 88 J/mol at 25.00 °C, which values are insignificantly different and show that D-bonds to THF could be up to 1196 ± 38 J/mol stronger than D-bonds to EO at the same temperature. Again the enthalpy difference due to non-D-bonded van der Waals interactions will reduce that between the D-bonds alone to some value smaller than 1196 J/mol.

The negative b_{11} values between -3400 and -2900 J/mol imply that water H-bonds with water at infinite dilution in THF are on the average some 1600 J/mol stronger, lower in enthalpy, than water H-bonds in pure water. However, this value is again an upper limit since our model (1) defines b_{11} to include enthalpy changes from non-H-bonded interactions together with those from the water–water H-bonding changes. These negative b_{11} values in THF solutions with $x_1 < 0.25$ are consistent with the formation of strongly H-bonded, unbranched water chains, with THF forming weaker H-bonds with those protons not bonded to water along the chains. As x_1 increases from 0.25 to 0.5 the one-dimensional water chains progressively cross-link to form two-dimensional water surfaces. The temperature coefficients of b_{11} show that the enthalpy difference between water–water H-bonds in THF and in pure water is reduced at higher temperatures.

The b_{11} value at 10.00 °C for the H_2O–EO system (1) is 2130 ± 69 J/mol larger than for the H_2O–THF system and mainly reflects the larger attractive van der Waals interactions between the water chains and the THF medium.

Acid Ionizations of Nitroalkanes in Aqueous Solution

TAKEKI MATSUI AND LOREN G. HEPLER
Department of Chemistry, University of Lethbridge, Lethbridge, Alberta

Received November 20, 1972

Calorimetric measurements have led to ΔH^0 values for ionization of nitromethane, nitroethane, 1-nitropropane, and 2-nitropropane in aqueous solution at 298 °K. Combinations of these enthalpies with free energies from equilibrium constants for ionization have led to ΔS^0 values for the ionization reactions. It is noted that the trend toward decreasing pK with methyl substitution in nitroalkanes is unusual compared to phenols and carboxylic acids. Similarly, correlations of ΔS^0 with ΔG^0 and ΔH^0 are different for nitroalkanes than for other acids.

Les mesures calorimétriques ont conduit à des valeurs ΔH^0 pour l'ionisation du nitrométhane, nitroéthane, nitro-1 propane et nitro-2 propane en solution aqueuse à 298 °K. Les combinaisons de ces enthalpies avec les énergies libres obtenus à partir des constantes d'équilibre pour l'ionisation, ont fourni des valeurs ΔS^0 pour les réactions d'ionisation. Il est à remarquer que l'évolution avec le pK décroissant par la substitution du méthyle dans les nitroalcanes est inhabituelle comparée aux phénols et aux acides carboxyliques. De même les corrélations de ΔS^0 avec ΔG^0 et ΔH^0 sont différentes pour les nitroalcanes comparées aux autres acides. [Traduit par le journal]

Introduction

The nitroalkanes are interesting acids for several reasons. First, they are "carbon acids" rather than the more usual —O—H and —N—H acids that have been extensively investigated. Further, the nitroalkanes have a variety of unusual acid–base properties as described below.

Several recent investigations (1–5) of nitroalkanes have been concerned with the related problems of equilibrium and rate constants for proton transfer reactions (acid ionizations) and acid–base catalysis, in part because of Bronsted coefficients that are outside the "normal" range of zero to unity. Although not specifically concerned with the particular compounds of interest in our investigations reported here, the recent work of Rose and Stuehr (6) shows that enthalpy and entropy data can provide useful additions to the understanding gained from considerations of free energies in the form of equilibrium and rate constants.

Much of the earlier interest in the nitroalkanes centers on the aci-nitro tautomerism, as reviewed thoroughly by Nielsen (7). As a result, we now have K values for the tautomeric equilibria, which we will refer to later.

Possibly because of concentration of interest in the areas mentioned above, little attention has been paid to the fact that the pK values for ionization of aqueous nitroalkanes show unusual trends. On the basis of ionization constants for a large number of acids (8), we know that replacement of hydrogen by a methyl group generally leads to a *small* change in pK, almost always a small increase. Thus we might expect nitroethane to be a very slightly weaker acid than nitromethane. Further, the statistical effect of having only two ionizable protons in nitroethane as compared to three in nitromethane should make nitroethane a weaker acid by $\Delta pK = 0.2$. But we have $pK = 10.2$ for nitromethane and $pK = 8.2$ for nitroethane. Thus nitroethane is a considerably stronger acid than nitromethane, rather than a somewhat weaker acid as might have been expected. A 2-nitropropane with $pK = 7.7$ is an even stronger acid.

We have undertaken calorimetric measurement of the enthalpies of ionization of nitromethane, nitroethane, 1-nitropropane, and 2-nitropropane with the intention of obtaining some understanding of the unusual acidities of these compounds and the longer range hope of providing data (6) that will prove useful in connection with the relationship between equilibrium and rate constants commonly expressed in terms of the Bronsted coefficient.

Experimental

Calorimetric measurements were made with an LKB 8700 Precision Calorimetry System used as an ampoule calorimeter. All measurements refer to 25.00 ± 0.05 °C, with results reported in terms of the defined calorie (1 cal = 4.1840 J). Concentrations of nitroalkanes and of sodium hydroxide ranged from 0.015 to 0.030 M and 0.03 to 0.05 M, respectively.

TABLE 1. Enthalpies of solution and ionization of nitroalkanes*

Acid	ΔH_1 (kcal mol^{-1})	ΔH_2 (kcal mol^{-1})	ΔH^0_{ioniz} (kcal mol^{-1})

Nitroethane	0.17±0.01	−10.75±0.01	2.42
1-Nitropropane	0.10±0.02	−10.68±0.03	2.56
2-Nitropropane	0.00±0.01	−13.20±0.15	0.14

*All ± values indicate standard deviations.

Reagent grade nitromethane from Fisher Scientific Company was purified by fractional distillation at 100 mm Hg pressure, followed by two fractional freezings in which two thirds of the sample was discarded as liquid. The resulting material was dried over Drierite and then fractionally distilled again. Practical grade nitroethane, 1-nitropropane, and 2-nitropropane from Baker Chemical Company were purified by three careful fractional distillations at 100 mm Hg. Vapor–liquid chromatography with a silicone column showed that all purified nitroalkanes were at least 99.5 mol% pure. Consistent calorimetric results were obtained with samples prepared at different times as described here. Carbonate free sodium hydroxide solutions were prepared and standardized by usual methods, and water was distilled from alkaline permanganate shortly before each calorimetric measurement.

Results and Discussion

Results of our calorimetric determinations of heats of solution of liquid nitroalkanes in water and in an excess of aqueous sodium hydroxide are summarized in Table 1. The calorimetric reactions are represented by

[1] $R_1R_2CHNO_2(liq) = R_1R_2CHNO_2(aq) \quad \Delta H_1$

and

[2] $R_1R_2CHNO_2(liq) + OH^-(aq) = R_1R_2CNO_2^-(aq) + H_2O(liq) \quad \Delta H_2$

Because solutions used were very dilute, we take these enthalpies to be equal to the desired standard state quantities represented by ΔH_1^0 and ΔH_2^0.

The enthalpies of ionization of aqueous nitroalkanes that are represented by

[3] $R_1R_2CHNO_2(aq) = H^+(aq) + R_1R_2CNO_2^-(aq) \quad \Delta H^0_{ioniz}$

have been obtained from ΔH_1^0 and ΔH_2^0 by way of

[4] $\Delta H^0_{ioniz} = \Delta H_w^0 - \Delta H_1^0 + \Delta H_2^0$

in which $\Delta H_w^0 = 13.34$ kcal mol^{-1} is the standard enthalpy of ionization of water (8).

We have also determined the enthalpies of reaction of aqueous nitroalkanes with aqueous hydroxide. For these measurements an ampoule containing a small excess of concentrated sodium hydroxide was broken in the calorimeter reaction vessel, which contained a weighed amount of dissolved nitroalkane. The calorimetric reaction is represented by

[5] $R_1R_2CHNO_2(aq) + OH^-(conc) = R_1R_2CNO_2^-(aq) + H_2O(liq)$

Separate determination of the enthalpy of dilution of the concentrated sodium hydroxide permitted evaluation of the enthalpy of neutralization of nitroalkane by dilute hydroxide that is represented by

[6] $R_1R_2CHNO_2(aq) + OH^-(aq) = R_1R_2CNO_2^-(aq) + H_2O(liq) \quad \Delta H_6$

Because solutions appropriate to reaction 6 were very dilute, our ΔH_6 values in Table 2 are taken to be equal to the standard state values for this reaction. The enthalpies of ionization of the aqueous nitroalkanes have been calculated as

[7] $\Delta H^0_{ioniz} = \Delta H_w^0 + \Delta H_6^0$

with results that are also listed in Table 2.

The ionization reaction represented by eq. 3 refers to ionization of the equilibrium mixture of *aci* and nitro forms of the weakly acidic compounds under consideration. Our ΔH^0_{ioniz} values are therefore the enthalpies of ionization of one mole of equilibrium mixture of nitro and aci

TABLE 2. Enthalpies of neutralization and ionization of nitroalkanes*

Acid	ΔH_6 (kcal mol^{-1})	ΔH^0_{ioniz} (kcal mol^{-1})

1-Nitropropane	7.7	10.5	0.0_8	$-35._1$

forms. The corresponding "apparent" equilibrium constant is

$$[8] \qquad K_{app} = \frac{[H^+][anion]}{[aci] + [nitro]}$$

We have used pK_{app} values (9, 10) to calculate corresponding ΔG^0_{ioniz} values. Combination of these ΔG^0_{ioniz} values with our "best" ΔH^0_{ioniz} values (derived as weighted averages of our calorimetric results already listed in Tables 1 and 2) leads to ΔS^0_{ioniz} values, which also refer to ionization of one mole of equilibrium mixture of the two forms of neutral nitroalkane. All of these quantities are listed in Table 3.

We first note that Turnbull and Maron (9) reported pK values (their estimated uncertainties $\sim \pm 0.02$) based on glass electrode measurements at three temperatures and were thus able to calculate $\Delta H^0_{ioniz} = 6.2$, 1.7, and 3.4 kcal mol^{-1} for nitromethane, nitroethane, and 2-nitropropane, respectively. The reported uncertainties in pK values are of little consequence with respect to ΔG^0_{ioniz} values, but our application of King's (11) method of analysis shows that uncertainties in derived ΔH^0_{ioniz} values are at least $\sim \pm 1$ kcal mol^{-1}. Thus the agreement between the $\Delta H^0_{ioniz} = 6.2$ kcal mol^{-1} from Turnbull and Maron (9) and our calorimetric $\Delta H^0_{ioniz} = 5.9_3$ kcal mol^{-1} is remarkably good and the agreement for nitroethane (1.7 *vs.* 2.4_0 kcal mol^{-1}) is as good as can be expected. We believe that the large discrepancy (3.4 *vs.* 0.0_8 kcal mol^{-1}) for 2-nitropropane can be mostly attributed to errors in the d ln K/dT values from Turnbull and Maron (9).

Now we briefly consider some pK values for some other acids. Methyl substitution in phenol to form cresols, xylenols, and trimethylphenols leads to increases in pK ranging from 0.15 for *m*-cresol to 0.92 for 2,4,6-trimethylphenol, all at 298 °K. Similarly, acetic acid is a weaker acid than is formic acid, and propionic acid is weaker than acetic acid. Both *m*-toluic acid and *p*-toluic acid have larger pK values than does acetic acid, but *o*-toluic acid is stronger (Δp$K = 0.29$) than benzoic acid in aqueous solution at 298 °K.

Christensen, Izatt, and Hansen (12) have noted a general linear relationship between ΔG^0 and ΔS^0 values for ionization of carboxylic acids in aqueous solution, and we find a generally similar relationship for phenol and substituted phenols. In both cases there is a trend toward less negative ΔS^0 of ionization as ΔG° becomes smaller. But the trend for the nitroalkanes is in the opposite direction, with ΔS^0 becoming more negative as ΔG^0 becomes smaller. Similarly, the lines in graphs of ΔH^0 against ΔS^0 have opposite slopes for phenols and nitroalkanes. We also note that the entropies of ionization of the nitroalkanes are more negative than entropies of ionization of most carboxylic acids and phenols.

As already mentioned, Turnbull and Maron (9) have determined equilibrium constants for the aci–nitro equilibria. Their results show that these nitroalkanes are very largely in the nitro form in aqueous solution. It therefore follows that the pK, ΔG^0, ΔH^0, and ΔS^0 values for ionization reported here (Table 3) refer almost entirely to the nitro forms of these acids.

Wheland and Farr (10) have suggested that 2-nitropropane is a stronger acid than nitromethane because in the former compound the lines of force between the large dipole moments of the nitro group and the proton pass largely through the (low dielectric constant) methyl group, while in nitromethane the corresponding lines of force pass mostly through the (high dielectric constant) water. They have also extended this argument to nitroethane and 1-nitropropane. This kind of explanation, partly involving differences in solute–solvent interactions, suggests that there might be something "unusual" in the ΔH^0 and ΔS^0 values for ionization of these acids. As noted above, the ΔH^0 and ΔS^0 values we have found (Table 3) are "unusual", but we have no satisfactory explanation beyond that already offered by Wheland and Farr (10).

We are grateful to Dr. Douglas Dolman for helpful discussions and the National Research Council of Canada for support of this research.

Fragmentation and Rearrangement Processes in the Mass Spectra of Perhalogenoaromatic Compounds. Part IX.[1] Pentafluorophenol and Pentafluorothiophenol Derivatives of Group IV

G. F. LANTHIER[2] AND J. M. MILLER[3]

Department of Chemistry, Brock University, St. Catharines, Ontario

AND

A. J. OLIVER

Department of Chemistry, York University, Downsview, Ontario

Received November 3, 1972

The mass spectra of $R_3MSC_6F_5$ and $R_3MOC_6F_5$ (R = CH_3 or C_6H_5; M = Si, Ge, Sn) are reported and compared with the corresponding pentafluorophenyl derivatives. The sulfur and oxygen compounds show fewer rearrangements leading to the formation of metal fluorides than do simple C_6F_5 derivatives. The ions R_3M^+ are usually observed as the base peaks. Ions containing Sn—S appear more stable than Sn—O species, while the reverse seems true for silicon.

Les spectres de masse du $R_3MSC_6F_5$ et du $R_3MOC_6F_5$ (R = CH_3 ou C_6H_5; M = Si, Ge, Sn) sont décrits et comparés avec les dérivés pentafluorophényles correspondants. Les composés comportant un soufre ou un oxygène subissent moins de réarrangements conduisant à la formation de fluorures métalliques qu'en subissent les dérivés C_6F_5 simples. Les ions R_3M^+ sont habituellement observés et représentés comme pics de base. Les ions contenant les espèces Sn—S semblant être plus stables que ceux contenant les espèces Sn—O, alors que la relation inverse semble être vérifiée dans le cas du silicium.

Can. J. Chem., **51**, 1945 (1973)

Introduction

We have previously studied the mass spectra of perfluoroaromatic derivatives of Group IV (1–4) and Group VI (1, 5) and noted extensive fluorine transfer from carbon to the central atom of the former but not the latter. We now report on a series of Group IV derivatives containing either the M—O—C_6F_5 or M—S—C_6F_5 groups and compare the fluorine transfer reactions of these compounds with the simple metal–pentafluorophenyl derivatives.

Experimental

The compounds in this study were prepared as described previously (6). Mass spectra were obtained at Brock University on an A.E.I. MS 30 double beam, double focusing mass spectrometer at 70 eV with a 4 kV accelerating voltage using a 300 μA trap current and a source temperature of 200°. Samples were admitted to beam 1 via the all glass heated inlet system at temperatures between 100° and 200°. PFK was admitted into beam 2 via a gas/liquid probe to serve as a chemical mass marker, recorded simultaneously, but not interfering, with the system under investigation. No problems of metal deposition in the source were noted. Samples were also checked for purity by passing them through a Pye 104 gas chromatograph (3% SE-30, 5 ft glass column) directly into the beam 2 of the MS 30 via a membrane separator. The spectrum recorded for the g.c. effluent corresponded directly with those obtained by batch insertion. Metastable ions and overlapping isotopic peaks were analyzed by computer techniques as described previously (1).

Results and Discussion

The partial mass spectra of the $(C_6H_5)_3MEC_6F_5$ (M = Si, Ge, Sn; E = O, S) are reported in Table 1 while the corresponding trimethyl derivatives are shown in Table 2. The metastable-ion supported fragmentations are shown in partial fragmentation Schemes 1–4, where solid lines indicate a metastable supported transition for at least one metal while dotted lines show ions formed by undetermined routes.

Fragmentation of the Parent Ions

The parent ion abundances are low for the triphenyl derivatives of germanium and tin but reasonably strong in all other cases. All parent ions lose a $C_6F_5O^\cdot$ or $C_6F_5S^\cdot$ unit to give the very abundant (14–60% of the total ion current)

*Ions less than 1% of the base peak and low mass hydrocarbon ions are omitted, unless necessary for comparisons and unless verified for metal containing ions by the appropriate isotopic abundances.

R_3M^+ ion (R = C_6H_5 or CH_3) which forms the base peak except in the case of $(CH_3)_3SiOC_6F_5$ which has as its base peak the $(CH_3)_2SiF^+$ ion, and for its sulfur analog in which a $H_2SiC_5F_3^+$ ion is of equal abundance to $(CH_3)_3Si^+$. This is consistent with the normal tetra-alkyl and aryl derivatives of Group IV which usually have the R_3M^+ ion as the base peak (7), although this is not the case for R = C_6F_5 (3).

An alternate route to the trisubstituted metal involves the loss of either a $C_6H_5^{\cdot}$ or $CH_3^{\cdot}$ radical, the M—O or M—S bond remaining intact. Although no metastables are observed for these transitions in the case of the methyl derivatives loss of a $CH_3^{\cdot}$ group is common, but if phenyl groups are present loss of $C_6F_5O^{\cdot}$ or $C_6F_5S^{\cdot}$ is much preferred. This may be indicative of some interaction of the phenyl π-system with the metal, strengthening the M—C bond.

Other observed species formed from the parent ions involve loss of HF in the case of $(C_6H_5)_3SiOC_6F_5$ and loss of $C_6F_4O^{\cdot}$ or $C_6F_4S^{\cdot}$ to yield $(C_6H_5)_3MF^+$ ions.

Fragmentation of R_3M^+ and $R_2MEC_6F_5^+$

The behavior of the R_3M^+ ions closely parallels that of the equivalent ions formed in the analogous R_4M or $R_3MC_6F_5$ cases (4, 7). Contrary to previous observations (3), the germanes now have the weakest parent ions, and

*Doubly charged ion.

the highest abundance of the R_3M^+ species. In this study only two metastable supported transitions from the R_3M^+ ion are observed when R = C_6H_5; namely the loss of either a molecule of benzene or a molecule of hydrogen. After the loss of benzene the resulting $C_{12}H_9M^+$ ions eliminate a molecule of acetylene, characteristic of phenylated organometallic compounds. $(CH_3)_3M^+$ ions are of lower abundance than the analogous $(C_6H_5)_3M^+$ species, and the only observed metastable transition from the trimethyl-metal ion is loss of a molecule of ethane, yielding CH_3M^+, a species of increasing stability as the metal becomes heavier. A similar trend is not so pronounced for the phenyl derivatives. In their case C_6H_5M may be the neutral species eliminated, leaving a stable biphenyl ion $(C_6H_5)_2^{+\cdot}$ as the charged species, which is observed for silicon and tin, but not for the germanium derivative.

Just as the loss of C_6F_4 was observed from various three coordinate tin ions containing the C_6F_5 group (4) we here observe a metastable for loss of OC_6F_4 from $(CH_3)_2GeOC_6F_5^+$ yielding the $(CH_3)_2GeF^+$ ion. Analogous reactions presumably account for the formation of $C_{12}H_{10}MF^+$ and $(CH_3)_2MF^+$ ions observed for most of the compounds studied.

The formation of the ion $C_2H_5GeSC_6F_4^+$ by the metastable supported loss of HF from $(CH_3)_2GeSC_6F_5^+$ is unique in that the analogous daughter ions (1.1% for the germane derivative) are not observed for any of the other compounds studied as part of this investigation. Loss of

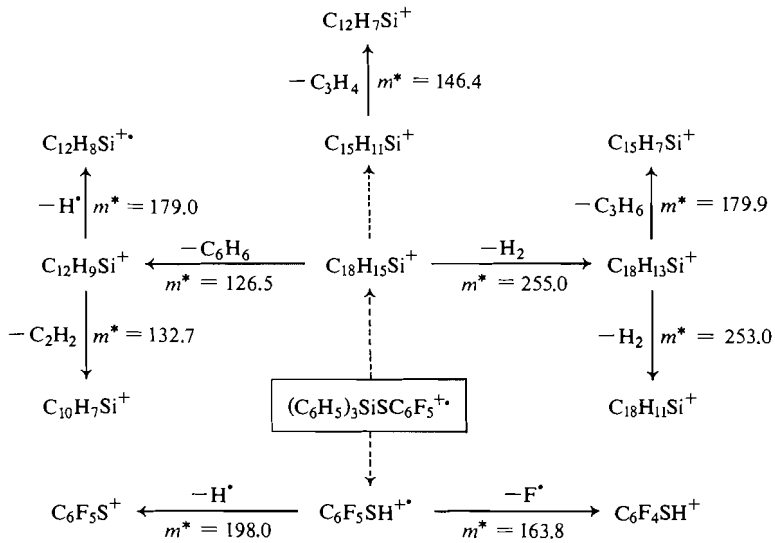

SCHEME 2. Fragmentation of $(C_6H_5)_3SiSC_6F_5$

another $CH_3^\cdot$ is observed from $(CH_3)_2GeSC_6F_5^+$, the resulting $CH_3MSC_6F_5^{+\cdot}$ not having an abundant analog in the spectra of either the oxygen containing systems or the phenylated derivatives. Interestingly, the only abundant doubly charged ions correspond to $(CH_3)_2ME C_6F_5^{2+\cdot}$ (E = O or S), and are not observed for the phenyl derivatives.

Other Metastable Supported Transitions

Metastable ions are observed for various other transitions involving either phenyl–M or methyl–M containing ions, but these are entirely in accord with those reported previously (4, 7). The phenyl derivatives also show several metastable supported transitions which involve fragmentation based on either $C_6F_5OH^{+\cdot}$ or

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

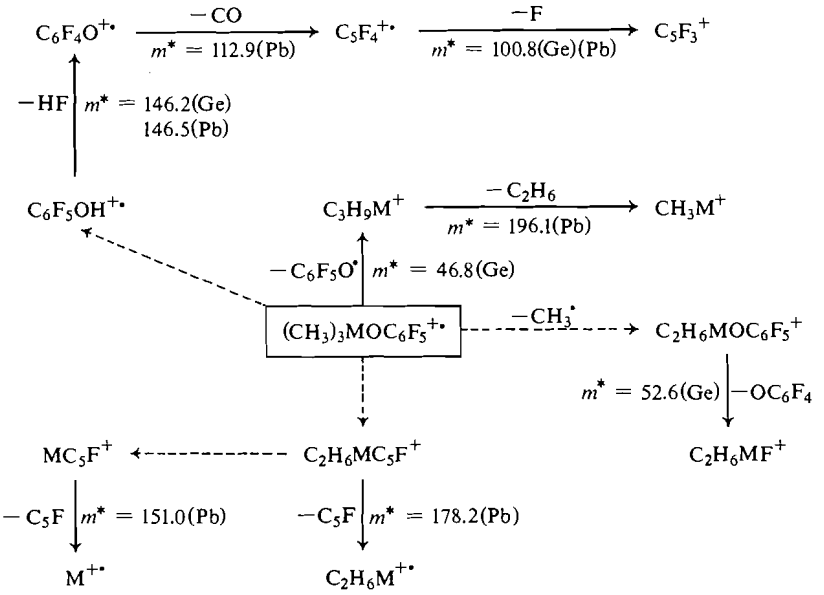
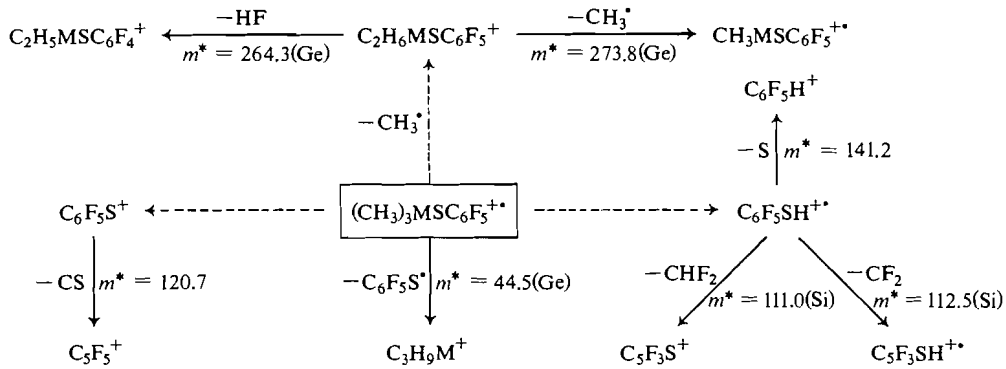


SCHEME 3. Fragmentation of $(CH_3)_3MOC_6F_5$



SCHEME 4. Fragmentation of $(CH_3)_3MSC_6F_5$

$C_6F_5SH^+$. Whereas in the spectrum of pentafluorophenol, Smithson *et al.* (8) report metastables for the loss of CFOH from the parent, followed by loss of F$^{\cdot}$, we observed, from the $C_6F_5OH^{+\cdot}$ ion formed in the spectra of $(C_6H_5)_3MOC_6F_5$, the metastable supported loss of $CF_2OH^{\cdot}$, or $COH^{\cdot}$, indicative of either different energetics or structure for our $C_6F_5OH^{+\cdot}$ ions. We plan to follow up this difference using recently developed metastable "defocussing" techniques (9). Similarly, where loss of S and CSH from $C_6F_5SH^{+\cdot}$ has been reported for the pure thiophenol (8), we observe metastables only for the loss of H$^{\cdot}$ or F$^{\cdot}$ A different pattern is followed by our trimethyl derivatives. We now observe metastables for the loss of HF from $C_6F_5OH^{+\cdot}$, followed by loss from the resulting $C_6F_4O^{+\cdot}$ of a molecule of CO, followed by loss of F$^{\cdot}$, *i.e.* differing in terms of observed metastables from both the spectrum of pure C_6F_5OH and that of $C_6F_5OH^{+\cdot}$ formed by electron impact on $(C_6H_5)_3MOC_6F_5$ derivatives. If we look at $(CH_3)_3MSC_6F_5$ (Scheme 4), differences are again observed, loss of either S, CF_2, or CHF_2 neutrals being shown from the $C_6F_5SH^{+\cdot}$ present in the spectrum. These observed differences indicate that the pentafluorophenol and pentafluorothiophenol ions are formed by a re-

arrangement involving a hydrogen abstraction, rather than arising from either impurities or simple decomposition of the organometallic compounds under study. In almost every case the $C_6F_5OH^{+\cdot}$ and $C_6F_5SH^{+\cdot}$ ions were more abundant than the expected $C_6F_5O^+$ and $C_6F_5S^+$ species.

Hydrocarbon Ions

Phenyl ions were usually observed for the compounds studied as were biphenyl (with the exception of the Ge derivatives) ions, the latter being more abundant than the former. This was also the case for $(C_6H_5)_3SnC_6F_5$ (4), although for $(C_6F_5)_4M$ compounds the perfluorobiphenyl ions were not as abundant as the $C_6F_5^+$ ions. There was no evidence from the spectra of either the phenyl or methyl series for rearrangements involving the transfer of oxygen or sulfur atoms to either neutral or ionic hydrocarbon species. The only mixing of substituents that took place at all was the previously discussed loss of HF, the formation of $C_6F_5EH^{+\cdot}$ ions and the formation of $C_6F_5H^{+\cdot}$. The latter are quite common in spectra of hydrocarbon/pentafluorophenyl organometallics.

Other Considerations

In Table 3 we show the percent of the total positive ion current which is carried by metal-containing ions.

As has been previously observed (3), silicon derivatives usually have the lowest abundance of metal-containing ions, perhaps due to the low abundance of silicon and silicon fluoride ions. These appear to prefer elimination as neutral species, leaving hydrocarbons or fluorocarbons as the charge-carrying species. Oxygen or sulfur have much less influence than do methyl or phenyl. In the case of the tin derivatives the abundances observed are very similar to those which we have reported for $(CH_3)_3SnC_6F_5$ (93%) and $(C_6H_5)_3SnC_6F_5$ (62%).

TABLE 3. Percentage of metal-containing ions

	% for M =			
Compound	Si	Ge	Sn	Pb
$(CH_3)_3MOC_6F_5$	69.7	78.0	—	57.5
$(CH_3)_3MSC_6F_5$	51.9	79.3	85.8	—
$(C_6H_5)_3MOC_6F_5$	50.5	72.5	63.0	—
$(C_6H_5)_3MSC_6F_5$	42.4	76.9	59.7	—

TABLE 4. Percentage of metal–fluoride containing ions

	% for M =

$(C_6H_5)_3MOC_6F_5$	9.6	1.4	0.5	—
$(C_6H_5)_3MSC_6F_5$	0.1	0.0	3.1	—

Table 4 summarizes the abundances of ions which appear to contain fluorine that has migrated to the metal atoms. Metal fluoride species are more common in the spectra of the methyl derivatives compared to their phenyl analogs, perhaps as a result of interaction of the aromatic ring electrons with vacant "d" orbitals on the metals. We had previously postulated (1, 3) the necessity of vacant orbitals on the metal atom if rearrangements leading to the formation of metal fluorides are to be observed. Another apparent trend for the oxygen containing compounds is a decrease in metal–fluoride ion abundance as we go to heavier metals for the methyl derivatives, compared to a corresponding increase for the phenyl compounds. This may again result from more effective p_π–d_π interaction between phenyl and silicon than between phenyl and tin.

A similar reversal is observed as we change from the pentafluorophenol to the thiophenol derivatives. As we compare the abundance of M—O *vs.* M—S containing ions (Table 5), we find the metal–sulfur species increasing in abundance as we go to heavier metals, while the reverse is observed for metal–oxygen containing ions. The tin–oxygen bonds are cleaved more readily than those of tin–sulfur, while silicon–oxygen bonds are retained to a greater extent than silicon–sulfur bonds. Germanium is anomalous, in that the $(C_6H_5)_3MEC_6F_5$ (E = O or S) compounds very readily lost C_6F_5O— or C_6F_5S— so there were therefore few sulfur or

oxygen containing species observed. Again the abundances are lower for the phenyl derivatives than for the methyls, due to the greater stability of the R_3M^+ ions when R = phenyl than when R = methyl, presumably as a result of some form of π interaction, and similarly the greater stability of the oxygen and sulfur containing ions for the methyl derivatives where there is no back donation competition from phenyls.

We can thus summarize our results by characterizing these spectra as typical of R_3MX compounds, and the behavior of X = $-SC_6F_5$ or $-OC_6F_5$ is not radically different from the case where X = C_6F_5. Methyl or phenyl substitution is responsible for far greater differences in fragmentation.

Crystal and Molecular Structure of tetrakis(4-Methylpyridine)nickel(II)perchlorate, $[Ni(II)(C_6H_7N)_4][ClO_4]_2$

N. Bose and H. Lynton

Department of Chemistry, University of New Brunswick, Fredericton, New Brunswick

Received November 20, 1972

Crystals of tetrakis(4-methylpyridine)nickel(II)perchlorate, $Ni(C_6H_7N)_4(ClO_4)_2$, are monoclinic, space group $C2/c$, with $a = 18.38(1)$, $b = 10.71(1)$, $c = 15.58(1)$ Å, $\beta = 109.83(5)°$, and four molecules in the unit cell. The final atomic parameters were obtained from a block-diagonal least squares refinement using anisotropic thermal parameters. The hydrogen atom positions were established but the parameters were not refined. The final agreement residual for 1199 observed reflections is $R = 0.049$. The structure consists of discrete $Ni(C_6H_7N)_4^{2+}$ and ClO_4^- groups. The perchlorate ion is disordered. The 4-methylpyridine rings are in a square planar arrangement about the nickel atom.

Les cristaux du perchlorate nickel(II) tétrakis (méthyl-4 pyridine) $Ni(C_6H_7N)_4(ClO_4)^2$ sont du type monoclinique appartenant au groupe $C2/c$ avec les paramètres $a = 18.38(1)$, $b = 10.71(1)$, $c = 15.58(1)$ Å, $\beta = 109.83\ (5)°$ et possèdent quatre molécules par maille unitaire. Les derniers paramètres atomiques furent obtenus à l'aide d'un raffinement des moindres carrés (matrice bloc-diagonale), en utilisant des paramètres thermiques anisotropiques. Les positions des atomes d'hydrogène furent établies mais les paramètres ne furent pas raffinés. Le résidu final en accord avec les 1199 réflections observées est $R = 0.049$. La structure se compose donc des groupes $Ni(C_6H_7N)_4^{2+}$ et ClO_4^- séparés. L'ion perchlorate est désordonné. Les cycles méthyl-4 pyridine se trouvent dans un arrangement carré-plan autour de l'atome de nickel. [Traduit par le journal]

Can. J. Chem., **51**, 1952 (1973)

Introduction

Magnetic and spectroscopic data on $Ni(C_6H_7N)_4(ClO_4)_2$ were interpreted by Brewer and co-worker (1). They showed that this yellow compound has square planar geometry with the perchlorate ions not coordinated to the nickel atom. We are now reporting an X-ray structure analysis which supports the previous conclusions.

Experimental

Crystals were grown by slow evaporation of solvent, methyl chloride, from a solution of the compound supplied by M. S. Sun. A single crystal was sealed inside a thin-walled Lindeman glass capillary for protection from the atmosphere.

Crystal data were observed as follows:

$Ni(C_6H_7N_4)_4(ClO_4)_2$ f.w. = 630.00

Monoclinic, $a = 18.38(1)$, $b = 10.71(1)$, $c = 15.58(1)$ Å, $\beta = 109.83(5)°$, $z = 4$, $\rho_o = 1.44(2)$, $\rho_c = 1.44$, $v = 2885.1$ Å^3 (20 °C, MoKα, $\lambda = 0.71069$ Å).

The unit cell dimensions and their estimated standard deviations (in parentheses) were obtained from a least squares evaluation of positions of 12 independent reflections. The space group is either $C2/c$ (C_{2h}^6) or Cc (C_s^4), No. 15 or 9 in International tables for X-ray crystallography. Vol. 1(2).

The intensity data were collected on a Picker computer-controlled four angle diffractometer using a $\theta/2\theta$ scan with β-filtered MoKα radiation and a scintillation detector. The two octants, hkl and $\bar{h}kl$, were explored to a maximum 2θ of 45°. There were 1908 accessible reflections in this region of which 1199 were considered observed. The threshold was taken as $0.10 \times$ backgound count or 25 counts, whichever was greater. The specimen was a needle-shaped crystal with dimensions $0.48 \times 0.20 \times 0.24$ mm, the needle direction being parallel to c-axis. The c-axis of the crystal was mounted along the ϕ direction of the diffractometer. The linear absorption coefficient for MoKα radiation is $\mu = 9.1$ cm^{-1}. No absorption or extinction corrections were applied.

Structure Analysis

The positions of the nickel and chlorine atoms were established from a three-dimensional Patterson synthesis. All of the other non-hydrogen atoms were then located from a three-dimensional Fourier synthesis based on the phases determined by the nickel and chlorine atoms.

The nickel atom was found in special position $4a$; all other atoms were found in general positions $8f$ of the space group $C2/c$.

The method of refinement was by successive cycles of block-diagonal least squares, using 3×3 matrices for the positional parameters and 6×6 matrices for the anisotropic thermal parameters of each atom. The quantity mini-

mized was $\sum w(|F_o| - |F_c|)^2$ for observed reflections only, using the weighting function

$$w = \frac{1}{1 + [(|F_o| - P_2)/P_1]^4}$$

where $P_1 = 35.00$ and $P_2 = 45.00$. Scattering factor curves for Ni, Cl, O, N, C, and H were used as given in ref. 3, Table 3.3.1.A. Real and imaginary dispersion corrections were applied to the scattering curves of nickel (3, see Table 3.3.2.C.). The final agreement residual $R = \sum(|F_o| - |F_c|)/\sum|F_o|$ for all atoms was 0.049.

During the early stages of the refinement the relatively high thermal parameters and large coordinate shifts of the two oxygen atoms O(1) and O(4) suggested further investigation of the perchlorate group would be necessary. Fourier and difference syntheses showed the presence of a fifth peak within bonding distance of the chlorine at about half the electron density expected for an oxygen atom. The electron densities of two of the established oxygen positions were also low. It was decided to include all five oxygen atoms and refine the individual occupation factors; final values for these are shown in Table 1. The final agreement residual for all atoms other than hydrogen was 0.062.

A difference synthesis revealed all hydrogen atoms as peaks of electron density 0.4 to 0.6 e Å^{-3}, and no other residual electron density greater than 0.3 e Å^{-3}. The hydrogen atoms were assigned isotropic thermal parameters equal to the carbon atoms to which they are attached. The positions and the thermal parameters for the hydrogen atoms were not refined during the subsequent least squares cycles. In the last cycle no parameter shift exceeded 0.1 times the estimated standard deviation. The final agreement residual for the observed reflections for all atoms with the space group $C2/c$ was $R = 0.049$. The decrease in the residual R obtained by inclusion of the hydrogen atoms is significant by Hamilton's test (4) at the 0.005 (0.5%) level.

The structure was also refined in the other possible space group Cc and a residual of 0.057 obtained for all atoms other than hydrogen. Hamilton's test shows that the decrease in the residual obtained by assuming space group Cc is not significant. This is supported by examination of the normalized structure factor table (Table 4) which shows that the structure is nearer to centrosymmetric.

A set of structure factors for the final parameters given in Tables 1 and 2 has been placed in the Depository of Unpublished Data.[1]

Discussion

The intramolecular bond distances and angles are given in Table 3. The stereochemistry of the molecule and the numbering scheme is shown in Fig. 1.

The perchlorate ions are not bonded to the nickel atom, the shortest nickel–oxygen distance, Ni—O(2), being 3.290(8) Å. The Ni(4-methylpyridine)$_4^{2+}$ ion exhibits square-planar coordination of the ligands. Within experimental

error, the 4-methylpyridine rings are planar (Table 5) with the rings making angles of 117.5 and 73.1° with the plane of the nitrogens.

The sum of the occupation factors for the five oxygen positions is 4.168 with the O(2) and O(3) positions fully occupied. From this it seems that the nature of the disorder of the perchlorate ions is quite complex. Cl—O(1) and Cl—O(2) are not significantly different and neither are Cl—O(4) and Cl—O(5) but the mean values for these pairs are significantly different from each other (t = 3.5) and from Cl—O(3) (t = 3.0 and 5.1).

The overall mean Cl—O distance 1.391 Å and the range of O—Cl—O angles 7.17 to 153.0° are compared with some recent results for dis-

ordered perchlorates in Table 6. A recently determined structure, (4-cyanopyridine)Hg(I)perchlorate (11), with an ordered perchlorate ion gives Cl—O distances of 1.45(4), 1.47(4), 1.46(3), and 1.42(4) Å with a range of bond angles 107(2)–113(2)°. Volume III of International tables for X-ray crystallography, p. 273 quotes the range 1.41–1.48(±6) Å for perchlorate ions. The disordered structures show a significantly shorter Cl—O distance which is associated with libration of the group. (5, 8, 9). A correction for riding motion raises the mean Cl—O distance to 1.453 Å in good agreement with the length found in ordered structures.

The Ni—N distances of 1.900(5) and 1.895(5) Å agree very well with 1.897(3) Å in tetrakis(3,4-dimethylpyridine)Ni(II)perchlorate (6), 2.093(2)

Micellar Effects upon *p-n*-Butylaniline Catalyzed Decarboxylation of Oxalacetic Acid

LEO KA-MING LAM AND DONALD E. SCHMIDT, JR.
Department of Chemistry, University of Windsor, Windsor, Ontario
Received November 27, 1972

p-n-Butylaniline ([nBA] = 1×10^{-3} *M*) incorporated in cationic micelles of cetyltrimethylammonium bromide ([CTABr] = 6×10^{-3}*M*) was found to enhance the rate of decarboxylation of oxalacetic acid (OAA) 45-fold while nBA alone only increases the rate six-fold as compared to the rate of spontaneous decarboxylation at the same p*H*. Anionic micelles of sodium dodecyl sulfate ([SDS] = 6×10^{-3} *M*) completely inhibited the catalytic effect of nBA. Together with the effects of added salts and the change of p*H* on the rate of the reaction the role of micelles in the decarboxylation of OAA is discussed.

La *p-n*-butylaniline ([nBA] = 1×10^{-3} *M*) incorporée dans les micelles cationiques de bromure de cétyltriméthylammonium ([CTABr] = 6×10^{-3} *M*) augmente la vitesse de décarboxylation de l'acide oxaloacétique (OAA) de 45 fois tandis que la nBA seule n'accroît cette vitesse que de six fois comparée à la vitesse de décarboxylation spontanée au même p*H*. Les micelles anioniques de sulfate de sodium dodécyle ([SDS] = 6×10^{-3} *M*) inhibent complètement l'effet catalytique de la nBA. Les effets de sels ajoutés, l'influence du p*H* sur la vitesse de la réaction et le rôle des micelles dans la décarboxylation de l'OAA ont été discutés. [Traduit par le journal]

Introduction

Decarboxylation of oxalacetic acid is accelerated in the presence of primary amines. Aniline is a particularly effective catalyst (1). The formation of a Schiff's base between the anilinium ion and the keto-acid has been suggested as the rate-determining step for this reaction in acidic medium (1). Westheimer *et al.* (2, 3) proposed that a hydrogen-bonded Schiff's base rather than the conjugate acid was the reactive intermediate. A later investigator (4) felt that the carbinolamine formation rather than Schiff's base formation was the rate-determining step but this conclusion has been criticized by others (5, 6). There seems little doubt that the amine-catalyzed decarboxylation of oxalacetic acid involves at some step the nucleophilic attack of the amine upon the carbonyl carbon of the acid.

The mechanism of amine-catalyzed decarboxylation of β-keto acids has received considerable attention because of its importance as a model system for enzymatic decarboxylation (7). For this same reason the catalytic effects of various metal cations (8–15), amines (1, 4, 16–18), and amino acids (19, 20) upon the decarboxylation have been investigated.

We feel that the catalytic effects of amines upon the decarboxylation of oxalacetic acid may be further enhanced in the presence of micelles whose structure is known to be in general similar to that of proteins (21). Substrate specificity and rate enhancement in micellar solution, as in the case of enzyme-catalyzed reactions, have been observed (22–29). Towards this end we have chosen to form a micelle from cetyltrimethylammonium bromide (CTABr). Micelles of CTABr are reported to strongly enhance the decarboxylation of 6-nitrobenzisoxazole-3-carboxylate (28, 30). To further facilitate the decarboxylation, we have chosen *p-n*-butylaniline as the catalytic amine. N.m.r. studies indicate that the nucleophilic amino group would be favorably situated on the positively charged surface of the micelle (31) where the substrate oxalacetate ion is likely to be found.

