marked changes in going from atomic dispersion to bulk metal (7, 8). The difference between the work function of platinum metal (5.4 eV) and the first ionization potential of the atom (9.0 eV) reflects these electronic changes. Some part of the change between atomic and metallic properties might be expected to occur in the range of particle sizes 1 to 10 nm, as the diameter of the metallic atom is 0.27 nm. However we were not able to demonstrate any clear variation in specific rate coefficient solely with particle size. On examining the data from one set of catalysts (Fig. 5), it seemed that a clear particle size effect had been demonstrated. Unfortunately, when the data from the second set of catalysts was examined, they did not fall on the same curve, and it appeared that the fall in specific rate coefficient at higher sintering temperatures correlated better with the sintering temperature itself, rather than with the particle size produced at that temperature.

There is some indication that the maximum specific rate coefficient is lower for smaller particle sizes if the platinum black of McKee and Norton (22) may be taken as equivalent to a catalyst given only mild sintering. The films of Kemball (11) may be somewhat more ordered and are thus expected to give lower rate coefficients, as discussed below. However, the lower specific rate coefficients with smaller particle sizes may not, in fact, be real. We have previously noted (1) that on chemisorbing H_2 on platinum, the H to Pt ratio is somewhat greater than 1.0 for some very highly dispersed catalysts. In the present case it is about 1.2. The areas given are based on one H atom taken up per surface platinum atom. If more than one is taken up the measured areas will be too large and hence the specific rate coefficients too small. On the other hand, Coenen *et al.* (23) have noted a well defined maximum in the specific rate for hydrogenation of liquid benzene at a particle size of 1.2 nm. Particles smaller than this had a smaller specific rate.

In any case, we were not able to demonstrate any large variation in specific rate coefficients between catalysts receiving the same heat treatment. Thus the D_2–CH_4 exchange, even with activation energies of about 80 kJ mol^{-1}, is probably a "facile" reaction in Boudart's terminology (6). Apparently any electronic changes as the particle size is reduced do not affect the specific rate coefficient. This behavior seems common to a number of reactions such as H_2–D_2 exchange (24), hydrogenations (24–26), dehydrogenations (26), and some simple hydrogenolyses (27). Conversely the isomerization of neopentane (6) is known to be demanding and shows a particle size effect. It is thought that this reaction requires a special triple adsorption site, and thus is demanding for geometric reasons. The same is true for the skeletal reactions of C_6 alkanes studied by Anderson *et al.* (5).

Very large variations in specific rate coefficients with sintering temperature are noted within each series of catalysts. Figure 4 shows that the decrease in specific rate coefficient is associated with the pre-exponential term in the Arrhenius expression, and is not due to a change in activation energy. Possibly the reaction takes place at defects or special adsorption sites which are eliminated by sintering.

A related possibility is that the platinum (111) face, which is a lower energy face and is thus developed on sintering, is ineffective in catalyzing this exchange. Anderson and MacDonald (4) found that the exchange of ethane and propane with D_2 was much slower over (111) nickel than it was over (100) nickel, although, with nickel, the methane–deuterium reaction was not sensitive to surface structure. The platinum (111) face has been shown to adsorb a number of gases, including hydrogen and oxygen, with much more difficulty than does polycrystalline platinum (27). Possibly methane is not easily adsorbed on this face, but is adsorbed on the steps and facets present in the smaller particles (28). Reconstruction of such features could also explain the small increases in specific rate when the catalysts are heated up to 500 °C.

Another possible explanation of the drop in specific rate coefficients with increasing sintering temperature is the diffusion of poisons to the platinum surface. Indeed, Schlatter and Boudart (29) have recently shown that small amounts of carbonaceous material originally adsorbed on the silica gel were able to poison their 0.05% platinum on silica gel catalysts for the hydrogenation of ethylene. However these poisons were removed by giving the catalyst one dose of air at 300 °C. A similar procedure did not affect our specific rate coefficients and it is hard to see how such poisons could survive the sintering procedure. Also our catalysts contain 100 times

For personal use only.

as much platinum as those of Schlatter and Boudart, and therefore should be less susceptible to poisons from the gel. At these reaction temperatures oxygen poisoning should not be apparent. The role of other types of poisons cannot be determined, but it should be recalled that even the least active catalyst has a platinum surface area of 1400 $m^2\ kg^{-1}$, so that about 30 μmol of poison per gram would be required to cover the surface uniformly.

The studies of methane–deuterium exchange over films by Kemball (10–12) showed that CH_3D was formed by step-wise exchange:

[5] $$CH_4 + 2S \rightarrow CH_3—S + H—S$$

[6] $$D_2 + 2S \rightarrow 2D—S$$

[7] $$CH_3—S + D—S \rightarrow CH_3D + 2S$$

[8] $$H—S + D—S \rightarrow HD + 2S$$

where S represents a surface site. Other more highly deuterated products were formed by processes involving methylene radicals, whose hydrogen atoms were easily exchanged. The parameter M is clearly related to the ratio of rates for these two processes. Pure step-wise exchange gives M equal to 1, whereas multiple exchange leads to M values up to 4.

Our results show little variation of M within each series, implying that the relative rates are not affected by sintering but only the number of sites. The ion exchanged catalysts gave M about 1.7 whereas the impregnated catalysts gave M about 1.25. Thus both series of catalysts gave more step-wise than multiple exchange, but the multiple exchange contribution was greater with the smaller particles. On low temperature films at 259 °C, Kemball observed $M = 2.43$ (30). Thus significantly less highly deuterated methanes were produced on our supported catalysts, *i.e.* less CH_2 is initially formed on their surfaces. The activation energy for multiple exchange is higher, and formation of adsorbed methylene requires more energy. Sites with the energy required to form this methylene seem to be less abundant on the supported catalysts than on the film. They are also less abundant on the impregnated catalyst than on the ion exchanged catalyst. This suggests that a true particle size effect may be observable in this respect. The smaller particles should have more special uncoordinated sites (2). It is interesting to note that sintering does not change M significantly even though the particle size changes. This supports our observation that it is the pre-exponential factor and not the activation energy which changes to alter the rate. Sintering seems to remove a portion of the platinum surface, and make it entirely ineffective as a catalyst. It does not seem to modify the energetics of the reaction. Cece and Gonzales (13) noted an increase in M over nickel catalysts as the size increased. However, their smallest particles were about 1.9 nm, which corresponds to the size of particles on our impregnated catalysts.

We were not able to demonstrate any crystallite size effect on the specific rate coefficient for methane–deuterium exchange over supported platinum, but the sintering procedure used to grow platinum particles reduced the specific rate coefficient by other processes. There may be some particle size effect on the relative amount of multiple exchange. This work also provides a further example of the fact that supported catalysts can, under good conditions, yield specific rate data comparable to those obtained on powders and films.

We would like to thank D. Bell, L. M. Carefoot, and G. J. Lobban of the Analytical Science Branch, WNRE, for the mass spectrometric analyses and N. S. McIntyre and M. G. Cook of the same branch for platinum analyses. E. E. Sexton took the electron micrographs and M. Duclos measured the X-ray spectra. We thank our colleagues for useful discussions.

Reaction Kinetics of Ground State Fluorine, F(^{2}P), Atoms. I. Measurement of Fluorine Atom Concentrations and the Rates of Reactions F + CHF_3 and F + Cl_2 using Mass Spectrometry

MICHAEL A. A. CLYNE, DONALD J. MCKENNEY,[1] AND (IN PART) RONALD. F. WALKER
Department of Chemistry, Queen Mary College, Mile End Road, London E1 4NS, England

Received May 14, 1973

Reactions of F(^{2}P) atoms generated by a 2.45 GHz discharge in dilute F_2 + He mixtures have been studied mass spectrometrically with a beam inlet system from a fast flow reactor. F atom concentrations have been measured from the consumption of Cl_2 in the simple and extremely rapid bimolecular reaction 1

[1] $$F + Cl_2 \rightarrow FCl + Cl \quad \Delta U^0_{298} = -9 \text{ kJ mol}^{-1}$$

k_1 was determined to be $(1.1 \pm 0.3) \times 10^{-10}$ cm^3 molecule^{-1} s^{-1} at 300 °K.

Rate measurements for the reaction 2, which forms CF_3 radicals, are reported, over the range 301 to 667 °K,

[2] $$F + CHF_3 \rightarrow HF + CF_3 \quad \Delta U^0_{298} = -141 \text{ kJ mol}^{-1}$$

$$\log_{10} k_2 \text{ (cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}) = (-10.98 \pm 0.09) - (522 \pm 164)/T$$

A less detailed survey of the rates at 298 °K of a series of reactions of F with H_2, CH_4, CH_3Cl, CH_2Cl_2, and $CHCl_3$, is also given; in these cases, the source of F was a discharge in CF_4 + Ar, and [F] was measured by titration with ClNO.

Les réactions des atomes F(^{2}P) créés par décharge à 2.45 GHz dans des mélanges dilués de F_2 + He, ont été étudiées par spectrométrie de masse avec un système d'introduction constitué d'un réacteur à flux rapide. Les concentrations en atomes F ont été mesurées à partir de la disparition de Cl_2 selon une réaction bimoléculaire simple et extrêmement rapide 1

[1] $$F + Cl_2 \rightarrow FCl + Cl \quad \Delta U^0_{298} = -9 \text{ kJ mol}^{-1}$$

avec $k_1 = (1.1 \pm 0.3) \times 10^{-10}$ cm^3 molécule^{-1} s^{-1} à 300 °K.

Les mesures de vitesse pour la réaction 2 qui engendre des radicaux CF_3, ont été rapportées dans l'intervalle 301 à 667 °K,

[2] $$F + CHF_3 \rightarrow HF + CF_3 \quad \Delta U^0_{298} = -141 \text{ kJ mol}^{-1}$$

$$\log_{10} k_2 \text{ (cm}^3 \text{ molécule}^{-1} \text{ s}^{-1}) = (-10.98 \pm 0.09) - (522 \pm 164)/T$$

Un survol moins détaillé des vitesses de réactions de F sur H_2, CH_4, CH_3Cl, CH_2Cl_2 et $CHCl_3$ à 298 °K a été également présenté; dans ces cas, la source de F provient d'une décharge de CF_4 + Ar et [F] a été titré par NOCl. [Traduit par le journal]

Can. J. Chem., 51, 3596 (1973)

Introduction

The rates of elementary abstraction reactions involving ground state F(^{2}P) atoms are less satisfactorily known than the rates of corresponding reactions involving Cl atoms. (No distinction is made here between $^2P_{3/2}$ and $^2P_{1/2}$ J-excited atoms having the $2p^5$ ground state electronic configuration; at 300 °K, the equilibrium ratio $[^2P_{1/2}]/[^2P_{3/2}] \simeq 0.08$.) In particular, very few measurements exist of absolute rate constants of reactions suitable for use as primary standards in competitive fluorinations, such as

[3] $$F + H_2 \rightarrow HF + H$$

For this reaction, which seems to be the most fully studied of the series F + RH, the range of recent values of k_3 (cm^{-3} molecule^{-1} s^{-1}) at 298 °K is 1.8×10^{-11} (1) to 6.3×10^{-11} (2), including the intermediate value of 3×10^{-11} (3). Earlier, an indirect value of 1.1×10^{-11} cm^3 molecule^{-1} s^{-1} was suggested (4), but since this value is based on assumed Arrhenius parameters for the F + C_2H_6 reaction, it must be regarded as an estimate.

Two of the few direct measurements of the rates of other F atom reactions are the recent studies by Warnatz *et al.* (5) of the reaction

[1] $$F + Cl_2 \rightarrow FCl + Cl$$

and by Kolb and Kaufman (6) of the reaction

$$F + CCl_4 \rightarrow FCl + CCl_3$$

In both cases, mass spectrometric analysis with molecular beam sampling was used.

The scarcity of data on F atom elementary reactions is partially due to the high reactivity of F_2, which often accompanies F atoms, and which thus may complicate the kinetic behavior of F. A second problem is the absence of well-characterized methods for the measurement of F atom concentrations. In addition, most F atom reactions involving abstraction of an H atom are rapid, thus leading to difficulties in the isolation of a single elementary process in studies of F + RH reaction rates. Recently, Homann *et al.* (1) have described the use of a titration based on the reaction

$$F + ClNO \rightarrow FCl + NO$$

however, this method has certain drawbacks such as the difficulty of accurate calibrations with the extremely reactive FCl molecule, and the reaction of NO with F_2 (7) reforming F atoms, in the presence of F_2

$$NO + F_2 \rightarrow FNO + F$$

The use of the $F + H_2$ reaction for the measurement of [F] also entails problems (1) due to the secondary reaction of the H atoms formed with F_2 and by other processes.

The first part of the present work describes a method for the measurement of F atoms (in the presence of F_2) based on the rapid reaction

[1] $$F + Cl_2 \rightarrow FCl + Cl$$

using molecular beam mass spectrometry and a discharge flow system; the consumption of Cl_2 is used to measure [F]. Also, new measurements of k_1 at 298 °K are reported; these confirm the extreme rapidity of the $F + Cl_2$ reaction. The second part of this paper describes the application of this method to the determination of the rate constant from 300 to 667°K for the reaction.

[2] $$F + CHF_3 \rightarrow CF_3 + HF$$

which is a possible clean source of CF_3 radicals. Finally, we briefly describe the results of less extensive measurements of the rates at 298 °K of a variety of F + RH reactions.

Experimental

The mechanisms and rates of reactions of F^2P atoms with compounds RH were investigated by mass spectrometric analysis from a rapid discharge-flow apparatus.

Production of $F(^2P)$ Atoms

In the work on the $F + H_2$, CH_4, CH_3Cl, CH_2Cl_2, and $CHCl_3$ reactions described here, a stream of $F(^2P)$ atoms was produced by means of a 2.45 GHz microwave discharge (25 W) in a mixture of CF_4 (1%) and Ar (6, 8, 9) using a silica discharge tube (10 mm i.d.). The atoms were pumped from the discharge tube through the length of a flow tube of cylindrical cross section (24.1 mm i.d.) provided with a number of reagent inlet jets, beyond which a small sample of gas was continuously sampled from the center of the gas flow to the ion source of a mass spectrometer (see below). As well as $F(^2P)$ atoms, the products of the CF_4 + Ar discharge detected mass spectrometrically included numerous CF^+, CF_2^+, CF_3^+ ions derived from molecular species such as CF_4 and C_2F_6, as well as appreciable SiF_4 and O_2 derived mostly from interaction between the plasma and the silica walls of the discharge tube.

While there was no evidence for any complications in our system due to any unrecombined molecular radicals produced by the discharge, it was felt that the CF_4 + Ar discharge as a source of $F(^2P)$ atoms for quantitative kinetic studies, should be superseded, if possible. Accordingly, a low power microwave discharge (40 W) in a mixture of F_2 ($\simeq$1%) + He ($\simeq$99%) using a F_2 (5%) + He mixture from B.O.C. was investigated as a source of $F(^2P)$ (10, 25).[2] Initially, a discharge tube coated with H_3PO_4, as employed for the production of Cl and Br atoms (11), was used; in this case, low yields of $F(^2P)$ were obtained, with extremely large formation of HF and of species giving PF^+, POF^+ mass peaks. Substitution of a clean silica discharge tube led to formation of large amounts of $F(^2P)$ atoms, containing SiF_4 as the only major impurity (derived mainly from interaction within the discharge zone). Mass spectrometric measurements, using the molecular ion F_2^+ m/e 38 intensities, showed that at least 80% dissociation of F_2 could be achieved when the flow entering the discharge contained $\simeq$0.1% F_2, and at least 60% dissociation from $\simeq$1% F_2. Use of an alumina discharge tube, which eliminates formation of SiF_4 within the discharge (12) was not adopted, since an appreciable formation of SiF_4 occured outside the discharge by interaction of F atoms with the flow tube walls especially at temperatures above 300 °K. This was demonstrated by observation of SiF_4 production when F was removed by reaction with Cl_2 between the discharge tube and the flow tube.

Conventional vacuum techniques were found adequate for handling the diluted F_2 (5%) + He gas mixture; all stopcocks were lubricated with fluorocarbon grease (Voltalef), and fluorocarbon oil (Kel-F) was used for manometers where necessary.

[2]We thank P. B. Davies, R. G. McDonald, and B. A. Thrush for their assistance in introducing us to the F_2 + He gas mixtures.

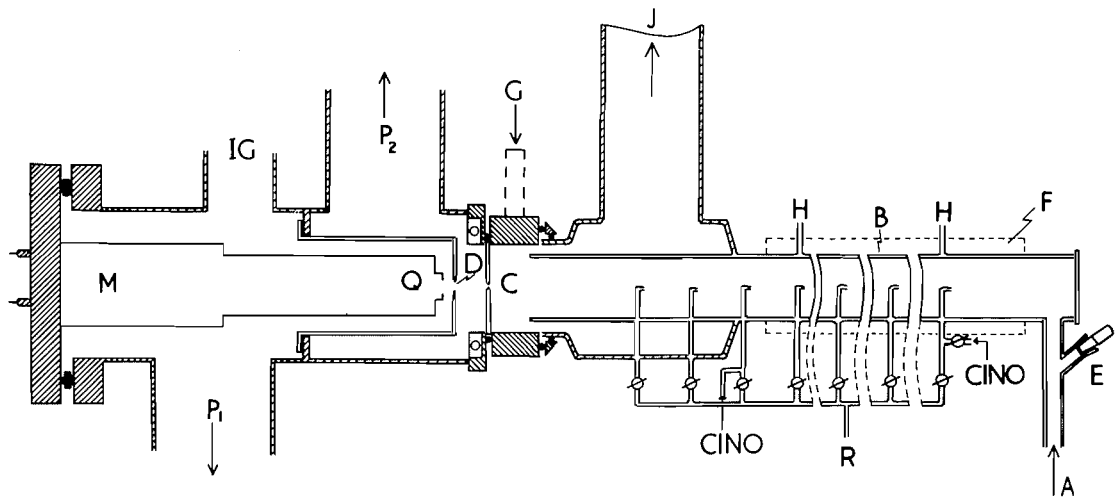

FIG. 1. Schematic arrangement of flow system with on-line mass spectrometric studies of F atom reactions. *A*, flow of F atoms in He carrier from discharge; *B*, silica flow tube; *C*, first pinhole (0.7 mm) separating flow tube from differentially-pumped chamber; *D*, second pinhole (0.7 mm) separating differentially-pumped chamber from quadrupole mass spectrometer *Q* (E.A.I. 150/A); *E*, access to discharge tube; *F*, furnace; *G*, 50 mm gate valve; *H*, connections to total pressure manometer; *IG*, ion gauge; *J*, connection to cold traps and large pump (60 l s^{-1}); *M*, multiplier; P_1, P_2, pumping lines for quadrupole chamber and for differentially-pumped chamber; *R*, reagent inlets.

Flow System for Kinetic Studies

The flow system for kinetic studies of F atom reactions was similar to that described previously (13) except that eight inlet jets were provided at intervals along the flow tube, allowing up to eight different reaction times to be used. In order to obtain the maximum flow velocity for the kinetic studies of the extremely rapid reaction

$$F + Cl_2 \rightarrow ClF + Cl$$

a relatively high flow rate of helium ($\simeq 5 \times 10^{20}$ atom s^{-1}) was employed instead of argon as the carrier gas for the F atom flow. At 300 °K, the maximum linear velocity of flow was then 60 m s^{-1}. Under these conditions, mixing of reactant Cl_2 added to the F atom stream at the inlet closest to the mass spectrometer inlet system was detectably incomplete, as indicated by the constancy of the Cl_2 ion current when the same Cl_2 concentration was added at each inlet jet in the absence of F. Only the remaining seven more distant inlet jets were therefore used for kinetic studies of the F + Cl_2 system. Under these conditions, an appreciable pressure gradient ($\leqslant 25\%$) existed across the reaction zone; the mean pressure was used in all cases for the kinetic analysis. Much lower flow velocities were used for the F + CHF_3 reaction studies, leading to a negligible ($< 5\%$) pressure gradient.

Mass Spectrometer Inlet System

A system of two coaxial pinholes (0.7 mm diameter), separated by a differentially pumped chamber, was used as the interface between the flow tube and the mass spectrometer ion source (Fig. 1). With the flow tube maintained at a pressure of $\simeq 200$ N m^{-2}, the ion source pressure was $\simeq 7 \times 10^{-4}$ N m^{-2}. The inlet system was newly constructed (Fig. 1), and incorporated most of the useful features of the two previous inlet systems (13, 14), without their disadvantages. (*i*) The distance between the first pinhole and ion source was 3 cm, favoring beam formation which is found advantageous for the detection of atoms and radicals, and for maximizing signal-to-background ratios in the mass spectrometer (14). (*ii*) More rapid pumping than previously (13) was provided both in the mass spectrometer chamber, and in the differential chamber separating the two pinholes. The combination of rapid pumping and small separation of the pinholes was achieved using the annular design shown in Fig. 1, based on a 100 mm diameter outer chamber. (*iii*) Although the all-metal mass spectrometer and its vacuum chamber could be baked up to 600 °K, temperature zoning using a water-cooled flange in conjunction with a 50 mm Viton-sealed gate valve allowed isolation of the baked system from the flow tube.

As before, pumping was achieved by means of two identical sets consisting of a double-stage rotary pump, alumina foreline trap, diffusion pump (Edwards, Model EO2, 0.15 m^3 s^{-1} nominal speed, charged with polyphenyl ether), chevron baffle, and liquid N_2 cold trap. Without bakeout the background pressure in the mass spectrometer was routinely 3×10^{-6} N m^{-2} shortly after cessation of sampling from the flow tube, and lower pressures were attainable after continued pumping of the isolated system.

Reagents

Fluoroform was an Air Products (98%) product; the source of F_2 has been described; the remaining reagents were as given previously (13). The fluoroform and chlorine were purified by repeated trap-to-trap distillation under vacuum.

Results and Discussion

Measurement of F(^2P) Atom Concentrations

In one of the few quantitative kinetic studies of F atom reactions, that of Wagner and his co-workers (1, 5), titration of F atoms with nitrosyl

chloride has been used to measure absolute F atom concentrations

[4] $$F + ClNO \rightarrow FCl + NO$$

The FCl yield in reaction 4 was measured mass spectrometrically by reference to addition of known concentrations of FCl from a cylinder. This method is closely analogous to the corresponding titration reaction of Cl and Br $^2P_{3/2}$ atoms with ClNO, which have been shown to be very rapid (15) and stoichiometric to form NO (11)

$$Cl + ClNO \rightarrow Cl_2 + NO$$
$$k^{298} = (3.0 \pm 0.5) \times 10^{-11} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1} \text{ (15)}$$

$$Br + ClNO \rightarrow BrCl + NO$$
$$k^{298} = (1.0 \pm 0.2) \times 10^{-11} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1} \text{ (15)}$$

The F + ClNO titration must be regarded at the present time as less well-established than the corresponding Cl + ClNO and Br + ClNO titrations (11), since k_4 is not known. Also, FCl is a difficult compound to prepare in a pure state, and it can be expected to react appreciably with glass or silica apparatus (13, 16). Consequently, the calibration of FCl mass spectral ion current may be subject to systematic errors. A variant of the F + ClNO titration, measurement of the concentration of ClNO required to just remove all the F atoms, eliminates the problems of handling FCl, and this method has been used in our preliminary measurements of a number of F + RH rate constants described here. The criterion for consumption of F was taken as no further increase in FCl^+ ion currently on addition of ClNO. Similar limitations of this variant of the ClNO titration method for measurement of [F] to those discussed for measurement of [Cl] and [Br] (11) are expected. At high concentrations of F (and thus of ClNO), the reaction, NO + F_2 → FNO + F, may occur to an appreciable extent, leading to an erroneous value for [F] (7).

The Reaction F + Cl_2 → FCl + Cl as a Titration for [F]

Following preliminary work using the F + ClNO titration (5), we have evaluated the reaction 1

[1] $$F + Cl_2 \rightarrow FCl + Cl \quad \Delta U^0_{298} = -9 \pm 3 \text{ kJ mol}^{-1} \text{ (17)}$$

previously rejected by Wagner *et al.* (5), as a possible titration reaction for the measurement of [F]. The reason for the earlier rejection of this reaction (5) was that the secondary reaction

$$Cl + F_2 \rightarrow FCl + F$$

was expected to be rapid, and consequently F could be partially regenerated by reaction of Cl atoms from reaction 1 with undissociated F_2. This view cannot be sustained, since work in our laboratory (18) and elsewhere (19) shows that the rate of reaction of Cl with F_2 is slow, with a rate constant of $\leqslant 5 \times 10^{-14}$ cm^3 molecule^{-1} s^{-1} at 298 °K (18); the only value previously reported (3.5×10^{-9} cm^3 molecule^{-1} s^{-1}) (20) is an otherwise unfounded estimate based on an analogy with other elementary exothermic reactions. Reaction 1 thus appears to be a promising titration reaction, especially since its rate approaches the hard sphere bimolecular collision frequency at 298 °K (k_1^{298} = 9.1×10^{-11} cm^3 molecule^{-1} s^{-1} according to ref. 5). The equilibrium constant for reaction 1 at 298 °K (using the J.A.N.A.F. thermochemical data (17)[3] is 40. Hence the reverse reaction, FCl + Cl → F + Cl_2 is unlikely to be important below 300 °K, even in the titration of F with Cl_2 to the end point, in which the initial concentrations of F and Cl_2 are approximately equal. With $[Cl_2]_0/[F]_0 > 1$, which leads to a smaller effect of the reaction FCl + Cl, measurement of [F] as $[Cl_2]$ consumed in reaction 1 is straightforward mass spectrometrically, and the calibration of Cl_2^+ ion current with known Cl_2 concentrations is an established technique (11).

Determination of [F] in this manner was verified by comparison of $[Cl_2]$ consumed with relative [FCl] formed in the F + Cl_2 reaction. These experiments verified the absence of detectable Cl atom recombination in the flow tube, or in the sampling system, since Cl_2 consumption, but not FCl formation, would be affected by Cl atom recombination. It was noted that the Cl_2^+ mass peak was completely absent, when Cl_2 was added to excess F under conditions of complete reaction, thus confirming the absence of Cl atom recombination within the sampling system.

Rate constant k_1 for the reaction F + Cl_2 → FCl + Cl

The rate of consumption of Cl_2 at 300 °K was measured mass spectrometrically (m/e 70, $^{35}Cl_2^+$) in the presence of an excess of F atoms; time

[3]These data are based on the lower of two possible values for D_0^0 (FCL). In the (unlikely) event that the higher value for D_0^0 (FCL) is correct, $-\Delta U^0_{298}$, and hence K_{equil}, would be greater than 40.

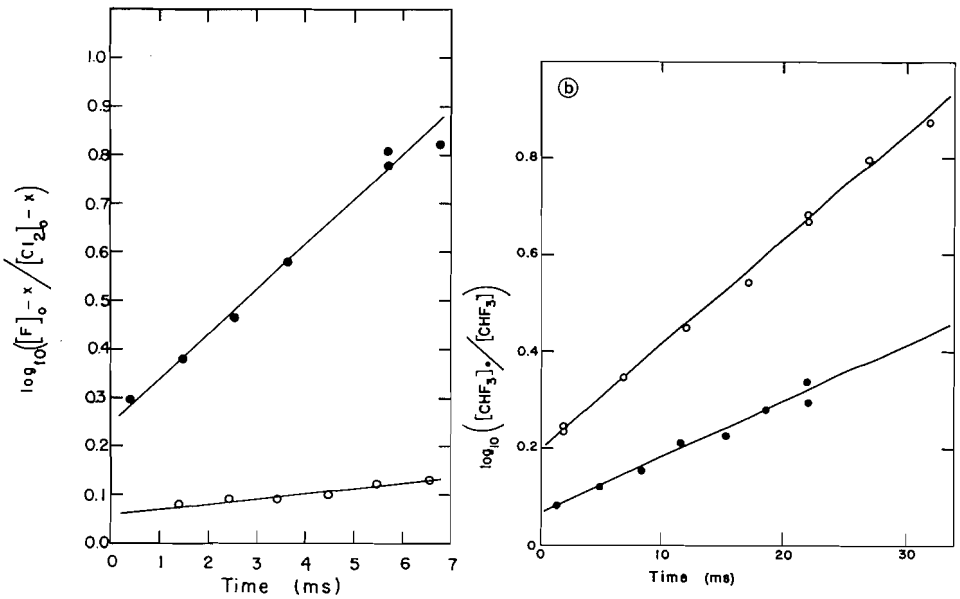

FIG. 2. (*a*) Second order decay plot for the reaction, F + Cl_2 → FCl + Cl (298 °K): ●, $[F]_0 = 5.6 \times 10^{12}$ atom cm^{-3}; ○, $[F]_0 = 3.0 \times 10^{12}$ atom cm^{-3}.
(*b*) Pseudo first-order decay plot for the reaction F + CHF_3 → HF + CF_3 (301 °K): ●, $[F]_0 = 1.3 \times 10^{14}$ atom cm^{-3}; ○, $[F]_0 = 1.9 \times 10^{14}$ atom cm^{-3}. Zero of time scale differs from reaction time = 0.

variation was by addition of the same $[Cl_2]$ at a series of inlets equally spaced at increasing intervals along the flow system from the mass spectrometer inlet system. Kinetic analysis was carried out according to eq. 5,

$$[5] \quad \frac{1}{[F]_0 - [Cl_2]_0} \ln \left\{ \frac{[Cl_2]_0([F]_0 - x)}{[F]_0([Cl_2]_0 - x)} \right\} = kt$$

where x is the concentration of F or Cl_2 that has reacted in time t; $[Cl]_0$ and $[F]_0$ are the initial concentrations. Figure 2 (*a*) shows typical data for the variation of $\log_{10} \{([F]_0 - x)/([Cl_2]_0 - x)\}$ with time.

Since preliminary data showed that the F + Cl_2 reaction was extremely rapid, it was possible to use this reaction for the measurement of [F] as described above. Although the rate of reaction of $\simeq 5 \times 10^{12}$ atom cm^{-3} of F with $\simeq 7 \times 10^{12}$ molecule cm^{-3} of Cl_2 was incomplete within a 5–10 ms time scale, the rate of the same concentration of F with an excess of Cl_2 ($\simeq 25 \times 10^{12}$ molecule cm^{-3}) was complete in this same time scale. The concentration of F under these conditions was taken to be equal to the concentration of Cl_2 consumed, measured mass spectrometrically. The completeness of the F + Cl_2 reaction was verified by noting that, for a constant value of [F], $[Cl_2]$ consumed was independent of time and of $[Cl_2]$ added.

The extreme rapidity of the F + Cl_2 reaction limited the range of conditions accessible for the measurements of the small concentrations of Cl_2 which were required to be measured in the kinetic study, and error limits of ± 25% were estimated for the new value of k_1 given in Table 1*a*.

The value now found for k_1, $(1.1 \pm 0.3) \times 11^{-10}$ cm^3 $molecule^{-1}$ s^{-1} at 300 °K, may be compared with the determination (also using a discharge flow system), using $5[F]_0 = [Cl_2]_0$ with mass spectrometric detection of F removal, FCl formation, and Cl formation by Warnatz *et al.* (5), $\log_{10} k_1$ (cm^3 $molecule^{-1}$ s^{-1}) = $-9.04 - 732/T$, giving $k_1^{298} = 8.6 \times 10^{-11}$. No error limits for k_1 were given by these workers (5).

Rate constant k_2 for the reaction F + CHF_3 → CF_3 + HF

The rate of reaction of fluoroform, CHF_3, with an excess of F atoms was measured using a similar technique to that used for the F + Cl_2 system. In this case pseudo first order kinetic analysis according to eq. 6 was employed.

$$[6] \quad \ln \{[CHF_3]_0/[CHF_3]\} = k_2[F]t$$

200	667	2.17	0.49	18.6

The relative concentration of CHF_3 was followed mass spectrometrically using the m/e = 51 CHF_2^+ ion peak. (The parent ion peak m/e = 70 CHF_3^+ was not observed.) The initial concentration ratio $[F]/[CHF_3]_0$ was generally around 5; no corrections for F consumption in the $F + CHF_3$ reaction were made, since it was assumed that the F atom concentration would be kept approximately constant by means of the reaction scheme,

$$F + CHF_3 \rightarrow CF_3 + HF,$$

$$CF_3 + F_2 \rightarrow CF_4 + F.$$

Figure 2*b* shows typical data for the pseudo first order decay of $[CHF_3]$ in the presence of excess [F]. A total of 22 sets of measurements were made over the temperature range 301 to 667 °K, and the resulting values for k_2 are given in Table 1*b*. Since k_2 was found to be at least 10^2 less than k_1 up to 500 °K, the effect of wall reaction of F atoms upon the $F + CHF_3$ reaction was marked in comparison with that upon the $F + Cl_2$ reaction. Although negligible at temperatures below 500 °K, the wall reaction of F at high temperatures was found to be as high as 50% attenuation of initial F through the length of the reaction zone. Observations of m/e 38 (F_2^+) suggested that wall recombination was negligible compared with wall reaction (*i.e.* to form $SiF_4 + O_2$). In these cases, the mean value for [F] was used for kinetic analyses in eq. 6.

The least mean squares Arrhenius plot (Fig. 3) gave the following temperature variations for k_2 (301–667 °K), and an activation energy of (10.0 ± 3.1) kJ mol^{-1}

$CHCl_3$	12	1.7–3.3	0.53 (±25%)

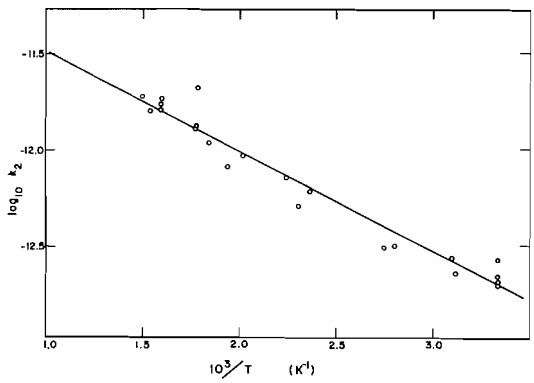

FIG. 3. Arrhenius plot for the reaction F + CHF_3 → HF + CF_3. k_2 in cm^3 molecule^{-1} s^{-1}.

$$\log_{10} k_2\ (\text{cm}^3\ \text{molecule}^{-1}\ \text{s}^{-1}) = (-10.98 \pm 0.09) - (522 \pm 164)/T$$

The stated error is 2σ (σ is the standard error of the estimate).

Rate Constants for the Reaction F + $CHCl_3$, CH_2Cl_2, CH_3Cl, CH_4, and H_2

Rate measurements at 298 °K of a series of F atom reactions which abstract an H atom were carried out using a discharge in CF_4 + Ar mixture as the source of F(^{2}P) atoms. Kinetic analysis was carried out as described above, with [F] ≫ [RH]. These studies were carried out with an earlier mass spectrometric sampling system (13), and absolute F atom concentrations were measured using ClNO titration as described above. The values for the rate constants found here we believed to be less accurate than those for the F + CHF_3 and F + Cl_2 reactions which were determined with improved techniques. However, the existing data on the rate constants for all F atom reactions are sufficiently poor that the present results are thought to represent a considerable improvement in precision. The error limits estimated for the present rate constant measurements widen as the rate constant increases, approaching the lower limit of sensitivity of the apparatus, for the F + CH_4 reaction. Figure 4 shows the data for the F + H_2 reaction; all values for $-d \ln [H_2]/dt$ are plotted as a function of [F]; the gradient of this plot is equated to the second order rate constant k_{H_2}. The scatter of these results is typical of the whole series of rate measurements described in this section. Table 2 summarizes the values obtained for k_{CHCl_3}, $k_{CH_2Cl_2}$, k_{CH_3Cl}, k_{CH_4}, and k_{Cl_2} and their estimated errors.

Cl + CHF_3	−2.3	$-11.55 - (1830 \pm 22/T)$	2.8×10^{-12}	35.1 ± 0.4	23
Cl + $CHCl_3$	−51.9	$-10.94 - (725 \pm 20/T)$	1.15×10^{-11}	14.0 ± 0.4	22

[a]Reference 24.
[b]$\log_{10} k_{A,B} = A - E/2.303\ RT$.

No detailed discussion is given of the present values for these rate constants, k_{RH}, in relation to existing data (1–4, 21) except to note that no anomalies are now apparent, within the admittedly wide range of all the data. The relative values of k_{RH} generally agree satisfactorily with those based upon competitive fluorination studies (4, 22).

Rate Constants for Reaction $A + CHB_3 \xrightarrow{k_{A,B}} HA + CB_3$

Reactions of the type A + CHB_3, where A is F or Cl, and B is a halogen, should be a good source of CB_3 radicals for kinetic studies. Quantitative kinetic data are now available for the following (all exothermic) reactions: F + CHF_3, F + $CHCl_3$, Cl + CHF_3, Cl + $CHCl_3$; Table 3 shows a summary of these data, together with the corresponding values of ΔU^0_{298}.

In fact, none of these reactions is sufficiently rapid at 300 °K with the possible exception of the F + $CHCl_3$ reaction, to be a good source of CB_3 radicals for kinetic studies in flow systems.[4] This is because of the rapid recombination rate of CB_3 radicals, which leads to overlapping of the regions of production and consumption of these radicals.

Further Rate Measurement of F Atom Reactions

The method of measurement of F using the F + Cl_2 reaction, with mass spectrometric analysis of Cl_2 consumption, has been demonstrated for the determination of a rate constant approaching half the bimolecular collision rate at 300 °K (the F + Cl_2 reaction). The use of a more sensitive and noise-free mass spectrometer than the type used here would offer clear advantages for systematic measurements of a range of F atom reaction rate constants, such as F + H_2, over a wide temperature range.

We thank Science Research Council and the Ministry of Defence for partial support of this work.

One of us (D.J.M.) wishes to thank the Queen Mary College for the use of their facilities and Dr. M. A. A. Clyne and his group for generous and stimulating hospitality.

[4]Rapid atom-switching reactions (6) might preclude the use of the F + $CHCl_3$ reaction as a "clean" source of CCl_3 radicals.

Di-imide: Some Physical and Chemical Properties, and the Kinetics and Stoichiometry of the Gas-phase Decomposition[1]

C. WILLIS AND R. A. BACK

Division of Chemistry, National Research Council of Canada, Ottawa, Canada K1A 0R6

Received May 7, 1973

Preparation of di-imide by passing hydrazine vapor through a microwave discharge yields mixtures with NH_3 containing typically about 15% N_2H_2, estimated from the gases evolved on decomposition. The behavior of the mixture (which melts at −65 °C) on warming from −196 to −30 °C suggests a strong interaction between the components. Measurements of magnetic susceptibility and e.p.r. experiments showed that N_2H_2 is not strongly paramagnetic, which with other observations points to a singlet rather than a triplet ground-state.

Di-imide can be vaporized efficiently, together with NH_3, by rapid warming, and the vapor is surprisingly long-lived, with a typical half-life of several minutes at room temperature. The near-u.v. (3200–4400 Å) absorption spectrum of the vapor was photographed; it shows well-defined but diffuse bands, with $\varepsilon_{max} = 6(\pm 3)$ at 3450 Å.

Di-imide decomposes at room temperature in two ways:

$$N_2H_2 \rightarrow N_2 + H_2$$

$$2\ N_2H_2 \rightarrow N_2H_4 + N_2$$

Formation of NH_3 was not observed but cannot be ruled out. The decomposition of the vapor is complicated by a sizeable and variable decomposition that occurs rapidly during the vaporization. The stoichiometry of this and the vapor-phase decomposition depends on total pressure and di-imide concentration. The kinetics of the decomposition of the vapor were studied from 22 to 200 °C by following the disappearance of N_2H_2 by absorption of light at 3450 Å, or the formation of N_2H_4 by absorption at 2400 Å, and by mass spectrometry. The kinetics are complex and can be either first- or second-order, or mixed, depending on surface conditions. The effect of olefin additives on the decomposition was studied, and is also complex.

Mechanisms for the decomposition are discussed, including the possible role of *trans-cis* isomerization. The relatively long lifetime found for di-imide in the gas phase suggests that it may be an important intermediate in many reactions of hydronitrogen systems.

La préparation de la di-imide par passage de vapeur d'hydrazine à travers une décharge microonde conduit à des mélanges de NH_3 contenant environ 15% de N_2H_2, calculés à partir du dégagement gazeux issu de la décomposition. Le comportement de ce mélange (fondant à −65 °C) lors du réchauffement de −196 à −30 °C laisse penser à une interaction forte entre les constituants. Les mesures de susceptibilité magnétique et les expériences de r.p.e. montrent que N_2H_2 n'est pas fortement paramagnétique ce qui, avec d'autres observations, indique un état fondamental singulet plutôt que triplet.

La di-imide avec NH_3 peut être efficacement volatilisée par un chauffage rapide et la vapeur possède une durée de vie longue (ce qui est surprenant) dont la période type est de plusieurs minutes à la température ambiante. Les spectres d'absorption de la vapeur dans le proche u.v. (3200–4400 Å) ont été photographiés et montrent des bandes bien définies quoique diffuses avec $\varepsilon_{max} = 6(\pm 3)$ à 3450 Å.

La di-imide se décompose à la température ambiante de deux façons

$$N_2H_2 \rightarrow N_2 + H_2$$

$$2\ N_2H_2 \rightarrow N_2H_4 + N_2$$

La formation de NH_3 n'a pas été observée mais n'a pas pu être écartée. La décomposition de la vapeur a été compliquée par une autre, notable et variable, qui se produit rapidement lors de la vaporisation. La stoechiométrie de cette dernière et la décomposition en phase vapeur dépendent de la pression totale et de la concentration en di-imide. Les cinétiques de décomposition de la vapeur ont été étudiées de 22 à 200 °C en suivant la disparition de N_2H_2 par absorption de la lumière à 3450 Å et par spectrométrie de masse. Les cinétiques sont complexes et peuvent être soit du premier ou du second ordre, ou un mélange des deux dépendant des conditions de la surface. L'effet de l'addition d'oléfines sur la décomposition a été étudié et est également complexe bien qu'une légère réduction ait été observée.

Les mécanismes de la décomposition ont été discutés incluant le rôle possible d'une isomération *cis-trans*. La durée de vie relativement longue trouvée pour la di-imide en phase gazeuse laisse penser à son importance en tant qu'intermédiaire dans les nombreuses réactions de systèmes hydroazotés.

Introduction

Di-imide, HN=NH, the isoelectronic analog of ethylene and O_2, and the first member of the *azo* family of compounds, is of great interest to the chemist. It has generally been thought to be so unstable, however, as to have only a very fleeting existence at room temperature, and our knowledge of it is therefore limited. It appears to be a very active reducing agent in solution in which it can be generated *in situ* by a variety of methods (1), although it has never been detected or isolated in any of these systems. It has been produced and identified spectroscopically in low-temperature matrices (2, 3). It has also been produced and detected in the gas phase in several laboratories. Foner and Hudson (4), in 1958, were the first to detect and identify di-imide, using a mass spectrometer. Di-imide was produced by an electric discharge in hydrazine or hydrazoic acid vapor in a fast-flow system, and was detected downstream from the discharge. They also showed that it could be trapped at −196 °C and regenerated in the gas phase on warming. Blau *et al.* (3) obtained the infrared spectrum of the vapor in a similar system. Trombetti studied the absorption spectrum of the vapor in the ultraviolet and the infrared, using a similar flow system (5). These experiments and those of Foner and Hudson indicated a lifetime of at least a second or two for di-imide vapor at room temperature. There is one other brief report in a Ph.D. thesis by Mock at Harvard (6) which suggests a much longer lifetime. Mock generated di-imide vapor by a microwave discharge through hydrazine and by the thermal decomposition of anthracene di-imine, and observed an apparent half-life of a few *minutes* at low pressure in the inlet manifold of a mass spectrometer, with a measurable signal at $m/e = 30$ persisting for as long as 20 min. Lack of reproducibility and other uncertainties in these experiments led Mock to be understandably cautious in suggesting that di-imide might have a lifetime of this magnitude at room temperature.

With this background, the present work was undertaken to learn more about the chemistry of di-imide vapor, its lifetime, and its mode of decomposition. At an early stage of our experiments it became clear that di-imide was much more stable than generally suspected, and in fact has a lifetime in substantial agreement with Mock's observations. A brief preliminary account of some of this work has already been published (7).

Experimental and Results

Preparation of Di-imide

Di-imide was prepared by a method similar to those of Foner and Hudson (4), Trombetti, (5), and others, with some modifications. Because we appear to have been able to prepare di-imide in larger amounts and higher concentrations than before, this will be described in some detail.

Anhydrous hydrazine (purity >99%) obtained from Matheson, Coleman and Bell was thoroughly degassed by prolonged pumping with stirring. No attempt was made to dry the hydrazine further, although care was taken not to introduce moisture since water appears to catalyze the decomposition of di-imide. Vigorous stirring of the hydrazine, and a water bath around the reservoir held slightly below room temperature, served to maintain a smooth and adequate flow of vapor. A Teflon-and-glass needle valve controlled the flow rate and pressure of hydrazine vapor. Hydrazine vapor flowed through a quartz tube (13 mm o.d.) in which a microwave discharge was excited with an open-reflector antenna powered by a Raytheon 2450 MHz 100-watt therapy unit. The discharge was initiated by a Tesla coil at a fairly low pressure of hydrazine, giving a hot, intense blue–white discharge which yielded no di-imide. Hydrazine pressure was then increased to the point just before the discharge went out (~10 Torr), giving a blueish barely visible discharge with a yellowish core which generated optimum amounts of di-imide. The open-reflector antenna produced more di-imide than did a closed, tuned cavity with better coupling and a more intense discharge. A constriction in the quartz tube just below the discharge improved yields, probably by permitting a higher hydrazine pressure for a given flow rate. Although an apparently feeble, rather cool discharge gave the most di-imide, the yield was nevertheless roughly proportional to the power output of the microwave generator, which was usually set at 100%.

Hydrazine was condensed at −78 °C in a U-trap 30 cm below the discharge. This trap was short and wide to minimize blocking and to give rapid passage of gases. A second U-trap further downstream, made of 15 mm o.d. tubing, was cooled in liquid nitrogen, and di-imide con-

For personal use only.

densed as a bright yellow solid in a ring starting about 5 mm above the surface of the coolant and extending for several cm. Ammonia condensed with the di-imide but was also spread out through the first arm of the U-trap. The intensity of the yellow color in the trap was a convenient indicator of the efficiency of di-imide production. Noncondensible gases, N_2 and H_2, were pumped away continuously. Operation of the discharge for 5 min typically produced an estimated 400 μmol of N_2H_2 and about 10 times as much NH_3 in the trap. Considerable amounts of N_2 and H_2 were formed, and about 90% of the original N_2H_4 was recovered in the first trap, so that the yield of N_2H_2 was less than 1% of the hydrazine passed through the discharge.

To transfer di-imide efficiently from the trap at −196 °C to the gas phase, it was found essential to vaporize it as rapidly as possible. This was done by quickly raising a beaker of warm water (60 to 70 °C) around the trap. Some decomposition always occurred during vaporization, but with this technique di-imide could be vaporized and immediately recondensed in another trap at −196 °C with less than 20% loss. Losses were greater with larger samples, probably because gases evolved hindered the distillation. Large samples were therefore prepared by distilling and collecting smaller batches; as much as 0.5 g of di-imide was collected in this way on several occasions. Attempts to remove some of the tenfold excess of ammonia by pumping as it warmed up, or other fractional distillation, met with limited success despite the apparent higher volatility of ammonia (see Fig. 1 and Table 1).

Finally, it is pleasant to report that in none of our experiments with di-imide in the solid, liquid, or vapor phase, at temperatures up to 200 °C, was there any sign of explosive behavior. The invariable presence of ammonia as a diluent may be a factor in this observation. Di-imide should undoubtedly be treated with some respect despite its apparent docility, as the decomposition to N_2 and H_2 must be highly exothermic (4).

Properties of Solid and Liquid Mixtures of Di-imide with Ammonia

The solid di-imide trapped with ammonia was stable indefinitely at −196 °C, and appeared unchanged on warming to temperatures of about −100 °C. On further warming a visible change occurred at about −81 °C, when the ring of di-imide appeared to wet the glass surface, became whitish-yellow in color, but remained solid, adhering to the walls of the tube. Nothing further happened until −65 °C, when the solid ring melted sharply and ran down to the bottom of the trap as a pale yellow liquid.

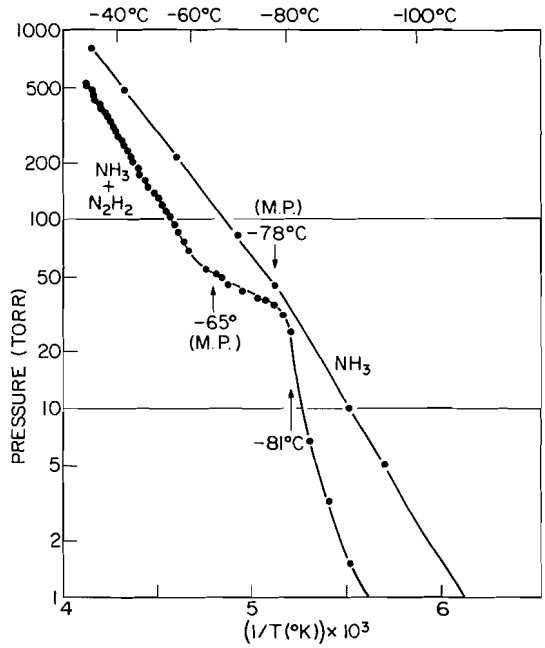

FIG. 1. Van't Hoff plot of ambient pressure over solid and liquid N_2H_2–NH_3 mixture during slow warming.

The behavior on warming was affected considerably by the ambient pressure. If the trap was open to the pumps or attached to a large evacuated volume, and the liquid nitrogen removed, the mixture at first sublimed away, and on melting bubbled vigorously and boiled away. Little or no di-imide could be recovered from the vapor produced from the liquid mixture, even though the latter retained its yellow color as it boiled away; the decomposition appears to occur somehow during the vaporization process itself. In several experiments the trap was immersed in cold liquid isopentane at about −100 °C, and the temperature raised steadily to −30 °C over a period of about 30 min. The volume available for evolved gases was about 200 cc and a manometer was attached. Figure 1 shows the pressure as a function of temperature in a Van't Hoff plot (log p *vs.* $1/T$ (°K)), and for comparison, the known vapor pressure of ammonia. Several points may be noted. No massive evolution of noncondensible gas (N_2 or H_2) accompanied the

*Numbers in columns 6, 7, and 8 not in parentheses are based on the assumption that reaction 3 does not occur; numbers in parentheses are based on the alternate extreme assumption that reaction 2 does not occur. Column 7 shows di-imide yield as a percentage of the total condensable gas (N_2H_2, NH_3 + N_2H_4) present in the trap prior to vaporization.

warming; the pressure was always less than the vapor pressure of ammonia. The solid mixture underwent the changes at −81 and −65 °C described above with no sharp changes in pressure. At temperatures above −65 °C, the liquid was bubbling gently and was probably close to its boiling point from −65 to −30 °C. The heating rate was slow enough that self-cooling of the liquid by evaporation should have been minimal, so that the pressure measured in this region was probably close to the saturation vapor pressure of the NH_3–N_2H_2 mixture. The fact that this was always much less than that of ammonia means both that N_2H_2 is much less volatile and depresses the vapor pressure of the mixture, and that the two compounds interact strongly to form a very nonideal binary mixture. Recent infrared spectra (8) of N_2H_2–NH_3 mixtures in a low-temperature matrix gave evidence for strong hydrogen-bonding, approaching compound formation, on warming from −261 to −240 °C, lending support to our present conclusions.

The physical transitions at −81 and −65 °C are of interest. Pure NH_3 melts at −78 °C, and the first transition might correlate with this melting point, depressed by the N_2H_2 present. Actual melting does not occur, however, and the observed behavior suggests instead formation of a solid solution of NH_3 and N_2H_2 at this point. The ambient pressure falls away from that of pure NH_3 between −81 and −65 °C, perhaps due to a changing composition of the solid solution, while the sharp and invariant melting point at −65 °C suggests a eutectic point. The linear Van't Hoff plot above −65 °C indicates formation of something like an azeotrope at these temperatures.

The slow warming experiment was repeated but with an atmosphere of nitrogen added at the beginning so that no boiling occurred; excess gases evolved were allowed to vent through the manometer. The same transitions occurred at −81 and −65 °C, and there was no visible evolution of gas from the liquid at temperatures up to −25 °C. The latter observation and the persistence of the yellow color suggest that di-imide in ammonia solution is fairly stable in this temperature range.

Magnetic Properties of Di-imide

Trombetti has suggested that the ground state of di-imide is a triplet, ^3B_g, analogous to the $^3\Sigma_g^-$ state of O_2. If this is true, di-imide should, like O_2, be strongly paramagnetic. We therefore examined samples of di-imide, mixed with ammonia as usual, in the solid, liquid, and vapor phases in a Varian E-12 e.p.r. spectrometer.[2] No absorption was observed in any of the samples.

[2]We are grateful to Drs. K. F. Preston and J. R. Morton for their cooperation in these experiments.

The solid sample was held at −150 °C and the liquid at −60 °C. The vapor was studied at room temperature in a flow system with a total pressure of several Torr and an estimated partial pressure of N_2H_2 of at least 50 mTorr. A few mTorr of O_2 gave a large signal under similar conditions.

Because a negative result in a spin resonance experiment is perhaps not conclusive, measurements of the magnetic susceptibility of di-imide were undertaken, using a Gouy balance.[3] Two samples were prepared, one by distillation of about 25 mg of the N_2H_2–NH_3 mixture from the U-trap and condensation at −196 °C in the 3 mm o.d. Pyrex tube used in the susceptibility measurements. The other sample (about 60 mg) was prepared by sealing the sample tube to the bottom of the U-tube and scraping the N_2H_2–NH_3 solid from the walls with a magnet sealed in glass, so that it fell into the sample tube as a flaky powder. After filling, both sample tubes were sealed under vacuum and stored at −196 °C. Magnetic susceptibility measurements were made with the samples cooled in liquid oxygen in a special Dewar flask.

Both samples showed a very slight paramagnetism after correction for the diamagnetism of the ammonia and the Pyrex tube. Di-imide content was estimated from the gases evolved on decomposition of samples prepared in a similar way (see below). The slight paramagnetism observed was about 1% of that expected if di-imide had the same magnetic susceptibility as O_2. The source of this weak paramagnetism is not known, and further experiments are planned, but it is clear that solid N_2H_2 at −184 °C is not strongly paramagnetic. This observation and the absence of an e.p.r. absorption appear to weigh strongly against a triplet ground state.

The Absorption Spectrum of Di-imide in the Near-u.v.

In addition to the i.r. and vacuum-u.v. spectra which he studied extensively, Trombetti (5) also reported a very weak, apparently continuous absorption centered around 3500 Å which showed no structure except a slight indication of banding with N_2D_2. We have confirmed the existence of this absorption, and have been able to examine it in much more detail, probably because we attained much higher pressures of di-imide than Trombetti. The spectrum was photographed using a Hilger medium-dispersion quartz spectrograph.[4] A large sample of N_2H_2 and NH_3 was rapidly vaporized into a 7-liter cell, 2 m long, to give a total pressure close to atmospheric and an estimated partial pressure of N_2H_2 of perhaps 50 Torr. Multiple-reflection mirrors gave a light path of 72 m. A strongly banded spectrum was obtained which decayed over a period of a few minutes. Figure 2 shows a densitometer trace from the spectroscopic plate, together with the absorption spectrum of azomethane (9) for comparison. A detailed analysis of the N_2H_2 spectrum will be published elsewhere (10). Spectra taken at higher resolution showed no rotational structure, presumably indicating strong pre-dissociation of the upper state. The absorption by N_2H_2 at 3450 Å proved to be a very convenient way to monitor its concentration during decomposition (see below).

The Electronic Structure of Di-imide in the Ground-state

Di-imide in a sense lies midway between its isoelectronic analogs, O_2 and C_2H_4, so that one might expect either a triplet ground-state, like O_2, or a singlet like C_2H_4. Another isoelectronic species, HNO, which might be regarded as a

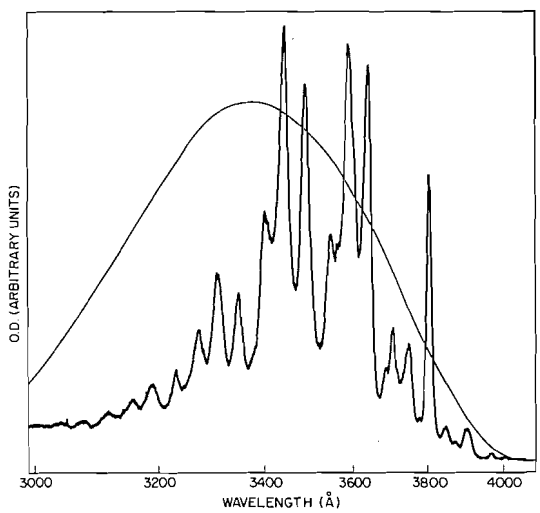

FIG. 2. Densitometer trace from spectrographic plate showing the banded near-u.v. absorption spectrum of N_2H_2 vapor. Also shown is the absorption spectrum of azomethane (8).

[3]We are grateful to Dr. A. D. Westland of the University of Ottawa for performing the magnetic susceptibility measurements.

[4]We wish to thank Dr. D. A. Ramsay, W. Goetz, M. Barnett, and F. Alberti of these Laboratories for their cooperation in these and later spectroscopic experiments.

"hybrid" of di-imide and O_2, very probably has a singlet ground-state (11). The nature of the ground-state of N_2H_2 has not yet been clearly established. There now appears to be, however, a substantial body of evidence, including some of our present observations, for a singlet rather than a triplet:

(*a*) Di-imide showed no appreciable paramagnetism in the gas phase at room temperature, in the liquid at -60 °C, or in the solid at -184 or -196 °C.

(*b*) All other known azo compounds (*i.e.*, substituted di-imides) have singlet ground-states. The near-u.v. spectra of di-imide and azomethane (Fig. 2) are strikingly similar, if one ignores the vibrational structure in the former. Furthermore, we can estimate a decadic extinction coefficient for di-imide at the maximum (3450 Å) of $6(\pm 3)$ (cm $M)^{-1}$, close to the value of 4.7 at 3380 Å for azomethane (9). All other known azo compounds have singlet ground-states, and the near-u.v. absorption is generally agreed to arise from an $n \rightarrow \pi^*$ transition. If di-imide had a triplet ground-state, the near-u.v. transition would be quite different from that of the azoalkanes, and it would seem highly fortuitous that the spectra should be so similar in respect to both λ_{max} and ε_{max}.