Experimental

Materials

Oxalacetic acid (OAA) was obtained from Sigma Chemical Company (St. Louis, Mo.) and was used without further purification. A 1×10^{-3} *M* aqueous solution of OAA was freshly prepared daily.

p-n-Butylaniline, 97% (nBA) was obtained from Aldrich Chemical Co. The compound was purified by vacuum distillation through a 3-in. Vigreux column (b.p. 120–121° at 15 mm). The compound rapidly turned yellow at room temperature. The distilled material was kept under an atmosphere of helium in sealed tubes and was refrigerated when it was not in use. Solutions of 1.25×10^{-2} *M* of nBA in 0.02 *M* buffers (sodium acetate – acetic acid from p*H* 4–5.5; sodium monochloroacetate – monochloroacetic acid from p*H* 4–2.5) were prepared. At

†Average values of duplicate runs.

pH values greater than 5 the solubility of nBA decreases considerably. To effect a solution of nBA in these cases, the amine was dissolved directly in a buffer containing the desired amount of cetyltrimethylammonium bromide (CTABr). Thus nBA was incorporated into the micelles and the system became homogeneous.

Cetyltrimethylammonium bromide (CTABr) was obtained from Eastman Organic Chemicals and was purified by the method of Duynstee and Grunwald (32). Solutions of CTABr at $1 \times 10^{-3} - 8 \times 10^{-3}$ M were prepared in 0.02 M buffers of pH 2.5–5.5.

Sodium dodecylsulfate (SDS) was obtained from Fisher Chemical Company and was recrystallized before use (32). Solutions of SDS at $1 \times 10^{-3} - 8 \times 10^{-3}$ M in 0.02 M buffers at pH 4.13, were prepared.

Aniline (B.D.H.) was distilled over zinc dust and used immediately in kinetic determinations.

Kinetic Studies

The decarboxylation of OAA at 30° was followed spectrophotometrically by the method of Kosicki and Lipovac (13). Kinetic data were obtained on a Gilford Model 2000 absorbance recorder attached to a Beckman DU monochromator equipped with a water-jacketed cell compartment. Buffered solutions of CTABr and nBA were mixed to the desired molar ratio and placed in a 30° temperature bath for at least 30 min prior to use. Into each cuvette were pipetted 2.90 ml of CTABr–nBA solution and 0.10 ml of OAA solution. The reaction mixture was mixed and placed in the cell compartment. In several parallel measurements using a Gilson differential respirometer, the rate of evolution of carbon dioxide was found to parallel the rate of disappearance of the enol form of OAA as determined spectrophotometrically. In each case the reaction was pseudo first-order in OAA and excellent first-order plots were obtained. The reaction was first order with respect to nBA over the concentration range of $5 \times 10^{-5} - 1 \times 10^{-3}$ M when nBA is incorporated into the micelle of [CTABr]/[nBA] = 6.

The pH values of all the solutions were measured on a Radiometer model 26 pH meter. These pH values were obtained in the presence of the detergent.

Results and Discussion

Micelles formed in a solution of CTABr (6×10^{-3} M) and nBA (1×10^{-3} M) at pH 4.13 enhance the decarboxylation of OAA about 45-fold (Table 1). At the same pH, CTABr (6×10^{-3} M) alone enhances the decarboxylation only three-fold while nBA (1×10^{-3} M) enhances the reaction about six-fold. Incorporation of the hydrophobic portion of the *p-n*-butylaniline molecule into the hydrophobic region of the micelle apparently leaves the amino function exposed on or near the positively charged micelle surface such that effective interaction with OAA results. When aniline (1×10^{-3} M) was incorporated into a CTABr (6×10^{-3} M) micelle, the rate of decarboxylation was enhanced about 11-fold. Incorporation of aniline into a micelle seems to make this amine a less effective catalyst than the free amine. The second-order rate constant for decarboxylation with aniline in a micelle is 65 M^{-1} min^{-1} at 30° while for the free amine this increases to 79 M^{-1} min^{-1} (4) at 25°. Assuming the nucleophilicity difference between aniline and nBA is negligible, this result seems to indicate the importance of an orienting effect of the hydrophobic *n*-alkyl chain in nBA so as to place the amine in an optimal position for interaction with OAA.

The variation of the first-order rate constant, k, with an increasing [CTABr]/[nBA] ratio at fixed nBA concentration exhibits the typical kinetic form of a micelle-catalyzed reaction (Fig. 1); that is, k increases to a plateau value, and then remains constant over a fairly wide range (26, 28, 33, 34). The reaction rate reaches a maximum value of 2.36×10^{-1} min^{-1} at [CTABr]/[nBA] = 3 and remains constant at least up to [CTABr]/[nBA] = 8. This represents an increase of 8-fold over the reaction catalyzed by nBA alone ($k = 3.0 \times 10^{-2}$ min^{-1}) at pH 4.13. This initial increase in the rate of the decarboxylation for [CTABr]/[nBA] ratio from 0 to 3 followed by a constant rate of decarboxylation for [CTABr]/[nBA] ratios from 3 to 8 was found at pH values of 2.26, 3.50, 4.35, 4.72, and 5.50.

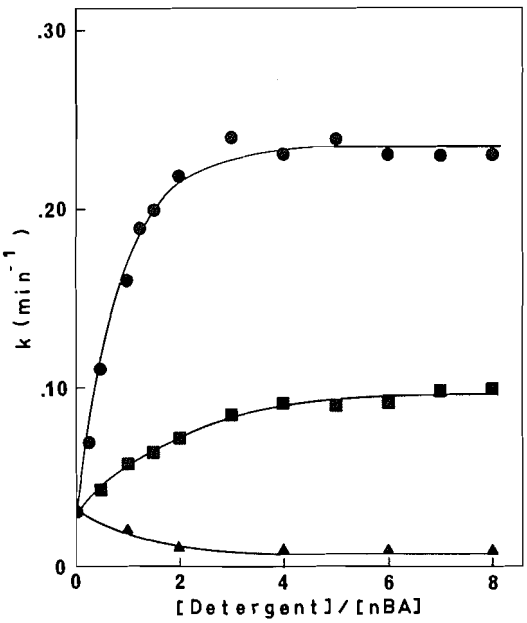

FIG. 1. Rate of oxalacetic acid decarboxylation at increasing ratios of detergent to *p-n*-butylaniline. All rate constants were obtained at 30°, pH = 4.13, and 1 × 10^{-3} M nBA. Concentration of the detergent is as noted.-●-, CTABr in 0.02 M sodium acetate – acetic acid buffer; -■-, CTABr in 0.02 M sodium acetate – acetic acid buffer with 0.5 M sodium bromide added; -▲-, SDS in 0.02 M sodium acetate – acetic acid buffer.

The catalytic effect of micelles is often interpreted in terms of their ability to bring together the reactants. The equilibrium concentration of OAA ion at the micelle–water interface (the Goug–Chapman double layer) (21) is higher than that in the bulk solution. When nBA molecules are incorporated in the micelles, the *n*-butyl chain is preferentially solubilized in the hydrocarbon core of the micelle (31). This leaves the aromatic part with the nucleophilic amino group in the Stern layer. Thus the amino group is brought into close approximation with the OAA ion. This simple picture of electrostatic attraction may be only partly responsible for the rate enhancement.

Added 0.05 M sodium bromide decreases the rate of decarboxylation, but the catalytic effect of the mixed CTABr–nBA micelles upon the reaction is still evident. A plot of first-order rate constants (Fig. 1) of decarboxylation in the presence of 0.05 M sodium bromide against [CTABr]/[nBA] ratio from 0 to 8 gives a curve qualitatively similar to that found in the absence of added salt. According to the hypothesis that the steepness of the k *vs.* micelle concentration plot is related to the strength of micelle–substrate interaction (28), oxalacetate ions appear to be adsorbed less strongly to the micelle surface in the presence of added bromide ions. Reduction in the electrostatic attraction of substrate ions to the area of the nucleophilic amine decreases the overall rate. Other inorganic salts also decrease the rate (Table 2). As observed by others, several additional anions, iodide and perchlorate, could not be examined as inhibitors since they yielded insoluble material in the presence of detergent (29). Increasing concentrations of both sodium fluoride and sodium bromide progressively decrease the decarboxylation rate in the presence of micelles to a value near that of the reaction catalyzed by nBA alone (Table 3). Increasing concentrations of the sodium acetate – acetic acid buffer do not seem to have much effect upon the rate of micellar-catalyzed decarboxylation at pH 4.13. This result is rather surprising as acetate has been reported to promote the catalysis of OAA by aniline (14).

In contrast to the enhancement of the rate of nBA-catalyzed decarboxylation of OAA by cationic micelles, anionic micelles of SDS and nBA markedly inhibit the rate of decarboxylation (Fig. 1). At a ratio of [SDS]/[nBA] of 8 the anionic micelle effectively alleviates the catalysis of nBA on the reaction to such an extent that the rate falls to that of a spontaneous decarboxylation at pH 4.13. SDS (1 × 10^{-3} M) at pH 4.13 in 0.02 M acetate buffer does not retard the decarboxylation of OAA (k = 0.0050 min^{-1}). Anionic micelles would repel the oxalacetate ion

TABLE 2. Inhibition of decarboxylation of OAA by various sodium salts at concentration of 0.05 M in solutions of [CTABr]/[nBA] = 6 in 0.02 M sodium acetate – acetic acid buffer of pH = 4.13 at 30°

from the nBA molecules which are incorporated into the micelle.

The nBA molecules are incorporated into both the CTABr micelles (Table 4) and the SDS micelles (Table 5). Both the λ_{max} and the extinction coefficient change as the ratio of detergent to nBA increases. The aniline portion of nBA must be near the charged surface of both types of micelle since in the CTABr micelle the extinction coefficient increases with increasing CTABr, while in the SDS micelle it decreases with increasing SDS. If the nBA were incorporated entirely in the hydrocarbon portion of the micelle, common to both types of micelle, one would expect the extinction coefficient to change in only one direction.

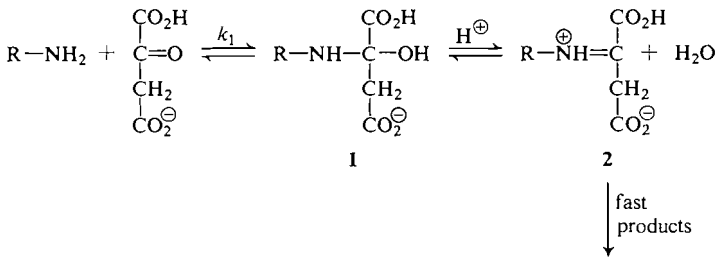

SCHEME 1

It has also been suggested that the catalytic effect of micelles is due to their ability to stabilize the rate-determining transition state (29). The transition state in the amine-catalyzed decarboxylation of OAA has not been clearly established (1–4, 6). Furthermore, the rate-determining step of the reaction is both p*H* and solvent dependent (4). The generally accepted mechanism is an initial nucleophilic attack of the amine on the OAA to form carbinolamine **1** (Scheme 1). Compound **1** reversibly forms the protonated Schiff's base **2** which rapidly decarboxylates (4). Both **1** and **2** have been proposed as the reactive intermediates of the reaction (4, 1). The p*H* rate profile for the micellar-catalyzed decarboxylation of OAA at [CTABr]/[nBA] = 6 is a typical bell-shape curve (Fig. 2). The p*H*–rate profile for aniline-catalyzed decarboxylation (4), nBA-catalyzed decarboxylation, and spontaneous decarboxylation (14) are bell-shape. The p*H* maxima are, respectively, 3.9, 4.2, and 3.5.

For the micelle-catalyzed decarboxylation the decrease in rate from p*H* 3.9 to 2.5 may be due to the decreased rate of formation of carbinolamine as the *p-n*-butylaniline is removed as *p-n*-butylanilinium ion. From p*H* 3.9 to 5.5 the rate decreases as less hydrogen ion is available for conversion of **1** to **2**. One might suggest that the micelle catalyzes the reaction by increasing the absolute value of k_1. This might be due to the greater polarizability of the carbonyl group in the presence of the positively charged micelle surface. Since the absolute value of k_1 is a factor for k_{obs} at both extremes of p*H*, any factor which will enhance the rate of attack of amine on OAA will speed the entire reaction. Increase in counter ion concentration or formation of an anionic micelle would retard the reaction as both

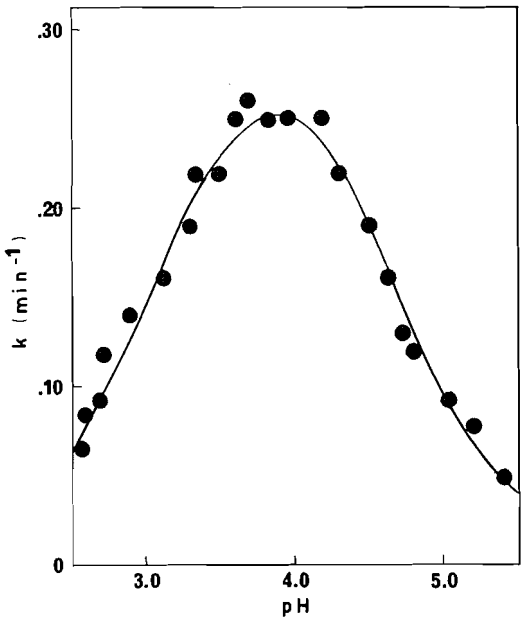

FIG. 2. p*H*-Rate profile for the decarboxylation of oxalacetic acid by mixed micelles of *p-n*-butylaniline and cetyltrimethylammonium bromide.

Experiments conducted at 30° with [nBA] = 1×10^{-3} *M* and [CTABr] = 6×10^{-3} *M*. Sodium acetate – acetic acid was used as a buffer for p*H* values of 4.1–5.4. Sodium monochloroacetate – monochloroacetic acid was used as a buffer for p*H* values of 2.5–4.0. The points are experimental, whereas the curve is calculated by computer best-fit from an equation for bell shaped curves (35):

$$k = \frac{k_o}{1 + \frac{[H^+]}{K_1} + \frac{K_2}{[H^+]}}$$

where $K_1 = 7.53 \times 10^{-4}$ *M*, $K_2 = 2.52 \times 10^{-5}$ *M*, and $k_o = 0.349$ min^{-1}.

effects would essentially decrease the cationic character around the carbonyl group and make it less polarizable.

Quaternary Nitrogen Heterocycles. II. Kinetics of Reversible Pseudobase Formation from *N*-Methyl Heterocyclic Cations[1]

JOHN W. BUNTING AND WILLIAM G. MEATHREL

Department of Chemistry, University of Toronto, Toronto, Ontario M5S 1A1

Received January 24, 1973

The kinetics of the formation and decomposition of the pseudobases from the 2-methyl-4-nitroisoquinolinium, 10-methylacridinium, and 10-methyl-9-phenylacridinium ions have been studied. The p*H*–rate profiles of these reactions indicate that for each of these ions, pseudobase formation may kinetically involve either attack of a water molecule or of hydroxide ion on the heterocyclic cation depending upon the p*H* of the reaction. Pseudobase decomposition to the cation may occur through either the neutral or protonated pseudobase species or their kinetic equivalents. The temperature dependences of the equilibrium and kinetics are reported for each ion, and deuterium isotope effects for the reactions of the 2-methyl-4-nitroisoquinolinium ion have been measured. Possible mechanisms for the reactions are discussed on the basis of the observed activation parameters and isotope effects and are compared with related reactions.

Les cinétiques de formation et de décomposition des pseudobases à partir des ions du méthyl-2 nitro-4 isoquinolinium, méthyl-10 acridinium et méthyl-10 phényl-9 acridinium ont été étudiées. Les profils de vitesse en fonction du p*H* de ces réactions indiquent que pour chacun de ces ions, la formation de la pseudobase fait intervenir cinétiquement, soit l'attaque d'une molécule d'eau soit un ion hydroxyde sur le cation hétérocyclique selon le p*H* de la réaction. La décomposition de la pseudobase en cation pourrait se produire soit par l'intermédiaire de la pseudobase sous forme neutre ou protonée ou encore leurs équivalents cinétiques. Les équilibres et les cinétiques en fonction de la température ont été rapportés pour chaque ion; les effets isotopiques du deutérium pour les réactions de l'ion méthyl-2 nitro-4 isoquinolinium ont été mesurés. Les mécanismes possibles de ces réactions ont été discutés à partir des paramètres d'activation observés et des effets isotopiques, puis comparés aux réactions apparentées.

[Traduit par le journal]

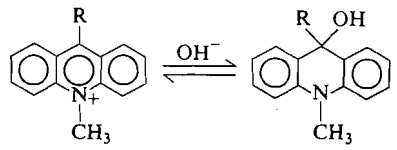
Can. J. Chem., **51**, 1965 (1973)

Recently, we reported (1) the structures of the pseudobases (QOH) formed by the addition of hydroxide ion to various aromatic *N*-methyl heterocyclic cations (Q^+), and also equilibrium constants for pseudobase formation (eq. 2; K_w is the ionic product of water). We have now

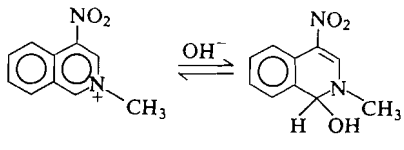
[1] $$Q^+ + OH^- \rightleftharpoons QOH$$

[2] $$K_{ROH} = \frac{[H^+][QOH]}{[Q^+]} = K_w \cdot \frac{[QOH]}{[Q^+][OH^-]} = K_w \cdot K$$

carried out a comprehensive study of the kinetics of pseudobase formation and decomposition for three such quaternary heterocyclic cations: the 10-methylacridinium[2] (**1**; R = H), 10-methyl-9-phenylacridinium (**1**; R = Ph), and 2-methyl-4-nitroisoquinolinium (**3**) ions. The p*H*–rate profiles and temperature dependences



1 **2**



3 **4**

of these reactions have been determined and have been used to interpret the reaction mechanisms. In addition, hydrogen isotope effects have been measured for the reactions of **3** and **4** and preliminary measurements of the catalytic effects of buffer species have been made.

We have been unable, at the present time, to carry out a complete investigation of the dependence of the rates of these reactions on the structure of the heterocyclic cation, because for

[1]For Part I, see ref. 1.

[2]We previously referred to this cation as the 9-methylacridinium ion (1). In the IUPAC systematic nomenclature this is the 10-methylacridinium ion (2).

most of the cations considered previously (1), the equilibrium of eq. 1 is established too rapidly to allow study by the stopped-flow technique.

Results

The observed pseudo first-order rate constants, k_{obs}, for the combined formation and decomposition of the pseudobase of the 10-methyl-9-phenylacridinium ion (**1**; R = Ph) are plotted in Fig. 1 as a function of the pH at four temperatures. In general, k_{obs} is the sum of the pseudo first-order rate constants, k_f and k_d respectively, for the formation and decomposition of the pseudobase. Thus

$$k_{obs} = k_f + k_d$$

At equilibrium

$$k_f[Q^+] = k_d[QOH]$$

and hence

$$\frac{k_f}{k_d} = \frac{[QOH]}{[Q^+]} = \frac{K_{ROH}}{[H^+]}$$

Therefore,

[3] $$k_f = \frac{k_{obs}}{1 + [H^+]/K_{ROH}}$$

and

[4] $$k_d = \frac{k_{obs}}{1 + K_{ROH}/[H^+]}$$

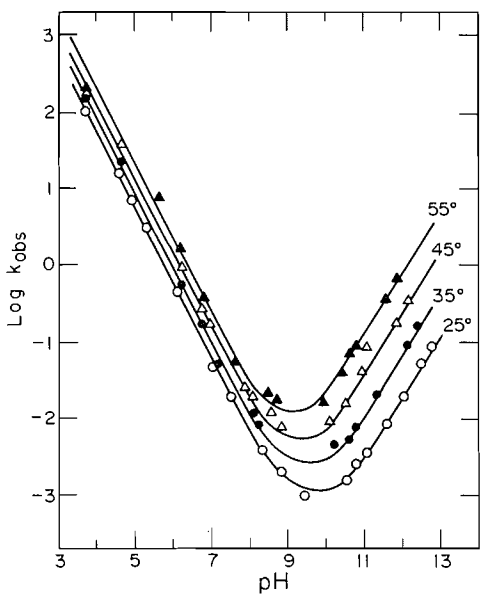

FIG. 1. The pH and temperature dependence of k_{obs} (s^{-1}) for the formation and decomposition of the pseudobase of the 10-methyl-9-phenylacridinium cation. Ionic strength of buffers = 0.1.

Typical values of k_f and k_d calculated from eqs. 3 and 4 are given in Table 1. The appropriate pK_{ROH} values at each temperature are collected in Table 2. Complete pH profiles for k_f and k_d at each temperature are given in Fig. 2 for the interconversion of **1** and **2** (R = Ph). Similar plots of k_{obs}, k_f, and k_d for the 10-methylacridinium ion are given in Fig. 3, and for the 2-methyl-4-nitroisoquinolinium ion in Fig. 4, at

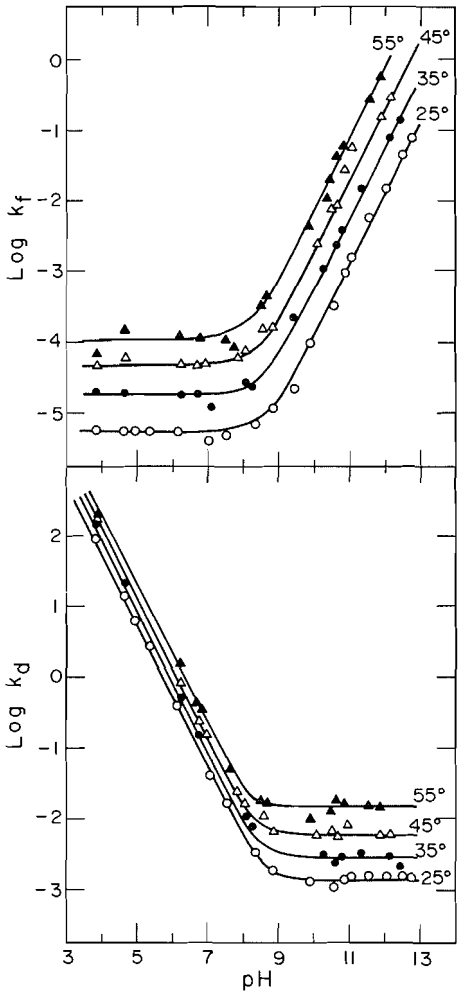

FIG. 2. The pH and temperature dependence of $k_f(s^{-1})$ and $k_d(s^{-1})$ for the formation and decomposition of the pseudobase of the 10-methyl-9-phenylacridinium ion. Ionic strength of buffers = 0.1.

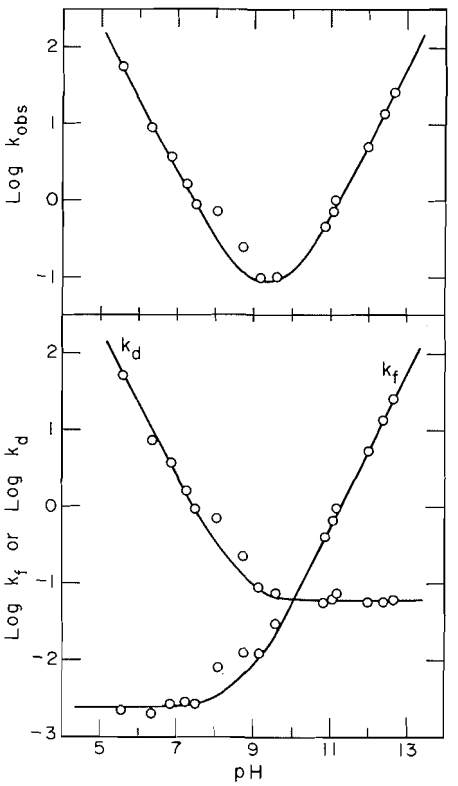

FIG. 3. The pH dependence of (*a*) k_{obs}, (*b*) k_i and k_d for the formation and decomposition of the pseudobase of the 10-methylacridinium cation at 25°. Ionic strength of buffers = 0.1; all rate constants in s^{-1}.

25°. Similar data were also obtained for these two ions at 15, 35, 45, and 55°.

The pH profiles of k_{obs}, k_f, and k_d are similar in shape for all three cations, but are displaced on the pH scale owing to the difference in the pK_{ROH} values of these ions. The pH profiles at each temperature can be fitted by equations of the form:

$$[5] \qquad k_d = k_1[H^+] + k_2$$

$$[6] \qquad k_f = k_3[OH^-] + k_4$$

The rate constants, k_1, k_2, k_3, and k_4, are formally defined by the equations:

$$[7] \qquad Q^+ + H_2O \underset{k_1}{\overset{k_4}{\rightleftharpoons}} QOH + H^+ \qquad K_{ROH} = k_4/k_1$$

$$[8] \qquad Q^+ + OH^- \underset{k_2}{\overset{k_3}{\rightleftharpoons}} QOH \qquad K = k_3/k_2$$

Values of k_1, k_2, k_3, and k_4 are collected in Table 3. Activation parameters calculated from Arrhenius plots for each of these four rate constants are given in Table 4.

In Fig. 4, the rates of formation and decomposition of the pseudobase from the 2-methyl-4-nitroisoquinolinium cation in H_2O and D_2O are compared at 25°. Equilibrium and kinetic constants in D_2O and H_2O are compared in Table 5, and the isotope effects are tabulated.

The results of a limited investigation of buffer catalysis of the reactions of **3** and **4** are indicated in Fig. 5 and Table 6. The buffer catalytic rate constant, k_B is defined in terms of the total con-

of pK_{ROH}. Reactions of the following cations were too fast to allow study by the stopped-flow technique: 1-methyl-1,5-naphthyridinium; 6-methyl-1,6-naphthyridinium; 7-methyl-1,7-naphthyridinium; 1-methyl-1,8-naphthyridinium; 1-methyl-x-nitroquinolinium (x = 5, 6, 7, 8); 2-methyl-5-nitroisoquinolinium; 2-methylphthalazinium; and 1-methylquinoxalinium. Thus, although the 2-methyl-4-nitroisoquinolinium ion (pK_{ROH} = 5.0) is much more susceptible to hydroxide addition than any of the above cations (pK_{ROH} = 8.6–13 (1)), it is the only ion of this type amenable to investigation by the stopped-flow kinetic technique. Although the second-order rate constant for hydroxide attack on **3** is presumably greater than for the other cations listed above, the low pK_{ROH} value allows the investigation of pseudobase formation at pH values where the pseudo first-order rate constant for hydroxide attack (*i.e.* $k_3[OH^-]$) is relatively small.

Discussion

The temperature dependence of the pK_{ROH} values for pseudobase formation from the three heterocyclic cations in Table 2 suggests that the stability of the cation relative to its pseudobase decreases as the temperature increases. However, these pK_{ROH} values include a contribution from the ionic product of water, K_w. Correction for the temperature dependence of K_w (3), shows that the association constant, K, actually decreases with increasing temperature for the 2-methyl-4-nitroisoquinolinium and 10-methylacridinium cations (see Table 2). Thus despite the temperature dependence of the pK_{ROH} values, these cations are in fact stabilized relative to the corresponding pseudobases by an increase in temperature. The equilibrium constant, K, for the 10-methyl-9-phenyl-acridinium cation appears to be almost temperature independent over the range 25–55°. Furthermore, although the pK_{ROH} values suggest the pseudobase–cation equilibrium is more temperature-dependent in the acridine systems than for the 2-methyl-4-nitroisoquinolinium cation, this is again an artifact resulting from the contribution of pK_w to the pK_{ROH} values. From the association constants, K, it is clear that the temperature dependence of the equilibrium is much greater for the 2-methyl-4-nitroisoquinolinium ion than for either of the two acridinium ions.

A van't Hoff plot of the equilibrium data is shown in Fig. 6 for the two systems having temperature-dependent equilibria. In each case the plot is apparently linear, and we have derived values of $\Delta H^0 = -10.8$ kcal/mol and $\Delta S^0 = +4.5$ e.u. for pseudobase formation from the 2-methyl-4-nitroisoquinolinium cation

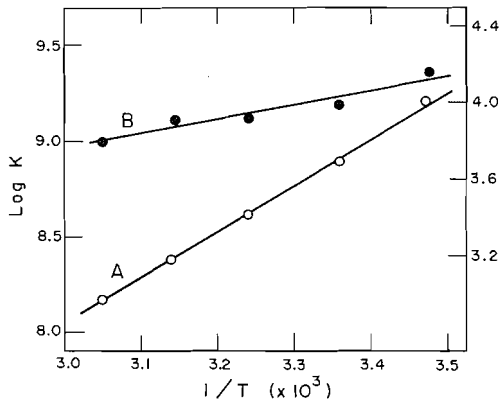

FIG. 6. Dependence of log K on temperature for the 2-methyl-4-nitroisoquinolinium (A, left hand ordinate) and 10-methylacridinium (B, right hand ordinate) ions.

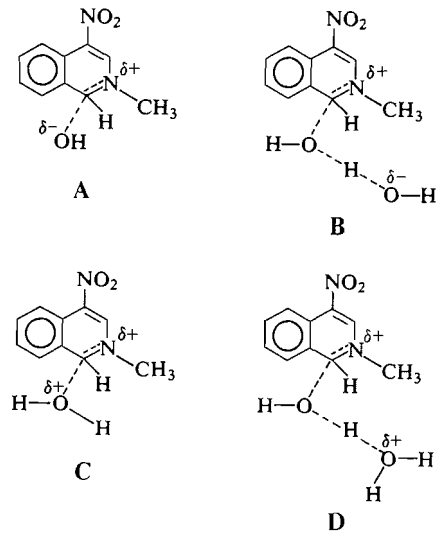

and $\Delta H^0 = -2.9$ kcal/mol and $\Delta S^0 = +8.7$ e.u. for the 10-methylacridinium ion.

It is clear from the representative data in Fig. 5 that the reversible formation of pseudobases from these heterocyclic cations is subject to catalysis by buffer species. However, the pH-dependence of the catalysis by any given buffer is complex, and we have been unable to assign the catalysis as being of a simple general-acid or general-base type. A complete definition of these catalytic effects will require a further extensive study. Despite the complexity of this buffer catalysis, a smooth pH–rate profile is obtained for each reaction (Figs. 1–4) when the buffer solutions are made up so as to give a total ionic strength 0.1 from the buffer species alone without any added neutral salt. This is true despite the fact that eight different buffers of widely varying chemical type were used over the pH range covered by these experiments.

The empirical eqs. 5 and 6 suggest that two kinetically distinguishable pathways are available for each of pseudobase formation and decomposition in the pH ranges that we have studied. For each cation, the rate of pseudobase formation is pH-independent (k_4 in eq. 6) at the lower pH values in the range that was amenable to our experimental techniques. This term is interpretable either as a rate-determining attack of a water molecule on the heterocyclic cation followed by a rapid deprotonation (transition state **C**) or alternatively as the general-base catalyzed attack (by another water molecule) of a molecule of water on the heterocyclic cation (transition state **D**). In more basic solutions, this mechanism becomes unimportant compared with the direct attack of hydroxide ion ($k_3[OH^-]$) on the heterocyclic cation (transition state **A**), or alternatively the kinetically equivalent hydroxide ion catalyzed attack (as a general-base) of a water molecule on the cation (transition state **B**).

The mechanistic significance of the terms in eq. 5 for pseudobase decomposition must, of course, be the microscopic reverse of the interpretations given above for the pseudobase formation reactions. Thus, $k_1[H^+]$ is the microscopic reverse of the k_4 term, and may be formally interpreted as either the spontaneous loss of a molecule of water from the O-protonated pseudobase (*i.e.* specific-acid catalysis; transition state **C**) or alternatively as elimination of hydroxide ion from the neutral pseudobase molecule with the aid of H_3O^+ as a general-acid catalyst (transition state **D**). The k_2 term is the microscopic reverse of $k_3[OH^-]$, and so formally represents either the spontaneous decomposition of the pseudobase to heterocyclic cation and hydroxide ion (transition state **A**) or the kinetically equivalent general-acid catalysis of this reaction by a water molecule (transition state **B**).

The observed kinetic isotope effect $k_4^H/k_4^D = 2.6$ with the 2-methyl-4-nitroisoquinolinium ion seems to be too large to be attributed to a transition state such as **C** which does not involve a rate-determining proton transfer. This solvent isotope effect is more consistent with a transition state such as **D** in which a proton transfer occurs to a water molecule acting as a general-base. This postulate further suggests that the $k_1[H^+]$ term in pseudobase decomposition must

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

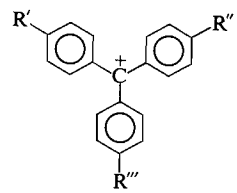
represent general-acid catalysis by H_3O^+ of the elimination of a hydroxide ion. Although the measured solvent isotope effect $k_1^H/k_1^D = 0.61$ is in the range usually associated with specific-acid catalysis (*i.e.* transition state **C**), there are a number of recent examples in the literature of genuine general-acid catalysis for which similar solvent isotope effects have been found. Thus, in the hydrolysis of ortho esters and of some acetals and ketals isotope effects in the range $k^H/k^D = 0.37$–0.75 have been observed for general-acid catalysis (4, 5). These reactions are somewhat related to pseudobase decomposition, and similar isotope effects might be expected.

The entropies of activation for the k_4 term (Table 4) do not distinguish between the postulated transition states **C** and **D**. The entropies of activation for the reverse step (k_1) vary between -10 and 0 e.u. A value of $\Delta S^{\ddagger} \approx 0$ for this step, as is found for the pseudobases from the 2-methyl-4-nitroisoquinolinium and 10-methylacridinium ions, might be interpreted in terms of transition state **D** if proton transfers occur along pre-formed hydrogen bonds between the pseudobase hydroxyl group and solvating water molecules. The ratios k_1/k_2 and k_3/k_4 for reactions of **1** and **2** are similar for the 9-unsubstituted and 9-phenyl acridine systems (Table 3). We feel that this observation is also most readily accounted for if transition states analogous to **B** and **D** are involved. Since **A** and **C** require formally charged species attacking or being formed at C-9, the enhanced solvation requirements of such species might be expected to be reflected in different k_1/k_2 and k_3/k_4 ratios for the 9-unsubstituted and 9-phenyl derivatives.

The entropies of activation observed for k_3 terms also seem to be too negative to be merely reflecting direct hydroxide attack on the heterocyclic cations. One might predict that such a direct attack would have an entropy of activation similar to the entropy of formation of the pseudobase from heterocyclic cation and hydroxide ion. The greatest discrepancy is between $\Delta S^{\ddagger} = -17$ e.u. for hydroxide ion attack on the cation (k_3) and $\Delta S = +8.7$ e.u. for the equilibrium association of the cation and anion in the 10-methylacridinium system. Interpretation of this reaction as hydroxide ion acting as a general-base for attack by a water molecule would therefore seem to be more consistent with the observed entropies of activation. Such general-base catalysis would be expected to exhibit a considerable solvent isotope effect; however, a small inverse isotope effect ($k_3^H/k_3^D = 0.9$) is actually observed. Although unusual, small isotope effects for general-base catalyzed reactions have been previously observed. Thus, $k^H/k^D = 1.1$ for the general-base catalyzed attack of glycine on phenyl acetate (6). The k_2 step, which is the microscopic reverse of the k_3 term, would then be interpreted as general-acid catalyzed (by a water molecule) decomposition of the neutral pseudobase to the heterocyclic cation. The observed isotope effect $k_2^H/k_2^D = 2.0$ and entropies of activation (-14 to -24 e.u.) are consistent with such an interpretation.

This suggestion that transition state **B** more accurately reflects the hydroxide ion catalyzed reaction than does transition state **A**, is similar to the recent observation that hydroxide attack on the malachite green cation (**5**) to give the carbinol occurs via a general-base mechanism (7). This description of the transition state is also consistent with Ritchie's postulate (8) that the transition states for some related cation–anion nucleophilic addition reactions involve considerable separation of the cation and anion, and are probably somewhat similar to an ion-pair separated by one solvent water molecule. The interpretation of the mechanisms of these reactions in terms of transition states such as **B** and **D** is also supported by our observation of the importance of buffer catalysis in these reactions.

Pseudobase formation from the 10-methylacridinium cations is formally closely related to carbinol formation from triphenylmethyl carbonium ions. These latter reactions have been



5 R′ = H; R″ = R‴ = $N(CH_3)_2$
6 R′ = R″ = R‴ = $N(CH_3)_2$

extensively studied (9–14). In particular, a comparison between the 10-methylacridinium cation (**1**; R = H) ($pK_{ROH} = 9.86$ (1)) and the crystal violet cation (tris(4-dimethylaminophenyl)-methyl carbonium ion **6**) ($pK_{ROH} = 9.36$ (14)) is of interest since the equilibrium constants for hydroxide addition to these two ions are quite

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

similar. At 25°, the pseudo first-order rate constant for attack of water on **6** is 3.5×10^{-5} s^{-1} (9) compared with 2.43×10^{-3} s^{-1} for **1** (R = H). For attack by hydroxide ion, the second-order rate constants are 0.205 M^{-1} s^{-1} for **6** (9) and 552 M^{-1} s^{-1} for **1** (R = H). Thus, although the equilibrium constant for hydroxide addition to **6** is about threefold larger than for **1** (R = H), water attack is 150 times faster and hydroxide attack is over 2500 times faster on **1** (R = H) than on **6**. These rate differences probably arise from steric effects resulting from the presence of an additional aromatic ring on the electrophilic carbon in **6**. In fact, the rates of hydroxide and water attack (k_3 and k_4 in Table 3) on the 10-methyl-9-phenylacridinium ion (**1**; R = Ph) which should involve similar steric effects to the analogous reactions of **6** are within a factor of 10 of the same rate constants for **6**. The result of the above comparison of **1** (R = H) and **6** is not surprising in view of the general observation that in such anion–cation combination reactions there appears to be little correlation between kinetic and equilibrium structural effects (8, 15). Comparison of the relative rates of hydroxide and water attack on these heterocyclic cations gives $\log k_3 - \log k_4 = 5.4$ for both **1** (R = H) and **1** (R = Ph) and $\log k_3 - \log k_4 = 6.9$ for **3** (at 25°). Both of these values are somewhat greater than might be expected (4.5) if Ritchie's N_+ values (15) are assumed to be applicable in these systems.

Experimental

Materials

10-Methylacridinium iodide and 2-methyl-4-nitroisoquinolinium iodide were synthesized as previously described (1). 9-Phenylacridine was prepared from benzoic acid and diphenylamine (16). Methylation with methyl iodide gave 10-methyl-9-phenylacridinium iodide, m.p. 250° (after recrystallization from methanol), lit. m.p. 148–150° (?) (17).

Anal. Calcd. for $C_{20}H_{16}IN$: C, 60.5; H, 4.03; I, 32.0; N, 3.53. Found: C, 60.1; H, 4.51; I, 31.8; N, 3.52.

Buffer solutions were made up from the best available commercial grades of reagents. Buffers used were: chloroacetate (pH < 3); formate (pH = 3–4.5); succinate (pH = 4.5–6); phosphate (pH = 6–8); borate (pH = 8–9.5); carbonate (pH = 9.5–11); phosphate (11–12); standard potassium hydroxide solutions (pH > 12). All kinetic runs were carried out in buffers of ionic strength 0.1, unless indicated otherwise. When necessary, potassium chloride was used as a neutral electrolyte.

Methods

The pK_{ROH} values were measured as previously described (1); by potentiometric titration for the 2-methyl-4-nitroisoquinolinium ion and spectrophotometrically for the 10-methyl- and 10-methyl-9-phenylacridinium ions. All pH measurements were made with a Corning Model 12 Research pH Meter standardized at the reaction temperature with standard buffers (18). All pD values were obtained by the addition of 0.40 to the pH meter reading (19).

Reaction kinetics were measured either with a Durrum–Gibson stopped-flow spectrophotometer or a Cary 16K spectrophotometer (for reactions of the 10-methyl-9-phenylacridinium ion having half times greater than 1 min) by mixing aqueous solutions of the heterocyclic cation (for pseudobase formation) or of the pseudobase (for pseudobase decomposition) with double strength buffer solutions. All solutions were pre-equilibrated at the reaction temperatures (±0.1 °C). All pH values were independently checked after a similar dilution of the stock buffer solutions. Reactions were followed at 410 nm for the 2-methyl-4-nitroisoquinolinium cation, 342 nm for the 10-methylacridinium ion, and 286 nm for the 10-methyl-9-phenylacridinium ion. First-order kinetic plots of $\log (D - D_\infty)$ *vs.* time were prepared, where D is the optical density at time t and D_∞ is the equilibrium optical density. In all cases, such plots were linear for at least 90% of the reaction, and pseudo first-order rate constants (k_{obs}) were determined from the slopes of these lines. The individual rate constants for pseudobase formation (k_f) and decomposition (k_d) were determined as described above.

This research was supported by a grant from the National Research Council of Canada, and a Province of Ontario Graduate Fellowship awarded to W.G.M. We thank Mr. E. P.-C. Wong for the synthesis of 9-phenylacridine and its methiodide salt.

Bufadienolides. 17. Synthesis of 14α- and 14β-Artebufogenin[1]

YOSHIAKI KAMANO AND GEORGE R. PETTIT[2]

Department of Chemistry, Arizona State University, Tempe, Arizona 85281

Received November 24, 1972

Treatment of resibufogenin (**1***a*) or its acetate (**1***b*) with perchloric acid or hydrochloric acid gave 14α- and 14β-artebufogenin (**5***a* and **6***a*, or **5***b* and **6***b*), in addition to 15α-hydroxy-bufalin (**4***a* or *b*). Reaction of epoxide **1***b* with chloranil or boron trifluoride etherate easily afforded 14α- and 14β-artebufogenin acetate (**5***b* and **6***b*) in good yields. Analogous reaction of the isomeric 3β-hydroxy-14α,15α-epoxide **3***a* with perchloric acid, hydrochloric acid, or sulfuric acid again led to 14α- and 14β-artebufogenin (**5***a* and **6***a*) and the 14β,15α-dihydroxy-derivative **4***a*. Similar reaction with periodic acid gave **6***a* and **4***a*.

Lors du traitement de la résibufogénine (**1***a*) ou de son acétate (**1***b*) avec de l'acide perchlorique ou avec de l'acide chlorhydrique, on a obtenu l'artébyfagénine-14α et 14β (**5***a* et **6***a* ou **5***b* et **6***b*), en plus de l'hydroxy-15α bufaline (**4***a* ou **4***b*). La réaction de l'époxyde **1***b* avec du chloranil ou avec de l'éthérate de trifluorure de bore a produit aisément [l'acétate-14α et 14β d'arté bufogénine (**5***b* et **6***B*) avec d'excellents rendements. La réaction similaire de l'époxyde-14α,15α hydroxy-3β isomérique avec de l'acide perchlorique, de l'acide chlorhydrique ou de l'acide sulfurique a conduit de nouveau à l'artébufogénine-14α et 14β (**5***a* et **6***a*) et le dérivé dihydroxy-14β,15α (**4***a*). La réaction identique avec l'acide periodique a conduit aux produits **6***a* et **4***a*. [Traduit par le journal]

Can. J. Chem., 51, 1973 (1973)

In one of the early studies (1) which preceded the bufadienolide structural assignment, 14α-artebufogenin (**5***a*) was prepared from the 14β,-15β-epoxide, resibufogenin (**1***a*), by reaction with concentrated hydrochloric acid and later (2) using perchloric acid. Recently (3), we noted that a small amount of 14α-artebufogenin (**5***a*) could be isolated by column chromatography of 3β,14β-dihydroxy-15α-bromo-5β-bufa-20,22-dienolide (**2**) on alumina. Treatment of the 14α-isomer (**5***a*) with alumina (2) or hydrochloric acid (4) has afforded the epimeric 14β-artebufogenin (**6***a*). Also epimerization of the 14β-isomer (**6***a*) with acid (5) has afforded 14α-artebufogenin (**5***a*). A more direct route to 14β-artebufogenin (**6***a*) has not heretofore been reported.