(*c*) If the ground-state of N_2H_2 were a triplet, one might expect a weak triplet–singlet absorption analogous to the $^1\Sigma_g^+ \leftarrow {}^3\Sigma_g^-$ observed in O_2 near 7650 Å. A careful search was conducted for absorption in N_2H_2 between 4500 and 9100 Å, using a 21 ft Eagle spectrograph and path lengths of 80 m, without success. It should be noted that no such absorption at wavelengths longer than that of the near-u.v. $n \rightarrow \pi^*$ transition appears to have been reported for any other azo compound.

(*d*) A molecular orbital calculation of the energies of the electronic states of *trans*-di-imide predicts a singlet ground-state, with the lowest triplet, formed by an $n_+ \rightarrow \pi^*$ transition, lying some 2.8 eV higher (12). It also suggests that the first excited singlet, also an $n_+ \rightarrow \pi^*$ state, is responsible for the near-u.v. absorption, and predicts an energy of 3.92 eV above the ground-state, corresponding to a wavelength of 3160 Å. The treatment also predicts several excited singlet states of about the right energy to account for the strong absorption in the vacuum-u.v.

(*e*) Very recent measurements of the i.r. spectrum of di-imide vapor (13) show an intensity alternation which appears to be unambiguous evidence for a singlet ground-state.

The only evidence for a triplet ground-state is the rotational structure observed by Trombetti (5) in the vacuum-u.v. absorption spectrum, in particular an intensity alternation with the even lines stronger than the odd. This was interpreted as evidence for a ground-state of B_u or B_g electronic symmetry, and from the correlation rules it was concluded that it must be ^3B_g, analogous to the $^3\Sigma_g^-$ ground-state of O_2. There is no obvious alternative to this interpretation. Trombetti's spectrum was obtained using a flow system in which the di-imide passed through the absorption cell within several seconds of its formation in a discharge. This raised the possibility that the spectrum observed was not that of ground-state N_2H_2, but of a short-lived excited triplet state. We have therefore photographed the vacuum-u.v. spectrum again under similar flow conditions; the flow was then stopped, isolating di-imide in the absorption cell, and spectra were taken at intervals as the di-imide decayed. All spectra obtained were essentially identical to Trombetti's, and decayed slowly over a period of several minutes. The intensity alternation in the rotational structure was confirmed, clearer than before because the spectroscopic light source was more uniform, and there seems no doubt that the spectrum observed in the vacuum-u.v. belongs to the same species of di-imide that we have been studying in the present work.

All things considered, the evidence at the present time strongly suggests that di-imide has a singlet ground-state. It is not clear, however, how the vacuum-u.v. spectrum can be reconciled with this conclusion, and until this conflict has been resolved some doubt must remain.

The Decomposition of Di-imide; Products and Stoichiometry

When di-imide decomposes at room temperature, the only products we have observed are N_2, H_2, and N_2H_4. Ammonia may also be produced (see below) but we have no positive evidence for its formation. The only other hydronitrogen compound known to be stable at room temperature is HN_3, which does not appear to be formed. The decomposition may thus be described, formally at least, as the sum of three reactions

[1] $$N_2H_2 \rightarrow N_2 + H_2$$

[2] $$\rightarrow \tfrac{1}{2}(N_2 + N_2H_4)$$

[3] $\rightarrow \frac{2}{3}(N_2 + NH_3)$

In our initial experiments, measurements of the N_2 and H_2 formed in the decomposition was used to assay the amount of di-imide present. The extent of reaction 1 is measured simply by the yield of H_2. Analysis of N_2 and H_2 alone cannot distinguish between reactions 2 and 3. The total di-imide decomposed, however, must lie between $H_2 + 1.5(N_2 - H_2)$ and $H_2 + 2(N_2 - H_2)$, the two limits corresponding to the absence of reactions 2 and 3, respectively. Table 1 shows estimates of the di-imide content of a variety of samples estimated in this way. In each case the sample was isolated in a trap at -196 °C, thoroughly pumped to remove all volatile gases, vaporized into a suitable closed volume by warming, and the di-imide allowed to decompose at room temperature for 20 min, essentially to complete decomposition. N_2 and H_2 were removed through traps at -196 °C by a Toepler pump, measured in a gas burette, and analyzed with a hot Pd thimble. Ammonia present in the traps, together with hydrazine, was vaporized and measured as a gas.

In the first estimate of the rate of decomposition, N_2H_2 was rapidly vaporized, rapidly recondensed at -196 °C after a variable time interval, and the noncondensible gases removed for analysis. The remaining N_2H_2 was then allowed to decompose completely, and the gases measured. Di-imide decomposed and di-imide remaining for each decay time was estimated as before from the measurement of N_2 and H_2. These experiments showed that N_2H_2 vapor decayed with half-life of several minutes. It was also found that even when the di-imide was recondensed within 2 or 3 s of vaporization, a sizeable and variable amount decomposed, never less than about 20%, apparently during the vaporization process itself. It also appeared that the stoichiometry of this decomposition was different from that of the subsequent slow decomposition of the vapor, with relatively more H_2 produced in the latter. To distinguish between the two processes, a sample-splitting technique was required because the decomposition during vaporization was not reproducible. A sample of di-imide was rapidly vaporized simultaneously into two nearly identical 100 ml Pyrex bulbs. Each bulb was then isolated, and in one the di-imide was allowed to decompose completely, while di-imide in the other was rapidly removed and condensed (within 1 or 2 s) at -196 °C. Product gases from the first bulb were those from both the vaporization process and the vapor-phase decomposition, while those from the second were from the vaporization process only. Data obtained in this way are shown in Table 2. The sizeable extent and the irregular variation of the fraction of the N_2H_2 decomposed during vaporization (column 6) may be noted. The ratio of products, H_2/N_2, was found to vary systematically with the amount of N_2H_2 decomposed, and in a different way for each of the two decomposition processes; this is shown in Fig. 3. For the slow decomposition of the vapor the ratio tends towards unity as the amount of N_2H_2 tends towards zero, and towards zero at high concentration of N_2H_2. The H_2/N_2 ratio for the decomposition during vaporization is partially complementary, approaching zero at low N_2H_2 concentrations and levelling out at about 0.31 at high.

Estimation of the relative importance of reactions 2 and 3 proved difficult. Colorimetric determination of N_2H_4 (14) produced in the overall decomposition of N_2H_2 always gave values considerably in excess of $N_2 - H_2$, an impossible result, probably because of extra N_2H_4 coming from stopcock grease and glass surfaces. A direct spectrophotometric measurement of N_2H_4 in the gas phase seemed more promising. The absorption spectrum of hydrazine vapor above 2000 Å was measured[5] and is shown in Fig. 4 together with that of NH_3 (15). Figure 5 shows partial pressure of N_2H_4 measured by light absorption at 2400 Å (where absorption by ammonia was completely negligible) following rapid vaporization of N_2H_2 (with NH_3) from the U-trap into a 10 cm cylindrical quartz cell mounted in a Heath single-beam spectrophotometer. The figure shows clearly the

[5]The only previous information about the absorption spectrum in this region appears to be in the brief accounts by Imanishi in 1931 and Hilgendorff in 1935 (16). Imanishi reported bands with maxima at 2326, 2320, 2276, 2250, and 2225 Å, followed by a continuum below 2200 Å. The only bands we observed, either in the spectrophotometer or in a photographic spectrum taken with a medium-dispersion Hilger spectrograph, correlated with those of NH_3, an impurity which is difficult to remove completely (these were subtracted from the spectrum shown in Fig. 4). It seems probable that Imanishi's bands had a similar origin, although the wavelengths reported seem to be about 100 Å units too high. Hilgendorff reported a highly structured spectrum, undoubtedly that of an impurity.

*First and sixth columns are based on assumption that reaction 3 does not occur, *i.e.*, N_2H_2 decomposed $= H_2 + 2(N_2 - H_2)$.

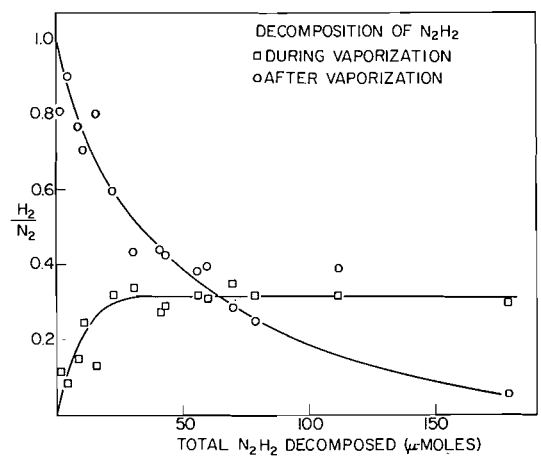

FIG. 3. Product ratios from the decomposition of N_2H_2, using sample-splitting technique.

N_2H_4 initially present, formed during the rapid vaporization, and then the slow increase, over a period of minutes, as the N_2H_2 decomposed. In a series of experiments, di-imide was vaporized into the spectrophotometer cell and isolated. Initial and final pressures of N_2H_4 were measured as in Fig. 5, and after complete decomposition of the N_2H_2, N_2 and H_2 were removed from the cell and measured. Results are shown in Table 3, with all quantities expressed as partial pressures in the reaction cell. Most notable is the large and irregular variation (from 17 to 71%) in the fraction of the total hydrazine present initially, illustrating again the irreproducible character of the decomposition during vaporization. Total product yields were more reproducible; Fig. 6 shows plots of H_2 and N_2H_4 ($\times 2$), which should be equal to the N_2H_2 consumed in reactions 1 and 2, respectively, against total N_2H_2 decomposed. Figure 7 shows a plot of total hydrazine *vs.* $N_2 - H_2$, which should have a slope of one (the straight line in the figure) if reactions 1 and 2 were the only sources of N_2. Yields of N_2H_4 fell well below $N_2 - H_2$ at the higher pressures, which might be attributed to the occurrence of reaction 3. An equally probable cause, however, is a partial fractionation of the sample during the vaporization from the U-trap, as the less-volatile N_2H_4 would tend to be left behind.

To avoid these problems, a sample-splitting technique was used as before to correct for the N_2 and H_2 formed during vaporization. This permitted comparison of yields of N_2 and H_2 from the vapor-phase decomposition alone with the corresponding yields of N_2H_4 built up during the di-imide decay. From such measurements, hydrazine yields were found, within

*Based on total N_2 and H_2 recovered from reaction vessel after complete decay, assuming $N_2H_2 = H_2 + 2(N_2 - H_2)$. This includes therefore N_2H_2 decomposed during vaporization, the products from which entered the reaction vessel, as well as N_2H_2 which actually entered the reaction vessel as such.

considerable scatter, to be somewhat in excess of the value of $N_2 - H_2$, suggesting that ammonia formation via reaction 3 was not important in the vapor-phase decomposition.

An attempt was also made to detect ammonia production during the decay of N_2H_2 by following the light absorption simultaneously at two wavelengths, 2192 and 2166 Å, the first at a minimum and the second at a maximum in the NH_3 spectrum (Fig. 4). The increase in optical density during the decay was found to be just proportional to the extinction coefficient of N_2H_4 at each wavelength, implying that only N_2H_4 was produced. The strong absorption by NH_3 initially present made this measurement rather insensitive, however, and permitted only

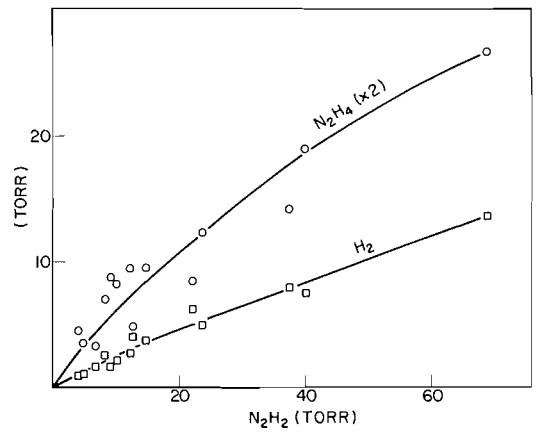

FIG. 6. Yields of H_2 and N_2H_4(× 2) from the decomposition of N_2H_2, corresponding to consumption of N_2H_2 in reactions 1 and 2, respectively.

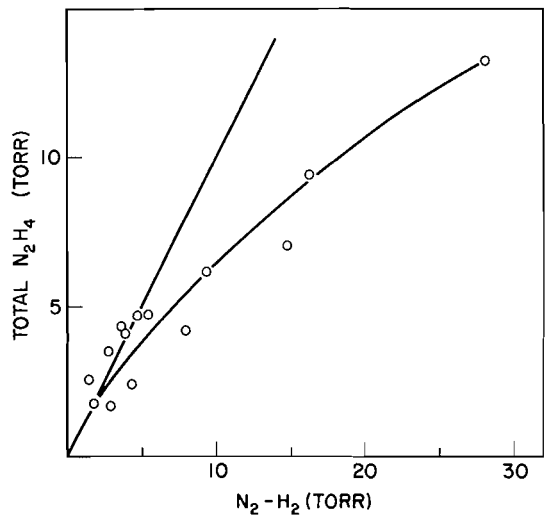

FIG. 7. Yield of N_2H_4 vs. (N_2 − H_2) from the decomposition of N_2H_2. The straight line corresponds to $N_2H_4 = N_2 - H_2$, the stoichiometry expected if reactions 1 and 2 were the only sources of N_2.

a rather large upper limit for reaction 3 of 50% of reaction 2.

To sum up, we have no positive evidence for the occurrence of reaction 3, but the large excess of NH_3 always present and the experimental scatter in the product analysis make it difficult to rule out completely.

The Kinetics of the Decomposition of Di-imide

The kinetics of the vapor-phase decomposition was studied directly by following the absorption of light at 3450 Å in the spectrophotometer cell. A typical decay curve is shown in Fig. 8, and a first-order plot of the same data in Fig. 9. The decay was also followed by observing the increase in N_2H_4 with time by monitoring the absorption at 2400 Å, as in Fig. 5. Essentially identical data were obtained from the disappearance of N_2H_2 and the formation of N_2H_4, indicating a roughly constant stoichiometry throughout the course of the decomposition.

The rate of decomposition appeared to depend on the condition of the surface of the reaction cell. Exposure to air or water vapor always ap-

preciably increased the rate of decomposition, which subsequently returned to its normal value after prolonged pumping (overnight or longer). The cell was given no special surface treatment, and after prolonged pumping and exposure a few times to the N_2H_2–NH_3 mixture and its decomposition products, the rate of decomposition became reproducible to about $\pm 10\%$. A dozen experiments, done intermittently over a period of weeks under roughly similar conditions, gave a first-order rate constant of 3.8 (± 0.5) $\times$ 10^{-3} s^{-1} for the disappearance of di-imide at 22 °C. In another series of experiments the rate of decomposition was measured with varying amounts of di-imide, corresponding roughly to the conditions of the stoichiometric measurements in Fig. 3. The first-order rate constant showed a steady decrease with increasing amounts of N_2H_2, approximately parallel to the decrease in H_2/N_2 from the gas-phase reaction. The cell used in these and most of the other experiments was a quartz cell with Suprasil windows, obtained from Hellma (Canada) Ltd. In a similar cell, 20 cm long, made in our glass shop from commercial quartz tubing and Suprasil windows, rates of decomposition were 2 or 3 times faster, and none of a variety of treatments of the surface had much effect. The decay in a Pyrex vessel was also appreciably faster than in the Hellma cell, which appears to have a surface which is relatively inactive in promoting decomposition of di-imide.

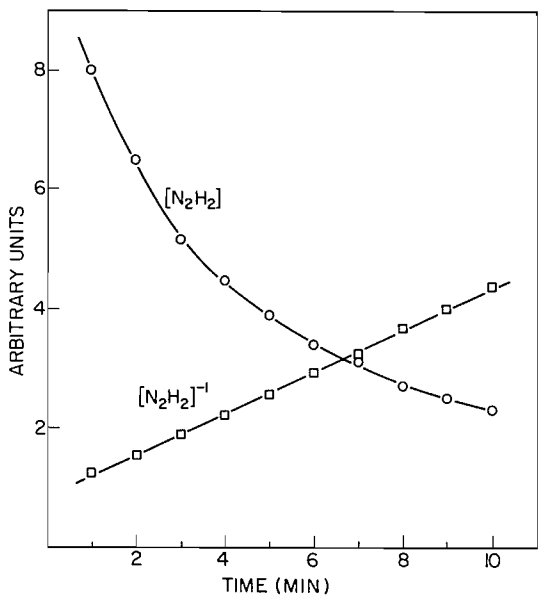

FIG. 10. Plots showing second-order disappearance of N_2H_2 vapor in cell conditioned by butadiene; followed by light absorption at 3450 Å.

A more striking surface effect was observed following some experiments in which the Hellma cell was exposed to butadiene at 200 °C. Subsequently, for several days afterwards, the decomposition of di-imide was markedly slower and showed second-order kinetics. Decay data at 33 °C in the butadiene-conditioned cell are shown in Fig. 10. At higher temperatures, mixed first-and-second-order kinetics were observed, tending towards first-order at longer times. The initial second-order rate constant increased with increasing temperature between 30 and 200 °C, corresponding roughly to an activation energy of about 20 kcal/mol. The half-life at 200 °C, the highest temperature studied, was about 14 s. Over a period of days, with pumping, the cell slowly reverted to its former behavior and di-imide decomposed at about its former rate, generally with simple first-order kinetics. In some experiments an upward curvature was evident in the first-order plot, usually at the beginning of the decay, and examination of earlier data showed that this had occurred in some cases prior to the conditioning by butadiene (Fig. 9, for example, shows distinct curvature). It may be concluded from these experiments that there are (at least) two modes of decomposition of di-imide in the vapor-phase; that the first-order decay in the "normal" cell is surface dependent and was inhibited by conditioning with butadiene at 200 °C, and that the slower, second-order reaction only became evident when the first-order process was inhibited or the N_2H_2 concentration was high.

The decomposition of N_2H_2 was also studied briefly by mass spectrometry.[6] Di-imide (with the usual ammonia) was rapidly vaporized into a tubular Pyrex vessel of about 0.8 l volume to give a total pressure not exceeding a few Torr. A pinhole in a metal disc at one end led to the ionization chamber of an EAI Quad 250A mass spectrometer. Mass spectra were recorded at 10- or 30-s intervals. Signals at m/e = 1, 2, 28, 31, and 32 increased, confirming that H_2, N_2, and N_2H_4 were products of the decomposition, while those at 30 and 29, from N_2H_2, decreased.

[6]Dr. M. R. Dunn collaborated in these experiments.

For personal use only.

Both product formation and di-imide disappearance followed first-order kinetics with a half-life appreciably shorter than that observed in the quartz cell. The faster decay may reflect a more active surface or perhaps the relatively low total pressure and partial pressure of N_2H_2. Once again, the amount of NH_3 initially present was too large to observe with any accuracy whether or not this was a product of the decomposition.

The Effect of Added Gases on the Decomposition of N_2H_2

Figure 11 shows the effect of several added gases on the product ratio, H_2/N_2, for gas-phase decomposition of N_2H_2. The additive was in each case condensed at -196 °C with a roughly constant amount of N_2H_2 and NH_3, and the mixture rapidly vaporized together. Sample splitting was used as before to correct for decomposition during vaporization.

All the additives caused a reduction in the H_2/N_2 ratio. Total product yields were somewhat enhanced, probably because more N_2H_2 was swept into the reaction vessels from the U-trap by the vaporization of the additive. The effect of NH_3 on the H_2/N_2 ratio is significant because NH_3 was present in all our experiments with di-imide. This raises the possibility that the effective variable in Table 2 and Fig. 3 is the pressure of NH_3 rather than the amount of N_2H_2, since the two were roughly proportional. It appears however that the reduction in H_2/N_2 in the experiments shown in Fig. 3, in which the highest pressure of NH_3 was less than 760 Torr, is too large to be explained entirely in this way, although it may be an important factor.

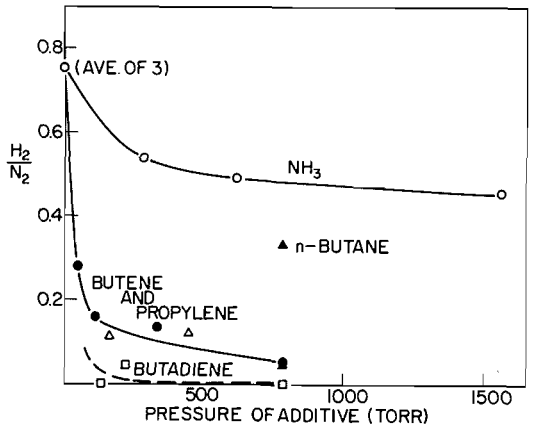

FIG. 11. Effect of additives on the H_2/N_2 ratio from the decomposition of N_2H_2 in the vapor phase.

While *n*-butane was somewhat more effective than NH_3 in reducing the H_2/N_2 ratio, the olefins were very much more effective (Fig. 11). This suggests a reaction of the latter with di-imide, so their effect on the rate of disappearance of di-imide was examined. This was complicated by the surface effects noted earlier, but by alternating experiments with and without olefin present, it was possible to conclude that pressures up to 500 Torr of propylene and *cis*-butene-2 had virtually no effect on the rate of decay, but that butadiene definitely enhanced the rate, perhaps by a factor of 2 with 500 Torr at 33 °C. Pressure of NH_3 in these experiments was typically about 200 Torr. Analysis by gas chromatography showed that butene-1 was formed in the reaction with butadiene, but the amounts were small, less than 5% of the N_2H_2 decomposed. The effect of olefins, and particularly of butadiene, on the decomposition of N_2H_2 thus presents some curious contradictions; a strong suppression of H_2 formation in the gas-phase decomposition (Fig. 11), a much lesser effect on the rate of di-imide disappearance, and relatively little formation of reduction products.

Several other gases were tested for their effect on the rate of disappearance of N_2H_2. Propane, *n*-butane, and nitrogen had no effect at pressures close to atmospheric. Oxygen increased the rate to about the same extent as butadiene.

The Mechanism of the Decomposition of Di-imide

The present study has shown that the decomposition is surprisingly complex, both kinetically and stoichiometrically. The decomposition during vaporization seems most unusual. This is a rapid process, complete in no more than 1 or 2 s. It yields predominately $N_2H_2 + N_2$, but with H_2 becoming important with increasing amount of N_2H_2 (Fig. 3). It does not involve unstable species from the discharge trapped at -196 °C, because it still occurs after one or more trap-to-trap distillations, each new vaporization causing new decomposition. The major part of this decomposition is perhaps most simply explained by a bimolecular reaction

$$[4] \qquad 2\,N_2H_2 \rightarrow N_2 + N_2H_4$$

essentially the same as that occurring more

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

slowly in the vapor phase, but greatly enhanced by the much higher concentrations present in the transient liquid phase formed during the rapid vaporization of the NH_3–N_2H_2 mixture. Formation of H_2 and the increase in the H_2/N_2 ratio with increasing sample size is less easily explained.

There appears to be good evidence for at least two concurrent processes in the decomposition of the vapor. It is reasonable to suggest that reaction 1, occurring largely as a surface reaction, can account for the high value of the H_2/N_2 ratio, approaching unity, at low sample size (Fig. 3); a gas-phase component of this reaction cannot be ruled out. The decrease in H_2/N_2 evident in Figs. 3 and 11 can be explained by reaction 4, occurring as a second-order gas-phase reaction which becomes more important as N_2H_2 concentration increases or reaction 1 is suppressed. The kinetic studies, however, showed that disappearance of N_2H_2 could still be purely first-order under conditions where H_2/N_2 was much less than unity and production of N_2 and N_2H_4 must have been important, which requires that reaction 4 proceed in part by first-order kinetics. One interesting possibility, tentatively suggested by Mock (6) and others, is that the rate-controlling step could be the *trans–cis* isomerization of N_2H_2, followed by rapid disappearance of *cis*-N_2H_2 via reaction 4 or reaction 1. *cis*-Di-imide has been observed only in the low-temperature matrix-photolysis of HN_3 in which it was presumably formed by reactions of NH radicals (2). It seems fairly well established that only the *trans* form is present in the vapor phase at room temperature and can be trapped downstream from a discharge in hydrazine vapor (5). This suggests that the *cis* isomer is unstable, and certainly *cis* conformation would seem to be required for reactions 1 and 4. Two theoretical treatments of the *cis–trans* isomerism are inconclusive; one indicated that the *cis* isomer is about 8 kcal/mol more stable (thermodynamically) than the *trans*, with a low activation energy (~12 kcal) for isomerization (17), while the other predicted just the reverse, the *trans* form more stable and a sizeable barrier (~40 kcal) for isomerization (18). *cis*-Di-imide might also be invoked in explaining the decomposition during vaporization. Formation of a certain fraction of *cis* isomer in the liquid phase, followed by rapid decomposition via reactions 1 and 4, could account for some of the unusual features.

In the present discussion of mechanisms, molecular rather than free-radical reactions have been suggested. Plausible free-radical chains can certainly be written, but the low activation energy, the sizeable reaction rate at room temperature, and the lack of inhibition by olefins make these appear rather unlikely. Reactions forming ammonia have also not been discussed because we have no positive evidence for its formation.

Di-imide as an Intermediate in Other systems

Di-imide has been postulated as a transient intermediate in a variety of gas-phase reactions. These include the combination of NH radicals (19, 20), the reaction of NH with HNCO (21) and with HN_3 (22), and in the photolysis (23), pyrolysis (24), and glow discharge decomposition (25) of N_2H_4. It has been detected as an intermediate in the decomposition flame of N_2H_4 (26), and in the reaction of O with N_2H_4 (27). In most of these systems di-imide has been regarded as a very short-lived transient that rapidly decomposed, usually to give simply $N_2 + H_2$. The relatively long lifetime observed in the present study suggests that di-imide could play a much more complex role in the chemistry of these and other hydronitrogen reaction systems. It might well be a major primary product in processes such as photolysis, pyrolysis, or radiolysis, disappearing by a variety of rapid secondary reactions. The mechanisms of such hydronitrogen systems have remained surprisingly obscure and intractable (the precise mode of formation of N_2 in the photolysis of NH_3, for example, is not known) and the possible participation of di-imide as a reactive intermediate in some of these systems should be considered.

Di-imide of course has also been postulated as a transient reactive intermediate in aqueous and other solutions in which it is generated *in situ* (1). There seems little doubt that the active reducing agent in these systems is in fact di-imide, although its behavior (rapid and efficient reduction of olefins, or in their absence "self reduction" (reaction 4), with little or no decomposition to N_2 and H_2 (reaction 1)) seems markedly

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

different than that of di-imide in the present study. The difference presumably must be attributed to solvation effects which greatly enhance the rates of the reduction reactions of di-imide. This might involve facilitation of the *trans–cis* isomerization, or preferential formation of the *cis* isomer, since the reduction reactions would seem to require a *cis* configuration. The decomposition of di-imide during vaporization observed in the present work is not unlike the self reduction seen in solution, both in its rapidity and in the preferential decomposition to N_2H_4 and N_2. This tends to support the suggestion that it occurs in a transient liquid ammonia solution formed during the vaporization process, although the apparent stability of di-imide–ammonia mixtures at temperatures up to $-30\,^{\circ}C$ implies a sizeable activation energy if the reaction is to be rapid at the only moderately higher temperatures possible in the vaporizing liquid.

Summary and Conclusions

The present paper describes an investigation of some of the chemistry of "free" di-imide ("free" rather than prepared *in situ* in a reactive medium). The chemistry is obviously complex; more questions have been raised than answered, and much more work is required. Our chief findings may be summarized:

(*1*) It has been established that di-imide is much more stable than was generally supposed, having a lifetime of minutes at room temperature.

(*2*) Preparation, techniques of handling, and analysis of di-imide have been studied and described. Some physical properties of di-imide and di-imide–ammonia mixtures have been measured. Measurements of magnetic susceptibility and e.s.r. experiments showed that di-imide is apparently not strongly paramagnetic.

(*3*) The near-u.v. absorption spectrum of the vapor was measured, and except for a strongly banded structure, was found to be closely similar both in λ_{max} and ε_{max} to that of azomethane and other alkyl azo compounds. This, and the lack of paramagnetism suggest that the ground-state of di-imide is a singlet rather than a triplet.

(*4*) The decomposition of di-imide vapor is complicated by a rapid and sizeable decomposition during vaporization as well as the relatively slow decomposition in the vapor phase. Products of the decomposition are N_2, H_2, N_2H_4, and possibly NH_3. Stoichiometry of the two modes of decomposition was different and was affected by sample size, total pressure and presence of added gases.

(*5*) Kinetics of the decomposition of the vapor was studied spectrophotometrically by following the decrease in light absorption by N_2H_2 at 3450 Å, or the increase in absorption by N_2H_4 at 2400 Å. Kinetics were usually approximately first-order, but the decomposition showed a strong surface dependence, and became second-order in a cell conditioned with butadiene. The kinetics are obviously complex, with at least two concurrent processes involved, a decomposition to $N_2 + H_2$, and a bimolecular reaction yielding $N_2 + N_2H_4$, and with reactions occurring both in the gas phase and on the surface. Mechanisms have been tentatively suggested, and the possible role of *cis*-di-imide discussed.

Scope and Limitations of a Cyclization Leading to Phenanthrene Derivatives

C. SCHMIDT[1] AND J. THAZHUTHAVEETIL
Department of Chemistry, University of Prince Edward Island, Charlottetown, Prince Edward Island

Received April 30, 1973

The scope and limitations of a modified Bogert–Cook cyclization was investigated. It was found that the sequence is applicable only for the unsubstituted and the meta-substituted series.

La généralité et les limitations d'une réaction de cyclisation de Bogert–Cook modifiée ont été examinées. Il a été trouvé que la séquence est applicable uniquement aux séries de composés non substitués ou substitués en mêta. [Traduit par le journal]

Can. J. Chem., **51**, 3620 (1973)

Recently we reported on a sequence (1) which could be regarded as a modification of the Bogert–Cook (2) reaction (**1** → **2** → **3**). For obvious reasons this reaction would be more useful if it could be extended to compounds in which the aromatic nuclei are carrying potential functional groups. The present paper gives a full account on the unsubstituted example and reports on all compounds carrying one methoxy group in the aromatic ring. It has been found that the sequence is applicable only to the meta-substituted and the unsubstituted series. Starting with the ortho- and para-substituted Nef adducts **7***a* and *b* led to no useful products.

Results and Discussion

The addition of the appropriately substituted sodium phenylacetylide to 2,6-dimethylcyclohexanone in liquid ammonia led to the acetylene alcohols **1***a* and **1***b* and **7***a* and **7***b*. Apparently only one stereoisomer was formed in these Nef reactions corroborated by the fact that **7***a* and *b* were obtained in crystalline form. Although *o*-methoxyphenylacetylene was previously prepared from benzofurane using a sealed tube (3, 4), we developed a more practical preparation starting with *o*-methoxyacetophenone. The so far neglected traditional method gives a 35% yield after purifying the product as the silver salt.

The Rupe rearrangment of acetylenic alcohols **1***a* and *b* gave unsaturated ketones **2***a* and *b*, respectively, in 60% yield. In both reactions a less polar unidentified polymer was also formed whose formation could not be avoided under various conditions.

Cyclization of unsaturated ketone **2***a* to the tricyclic product **3***a* was carried out in polyphosphoric acid in 90% yield. The appearance of a saturated carbonyl group (i.r. 1710 cm^{-1}) and a three-proton singlet at 8.93 τ corresponding to the angular methyl group are evidence for the tricyclic structure in **3***a*.

From **2***b* the cyclization in polyphosphoric acid led to a crystalline mixture of monoketone **3***b* and diketone **4***b*. The latter compound must have been formed as a result of atmospheric oxidation. Due to the experimental features of the reaction it was impossible to exclude oxygen completely. Since the two compounds could not be separated by re-crystallization or chromatography the entire sample was subjected to SeO_2 oxidation leading to the pure diketone **4***b* in 75% yield.

For diketone **4***b* there is an alternative structural possibility **6**; a similar structure is possible for the corresponding monoketone **3***b*. It is well known from the vast information concerning aromatic substitutions that the formation of a 1,2,3-vicinal trisubstituted isomer is disfavored in comparison to the 1,2,4-trisubstituted compound (5). Since only one isomer was formed in the cyclization, structure **4***b* rather than **6** is assigned to the diketone. This is corroborated by the 220 MHz n.m.r. of diketone **4***b*. The extracted coupling constants in the aromatic region, $J_{6,8}$ = 3.0 Hz, $J_{5,8}$ = 0.1 Hz, and $J_{5,6}$ = 8.8 Hz are in agreement with the accepted meta, para, and ortho values, respectively (6). Structure **6** would have been expected

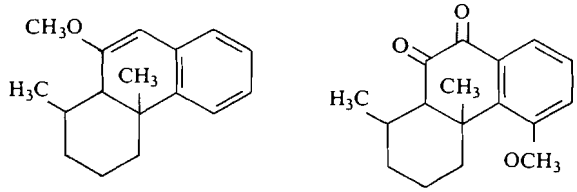
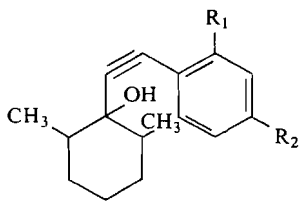
a R=H
b R=OCH$_3$



5 6



7

a R_1=OCH$_3$; R_2=H
b R_1=H; R_2=CH$_3$O

to have two coupling constants of 8 Hz and another of 3 Hz. The central hydrogen should have appeared as a triplet with two ortho couplings, contrary to the actual splitting pattern: τ 2.73 (m), 2.62 (d), and 2.40 (d).

When the *o*-methoxy substituted phenylacetylene alcohol **7***a* was refluxed with formic acid the product formed contained no carbonyl and its n.m.r. showed the absence of the methoxy group. Consequently it was not investigated any further. The para-substituted isomer **7***b* under the same conditions led to the formation of unidentified polymers only.

The stereochemistry of tricyclic ketone **3***a* was erroneously assigned in our previous publication as *trans* (1). This error should now be corrected.

In order to elucidate the stereochemistry of the ring juncture in **3***a* an attempt was made to isomerize it to the thermodynamically more stable product. The alkaline treatment of **3***a* led to complex changes. Refluxing in methyl alcohol containing hydrochloric acid led to the enol ether **5** and diketone **4***a*. In the absence of oxygen under the same conditions only enol ether **5** and monoketone **3***a* were recovered. The fact that enol ether **5** was also formed during the attempted isomerization indicates that enolization indeed took place thus providing suitable conditions for equilibration. This contention could be corroborated by demonstrating that deuterium was incorporated into ketone **3***a* at positions 9 and 10a when the same reaction was carried out in CH_3OD. Therefore, it can be concluded that the thermodynamically more stable isomer was formed during the cyclization, and the necessary conditions were provided for the isomerization.

It is now generally accepted that in angularly methylated hexahydrophenantrene systems the *cis* isomer is more stable than the corresponding *trans*-fused compound (7–9). Therefore, the ring junction in **3***a* is reassigned as *cis*. With SeO_2 the monoketone **3***a* was oxidized to diketone **4***a*. In the n.m.r. of the latter compound a clearly resolved one-proton doublet at $\tau = 7.45, J = 10$ Hz indicates a *trans*-diaxial relationship of the two hydrogens at C-1 and C-10*a*. Consequently, the 4-methyl group in **4***a* is assigned equatorial.

The same stereochemistry is assigned to diketone **4***b* since the angular methyl signal and the one-proton doublet assigned to H_{10a} deviated less than 0.04 p.p.m. in the two diketones. While in the Bogert–Cook reaction a *cis–trans* mixture is formed (8,9), in this cyclization only the *cis* isomer is formed. Naturally the possibility cannot be excluded that the *trans*-fused isomer was also formed in this reaction and then it subsequently isomerized to the thermodynamically more stable *cis*-isomer under the conditions of cyclization. The obtained stereochemical outcome can however be explained more coherently on mechanistic grounds. It is recognized that the unexceptional pathway of *trans*-diaxial addition of a proton and an aryl group on the $\Delta^{1,2}$ double bond of unsaturated ketone **2** should produce the stereochemistry of tricyclic ketone **3**.

Due to its predictable stereochemical outcome, the cyclization discussed here is now used in some synthetic studies in the field of diterpenes.

Experimental

All melting points were taken on a Fisher-Johns melting point apparatus and are uncorrected. The elemental analyses were carried out by Pascher Mikroanalytical Laboratorium, Bonn, West Germany, and Schwarzkopf Mikroanalytical Laboratory, Woodside, N.Y. The i.r. spectra were recorded on a Perkin-Elmer Model 137B infracord spectrophotometer. The u.v. spectrograms were taken on a Coleman-Hitachi Model 124 double-beam grating spectrophotometer. The n.m.r. spectra were recorded on a Varian Associates T60 spectrophotometer. The mass spectra were obtained with a Hitachi Perkin-Elmer Model RMS-4 spectrometer.

1-(Phenylethynyl)-2,6-dimethylcyclohexanol (1a)

To 100 ml of liquid ammonia containing 20 mg of ferric nitrate 240 mg of sodium was added in three portions. The flask was equipped with a magnetic stirrer and a drying tube containing soda lime. After the disappearance of the blue color 1.09 g of phenylacetylene dissolved in 5 ml of dry tetrahydrofuran was added. Stirring was continued for 30 min, then a solution of 1.19 g of 2,6-dimethyl-cyclohexanone in tetrahydrofuran (2 ml) was added in 10 min. The reaction mixture was stirred for 4 h then 2 g of ammonium chloride was added. After the evaporation of ammonia the product was dissolved in water and extracted with ether (4 × 35 ml). The combined ether extracts were washed in succession with saline, diluted sulfuric acid, and sodium bicarbonate solution. After drying ($MgSO_4$) and evaporation 2.0 g (92%) of oily product was obtained. An analytical sample was obtained by microdistillation at 120°/0.5 mm Hg. Mass spectrum (70 eV) *m/e* (relative intensity) 228 (31, parent peak), 210 (13), 171 (80), 129 (38), 102 (100), etc.; i.r. (CCl_4) 3400, 2840, 1600, 1485, 1155 cm^{-1}; u.v.$_{max}$ (95% C_2H_5OH) 252 mμ (ε 17 100), 242 (20 000); n.m.r. (CCl_4) τ 8.85 (d, 6, J = 6 Hz, methyls), 8.60 (cyclohexane protons), 2.80 (m, 5, aromatic protons).

Anal. Calcd. for $C_{16}H_{20}O$: C, 84.16; H, 8.83. Found: C, 84.18; H, 8.85.

1-(2,6-Dimethylcyclohexene-1-yl) Benzyl Ketone (2a)

The acetylenic alcohol **1***a* (1.06 g) was refluxed in 50 ml of 80% formic acid for 2 h. The reaction mixture was diluted with water and extracted with ether (4 × 100 ml). The organic layer was washed with sodium bicarbonate solution and then dried ($MgSO_4$). After evaporation 0.90 g of an oil was obtained. The product consisted of two components which were separated by thick layer chromatography on silica gel plates using benzene for development. The more polar compound **6***a* was isolated in 60% yield (0.605 g). An analytical sample was prepared by microdistillation at 95°/0.3 mm Hg. Mass spectrum (70 eV) *m/e* (relative intensity) M^+ ion (228) absent, 138 (25), 137 (65), 109 (100), 91 (63), etc.; i.r. (CCl_4) 2875, 1685, 1450 cm^{-1}; u.v.$_{max}$ (95% C_2H_5OH), 244 mμ (3800), 211 (8044); n.m.r. (CCl_4) τ 9.18 (d, 3, J = 8 Hz, CH—CH_3), 8.40 (s, 3, =C—CH_3), 6.40 (s, 2, CO—CH_2—Ph), 2.83 (s, 5, aromatic protons).

Anal. Calcd. for $C_{16}H_{20}O$: C, 84.16; H, 8.83. Found: C, 84.13; H, 8.85.

The less polar compound did not contain a carbonyl (i.r.) and it was not characterized any further.

10(9H)-1,2,3,4,4a,10aα-hexahydro-1α,4aα-dimethylphenanthrone (3a)

(a) Preparation

A sample of 1.046 g of unsaturated ketone **2***a* was heated with polyphosphoric acid (8 g) at 120 °C for 10 min. The cooled reaction mixture was diluted with water and extracted with ether. The organic layer was washed successively with saline and 10% sodium bicarbonate. The ether solution was dried ($MgSO_4$) then evaporated to dryness (1.02 g, 96%). T.l.c. revealed the presence of one component. The solid product was recrystallized from pentane, m.p. 64–65°. Mass spectrum (70 eV) *m/e* (relative intensity) 228 (77, parent), 213 (94), 195 (100), 159 (97); i.r. (CCl_4) 2875, 1710, 1450, 1240 cm^{-1}; u.v.$_{max}$ (95% C_2H_5OH) 282 mμ (ε 1384) and 209 (9300); n.m.r. ($CDCl_3$) τ 9.20 (d, 3, J = 7 Hz, 1-methyl), 8.93 (s, 3, angular methyl), 6.50 (s, 2, CO—CH_2—Ph), 2.80 (m, 5, aromatic).

Anal. Calcd. for $C_{16}H_{20}O$: C, 84.16; H, 8.83. Found: C, 84.14; H, 8.80.

(b) Equilibration of Tricyclic Ketone 3a

The alkaline treatment of **3***a* led to a complicated mixture. Next an acidic treatment was tried.

Ketone **3***a* (276 mg) was refluxed for 3 h in 10 ml of methanol containing 2 drops of concentrated hydrochloric acid. After cooling, the reaction mixture was diluted with water and extracted with ether (4 × 40 ml). The combined ether extracts were washed with saline, sodium bicarbonate solution (5%), and saline in succession. The product consisted of three components which were separated by thick layer chromatography on a silica gel plate using 10:90 ether–benzene for development. The most polar product was isolated in crystalline form (66 mg, 24%). This sample was shown to be identical with diketone **4***a* prepared from monoketone **3***a* with SeO_2 oxidation (*vide infra*).

To the least polar oily product (51 mg, 20%) enol ether structure **5** was assigned; i.r. (CCl_4) 2900, 1647, 1486, 1450, 1370, 1282, 1235, 1193, 1152, 1026 cm^{-1}; u.v.$_{max}$ 277 mμ (11 754), 222 (15 557); n.m.r. ($CDCl_3$) τ 9.1 (d, 3, J = 6 Hz, 1-methyl), 8.87 (s, 3, angular methyl), 6.28 (s, 3, O—CH_3), 4.55 (s, 1, proton at C-9), 2.33 (m, 4, aromatic protons) mass spectrum (70 eV) *m/e* (relative intensity) 242 (38, parent peak), 227 (31), 173 (25), 172 (100), 141 (33), 129 (37), 128 (38). A sample was distilled for analysis at 100°/1 mm Hg.

Anal. Calcd. for $C_{17}H_{22}O$: C, 84.25; H, 9.14. Found: C, 84.23; H, 9.16.

From the middle band of the chromatogram monoketone **3***a* (75 mg) was recovered. When the reaction was carried out under nitrogen only the starting material **3***a* and the enol ether **5** were isolated.

The same isomerization experiment was carried out in the presence of CH_3OD. Ketone **3***a* (200 mg) was refluxed in CH_3OD (2 ml) in the presence of CF_3COOD (0.1 ml) + D_2O (0.2 ml) for 3 h in a nitrogen atmosphere. After evaporation to dryness the entire sample was chromatographed on a silica gel plate (20 × 20). From the least polar band ketone **3***a* (75 mg) was recovered. Its n.m.r. showed that the singlet at 6.50 (CO—CH_2—Ph) decreased to about one fourth its original height. Another slight change was noticeable at 7.9 attributable to position 10*a*. In the aromatic region the signals decreased also by 25%. The position and intensity of the signals at 9.1 (d) and 8.87 (s) have not changed.

1,2,3,4,4a,10aα-Hexahydro-1α,4aα-dimethylphenanthrenequinone (4a)

A solution of monoketone **3***a* (150 mg) in 3 ml of dioxane was mixed with sublimed selenium dioxide (100 mg) and a drop of water. The mixture was stirred and refluxed for 6 h. When the oxidation was complete (t.l.c.) the mixture was filtered. The filtrate was diluted with ether and washed with saline. After drying ($MgSO_4$) and evaporation to dryness, 140 mg (88%) of crystalline diketone was obtained. It was recrystallized from pentane, yellow needles, m.p. 115–117°. Mass spectrum (70 eV) *m/e* (relative intensity) 242 (35, parent), 214 (11), 199 (29), 181 (31), 171 (30), 159 (57), 129 (71), 128 (100); i.r. (CCl_4) 2860, 1730, 1695, 1435, 1370, 1307, 1235 cm^{-1}; u.v.$_{max}$ (95% C_2H_5OH) 283 mμ (ε 8750), 209 (10 454), n.m.r. τ 9.18 (d, 3, J = 6 Hz, 1-methyl), 8.67 (s, 3, angular methyl), 7.45 (d, 1, J = 10 Hz, proton at C-10a), 2.47 (m, 4, aromatic protons).

Anal. Calcd. for $C_{16}H_{18}O_2$: C, 79.31; H, 7.49. Found: C, 79.34; H, 7.51.

1-(m-Methoxyphenylethynyl)-2,6-dimethylcyclohexanol (1b)

The acetylene alcohol **1***b* was prepared as described for **1***a* in a 90% yield using *m*-methoxyphenylacetylene (10). T.l.c. examination showed only one major component and a small amount of polymers. It was purified by thick layer chromatography on silica plates using benzene for development. An analytical sample was distilled at 102°/0.3 mm Hg. Mass spectrum (70 eV) *m/e* (relative intensity) 258 (36), 240 (67), 225 (25), 201 (54), 155 (100); i.r. (CCl_4) 3400, 2890, 1587, 1497, 1157 cm^{-1}; u.v.$_{max}$ (95% C_2H_5OH) 298 mμ (ε 2921), 290 (2900), 252 (15 357), 243.5 (15 357); n.m.r. ($CDCl_3$) τ 8.83 (d, 6, J = 6 Hz, methyls), 8.55 (cyclohexane protons), 6.20 (s, 3, OCH_3), 3.0 (m, 5, aromatic protons).

Anal. Calcd. for $C_{17}H_{22}O_2$: C, 79.03; H, 8.58. Found: C, 79.07; H, 8.53.

1-(2,6-Dimethylcyclohexene-1-yl) m-Methoxybenzyl Ketone (2b)

The acetylenic alcohol **1***b* (9.3 g) was refluxed with 80% formic acid for 2 h and worked-up as described for **2***a*. The two-component mixture was separated by column chromatography on silica gel eluting with benzene. The less polar component contained no carbonyl and had a tendency to polymerize.

The more polar component (5.2 g) was isolated as an oil in 55% yield. Mass spectrum (70 eV) *m/e* (relative intensity) 258 (3, parent), 243 (2), 225 (1), 150 (50), 137 (82), 135 (100); i.r. (CCl_4) 2825, 1675, 1587, 1477, 1443, 1250, 1143, 1042 cm^{-1}; u.v.$_{max}$ (95% C_2H_5OH) 310 mμ (ε 690), 282 (2670), 275 (2987), 208 (15 960); n.m.r. ($CDCl_3$) τ 9.08 (d, 3, J = 6 Hz, CH—CH_3), 8.38 (s, 3, =C—CH_3), 6.23 (s, 5, OCH_3 and CO—CH_2—Ar), 3.20 (m, 4, aromatic). A sample was distilled at 105°/0.3 mm Hg for analysis.

Anal. Calcd. for $C_{17}H_{22}O_2$: C, 79.03; H, 8.58. Found: C, 79.05; H, 8.56.

10(9H)-1,2,3,4,4a,10aα-Hexahydro-1α,4aα-dimethyl-7-methoxyphenanthrone (8b) and 1,2,3,4,4a,10aα-Hexahydro-7-methoxy-1α,4aα-dimethylphenanthrenequinone (4b)

A 1.2 g sample of unsaturated ketone **2***b* was heated with polyphosphoric acid (8 g) at 110° for 10 min. The

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

reaction mixture was worked-up as described for **3***a*. The yield of the crystalline product, m.p. 71–75 °C was nearly quantitative. However, even after several recrystallizations from different solvents the pure ketone **3***b* could not be isolated. The contaminant was the corresponding α-diketone, **4***b*, as recognized from the mass and n.m.r. spectra of the samples.

Consequently the mixture was oxidized to pure **4***b*. A solution of **3***b* and **4***b* (142 mg) in dioxane (3 ml) was mixed with sublimed selenium dioxide (80 mg) and a drop of water and heated under reflux for 6 h. When the oxidation was complete (t.l.c.) the product was filtered, diluted with ether, washed with brine, and dried ($MgSO_4$). After evaporation 103 mg (73%) of crystalline diketone was isolated. It was recrystallized from pentane, m.p. 133–135°. Mass spectrum (70 eV) *m/e* (relative intensity) 272 (93, parent), 257 (12), 244 (25), 229 (100), 201 (50); i.r. ($CHCl_3$) 2850, 1724, 1678, 1602, 1493, 1460, 1319, 1285 cm^{-1}; u.v.$_{max}$ (95% C_2H_5OH) 286 mμ (ε 5900), 226 (17 400); n.m.r. at 220 MHz ($CDCl_3$) τ 9.20 (d, 3, J = 6 Hz, CH—CH_3), 8.72 (s, 3, angular methyl), 7.49 (d, 1, J = 10 Hz, proton at C-10a), 6.13 (s, 3, OCH_3), 2.73 (m, 1, $J_{5,6}$ = 8.8 Hz, $J_{6,8}$ = 3.0 Hz, H_6), 2.62 (d, 1, $J_{5,6}$ = 8.8 Hz, $J_{5,8}$ = 0.1 Hz, H_5), 2.40 (d, 1, $J_{6,8}$ = 3.0 Hz, $J_{5,8}$ = 0.1 Hz, H_8).

Anal. Calcd. for $C_{17}H_{20}O_3$: C, 74.97; H, 7.40. Found: C, 74.99; H, 7.42.

o-Methoxyphenylacetylene

To a well-cooled solution of *o*-methoxyacetophenone (35 g) in benzene (100 ml) phosphorous pentachloride (50 g) was added in 45 min while stirring. The product was allowed to stand overnight at room temperature. The yellow solution was poured on ice and extracted with ether (3 × 100 ml). The combined ether extracts were washed with water, dried ($MgSO_4$) and evaporated to dryness. The product was mixed with 95% ethanol (42 ml) and potassium hydroxide (34 g) and refluxed for 24 h. Prior to working-up the mixture was tested for the complete disappearance of the dichloride (t.l.c.). The brown reaction mixture was poured on ice-water and extracted with ether (3 × 100 ml), then the ether was removed by atmospheric distillation. The residue was dissolved in ethyl alcohol (100 ml) and to the magnetically stirred solution 5% $AgNO_3$ solution was dripped until no more precipitate formed. The precipitate was filtered by suction, washed with ethyl alcohol then with ether. After suspending the precipitate in water (200 ml), 35 g of NH_4SCN was added and the mixture was stirred in the presence of ether (200 ml). The AgSCN was removed by filtration on a Buchner funnel and the filtrate was extracted with ether (4 × 100 ml). The combined ether extracts were washed with saline, dried ($MgSO_4$), and the product was distilled at 78–84°/7 mm Hg. Yield: 12 g (35%) colorless oil. Mass spectrum (70 eV) *m/e* (relative intensity) 132 (45, parent), 131 (33), 117 (11), 89 (100); u.v.$_{max}$ (95% C_2H_5OH) 301 mμ (ε 3945), 292 (3945), 250 (11 000), 239 (10 620); i.r. (CCl_4) 3448, 1600, 1274, 1242, 1042 cm^{-1}; n.m.r. ($CDCl_3$) τ 6.70 (s, 1, C≡CH), 6.2 (s, 3, OCH_3), 3.1 (s, 4, aromatic protons). The product was previously characterized (3,4).

1-(o-Methoxyphenylethynyl)-2,6-dimethylcyclohexanol (7a)

Preparation

The Nef addition between 2,6-dimethylcyclohexanone and *o*-methoxyphenylacetylene was carried out as described for **1***a*. A crystalline product was obtained (yield 97%). The analytical sample was prepared by recrystallization from ether, m.p. 84–86°. Mass spectrum (70 eV) *m/e* (relative intensity) 258 (36, parent), 240 (3), 227 (19), 201 (61), 159 (20), 131 (34), 69 (100); i.r. ($CHCl_3$) 3550, 2837, 1595, 1486, 1453, 1282, 1250, 1151, 1117, 1045, 954, 939 cm^{-1}; u.v.$_{max}$ (95% C_2H_5OH) 301 mμ (ε 6161), 292 (6140), 154.5 (20 026), 243 (17 713); n.m.r. ($CDCl_3$) 8.77 (d, 6, J = 6 Hz, methyls), 8.53 (cyclohexane protons), 6.47 (s, 3, OCH_3), 2.90 (m, 4, aromatic protons).

Anal. Calcd. for $C_{17}H_{22}O_2$: C, 79.03; H, 8.58. Found: C, 79.01; H, 8.60.

Formolysis of acetylene alcohol (7a)

A 1.925 g sample of **7***a* was refluxed with 80% formic acid (25 ml) for 3 h. The solution was then diluted with water and extracted with chloroform (3 × 100 ml). The combined chloroform extracts were washed in succession with water, 10% sodium bicarbonate, and water. The dried ($MgSO_4$) solution was evaporated to dryness. A single compound was produced according to t.l.c., which did not contain any carbonyl (i.r.) and lost the methoxy group (n.m.r.). Therefore it was not fully characterized.

1-(p-Methoxyphenylethynyl)-2,6-dimethylcyclohexanol (7b)

Preparation

The Nef addition between 2,6-dimethylcyclohexanone and *p*-methoxyphenylacetylene (11) was carried out as described for **1***a* in 93%. The crystalline product was homogeneous according to t.l.c. It was recrystallized from pentane, m.p. 46–47°. Mass spectrum (70 eV) *m/e* (relative intensity) 258 (24, parent), 244 (21), 243 (100), 225 (31), 201 (33), 135 (98); i.r. (CCl_4) 3500, 2840, 1603, 1500, 1450, 1280, 1260, 1170, 1153, 1035, 960, 940, 833 cm^{-1}; u.v. max (95% C_2H_5OH) 297 mμ (ε 3354), 285.5 (4128), 261 (23 220), 252 (24 940); n.m.r. ($CDCl_3$) τ 8.87 (d, 6, J = 6 Hz, CH—CH_3), 3.0 (g, 4, aromatic).

Anal. Calcd. for $C_{17}H_{22}O_2$: C, 79.03; H, 8.58. Found: C, 79.05; H, 8.56.

The formolysis of **7***b* led to an unidentified polymer.

The financial assistance of the National Research Council of Canada and the Senate Research Committee of University of Prince Edward Island is gratefully acknowledged. The technical assistances of Miss K. Felderhof and Mrs. E. Schmidt are greatly appreciated. The author also wishes to thank Mrs. P. Liu for secretarial work. The administration of the University is thanked for encouragement. Dr. A. A. Grey and the Ontario Research Foundation are thanked for 220 MHz n.m.r. spectra.

A Revision of the Stereochemistry of Lactucin

FRANK WILLIAM BACHELOR
Department of Chemistry, The University of Calgary, Calgary, Alberta T2N 1N4

AND

SHÔ ITÔ
Department of Chemistry, Tohoku University, Sendai, Japan

Received February 5, 1973

On the basis of circular dichroism measurements on lactucin, hydroxyachillin, and acetoxyachillin the stereochemistry of the C-5 hydrogen has been revised to the 5α configuration. The reasons for the former erroneous assignment are reexamined and the structures of several hexahydrolactucin derivatives are reinterpreted.

En se basant sur des mesures de dichroisme circulaire de la lactucine, de l'hydroxyachilline et de l'acétoxyachilline, la stéréochimie de l'hydrogène en C-5 a été révisée et la configuration 5α lui a été attribuée. Les raisons qui ont amenées l'attribution erronée précédente sont réexaminées et les structures de plusieurs dérivés de l'hexahydrolactucine sont réinterprétées.

[Traduit par le journal]

Can. J. Chem., **51**, 3626 (1973)

Lactucin (**1***a*) was the first of a group of sesquiterpenoid lactones to be isolated which contain a carbonyl group at carbon atom 2 of the guaiane carbon skeleton and a unique cross conjugated system (1, 2). Since then, other sesquiterpene lactones have been isolated which have the same chromophore but which vary mainly in their oxygenation pattern and stereochemistry. Among these are matricarin (**2***a*) (3), the achillins (**3***a*, *b*, *c*) (4), and leucodin (**2***c*) (5). The stereochemistry of these latter compounds has been firmly established (6, 7) and lactucin (**1**) appears to be the only member of this group which contains a 5β-hydrogen atom. We have examined the n.m.r. and circular dichroism (c.d.) spectra of lactucin (**1**), hydroxyachillin (**3***b*), and acetoxyachillin (**3***c*) and find that the stereochemistry of the former compound at C-5 must be revised to the α-configuration.

An examination of the n.m.r. of these three compounds shows a great deal of similarity as a whole. Furthermore, all protons have been assigned properly for lactucin and the coupling constants determined by nuclear magnetic double resonance (n.m.d.r.) experiments (Table 1). Thus, coupling constants $J_{5,6}$, $J_{6,7}$, $J_{7,8}$ shown in Table 1 are in good agreement with those in hydroxyachillin and acetoxyachillin. This strongly suggests that these three natural lactones have the same *trans* configurations at C_5—C_6, C_6—C_7, and C_7—C_8.

The identical absolute stereochemistry in these compounds was concluded from their c.d. spectra (*cf.* Table 2). Circular dichroism curves of hydroxyachillin and acetoxyachillin are composed essentially of three maxima, which can be attributed to the n–π* transition of the γ-lactone, π–π* and to the n–π* transition of the dienone. The assignment of the strong positive transition at 252–255 nm to the π–π* transition of the unsaturated system was supported by the strong u.v. absorption at 253 nm (ε 13 200).