In the present report we wish to describe new syntheses of 14α- and 14β-artebufogenin (**5***a* and **6***a*) from resibufogenin (**1**) and the isomeric (2) 14α,15α-epoxide **3**. The latter epoxide (**3**) was prepared from 14-dehydrobufalin by oxidation with meta-chloroperbenzoic acid (3)[3]. When 3β-hydroxy-14β,15β-epoxide **1***a* was treated with 70% perchloric acid in acetone (2) and the product carefully chromatographed, 14α-artebufogenin (**5***a*), 14β-artebufogenin (**6***a*), and 3β,-14β,15α-triol **4***a* were obtained in respectively 69 and ~9% yields. Analogous treatment of 3β-acetoxy-14β,15β-epoxide **1***b* gave 14α-artebufogenin acetate (**5***b*), 14β-artebufogenin acetate (**6***b*), 3-acetoxy-14β,15α-diol (**4***b*), and 14α-artebufogenin (**5***a*) (5) in respectively 73, 8, 12, and 8% yields.

Reaction of resibufogenin (**1***a*) with 2 *N* hydrochloric acid in acetone gave 14α-artebufogenin (**5***a*), 14β-artebufogenin (**6***a*), and 15α-hydroxybufalin (**4***a*) in 62, 23.5, and 6% yields. Extension of the reaction to 3β-acetate **1***b* gave the corresponding 3β-acetates, **5***b*, **6***b*, and **4***b* in 60, 22, and 10% yields. The higher yield of 14β-epimer (**6***a* or *b*) resulting from reaction with hydrochloric acid may have been due to the longer contact time. It should also be mentioned that certain etianic acid (7) and pregnane (8) 14β,15β-epoxides have been converted to 14β,15α-dihydroxy derivatives by treatment with perchloric acid.

Reaction of 3β-acetoxy-14β,15β-epoxide **1***b* with chloranil in refluxing xylene or at room temperature with boron trifluoride etherate afforded only the 14α*H*-15-oxo- and 14β*H*-15-oxo-isomers (**5***b* and **6***b*). Best conversion was found using boron trifluoride etherate. Here 14β-artebufogenin was obtained in 60% yield and the 14α-epimer in 20% yield.

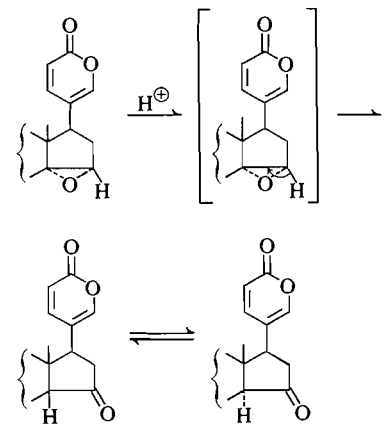
Application of the preceding reaction with 4 *N* hydrochloric acid to 3β-hydroxy- or 3β-acetoxy-14α,15α-epoxide **3***a* or *b* gave the 14α*H*-15-oxo- (**5***a* or *b*), 14β*H*-15-oxo- (**6***a* or *b*), and 14β,15α-dihydroxy derivatives (**4***a* or *b*) in respectively 26 or 21, 18 or 14, and 49 or 48% yields. With dilute sulfuric acid in acetone–water as acid catalyst detailed column chromatography of the product led to the 14α*H*- (**5***a* or *b*) and 14β*H*-isomers (**6***a* or *b*) as well as the 14β,15α-dihydroxy derivative (**4***a* or *b*) (3). Similar results were obtained by subjecting 3β-hydroxy-14α,15α-epoxide **3***a* to treatment with dilute perchloric acid in chloroform–acetone. However, reaction of α-epoxide **3***a* with periodic acid in chloroform–acetone gave 14β-artebufogenin (**6***a*) and 15α-hydroxy-bufalin (**4***a*) in 14 and 53% yields. Only a trace of 14α-artebufogenin was detected.

Mayo (9) has suggested that conversion of 14β,15β-epoxides to 14α*H*-15-oxo-derivatives using perchloric acid may be attributed to a 1,2-shift of the C-15 proton. An analogous mechanistic pathway may be operative in the acid-catalyzed reactions we have observed with resibufogenin (**1**) and the corresponding 14α,15α-epoxide **3** (see Scheme 1). In the latter



SCHEME 1

case, formation of 14α-artebufogenin is probably the result of epimerizing 14β-artebufogenin. The formation of 14β,15α-diols from 14α,15α-epoxides is analogous to observations made in several earlier studies (10) and we wish to thank a referee for providing this information.

We have previously obtained both 14-dehydrobufalin and resibufogenin (**1***a*) by total synthetic routes (3). Thus, the reactions described above leading to 14α- and 14β-artebufogenin complete total syntheses of these substances.

Experimental

The general experimental techniques have been summarized in the experimental introduction of ref. 3. Authentic specimens of alcohols **4***a* and *b* and the artebufogenins were prepared as previously described (3, 11). The identity of each product was confirmed by results of chromatographic and spectral comparisons with the respective authentic sample. All melting points were observed using a micro hot-stage apparatus (Reichert, Austria) and are uncorrected. Column chromatography refers to the dry method using silica gel (12). All solvent extracts of aqueous solutions were dried over anhydrous sodium sulfate. The identity of each product was established by mixture melting determination and i.r. spectral comparison with an authentic sample.

Epoxide Ring Opening with 3β-Hydroxy-14β,15β-epoxy-5β-bufa-20,22-dienolide (Resibufogenin, 1a)

Method A. With Perchloric Acid

To a solution of epoxide **1***a* (115 mg) dissolved in acetone (6 ml), 0.05 ml of 72% perchloric acid was added and the mixture was allowed to stand for 30 min at room temperature. The mixture was poured into ice–water and extracted with chloroform. The extract was washed with water, and concentrated *in vacuo* to dryness. The residue (99 mg) was chromatographed on a column of silica gel. Elution with ligroin–acetone 5:1 and 3:1 gave 14α-isomer **5***a* (79 mg), m.p. 265–267° as colorless prisms from acetone, 14β-isomer **6***a* (11 mg), m.p. 128–130° as colorless prisms from methanol, and diol **4***a* (11 mg), m.p. 272–273° as colorless needles from acetone.

Method B. With Hydrochloric Acid

Hydrochloric acid (4 ml of 2 *N*) was added to a solution of **1***a* (100 mg) in acetone (12 ml) and the mixture was allowed to stand for 24 h at room temperature. The mixture was poured into ice–water and extracted with chloroform. The extract was washed with water and solvent evaporated. The residue (97 mg) was chromatographed on a column of silica gel. Elution with ligroin–acetone (5:1) gave **5***a* (62 mg, m.p. 266–267°), **6***a* (24 mg, m.p. 127–129°), and **4***a* (6 mg, m.p. 271–273°).

Epoxide Ring Opening with 3β-Acetoxy-14β,15β-epoxy-5β-bufa-20,22-dienolide (Resibufogenin Acetate, 1b)

Method A. With Perchloric Acid

To a solution of **1***b* (75 mg) in acetone (5 ml), 0.05 ml of 70% perchloric acid was added and the mixture was allowed to stand for 30 min at room temperature. The residue (71 mg) was chromatographed on a column of silica gel. Elution with ligroin–acetone, 19:1, 9:1, and 5:1, provided **5***b* (55 mg), m.p. 221–223°, **6***b* (6 mg), m.p. 233–235°, **4***b* (9 mg), m.p. 271–273°, and **5***a* (6) (6 mg), m.p. 263–265° all as colorless prisms from acetone.

Method B. With Hydrochloric Acid

In the manner described above (**1***a*, method B) β-epoxide **1***b* (50 mg) in acetone (5 ml) was treated with 2 ml of 2 *N* hydrochloric acid. The product (48 mg) was chromatographed on a column of silica gel. Elution with ligroin–acetone 19:1, 9:1, and 5:1 afforded **5***b* (30 mg, m.p. 222–223°), **6***b* (11 mg, m.p. 232–234°), and **4***b* (5 mg, m.p. 269–272°).

Method C. With Chloranil

Chloranil (40 mg) was added to a solution of **1***b* (22 mg) in xylene (5 ml), and the mixture was heated at reflux for 45 min. After dilution with benzene, the mixture was poured into water. The benzene layer was washed with water, dilute sodium bicarbonate, and water, and evaporated to dryness. The residue (30 mg) was chromatographed on a column of silica gel. Elution with ligroin–acetone (9:1) afforded **5***b* (11 mg, m.p. 223–225°) and **6***b* (8 mg, m.p. 223 ~ 234°).

Method D. With Boron Trifluoride Etherate

Freshly distilled boron trifluoride etherate (0.2 ml) was added to a solution of **1***b* (20 mg) in benzene (2 ml)–ether (1 ml), and the mixture was allowed to stand for 10 min at room temperature. After dilution with benzene, the mixture was poured into ice–water. The benzene–ether layer was washed with water, dilute sodium bicarbonate solution, and water, and evaporated *in vacuo* to dryness. The residue (23 mg) was chromatographed on a column of silica gel. Elution with ligroin–acetone (9:1) gave **5***b* (11 mg, m.p. 222–224°) and **6***b* (4 mg, m.p. 232–235°).

Epoxide Ring Opening with 3β-Hydroxy-14α,15α-epoxy-5β-bufa-20,22-dienolide (3a)

Method A. With Perchloric Acid

To a solution of α-epoxide **3***a* (0.20 g) in chloroform (3 ml) – acetone (12 ml), 0.1 ml of 72% perchloric acid solution was added and the mixture was allowed to stand for 48 h at room temperature. After isolation in the manner described above, the product (0.22 g) obtained was chromatographed on a column of silica gel. Elution with ligroin–ether, 5:1 and 3:1, gave **6***a* (57 mg, m.p. 128–130°, prisms from methanol), **5***a* (6 mg, m.p. 266–267°, prisms from acetone), and **4***a* (110 mg, m.p. 271–273°, needles from acetone).

Method B. With Hydrochloric Acid

A solution of α-epoxide **3***a* (70 mg) in chloroform (3 ml) – acetone (12 ml) was treated with 1.5 ml of 4 *N* hydrochloric acid with stirring for 24 h at room temperature. Extraction with chloroform and separation as described above gave the product (68 mg), which was chromatographed on a column of silica gel. Elution with ligroin–ether, 5:1 and 3:1, provided **6***a* (15 mg, m.p. 127–130°), **5***a* (13 mg, m.p. 266–268°), and **4***a* (34 mg, m.p. 272–273°).

Method C. With Sulfuric Acid

To a solution of **3***a* (100 mg) in chloroform (15 ml) – acetone (6 ml) – water (1 ml) was added 1.5 ml of 2 *N* sulfuric acid and the mixture was allowed to stand for 48 h at room temperature. The mixture was poured into water and extracted with chloroform. The extract was washed with water and evaporated (*in vacuo*) to dryness. The product (98 mg) was chromatographed on a column of silica gel. Elution with ligroin–acetone, 5:1 and 3:1, provided **6***a* (18 mg, m.p. 127–130°), **5***a* (4 mg, m.p. 265–268°), and **4***a* (7 mg, m.p. 215–218°).

Method D. With Periodic Acid

To a solution of **3***a* (80 mg) in chloroform (3 ml) – acetone (12 ml) – water (0.2 ml), 60 mg of periodic acid dihydrate was added and the mixture was allowed to stand for 18 h at room temperature. The mixture was poured into water, extracted with chloroform, and the extract was washed with water, and evaporated (*in vacuo*) to dryness. The product (56 mg) was chromatographed on a column of silica gel. Elution with ligroin–acetone (3:1) gave **6***a* (11 mg, m.p. 125–129°) and **4***a* (42 mg, m.p. 271–273°). On t.l.c. (solvent: acetone–chloroform–cyclohexane (3:3:4), silica gel plate developed with concentrated sulfuric acid), the mother liquor of recrystallized **6***a* showed a spot corresponding to **5***a*.

Epoxide Ring Opening with 3β-Acetoxy-14α,15α-epoxy-5β-bufa-20,22-dienolide (3b)

Method A. With Hydrochloric Acid

A solution of α-epoxide **3***b* (0.10 g) in acetone (10 ml) – water (0.1 ml) was stirred with 2 ml of 4 *N* hydrochloric acid for 24 h at room temperature. Following initial separation as described above, the product (99 mg) was chromatographed on a column of silica gel. Elution with ligroin–acetone (9:1 and 5:1) provided **6***b* (26 mg, m.p. 234–235°), **5***b* (14 mg, m.p. 221–222°), and **4***b* (43 mg, m.p. 280–282°).

Method B. With Sulfuric Acid

To a solution of **3***b* (100 mg) in acetone (20 ml) – water (0.5 ml), 2.5 ml of 1 *N* sulfuric acid solution was added and the mixture was allowed to stand for 48 h at room temperature. The solution was poured into water and extracted with chloroform. After isolation (see above) the product (98 mg) was chromatographed on a column of silica gel. Elution with ligroin–acetone mixture (9:1 and 3:1) provided **5***b* (6 mg, m.p. 221–223°), **6***b* (14 mg, m.p. 234–236°), and **4***b* (62 mg, m.p. 280–283°).

Method C. With Boron Trifluoride Etherate

A solution of **3***b* (20 mg) in 4 ml of benzene–ether (1:1) was treated with freshly distilled boron trifluoride etherate for 10 min at room temperature. Isolation of product was performed as described above and provided 21 mg, which was chromatographed on a column of silica gel. Elution with ligroin–acetone (9:1) gave **6***b* (12 mg, m.p. 232–234°) and **5***b* (4 mg, m.p. 222–225°).

The present investigation was supported by Public Health Service Research Grants CA-10612-04, CA-11451-03, and CA-10115-04 from the National Cancer Institute.

Dissymmetric Oxidation With Methyl 4-Tolyl (*R*)-Sulfoxide

M. H. BENN, PATRICIA CHRISTENSEN, DAN KJERSGAARD, AND CHURAI WATANATADA

Department of Chemistry, The University of Calgary, Calgary, Alberta T2N 1N4

Received August 2, 1972

Methyl 4-tolyl (*R*)-sulfoxide can be used to oxidize (±)-borneol by the carbodiimide–sulfoxide procedure: (−)-camphor is formed in low optical yield; and the residual borneol is correspondingly enriched with its (+)-(1*R*,2*S*,4*R*)-enantiomer.

Le sulfoxyde de méthyle et de tolyle-4 peut être utilisé pour oxyder le bornéol-(±) selon le procédé carboimide-sulfoxyde: le camphre-(−) est obtenu dans des proportions optiquement faibles. Le bornéol résiduaire se trouve enrichi de façon correspondante dans son énantiomère (+)-(1*R*,2*S*,4*R*).

Although dimethyl sulfoxide (**1***a*) appears to be a reagent of choice in the oxidation of primary and secondary alcohols by the sulfoxide–carbodiimide procedure there have been reports that it can be replaced by other sulfoxides; albeit tetramethylene sulfoxide seems to be the only specifically identified substitute (1, 2). If the mechanism of the oxidation is as shown in Scheme 1 (2, 3), it therefore seemed possible that dissymmetric oxidations (the selective oxidation of one enantiomeric alcohol in the presence of the other) might be achieved with a suitable optically-active sulfoxide. We describe here the results of an investigation designed to explore this possibility.

As a conveniently accessible (4) dissymmetric sulfoxide, of known absolute configuration (5), we chose methyl 4-tolyl(+)-(*R*)-sulfoxide (**1***b*). Preliminary experiments with racemic **1***b* established that, in combination with dicyclohexyl carbodiimide (**2**) and phosphoric acid, or pyridinium trifluoroacetate, this sulfoxide could be used to oxidize 1-phenylethanol to acetophenone. However, elevated temperatures were required and, as when dimethyl sulfoxide was employed, the overall conversion of alcohol to ketone was low, with much of the alcohol being lost in side reactions. In addition this system was unattractive for we anticipated that, at the relatively high temperatures which seemed to be needed for the oxidation, acid-catalyzed racemization of the sulfoxide might become troublesome (6). We, therefore, decided to concentrate upon a study of the oxidations of borneol and isoborneol: oxidations which proceed in high yield with dimethyl sulfoxide and in which the product ketone, camphor (**8**), as well as recovered alcohol, could be examined for optical activity.

A summary of the results of these experiments is given in Table 1.

Under the conditions which we employed, isoborneol either resisted oxidation or was predominately converted into camphene. However, racemic borneol (**4**) was oxidized to laevorotatory camphor. The residual borneol was dextrorotatory, thus confirming the selective dissymmetric oxidation of (−)-(2*R*)-borneol by (+)-(*R*)-**1***b*.[1]

The optical purity of **8** and the recovered **4** was very low, 7 and 4% respectively; a result which does not seem attributable to racemization of the sulfoxide since recovered **1***b* was still 62% optically pure. We conclude that either there was poor stereoselection in the formation of the tetracovalent-sulfur intermediate **5** (little preference for the formation of **9***a* rather than *b*); or that if, as Moffat has recently considered (3), **5** is by-passed by the concerted process shown in Scheme 2 this, too, shows little stereoselectivity.

Experimental

Rotations were measured using a Durrum-JASCO O.R.D./C.D. Model 5 spectrometer. A Bendix 2500 gas chromatograph was used for the g.l.c. analyses. The p.m.r. spectra were recorded on Varian A-60 and HA-100 spectrometers. Melting points are uncorrected.

Methyl 4-Tolyl Sulfoxide

Optically active **1***b* was prepared by the literature procedure (5), and had m.p. 76–78°, $[\alpha]_D^{25}$ +145 ± 1° (*c* 3, acetone); lit. (5) m.p. 73.0–74.5°, $[\alpha]_D^{27}$ +145.5° (acetone).

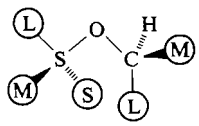
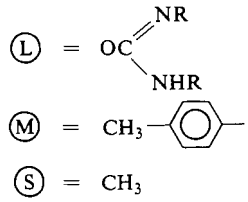
9a



9b



Racemic **1***b* was prepared by the periodate oxidation of methyl 4-tolyl sulfide (7) b.p. 109–112°/0.2 mm, m.p. 55–60°; lit. (7) b.p. 141°/4 mm, m.p. 52–53°.

Catalysts

The crystalline phosphoric acid used was a commercial product (Matheson, Coleman & Bell); the pyridinium trifluoracetate catalyst was prepared *in situ* from trifluoroacetic acid and pyridine (1).

Alcohols

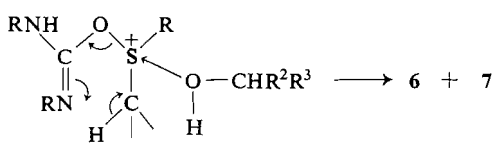
(±)-1-Phenylethanol was prepared by the sodium borohydride reduction of acetophenone. It had b.p. 100–120°/12–15 mm and was ketone-free by g.l.c. analysis (125°/PEGA).

(±)-Isoborneol (Matheson, Coleman, and Bell, practical grade) was recrystallized from acetone – petroleum ether, and then had $[\alpha]_D^{25}$ +0.02° + 0.02° (*c* 5, ethanol), and was >98% pure by g.l.c. analysis (trace of borneol present).

(±)-Borneol; as "racemic borneol" (Nutritional Biochemicals Corp.) had $[\alpha]_D^{25}$ −22.7 ± 0.5° (*c* 5, ethanol), the genuinely racemic isoborneol was epimerized (8) to a mixture of borneol and isoborneol (73:27 by g.l.c. analysis), $[\alpha]_D^{30}$ −0.3 ± 0.1° (*c* 2.5, ethanol) and this product was used in the oxidations.

Oxidation of (±)-1-Phenylethanol

Dicyclohexyl carbodiimide (5.20 g, 25 mmol), (±)-1-phenylethanol (5.50 g, 45 mmol), and methyl 4-tolyl sulfoxide (3.4 g, 22 mmol) were dissolved in sodium – dry benzene (20 ml). To this was added a solution of trifluoroacetic acid (1.26 g, 11 mmol) and pyridine (1.75 g, 22 mmol) in dry benzene (5 ml).



3

SCHEME 2

The reaction mixture was stirred, at room temperature, for 24 h, with rigorous exclusion of moisture. No reaction had taken place so the mixture was stirred and refluxed for 72 h (bath 85°), during which time some solid separated. The reaction mixture was cooled and water (5 ml) added followed by 2 *N* hydrochloric acid (5 ml). After stirring this mixture for 30 min, it was filtered. The filtrate was diluted with ether (50 ml) and the ether phase was washed successively with aqueous sodium bicarbonate, and water, and then dried ($MgSO_4$). Evaporation yielded a pale-brown oil which was distilled to yield a fraction b.p. 90–94°/12 mm. (804 mg) which gave a positive reaction with 2,4-dinitrophenylhydrazine reagent, and was shown by g.l.c. analysis (125°/PEGA) to contain 1-phenylethanol and acetophenone (*ca.* 14:1).

Oxidation of Borneol

Methyl 4-tolyl (+)-(*R*)-sulfoxide (1.54 g, 10 mmol), (±)-borneol-isoborneol (0.77 g, 5 mmol) and dicyclohexyl carbodiimide (3.1 g, 15 mmol) were dissolved in anhydrous benzene (10 ml). To the stirred solution, warmed to 30°, was added crystalline phosphoric acid (180 mg, 1.8 mmol). The reaction mixture was kept at 30°, with rigorous exclusion of moisture, and stirred for 16 h. A white precipitate separated. Additional crystalline phosphoric acid was added (134 mg, 1.4 mmol) and stirring continued for a further 72 h. An n.m.r. analysis revealed only 6% of camphor in the reaction mixture so the temperature was raised to 50° and more phosphoric acid (105 mg, 1.1 mmol) was added. After a further 19 h, p.m.r. analysis revealed that the yield of camphor had risen to *ca.* 25–30%, with 10% camphene, 20% isoborneol, and 35% borneol (as well as dicyclohexyl carbodiimide, methyl 4-tolyl sulfoxide, and methyl tolyl sulfide).

A solution of oxalic acid dihydrate (1.9 g, 15 mmol) in water (50 ml) was then added to the cold reaction mixture, followed by ether (50 ml). After this mixture had been stirred for 1 h it was filtered. The ether phase was separated and washed with aqueous sodium hydrogen carbonate, and water (×3), then dried ($MgSO_4$) and evaporated.

The residue was separated by p.l.c. on Merck silica gel PF 254 + 366 (1m × 20 cm × 1 mm; $CHCl_3$). Extraction of the appropriate bands with chloroform followed by careful evaporation of these extracts (the evaporation of solvent under water-pump pressure was stopped 30 s after the last chloroform disappeared, and the flasks allowed to stand for 5–10 min at room temperature, after which they were of essentially constant weight) yielded the following materials:

(*1*) R_F 0.60 ± 0.06, (−)-camphor (68 mg) (>99.5% by g.l.c. analysis, DEGS, 140°), $[\alpha]_D^{30}$ −2.9 ± 0.2 (*c* 2.4, $CHCl_3$). A second fraction R_F 0.48 ± 0.06, also proved to be camphor (20 mg) (>97% by g.l.c.) $[\alpha]_D^{30}$ −1.7 ± 0.2° (*c* 0.7, $CHCl_3$); lit. (11) $[\alpha]_D$ −41.2°.

(*2*) R_F 0.39 ± 0.03, isoborneol (88 mg) (99% isoborneol:borneol, 93:7 by g.l.c. DEGS 140°), $[\alpha]_D^{30}$ +0.2° ± 0.2 (*c* 2, ethanol).

(*3*) R_F 0.30 ± 0.06, borneol (105 mg) (100% borneol:isoborneol, 97:3 by g.l.c. DEGS, 140°) $[\alpha]_D^{30}$ +0.8 ± 0.2° (*c* 1.8 ethanol); lit. (12) $[\alpha]_D$ +37°.

Formation of New Tetradentate Schiff Base Metal Chelates

ABDUL MALEK AND JAMES M. FRESCO
Department of Chemistry, McGill University, Montreal, Quebec
Received November 3, 1972

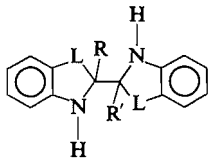
Condensation products of *o*-aminophenol, *N*-substituted-*o*-aminophenols, and 8-amino-1-naphthol with α-diketones have been compared. The basis for the lack of reactivity of these products to yield Schiff base chelates for the cases where the parent diketone is different from glyoxal was examined. Steric factors alone did not appear to influence the reaction.

On a comparé les produits de condensation du *o*-aminophénol, des *o*-aminophénols *N*-substitués, et du amino-8 naphtol-1 avec des α-dicétones. On a examiné la raison du manque de réactivité de ces composés à former des chélates bases de Schiff lorsque la dicétone n'est pas le glyoxal. Les facteurs stériques par eux seuls n'ont pas paru influencer la réaction.

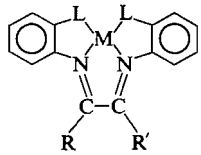
Can. J. Chem., **51**, 1981 (1973)

Introduction

Evidence (1–9) has accumulated in recent years to show that metal ions change the nature of the condensation product of α-diketones with either *o*-hydroxy, or *o*-mercaptoamines and β-mercaptoethylamine. In the absence of metal ions, the condensation product is usually heterocyclic **1** where L is oxygen or sulfur. But the presence of metal ions results in stabilization of the quadridentate Schiff base **2** through complex formation.



1



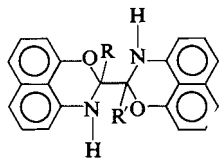
2

Paths that the heterocycle or the corresponding Schiff base tautomer may follow to form the metal chelate have been investigated (1).

It has been shown (10) that the sulfur analogs of structural type **1** undergo metal ion-induced rearrangement more readily than the oxygen analogs. Metal chelates of the thio analog of **1** in which R and R′ are different substituted groups were isolated. However, the oxygen analog reacts with metal ions only when R = R′ = H. This unreactivity was unexpected since the condensation product of *o*-aminothiophenol with salicylaldehyde is the heterocyclic benzthiazoline whereas that of *o*-aminophenol is a Schiff base (7, 11). No chelates of the oxygen analog of structural type **2** with R and R′ groups other than hydrogen atoms have been reported and no satisfactory explanation exists as to why those compounds do not form chelates. Bayer and coworkers (3, 4) explained this lack of chelate formation by assuming that there is steric hindrance between the substituted groups which destabilizes the chelate.

From an examination of models it seems highly unlikely that steric hindrance between the substituted groups is a major factor which can account for such a striking difference in reactivity of these compounds.

The metal chelates of structural type **2**, in which L = NR″(R″ = H, CH_3, C_6H_5, etc.), have not yet been reported. Since a comparison of the spectroscopic and chemical properties of the chelates of structural type **2** where L is varied could provide an understanding of the differences in the reactivities of the parent ligand molecules, a number of these compounds were prepared for study. In addition, since naphthoxazinines **3** provide a case analogous to that of structural



3

type **1** but with the difference that in the former case a six-membered heterocyclic ring is involved, it was of further interest to study the reactivity of these compounds with metal ions and compare them with those of structural type **2**.

Experimental

Materials

o-Aminophenol obtained from Eastman Organic Chemicals was recrystallized from ethanol before use. *N*-Methyl-*o*-phenylenediamine monohydrochloride (Eastman), *N*-phenyl-*o*-phenylenediamine (Eastman), glyoxal, 40% aqueous solution (Fisher Scientific Company), pyruvaldehyde, 40% aqueous solution (J. T. Baker Chemical Co.), diacetyl (Fisher), benzil (Eastman), and 2,2′-pyridil (Aldrich Chemical Co. Inc.) were used without further purification. Eastman 8-amino-1-naphthalenesulfonic acid was used for the preparation of 8-amino-1-naphthol hydrochloride without prior purification. Reagent grade nickel chloride hexahydrate and nickel acetate tetrahydrate were obtained from Fisher. Deuterated solvents were obtained from Stohler Isotope Chemicals.

General Methods of Preparation

(i) Benzoxazolines and their Chelates

Benzoxazoline and the 2,2′-mono or disubstituted analogs prepared by the method described by Murase (12) were recrystallized from ethanol.

The nickel chelates were obtained by the following procedure. After dissolution of 0.01 mol of the ligand in 50 ml dry acetone, the solution was shaken in a stoppered flask in the presence of solid sodium hydroxide pellets for 24 h. Upon addition of the pellets, a red–yellow color gradually appeared. Fine particles of the disodium salt of the Schiff base were easily separated from the sodium hydroxide pellets by decantation and subsequent filtration. The yellow disodium salt was unstable in contact with water and alcohols. The nickel chelate was formed by direct addition of the crude sodium salt to an ethanolic solution of nickel chloride (0.01 mol) with vigorous stirring. On addition of water to the ethanol solution the blood-red colored chelate was precipitated. This was filtered, washed first with water and then acetone. Recrystallization from ethanol yielded the pure compound which was dried under vacuum over P_2O_5.

The nickel chelate of 2,2′-bibenzoxazoline was also prepared by direct reaction of nickel acetate with the ligand in ethanol solution as described by Bayer (3). Both methods of preparation yielded identical compounds.

(ii) Naphthoxazinines and their Chelates

The 2,2′-naphthoxazinines were obtained by reaction of 8-amino-1-naphthol with the appropriate α-diketone in a 1:2 molar ratio. The hydrochloride of 8-amino-1-naphthol was obtained from 8-amino-1-naphthalenesulfonic acid by alkali fusion (13). The following procedure was used for the preparation of naphthoxazinines. A 0.02 mol sample of 8-amino-1-naphthol hydrochloride was dissolved in 100 ml water which was previously boiled and cooled to 70°. To this solution a slight excess of the calculated amount of sodium acetate was added to neutralize the acid. A 0.01 mol sample of α-diketone dissolved in a minimum volume of water was added to the 8-amino-1-naphthol solution and the mixture held at this temperature with occasional shaking for about 1 h. Precipitates usually formed gradually. After cooling, the crystals were filtered and washed with water. Recrystallization from ethanol yielded pure compounds.

The nickel chelates of 2,2′-binaphthoxazinine were obtained by the reaction of the ligand with nickel acetate. After 0.01 mol nickel acetate dissolved in 50 ml of ethanol was added to 0.01 mol of the ligand dissolved in 30 ml ethanol, the mixture was refluxed for 1 h. The dark green product formed was separated by filtration and recrystallized from dichloromethane using a Soxhlet extraction system.

(iii) Condensation Products of α-Diketones with N-Methyl- or N-Phenyl-o-phenylenediamine and their Chelates

A solution of 0.02 mol *N*-methyl- or *N*-phenyl-*o*-phenylenediamine in water or ethanol was cooled in an ice bath. A 0.01 mol sample of the appropriate diketone dissolved in water or ethanol was then added slowly with stirring to the amine solution over a period of 1 h. The product appeared gradually and the reaction mixture was stirred overnight. The Schiff base was collected by filtration and was recrystallized from ethanol.

The nickel chelates were prepared by using either one of the following two methods:

Method A: A mixture of 0.02 mol of *N*-methyl- or *N*-phenyl-*o*-phenylenediamine and 0.01 mol of α-diketone dissolved in 50 ml acetone was placed in a stoppered flask. A 0.01 mol sample of nickel chloride dissolved in 20 ml 1:1 ammoniacal solution was added and the contents were allowed to stand at room temperature with occasional stirring for about 1 week. Red or green-colored crystals formed slowly. At the end of the reaction the volume of the solution was reduced by evaporation to increase the yield. After collection by vacuum filtration, the chelate was purified by repeated recrystallization from ethanol–water mixtures.

Method B: This method is essentially the same as the previous one, except the metal ion was reacted directly with the Schiff base obtained by a separate preparation. Both methods provided the same chelate.

Analyses

Microanalyses for carbon, hydrogen, and nitrogen were performed by the Scandinavian Microanalytical Laboratory, Box 25, 2730 Herlev- DK, Denmark.

Nickel was determined by an EDTA titrimetric method (14, 15) after the sample had been ashed at 600° for 1 h and then dissolved in dilute hydrochloric acid. Analytical results are shown in Table 1.

Spectroscopic Measurements

Low resolution mass spectra were obtained with an A.E.I.-MS-902 double focusing mass spectrometer using 70 eV electrons and 8 kV accelerating voltage. The samples were introduced by direct evaporation. A low temperature range (120–130°) was sufficient to obtain the spectra of the free ligands.

Visible and u.v. spectra were recorded with an UNICAM SP 800 u.v. spectrophotometer and with a Beckman DB spectrophotometer connected to a Sargent–Welch SRLG recorder. Absorbance measurements were made in ethanol using 1 cm matched quartz cells.

I.r. spectra in the range 4000–250 cm^{-1} were recorded with a Perkin–Elmer Model 521 grating spectrophotometer. The samples were measured either as KBr pellets, CsBr pellets or as Nujol mulls supported between CsBr plates. Calibration of frequency readings was performed with polystyrene films.

N.m.r. spectra were obtained by using a Varian model

T-60 spectrometer. The specifications given by the manufacturer are as follows: H_0 field strength 14 092 G; H rotating field frequency 60 MHz (for proton resonance at 14 092 G); resolution: the full line width at half amplitude is ≥ 0.5 Hz; sensitivity: average signal to noise ratio 12:1.

Tetramethylsilane was used as internal or external standard. Measurements were made in chloroform-*d*, dimethylsulfoxide-*d* and pyridine-*d*.

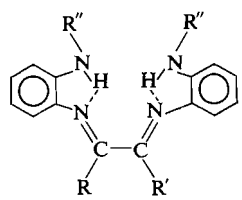
Results and Discussion

Structures of the Schiff Bases

It has been reported (12) previously that the dicondensation of *o*-aminophenols with α-diketones results in the formation of heterocyclic compounds **1**, L = O.

Although in some restricted cases (1) it was possible to isolate the intermediate Schiff bases, in most cases the heterocyclic compound is the only product. A structurally similar compound, 8-amino-1-naphthol was found in the present study to condense with α-diketones forming exclusively the heterocycle, naphthoxazinine **3**.

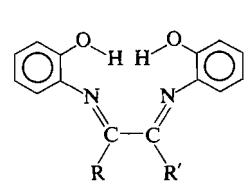
In contrast to the previous two cases, 2 mol of *N*-methyl- and *N*-phenyl-*o*-phenylenediamines were found to condense with α-diketones to give yellow-colored Schiff bases, **4**. Spectroscopic and chemical evidence in favor of **3** and **4** and additional evidence supporting **1** are discussed in the following sections. The results are summarized in Tables 2 and 3.



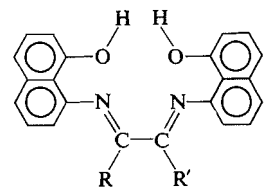
4

(i) I.r. Spectra

All the above three types of compounds have a characteristic sharp band near 3300 cm^{-1} (Table 2). This band is absent in the corresponding metal chelates (Fig. 1). In his investigations with 2,2′-bibenzoxazoline compounds, **1**, Murase (12) assigned this band to the N—H stretching frequency. The presence of this sharp band in the condensation products of 8-amino-1-naphthol with α-diketones indicates that the resultant compounds have the heterocyclic structure **3**. No broad O—H stretching band in the high frequency region was observed in the spectra of these compounds. This indicates the absence of possible Schiff base forms **5** and **6**.



5



6

The N—H band in the condensation products of *N*-(substituted)-*o*-phenylenediamine with α-diketones is relatively broader and split; this indicates intramolecular hydrogen bonding of the N—H hydrogen with the azomethine nitrogen **4**.

(ii) U.v. Spectra

The spectra of the dicondensation products of *o*-aminophenol and 8-amino-1-naphthol with α-diketones are closely related to those of the primary amines themselves, Table 4. All of these compounds are colorless. The presence of the chromophore such as conjugated azomethine

(>C=N—) linkage in these compounds should therefore be discounted. This implies that these compounds are heterocyclic.

The spectra of the dicondensation products of *N*-(methyl or phenyl)-*o*-phenylenediamine with α-diketones on the other hand are different than those of the primary amines, Table 4. These compounds are yellow in color, which indicates the presence of chromophoric (>C=N—) linkage, structure **4**.

Base-induced rearrangement. Murase (16) reported earlier that although **1** (R = R′ = H) was insoluble in aqueous alkali, a reddish-yellow color was produced when an excess of potassium hydroxide was added to its ethanol solution and another absorption maximum was observed at 467 nm. This was explained by assuming that 2,2′-bibenzoxazoline tautomerizes to the corresponding Schiff base under the influence of base to yield the anion of **5**.

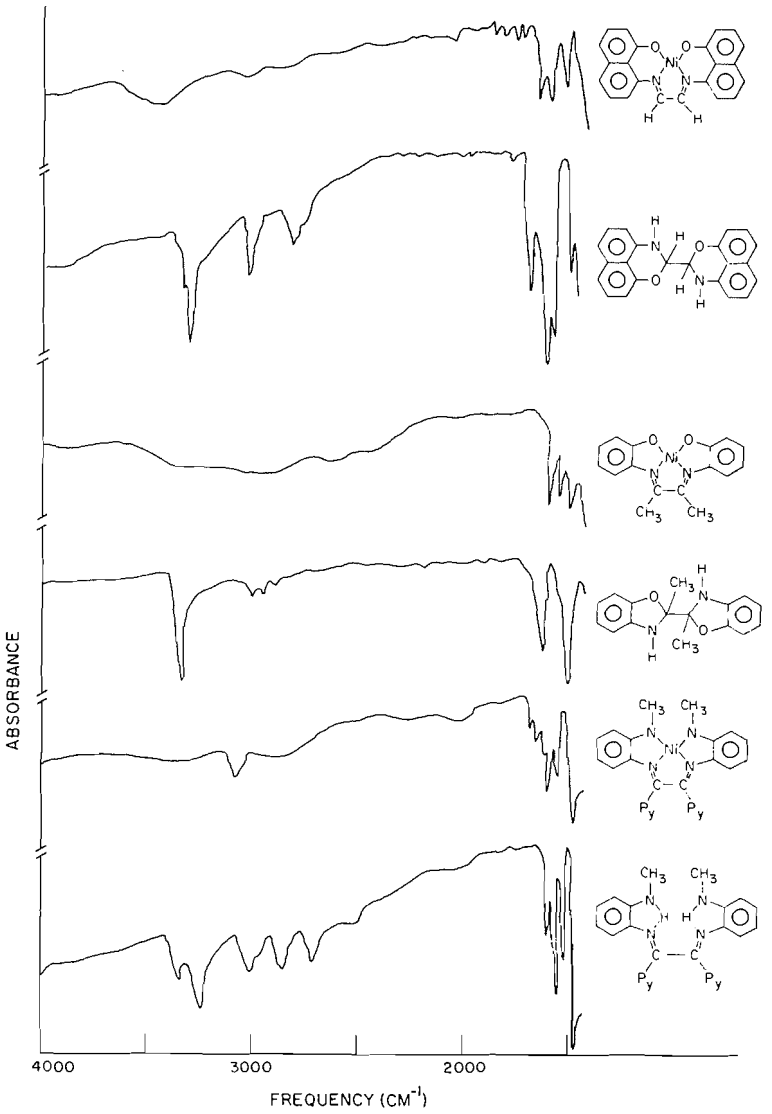

FIG. 1. Comparison of high frequency (4000–1500 cm^{-1}) i.r. spectra of nickel tetradentate chelates and the corresponding free ligands.

The present authors also showed that 2,2′-di- or monosubstituted bibenzoxazolines did not undergo such a rearrangement under identical conditions.

In the present study it was found that substituted bibenzoxazolines and substituted naphthoxazinines developed a reddish-yellow color when a small piece of solid NaOH was added to their dimethylsulfoxide or acetone solutions. The observation was supported by the appearance of new absorption bands in their spectra, Table 4. In all cases the absorption band of the ligands near 300 nm shifted to a higher wavelength after the addition of NaOH. Typical examples are shown in Figs. 2 and 3, and the results are shown in Table 4. This change in the u.v. spectra may be related to the tautomerization of the heterocyclic compound to the corresponding Schiff base. The reason why only unsubstituted 2,2′-bibenzoxazoline and 2,2′-binaphthoxazinine and not their substituted analogs undergo such a change in ethanol and methanol has not been established. It is possible that the Schiff base anion of the substituted analog is such a strong base that it

will immediately rearrange to the heterocyclic form in a protic solvent such as alcohol or water.

The u.v. spectra of the compounds of structural type **4** do not undergo any change on the addition of alkali. This indicates that these compounds have the open Schiff base structure.

(iii) Mass Spectra

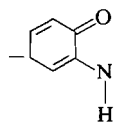
The fragmentation pattern in the mass spectra of the compounds of structural types **1**, **3**, and **4** are readily reconcilable with their molecular structures.

In Table 3 the melting points of the compounds and *m/e* values are listed. The relative peak intensities are indicated within brackets. Each peak indicated by its *m/e* value in Table 3 is usually accompanied by a few other peaks of relatively lower intensities; these are not listed.

The mass spectra of compounds of structural types **1** and **3** are uncluttered in the mass region between the molecular peak M and M/2 and have very few peaks of low intensity. This indicates the presence of stable closed structures and that the central carbon–carbon bond between the heterocyclic rings is easily cleaved, breaking the molecule into two halves.

The spectra of the compounds of structural type **4** have complicated patterns between M and M/2. This high mass region has various intense peaks which are assignable to different fragments of the parent molecule. An open-type structure of these compounds is therefore indicated.

It is interesting to note that the mass spectra of **1** have a characteristic peak at *m/e* M − 107. The mass number 107 can be assigned to the fragment



This indicates that the heterocycle is broken at the aliphatic end (breaking the C—O and C—N bonds) before the whole molecule is broken into two halves. The spectra of **3** do not have such characteristic intense bands at M − 156. The difference in the mass spectra of these compounds may be due to the relatively greater stability of six-membered heterocyclic rings of **3** compared to five-membered rings of **1**.

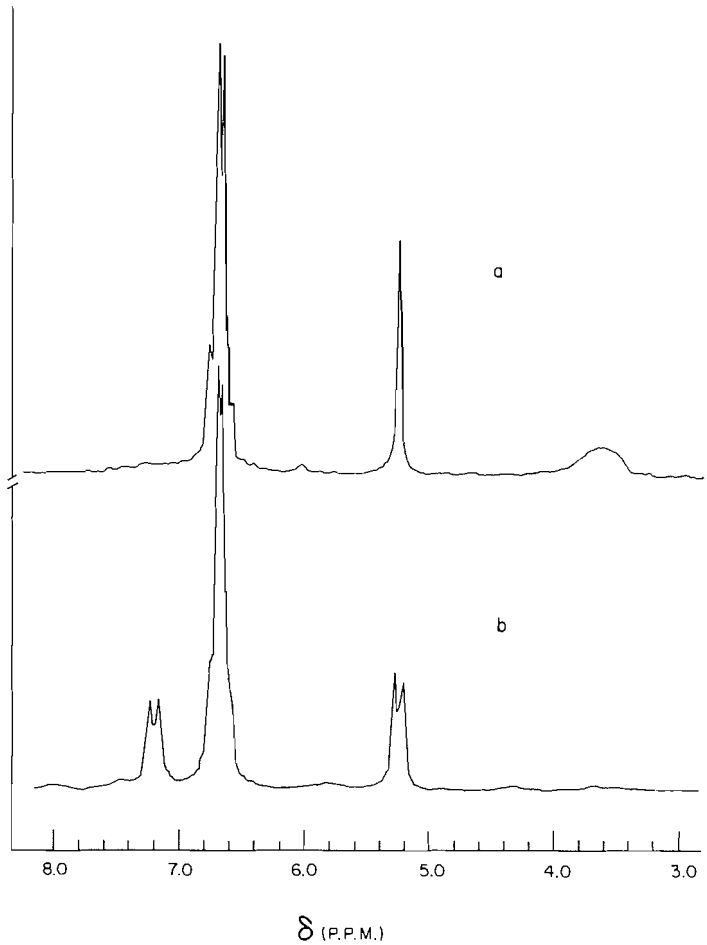

FIG. 4. N.m.r. spectra of 2,2′-bibenzoxazoline in deuterated DMSO; (*a*) spectrum after addition of D_2O; (*b*) normal spectrum.

(iv) N.m.r. Spectra

The results of the n.m.r. spectra are shown in Table 2. These results are compatible with the heterocyclic structures of compounds **1** and **3** and open Schiff base structures of **4**. The N—H signal in the **4** compounds appears upfield compared to those of **3** and **1**. The N—H signal was identified by the fact that it exchanges readily with water; the N—H signal vanishes when D_2O is added to the solution of these compounds.

In the bibenzoxazoline compounds **1***a* and *b*, the C—H and N—H protons mutually split each other. This is exemplified by the spectra of **1***a*, Fig. 4. On deuteration the N—H signal vanishes and the C—H doublet collapses into a singlet.

Quadridentate Schiff Base Metal Chelates

In spite of previous claims (3, 4, 7) that the compounds of structural type **1** (R = R′ = substituted groups) do not form metal chelates, successful methods have been developed in the present study for the preparation of these metal chelates. Additionally, the preparation of the metal chelates of **3** and **4** are reported for the first time. The u.v. spectra of the nickel chelates of these compounds are shown in Table 4 and compared with the spectra of the corresponding sodium salts.

Bayer and his co-workers (3, 4) were the first to show that **1** and its thio analog rearrange in the presence of metal ions to form the metal chelates

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

2. They showed in the case of **1** that such a rearrangement and subsequent chelate formation took place only when R and R′ are hydrogen atoms. No chelates were formed when one or both of the hydrogen atoms were replaced by substituted groups.

Bayer explained this lack of chelate formation in terms of steric hindrance from larger R groups. But the fact that the thio analogs of these compounds (1–3) and **4** readily form metal chelates, dispels the validity of such an explanation.

As noted earlier, Murase (16) showed that 2,2′-bibenzoxazoline **1** (R = R′ = H) developed a color when an excess of KOH was added to its solution in ethanol and another absorption maximum was observed at 467 nm. He ascribed this color and the new band to the Schiff base **5**. He also showed that no such phenomenon was observed in the case of 2-substituted or 2,2′-disubstituted compounds. He concluded that the substituted bibenzoxazolines **1** did not form metal chelates because of their inability to rearrange to the corresponding Schiff base chelates. In the case of 2,2′-binaphthoxazinine **3**, a similar trend was also observed. Through direct reaction with metal acetates, chelate formation took place only when R and R′ were H atoms.

It was found in the present study that all the compounds of structural types **3** and **1** developed a red or yellow color in a molten NaOH–KOH mixture. These colored compounds could be extracted into DMSO. It was later found that the same color also developed when these compounds were shaken in acetone or DMSO in the presence of solid NaOH pellets for several hours. This change in color was associated with shifting of the u.v. bands to higher wave length, Table 4, indicating the tautomerization of the heterocyclic compounds to the open Schiff base form. In acetone, the sodium salt of the Schiff base precipitated out and could easily be separated. The metal chelates were then easily prepared by simply adding the sodium salt to the metal salt in ethanol solution.

The sodium salts of these compounds are very unstable in water, methanol, and ethanol. In ethanol the sodium salts were shown to be converted back to the original cyclic compounds. The rate of this rearrangement to the cyclic form, **1**, is very fast in the case of the 2,2′-substituted compounds and is much slower in the case of the unsubstituted one.

It is now evident from the present study that the reason why **1** and **3** (where R or R′ are substituted groups) do not form metal chelates under mild conditions is not because of steric hindrance between the substituted groups, as was assumed before (3, 4), but rather due to other factors such as electronic, kinetic, or other steric effects.

The authors thank the National Research Council of Canada for financial support of this work.

A Wide Line Nuclear Magnetic Resonance Study of Molecular Motion in *n*-Alkyl Ammonium Chlorides

J. TSAU AND D. F. R. GILSON

Chemistry Department, McGill University, P.O. Box 6070, Montreal 110, Quebec

Received December 22, 1972

Wide line n.m.r. studies of *n*-alkyl ammonium chlorides, C_3–C_{10}, show two transitions. The first transition is due to reorientation about the chain axis, the second to a transition to a mesomorphic phase. This phase is probably similar to that observed for the alkali metal salts of fatty acids.

Les études par r.m.n. des chlorure de *n*-alkyl ammonium C_3–C_{10} montrent deux transitions. La première transition est due à la réorientation autour de l'axe de la chaîne, la seconde à une transition en une phase mésomorphe. Cette phase est probablement similaire à celle observée pour les sels alcalins d'acides gras.

Introduction

The occurrence of solid–solid phase transitions in various homologous series of *n*-alkyl derivatives is well known. Wide line nuclear magnetic resonance methods have been used to study molecular motions in such series, particularly the alkanes themselves (1–3), and the fatty acids and their soaps (4–7). In their extensive studies of the alkali metal salts of fatty acids Dunell and co-workers have observed two line width and second moment transitions, the first due to a change from one crystal form to another, the second due to the appearance of a mesomorphic phase characterized by a low value for the second moment resulting from extensive molecular motion. In general the temperatures of the crystal–crystal transitions for each compound agree well with values obtained by calorimetric or hot stage microscope methods but there is much poorer correlation for the transitions to the "waxy" phase (5).

We have reported (8) the results of a differential scanning calorimetric (d.s.c.) study of the series of *n*-alkyl ammonium chlorides and bromides (C_1 to C_{16}). Transition temperatures and enthalpies were obtained, in some cases these depended on the thermal history of the sample, and entropies of fusion were also measured. The entropy values were less than 5 cal deg^{-1} mol^{-1} indicating the possible existence of a mesomorphic phase analogous to the alkali metal fatty acid salts.

X-Ray structural information on the *n*-alkyl ammonium chloride series is limited, and, with few exceptions, restricted to room temperature studies. The early members of the series, up to C_{10}, have a tetragonal structure at room temperature with the exception of ethyl ammonium chloride which is monoclinic (9–13). The higher members are monoclinic or orthorhombic (14–16). The structures of *n*-propyl and *n*-pentyl ammonium chlorides have been studied at low temperatures and both undergo transitions to a monoclinic structure (12, 13). The d.s.c. studies showed that transitions occurred at or below room temperature for chain lengths less than eight carbon atoms. It appears reasonable therefore to assume that the high temperature phases of the members of the series are tetragonal and a transition to a monoclinic or orthorhombic phase occurs at lower temperatures. The presence of either molecular rotation or statistical disorder in the tetragonal phase has been proposed (16) to explain the conflict between molecular symmetry and site symmetry. The present paper describes the results of a wide line n.m.r. investigation of the *n*-alkyl ammonium chloride salts from C_3 to C_{10}. A study of the methyl ammonium halides has been reported earlier (17).

Experimental

The *n*-alkyl ammonium chlorides were prepared by passing hydrogen chloride gas into a solution of the amine in chloroform or ether, followed by recrystallization (3×) from mixed solvents, ethanol–ether (C_3–C_5), or chloroform–ether (C_6–C_{10}).

Wide line n.m.r. spectra were obtained at 60 MHz using a spectrometer consisting essentially of Varian components with a V3400 high field 9 in. magnet and Fieldial Mark II regulator. Sample temperatures were controlled by a cooled, or heated, flow of dry nitrogen gas through a Dewar system, and measured with copper–

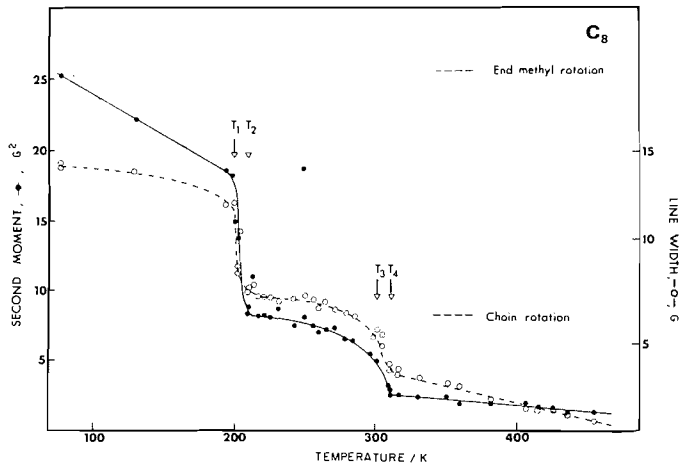

FIG. 1. Temperature dependence of the second moment (filled circles) and line width (open circles) for *n*-octyl ammonium chloride.

constantan thermocouples placed upstream and downstream from the sample. Second moments were computer calculated from the experimental derivative curves, using a program written in this laboratory, and corrected for finite modulation width.

Results

In general the line widths and second moments show similar behavior for all compounds; a gradual decrease from a value greater than 22 G^2 at 77 °K to a value in range of 15 to 18 G^2 at the first transition point, T_1. The second moment then shows an abrupt decrease to a value between 5 and 8 G^2, at temperature T_2, followed by a second transition at a higher temperature, T_3, to a value of 2 to 3 G^2. A steady decrease in second moment then continues to values of about 0.5 G^2 at the melting points. The temperature dependences of the line width and second moment are shown in Fig. 1 for *n*-octyl ammonium chloride. For *n*-butyl and *n*-pentyl ammonium chlorides the two transition temperature ranges are almost coincident. Table 1 lists the transition temperatures and experimental second moment values and also includes the transition temperature of the closest transitions observed in the d.s.c. studies (8).

Discussion

If the crystal structure of a compound is known in sufficient detail the theoretical second moment can be calculated from the van Vleck formula (18). In cases where the structure is not known it is the usual practice to divide the second moment into two contributions, the intramolecular contribution, S_1, and the intermolecular contribution, S_2, The intramolecular second moment can be calculated using accepted values for bond lengths and angles, but the intermolecular contribution must be estimated either by approximate calculations or by comparison with values obtained or calculated for similar compounds. Thus for the *n*-alkyl ammonium chlorides the intramolecular second moments were calculated using bond lengths; C—C = 1.540, C—N = 1.470, C—H = 1.096, and N—H = 1.045 Å and all bond angles were assumed to be tetrahedral. The intermolecular contribution was estimated from values found for other long chain compounds. For the hydrocarbon *n*-$C_{29}H_{60}$ a rigid lattice value of 7.8 G^2 was obtained by Andrew using the known crystal structure (1). In their studies of carboxylic acids and their salts Dunell and co-workers (4–6) have obtained contributions ranging from 6.4 G^2 for potassium caprate and caproate to 9.4 G^2 estimated for sodium stearate. The intermolecular second moment for methyl ammonium chloride in the high temperature form was estimated to be 8.8 G^2 (17). A value of 8.0 G^2 is adopted for the present purposes. In Table 2 the calculated total rigid lattice second moments are listed. In all cases the theoretical values are considerably higher than the experimental. This is not an unexpected result since it is generally observed for long chain compounds and is usually explained as due to the rotation of the end-methyl groups. The calculated second moments for the end-methyl group reorientation case are listed

in Table 2. Agreement with the experimental values at 77 °K is adequate if the uncertainty in the intermolecular second moment is considered. It is possible that the $-\overset{+}{N}H_3$ group reorients as well as, or instead of, the methyl group. Both these possibilities are discarded; the first would reduce the second moment such that unreasonably large intermolecular contributions would be required to explain the magnitudes of the experimental values. Reorientation of the ammonium rather than the methyl group seems unlikely since the polar end of the chain is involved in hydrogen bonding and electrostatic interactions with the neighboring chloride ions.

The observed large reductions in the second moments of long chain compounds generally arise from reorientation about the long chain axis. In calculating the theoretical second moment for this case the same difficulties are encountered as for the rigid lattice calculation; the intramolecular second moment can be obtained fairly easily but the intermolecular contribution cannot. Smith (19) has reviewed the various reduction factors used by different authors. These range from 0.25 to 0.8 and have been applied to "spherical" as well as long chain compounds. In the present case a one-third reduction factor, appropriate to the long chain compounds (1), has been used and the calculated second moments are given in Table 2. The experimental second moments in the region between the two transitions *i.e.* between T_2 and T_3, Fig. 1, are slightly lower than the calculated values but the agreement is again satisfactory in view of the approximations. Between 77 °K and T_1 the second moment decreases steadily. This behavior is commonly observed for long chain compounds and is attributed to increasing amplitudes of torsional motion of the chain. The amplitude necessary to account for the observed reduction in second moment is, however, rather large and some additional motion, such as wagging of the chain, must also occur.

Except for the *n*-octyl and *n*-nonyl compounds the T_1–T_2 n.m.r. transitions correlate approximately with the thermal transitions observed in the d.s.c. study (8) but occur some 10 to 20° lower in temperature. It seems probable that the onset of chain rotation facilitates a crystal–crystal transition.

The second moment transitions which occur over the temperature range T_3 to T_4 reduce the second moments to values of about 2 G^2. These transitions correlate approximately with the d.s.c. transitions which have the largest enthalpy. The low values of the second moment show that molecular motion of a translational nature must occur. This behavior is similar to that observed for the alkali metal salts of fatty acids except that there is no narrow line of modulation width present in the spectra of the *n*-alkyl ammonium chlorides. It appears that the ammonium salts are less susceptible to the presence of impurities and "liquid-like" motion does not occur. The translational motion must involve large groups of molecules and is probably the same as that described by Skoulios and Luzatti (20) for the "waxy" phase of the sodium soaps. This model consists of a double layered ribbon of molecules arranged so that the hydrocarbon chain resembles the bristles on a bottle brush. The member of molecules involved is not known although the ordered domains in mesophases of the liquid crystal type are estimated to be 10^{-5} to 10^{-6} cm in diameter. That a large number of molecules must be involved is evident from the fact that X-ray powder diffraction data can be obtained at temperatures above T_4 (21), but the intensities of the long spacing reflections decrease fairly rapidly with increasing order. A similar behavior

has been reported for *n*-alcohols (22). The presence of translational motion is consistent with the observed low entropies of fusion (8), although this parameter may also be lowered by the presence of molecular order in the liquid phase.

Allene Oxide Intermediates: Vinylidene Carbene Addition to Carbonyl Compounds

YU-NENG KUO[1] AND MARTIN J. NYE[2]

Department of Chemistry, University of Guelph, Guelph, Ontario

Received August 10, 1972

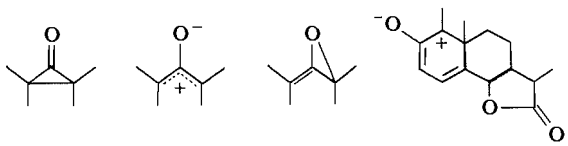
Solutions of fluorenylidene carbene (**10**) have been generated by treatment of 9-(aminomethylene)-fluorene (**9**) with *n*-butyl nitrite. This vinylidene carbene forms a 1:1 adduct with azobenzene, and with acetone pivaldehyde and tolualdehyde it forms 1:2 adducts containing the 5-fluorenylidene-1,3-dioxolane ring system. Evidence for the intermediacy of an allene oxide (**3**) is presented.

Les solutions de carbène fluorinylidène (**10**) ont été obtenues en traitant l'aminométhylène-9 fluorène (**9**) par le nitrite de *n*-butyle. Ce vinylidène carbène forme un adduit 1:1 avec l'azobenzène et avec l'acétone, le pivaldéhyde et le tolualdéhyde des adduits 1:2 contenant le système cyclique fluorenylidene-5 dioxolane-1,3. L'intermédiaire alleneoxyde (**3**) a été mis en évidence. [Traduit par le journal]

Can. J. Chem., **51**, 1995 (1973)

Introduction

The three isomeric systems: cyclopropanone (**1**), oxyallyl (**2**), and allene oxide (**3**) have attracted attention for a long time as reactive intermediates, and in recent years substituted cyclopropanones (1) and allene oxides (2) have been synthesized. However, there is only one report of an isolation of an oxyallyl system by Fisch and Richards (3), who suggest the structure **4** for the unstable blue non-paramagnetic species obtained in a frozen glass by radiation of lumisantonin; and for this one case, evidence is weak.



1 **2** **3** **4**

Concerning the experimental thermodynamic stabilities of the three systems, all that is known so far is that 1,1-di-*tert*-butylallene-1,2-oxide[3] (4*a*) and 1,3-di-*tert*-butylallene oxide (2) are less stable than the corresponding cyclopropanones, since both can be thermally isomerized to the cyclopropanone; whereas 1,1,3-tri-*tert*-butylallene-1,2-oxide (4*b*) is very stable thermally and has not been isomerized. Theoretical calculations were first carried out by Burr and Dewar (5) in 1954 using the LCAO method, and oxyallyl was predicted to be less stable than cyclopropanone. Next came a contradictory result by Hoffmann (6) in 1968 using an extended Hückel method, which indicated that oxyallyl should be 60 kcal more stable than allene oxide which should be 7 kcal more stable than cyclopropanone. Then in 1970, Dewar and coworkers (7) confirmed the 1954 result using the newer MINDO/2 method giving cyclopropanone 78 kcal more stable than oxyallyl.

Obviously much more experimental data relevant to the relative stabilities of the isomers (**1–3**) are called for, and high in priority is the synthesis of more examples. One approach is to attempt to synthesize substituted examples of each of the three isomers by carefully selecting stabilizing substituents.

The work reported in this paper was initiated in order to synthesize system **5** and its isomers **6**, **7**, and **8**, and then to investigate their relative stabilities and the possibility of interconversion. This particular system was chosen because the allene oxide **5** might prove to be more stable than the cyclopropanone **7** in contrast to the *tert*-butyl substituted systems. The reasons for this suggestion are firstly that molecular models of **5** show less steric crowding than those of **7** for most R substituents, and secondly that the extra conjugation in **5** might stabilize it relative to **7**. This latter idea is backed up by the fact that the enol **13***a* in acetonitrile solvent contains none of its *aldo* tautomer detectable by n.m.r. (8). The oxyallyl system **6** might also be appreciably stabilized if R'' is a carbonium ion stabilizer such as *p*-tolyl.

[1]Present address: Department of Chemistry, California State University, San Francisco, California.

The synthetic approach to **5** was based on Curtin *et al*'s (9) synthesis of the methylenecyclopropane **11** by treating the enamine **9** with isoamyl nitrite in the presence of 2,3-dimethyl-2-butene. The presumed (9) reaction sequence is initial formation of a diazonium salt followed by loss of nitrogen and a proton to give the carbene **10** which then adds to the alkene to give **11** (see Scheme 1). If one simply replaces the alkene in this synthesis by any other doubly-bonded molecule represented by the general formula X=Y, then on paper one has a general synthesis of compounds of general formula **14**. If X=Y is a carbonyl compound, the product should be an allene oxide, **5**.

This paper reports attempts at this method of synthesis of allene oxides.

Results and Discussion

Numerous different sets of conditions were tried for the reaction between 9-(aminomethylene)-fluorene, *n*-butyl nitrite, and various doubly-bonded molecules. The first part of the reaction, the generation of the carbene **10** with loss of nitrogen was followed by measurement of the volume of gas evolved. The rate was found to be very sensitive to the composition of the medium. For example, while more than 50% of the expected volume of nitrogen is evolved within an hour when the solvent is benzene at 35 °C, no appreciable reaction is observed when the solvent is ether under the same conditions. It was found in general most satisfactory to dispense with the solvent except for solids and reactants in short supply. The temperature generally was raised slowly until at least 50% of the quantitative volume of gas had evolved. The products were then separated by column chromatography.

The following ketones and aldehydes were used as the doubly-bonded reactant: di-*tert*-butyl ketone, acetone, acetophenone, pivaldehyde, tolualdehyde, and chloral. In no case was a stable 1:1-adduct with the carbene **10** obtained. However, in three cases 1:2-adducts having structures **12***a*, *b*, and *c* were isolated as stable crystalline compounds.

The structures were assigned from the spectra of three compounds which are given in tabular form in Table 1. In the p.m.r. spectra, the aliphatic protons of compounds **12***a*, *b*, and *c* occurred at the expected chemical shifts with expected intensity and multiplicity. There was

no indication of geometric isomers in **12***b* and *c*, so it is assumed that the isolated compounds are the least hindered *trans* isomers. The aromatic multiplet has a revealing feature for each of **12***a*, *b*, and *c*: a one-proton quartet,[4] is isolated at unusually low field around δ 8.0–8.4 p.p.m. This is interpreted as originating from the proton on C-1 of **12**, which is deshielded by the neighboring oxygen atom of the enol ether. The postulate is corroborated by the observation of a similar quartet for 9-(hydroxymethylene)-fluorene (**13***a*) at δ 8.1–8.3 p.p.m. In the u.v. spectra, four bands characteristic of the fluorenylidene chromophore appear around 285, 295, 315, and 330 nm for all three compounds and the enol **13***a*, whereas compounds containing the fluorene chromophore normally do not absorb above 310 nm. The mass spectra of **12***a*, *b*, and *c* show the expected molecular ions, and the i.r. spectra have no contradictory features.

[4]This quartet has four main peaks spaced approximately equidistantly and of similar intensities, and each shows a further poorly-resolved fine structure.

The structures of the products are compatible with intermediate formation of the desired allene oxide followed by its cycloaddition to a further molecule of carbonyl compound. Evidence for the intermediacy of a 1:1 adduct is the analogy to Curtin's work in which a 1:1 adduct (**11**) was isolated, and the following experimental evidence. During column chromatography over silica gel of the product mixture from the reaction between 9-(aminomethylene)-fluorene, acetophenone, and *n*-butyl nitrite, after all the acetophenone had been eluted, a later fraction had a p.m.r. spectrum showing the ratio of aliphatic to aromatic protons exactly right for the allene oxide **5***e* and yet the peaks corresponded to a 50/50 mixture of acetophenone and an unidentified aromatic hydrocarbon product (which must contain a multiple of eight hydrogen atoms). The hydrocarbon product was dark and polymeric in form and resisted attempts to purify it. It is only possible to explain the above observations in terms of decomposition of the chromatographic fraction in question; and it is possible that this fraction contained the allene oxide, which decomposed on work-up to acetophenone and the carbene **10**, which subsequently decomposed to the unidentified product. An alternative mechanism involving a carbonyl

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

ylid intermediate instead of **5** cannot however be ruled out, and Martin *et al.* (10) believe such a mechanism to occur during 1:2 adduct formation between dichlorocarbene and benzaldehyde. Evidence on this point could be obtained if the fluorenylidene-1,3-dioxolane products (**12**) would undergo reverse cycloaddition to give back the 1:1 adduct transiently, which could then add to an alkene to give a product, the structure of which would distinguish between the two mechanisms. Along this line **12***b* was heated at 200° for 1 h with dimethylfumarate, but starting material was recovered quantitatively. It is of interest, however, that in the mass spectrometer, **12***c* shows a 50% peak of mass 296 corresponding to the radical ion **16** of the 1:1 adduct, which must arise by loss of a tolualdehyde fragment from the molecule. Likewise **12***a* has a prominent peak *m/e* 234 (4%) corresponding to loss of an acetone fragment, but for **12***b* the peak due to loss of pivaldehyde (*m/e* 274 (4%)) is not prominent; instead a strong peak at 291 (15%) is observed by preferential loss of a *tert*-butyl group. A further uncertainty about the mechanism of the formation of **12** is the fact that it is not experimentally established whether or not the carbene **10** is an intermediate. One can equally well arrive at the products via the diazo intermediate **15** (11) which might then add to the carbonyl reactant before it loses a molecule of nitrogen. However if the carbene **10** is generated, its addition to two molecules of carbonyl compound is reasonable by analogy to other work (10, 12).

After having looked at cycloadditions to the C=O double bond, it was of interest to find out whether a C=N double bond would behave in the same way. Experimentally, neither *N*-phenyl- or *N*-methyl-*p*-tolualdimine yielded products of the desired type. Instead of the new compound *N*-(fluorenylidenemethyl)-*p*-tolualdimine (**13***b*) was obtained in both cases. This product was still obtained if the butyl nitrite was omitted in the reaction conditions. Its formation can be rationalized in terms of addition of 9-(aminomethylene)-fluorene across the double bond of the imine, followed by elimination of aniline or methylamine. The structure of **13***b* is supported by its ready hydrolysis with acid to **9** and tolualdehyde; in fact it was very difficult to isolate in good yield because of its instability to acids and bases. In the absence of catalysts, solutions of **13***b* remain unchanged when heated at 250° for half an hour.

Next to be looked at was the cycloaddition of carbene **10** to N=N double bonds. Azobenzene was treated with 9-(aminomethylene)-fluorene and *n*-butyl nitrite to yield a white crystalline substance m.p. 238–239° having correct elemental analysis and molecular weight (from mass spectroscopy) for the desired product **14***c*. The p.m.r. spectrum showed a complex multiplet between δ 5.7 and 8.2 p.p.m. Since absorption up-field of δ 6.5 p.p.m. is difficult to explain in terms of structure **14***c*, it is thought that **14***c* may have been formed initially, but rearranged intramolecularly to give a product containing a pyrrole ring. The u.v. spectrum is compatible with this idea since it shows a shoulder at 317 nm (ε 9600) indicating more conjugation than in fluorene.

Although adducts were successfully isolated in the cases reported above, yields were low and these positive results were only obtained after numerous variations in the conditions. The inherent difficulty of the reaction is that there exist numerous alternative side-reactions which the reactants can undergo. Most of the products isolated by column chromatography were non-crystalline, but three crystalline side-products were often isolated: the secondary amine **13***d*, 9,9′-biformyl-9,9′-bifluorenyl (**17**) and fluorenone. **13***d* has been suggested by Curtin *et al.* (9) to arise from insertion of the carbene **10** in the NH bond of **9**. He also proposed that **17** could be formed by initial nitrosation of the 9- carbon atom of 9-(aminomethylene)-fluorene followed by loss of nitric oxide to give a radical which dimerizes to give the imine of **17** and thence **17** itself by hydrolysis during work-up. Fluorenone might arise by autoxidation of **9** during work-up for which there are analogies in the literature (13).

Conclusion

Evidence is presented for the intermediacy of allene oxides **5** or their isomers **6**, **7**, and **8**, when 9-(aminomethylene)-fluorene (**9**) is treated with *n*-butyl nitrite in the presence of aldehydes and ketones. The intermediate would then add a further molecule of aldehyde or ketone to give the 1:2 adducts (**12**). It is suggested that further attempts to isolate a stable allene oxide of type **5** should be tried by using different aldehydes and ketones, since the concentration of **5** in the reaction vessel should depend directly on the relative rates of conversion of **10** to **5** and **5** to **12**, and both these rates should depend on the steric

For personal use only.

and electronic effects of R′ and R″, the substituents on the aldehyde or ketone.

Experimental

Melting points were determined on a Meltemp apparatus and are uncorrected. I.r. spectra were obtained on a Beckman model IR5A spectrophotometer in Nujol mulls unless otherwise stated. U.v. spectra were run on a Unicam SP800 spectrophotometer at 25 °C in 1 cm cells. P.m.r. spectra were recorded on a Varian A60A spectrometer using an internal TMS standard. Mass spectra were run on a Varian-Mat CH-7 spectrometer. Microanalyses were performed by A. B. Gygli, Microanalysis Laboratories Limited, Toronto. The following experimental results are selected as examples from the many varied conditions used.

*9-(Hydroxymethylene)-fluorene (**13a**)*

The method used was similar to that of Wislicenus and Waldmuller (14). A mixture of 6.3 g potassium methoxide, 15 g fluorene, 6.7 g ethyl formate, and 75 ml dry ether was refluxed for 4 h over a steam bath. The mixture was cooled and then extracted with 75 ml of water. The water layer was washed with several small portions of ether and then acidified with dilute sulfuric acid. The oil which separated was extracted with ether, and the ether solution washed with dilute sodium bicarbonate solution and then water. The resulting solution was dried over anhydrous magnesium sulfate. Removal of drying agent and evaporation of the ether left a residue of 16.5 g crude product which was distilled under reduced pressure to give 9 g (51%) 9-(hydroxymethylene)-fluorene. I.r.: 3300, 1710, 1681, 1449, 781 cm^{-1}. U.v. and p.m.r.: see Table 1. This compound is a skin irritant, and contact with the hands should be carefully avoided.

*9-(Aminomethylene)-fluorene (**9**)*

The method used was similar to that of Von and Wagner (15). A solution of 12.5 g freshly distilled 9-(hydroxymethylene)-fluorene in 35 ml of dry benzene was placed in an ice bath and dry ammonia gas was passed in for 4 h. Evaporation of the solvent yielded a pale yellow solid, which was extracted with boiling 25% benzene in petroleum ether (b.p. 90–100 °C) mixture. One gram of the secondary amine **13***d* was left undissolved: m.p. 315–317 °C; i.r. 1645, 1274, 769, 719 cm^{-1}. The solution was evaporated to yield 9-(aminomethylene)-fluorene: m.p. 145–147°; i.r. 3472, 3356, 1661, 1285, 775, 734 cm^{-1}; p.m.r. δ 8.1–7.1 p.p.m. (multiplet) 9H (aromatic and vinyl) 5.5 p.p.m. (broad) 2H (NH_2).

*2,2,4,4-Tetramethyl-5-fluorenylidene-1,3-dioxolane (**12a**)*

Butyl nitrite, 8.24 g, was added to a refluxing solution of 9-(aminomethylene)-fluorene, 10.80 g in acetone, 200 ml under an atmosphere of nitrogen. After refluxing for 24 h the solvent was removed *in vacuo* to give 12.2 g of red oil. This was separated by quantitative t.l.c. using 2 mm thickness of Merck Kieselgel G and 15% *n*-hexane in benzene as the solvent. A u.v. lamp was used to visualize the bands. A band having $R_f = 0.3$ yielded 1.2 g of gum which on crystallization from acetone twice gave crystals (0.4 g) of 9,9′-biformyl-9,9′-bifluorenyl (**17**), m.p. 214–215° (lit. (9) m.p. 215–217°); p.m.r. ($CHCl_3$-*d*) δ 9.83 (singlet) 2H (CHO), 7.6–7.0 p.p.m. (multiplet) 16H (aromatic). Evaporation of the mother liquor followed by recrystallization of the gum from hexane yielded 5.0 mg of fluorenone, m.p. 81–82°; i.r. 1718, 1597, 1299, 919, 736; p.m.r. ($CHCl_3$-*d*) 7.8–7.2 p.p.m. (multiplet) (aromatic) identical with authentic sample. A chromatographic band having $R_f = 0.5$ yielded 0.34 g of gum which was crystallized from petroleum ether (b.p. 40–60 °C) to yield 0.17 g (1%) colorless crystals of 2,2,4,4-tetramethyl-5-fluorenylidene-1,3-dioxolane. This was further purified by vacuum sublimation at 90 °C: m.p. 145–146°; i.r. (KBr disk) 1613, 1370, 1263, 1163, 971, 917, 736 cm^{-1}; p.m.r. and u.v. see Table 1; m.s. base peak *m/e*: 206, parent peak (10%) *m/e*: 292.

Reaction between 9-(Aminomethylene)-fluorene, n-Butyl Nitrite, and Acetophenone

n-Butyl nitrite (1.33 g) was added to a solution of 1.99 g 9-(aminomethylene)-fluorene and 1.56 g acetophenone in 200 ml benzene. After being kept at room temperature for 2 h, the solution was warmed to 60 ± 5° for 12 h. The solvent was then removed by a current of nitrogen to yield a red oil, which was poured onto a silica gel (Woelm activity 1) chromatographic column. Elution with benzene – *n*-hexane mixtures of increasing polarity yielded first acetophenone, then a very small amount of gum showing only aromatic protons in its p.m.r. spectrum, and next 150 mg of a gum which appeared to be a 50/50 mixture of acetophenone and an eight-proton aromatic compound.

*2,4-Di-tert-butyl-5-fluorenylidene-1,3-dioxolane (**12b**)*

To a solution of 3.2 g 9-(aminomethylene)-fluorene in 20 ml pivaldehyde was added 2.4 g of *n*-butyl nitrite. The reaction was carried out under nitrogen in a closed system connected to a gas burette. Eighty percent of the calculated volume of nitrogen expected based on 9-(aminomethylene)-fluorene was evolved after 12 h at room temperature. The excess pivaldehyde was evaporated *in vacuo* and the resulting oil chromatographed through a column of neutral alumina (Woelm activity 1). Elution with benzene – petroleum ether (b.p. 60–80°) of increasing polarity yielded 310 mg (5%) of 2,4-di-*tert*-butyl-5-fluorenylidene-1,3-dioxolane. It was recrystallized twice from petroleum ether (b.p. 60–80°): m.p. 150–151°; i.r. 1650, 1183, 1093, 980, 767, 732 cm^{-1}; p.m.r. and u.v. (see Table 1); mass spectra base peak *m/e*: 191, parent peak (15%) *m/e*: 348.

Anal. Calcd. for $C_{24}H_{28}O_2$: C, 82.73; H, 8.08. Found: C, 82.82; H, 8.00.

*2,4-Di-p-tolyl-5-fluorenylidene-1,3-dioxolane (**12c**)*

n-Butyl nitrite (390 mg) was added to a solution of 490 mg 9-(aminomethylene)-fluorene and 4.33 g *p*-tolualdehyde in 200 ml benzene. The reaction mixture was kept at room temperature for 2 h, at 60 ± 5° for 12 h, and then the solvent was evaporated in a current of dry air to give a red oil which was separated by column chromatography over silica-gel (Woelm activity 1). Elution with *n*-hexane – benzene mixtures yielded 87 mg (8.3%) of 2,4-di-*p*-tolyl-5-fluorenylidene-1,3-dioxolane. It was recrystallized twice from petroleum ether (b.p. 60–80°), m.p. 213–214°; i.r. (KBr disc) 1653, 1198, 1176, 813, 769, 731 cm^{-1}; p.m.r. and u.v. see Table 1; mass spectra base peak *m/e*: 268, parent peak (7%) *m/e*: 416.

Anal. Calcd. for $C_{30}H_{24}O_2$: C, 86.51; H, 5.81. Found: C, 86.44; H, 5.86.

N-(Fluorenylidenemethyl)-p-tolualdimine (13b)

n-Butyl nitrite (580 mg) was added to a solution of 3.05 g *N*-phenyl-*p*-tolualdimine and 500 mg 9-(aminomethylene)-fluorene in 200 ml of benzene. After keeping the reaction mixture at room temperature for 2 h and then warming it to 60 ± 5° for 12 h, the solvent was removed by passing a current of dry air to give a red oil which was separated by column chromatography over silica-gel (Woelm activity 1). The fraction eluting with benzene (60%) – *n*-hexane (40%) solvent yielded 30 mg of yellow crystalline *N*-(fluorenylidenemethyl)-*p*-tolualdimine. It was purified by vacuum sublimation at 100° and recrystallization from ether: m.p. 146–147°; i.r. 1538, 1166, 966, 813, 778, 730 cm^{-1}; p.m.r. (CCl_4) δ 8.8–8.5 (quartet) 1H (C-1 aromatic proton), 8.14 (singlet) 1H (aldiminic CH), 7.8–6.9 (multiplet) 12H (aromatic and vinyl), 2.33 p.p.m. (singlet) 3H (methyl); u.v. λ_{max} (95% ethanol) 236 (ε 44 000), 261 (ε 36 000), 271 (ε 36 000), 375 (ε 36 000) nm; mass spectra parent peak *m/e*: 295.

Anal. Calcd. for $C_{20}H_{17}N$: C, 89.57; H, 5.84; N, 4.59. Found: C, 89.62; H, 6.07; N, 4.52.

Reaction between 9-(Aminomethylene)-fluorene, n-Butyl Nitrite, and Azobenzene

A solution of 2.14 g 9-(aminomethylene)-fluorene, 2.06 g azobenzene, and 1.16 g *n*-butyl nitrite in 250 ml dry ether was refluxed for 40 h. Since the i.r. spectrum showed that much 9-(aminomethylene)-fluorene remained, the solvent ether was distilled from the reaction mixture and 200 ml of the solvent benzene added. Azobenzene (210 mg) and 280 mg butyl nitrite were also added. After refluxing for a further 58 h, the i.r. spectrum of the mixture showed only a small NH band. The solvent was removed *in vacuo* to give a red oil. Column chromatography over silica-gel (Woelm activity 1) yielded 230 mg (5.8%) of a white crystalline compound eluted with 40% benzene in *n*-hexane. It was recrystallized from chloroform twice: m.p. 238–239°; i.r. (KBr disc) 1491, 1449, 773, 735, 699 cm^{-1}; p.m.r. ($CHCl_3$-*d*) δ 8.2–5.7 p.p.m. (multiplet); u.v. λ_{max}(CCl_4) 294 (ε 17 200), 305 (ε 17 600), 316 (inflection) (9600) nm; mass spectra base peak *m/e*: 77, parent peak (83%) *m/e*: 358.

Anal. Calcd. for $C_{26}H_{18}N_2$: C, 87.12; H, 5.06; N, 7.82. Found: C, 87.29; H, 5.20; N, 7.73.

The Synthesis of *gem*-Halonitro Sugars and Their Conversion into Epoxynitro Sugars[1]

HANS H. BAER AND WERNER RANK

Department of Chemistry, University of Ottawa, Ottawa, Canada K1N 6N5

Received December 12, 1972

Halogenation of methyl 4,6-*O*-benzylidene-3-deoxy-3-nitrohexopyranosides having the α-D-*talo*, β-D-*galacto*, and α-D-*galacto* configurations, and of the 2,3-dideoxy-3-nitro β-D-*lyxo* and α-D-*lyxo* analogs, smoothly furnished 3-halo-3-deoxy-3-nitro derivatives. The glycosides were chlorinated in methanolic solution with aqueous sodium hypochlorite, and similarly brominated with either bromine in the presence of alkali or *N*-bromoacetamide in the presence of sodium acetate. The analogous nitro glycosides having the β-D-*arabino*, β-D-*manno*, α-D-*manno*, and β-D-*gluco* configurations and also the 2-acetates of the last three compounds were brominated likewise whereas the α-D-*gluco* isomer and its 2-acetate were resistant under the conditions examined. The preferred C-3 configuration in the halonitro products appeared to be that which has an equatorial nitro group and an axial halogen atom in the normal pyranose chair conformation ($^4C_1$). In most instances the halogenation was found to be highly stereoselective in that sense although in some cases the inverse C-3 epimer was formed in a minor proportion. Base treatment of some of the halohydrins led to 2,3-anhydro-3-nitro glycosides. Such epoxide formation may be associated with epimerization at C-2 and -3, for which a mechanism involving a retrograde Henry reaction is postulated.

L'halogénation des méthyl benzylidène-4,6-*O* déoxy-3 nitro-3 hexopyranosides ayant les configurations α-D-*talo*, β-D-*galacto*, et α-D-*galacto*; et des analogues dideoxy-2,3 nitro-3 β-D-*lyxo* et α-D-*lyxo*; conduit aux dérivés halo-3 deoxy-3 nitro-3 selon des réactions douces. Les glycosides ont été chlorés en solution méthanolique par l'hypochlorite de sodium aqueux et bromés de la même façon soit par le brome en présence d'alcalis soit par le *N*-bromo acétamide en présence d'acétate de sodium. Les glycosides analogues nitro ayant les configurations β-D-*arabino*, β-D-*manno*, α-D-*manno* et β-D-*gluco* de même que les acétates en 2 des trois derniers composés ont été bromés de la même façon tandis que l'isomère α-D-*gluco* et son acétate en 2 sont résistants dans les conditions étudiées. La configuration préférée sur le C-3 des produits halonitro apparait être celle qui possède un groupe nitro équatorial et un atome d'halogène axial, dans la conformation chaise normale du pyranose ($^4C_1$). Dans la plupart des exemples, l'halogénation est hautement stéréosélective bien que dans certains cas il se forme en proportion mineure, de l'épimère inverse sur le C-3. Le traitement basique de certains de ces halohydrines conduit aux anhydro-2,3 nitro-3 glycosides. Une telle formation d'époxyde peut être associée à l'épimérisation sur le C-2 et -3 pour laquelle un mécanisme faisant intervenir une réaction de "retro-Henry" a été postulé.

[Traduit par le journal]

Can. J. Chem., **51**, 2001 (1973)

Primary and secondary aliphatic nitro compounds are readily halogenated in the presence of base to afford geminal halonitro derivatives (2, 3). Even though this has long been known, such halogenations apparently have never been tried in nitro carbohydrates, and the few halogen derivatives so far prepared in this field were not of the geminally substituted type. Thus, 2,4,6-tri-*O*-acetyl-3-deoxy-3-nitro-α-D-glucopyranosyl bromide has been made (4) by one of the customary methods for acetobromo sugars from the corresponding α-tetraacetate, and vicinal iodonitro derivatives have been shown (5) to arise by the addition of nitryl iodide to unsaturated sugars. We now report the preparation of several 3-chloro- and 3-bromo-3-deoxy-3-nitrohexopyranosides and describe reactions which some of the products undergo, in particular, epimerization and epoxide formation controlled by stereochemical factors.

Chlorinations were performed by treating the 4,6-*O*-benzylidenated nitro glycosides in methanolic solution with aqueous, 5% sodium hypochlorite solution (or with "Javex" household bleach), normally at room temperature. Crystalline chloro derivatives were smoothly obtained in yields ranging from 75 to over 90%. For bromination, two methods were employed, usually with equal success. The first was similar to the chlorination just mentioned and consisted of generating the sugar nitronate by the provision of alkali at low temperature, which was then followed by bromine addition (Br_2 method).

[1]Part XXVIII in a series on reactions of nitro sugars. For Part XXVII see ref. 1.

In the second method *N*-bromoacetamide in the presence of sodium acetate was employed as the brominating agent (NBA method). The latter procedure was especially useful for compounds containing ester groups liable to cleavage under the alkaline conditions of the former procedure.