The c.d. curve of lactucin contains four transitions. Three transitions at 210!, 248, and 350 nm are in accord with the u.v. maxima, 210! (ε 14 000), 254 (ε 14 200), and 330 (ε 77) and can be assigned to the π–π* transition of the unsaturated lactone, π–π*, and n–π* transition of the dienone system, respectively. The fourth transition at 275 nm is ascribable to the n–π* transition of the unsaturated lactone from the following considerations. A c.d. study of Stöcklin, *et al.* (8) clearly established that (*i*) in spite of a negligible u.v. maximum, the *trans*-α-methylene-γ-lactones incorporated in a guaiane skeleton invariably exhibit a negative Cotton effect due to their n–π* transition at 250–265 nm when the lactones are closed at C-6 and (*ii*) this situation is not altered by the neighboring oxygen functions, unlike the case of *cis* lactones. The 230–300 nm region in the c.d. curve of lactucin is therefore explicable as the result of the overlap of the

π–π* transition of the dienone system at ~255 nm and the n–π* transition of the unsaturated lactone at ~265 nm which possess opposite sign. Thus, in all three compounds examined, the π–π* transition of the cross conjugated dienone system has the same positive sign, and therefore, the same chirality. Since the stereochemistry of the C-5 hydrogen atom has been firmly established as α in acetoxyachillin (**3***c*) (7) this must also be the case with lactucin.

The difference in sign of the n–π* transition of the unsaturated ketones is probably caused by the presence of a hydroxymethylene group in lactucin. The reversion of the sign by the presence of hydroxyl or acetoxyl or epoxy groups has precedents (9) and even in these instances the extrema due to the n–π* transition is not affected.[1]

In view of this revision of stereochemistry, it is necessary to reexamine the original proposals to understand why erroneous conclusions were reached. All three of these proposals (1, 2, 10) were based on hexahydrolactucin (**4**). Barton and Narayanan (1) prepared a benzylidene derivative from hexahydrolactucin by isomerizing it first with alcoholic alkali, followed by the reaction with benzaldehyde in acid. They proposed structure **5** for this compound. An adduct of this kind cannot be formed at all if the 8-hydroxyl group and the hydroxymethylene groups are *cis* to each other and also to the 5-hydrogen atom. We propose that the benzylidene compound is in fact the rearranged lactone **6** with the benzylidene bridge across the 6-hydroxyl and hydroxymethylene groups. The conformational analysis of Hendrickson (8) was based on this compound (**5**) and was obviously also incorrect.

Šorm and co-workers (2) based their stereochemistry on the optical rotatory dispersion (o.r.d.) spectrum of hexahydrolactucin and concluded that it had a 1α, 5β hydrogen configuration (**7**). This was based on comparison with the o.r.d. of 15-oxocholestanone (**8**) (11) which contains the *trans*-linked perhydroindanone system. Both showed positive Cotton effects.

However, a survey of the literature revealed that it is not necessarily correct. For example, the compounds **9**–**11**, all containing the *cis*-fused perhydroindanone system, also show positive Cotton effects (12, 13). In addition, compound **12** with the opposite configuration shows a comparable negative Cotton effect (14). The sign of the Cotton effect reveals only the configuration of the hydrogen atom at C-1 but not that at C-5. The smaller amplitude of the Cotton effect ($[\alpha]_{max}$ +1682°) implies a *cis*-perhydroindan-1-one.

A Unique Menschutkin Reaction Involving Fragmentation and Cyclization[1]

RAPHAEL M. OTTENBRITE AND G. RODNEY MYERS
Department of Chemistry and Pharmaceutical Chemistry, Virginia Commonwealth University Richmond, Virginia 23219

Received February 23, 1973

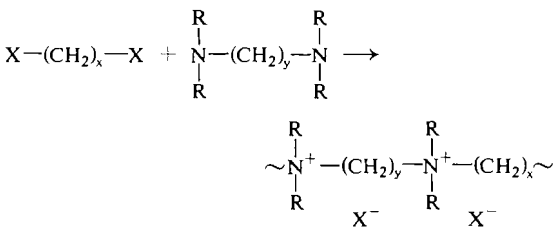
It was found that *N,N,N',N'*-tetramethylmethylenediamine reacted with a number of dihalides to form the corresponding cyclic quaternary ammonium compound and dimethylamine hydrohalide. The process involves a Menschutkin reaction with fragmentation of *N,N*-dimethylmethyleneamine followed by a second Menschutkin reaction to form a cyclic compound. The reaction proceeds best in a polar solvent and the yields are moderate to good.

On a trouvé que la *N,N,N',N'*-tétraméthylméthylènediamine réagit avec un certain nombre de dérivés dihalogénés pour former le sel d'ammonium quaternaire correspondant ainsi que l'halohydrate de la diméthylamine. Ce processus implique une première réaction de Menschutkin provoquant la fragmentation de la *N,N*-diméthylméthylèneamine suivie d'une deuxième réaction de Menschutkin pour former le composé cyclique. La réaction se fait le mieux dans un solvant polaire et les rendements sont de modérés à bons. [Traduit par le journal]

Can. J. Chem., 51, 3631 (1973)

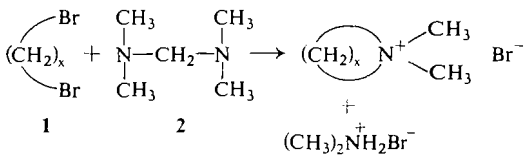
Introduction

The Menschutkin reaction (1) is a well-known process for the formation of quaternary ammonium salts from tertiary amines. It also has been used for the synthesis of quaternary ammonium polyelectrolytes (2) by reacting tertiary diamines with dihalides.



During studies of preparation of new cationic polymers, we observed that *N,N,N',N'*-tetramethylmethylenediamine did not give the expected linear cationic polymer when reacted with dihalides such as 1,4-dibromobutane and 1,5-dibromopentane. It was found that the corresponding cyclic dimethyl quaternary ammonium compounds, 1,1-dimethylpyrrolidinium bromide and 1,1-dimethylpiperidinium bromide, were obtained instead.

This unusual behavior of *N,N,N',N'*-tetramethylmethylenediamine was also observed by



Noguchi and Rembaum (3), who suggested that the reaction product in the case of 1,5-dibromopentane was a 12-membered cyclic diammonium compound. This did not appear feasible from the viewpoint of the initial spectra and thus stimulated our interest in the present work. We, therefore, wish to report the investigation of this reaction and its application to other dihalocompounds.

Results and Discussion

To substantiate that the products that we obtained were in fact the five- and six-membered cyclic quaternary ammonium compounds, these specific compounds were prepared by an independent method (4). Authentic samples of 1,1-dimethylpyrrolidinium bromide and 1,1-dimethylpiperidinium bromide were prepared by reacting dimethylamine with 1,4-dibromobutane and 1,5-dibromopentane, respectively. These compounds were compared spectrometrically with the compounds obtained from *N,N,N',N'*-tetramethylmethylenediamine (2) reacted with the same dibromides.

The i.r. spectrum of the product obtained from dimethylamine and 1,4-dibromobutane was iden-

[1]Presented in part at the 55th Canadian Chemical Conference of the Chemical Institute of Canada, Quebec, June, 1972.

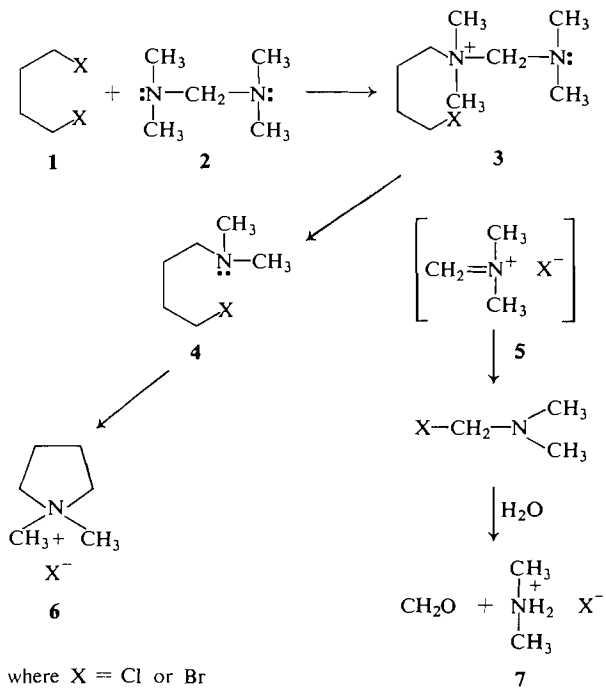

SCHEME 1. Proposed scheme of the cyclization reaction.

tical with the spectrum of the product obtained from dimethylamine and 1,4-dibromobutane. In addition, the n.m.r. spectra were identical. The most convincing evidence was obtained from mass spectra. A very good correlation between the intensities of the individual major peaks was found for both of these compounds; (a similar correlation was found for the minor peaks not listed in the Experimental). It was concluded that the compound obtained from **2** and 1,4-dibromobutane is, in fact, 1,1-dimethylpyrrolidinium bromide.

Similarly, the i.r. and n.m.r. spectra obtained from the products obtained from **2** and from dimethylamine with 1,5-dibromopentane were identical. The mass spectra support the conclusion that the product from **2** and 1,5-dibromopentane is 1,1-dimethylpiperidinium bromide.

It is postulated that compounds **1** and **2** initially undergo a Menschutkin reaction to form a quaternary ammonium intermediate **3**, as illustrated in Scheme 1. This intermediate then appears to undergo cleavage of *N*,*N*-dimethyl(methylene)ammonium halide (**5**) to produce another tertiary amine **4**. This tertiary amine can undergo a second Menschutkin reaction intramolecularly with the remaining halide to form the cyclic quaternary ammonium bromide **6**. We have been unable to isolate intermediate **3** even in nonpolar solvents. Apparently, the energy requirement for this fragmentation step must be low.

The n.m.r. spectrum of the reaction mixture of 1,4-dichlorobut-2-ene and **2** in CCl_3D indicates peaks at δ 3.68 and 8.70 besides those representing the cyclic product. Recently, Schreiber and co-workers (5) have reported the preparation of dimethyl(methylene)ammonium iodide (under anhydrous conditions and N_2 atmosphere) which has n.m.r. peaks at δ 3.67 and 8.18. Thus we feel that **5** is an intermediate in our reaction although its isolation has eluded us. Upon addition of D_2O to the n.m.r. sample tube the peaks at δ 3.68 and 8.70 disappear and a peak at δ 2.73, which is in the region for dimethylammonium chloride (**7**), appears. Further, after quenching a larger scale reaction mixture in H_2O, the 2,4-dinitrophenylhydrazone derivative of formaldehyde was obtained.

The reaction of *N*,*N*,*N*′,*N*′-tetramethylmethylenediamine with 1,4-dibromobutane and with 1,5-dibromopentane was carried out in three

different solvents: chloroform, acetonitrile, and dimethylformamide. Cyclic products were obtained in each case. The yields were better and rates of reaction appeared to be faster in the more polar solvents, as indicated by the data given in Table 1.

The reaction of **2** was carried out with other dihalides as well. These results are listed in Table 2. Good yields were obtained with halogens in the 1,4- and 1,5-positions. No cyclic product, however, was obtained with the 1,3-dibromopropane. Here the internal strain is too great for easy cyclization, and consequently low molecular weight polymers were obtained instead. The

For personal use only.

1,6-dibromohexane yielded only a small amount (11%) of cyclic product, the low yield being due to the general difficulty in achieving ring formation.

Experimental

The n.m.r. spectra were determined with a Varian A-60, i.r. spectra with a Perkin-Elmer model 257 and the mass spectra with a Dupont model 21-104. The samples were vaporized into the inlet system at 135° and introduced into the source at 250° by heating with a heat gun until enough sample was introduced to obtain the spectrum. Elemental Analyses were obtained on a Perkin-Elmer Analysis Model 240.

Preparation of 1,1-Dimethylpyrrolidinium Bromide with N,N,N′,N′-Tetramethylmethylenediamine

N,N,N′,N′-Tetramethylmethylenediamine (**2**) (2.04 g, 0.02 mol) was added to a solution of 1,4-dibromobutane (4.32 g, 0.02 mol) in 20 ml of acetonitrile. The reaction flask was sealed and the solution stirred by means of a magnetic stirrer. A precipitate appeared within a few hours and the reaction was stirred for 2 days. After this time, precipitation was completed by the addition of 100 ml of 1:1 anhydrous acetone–ether mixture. The product was collected by filtration and washed with dry ether. Recrystallization from isopropanol yielded needle-like crystals that were slightly hygroscopic, 2.2 g, 74%: m.p. (dec.) 340°; ν (KBr) (C—H stretching) 3000–2950, (CH_3 bending) 1465 and 1375, (C—N stretching) 1275, 1250, 1220, and 1000 cm^{-1}; n.m.r. (D_2O, internal standard DSS) δ 2.25 (m, 4), 3.17 (s, 6, N—CH_3), and 3.72 (t, 4, J = Hz, CH_2—N); mass spectrum *m/e* (relative intensity) 28 (43), 42 (100), 57 (85), 84 (84), 85 (48).

Anal. Calcd. for $C_6H_{14}NBr$: C, 40.01; H, 7.78; N, 7.78. Found: C, 39.79; H, 7.83; N, 7.63.

Preparation of 1,1-Dimethylpyrrolidinium Bromide with Dimethylamine

Dimethylamine (4.5 g, 0.1 mol) was added to a solution of 1,4-dibromobutane (4.32 g, 0.02 mol) in 20 ml of methanol. The reaction vessel was sealed with a rubber stopper and the mixture was stirred for 2 days. The mixture was then heated to boiling and Na_2CO_3 was added to decompose the dimethylamine hydrobromide. The mixture was boiled for another 10 min to drive off all the liberated dimethylamine. The hot mixture was filtered and the methanol evaporated. The crude product was obtained quantitatively. Recrystallization was effected from isopropanol: ν (KBr) (C—H stretching) 3000–2940, 1275, 1220, and 1000 cm^{-1}; n.m.r. (D_2O, internal standard DSS) δ 2.25 (m, 4), 3.17 (s, 6, N—CH_3), and 3.72 (t, 4, J = 7 Hz, CH_2—N); mass spectrum *m/e* (relative intensity) 28 (46), 42 (100), 57 (84), 84 (81), 85 (45).

Anal. Calcd. for $C_6H_{14}NBr$: C, 40.01; H, 7.78; N, 7.78. Found: C, 40.43; H, 7.89; N, 7.84.

Preparation of 1,1-Dimethylpiperidinium Bromide with 2

A procedure similar to that described above was followed using **2** (2.04 g, 0.02 mol) with 1,5-dibromopentane in 20 ml of acetonitrile. The product was recrystallized from propanol as hygroscopic needles, (77%): m.p. (dec.) 340°; ν (KBr) (C—H stretching) 3000–2940, (CH_3 bending) 1460 and 1375, (C—N stretching) 1230, and characteristic doublets at 1120, and 1030, 980, 940, and 875 cm^{-1}; n.m.r. (D_2O) δ 1.85 (m, 6), 3.11 (s, 6, N—CH_3), 3.37 (t, 4, J = 5.5 Hz, CH_2—N); mass spectrum *m/e* (relative intensity) 28 (40), 42 (54), 43 (46), 70 (23), 98 (100), 99 (37).

Anal. Calcd. for $C_7H_{16}NBr$: C, 43.31; H, 8.31; N, 7.22. Found: C, 43.43; H, 8.19; N, 7.34.

Preparation of 1,1-Dimethylpiperidinium Bromide with Dimethylamine

A procedure similar to that described above was followed using dimethylamine (4.32 g, 0.02 mol) with 1,5-dibromopentane in 20 ml of methanol. The product was recrystallized from propanol: ν (KBr) (C—H stretching) 3000–2940, (CH_3 bending) 1460 and 1375, (C—N stretching) 1230, and characteristic doublets at 1120 and 1030, 980, 940, and 875 cm^{-1}; n.m.r. (D_2O) δ 1.85 (m, 6), 3.11 (s, 6, N—CH_3), 3.37 (t, 4, J = 5.5 Hz, CH_2—N); mass spectrum *m/e* (relative intensity) 28 (41), 42 (50), 43 (63), 70 (22), 98 (100), 99 (38).

Anal. Calcd. for $C_7H_{16}NBr$: C, 43.31; H, 8.31; N, 7.22. Found: C, 43.39; H, 8.38; N, 7.31.

Procedures for Other Cyclization Reactions with 2.

A general procedure similar to that used in preparing 1,1-dimethylpyrrolidinium bromide was followed in each case. The yields and reaction times are listed in Tables 1 and 2.

The authors wish to thank the National Science Foundation for their financial support through Grant GP 26616. We are also indebted to Dr. Richard Kornfeld of Philip Morris Research Center, Richmond, Virginia, for the mass spectra work and to David Taylor for his assistance in the laboratory.

Restricted Internal Rotation in 1-Arylhydantoins, 3-Arylhydantoins, and 3-Aryl-2-Thiohydantoins: Reversal of the Effective Sizes of Methyl and Chlorine

LAWRENCE D. COLEBROOK, H. GWYNNE GILES, ALESSANDRO GRANATA, AND SIDDIK ICLI
Department of Chemistry, Sir George Williams University, Montreal 107, Quebec

AND

JAMES R. FEHLNER
Department of Chemistry, University of Rochester, Rochester, New York 14627

Received November 14, 1972[1]

In 1-arylhydantoins an *o*-methyl group is effectively larger than an *o*-chloro substituent in restricting rotation about the aryl-C—N bond, whereas in 3-arylhydantoins and 3-aryl-2-thiohydantoins the reverse order of sizes is observed. This difference is attributed to repulsion between the chlorine atom and a carbonyl oxygen atom in the torsional transition state of the 3-aryl compounds.

Dans les aryl-1 hydantoines, un groupe méthyle en ortho est effectivement plus volumineux qu'un substituant chloro en ortho lorsqu'il s'agit d'empêcher la rotation du groupe aryle autour du lien C—N; toutefois dans les aryl-3 hydantoines et les aryl-3 thio-2 hydantoines la grosseur relative des groupes est renversée. Cette différence est attribuée à la répulsion entre l'atome de chlore et l'atome d'oxygène du carbonyle dans l'état de transition de torsion. [Traduit par le journal]

Can. J. Chem., 51, 3635 (1973)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

It has commonly been observed (1, 2) that a methyl group exerts a steric effect greater than that of a chlorine atom, for example, in restricting internal rotation in hindered biphenyls (1). This order is consistent with the relative size of these groups as determined by X-ray crystallographic measurements of van der Waals radii (3).

In an n.m.r. study of restricted rotation about aryl-C—N bonds in 1-arylhydantoins we have found that the same order of relative sizes applies. The free energies of activation for rotation about the C—N bond joining the aryl and heterocyclic moieties are 0.5–1.5 kcal/mol higher for the *o*-methyl compounds than for the *o*-chloro compounds (Table 1).

In contrast, the free energies of activation for rotation of the 3-arylhydantoins and the 3-aryl-2-thiohydantoins (Table 2) indicate a reversal in the relative steric effects of the *o*-methyl and the *o*-chloro substituents on the aryl group. The free energy barriers to rotation about the aryl-C—N bonds are 0.9–2.1 kcal/mol higher for the chloro than for the methyl compounds. This reversal in the relative influences of the *o*-chloro and the *o*-methyl substituents is attributed to the nature of the interactions within the molecules in the transition states for internal rotation.

The rate constants for the internal rotation process in the 1-aryl- and the 3-arylhydantoins were obtained by complete n.m.r. line shape analysis of the temperature dependent 5-methyl or *o*-tolyl-methyl signals over a range of temperatures, using an iterative fitting procedure. The linear least-squares method was used to fit the Arrhenius equation to the data. Except in the cases of **1***a* and *b*, the free energies of activation

are reported (Tables 1 and 2) for a temperature common to, or falling between, the ranges used for the pair of compounds being compared. For compounds **1***a* and *b*, which could not be studied over an extended temperature range, the rate constants were obtained in the coalescence point region and are reported for the coalescence temperature. Because of the high rotational barriers, the spectra of the thiohydantoins, **3***a* and *b*, do not show collapse at the boiling point of the solvent. Rate constants (at a single temperature) were obtained for **3***a* and *b* by following the equilibration of the thermodynamically less stable diastereomer by repetitively recording the n.m.r. spectrum and measuring the areas under the peaks. The values of $\Delta G^{\ddagger}$ quoted for **1***a* and *b*, **2***c–f*, and **3***a* and *b* correspond to conversion of the less to the more thermodynamically stable rotamer.

Discussion

In their internal rotational ground states, these molecules are expected to adopt conformations with large dihedral angles between the aryl and hetero ring systems because of steric interaction between the *ortho* substituents on the aryl group and the hetero ring. The existence of significant chemical shifts between diastereotopic groups and between protons, located on the hetero ring, of diastereomeric rotational isomers is consistent with anisotropic shielding by the unsymmetrically substituted aryl groups which are constrained to adopt conformations not coplanar with the hetero ring. Since the molecules should have sufficient flexibility in the ground states to minimize steric interactions between the two ring systems it is probable that most of the influence on the values of $\Delta G^{\ddagger}$ in these series of compounds of importance in this study arises from interactions in the transition states.

Ground state effects of substituents are most easily recognized when the rotational isomers are diastereomeric, so that the equilibrium constant is not unity. Comparison of the equilibrium ratios of rotamers of the methyl and the chloro compounds reveals differences consistent with the reversal of the effective sizes of these groups in the 1-aryl and the 3-aryl series. Difficulties in obtaining satisfactory low temperature spectra of **1***a* and *b* precluded accurate measurement of the equilibrium constants, but it is clear that the deviation from unity in the equilibrium ratio is greater for the methyl compound, **1***a*, than for the chloro compound, **1***b*. This is expected if the methyl group is effectively larger than chlorine in the rotational ground states. In contrast, the equilibrium constants at ambient temperature of the 3-aryl-2-thiohydantoins, **3***a* and *b*, are 1.4 ± 0.1 and 1.7 ± 0.1 (90% confidence limits), respectively, the chloro substituent exerting a greater influence than the methyl group in the ground state. Ground state free energy differences between rotamers are, in all cases, smaller than the differences in free energies of activation reported in Tables 1 and 2. The nature of the interactions leading to non-unity equilibrium constants, particularly in the 3-aryl series, is not yet clear and is the subject of further investigation.

In the 1-arylhydantoins there are two possible transition states for rotation, the *o*-aryl substituent passing either the substituents in the 5-position or the 2-carbonyl group. The significant differences between the rotational barriers of 1-arylhydantoins and 3-arylhydantoins (in which the *o*-aryl substituent must pass a carbonyl group) (Tables 1 and 2), the large increase in $\Delta G^{\ddagger}$ on the introduction of a second methyl group in the 5-position (Table 1), and the failure in this laboratory to observe restricted rotation at temperatures as low as −78 °C in 1-arylhydantoins lacking a substituent in the 5-position, are taken as evidence that the more bulky *ortho* substituent must pass the 5-position in the preferred transition state for rotation in the 1-arylhydantoin series. This conclusion is supported by a study of Dreiding models. In this series, the interaction between the substituents in the 5-position of the heterocyclic moiety and the *o*-chloro or *o*-methyl group should be of a normal steric character.

In the 3-arylhydantoin or 3-aryl-2-thiohydantoin series, the *o*-chloro or *o*-methyl substituent must pass a carbonyl oxygen atom in the transition state for rotation. The preferred pathway in the 2-thiohydantoins must be the one in which the bulky *ortho* substituent passes the carbonyl rather than the more bulky thiocarbonyl group. The two possible transition states in the 3-arylhydantoins appear to be very similar in energy, the *o*-aryl substituent passing either the 2- or the 4-carbonyl oxygen atom. Available evidence does not indicate which of these is the preferred pathway or if there is a significant energy difference between them. It is likely that the increase in the effective size of chlorine relative to methyl results from electrostatic repulsion between the electronegative chlorine and oxygen atoms which increases the energy of the transition state. This influence is lacking in the preferred transition state for rotation in the 1-arylhydantoins.

In addition to its steric effects and through-space electronic effects as an *ortho* substituent, a chlorine substituent on the aryl group may possibly influence the barriers to rotation by through-bond field or mesomeric effects. Mesomeric effects are likely to be significant only in or near the transition state for rotation of the aryl group. In the transition state, the aryl and heterocyclic moieties must be approximately coplanar, allowing maximum or near maximum conjugation between the aryl π-electron system and the lone pair of electrons on the heterocyclic nitrogen atom at the point of attachment. Through-bond field effects may operate in both the transition and the ground states. By influencing the electron distribution in the hetero ring, a chloro substituent might cause sufficient changes in bond lengths and bond angles in the ground and transition states to influence the free energies of activation.

In order to determine the electronic influence of a chlorine substituent on the rotational barriers, the free energies of activation of 3-(2-methyl-4-chlorophenyl)-5-methylhydantoin, **2***g*, and 3-(2-methyl-4-chlorophenyl)-5-phenylhydantoin, **2***h*, both containing a *p*-chloro substituent, were compared (at the same temperature) with those of **2***e* and *c*, respectively. No significant changes in the values of $\Delta G^{\ddagger}$ were observed on the addition of this substituent. Since the through-bond influence of an *o*-chloro substituent should be similar to that of a *p*-chloro substituent, it is concluded that the observed influence of an *o*-chloro substituent is primarily a through-space effect.

Experimental

Proton Magnetic Resonance Measurements

P.m.r. spectra were taken on a Varian HA-100 spectrometer operating in the field sweep mode and employing the standard variable temperature equipment. The temperature dependent portions of the spectra were recorded at maximum convenient scale expansion. Temperatures, believed to be accurate to ± 2 °C, were determined immediately after each spectrum was taken by measuring the peak separation of a standard Varian ethylene glycol or methanol sample.

Data Processing

The spectra of **1***a*-**2***h* were digitized from the charts through the use of a Hewlett-Packard 2114A computer,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

F-3B Line Follower, and 7001AM X-Y recorder. Following transfer from storage on paper tape to magnetic tape, the digitized spectra were subjected to complete line shape analysis by a CDC 3300 or CYBER 70-72 computer using a non-linear regression programme incorporating the appropriate line shape functions.[2] The computer fitted a calculated spectrum to each digitized experimental spectrum, varying the line shape and intensity parameters in an iterative sequence until a best fit was obtained. The natural line width parameters were held constant during fitting at values determined from spectra recorded at sample temperatures where exchange broadening was absent or minimal. This restriction is necessary because the fitting procedure cannot make an adequate distinction between the effects of varying the line width and the lifetime parameters. Possible sources of error associated with temperature dependent chemical shifts (5) were minimized by having the computer find the true chemical shifts for most of the temperature dependent spectra during line shape analysis. Since the fitting process becomes rather insensitive to the chemical shift difference in the coalescence point region and above, the chemical shift parameters were held constant at values extrapolated from lower temperature spectra whenever a plot of chemical shift difference *vs.* temperature revealed significant scattering of points. Such scattering appeared only near the coalescence point, consistent chemical shift values being returned by the computer over most of the temperature range. Extrapolation was limited to the coalescence point region, since chemical shift errors could become significant if extrapolation were continued much beyond this point. Since the lifetime parameters for the two sites were optimized independently, the regression procedure compensated for unequal populations. Computer generated plots of superimposed digitized experimental and best-fit spectra were used for visual checks on the quality of the fitting.

The random error ranges quoted in Tables 1 and 2 are based on linear regression analysis of the fit to the Arrhenius equation in logarithmic form, except for **3***a* and *b*, in which cases the errors are based on non-linear regression analysis of the equilibration data. Systematic errors which are likely to be important in this study may arise from incorrect assignment of the chemical shift and line width parameters in the fitting procedure, and from errors in temperature measurement (5). Experience has shown that the fitting procedure used in this study is sufficiently sensitive to the chemical shift difference (except in the coalescence point region) that errors arising from inaccurate chemical shift differences being employed are likely to be unimportant. A potentially more serious source of systematic error is an incorrect assignment of the natural line width, since the values of the lifetime parameters returned by the computer are very sensitive to the fixed value of the line width parameter employed in the fitting procedure when exchange broadening makes a small contribution to the overall line width (5). In consequence, care must be taken in determining the value of the natural line width to be used in the calculation. Since the measured line widths employed in this study should be reasonably accurate over the sensitive slow exchange region, the systematic line width errors in $\Delta G^{\ddagger}$ are estimated to be less than 0.1 kcal/mol. In general, the error ranges reflect the insensitivity of the $\Delta G^{\ddagger}$ function to both random and systematic errors in the line shape analysis.

The most significant systematic errors in this study are likely to arise from errors in temperature measurement. A systematic temperature calibration error of 2° would produce errors in $\Delta G^{\ddagger}$ of about 0.1 kcal/mol.

Systematic errors must be considered in addition to the random errors quoted in Tables 1 and 2 in evaluating the probable accuracy of the values of $\Delta G^{\ddagger}$ obtained. However, when differences in $\Delta G^{\ddagger}$ values obtained under similar conditions are considered, systematic errors should be less important, provided that these errors are consistently in the same direction. This should be particularly true of systematic temperature errors if results obtained at similar temperatures are being compared. Thus the contribution of systematic errors to the free energy of activation differences in Tables 1 and 2 should be small.

The thermodynamically less stable diastereomeric rotational isomers of **3***a* and *b* were obtained in better than 95% isomeric purity by careful recrystallization from ethanol of the mixture of isomers obtained on synthesis. Equilibration to the thermodynamic mixture of rotamers was followed by repetitively recording the methyl region of the spectra while the sample was maintained at a constant temperature in the n.m.r. spectrometer. The relative proportions of the rotational isomers contributing to the time dependent spectra during equilibration were determined by matching the experimental spectra with a DuPont 310 Curve Resolver, using Lorentzian line shapes. Rate constants were obtained by fitting the experimental ratio *vs.* time curve with the appropriate isomerization function for a reversible first order reaction, using the non-linear regression programme (6).

Materials

The 1-aryl-5-methylhydantoins, **1***a* and *b*, were prepared from *N*-(*o*-tolyl)alanine or *N*-(*o*-chlorophenyl)alanine, respectively, and urea by the method of Wada (7). The 1-aryl-5,5-dimethylhydantoins, **1***c* and *d*, were prepared from *o*-toluidine or *o*-chloroaniline, respectively, and *N*-(2-bromo-2-methylpropionyl)urea (obtained by reaction between 2-bromo-2-methylpropionyl bromide and urea (8)) by the method of Mazover (9).

The 3-arylhydantoins, **2***a–f*, were prepared from *o*-tolyl isocyanate or *o*-chlorophenyl isocyanate and alanine, 2-methylalanine, or α-phenylglycine by the method of Behr and Clarke (10). The 3-aryl-2-thiohydantoins, **3***a* and *b*, were prepared from *o*-tolyl isothiocyanate or *o*-chlorophenyl isothiocyanate (obtained by reaction between *o*-chloroaniline and thiophosgene (11)) and the amino acids, by the method of Pujari and Rout (12). The 2-methyl-4-chlorophenyl isocyanate required for the

[2]In most cases, the line shape equation employed was that formulated by Gutowsky and Holm (4). The six parameters required to specify the line shape and intensity are: the mean lifetimes (not necessarily equal) on each of the two sites, the two chemical shifts, the line width in the absence of exchange broadening (assumed to be identical on each site), and a scaling factor. The Gutowsky and Holm method was extended to simulate the effect of the temperature independent spin coupling between the C-5 methine and methyl protons on the C-5 methyl signal in cases **1***a* and *b*, and **2***f*.

preparation of **2***g* and *h* was prepared from 2-methyl-4-chloroaniline and phosgene using the method of Shriner *et al.* (13).

These compounds were characterized through their p.m.r. and i.r. spectra and elemental analysis or mass spectra.

A Low Temperature Infrared Study of Hydrogen Bonding in *N*-Alkylacetamides

MARIE-CLAUDE BERNARD-HOUPLAIN AND C. SANDORFY
Département de Chimie, Université de Montréal, Montréal, Québec

Received April 19, 1973

The infrared spectra of *N*-methylacetamide and two other secondary amides were measured in solution at temperatures ranging from 22 to −190 °C in both the fundamental and the overtone regions. At least two hydrogen bonded species are found as association increases with decreasing temperature. The effect of hydrogen bond formation on the anharmonicity of the NH stretching vibration and on the NH stretching – NH bending coupling constant is examined.

Les spectres infrarouges du *N*-methylacetamide et de deux autres amides secondaires ont été mesurés en solution, à des températures allant de 22 à −190 °C, à la fois dans la région de la fondamentale et dans celle des harmoniques. On a établi l'existence d'au moins deux espèces associées par liaison hydrogène en abaissant la température. On a examiné l'effet de la liaison hydrogène sur l'anharmonicité de la vibration de valence NH, et sur la constante de couplage entre les vibrations NH de valence et de déformation.

Introduction

In three previous publications (1–3) we reported the results of a low temperature infrared solution study of the self-association of secondary amines. In the present paper we are dealing mainly with *N*-methylacetamide (NMA), although results obtained on *N*-ethylacetamide and *N*-methylpivalamide will also be mentioned.

In a sense, hydrogen bonding in NMA is still a case of self-association, since the same molecule is proton donor and acceptor at the same time. The donor and acceptor sites are different, however, so that the case of amides is intermediate between self-association as it exists in alcohols or amines and association between different molecules. There is general agreement that hydrogen bonding in the case of amides is of the N—H---O type. It is generally admitted too that the CONH group is coplanar because of an appreciable degree of conjugation between the π electrons of the carbonyl group and the nitrogen lone pairs. In *N*-alkyl-amides *cis–trans* isomerism is possible around the C—N bond. The bands due to the fundamental vibrations of dissolved secondary amides were thoroughly studied by several authors (see ref. 4). Attention has also been paid to the overtones of these vibrations (5–8).

We are now presenting the results of a combined low temperature and overtone study, similar to those which were carried out in this laboratory on amines, alcohols (9, 10), and thiols (11).

As in our previous experiments the solvent was a 1:1 mixture of CCl_3F and CF_2Br–CF_2Br (FR) which sets to a glass at low temperatures making it possible to measure solution spectra down to −190 °C. As before we were seeking information on changes in association with decreasing temperature and on the anharmonicity of the vibrations.

The following symbols will be used in connection with the vibrations of an X—H---Y system: ν_1 the X—H stretching vibration; ν_2 the X—H in-plane bending vibration; ν_3 the X---Y bridge stretching vibration.

The fundamentals and overtones will be called ν_i^{01}, ν_i^{02}... where the upper indices stand for the vibrational quantum numbers of the lower and upper levels. Combinations will be referred to as $\nu_1 + \nu_2$, $\nu_1 + 2\nu_2$,... The anharmonicity and coupling constants will be called X_{11}, X_{12},...

There is certain confusion in the literature concerning the signs of anharmonicity constants and our own previous publications are no exception. We shall henceforth take a constant to be negative if its existence diminishes a vibrational frequency and positive if it increases it. Thus anharmonicity constants will be generally negative.

Experimental

The amides were supplied by Eastman Organic Chemicals; *N*-methyl- and *N*-ethylacetamides were distilled and dried under vacuum. *N*-methylpivalamide was used without further purification.

The solvents were 1:1 mixtures of CCl_3F (Freon 11)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

and $C_2Br_2F_4$ (Freon 114B2) (FR) obtained from Dupont de Nemours Co. of Canada. They were distilled and kept over phosphorus pentoxide.

N-methylacetamide-d_6 ($CD_3CONHCD_3$) was purchased from Merck, Sharp and Dohme of Canada Ltd. and was of a minimum isotopic purity of 99%.

N-methylacetamide-N-*d* was prepared by exchange with heavy water (12, 13) and was of a minimum isotopic purity of 95%.

All products were kept and handled in an inert atmosphere to avoid moisture adsorption.The solutions were prepared gravimetrically in volumetric flasks and the concentration was corrected for solvent contraction, admitting a linear dependence of volume with temperature.

The NH fundamentals were measured on a Perkin Elmer 621 spectrometer and the overtones on a Cary 17 instrument.

Other experimental details were given in previous publications from this laboratory (14, 15).

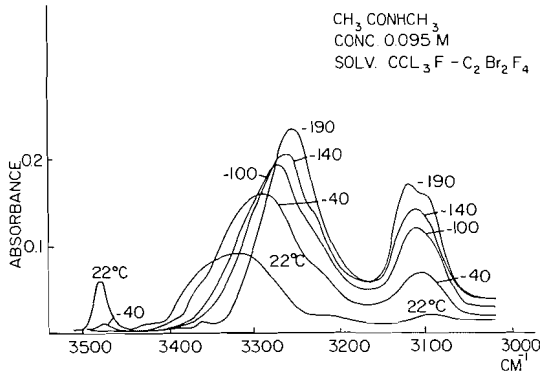

FIG. 1. The infrared spectrum (3500–3000 cm^{-1}) of *N*-methylacetamide at different temperatures in a 1:1 mixture of CCl_3F and CF_2Br–CF_2Br. Concentration at 22 °C: 0.095 *M*; cell length: 0.149 mm.

The Fundamentals

NMA exists practically only in the *trans* form (16). The free NH fundamental is at 3476 cm^{-1} in CCl_4 solution (17). At room temperature, with increasing concentration an associated band appears at 3370 cm^{-1} and moves gradually to lower frequencies. At about 1 *M* the maximum reaches 3300 cm^{-1} and remains there even for the pure liquid. This large shift and the shape of the band indicates that association does not stop at the dimer stage but that higher polymers are successively formed. In sufficiently concentrated solutions a shoulder is observed at 3225 cm^{-1} which has been assigned by Cannon (18) and by Fillaux and De Lozé (19) to a combination of the amide I (mainly C=O stretching) and amide II (mainly NH bending) bands. Another band, at 3100 cm^{-1}, was the target for much discussion (20–23). It has been assigned to the first overtone of amide II in Fermi resonance with the associated NH stretching vibration or to a combination of the NH stretching vibration with a low frequency bridge vibration.

Figure 1 shows the spectra of a 0.095 *M* solution of NMA in FR at different temperatures. The free band is at 3482 cm^{-1} at 22 °C and has a half-width of 18 cm^{-1}. When temperature is decreased, the associated band becomes gradually stronger and moves from 3330 cm^{-1} at 22 °C to 3256 cm^{-1} at −190 °C. The half-width of this band goes from 120 cm^{-1} at 22 °C to 80 cm^{-1} at −190 °C. This is likely to be due to the elimination of certain solute–solvent configurations with unfavorable Boltzmann factors and to the slowdown of thermal motion.

The intensity of the 3100 cm^{-1} band also increases with decreasing temperature. However, this band moves slightly to *higher* frequencies with decreasing temperature. This all but rules out its assignment to an NH *stretching* vibration or to a combination containing that vibration. It disappears upon deuteration, however, showing that it is an NH band. At −190 °C the ratio of the intensities of the NH stretching band and of the 3100 cm^{-1} band is practically independent of concentration between 0.02 and 0.4 *M*. Its intensity increases with decreasing temperature showing that it cannot belong to a difference tone. These facts are all in favor of the assignment of the 3100 cm^{-1} band to the first overtone of the amide II vibration. As temperature decreases the NH stretching band shifts lower, the overtone shifts higher, so that their mutual distance diminishes. Fermi resonance becomes more important and the relative intensity of the overtone with respect to ν_1 increases (Fig. 1).

At the lowest temperature the 3100 cm^{-1} band has two peaks, at 3100 and 3120 cm^{-1}. This could be due to two different associated species as indicated by the existence of two carbonyl bands (see below).

We carried out the same measurements on NMA-d_6 (Fig. 2). The NH stretching region remained the same while the 3100 cm^{-1} band underwent a shift of about 20 cm^{-1} to lower wavenumbers. Since, at the same time, the amide II band shifts by about 10 cm^{-1}, this amounts to an additional argument in favor of the assignment of the 3100 cm^{-1} band to the first overtone of the amide II vibration.

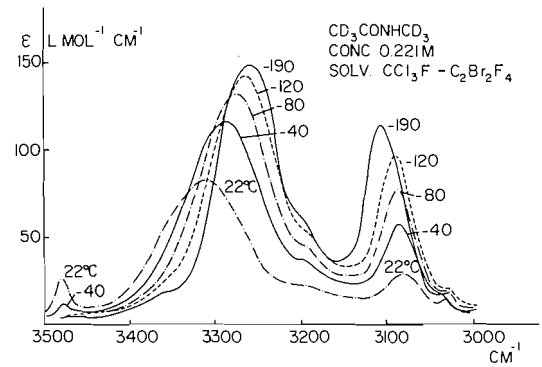

FIG. 2. The infrared spectrum (3500–3000 cm^{-1}) of *N*-methylacetamide-d_6 at different temperatures in a 1:1 mixture of CCl_3F and CF_2Br–CF_2Br. Concentration at 22 °C: 0.221 *M*; cell length: 0.160 mm.

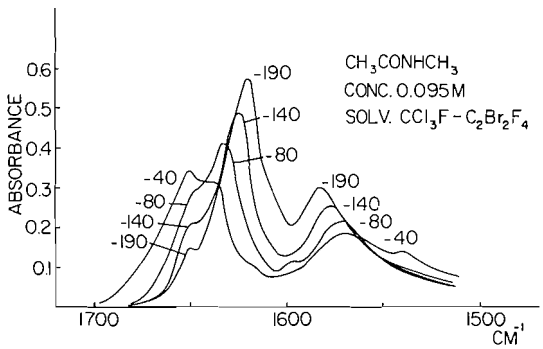

FIG. 3. The infrared spectrum (1700–1500 cm^{-1}) of *N*-methylacetamide at different temperatures in a 1:1 mixture of CCl_3F and CF_2Br–CF_2Br. Concentration at 22 °C: 0.095 *M*; cell length: 0.149 mm.

While the frequency difference between the free NH stretching band measured at 22 °C and the associated band measured at −190 °C is about 230 cm^{-1}, it is only 60 cm^{-1} for the amide II band (1582 cm^{-1} at −190 °C) and, as expected, it is in the opposite sense. The associated amide II band is not very sensitive to temperature changes, it shifts only by about 25 cm^{-1} from 22 to −190 °C toward higher frequencies (Fig. 3).

ν_1^{01} and ν_2^{02} are in Fermi resonance and we shall need their unperturbed values. For computing these we supposed that without Fermi resonance the intensity of ν_2^{02} would be negligible and then used the related equations as given, for example, by Overend (p. 351–352, in ref. 24). The band areas were planimetered out and are, of course, approximate. Table 1 gives the observed and unperturbed values for ν_1^{01} and ν_2^{02} as well as the observed values of ν_2^{01}. ρ stands for the ratio of the observed intensities of ν_1^{01} and ν_2^{02}. From the unperturbed frequencies of ν_2^{02} given in Table 1 we computed the anharmonicity constant for ν_2. It has the low value of about −10 cm^{-1} at −190 °C.

The free amide I (carbonyl) band is found at 1690 cm^{-1} at room temperature. As temperature is lowered two associated bands appear successively (Fig. 3). The one of higher frequencies varies little with temperature while the one of lower frequency shifts rapidly to lower values. At −190 °C the two bands are at 1650 and 1620 cm^{-1} respectively.

Overtones and Combination Tones

In very dilute CCl_4 solutions the free ν_1^{02} band is at 6810 cm^{-1} (half-width 30 cm^{-1}). With increasing concentration three more bands appear; they are at about 6550, 6380, and 6280 cm^{-1} for the pure liquid. In order to interpret these spectra we measured those of NMA-*N*-*d* and NMA-d_6. In alcohols NH + CH type combination bands complicate the respective part of the spectrum (25). This is not the case for amines but the stronger hydrogen bonds present in the amides make them an intermediate case and we wanted to ascertain if such combinations are present in NMA. The result was that the 6280 cm^{-1} band disappeared for both of the deuterated molecules so it must be NH + CH. The two other bands (6550 and 6380 cm^{-1}) remained in NMA-d_6, however.

Figures 4 and 5 show the spectra of NMA (0.095 *M*) and NMA-d_6 (0.221 *M*) in the NH stretching overtone region, at different temperatures in FR. The free band is at 6819 cm^{-1} at room temperature, yielding an anharmonicity constant $(\nu_1^{02}/2) - \nu_1^{01} = -72$ cm^{-1}, a value similar to those found for amines. The free band is still well distinguished at −130 °C while at similar concentrations its fundamental had disappeared at −60 °C. This again underscores the fact that the relative intensity of the free bands is greater at the overtone level than at the level of the fundamental (1, 25).

The comparison of the spectra of NMA and NMA-d_6 shows again that the band at about 6250 cm^{-1} of the former is due to NH + CH combinations. The relative intensity of the two remaining associated bands varies with temperature. Their frequencies shift from 6550 to

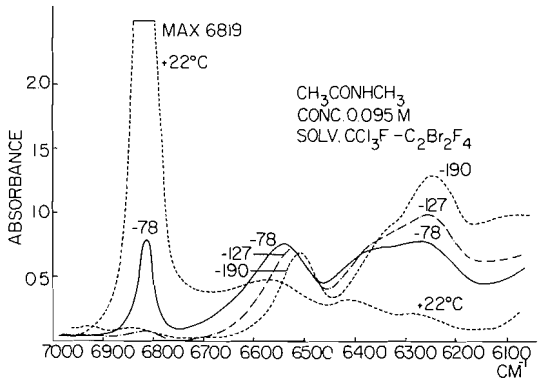

FIG. 4. The infrared spectrum (7000–6100 cm^{-1}) of *N*-methylacetamide at different temperatures in a 1:1 mixture of CCl_3F and CF_2Br–CF_2Br. Concentration at 22 °C: 0.095 *M*; cell length: 8.5 cm.

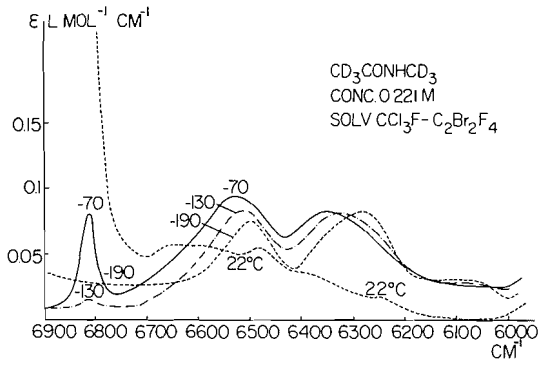

FIG. 5. The infrared spectrum (6900–6000 cm^{-1}) of *N*-methylacetamide-d_6 at different temperatures in a 1:1 mixture of CCl_3F and CF_2Br–CF_2Br. Concentration at 22 °C: 0.221 *M*; cell length: 8.5 cm.

6500 and from 6375 to 6282 cm^{-1} respectively from −20 to −190 °C.

The first associated band (6500 cm^{-1} at −190 °C) might receive contributions from the NH stretching overtone of the less associated species, from N—H---O=C end groups and from the $\nu_1 + 2\nu_2$ combination of the more highly associated species. We assign the second associated band (6282 cm^{-1} at −190 °C) to the first NH stretching overtone of the more highly associated species whose existence has been inferred from observations made in the fundamental region. We shall call these species oligomer and polymer respectively but we shall make no attempt to estimate the number of monomers contained in the adducts.

The higher frequency band (6500 cm^{-1} at −190 °C) cannot be the overtone of the polymer fundamental. This would yield an anharmonicity constant of −6 cm^{-1} with the observed frequencies; if we use the unperturbed value of ν_1 we obtain a positive anharmonicity. Both would contradict all previous observations. Furthermore the very moderate temperature shift of this band (much less than that of the fundamental) also contradicts its assignment to the polymer.

Still another contribution to the apparent intensity of the 6500 cm^{-1} band might be the polymer $\nu_1 + 2\nu_{C=O}$ combination. The $\nu_1 + \nu_{C=O}$ combination, however, was too weak to be observed and the contribution of $\nu_1 + 2\nu_{C=O}$ is therefore not expected to be significant.

For all these reasons we assign the 6282 cm^{-1} band to the first overtone of the polymer NH stretching vibration.

The rapid shift to lower frequencies of the "polymer" band with decreasing temperature is characteristic of stretching overtones (93 cm^{-1} from −20 to −190 °C). The shift of $\nu_1 + \nu_2$, for example, is much slower: only about 30 cm^{-1}. At the same time ν_1 shifts by 50 cm^{-1} to lower frequencies and ν_2 by 24 cm^{-1} to higher frequencies. Asselin and Sandorfy (26) made similar observations for alcohols. Lucazeau and Sandorfy (27) gave examples to the effect that the shifting of combination bands is usually

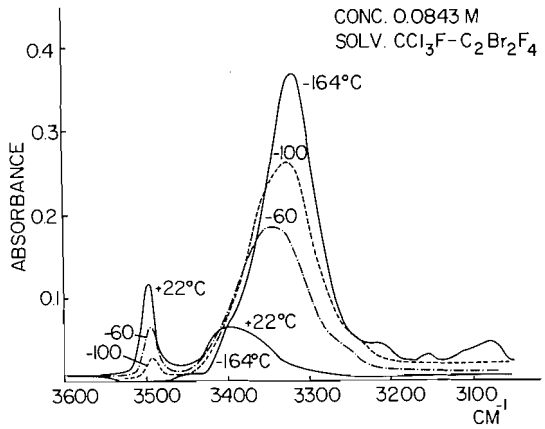

FIG. 6. The infrared spectrum (3600–3100 cm^{-1}) of *N*-methylpivalamide at different temperatures in a 1:1 mixture of CCl_3F and CF_2Br-CF_2Br. Concentration at 22 °C: 0.0843 *M*; cell length: 0.149 mm.

intermediate between that of their constituting fundamentals.

In order to ascertain if there are bands due to simultaneous excitation in the overtone region similar to those which were found for alcohols (15) we carried out an isotopic isolation experiment measuring the spectrum of a 1:9 mixture of NMA and NMA-*N*-*d* from 22 to −190 °C. No significant changes were observed. This eliminates this possibility which was unlikely anyway, since no two N—H bonds are directly linked together in the amide polymers or oligomers.

Measurements similar to those reported for NMA were also carried out on *N*-ethylacetamide. Since the results were practically the same as for NMA we shall not describe them.

N-methylpivalamide yielded one interesting observation. In this sterically hindered molecule ν_1 is at higher frequencies since the hydrogen bonds are weaker, 3340 cm^{-1} at −176 °C (Fig. 6). The ν_2 deformation band is at lower frequencies, 1545 cm^{-1} at −176 °C. Therefore ν_2^{02} is more widely separated from ν_1 and it is much weaker as for NMA. This shows that there is practically no Fermi resonance in this case and, on the other hand it corroborates the assumption that Fermi resonance does take place for NMA between ν_1^{01} and ν_2^{02}.

Discussion

The main purpose of our work has been to examine the effect of hydrogen bond formation on anharmonic coupling constants in the case of secondary amides.

The calculation of the anharmonic coupling constants is hampered by the fact that both the fundamental and the overtone of ν_1 might be influenced by Fermi resonance—with ν_2^{02} and $\nu_1 + 2\nu_2$ respectively—and all we can do is to compute upper and lower limits for X_{11}, X_{22}, and X_{12} using first the observed values of the frequencies and then their unperturbed values.

For the three-atomic model the frequencies are given, to the second order, by the following formulae if ω_1 and ω_2 are the harmonic frequencies of ν_1 and ν_2 and the X_{ij} are the anharmonic coupling constants.

$$[1]\quad \nu_1^{01} = \omega_1 + 2X_{11} + \tfrac{1}{2}X_{12} + \tfrac{1}{2}X_{13}$$

$$[2]\quad \nu_2^{01} = \omega_2 + 2X_{22} + \tfrac{1}{2}X_{12} + \tfrac{1}{2}X_{23}$$

$$[3]\quad \nu_1 + \nu_2 = \omega_1 + \omega_2 + 2X_{11} + 2X_{22} + 2X_{12} + \tfrac{1}{2}X_{13} + \tfrac{1}{2}X_{23}$$

$$[4]\quad \nu_1^{02} = 2\omega_1 + 6X_{11} + X_{12} + X_{13}$$

$$[5]\quad \nu_2^{02} = 2\omega_2 + 6X_{22} + X_{12} + X_{23}$$

$$[6]\quad \nu_1 + 2\nu_2 = \omega_1 + 2\omega_2 + 2X_{11} + 6X_{22} + \tfrac{7}{2}X_{12} + \tfrac{1}{2}X_{13} + X_{23}$$

The observed frequencies are, all for −190 °C and for the polymeric species of NMA,

ν_1^{01}	3256 cm^{-1}
ν_2^{01}	1582 cm^{-1}
ν_2^{02}	3110 cm^{-1}
$\nu_1 + \nu_2$	4882 cm^{-1}
ν_1^{02}	6282 cm^{-1}

From these we obtain

$$X_{11} = \frac{\nu_1^{02}}{2} - \nu_1^{01} = -115\,cm^{-1}$$

$$X_{22} = \frac{\nu_2^{02}}{2} - \nu_2^{01} = -27\,cm^{-1}$$

$$X_{12} = (\nu_1 + \nu_2) - \nu_1^{01} - \nu_2^{01} = +44\,cm^{-1}$$

Using these constants we can estimate the value of $\nu_1 + 2\nu_2$. The sum of the observed ν_1^{01} and twice the observed ν_2^{01} is:

$$\omega_1 + 2\omega_2 + 2X_{11} + 4X_{22} + \tfrac{3}{2}X_{12} + \tfrac{1}{2}X_{13} + X_{23} = 3256 + 2 \times 1582 = 6420\,cm^{-1}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

This is lower than the $\nu_1 + 2\nu_2$ combination [6] by $2X_{22} + 2X_{12}$. Using the above values for X_{22} and X_{12} we have that

$$\nu_1 + 2\nu_2 = 6420 - (2 \times 27) + (2 \times 44) = 6454\ \text{cm}^{-1}$$

while the observed, apparent peak is at 6500 cm^{-1}. If, instead of using the observed frequencies we take the unperturbed values of ν_1^{01} and ν_2^{02} which are 3221 and 3145 cm^{-1} respectively we obtain

$$X_{11} = -80\ \text{cm}^{-1}$$
$$X_{22} = -10\ \text{cm}^{-1}$$
$$X_{12} = +79\ \text{cm}^{-1}$$
$$\nu_1 + 2\nu_2 = 6525\ \text{cm}^{-1}$$

The unperturbed frequencies should not be considered as very accurate. We are dealing with two broad bands whose different parts are affected to different degrees by Fermi resonance. Since the wings facing each other are likely to be affected most the split of the maxima appears to be larger than it is in reality and the unperturbed values lie probably somewhere at halfways between the observed and calculated values. Thus we can give X_{22} an estimated value which is intermediate between -10 and -27. We cannot compare this value to the corresponding value of the free species since ν_2^{02} was not found for the latter.

The coupling constant X_{12} has a value between $+44$ and $+79\ \text{cm}^{-1}$. This is a very significant change from $-7\ \text{cm}^{-1}$ (22 °C) which is the value we obtained for the free species.

The case of X_{11} is more delicate. The mean value of -115 and $-80\ \text{cm}^{-1}$ would be $-98\ \text{cm}^{-1}$ which we believe is close to its real value. The problem is complicated by the possibility of still another Fermi resonance, between ν_1^{02} and $\nu_1 + 2\nu_2$. However, the above calculations show that $\nu_1 + 2\nu_2$ falls into the 6500 cm^{-1} region close to its observed value. Therefore we do not believe that the unperturbed value of ν_1^{02} is greatly different from the observed one. At any rate, our value of X_{11} remains somewhat uncertain. In spite of this it seems to be reasonable to conclude to a moderate increase in X_{12} upon hydrogen bond formation. What causes the uncertainty is essentially the fact that, unlike in the cases of alcohols and amines, $\nu_1 + 2\nu_2$ has a frequency higher, not lower, than ν_1^{02}. Thus while the X_{11} computed with disregard of Fermi resonance are minimum values for alcohols and amines (because the frequency of the overtones was heightened by the resonance) this is not so for amides.

The anharmonicity of ν_2 is weak and still negative but hydrogen bonding increases its value. More important than this is the large increase in the value of the coupling constant X_{12} which becomes positive upon hydrogen bond formation.

Since X_{12} enters the expression of ν_2^{01} [1] it actually raises its frequency by a nonnegligible amount. The usual $\Delta\nu$–ΔH relationships cover probably a number of such anharmonic contributions.

Conclusions

Our low temperature measurements give evidence to the existence of at least two hydrogen bonded adducts for non-sterically hindered amides. The pattern of association is closer to that of alcohols than to that of amines. Contrary to amines the overtones of the associated NH stretching vibration are readily identified.

Associated amides have well defined in-plane deformation bands and there is strong anharmonic coupling between these and the NH stretching vibration. The sizable increase in the value of these coupling constants upon hydrogen bond formation and the Fermi resonance it causes constitute a significant fact for the understanding of the nature of hydrogen bonding.

The Racemization of Sulfonium Salts. III. The Racemization of Arylsulfonium Salts

DAVID DARWISH[1] AND CHRISTOPHER E. SCOTT[2]

Department of Chemistry, University of Alberta, Edmonton, Alberta T6G 2G2

Received April 12, 1973

The rate constants for racemization by inversion of a variety of monoaryl- and diarylsulfonium salts are reported. There is a marked steric effect upon the rate of the racemization reaction. An estimate is made of the half-life for racemization of acyclic optically active triarylsulfonium salts.

On rapporte les constantes de vitesses pour la racémisation par inversion d'un certain nombre de sels de mono- et diarylsulfonium. Un effect stérique important influence la vitesse de la réaction de racémisation. Une evaluation est faite de la demi-vie pour la racémisation de sels optiquement actifs de triarylsulfonium acycliques.

Can. J. Chem., 51, 3647 (1973)

In this communication we report on the racemization by inversion (1) of a number of optically active monoaryl- and diarylsulfonium salts, **1** and **2**, respectively. In Table 1 the rate constants for racemization of these salts are compared with one another and with the rate constants for racemization of isopropylethylmethylsulfonium perchlorate, **3**, and benzylethylmethylsulfonium perchlorate, **4** (2). The data provide information on both the electronic and steric effects upon the racemization reaction and allow the estimation of a lower limit for the rate of racemization of acyclic triarylsulfonium salts at 25°.

All the optically active sulfonium salts were prepared by resolution of the corresponding (−)-dibenzoyl hydrogen tartrate salts followed by replacement of the dibenzoyl hydrogen tartrate anion by perchlorate. The salts had the following physical properties[3] [compound, m.p. (°C), $[\alpha]_{365}^{25}$ (°, methanol), concentration (g/100 ml)]: (+)-**1***a*, 74.8–75.8, 10.0,[4] 1.21; (−)-**1***a*, 80.5–82.0, −17.0,[4] 1.10; (+)-**1***b*, 79.6–80.2, 19.5, 0.945; (−)-**1***b*, 34.0–34.5, −69.5, 0.922; (+)-**1***c*, 129.8–130.6, 13.3,[4] 0.926; (−)-**1***c*, 129.8–130.6, −31.2,[4] 0.868; (+)-**1***d*, 27.5–28.5, 32.5,[4] 0.999; (−)-**1***d*, 71.0–71.5, −18.7,[4] 1.21; (+)-**1***e*, 42.0–47.0, 41.3, 1.03; (−)-**1***e*, 50.0–54.0, −19.7, 1.11; (+)-**1***f*, 37.5–39.0, 24.0, 1.20; (−)-**1***f*, 32.5–34.0, −10.8, 1.30; (+)-**2***a*, 56.5–59.5, 21.2, 0.979; (−)-**2***a*, 47.0–50.0, −15.2, 1.17; (+)-**2***b*, 39.0–40, 50.3, 1.05; (−)-**2***b*, 64.0–68.5, −8.1, 1.07; (−)-**3**, 155–160, −10.6, 0.824.

The rate constant for racemization ($k_{rac} = k_\alpha - k_t$) of the active salt is the difference between the polarimetric rate constant, k_α, and the titrimetric rate constant, k_t (2). For all the compounds reported here, except **1***d*, we find $k_\alpha/k_t > 300$, so $k_{rac} = k_\alpha$ within 0.3%.

The rate constants for racemization of **1***a* in solvent methanol are $(2.88 \pm 0.11) \times 10^{-5}\ s^{-1}$ at 50.0° and $(0.074 \pm 0.002) \times 10^{-5}\ s^{-1}$ at 25°.

Two features are clear from the relative rate data. Firstly, aryl groups do not have an appreciable electronic effect upon the rate of racemization of sulfonium salts. A comparison of **1***a* and **3**, where the steric effects of the phenyl and isopropyl groups should be similar, shows that the rate constants for racemization of these salts differ by less than a factor of 2. Similarly a comparison of **1***b*, **1***c*, and **1***d* with **1***a* shows that introduction of a *p*-methoxy, *p*-hydroxy, or *p*-nitro group onto the phenyl group leads to an

[a]Both the (+)- and (−)-enantiomers of each system had identical rates of racemization except for **3** in which only the (−)-enantiomer was obtained.

increase in rate of racemization of less than a factor of 2. Both electron donating and electron withdrawing groups increase the rate of racemization by small amounts. In the presence of 1 equiv. of sodium methoxide in methanol, **1***c* is converted to the corresponding zwitterion (p-O^-) and this material racemizes only 4.3 times faster than **1***a*. This again confirms that any electronic effect associated with substitution on the aromatic ring is very small.

In contrast, there is a marked steric effect upon the racemization rate. In each of the sets of compounds (**4**; **1***a*, **1***b*, **1***c*, or **1***d*), (**4**; **3**), and (**1***a*; **2***a*) a primary alkyl group (not a methyl) has been replaced by an aryl group or an isopropyl group on the sulfonium sulfur atom while maintaining the rest of the substituents constant. Each of these changes results in an increase in the rate constant for racemization by a factor of between 5 and 10. The sets (**1***a* or **3**; **1***e* or **1***f*) and (**2***a*; **2***b*) show that replacement of a methyl group by another primary alkyl group also increases the magnitude of k_{rac} by a factor of *ca.* 10. This result is difficult to rationalize on anything but steric effects. Replacement of a methyl group by an aryl group in set (**1***a*; **2***b*) increases k_{rac} by nearly two powers of 10. These data provide the first strong evidence for steric effects upon the inversion of an acyclic pyramidal system. Steric acceleration of pyramidal inversion has been reported in cyclic systems such as the aziridines, oxaziridines (3), and phosphetanes (4). It has been reported (5) that steric effects are not important in the racemization of acyclic phosphines and sulfoxides.

Using the approximation that replacement of the ethyl group in **2***b* by a substituted phenyl group will increase the rate constant for racemization by a factor of 10, it can be estimated that at 25° in solvent methanol the value of k_{rac} will be $8 \times 10^{-4}\ s^{-1}$ for the racemization of an optically active triarylsulfonium salt, corresponding to a half-life of *ca.* 15 min for the racemization. This estimate is a minimum value for k_{rac} (maximum value for the half-life) since it was made on the assumption that steric effects will be additive in $\log k_{rac}$ whereas one anticipates that at some stage steric effects should cease to be additive and give rise to very large rate accelerations with small structural changes. It is however clear that the previous attempts to prepare optically active triarylsulfonium salts which led to the isolation of racemic sulfonium salts (6, 7[5]) can be accounted for by rapid racemization of the sulfonium salt during the reaction and isolation procedure.

A Modified Triester Method for the Synthesis of Deoxyribopolynucleotides

K. ITAKURA, C. P. BAHL, N. KATAGIRI, J. J. MICHNIEWICZ, R. H. WIGHTMAN,[1] AND S. A. NARANG[2]

Division of Biological Sciences, National Research Council of Canada,[3] Ottawa, Canada

Received June 28, 1973

A modified triester method has been developed for the synthesis of oligonucleotides starting from mononucleosides as more economical starting materials. A pentadecanucleotide has been successfully prepared.

Une méthode modifiée faisant appel au triester a été développée pour la synthèse d'oligonucléosides comme produits de départ plus économiques. Un pentadécanucléotide a été préparé avec succès.

To date, there still remain some crucial methodological problems which must be solved before the chemical synthesis of polynucleotides becomes a reasonably efficacious process. The triester method has recently been examined in various laboratories (1–4) in an attempt to overcome some of the difficulties inherent in the "diester approach", such as low yields with increasing chain length, instability of the internucleotidic phosphodiester bond and cumbersome purification procedures. The essential feature of the "triester approach" involves phosphorylation of the terminal 3′-hydroxyl group of a 5′-protected mononucleoside **1** with a simple monophosphate ester (for example, β-cyanoethyl phosphate, phenyl phosphate, or β,β′,β′-trichloroethyl phosphate) and triisopropylbenzenesulfonylchloride (TPS) followed by subsequent condensation with the primary 5′-hydroxyl group of an incoming suitably 3′-protected nucleoside **6** and additional TPS. Since each internucleotidic bond is present in the desired product as a triester function, purification at each stage by more conventional techniques such as organic solvent extraction followed by a simple chromatography on silica gel columns becomes possible. However, we have observed that the initial phosphorylation reaction of the 3′-hydroxyl group of the starting 5′-protected mononucleoside **1** is incomplete, thus the addition of the incoming 3′-protected mononucleoside **6** leads to a very complicated reaction mixture. These mixtures cannot be completely separated using ordinary silica gel chromatography, hence the advantage of large scale synthesis and high yields is somewhat nullified. However, this difficulty can be overcome by the following simple modification which has also been recently employed by Cramer *et al.* (5). It involves initial phosphorylation of the 5′-protected nucleoside **1** with a suitably substituted phosphate **2** in the presence of TPS, followed by isolation of the phosphorylated product **3** by silica gel column chromatography in 80–85% yield. The phosphodiester group of **3** was further protected with cyanoethanol and TPS to obtain **4** in quantitative yield.

In this communication, we wish to report the effectiveness of compound **4** as the starting material in the synthesis of a pentadecadeoxypolynucleotide (see Scheme 1). Synthesis of dinucleotide was carried out by condensing an anhydrous pyridine solution of 5′-protected nucleoside 3′-phenyl phosphate **3** (20 mmol) with **4** (15 mmol) in the presence of TPS for 20 h at room temperature. After the usual workup, the fully protected dinucleotide was obtained in 70–80% yield by silica gel chromatography. Specific deblocking of the cyanoethyl group with 0.1 *N* aqueous sodium hydroxide in dioxane (4:1 v/v) for 30 seconds at 0° gave **5** which on further condensation with **6** or **4** in the presence of TPS yielded trinucleotides in isolated yields of 65–70%. Employing similar conditions hexanucleotide **11**, nonanucleotide, dodecanucleo-

tide, and pentadecanucleotide were synthesized in 60, 40, 40, and 20% yields respectively.

The internucleotide phosphate protecting group (phenyl or *o*-chlorophenyl) was removed by treatment with 0.1 *N* sodium hydroxide – dioxane at room temperature. Recovery of the required diester products were 80–90% up to the hexanucleotide but dropped dramatically for the higher chain lengths (*ca.* 20–30%). This difficulty was overcome by using *p*-(methylthio)phenyl as

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

a new protecting group for the internucleotide phosphate. This was removed by alkaline treatment after oxidation with *N*-chlorosuccinimide (6) or sodium metaperiodate. The monomethoxytrityl group was removed by acetic acid treatment. Each unprotected intermediate was checked for its purity by t.l.c. on silica gel plates (7) by using aqueous solvent systems such as (i) *n*-propanol – concentrated ammonium hydroxide – water (55:10:35 v/v) and (ii) isobutyric acid – 0.1 *M* ETDA – 1 *M* ammonium hydroxide (100:1.6:60 v/v). Finally these compounds were characterized by their complete degradation with spleen and snake venom phosphodiesterase enzymes.

In conclusion, the modified triester approach for the large scale synthesis of higher polynucleotides seems very promising. Work is in progress for the synthesis of defined sequences and also in the development of more sophisticated protecting groups for the internucleotide phosphate.

One of us (R.H.W.) wishes to acknowledge with thanks Professor C. B. Reese, Cambridge University, for the experience gained in triester work during part of a sabbatical leave (December 1971 to March 1972).

Pulse Radiolysis of Liquid Deuterated Ammonia[1]

WILLIAM ARTHUR SEDDON, JOHN WALLACE FLETCHER, JOHN JEVCAK, AND FRED CHARLES SOPCHYSHYN

Physical Chemistry Branch, Atomic Energy of Canada Limited, Chalk River Nuclear Laboratories, Chalk River, Ontario

Received May 24, 1973

Pulse radiolysis of solutions of alkali metal amides in deuterated ammonia at −15 °C produces an initial absorption with a maximum at 1500 nm due to the solvated electron, e_{am}^-. This decays on a microsecond time scale giving a residual long lived absorption with a slightly broader spectrum and a maximum displaced to 1640 nm. We suggest the residual absorption is an equilibrium mixture of e_{am}^- and a metal–electron species. The initial decay of e_{am}^- is suppressed by scavenging ND_2 and/or ND^- radicals with dissolved D_2 (1 atm) or $NaBH_4$. Evidence is also obtained for the reaction $ND^- + D_2 \rightarrow e_{am}^-$. It is estimated that $k(e_{am}^- + ND_2)$ and $k(BH_4^- + ND_2) = 2.5 \times 10^{10}$ and 7×10^7 M^{-1} s^{-1}, respectively. Measurements of the initial yield in NH_3 and ND_3 give $G_{e_{am}^-} = 3.3 \pm 0.3$ and 3.6 ± 0.4 molecules/100 eV, respectively.

La radiolyse pulsée de solutions d'amidures de métaux alcalins dans l'ammoniac deuterié à −15 °C provoque une absorption initiale avec un maximum à 1500 nm due à l'électron solvaté e_{am}^-; ce dernier ayant une durée de vie de l'ordre du microseconde conduit à une absorption résiduelle de longue durée avec un spectre plus large et un maximum déplacé à 1640 nm. Nous suggérons que l'absorption résiduelle est un mélange à l'équilibre de e_{am}^- et d'espèce métal–électron. La disparition initiale de e_{am}^- est supprimée par piégeage des radicaux ND_2 et (ou) ND^- par du D_2 dissous (1 atm) ou $NaBH_4$. La réaction $ND^- + D_2 \rightarrow e_{am}^-$ a été également mise en évidence. On a calculé que $k(e_{am}^- + ND_2)$ et $k(BH_4^- + ND_2)$ valaient respectivement 2.5×10^{10} et 7×10^7 M^{-1} s^{-1}. Les mesures de rendement initial en NH_3 et ND_3 ont conduit à $G_{e_{am}^-} = 3.3 \pm 0.3$ et 3.6 ± 0.4 molécules/100 eV respectivement.

Introduction

Extensive investigations on the physical properties of solutions of alkali metals in liquid ammonia have shown that in very dilute solution the predominant species are the solvated electron e_{am}^-, and the metal cation M^+ (1–3). At higher concentrations it is also generally accepted that these species are in equilibrium with an intermediate species of stoichiometry M, probably best described as an ion pair, $(M^+ - e_{am}^-)$. However spin pairing occurs to a considerable extent (4), and magnetic susceptibility studies show that over 90% of the spins are paired in 10^{-1} M solutions of sodium and potassium (5). The nature of this interaction is less obvious and the species e_2^{2-}, M^-, and M_2 have been invoked to explain such results.

Despite this clear evidence of cation–electron interaction the optical spectrum and molar extinction coefficient for e_{am}^- are virtually independent of concentration and the nature of the alkali metal cation (6–8). Nevertheless the peak position is slightly concentration dependent (7, 8). This shift correlates well with the onset and extent of spin pairing (9), and the overall spectrum

can be analyzed as a composite of two broadly overlapping absorbances (10).

Pulse radiolysis studies in liquid NH_3 have been reported previously (11–15), while Lok *et al.* (16) have compared the spectrum of solvated electrons as determined by pulse radiolysis and alkali metal solution studies for ammonia and a series of amines and ethers. The agreement between the peak positions in all cases is good. However, in some cases the spectrum attributed to solvated electrons in metal solutions tends to be somewhat broader and the peak positions at slightly higher energies than those found by pulse radiolysis. These observations, taken in conjunction with the concentration effect on the peak position in liquid ammonia, suggested to us that a time dependent shift and broadening of the optical spectrum might be observed in the pulse radiolysis of alkali metal amide solutions.

Using fast infrared detection techniques (17), and ND_3 to minimize solvent absorption (6), we have therefore reinvestigated the solvated electron absorption spectrum in liquid ammonia as a function of time, amide concentration, and temperature. Since measured radiolytic yields for e_{am}^- in liquid ammonia vary considerably we have also attempted to resolve this discrepancy and deduce a more reliable value than the previous determinations which range from $G_{e_{am}^-} =$ 0.35 to 3.0 molecule/100 eV (11, 12, 14, 18, 19).

Experimental

Details of the pulse radiolysis facility and infrared detection techniques have been presented elsewhere (17, 20–22). Briefly, solutions were irradiated with 0.5 to 2.0 μs pulses from a 2.5 MeV Van de Graaff accelerator. Rectangular quartz irradiation cells with an optical path length of 0.5 to 2.0 cm were mounted in a specially designed flow system consisting of an upper reservoir and a lower drainage bulb (22).

For low temperature studies separate jacketed flow systems were constructed in which the reservoir, drain, and float valve were cooled with cold ethanol circulated by a Neslab LT-9 thermostatic circulator. The cell itself was cooled to the same temperature with cold ethanol and N_2 gas in a manner similar to that described by Wardman (23). Temperatures were monitored continuously with a Comark type 1603 electronic thermometer.

Anhydrous liquid ammonia (Matheson Ltd.) was purified by reaction with sodium or potassium followed by fractional distillation into stainless steel storage vessels. Deuterated ammonia obtained from Merck, Sharpe and Dohme Ltd., or synthesized from NaCN and D_2O (24), was purified in a similar manner. $NaBH_4$ (Fisher Chemicals) was used as received.

Potassium (Fisher Chemicals) or sodium (Baker reagent) were stored in a dry box and freshly pressed in the form of 0.1 to 1.0 mm diameter wire of calibrated weight per unit length. Appropriate quantities were placed in a 2–3 mm diameter Pyrex tubing and transferred, either under vacuum or 1 atm D_2 pressure, to the reservoir of the flow system. Metal amide solutions were then obained by distilling ammonia from the lower bulb to the upper reservoir onto the appropriate amount of metal and then bleaching the resulting blue solutions using electrolyzed platinum (25). With this technique fresh solutions of the same or different amide concentrations can be made after each cycle by redistilling the irradiated ammonia from the lower bulb back onto fresh amounts of alkali metal in the reservoir. However it was difficult to obtain solutions completely free of amide since there was always some "carry over" associated with the distillations.

Transient optical absorptions in the region 1000–2000 nm were monitored with a Spectronics SD-8721-2 InSb photovoltaic detector with a rise time (0–100%) $\leqslant$ 200 ns (17). Spectra were obtained using a Bausch and Lomb *f* 3.5 high intensity grating monochromator at a band width $\leqslant$ 40 nm.

For most of the experiments three oscilloscope traces were recorded on a single Polaroid photograph. Examples are given in Figs. 4 and 5 where curve *A* shows the output profile of the analyzing light flash on a time scale of 500 μs/division. Curve *B* shows the transient signal recorded simultaneously with *A*, but at a higher gain, while curve *C* represents the analyzing light baseline on the same amplification and time scale as *B*. The transient signal at lower gain is superimposed on curve *A*.

Results and Discussion

Spectra

The spectrum observed immediately after the pulse in 1.4×10^{-2} *M* potassium deuteroamide solutions in ND_3 is shown in Fig. 1. Using ND_3 permits measurements up to about 2000 nm. As noted previously (11, 13), the transient absorption consists of an initial rapid decay followed by a long lived slow component (inset Fig. 1). At -15 °C the initial absorption (curve 1) has a maximum at 1500 nm while the spectrum of the long lived absorption, observed after 150 μs, has a maximum shifted slightly to 1640 nm. The longer time scale spectrum (curve 2) is normalized to the same relative intensity as spectrum 1. Although small this shift was quite reproducible and comparisons of many experiments indicated the long lived absorption to be somewhat broader.

There seems little doubt that the initial absorption is due to the solvated electron e_{am}^-. Allowing for the isotopic shift in the maximum of 400 cm^{-1} (100 nm) in changing solvent from ND_3 to NH_3 (26), our initial maximum is in good agreement with the peak absorption at 1600 nm obtained for e_{am}^- on the pulse radiolysis of liquid NH_3 at -15 °C (13). Furthermore the maximum

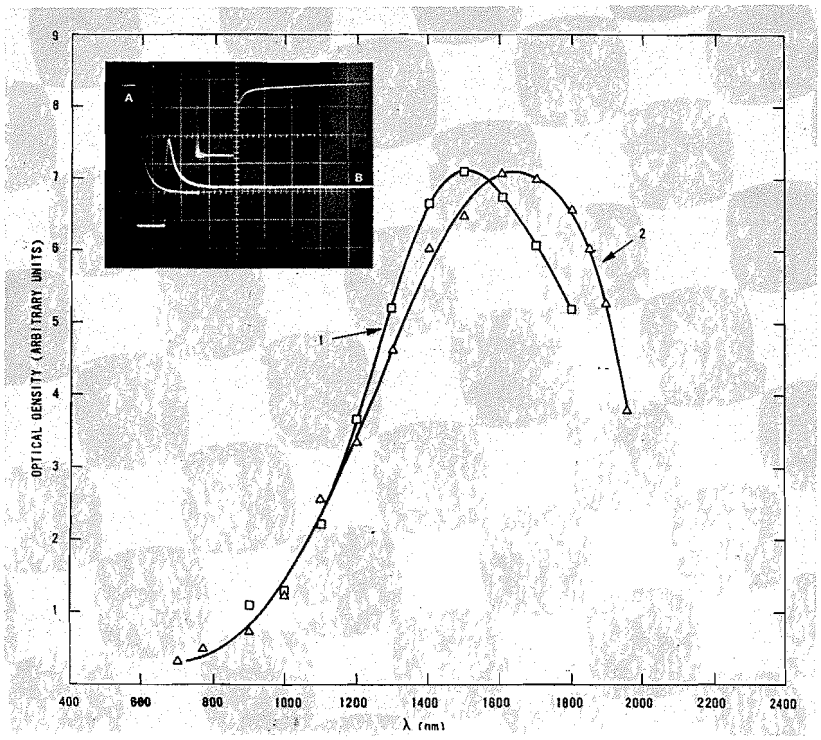

FIG. 1. Optical spectra observed on the pulse radiolysis of solutions containing 1.4×10^{-2} *M* KND_2 in ND_3 at -15 °C. Curve 1, immediately after the pulse; curve 2, 150 μs after the pulse. The inset (trace *B*) shows the transient signal monitored at 1400 nm in a 2.0 cm cell. Ordinate 25% absorption/division, abscissa 5 μs/division, dose/pulse $\sim 3 \times 10^{20}$ eV/l. Trace *A*, see experimental.

observed by pulse radiolysis shifts to higher energies with decreasing temperatures (Fig. 2) with the corresponding blue shift equivalent to a temperature coefficient of ~ 17 cm^{-1}/°C. Comparing this shift with alkali metal ammonia solutions we find values of 14.3 cm^{-1}/°C obtained by Burow and Lagowski (6) using a 2.8×10^{-4} *M* solution of sodium in ND_3 and 21.8 cm^{-1}/°C deduced by Hurley *et al.* (26), for e_{am}^- in sodium/ND_3 solutions extrapolated to infinite dilution (Fig. 3.)

However, in previous pulse radiolysis studies there has been no attempt to compare both the initial and residual absorptions. Although slight, the time dependent shift in peak position we observe is toward longer wavelengths and is consistent with the results observed in alkali metal ammonia solutions (7, 8). For example, in liquid NH_3 at -65 °C the data of Douthit and Dye (7) show a shift in the wavelength of the absorption maximum from 1400 to 1480 nm with increasing concentrations of sodium from $\sim 5 \times 10^{-4}$ to 4×10^{-3} *M* (9). Similarly from optical spectra measured in dilute solutions ($5 \times 10^{-6} - 5 \times 10^{-4}$ *M*) of sodium and potassium in ND_3 (6, 26) it appears that at infinite dilution the absorption maximum lies at shorter wavelengths.

The solid triangles and squares shown in Fig. 3 illustrate the effect of decreasing temperature on the absorption maxima of the initial and long lived species respectively, in 1.4×10^{-2} *M* potassium deuteroamide solutions. The remaining data obtained for sodium solutions in ND_3 were presented by Hurley *et al.* (26) and are shown for comparison. The alkali metal results show a slight shift of the maximum with concentration at the lower temperatures even in 2×10^{-4} *M* solution. On this basis, and from the difference we observed in the short–long time pulse radiolysis spectrum at -15 °C, we expected that such a shift might become more significant at lower temperatures, particularly at the higher concentration used in our experiment.

From Fig. 3 we can see that the maxima of the

For personal use only.

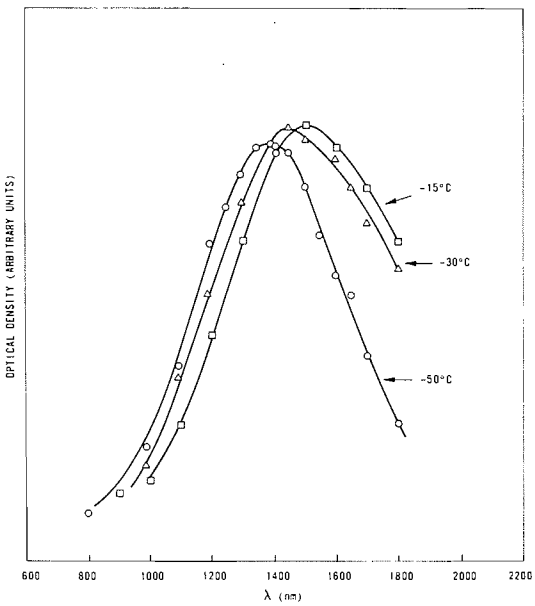

FIG. 2. Effect of temperature on the optical spectra observed immediately after the pulse in solutions containing 1.4×10^{-2} *M* KND_2 in ND_3.

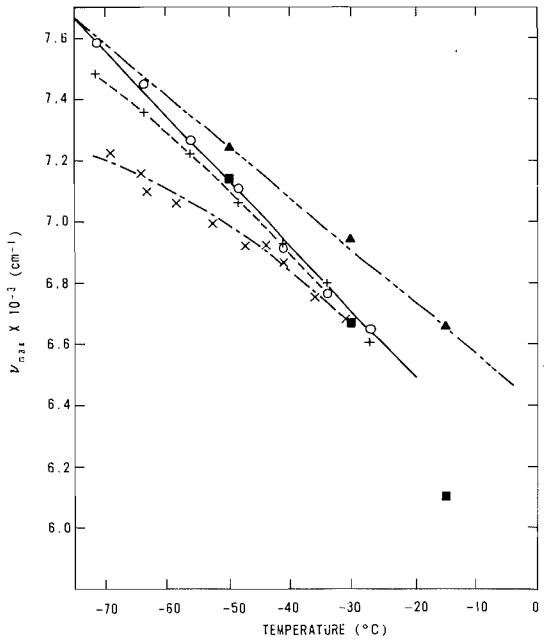

FIG. 3. Effect of temperature on the e_{am}^- maximum in ND_3. Symbols 0, +, and × are data for sodium in ND_3 taken from ref. 26: ○, Hurley infinite dilution; +, Hurley 1.94×10^{-4} *M*; ×, Burow and Lagowski 2.86×10^{-4} *M*. Solid symbols, this work in solutions containing 1.4×10^{-2} *M* KND_2; ▲, immediately after the pulse; ■, 150 μs after the pulse.

initial e_{am}^- absorption (closed triangles) lies at higher energies than the corresponding absorption in alkali metal solutions. The results extrapolate to the infinite dilution value deduced by Hurley *et al.* (26) and support their contention that there is an appreciable shift of the peak position even at low metal concentrations. However, the difference between λ_{max} for the initial and final species did not increase with decreasing temperature in the manner suggested by the alkali metal studies. On the contrary the largest effect was observed at the highest temperature. Considering all the experimental parameters it may simply be that our technique is too imprecise for a definitive answer with respect to the temperature effect. The situation is further complicated in that the existence of ion pairs or spin-paired species probably results in temperature-dependent equilibria among species with slight differences in spectra. Nevertheless the results suggest to us that the residual absorption is best considered as a composite of two, or more, overlapping bands corresponding to e_{am}^- and a metal–electron species.

It is worth noting that our recent results in ethylamine (22, 27), demonstrate that the solvated electron and ion-paired species do have similar, but distinct spectra, with the latter absorbing at higher energies. This is consistent with the observations of Lok *et al.* (16), implying again that the peak positions assigned to solvated electrons in alkali metal solutions correspond to equilibrium mixtures of electron and metal–electron species.

Decay Kinetics of e_{am}^-

In agreement with Dye *et al.* (13), we find the initial rate of e_{am}^- decay in ND_3 follows second order kinetics. This rate of decay is independent of amide concentration. However, the relative proportion of the fast to slow component increases with dose and decreases with amide concentration.

In "pure" and basic ammonia solutions the initial decay of e_{am}^- appears to be due to second order reactions with other radical species produced during the pulse.

[1*a*] $$e_{am}^- + NH_2 \rightarrow NH_2^-$$

[1*b*] $$e_{am}^- + NH \rightarrow NH^-$$

[1*c*] $$e_{am}^- + H \rightarrow NH_2^- + H_2$$

Other workers (12, 13, 19) have suggested that reaction 1*a* is the most important. Since the initial decay is independent of base then the dissociation of NH_2, reaction 2*f*, is either quite slow or, by analogy with aqueous solutions (28), $k_{1a} \sim k_3$.

[2] $$NH_2 + NH_2^- \underset{r}{\overset{f}{\rightleftharpoons}} NH^- + NH_3$$

[3] $$e_{am}^- + NH^- \rightarrow 2\,NH_2^-$$

Assuming approximately equal concentrations for e_{am}^- and $NH_2(NH^-)$ and the extinction coefficient $\varepsilon_{e_{am}^-} = 4.9 \times 10^4\ M^{-1}\ cm^{-1}$ for e_{am}^- in metal ammonia solutions (6), then $k_{1a} = 2.5 \times 10^{10}\ M^{-1}\ s^{-1}$. This is in good agreement with the value of $> 10^{10}\ M^{-1}\ s^{-1}$ deduced by Dye *et al.* (13).

It is worth noting here that alkali metal amides are only weakly dissociated in liquid ammonia and that the concentration of NH_2^- is only about 10% in 10^{-2} *M* KNH_2. Values for the dissociation constant range from 2.23×10^{-2} *M* for sodium amide to 1.02×10^{-1} *M* for potassium and cesium amides (29). No distinction is made between reactions involving NH_2^- or KNH_2.

In "pure" ammonia the second order decay of e_{am}^- is complete. The addition of base results in an increasing contribution due to the long lived e_{am}^- species, possibly due to the removal of radiolytically formed NH_4^+,

[4] $$NH_4^+ + NH_2^- \rightarrow 2\,NH_3$$

in competition with

[5] $$e_{am}^- + NH_4^+ \rightarrow NH_3 + H$$

However Dye *et al.* (13) set an upper limit of $k_5 = 6 \pm 2 \times 10^5\ M^{-1}\ s^{-1}$, which suggests reaction 5 is insignificant at low doses. The relative proportion of the long lived component does however increase with amide concentration. In part this may be due to reaction 6, analogous to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

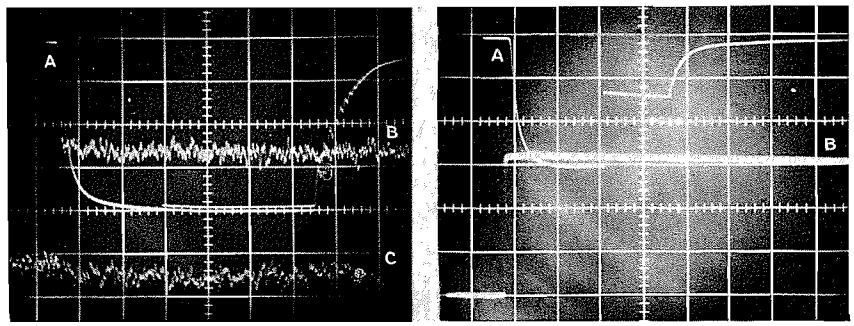

FIG. 5. Oscilloscope traces showing the transient absorptions observed in basic solutions containing $NaBH_4$ in ND_3 and NH_3. Left 1500 nm, 2.0 cm cell, 5×10^{-4} *M* $NaND_2$ and 9×10^{-4} *M* $NaBH_4$ in ND_3; trace *B*, ordinate 1.0% absorption/division, abscissa 5 μs /division, dose/pulse $\sim 2 \times 10^{18}$ eV/l. Right 1400 nm, 1.0 cm cell 3.6×10^{-3} *M* $NaNH_2$ and 1.3×10^{-1} *M* $NaBH_4$ in NH_3; trace *B*, ordinate 16.7% absorption/division, abscissa 50 μs/division, dose/pulse 1.6×10^{20} eV/l. Traces *A* and *C*, see experimental.

the corresponding reaction in aqueous solution (30).

$$[6] \qquad H + NH_2^- \rightarrow e_{am}^-$$

Although our evidence is not conclusive one cannot exclude the rapid formation of a spin-paired species such as M_2 via the neutral ion-pair M

$$[7] \qquad e_{am}^- + M^+ \rightleftharpoons M$$

$$[8] \qquad 2M \rightleftharpoons M_2$$

Species of this nature are clearly formed in alkali metal ammonia solutions (1), and as mentioned above probably contribute to the long lived absorption.

Effect of Added Hydrogen/Deuterium

An increase in the stability of radiolytically produced e_{am}^- has been observed by Belloni *et al.* (19) during the γ-radiolysis of basic solutions of liquid ammonia containing dissolved H_2. Our pulse radiolysis results using both NH_3 and ND_3 show that the initial rapid decay of e_{am}^- can be suppressed in basic solutions containing $\sim 1.7 \times 10^{-3}$ *M* H_2/D_2 (1 atm, −15 °C (31)). Furthermore, at doses $\leqslant \sim 10^{19}$ eV l^{-1} an additional increase in absorption can be seen immediately following the pulse in solutions ranging from 1.4×10^{-5} *M* to 1.4×10^{-3} *M* sodium amide. At higher doses per pulse only a small amount of initial decay is observed, in sharp contrast to the results obtained in the absence of H_2/D_2. These changes are illustrated in the oscilloscope traces reproduced in Fig. 4.

Belloni *et al.* (19) attribute this enhanced stability to the removal of NH_2 radicals, reaction 9 followed by [6],

$$[9] \qquad H_2 + NH_2 \rightarrow H + NH_3$$

$$[6] \qquad H + NH_2^- \rightarrow e_{am}^-$$

Alternatively they suggest the basic entity, NH^-, reacts directly with H_2 to form e_{am}^-

$$[10] \qquad H_2 + NH^- \rightarrow e_{am}^-$$

Reactions 6 and 10 were also proposed much earlier by Dainton *et al.* (18). Our results cannot differentiate between the two possibilities but it is likely that [10] is energetically more favorable. In the gas phase reaction 9 is slow with an estimate for $k_9 \sim 3 \times 10^3\ M^{-1}\ s^{-1}$ (18).

The stationary state concentration of e_{am}^- (32) produced via equilibrium [11] is not a significant factor, relative to the pulse concentrations, in 10^{-3} *M* amide solutions.

$$[11] \qquad \tfrac{1}{2}H_2 + NH_2^- \rightleftharpoons e_{am}^- + NH_3$$

$$K_{-11} = \frac{[NH_2^-]P_{H_2^{1/2}}}{[e_{am}^-]} = 5 \times 10^4\ \text{atm}^{1/2}$$

at low amide concentrations.

Effect of Borohydride Ion

Pulse radiolysis studies in aqueous solution (33) show that the borohydride ion, BH_4^-, reacts with the OH radical with a rate constant $k_{12} = 1.2 \times 10^{10}\ M^{-1}\ s^{-1}$

$$[12] \qquad OH + BH_4^- \rightarrow OH^- + BH_4$$

In liquid ammonia we would expect the corresponding reaction to involve the NH_2 radical

$$[13] \qquad NH_2 + BH_4^- \rightarrow NH_2^- + BH_4$$

Assuming that the rate of decay of e_{am}^- is pre-

dominantly affected by competition between reactions 1*a* and 13, then the stability of radiolytically produced e_{am}^- ought to be enhanced in solutions containing BH_4^-. Figure 5 confirms this prediction showing a long lived e_{am}^- absorption in basic solutions of ND_3 and NH_3 containing 9×10^{-4} and 1.3×10^{-1} *M* $NaBH_4$, respectively.

An estimate of k_{13} can be obtained on the basis of a simple competition between reactions 1*a* and 13 where

$$[A] \quad d[NH_2]/d[e_{am}^-] = 1 + k_{13}'/k_{1a}[e_{am}^-]$$

and k_{13}' (the pseudo first order rate constant) = $k_{13}[BH_4^-]$. Assuming at the end of the pulse, time t_0, that the initial concentration $[NH_2]_0 = [e_{am}^-]_0$ and at long times, t_∞, that $[NH_2]_\infty = 0$, then integrating *A* gives

$$[e_{am}^-]_\infty = OD_\infty/\varepsilon_{e_{am}^-} = 2.303k_{13}'/k_{1a} \log \frac{[e_{am}^-]_0}{[e_{am}^-]_\infty}$$

Therefore

$$[B] \quad OD_\infty = 2.303k_{13}'/k_{1a}\varepsilon_{e_{am}^-} \log \frac{OD_0}{OD_\infty}$$

where OD_0 and OD_∞ represent the optical density of e_{am}^- at t_0 and t_∞. In basic solutions containing 9×10^{-4} $NaBH_4$ a plot of OD_∞ against log OD_0/OD_∞ gave a reasonable straight line with a slope 2.303 $\varepsilon_{e_{am}^-} k_{13}'/k_{1a} = 0.29$. Taking $k_{1a} = 2.5 \times 10^{10}\ M^{-1}\ s^{-1}$ and $\varepsilon_{e_{am}^-} = 4.9 \times 10^4\ M^{-1}\ cm^{-1}$ we obtain $k_{13} = 7 \times 10^7\ M^{-1}\ s^{-1}$.

Figure 6 shows a plot of OD_0 and OD_∞ (after 400 μs) as a function of dose per pulse with the curves calculated on the basis of k_{13} and eq. *B*. The overall agreement is quite good but the fit falls off somewhat with increasing dose. This may be due to the second order disappearance of NH_2 radicals assuming relatively greater importance at higher dose rates.

$$[14] \quad NH_2 + NH_2 \rightarrow N_2H_4$$

Separate experiments in 10^{-3} *M* basic solutions containing D_2 (1 atm) and 6×10^{-4} *M* $N_2H_4 \cdot H_2SO_4$ showed no evidence of either a build up or decay following the initial e_{am}^- absorption. This supports Belloni's conclusion that e_{am}^- does not react rapidly with either N_2H_4 or the basic entity $N_2H_3^-$ (19). The slow e_{am}^- decay ($t_{1/2} > 10$ ms) observed in borohydride solutions may be due to

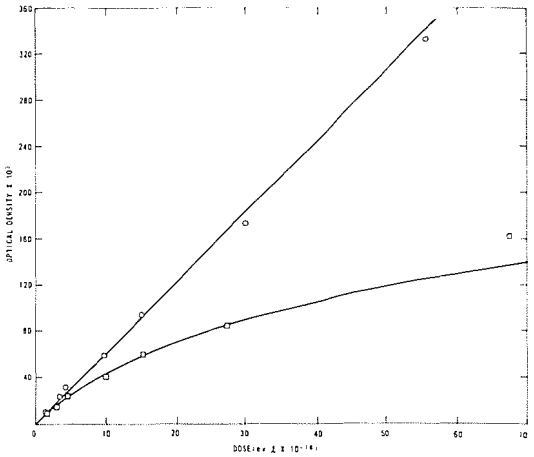

FIG. 6. Optical density of the transient species monitored in a 2.0 cm cell at 1500 nm and −15 °C in solutions containing 5×10^{-4} *M* $NaND_2$ and 9×10^{-4} *M* $NaBH_4$ in ND_3; ○, immediately after the pulse; □, 400 μs after the pulse. Curves are calculated on the basis of equation *B* (see text).

$$[15] \quad e_{am}^- + BH_4 \rightarrow BH_4^-$$

for which we estimate $k_{15} \sim 10^3 \pm 10\ M^{-1}\ s^{-1}$.

Finally the addition of $\sim 2.5 \times 10^{-2}$ *M* $NaBH_4$ to a 1×10^{-3} *M* amide solution containing D_2 (1 atm) produces a signal comparable to Fig. 5 (upper left) and prevents the build up of e_{am}^- such as observed in Fig. 4 (upper left). Since borohydride reacts with NH_2 radicals, reaction 13, this again supports the suggestion that $NH_2(NH^-)$ radicals react with H_2 to produce e_{am}^-.

The results obtained in basic ammonia solutions are quite different to those observed in amines. In amine solutions the addition of dilute concentrations of base completely removes the fast decay and results in the formation of metal–electron species having different spectra (22).

Yield of e_{am}^- in NH_3 and ND_3

Considerable discrepancy exists in the literature concerning the radiolytic yield of e_{am}^-. Values range from $G_{e_{am}^-} \sim 0.35$ (11, 18), 0.75 (19), 1.2 (14) to ~3 mol/100 eV (12). In "pure" ammonia or slightly basic solutions we find the initial absorption is drastically reduced on repetitive pulsing. Therefore measurements were always made using a fresh solution for each pulse. The initial yield was determined immediately after the pulse in basic solutions of NH_3 and ND_3 and in the presence of H_2/D_2 and/or

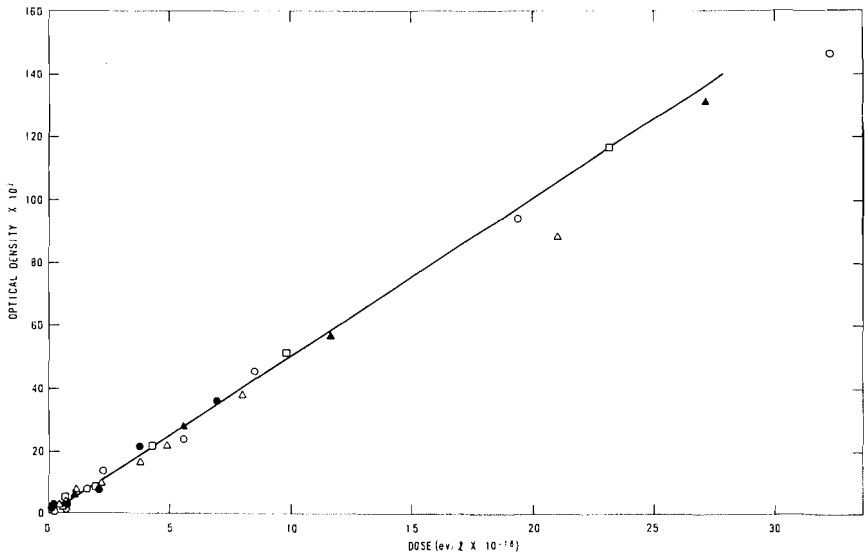

FIG. 7. Optical density of the transient species observed immediately after the pulse in basic solutions of NH_3 containing 1 atm of H_2. Wavelength 1420 nm, path length 2.0 cm; △, 0.01 mM; ○, 0.1 mM; ●, 10 mM; □, 50 mM; and ▲, ~200 mM $NaNH_2$ respectively.

varying concentrations of $NaBH_4$. Yields were deduced by comparison with the thiocyanate dosimeter taking at the peak wavelength $\varepsilon_{e_{am}^-} = 4.9 \times 10^4\ M^{-1}\ cm^{-1}$ and $G\varepsilon$ for $(SCN)_2^- = 2.1 \times 10^4$ (34–36). Dosimetry corrections based on stopping powers per gram for 2.20 MeV electrons in H_2O and ND_3 (37) were within 1% of electron density corrections using $\rho(NH_3) = 0.659\ g\ cm^{-3}$ and the ratio $\rho(ND_3)/\rho(NH_3) = 1.184$ (38).

Figure 7 shows a plot of the optical density, monitored at 1420 nm, as a function of dose for a series of sodium concentrations in NH_3/H_2 solutions. The production of e_{am}^- is linear with dose up to about $2.6 \times 10^{19}\ eV\ l^{-1}$ (~400 rads/pulse). From the slope of this and other similar plots in the absence of H_2 and/or presence of $NaBH_4$ we deduce $G_{e_{am}^-}(NH_3) = 3.3 \pm 0.3$. Similar measurements in ND_3 monitored at 1500 nm were slightly less reproducible giving $G_{e_{am}^-}(ND_3) = 3.6 \pm 0.4$. Although our precision is poor these results suggest a similar trend to the increased yield observed in aqueous solution between H_2O and D_2O (39).

We are unable to explain the low values in the literature unless such results are questionable in terms of dose and/or impurity effects. The high values we obtain certainly merit a re-examination of the mechanism and fate of e_{am}^- in the radiation chemistry of liquid ammonia.

Determination of the Heat of Formation of Octafluorotoluene and Calculation of $D[C_6F_5—F] - D[C_6F_5—CF_3]$

MICHAEL J. KRECH
Chemistry Department, Wilfred Laurier University, Waterloo, Ontario

AND

STANLEY JAMES W. PRICE[1] AND WAYNE F. YARED
Chemistry Department, University of Windsor, Windsor, Ontario N9B 3P4

Received April 24, 1973

The heat of formation of octafluorotoluene has been determined using the direct combustion method previously developed for hexafluorobenzene. As in the hexafluorobenzene case the combustion of octafluorotoluene in oxygen yields CO_2, CF_4, and F_2. With a ten-fold excess of oxygen the CO_2 to CF_4 ratio is 3.85 ± 0.06. A full material balance was obtained. The value of $\Delta H_{f298}^0(C_6F_5CF_{3,g}) = -303.2 \pm 1.8$ kcal mol^{-1} may be combined with the enthalpies of formation of C_6F_6, CF_3, and F to give $D[C_6F_5—F] - D[C_6F_5—CF_3] = 55.7 \pm 4.0$ kcal mol^{-1}.

La chaleur de formation de l'octafluorotoluène a été déterminée en faisant appel à la méthode de combustion directe mise au point antérieurement. Comme dans le cas de l'hexafluorobenzène, la combustion de l'octafluorotoluène dans l'oxygène fournit du CO_2, du CF_4 et du F_2. Avec de l'oxygène en excès (10 fois la quantité nécessaire), le rapport de CO_2 sur CF_4 est de 3.85 ± 0.06. Une balance complète de tous les réactifs a été obtenue. La valeur de $\Delta H_{f298}^0(C_6F_5CF_{3,g}) = -303.2 \pm 1.8$ kcal/mol peut être combinée avec les enthalpies de formation de C_6F_6, CF_3 et F pour donner $D[C_6F_5—F] - D[C_6F_5—CF_3] = 55.7 \pm 4.0$ kcal/mol. [Traduit par le journal]

Can. J. Chem. 51, 3662 (1973)

Introduction

Enthalpies of formation have previously been reported for C_6F_6 (1–3), C_6F_5H (2), C_6F_5Cl (2), C_6F_5OH (2), and $C_6F_5CH_3$ (2). With the exception of the study of C_6F_6 done in this laboratory (3) all determinations involved combustion using an auxiliary material to ensure complete combustion and minimize CF_4 formation, containment of the sample in either polyester bags of polyethylene capsules and the use of water in the bomb to convert fluorine containing products other than CF_4 into aqueous HF. In the case of C_6F_5Cl a solution of As_2O_3 was used to reduce all chlorine to the chloride.

The present paper describes the measurement of the heat of combustion of octafluorotoluene in a platinum lined rotating bomb using the method previously developed for hexafluorobenzene (3). No water or other auxiliary materials are employed. The compound is contained in an open platinum crucible. With approximately a tenfold excess of oxygen complete combustion is easily obtained and the only products are CO_2, CF_4, and F_2.

Experimental

Octafluorotoluene

The octafluorotoluene used was obtained from the Imperial Smelting Corporation. Three bulb-to-bulb distillations were carried out with head and tail fractions being discarded each time. The final product had the following physical properties (values in parentheses are those reported by the manufacturer (4)]: b.p. = 103.8 °C (104.0), $n_D^{25} = 1.3649$ (1.3656), s.g. at 20 °C = 1.762 (1.766). Analysis by gas chromatography (t.c. detector, 6 ft × 1/4 in o.d. polypropylene glycol column, isothermal operation at 110 °C, He carrier, 60 cc/min) showed one minor impurity which was estimated to represent about 0.01% of the sample. The impurity had a corrected relative retention with respect to the octafluorotoluene of 1.57. Further identification or purification was not attempted.

A modified Ramsay–Young system was used to measure the vapor pressure of C_7F_8 over the range 12–61 °C. Approximately 40 vapor pressure measurements were made over two separate runs. As in the case of C_6F_6 (3) the conventional $\log p$ *vs.* $10^3/T$ plot was very slightly curved. The data may be represented by

$$[1] \quad \log_{10} P\,(\text{cm}) = 29.098 - \frac{3122.2}{T} - 7.348 \log_{10} T$$

The resulting heat of vaporization and average heat capacity differences (vapor–liquid) are $\Delta H_{298}^0 = 9.95 \pm 0.05$ kcal mol^{-1} and $\langle \Delta C_p \rangle$ 12–61 °C $= -14.6$ cal deg^{-1} mol^{-1}. The error limits on ΔH are representative of the uncertainty in the precision only.

1.374	0.7297				−304.1

* = molar ratio. Additional typical data (see ref. 9 for notation): ΔE, ign/cal = 2.41, ε(cal)(−Δt_c)/cal = −3188.3, $\Delta E_c^0/M$(compound)/cal g^{-1} = −2250.

†% theoretical yield (to nearest whole %) based on the average CO_2/CF_4 molar ratio, 3.85, and on the assumption that the only products are CF_4, CO_2, and F_2.

As previously noted (3) the boiling points and $\langle \Delta C_p \rangle$ values for C_6H_6 and C_6F_6 are very similar. The boiling point of C_7F_8 is approximately 7° lower than that of C_7H_8 but the $\langle \Delta C_p \rangle$ values are again very close ($\langle \Delta C_p \rangle$ 25 °C for toluene −12.8 cal deg^{-1} mol^{-1} (5)).

Full fluorination of C_6H_6 or $C_6H_5CH_3$ has only a small effect of $\Delta H^0_{vaporization}$ *e.g.* $\Delta H_{vap}^0(C_6F_6) - \Delta H_{vap}^0(C_6H_6) = 0.5$ kcal mol^{-1}, $\Delta H_{vap}^0(C_7F_8) - \Delta H_{vap}^0(C_7H_8) = 0.87$ kcal mol^{-1}. Obviously, however, the values per gram differ by more than a factor of two. It is perhaps interesting to note that at least in the case of benzene and toluene full fluorination produces almost identical decreases in the heat of vaporization per gram (58.3 and 57.8 cal g^{-1}, respectively).

Apparatus and Calorimetric Procedure

The apparatus and all procedures were identical to those previously used for C_6F_6 (3).

The rate of loss of $C_6F_5CF_3$ from the platinum crucible in which it was weighed was determined to be 0.11 mg s^{-1}. The time between weighing the crucible containing the octafluorotoluene and sealing the bomb was such that less than 0.3% of the total sample was lost by evaporation. The correction for weight loss based on the time from weighing to sealing and on the rate of evaporation is estimated to be accurate to better than ±3%. The error in sample weight generated by the open dish procedure should therefore be less than 0.01%.

Analysis of Reaction Products

All analytical procedures were essentially the same as those used for hexafluorobenzene (3). Using a 6 ft. × 1/4 in. o.d. silica gel column at 25 °C with a helium carrier flow rate of 15 cc/min, uncorrected retention times for O_2, CF_4, and CO_2 are 1 min 30 s, 3 min 12 s, and 12 min 36 s, respectively.

Results and Discussion

The results of the $C_6F_5CF_3$ combustion studies are given in Table 1. The average CO_2/CF_4 ratio is 3.85 with a *probable error* (6) of ±0.011. It should be noted that a change of 0.01 in this ratio leads to a change of approximately 0.38 kcal mol^{-1} in ΔH_{f298}^0 ($C_6F_5CF_{3,g}$). As previously reported (3) gas chromatographic calibration for CO_2 may be done with the pure gas. However, under conditions used in the present work calibration for CF_4 must be done with CF_4–O_2 mixtures similar to those in the bomb after combustion. Calibration with pure CF_4 leads to an error in the CO_2/CF_4 ratio that results in an error of about 7–8 kcal mol^{-1} in ΔH_{f298}^0 ($C_6F_5CF_{3,g}$).

The only detectable products are CO_2, CF_4, and F_2. The material balance for carbon shown in Table 1 indicates that formation of other carbon containing products is unlikely. A similar observation may be made with respect to fluorine compounds. However, the handling and analysis of fluorine is subject to greater uncertainty and this is reflected in the greater scatter in per cent of the theoretical fluorine obtained.

To determine if small quantities of F_2O are produced the contents of the bomb were analyzed by gas chromatography using a 6 ft × 1/4 in. o.d. silica gel column at −60 °C with a helium flow rate of 15 cc/min. Under these conditions the relative retention of F_2O to O_2 is 3.75 so that any peak for F_2O is well separated from the massive O_2 peak. No F_2O could be detected. Mass spectrometric tests for F_2O (based on m/e = 54 and 35) were also negative.

Based on the observed products and the average CO_2/CF_4 ratio of 3.85 the combustion reaction may be written,

$$[2]\quad C_6F_5CF_3 + 5.556O_2 \rightarrow 5.556CO_2 + 1.444CF_4 + 1.112F_2$$

With the exception of $C_6F_5CF_3$ all reactants and products are in the gaseous state. The

octafluorotoluene is present largely as a liquid but under the initial conditions used (23.5 °C, 450 p.s.i. O_2, 320 cc bomb) 0.125 g will be in the vapor state at the time of combustion.

For calculation of ΔH_{f298}^0 ($C_6F_5CF_{3,g}$) the standard heats of formation of the combustion products were taken as ΔH_{f298}^0 ($CO_{2,g}$) = −94.0517 kcal mol^{-1} (7); ΔH_{f298}^0 ($CF_{4,g}$) = −223.0 kcal mol^{-1} (8). The required correction for the $C_6F_5CF_3$ in the liquid state, $[(w - 0.125)/w]\Delta H_{298}^0$ (vaporization) where w = weight of the $C_6F_5CF_3$ sample in grams, was based on the heat of vaporization determined in the present work, 9.95 kcal mol^{-1}. The average value of ΔH_{f298}^0 ($C_6F_5CF_{3,g}$) is −303.2 ± 1.8 kcal mol^{-1}. The statistical probable error of the mean (6) is ±0.55 kcal mol^{-1}. Based on factors other than possible errors in the heats of formation of CO_2 and CF_4 an overall error of ±2.0 kcal mol^{-1} is estimated.

The value for ΔH_{f298}^0 ($CO_{2,g}$) is well established. However an alternate value for ΔH_{f298}^0 ($CF_{4,g}$) is available, −221 kcal mol^{-1} (7). This leads to ΔH_{f298}^0 ($C_6F_5CF_{3,g}$) = −300.3 kcal mol^{-1}.

Based on ΔH_{f298}^0 (F,g) = 18.9 kcal mol^{-1} (7), ΔH_{f298}^0 ($CF_{3,g}$) = −114 kcal mol^{-1} (7), ΔH_{f298}^0 ($C_6F_{6,g}$) = −226.0 kcal mol^{-1} (3), and ΔH_{f298}^0 ($C_6F_5CF_{3,g}$) = −303.2 kcal mol^{-1} $D[C_6F_5—F] - D[C_6F_5—CF_3]$ = 55.7 ± 4.0 kcal mol^{-1}. Use of ΔH_{f298}^0 ($C_6F_{6,g}$) and ΔH_{f298}^0 ($C_6F_5CF_{3,g}$) based on ΔH_{f298}^0 (CF_4) = −221 kcal mol^{-1} (−224.0 kcal mol^{-1} and −300.3 kcal mol^{-1} respectively) leads to only a slight increase in the bond energy difference (56.6 *vs.* 55.7 kcal mol^{-1}). In any case the bond energy difference calculation should be based on ΔH_{f0}^0 values. However for two such similar molecules the integrated ΔC_p correction should approximately cancel, making the error due to the use of 298 °K values negligible.

A comparison may be made of $D[C_6H_5—H] - D[C_6H_5—CH_3]$ with the corresponding difference in the perfluoro compounds. From high temperature studies of the reaction of CF_3 with benzene (10) $D[C_6H_5—H]$ = 110.2 kcal mol^{-1}. Benson and O'Neal (11) have estimated $D[C_6H_5—CH_3]$ as 102 kcal mol^{-1}. Using the more recent value of $\Delta H_{f298}^0(C_6H_{5,g})$ = 77.9 kcal mol^{-1} (10) leads to $D[C_6H_5—CH_3]$ = 99.9 kcal mol^{-1}. The difference $D[C_6H_5—H] - D[C_6H_5—CH_3]$ = 10.3 kcal mol^{-1} is obviously much less than in the perfluoro case, 55.8 kcal mol^{-1}. Since independent values of $D[C_6F_5—F]$ and $D[C_6F_5—CF_3]$ are not available individual comparisons cannot be made. In the simple aliphatics $D[CH_3—CH_3]$ = 88 kcal mol^{-1} (11), $D[CF_3—CF_3]$ = 92 kcal mol^{-1} (11), $D[CH_3—H]$ = 104 kcal mol^{-1} (10) and from thermochemistry (7) $D[CF_3—F]$ = 126 kcal mol^{-1}. It is tempting to say on this basis that $D[C_6F_5—CF_3]$ may be approximately equal to $D[C_6H_5—CH_3]$ so that $D[C_6F_5—F] \gg D[C_6H_5—H]$. However this ignores the implications of full fluorination of the aromatic ring which might in fact lead to $D[C_6F_5—CF_3] < D[C_6H_5—CH_3]$. An independent determination of either $D[C_6F_5—CF_3]$ or $D[C_6F_5—F]$ is obviously needed.

Photodecomposition of Fe(III) Aminopolycarboxylates

JOHN H. CAREY AND COOPER H. LANGFORD[1]
Department of Chemistry, Carleton University, Ottawa, Canada K1S 5B6

Received May 22, 1973

Aminopolycarboxylate complexes of Fe(III) and Cu(II) may have an interesting natural water photochemistry. As a convenient model system, the photodecarboxylation of ferric–EDTA complexes was studied at 30.0 °C using 3500 Å light. The hydrolytic forms present at p*H* of 8.00 and 9.00 were observed to have quantum yields below 0.10 and varying from species to species. The oxo-bridged dimer was unreactive. This is discussed from the viewpoint of the changed spin selection rules and changed spectral states of the dimer as compared to monomer. The reaction products in the ferric–EDTA system were seen to parallel those of the previously studied ferric–NTA system; the primary products of the reaction being CO_2, CH_2O, Fe(II), and ethylenediaminetriacetic acid.

Les complexes du type aminopolycarboxylate de Fe(III) et de Cu(II) semblent posséder une photochimie intéressante dans l'eau naturelle. La photodécarboxylation de complexes EDTA–Fe(III) a été étudiée, comme système modèle, à 30.0 °C en utilisant une source lumineuse irradiant à 3500 Å. Les formes hydrolytiques présentes à p*H* 8.00 et 9.00 possèdent, comme il a été observé, des rendements quantiques inférieurs à 0.10 variant selon les espèces. Le dimère oxo-ponté n'est pas réactif. Ce fait est discuté en ce qui a trait aux règles de sélections de spin et aux états d'excitation qui, pour le dimère, sont différents de ceux du monomère. Les produits de réaction dans le système EDTA–Fe(III) se sont révélés être en accord avec ceux obtenus antérieurement dans le cas du système NTA–Fe(III); les principaux produits de la réaction sont CO_2, CH_2O, Fe(II) et acide éthylènediaminetriacétique.

Introduction

The decomposition reactions of aminopolycarboxylates have assumed importance in recent years due to their proposed use as detergent builders, their accumulation in waste waters (1, 2), and other reasons. The chemistry of nitrilotriacetic acid (NTA) and similar aminopolycarboxylates in natural waters consists mainly of the reactions of their metal complexes; significantly those formed with iron and copper (2). The photochemical degradation of ferric nitrilotriacetate complexes has been studied and the decomposition pathway shown to be

$$2[Fe^{III}(NTA)] \rightarrow [Fe^{II}(NTA)]^- + [Fe^{II}(IDA)] + CH_2O + CO_2$$

$$[Fe^{II}(IDA)] \xrightarrow{O_2} [Fe^{III}(IDA)]$$

The quantum efficiency of this decomposition decreases with increasing p*H* (2).