In many of the halogenations investigated, only one of the two possible C-3 epimeric products was encountered, and on account of the excellent yields it can be stated that the reactions were highly stereoselective. In some cases the second epimer was formed, too, but normally in a minor proportion. We assume that the favored epimer in all events is that which in the stable chair conformation bears the nitro group in equatorial and the halogen atom in axial orientation.

This assumption is based on the analogy to protonation of pyranoside 3-nitronates which invariably produces an equatorial nitro group (6, 7). N.m.r. data of the new products as well as certain chemical reactions were consistent therewith, and hence we have assigned formulas and configurational notations[2] on this premise. It must be admitted, however, that rigorous proof for the configuration of the halonitro carbon atom has not been advanced. In the account that follows, the chemistry of compounds having a *cis*-fused 4,6-benzylidene acetal ring will be treated first, and that of *trans*-fused acetals will be dealt with thereafter. A recent study (9) had revealed considerable differences in the ease of nitronate formation (*i.e.*, proton abstraction from C-3) in dependence of the over-all configuration of the molecule. Since the process of nitronate formation has to precede introduction of a halogen atom it could be expected that there would also be a strong influence of configuration upon the course of halogenation.

Reactions with cis-Fused Acetals

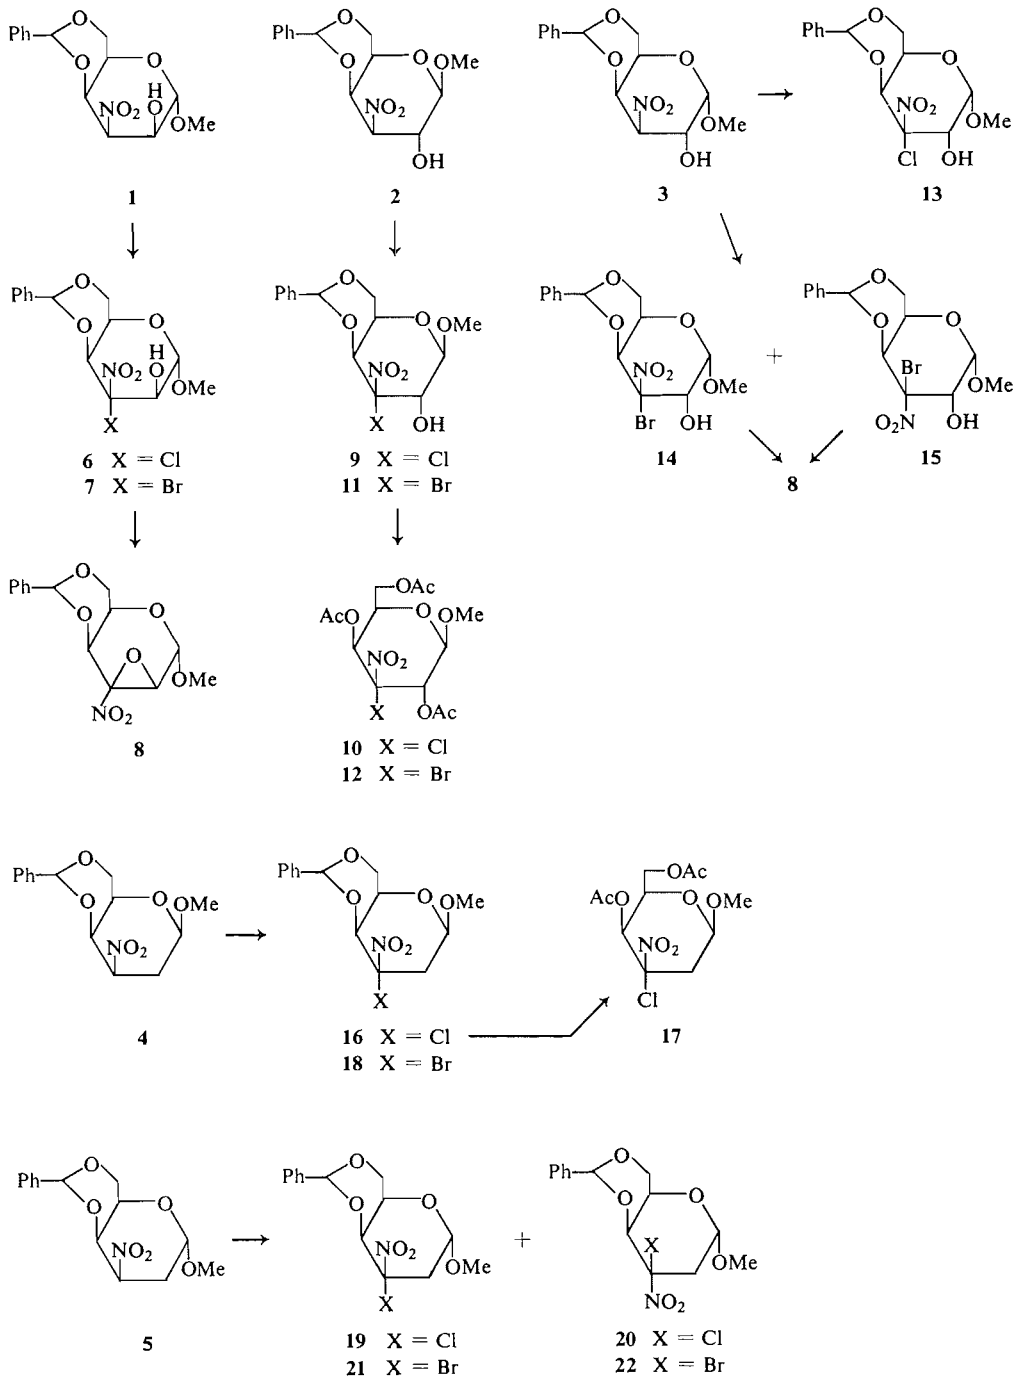
Consonant with the observed, facile formation of their nitronates (9), the methyl 4,6-*O*-benzylidene-3-deoxy-3-nitrohexopyranosides with the α-D-*talo* (**1**), β-D-*galacto* (**2**), and α-D-*galacto* (**3**) configurations, and the methyl 4,6-*O*-benzylidene-2,3-dideoxy-3-nitro-β- and α-D-*lyxo*-hexopyranosides (**4** and **5**) all furnished 3-halo derivatives smoothly in high yields.

Chlorination of **1** gave methyl 4,6-*O*-benzylidene-3-chloro-3-deoxy-3-nitro-α-D-idopyranoside (**6**) which could be isolated in 85% yield when the reaction was performed at 0°. When it was performed at room temperature, **6** could not be isolated but was converted into methyl 2,3-anhydro-4,6-*O*-benzylidene-3-nitro-α-D-talopyranoside (**8**) which crystallized in over 80% yield. This epoxide had previously been obtained in a different way (10). Bromination of **1** by either the Br_2 or the NBA method readily furnished the bromonitro analog **7**. Sodium borohydride reduction of **7** according to Iffland and Criner (11) regenerated **1**, demonstrating that bromination was not attended by any unexpected structural or configurational change. A short treatment of **7** with sodium hydroxide at 25° led to the epoxide **8** in 90% yield. The facile formation of **8** from **6** and **7** strongly supports the *trans*-diaxial halohydrin grouping in these compounds (12*a*).

Chlorination as well as bromination by either method, of the β-D-*galacto* isomer **2** similarly afforded halogen derivatives as single products in good yields. They were methyl 4,6-*O*-benzylidene-3-chloro-3-deoxy-3-nitro-β-D-gulopyranoside (**9**) and its bromo analog **11**. Both products were characterized further by acid-catalyzed debenzylidenation followed by acetylation, to give methyl 2,4,6-tri-*O*-acetyl-3-chloro-3-deoxy-3-nitro-β-D-gulopyranoside (**10**) and its bromo analog **12**, respectively. As in the aforementioned case of **7**, borohydride reduction of **11** regenerated the starting sugar **2** (90% yield). Unlike **7**, however, the bromohydrin **11** did not give an epoxide upon treatment with aqueous alkali. Instead, debromination producing **2** occurred in reversal of the bromination, with the abstraction of Br^+ ion being evidenced by a positive potassium iodide – starch test. When **11** was refluxed in 0.03 *N* methanolic sodium methoxide solution for 20 min it partly survived but largely decomposed with liberation of benzaldehyde.[3] The fact that no epoxynitro sugar was formed in any

[2]Following a suggestion by Professor D. Horton, Columbus, Ohio, and pending the adoption of an official international nomenclature rule for the configuration of sugars that bear unequal geminal substituents on the ring we use the established configurational designations combined with the sequence rule of Cahn *et al.* (8). The substituent which according to this rule has the *higher* priority is thought of as replacing the *hydroxyl group* at the carbon concerned. Thus, for example, if H-3 in the formula of 3-deoxy-3-nitro-D-glucose is replaced by bromine or chlorine (both of which have priority over nitro), the resultant halonitro sugar is regarded as a derivative of D-allose with the halogen atom occupying the place of OH, and the NO_2 group, that of H.

[3]The benzylidene acetal ring in **2** is known to be quite labile towards base (7).



of these base treatments supported the *cis*-bromohydrin configuration.

Chlorination of the α-D-*galacto* isomer **3** afforded methyl 4,6-*O*-benzylidene-3-chloro-3-deoxy-3-nitro-α-D-gulopyranoside (**13**) in over 90% yield. Contrasting with the stereoselectivity of this reaction and all the halogenations of **1** and **2**, bromination of **3** resulted in mixtures of epimers. The Br_2 method gave a crude product (yield, 91%) which exhibited two spots on t.l.c. and showed two benzylidene methine proton resonances (τ 4.48 and 4.30) in an intensity ratio

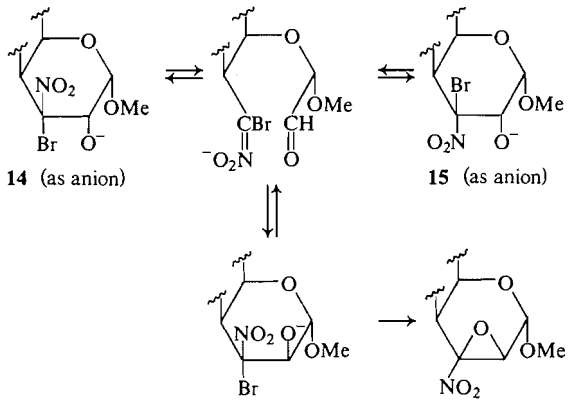

SCHEME I

55:45. Upon chromatographic separation the pure crystalline epimers were isolated in yields of 49 and 33%. The preponderant product was considered to be that which has an equatorial nitro group, *i.e.*, methyl 4,6-*O*-benzylidene-3-bromo-3-deoxy-3-nitro-α-D-gulopyranoside (**14**), and the lesser product was assigned the α-D-*galacto* configuration (**15**). Bromination of **3** by the NBA method gave **14** and **15** in the ratio of 85:15. Reductive removal of the bromine reconverted both **14** and **15** into **3**, thus confirming the epimerism. Interesting observations were made when the products were treated with alkali. It might have been expected that at least one of them (**14**) would incur debromination, like its β-anomer **11**, to give the starting glycoside **3**. However, **14** remained unchanged for 20 h in a methanolic, 0.03 *N* sodium hydroxide solution at room temperature. In refluxing sodium methoxide solution it appeared to suffer far-reaching decomposition (like **11**) but a crystalline product could nevertheless be isolated in 25% yield. The same product arose slowly (10 h) in high yield (72%) from the epimer **15** by action of methanolic hydroxide even at room temperature. Surprisingly it proved identical with the epoxide **8** previously engendered from **1** (via **6** or **7**). These results clearly imply epimerization at C-2, a phenomenon not observed in the alkali treatments of the halonitro compounds having the α-D-*ido* or β-D-*gulo* configuration. The following explanation is offered.

The three bromonitro α-D-glycosides (**7**, **14**, and **15**) have in common substantial strain due to non-bonded interaction of the axial, glycosidic methoxyl group and the axial substituent at C-3. Whereas the structure of **7** with a *trans*-diaxial halohydrin arrangement is conducive to rapid epoxide formation upon proton abstraction from OH-2, this is not the case for **14** and **15**. However, these two compounds may undergo (reversible) ring opening by way of a retrograde Henry reaction, are thus able to epimerize, and therefore they, too, eventually furnish the epoxide **8** (Scheme 1). It appears plausible that ring cleavage occurs more readily in **15** than **14** since an axial nitro group is associated with a higher conformational free energy than an axial bromine atom.[4] In the β-glycoside **11**, which lacks 1,3-diaxial strain, the driving force for a retrograde Henry reaction is diminished, and abstraction of Br^+ by base was observed instead.

The 2-deoxy glycosides **4** and **5** also reacted readily, giving high yields of halonitro derivatives. The β-anomer **4** gave single products, namely methyl 4,6-*O*-benzylidene-3-chloro-2,3-dideoxy-3-nitro-β-D-*xylo*-hexopyranoside (**16**) and its bromo analog **18**. Debenzylidenation of **16** followed by acetylation furnished the corresponding 4,6-diacetate **17**. By contrast, the α-anomer **5** gave mixtures of 3-epimeric halonitro compounds, both in chlorination (the α-D-*xylo* (**19**) and α-D-*lyxo* (**20**) epimers in the ratio 86:14) and in bromination by either method (the α-D-*xylo* (**21**) and α-D-*lyxo* (**22**) epimers in ratios of about 75:25). The epimers could be distinguished by the chemical shifts of their benzylidene methine protons and they were separated by column chromatography. The minor components (**20** and **22**) were characterized by physical data and not by elemental analysis, but spectroscopic evidence including mass spectra supported the structural assignments (see Experimental).

Reactions with trans-Fused Acetals

In nitro glycosides possessing a *trans*-fused 4,6-*O*-benzylidene ring we have so far investigated brominations only. Methyl 4,6-*O*-benzylidene-2,3-dideoxy-3-nitro-β-D-*arabino*-hexopyranoside (**23**) gave with NBA an amorphous bromo derivative (yield, 87%) which appeared uniform according to its n.m.r. spectrum and

[4]For substituted cyclohexanes, values of approximately 0.5 and 1.05 kcal/mol are given for the bromo (12*b*) and nitro (13) substituents, respectively. In 3-deoxy-3-nitro pyranosides an even higher value for the nitro group must be postulated from the results of recent studies in this laboratory (6).

t.l.c. It was assigned the β-D-*ribo* configuration (**24**).

Considerably more complicated were the reactions performed with D-*gluco* and D-*manno* derivatives. It must be recalled in this connection that in the presence of alkali these nitro glycosides form nitronate much less readily than their D-*galacto* and D-*talo* isomers, and moreover that the D-*manno* derivatives are liable to incur rapid epimerization at C-2 (9).

Bromination of the β-D-mannoside **26** at 0° by the Br_2 method did not go to completion. It afforded a mixture which according to integration of signals (τ 4.23, 4.32, 4.42, and 4.48) contained four products in the ratio 5:10:35:50. The compounds present to the extent of 10 and 50% were shown by chromatographic isolation to be unreacted **26** (τ 4.32) and the β-D-glucoside **25** (τ 4.48), respectively. The latter obviously arose by epimerization and failed to be brominated. The two remaining products, together 40% of the mixture, were bromonitro compounds as was first suggested by a shift of the asymmetric nitro vibration from 1550 to 1565 cm^{-1} (14). Although they could be separated chromatographically from the non-brominated material, they could not be separated from each other and were never isolated individually; nevertheless, they were assigned, on the basis of subsequently described experiments, the structures of methyl 4,6-*O*-benzylidene-3-bromo-3-deoxy-3-nitro-β-D-allopyranoside (**27**) (major product, τ 4.42) and -altropyranoside (**28**) (minor product, τ 4.23). The NBA method proved more effective, **26** yielding almost quantitatively a mixture of **27** and **28** in a ratio of 4:1. The near identity of the mixtures of bromo derivatives obtained by the two methods was established by comparison of their i.r. and n.m.r. spectra and optical rotations.[5] It is most noteworthy that either bromination caused extensive epimerization at C-2; whereas for the Br_2 method this could be expected in the light of previous results concerning the action of alkali upon **26** (9), it is remarkable that the sodium acetate present in the NBA method apparently suffices to give the same result.

Bromination of the β-D-glucoside **25** by NBA also produced **27** and **28**, again in a similar ratio (75:15), with some **25** (10%) remaining unre-

[5]A similar mixture of **27** and **28** was produced, also in high yield, by substituting *N*-bromo-succinimide for NBA. Cleavage of the benzylidene ring with concomitant introduction of bromine at C-6 was not observed under our reaction conditions which differ from those of Hanessian's NBS reaction (15).

acted. The *manno* isomer **26** was not detected in the product whose n.m.r. spectrum was practically identical with those of the previously obtained mixtures of **27** and **28**, except for weak signals due to remnant **25**. This result was also borne out by close similarities in i.r. spectra and optical rotations. The Br_2 method proved ineffective for bromination of **25**.

Acetylation of a mixture of **27** and **28** by the mild procedure using acetyl chloride in the presence of triethylamine (4, 16) furnished separable 2-acetates **29** and **30** which were isolated in pure form in yields of 70 and 15%. The same acetates were obtained, each in 95% yield and evidently as single products, upon NBA bromination of the 2-*O*-acetyl derivatives **31** and **32** (of **25** and **26**, respectively). Clearly, with the 2-OH group being blocked by acetylation, no epimerization took place on C-2 and the configurations of **27** and **28** at this site have thus been established. In accord therewith were the $J_{1,2}$ coupling constants of **29** (8 Hz) and **30** (0 Hz).

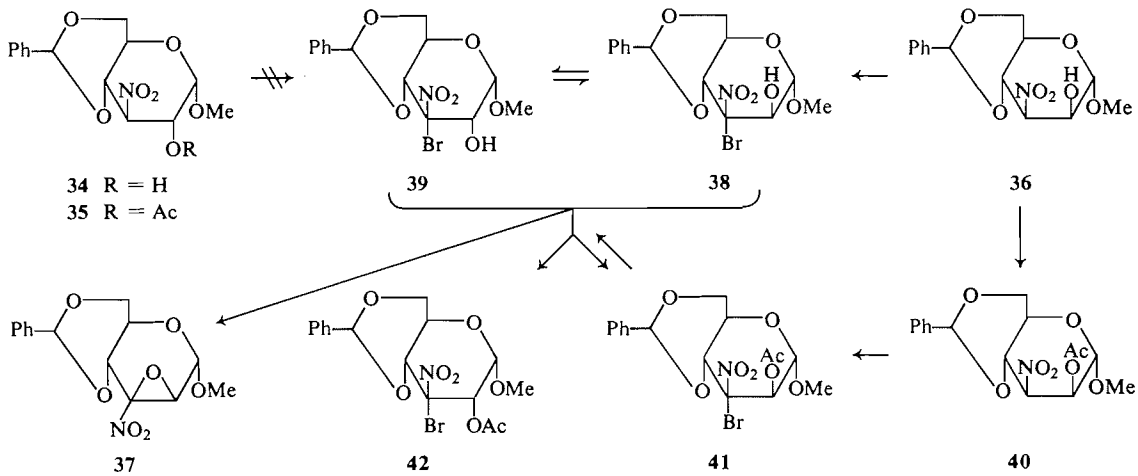
Treatment of the β-D-*altro* bromonitro acetate **30** with 0.04 *N* sodium methoxide in methanol at 0° or at room temperature led to deacetylation followed by 2-epimerization, to give mixtures of **27** and **28**, with the β-D-*allo* derivative (**27**) preponderating four- to five-fold. That is to say, base treatment of **30** at low temperatures produced the same bromonitro compounds, and in virtually the same proportions, as did bromination of **25** or **26**. Reacetylation of a mixture originating from **30** led to isolation of the epimeric, β-D-*allo* acetate **29** in a yield of 65%. The conclusion to be drawn from all these results is that the bromonitro glycosides **27** and **28** (but not their acetates) are readily interconvertible by base, and that a thermodynamic equilibrium tends to be established between them. The epimerization observed in the course of bromination of the β-D-glucoside **25** must exclusively take place on this stage (*i.e.* in **27**) since **25** itself does not epimerize to **26**. The epimerization occurring in the bromination of the β-D-mannoside **26**, shown above to be possible at the stage of **28**, may also take place in **26** itself as can be inferred from previous work,[6] so that perhaps both pathways are utilized in this instance.

Compound **28**, which possesses a *trans*-diaxial bromohydrin structure, was expected to give quite readily an epoxide when treated with base. As previously mentioned, the liberation of **28** from its acetate by methoxide at low temperature was succeeded by partial 2-epimerization; there was no evidence for epoxide formation. However, when mixtures of **27** and **28** were *refluxed* in methoxide-containing methanol for 30 min, epoxide formation did occur. Thus methyl 2,3-anhydro-4,6-*O*-benzylidene-3-nitro-β-D-mannopyranoside (**33**) was isolated in yields of 78 and 84% upon such treatment of the closely similar isomer mixtures originating from brominations of **25** and **26**, respectively. Yields were smaller (41 and 37%) when the acetates **29** and **30** were treated *directly* with boiling methoxide solution, instead of being first saponified (and allowed to epimerize) in the cold; a certain degree of degradation was noticed in these cases.[7] At any rate, the amount of epoxide **33** formed in each instance far exceeded the supply of **28**. This was true even for the alkali treatment of **30** since epimerization following its deacetylation was faster than epoxide formation. The bulk of **33** must therefore be provided by **27** through a mobile, epimeric equilibrium. The epimerization is thought to proceed by reversible ring opening as discussed for **14** and **15**, above.

In the α-anomers of this configurational series, brominations proceeded more sluggishly if at all. Thus, methyl 4,6-*O*-benzylidene-3-deoxy-3-nitro-α-D-glucopyranoside (**34**) failed to react in the Br_2 procedure, and it did not react with NBA in methanol and sodium acetate even when heated under reflux for as long as 10 h. Its 2-acetate **35**, too, was completely inert towards NBA under conditions which had led to nearly quantitative bromination of the β-anomer **31** (3 h at 25°). The α-D-*manno* isomer **36** was only partially brominated by the NBA method although the β-anomer (**26**) had been brominated completely. The mixture obtained was judged on the basis of t.l.c. and n.m.r. evidence (see

[6]Compound **26** was completely (that is, within the limits of detectability by t.l.c.) converted into **25** under conditions of alkalinity comparable to those prevailing in the Br_2 method of bromination (9).

[7]Liberation of benzaldehyde was observed, which is indicative of base-catalyzed β-elimination of the C-4 acetal linkage and implies carbanion formation at C-3. One can only surmise that, at elevated temperature, abstraction of bromine from C-3 becomes markedly competitive with deacetylation. Nitronate so generated would no longer be able to produce epoxide but would undergo other transformations. Compare the behavior of **11** in alkaline media.



Experimental) to contain some starting material **36**, about 25% of the 2-epimer **34**, and approximately 30% of each of two new products. No attempt was made to separate the products but the presence of two bromonitro derivatives was confirmed by base treatment which afforded the known (10) epoxide, methyl 2,3-anhydro-4,6-*O*-benzylidene-3-nitro-α-D-mannopyranoside (**37**). The latter was isolated in a yield of 51%, which implies that both bromonitro sugars present must have contributed to its formation. Undoubtedly, one of them was methyl 4,6-*O*-benzylidene-3-bromo-3-deoxy-3-nitro-α-D-altropyranoside (**38**) and the other, most likely its α-D-*allo* isomer **39**, in analogy to the β-series. Bromination of the 2-acetate **40** of the α-D-mannoside **36** gave in high yield the 2-acetate **41** of **38** as a crystalline but rather sensitive compound. Deacetylation of **41** at room temperature produced what according to the n.m.r. spectrum was a 2:3 mixture of the same bromonitro sugars that arose in the bromination of **36** (*i.e.* presumably **38** and **39**), and treatment of the deacetylated mixture (or of **41** directly) with refluxing methanolic methoxide again gave the epoxide **37** (yields, 76–82%). Reacetylation of the mixture gave acetates in an approximate ratio of 2:3, and although these could not be separated either, the n.m.r. spectrum suggested that the lesser component was **41**. The major component, then, must have been the acetate of **39**, *i.e.*, presumably the α-D-*allo* derivative **42**. In summary, then, the experiments in this anomeric series have shown that α-D-*manno*, but not α-D-*gluco*, derivatives are effectively brominated by NBA, that epimerizations occur if 2-OH is unprotected, and that the bromonitro derivatives are readily converted into an epoxide.

Stereochemical Considerations

In all the halogenations studied, the preferred configuration arising at C-3 was that which places the nitro group equatorially when the pyranoside ring occupies the normal chair conformation. In a majority of instances a single halonitro derivative was obtained in a high yield, and in certain cases where two products arose these were epimeric at C-2 but stereochemically identical at C-3. However, in some instances C-3 epimers having an axial nitro group were formed as minor products. An explanation for these observations is now to be attempted.

One possibility to be considered is steric control of the approaching, halogen-transferring agent. In principle, the carbanionic site (C-3) in all the nitronates should be freely accessible for attack from the lower side of the glycoside ring while attack from the upper side should be sterically hindered by the axial hydrogen atoms and (or) oxygen functions situated at C-2 and -4. This factor would generally favor axial placement of the incoming halogen and consequently, equatorial placement of the nitro group, and would requi re no qualification for the β-glycosides all of which were indeed halogenated in a stereochemically uniform way. In α-glycosides the axial but more remote methoxyl group presumably reduces somewhat the accessibility of the lower pyranoside face, thereby tending to diminish the degree of stereoselectivity. This was seen in the halogenations of the α-D-*galacto*

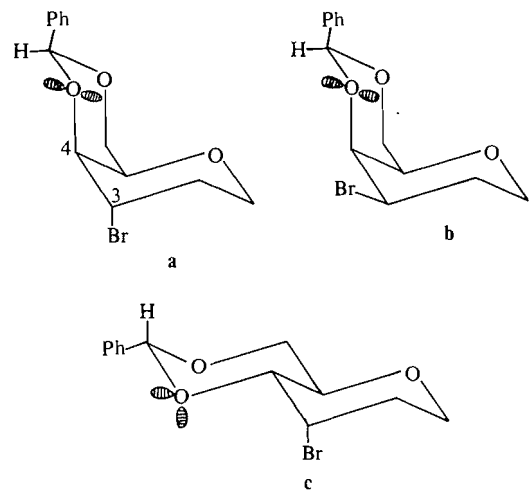
and α-D-*lyxo* glycosides (**3** and **5**), and bromination seemed to be affected more so than chlorination. In the α-D-*talo* compound (**1**) this effect was not evident, probably because it is small relative to the especially severe hindrance afforded by the two axial oxygen functions on the upper side of the ring. If this line of reasoning is valid one should have expected the α-D-*manno* acetate **40** to give, in addition to the bromo derivative **41** that was produced, at least a small proportion of the corresponding 3-epimer. However, no evidence for formation of the latter has so far been obtained. A similar expectation does not necessarily apply to bromination of the non-acetylated α-D-*manno* compound **36**, since an epimer with axial nitro group, if it is formed as a primary product, may well be too unstable for observation and may suffer rapid epimerization to **38** and (or) **39**.

A further point of interest is the complete inertness of α-D-*gluco* derivatives (**34** and **35**) towards bromination even by the NBA method. It would be hard to visualize that they constitute a category apart as far as the facility of approach of the halogenating agent is concerned. Rather, we are inclined to believe that they failed to form the requisite nitronate salt in the weakly basic reaction medium. The particularly low nitromethylene acidity in 3-deoxy-3-nitro pyranosides having a 2,3,4-triequatorial substituent arrangement has been observed and explained previously (6, 9, 17, 18), but the present finding of an apparent difference in degree between α- and β-anomers is remarkable. Possibly it is a manifestation of a polar effect by which the methoxyl group, through the direction of its dipole in α-glycosides, opposes the development of carbanionic character at C-3.

Spectroscopic Evidence in Support of Configurational Assignments

In earlier work (18) the chemical shift of the benzylidene methine proton signal in n.m.r. spectra of 4,6-*O*-benzylidene-3-deoxy-3-nitrohexopyranosides has proved of diagnostic value for differentiating stereoisomers. Regularities in such shifts observed in the present work tend to support the C-3 configurations of the halonitro derivatives as assigned on the basis of chemical considerations. Table 1 shows that introduction of a halogen atom at C-3 has in some cases little or no effect upon the τ-value of the methine signal whereas in other cases a small but distinct downfield shift (0.1–0.2 p.p.m.) is observed. Virtually unaffected are the signals in those halogen derivatives which possess a *cis*-fused acetal structure and arise either as single (**6**, **7**, **9**, **11**, **13**, **16**, **18**) or as predominant epimers (**14**, **19**, **21**). The group characterized by the downfield shift comprises the minor epimers (**15**, **20**, **22**) in the *cis*-acetal series and all of the products having a *trans*-fused acetal ring. These observations are best explained by assuming that the methine proton experiences a change in shielding when the C_3-halogen bond is *gauche* to the C_4-oxygen bond (*i.e.*, parallel to one of the nonbonding orbitals of O-4) while no such effect is associated with an *anti* orientation of these bonds. When the pyranoside rings are depicted in the $^4C_1$ conformation in agreement with coupling constants found for H-1 and -4, the chemical shift data are thus consistent with the C-3 configurations as allocated. (See the partial formulas **a**–**c**).



Also in accord with configurations assigned to C-3 are the chemical shifts of the anomeric proton signals insofar as these signals are discernible. In halonitro derivatives presumed to have the "normal" C-3 configuration (impyling axial halogen), the signal of an equatorial H-1 (in α-glycosides) is either virtually unaffected or shifted slightly downfield, and the signal of an axial H-1 (in β-glycosides) is markedly shifted downfield. By contrast, the "abnormal" compounds **15**, **20**, and **22** exhibit a moderate upfield shift of their H-1 signal. At the same time the anomeric methoxyl signals of these three compounds occur about 0.1 p.p.m. upfield from

those of their precursors whereas in all other cases the influence of halogenation upon these signals appears insignificant.

Table 1 shows, furthermore, that the chemical shift of the benzylidene methine proton in non-halogenated glycosides incurs no significant change upon acetylation of the compound in position 2; compare **25**, **26**, **34**, and **36** with their respective 2-acetates **31**, **32**, **35**, and **40**. Assuming that the same holds true for the corresponding bromonitro glycosides one can correlate the 2-acetates **29** and **30** (which were isolated) with the non-acetylated bromination products that show τ 4.42 and 4.23, respectively, and that could not be separated but were designated on this basis as **27** and **28**. By a similar argument one can attribute formulas **38** and **39** to the components showing τ 4.24 and 4.43, of the mixtures resulting from bromination of **36** or deacetylation of **41**.

Experimental

For general preparative instrumental techniques see preceding articles of this series (*e.g.*, refs. 1, 10, 18). Optical rotations were measured at room temperature in chloroform solutions (*c*, 0.5–1) unless otherwise indicated. I.r. spectra were obtained from Nujol mulls on a Beckman IR-20 instrument. The n.m.r. data given for the characterization of compounds (Table 1 and elsewhere)

were obtained with a Varian HA-100 spectrometer; a T-60 spectrometer was used for monitoring reactions. The data refer to $CDCl_3$ solutions with TMS as internal standard. The following solvent systems (v/v) were employed for t.l.c. and column chromatography on silica gel: A, carbon tetrachloride – ethyl acetate (7:3); B, the same (4:3); C, petroleum ether (b.p. 30–60°) – ethyl acetate (2:3); D, the same (3:2).

Materials

The nitro glycosides to be halogenated were obtained according to the references given in parentheses: **1** (18), **2** (18, 19), **3** (18), **4** (1), **5** (1), **23** (1, 21*a*), **25** (18, 20, 21*b*), **26** (18, 19), **31** (20, 21*b*, 22), **32** (16), **34** (18, 19), **35** (23), **36** (18). The hitherto unknown *methyl 2-O-acetyl-4,6-O-benzylidene-3-deoxy-3-nitro-α-D-mannopyranoside* (**40**) was prepared by acetylation of **36** with acetyl chloride and triethylamine in methylene chloride as described (16) for the acetylation of **32** (see also the preparation of **29** from **27** + **28**). It was obtained as an amorphous powder in 86% yield; $[\alpha]_D$ +4.5°; ν_{max} 1745 and 1560 cm^{-1} ($OCOCH_3$ and NO_2). N.m.r. (in $CDCl_3$): τ 2.66 (m, 5H, phenyl), 5.03 (q, 1H, H-3), and Table 1; $J_{1,2}$ = 1.5, $J_{2,3}$ = 3.5, $J_{3,4}$ = 11 Hz.

Anal. Calcd. for $C_{16}H_{19}NO_8$ (353.3): C, 54.40; H, 5.42; N, 3.97. Found: C, 54.56; H, 5.29; N, 3.97.

Preparation of Halonitro Glycosides: General

Chlorinations were performed using a reagent grade, 5% aqueous sodium hypochlorite solution, or with equal success, commercial household bleach *Javex*, a product of Bristol-Myers Canada Limited, containing 6% sodium hypochlorite. Brominations were carried out with bromine in alkaline medium (Br_2 method) or with *N*-bromoacetamide in the presence of sodium acetate (NBA method). The procedures are detailed for compounds **6** and **7**. The remaining halonitro derivatives were obtained in the same general way, with occasional modifications as specified. Reactions were routinely monitored by t.l.c.

Upon completion of the halogenations, the products were isolated in one of two ways depending upon their solubility. In each case, the methanolic reaction solution was diluted with water, and part of the methanol was removed by evaporation under reduced pressure (bath temperature, 35°). Frequently the halogenated product separated thereby in crystalline and nearly pure form in large quantity. It was collected by filtration, washed with cold water, and dried in a desiccator before being recrystallized as necessary and specified. This *precipitative procedure* is referred to as work-up (P). When precipitation was unsatisfactory, the solution was concentrated further until most of the methanol was removed, and the remaining aqueous solution was then extracted three times with chloroform. The combined extract was washed twice with water, dried over anhydrous sodium sulfate, and evaporated to afford the product usually in nearly pure form. This *extractive procedure* is referred to as work-up (E).

Methyl 4,6-O-Benzylidene-3-chloro-3-deoxy-3-nitro-α-D-idopyranoside (6)

To an *ice cold* solution of **1** (124 mg) in methanol (30 ml) was added hypochlorite solution (1.2 ml). Inspection by t.l.c. (solvent B) after 5 and 15 min showed absence of **1** and presence of a single, faster moving spot. The solution was neutralized at 0° with 2 *N* acetic acid and worked-up (P). The crude product was recrystallized from ethanol–water to furnish **6** (117 mg, 85%); m.p. 104–105°, $[\alpha]_D$ +48.3°, ν_{max} 3480 and 1570 cm^{-1} (OH and NO_2).

Anal. Calcd. for $C_{14}H_{16}ClNO_7$ (345.7): C, 48.70; H, 4.65; Cl, 10.27. Found: C, 48.80; H, 4.86; Cl, 10.40.

Methyl 4,6-O-Benzylidene-3-bromo-3-deoxy-3-nitro-α-D-idopyranoside (7)

(a) Br_2 Method

To an ice-cold solution of **1** (103 mg) in methanol (15 ml) was added aqueous, 0.1 *N* sodium hydroxide (3.7 ml). The mixture was stirred for 5 min after which bromine was added in small drops until the color of the solution remained slightly yellow. Stirring was then continued for another 5 min and followed by work-up (E). The white product (104 mg) was recrystallized from chloroform–pentane to give **7** (96 mg, 74%); m.p. 126–128°, raised to 129–130° by a second recrystallization. The product had $[\alpha]_D$ +45.5° and ν_{max} 3550, 3490 (OH) and 1565 cm^{-1} (NO_2).

Anal. Calcd. for $C_{14}H_{16}BrNO_7$ (390.3): C, 43.14; H, 4.13; Br, 20.46. Found: C, 43.26; H, 4.17; Br, 20.83.

(b) NBA Method

To a solution of **1** (200 mg) in methanol (20 ml) was added NBA (100 mg) and a saturated, aqueous solution of sodium acetate (2 ml). The reaction mixture was agitated for 30 min at room temperature. Work-up (E) afforded **7** (235 mg, 94%), m.p. 127–129° and undepressed upon admixture of **7** from the Br_2 method. The i.r. spectra of the two products were identical.

Methyl 4,6-O-Benzylidene-3-chloro-3-deoxy-nitro-β-D-gulopyranoside (9)

Chlorination of **2** (62 mg) was carried out at room temperature. According to t.l.c. (solvent C) no **2** was left after 10 min, and a single, faster moving spot was seen. The reaction mixture was allowed to stand for another 15 min, and work-up (E) then gave crude **9** (72 mg) which was recrystallized from ethyl acetate – petroleum ether to give pure **9** (58 mg, 76%); m.p. 166–167°; $[\alpha]_D$ +35.1°, ν_{max} 3480 and 1570 cm^{-1} (OH and NO_2).

Anal. Calcd. for $C_{14}H_{16}ClNO_7$ (345.7): C, 48.70; H, 4.65; Cl, 10.27. Found: C, 48.62; H, 4.78; Cl, 10.26.

Methyl 2,4,6-Tri-O-acetyl-3-chloro-3-deoxy-3-nitro-β-D-gulopyranoside (10)

Compound **9** (200 mg) was debenzylidenated by treatment (24) with 90% trifluoroacetic acid (5 ml) for 20 min at room temperature. The syrupy product obtained upon evaporation failed to crystallize and was therefore acetylated by the boron trifluoride method (22), a reaction time of 20 min being allowed. The acetylation mixture was poured into and stirred with ice water, and the oily product which separated was extracted into chloroform (3 × 30 ml). The extract was washed twice with 5 ml of cold, saturated sodium bicarbonate solution and twice with 5 ml of water. Drying (Na_2SO_4) and evaporation of the solvent gave **10** as a syrup which could be crystallized from chloroform–pentane. The product showed m.p. 91–92°, $[\alpha]_D$ −6.3°, ν_{max} 1765, 1745 ($OCOCH_3$), and 1575 cm^{-1} (NO_2).

Anal. Calcd. for $C_{13}H_{18}ClNO_{10}$ (383.8): C, 40.72; H, 4.73; Cl, 9.25. Found: C, 40.77; H, 4.71; Cl, 9.48.

For personal use only.

Methyl 4,6-O-Benzylidene-3-bromo-3-deoxy-3-nitro-β-D-gulopyranoside (11)

(a) Br_2 Method

To an ice-cooled suspension of **2** (311 mg) in methanol (40 ml) was added aqueous 0.1 *N* sodium hydroxide (11 ml). After stirring for 4 min a clear solution resulted to which bromine was added dropwise until a light yellow color persisted. Stirring at 0° was continued for 15 min and then followed by work-up (P). The product **11** (281 mg, 72%) showed m.p. 75–78°, $[\alpha]_D$ +31.6°, ν_{max} 3450 (OH) and 1565 cm^{-1} (NO_2).

Anal. Calcd. for $C_{14}H_{16}BrNO_7$ (390.2): C, 43.14; H, 4.13; Br, 20.46; N, 3.59. Found: C, 43.03; H, 4.24; Br, 20.38; N, 3.80.

(b) NBA Method

The reaction mixture was heated at reflux temperature for 1 h and then worked-up (P) to furnish **11**, m.p. 77–79°, in a yield of 69%. The i.r. spectrum was identical with that of **11** from (*a*).

Methyl 2,4,6-Tri-O-acetyl-3-bromo-3-deoxy-3-nitro-β-D-gulopyranoside (12)

Compound **11** (140 mg) was debenzylidenated, and the syrupy product acetylated, as described for the preparation of **10** from **9**. Prolonged trituration of the acetylation mixture with ice water gave the triacetate **12** as a solid (103 mg after drying; m.p. 107–108°) which was recrystallized from ethyl acetate – petroleum ether; m.p. 112–113°, $[\alpha]_D$ +25°, ν_{max} 1765, 1740 ($OCOCH_3$) and 1570 cm^{-1} (NO_2).

Anal. Calcd. for $C_{13}H_{18}BrNO_{10}$ (428.2): C, 36.48; H, 4.24; Br, 18.67; N, 3.27. Found: C, 36.60; H, 4.31; Br, 18.69; N, 3.32.

Methyl 4,6-O-Benzylidene-3-chloro-3-deoxy-3-nitro-α-D-gulopyranoside (13)

The glycoside **3** (120 mg) in methanol (15 ml) was treated with hypochlorite solution (1 ml) for 1 h at room temperature. Formation of a uniform product moving faster than **3** was indicated by t.l.c. (solvent D). Work-up (E) furnished crystalline **13** (123 mg, 92%) which upon recrystallization from ethanol–water melted at 121–122°; $[\alpha]_D$ +144°, ν_{max} 3540 and 1570 cm^{-1} (OH and NO_2).

Anal. Calcd. for $C_{14}H_{16}ClNO_7$ (345.7): C, 48.70; H, 4.65; Cl, 10.27. Found: C, 48.53; H, 4.77; Cl, 10.13.

Methyl 4,6-O-Benzylidene-3-bromo-3-deoxy-3-nitro-α-D-gulopyranoside (14) and -α-D-galactopyranoside (15)

(a) Br_2 Method

The glycoside **3** (311 mg) in methanol (40 ml) was treated with 0.1 *N* sodium hydroxide solution (11 ml) for 5 min at 0° and then brominated during 15 min. Work-up (P) afforded a white solid material (355 mg) which according to the t.l.c. (solvent B) was free from starting material but contained two products in similar proportions. An n.m.r. spectrum of the material exhibited two sharp singlets at τ 4.30 and 4.48 with an intensity ratio of 45:55 (benzylidene methine protons). The mixture was chromatographed on a column of silica gel (20 g) which was eluted with solvent C. A clean separation was achieved. The faster moving fraction gave the α-D-*galacto* isomer **15** (130 mg, 33%), m.p. 66°, $[\alpha]_D$ +160.3°, ν_{max} 3540 and 1560 cm^{-1}. The slower fraction gave the α-D-*gulo* isomer **14** (190 mg, 49%), m.p. 118–120°, $[\alpha]_D$ +108°, ν_{max} 3510 and 1560 cm^{-1}.

Anal. Calcd. for $C_{14}H_{16}BrNO_7$ (390.2): C, 43.14; H, 4.13; Br, 20.46. Found for **14**: C, 42.85; H, 4.22; Br, 20.45. Found for **15**: C, 43.27; H, 4.15; Br, 20.72.

(b) NBA Method

The glycoside **3** (93 mg) was completely brominated after 30 min at room temperature. The solid product obtained upon work-up (P) exhibited n.m.r. signals at τ 4.30 and 4.48 in an intensity ratio of 15:85. Column chromatography as described under (*a*) furnished **15** (12.6 mg, 11%) melting at 65–67° and **14** (82 mg, 71%) melting at 119–120°. Identity of the products with those obtained under (*a*) was confirmed by their i.r. spectra.

Methyl 4,6-O-Benzylidene-3-chloro-2,3-dideoxy-3-nitro-β-D-xylo-hexopyranoside (16)

The nitro glycoside **4** (177 mg) was chlorinated in methanol (45 ml) with hypochlorite solution (1.8 ml) at room temperature for 20 min. According to t.l.c. (solvent D) the reaction appeared complete after 10 min. Work-up (E) gave a syrup which was converted into a solid (182 mg, 92%) by dissolution in ethanol and careful addition of water; m.p. 48–49°, $[\alpha]_D$ +18.2°, ν_{max} 1565 cm^{-1} (NO_2).