The charge transfer region of the cupric complex has also been shown to be active in photodecarboxylation along a similar pathway and the variation of formaldehyde quantum yields with p*H* resembled that obtained in the FeNTA system (3). Since it is known that ferric complexes of aminopolycarboxylates form dimeric structures in basic solutions (4) the possibility that the dimer may be responsible for this p*H* dependence of quantum efficiency has been raised (2).

Although the ferric ethylenediaminetetraacetate (EDTA) complex has been known for some time to undergo photodecarboxylation, the products other than CO_2 have not been determined (5). There has, however, been extensive work done on monomer–dimer equilibria as well as studies on the electronic and crystal structures of the dimer (5–10). The dimer is a strongly colored species exhibiting a much more intense ligand field spectrum than the monomer. This is interpreted to indicate that the transition from the $^6A_1$ ground state to quartet excited states has been made more allowed by dimerization (9). (This may reflect relaxation of the spin selection rule due to spin–spin interaction across the oxo-bridge. Spin–spin coupling is thought to be responsible for the lowering of the magnetic moment of iron complexes upon dimerization (9).)

It is plausible to suggest that the increase in allowed character of the ligand field transitions makes ligand field states more efficient for relaxation of a charge transfer excited state and

[1]To whom correspondence should be addressed.

thus leads to a lower quantum efficiency of reaction in the dimer (2).

In order to investigate the effect of dimer concentration on quantum yield and also to determine whether the proposed pathway for Fe(III)-NTA decarboxylation may be extended to other aminopolycarboxylate complexes, we have conducted a study of the photochemistry of Fe(III)–EDTA in basic solutions.

Experimental

The NaFe(III)EDTA·$3H_2O$ was prepared according to standard procedures (11) and recrystallized twice from distilled water. Solutions to be irradiated were made up from a 0.1 *M* FeEDTA stock solution and were buffered in 1.15×10^{-2} *M* Na_2EDTA. The p*H* was adjusted to p*H* 8.00 and 9.00 using a Fisher "accumet" p*H* meter. It was found that when 0.1 *M* NaOH was added to the more concentrated iron solutions (> 0.02 *M*) precipitation of some of the iron occurred, even when vigorously stirred with a magnetic stirrer. This problem was eliminated by changing the order of the additions. The amount of 0.1 *M* NaOH needed was estimated with the aid of a trial run. The Na_2EDTA buffer (5 ml, 6.25×10^{-2} *M*) was added to the required amount of base and the solution diluted to 15 or 20 ml. The appropriate amount of FeEDTA stock solution was then added and the solution was further diluted to 24 ml. The p*H* of this solution was adjusted to 8.00 or 9.00 using 0.1 *M* NaOH and then was diluted to 25 ml. With suitably pure FeEDTA, no precipitate occurred at concentrations below 0.040 *M*. All preparations were made under red safelights and solutions were stored in foil-wrapped flasks until use.

Irradiations were performed in a jacketed Pyrex cell of 2 cm diameter which was thermostated to 30.0 ± 0.1 °C. The cell was sealed with a serum cap and nitrogen was bubbled for 20 min to deaerate the solution. After deaeration, solutions were immediately irradiated at 3500 Å in a Rayonnet photoreactor to 1–5% reaction. The photolytes were analyzed for Fe(II) with buffered *o*-phenanthroline solution (12) which had also been deaerated. Light intensities were determined using ferrioxalate actinometry (12).

Several solutions of 0.1 *M* FeEDTA were deaerated and irradiated until decolorization was obtained. The iron(II) was re-oxidized by bubbling air through the solutions for 12 h and then iron was completely precipitated by addition of NaOH. The precipitate was removed by centrifugation and the supernatant was concentrated on a rotary evaporator. Addition of ethanol precipitated a gummy white solid. The precipitate was washed with ethanol and ether and air dried. This material was assumed to contain product aminopolycarboxylate ligands and EDTA. Cobalt complexes of these ligands were synthesized following published procedures and separated by ion exchange (13). Nuclear magnetic resonance spectra were recorded in D_2O on a Varian T-60 spectrophotometer and visible–u.v. measurements were made in either a Cary 14 or a Gilford 240 spectrophotometer.

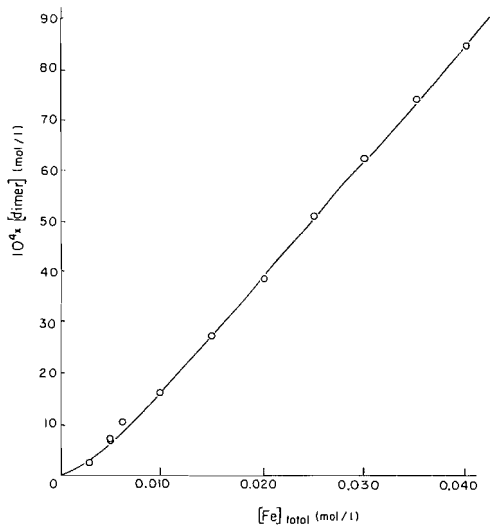

FIG. 1. The dimer concentration at p*H* = 9.00 as a function of total iron concentration.

Results and Discussion

Effect of Dimer on Quantum Yield

The effects of the various hydrolytic forms of FeEDTA upon the quantum efficiency of photoreduction were studied by irradiation of solutions of FeEDTA buffered to p*H* 8.00 and 9.00. One coordination position in FeEDTA complexes is occupied by a solvent derived ligand. In addition to oxo-bridged dimer, hydroxo monomer is present at these p*H* values. At p*H* of 8.00, both hydroxo and aquo monomers are present with an hydroxo/aquo monomer ratio of 3.6 (4). When the p*H* is increased to 9.00, however, 97% of the monomer is present as hydroxo monomer and for this reason, the aquo monomer was not considered a significant absorber at the higher p*H* and was omitted from calculations. The dimer/monomer ratio was adjusted by varying the total iron concentration. The variation of dimer concentration with total iron at p*H* 9.00 is shown in Fig. 1.

The quantum efficiencies for photoreduction, based on production of iron(II), for various total iron concentrations are given in Table 1. After an initial decrease in yield as total iron increased, a plateau value was reached for each p*H* as shown in Fig. 2(*a*) and (*b*). A comparison of Fig. 1 and Fig. 2(*b*) reveals that the limiting value for quantum yield was reached at nearly the same total iron concentration as the curve in Fig. 1

became linear. Thus, when the dimer/hydroxo monomer ratio became constant, as shown by linearity in Fig. 1, the quantum yield also became constant.

If the quantum yields of the hydroxo-monomer and the dimer are different, then the observed quantum yield will depend on the fraction of light absorbed by each species. Thus, at pH of 9.00 we have eq. 1.

$$[1] \qquad \Phi_{obs} = A_d\Phi_d + A_{mOH}\Phi_{mOH}$$

In eq. 1, A_d = fraction of light absorbed by dimer, A_{mOH} = fraction of light absorbed by hydroxo monomer, Φ_d = quantum yield of dimer, Φ_m = quantum yield of hydroxo monomer and, finally, Φ_{obs} = observed quantum yield. The fraction of light absorbed by each species can be calculated if both the concentrations and molar absorptivities are known. In dilute solution, at pH = 11.00, only hydroxo monomer is present and a molar absorptivity at 350 nm of 770 was estimated. Using this value and the absorption spectra recorded at pH = 9.00 in short (0.1 mm) path length cells, a dimer absorptivity of 5100 at 350 nm was estimated. (The dimer concentrations could be obtained from the absorbance at 540 nm (11) using a molar absorptivity of 121.)

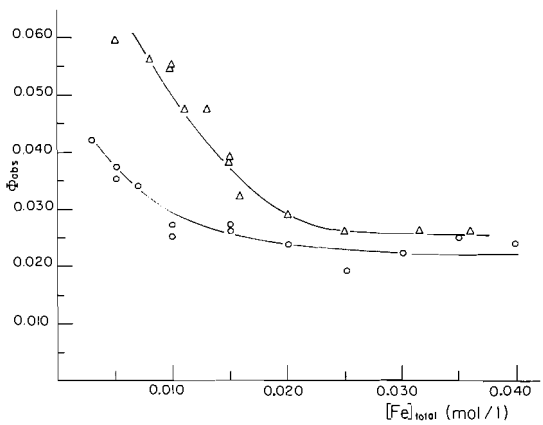

FIG. 2. The quantum yield for photoreduction based on Fe(II) production as a function of total iron concentration: (*a*) pH = 8.00 (△) (*b*) pH = 9.00 (○).

The correlation between the fraction of light absorbed by dimer and observed quantum yield is shown in Fig. 3. This analysis was not performed on the data for pH = 8.00 since there were three absorbing species.

From the intercepts of Fig. 3, quantum yields of hydroxo-monomer and dimer can be estimated, as Φ(monomer) = 0.065, and Φ(dimer) ≃ 0. These values confirm the earlier speculation that the reduction of quantum yield in basic solution is predominantly due to dimer formation. This indicates the existence of an efficient pathway for radiationless relaxation which doesn't exist in the monomers. The possibility that this pathway may involve relaxation through ligand field states transitions to which have been made more allowed in the dimer has already been mentioned. The ligand field bands of the dimer are claimed to be a factor of 10 more intense than the corresponding bands in the monomers, pre-

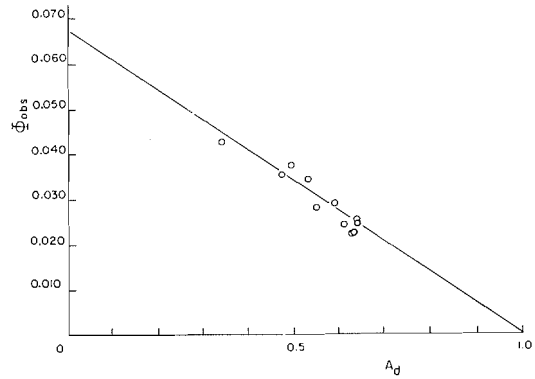

FIG. 3. The variation of quantum yield for photoreduction based on Fe(II) production as a function of the fraction of light absorbed by the dimer (A_d), based on the relationship $\Phi_{obs} = \Phi_m - A_d\ (\Phi_m - \Phi_d)$ which is easily derived from eq. 1.

sumably due to relaxation of the spin selection rules through spin–spin coupling across the Fe—O—Fe bridge. Thus, a pathway for radiationless relaxation which involved coupling of the charge transfer excited state with these ligand field states may be more efficient in the dimer.

In the u.v. spectrum of the dimer, however, there are several absorption maxima which have been termed simultaneous-pair electronic (s.p.e.) bands (8). These correspond to simultaneous excitation to ligand field states on both iron centers by absorption of one photon. It is claimed that pair transitions in which spin does not change on excitation are fully allowed. Thus, these s.p.e. bands may be very intense and the possibility arises that the 350 nm light absorbed by the dimer may not excite the molecule predominantly to a charge transfer excited state but to excited ligand field states on both iron atoms. The ligand field band of the dimer was irradiated at 540 nm, a wavelength where only dimer absorbs. No photoreduction could be observed. Thus a very low quantum yield for the photoredox process would not be unexpected if excitation led to ligand field excited states. Unfortunately, no assignment can be made as to the degree to which charge transfer or s.p.e. states is excited. This distinction may not be necessary, however, since the existence of the s.p.e. bands iso-energetic with the charge transfer bands probably would allow strong coupling to occur between these states. Thus, an efficient pathway could be provided for the deactivation of charge transfer excited states through energy transfer to ligand field states with which they are strongly coupled. That this happens may be indicated from the assignment of Φ_d since some measurable degree of photoreduction should occur if charge transfer states are populated and do not relax efficiently. From Fig. 3, it is apparent that a conservative upper limit of 0.010 can be assigned to Φ_d and the actual value is probably much nearer zero. Thus, since significant reduction is not observed in the dimer, it seems that the charge transfer state is strongly coupled to some other states which are inactive to photoreduction.

Stoichiometry

The Fe–NTA system has as primary products of the photoreduction, carbon dioxide, formaldehyde, and the iron(II) complexes of NTA and IDA. In the Fe–EDTA system, the presence of formaldehyde was confirmed by the formation of a 2,4-dinitrophenylhydrazone derivative (m.p. 163–165 °C) upon the addition of 2,4-dinitrophenylhydrazine reagent (14). Formaldehyde quantum yields were determined using the method of Lappin and Clark (15) on samples irradiated to less than 5% conversion and are given in Table 2. They confirm, within the limits of experimental uncertainty, the 2:1 ratio of iron(II) to formaldehyde in the products. In order to determine the other product of the ligand oxidation, a "decolorized" solution was reoxidized and the iron precipitated. The ligand mixture, which was expected to be 50% EDTA and 50% oxidized product, was reacted with cobalt(II) in air to produce the cobalt(III) complexes. After separation of these complexes by ion exchange, according to established procedure (13), the two aquo complexes obtained were converted to chloro complexes (13) and the n.m.r. spectra recorded in mixtures of HCl with D_2O to limit solvent ^1H concentrations. The two spectra are shown in Fig. 4. The spectrum of Co(EDTA)Cl shown resembles that reported by Day and Reilley (16) for the same complex, while that of the oxidized ligand is very similar to the spectrum of $Co(ED3A)NO_2$ (ED3A = ethylenediaminetriacetic acid) reported by Blackmer, Hamm, and Legg (13). In particular, both the oxidized ligand complex and $Co(ED3A)NO_2$ exhibit a broad band at 6.5 p.p.m. indicative of an amine proton. Both spectra have doublets at 3.2 and 3.5 p.p.m. and a singlet at 4.7 p.p.m. The

0.00600	0.021 ± 0.002	0.035 ± 0.002	1.8
0.00800	0.019	0.032	1.7

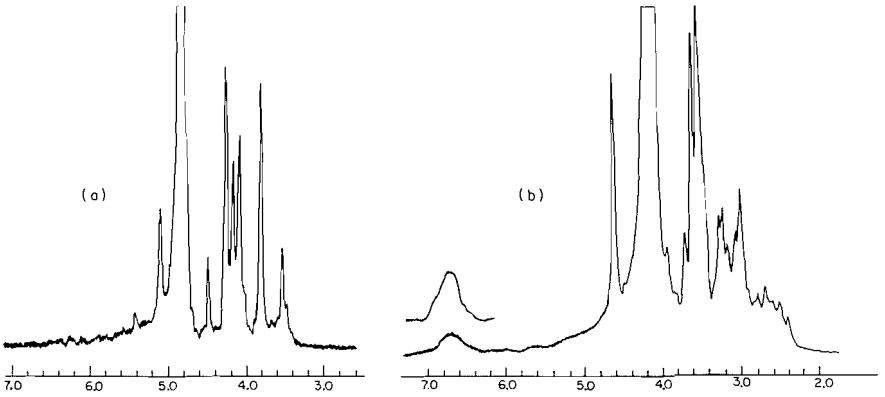

FIG. 4. The n.m.r. spectra of the cobalt complexes prepared by treating cobalt(II) with the ligand mixture obtained by precipitation of the iron from a photolyzed sample of FeEDTA. The complexes were separated by ion exchange since species (*a*) was neutral at pH = 5.00, while species (*b*) was anionic at pH = 5.00.

several peaks seen by Blackmer *et al.* in the 4.0 p.p.m. region were an unresolved peak in our spectrum. The assignment of an amine function to the oxidized ligand was confirmed by a ninhydrin test performed on the ligand mixture and on pure EDTA. The test was positive only for the oxidized ligand mixture. (Although the alternative of the $=N—CH_2\cdot$ radical to abstracting a hydrogen to produce $=N—CH_3$ was considered, the n.m.r. spectrum shows this is not the case since the spectrum of $Co(MeEDTA)NO_2^-$ is known and has a methyl proton singlet at 2.0–2.5 p.p.m. (17).)

In another experiment, two identical samples of 0.1 *M* FeEDTA were taken. One was decolorized as before and the other left in the dark. The iron was precipitated from both and upon precipitation of the ligands with ethanol, n.m.r. spectra in D_2O were recorded. These are shown in Fig. 5. That obtained for an unirradiated sample was identical to a bench sample of Na_2EDTA. The irradiated sample exhibited a splitting of both original peaks. The peak due to $N—CH_2—$ protons was split into two approximately equal broadened peaks which indicates that one end of the EDTA is now different from the other. The peak due to the $N—CH_2—COO^-$ protons also is split but in appropriately a 2:1 ratio. Both these observations are consistent with removal of one acetate group and substitution of a proton which would exchange rapidly in D_2O. There was no peak at low δ which might be expected if an $—N—CH_2\cdot$ radical formed by initial loss of CO_2 could pick up a hydrogen to give $—N—CH_3$.

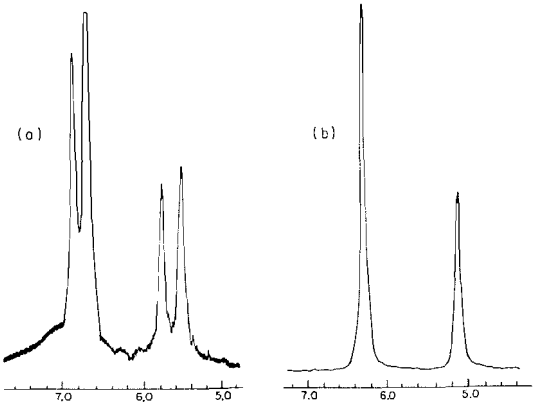

FIG. 5. The n.m.r. spectra of the ligands obtained after precipitation of the iron from two solutions of FeEDTA; (*a*) a sample irradiated to decolorization and reoxidized and (*b*) an unirradiated sample.

[2b] 
[2c] 
From these results, we propose that a plausible pathway for photodecarboxylation of ferric aminopolycarboxylates can be represented by eq. 2.

Since formaldehyde has been observed in the cupric–NTA photoreaction this pathway may be general. It is worth noting that non-biological decomposition of amino acids by natural waters is slow (18) and that a parallel photochemical path for amino acids may well be significant.

The Reactions of Active Nitrogen with Simple Alcohols[1]

JOHN M. ROSCOE AND SHARON G. ROSCOE
Department of Chemistry, Acadia University, Wolfville, Nova Scotia

Received April 19, 1973

The reactions of active nitrogen with CH_3OH, C_2H_5OH, n-C_3H_7OH and iso-C_3H_7OH have been studied as a function of temperature. The rate constants for these reactions fit the following expressions:

N + CH_3OH	$\log k = 11.38 \pm 0.08 - (36 \pm 4)/RT$
N + C_2H_5OH	$\log k = 11.30 \pm 0.04 - (35 \pm 2)/RT$
N + n-C_3H_7OH	$\log k = 9.44 \pm 0.04 - (30 \pm 2)/RT$
N + iso-C_3H_7OH	$\log k = 11.93 \pm 0.05 - (39 \pm 2)/RT$

(Activation energies are in kJ/mol. Rate constants are in l mol^{-1} s^{-1}.)

Experiments with CH_3OH, CH_3OD, and CD_3OD indicate a small primary isotope effect for OH and a secondary isotope effect for CH. This, with other data, implies that abstraction of a H atom from the alcohol is not an important initial step.

Consumption of N atoms ranged from 4.7 to 7.1 times the alcohol consumed. With the exception of the reaction of active nitrogen with iso-C_3H_7OH, the only detectable stable reaction product was HCN. Intervention of O atoms as intermediates appears to be important in all the reactions. In the reaction of active nitrogen with iso-C_3H_7OH, acetone, and acetonitrile were also found as products in amounts of about 26% and 14% respectively of the HCN yield. These products appear to arise through O atom intervention.

Mechanisms for the reactions and the nature of the activated state in the initial step are discussed.

Les réactions de l'azote actif avec le CH_3OH, le C_2H_5OH, le n-C_3H_7OH et l'iso-C_3H_7OH ont été étudiées en fonction de la température. Les constantes de vitesse de ces réactions peuvent être exprimées par les expressions suivantes:

N + CH_3OH	$\log k = 11.38 \pm 0.008 - (36 \pm 4)/RT$
N + C_2H_5OH	$\log k = 11.30 \pm 0.04 - (35 \pm 2)/RT$
N + n-C_3H_7OH	$\log k = 9.44 \pm 0.04 - (30 \pm 2)/RT$
N + iso-C_3H_7OH	$\log k = 11.93 \pm 0.05 - (39 \pm 2)/RT$

(les énergies d'activation sont exprimées en kJ/mol. Les constantes de vitesse sont exprimées en l mol^{-1} s^{-1}.)

Les expériences avec le CH_3OH, CH_3OD et CD_3OD ont révélées la présence d'un faible effet isotopique primaire pour OH et d'un effet isotopique secondaire pour CH. Ce fait, combiné avec d'autres résultats, implique que la perte d'un atome H appartenant à l'alcool n'est une étape initiale importante.

La consommation des atomes d'azote est de 4.7 à 7.1 fois plus grande que celle de l'alcool. A l'exception de la réaction de l'azote actif avec l'iso-C_3H_7OH, les seul produit stable qui fut détecté était le HCN. L'intervention des atomes d'oxygène comme intermédiaires semble être importante pour toutes les réactions. Dans la réaction de l'azote actif avec l'iso-C_3H_7OH, on a trouvé comme produits de réaction, l'acétone et l'acétonitrile dans des quantités égales à 26 et 14% respectivement du rendement en HCN. Ces produits semblent provenir de l'intervention de l'atome d'oxygène lors de la réaction.

On discute des mécanismes réactionnels et de la nature de l'état activé lors de l'étape initiale.

Can. J. Chem. 51, 3671 (1973)

The only previous work on the reactions of active nitrogen with alcohols is that on the reactions of CH_3OH (1) and of C_2H_5OH and iso-C_3H_7OH (2). These reactions were reported to give HCN and H_2O as the main condensable products, together with lesser amounts (less than 2%) of C_2H_6, CH_3CN, C_2H_4, C_2N_2, and CO. The activation energies of the reactions were estimated to range from 13 to 15 kJ/mol. Our interest in these reactions stemmed from their rather small activation energies which implied somewhat faster reactions than those of active nitrogen with other saturated organic compounds.

[1]Presented in part at the 55th Canadian Chemical Conference of the Chemical Institute of Canada, Quebec, June, 1972.

Since the earlier work did not clearly establish either the initial steps in these reactions or their mechanisms, we decided to investigate them in more detail.

Experimental

The reactions were studied in a conventional flow system similar to that described by Westenberg and deHaas (3). The apparatus differed from theirs in that the moveable reactant inlet entered at the end of the reaction vessel downstream from the discharge and either a high voltage d.c. discharge or a microwave discharge could be used to produce the active nitrogen. The reaction vessel was coated with boric acid for most of the experiments, and no difference was found between the results obtained in a clean reactor and the coated reactor. The results obtained with the high voltage discharge were the same as those obtained with the microwave discharge, the latter being preferred because of its greater convenience. Nitrogen (Linde 99.99%) was purified by passing it through a furnace packed with copper turnings and heated to 400 °C, a furnace packed with oxidized copper turnings and heated to 400 °C, and a trap cooled in liquid nitrogen.[2] The entire purification train operated at atmospheric pressure and the purified N_2 was metered from it through a needle valve and a calibrated capillary. All alcohols were purified by repeated fractional distillation until no impurities could be detected by gas chromatography. Their purity was estimated to be better than 99.999%. In addition, CH_3OH and C_2H_5OH were refluxed with a small quantity of magnesium turnings and iodine before fractional distillation.

Nitrogen atoms were measured by the NO titration method (4, 5) using photometric end point detection. Spectroscopic examination of the gas stream immediately downstream from the titration point showed no emission other than that from NO or NO_2 near the titration end point. The NO used in these titrations was purified by passing it through silica gel at −80 °C followed by bulb-to-bulb distillation.

Reaction products, with the exception of HCN, were analyzed by gas chromatography on a 10-foot Porapak Q column using either a flame ionization or a thermal conductivity detector as required. The reaction products could be sampled directly with a Toepler pump for analysis by gas chromatography, or they could be collected in traps cooled in liquid nitrogen, dissolved in a suitable solvent, and then analyzed. The identity of the reaction products was confirmed by separating them by gas chromatography on an 8-foot column of 10% Carbowax on Chromosorb W and comparing their infrared and n.m.r. spectra with those of authentic samples. Infrared spectra were recorded on a Perkin–Elmer model 457 spectrometer and n.m.r. spectra were obtained with a Perkin–Elmer model R24 60 MHz spectrometer.

HCN was determined by trapping it for a known time and titrating it with $AgNO_3$ (6).

[2]Unpublished results by A. A. Westenberg, J. M. Roscoe, and N. deHaas show that this purification procedure is necessary even with nitrogen of 99.997% purity.

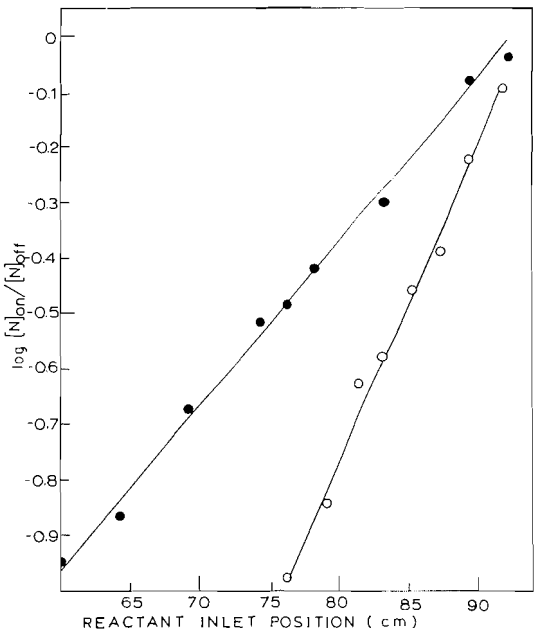

FIG. 1. Typical pseudo-first order kinetic plot. ○, $T = 449$ °K, [iso-C_3H_7OH] = 7.53×10^{-7} M, [N] = 4.35×10^{-8} M; ●, $T = 391$ °K, [iso-C_3H_7OH] = 1.17×10^{-6} M, [N] = 1.10×10^{-7} M.

Rate constants were measured in the presence of at least a 10-fold excess of alcohol to ensure pseudo-first order kinetics. Typical results are shown in Fig. 1. The N atom concentrations were measured with the reactant "on" and "off" at each reaction time to cancel first order atom loss at the walls (3).

Results and Discussion

Kinetics

Preliminary experiments on the reaction of CH_3OH with active nitrogen gave an activation energy of 13 kJ/mol, in excellent agreement with the results of the earlier work (1). The alcohol used in these experiments contained about 0.1% of an impurity as indicated by gas chromatography. When the CH_3OH was purified as outlined in the experimental section, it reacted with active nitrogen with an activation energy of 36 ± 4 kJ/mol. It was concluded that the reaction of CH_3OH and presumably the reactions of the other alcohols are sensitive to very small amounts of impurities and that rigorous purification was necessary.

The only exothermic reaction that can be written for the attack of a N atom on CH_3OH is

[1] $N + CH_3OH \rightarrow HNO + CH_3$ ($\Delta H = -38$ kJ/mol)

	344	1.09	4.52	3.50	11	8.6
	346	1.12	4.46	3.72	11	9.1
						Average = 8 ± 1

Since HNO has the ground state term $^1\Delta$ (7), this reaction might not conserve spin and could have a relatively large activation energy. However, there is also a $^3\Sigma^-$ term which is thought to lie very close to the $^1\Delta$ term (7). If the HNO were formed in the $^3\Sigma^-$ state, it is likely that the reaction would still be exothermic and spin would then be conserved.

Although it is generally felt that N (^4S) atoms are the main reactive species in active nitrogen, significant concentrations of N_2 $A(^3\Sigma_u^+)$ may also be present (8) and these species have been implicated in some of the slower reactions of active nitrogen (ref. 8, p. 505). Meyer and coworkers have found that N_2 $A(^3\Sigma_u^+)$ is quenched by CH_3OH possibly producing CH_3 and OH radicals (9), and it is therefore necessary to examine the possibility that the reactions studied here might be initiated in this way.

In experiments such as ours, N_2 $A(^3\Sigma_u^+)$ formed in the discharge is efficiently quenched at the walls well upstream from the reactant inlet (10) so the only significant source of these excited molecules is homogeneous recombination of N atoms. This would have given second order consumption of N atoms rather than the observed first order behavior. Furthermore, the rate constants would then have varied with the N atom concentration. Such variation was not observed in spite of a ten-fold variation in the N atom concentration.

If the reactions studied here were initiated by quenching of N_2 $A(^3\Sigma_u^+)$, both the initial step and the subsequent reactions of the resultant free radicals with N atoms would have relatively small activation energies. Our experiments, on the other hand, indicate rather large activation energies for the reactions of the alcohols with active nitrogen.

The concentration of N_2 $A(^3\Sigma_u^+)$ in active nitrogen has been estimated to be about 10^{-3} times the N atom concentration (11). It is unlikely that such a small concentration of these excited species could cause the observed rate of consumption of N atoms. Furthermore, since the concentration of these excited molecules depends on the square of the N atom concentration, the importance of quenching in the overall reaction should decrease rapidly with increasing reaction time and consequent rapid consumption of N atoms.

As will be seen later, the suggestion that N atoms are responsible for initiating the reactions of active nitrogen with the alcohols allows us to postulate a mechanism which is consistent and general for all the reactions studied and which quantitatively accounts for the observed stoichiometries of the reactions. The assumption of initiation by N_2 $A(^3\Sigma_u^+)$ does not yield such a mechanism.

In view of the above discussion, we are led to reject quenching of N_2 $A(^3\Sigma_u^+)$ as an important initial step in the reactions of active nitrogen with the alcohols, although it may possibly intervene to a very small extent.

In an effort to obtain more definitive information about the initial step in the reaction of CH_3OH with active nitrogen, the deuterium isotope effect was measured for this reaction. The results are summarized in Table 1.

In experiments with CH_3OH and CH_3OD, the isotope effect ratio was 3.6 ± 0.4 which is greater than the value for a secondary effect (2.0 for O—D (12)) but less than the maximum value for a primary effect (18 for D (12)). This implies that the O—H bond is weakened but not entirely broken in the activated state. In experiments with CH_3OD and CD_3OD, the isotope

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

effect ratio was 2.2 ± 0.6 which compares favorably with the maximum value of 1.74 for a secondary isotope effect for C—D (ref. 12, p. 98). This implies that abstraction of a H atom from the CH_3 group is unimportant. A plausible activated state might be

$$N + CH_3OH \rightarrow \left[CH_3\text{---}O\overset{N}{\cdots\cdots}H \right]^{\ddagger} \rightarrow CH_3 + HNO$$

A general initiation step for the reactions of N atoms with the alcohols would then be

[2] $$N + ROH \rightarrow R + HNO$$

The kinetic data are summarized in Table 2 and Fig. 2. The preexponential factor for the reaction of n-C_3H_7OH with active nitrogen is significantly smaller than those for the other reactions. Assuming that the [CNOH] part of the activated state makes the main contribution to the entropy of activation, the entropy of this group may be estimated from the measured entropy of activation and tables of partial bond entropies (13). The pertinent data are presented in Table 3. The results for CH_3OH, C_2H_5OH, and iso-C_3H_7OH give a remarkably constant value of 178 ± 2 J mol^{-1} deg^{-1} for the partial group entropy of [CNOH]. The value obtained for the reaction of active nitrogen with n-C_3H_7OH is 38 J mol^{-1} deg^{-1} less than this.

The only structural difference between n-C_3H_7OH and the other alcohols is the presence of a β-CH_3 group. This can produce two effects. First, rotation of the C_2H_5 group about the C_2H_5—CH_2OH bond may be hindered in the activated state by the [NOH] group, while this rotation should not be hindered to the same extent in n-C_3H_7OH itself. Thus, the relatively free rotation of the C_2H_5 group would be replaced, in the activated state, by a torsional mode. Since the other alcohols studied do not have β-CH_3 groups, this hindered rotation would not be important. Secondly, rotation of [NOH] about the C---O bond in the activated state may be hindered by the C_2H_5 group. In the reactions of the other alcohols, rotation of [NOH] about the C---O bond should not be greatly hindered. This means that only in n-C_3H_7OH would rotation of [NOH] be effectively a torsional mode. These two torsional modes would make the entropy of activation and hence the entropy of the [CNOH] group in the reaction of n-C_3H_7OH smaller than for the reactions of the other alcohols. These conclusions are borne out by examination of space-filling models of the alcohols.

With the exception of n-C_3H_7OH, the activation energies of the reactions of active nitrogen with the alcohols increase with increasing C—O bond strength (14) within experimental error. This is reasonable if the C—O bond is broken in the rate determining step. Since a smaller activation energy was found for the n-C_3H_7OH reaction, an additional factor must be considered here. The small entropy of activation for this reaction relative to the values obtained for the reactions of the other alcohols implies that a smaller proportion of collisions are reactive. The rotation of the C_2H_5 group in n-C_3H_7OH effectively hinders attack by the N atom at the end of the O—H bond nearest the O atom. In terms of the postulated initiation step, steric hindrance to N atom attack in the reaction of n-C_3H_7OH hinders collisions that would tend to increase the activation energy since they occur at one end of the O—H bond and require more than the average energy to form the cyclic activated state. Collisions occurring between the O and H atoms require less energy since they orient the N atom favorably for formation of the cyclic complex. It seems possible, then, that the lower activation energy for the reaction of n-C_3H_7OH might simply reflect an average over a larger proportion of lower energy reactive collisions than was true for the reactions of the other alcohols.

Reaction Mechanisms

Since the products of the reactions of iso-C_3H_7OH with active nitrogen differed from those of the reactions of the other alcohols, the results for the reactions of the other alcohols will be discussed first.

The only stable product detected in the reactions of CH_3OH, C_2H_5OH, and n-C_3H_7OH with active nitrogen was HCN. The yields of HCN are plotted against the relative alcohol concentration in Fig. 3. The stoichiometries of these reactions are given in Table 4. The average values of $\Delta[ROH]/\Delta[N]$ were used to convert the measured (effective) rate constants to the absolute rate constants reported in Tables 1 and 2. In all cases, a relatively small proportion of the N atoms consumed are found as HCN.

The failure to detect measureable amounts of H_2O in the reactions of the alcohols with active

nitrogen differs from the results of the earlier work (1, 2) in which substantial amounts of H_2O were found. The present experiments used gas chromatography on Porapak Q to determine H_2O, while the earlier experiments used the Karl Fischer titration. The limit of detection of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

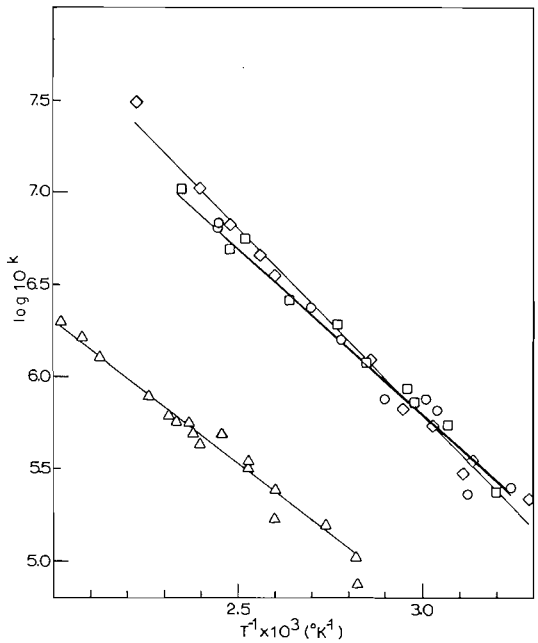

FIG. 2. Arrhenius plots for the reactions of active nitrogen with the alcohols. ○, CH_3OH; □, C_2H_5OH; △, n-C_3H_7OH; ◇, iso-C_3H_7OH.

H_2O by gas chromatography was about 10^{-10} M or $[H_2O]/\Delta[N] = 10^{-3}$ compared with about 10^{-5} M using Karl Fischer reagent. Our experiments should therefore have been more sensitive for the determination of H_2O than the method used in the earlier work. Furthermore, blank determinations showed that Karl Fischer reagent titrates HCN and iso-C_3H_7OH making it useless for accurate H_2O determinations. This may well have been a source of error in the earlier work.

The following general mechanism quantitatively accounts for the observed stoichiometries of the reactions of the normal alcohols with active nitrogen.

[1a] $C_nH_{2n+1}OH + N \rightarrow HNO + C_nH_{2n+1}$

[3] $C_nH_{2n+1} + nN \rightarrow nHCN + \frac{n+1}{2} H_2$

[4] $HNO + N \rightarrow NH + NO$

[5] $NH + N \rightarrow N_2 + H$

[6] $NO + N \rightarrow N_2 + O$

An alternative to reaction 3 might be

[7] $C_nH_{2n+1} + N \rightarrow C_mH_{2m+2} + HCN$ $(m = n - 1)$

Since the saturated hydrocarbons C_mH_{2m+2} are unreactive with active nitrogen (15), reaction 7 would reduce the stoichiometric ratios far below those measured. The strongest reason for rejecting reaction 7, however, is that saturated hydrocarbons were not detected among the reaction products.

Reaction 3 is intended to give the ultimate fate of the organic free radicals. The details of the elementary steps involved are still a matter of controversy. Inclusion of reaction 3 does, however, give the experimentally observed stoichiometries.

The reactions postulated so far produce both H atoms and O atoms. Wagner and co-workers have recently reported an activation energy of 22 kJ/mol for the reaction of H atoms with CH_3OH (16), and it seems reasonable to expect similar activation energies for the reactions of H atoms with the other alcohols. This relatively large activation energy should effectively prevent H atoms from intervening efficiently in the reactions of the alcohols with active nitrogen. In particular, such intervention in the reaction of CH_3OH with active nitrogen would have produced H_2O and CH_4 (16). The apparent absence of these species among the reaction products suggests that H atom intervention is indeed negligible.

Cvetanović and co-workers have investigated the reactions of several alcohols with O atoms (17, 18). From their data, it appears that these reactions are some 100 times faster than the corresponding N atom reactions at room temperature. As a result, intervention of the O atoms from reaction 6 must be considered in interpreting the results of the N atom reactions with the alcohols.

Cvetanović has shown that the reaction of O atoms with CH_3OH is initiated by (18)

[8] $O + CH_3OH \rightarrow CH_2OH + OH$

followed by

[9] $CH_2OH \rightarrow H_2C{:}O + H$

[10] $2\,CH_2OH \rightarrow HOCH_2CH_2OH$

of which reaction 9 seems to be the more important. Formaldehyde formed in [9] would react with active nitrogen to produce CO (19). However, neither CO nor ethylene glycol were found in the reaction products from the reaction of CH_3OH with active nitrogen suggesting either

that O atom intervention is unimportant or that the products of reaction 8 react very rapidly with active nitrogen. Thrush has shown that OH radicals react very rapidly with N atoms (20). It will also be seen that the reaction of iso-C_3H_7OH with active nitrogen cannot be easily explained without including O atom intervention. The following general mechanism may therefore be suggested to account for the intervention of O atoms in the reactions of the alcohols with active nitrogen.

[8a] $\quad O + C_nH_{2n+1}OH \rightarrow C_nH_{2n}OH + OH$

[11] $\quad N + OH \rightarrow NO + H$

[6] $\quad N + NO \rightarrow N_2 + O$

[12] $\quad nN + C_nH_{2n}OH \rightarrow nHCN + \frac{n}{2}H_2 + OH$

The stoichiometries with respect to HCN production and alcohol consumption are identical to those from the reactions initiated by N atom attack on the alcohol (reactions 1a, 3–6) and intervention in this way by O atoms is therefore consistent with the observed stoichiometries for the reactions of the primary alcohols.

An alternative to reaction 12 is

[13] $\quad N + C_nH_{2n}OH \rightarrow HCN + C_mH_{2m+1}OH \; (m = n - 1)$

This reaction does not conserve spin and is therefore likely to be slow. Furthermore, it produces H_2O in the CH_3OH reaction and lower alcohols in the other reactions. The failure to detect these species among the reaction products suggests that reaction 13 is relatively

unimportant. The occurrence of reaction 13 to any significant extent would alter the predicted stoichiometries so that the mechanism would no longer be consistent with experiment. It is therefore concluded that reaction 13 is relatively unimportant.

The reactions postulated so far produce aliphatic free radicals (R) and OH radicals. Further complication of the reactions by R would produce saturated hydrocarbons which do not react readily with active nitrogen (15). The absence of such substances among the reaction products suggests that intervention by R is relatively unimportant. Similarly, intervention by OH would produce H_2O by attack on the parent alcohol and the absence of H_2O from the reaction products indicates that OH intervention is also unimportant.

It seems reasonable to assume that N atoms attack iso-C_3H_7OH in the same way as the other alcohols and that the general mechanism postulated earlier applies. The predicted stoichiometries would then be the same as for n-C_3H_7OH. The measured stoichiometries differ greatly from those for n-C_3H_7OH (Fig. 3, Tables 4 and 5). In addition, both acetone and acetonitrile were found among the reaction products and the general mechanism without O atom intervention gives no means of producing these species. A satisfactory explanation of these discrepancies can, however, be found in the O atom intervention in this reaction. Reaction 8*a* would produce a $(CH_3)_2COH$ radical which differs from the radicals formed from the primary alcohols in having no α-H atom. Attack by a N atom might thus not produce HCN directly, but could result in the reaction

[14] $N + (CH_3)_2COH \rightarrow CH_3CN + CH_3 + OH$

In addition, acetone could be formed in the reaction

[9*a*] $(CH_3)_2COH \rightarrow (CH_3)_2C{:}O + H$

The appearance of both acetone and acetonitrile suggests that $(CH_3)_2COH$ radicals may react less readily with N atoms than RCHOH radicals since reaction 9 was apparently unimportant in the reactions of the primary alcohols. The apparent absence of pinacol from the reaction products confirms Cventanović's observation that dimerization is less important than disproportion of the alkoxyl radicals via [9] (18).

The ratio $[(CH_3)_2C{:}O]/[CH_3CN]$ was 1.8 ± 0.2 from the results of eight runs in which the iso-C_3H_7OH concentration was large enough to ensure that this is a limiting value. This result may be combined with the HCN limiting yield to estimate the relative lengths of the reaction sequences initiated by O atoms and N atoms respectively, according to the mechanisms postulated above. Such a calculation indicates that the O atom initiated reaction takes place 1.2 times for each occurrence of the N atom initiated sequence. From this, the remaining stoichiometric ratios may be calculated and compared with the experimental values as shown below.

Stoichiometric ratios

Ratio	Calculated	Found
$\Delta[C_3H_7OH]/\Delta[N]$	0.20	0.21 ± 0.01
$[CH_3CN]/\Delta[N]$	0.039	0.043 ± 0.008
$[(CH_3)_2C{:}O]/\Delta[N]$	0.071	0.079 ± 0.008

The results are in good agreement with the calculated values and suggest that the postulated mechanism is essentially correct.

Reaction of Active Nitrogen with Tetrachloroethylene

WILLIAM ERNEST JONES AND MANIT RUJIMETHABHAS[1]
Department of Chemistry, Dalhousie University, Halifax, Nova Scotia

Received January 2, 1973

The reaction of active nitrogen with tetrachloroethylene yielded cyanogen chloride, trichloroacetonitrile, cyanogen, chlorine, and carbon tetrachloride. In addition, a yellow–brown polymer was found on the glass wall. A brief discussion of a possible mechanism is given.

La réaction de l'azote actif avec le tétrachlorure d'éthylène conduit à un mélange de chlorure de cyanogène, de trichloroacétonitrile, de cyanogène, de chlore et de tétrachlorure de carbone. De plus un polymère jaune–brun se retrouve sur la paroi du verre. Une brève discussion du mécanisme possible est présentée. [Traduit par le journal]

Can. J. Chem. **51**, 3680 (1973)

Introduction

The reaction of active nitrogen with tetrachloroethylene (TCE) at room temperature gives a bright peach-colored flame. However, the flame boundary is not as well defined as it is in the reaction of active nitrogen with perfluorocarbons. It is therefore impossible to study the kinetics by the diffusion flame method as has been done with the perfluorocarbons (1). At a high reactant flow rate, the flame is quenched only a few centimeters from the reactant nozzle. As the flow rate of TCE decreases, the flame extends farther down stream from the reaction vessel. For example, at a very small TCE flow rate and in a well-darkened room, the flame emission can be seen to extend to the product trap. The gaseous products are: cyanogen chloride (CNCl), trichloroacetonitrile (CCl_3CN), cyanogen ($(CN)_2$), chlorine (Cl_2), carbon tetrachloride (CCl_4), and unreacted TCE. A yellow–brown solid "polymer" forms as a deposit on the glass wall of the reaction vessel and on the reactant inlet.

Jennings and Linnett (2, 3) investigated the emission from the reaction flame of active nitrogen with TCE and found the CN violet and red systems and C—Cl bands. However, no bands corresponding to the C_2 swan bands or to the then unknown N—Cl molecule were detected. Kiess and Broida (4) studied the reaction flame by using active nitrogen generated by electrodeless discharge and reported that the CN(0,0) violet emission was much more intense than the CN(10,4) red emission. The authors could not indicate any specific mechanism leading to the CN emission.

Previous workers have not investigated the products of the reaction. In this paper, we report the determination of the reaction products.

Experimental

Apparatus

The reaction was studied in a conventional fast flow system with a Pyrex reaction vessel of 40 cm length and 6 cm o.d. Purified nitrogen from Canadian Liquid Air Corporation was further purified by passing it through (*a*) a liquid nitrogen trap packed with copper turnings, (*b*) a column of heated copper at 425 °C, and (*c*) another liquid nitrogen trap. The purified nitrogen passed through a capillary flow meter and was activated by a condensed electric discharge. The nitrogen atom concentration was obtained by the NO gas titration technique (5, 6). The nitrogen atom flow rate was found to be 3.2 μmol s^{-1} at 1.75 Torr. The reaction products were studied by gas chromatography using a 10 ft column packed with chromosorb P coated with 30% tricresyl phosphate. The separation was most effective when the column oven was subjected to a non-linear temperature program. After introduction of the sample, the column remained at room temperature for 7 min, and then was heated to 370 °K where it remained until the last compound appeared. The products were identified by comparison of retention times and the identification was checked by infrared and mass spectroscopy.

A reaction vessel 60 cm long and 2.5 cm in diameter was used to study the emission from the reaction. Both ends of this reaction vessel were equipped with quartz windows. The flame was monitored by viewing the reaction vessel end-on with a Heath EU-700 monochromator at a slit width of 350 μ. The emission bands were recorded from 2000–7500 Å. For these reactions, the active nitrogen was generated by a 200 W microwave unit operating at 2450 MHz and at a power output of 75–80%. The reaction was studied at 1.2 Torr.

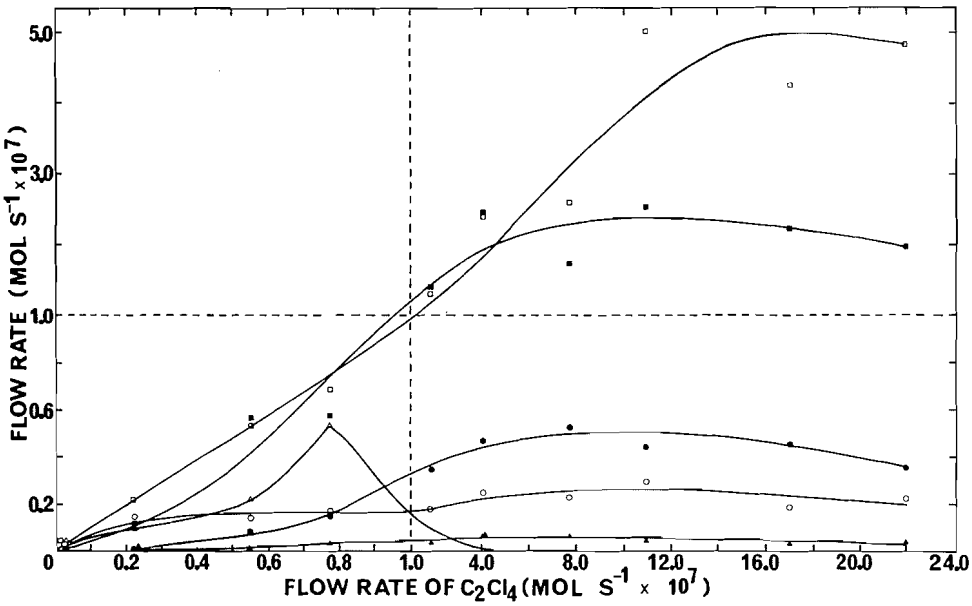

FIG. 1. Reaction of active nitrogen with tetrachloroethylene at 25 ± 5 °C. □ = C_2Cl_4 reacted; product flow rates are: ○ = $(CN)_2$; △ = Cl_2; ■ = CNCl; ▲ = CCl_4; ● = CCl_3CN. The dashed lines indicate change of scale.

Materials

TCE and CCl_3CN were obtained from Eastman Kodak Company. The TCE was purified by double distillation and stored away from light. $(CN)_2$ and Cl_2 were obtained from Matheson of Canada Ltd. The $(CN)_2$ was purified by bulb-to-bulb distillation. CCl_4 was obtained from Fisher Scientific Co. The CNCl was prepared by a standard method (7) and purified by bulb-to-bulb distillation. TCE, CCl_3CN, $(CN)_2$, CCl_4, and CNCl were all degassed at Dry Ice – acetone temperature while Cl_2 was degassed at liquid nitrogen temperature.

NO was obtained from Matheson of Canada Limited and purified by condensation in and evaporation from ascarite (8–20 mesh). It was condensed at liquid nitrogen temperature and degassed.

Results and Discussion

The reaction of active nitrogen with TCE yields CNCl, CCl_3CN, $(CN)_2$, Cl_2, and CCl_4. It also yields a yellow-brown polymer on the glass wall of the reaction vessel. The yield of these products at various flow rates of TCE is given in Table 1,[2] and shown graphically in Fig. 1. From Fig. 1, it can be seen that at very low TCE flow rates, the only detectable products are $(CN)_2$, Cl_2, and CNCl. At low flow rates, the flame emission was found to extend downstream from the TCE nozzle to the product trap. As the ratio [TCE]/[N] was increased by increasing the TCE flow rate, the flame "tail" was shortened until, at high TCE flow rates, the flame was completely quenched within a few centimeters of the TCE nozzle. The product flow rate of CNCl increased as CCl_4 and CCl_3CN began to appear. The product flow rates reached maximum values at about 1.1 μmol s^{-1} of TCE (Fig. 1).

Carbon balances have been found to be better than 95% at very low TCE flow rates and as poor as 50% at high TCE flow rates. The poor carbon balances at high TCE flow rates are probably due to increasing formation of polymer since the polymer appeared to build up on the wall much more rapidly at high flow rates than at low flow rates. Unfortunately, it was not possible to make quantitative measurements of the polymer yield.

Elemental analysis of the polymer showed it to have the composition C : N : Cl = 1.6 : 1.0 : 1.6. A sample of the polymer, which collected on the reaction vessel walls during a number of runs, was decomposed under vacuum over the temperature range 298–523 °K. The major product was Cl_2 with relatively small amounts of C_2Cl_4,

CCl_4, CNCl, and N_2 also being formed. After several hours of decomposition, the residue had turned very dark in color.

Up to a TCE flow rate of 0.4 μmol s^{-1}, approximately 50% of the chlorine originally present could be accounted for. Above this flow rate, the amount of chlorine which could be accounted for by the products decreased drastically. The polymer contained a certain amount of chlorine. However, this amount was not sufficient to account for the chlorine loss at high flow rates. It was noted that, even at very low temperatures (80 °C), small amounts of Cl_2 evolved from the polymer. It is possible that Cl_2 was physically adsorbed by the polymer. If physical adsorption did not occur, the reported elemental analysis for chlorine must be low. It was also possible that Cl_2 was adsorbed by stopcock grease present in the system. This was found to occur in the reaction of active nitrogen with $COCl_2$ (8).

The reaction flame consisted of an intense emission composed of the CN red ($A^2\Pi$–$X^2\Sigma^+$) and CN violet ($B^2\Sigma^+$–$X^2\Sigma^+$) systems (9). Since the work of Jennings and Linett (2, 3), a spectrum of the NCl molecule has been observed in the region 615–703 nm (10). Although this region was studied carefully, no spectrum of the NCl radical was observed. However, as noted by Colin and Jones (10), the NCl spectrum is extremely weak and difficult to observe against the CN emission background.

When the flow rate of TCE was adjusted properly, the flame emission near the nozzle was very intense while, farther down stream, the emission appeared to oscillate with an extremely bright pink–white flame. Such an oscillatory phenomenon suggested that the flame involved chain reactions (11). This flame oscillation was clearly visible in the system in which the active nitrogen was generated by the microwave discharge. However, it was barely observed in the system where the condensed electric discharge was used to activate the nitrogen. This was probably due to the oscillation of the discharge itself.

Because of the formation of polymer and the resulting significant loss of carbon and chlorine, it was difficult to determine the kinetics and, with the present information, it is only possible to discuss several general reactions which are important in the overall mechanism.

The primary step may involve attack by $N(^4S)$ as in reaction 1 or energy transfer from the excited molecule $N_2(A^3\Sigma_u^+)$ as in reaction 2.

[1] $N(^4S) + C_2Cl_4 \rightarrow [C_2Cl_4N]_{complex} \rightarrow$ products

[2] $N_2(A^3\Sigma_u^+) + C_2Cl_4 \rightarrow N_2(X^1\Sigma_g^+) + C_2Cl_4^*$

Both reactions 1 and 2 would yield chlorocarbon radicals and Cl while reaction 1 would also yield CNCl.

The chlorocarbon radicals would subsequently react with nitrogen atoms as in the following reactions:

[3] $RCl + N \rightarrow CNCl + R'$

[4] $RCl + N \rightarrow CNCl + R'' + Cl$

Reactions 3 and 4 as well as reaction 1 would account for the major product CNCl.

In addition to the chlorocarbon radicals formed in reactions 1 and 2, the radical C_2Cl_5 would be formed by adding chlorine atoms to C_2Cl_4 as in reaction 5.

[5] $C_2Cl_4 + Cl \rightarrow C_2Cl_5$

This reaction is known to occur readily (12–14).

Cyanogen results from the recombination of CN radicals formed when CNCl is excited by $N_2(A^3\Sigma_u^+)$ as in reactions 6 and 7.

[6] $N_2(A^3\Sigma_u^+) + CNCl \rightarrow N_2(X^1\Sigma_g^+) + CNCl^*$

[7] $CNCl^* \rightarrow CN + Cl$

These reactions have been proposed by Bayes (15) from studies of the reaction of active nitrogen with CNCl.

The CN radicals, formed as in reaction 7, may also attack CNCl to form $(CN)_2$ and Cl. They might also attack CCl_3 to yield the second major product of the reaction CCl_3CN as in the following reaction:

[8] $CCl_3 + CN \rightarrow CCl_3CN$

The product CCl_4, which is formed in relatively smaller amounts, probably results from the addition of Cl atoms to CCl_3.

Despite the fact that no spectra of NCl were observed in the emission flame, it is impossible to eliminate it as an intermediate species. NCl would be expected to form as in the following reaction:

[9] $Cl_2(^1\Sigma) + N(^4S) \rightarrow NCl(^3\Sigma) + Cl(^2P)$

This reaction has been proposed by Phillips and

co-workers (16, 17) in their study of the reaction of active nitrogen with Cl_2. If NCl formed, it would react rapidly (18) with $N(^4S)$ as in reaction 10.

[10] $$NCl + N(^4S) \rightarrow N_2 + Cl$$

Thus, the formation of NCl and its subsequent reaction with $N(^4S)$ could explain the significant loss of N atoms during the active nitrogen–TCE reaction. A maximum 23% of the original concentration of N atoms appears in the products (Table 1).

Structure cristalline et moléculaire du cyclopentadiényle dicarbonyle dioxyde de soufre manganèse $MnC_5H_5(CO)_2SO_2$

CLAUDE BARBEAU ET RAM JANAM DUBEY
Département de Chimie, Université Laval, Québec, Québec

Reçu le 1 mai 1973

Le composé $MnC_5H_5(CO)_2SO_2$ cristallise dans le système monoclinique, groupe d'espace $P2_1/c$, dans une maille de dimensions $a = 10.98(2)$ Å, $b = 10.63(2)$ Å, $c = 7.43(2)$ Å. $\beta = 100.75(8)°$ avec $Z = 4$. La structure a été déterminée à partir de 1512 réflexions recueillies sur films de chambre de précession. Le facteur résiduel R se situe à 0.093 après affinement par moindres carrés (matrice complète). La liaison Mn—S (2.037(5) Å) paraît très forte en présentant une distance inférieure de 0.3 Å à la somme des rayons covalents. La distance moyenne Mn—$C_{C_5H_5}$ (2.09(2) Å) est inférieure à celle généralement observée dans les complexes cyclopentadiényle-manganèse. Les deux groupements CO sont distincts. Un encombrement au niveau des ligands SO_2 et CO pourrait expliquer en partie l'instabilité du complexe.

The compound $MnC_5H_5(CO)_2SO_2$ crystallizes in the monoclinic system, space group $P2_1/c$, in a unit cell of dimensions $a = 10.98(2)$ Å, $b = 10.63(2)$ Å, $c = 7.43(2)$ Å, $\beta = 100.75(8)°$ with $Z = 4$. The structure was determined from 1512 reflections obtained on films from a precession camera; the residual factor, R, was 0.093 after a full matrix least-squares refinement. The Mn—S bond seems very strong having a length (2.037(5) Å) which is smaller than the sum of the covalent radii by 0.3 Å. The average distance Mn—$C_{C_5H_5}$ (2.09(2) Å) is less than that usually observed in manganese-cyclopentadienyl complexes. The two CO groups are distinct. The instability of the complex might be explained, in part, by the crowding of the SO_2 and CO ligands. [Journal translation]

Can. J. Chem. **51**, 3684 (1973)

Introduction

Dans notre étude sur l'influence d'un groupe donneur D sur les paramètres atomiques du métal carbonyle $MnC_5H_5(CO)_{3-x}D_x$, nous avons déjà montré (1) que la triphénylphosphine n'affectait que les liaisons Mn—C—O. A l'opposé de $P(C_6H_5)_3$, le groupe SO_2 remplace difficilement une molécule de monoxyde de carbone de $MnC_5H_5(CO)_3$ en formant un composé (*a*) beaucoup moins stable (*b*) dont le moment dipolaire est plus faible (2) et (*c*) qui présente des fréquences de vibration de valence CO beaucoup plus élevées que le composé $MnC_5H_5(CO)_2P(C_6H_5)_3$ (2).

L'étude de ce composé a été entreprise dans le but de connaître les conséquences structurales sur le reste de la molécule du remplacement d'un groupe CO par un ligand qui possède les qualités à la fois d'un acide et d'une base de Lewis.

Partie expérimentale

Le remplacement d'un groupe CO par le dioxyde de soufre s'effectue par voie indirecte en utilisant le complexe $MnC_5H_5(CO)_2CH_3OH$ comme intermédiaire.

Une solution de 300 mg de $MnC_5H_5(CO)_3$ dans 50 ml de méthanol est soumise à l'irradiation d'une lampe à vapeur de mercure de type General Electric H-100 A4/T. Le monoxyde de carbone est chassé de la solution par le passage continu d'un courant d'azote. Lorsque le complexe rouge vif $MnC_5H_5(CO)_2CH_3OH$ est formé, on introduit graduellement du dioxyde de soufre en faisant barboter alternativement de l'azote et un mélange N_2–SO_2. La solution passe alors lentement du rouge à l'orangé, coloration caractéristique de $MnC_5H_5(CO)_2SO_2$. Puisque un excès de SO_2 conduit à la décomposition du complexe, le passage du mélange N_2–SO_2 est interrompu dès que la coloration orangée s'atténue ou qu'une teinte verte apparaît. Après l'évaporation sous vide de la solution, on retire du résidu la quantité de $MnC_5H_5(CO)_3$ qui n'a pas réagi, en sublimant sous vide à 40 °C. $MnC_5H_5(CO)_2SO_2$ est obtenu pur (~100 mg) par sublimation subséquente sous vide à 70 °C.

L'évaporation lente, sous atmosphère d'azote, d'une solution saturée de $MnC_5H_5(CO)_2SO_2$ dans l'éthanol, donne des cristaux orangés tabulaires de dimensions moyennes 0.5 × 0.3 × 1.0 mm.

Données cristallines

$C_7H_5MnO_4S$ m.m. 240.1

Monoclinique $P2_1/c$, $a = 10.98(2)$, $b = 10.63(2)$, $c = 7.43(2)$ Å, $\beta = 100.75(8)°$, $V = 851$ Å^3, $\rho_o = 1.85(2)$, $Z = 4$, $\rho_c = 1.87$ (20 °C, Mo K$\bar{\alpha}$, $\lambda = 0.71069$ Å).

La mesure de la densité a été effectuée selon la méthode de flottaison dans une solution aqueuse de bromure de zinc et de chlorure de césium.

Les paramètres cristallins ont été obtenus à partir de clichés de chambre à précession de Buerger en utilisant des réflexions de haut indice sur les niveaux zéro, après calibrage avec un cristal de chlorure de sodium.

Le groupe spatial $P2_1/c$ est déduit de l'extinction systé-

[a]Le facteur de température de chaque atome est de la forme $\exp\{-2\pi^2(a^{*2}h^2U_{11} + b^{*2}k^2U_{22} + c^{*2}l^2U_{33} + 2a^*b^*hkU_{12} + 2a^*c^*hlU_{13} + 2b^*c^*klU_{23})\}$.
[b]Les écarts-types sont indiqués entre parenthèses.

matique des réflexions $0k0$ pour $k \neq 2n$ et de celle des réflexions $h0l$ pour $l \neq 2n$.

La chambre à précession de Buerger a été utilisée pour obtenir les intensités de 12 strates (3 le long de chaque axe cristallin et 3 le long de $[0\bar{1}1]$). Quarante clichés avec des temps d'exposition se situant entre 10 min et 16 h ont servi à recueillir les intensités de plus de 2000 réflexions. L'instabilité du composé sous les rayons X a nécessité l'utilisation de cinq cristaux dont les dimensions se situaient autour de 0.2 × 0.3 × 0.2 mm. Les intensités ont été mesurées à l'aide d'un microdensitomètre de type Wooster Mark IV. Toute réflexion visuellement absente a été considérée non-observée; l'intensité attribuée à chacune de ces réflexions correspond à la moitié de l'intensité minimale. La mise sur échelle commune de toutes les données photographiques a été faite selon la méthode de Hamilton, Rollet, et Sparks (3). Le coefficient d'absorption linéaire ayant comme valeur $\mu = 18.1\ cm^{-1}$, seules les corrections de Lorentz et celles de polarisation ont été apportées sur les intensités. 1512 réflexions indépendantes ont servi aux calculs effectués sur ordinateur IBM 360/50 à l'aide des programmes du système X-RAY-70 de Stewart (4).

Détermination de la structure

Les coordonnées de l'atome Mn ont été obtenues à partir de la fonction de Patterson tridimensionnelle. Deux synthèses de Fourier ont permis de localiser les autres atomes. Le facteur de désaccord

$$R = \sum(|\,|F_o| - |F_c|\,|)/\sum|F_o|$$

se situait alors à 0.33.

L'affinement des paramètres atomiques et des coefficients d'agitation thermique a été réalisé par la méthode des moindres carrés (matrice complète) en minimisant la quantité $S = \Sigma w(|F_o| - |F_c|)^2$.

Quatre cycles d'affinement en isotropie thermique et avec des poids w unitaires ont amené l'indice R à 0.15. Trois itérations en anisotropie thermique amènent un abaissement de R jusqu'à 0.094. A ce stade, la pondération utilisée $w(=1/\sigma^2)$ a été exprimée en termes de $\sigma = 0.062F_o + 1.199 + 4.616/F_o$, les coefficients étant choisis pour minimiser l'écart entre les facteurs de structure observés et calculés. Deux cycles d'affinement en anisotropie ont donné un R final de 0.092 pour les 1056 réflexions observées. L'indice résiduel pour l'ensemble des 1512 réflexions est 0.093.

Une série différence-Fourier n'a montré aucun pic significatif, la valeur maximale étant inférieure à 0.9 e/Å^3. Au cours des deux derniers cycles les paramètres n'ont subi aucun changement supérieur à 0.06σ tandis que le changement moyen était 0.01 fois l'écart-type.

Les facteurs de forme atomique utilisés sont ceux de Cromer et Mann (5). La liste des facteurs de structure observés et calculés a été versée au dépôt des données non publiées.[1] Les valeurs finales des paramètres apparaissent dans le tableau 1.

Description de la structure

La fig. 1 représente une vue de la maille élémentaire projetée sur le plan 010 alors que la fig. 2 montre une des quatre molécules avec quelques-uns des paramètres moléculaires présentés au tableau 2.

Les deux composés $MnC_5H_5(CO)_3$ (**1**) (6) et $MnC_5H_5(CO)_2SO_2$ (**2**), présentés en projection orthogonale à la fig. 3, cristallisent dans le même système selon des paramètres cristallins assez semblables (819 et 851 Å^3). L'empilement est cependant réalisé de façon plus dégagée avec **2** puisque la distance intermoléculaire minimale (sans tenir compte des atomes H) est de 4.2 Å alors qu'elle n'est que de 3.4 Å dans **1**. Les atomes Mn sont distants de 7.4 Å. Comme le montrent la fig. 3 et le tableau 4, aucune rotation

[a]Les écarts-types sont indiqués entre parenthèses.

Mn—SO_2. Ce dernier plan se présente quasi-perpendiculaire (89°) à celui du cyclopentadiényle. Cette orientation place O(5) à mi-distance des carbones carbonyle C(1) (3.22(3) Å) et C(2) (3.12(3) Å). L'atome O(4) se situe alors voisin du carbone C(8) (3.03(5) Å) du cyclopentadiényle. Ces distances C---O sont très voisines de la somme des rayons van der Waals (7) de l'oxygène (1.50 Å) et du carbone (1.70 Å). Contrairement à beaucoup de composés (8), où l'angle entre la normale au plan de SO_2 et l'axe de liaison Mn—S se situe autour de 20°, nous observons un angle de 90°, angle attendu si l'hybridation au niveau du soufre est de type sp^2. Cet angle de 90° est également observé dans $[Ru(NH_3)_4(SO_2)Cl]Cl$ (**3**) (9). Dans **2** et **3** l'indice de coordination du métal est 6 tandis que dans les composés où l'angle est voisin de 20° l'indice était égal ou inférieur à 5. Sans rejeter l'hypothèse de l'hybridation sp^2, on doit cependant remarquer que l'arrangement de SO_2 dans **2** et **3** présente le minimum d'interactions avec les autres ligands.

Les plus fortes interactions intramoléculaires ont apparemment lieu entre C(1) et S (2.77(2) Å) et entre C(2) et S (2.73(2) Å). Ces distances sont

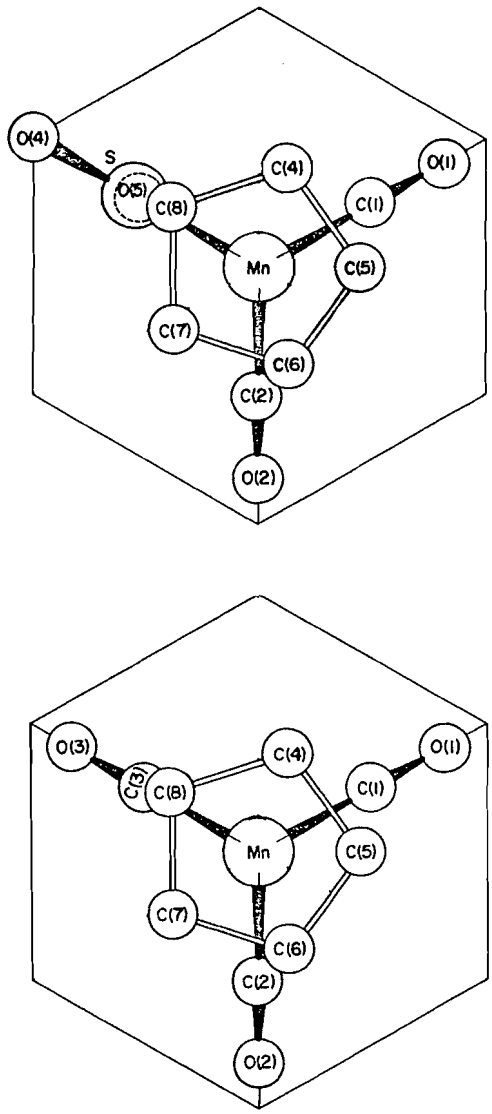

FIG. 3. Projection orthogonale des composés $MnC_5H_5(CO)_3$ et $MnC_5H_5(CO)_2SO_2$ dans un plan parallèle à celui du cycle cyclopentadiényle.

inférieures de 0.7 Å à la somme des rayons de van der Waals du carbone (1.70 Å) et du soufre (1.80 Å). Des répulsions de charge se manifestant à si courte distance pourraient expliquer la faible stabilité du composé **2** et l'impossibilité apparente à préparer et à isoler le composé disubstitué $MnC_5H_5(CO)(SO_2)_2$.

Alors que les distances M—S, observées dans la plupart des composés contenant M—SO_2 (8), sont très voisines (±0.1 Å) de la somme des rayons covalents du soufre (1.04 Å) et du métal M, la distance Mn—S (2.037(5) Å) est inférieure par plus de 0.3 Å à la somme des rayons covalents de S et de Mn (1.39 Å) (10). De nouveau le dioxyde de soufre se comporte de façon analogue dans les composés **2** et **3** (Ru—S = 2.072(3) Å). Dans ces deux composés d'arrangement octaédrique, la liaison M—S présente fort probablement un caractère élevé de double liaison résultant d'un retour de charges M → SO_2, ce qui serait conforme aux propriétés d'acide de Lewis du dioxyde de soufre. La liaison S—O du SO_2 présente une distance (1.40(1) Å) et une ouverture angulaire O—S—O (112.6(8)°) semblables aux valeurs observées dans les complexes métalliques (8), et assez voisines de celles obtenues pour le dioxyde de soufre cristallin, (1.43(2) Å) et (120(2)°) (11). L'écart minime ($-30\ cm^{-1}$) dans les fréquences de vibration de valence de SO_2 en passant de SO_2 cristallin (1140 et 1303 cm^{-1}) (12) à $MnC_5H_5(CO)_2SO_2$ (1110 et 1270 cm^{-1} (Nujol)), la similitude des fréquences S—O dans les complexes métalliques (8) ainsi que l'invariance statistique des distances S—O tendent à indiquer que la liaison Mn—S est formée sans que la liaison S—O en soit affectée.

Toute liaison π de retour (M→S) s'effectuerait donc par voie de recouvrement d'orbitales atomiques vides du soufre avec les orbitales remplies du métal.

Au niveau du cycle cyclopentadiényle, peu de changements statistiquement significatifs sont apparus à la suite du remplacement d'un groupement CO par SO_2. La distance moyenne Mn—$C_{C_5H_5}$ (2.09(2) Å) dans **2** est "inférieure" à la moyenne de 2.15(2) Å, observée dans tous les composés du cyclopentadiényle manganèse. La distance moyenne C—C est cependant semblable à celle observée dans $MnC_5H_5(CO)_3$ (6) (tableau 4). Le coordinat SO_2 provoque, à l'intérieur des liaisons Mn—C—O, des changements moins importants que le coordinat $P(C_6H_5)_3$. En effet, les fréquences de vibration de valence C—O dans **2** (2000–1956 cm^{-1}) sont plus voisines de celles de $MnC_5H_5(CO)_3$ (2028–1940 cm^{-1}) que ne le sont les fréquences C—O dans $MnC_5H_5(CO)_2P(C_6H_5)_3$ (1930–1861 cm^{-1}). D'autre part, le groupement C(2)—O(2) présente une distance Mn—C (1.788(16) Å) et une distance C—O (1.147(17) Å) égales à celles observées dans $MnC_5H_5(CO)_3$ (1.79(2)–1.14(2) Å) alors que dans $MnC_5H_5(CO)_2P(C_6H_5)_3$ les distances Mn—C (1.766(12)–1.740(10) Å) et

OC—Mn—CO	90.5(6)	92.4(4)	91[e]
X—Mn—CO	92.9(5)	91.6(3)	92[e]
Mn—C—O	178(1)	178(1)	179[e]

[a]Distances en Angströms et angles de valence en degrés.
[b]C(3)—O(3), groupement qui occupe la même position relative que SO_2 ou $P(C_6H_5)_3$.
[c]Les deux distances ne sont pas statistiquement indentiques.
[d]L'écart indiqué est la moyenne des écarts-types estimés.
[e]Aucun écart-type n'est fourni.

C—O (1.168(12)–1.173(11) Å) (1) montrent que la liaison Mn—C—O a été affectée par un retour π plus important que dans $MnC_5H_5(CO)_3$. Les paramètres associés au groupement C(1)—O(1) pouraient expliquer en partie certaines observations faites sur d'autres régions de la molécule **2**. Sans rejeter la possibilité que les paramètres structuraux de C(1) soient légèrement erronés, on doit cependant noter que C(1)—O(1) est le coordinat situé le plus près d'une position trans au carbone du cycle qui forme la plus courte liaison Mn—C dans **2** (2.07(2) Å) et la plus longue dans $MnC_5H_5(CO)_2P(C_6H_5)_3$ (2.16(2) Å). En outre on observe un angle S—Mn—C(1) voisin de 95°, valeur semblable à celle de l'angle C(3)—Mn—C(1) observée dans $MnC_5H_5(CO)_3$ mais différente de celle de 90° pour l'angle P—Mn—C(1) dans $MnC_5H_5(CO)_2P(C_6H_5)_3$ et les angles C(1)—Mn—C(2) et C(2)—Mn—X(C(3),S,P) dans les trois composés. La forte interaction S----C(1) pourrait causer, par répulsion coulombique, l'ouverture angulaire observée.

Conclusion

Le remplacement d'un groupement CO par SO_2 introduit des changements au niveau de la liaison Mn—$C_{C_5H_5}$ en favorisant une courte liaison Mn—S par voie de liaison dative Mn→S importante. La disposition de SO_2 relative aux autres ligands, l'encombrement autour du manganèse et la présence de dipoles peuvent être considérés comme facteurs importants de l'instabilité du composé $MnC_5H_5(CO)_2SO_2$.

Erratum: The Electronic Spectra of Tetragonal Chromium(III) Complexes

M. KEETON, B. FA-CHUN CHOU, AND A. B. P. LEVER
The Department of Chemistry, York University, Downsview, Ontario

Received August 24, 1973

(Ref.: Can. J. Chem. **49**, 192 (1971))

Can. J. Chem. **51**, 3690 (1973)

In Table 3, the parameter set for $Cren_2(OH)_2^+$ was incorrectly calculated. The correct values are: *Ds*, −1183; *Dt*, 150; Δ_1, −4302; Δ_3, −3987; $e_{\pi L}'$, 0*; $e_{\sigma L}'$, 6640; $e_{\pi Z}'$, 2151; $e_{\sigma Z}'$, 8633; $d\pi$, 2151; $d\sigma$, 1495; *B*, 789; Dq_L, 1992; Dq_Z, 1730 cm^{-1}; Assignment, II.

The correction does not materially alter the discussion except that the hydroxyl ion is seen to be as good a π donor as fluorine towards chromium(III) and to be a substantially better σ donor than fluorine.

Crystal and Molecular Structure of Benzylidenimine Tetrasulfide, $(C_6H_5CHN)_2S_4$

JAMES C. BARRICK, CRISPIN CALVO, AND FREDRIC P. OLSEN
Department of Chemistry, McMaster University, Hamilton, Ontario L8S 4M1

Received April 18, 1973

The structure of the title compound has been determined. Crystals are monoclinic with space group $P2_1/a$, $Z = 4$, $a = 13.83(1)$, $b = 19.66(2)$, $c = 5.983(5)$ Å, $\beta = 101.4(1)°$, $d_{calcd} = 1.404$, $d_{obs} = 1.40(1)$. A full-matrix least-squares refinement on 1085 unique reflections of positive intensity measure produced a conventional R of 0.066. The spiral arrangement of the S_4 chains (nearly generating a 3_1 axis) is such that the two aromatic rings are eclipsed. Alternation in bond length along the sulfur chain was observed, the long inner bond being 2.083(4) Å and the shorter outer bonds averaging 2.026(3) Å in length. No intermolecular non-bonding interactions involving sulfur were found.

La structure du composé en titre a été déterminée. Les cristaux sont monocliniques, de groupe d'espace $P2_1/a$, avec $Z = 4$, $a = 13.83(1)$, $b = 19.66(2)$, $c = 5.983(5)$ Å, $\beta = 101.4(1)°$, $d_{calcd} = 1.404$, $d_{obs} = 1.40(1)$. Un raffinement par les matrices des moindres carrés appliqué aux 1085 réflexions uniques d'intensité positive mesurée conduit à un R conventionnel de 0.066. L'arrangement en spirale des chaînes S_4 (créant presque un axe 3_1) est tel que les deux cycles aromatiques sont éclipsés. Une alternance dans les longueurs de liaison le long de la chaîne sulfurée a été observée, les grandes liaisons vers l'intérieur étant de 2.083(4) Å et les liaisons courtes vers l'extérieur de 2.026(3) Å en moyenne. Des interactions non liantes mettant en jeu le soufre ont été trouvées. [Traduit par le journal]

The reaction of tetrasulfur tetranitride with benzylamine leads to a product (1) formulated (2) as benzylidenimine tetrasulfide. This material appears to be a rather common product from reactions of species containing sulfur and benzyl groups; it has also been isolated from the reaction of benzylamine with sulfur in the presence of lead oxide (2, 3), from the decomposition of *N*-benzylheptasulfurimide (4), from the reaction of sulfur monochloride (5, 6), or disulfur trichloride (5) with benzylamine and from the decomposition of benzylamine disulfide (6). At least four alternate structures have been suggested although the combined evidence of elemental analysis, molecular weight, i.r., and n.m.r. would seem to eliminate most of them.

Recently, the structures of several tetrasulfides have been determined. These include tetraethoxy-2,3,4,5,10,11,12,13-octathiatricyclo-[12,2,2,2$^{(6,9)}$]eicose-6,8,14,16,17,19-hexaene (**2**) (7), 1,2,3,4-tetrathiadecaline (**3**) (8), *N*,*N*′-dimethyl-3,6-epitetrathio-2,5-piperazinedione (**4**) (9, 10) and bis(cyclopentadienyl)tungsten tetrasulfide (**5**) (11). In **3**, the 3 sulfur–sulfur bond lengths were of equal length while in **2** and **4** alternation of sulfur–sulfur bond lengths in the order short-long-short was observed and in **5** alternation in the order long-short-long was found. Possible similar alternation of bond lengths has been reported previously (12–14) in inorganic sulfur chains but with a lack of consistency or conviction. Only in the recent cases are differences in sulfur–sulfur bond lengths clearly outside the experimental errors in the measurements.

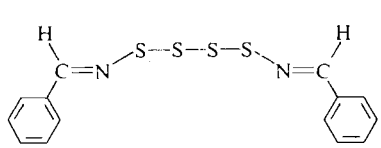
In view of the interest in bond length alternation in organotetrasulfides and to resolve any residual uncertainty in the structure of **1**, we have determined the crystal and molecular structure of this material.

Experimental

Crystal Data

Benzylidenimine tetrasulfide, $(C_6H_5CHN)_2S_4$, was obtained from the reaction of sulfur with benzylamine in the presence of lead oxide as previously described (6). Recrystallization from hot methanol gave yellow needles of m.p. 100.5–102 °C. Crystals suitable for X-ray analysis were subsequently grown from benzene solution.

Weissenberg photographs (hkn, $n = 0$–5) showed systematic absences of type $k = 2n + 1$ on the $0k0$ axis and $h = 2n + 1$ in the $h0l$ layer establishing the space group $P2_1/a$. Accurate unit cell parameters were determined by least squares adjustment of a, b, c, and β to 2θ, ω, and χ angles for 15 well-centered reflections collected at room temperature on a Syntex P$\bar{1}$ Automatic Diffractometer and were $a = 13.83(1)$, $b = 19.66(2)$, $c = 5.983(5)$ Å, and $\beta = 101.4(1)°$. The density, measured by



1

flotation in *n*-heptane/carbon tetrachloride, was 1.40(1) g/cm^3; calcd. for $Z = 4$, 1.404 g/cm^3.

Collection of Data and Solution of the Structure

The preliminary (15) solution of the structure was carried out on intensity data obtained from *hkn*(n = 0–5) CuK$_\alpha$ Weissenberg and *skl*(s = 0–4) MoK$_\alpha$ Precession film data. Following data reduction, the application of direct methods in the X-Ray 67 system of programs to the 1038 observed symmetry independent reflections determined enough phases to allow the positions of the four sulfur atoms to be discerned in a Fourier synthesis (E-map). Alternating electron density and difference syntheses with least squares refinement of atomic positions led gradually to the location of the remaining non-hydrogen atoms. Introduction of anisotropic thermal parameters decreased the discrepancy index from 0.15 to 0.075. Although the structure refined readily, up to 4σ variations in carbon–carbon lengths were observed in the aromatic rings. Possible explanations including libration and disorder were considered, but the quality of the data was judged insufficient to allow an unequivocal conclusion.

Subsequently, a new set of intensity data was collected to $2\theta = 40°$ on a Syntex $P\bar{1}$ Automatic Diffractometer using carbon monochromatized MoKα radiation (λ = 0.71069 Å) with a monochromator setting of 12°. The linear absorption coefficient was 5.6 cm^{-1}, and the crystal dimensions were 0.15 × 0.18 × 0.35 mm (the long axis being parallel to the ϕ axis). Maximum variations in transmission factors were ± 1%, consequently, no absorption corrections were made. Intensities were measured using a variable scan time in the θ–2θ technique with stationary counts on each side of the peak for 1/2 of the scan time to establish background. Thus, the peak intensity, $N_{Pk} = N_T - N_{Bg1} - N_{Bg2}$ where N_T is the total peak count and N_{Bg1} and N_{Bg2} are background counts. σ_I's were derived from

$$\sqrt{\sigma_{Pk}^2 + (0.02|F_o|^2)^2}$$

where the second term allows for machine instability and

$$\sigma_{Pk} = \sqrt{N_T + N_{Bg1} + N_{Bg2}}$$

After averaging equivalent reflections, 1085 unique reflections of positive intensity measure remained of which 737 had $I > 3\sigma$ and were considered as "observed". After correction for Lorentz and Polarization effects using the XRAY-67 Program DATRDN, these gave the structure factors used for comparison with those calculated from the model structure.[1]

Refinement of the 182 positional and anisotropic thermal parameters, including a parameter for extinction corrections (17, 18), by full-matrix least squares methods using the program CUDLS[2] led to an unweighted discrepancy index of 0.066 for all reflections and a weighted value of 0.038 where

$$R = \frac{\sum ||F_o| - |F_c||}{\sum |F_o|}$$

and

$$R_W = \sqrt{\frac{\sum w(|F_o| - |F_c|)^2}{\sum w|F_o|^2}}$$

The function minimized in the least squares refinement was $\Sigma w(F_o - F_c)^2$. Unobserved reflections ($I < 3\sigma$), measuring more than their calculated values, were given zero weight and did not affect the refinement while those measuring less than their calculated value did. In the last cycle, 240 reflections with $I < 3\sigma$ supplemented the 737 with $I > 3\sigma$ in this manner. The weighting scheme used took the form

$$W = 1/[0.011|F_o| + 0.0027|F_o|^2 + 364\sigma^2/|F_o|^2]$$

where the σ's were derived from counting statistics. The maximum shift/error in the final cycle was 0.16. The hydrogen atoms were included in their expected positions with $U_{iso} = 0.06$ Å^2, but were not refined.

Table 1 lists observed and calculated structure factors[3] and Table 2 gives atomic positions and temperature

[1]Atomic scattering factors used were those quoted in the International Tables (16).

factors[4] along with their estimated standard deviations. Table 3 gives bond lengths and angles and their estimated standard deviations.

Results and Discussion

Figure 1 shows a stereoscopic view of the molecule looking down the *a* axis. The structure is clearly monomeric with an S_4 chain terminated by benzylidenimine fragments. The two aromatic rings are approximately superimposed since the sulfur chain folds back upon itself nearly generating a non-crystallographic 3_1 axis extending over the four sulfur atoms as shown in Fig. 2.

Phenyl Rings

The average C—C distance within the rings is 1.372 Å with maximum and average deviations of 0.018 and 0.008 Å. The maximum deviation from the average is 1.2σ, and the average value is in good agreement with the accepted (19) value of 1.392(4) Å considering that corrections for translational and librational effects have not been applied. The average bond angle within the rings is 120.2° with maximum and average deviations of 2.9° and 1.0°, respectively. Both rings are quite planar with maximum and average deviations of 0.015 Å (C_2,C_3) and 0.009 Å. The least squares plane defined by $C_2 \ldots C_7$ (Ring A) makes an angle of 21.9° with that defined by $C_9 \ldots C_{14}$ (Ring B) so as to tilt C_5 and C_{12} apart (4.62 Å) and C_2 and C_9 together (3.67 Å). The planes of rings A and B intersect the 3_1 axis at angles of 83° and 81.5°, respectively.

C–Phenyl and C–N Bonds

The aliphatic C—C bonds, averaging 1.460(8) Å, are short as expected for conjugation of the aromatic ring with the C—N double bond. C_1 and C_8 lie within 0.05 and 0.07 Å, respectively,

[4]Thermal factors are in Å² and were obtained from $U_{ij} = \beta_{ij}/2\pi^2 a_i^* a_j^*$ where the β_{ij}'s appear as the effect of temperature through $\exp[-\beta_{11}h^2 + 2\beta_{12}hk \ldots)]$ in the structure factor expression and the a_i^*'s are the reciprocal lattice vectors. These units were chosen so that U = mean square thermal displacement directly.

*Estimated standard deviations (in parentheses) include both positional uncertainty in refinement and also that arising from errors in the cell parameters.

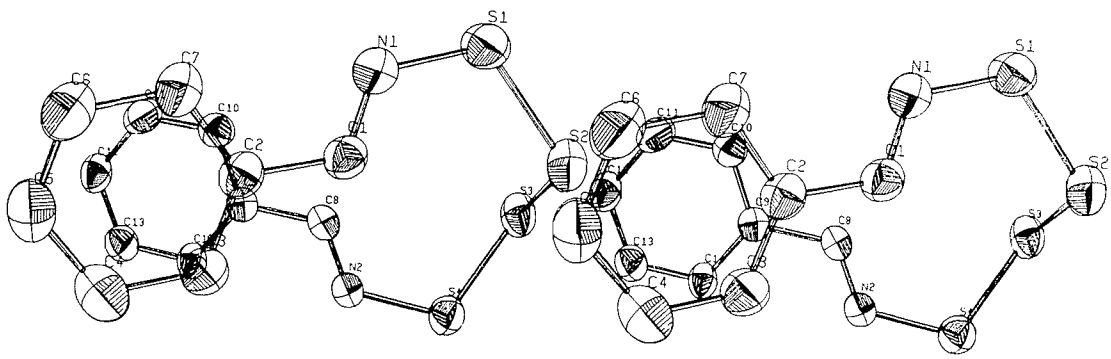

FIG. 1. Stereoscopic view of benzylidenimine tetrasulfide looking down the *a* axis.

of the planes of the rings while N_1 and N_2 lie 0.32 and 0.25 Å, respectively, from these planes. The C—C—N angles average 121.6(7)°. The C—N double bonds average 1.271(8) Å. All these bond lengths and angles are reasonable and in good agreement with those previously found in benzylidenimine fragments (20). The C—N—S angles average 124.0(4)° and the C—C—N—S dihedral angles are 1.1° and 3.0°, respectively, for C_1—N_1 and C_8—N_2. The tilt of the planes of the aromatic rings leads to a C_1—C_8 distance of 3.20 Å. The nitrogens are in a "*trans*" rather than a "*cis*" arrangement, however, and are quite far apart.

Sulfur–Nitrogen Bonds

The average N—S distance at 1.655(5) Å is short in comparison to the value of 1.76 Å found in sulfamic acid (21) or the sum of the single bond covalent radii (22) of 1.74 Å but is not unusual when compared to other typical sulfur nitrogen

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

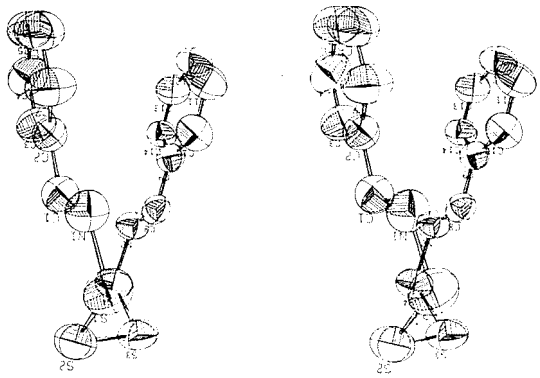

FIG. 2. Stereoscopic view of benzylidenimine tetrasulfide looking down the pseudo-3_1 axis of the sulfur chain.

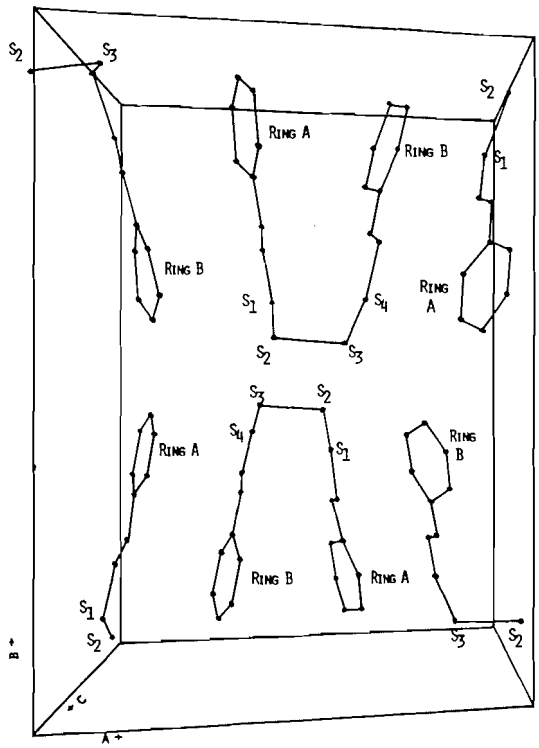

FIG. 3. Packing of benzylidenimine tetrasulfide.

"single" bonds where a lone pair resides on nitrogen and some $d\pi$–$p\pi$ overlap is likely to occur. Examples for comparison include 1.66 Å in (23) (*p*-chlorophenyl)$_2S_3N_2$, 1.66 Å in (24) $S_4N_4F_4$, 1.628 Å in (25) 1,2,5-thiadiazole and 1.672 Å in (26) 1,3-$S_6N_2H_2$. Normal "double" bonds between S and N are generally shorter with typical lengths of 1.54 Å in (24) $S_4N_4F_4$, 1.55 Å in (23) (*p*-chlorophenyl)$_2S_3N_2$, 1.53 and 1.56 Å in (27) di-*p*-tolylsulfurdiimide, and 1.533 Å in (28) $(CH_3)_2S(NH)_2$. The N—S—S angles average 111.5(3)°. The C—N—S—S dihedral angles are surprisingly small at 3.0 and 3.3°, respectively, for N_1—S_1 and N_2—S_4.

The Sulfur–Sulfur Bonds

As a consequence of the small dihedral angles around both the N—S and C—N bonds, each C—N—S—S unit lies quite near to the plane of the aromatic ring to which it is bound. For ring B, S_3 and S_4 lie 0.03 and 0.36 Å out of the plane while for ring A, S_1 and S_2 lie 0.41 and 0.07 Å from the plane defined by the ring carbon atoms. Thus, the molecule might be considered as two approximately coplanar units (see Fig. 3) joined by the S_2—S_3 bond. Planes fit to the two halves of the molecule have maximum and average deviations of 0.18 and 0.07 Å and make an angle of 22.5°, *i.e.*, only 0.6° greater than the planes generated by the ring carbons alone. The outer two ("in plane") sulfur–sulfur bond lengths differ by 0.013 Å with a σ_Δ of 0.006 Å where $\sigma_\Delta^2 = \sigma_1^2 + \sigma_2^2$ and are therefore judged "equivalent". The best value is 2.026(3) Å where $\sigma^2 = 1/\sum(1/\sigma_i^2)$. The bond angles $S_1S_2S_3$ and $S_2S_3S_4$ differ by 0.4(4)° with an average value of 106.2(2)°. In comparing the inner ("between planes") and outer ("in plane") sulfur bond lengths, correlation must be considered, and $\sigma_\Delta^2 = \sigma_{AB}^2 + \sigma_{AC}^2 + \sigma_A^2 \cos\theta$ where σ_{AA} and σ_{AC} are the e.s.d.'s on the two bonds, σ_A is the isotropic positional error on the shared atom and θ is the angle between the bonds. The "between plane" S—S bond length is 2.083(4) Å. The difference between the inner and outer S—S bonds is then 0.057 Å with a σ_Δ of 0.006 Å. This difference of between 9 and 10 pooled standard deviations cannot be explained away as random experimental error. Since no systematic errors of this magnitude appear likely, the "between planes" S—S bond is judged significantly longer than the "in plane" S—S bonds. Therefore, alternation of S—S bond length of type short-long-short, occurs in the tetrasulfide chain.

This situation is directly analogous to that observed in **2** and **4**. There is excellent agreement in the lengths of the outer (short) bonds between the three structures, 2.026(3) Å in benzylidenimine tetrasulfide, 2.028(2) in **2** and 2.0244(9) in **4**.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

The longer internal S—S bonds are less obviously equivalent. In **2**, the internal bond is 2.066(2) Å while in benzylidenimine it is 2.083(4) Å and in **4** it is 2.076(1). These lengths compare to a S—S bond length of 2.048(2) Å in (29, 30) elemental S_8.

The benzylidenimine tetrasulfide molecular geometry is such that the two organic parts of the molecule are on one side of the spiral of sulfur atoms. Within the unit cell two spirals pack back to back (Fig. 3). These pairs extend throughout the crystal in the *c* direction.

The closest intermolecular contact distance (ignoring hydrogen atoms) is 3.54 Å (C_1—C_9), a distance in good agreement with the effective thickness of the aromatic ring. The closest intermolecular contact distance involving sulfur is 3.56 Å (C_{12}—S_2) where the sum of van der Waals radii is 3.55 Å.

The van der Waals radius of sulfur is generally taken as 1.85 Å; the closest S—S intermolecular contact is 3.73 Å (S_1—S_3) with others at 3.74 (S_2—S_4), 3.75 (S_2—S_3) and 3.82 Å (S_2—S_3). The intramolecular $C_1 \ldots S_2$ and $C_8 \ldots S_3$ distances are however rather short at 3.23 and 3.21 Å. This point is of interest in relation to the structure (7) of **2** where quite substantial non-bonding interactions between oxygen and the outer S atoms of the tetrasulfide chain offered a possible explanation for the S—S bond length alternation observed in that compound.

This work was carried out under a grant from the National Research Council of Canada.

Crystal and Molecular Structure of Benzylidenimine Trisulfide

JAMES C. BARRICK, CRISPIN CALVO, AND FREDRIC P. OLSEN
The Department of Chemistry, McMaster University, Hamilton, Ontario L8S 4M1

Received April 18, 1973

The crystal and molecular structure of benzylidenimine trisulfide has been determined. Crystals are orthorhombic with $a = 16.610(2)$, $b = 9.984(6)$, $c = 4.386(4)$, $Z = 2$ and space group $P2_12_12$. 773 unique reflections of positive measured intensity, recorded with a Syntex P$\bar{1}$ Automatic Diffractometer, were refined by full-matrix least-square methods to a conventional R value of 0.023. The molecule has a crystallographic two-fold axis and S—S bond lengths of 2.051(1) Å. These are intermediate in length between the long inner and short outer S—S bonds of the chemically analogous tetrasulfide. The S—N and N—C bond lengths are 1.661(3) and 1.269(3), respectively. The crystal packing is determined by S—S van der Waals interaction between adjacent molecules along the c axis.

La structure cristalline et moléculaire du trisulfure de benzylidénimine a été déterminée. Les cristaux sont orthorhombiques avec $a = 16.610(2)$, $b = 9.984(6)$, $c = 4.386(4)$, $Z = 2$ et le groupe d'espace est $P2_12_12$. 773 réflexions uniques d'intensité mesurée positive et enregistrées sur un diffractomètre automatique Syntex P$\bar{1}$, ont été raffinées par la méthode des matrices des moindres carrés jusqu'à une valeur conventionnelle pour R de 0.023. La molécule a un axe cristallographique d'ordre 2 et les longueurs des liaisons S—S sont de 2.051(1) Å. Celles-ci sont intermédiaires entre les longues liaisons internes et les courtes liaisons externes S—S des analogues chimiques tétrasulfurés. Les longueurs des liaisons S—N et N—C sont de 1.661(3) et 1.269(3), respectivement. Le remplissage du cristal est déterminé par les interactions S—S de Van der Waals entre les molécules adjacentes le long de l'axe c.

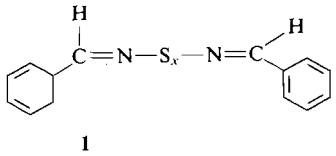
Alternation of sulfur–sulfur bond lengths has been observed in benzylidenimine tetrasulfide (1), **1***a*, as well as in 7,15,17,19-tetraethoxy-2,3,4,5,10,11,12,13-octathiatricyclo[12,2,2,$2^{6,9}$]-eicosa-6,8,14,16,17,19-hexaene (2), **2**, *N*,*N*′-dimethyl-3,6-epitetrathio-2,5-piperazinedione (3, 4), **3**, and bis(cyclopentadienyl)tungsten tetrasulfide (5), **4**, but not in 1,2,3,4-tetrathiadecalin, **5**, (6). Possible explanations might include such factors as "butadiene-like" conjugation across the S_4 chain (2), inductive effects leading to shortening of the outer S—S bonds in **1***a*–**4**, resonance forms involving dπ–pπ overlap at the terminal sulfur in **1***a*–**4** leading to redistribution of electron density along the sulfur chain, hyperconjugation (7), and internal redistribution of electron density within the tetrasulfide chain. A choice between these explanations cannot reasonably be made based only on the observed tetrasulfide bond length alternation since there is no well established "normal" sulfur–sulfur single bond length. (The value in elemental sulfur may well contain contributions from dπ–pπ double bonding, and thus this is not an acceptable reference.) Accurate structural data providing both bond lengths and angles on a series of closely related compounds with varying number of atoms in the sulfur chain would be invaluable.

This paper reports the crystal and molecular structure of benzylidenimine trisulfide, (**1***b*), with a view to providing data which can be compared with that of benzylidenimine tetrasulfide (**1***a*) and benzylidenimine disulfide, (**1***c*), reported in a paper to follow.

Experimental

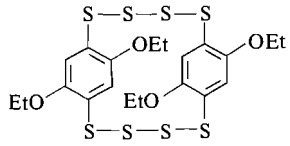
Preparation of Compound

Benzylidenimine trisulfide was obtained from the reaction of sulfur with benzylamine (in presence of lead oxide) at the 3:1 molar ratio calculated (8) to maximize the yield of this product. The crude material was taken up in ether and filtered to remove lead sulfide. The ether was removed under vacuum and the product recrystallized from an amount of refluxing methanol sufficient to dissolve approximately half the product. Upon cooling to room temperature, the bulk of the tetrasulfide was precipitated and removed. The solution was then refrigerated for several hours whereupon a crop of fairly pure disulfide precipitated. The remaining solution was concentrated to a small volume and chilled to precipitate a mixture of about equal parts of benzylidenimine tri- and tetrasulfides. This material was taken up in a hot benzene–hexane solution and upon cooling gave the desired trisulfide in 90–95% purity. A subsequent recrystallization of the latter from benzene–hexane gave white needles of m.p. 125–126 °C, lit. (8) 125–126°. Using

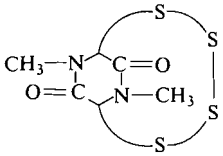


1

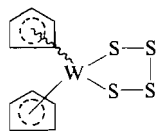
a $x = 4$
b $x = 3$
c $x = 2$



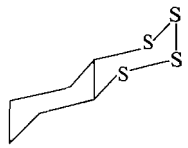
2



3



4



5

this method approximately 0.5 g of high purity trisulfide could be obtained from 10 g of benzylamine.

Crystal Data

$C_{14}H_{12}N_2S_3$

Orthorhombic, $a = 16.610(2)$, $b = 9.984(6)$, $c = 4.386(4)$ Å, $V = 727.3$ Å^3, $D_m = 1.4$, $Z = 2$, $D_c = 1.390$, space group $P2_12_12$.

Weissenberg photographs established the crystal system as orthorhombic and showed systematic absences of the type $h00$ for h odd and $0k0$ for k odd. Accurate unit cell parameters were obtained by least-squares adjustment of the lattice parameters to the experimental values of 2θ, ω, and χ using 13 well centered reflections measured on a Syntex P$\bar{1}$ Automatic Diffractometer with graphite monochromatized (take off angle of 12°) MoK$_\alpha$ radiation ($\lambda = 0.71069$ Å).

Intensity data to $2\theta = 40°$ were recorded on the above diffractometer in the θ–2θ technique. Stationary counts on each side of the peak for one half the scan time established background. Thus, the peak intensity, $N_{Pk} = N_T - N_{Bg1} - N_{Bg2}$ where N_T is the total peak count and N_{Bg1} and N_{Bg2} are background counts. σ_I's were derived from $\sqrt{\sigma_{Pk}^2 + (0.02|F_o|^2)^2}$ where $\sigma_{Pk}^2 = N_T + N_{Bg1} + N_{Bg2}$. The linear absorption coefficient was 4.9 cm^{-1} and the crystal used had dimensions of 0.27 mm × 0.39 mm × 0.59 mm (with the long axis parallel to the spindle axis). After averaging of equivalent reflections, 773 symmetry independent reflections of positive intensity measure remained of which 715 had $I > 3\sigma$ and were treated as "observed". After correction for Lorentz and polarization effects using the XRAY-67 Program DATRDN these gave the structure factors used to calculate Patterson functions and for comparison with those calculated from model structures.[1]

Solution of the Structure

The central sulfur was placed on the two-fold axis as required by the number of formulae units per cell ($Z = 2$). The $hk0$ and $0kl$ Patterson projections yielded the coordinates of the S and N atoms. Carbon positions were then gradually located from successive electron density and difference Fourier syntheses (SYMFOU)[2] and least-squares refinement (CUDLS)[2]. Hydrogen atom positions with isotropic temperature factors were refined from the positions corresponding to sp^2 hybridization at carbon and a C—H bond length of 0.97 Å. The function minimized in the full-matrix least squares refinement was $\Sigma w(F_o - F_c)^2$. Unobserved reflections measuring more than their calculated values did not effect the refinement while those measuring less than their calculated value did. In the final cycle there were 58 such reflections which supplemented the 715 observed reflections. When anisotropic temperature factors were refined for all non hydrogen atoms, a total of 112 parameters were varied including those for scale and extinction (10, 11) corrections. The weighting scheme used in the final cycle of refinement took the form

$$w = 1/[0.007 + 0.007|F_o| + 0.00012|F_o|^2 + 12\sigma^2/|F_o|^2]$$

where the σ's were derived from counting statistics. The maximum shift/error was 0.054 in the final cycle of refinement. The final unweighted R was 0.023 for the observed reflections and 0.026 for all reflections; the weighted R for both cases was 0.031 where

$$R = \frac{\sum ||F_o| - |F_c||}{|F_o|}$$

and

$$R_w = \sqrt{\frac{\sum w(|F_o| - |F_c|)^2}{\sum w|F_o|^2}}$$

The calculated and observed structure factors are listed[3] in Table 1 and the final values of the positional

[1]Atomic scattering factors used were those quoted in the International tables (9).

[2]Computer programs CUDLS and SYMFOU were written locally by J. Stephens and J. Rutherford, respectively.

[3]Table 1 is available, at a nominal charge, from the Depository of Unpublished Data, National Science Library, National Research Council of Canada, Ottawa, Canada K1A 0S2.

and thermal[4] parameters of all atoms are given in Table 2. Table 3 lists bond lengths and angles of interest.

Results and Discussion

Figure 1 shows the molecule looking down the b axis. The molecule contains a crystallographic two-fold axis which lies along the c axis. The overall structure is clearly that of benzylidenimine trisulfide with a molecular conformation in which the two aromatic rings are well separated from each other as opposed to benzylidenimine tetrasulfide where the two rings were nearly eclipsed (1).

The Phenyl Ring

The phenyl ring carbons are quite planar with maximum and average deviations of 0.004 (C_5) and 0.002 Å, respectively. The average carbon–carbon bond length (in the ring) of 1.381 Å,

[4]All temperature factors reported herein are in Å^2 and were obtained from $U_{iso} = B_{iso}/8\pi^2$ and $U_{ij} = \beta_{ij}/2\pi^2 a_i^* a_j^*$ where the β_{ij}'s appear as the effect of temperature through $\exp[-\beta_{11}h^2 + 2\beta_{12}hk...]$ in the structure factor expression and the a_i^*'s are the reciprocal lattice vectors. These units are chosen so that U = mean square thermal displacements directly.

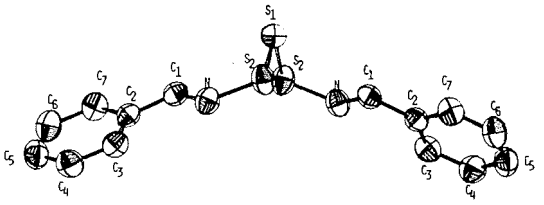

FIG. 1. View of benzylidenimine trisulfide looking down the *b* axis.

with maximum and average deviations of 0.015 (C_5—C_6) and 0.006 Å, is in good agreement with values of 1.372 in the tetrasulfide (**1***a*) and 1.380 in **2** (2). Considering that translational and librational corrections have not been applied, it agrees well with the accepted (12) value of 1.392(4) Å. The average C—C—C angle for the ring is 120.0° with maximum and average deviations of 1.3° (C_2) and 0.5°. The average carbon–hydrogen bond distance refined to 0.92 Å with maximum and average deviations of 0.09 and 0.03 Å. Riding corrections (13), if applied, would lead to an average value of 0.94 Å. The maximum deviations of a ring hydrogen from the plane defined by C_2—C_7 is 0.05 Å (H_6) and the average deviation for the five is 0.04 Å.

The C-Phenyl and C–N Bonds

The aliphatic C—C bond at 1.464(4) Å and the C—N double bond at 1.269(3) Å are both in excellent agreement with the corresponding values of 1.460(8) and 1.271(8) Å observed in benzylidenimine tetrasulfide (**1***a*). As expected for conjugation of the C—N double bond with the aromatic ring, C_1 and N lie just 0.013 and 0.020 Å from the plane defined by the ring carbon atoms. The C—C—N and C—N—S angles at 121.9(4)° and 126.0(2)° compare well with values of 121.6(4)° and 124.0(4)° in the tetrasulfide. The C—C—N—S dihedral angle at 1.5° is also in good agreement with the corresponding values of 1.1° and 3.0° found in the tetrasulfide.

The Sulfur–Nitrogen Bond

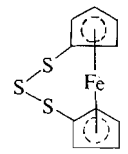
As in the tetrasulfide, the N—S distance is short compared to sulfamic acid but is typical of more ordinary "single bond" lengths where some dπ–pπ overlap is likely. The value of 1.661(3) Å found here compares very well with the value of 1.655(5) Å found in the tetrasulfide. The N—S—S angle at 111.4(2)° and also the quite small C—N—S—S dihedral angle of 3.5° are indistinguishable from the values of 111.5(3)° for the former and 3.0 and 3.3° for the latter angles in the tetrasulfide. Thus, all structural aspects including bond lengths, angles, and dihedral angles at the C—C, C—N, and N—S bonds are effectively identical in benzylidenimine tri- and tetrasulfides.

The Sulfur–Sulfur Bond

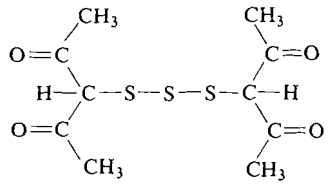
In benzylidenimine tetrasulfide, the molecular geometry could be described as two nearly coplanar units each containing a fairly short S—S bond and being joined by a fairly long S—S bond. These "in plane" bonds and "between plane" bonds in the tetrasulfide were 2.026(3) and 2.083(4) Å in length, respectively. The nearly identical molecular geometry in benzylidenimine trisulfide, including the comparable small C—N—S—S dihedral angle, requires that the whole unique half molecule be very nearly coplanar. Indeed, a single plane can be fit to the whole asymmetric unit in the trisulfide with maximum and average deviations (excluding hydrogen) of 0.031 (S_1) and 0.012 Å Thus, while the tetrasulfide was composed of two planes joined by an S—S bond, the full trisulfide molecule is composed of two planes sharing a common sulfur atom (S_1). Since the S—S bond in the trisulfide lies in the molecular plane, one might perhaps expect it to be comparable to the "in plane" S—S bonds in the tetrasulfide. The sulfur–sulfur bond length in the trisulfide is 2.051(1) Å. It therefore differs from the "in plane" tetrasulfide bonds by 0.025 Å with a σ_Δ of 0.003 Å where $\sigma_\Delta^2 = \sigma_1^2 + \sigma_2^2$. This difference of 8 pooled e.s.d.'s is taken as a "significant" difference especially considering the excellent agreement between all other aspects of the two structures. Comparing the trisulfide S—S bond with the longer "between planes" S—S bond in the tetrasulfide gives a difference of 0.032 Å with a σ_Δ of 0.004 Å, again 8 pooled e.s.d.'s, an amount taken as "significant". Thus, the S—S bond in benzylidenimine trisulfide is intermediate in length and unique from either the long or short S—S bonds in benzylidenimine tetrasulfide. Its length of 2.051(1) Å is in excellent agreement with those of 2.048(4) and 2.050(4) recently reported (14) in 1,2,3-trithio-3-ferrocenophene **6** and is somewhat shorter than the 2.083 Å found (15) in **7**.

Like the N—S—S angles, the S—S—S angles

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.



6



7

are very nearly identical in the tri- and tetrasulfide. The S—S—S angle is 106.9(2) in the trisulfide compared to 106.2(2)° in the tetrasulfide. The N—S—S—S dihedral angle in benzylidenimine trisulfide at 101.8° is, however, about 10° greater than that in the tetrasulfide where the comparable values were 90.6° and 94.3°. It is, however, less than the 106.5° found for the S—S—S—S dihedral angle in the tetrasulfide. Thus, the [C_6H_5CHNSS—] unit has nearly identical geometry in the two compounds save for a slight shortening of the S—S bonds in the tetrasulfide. There are slight differences in the dihedral angles at the sulfur–sulfur bond and the "extra" S—S bond in the tetrasulfide is quite long.

Within the crystal lattice, the three sulfur atoms form a vee pointing up the *c* axis. The two nitrogen atoms lie on opposite sides of the plane formed by these 3 sulfur atoms in contrast to **6** where the two adjoining atoms (carbon) lie on the same side of this plane. The sulfur vee's stack closely on top of one another to give an arrow effect pointing up the *c* axis. In the *b* direction, these arrows alternate side by side with screw related arrows pointing down through the structure. The cell is one molecule thick in *c*. The S_1—S_2 intermolecular non-bonding distance of 3.568 Å is just slightly less than the sum of van der Waal's radii (3.70 Å) and might indicate some possible weak interaction. Possible support for such an interaction comes from the observed decomposition of the crystal. On standing over a period of several months, a yellow streak develops down the middle of the crystal in the *c* direction. Eventually, the whole crystal becomes covered with a powdery yellow excrescence. This decomposition, which leads to major amounts of benzylidenimine di- and tetrasulfides (the latter yellow), could proceed by sulfur chain growth in the direction of the non-bonding interactions. It should be noted, however, that the intermolecular contact distance in elemental S_6 is (16) only 3.50 Å. It seems unlikely that interaction of this limited extent would result in any substantial effect on S—S bond lengths although this possibility cannot be fully excluded. As in the tetrasulfide, the $C_1 \ldots S_1$ intramolecular distance at 3.28 Å is rather short.

The Synthesis, Mössbauer and Infrared Spectra of some Dialkyltin Salts of Phosphorus Oxy-acids

T. CHIVERS AND J. H. G. VAN ROODE
Department of Chemistry, The University of Calgary, Calgary, Alberta T2N 1N4

AND

J. N. R. RUDDICK AND J. R. SAMS
Department of Chemistry, The University of British Columbia, Vancouver 8, British Columbia

Received April 11, 1973

A number of dialkyltin(IV) salts of phosphorus oxy-acids $R_2Sn(PO_2H_2)_2$ (R = CH_3, C_2H_5, *n*-C_4H_9), R_2SnPO_3X (R = CH_3, C_2H_5, *n*-C_4H_9, X = H; R = CH_3, X = F, OH), and $[(CH_3)_2Sn]_3(PO_4)_2$ have been prepared in aqueous solution from the appropriate dialkyltin(IV) dichloride and the sodium salts of phosphorus oxy-acids.

Infrared and ^{119}Sn Mössbauer spectra of the dialkyltin dihypophosphites, $R_2Sn(PO_2H_2)_2$, are consistent with hexacoordination for tin with the alkyl groups in *trans*-octahedral positions and bidentate bridging hypophosphite groups coordinated through oxygens. For the dialkyltin phosphites, R_2SnPO_3X, polymeric structures with a non-linear R_2Sn arrangement are involved, and the magnetic hyperfine Mössbauer spectrum (X = F) is consistent with either distorted *trans*-octahedral or distorted trigonal bipyramidal structures (with both apical or both equatorial methyl groups). In $[(CH_3)_2Sn]_3(PO_4)_2$ the three tin environments are indistinguishable by Mössbauer spectroscopy, but the high value of the asymmetry parameter $\eta \simeq 0.8$ suggests penta- rather than hexacoordination about tin, for which at least one three-coordinate oxygen per formula unit must be invoked.

Un nombre de sels de dialkylstannates d'oxy-acides de phosphore $R_2Sn(PO_2H_2)_2$ (R = CH_3, C_2H_5, *n*-C_4H_9), R_2SnPO_3X (R = CH_3, C_2H_5, *n*-C_4H_9, X = H; R = CH_3, X = F, OH) et $[(CH_3)_2Sn]_3(PO_4)_2$ ont été préparé en solution aqueuse à partir du dichlorure de dialkylstannate adéquat et des sels de sodium des oxy-acides de phosphore. L'infrarouge et le spectre de Mössbauer de ^{119}Sn des dihypophosphites de dialkylstannate, $R_2Sn(PO_2H_2)_2$, sont consistants avec l'hexacoordination de l'étain avec les groupes alkyles dans des positions octahédrique-*trans* avec les groupes hypophosphites bidentates formant des ponts par coordination avec les oxygènes. En ce qui concerne les phosphites de dialkylstannate, R_2SnPO_3X, des structures polymériques avec une non-linéarité pour les arrangements du R_2Sn sont impliquées, et le spectre magnétique hyperfin de Mössbauer (X = F), est consistant soit avec une forme octahédrique-*trans* distordue, ou une forme bipyramidale trigonale distordue (avec les deux groupes méthyles apicaux, ou équatoriaux). Dans $[(CH_3)_2Sn]_3(PO_4)_2$, les trois étains environnants sont indistinguables par la spectroscopie de Mössbauer, mais la grande valeur du paramètre assymétrique $\eta \simeq 0.8$ suggère une pentacoordination plutôt qu'une hexacoordination par rapport à l'étain, pour conclure enfin que l'un des trois oxygènes coordinants par unité de formule doit être invoqué.

Introduction

There has been considerable recent interest in organotin(IV) derivatives of inorganic acids but studies of such derivatives of phosphorus oxy-acids are few. Aqueous solutions of dimethyltin dichloride are known to react in a simple manner with $Na_2HPO_4 \cdot 12H_2O$ and $NaH_2PO_2 \cdot H_2O$ to give $(CH_3)_2SnHPO_4$ and $(CH_3)_2Sn(H_2PO_2)_2 \cdot 2H_2O$, respectively (1). Anhydrous triorganotin(IV) phosphates $(R_3Sn)_3PO_4$ (R = C_6H_5 (2), *n*-C_4H_9 (3)) have also been reported, but structural information is lacking. The recently described dialkyltin(IV) bis(difluorophosphates) $R_2Sn(PO_2F_2)_2$ (4), prepared by solvolysis of dialkyltin(IV) chlorides in an excess of difluorophosphoric acid, have been assigned a structure in which the tin atom is hexacoordinate with the alkyl groups in *trans*-octahedral positions and bidentate bridging difluorophosphate groups coordinated through oxygens, on the basis of ^{119}Sn Mössbauer and vibrational spectra. In view of the biological activity of organotin(IV) derivatives (5) and their use as pesticides and fungicides (5, 6), the products of reactions between organotin(IV) compounds and phosphates or phosphites appeared to be worthy of more detailed study.