Anal. Calcd. for $C_{14}H_{16}ClNO_6$ (329.7): C, 51.10; H, 4.89; Cl, 10.77. Found: C, 51.06; H, 4.80; Cl, 10.82.

Methyl 4,6-Di-O-acetyl-3-chloro-2,3-dideoxy-3-nitro-β-D-xylo-hexopyranoside (17)

Debenzylidenation (reaction time 1 h) and subsequent acetylation of **16** (330 mg) was performed as described for the conversion **9** → **10**. The syrupy product was crystallized from cyclohexane to give **17** (192 mg, 65%), m.p. 90–91°, $[\alpha]_D$ +27.5°, ν_{max} 1745 (shoulder at 1760) and 1570 cm^{-1} ($OCOCH_3$ and NO_2).

Anal. Calcd. for $C_{11}H_{16}ClNO_8$ (325.7): C, 40.60; H, 4.95; Cl, 10.86. Found: C, 40.76; H, 5.05; Cl, 10.81.

Methyl 4,6-O-Benzylidene-3-bromo-2,3-dideoxy-3-nitro-β-D-xylo-hexopyranoside (18)

The glycoside **4** (60 mg) was brominated by the NBA method at room temperature. The reaction was complete (t.l.c.) after 15 min and work-up (P) gave **18** (65 mg, 96%) as a white, amorphous powder; $[\alpha]_D$ +22°, ν_{max} 1565 cm^{-1}.

Anal. Calcd. for $C_{14}H_{16}BrNO_6$ (374.2): C, 45.05; H, 4.31; Br, 21.35. Found: C, 45.03; H, 4.12; Br, 21.35.

Methyl 4,6-O-Benzylidene-3-chloro-2,3-dideoxy-3-nitro-α-D-xylo-hexopyranoside (19) and -α-D-lyxo-hexopyranoside (20)

A solution of the glycoside **5** (250 mg) in methanol (30 ml) was treated with hypochlorite solution (2 ml) at room temperature for 2 h. The t.l.c. (solvent D) indicated formation of a major product and a faster moving, minor product. Work-up (E) furnished a syrup (240 mg, 85.5%) whose n.m.r. spectrum displayed two methine proton signals, τ 4.28 and 4.42, with an intensity ratio 14:86. The two products were separated by passage through a column of silica gel (20 g) using solvent D as eluant.

The faster moving fraction gave the α-D-*lyxo* isomer **20** (35 mg, 12.5%) which crystallized from ethanol–water; m.p. 122–123°, $[\alpha]_D$ +126°, ν_{max} 1570 cm^{-1}. The mass spectrum of **20** (mol. wt. 329.74) exhibited an intense molecular ion peak at *m/e* 329. An isotopic distribution pattern conforming to a chloro derivative was observed, A strong peak at *m/e* 298 likely resulted from loss of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

OCH_3, and less prominent peaks at *m/e* 223 and 192 were attributed to loss of C_6H_5CHO from the molecular ion and the aforementioned fragment. Another strong peak was at *m/e* 180.

The slower chromatographic fraction furnished the α-D-*xylo* isomer **19** (188 mg, 67%) which was also crystallized from ethanol–water; m.p. 101–102°, $[\alpha]_D$ +128°, ν_{max} 1565 cm^{-1}. Its mass spectrum also showed a molecular ion peak at *m/e* 329, and the fragmentation pattern was quite similar to that of **20** except for a medium intense peak at *m/e* 177 which was practically absent in the latter.

Anal. Calcd. for $C_{14}H_{16}ClNO_6$ (329.7): C, 51.10; H, 4.89; Cl, 10.77. Found: C, 51.04; H, 4.83; Cl, 10.79.

*Methyl 4,6-O-Benzylidene-3-bromo-2,3-dideoxy-3-nitro-α-D-xylo-hexopyranoside (**21**) and -α-D-lyxo-hexopyranoside (**22**)*

(a) Br_2 Method

The glycoside **5** (200 mg) in methanol (30 ml) was treated for 5 min with aqueous 0.1 *N* sodium hydroxide (6.8 ml). Bromine was then added dropwise in slight excess, and the reaction was allowed to proceed for another 10 min. Work-up (P) gave a crude solid (220 mg, 98%) which showed two spots, both faster than **5**, on t.l.c. with solvent A. The n.m.r. spectrum exhibited methine proton signals at τ 4.28 and 4.41 with an intensity ratio 25:75. The products were separated on a silica gel column (20 g) by elution with solvent A.

The faster moving product obtained from the column was the α-D-*lyxo* isomer **22** (41 mg, 21%), m.p. 105–106°, $[\alpha]_D$ +140.5° (*c*, 0.3), ν_{max} 1565 cm^{-1}. The mass spectrum showed intense molecular ion peaks at *m/e* 373 and 375 in accord with the composition $C_{14}H_{16}BrNO_6$. Less intense peaks were present at *m/e* M − 31, probably due to loss of OCH_3. A single peak of medium intensity was observed at *m/e* 262 and may have resulted from loss of HBr and OCH_3.

The second product eluted from the column was the α-D-*xylo* isomer **21** (156 mg, 69%); m.p. 103–104°, $[\alpha]_D$ +112.5°, ν_{max} 1565 cm^{-1}. Its mass spectrum was very similar to that of isomer **22** but showed an intense peak at *m/e* 221 which was not given by the latter.

Anal. Calcd. for $C_{14}H_{16}BrNO_6$ (374.2); C, 45.05; H, 4.31; Br, 21.35. Found: C, 45.02; H, 4.14; Br, 21.63.

(b) NBA Method

A 60-mg sample of **5** was brominated by NBA. The crude material obtained upon work-up (P) was identical to that obtained under (*a*) according to t.l.c. (solvent A) and n.m.r. spectroscopy, the spectrum showing an intensity ratio 22:78 for the τ 4.28 and 4.41 signals and being otherwise identical with that of the previous product mixture.

*Methyl 4,6-O-Benzylidene-3-bromo-2,3-dideoxy-3-nitro-β-D-ribo-hexopyranoside (**24**)*

The glycoside **23** (200 mg) was brominated by the NBA method at reflux temperature for 1 h. Work-up (P) afforded **24** (222 mg, 87%) as a white amorphous powder; $[\alpha]_D$ −26.2°, ν_{max} 1560 cm^{-1}.

Anal. Calcd. for $C_{14}H_{16}BrNO_6$ (374.2): C, 45.05; H, 4.31; Br, 21.35. Found: C, 45.19; H, 4.23; Br, 21.31.

*Bromination of Methyl 4,6-O-Benzylidene-3-deoxy-3-nitro-β-D-mannopyranoside (**26**)*

(a) Br_2 Method

A mixture of the glycoside **26** (311 mg) in methanol (25 ml) and aqueous 0.1 *N* sodium hydroxide (12.5 ml) was stirred in an ice water bath for 10 min. Bromine was added as in previous examples, and stirring at 0° was continued for 10 min. Work-up (P) gave a white solid material (319 mg) which exhibited four n.m.r. signals in the methine proton region (τ 4.23, 4.32, 4.42, and 4.49; intensity ratios 5:10:35:50). The t.l.c. (solvent A) showed one major spot having the same mobility as the nitro glucoside **25**, one slightly faster moving spot representing new product(s), and a weak, slow-moving spot having the mobility of starting material **26**. The mixture was chromatographed on silica gel (20 g) with the solvent A. All fractions were examined by t.l.c. and pooled appropriately. The fast-moving material (120 mg, $[\alpha]_D$ −39.8°, ν_{max} 1565 cm^{-1}) that was eluted first appeared homogeneous on t.l.c. but was revealed to be a mixture by its n.m.r. spectrum (methine proton signals at τ 4.42 and 4.23 in the ratio 85:15). The major component was assumed to be *methyl 4,6-O-benzylidene-3-bromo-3-deoxy-3-nitro-β-D-allopyranoside* (**27**), and the minor component, its β-D-*altro* isomer **28**.

Continued elution gave some mixed fractions which were discarded, and then a fraction containing pure **25** (93 mg) which was identified with an authentic sample by comparison of n.m.r. and i.r. spectra, t.l.c. and an undepressed mixture m.p. of 180–181°. A subsequent chromatographically uniform fraction gave starting material (**26**) which was identified similarly (mixed m.p. 194–196°, undepressed).

(b) NBA Method

The glycoside **26** (415 mg) was brominated for 1 h in refluxing methanol (40 ml) with NBA (200 mg) in the presence of sodium acetate (4 ml of a saturated aqueous solution). Work-up (P) gave a white solid (507 mg, $[\alpha]_D$ −35.5°) that appeared uniform on t.l.c. (various solvents) but showed two methine proton signals, at τ 4.42 and 4.23 in the intensity ratio 80:20. The i.r. spectrum was identical with that of the chromatographically purified mixture of **27** and **28** described under (*a*). A similar mixture was obtained by reaction with NBA for 5 h at room temperature.

(c) With N-Bromosuccinimide

Substitution of this reagent (71 mg) for NBA in the above reaction gave a product (106 mg, from 103 mg of **26**) whose n.m.r. spectrum was superimposable on that of the aforementioned mixture of **27** and **28**.

*Bromination of Methyl 4,6-O-Benzylidene-3-deoxy-3-nitro-β-D-glucopyranoside (**25**)*

Compound **25** (415 mg) was brominated with NBA as just described for **26**. After 1 h a small amount of **25** remained and a strong, faster moving product spot was observed on t.l.c. (solvent A). This picture did not change upon continued refluxing of the mixture for another 5 h. Work-up (P) gave a crude material (457 mg, $[\alpha]_D$ −41.2°) whose n.m.r. spectrum exhibited three methine proton signals, τ 4.22, 4.41, and 4.48, in the ratio 15:75:10. Except for some minor signals the spectrum was closely similar to that of the mixture of **27** and **28** obtained from

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

26, and the same was true for the i.r. spectrum. In view of these similarities and of the similar $[\alpha]_D$-value and t.l.c. pattern it was concluded that the product consisted of **27** and **28** (contaminated by some starting material).

Application of the Br_2 method as described for **26** gave no product after a reaction time of 15 min at 0°; a minute trace of product seemed to appear after 30 min at 25° (t.l.c. with solvent A). Unchanged **25**, m.p. 180°, was isolated in high yield.

Methyl 2-O-Acetyl-4,6-O-benzylidene-3-bromo-3-deoxy-3-nitro-β-D-allopyranoside (29)

(a) From the 2-Acetate 31

Compound **31** (200 mg) was brominated by the NBA method with a reaction time of 3 h at room temperature. Work-up (P) afforded 234 mg (95.5%) of a solid that was uniform in t.l.c. (solvent G) and upon recrystallization from ethyl acetate – petroleum ether afforded pure **29** (197 mg); m.p. 223–225°, $[\alpha]_D$ −69°, ν_{max} 1755 and 1570 cm^{-1} ($OCOCH_3$ and NO_2).

Anal. Calcd. for $C_{16}H_{18}BrNO_8$ (432.3): C, 44.50; H, 4.20; N, 3.24; Br, 18.45. Found: C, 44.58; H, 4.28; N, 3.09; Br, 18.70.

(b) From the Mixture of 27 and 28

A mixture (150 mg) of **27** and **28** originating from bromination of **26** (see earlier) was dissolved in methylene chloride (6 ml) and chilled (0°). To a cold solution of triethylamine (1.93 ml) in dry ether (30 ml) was added acetyl chloride (1.04 ml). The reagent, from which triethylammonium chloride precipitated copiously, was magnetically stirred at 0° for 5 min before the glycoside solution was added. The mixture was stirred for 30 min at 0° and then agitated briefly with cold water. Upon phase separation the aqueous layer was extracted twice with ether. The combined organic layer and extract was washed with three portions of water, dried over Na_2SO_4, and evaporated. The residue gave two spots on t.l.c. (solvent A), the faster spot being much stronger than the slower one. The n.m.r. spectrum showed signals in the region of τ 4.30–4.50 (methine proton and H-2 of **29**) and in the region of 4.10–4.20 (methine proton and H-2 of **30**) in an intensity ratio 80:20. Column chromatography of the mixture on 20 g of silica gel with solvent A led to isolation of the fast-moving component (117 mg, 70.5%) which according to its i.r. spectrum and m.p. 222–224° was identical with **29** described under (*a*). The slower component eluted from the column proved to be the isomer **30** (see the subsequent section).

Methyl 2-O-Acetyl-4,6-O-benzylidene-3-bromo-3-deoxy-3-nitro-β-D-altropyranoside (30)

(a) From the 2-Acetate 32

Compound **32** (150 mg) was brominated with NBA for 1 h at room temperature. Work-up (P) gave crude **30** (174 mg, 95%), m.p. 140–142°, $[\alpha]_D$ −76.2°. Upon recrystallization from ethanol–water the data were m.p 152–153°, $[\alpha]_D$ −80.8°, ν_{max} 1775 and 1565 cm^{-1}.

Anal. Calcd. for $C_{16}H_{18}BrNO_8$ (432.3): C, 44.50; H, 4.20; Br, 18.45. Found: C, 44.43; H, 4.30; Br, 18.64.

(b) From the Mixture of 27 and 28

The slow-moving product obtained from the column (see the preceding section) weighed 24.5 mg (15%), melted at 149–151°, and gave an i.r. spectrum identical with that of **30** from (*a*).

Attempted Bromination of α-D-Glucosides 34 and 35

Compound **34** (311 mg) and NBA (150 mg) were refluxed for 10 h in a mixture of methanol (30 ml) and saturated sodium acetate solution (3 ml). The t.l.c. gave no evidence for product formation, and work-up (P) led to recovery of **34** (242 mg, 78%), m.p. 166–167°, which was identified by its n.m.r. spectrum.

The 2-acetate **35** (100 mg) was similarly treated, with proportionate amounts of reagents, for a period of 3.5 h at room temperature. Upon work-up, 96 mg of unchanged **35**, m.p. 196–197°, was recovered.

Application of the Br_2 method to **34** (as described for **26**) gave no evidence for product formation (t.l.c. with solvent A) after 15 min at 0°, nor after 30 min at 25°. Unchanged **34**, m.p. 166–167°, was recovered.

Bromination of Methyl 4,6-O-benzylidene-3-deoxy-3-nitro-α-D-mannopyranoside (36)

The glycoside **36** (200 mg) was treated with an excess of NBA (400 mg) in refluxing methanol. Inspection by t.l.c. (solvent C) indicated that reaction had taken place but remained incomplete after 3 h; the pattern was essentially unchanged after 4 h. Work-up (P) then gave a white solid (213 mg) which t.l.c. showed to be not uniform but to contain at least one spot that moved faster than the starting material. Some of the latter appeared to be present also. The i.r. band attributable to the asymmetric stretching vibration of the nitro group was split, with one peak being at 1565 and the other at 1550 cm^{-1}. This suggested the presence of bromonitro and nitro sugars in the mixture. The n.m.r. spectrum of the material exhibited four methine proton signals at τ 4.24, 4.34, 4.43, and 4.48. By integration the first signal was seen to constitute 33%, and the last signal, 25% of the total intensity. The two intermediate signals integrated together (42%); however, the one at τ 4.43 could visually be judged to make the greater contribution by far. The signals at τ 4.34 and 4.48 were assigned to residual starting compound **36** and its α-D-*gluco* isomer **34**, respectively. The signals at τ 4.24 and 4.43 were tentatively attributed to *methyl 4,6-O-benzylidene-3-bromo-3-deoxy-3-nitro-α-D-altropyranoside* (**38**) and its α-D-*allo* isomer (**39**). No attempt was made to separate the products, but the presence of bromonitro sugars to an extent of over 50% was shown by the generation of an epoxide as will be described later on.

Methyl 2-O-Acetyl-4,6-O-benzylidene-3-bromo-3-deoxy-3-nitro-α-D-altropyranoside (41)

The 2-acetate **40** (100 mg) was brominated with NBA at room temperature for 2 h. Work-up (P) produced a crystalline material (103 mg, 85%); m.p. 152–153°, $[\alpha]_D$ +12.3°, ν_{max} 1760 and 1570 cm^{-1}. The n.m.r. data in Table 1 together with further observations ($J_{1,2} \sim 0$ Hz; disappearance of the H-3 quartet of **40**) were in accord with structure **41**. The microanalysis was not wholly satisfactory although it did indicate the presence of 93% of the expected amount of bromine in the sample. Instability of the compound resulting in loss of bromine during preparation and storage of the analytical sample might be an explanation.

Anal. Calcd. for $C_{16}H_{18}BrNO_8$ (432.3): C, 44.50; H, 4.20; Br, 18.45. Found: C, 45.97; H, 4.57; Br, 17.12.

Reactions of Halonitro Glycosides

Borohydride Reductions

For reductive debromination (11), sodium borohydride was added to the ethanolic solution of the bromonitro sugar at room temperature unless specified otherwise. Amounts of reagents and reaction times are given below. For work-up the reaction mixture was slightly acidified with *N* acetic acid, diluted with water, and partially evaporated under reduced pressure to remove most of the ethanol. The product began to separate in crystalline form during this operation; it was collected, washed with water, and dried, and it normally proved pure after one recrystallization from ethanol–water or as specified.

*(a) **1** from **7**.* Compound **7** (200 mg) and $NaBH_4$ (80 mg) in ethanol (40 ml) were allowed to react for 5 min in an ice-water bath. The product (128 mg, 80%), m.p. 174–175°, proved identical with an authentic sample of **1** (lit. m.p. 175° (23), 177–178° (18)) by its i.r. spectrum and on t.l.c. (solvent B). The t.l.c. also suggested the presence of a trace of epoxide **8**.

*(b) **2** from **11**.* Compound **11** (100 mg) and $NaBH_4$ (50 mg) in ethanol (20 ml) were allowed to react for 30 min at 25°. Identity of the product **2** (71 mg, 90%) with an authentic sample was established by comparison of i.r. spectra and an undepressed mixture melting point of 232° (lit. m.p. 230–231° dec. (19), 232° (21)).

*(c) **3** from **14**.* Compound **14** (170 mg) and $NaBH_4$ (80 mg) in ethanol (35 ml) were allowed to react for 10 min at 25°. Upon recrystallization from ethyl acetate – petroleum ether the product **3** (131 mg, 97%) was identical with an authentic sample according to i.r. and n.m.r. spectra; m.p. 165–167° (lit. m.p. 166–167° (18)).

*(d) **3** from **15**.* Compound **15** (20 mg) upon similar debromination gave **3** (12 mg, 75%) that was identified by its i.r. spectrum; m.p. 165–167°.

Alkaline Debromination and Epoxide Formation

*Methyl 2,3-anhydro-4,6-O-benzylidene-3-nitro-α-D-talopyranoside (**8**)*

*(a) From **1** via **6**.* The epoxide **8** was produced when the chlorination of **1** (see the preparation of **6**, above) was carried out at room temperature rather than at 0°. Thus, when **1** (62 mg) in methanol (15 ml) was treated with hypochlorite solution (0.6 ml), t.l.c. (solvent B) showed a single, faster moving spot (presumably **6**) after a reaction time of 15 min, and this spot was replaced by a slower spot corresponding to **8** after 35 min. Work-up (P) including recrystallization from ethanol–water gave **8** (50 mg, 81%), m.p. 215–216°. Its identity with known **8** was established by comparison of i.r. and n.m.r. spectra; lit. (10), m.p. 215–216°.

*(b) From **7**.* To a solution of **7** (35 mg) in methanol (2 ml) were added a few drops of aqueous *N* sodium hydroxide, and the mixture was stirred at 25° for 15 min during which time a white solid separated. Dilution with water and partial evaporation of the mixture afforded 25 mg (90%) of crystalline **8**, m.p. 214–215°.

*(c) From **15**.* Compound **15** (95 mg) was dissolved in methanol (30 ml) to which 1 ml of alcoholic, *N* sodium hydroxide was added. The slow generation of a product having the mobility of **8** was noticed on t.l.c. (solvent D) after a few hours, and the reaction appeared nearly complete after 10 h. The reaction mixture was diluted with water, and methanol was removed by evaporation whereby crystalline if slightly impure **8** (54 mg, 72%) was produced; m.p. 208–210°, $[\alpha]_D$ +89.0°; lit. $[\alpha]_D$ +91.8° (10).

*(d) From **14**.* When **14** was treated with base as under (*c*) it was recovered unchanged even after a prolonged time of exposure (20 h). However, when a sample (30 mg) in methanol (5 ml) together with 0.1 *N* sodium methoxide (1 ml) was heated to reflux for 20 min, reaction did take place to give a major, unidentified product of very low mobility (t.l.c. with solvent C) along with a minor product moving like **8**. Work-up as under (*c*) furnished crystalline **8** (6 mg, 25%), m.p. 213–215°, that was identified also by its i.r. spectrum. The unidentified material remained in the aqueous mother liquor.

*Debromination of **11***

A solution of **11** (50 mg) in ethanol (2 ml) was treated with 0.3 ml of aqueous *N* potassium hydroxide at room temperature. After 30 min all **11** had disappeared and a product having the mobility of **2** was formed (t.l.c. with solvent D). The reaction mixture was diluted with ethanol (10 ml), rapidly deionized by cation exchange, and immediately tested with potassium iodide – starch which produced a blue color. Evaporation of the solution and recrystallization of the residue from ethanol–water gave **2** (24 mg, 62%), m.p. and mixed m.p. 230–232°.

To a solution of **11** (80 mg) in methanol (5 ml) was added 0.1 *N* sodium methoxide in methanol (2 ml). After being refluxed for 20 min the reaction mixture was revealed by t.l.c. (solvent D) to contain a major, very slow-moving product beside some starting material. Dilution of the mixture with water caused **11** (16 mg) to separate; it was identified by its i.r. spectrum. The major reaction product could not be identified, but since a smell of benzaldehyde was noticed it likely was a degradation product. There was no chromatographic evidence for epoxide formation. (2,3-Anhydro glycosides of this type generally move faster than the corresponding 2-hydroxy derivatives.)

*Methyl 2,3-anhydro-4,6-O-benzylidene-3-nitro-β-D-mannopyranoside (**33**)*

*(a) From **30**.* Compound **30** (64.8 mg) was refluxed for 30 min in 0.035 *N* methanolic sodium methoxide solution (8 ml). The cooled solution was deionized with a cation exchange resin, diluted with water, and partially evaporated to remove methanol. A smell of benzaldehyde was noted. White crystals of **33** separated and were washed with water and dried (17 mg, 37%). The melting point, 179–180°, was raised to 182–183° by recrystallization from ethyl acetate – petroleum ether; $[\alpha]_D$ −68.4°. Microanalytical and spectral characterization of the product has been recorded (10).

*(b) From **29**.* Compound **29** (52 mg) gave **33** (15 mg, 40%) in the manner described under (*a*); m.p. 178–180°. The products were identical according to t.l.c., i.r., and n.m.r. spectra.

*(c) From mixtures of **27** and **28***

A mixture of **27** and **28** (60 mg; obtained from bromination of **26**) in methanol (5 ml) was refluxed for 30 min after addition of 0.1 *N* sodium methoxide solution (1.5 ml). Work-up as under (*a*) gave **33** (40 mg, 84%), m.p. 181–182°, identified also by its i.r. spectrum. A similar experiment using a mixture of **27** + **28** originating from

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

bromination of **25** gave **33**, m.p. 181–182°, in a yield of 78%.

Methyl 2,3-anhydro-4,6-O-benzylidene-3-nitro-α-D-mannopyranoside (37)

*(a) From **41**.* Compound **41** (65 mg) was refluxed for 30 min in 0.035 *N* methanolic sodium methoxide solution (8 ml). Upon cooling and dilution with water the reaction mixture deposited a voluminous precipitate of **37** which was collected, washed with water, and dried (38 mg, 82%). It melted at 173–174° and its i.r. spectrum was identical with that of **37** prepared by an independent method; lit. m.p. 173–174° (10).

*(b) From mixtures of **38** and **39**.* Eighty milligrams of the mixture of products obtained in the bromination of **36** and presumed to contain **38** and **39** was boiled for 20 min in 7 ml of 0.03 *N* sodium methoxide solution. The product obtained upon work-up and two recrystallizations from ethanol weighed 32.5 mg and proved identical with authentic **37** by an undepressed mixture m.p. 171–173°, and by its i.r. spectrum.

Similarly, a sample (60 mg) of the product of low-temperature deacetylation of **41** (see below) was heated in refluxing methanol (5 ml) and 0.1 *N* sodium methoxide solution (1.5 ml) for 30 min. Cooling and dilution with water gave a precipitate of **37** (36 mg, 76%), m.p. 172–173° (undepressed upon admixture of an authentic sample).

Deacetylation Accompanied by Epimerization

*(a) Reaction of **30**.*

To a solution of the β-D-*altro* acetate **30** (65 mg, 0.15 mmol) in methanol (5 ml) was added 0.30 mmol of sodium methoxide (3 ml of a 0.1 *N* solution). The mixture was allowed to stand at room temperature for 30 min after which time t.l.c. (solvent C) revealed absence of **30** and showed a single, slower spot. Deionization by cation exchange resin, dilution with water, and partial evaporation furnished a white solid (48 mg, 82%) showing $[\alpha]_D$ −38.2°. An n.m.r. spectrum exhibited two methine proton signals at τ 4.41 and 4.22, intensity ratio 80:20. The spectrum was virtually superimposable on those of the mixtures of **27** and **28** obtained in various brominations of **26** (see earlier). Since separation of the products was not possible, the mixture was acetylated by the acetyl chloride – triethylamine method (see the preparation of **29** from **27** + **28**). The solid mixture of acetates obtained was recrystallized twice from ethyl acetate – petroleum ether to give pure β-D-*allo* isomer **29** (34.5 mg, 65%), m.p. 223–225°. The identity of the product with **29** was confirmed by comparison of n.m.r. and i.r. spectra and by t.l.c. (solvent A).

When the above experiment was repeated with the use of only 0.15 mmol of $NaOCH_3$ and a reaction time of 1 h at 0°, the isolated product (52 mg) contained a small amount of unreacted **30** which could be removed by chromatography on silica gel (solvent C) and identified (m.p. 149–151°; i.r. spectrum). The main material eluted from the column (37 mg) was practically identical with previously obtained mixtures of **27** and **28** (product ratio, 85:15).

*(b) Reaction of **41***

To a solution of acetate **41** (86.4 mg, 0.2 mmol) in methanol (10 ml) was added 0.4 mmol of $NaOCH_3$ (4 ml of a 0.1 *N* solution). After 1 h at room temperature a seemingly uniform, more slowly moving product was formed (t.l.c., solvent A). Work-up (P) after 3 h gave a white solid (71 mg, 91%) which according to its i.r. spectrum (ν_{max} 3380 and 1560 cm^{-1}, OH and NO_2) was free from acetyl. The n.m.r. spectrum showed methine proton signals at τ 4.24 and 4.43, and corresponding OCH_3 signals at τ 6.61 and 6.55, tentatively assigned to **38** and **39**, respectively (ratio 4:6). Attempts to separate the products failed. The mixture (150 mg, from repeat experiments) was then acetylated with acetyl chloride and triethylamine in methylene chloride. (See the preparation of **29** from **27** + **28**.) Work-up afforded a solid material (153 mg) which appeared homogeneous on t.l.c. (various systems), having the same mobility as **41**. However, the n.m.r. spectrum revealed the product to be a mixture. The benzylidene methine signals overlapped with H-2 signals and therefore could not be analyzed, but there were two distinct singlets for *O*-acetyl protons, at τ 7.97 and 7.88 (intensity ratio 35:65; total intensity, 3H) which were tentatively attributed to **41** and its α-D-*allo* isomer **42**. Attempts to separate the mixture were unsuccessful.

Reactions of Phosphorus Pentachloride with Ethyl-, Vinyl-, and Ethynyl(trichloromethyl)carbinol and with 1,1,1-Trichloro-3-nonyn-2-ol[1]

E. Wilkins Reeve and Thomas F. Steckel

Chemistry Department, University of Maryland, College Park, Maryland 20742

Received July 20, 1972[2]

Reactions of phosphorus pentachloride with ethyl(trichloromethyl)carbinol (**2**), (trichloromethyl)-vinylcarbinol (**7**), ethynyl(trichloromethyl)carbinol (**11***a*), and 1,1,1-trichloro-3-nonyn-2-ol (**11***b*) have been studied. Whereas the reaction of phenyl(trichloromethyl)carbinol with phosphorus pentachloride leads to a nearly quantitative replacement of the hydroxyl group by chlorine, the reactions of the aliphatic (trichloromethyl)carbinols are more complicated. Thus the reaction of **2** with phosphorus pentachloride gave 18% of the normal product, 1,1,1,2-tetrachlorobutane (**3**), 13% of 1,1,2-trichloro-1-butene (**4**) from a dehydrohalogenation, and a higher boiling phosphate ester – acid chloride mixture. The alkynylcarbinols (**11**) gave tetrachlorobutynes (**12**) as well as tetrachloroallenes (**13**) by allylic rearrangement. A crystalline phosphate ester of **11***a* was also isolated. Several examples are given of catalytic rearrangements in the vapor phase of 1,1,1-trichloro-2-alkenes to 1,1,3-trichloro-1-alkenes.

On a étudié les réactions du pentachlorure de phosphore avec l'éthyl (trichlorométhyl) carbinol (**2**), le (trichlorométhyl) vinylcarbinol (**7**), l'éthènyl (trichlorométhyl) carbinol (**11***a*) et le trichloro-1,1,1 nonyn-3 ol-2 (**11***b*). Alors que la réaction du phényl (trichlorométhyl) carbinol avec le pentachlorure de phosphore conduit pratiquement quantitativement à la substitution du groupe hydroxyle par un chlore, la réaction avec les (trichlorométhyl) carbinols aliphatiques semble être beaucoup plus compliquée. Ainsi, la réaction de **2** avec le pentachlorure de phosphore conduit à la formation du produit normal (18%), tétrachloro-1,1,1,2 butane, (**3**) ainsi qu'à la formation du trichloro-1,1,2 butène-1 (**4**) (13%), provenant d'une déhydrohalogénation, et d'un mélange phosphate d'ester – chlorure d'acide ayant un point d'ébullition plus élevé. Les carbinols possèdant des groupes alcynes (**11**) produisent des tétrachlorobutynes (**12**) de même que des tétrachloroallènes (**13**) selon un mécanisme impliquant un réarrangement allylique. Un phosphate d'ester cristallin de **11***a* a aussi été isolé. Plusieurs exemples de réarrangements catalytiques en phase vapeur sont rapportés pour les trichloro-1,1,1 alcènes-2 entraînant la formation de trichloro-1,1,3 alcènes-1.

[Traduit par le journal]

Can. J. Chem., **51**, 2017 (1973)

The reaction of phosphorus pentachloride with phenyl(trichloromethyl)carbinol is known to give the corresponding chloride in 87% yield (1). When phenyl is replaced by an aliphatic group, a more complicated set of reactions occurs. The purpose of this work was to study the reactions of the compounds R—CHOH—CCl_3, where R is ethyl, vinyl, ethynyl, and nonynyl, with phosphorus pentachloride to determine the products formed in these reactions. These reactions are of importance because the hydroxyl group in trichloromethylcarbinols cannot be replaced by chlorine by treatment of the carbinol with concentrated hydrochloric acid; the presence of the trichloromethyl group prevents the usual displacement reaction from occurring, even when the alcohol is of the benzylic or allylic type.

The reaction of phosphorus pentachloride with alcohols has been used for over a century to replace the hydroxyl group with chlorine, but the mechanism by which this occurs is even now only imperfectly understood. Several facts are known. First, phosphorus pentachloride is $(PCl_4)^+(PCl_6)^-$ in the crystalline state (2) and in solvents such as phosphorus oxychloride, nitrobenzene, acetonitrile, and benzoyl chloride (3). The reaction occurs with initial stepwise replacement by alkoxy of the chlorines bound to phosphorus but no one has been able to isolate the pentacoordinate chloro ester, $ROPCl_4$ (4). This agrees with the observation that, while many pentacoordinate compounds of phosphorus are known, (5) they appear to be uncommon intermediates in nucleophilic displacements at tetracoordinate phosphorus (6). The reaction products include the alkyl chloride, always with inversion of configuration in the case of saturated alcohols (7); mono-, di-, and triphosphate esters, particularly from primary alcohols (4); and olefins from secondary alcohols, often accompanied by *trans*

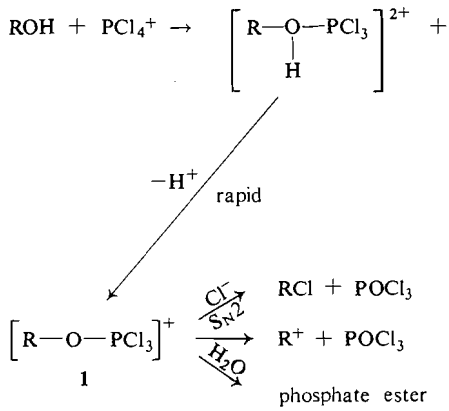

SCHEME 1

addition of chlorine to the double bond (8). Scheme 1 is consistent with the above experimental facts.

The above scheme incorporates the ideas of Gerrard (4) but assumes tetracoordinate intermediates. Independent evidence for the existence of **1** has been obtained from studies of the variation of electrical conductivity during the reaction of alcohols with phosphorus pentachloride in benzene (9).

In our work with vinyl and acetylenic carbinols (Schemes 3 and 4) the reaction intermediates must have a high degree of carbonium ion character to account for the allylic rearrangements observed, and the incipient carbonium ion could be formed by the heterolysis of the alkyl–oxygen bond of **1**. **1** can also react with excess carbinol with the replacement of two more of the phosphorus chlorines.

The reaction of ethyl(trichloromethyl)carbinol (**2**) with phosphorus pentachloride, which has not been studied previously, was found to yield four chlorinated hydrocarbons and ethyl α-chlorobutyrate (Scheme 2). The structures of the products were deduced from their spectra. Compound **5** rearranged completely to **6** during g.l.p.c. analysis.

With benzene instead of ether as the solvent, compounds **3**, **4**, and **5** + **6** were obtained in yields of 4, 2, and 8% respectively, ethyl α-chlorobutyrate was absent, and the major product consisted of another mixture distilling about 100° higher. This contained phosphorus, exhibited strong i.r. absorption at 1295 cm^{-1} characteristic of P=O, and showed splitting of the carbinyl proton attributable to phosphorus. It was concluded to be a mixture of mono- and dichlorophosphate esters of the starting carbinol. The residue appeared to be mostly the triphosphate ester.

As is the case with many unsubstituted alcohols (4), it is clear there is competition between phosphate ester formation and replacement of the hydroxyl group by chlorine. During the latter reaction, dehydrohalogenation occurs to **4** and **5**. Compound **4** is stable, but **5** is thermally unstable; on heating a mixture of **3**, **4**, and **5** at 135° for 2 h, about 50% of **5** is converted to **6**.

The tertiary alcohol, dimethyl(trichloromethyl)carbinol, does not react with phosphorus pentachloride under the above conditions. Others have found that the conversion of this carbinol to the chloride requires several hours heating at 80° with phosphorus pentachloride (10).

Colonge and Lartigau report that (trichloromethyl)vinylcarbinol and phosphorus pentachloride give *trans*-1,1,1,4-tetrachloro-2-butene (**9**) in 48% yield using ether as a solvent (11) (see Scheme 3). We duplicated their results and in addition found that, using benzene as the solvent, **9** was obtained in 34% yield and, based on i.r. and n.m.r. spectra, was contaminated with substituted vinylbenzenes. Unlike most allyl alcohols, (trichloromethyl)vinylcarbinol does not react with concentrated hydrochloric acid containing zinc chloride even after standing for 24 h at room temperature.

Compound **8** could not be isolated; only its allylic isomer **9** was obtained. Colonge and Ducarre (12) reported, on the basis of spectral evidence only, that **9** was stable to heat but was partially converted to **10** by light. We have found that this isomerization occurs quantitatively at 125° during g.l.p.c., and can be carried out catalytically on a preparative scale in 81% conversion by a single pass of the vapors of **9** over copper metal beads at 220°. The driving force for this reaction is probably the resonance stabilization afforded by the vinylidene chloride structure as compared to the unconjugated trichloromethyl group. Over alumina, **9** underwent decomposition.

The reaction of ethynyl(trichloromethyl)carbinol with phosphorus pentachloride has not been studied previously. As with the (trichloromethyl)vinylcarbinol, the reaction is unusual in that the expected chloride (**12***a*) is a minor product; the major component of the volatile

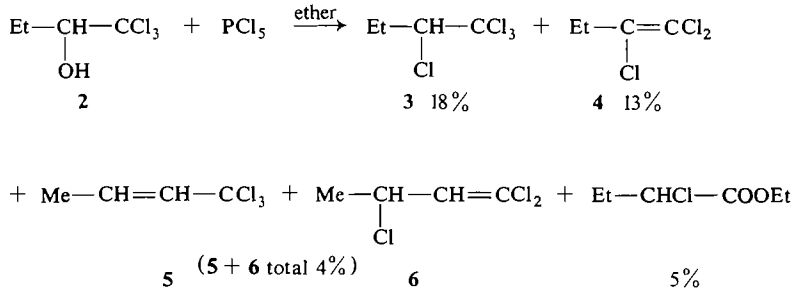
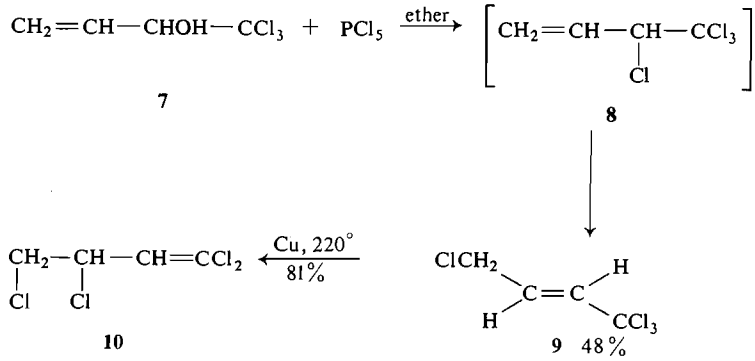


SCHEME 2



SCHEME 3

fraction of the reaction products is the allene **13***a* formed by an allylic rearrangement accompanying the displacement of the hydroxyl group (see Scheme 4). This presumably occurs by an S_Ni' mechanism.

The phosphate ester **14** could be isolated only when the reaction was carried out by adding phosphorus pentachloride, suspended in benzene, to a benzene solution of the starting carbinol **11***a*. The phosphate ester crystallized from the residue after the volatile fraction had been distilled. Products **12***a* and **13***a* are best obtained by adding the carbinol to the phosphorus pentachloride; thus a 7% yield of the alkyne **12***a* was obtained versus 1% by the reverse addition, but no phosphate ester could be isolated from the non-volatile portion. It seems likely that the triester was not formed with this mode of addition because the phosphorus pentachloride was in excess at all times during the reaction. This might give the monoalkyl chlorophosphate time to react to form the chlorinated hydrocarbons.

The alkyne **12***a* was a stable compound, not isomerized by distillation, by passage through a g.l.p.c. apparatus, or by passage over various catalysts in the vapor phase at 218°. In contrast, the allene **13***a* isomerized quantitatively to the butadiene **15***a* during g.l.p.c. regardless of the chromatographic column employed. The allene did not isomerize during distillation. Since chemical methods of separating the alkyne and allene isomers were unsuccessful, our best sample of **13***a* was an 85% pure (by n.m.r.) fraction, obtained by distillation, with the balance being the alkyne **12***a* together with minor impurities.

The rearrangement of the allene **13***a* to the butadiene **15***a* was found to occur quantitatively during a single pass of the allene in the vapor state over alumina at 218°. Copper beads were also effective in catalyzing the isomerization at this temperature, but two passes were necessary to obtain a 90% conversion. Glass wool, sand, and stainless steel wire loops had no catalytic effect. All attempts to carry out the isomerization

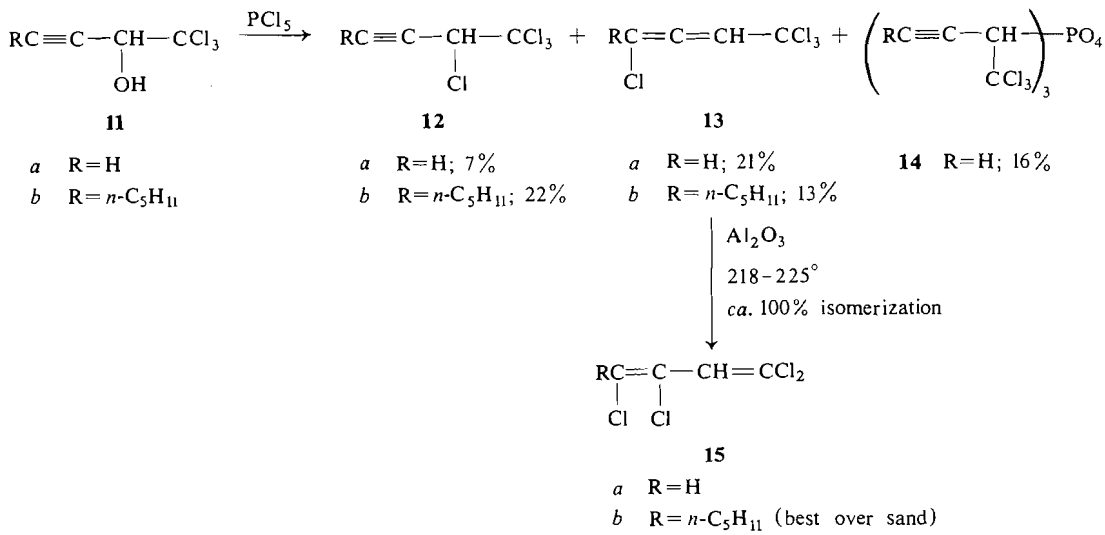

SCHEME 4

in the liquid phase over catalysts such as metallic copper, cupric chloride, copper chromite hydrogenation catalyst, and silica gel were unsuccessful.

To eliminate whatever effect the acetylenic proton might have on the above reactions, *n*-amylacetylene was prepared and converted to 1,1,1-trichloro-3-nonyn-2-ol (**11***b*) by reaction with chloral. The reaction of **11***b* with phosphorus pentachloride was studied by adding the phosphorus pentachloride to the carbinol using benzene as solvent. The crude product containing **12***b* (major component) and its allylic rearrangement product (**13***b*) was obtained in 84% yield (before distillation; 35% after distillation). The undistilled and the distilled materials gave identical n.m.r. spectra. Compound **12***b* was the major fraction formed; this involved a normal replacement of the hydroxyl group. The product **13***b* from the allylic rearrangement was the minor product.

The allene **13***b* rearranged to the diene **15***b* on g.l.p.c., and thus **13***b* could not be obtained pure. This rearrangement could also be carried out as before in the vapor phase at 225° over a variety of substances including alumina, sand mixed with copper powder, and sand alone. Since sand, which is considered to have no catalytic activity, seemed to be best, it appears that the conversion is thermal rather than catalytic. *cis* and *trans* isomers of **15***b* are possible and evidence for their existence was seen in the n.m.r. spectrum where two signals in the ratio of 3.5:1 were observed for the vinyl proton. The isomers were not separated by the g.l.p.c. columns used.