In this investigation aqueous solutions of

dialkyltin(IV) chlorides were allowed to react with aqueous solutions of $NaH_2PO_2 \cdot H_2O$, $Na_2HPO_3 \cdot 5H_2O$, $Na_2HPO_4 \cdot 2H_2O$, $NaH_2PO_4 \cdot H_2O$, $Na_3PO_4 \cdot 12H_2O$, and K_2PO_3F to give the dialkyltin(IV) salts of the corresponding phosphorus oxy-acids as insoluble white precipitates. Since the phosphorus oxy-anions studied are derived from either mono-, di-, or tri-basic acids a variety of structures is possible for the dialkyltin(IV) derivatives. We have investigated these structures using infrared and conventional Mössbauer spectroscopy. In three cases, $(CH_3)_2Sn(PO_2H_2)_2$, $(CH_3)_2SnPO_3F$, and $[(CH_3)_2Sn]_3(PO_4)_2$, the Mössbauer spectra were measured in the presence of a large magnetic field in order to determine the sign of the electric field gradient (e.f.g.) at the ^{119}Sn nucleus and magnitude of the asymmetry parameter, η, in an attempt to distinguish between various geometrical arrangements of groups around tin.

Experimental

I. Chemicals

The sources of chemicals are indicated below: $NaH_2PO_2 \cdot H_2O$, $Na_2HPO_3 \cdot 5H_2O$, and $NaH_2PO_4 \cdot H_2O$ (Fisher), $Na_2HPO_4 \cdot 2H_2O$ (Baker), $Na_3PO_4 \cdot 12H_2O$ (British Drug Houses), K_2PO_3F (Research Organic/Inorganic Chemical Corp.). These were reagent grade chemicals used without further purification. $(CH_3)_2SnCl_2$ and $(n\text{-}C_4H_9)_2SnCl_2$ were kindly donated by M and T Chemicals Inc.; $(C_2H_5)_2SnCl_2$ was prepared from $(C_2H_5)_4Sn$ by the redistribution procedure (7). Purification of organotin(IV) chlorides was carried out by vacuum sublimation where necessary.

II. Instrumentation

Infrared spectra were obtained using a Perkin–Elmer 337 spectrometer. The Mössbauer spectrometer has been described previously (8).

III. Preparations

(a) In Aqueous Solution

The preparations were carried out according to the previously described procedure (1). Aqueous solutions of the dialkyltin(IV) dichlorides (for $(n\text{-}C_4H_9)_2SnCl_2$ ether was used as solvent) were added to aqueous solutions of the sodium or potassium salts of the phosphorus oxy-acid in a stoichiometric ratio appropriate for the complete replacement of chlorines on tin by the phosphorus oxy-anion. White precipitates of alkyltin(IV) phosphates or phosphites were produced either immediately, on shaking for a few minutes, or on standing for a few days. The products were filtered off, washed with water then methanol, and dried in an Aberhalden pistol (80°/0.1 mm) before being submitted for analysis.

IV. Analytical Results

All compounds were identified by C and H microanalysis, performed by Chemalytics Inc., Arizona, U.S.A. P and F analysis were carried out by Alfred Bernhardt, Microanalytical Laboratory, Elbach, W. Germany. The results together with the melting or decomposition points are listed in Table 1.

V. Infrared Spectra

Infrared spectra were obtained as mulls (Nujol) using KBr plates (International Crystal Labs.). The major absorption bands, together with assignments, for the dialkyltin(IV) bishypophosphites and the dialkyltin(IV) phosphites are summarized in Tables 2 and 3, respectively. Infrared spectra for other compounds are shown below (cm^{-1}). $(CH_3)_2SnPO_3F$: 1211s, 1170s,b, 1050s, 920w, 880w,sh, 855s, 807s, 590s, 544m, 517m; $(CH_3)_2SnPO_4H$: 3300b, 1200w, 1132s, 1104s, 1065s, 1030s, 888s, 800s, 630w, 590m, 550m, 519m; $[(CH_3)_2Sn]_3(PO_4)_2$: 1194w, 1112s, 1070s,b, 1000s, 975s, 950m, 790s, 645w, 604w, 572w–m, 536w–m, 450m.

Results and Discussion

†Internal modes of the R group overlap the 1000–1200 cm^{-1} and are not included. Assignment of $\nu_{as}SnC_2$ and $\nu_s SnC_2$ is not possible due to overlap with PO_3 deformation modes.

$NaH_2PO_2 \cdot H_2O$, $Na_2HPO_3 \cdot 5H_2O$, $Na_2HPO_4 \cdot 2H_2O$, $Na_3PO_4 \cdot 12H_2O$, or K_2PO_3F to give high yields of the dialkyltin(IV) salts of the corresponding phosphorus oxy-acid. Analytical data and infrared spectra showed that these derivatives, after drying, were anhydrous. When aqueous solutions of dimethyltin dichloride and $NaH_2PO_4 \cdot H_2O$ were mixed a high yield of $(CH_3)_2SnPO_4H$, identified by analysis, infrared and ^{119}Sn Mössbauer spectra, was obtained. At pH 7, $[HPO_4^{2-}]/[H_2PO_4^-] \simeq 1$, and this ratio increases with increase in pH so that reaction with the doubly charged anion is perhaps not unexpected.

II. Infrared Spectra

The infrared spectra of the dialkyltin(IV) bishypophosphites are shown in Table 2. For the $H_2PO_2^-$ ion, assuming C_{2v} symmetry, there should be nine normal vibrations (9). All of these except one (the PH_2 twisting mode which belongs to the group A_2 and should

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

For personal use only.

occur only in the Raman spectrum) are observed in the infrared spectra of alkali metal hypophosphites and of dialkyltin(IV) bishypophosphites. This observation suggests that C_{2v} symmetry is conserved in the dialkyltin(IV) compounds as expected for a bidentate bridging $H_2PO_2^-$ group with bridging through oxygens. Table 2 shows the assignments of the remaining eight fundamentals for all $R_2Sn(PO_2H_2)_2$. The following features are interesting: (*a*) only one type of PO_2H_2 group appears to be present in the dialkyltin(IV) bishypophosphites; (*b*) increasing the size of the alkyl group has little effect on the frequencies of the eight fundamental vibrations; (*c*) positional changes have occurred when compared to the ionic $H_2PO_2^-$ in $NaH_2PO_2 \cdot H_2O$. Of the P—O stretching modes, the asymmetric one is lowered by about 85 cm^{-1} whereas the symmetric mode is lowered by <15 cm^{-1}. If coordination occurs through oxygen the net lowering of $\nu PO_{average}$ can be explained partly by charge withdrawal from the P—O into the Sn—O bond region as observed for dialkyltin(IV) bis(difluorophosphates) (4). The average P—H stretching mode is found at higher frequencies (35–65 cm^{-1}) compared to $H_2PO_2^-$, indicating an overall strengthening of the P—H bonds in the dialkyltin(IV) derivatives.

Further structural information is obtained from the tin–carbon stretching modes for dialkyltin(IV) bishypophosphites. In the infrared spectra only $\nu_{as}Sn—C_2$ and not $\nu_sSn—C_2$ is observed for all compounds, suggesting that the carbon–tin–carbon group is in a linear or nearly linear arrangement. The structural model most consistent with these observations is identical to the one suggested for other dimethyltin(IV) derivatives, $(CH_3)_2SnX_2$ (X = PO_2F_2 (4), sulfonate (10–12), F (13)): hexacoordination for tin with the methyl groups in *trans*-octahedral positions and the PO_2H_2 groups acting as bridging, bidentate ligands resulting in sheet-like polymers (see Fig. 1).

The infrared spectra of the dialkyltin(IV) phosphites R_2SnPO_3H are compared with the spectrum of K_2PO_3H in Table 3. The vibrational spectra of the HPO_3^{2-} ion have been analyzed assuming C_{3v} symmetry (9). As expected, three bands due to totally symmetric vibrations and three bands due to doubly degenerate vibrations are observed. The PO_3 symmetric and asymmetric stretching modes

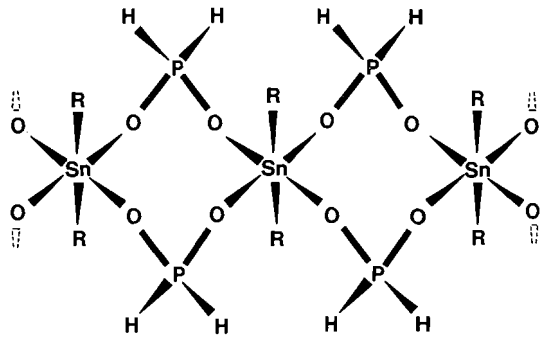

FIG. 1. Suggested structure for $R_2Sn(PO_2H_2)_2$ compounds.

were assigned to a sharp band at 980 cm^{-1} and a broad band at 1100 cm^{-1}, respectively (9). In $(CH_3)_2SnPO_3H$ these bands are shifted to 1015 cm^{-1} and *ca.* 1140 cm^{-1}, and the number of bands observed in the 1000–1200 cm^{-1} region indicates that there is a considerable lowering of the C_{3v} symmetry of the HPO_3^{2-} group. In the other two dialkyltin(IV) phosphites (R = C_2H_5, n-C_4H_9) this region of the spectrum is somewhat obscured by the bands due to the internal modes of the R groups. However, a small shift to higher frequency of ν_sPO_3 is observed. In $(CH_3)_2SnPO_3H$ both asymmetric and symmetric Sn—C_2 stretching frequencies are observed, suggesting a non-linear C—Sn—C arrangement. The high melting points and insolubility in nonpolar solvents of these compounds together with the infrared data suggest polymeric structures involving penta- or hexa-coordinate tin (see Section III).

Support for a polymeric structure for R_2SnPO_3X types comes from a comparison of the infrared spectrum of $(CH_3)_2SnPO_3F$ with that of K_2PO_3F. The following features in the spectrum of the dimethyltin(IV) derivative are significant: (*a*) $\nu_{as}PO_3$ is shifted *ca.* 30 cm^{-1} to lower frequency while ν_sPO_3 is shifted 45 cm^{-1} to higher frequency, (*b*) both $\nu_{as}SnC_2$ and ν_sSnC_2 are observed at 590 and 517 cm^{-1}, respectively, (*c*) νPF is shifted 140 cm^{-1} to higher frequency. Similar, but smaller, shifts in the PF_2 stretching frequencies have previously been observed for dialkyltin(IV) bisdifluorophosphates (4) and are explained in terms of back donation from lone pairs on fluorine into the empty 3d orbitals on phosphorus. The shift in νPF observed for $(CH_3)_2SnPO_3F$ clearly rules

out any F—Sn bonding and the possibility of a tetradentate PO_3F group. Hexacoordination about tin can, therefore, only be achieved if there is one trivalent oxygen per formula unit.

We consider next dimethyltin(IV) orthophosphate, $[(CH_3)_2Sn]_3(PO_4)_2$. The free anion has T_d symmetry and two strong bands corresponding to the anti-symmetrical (ν_3) stretching vibration (*ca.* 1080 cm^{-1}) and the ν_4 anti-symmetrical deformation (*ca.* 500 cm^{-1}) are expected in the infrared spectrum (14). In $[(CH_3)_2Sn]_3PO_4$ the symmetry of the PO_4 group is clearly considerably lowered since at least five bands can be resolved in the 950–1150 cm^{-1} region and three bands are observed in the 500–650 cm^{-1} region. In addition, both ν_sSnC_2 and $\nu_{as}SnC_2$ are observed in the infrared spectrum indicating a non-linear C—Sn—C structure. The infrared spectrum, and the high melting point and insolubility of this compound are consistent with a polymeric structure (see Section III).

III. ^{119}Sn Mössbauer Spectra

The splitting of the $I = 3/2$ excited state of the ^{119}Sn nucleus by an electric field gradient (e.f.g.) is given by

$$\Delta E_Q = \tfrac{1}{2}e^2qQ\,(1 + \eta^2/3)^{1/2}$$

where $eq = V_{zz} = -$(e.f.g.), eQ is the nuclear quadrupole moment, and the asymmetry parameter η is defined as

$$\eta = |V_{xx} - V_{yy}|/V_{zz}$$

The $V_{\alpha\alpha}$ are the diagonal elements of the e.f.g. tensor, chosen such that $|V_{zz}| \geqslant |V_{yy}| \geqslant |V_{xx}|$. A conventional Mössbauer measurement suffices to determine only $|\Delta E_Q|$. However, the application of a large magnetic field (e.g. 15–50 kG) lifts the degeneracy of the m_I substates and the resulting spectral pattern enables one to determine the sign of the quadrupole coupling constant e^2qQ and the magnitude of η. We adopt the usual sign convention for ^{119}Sn that e^2qQ is positive for a prolate charge distribution at the nucleus. Note that since eQ is negative for ^{119}Sn, e^2qQ and V_{zz} carry opposite signs.

Mössbauer isomer shifts (δ, relative to barium stannate), quadrupole splittings, and line widths (Γ, full-width at half-maximum) are given in Table 4, along with data for some related oxyacid derivatives. Two general comments can be made concerning these data. First, ΔE_Q values greater than 3 mm s^{-1} are observed for all the compounds, a fact which strongly suggests penta- or hexacoordination about tin. Second, in every case but one ($(n\text{-}C_4H_9)_2SnPO_3H$) resonant γ-ray absorption at room temperature is seen, indicative of bridged, polymeric structures. Since no special precautions were taken to control carefully the absorber thickness, the R values in Table 4 are only of semi-quantitative significance for inter-sample comparison.

Previously reported (4) infrared, Raman, and Mössbauer data for $(CH_3)_2Sn(PO_2F_2)_2$, and Mössbauer data for $(CH_3)_2Sn(PO_2H_2)_2$ and $(CH_3)_2Sn(HPhPO_2)_2$ are fully consistent with *trans*-octahedral structures in which linear $(CH_3)_2Sn$ groups are bridged by bidentate PO_2XX' moieties, analogous to the structure of $(CH_3)_2Sn(SO_3F)_2$ (10–12).

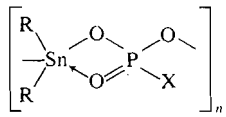

FIG. 2. Pentacoordinate structure for R_2SnPO_3X compounds.

We have now measured the Mössbauer spectrum of $(CH_3)_2Sn(PO_2H_2)_2$ at 4.2 °K in an applied longitudinal magnetic field of 50 kG. The quadrupole coupling constant e^2qQ is positive, confirming the prolate charge distribution expected for a *trans*-octahedral structure. Moreover, $\eta \simeq 0$, consistent with a (nearly) linear C—Sn—C arrangement and the absence of $\nu_s Sn—C_2$ in the infrared spectrum. The similar δ and ΔE_Q values observed for the diethyl- and dibutyltin(IV) hypophosphites leaves little doubt that these derivatives also have *trans*-octahedral structures.

On the other hand the infrared spectra of the $(CH_3)_2SnPO_3X$ compounds (X = F, H, OH) all show a band attributable to $\nu_s Sn—C_2$, and the Mössbauer quadrupole splittings are also somewhat lower than one might expect for oxy-acid derivatives having *trans*-octahedral symmetry. These results suggest that if the tin atom is hexacoordinate in these derivatives there is a fairly strong distortion of the C—Sn—C angle from 180°. Since such a structure also requires one trivalent oxygen per formula unit, it seemed wise to consider the possibility that the $(CH_3)_2SnPO_3X$ derivatives might have pentacoordinate structures (Fig. 2), similar to that proposed for poly(dibutyltin *n*-octylphosphonate) (15). If we assume a regular trigonal bipyramidal arrangement of the groups bonded to tin (distortions will be considered explicitly below), there are three possible configurations of the methyl groups: (*a*) apical–apical; (*b*) apical–equatorial; (*c*) equatorial–equatorial. On the basis of isovalent hybridization ideas one would expect structure (*c*) to be preferred and (*a*) to be highly unlikely. (It should be noted that in the $(CH_3)_2SnCl_3^-$ anion, both methyl groups are in the equatorial plane (16).) Since these various possibilities should lead to differences in η and the sign of e^2qQ, it was hoped that magnetically perturbed Mössbauer spectra together with the other data might allow a choice to be made.

In order to predict the sign of e^2qQ and magnitude of η expected for each of the possible structures we have used the point-charge formalism, in which the e.f.g. is taken to be a sum of contributions from the various ligands L:

$$eq = \sum_L [L](3\cos^2\theta_L - 1).$$

The [L] values are usually referred to as partial quadrupole splittings (p.q.s.). For each of the structures we consider here the e.f.g. tensor can be diagonalized for arbitrary [L] values (17). To observe general trends it is most convenient to calculate η and ΔE_Q as a function of the ratio [X]/[R], where X refers to the more electronegative substituent. It is well established for organotin(IV) compounds that the organic groups make the major contribution to the e.f.g. at tin, so that we need only consider the range $-1 \leqslant [X]/[R] \leqslant 1$. (In principle all p.q.s. values should have the same (negative) sign. However, a recently suggested empirical scale (18) arbitrarily sets $[Cl]^6 = 0$, where the superscript denotes the coordination number of tin in a given compound. On this scale, p.q.s. values for a number of oxy-acid anions have positive values, and for this reason we have included negative values of the ratio [X]/[R] in our calculations.)

In Fig. 3 are plotted calculated values of ΔE_Q (in units of $\frac{1}{2}eQ[R]$) and η for structures (*b*) and (*c*) as a function of [X]/[R]. Since eQ is negative for ^{119}Sn, we have assumed [R] is also negative in order to obtain the correct positive coupling constant for a *trans*-R_2SnX_4 species. For structure (*a*), $\eta = 0$ everywhere and ΔE_Q^{calcd} is a linear function of [X]/[R] ranging in value from $\frac{7}{2}eQ[R]$ to $+\frac{1}{2}eQ[R]$ as [X]/[R] increases from -1 to $+1$. For a *trans*-octahedral structure the corresponding ΔE_Q^{calcd} values range linearly from $+4eQ[R]$ to 0. Because the appearance of $\nu_s Sn—C_2$ in the i.r. spectra of these molecules argues against a linear C—Sn—C arrangement, we have also calculated the effect of distorting the latter two structures by lowering the C—Sn—C angle to 150°. In both cases there is only a small change in ΔE_Q^{calcd} over most of the range of [X]/[R], and for values of this ratio less than 2/3, η does not exceed about 0.4 in either case.

Since the e.f.g. tensor is traceless it is clear that η will be unity whenever one of the diagonal elements vanishes. For structures (*b*) and (*c*), V_{yy} is the first element to vanish as [X]/[R] increases from -1, and in both cases this occurs at [X]/[R] = 2/3. Values of the p.q.s. ratio greater than this are physically unreasonable

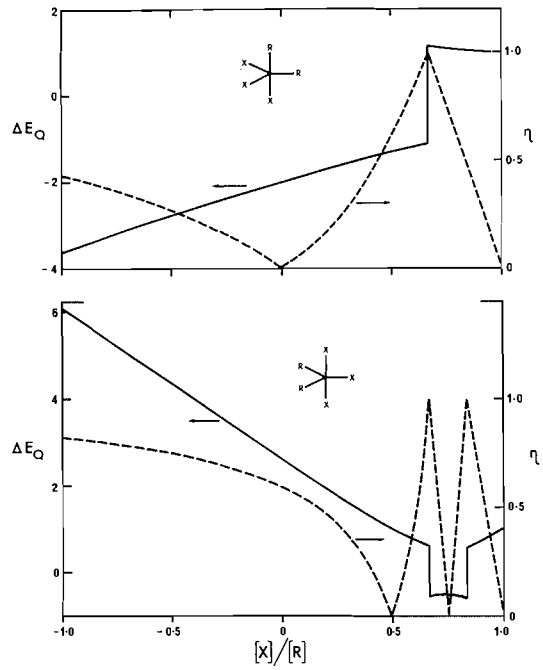

FIG. 3. Calculated values of ΔE_Q (in units of $\frac{1}{2}eQ[R]$) and η as a function of the partial quadrupole splitting ratio of the ligands for two different assumed R_2SnX_3 geometries.

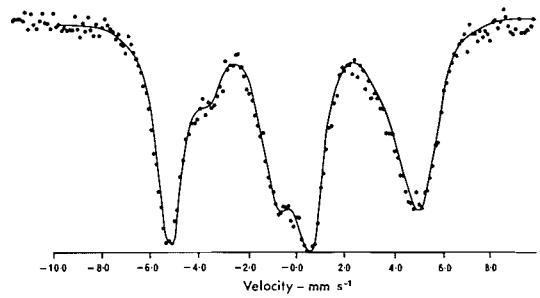

FIG. 4. Mössbauer spectrum of $(CH_3)_2SnPO_3F$ at 4.2 °K in an applied longitudinal magnetic field of 50 kG. The solid curve is the theoretically computed spectrum assuming $\Delta E_Q = +4.16$ mm s^{-1}, $\eta = 0.10$, $\Gamma = 1.20$ mm s^{-1}, $H'' = 50$ kG.

since they would imply that the σ-bonding characteristics of a methyl group and a PO_3X group are nearly the same; thus we need only be concerned with those portions of the curves lying to the left of this point. It should be noted that for structure (*b*) $\Delta E_Q^{\text{calcd}} < 0$ everywhere in this domain of [X]/[R] values while for structure (*c*) $\Delta E_Q^{\text{calcd}} > 0$.

The Mössbauer spectrum of $(CH_3)_2SnPO_3F$ at 4.2 °K in a longitudinal magnetic field of 50 kG is shown in Fig. 4, from which it is clear that e^2qQ is positive and η close to zero. This spectrum has been compared with theoretically computed spectra for a number of different η values, and best agreement is obtained for $\eta = 0.1$. The fit is nearly as good for $\eta = 0$, but noticeably poorer for $\eta = 0.2$, so that the value 0.1 is probably close to an upper limit for η.

While the positive sign of e^2qQ appears to rule out structure (*b*), it is worth considering the effects of distortions from regular trigonal bipyramidal bond angles. For all values of the R—Sn—R angle between the tetrahedral angle and its supplement (keeping all X—Sn—X angles fixed) the sign of e^2qQ remains negative for this structure. Distortions of the equatorial X—Sn—X bond angle between 109.5 and 180° (maintaining R—Sn—R at 90°) also fail to yield a positive e^2qQ for physically acceptable p.q.s. ratios. We, therefore, conclude that $(CH_3)_2SnPO_3F$ does not have structure (*b*).

It is somewhat more difficult to rule out structure (*c*) since the predicted sign of e^2qQ is correct. However, from Fig. 3 it will be seen that for $\eta < 0.1$ the only acceptable [X]/[R] values are those within the narrow range $0.46 < [X]/[R] < 0.52$. To compare the corresponding range of $\Delta E_Q^{\text{calcd}}$ values with the measured quadrupole splitting one would have to assign a p.q.s. value to the methyl group; unfortunately, there is no unique or even unambiguous way of doing this in the present case. What we *can* say is that the very small range of [X]/[R] values consistent with the measured η, and indeed the magnitude of [X]/[R] of about 0.5, make it appear exceedingly unlikely that $(CH_3)_2SnPO_3F$ has a regular structure of type (*c*).

It now remains to investigate the effects of distortions from strict trigonal bipyramidal bond angles for such a pentacoordinate structure. Throughout the region $-1 \leqslant [X]/[R] \leqslant 2/3$ the *z*-axis of the e.f.g. tensor is normal to both Sn—X bond axes (in the undistorted structure (*c*)), from which it follows that very large distortions of the X—Sn—X angles are required in order to cause an appreciable change in either η or $\Delta E_Q^{\text{calcd}}$. On the other hand, distortions of the R—Sn—R angle will have a much more

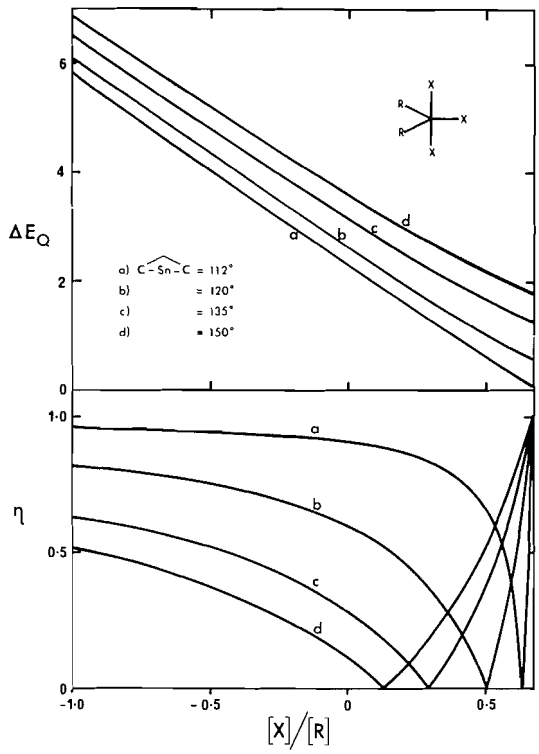

FIG. 5. Calculated values of ΔE_Q (in units of $\frac{1}{2}eQ[R]$) and η for a trigonal bipyramidal R_2SnX_3 compound with equatorial R groups as a function of the R—Sn—R angle. Other angles at tin are assumed to be undistorted.

pronounced influence since the R groups lie in the *yz* plane. We have, therefore, computed η and $\Delta E_Q^{\text{calcd}}$ for a number of R—Sn—R angles with the X—Sn—X angles undistorted. Some of the results are shown in Fig. 5. For an R—Sn—R angle of 109.5°, $V_{xx} = 0$, $V_{zz} = -V_{yy}$ and $\eta = 1$ independent of [X]/[R]; further closing of the angle leads to a negative sign for e^2qQ and results which are qualitatively similar to those for structure (*b*). For R—Sn—R angles greater than 120°, $\Delta E_Q^{\text{calcd}}$ increases monotonically with the bond angle for any value of the p.q.s. ratio $\leqslant 2/3$. At the same time the range of [X]/[R] consistent with $\eta \leqslant 0.1$ widens slightly and shifts towards smaller positive, and eventually negative, values. The net result of increasing the R—Sn—R angle is thus to make such a pentacoordinate structure somewhat more probable. It is appropriate to note, however, that on the p.q.s. scale of Clark *et al.* (18) the PO_3F^{2-} group would be expected (by comparison with data for other oxy-acid anions) to have a p.q.s. value such that the ratio $[PO_3F]/[CH_3]$ would be in the range 0.0 to −0.1. According to our calculations, consistency of this ratio with the observed η value would require a C—Sn—C angle of at least 150°.

We, therefore, appear to be left with three possible structures for $(CH_3)_2SnPO_3F$, none of which is inconsistent with the i.r. and Mössbauer data: distorted *trans*-octahedral, distorted trigonal bipyramidal with apical methyl groups, and trigonal bipyramidal with equatorial methyl groups and a C—Sn—C angle considerably larger than 120°. Of these, we consider the *trans*-octahedral structure to be the most likely, but there seems to be no way of making a definite choice from the available data.

Whatever the actual structure of $(CH_3)_2SnPO_3F$, it is not unreasonable to surmise that the other R_2SnPO_3X compounds reported here have similar structures. Thus in the methyltin derivatives both isomer shift and quadrupole splitting decrease as X is changed from F to H to OH, *i.e.*, as the strength of the parent acid decreases. Such a trend is not unexpected for essentially isostructural compounds (11, 19, 20) and the explanation parallels that given elsewhere (11).

The trends observed in isomer shifts and quadrupole splittings in the two series R_2SnPO_3H and $R_2Sn(PO_2H_2)_2$ (R = CH_3, C_2H_5, *n*-C_4H_9) also merit some comment. In each series δ increases from CH_3 to C_2H_5 and remains essentially constant for C_2H_5 and *n*-C_4H_9. Analogous trends have been observed (4) for dialkyltin(IV) difluorides, bis(difluorophosphates), bis(fluorosulfates), and bis(trifluoromethylsulfonates), as well as for some other isostructural pairs of CH_3 and C_2H_5 organotin compounds (21). In the absence of a significant structural change with change in R, these trends imply a greater electronegativity for CH_3 than for C_2H_5 or *n*-C_4H_9. This is consistent with the group electronegativities reported by Hinze (22) for CH_3 and C_2H_5, although we are not aware of a numerical value for *n*-C_4H_9. In terms of the bonding model we have proposed elsewhere (4, 11) for dialkyltin(IV) salts of oxyacids, the increase in δ from CH_3 to C_2H_5 and *n*-C_4H_9 for a given anion should be accompanied by an increase in ΔE_Q. While this is in fact the case for the $H_2PO_2^-$ salts, the opposite is observed for the HPO_3^{2-} derivatives. All four series of compounds (4)

R_2SnY_2 (R = CH_3, C_2H_5, n-C_3H_7, n-C_4H_9; Y = F, PO_2F_2, SO_3CF_3, SO_3F) show behavior similar to that in R_2SnPO_3H, but the explanation of these trends is not obvious. Conceivably, steric factors could be of importance.

In their Mössbauer spectra at liquid nitrogen temperature, none of the $(CH_3)_2SnPO_2X$ compounds (X = F, H, OH) shows any appreciable difference in width, intensity, or area of the two lines of the quadrupole doublet. However, at room temperature a pronounced integral asymmetry is observed for X = F and H, where the area ratios of high-energy to low-energy lines (A_h/A_l) are 0.74 and 0.83, respectively; there is also some indication of a slight asymmetry in the spectrum of $(CH_3)_2SnHPO_4$ (A_h/A_l = 0.93). This asymmetry is illustrated in Fig. 6 for $(CH_3)_2SnHPO_3$. Since for a given compound spectra at the two temperatures were always recorded on the identical absorber with identical orientation relative to the γ-ray beam, and since no asymmetry is observed at low temperature, these effects cannot be attributed to preferential orientation of the crystallites in the absorbers. The temperature dependence of the quadrupolar asymmetry in these compounds is characteristic of the Gol'danskii–Karyagin effect arising from an anisotropy of the lattice phonon modes, and we surmise this is the effect being observed. It is interesting that similar asymmetry is observed for $(CH_3)_2Sn(H_2PO_2)_2$ but not apparently for $(CH_3)_2Sn(PO_2F_2)_2$ (4) or $(CH_3)_2Sn(SO_3F)_2$ (11).

The remaining derivative, $[(CH_3)_2Sn]_3(PO_4)_2$ gives the lowest δ and ΔE_Q values of all the compounds reported here. Since there are only two phosphoryl groups per three tin atoms in a formula unit, one might expect to find two distinctly different environments for tin in this compound, *e.g.* one tetracoordinate and two pentacoordinate tin atoms. Although the line widths observed for this compound are somewhat broader than those found for the other derivatives they are not sufficiently broad to be interpreted in terms of two different coordination numbers for tin in the compound. In an external magnetic field of 50 kG the Mössbauer spectrum is essentially "first order"; *i.e.*, it does not appear to consist of two overlapping hyperfine-split patterns. Thus any difference in environments of the tin atoms in this compound is not detectable via Mössbauer spectroscopy. The quadrupole coupling constant e^2qQ for

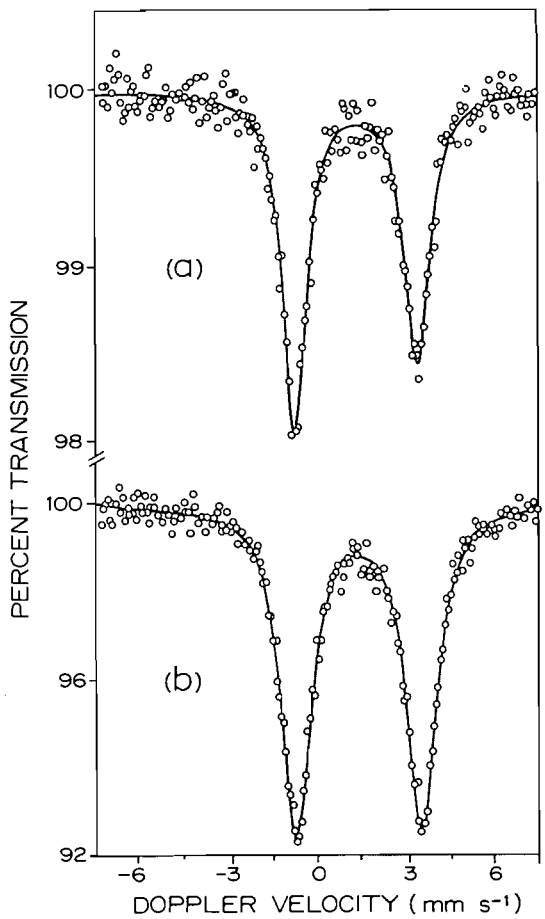

FIG. 6. Mössbauer spectra of $(CH_3)_2SnHPO_3$ at (*a*) room temperature, and (*b*) liquid nitrogen temperature.

$[(CH_3)_2Sn]_3(PO_4)_2$ is positive, as for the other dimethyltin derivatives studied here, but in this case η is large (η ≃ 0.8). This fact argues against a distorted *trans*-octahedral structure, and the ΔE_Q value is considerably larger than expected for a *cis*-octahedral compound. In view of the room-temperature Mössbauer resonance observed we are led to propose a bridged polymeric structure in which all the tin atoms are most probably pentacoordinate. For three five-coordinate tin atoms per formula unit, a total of fifteen bonds to tin are required. Six of these bonds are to CH_3 groups; the remaining nine must be supplied by the two PO_4^{3-} groups. Such a structure must, therefore, necessarily invoke at least one three-coordinate oxygen.

The Reduction of Acetamidopentaamminecobalt(III) by Chromium(II)

ROBERT J. BALAHURA AND LYNDA HUTLEY
Department of Chemistry, University of Guelph, Guelph, Ontario

Received May 25, 1973

The reduction of nitrogen bonded acetamidopentaamminecobalt(III) by chromium(II) has been studied. The acetamido complex is a reasonably strong acid attributed to the equilibrium

$$(NH_3)_5CoNH_2CO(CH_3)^{3+} \rightleftharpoons (NH_3)_5CoNHCO(CH_3)^{2+} + H^+$$

which has a pK_a of 2.16 ± 0.08 at 25.0° and μ = 0.01 *M*. The reduction process has the rate law

$$-\mathrm{d}\ \ln [(NH_3)_5CoNH_2CO(CH_3)]/\mathrm{d}t = k\ [Cr^{2+}]/[H^+]$$

For reduction of the conjugate base $k = k_{NH}K_a$ and $k_{NH} = 5.23 \times 10^{-2}\ M^{-1}\ s^{-1}$ at 25.1°, with ΔH = 14.5 ± 2 kcal mol^{-1} and ΔS = 16 ± 6 e.u. respectively. The rate law is indicative of an inner-sphere process. The orientation of the ligand is thought to be important for the reduction of the acetamido and the related carboxylato complexes, and this is discussed.

On a étudié la réduction par le chrome(II) du complexe acétamidopentaamine cobalt(III) lié à l'azote. Le complexe acétamido est un acide relativement fort obéissant à l'équilibre suivant:

$$(NH_3)_5CoNH_2CO(CH_3)^{3+} \rightleftharpoons (NH_3)_5CoNHCO(CH_3)^{2+} + H^+$$

et dont le pK_a est égal à 2.16 ± 0.08 à 25 °C (μ = 0.01 *M*). Le processus de réduction obéit à l'expression de vitesse suivante:

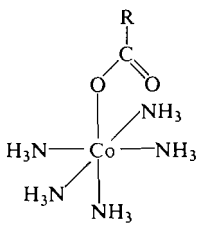
$$-\mathrm{d}\ \ln [(NH_3)_5CoNH_2CO(CH_3)]/\mathrm{d}t = k\ [Cr^{2+}]/[H^+]$$

Pour la réduction de la base conjuguée, la constante k est égale à $k_{NH}K_a$ ou $k_{NH} = 5.23 \times 10^{-2}\ M^{-1}\ s^{-1}$ à 25.1°; de même les valeurs de ΔH et de ΔS sont respectivement de 14.5 ± 2 kcal mol^{-1} et de 16 ± 6 u.e. L'expression de vitesse est caractéristique d'un processus du type sphère interne. L'orientation du coordinat est, semble-t-il, importante pour ce qui est de la réduction du groupe acétamido et des complexes carboxylate semblables; cette dernière relation est d'ailleurs discutée.

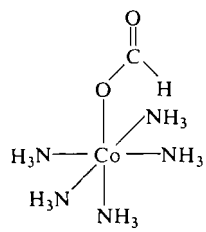
[Traduit par le journal]

Can. J. Chem. **51**, 3712 (1973)

The reduction of formatopentaamminecobalt(III) by chromium(II) is approximately twenty times faster than the reduction of the corresponding acetato complex (1). The small variation in rates for the reduction of $(NH_3)_5CoO_2C{-}R^{2+}$ for R = CH_3, C_6H_5, $ClCH_2$, Cl_2CH, and CF_3 can satisfactorily be explained by considering changes in steric requirements due to the R groups. Inductive effects appear to have a negligible effect on the rate of reduction. The rather large rate difference between the formato and the remaining carboxylato complexes may be a result of a different orientation of the bound formate with respect to the other carboxylates. The two possible configurations are shown below.



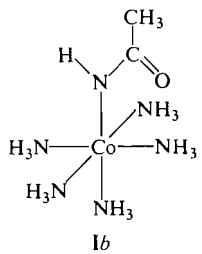
Ia



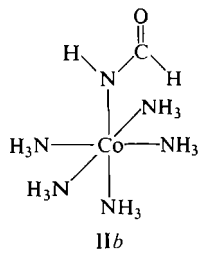
IIa

If configuration **I***a* is adopted by all the carboxylates except formate then regardless of whether the reductant attacks at the carbonyl or bound oxygen only small variations in rate due to steric effects would be expected. Based on models, one would predict that configuration **II***a* is only possible for the formato complex and would result in complete exposure of the carbonyl oxygen to attack by the reductant. Thus a much faster reduction rate might be anticipated.

The same argument can be applied to the reduction of the analogous formamido and acetamidopentaamminecobalt(III) complexes given below.



Ib



IIb

The chromium(II) reduction of formamido-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

For personal use only.

pentaamminecobalt(III) proceeds by attack of the reductant at the carbonyl oxygen producing $(OH_2)_5CrOC(H)NH_2^{3+}$ as product (2). It was of interest to study the reduction of the acetamidopentaamminecobalt(III) complex, **I***b*, in order to test the previous arguments.

Experimental Section

Reagents

Standard solutions of perchloric acid, lithium perchlorate, and chromous perchlorate were prepared as described previously (2).

All solutions for kinetic runs were handled using standard syringe techniques under an argon atmosphere.

Preparation of $[Co(NH_3)_5NHCO(CH_3)](ClO_4)_2$

Twenty grams of aquopentaamminecobalt(III) perchlorate were dissolved in approximately 100 ml of trimethylphosphate (or triethylphosphate) containing molecular sieves. To this solution 40 g of acetamide were added and the mixture heated on a steam bath for 4 h. After cooling. the mixture was filtered and the filtrate added to a solution of 500 ml of *s*-butyl alcohol and 500 ml diethyl ether in order to precipitate the complex. The complex so obtained was recrystallized from warm water and submitted to cation exchange chromatography on Rexyn 102(H) in the sodium ion form. The required complex was moved down the column with 0.3 *M* NaCl leaving behind higher charged species. The former was eluted from the column with 0.6 *M* NaCl and solid $NaClO_4$ added to precipitate the complex. This complex was recrystallized once from a dilute solution of $NaClO_4$.

Anal. Calcd. for $[(NH_3)_5CoNHCO(CH_3)](ClO_4)_2$: C, 6.00; H, 4.74; N, 21.0. Found: C, 6.08; H, 4.75; N, 20.9.

The visible absorption spectrum in water shows maxima at 251 nm (ε, 2.4 × 10^3), 351 nm (ε, 83.5), and 486 nm (ε, 71.1). In 1.0 *M* perchloric acid the protonated species $(NH_3)_5CoNH_2CO(CH_3)^{3+}$ predominates and has maxima at 341 nm (ε, 57.5) and 477 nm (ε, 61.5), with no maximum in the ultraviolet.

Solid $[(NH_3)_5CoNH_2CO(CH_3)](ClO_4)_3$ can be obtained by dissolving the basic form in water and adding concentrated perchloric acid until precipitation begins. This solid should not be washed with EtOH or ether since this causes removal of a proton and yields a mixture of the acidic and basic forms. Titration of a 5.8 × 10^{-3} *M* solution of $[(NH_3)_5CoNH_2CO(CH_3)](ClO_4)_3$ with 0.1 *M* KOH gave an equivalent weight of 496 as compared to the theroretical value of 502.

Determination of Ionization Constants

The equilibrium constant for the reaction

$$(NH_3)_5CoNH_2CO(CH_3)^{3+} \rightleftharpoons (NH_3)_5CoNHCO(CH_3)^{2+} + H^+$$

was determined potentiometrically by titrating 0.01 *M* solutions of the acid form of the complex with 0.1 *M* KOH at 25.0, 35.0, and 45.0 °C. An apparent pK_a was also evaluated spectrophotometrically at 265 nm at a constant ionic strength of 1.0 *M* using $LiClO_4$. The pK_a values were evaluated using the procedures outlined by Albert and Serjeant (3).

Kinetic Measurements

All reactions were carried out in cylindrical cells sealed with rubber serum caps in the absence of oxygen.

The reactions were run under pseudo first order conditions (reductant in a 15–20 fold excess over oxidant). The observed rate constant was determined from the slope of a plot of log $(A_t - A_\infty)$ *vs.* time, where A_t and A_∞ are the absorbances at time t and after the reaction is complete. The rate constant was also determined using the Guggenheim method (4). The latter method was found to be, in general, more reliable because the long reaction times made A_∞ difficult to determine due to air oxidation.

All reactions were followed by observing the decrease in absorbance of the cobalt(III) complex at 485 nm. Absorbance *vs.* time data was acquired using a Beckman Acta C111 Spectrophotometer. The temperature of the solution in the spectrophotometer cell was controlled by pumping water from a Colora constant temperature bath through special blocks which housed the cells. The temperature of the bath was regulated with a Thermistemp controller, with the thermistor probe inserted in the block which housed the cell.

Product analysis was carried out by ion exchange on Dowex 50W-X8 cation exchange resin at 0 °C using standard methods. The products were characterized spectrophotometrically. The extinction coefficients were determined using the chromium concentration which was determined spectrophotometrically as chromate. The stoichiometry of the reaction was shown to be 1:1 by collecting total chromium for a reaction where Co(III) and Cr(II) were the same.

Physical Measurements

p*H* measurements were made with a Radiometer model 26, p*H* meter.

Proton magnetic resonance spectra were obtained with a Varian A60 spectrometer.

Infrared spectra were recorded on a Beckman IR 12 Spectrophotometer.

Results

The analytical results are consistent with formulation of the complex as $(NH_3)_5CoNHC(=O^{2+})CH_3$.

It is important to establish the bonding atom unambiguously since there is a possibility of acetamide being bonded via the carbonyl oxygen as well as via the nitrogen of the NH_2 group.

Qualitatively, the complex is orange in color as expected for nitrogen coordination, as opposed to pink for oxygen coordination. The visible spectrum is also consistent with nitrogen bonding and is almost identical to that found for $(NH_3)_5CoNHC(=O^{2+})H$ (2).

The proton magnetic resonance spectrum shows the expected resonances due to the coordinated ligand $-CH_3$ at 8.03 τ and H—*H* at 6.27 τ. Also, the resonance due to the four *cis*-NH_3

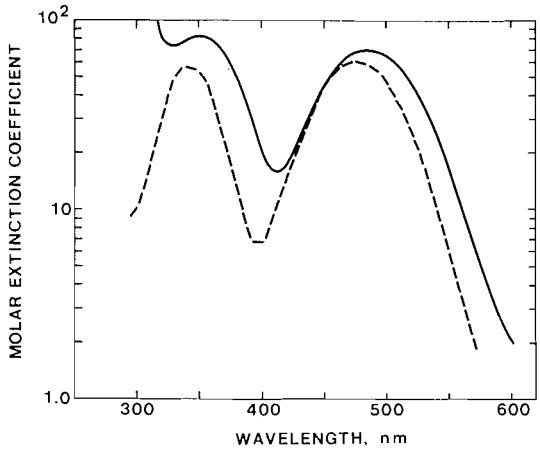

FIG. 1. Visible spectra of $[(NH_3)_5CoNHC(O)CH_3](ClO_4)_2$ in H_2O (—), and 1.0 *M* $HClO_4$ (---).

and the *trans*-NH_3 protons occurs at 6.77 τ. The latter observation is also indicative of nitrogen bonding as discussed previously (2).

The fact that the complex undergoes an acid–base reaction in the p*H* region 1–6 is the best evidence that the nitrogen is coordinated to cobalt. Since acetamide has a pK_a of approximately 14, a large enhancement of acidity would only be expected for protons which are bonded to the atom adjacent to $(NH_3)_5Co^{3+}$.

The large differences in the u.v. and visible spectra of the acetamido complex in H_2O and 1.0 *M* $HClO_4$ are then especially indicative of nitrogen coordination. The differences in the spectra are shown in Fig. 1. These changes are identical to those observed for the formamido (2) and sulfamato (5) complexes. The difference in the spectra in acidic and neutral solution can be understood in terms of the following acid–base equilibrium.

$$(NH_3)_5CoNH_2C(=O)CH_3^{3+} \underset{}{\overset{K_a}{\rightleftharpoons}} (NH_3)_5CoNHC(=O)CH_3^{2+} + H^+$$

The equilibrium constant for the above reaction was determined potentiometrically by titration of the acidic form with 0.1 *M* KOH. The pK_a's at 25.0, 35.0, and 45.0 °C are 2.16 ± 0.08, 2.04 ± 0.10, and 1.95 ± 0.10 respectively. These values give $\Delta H^0 = 4.8 \pm 3$ kcal mol^{-1} and $\Delta S^0 = 6 \pm 8$ cal mol^{-1} deg^{-1}.[1] At 25.0 °C the apparent pK_a determined spectrophotometrically at $\mu = 1.0$ ($LiClO_4$) is 2.94 ± 0.20. The increase in pK_a upon increase in the ionic strength results from stabilization of the higher charged species in the higher ionic strength medium. These values are consistent with those obtained previously for the formamide complex: 1.63 at low ionic strength and 2.16 at $\mu = 1.0$ $(LiClO)_4$. We have obtained a pK_a of 1.59 ± 0.08 for the formamide complex by potentiometric titration at 0.02 *M* in good agreement with the previously quoted value which was obtained spectrally.

A consideration of simple inductive effects would predict that the acetamide complex should be a weaker acid than the formamide complex due to the electron releasing effect of the methyl group in agreement with the experimentally determined values.

The infrared spectra of the acidic and basic forms of the complex are indicative of a delocalized system as shown.

$$(NH_3)_5CoN(H)=C(-O)CH_3^{2+}$$

The carbonyl stretching frequencies of the acid and base forms of the complex appear at 1695 cm^{-1} and 1560 cm^{-1} as opposed to 1714 cm^{-1} for the free ligand (6). One would expect the ν(C=O) for the acidic form to be very near the free ligand value since delocalization is not possible for this complex. The crystal structure of the basic form also indicates that the O=C=N system is delocalized (7).

The reduction of the acetamido complex was found to obey the following rate law:

$$[1] \quad \frac{-d \ln [(NH_3)_5CoNH_2CO(CH_3)]}{dt} = \frac{k[Cr^{2+}]}{[H^+]} = k_{obs}[Cr^{2+}]$$

[1]The errors assigned to the pK_a's were determined by taking the scatter from the mean of a set of results as defined in ref. 3. The rather large errors in ΔH^0 and ΔS^0 result from the overlap between data obtained at successive temperatures. The reproducibility of the results from determination to determination is ±0.02 pK_a unit which suggests a smaller deviation than is the case.

*μ = 1.0 ($LiClO_4$).
†Concentrations are initial values in molar units.
‡It is estimated that the individual rate constants are accurate to within 4%.

The data are given in Table 1. Figure 2 shows a plot of k_{obs} *vs.* $[H^+]^{-1}$ which is linear as predicted by the rate law. This rate law is consistent with the mechanism

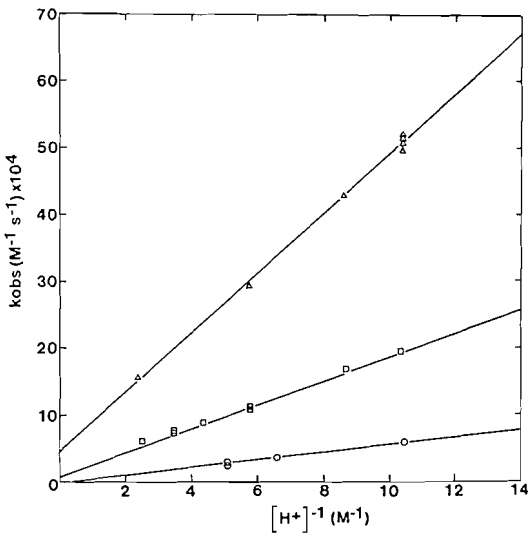

FIG. 2. Dependence of the reduction rate of acetamidopentaamminecobalt(III) by chromium(II) on [H^+], μ = 1.0 M ($LiClO_4$), ○, 25.1; □, 35.1; △, 45.0 °C.

$$(NH_3)_5CoNH_2CO(CH_3)^{3+} \underset{}{\overset{K_a}{\rightleftharpoons}} (NH_3)_5CoNHCO(CH_3)^{2+} + H^+$$

$$(NH_3)_5CoNHCO(CH_3)^{2+} + Cr^{2+} \xrightarrow{k_{NH}} \text{Products}$$

This mechanism gives the rate law

$$[2] \quad \frac{-d \ln [(NH_3)_5CoNH_2CO(CH_3)]}{dt} = \frac{k_{NH}K_a}{K_a + [H^+]} [Cr^{2+}]$$

Since $[H^+] \gg K_a$ for all the runs, $k = K_a k_{NH}$. The specific rate constant k_{NH} can be determined from the slope of the lines in Fig. 2 divided by the K_a at the appropriate temperature. Table 2 gives a summary of the kinetic parameters.

The intercept corresponding to the plots in Fig. 2 could represent the reduction of $(NH_3)_5CoNH_2CO(CH_3)^{3+}$. The values of the intercepts obtained from the least-squares treatment gave -1.4×10^{-5}, $+1.4 \times 10^{-4}$, and 5.3×10^{-4} M^{-1} s^{-1} at 25, 35, and 45 °C respectively. These values are approximately 500 times smaller than those for k_{NH} and could not be reliably estab-

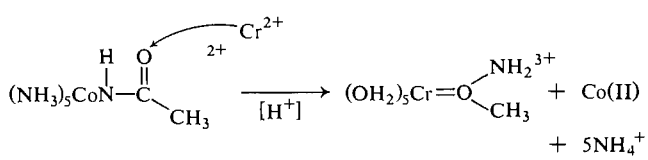
lished due to the difficulty in obtaining accurate data at high hydrogen ion concentrations.

The nature of the "products" in the proposed mechanism were investigated by cation exchange chromatography of reaction mixtures. In all cases only $Cr(OH_2)_6^{3+}$ was isolated when an oxygen bonded acetamide complex of $(OH_2)_5Cr^{3+}$ might be expected. However, due to the long times (10–30 h) involved for the reactions this initial product would probably be hydrolyzed to $Cr(OH_2)_6^{3+}$. In one analysis with [Co(III)] = 0.01, [Cr(II)] = 0.01 and $[H^+]$ = 0.07 the extinction coefficients of the Cr(III) product were higher than those of $Cr(OH_2)_6^{3+}$ and indicate that at least some acetamide complex remains after the long work up time. It was not possible to isolate this complex by further chromatography.

Discussion

The product analysis indicates that the final chromium(III) complex formed in the reaction is the hexaaquo ion. This would imply that an outer-sphere mechanism is the preferred mode of reaction. However, an outer-sphere reaction would not be expected to be sensitive to hydrogen ion concentration and the strong inverse hydrogen ion dependence indicated in the rate law favors the inner-sphere path. Following the arguments put forth regarding the reduction of the formamido complex the reaction of the acetamido complex probably also proceeds via attack at the carbonyl oxygen with initial transfer of the ligand as shown below:



The delocalized O=C=N bond system which is possible only in the basic form of the complex seems to provide the most favorable electron transfer path.

A comparison of the rate of reduction of the acetamido and formamido complexes at 25.0 °C shows that the latter is reduced about 34 times faster than the former. This could be due to the steric requirements of the acetamido complex. In this case, the methyl group would be forced up and away from the *cis*-ammines in the cobalt complex while the carbonyl oxygen is pointing down between two of the *cis*-ammines, **I***b*. This arrangement would sterically hinder attack at the carbonyl oxygen by the reductant. In the formamido complex the smaller hydrogen atom can point down between the two *cis*-ammines thus leaving the carbonyl oxygen pointing away from the plane of the *cis*-ammines and completely exposed to attack by the reductant, **II***b*. The same arguments can be applied to the reduction of the formato and acetato complexes. The similarity in the rate differences between the formato–acetato and formamido–acetamido systems supports the above arguments.

The crystal structures of the acetato (8) and acetamido (7) complexes indicate that, at least in the solid state, configuration **I** is adopted. More pertinent to solution studies is the fact that the formato complex has been shown to exist in configuration **II** by the observation of a nuclear Overhauser effect (9).

The authors wish to thank the National Research Council of Canada for an operating grant to R.J.B. (A6642) and also the referees for helpful criticism.

Kinetics of the Gas Phase Reactions of (+)-*trans*-2,3-Divinyloxirane

ROBERT J. CRAWFORD, VESNA VUKOV, AND HIROKAZU TOKUNAGA
Department of Chemistry, University of Alberta, Edmonton, Alberta T6G 2G2

Received July 20, 1973

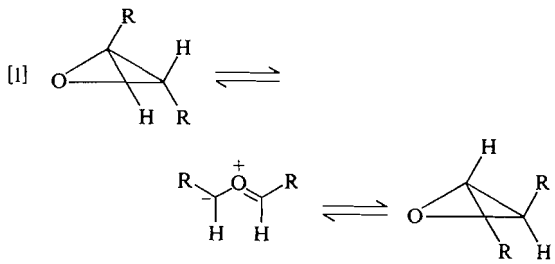
The racemization of (+)-2,3-divinyloxirane is facile at 150°, $\log (k_1/s^{-1}) = (11.3 \pm 0.5) - (30.1 \pm 0.4)/\theta$ where $\theta = 2.303RT$ in kcal mol^{-1}. A slower but competitive rearrangement yields racemic 2-vinyl-2,3-dihydrofuran. The mechanisms of these reactions are discussed in terms of electrocyclic processes.

La racémisation du (+) divinyl-2,3 oxiranne est facile à 150°, $\log (k_1/s^{-1}) = (11.3 \pm 0.5) - (30.1 \pm 0.4)/\theta$ où $\theta = 2.303RT$ exprimé en kcal/mol. Un réarrangement beaucoup plus lent mais compétitif conduit au vinyl-2 dihydro-2,3 furanne racémique. Les mécanismes de ces réactions sont discutés en termes de processus électrocycliques. [Traduit par le journal]

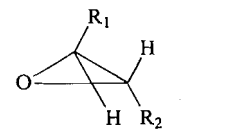
Can. J. Chem. **51**, 3718 (1973)

Introduction

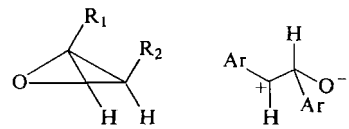
Thermally induced isomerizations of strained cyclic systems offer an excellent means of studying bond cleavage processes, thus cyclopropanes have been extensively studied (1). Oxiranes provide a similar vehicle with which to study both carbon–carbon and carbon–oxygen cleavage. Although such studies have been plagued by surface catalysis, recently there have been reported several studies which have minimized this drawback (2). The racemization of oxiranes offers a unique probe in examining the reaction in greater detail since it provides the most sensitive method of detecting the reversible electrocyclic process of carbonyl ylide formation (eq. 1) (3). We have previously examined, in



solution, the racemization and the *cis–trans* isomerization of 2,3-diaryloxiranes (3). The oxirane **1***a* racemizes, at 207°, 220 times more rapidly than it undergoes *trans* to *cis* isomerization. This observation was explained in terms of the carbonyl ylide intermediate for the racemization process. However it is not clear as to how the geometrical isomerization occurred. One possibility involves the intervention of a zwitterion species, *e.g.* **3**, produced by a carbon–oxygen heterolytic cleavage of **1***a*. Analogous intermediates have been implicated by Yankee and Cram (4) for the reactions of substituted cyclopropanes in solution.



1



2 **3**

a R_1 = phenyl; R_2 = *p*-tolyl
b $R_1 = R_2$ = vinyl

In order to minimize the complication of zwitterion formation, we have chosen an oxirane system that is readily isomerized in the gas phase. Both *cis*- and *trans*-2,3-divinyloxirane (**1***b* and **2***b*) have been synthesized and their conversions to vinyldihydrofuran (**4**) and 4,5-dihydrooxepin (**5**) have been observed (5, 6).