The allene **13***b* was unstable in the liquid phase. After 2 months at room temperature or 30 min at 150°, it was changed to a polymeric material. On heating **13***b* at 150° with finely divided copper metal for 10 min, a dark brown mixture was formed which contained some diene **15***b*. Thus in this case, copper has a limited catalytic effect in the liquid phase.

The alkyne **12***b*, in contrast to the allene **13***b*, was stable in the liquid phase, even when heated either alone or in the presence of copper metal or alumina. It was unaffected by passage of the vapor at 225° over sand or a 1:1 sand and copper powder mixture. However, over alumina at 225°, **12***b* lost two chlorine atoms to give 1,1-dichloro-1-nonen-3-yne (**16**) in about 10% yield, and no starting material could be recovered. During g.l.p.c. analysis at 195°, **12***b* also gave **16** in 5 to 10% yield, but most of the **12***b* could be recovered.

Experimental

Melting points and boiling points are corrected. The i.r. spectra were recorded on a Perkin–Elmer instrument Model 337, using thin films for liquid samples and potassium bromide pellets for solid samples. The mass spectra were recorded on a Varian M-66 mass spectrometer, and the n.m.r. spectra with a Varian A60A instrument. Chemical-shift values are expressed as δ values (p.p.m.) downfield from tetramethylsilane internal standard. Vapor phase chromatographic analyses were carried out on an F & M Model 300 with a helium flow

rate of 50 ml/min. The percentage composition figures given for the various fractions are g.l.p.c. percentages. The following chromatographic columns were used: Apiezon (10% Apiezon-L on 60/80 mesh silanized diatomaceous earth (Diatoport-S) packed in a 2 m × 6.35 mm copper tube), silicon fluid (20% Dow-Corning Silicon Fluid #710 on 30/60 mesh Chromosorb P packed in a 2 m × 6.35 mm copper tube), silicon gum rubber (F & M silicon gum rubber on Chromosorb P packed in a 0.7 m × 6.35 mm stainless steel tube).

Elemental microanalyses were performed by Dr. Franz J. Kasler.

*Ethynyl(trichloromethyl)carbinol (**11a**)*

This was prepared by a modification of Shapiro's method (13) in 51% yield from the reaction of sodium acetylide (14) and commercial anhydrous chloral at 0° for 2 h; b.p. 74–82° (14 mm) (lit. (13) 77–81° (16 mm)); n.m.r. ($CDCl_3$) δ 4.90 (1 H, d, J = 2.1 Hz, —C*H*OH—), 3.96 (1 H, broad s, —O*H*), 2.78 (1 H, d, J = 2.1 Hz, *H*C≡).

*1,1,1-Trichloro-3-nonyn-2-ol (**11b**)*

1-Heptyne (15) (32 g, 0.33 mol) in an equal volume of anhydrous ether was added over a 45-min period to 0.3 mol of ethylmagnesium bromide in refluxing ether. After refluxing 2 h, the reaction mixture was cooled in an ice bath under a nitrogen atmosphere and 49 g (0.33 mol) of chloral in an equal volume of ether was added over 1 h; the mixture was then stirred for an additional hour at room temperature. There was obtained 62 g (76%) of the carbinol **11***b*; b.p. 144–149° (16 mm) (lit. (16) 106–110° (4 mm) and 141–142° (12 mm)); n.m.r. (CCl_4) δ 4.69 (1 H, m, —C*H*OH—), 3.44 (1 H, s, O*H*), 2.26 (2 H, m, —CH_2C≡), 1.41 (6 H, m, (—CH_2—)$_3$), 0.91 (t, 3, CH_3—).

*(Trichloromethyl)vinylcarbinol (**7**)*

Twenty-six grams (0.15 mol) of ethynyl(trichloromethyl)carbinol (**11***a*) dissolved in 150 ml ethanol was hydrogenated at room temperature over 1.2 g of 10% palladium-on-carbon catalyst (17) until 0.15 mol of hydrogen had been absorbed. Distillation of the product combined from three such runs gave 61 g (78%) of the carbinol **7**; b.p. 84–87° (30 mm) (lit. 68–69° (12 mm) (13) and 75° (17 mm) (18)); n.m.r. ($CDCl_3$) δ 6.35–5.35 (3 H, m, H_2C=C*H*—), 4.54 (1 H, doublet with some long range splitting, J = 4.8 Hz, J' = 2.4 Hz, —C*H*OH—), 3.6 (1 H, s, —O*H*). The n.m.r. spectra showed the product to be 90–92% pure. Also present were peaks corresponding to the presence of approximately 5% each of **2** and **11***a*.

*Ethyl(trichloromethyl)carbinol (**2**)*

The ethynyl carbinol **11***a* was hydrogenated as above, but the reaction was allowed to go to completion. This took about 20 min, and shaking was continued for another 10 min. From 104 g of **11***a*, there was obtained on distillation 78 g (74%) of the carbinol 2; b.p. 79–84° (28 mm) (lit. (13) 67° (13 mm)); n.m.r. (CCl_4) δ 3.98 (1 H, d of d, J = 9.1, J' = 2.1 Hz, —C*H*OH—), 3.3 (1 H, s, —O*H*), 2.54–1.33 (2 H, m, —CH_2—), 1.12 (3 H, t, J = 7.2 Hz, CH_3—).

*Reaction of Ethyl(trichloromethyl)carbinol (**2**) with Phosphorus Pentachloride*

To 4.4 g (0.025 mol) of **2** dissolved in 16 ml of ether, stirred with a magnetic stirrer and cooled with an ice bath, was added a slurry of 10.4 g (0.05 mol) of phosphorus pentachloride in ether over a period of 10 min. The reaction mixture was stirred for 2 h at room temperature and then decomposed by pouring into ice and water. To this was added 20% potassium hydroxide solution in small portions until the water layer was just basic to litmus; the organic layer was separated, washed twice with 5% sodium carbonate solution, twice with water, dried ($MgSO_4$), concentrated, and distilled giving 1.7 g of a mixture (b.p. 61–76° (34 mm); lit. for **4**: (19) 58° (46 mm), for **6**: (20) 64° (50 mm)). G.l.p.c. analysis (silicon fluid column at 100°) showed the mixture to consist of 49% *1,1,1,2-tetrachlorobutane* (**3**) (18%), 30% *1,1,2-trichloro-1-butene* (**4**) (13%), 10% *1,1,3-trichloro-1-butene* (**6**) (4%), and 11% ethyl α-chlorobutyrate (12%). These compounds had retention times of 42, 15, 17, and 28 min respectively. The presence of 1,1,1-trichloro-2-butene (**5**) was shown by the n.m.r. spectrum of the distilled mixture of chlorinated hydrocarbons prior to g.l.p.c. analysis; it rearranged to **6** during g.l.p.c. analysis.

Spectral data on **3** purified by g.l.p.c.: i.r. of stronger bands (neat) 2970, 2935, 2875, 1450, 1090, 1015, 830, 790–770 (s), 680, and 610 cm^{-1}; n.m.r. (CCl_4) δ 4.25 (1 H, d of d, J = 10.3, J' = 2.3 Hz, —C*H*Cl—), 2.7–1.5 (2 H, m, CH_3CH_2—), 1.2 (3 H, t, J = 7.3 Hz, CH_3—).

Data on **4** purified by g.l.p.c.: i.r. of stronger bands (neat) 2975, 2930, 2875, 1600, 1455, 1425, 1130, 1045, 955, 900 (s), 810 (s), and 735 cm^{-1}; n.m.r. (CCl_4) δ 2.64 (2 H, quartet, J = 7.4 Hz, CH_3CH_2—), 1.18 (3 H, t, J = 7.4 Hz, CH_3—).

Data on **6** purified by g.l.p.c.: i.r. of stronger bands (neat) 2980, 2920, 1620 (s), 1445, 1375, 1260, 1215 (s), 1140 (s), 1010 (s), 925, 885 (s), 835, 670, and 620 (s) cm^{-1}; n.m.r. (CCl_4) δ 6.02 (1 H, d, J = 9.8 Hz, —C*H*=), 4.77 (1 H, m, —C*H*Cl—), 1.62 (3 H, d, J = 6.7 Hz, CH_3).

Identification of ethyl α-chlorobutyrate was based on spectral data obtained on the sample purified by g.l.p.c.: i.r. (neat) 1750 cm^{-1} (ester C=O) (lit. (21) 1750 cm^{-1}; n.m.r. (CCl_4) δ 4.18 (3 H, m, —C*H*Cl— and —CH_2O—), 1.99 (2 H, m, —CH_2CHCl—), 1.32 (3 H, t, J = 7.1 Hz, CH_3—), 1.03 (3 H, t, J = 7.4, CH_3).

Spectral data on **5** was obtained on a sample prepared from **2** and phosphorus pentachloride using benzene as solvent. The reaction mixture was distilled and the major component comprising 47% of the volatile fraction was identified as *1,1,1-trichloro-2-butene* (**5**) from the n.m.r. spectrum of the mixture. It rearranged to **6** on g.l.p.c. analysis and so its spectral data were measured using the 47% mixture: i.r. (neat) 1655 cm^{-1} (C=C); n.m.r. (CCl_4) δ 6.03 (2 H, m, —C*H*=C*H*—), 1.87 (3 H, d, J = 4.9 Hz, CH_3—).

In a separate experiment, the reaction mixture, after pouring into ice and water, was separated and washed with water ten times, stirred with water for 45 min, and washed twice more. Even though no alkali was used in the work-up, the composition of the undistilled product was nearly the same as above; by g.l.p.c.: 53% **3**, 11% **4**, 14% **5** plus **6**, and 18% ethyl α-chlorobutyrate; by n.m.r.: 60% **3** + ethyl α-chlorobutyrate, 21% **4**, 9% **5**, and 6% **6**.

*Reaction of (Trichloromethyl)vinylcarbinol (**7**) with Phosphorus Pentachloride*

To 3.5 g (0.02 mol) of **7** in 13 ml of dry ether at 0° was added a slurry of 8.3 g (0.04 mol) of phosphorus pentachloride suspended in 12 ml of dry ether over a 30 min period under the same conditions as in the reaction of **2**

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

above. There was obtained 2.4 g (60% yield) of material prior to distillation, and its n.m.r. spectrum showed it to be 97% *trans-1,1,1,4-tetrachloro-2-butene* (**9**). Distillation gave 1.8 g (48%) of **9**: b.p. 85–88° (21 mm) (lit. (11) b.p. 76–78° (15 mm)). The i.r. was identical with that in the literature (11). The n.m.r. (CCl_4) spectrum showed two narrow complex multiplets at δ 6.42 and 4.15 in the ratio of 1:1 (lit. (12) δ 6.4 (s), 4.1 (m)). The material gave proper elemental analyses for carbon, hydrogen, and chlorine.

*Catalytic Rearrangement of **9** to **10***

A small amount of **9** was injected through a septum into an 8 mm glass U tube packed with copper beads (2 mm diameter) and immersed in a Wood's metal bath (220°). Using nitrogen as a carrier gas, 81% of **10** was collected. No isomerization occurred with sand (Fisher Scientific sea sand) replacing copper. An analytical sample of **10**, *1,1,3,4-tetrachloro-1-butene*, was obtained by collection from the Apiezon g.l.p.c. column. The retention time was 8 min at 125°. Spectral data: i.r. of stronger bands (neat) 3040–2940 (w), 1615 (s), 1440, 1425, 1285, 1205, 1165, 1040, 930, 905 (s), 885 (s), 835 (s), 750, 710, and 625 cm^{-1}; n.m.r. (CCl_4) δ 6.02 (1 H, d, J = 9.7 Hz, —C*H*═), 5.05–4.65 (1 H, m, —C*H*Cl—), multiplet of four peaks at 3.79, 3.77, 3.71, and 3.64 (2 H, m, ClCH_2—). The n.m.r. spectrum is essentially the same as that reported by Colonge and Ducarre (12) for their 60% pure sample of **10**.

Anal. Calcd. for $C_4H_4Cl_4$: C, 24.77; H, 2.08; Cl, 73.15. Found: C, 24.91; H, 1.97; Cl, 73.04.

*Reaction of Ethynyl(trichloromethyl)carbinol (**11a**) with Phosphorus Pentachloride*

To 19.2 g (0.11 mol) of **11***a* dissolved in 60 ml of benzene (stirred and cooled in ice) was added (1 h) a slurry of 47 g (0.225 mol) of phosphorus pentachloride in 40 ml of benzene. After 1 h stirring at 25°, the mixture was poured into ice and the benzene layer was washed (10% sodium carbonate solution, then water), dried ($MgSO_4$), concentrated, and distilled (b.p. 76–81° (26 mm)) giving 4.5 g of a mixture consisting of 5% *3,4,4,4-tetrachloro-1-butyne* (**12***a*) (1% yield), 85% *1,4,4,4-tetrachloro-1,2-butadiene* (**13***a*) (17% yield), and 10% of other compounds (by g.l.p.c. analysis (silicon fluid column at 140°) and n.m.r.). Compounds **12***a* and **13***a* had apparent retention times of 10.7 and 12.3 min respectively; the latter retention time was that of **15***a*, isomerization having occurred. The residue from the distillation of the crude material solidified on cooling, and after recrystallization from cyclohexane, 3.4 g (16%) of *tris(1,1,1-trichloro-3-butyne-2-ol) phosphate* (**14**) was obtained, m.p. 79–80°.

Adding 13 g (0.075 mol) of the carbinol **11***a*, dissolved in 10 ml of benzene, to 31.2 g (0.15 mol) of phosphorus pentachloride suspended in 30 ml of benzene under the above conditions gave 4.6 g of volatile material, b.p. 85–90° (28 mm). G.l.p.c. and n.m.r. analyses showed it to be a mixture of **12***a* (7% yield) and **13***a* (21% yield) with about 10% of impurities. The sample of **12***a* for analysis was prepared by this procedure. No phosphate ester (**14**) could be obtained from the residue.

Spectral and analytical data on *3,4,4,4-tetrachloro-1-butyne* (**12***a*) purified by g.l.p.c.: i.r. of stronger bands (neat) 3300, 2940, 2130, 1210, 965, 815, 735, 665, and 610 cm^{-1}; n.m.r. ($CDCl_3$) δ 5.17 (1 H, d, J = 2.3 Hz, —C*H*Cl—), 2.84 (1 H, d, J = 2.3 Hz, *H*C≡); mass spectrum (70 eV), *M/e* very weak molecular ion peaks at 190 and 192.

Anal. Calcd. for $C_4H_2Cl_4$: C, 25.03; H, 1.05; Cl, 73.92. Found: C, 25.06; H, 1.11; Cl, 73.65.

Spectral and analytical data on *1,4,4,4-tetrachloro-1,2-butadiene* (**13***a*) of 85% purity obtained by distillation: i.r. of stronger bands (neat) 3290, 3145, 1955, 1345, 1225, 1130, 1110, 850, 805, 775, 755, 695, and 600 cm^{-1}; n.m.r. (CCl_4) δ 6.59 (1 H, d, J = 5.5 Hz, ClC*H*═), 6.21 (1 H, d, J = 5.5 Hz, ═C*H*—CCl_3); the mass spectrum (70 eV) showed the molecular ion isotopes as a cluster at *M/e* (relative intensity) 190 (100), 192 (125), 194 (52), 196 (13), and 198 (1). Molecular ion peaks for this compound are much stronger than for **12***a*, but not as strong as for **15***a*.

Anal. Calcd. for $C_4H_2Cl_4$: C, 25.03; H, 1.05; Cl, 73.92. Found: C, 25.30; H, 1.22; Cl, 73.64.

Spectral and analytical data on *tris(1,1,1-trichloro-3-butyne-2-ol)phosphate* (**14**): i.r. of stronger bands (KBr) 3290, 2935, 2135, 1280, 1070, 1030, 970, 910, 825, 800, and 670 cm^{-1}; n.m.r. (CCl_4) δ 5.50 (1 H, d of d, J = 8.2 Hz, J' = 2.1 Hz, >C*H*—CCl_3), 2.83 (1 H, d of d, J = 1 Hz, J' = 2.1 Hz, *H*C≡).

Anal. Calcd. for $C_{12}H_6Cl_9O_4P$: C, 25.54; H, 1.07; Cl, 56.55. Found: C, 25.30; H, 1.10; Cl, 56.35.

*Rearrangement of **13a** to **15a***

This occurred quantitatively during g.l.p.c. analyses regardless of the column employed. It was accomplished on a preparative scale over an alumina catalyst (Fisher activated alumina, 8–14 mesh) at 218° using the glass U tube apparatus described above for the isomerization of **9** to **10**. The isomerization was nearly 100%. The analytical sample of *1,1,3,4-tetrachloro-1,3-butadiene* (**15***a*) was purified by g.l.p.c. (silicon fluid column at 140°); i.r. of stronger bands (neat) 3080, 3035, 1615, 1585, 1255, 1115, 935, 905, 825, and 660 cm^{-1}; n.m.r. ($CDCl_3$) δ 6.60 (1 H, s), 6.36 (1 H, s); the mass spectrum (70 eV) showed the molecular ion isotopes as a cluster at *M/e* (relative intensity) 190 (100), 192 (126), 194 (62), 196 (12), 198 (1).

Anal. Calcd. for $C_4H_2Cl_4$: C, 25.03; H, 1.05; Cl, 73.92. Found: C, 25.30; H, 1.15, Cl, 74.10.

*Reaction of 1,1,1-Trichloro-3-nonyn-2-ol (**11b**) with Phosphorus Pentachloride*

To 7.3 g (0.03 mol) of **11***b* dissolved in 25 ml of benzene (stirred and cooled in ice) was added (30 min) a slurry of 12.5 g (0.06 mol) of phosphorus pentachloride in 15 ml of benzene. After 1 h stirring at 25°, the mixture was poured into ice and neutralized with 20% potassium hydroxide solution. The benzene layer was washed, dried and concentrated as before to yield 6.6 g of a crude product. Distillation was difficult because the material foamed, but was accomplished using Dow defoamers A and Q. There was obtained 2.9 g of a mixture distilling between 147–149° (22 mm). G.l.p.c. analysis (silicon fluid column at 195°) and its n.m.r. spectrum showed the mixture to consist of 60% *1,1,1,2-tetrachloro-3-nonyne* (**12***b*) (22% yield) and 35% *1,1,1,4-tetrachloro-2,3-nonadiene* (**13***b*) (13% yield). **12***b* and **13***b* had apparent retention times of 27 and 21 min respectively; the latter retention time was that of **15***b*, isomerization having occurred.

Spectral and analytical data on *1,1,1,2-tetrachloro-3-nonyne* (**12***b*) purified by g.l.p.c., first on the silicon fluid column at 195° (some decomposition), then on silicon gum rubber at 155°; i.r. of stronger bands (neat) 2960,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

2935, 2860, 2240, 1460, 1285, 1210, 845, 815, 780, 750, 730, and 612 cm^{-1}; n.m.r. (CCl_4) δ 5.05 (1 H, t, J = 2 Hz, —C*H*Cl—), 2.30 (2 H, m, —CH_2C≡), 1.43 (6 H, m, CH_3—CH_2—CH_2—CH_2—), 0.92 (3 H, poorly resolved triplet, CH_3—); the mass spectrum (70 eV) showed the molecular ion isotopes as a cluster at *M/e* (relative intensity) 260 (100), 262 (136), 264 (68), 266 (14), and 268 (1).

Anal. Calcd. for $C_9H_{12}Cl_4$: C, 41.26; H, 4.62; Cl, 54.12. Found: C, 41.50; H, 4.47; Cl, 53.85.

Spectral data on *1,1,1,4-tetrachloro-2,3-nonadiene* (**13***b*) obtained on a distilled sample consisting of 35% **13***b* and 60% **12***b*: i.r. (neat) 1970 cm^{-1} (allene); n.m.r. (CCl_4) δ 6.16 (1 H, t, J = 2.6 Hz, =C=C*H*—).

Rearrangement of **13***b* *to* **15***b*

This could be carried out at 220–225° over sand (preferred), a sand-copper powder mixture, or alumina using the glass U tube apparatus described above for the isomerization of **9** to **10**. The analytical sample of *1,1,3,4-tetrachloro-1,3-nonadiene* (**15***b*) was prepared and purified by g.l.p.c., first on the silicon fluid column at 195° (retention time = 21 min), and then reinjected on the Apiezon column at 170° (retention time = 19 min); i.r. of stronger bands (neat) 3030, 2960, 2930, 2860, 1590, 1460, 1370, 1265, 1110, 930–910, 850, 820, 750, and 675–655 cm^{-1}; n.m.r. (CCl_4) δ 6.50 and 6.34 (1 H, singlets in ratio of 3.5:1, *cis* and *trans* —C*H*=?), 2.53 (2 H, m, —CH_2—CCl=), 1.43 (6 H, m, —CH_2—CH_2—CH_2—), 0.92 (3 H, poorly resolved triplet, CH_3); the mass spectrum (70 eV) showed the molecular ion isotopes as a cluster at *M/e* (relative intensity) 260 (100), 262 (129), 264 (57), 266 (12), and 268 (1).

Anal. Calcd. for $C_9H_{12}Cl_4$: C, 41.26; H, 4.62; Cl, 54.12. Found: C, 41.48; H, 4.40; Cl, 53.93.

1,1-Dichloro-1-nonen-3-yne (**16**)

This was formed in 5% yield during g.l.p.c. of **12***b* on the silicon fluid column at 195°. The column effluent was collected and reinjected on the Apiezon column at 170°; the retention times of **12***b* and **16** on this latter column were 18 and 6 min respectively. Spectral and analytical data on **16**: i.r. (neat) 3030, 2960, 2930, 2850, 2210, 1580, 1460, 1275, 1170, 940–925, 825, 725, and 655 cm^{-1}; n.m.r. (CCl_4) δ 5.85 (1 H, t, J = 2 Hz, ≡C—C*H*=), 2.33 (2 H, m, —CH_2—C≡), 1.43 (6 H, m, —CH_2—CH_2—CH_2—), 0.93 (3 H, poorly resolved triplet, CH_3—); the mass spectrum (70 eV) showed the molecular ion isotopes as a cluster at *M/e* (relative intensity) 190 (100), 192 (58), 194 (8).

Anal. Calcd. for $C_9H_{12}Cl_2$: C, 56.57; H, 6.33; Cl, 37.10. Found: C, 56.30; H, 6.06; Cl, 36.80.

Compound **16** was also obtained in about 10% yield by passage of the vapors of **12***b* over alumina at 225°.

Silyl-substituted α,β-Unsaturated Ketones from the Reaction of Silylvinylmetallic Reagents with Acid Anhydrides

A. G. Brook and J. M. Duff

Department of Chemistry, University of Toronto, Toronto 181, Ontario

Received November 27, 1972

The reactions of a series of silyl-substituted vinylmetallic reagents with acetic and benzoic anhydride have been investigated as a general route to α,β-unsaturated ketones having a silyl group attached to the carbon–carbon double bond. The reaction has been found to be generally applicable for acetyl derivatives provided low temperatures are used but the reaction with benzoic anhydride gives poorer results. The i.r. and u.v. spectra of the ketones are discussed. The characterization of novel 1,4-dienes obtained as by-products in the syntheses is also described.

Les réactions d'une série de réactifs vinylmétalliques substitués par le silyle sur l'anhydride acétique et benzoique ont été étudiées comme voie générale d'accès aux cétones α,β insaturées avec un groupe silyle attaché à la double liaison carbone–carbone. La réaction est d'application générale pour les dérivés acétyles pourvu qu'on se place aux basses températures mais avec l'anhydride benzoique, cette réaction conduit à des résultats plus pauvres. Les spectres i.r. et u.v. des cétones ont été discutés. La caractérisation des dienes-1,4 nouveaux produits secondaires des synthèses, a été également donnée.

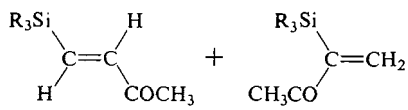
Can. J. Chem., **51**, 2024 (1973)

Some years ago several α,β-unsaturated ketones having a silyl group directly attached to the carbon–carbon double bond were synthesized by the hydrosilylation of an acetylenic ketone (1, 2). However, the reaction led to a mixture of α- and β-silylvinyl ketones which proved to be difficult to separate (eq. 1).

[1] $R_3SiH + HC{\equiv}CCOMe \longrightarrow$

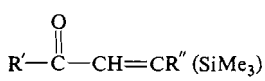


More recently Felix and Weber (3) described a different synthetic approach to β-silylvinyl ketones involving dehydrogenation of the saturated γ-ketosilanes (eq. 2). Another route recently

[2] $R_3SiCH_2CH_2COCH_3 \rightarrow R_3SiCH{=}CHCOCH_3$

used to prepare β-silylvinyl ketones and aldehydes involved the hydrolysis of silylallyl ethers (4) (eq. 3). It appeared to us that a more gen-

[3] $R{-}O{-}CR'{=}C{=}CR''(SiMe_3) \xrightarrow[H_2O]{H^+}$



erally applicable route to both α- and β-silyl isomers of this interesting class of compound would be through the coupling of silylvinylmetallic reagents with anhydrides, and the following deals with such couplings using acetic and benzoic anhydride.

Four previously described organometallic reagents were utilized: α-lithiovinyltriphenylsilane (**1**), (5), 1-lithio-1-triphenylsilyl-2-phenylethylene-*E* (**2**) (5), α-trimethylsilylvinylmagnesium bromide (**3**) (6), and β-trimethylsilylvinylmagnesium bromide (**4**) (6). All four reagents coupled with acetic anhydride to give the acetyl derivatives **1***a*, **2***a*, **3***a*, and **4***a* and the triphenylsilyl reagents, **1** and **2**, coupled with benzoic anhydride to give the benzoyl derivatives **1***b* and **2***b*. Using the optimum conditions for these preparations as described in Table 1, the yields varied from 30–80%. In general the couplings with acetic anhydride afforded reasonable yields, but the trimethylsilyl Grignard reagents, **3** and **4**, gave none of the expected benzoyl derivatives under any conditions attempted. All the α,β-unsaturated ketones obtained were stable to mild acidic or basic conditions and the volatile ketones **3***a* and **4***a* could be converted into 2,4-dinitrophenylhydrazones in good yield.

The reactions and the products formed are shown in Scheme 1.

The ketones were found to be very sensitive towards 1,4-addition reactions and in order to minimize further reactions during their preparation it was necessary to use low temperatures.

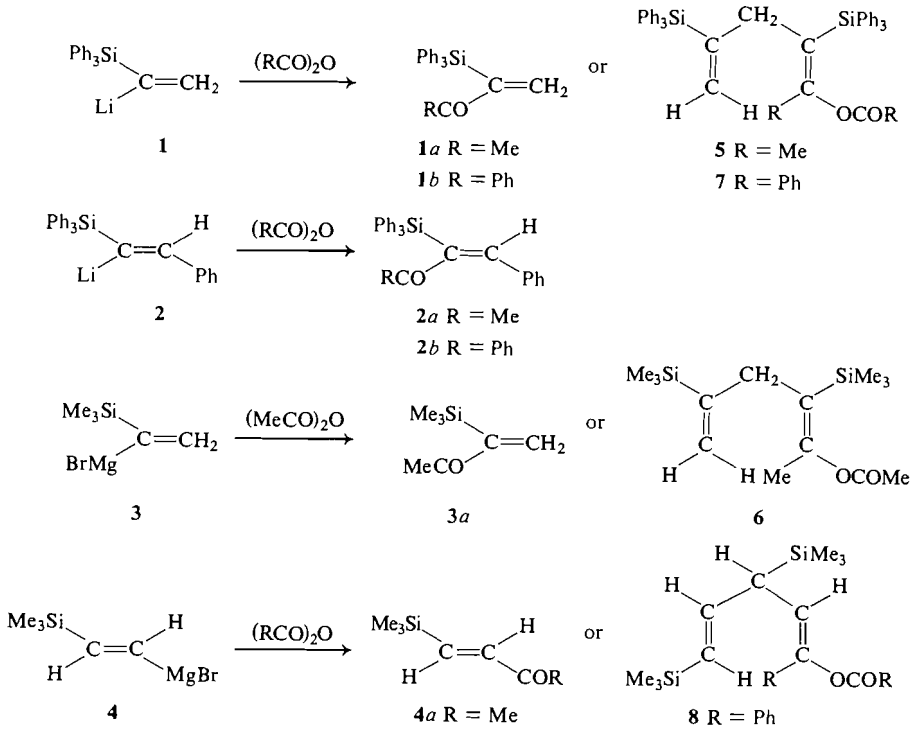
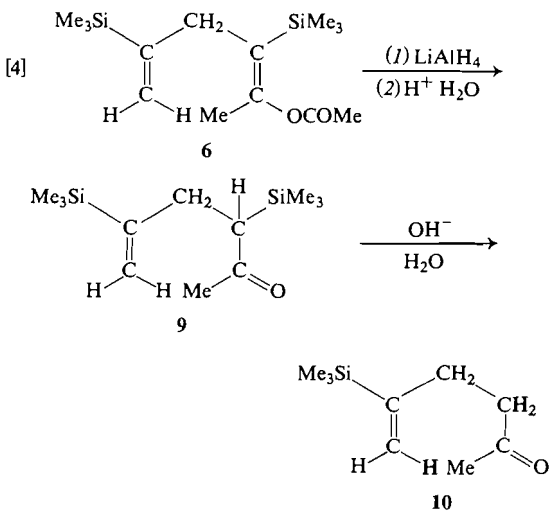


SCHEME 1. Reactions of silylvinylmetallic reagents with acid anhydrides.

The net result of these side reactions was the formation of 1,4-dienes. For example, treatment of α-lithiovinyltriphenylsilane with an excess of acetic anhydride at room temperature afforded a crystalline product (59% yield) along with a small amount of the α,β-unsaturated ketone. This product was assigned the structure **5**. The i.r. spectrum showed strong bands at 5.70 and 6.12 μ which are generally diagnostic of a vinyl acetate. The n.m.r. spectrum showed an aromatic multiplet (30H), two multiplets (each 1H) at δ 6.26 and 5.50 (vinyl protons), a similar multiplet (2H) at 2.95 attributable to the methylene group between two double bonds, and two singlets (each 3H) at 1.88 and 1.83 p.p.m. attributed to the two different methyl groups. The mass spectrum showed the expected parent ion at *m/e* 656. The geometry shown for the vinyl acetate double bond of **5** is assumed. Based on similar evidence, products from the reaction of **3** with acetic anhydride and **1** and **4** with benzoic anhydride were assigned structures **6**, **7**, and **8**, respectively (geometries assumed). The reaction thus appears to be general. As additional structural evidence **6** was subjected to the reactions shown in eq. 4.



Lithium aluminum hydride reduction followed by acid hydrolysis afforded the β-ketosilane **9** in high yield. This base-sensitive compound in aqueous alkaline dioxane gave the ketone **10** in 72% yield.

An obvious mechanism for the formation of these dienes is the 1,4-addition of the vinyl-

metallic reagent to the α,β-unsaturated ketone, in the normal manner, to give an enolate ion which is then acetylated or benzoylated by the remaining anhydride. To confirm this pathway 3-triphenylsilylbut-3-en-2-one (**1***a*) was treated with an equimolar amount of α-lithiovinyltriphenylsilane (**1**) at −78°. Hydrolysis gave the expected β-ketosilane **11** in high yield (see eq. 5).

[5] 
1 **1***a*

The important features of the i.r. and u.v. spectra of the α,β-unsaturated ketones are given in Tables 2 and 3. The carbonyl stretching wavelengths (5.93–6.05 μ) are normal for α,β-unsaturated ketones (typically 5.94–6.02 μ (7)), as previously noted by Felix and Weber (3) for a series of β-silylvinyl ketones. The shift to longer wavelength in the more polar solvent, acetonitrile, is also as expected (8).

The i.r. carbonyl band of β-ketosilanes is generally shifted to about 0.1 μ longer wavelength than that of their carbon analogs (9) (*e.g.* Me_3SiCH_2COMe, 5.89; Me_3CCH_2COMe, 5.82 μ). This effect, probably attributable to inductive release from silicon toward the carbonyl group, may not be as strongly pronounced in the α-silylvinyl ketones since the acetyl derivatives **1***a*–**4***a* absorb at very similar wavelengths.

Unfortunately only one of the six compounds prepared, **4***a*, showed a band (*ca.* 6.29 μ) which could be clearly assigned to a carbon–carbon double bond stretch. No similar band was observed in the α-isomer, **3***a*. Triphenylsilyl compounds in general have i.r. absorption at 6.28 μ and above, associated with the phenyl groups, which probably obscure the carbon–carbon double bond stretch in the four triphenylsilyl ketones.

Five of the six ketones prepared show a u.v. n → π* absorption band which shifts to shorter wavelength with increasing solvent polarity (Table 3). The two trimethylsilyl ketones **3***a* and **4***a* also show a π–π* band which shifts to longer wavelength with increasing solvent polarity. This shift, about 10 nm on changing from cyclohexane to water, is similar to that found in analogous carbon compounds (8).

Although the silyl-substituted α,β-unsaturated ketones undergo n–π* transitions at slightly lower energy than analogous carbon or unsubstituted compounds (typically 305–340 nm, ε 25–100) (7) the small effect is in marked contrast to the effect of direct silicon substitution at the carbonyl chromophore. For example, replacement of a methyl group of acetone by a triphenylsilyl group results in a lowering of the n → π* transition energy by about 26 kcal/mol. Effects of this magnitude (which would have resulted in a shift in λ_{max} from 320 to about 450 nm with silyl substitution) can definitely be ruled out for both α- and β-silylvinyl ketones.

It has been suggested (3) that the main effect of the β-silyl substituent on the n → π* transition of α,β-unsaturated ketones is in stabilizing the π* excited state. The similarity in the n → π* absorption of the α- and β-silyl isomers **3***a* and **4***a* tends to support this and confirms that direct conjugative interaction between the β-silicon atom and the carbonyl group is unimportant (eq. 6).

[6] $Si{-}C{=}C{-}C{=}O \nleftrightarrow \bar{S}i{=}C{-}C{=}C{-}\overset{+}{O}$

However, if lowering the π* level is the only significant effect of silyl substitution then one would predict similar π–π* absorption bands for **3***a* and **4***a*. This is clearly not the case. The π → π* band of the β-silylvinyl isomer, **4***a*, occurs at 13 nm longer wavelength (*ca.* 8 kcal/mol lower energy) and with a somewhat higher extinction coefficient, a result which is not inconsistent with conjugative interaction. It is also of interest to compare the π → π* bands of **3***a* and **4***a* in methanol (Table 3) with those of methyl vinyl ketone (λ_{max} (ethanol) 210), 3-methylbut-3-en-2-one (218), and pent-3-en-

2-one (220 nm)[1] (10). Whereas methyl substitution at the double bond causes moderate shifts to longer wavelength (8 nm for α and 10 nm for β) silyl substitution either causes a slightly greater increase (13 nm for β), or no increase at all in the transition wavelength.

To gain some insight into possible causes of these unexpected shifts we have carried out preliminary molecular orbital calculations of the CNDO/2 type (11) on the five model compounds, methyl vinyl ketone, 3-methylbut-3-en-2-one, *trans*-pent-3-en-2-one, and the silyl (*i.e.* SiH_3) analogs of the latter two compounds. Bond lengths were obtained from standard tables (12) and *S-trans* geometries were used. The important results are summarized, in a qualitative manner, in Fig. 1. As expected, each

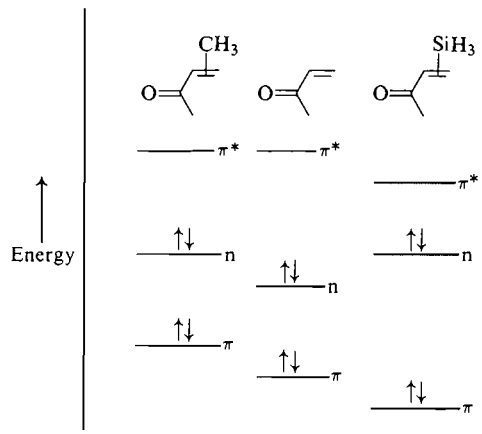

FIG. 1. Qualitative illustration of the results of CNDO calculations for silyl- and methyl-substituted α,β-unsaturated ketones.

compound showed an n-type orbital as the highest filled molecular orbital and a π-type orbital at somewhat lower energy. The lowest energy unfilled molecular orbital was also of the π-type and is designated as π*. The calculations showed a slight raising of the n level on substitution at the double bond with the effect being greatest, though still small, for the α-silyl compound. The π* level remained relatively unchanged with either α- or β-methyl substituents but with silyl substituents the π* energy was substantially lowered. These results are in accord with the observed longer n → π* transition wavelength in the silyl isomers. The effect of substitution on the π molecular orbital was somewhat unexpected. While methyl substitution caused a raising of the level silyl substitution resulted in an equally pronounced lowering of the energy. The predicted result on the π → π* transition are thus a bathochromic shift for the carbon-substituted ketones, as observed, while with the silyl ketones the net effect on the transition energy would depend on the relative amounts by which the π and π* levels were affected. Our calculations predicted a net bathochromic shift on silyl substitution (*i.e.* π* lowered more than π). However, it is reasonable to expect that these effects would depend to some extent on the position of the silyl substituent and the anomalous π → π* spectra of the silyl ketones could thus be explained by different degrees of interaction of an α- or β-silyl group with the π and π* orbitals.

The study of silyl-substituted α,β-unsaturated ketones is in an early stage at present and, in our opinion, more compounds, particularly suitable carbon and other Group IV analogs will be required before final conclusions may be drawn regarding their spectral properties. The present work has introduced a synthetic method which should serve to remedy the deficiency of compounds. Additionally, the demonstrated ease with which these compounds undergo 1,4-addition reactions has shown that they will be versatile intermediates in synthetic organosilicon chemistry.

Experimental

Experiments involving reactive organometallic reagents were carried out under nitrogen using dried, purified solvents. I.r. spectra were recorded on a Perkin–Elmer 237B instrument using 0.1 mm sodium chloride cavity cells. U.v. spectra were determined on Bausch and Lomb or Perkin–Elmer instruments in 10 mm silica cells for n → π* bands and 1 mm cells in the short wavelength region. N.m.r. spectra were determined on Varian A-60 or HR 100 instruments. Melting points were determined on a Fisher–Johns apparatus and are uncorrected.

Conditions of most runs, together with details of yields and analyses are summarized in Table 1.

*3-Triphenylsilylbut-3-en-2-one (**1a**)*

A solution of α-bromovinyltriphenylsilane (1.83 g, 5.0 mmol) in dry diethyl ether (75 ml) at room temperature was treated with 3.75 ml (6 mmol) of *n*-butyllithium in hexane (1.6 *M*). The resulting light yellow solution was stirred for 5 min then was cooled to *ca.* −78° using a Dry-Ice – acetone bath. Addition of acetic anhydride (0.944 ml, 10 mmol) to the resultant light-yellow suspension gave a fine white suspension. After 30 min at

[1]There is no significant difference between methanol and ethanol solvent as regards the π → π* transitions in α,β-unsaturated ketones (8).

−78° work-up with saturated aqueous ammonium chloride gave a thick oil which crystallized from 30 ml of pentane to give the desired product (1.35 g, 82%) as white solid, m.p. 112–115°. Recrystallization from hexane gave the analytical sample, m.p. 115–116°; n.m.r. (CCl_4) δ 6.27, 6.10 (2d, each 1H, J = 2 Hz) and 2.05 p.p.m. (s, 3H).

*2-Acetoxy-3,5-bis(triphenylsilyl)hexa-2,5-diene (**5**)*

When the above preparation was carried out at −20° a mixture (*ca.* 3:2, respectively) of the ketone **1***a* and compound **5** was obtained.

Addition of acetic anhydride to a solution of α-lithiovinyltriphenylsilane at room temperature gave a 59% yield of **5** on crystallization of the crude reaction product from pentane. Recrystallization from methylene chloride – methanol gave analytically pure material, m.p. 189–190°.

*α-Triphenylsilylvinyl Phenyl Ketone (**1***b*)*

To a solution of the organolithium reagent, prepared as above, from 0.92 g (2.5 mmol) of α-bromovinyltriphenylsilane in ether at −78° was added 0.68 g (3.0 mmol) of benzoic anhydride. After 30 min the resultant suspension was worked-up with saturated aqueous ammonium chloride solution to give an oil. The spectra of this oil indicated that a mixture of products was present. Chromatography on silica gel gave vinyltriphenylsilane (0.26 g, 36%) on elution with carbon tetrachloride. Elution with 1:1 benzene – carbon tetrachloride gave an oil (0.63 g) which was crystallized from hexane to give 0.41 g (42%) of the desired ketone, m.p. 116–120°. Recrystallization from hexane gave pure material, m.p. 120–121°; n.m.r. (CCl_4) δ 6.35, 6.21 p.p.m. (2d, J = 2 Hz).

*1-Benzoyloxy-1-phenyl-2,4-bis(triphenylsilyl)penta-1,4-diene (**7**)*

In a similar experiment to the above, the organolithium reagent from 0.45 g (1.23 mmol) of α-bromovinyltriphenylsilane was treated at −78° with benzoic anhydride (0.31 g, 1.35 mmol). The crude product obtained after work-up was crystallized from methylene chloride – methanol to give 0.18 g (38%) of compound **7**, m.p. 175–180°. Recrystallization from hexane gave the analytical sample, m.p. 175–177°; i.r. (CCl_4) 5.77, 6.26 μ (vinyl benzoate); n.m.r. (CCl_4) δ 6.33, 5.50 (2m, each 1H, C=CH_2), 3.25 p.p.m. (m, 2H, C=C—CH_2—C=C); mass spectrum 780 (2%, M), 303 (70%, $Ph_2SiOCOPh$), 259 (100%, Ph_3Si).

*3-Triphenylsilyl-4-phenylbut-3-en-2-one (**2***a*)*

1-Bromo-1-triphenylsilyl-2-phenylethylene-*Z* (13) (1.50 g, 3.4 mmol; prepared by dehydrobromination of 1,2-dibromo-1-triphenylsilyl-2-phenylethane with pyridine) in 50 ml of dry ether at room temperature was treated with *n*-butyllithium (4 mmol). The resultant deep yellow solution was cooled to −78° and then was treated with acetic anhydride (0.82 ml, 8.0 mmol) to give a fine gelatinous suspension. Work-up after 30 min with ammonium chloride solution gave a thick clear oil which was crystallized from hexane to give 0.91 g (67%) of the desired ketone, m.p. 127–128°; n.m.r. (CCl_4) δ 6.90 (s, 1H, C=CH—) and 1.80 p.p.m. (s, 3H, CH_3CO—).

*α-Triphenylsilylbenzalacetophenone (**2***b*)*

Using the same molar quantities as above, and identical conditions, treatment of the organolithium reagent from **2** with benzoic anhydride gave a complex mixture of products. Crystallization of the crude product from ethanol gave 0.71 g (58%) of *trans*-β-triphenylsilylstyrene. The residual product was chromatographed on silica gel. Elution with 1:1 benzene – carbon tetrachloride gave an oil (0.61 g) which was crystallized from hexane to give 0.46 g (29%) of the required ketone, m.p. 117–119°. Recrystallization from hexane gave m.p. 120–121°, n.m.r. δ 7.0–7.9 p.p.m. (aromatic multiplet).

*4-Trimethylsilylbut-3-en-2-one (**4***a*)*

The Grignard reagent prepared from 16.1 g (0.09 mol) of β-bromovinyltrimethylsilane and magnesium (2.43 g, 0.1 g atom) in 300 ml of tetrahydrofuran was cooled to *ca.* −120° in a liquid nitrogen – methylcyclohexane slush bath. The solution was treated (all at once) with 30.6 g (28.4 ml; 0.3 mol) of acetic anhydride. After 5 min the resultant suspension was allowed to warm up, and then was diluted with ether and worked-up. The organic layer was thoroughly washed with sodium bicarbonate solution to remove acetic acid and excess anhydride, was dried ($MgSO_4$) and then was distilled to a head temperature of 105°. The residue, 10.55 g of light yellow liquid, contained some THF and unidentified material along with the desired α,β-unsaturated ketone. G.l.p.c. analysis of the solution indicated a yield of *ca.* 66%. Pure samples of the ketone were obtained by preparative g.l.p.c. using a 5 ft. × ¼ in. column of 20% SE 30 on Chromosorb W (oven temperature 95°). The pure ketone was a colorless mobile liquid with a pleasant camphoraceous odor, n_D^{21} 1.4480; i.r. (CCl_4) 10.08 μ; n.m.r. (CCl_4) δ 6.89 and 6.40 (J = 19.5 Hz, CH=CH, AB pattern), 2.20 (s, 3H, CH_3CO—), 0.14 p.p.m. (s, 9H, Me_3Si). The large coupling constant between the vinylic protons and the presence of a band at 10.08 μ in the i.r. spectrum indicate that the ketone has *trans*-stereochemistry.

A sample of the purified ketone (0.10 g) was dissolved in dimethyl sulfoxide (10 ml) containing 0.16 g of 2,4-dinitrophenylhydrazine and one drop of concentrated hydrochloric acid. A precipitate formed, and after 5 min methanol was added to give 0.16 g of an orange solid. Recrystallization from methylene chloride – methanol gave the pure dinitrophenylhydrazone (0.14 g, 66%), m.p. 171–172°; n.m.r. ($CDCl_3$) δ 6.81, 6.51 (AB, J = 19.5 Hz, 2H) 2.18 (s, 3H, CH_3C=N—), and 0.22 p.p.m. (s, 9H, Me_3Si).

*1-Benzoyloxy-1-phenyl-3,5-bis(trimethylsilyl)penta-1,4-diene (**8**)*

A solution of the Grignard reagent, prepared from 5.37 g (0.03 mol) of β-bromovinyltrimethylsilane and 0.80 g (0.033 g atom) of magnesium in THF (100 ml), at *ca.* −78°, was treated with benzoic anhydride (6.80 g, 0.03 mol). After 30 min the resultant white suspension was warmed to room temperature and was worked-up as above by adding ether, and then washing in succession with ammonium chloride and sodium bicarbonate solutions. Removal of solvent at reduced pressure gave an oil which was chromatographed on silica gel, eluting with 1:1 benzene – carbon tetrachloride, to give the compound **8**, as a clear thick oil (2.51 g, 59%). This product

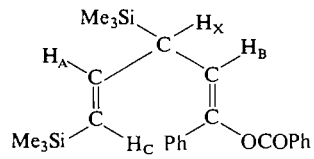
For personal use only.

was air sensitive, turning yellow on standing. A sample was distilled (190°/0.2 mm Hg, Kugelrohr); mass spectrum 408 (1%, M), 303 (6.5%, M − PhCO), 105 (70%, PhCO), 73 (100%, Me_3Si); i.r. (CCl_4) 5.75, 6.25 μ (C=O and C=C of a vinyl benzoate); n.m.r. (CCl_4, 100 MHz, see structure below) δ 6.06 (H_A), 5.93 (H_B), 5.54 (H_C),



2.92 (H_X) (J_{AX} = 7.4, J_{BX} = 11.4, J_{CX} = 1.2, J_{AC} = 19.6, J_{AB} = J_{BC} = 0 Hz), 0.06 p.p.m. (s, 18H, $2Me_3Si$).

3-Trimethylsilylbut-3-en-2-one (3a)

The Grignard reagent prepared from α-bromovinyltrimethylsilane (27.9 g, 0.15 mol) and magnesium (4.03 g, 0.16 g atom) in THF (275 ml) was diluted with ether (175 ml) and the solution was cooled to *ca.* −120° in a liquid nitrogen – methylcyclohexane slush bath. To the rapidly stirred suspension was added 71.2 g (67 ml; 0.60 mol) of acetic anhydride. After 5 min the mixture was warmed to room temperature and was worked-up as above using ammoniun chloride and sodium bicarbonate solutions. Distillation of the organic layer to a head temperature of 100° gave 33.6 g of light yellow residue. An n.m.r. spectrum indicated that this liquid contained a 1:1 mixture of the desired ketone and the diene, **6**. A similar experiment carried out at −78° gave a 1:4 mixture of ketone and diene respectively.

The volatile product was pumped (25°/0.1 mm) into a Dry-Ice – acetone trap to give 7.7 g of light yellow liquid. This liquid was estimated (by g.l.p.c.) to contain 82% of the desired ketone along with three minor unidentified contaminants. The approximate yield of ketone is thus 29%.

The ketone was purified by preparative g.l.p.c. using the conditions described above for its isomer. The pure compound, a faintly yellow, pleasant-smelling liquid, n_D^{21} 1.4396, boiled at 140° (760 mm) with decomposition. It also decomposed slowly at room temperature but was stable at −20° in the dark. N.m.r. (CCl_4) δ 6.54 and 6.22 (2d, each 1H, J = 2 Hz, C=CH_2), 2.31 (s, 3H, CH_3CO), 0.19 p.p.m. (s, 9H, Me_3Si).

A sample of the impure ketone (0.71 g; 82%) was dissolved in DMSO (10 ml) containing 2,4-dinitrophenylhydrazine (1.0 g) and one drop of concentrated hydrochloric acid. The 0.68 g of product was purified by chromatography on silica gel, m.p. 163–164°; n.m.r. (CCl_4) δ 6.24, 5.95 (2d, each 1H, J = 1.5 Hz), 2.20 (s, 3H, CH_3CO), 0.26 p.p.m. (s, 9H, Me_3Si).

2-Acetoxy-3,5-bis(trimethylsilyl)hexa-2,5-diene (6)

The less volatile product in the above preparation was distilled (120°/0.3 mm; Kugelrohr) to give the pure diene as an oil, n_D^{22} 1.4616; i.r. (liquid film) 5.70, 6.09 μ (C=C—O—$COCH_3$); n.m.r. (CCl_4) δ 5.42, 5.25 (2m, each 1H, C=CH_2), 2.75 (m, 2H, C=C—CH_2—C=C), 2.01 and 1.95 (2s, each 3H, MeC=C and MeC=O), 0.11 and 0.06 p.p.m. (2 s, each 9H, 2 Me_3Si); mass spectrum 284 (1%, M), 169 (13%, M − Me_3Si), 73 (100%, Me_3Si), 43 (19%, MeCO).

Degradation of 2-Acetoxy-3,5-bis(trimethylsilyl)hexa-2,5-diene (6)

(A) To 3,5-Bis(trimethylsilyl)hex-5-en-2-one (9)

A solution of **6** (14.2 g, 0.05 mol) in diethyl ether (100 ml) containing lithium aluminum hydride (1.14 g, 0.03 mol) was heated to reflux for 30 min. The resultant suspension was cautiously worked-up with a slurry of ice and ammonium chloride. Hydrochloric acid (10%) was added to dissolve the aluminum salt and the organic layer was separated, dried, and distilled to give 11.1 g (92%) of pure β-ketosilane **9**, n_D^{22} 1.4600; i.r. (film) 5.89 μ (C=O, β to Si); u.v. (cyclohexane) λ_{max} 285 nm (ε 92); n.m.r. (CCl_4) δ 5.42 and 5.23 (2m, each 1H, C=CH_2), 1.9 (s, 3H, CH_3CO), 0.04 (s, 18H, 2 Me_3Si), 2–3 p.p.m. (complex, 3H, CH_2—CH); mass spectrum 242 (12%, M), 73 (100%, Me_3Si) 43 (10%, CH_3CO).

Anal. Calcd. for $C_{12}H_{26}OSi_2$: C, 59.43; H, 10.81. Found: C, 59.64; H, 10.91.

(B) 5-Trimethylsilylhex-5-en-2-one (10)

A solution of 9.2 g of 3,5-bis(trimethylsilyl)hex-5-en-2-one (**9**, above) in dioxane (50 ml) – water (10 ml) was treated with 0.5 g of potassium hydroxide. The resultant solution was stirred at room temperature for 20 min and then was diluted with ether (3 vol) and was worked-up with dilute hydrochloric acid. The organic layer was dried and distilled to give pure 5-trimethylsilylhex-5-en-2-one (**10**), (5.02 g, 78%), b.p. 80.5°/10 mm; n_D^{20} 1.4460; i.r. (CCl_4) 5.81 μ (C=O); u.v. (cyclohexane) λ_{max} 281 nm (ε 27); n.m.r. (CCl_4) δ 5.53 and 5.34 (2m, each 1H, C=CH_2), 2.45 (m, 4H,—CH_2—CH_2—), 2.10 (s, 3H, CH_3CO), 0.10 p.p.m. (s, 9H, Me_3Si).

Anal. Calcd. for $C_9H_{18}OSi$: C, 63.47; H, 10.65. Found: C, 63.30; H, 10.68.

3,5-Bis(triphenylsilyl)hex-5-en-2-one (11)

A solution of α-bromovinyltriphenylsilane (1.83 g, 5 mmol) in diethyl ether (50 ml) at room temperature was treated with 3.44 ml (5.5 mmol; 1.6 *M*) of *n*-butyllithium. After 20 min the solution was cooled to *ca.* −78° and 1.64 g (5 mmol) of 3-triphenylsilylbut-3-en-2-one (**1a**) was added. The resultant suspension was worked-up with saturated ammonium chloride solution after 5 min to give a glass. Crystallization from hexane gave the required product as white needles, m.p. 131–133° (2.06 g, 67%). Several recrystallizations from hexane and methylene chloride – methanol raised the m.p. to 138–140°; i.r. (CCl_4) 5.90 μ (C=O β to Si); n.m.r. (CCl_4); 100 MHz) δ 5.97 and 5.60 (2m, each 1H, C=CH_2), 3.6–2.5 (m, 3H, CH_2—CH), 1.60 p.p.m. (s, 3H, CH_3CO).

Anal. Calcd. for $C_{42}H_{38}OSi_2$: C, 82.03; H, 6.23. Found: C, 81.92; H, 6.15.

Effect of Pressure on the Rates of Reaction of Hydrogen Atoms in the Radiolysis of Liquid Ethanol[1]

KAMAL N. JHA AND GORDON R. FREEMAN
Chemistry Department, University of Alberta, Edmonton, Alberta T6G 2G2

Received December 28, 1972

Competition between the reactions

[3] $$H + C_2H_5OH \rightarrow H_2 + CH_3CHOH$$

and

[5] $$H + S \rightarrow HS$$

was measured at 296 *K* at 1 bar and 5.4 kbar. Values of k_5/k_3 at 1 bar and $(\Delta V_5^* - \Delta V_3^*)$ averaged between 1 bar and 5.4 kbar for several solutes S are: cyclohexene, 56, +2.7 cm³/mol; hexene-1, 71, +2.6 cm³/mol; phenol, 25, −3.8 cm³/mol; benzene, 12, −6.5 cm³/mol. The volume of activation of hydrogen atom addition to the aromatic ring is about 8 cm³/mol more negative than that of addition to a mono-olefin. Rate constants of reaction of solvated electrons with these solutes at 295 K, measured by the pulse-radiolysisspectroscopy technique, are (M^{-1} s^{-1}): cyclohexene, $<1 \times 10^4$; hexene-1, 1×10^5; benzene, 4×10^6; phenol, 5×10^7. The phenol reaction with e^-_{solv} does not reduce the hydrogen yield by a proportionate amount, so phenol "catalyses" the decomposition of e^-_{solv} to form hydrogen, perhaps via $C_6H_5OH^-_{solv} \rightarrow C_6H_5O^-_{solv} + H$. The scavenging of hydrogen precursors by hexene-1, benzene, and aniline in *n*-hexane, reported in ref. 6, had $(\Delta V^*_{scavenging} - \Delta V^*_{H_2formation}) = 0, -6$, and -4 cm³/mol, respectively, all three of which may be attributed to hydrogen atom reactions. The yields of hydrogen from solutions of neohexane in cyclopentane at 1 bar and 5.4 kbar indicate that charge transfer occurs from cyclopentane to neohexane, and that the probability of charge transfer is independent of pressure. The methane yields from these solutions indicate that the decomposition of the neohexane ion formed by charge transfer from cyclopentane, to form methane, is inhibited by pressure.

La compétition entre les réactions

[3] $$H + C_2H_5OH \rightarrow H_2 + CH_3CHOH$$

et

[5] $$H + S \rightarrow HS$$

a été mesurée à deux pressions, 1 bar et 5.4 kbar, à 296 K. Le rapport k_5/k_3 a 1 bar, et la difference moyenne des volumes d'activation $(\Delta V_5^* - \Delta V_3^*)$ entre 1 bar et 5.4 kbar, pour plusieurs solutés S ont des valeurs respectivement: cyclohexane, 56, +2.7 cm³/mol; hexène-1, 71, +2.6 cm³/ml; phénol, 25, −3.8 cm³/mol; benzène, 12, −6.5 cm³/mol. La difference entre les volumes d'activation pour l'addition d'un atome H à un noyau aromatique et à un oléfine simple est: $(\Delta V^*_{arom} - \Delta V^*_{olef}) \approx -8$ cm³/mol. Les constantes de vitesse en M^{-1} s^{-1} des réactions e^-_{solv} + S, à 295 K, mesurées par la méthode radiolyse-spectroscopie-pulsée, sont: cyclohexène, $<1 \times 10^4$; hexène-1, 1×10^5; benzène, 4×10^6; phénol, 5×10^7. La réaction e^-_{solv} + phénol ne reduit que peu le rendement d'hydrogène; peut être s'agit-il de la réaction $C_6H_5OH^-_{solv} \rightarrow C_6H_5O^-_{solv} + H$. Les réactions des précurseurs d'hydrogène avec l'hexène-1, le benzène et l'aniline dans le *n*-hexane pour solvant, qui ont été signalées au rèf. 6, ont pour $(\Delta V^*_{scavenging} - \Delta V^*_{H_2formation})$ des valeurs de 0, −6, et −4 cm³/mol, respectivement; ces trois valeurs sont attribuées aux réactions de l'hydrogène atomique. Les variations des rendements d'hydrogène et de méthane obtenus pour des solutions de néohexane dans le cyclopentane, aux pressions de 1 bar et 5.4 kbar sont expliquées par le transfert de charge du cyclopentane au néohexane. La probabilité de transfert de charge ne change pas avec la pression, mais la probabilité de décomposition de l'ion néohexane produit par ce transfert diminue quand la pression augmente.

Can. J. Chem., **51**, 2033 (1973)

Introduction

The study of the effect of pressure upon the behavior of radiolysis intermediates in liquids is being pursued in several laboratories (1–10). The results obtained from such work in hydrocarbons indicate that the ease of scavenging electrons (6, 7) and hydrogen atoms (6) is independent of pressure, while the ease of scavenging positive ions appears to increase with increasing pressure (6, 7). Benzene and aniline were thought to be positive ion scavengers in *n*-hexane (6). These

solutes also scavenge hydrogen atoms (11–14) so it is necessary to obtain more information about their reactions with radiolytic species.

Ethanol was chosen as solvent because much is known about the behavior of electrons in it (10) and also because studies can be carried out in both neutral and acidic media. The advantage of strongly acidic solutions is that solvated electrons are rapidly converted into hydrogen atoms, resulting in a convenient medium to study hydrogen atom reactions.

It has been shown that the efficiencies of a variety of hydrogen atom reactions in water increase with increasing pressure (15).

Experimental

Absolute Ethanol from U. S. Industrial Chemical Co. was used. A u.v. spectroanalysis of the alcohol in a 10 cm cell indicated that the concentrations of probable impurities such as carbonyl compound and benzene were $< 1 \times 10^{-5}$ *M*.

Phillips Research Grade hexene-1, cyclohexene, and benzene were stirred with sodium–potassium alloy under vacuum for about 40 h to remove electron-scavenging impurities, then distilled into evacuated ampoules, sealed off, and stored in the dark. These ampoules were opened just prior to use to avoid peroxide formation. Analytical Reagent Grade phenol from B.D.H. Chemicals was mainly used as received because the purification by directional freezing and zone melting did not change the results of either the conventional scavenging or the pulse radiolysis experiments. Phillips Research Grade cyclopentane and neohexane (2,2-dimethylbutane) were purified by the sulfuric acid method described earlier (4). Baker and Adamson Analytical Reagent Grade perchloric acid (mole ratio $HClO_4/H_2O = 1/2$) was used as received.

The techniques used for steady state radiolysis and product analysis have been described elsewhere (1, 6, 10). Irradiation was performed at 296 K with a ^{60}Co γ source at a dose rate of 1×10^{17} eV/g min in ethanol. The dose was 2×10^{18} eV/g.

Rate constants for several reactions of solvated electrons were measured by pulse radiolysis. Solutions were deoxygenated by bubbling with ultrapure argon and irradiated with 0.1 μs pulses of 1.7 MeV electrons. The pulse dose was 3×10^{16} eV/g. The decay half life $t_{1/2}$ of the optical absorption signal at 680 nm was measured for several concentrations of each solute. A plot of $(0.693/t_{1/2})$ was made against solute concentration and the rate constant taken from the slope (16).

Results

Ethanol Solvent

The yield of hydrogen from neutral ethanol was $G(H_2) = 5.2$ at 1 bar and 5.7 at 5.4 kbar, in satisfactory agreement with previously reported values, 5.0 and 5.5, respectively (10).

Ethanol containing 0.10 *M* perchloric acid gave $G(H_2) = 6.1$ at 1 bar and 6.0 at 5.4 kbar.

Yields from the scavenging studies were based on the energy initially absorbed in the solvent only: $g(H_2) = G(H_2)/\varepsilon_s$, where ε_s is the electron fraction of solvent, including the acid when present. A correction was made for hydrogen produced by the direct radiolysis of hexene-1 and cyclohexene in the solutions, using $G(H_2) = 0.8$ (6) and 1.2 (17), respectively. The hydrogen yields from the direct radiolysis of benzene and phenol are so low that no correction was necessary (18).

The decreases in the hydrogen yield, $\Delta g(H_2)$, plotted against the molar concentrations of hexene-1 and cyclohexene in neutral ethanol at 1 bar and 5.4 kbar are shown in Fig. 1. The efficiency of scavenging hydrogen precursors by the olefins decreases with increasing pressure. The efficiency of hexene-1 is slightly higher than that of cyclohexene at both 1 bar and 5.4 kbar.

Figure 2 displays $\Delta g(H_2)$ as functions of benzene and phenol concentrations in neutral ethanol. At high solute concentrations the scavenging efficiencies of the aromatics increase slightly with increasing pressure, although there appears to be a cross-over at low concentrations.

The cross-over of the scavenging curves in Fig. 2 might be due to the participation of two intermediates, such as solvated electrons and hydrogen atoms. Solvated electrons were removed from the competition by rapidly converting them to hydrogen atoms with 0.1 *M* perchloric acid. The effects of benzene and phenol on the hydrogen yields from the acidic solutions are shown in Fig. 3. The scavenging efficiencies of the aromatics increase with pressure at all concentrations. The cross-over was therefore removed

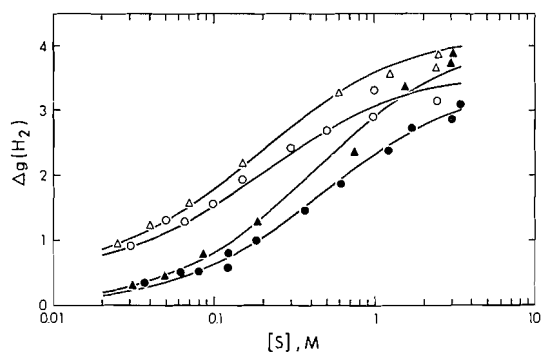

FIG. 1. Decrease in hydrogen yield $\Delta g(H_2)$ from neutral ethanol caused by hexene-1 (△) and cyclohexene (○). Open points, 1 bar; closed points, 5.4 kbar. [S] represents the solute concentration. The curves were calculated from eq. 7.

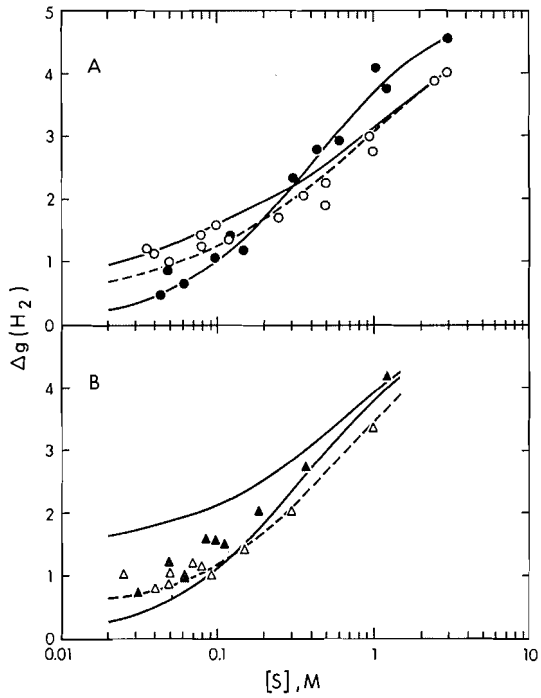

FIG. 2. Decrease in hydrogen yield $\Delta g(H_2)$ from neutral ethanol caused by benzene (○) and phenol (△). Open points, 1 bar; closed points, 5.3 kbar. [S] represents the solute concentration. The full curves were calculated using the rate constants and ratios in Tables 1 and 3. The dashed curves refer to 1 bar and the ratios in Table 3, but use $k_4' = 1 \times 10^6\ M^{-1}\ s^{-1}$ for benzene and $1 \times 10^5\ M^{-1}\ s^{-1}$ for phenol.

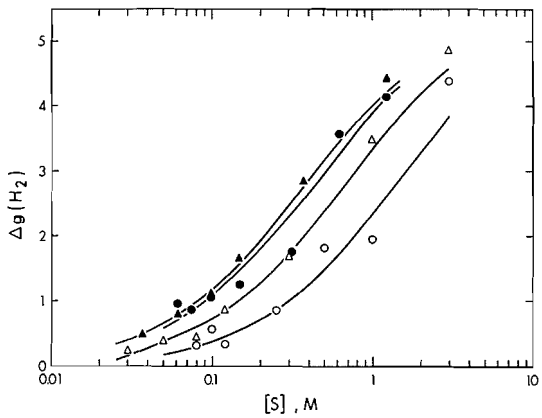

FIG. 3. Decrease in hydrogen yield from acidic ethanol (0.10 M perchloric acid) caused by benzene (○) and phenol (△). Open points, 1 bar; closed points, 5.4 kbar. The curves were calculated from eq. 7.

by the addition of acid, and the remaining $\Delta g(H_2)$ may be attributed to hydrogen atom scavenging.

Olefins could not be used in acidic solutions due to their reactivity with acid.

The values of the rate constants of reaction of solvated electrons with the solutes used in this work were measured by the pulse radiolysis technique, and are listed in Table 1.

Cyclopentane Solvent

The scavenging efficiency of benzene in acidic ethanol increased with increasing pressure (Fig. 3). The same effect in *n*-hexane solvent was attributed to positive charge scavenging (6). An attempt was therefore made to obtain more information about the effect of pressure on the efficiency of charge transfer in liquids.

The yields of hydrogen and methane from the radiolysis of certain saturated hydrocarbon binary solutions deviate from the values "expected" on the basis of the electron fractions of the components (19–22). The deviation has been attributed to charge transfer occurring from the component with the higher ionization potential (I.P.) to the one with the lower I.P. To study the effect of pressure on such systems the yields of hydrogen and methane from solutions of neohexane (2,2-dimethylbutane, I.P. = 10.04 eV (23)) in cyclopentane (I.P. = 10.52 eV (23)) were measured at 1 bar and 5.4 kbar. The yields of hydrogen and methane from pure cyclopentane were not affected by pressure, but those from pure neohexane decreased by 18% and 27%, respectively, when the pressure was increased from 1 bar to 5.4 kbar (Table 2).

Charge transfer from cyclopentane to neohexane would decrease the hydrogen yield and increase that of methane relative to those expected on the basis of the electron fractions of the components of the solution (19, 22). Thus, if charge transfer occurs, $\Delta G = (G_{expected} - G_{observed})$ should be positive for hydrogen and negative for methane. The numbers in parentheses in Table 2

TABLE 2. H_2 and CH_4 yields obtained from cyclopentane/neohexane solutions at 296 K

	$G(H_2)$		$G(CH_4)$	
ϵ_{NH}*	1 bar	5.4 kbar	1 bar	5.4 kbar
0.00	5.1	5.1	0.03	0.03
0.20	3.88(+0.76†)	3.74(+0.80†)	0.51(−0.16†)	0.28(−0.02†)
0.41	3.44(+0.72†)	3.28(+0.68†)	1.12(−0.43†)	0.53(−0.02†)
1.00	2.81	2.31	1.64	1.20

*ϵ_{NH} = electron fraction of neohexane.
†$\Delta G = (G_{expected} - G_{observed})$, where $G_{expected} = (G_{CP}\epsilon_{CP} + G_{NH}\epsilon_{NH})$, and G_{CP} and G_{NH} represent the product yields from pure cyclopentane and neohexane, respectively.

are ΔG values. The hydrogen yields indicate that charge transfer occurs from cyclopentane to neohexane and that the probability of the reaction is independent of pressure. The methane yields also indicate that charge transfer occurs at 1 bar but $\Delta G(CH_4)$ is very small at 5.4 kbar. High pressure therefore inhibits either the formation of the methane precursor ion by charge transfer, or the decomposition of that ion ($\Delta V^{\ddagger}_{decomposition} - \Delta V^{\ddagger}_{deactivation} \approx 14 \pm 3$ cm^3/mol).

The effects of benzene and aniline on the hydrogen yields from *n*-hexane at high and low pressures (6) were similar to those of benzene and phenol on the yields from acidic ethanol (Fig. 3). It therefore seems probable that the aromatics scavenged hydrogen atoms, rather than positive charge, in *n*-hexane.

Discussion

Neutral Ethanol

The mechanism of hydrogen formation in the γ radiolysis of liquid ethanol can be represented as follows (10, 24).

[1] $C_2H_5OH \rightsquigarrow e^-_{solv}, H^+_{solv}, H$, radicals

[2] $e^-_{solv} \rightarrow C_2H_5O^-_{solv} + H$

[3] $H + C_2H_5OH \rightarrow H_2 + CH_3CHOH$

Reaction 1 represents the situation after geminate neutralization is complete, so e^-_{solv} and H^+_{solv} here represent only the free ions.

In the presence of a trace of electron scavenger, such as the acetaldehyde produced during radiolysis (24, 25), some of the free ion solvated electrons are scavenged and do not produce hydrogen.

[4] $e^-_{solv} + S \rightarrow S^-_{solv} \rightarrow$ no H or H_2

A trace of scavenger has much less effect at high than at low pressures because the value of the ratio k_4/k_2 decreases rapidly with increasing pressure. The value of k_4/k_2 is nearly two orders of magnitude smaller at 5.4 kbar than that at 1 bar (10), which explains why $G(H_2)$ is larger at the high than at the low pressure.

Hexene-1 and Cyclohexene in Neutral Ethanol

Mono-olefins scavenge hydrogen atoms (13, 26, 27). They do not react to an appreciable extent with solvated electrons in the ethanol system (Table 1). Thus, in the hexene-1 and cyclohexene solutions reactions 5 and 6 compete with reaction 3.

[5] $H + S \rightarrow SH$

[6] $H + S \rightarrow H_2 + R'$

where S represents a solute, in this case an olefin.

The curves in Fig. 1 were calculated from eq. 7.

$$[7] \quad \Delta g(H_2) = \Delta g(H_2)_{max}\left\{1 + \frac{k_3[C_2H_5OH]}{(k_5 + k_6)[S]}\right\}^{-1}$$

The values of $\Delta g(H_2)_{max}$ and $(k_5 + k_6)/k_3$ were obtained from plots of $\{\Delta g(H_2)\}^{-1}$ against $\{[C_2H_5OH]/[S]\}$, such as those in Fig. 4, and are listed in Table 3. Probable errors in values of $\Delta g(H_2)_{max}$ are ± 0.1, and in the rate constant ratios are $\pm 10\%$.

The values of $\Delta g(H_2)_{max}$ are larger at 5.4 kbar than at 1 bar because the acetaldehyde impurity prevents some of the hydrogen atoms from forming at 1 bar, due to competition between [2] and [4]. The impurity has a negligible effect on the hydrogen yield at 5.4 kbar, where the loss of electrons through [4] is small (10).

Estimates of k_6/k_5 were obtained by assuming that $k_6/k_5 = 0$ for benzene and putting the total scavengable hydrogen atom yield equal to the value of $\Delta g(H_2)_{max}$ obtained with benzene (see later). Hence,

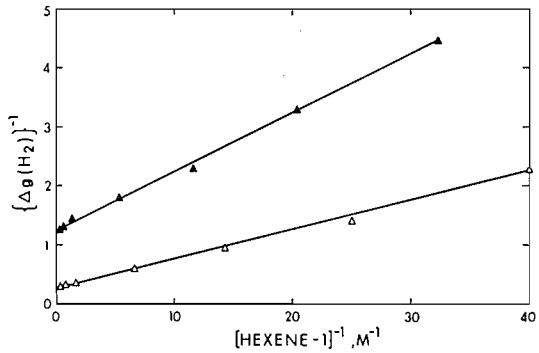

FIG. 4. Plots of $\Delta g(H_2)^{-1}$ against [hexene-1]$^{-1}$ for neutral ethanol (eq. 7). △, 1 bar; ▲, 5.4 kbar (▲ displaced vertically by 1.0 unit for clarity).

$$[8] \quad k_6/k_5 = \frac{\Delta g(H_2)_{max}^{\text{benzene}} - \Delta g(H_2)_{max}^{\text{olefin}}}{\Delta g(H_2)_{max}^{\text{olefin}}}$$

where $g(H_2)_{max}^{\text{benzene}} = 4.7$ at 1 bar and 5.2 at 5.3 kbar. The value $k_6/k_5 = 0.27$ obtained for hexene-1 in ethanol (Table 3) agrees with the value 0.31 reported by Hardwick for hexene-1 in *n*-hexane (27), but the value 0.52 for cyclohexene in ethanol is double the 0.23 reported for cyclohexene in *n*-hexane (27). There are not sufficient data to speculate about the reason for the difference.

The values of rate constant ratios at two pressures were substituted into eq. 9 to obtain the differences in the volumes of activation $\Delta V^{\ddagger}$ of competing reactions.

$$[9] \quad \log\frac{(k_a/k_b)_{P_1}}{(k_a/k_b)_{P_2}} = \frac{(P_2 - P_1)}{2.3RT}(\Delta V_a^{\ddagger} - \Delta V_b^{\ddagger})$$

where $(P_2 - P_1)/2.3RT = 0.095$ mol/cm^3 in the present work. One observes that $(\Delta V_5^{\ddagger} - \Delta V_3^{\ddagger}) \approx +2.7$ cm^3/mol and $(\Delta V_6^{\ddagger} - \Delta V_5^{\ddagger}) = 0$ for both olefins. The latter value is the same as that, $(\Delta V_{10}^{\ddagger} - \Delta V_5^{\ddagger}) = 0$, obtained for hexene-1 in *n*-hexane solvent (6).

$$[10] \quad H + n\text{-}C_6H_{14} \rightarrow H_2 + C_6H_{13}$$

Benzene and Phenol in Acidic Ethanol

In acidic ethanol reactions 2 and 4 are replaced by [11].

$$[11] \quad e^-_{solv} + H^+_{solv} \rightarrow H$$

The results in Fig. 3 were plotted according to eq. 7. The value of $\Delta g(H_2)_{max}$ was taken as $[g(H_2)_0 - 0.5]$, where the unscavengable yield of 0.5 units was estimated from a reworking of earlier results for neutral ethanol (32), and is assumed to be the same in the acidic alcohol, independent of pressure. The values of $(k_5 + k_6)/k_3$ obtained from the plots are listed in Table 3.

Contrary to the behavior of the olefins, the scavenging efficiencies of the aromatic compounds increased with increasing pressure (Table 3). The volume of activation for hydrogen atom addition to benzene is 9 cm^3/mol more negative than that for addition to cyclohexene. The reason for such a difference is not obvious, but the more negative value is associated with the lower rate constant, and more negative volumes of activation are usually associated with more negative entropies of activation (28).

Earlier results (6) may be analysed to obtain $(\Delta V^{\ddagger}_{\text{scavenging}} - \Delta V^{\ddagger}_{H_2\text{formation}})$ in *n*-hexane solvent. The values obtained for several scavengers are listed in Table 4. The difference between hexene-1 and benzene in *n*-hexane is similar to that in ethanol. The present results might indicate that the negative volumes of activation of the benzene and aniline reactions in *n*-hexane were at least partly due to hydrogen atom scavenging, rather than to positive charge reactions as suggested earlier (6).

Benzene and Phenol in Neutral Ethanol

Benzene and phenol have been reported to react with electrons (11, 13) as well as with hydrogen atoms (12–14). An attempt was made to fit the results in Fig. 2, using the hydrogen atom rate constant ratios given in Table 3 and the solvated electron rate constants in Table 1. The total reduction in hydrogen yield was the sum of the yields of scavenged electrons and hydrogen atoms.

$$[12] \quad \Delta g(H_2) = g(e^-_{solv})_{scav} + g(H)_{scav}$$

When $g(e^-_{solv})_{scav}$ was smaller than the free ion yield g_{fi}, the former was calculated from eq. 13.

$$[13] \quad g(e^-_{solv})_{scav} = \left\{\frac{k_4[\text{impurity}] + k_4'[\text{solute}]}{k_2 + k_4[\text{impurity}] + k_4'[\text{solute}]}\right\} g_{fi}$$

At 1 bar, $k_2 = 1.2 \times 10^5$ s^{-1} (29), $k_4[\text{impurity}] = 5 \times 10^4$ s^{-1} and $g_{fi} = 1.7$ (10). The value of $k_4[\text{impurity}]$ was estimated from the observed $g(H_2) = 5.2$ from otherwise pure ethanol and $g(H_2)_0 = 5.7$.

When $g(e^-_{solv})_{scav}$ was greater than g_{fi}, the contribution from spur reactions was read from a

Scavenger	$\Delta V^{\ddagger}_{scav} - \Delta V^{\ddagger}_{H_2 formation}$ (cm^3/mol)
Carbon tetrachloride	0
Hexadiene-1,3	0
Hexene-1	0
Aniline	−4
Benzene	−6
Benzene in hexane containing 10 mol % ethanol	−9

*Calculated from data in ref. 6.

$g(N_2)$ *vs.* $[N_2O]$ curve (30), using $k(e^-_{solv} + N_2O) = 5 \times 10^9\ M^{-1}\ s^{-1}$ at 1 bar (31) and converting k_4'[solute] into appropriate values of $k(e^-_{solv} + N_2O)[N_2O]$.

Values of $g(H)_{scav}$ were calculated fror [14].

$$[14] \quad g(H)_{scav} = \left\{\frac{k_5[\text{solute}]}{k_3[C_2H_5OH] + k_5[\text{solute}] + k_6[\text{solute}]}\right\} \times g(H)_{max}$$

where $g(H)_{max} = [g(H_2)_0 - 0.5 - g(e^-_{solv})_{scav}]$.

The $\Delta g(H_2)$ curve calculated in the above manner for the phenol solutions at 1 bar was much too high (Fig. 2). To obtain reasonable agreement with the experimental results the value of k_4' had to be reduced by one to two orders of magnitude below that given in Table 1. The dashed curve in Fig. 2*B* was calculated using k_4' 50-fold smaller than the value in Table 1. Benzene showed similar behavior at 1 bar (Fig. 2*A*), but k_4' had to be reduced by a factor of only 2 to 4 to obtain reasonable agreement with experiment. This discrepancy between pulse radiolysis and competition kinetics behavior of phenol, and to a much lesser extent benzene, is not understood. Perhaps [15] occurs. Benzene remains anomalous.

$$[15] \quad C_6H_5OH^-_{solv} \rightarrow C_6H_5O^-_{solv} + H$$

It should be stated that postulation of reaction of quasifree (dry) electrons with phenol and benzene would make the above discrepancies worse.

At 5.3 kbar, hydrogen atom scavenging accounted for essentially all of $\Delta g(H_2)$. The high pressure curves in Fig. 2 were calculated by assuming electron scavenging to be negligible; it might have made some contribution in the phenol solutions (Fig. 2*B*).

Conclusions

$\Delta V^{\ddagger}$ for hydrogen atom addition to an aromatic ring is significantly more negative than that for hydrogen atom addition to a monoolefin.

The apparent rate of reaction of solvated electrons with phenol is much greater when measured by pulse radiolysis than when measured by kinetic analysis of hydrogen yields.

Gas Phase Reactions of Fluorine Atoms[1]

THOMAS LONG POLLOCK AND WILLIAM ERNEST JONES
Chemistry Department, Dalhousie University, Halifax, Nova Scotia

Received December 27, 1972

The rate of reaction of F atoms with a series of compounds, CH_4, CH_3F, CH_2F_2, CHF_3, $CHClF_2$, HCl, $CBrF_3$, NH_3, and PH_3 has been determined relative to the chemiluminescent reaction

$$F + NO + Ar \rightarrow FNO^* + Ar \rightarrow FNO + Ar + h\nu$$

by photometry. The fluorine atoms were produced in a flow system from the fluid mixing of molecular fluorine and nitric oxide diluted with argon.

La vitesse de réaction des atomes de fluor avec une série de composés, CH_4, CH_3F, CH_2F_2, CHF_3, $CHClF_2$, HCl, $CBrF_3$, NH_3, et PH_3, a été déterminée en ce qui a trait à la réaction de chemiluminescence suivante

$$F + NO + Ar \rightarrow FNO^* + Ar \rightarrow FNO + Ar + h\nu$$

par photométrie. Les atomes de fluor été produits dans un système à écoulement à partir d'un mélange fluide de fluor moléculaire et d'oxyde azotique dilué à l'aide d'argon.

[Traduit par le journal]

Can. J. Chem., **51**, 2041 (1973)

Introduction

There are few kinetic results available for the reactions of fluorine atoms. Absolute values have been measured for the H_2 (1–4), CH_4 (4, 5), CH_3I (6), CF_3I (6), CCl_4 (7–9), Cl_2 (10), HCl (4), and NO (11) reactions with fluorine atoms. Relative rate determinations by measurement of the total chemiluminescence of HF (12) and product analysis (13–17) have extended the range of compounds to C_1–C_5 alkanes (13, 14, 16) as well as the chlorinated C_1 and C_2 hydrocarbons and fluorocarbons (15–17). Complementing these determinations of the overall rate constants have been the studies designed to elucidate the relative populations of the various vibrational levels of the product HF (12, 18–21).

The reactivity of molecular fluorine and the absence of a simple method for determination of the concentration of fluorine atoms has led to the development of some exotic sources of fluorine atoms in an attempt to circumvent the production of molecular fluorine. These include the photolysis of heavy metal fluorides (4, 18) the electrodeless discharge of CF_4 or SF_6 (9, 12, 21) and the thermal dissociation of N_2F_4 followed by titration of NF_2 with active nitrogen to generate F atoms (2, 5, 10). In a similar vein, Cool and Stephens (22) utilized the fast reaction between molecular fluorine and nitric oxide at room temperature as a fluorine atom source

$$[1] \qquad F_2 + NO \rightarrow FNO + F$$

to initiate the first true chemical laser by fluid mixing. We have chosen to develop this method as a source of fluorine atoms since a subsequent reaction is the combination of F atoms with NO into an electronically excited manifold of FNO which may then decay by emission.

$$[2] \qquad F + NO \xrightarrow{M} FNO^*$$

$$[3] \qquad FNO^* \rightarrow FNO + h\nu$$

This means that the reaction is self-monitoring and photometry of the emission provides a measure of the fluorine atom concentration when the NO is in large excess. Addition of a compound RX capable of reacting with F will cause a decrease in the intensity of the emission proportional to the decrease in the concentration of F atoms thus providing a measure of the relative rates of reactions 2 and 7.

$$[7] \qquad F + RX \rightarrow XF + R$$

Experimental

The fast-flow apparatus consisted of a 40 mm Pyrex cylinder which the F_2 + Ar entered axially from a 10 mm tube while the NO or NO + reactant flowed into the F_2 atmosphere from twenty 0.5 mm jets situated normally to the axial flow (Fig. 1). Gas flows were controlled by needle valves and monitored by capillary flow meters.

[1]The research for this paper was supported by the Defence Research Board of Canada, Grant number 9530-115.

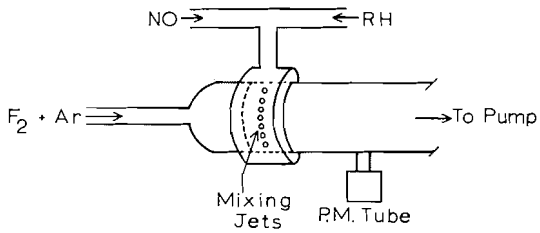

FIG. 1. Schematic of reaction vessel.

Calibrations were either by bleed-out rate from a known volume (NO and reactant) or a bubble flow meter (Ar and F_2). Nitrogen was used as the calibrating gas for the F_2 capillary and the ratio of their viscosities was used to determine the F_2 flow. The pressure in the reaction vessel was measured with a Kel-F 10 oil manometer at the outlet. The 250 l/min pump was protected from fluorine by a charcoal trap. Typical flow conditions were 300 μmol s^{-1} at 3.7 Torr argon which gave a linear velocity of 50 cm s^{-1}.

The photomultiplier tube (EMI 9592B) operating at e.h.t. 1050 V monitored the emission through a tube 8 mm i.d. × 6 cm long situated 5 cm from the mixing jets. The results reported were obtained with the photomultiplier tube positioned at the point of maximum luminosity, determined experimentally. The same results were obtained when the tube was 13 cm from the mixing jets.

Fluorine (Matheson) was supplied from a barricaded tank through thoroughly passivated copper tubing and an activated NaF trap to remove any HF via a Whitey 34RS metering valve to the flow capillary of the Pyrex vacuum system. Ar and H_2 (Canadian Liquid Air) were passed through a molecular sieves column. NO was introduced through supported NaOH at −78 °C. The reactant gases CH_4, CH_3F, CHF_3, $CHClF_2$, HCl, NH_3, PH_3, and $CBrF_3$ (Matheson) were thoroughly degassed and used without further purification as was CH_2F_2 (DuPont).

Purity checks were made on a gas chromatograph equipped with a Gow–Mac thermal conductivity cell and columns of 1/4 in. o.d. copper tubing packed with either 3% squalane on 60–80 mesh silica gel or 20% TCP on 60–80 mesh Gas–Chrom P.

Some samples were also analyzed by mass spectrometry and i.r. spectroscopy.

Results