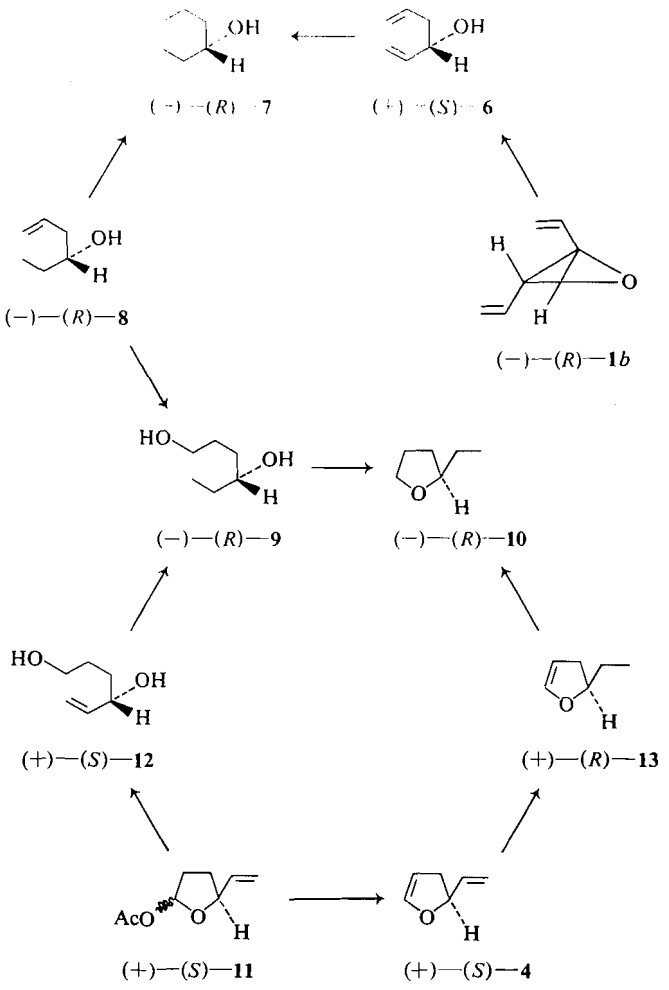

SCHEME 1

Results

(a) Synthesis and Stereochemistry

Chiral **1***b* was prepared in two ways. When samples prepared by the partial asymmetric destruction of **1***b* using di-3-pinanylborane (7) were studied, a significant infinity rotation was observed. Subsequently we prepared and resolved, via the brucine salt of the phthalate half-ester, samples of *threo*-4-chloro-1,5-hexadien-3-ol. The infinity rotations observed in the racemization studies of the oxirane prepared in this latter manner were essentially equal to zero. The absolute configuration and optical purity of **1***b* has been correlated with **4** and with (+)-3-hexanol (8) (Scheme 1). The rotational data for each of the compounds used are listed in Table 1.

(b) Kinetics of the Conversion of 1b to 4 and 5

Vogel and Gunther (5) have referred, in a footnote, to an earlier study carried out in Cologne and report $\Delta H^{\ddagger} = 36.0$ kcal mol^{-1} and $\Delta S^{\ddagger} = -0.4$ e.u. The product proportions (**4** and **5**) were said to be "practically independent of temperature", and thus it was concluded that **4** and **5** likely arise from a common intermediate. It was necessary for our purposes to define more exactly the kinetics and any temperature dependence of the product ratio. Table 2 gives the rate data and the product proportions observed from samples of **1***b* at 700 Torr. The samples were analyzed by gas chromatographic (g.c.) techniques using 1,2-dimethoxyethane as an internal standard and a Hewlett Packard

3370A electronic integrator. A typical rate study is given in the Experimental section. Partitioning the data into separate rate constants gives the activation parameters indicated in Table 3. The rate constants correspond to those indicated in Scheme 2.

(c) Racemization of 1b

Samples of **1***b* were degassed in Pyrex break-seals and the amount was adjusted to give 1 atm at 150°. The samples were heated for the appropriate length of time in a well thermostated oil bath. After quenching the reaction in an ice-water bath the break-seals were attached to the vacuum line, opened, and the contents transferred to a tared 1-ml volumetric flask. The contents of the flask were allowed to come to room temperature and the flask was removed from the vacuum line and weighed. In each case the vapor transfer was quantitative. 2-Propanol was then added to a volume of 1 ml and the weight of the solution measured accurately. The concentration of **1***b* in 2-propanol was calculated on a percentage weight basis to avoid volumetric errors. The rotations of the solutions, at 25°, were then measured at four wavelengths and the appropriate

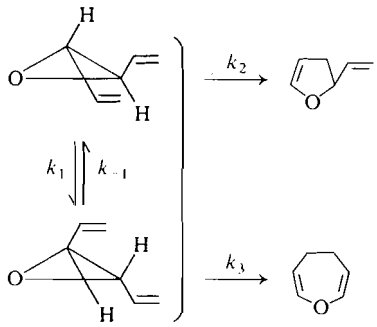

SCHEME 2

cell corrections were made. A typical run is given in the Experimental section. Using data obtained at 365 nm, rate constants could be duplicated to within $\pm 1\%$. The rate data for the racemization is listed in Table 4. The observed rate of loss of optical activity is given by k_α and the value for k_1 was obtained from the relationship $2k_1 = k_\alpha - (k_2 + k_3)$. The values of k_2 and k_3 were obtained by extrapolation from the rates at higher temperatures. The activation parameters for the rate k_1 are listed in Table 3 along with those for the other processes measured.

(d) Stereochemistry of the Formation of **4**

The formation of **4** may occur via a sigmatropic $\sigma^2a + \pi^2s$ process (9) in which case (−)-(*R*)-**1***b* would produce (−)-(*R*)-**4** by inversion of the migrating center. Upon inspection of molecular models it would seem that a $\sigma^2s + \pi^2a$ process is not a probable pathway. It is possible that **4** is produced from **1***b* via a carbonyl ylide, in which case the **4** produced directly from chiral **1***b* would be racemic. Chuche and collaborators (10) have invoked carbonyl ylides to explain the stereochemistry of the dihydrofurans produced from vinyloxiranes. Control samples of **4** did not racemize at temperatures less than 250°. A sample of (−)-(*R*)-**1***b* of 81.3% optical purity was heated to 200.01 ± 0.02° for 10.5 h and the vinyldihydrofuran (**4**) was separated and purified by preparative gas chromatography. The 2-vinyl-2,3-dihydrofuran produced was greater than 99.6% racemic. Taking into account the competitive racemization of **1***b* the **4** produced would have displayed a $[\alpha]^{25}_{365}$ −4.70°.[1] The value observed, +0.285°, is indicative of a small excess of retention over inversion. The size of the measured rotation, +0.068°, at 365 nm, could be due to trace impurities even though care was taken to prevent such possibilities.

[1]From optically pure **1***b* we would expect to find **4** of $k_2/0.698k_\alpha$ enantiomeric purity. At 200° this ratio is 0.0659. The factor 0.698 comes from the percentage of **4** in the final mixture of **4** and **5**.

Experimental

The i.r. spectra were obtained on a Perkin-Elmer 421 Spectrophotometer and the n.m.r. spectra were obtained using a Varian A-60. All rotations were measured in a thermostated cell on a Perkin-Elmer Model 141 Polarimeter. Preparative gas chromatography (g.c.) was carried out using a Nester Faust Model 850 Prepkromatic.

Resolution of trans-2,3-Divinyloxirane (1b) by Di-3-pinanylborane

A mixture of racemic **1***b* (5.10 g, 20 mmol) and diglyme (5 ml) was placed in a 50-ml three-necked flask equipped with a condenser, magnetic stirrer, and a rubber septum. The mixture was cooled to −20° and kept under an atmosphere of nitrogen. Di-3-pinanylborane (20 mmol) in diglyme was introduced, using a syringe, in a dropwise manner through the rubber septum. The reaction mixture was maintained at −20° for 1 h and then allowed to warm to 0°. Water (5 ml) was added and the mixture distilled at 10 Torr. The distillate consisted of unreacted **1***b*, some (+)-α-pinene, water, and diglyme. After drying over anhydrous sodium sulfate the unreacted **1***b* was isolated by preparative g.c. (10 ft, 15% β,β′-oxydipropionitrile on firebrick, 60°). The presence of about 1% of **5** was indicated as the only impurity by analytical g.c. The recovered **1***b* (2.0 g) was optically active $[\alpha]^{24}_{365}$ −8.74° (5.33 g/100 ml, 2-propanol), calculated optical purity of 8.14%.

Preparation of (+)-(S)-1,5-Hexadien-3-ol (6) from (−)-(R)-1b

The epoxide (−)-(*R*)-**1***b* (300 mg, 3.1 mmol, optical purity 8.14%) in dry ether (2 ml) was added dropwise to a solution of lithium aluminum hydride (0.114 g, 3.1 mmol) in dry ether (6 ml). After the addition, the mixture was stirred at room temperature for 3 h. The excess hydride was then destroyed by the addition of moist ether at 0°. The aluminate complex was decomposed by the addition of 3 *M* sodium hydroxide and the solution extracted three times with ether. After drying over anhydrous sodium sulfate the ether layer was concentrated by fractional distillation and the product (+)-(*S*)-**6** was isolated by preparative g.c. (15% carbowax on chromosorb B, 70°), $[\alpha]^{25}_{365}$ +9.15° (2.12 g/100 ml, 2-propanol). The n.m.r. and i.r. spectra of the product were identical with an authentic sample (11).

Diimide Reduction of (+)-(S)-6 to (−)-(R)-3-Hexanol (7)

A sample of (+)-(*S*)-**6** (2.7 g, 27 mmol), $[\alpha]^{25}_{365}$ +49.73° (10.2 g/100 ml, 2-propanol) obtained by resolution of the brucine salt of 1,5-hexadien-3-yl hydrogen phthalate, was placed in a 500-ml flask along with sodium azodicarboxylate (17.8 g, 137 mmol) in methanol (220 ml). The suspension was stirred and acetic acid (13.2 g, 220 mmol) in methanol (137 ml) was added dropwise. After stirring for an additional 30 min water was added

until the yellow color disappeared. The mixture was extracted several times with pentane and the combined extracts were dried over anhydrous sodium sulfate. The drying agent was then removed and the solution distilled through a Vigreux column. Yield, 2.1 g (80%); b.p. 129°/700 Torr; $[\alpha]^{22}_D$ −2.593° (neat, l = 1 dm, density 0.819 g ml^{-1}); $[\alpha]^{22}_{365}$ −4.950° (neat, l = 1 dm, density 0.819 g ml^{-1}); $[\alpha]^{22}_D$ −3.314° (5.26 g/100 ml, 2-propanol). Kenyon and Poplett (8) give $[\alpha]^{22}_D$ −7.13° for optically pure (−)-(*R*)-3-hexanol. The n.m.r. and i.r. spectra were identical with those of an authentic sample of 3-hexanol.

*Resolution of 5-Hexen-3-ol (**8**)*

The alcohol, **8**, was prepared by the procedure of Gaudemar (13) using activated zinc, allyl bromide, and propionaldehyde in tetrahydrofuran (THF). The alcohol was partially resolved through its phthalate half-ester following the procedure of Levine and Haller (12). See Table 1 for the rotational data.

*Preparation of (−)-(R)-1,4-Hexanediol (**9**) from (−)-(R)-**8***

A solution of diborane in THF (23 ml, 15 mmol) at 0° was added dropwise to (−)-(*R*)-**8** (3.0 g, 25 mmol) in dry THF (75 ml). The mixture was stirred 30 min before the excess diborane was decomposed with moist THF at 0°. Sodium hydroxide (45 ml, 3 *M*) was added followed by hydrogen peroxide (15 ml, 30%) while the temperature was maintained at 30–50°. After 1 h solid potassium carbonate (40 g) was added and the THF layer separated. The aqueous layer was extracted twice with THF and the THF portions combined and dried over anhydrous magnesium sulfate. The drying agent was removed by filtration and fractional distillation gave the product **9** (3.2 g, 90%), b.p. 128–131°/16 Torr (lit. (14) 134–135°/19 Torr). Analysis by g.c. indicated the presence of 3% of 2,4-hexanediol as the only impurity. The rotational data is given in Table 1.

*Preparation of (−)-(R)-2-Ethyltetrahydrofuran (**10**) from (−)-(R)-**9***

The procedure used was essentially that of Coates and Melvin (15). *p*-Toluenesulfonyl chloride (5.2 g, 27 mmol) was added slowly to a solution of (−)-(*S*)-**9** (3.6 g, 25 mmol) in dry pyridine (36 ml) maintained at 0°. The reaction mixture was allowed to warm to room temperature and stirring continued for 30 min. Cold water was then added and the reaction mixture was extracted six times with pentane. The pentane extracts were combined and washed with 2 *N* hydrochloric acid then dried over anhydrous magnesium sulfate. Careful fractionation through a spinning band column gave (−)-10 (0.97 g, 30%) of greater than 99% purity by g.c., b.p. 106°/700 Torr (lit. (16) 108°/758 Torr).

*Resolution of 2-Acetoxy-5-vinyltetrahydrofuran (**11**)*

A solution of **11** (65.4 g, 420 mmol) (17) in dry THF (50 ml) was added over a period of 1 h to a suspension of di-3-pinanylborane (7) (160 mmol) in ether and diglyme at −15 to −20°. The reaction mixture was stirred for 4 h at 0° and then water (6 ml) was added to destroy the excess borohydride. All of the volatile components were then distilled at 0.1 Torr and 50°. The crude distillate contained diglyme, α-pinene, ether, and (+)-(*S*)-**11**. Fractional distillation gave 20.4 g (63%) of **11**, b.p. 68–71°/4.5 Torr (17). See Table 1 for rotational data.

While the method of synthesis of **11** (17) does not preclude an isomeric pair, the reactant was primarily of one isomer, as judged by n.m.r., and after the resolution process consisted of a ratio of 20:1. No attempt was made to identify these isomers.

*Preparation of (+)-(S)-3-Vinyl-2,3-dihydrofuran (**4**) from (+)-(S)-**11***

A solution of (+)-(*S*)-**11** (20 g, 138 mmol) in ether (160 ml) was passed slowly, in a stream of nitrogen, through a column of glass beads heated to 245°. The condensate from the Dry-Ice – acetone trap was then washed three times with a saturated sodium carbonate solution and dried over anhydrous sodium sulfate. After filtration the solution was concentrated to 10 ml and then subjected to preparative g.c. (column 6 ft, β,β′-oxydipropionitrile, 60°). Yield 3.6 g (30%) of (+)-**4**. See Table 1 for rotational data. The n.m.r. and i.r. spectra were identical to those obtained from an authentic sample.

*Diimide Reduction of (+)-(S)-**4** to (+)-(R)-**13***

The technique used to reduce **4** to **13** was essentially that described above for the reduction of **6** to 7. Some reduction (approximately 10%) to **10** did occur, but the major product isolated by preparative g.c. (6 ft, β,β′-oxydipropionitrile, 60°) was (+)-(*R*)-**13** (68%). The n.m.r. spectrum δ_{TMS} ($CDCl_3$): 0.96 (t, 3H, CH_3); 1.59 (*q*, 2H, —CH_2—); 7.5 (m, 2H, ring CH_2); 4.5 (m, 1H, 3° ring H); 4.86 (*q*, 1H, *J* = 2.8 Hz, vinyl H); 6.26 (*q*, 1H, *J* = 2.5 Hz, vinyl H).

*Reduction of (+)-(R)-**13** to (−)-(R)-2-Ethylfuran (**10**)*

A solution of sodium borohydride (170 mg, 4.47 mmol) in methanol (4 ml) was added dropwise to a solution of rhodium trichloride trihydrate (342 mg) in methanol (90 ml). Charcoal (2 g) was then added to the solution under an atmosphere of nitrogen. The flask was then immersed

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

in a Dry-Ice – acetone bath and (+)-(*R*)-**13** (1.7 g, 17 mmol) was added. Hydrogen was then passed through the flask for 4 h at −78°, 2 h at −30°, and 2 h at 0°. The reaction mixture was filtered and 200 ml of water was added. The solution was extracted with pentane and the pentane layer, after drying over anhydrous sodium sulfate, was concentrated to 10 ml. Preparative g.c. (6 ft, β,β′-oxydipropionitrile, 65°) gave 1.23 g (73%) of (−)-**10**. See Table 1 for rotational data. The n.m.r. and i.r. spectra were identical with those of an authentic sample (16).

*Reduction of (+)-(S)-**11** to (+)-(S)-5-Hexene-1,4-diol (**12**)*

A solution of lithium aluminum hydride (20 g, 520 mmol) dissolved in dry ether (250 ml) was placed in a 1-l three-necked flask fitted with a dropping funnel, reflux condenser, and a gas inlet tube. Upon cooling to 0° a solution of (+)-**11** (13 g, 87 mmol) was added dropwise over a period of 2 h. The reaction mixture was then allowed to stand overnight at room temperature and ethyl acetate was added to destroy the excess hydride. Water was then added carefully followed by Celite (40 g). The ether solution was filtered and the Celite residue was washed six times with ether. The combined ether portions were concentrated to 100 ml and dried over anhydrous sodium sulfate. The ether was then removed and distillation gave 9.04 g (94%) of (+)-**12**, b.p. 65–67°/0.01 Torr (lit. (18) 98–100°/1.8 Torr). See Table 1 for rotational data.

*Reduction of (+)-(S)-**12** to (−)-(R)-1,4-Hexanediol (**9**)*

The procedure used was the same as that for the reduction of **6** to **7**. From 63 mmol of **12** there was obtained 6.97 g (74%) of **9**. The i.r. n.m.r., and g.c. retention time were identical with those of the sample obtained by the hydration of **7**, except that there was no trace of 2,4-hexanediol as an impurity.

Preparation of threo-4-Chloro-1,5-hexadiene-3-ol

A 2:1 mixture of **1***b* and **5** (38 g, 390 mmol) was added simultaneously with dry hydrogen chloride to anhydrous ether (400 ml) containing a small amount of thymol blue maintained at −50°. The red color indicated the presence of excess hydrogen chloride. Upon completion of addition the reaction mixture was washed with cold aqueous sodium bicarbonate, then with a saturated sodium chloride solution. The ether layer was dried over anhydrous sodium sulfate, filtered, and concentrated. Distillation caused darkening and isomerization so the crude alcohol was used directly in preparing the half-ester.

Preparation of threo-4-Chloro-1,5-hexadien-3-yl Hydrogen Phthalate

The crude *threo*-4-chloro-1,5-hexadien-3-ol (35 g, 260 mmol) was added to dry pyridine (48 ml) and phthalic anhydride (38.6 g, 280 mmol). The mixture was stirred overnight at room temperature and then warmed to 85° for 1 h before ice, ether, and concentrated hydrochloric acid (72.5 ml) were added. The ether layer was separated and the aqueous layer extracted several times with ether. The combined ether layers were dried over anhydrous sodium sulfate and after filtration the solvent was removed. The remaining syrup (63 g) was poured into a solution of sodium carbonate (22 g) in water (24 ml). The solution was extracted with ether and the extracts discarded. Concentrated hydrochloric acid (60 ml) was added to the aqueous layer and the phthalate extracted with chloroform. After drying the chloroform was removed and there remained 50.2 g (67% based on crude chlorohydrin) of the phthalate ester which after being recrystallized from a benzene – Skelly B mixture gave m.p. 72–72.5°.

Anal. Calcd. for $C_{14}H_{13}ClO_4$: C, 59.89; H, 4.63; Cl, 12.65. Found: C, 59.68; H, 4.84; Cl, 12.42.

Resolution of threo-4-Chloro-1,5-hexadien-3-yl Hydrogen Phthalate and its Conversion to (−)-1b

threo-4-Chloro-1,5-hexadien-3-yl hydrogen phthalate (38.7 g, 140 mmol) was added to dry acetone (100 ml) and the solution heated to boiling. Brucine (37.8 g, 82 mmol) was added and the clear solution allowed to cool slowly to 0°. The solid was collected and repeatedly crystallized from acetone until the m.p. raised to 150–151°. The half-ester was isolated by extraction with ether from an acidified solution of the salt. After removal of the ether there remained 7.5 g of the phthalate $[\alpha]^{21}_{D}$ +13.20, (2.84 g/100 ml, 2-propanol).

The resolved half-ester (7.5 g, 26 mmol) was dissolved in aqueous sodium carbonate and the solution added dropwise to a hot solution of sodium hydroxide (10-fold excess) such that water and the divinyloxirane distilled out. The oxirane layer was separated and dried over 4A molecular sieves. Yield 2 g, 78%. G.c. analysis indicated a purity of greater than 98%. The impurities were identified by mass spectrograph – g.c. to be acetone, ether, and allylmethyl ketone. $[\alpha]^{21}_{589}$ −8.48; $[\alpha]^{21}_{365}$ −87.35, (4.41 g/100 ml, 2-propanol).

Racemization Kinetics

In a typical run a sample of (−)-(*R*)-**1***b* (about 1 mmol) was weighed and degassed on a vacuum line. It was then vapor transferred to a 30 ml break-seal. The tube was sealed off and removed from the vacuum line to a constant temperature bath. At the appropriate time the tube was removed and quenched in an ice-water bath. It was then attached to the vacuum line and after a pressure of 10 microns was achieved the break-seal was opened and the contents vapor transferred to weighed 1-ml volumetric flask cooled in liquid nitrogen. The contents of the volumetric flask were then allowed to come to room temperature and after careful removal of any grease from the joint the flask was weighed. Isopropyl alcohol was added up to a volume of 1 ml and the weight of the solution obtained. Concentrations of **1***b* in the solution were calculated in percentage weight to avoid any volumetric error. A tube corresponding to zero time and an infinity tube were put through the same manipulations for each run.

The solution was then transferred to a thermostated polarimeter tube (1-ml volume, 1.001 dm long) and the rotation was measured. Precision of the measurement was ±0.002°. All samples were analyzed by g.c. after the rotation was measured. A sample run at 160.09° consists of the following data: 10^5 s, $[\alpha_t]/[\alpha_0]$; 0.180, 0.846; 0.540, 0.479; 0.900, 0.302; 1.14, 0.213; 1.50, 0.126; 1.80, 0.0843; infinity tube 3 days, 0.000. These results give $k_\alpha = (14.2 \pm 0.2) \times 10^{-5}\ s^{-1}$.

Kinetics of the Rearrangement of 1b to 4 and 5

A sample of **1***b* (25–30 mg) was placed in a 10 ml ampoule, degassed by three freeze–thaw cycles, sealed, and placed in a constant temperature oil bath. The tubes were removed from the bath at the appropriate time and the reaction was quenched. After opening, each tube was analyzed, in pentuplicate, on a Perkin-Elmer Model 900 Gas Chromatograph equipped with a Hewlett Packard 3370A Integrator. Some runs were conducted using 1,2-dimethoxyethane as a reference and some without a reference. A 150 ft, β,β′-oxydipropionitrile wall-coated column was used at 60° with a flame detector. A sample run at 190.30 ± 0.05° for the rate of disappearance of **1***b* is: 10^3 s $[\mathbf{1}b]^t/[\mathbf{1}b]^0$; 1.80, 0.863; 6.60, 0.582; 9.00, 0.464; 12.0, 0.369; 14.4, 0.289; 16.8, 0.236; 19.2, 0.185; these results give $k_2 + k_3 = (8.80 \pm 0.12) \times 10^{-5}$ s^{-1}.

Product Studies

(*a*) Sealed ampoules of **1***b* were heated for approximately two half-lives at temperatures from 160 to 220°. Each sample was then analyzed and the final kinetic results, along with the probable error as calculated from the standard deviation, are shown in Table 3.

(*b*) A sample of *trans*-2,3-divinyloxirane (1.5 g, 16 mmol) $[\alpha]^{25}_{365}$ −87.35, 81.3% optical purity was degassed and sealed into tubes such as to render a pressure of 1 atm at 200°. The tubes were then placed in a thermostated oil bath at 200.0 ± 0.1° for 10.5 h (10 half-lives for $k_2 + k_3$). The vinyldihydrofuran produced was separated from the 4,5-dihydrooxepine by preparative g.c. and its rotation measured $[\alpha]^{22}_{365}$ +0.058° (neat, 1 cm), $[\alpha]^{22}_{365}$ +0.285° (23.8 g/100 ml, 2-propanol). Thus, the product **4** was found to be greater than 99.6% racemic.

Discussion

(*a*) *The Mechanism of the Racemization Process*

The most facile reaction of the oxirane, **1***b*, is the racemization process. Since this is formally a simultaneous inversion of two chiral centers the reversible conrotatory opening of the oxirane to produce a carbonyl ylide best fits the requirements (see eq. 1) (3, 19). It is of interest to note that a negative entropy of activation ($\Delta S^{\ddagger}$ −9 e.u.) occurs during this bond cleavage reaction. This is consistent with the loss of the rotational degrees of freedom associated with the two vinyl groups.

(*b*) *The Mechanism of Vinyldihydrofuran Foundation*

The oxirane **1***b* may open to carbonyl ylides of 10 different configurations (see Fig. 1); of these *a–f* are produced by a conrotatory ring opening. The vinyldihydrofuran, **4**, is produced by the formation of the carbon–carbon bond between positions 2 and 3. Since the major part of the vinyldihydrofuran produced is racemic, even for that which has not racemized at the

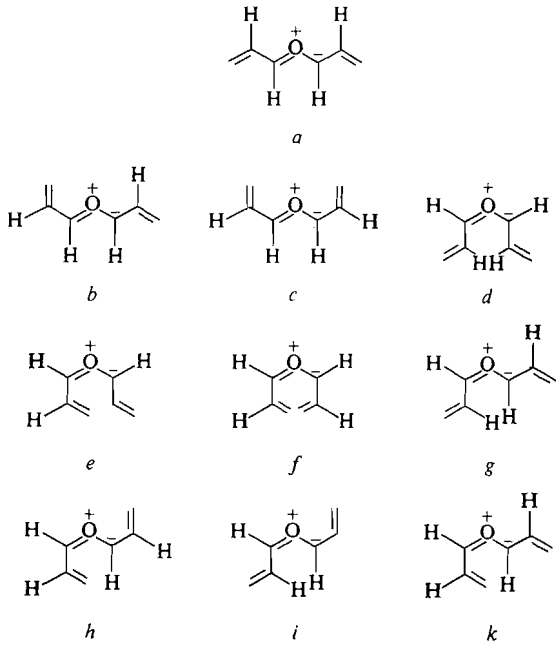

FIG. 1. Configurations of carbonyl ylide **13**.

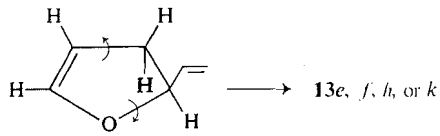
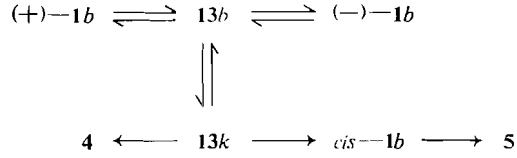
epoxide stage, then a planar intermediate such as the carbonyl ylide is a reasonable candidate as an intermediate. The opening of a ring such as **4** is disrotatory and could produce carbonyl ylide **13***e*, *f*, *h*, or *k*. While *e* and *f* are common



to both sets, *i.e.* those arising from **1***b* and **4**, they are also sterically very crowded. The stereochemical studies of Chuche and co-workers (10) indicate that an isomerization about the carbon–oxygen bond of the carbonyl ylide must occur, the *cis*-oxirane being ruled out since it gives rise to the dihydrooxepine exclusively (6). Isomerization at the carbonyl ylide stage is similarly capable of explaining the *trans–cis* isomerization of oxirane (resulting in the formation of **5**). Thus a scheme such as



is capable of fitting all of the stereochemical and kinetic data. Schemes using carbonyl ylide **13***c* and its isomerization to **13***h* are equally valid. For the conversion of (+)-**1***b* to **4** the data require that we have at least one planar intermediate and it is most readily reconciled with an isomerization from one of the members of the set **13***a*–**13***b* to the set **13***g*–**13***k*.

(c) The Zwitterion Intermediate **3**

This study was initially undertaken to minimize the role of the zwitterion intermediate **3**. In the 2,3-divinyloxirane system if any of the *cis* isomer is produced then it will be immediately converted to 4,5-dihydrooxepine (**5**) (6), and thus the rate of *trans* to *cis* isomerization in this system cannot exceed the value of k_3. The ratio k_1/k_3 at 200° for **1***b* is 22.6 while for **1***a* the same rate ratio at 200° is 212 (3). If the geometrical isomerization, as manifested by dihydrooxepine formation, is a feasible gas phase process proceeding via the cleavage of the carbon–carbon bond then it is not unlikely that the *trans–cis* isomerization occurs via a carbonyl ylide isomerization. While the carbonyl ylide as written looks like a very polar structure it would appear that solvation is not critical to the formation of such a species. We are now attempting to elucidate whether there are any significant solvent effects upon carbonyl–ylide ring openings.

The authors wish to acknowledge the financial assistance of the National Research Council of Canada. They also wish to thank Mrs. Fay Podruzny for measuring product proportions. We wish to acknowledge fruitful discussions with Prof. Josselin Chuche of Reims, France.

Lanthanide Induced Enhancement of Enantiomeric Shifts in Chiral Solvents and its Use in the Determination of Optical Purity

C. P. R. JENNISON[1] AND DONALD MACKAY
Department of Chemistry, University of Waterloo, Waterloo, Ontario

Received May 22, 1973

The chemical shift difference (Δv) between corresponding groups in enantiomers in the presence of both a chiral solvent ((−)-2,2,2-trifluorophenylethanol or (+)-1-phenylethylamine) and an achiral lanthanide shift reagent ($Eu(dpm)_3$ or $Eu(fod)_3$) is much greater than in the chiral solvent alone. In general, for simple molecules having one coordination site the Δv was smaller than that obtained with the chiral shift reagent $Eu(HFC)_3$. Comparable values of Δv, however, were obtained with the 1,3,4-oxadiazine derivatives **4***a* and *b*, and **5**, suggesting that the "chiral solvate shift system" is best suited to differentiating more complex enantiomers having several coordination sites.

The shift system was used to determine the optical purity of two partially resolved substances. One of these was the (+)-oxadiazine **4***a*, produced in the asymmetric isomerization of the bridged pyridazine **3***a* by (+)-camphor-10-sulfonic acid, and optically enriched by only one fractional crystallization. The enantiomeric enrichment in the isomerization was 4.21 ± 0.08%.

La différence de déplacement chimique (Δv) entre groupes correspondants dans des énantiomères en présence à la fois d'un solvant chiral ((−)-trifluoro-2,2,2 phényléthanol ou (+)-phényl-l éthylamine) et d'un réactif "shift" achiral ($Eu(dpm)_3$ ou $Eu(fod)_3$) est beaucoup plus grande que dans le cas du solvant chiral seul. En général, pour des molécules simples ayant un site de coordination, Δv est plus petit que la valeur obtenue avec le réactif chiral $Eu(HFC)_3$. Cependant, des valeurs comparables de Δv ont été obtenues avec les dérivés d'oxadiazine-1,3,4, **4***a* et *b*, et **5**, laissant penser que le système solvaté par un solvant chiral est plus adapté à la différenciation des énantiomères plus complexes possédant plusieurs sites de coordination.

Ce système a été utilisé pour déterminer la pureté optique de deux substances partiellement résolues. L'une d'elles était la (+)-oxadiazine **4***a* produite par isomération asymétrique de la pyridazine pontée **3***a* par l'acide (+)-camphosulfonique-10 puis enrichie optiquement par une seule cristallisation fractionnée. L'enrichissement optique de l'isomération a été de 4.21 ± 0.08%.

[Traduit par le journal]

Can. J. Chem. **51**, 3726 (1973)

Introduction

The rendering of enantiomeric groups anisochronous in the presence of a chiral solvent (1, 2, 8, 9) or more recently of lanthanide derived chiral shift reagents (3–9) has now been thoroughly documented. Determinations of absolute configuration (1, 2, 10–13), optical purity (1, 6), and geminal coupling constants (7, 8) have been made possible without the necessity of first making the groups diastereomeric by suitable chemical transformations.

We have recently reported (14) the successful asymmetric isomerization of the Diels–Alder adduct **1** to the optically active 1,3,4-oxadiazine derivative **2** under the influence of (+)-camphor-10-sulfonic acid as catalyst. The product was optically enriched by fractional crystallization and its optical purity then determined both by the isotopic dilution method (15) and by converting the sample into a mixture of diastereomeric methoxymandelyl derivatives which was analyzed by n.m.r. spectroscopy (16). The value obtained corresponded to an enantiomeric enrichment of 1.34% in the original isomerization of the adduct.

We reasoned that the highly substituted derivative of **1**, the adduct **3***a*, would be more stereoselective in its isomerization to **4***a* with the same catalyst. We became interested in methods for the direct determination of the optical purity of structures like **2** and **4** without resorting to their conversion into diastereomers.[2] The

[1]On leave of absence from the Department of Chemical and Metallurgical Technology, Ryerson Polytechnical Institute, Toronto, Ontario, Canada.

[2]An objection to this approach, apart from the extra steps involved. is that conversion may not occur equally efficiently with each enantiomer and that there may be some induced loss of configurational purity at the original optically active centers. Either effect would cause the diastereomeric ratio to differ from the enantiomeric one. In any event attempts to make diastereomers from **4***a* by the methods successfully used for **2** caused extensive decomposition.

a R = Ph
b R = Me

presence of functional groups in **2** and **4** which should be responsive both to solvation by a hygrogen-bonding chiral solvent and to coordination by a lanthanide suggested to us a use for a combination of these reagent types. We thought such a combination, for which we propose the term "chiral solvate shift system" would prove superior in separating enantiomeric hydrogens than a chiral solvent alone and might be comparable or superior in effectiveness to a chiral lanthanide. The shift between enantiomeric hydrogens generated by the chiral solvent could be enhanced by coordination of the lanthanide with the substrate, the chiral solvent, or both. An advantage of the chiral solvate shift system lies in the ready availability, commercially or by synthesis, of a range both of suitable optically pure solvents and of lanthanide derivatives, which provides the potentially large choice of combinations which might be needed for a broad spectrum of substrate types.

We now report advantages and limitations of chiral solvate shift systems obtained from *R*-(+)-1-phenylethylamine (PEA) and *R*-(−)-1-phenyl-2,2,2-trifluoroethanol (TFPE) as solvents, and $Eu(dpm)_3$ and $Eu(fod)_3$ as shift reagents. As substrates we have used not only the oxadiazines **4***a* and *b*, and the related derivative **5** from 2,5-dimethyl-3,4-diphenylcyclopentadienone, but also the simpler models, the racemic compounds 1-phenylethylamine (**6**), amphetamine (1-methyl-2-phenylethylamine) (**7**), methyl alanate (**8**), and methyl phenyl sulfoxide (**9**), which were examined in some detail. For comparison purposes results for most of the latter compounds with chiral solvents alone or with chiral lanthanides were obtained from the literature or were determined by us under conditions similar to those used for our chiral solvate shift systems.

PEA TFPE

Experimental

R-(+)-1-Phenylethylamine, $[\alpha]_D^{20}$ 36° minimum (neat) was supplied by Baker Chemical Co., $Eu(dpm)_3$ and $Eu(fod)_3$ by Pierce Chemical Co., and $Eu(HFC)_3$ (tris(3-heptafluoropropylhydroxymethylene-(+)-camphorato)europium) by Stohler Isotope Chemicals. *R*-(−)-1-Phenyl-2,2,2-trifluoroethanol was synthesized as described by Pirkle *et al.* (17) and had $[\alpha]_D^{20}$ −39.8° (97% optical purity).

(±)-Amphetamine was made by admixture of the enantiomeric forms purchased from Aldrich Chemical Co. (±)-Methyl phenyl sulfoxide was prepared by oxidation of the sulfide (Eastman) (18). (±)-Methyl alanate was stored as the hydrochloride from which it was liberated as needed by passing dry ammonia into a suspension in the n.m.r. solvent and filtering. Excess of dissolved ammonia was removed by addition of sufficient ester hydrochloride and re-filtering.

The synthesis and properties of 3*a* and *b*, **4***a* and *b*, and **5** will be discussed fully in forthcoming publications as part of a general study of isomerization reactions of adducts of azodiaroyl compounds; their structures have been unambiguously assigned.

N.m.r. spectra were obtained on a Varian T-60 or HA-100 spectrometer. The r.f. level was at all times optimized and the spectra recorded at sweep rates of 1 or 2 Hz s^{-1}. Values for chemical shift separations are accurate to within ± 0.002 p.p.m.

Solutions for Tables 1 and 2 were made by weighing out the calculated quantities of substrate, chiral solvent, and achiral solvent in the molar ratios indicated. The lanthanide was then added in the required amounts to give

1	3	2	0.3	0.3	3	0.044

successive runs at increasing lanthanide concentrations. Solutions for Table 3 were made by weighing out all four components for the initial solution and then diluting with known weights of achiral solvent. The total volumes were obtained using the densities of the solvents and the substrate, the volume of the lanthanide being ignored. Volume changes on mixing were shown to be negligible.

Asymmetric Isomerization of 3a

To a solution of the adduct **3***a* (6.5 g, 13.4 mmol) in dry benzene (800 ml) was added (+)-camphor-10-sulfonic acid (0.325 g, 10.0 mol%) and the resulting solution was shaken for 2 min. It was then immediately extracted with 2 × 50 ml portions of 2% sodium hydrogen carbonate, washed with water (50 ml), dried ($MgSO_4$), and evaporated to give the oxadiazine **4***a* (6.0 g, 92%) of $[\alpha]_{578}^{20}$ 8.80° (benzene, 0.160 g in 13.0 ml). A Zeiss photoelectric precision polarimeter was used for the determination of optical rotations.

Fractional crystallization from methanol gave little optical enrichment, though it was the solvent of choice in the work-up of optically active **2** (14). Benzene – petroleum ether (b.p. 35–60°) was successful, a 4.0 g sample giving almost racemic oxadiazine as a crystalline precipitate, m.p. 161.5–163° and from the mother liquor 0.24 g of oxadiazine of $[\alpha]_{578}^{20}$ 44.8° (benzene, 0.240 g in 3.0 ml).

Determination of Optical Purity

Amphetamine

A mixture of the enantiomers with the (−)-form in excess to give an optical purity of 22.6% was prepared and analyzed at 60 MHz and 35° in PEA–benzene in the presence of $Eu(dpm)_3$ (molar ratio 1:3:3:0.2). The two enantiomeric methyl doublets are shown in Fig. 1, J = 6.4 Hz, $\Delta\nu_{Me}$ = 2.8 Hz, and $w_{\frac{1}{2}} < 2$ Hz. The optical purity was found to be readily measurable as the average of the peak heights for each doublet, which were in the ratio of 1.60 ± 0.09:1, corresponding to an optical purity of 23.0 ± 1.2%. Direct area determination was not attempted in view of the difficulties arising from peak overlap.

Oxadiazine (4a)

The optically enriched sample of $[\alpha]_{578}^{20}$ 44.8° (benzene), described above, was analyzed at 100 MHz in TPFE–benzene in the presence of $Eu(fod)_3$. At 35° $\Delta\nu_{Me}$ was 14 Hz, but the peak resolution was rather poor, $w_{\frac{1}{2}}$ being 5–6 Hz. At 70°, for a molar composition of 1:15:5:0.20,[3] much sharper methyl lines were obtained, with a value of $w_{\frac{1}{2}}$ = 2.2 Hz for the more intense one, and even though $\Delta\nu_{Me}$ was reduced to 8.0 Hz, separation was nearly complete[4] (Fig. 2). Area ratios were determined by

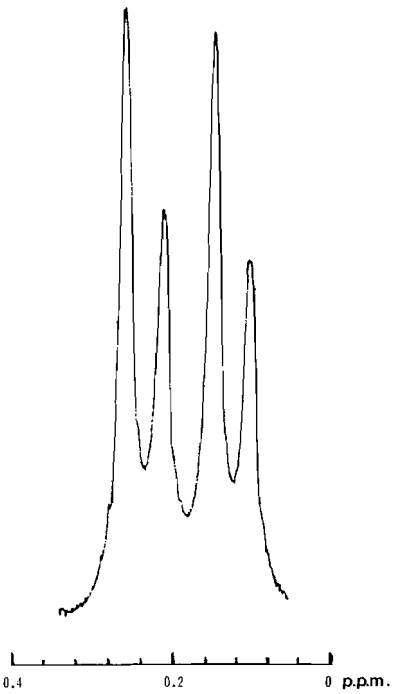

FIG. 1. 60 MHz spectrum of the Me doublets of amphetamine of 22.6% optical purity at 35° in PEA–benzene in the presence of $Eu(dpm)_3$ (mol ratio 1:3:3:0.2).

[3]The higher temperature allowed a large proportion of the rather viscous TFPE to be used.

[4]The decrease of ligand induced shifts with increasing temperature has been noted by others (19). We have found it to be quite general for enantiomeric shifts as well.

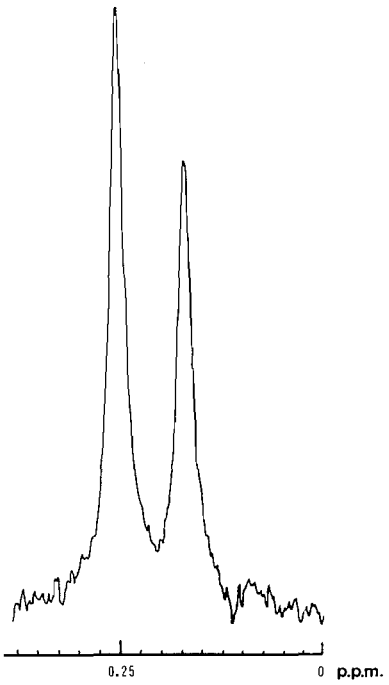

FIG. 2. 100 MHz spectrum of enriched (±)-oxadiazine **4***a* at 70° showing the quaternary Me in TFPE–benzene in the presence of $Eu(fod)_3$ (mol ratio 1:15:5:0.2).

photocopying (10 times), cutting out, and weighing, and showed the optical purity to be 21.4 ± 0.4%. This value leads to an enantiomeric enrichment of 4.21 ± 0.08% in the original isomerization and a rotation of $[\alpha]_{578}^{20}$ 209 ± 4° (benzene) for optically pure **4***a*.

Results and Discussion

Table 1 shows the effect on the shift ($\Delta\nu_{Me}$) between the methyl groups in the enantiomers of the substrates S (**4**–**9**) caused by variation in the nature of the chiral solvent CS, the achiral solvent AS (benzene or chloroform-*d*), and the lanthanide L. The enantiomeric shifts, under otherwise comparable conditions, are shown in brackets for CS only and for the chiral lanthanide $Eu(HFC)_3$.

Consecutive entries for the same system show the effect of variations in the molar ratios of S:CS:AS:L.

The chiral solvate systems are clearly in general superior to CS alone.[5] They are inferior to $Eu(HFC)_3$ in the case of the simple models **6**–**9** with one coordination site, but are comparable or in some instances superior for the structurally more complex oxadiazines **4** and **5** which contain a number of coordination sites.

For **6**–**9** $Eu(fod)_3$ was in all cases ineffective, molecules like these clearly requiring the more sterically demanding $Eu(dpm)_3$. Both lanthanides gave enantiomeric shifts with the oxadiazines but $Eu(fod)_3$ gave larger shifts, probably due to its greater Lewis acidity, since the oxadiazines are only weakly basic.

Both chiral solvents were successful in general (two exceptions in the case of TFPE with **7** and **9** are noted) but for the oxadiazines the alcohol was the solvent of choice. Its greater hydrogen-bonding power is evidently utilized to full advantage with the large number of potential hydrogen bonding sites in the substrates.

The effect of variation in concentration within a given system is shown in Table 2 for the methyl groups in (±)-1-phenylethylamine at nine different compositions of the amine in $CDCl_3$–TFPE in the presence of $Eu(dpm)_3$; the ratio of S:(CS + AS) is held constant. The $\Delta\nu_{Me}$ values are strongly tied to the L:S ratio for constant CS:S ratio (runs 1, 6, and 8, and runs 7 and 9), though not quite in a linear fashion. The shift is very sensitive to the CS:S ratio below a value of about unity (runs 2–5), at which it reaches a maximum and then decreases rather slowly as the ratio rises (runs 5–7), till the point where viscosity reduces the resolution and line separation is obscured.

Solvation by TFPE may be presumed to occur preferentially at the amine and it is probable that at low TFPE concentrations the mechanism is one in which unsolvated lanthanide enhances the methyl shift difference between diastereomeric assemblies of solvated amine. At a solvation level of 1:1 or less, one "side" of the amine is still exposed for direct coordination with the lanthanide. Further addition of TFPE works adversely, either because it solvates the amine further and inhibits coordination action, or because it starts to solvate the lanthanide, in preference to the monosolvated amine, and by thus competing for the lanthanide reduces the bound time of the latter with the amine, and hence the enantiomeric shift.

The optimum solvation level of 1:1 found for 1-phenylethylamine may of course not be general for other substrates. However, our

[5]The measurements of $\Delta\nu_{Me}$ in CS alone were all made at 60 MHz. Though most of them show zero value, it is likely that separations of up to 0.01 p.p.m. might have been detected for some of them at 100 MHz.

TABLE 3. Effect of [L] on the shift between enantiomeric methyl groups of (±)-1-phenylethylamine in benzene containing (*a*) TFPE and $Eu(dpm)_3$ and (*b*) $Eu(HFC)_3$

	S:CS:AS:L (mol ratio)				[L] × $10^2(M)$	$\Delta\nu_{Me}$ (p.p.m.)
(*a*)	1	2	3	0.2	29	0.050
	1	2	12	0.2	13	0.048
	1	2	48	0.2	4.0	0.041
	1	2	84	0.2	2.3	0.039
(*b*)	1		5	0.1	16	0.117
	1		11	0.1	9.3	0.117
	1		17	0.1	6.0	0.117
	1		23	0.1	4.4	0.117
	1		100	0.1	1.1	0.083
	1		550	0.1	0.2	0.048
	1		1100	0.1	0.1	0.015

experiments suggest that for simple molecules no advantage is to be gained with CS:S ratios higher than 2 or 3, but that for substrates like the oxadiazines, with a large number of sites capable of hydrogen bonding, improvements can be expected for CS:S ratios up to about 10.

For strongly coordinating substrates at least the enantiomeric shift is rather insensitive to the absolute [L] over a wide concentration range provided an appropriate [L]/[S] is maintained. This is illustrated in Table 3*a* which shows the effect of dilution with AS, again on the 1-phenylethylamine–TFPE–$Eu(dpm)_3$ system at a fixed molar ratio of 1:2:0.2. A 10-fold drop in [L] causes only a slight decrease in $\Delta\nu_{Me}$. The chiral shift reagent $Eu(HFC)_3$ likewise gives shift values which remain almost unchanged till a very low [L] is reached[6] (Table 3*b*).

Despite the success of the chiral solvate shift systems in generating enantiomeric shifts for a range of racemic substrates[7] we failed to obtain any enantiotopic shifts between the protons of prochiral methylene (*e.g.* benzyl alcohol, benzylamine, or benzyl cyanide) or methyl (*e.g.* dimethyl sulfoxide) groups, or between the methyl groups in *meso* compounds (*e.g. meso*-dimethyl tartrate). In this respect our shift system is quite inferior to chiral lanthanides like $Eu(HFC)_3$ with which impressive results have been reported, especially with benzylic protons (7).

The utilization of enantiomeric shifts in the determination of optical purity requires the shift to be great enough to provide complete or nearly complete peak separation, in order that peak area determinations can be made.

Many of the examples of Table 1 did not show sufficient separation to be useful in this sense but two examples are given in Figs. 1 and 2 which illustrate the potential of the method. Figure 1 shows the methyl doublet portion of the 60 MHz spectrum of a prepared sample of (−)-amphetamine of 22.6% optical purity. Good agreement with this value was obtained simply from peak height measurements (see Experimental Section). The peaks in Fig. 2 are those of the quaternary methyl groups in the 100 MHz spectrum of the oxadiazine **4***a*, and represent the fulfilment of our objective stated earlier, namely the direct determination of the optical purity of the product of an asymmetric reaction.

The isomerization of the adduct **3***a* in the presence of (+)-camphor-10-sulfonic acid was carried out under conditions identical to those used for **1** (14). The oxadiazine **4***a*, formed essentially quantitatively, had $[\alpha]_{578}^{20}$ + 8.80 (benzene). Fractional crystallization from benzene – petroleum ether (b.p. 35–60°) gave a nearly racemic crystalline precipitate and evaporation of the mother liquor gave crystalline material of $[\alpha]_{578}^{20}$ + 44.8° (benzene). The optical purity of this partially resolved sample was determined directly by 100 MHz n.m.r. analysis of TFPE–benzene in the presence of $Eu(fod)_3$ at 70° (Fig. 2). Area determination led to an optical purity of 21.4 ± 0.4%, corresponding to an enantiomeric enrichment of 4.21 ± 0.08% in the original asymmetric isomerization and a rotation of $[\alpha]_{578}^{20}$ 209 ± 4° for optically pure **4***a*. The stereoselectivity is thus much greater in the isomerization of **3***a* than of **1**, as expected.

We thank the National Research Council of Canada and the University of Waterloo for financial support of this work.

[6]A concentration of [L] = 1×10^{-2} *M* represents the use of about 6 mg each of $Eu(HFC)_3$ and the amine in the n.m.r. sample tube. Indeed for both shift systems the lower limit of observation of the enantiomeric shift in this particular substrate was set by the capabilities of the spectrometer.

[7]We had failures here too, notably dimethyl tartrate, 2-butanol, 2-octanol, benzoin, and 1-phenylethanol.

Estimation of Phenols by the 4-Aminoantipyrine Method. II. Products from *para*-Substituted Alkylphenols

PETER F. JONES AND K. E. JOHNSON

Regina Water Research Institute, University of Saskatchewan, Regina, Saskatchewan S4S 0A2

Received May 17, 1973

4-Aminoantipyrine reacts with *p*-alkylphenols on oxidation with potassium ferricyanide to give yellow *ortho*-quinoneimides. These undergo a thermal and base-catalyzed rearrangement to benzodihydrooxazepines.

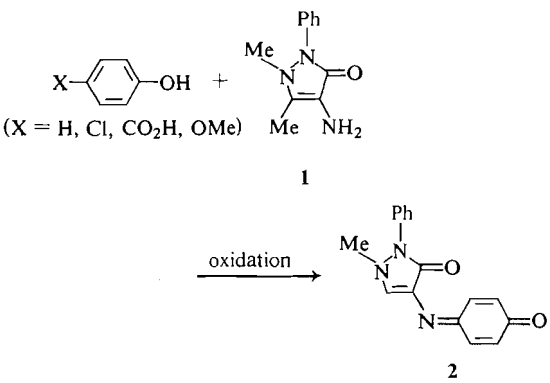
L'amino-4 antipyrine réagit avec les *p*-alkylphénols oxydés par le ferricyanure de potassium pour donner des *ortho*-quinonimides jaunes. Ces dernières se transforment sous l'influence de la chaleur ou des bases pour fournir des benzodihydrooxazépines. [Traduit par le journal]

Can. J. Chem. **51**, 3733 (1973)

We have recently confirmed (1) that the colorimetric estimation, using 4-aminoantipyrine (**1**), of phenols which are either unsubstituted, or have a readily eliminated substituent at the *para* position, involves oxidative *para* coupling to form red *p*-quinoneimide dyes **2** (see Scheme 1).

We now report the results of a study where the *para* position of the phenol is blocked by an alkyl group. Emerson (2) found that phenols having an alkyl, aryl, nitro, nitroso, benzoyl, ester, or aldehyde group in the *para* position did not show a color response to the 4-aminoantipyrine test. From this he correctly concluded that a positive color reaction involved oxidative *para* coupling. However, Czech workers (3) have recently reported that when the Emerson reaction is carried out with *p*-alkylphenols using higher concentrations of reagents, a turbidity is produced. The precipitate was isolated from *p*-cresol. Although initially yellow, on purification it gave a white, photochromic solid, m.p. 225–227°. On the sole basis of a molecular formula, itself incorrectly computed from elemental analyses, it was concluded that the latter compound arose from *ortho* coupling.

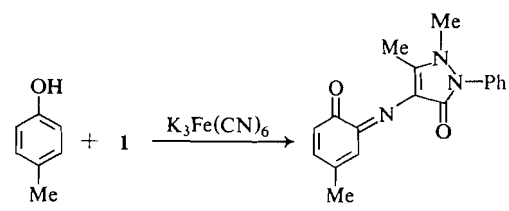
The lack of conclusive evidence for this, the first reported example of oxidative *ortho* coupling in this system, has led us to reinvestigate the reaction. The oxidation of a mixture of *p*-cresol and 4-aminoantipyrine by potassium ferricyanide did indeed result in the formation of a yellow precipitate (Scheme 2). Recrystallization from ethanol gave a cream solid, m.p. 224–227°, which appears to be the same product as that previously reported. However, the p.m.r.



SCHEME 1

spectrum of this compound revealed that it could not be the *o*-quinoneimide adduct **3***a*, since it displayed only two methyl singlets, whereas **3***a* should have three such signals.

Comparison of the p.m.r. spectrum of the crude original product with that of the purified sample showed that the latter was not present to



SCHEME 2

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

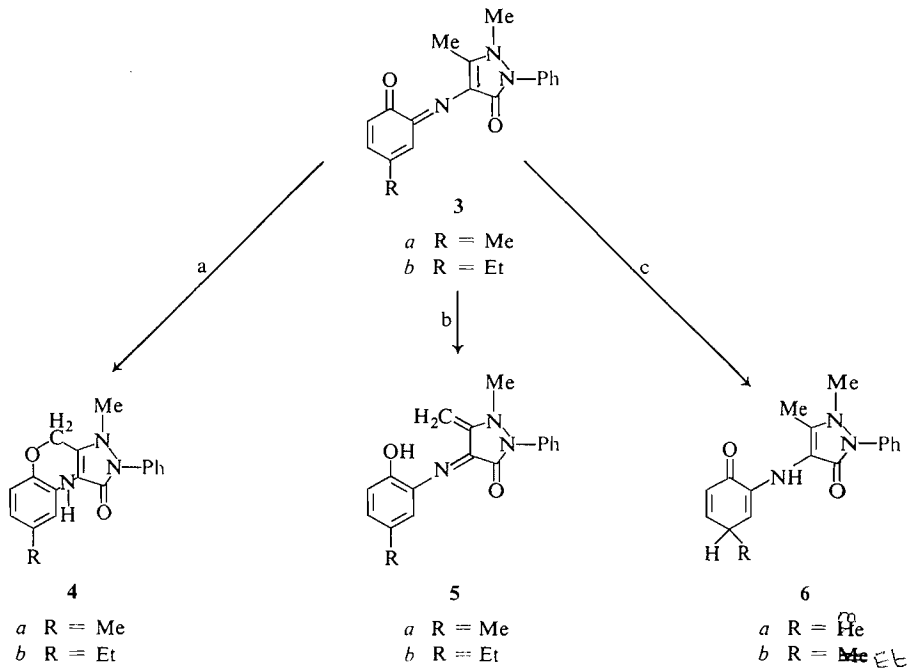

SCHEME 3

any extent initially. This suggests that recrystallization must have resulted in decomposition of the initial adduct. Accordingly, conditions were sought where the initial yellow adduct could be purified without decomposition. This was simply achieved by using non-hydroxylic solvents in the recrystallization step. A bright yellow solid was obtained, whose p.m.r. spectrum displayed the three methyl singlets required for **3***a*.

The p.m.r. spectra of the two compounds differ notably in the removal of a C—Me singlet at δ 1.52 originally present in **3***a*, and its replacement by a two proton singlet at δ 5.00 in the rearranged product. The position of the latter signal is suggestive of the formation from a methyl group of either an exocyclic methylene group or the allylic protons of an allyl ether. In the i.r. spectrum of the rearranged product, bands at 2.95 and 3.05 μ, absent in starting **3***a*, indicate the formation of an —OH or —NH group. Further evidence for this is seen in the p.m.r. spectrum of the rearranged compound by the presence of a broad, one proton singlet at δ 6.12, which is removed on deuteration. From these observations, two different reactions appear possible, either the loss of the antipyryl *C*-methyl group to form a phenol **5***a* (path *b*) or the heterocycle **4***a* (path *a*),[1] or the removal of the methyl group of the original phenol to give a *para*-quinonemethide, **6***a* (path *c*) (see Scheme 3).

The above evidence is insufficient to allow a decision between these possibilities. Accordingly, to find which of the two *C*-methyl groups was involved in the above rearrangements, the reaction was carried out with *p*-ethylphenol under conditions where the rearranged product would be expected. In this case, it should be simple to distinguish the formation of **4***b* or **5***b* from that of the *p*-quinonemethide **6***b*.

In fact, the p.m.r. spectrum of the reaction product clearly reveals that path *c* cannot be the operative reaction, since the retention of the ethyl group, and also the formation of the methylene group as a two proton singlet at an identical position to that of the rearrangement product from *p*-cresol can be seen. On the basis of the spectroscopic evidence alone, it is difficult to distinguish between the formation of the phenols **5***a* and *b* or their ring closed counterparts, the substituted dihydro-oxazepines **4***a* and *b*. The observation that the methylene protons appear as a singlet might seem to favor **4***a* and *b*,

[1]We thank a referee for pointing out this possibility.

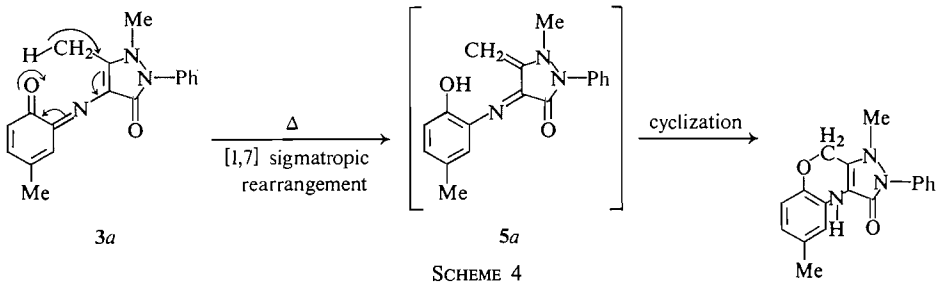
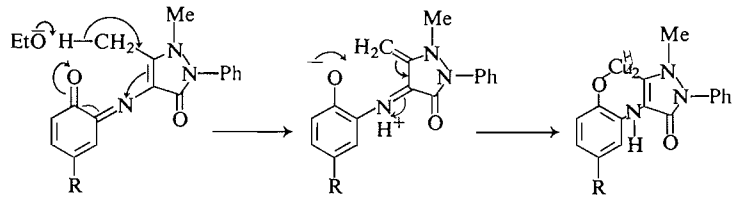


SCHEME 4



SCHEME 5

whose allylic protons are equivalent, whereas the methylene protons of **5***a* and *b* should be non-equivalent. However, it is frequently found that non-equivalent exocyclic methylene protons do not show geminal coupling (4*a*), therefore the phenol structures cannot be ruled out on this basis. They may be rejected on chemical evidence, however, since the *p*-cresol rearrangement product is completely insoluble in 5% aqueous sodium hydroxide and gives no color with ferric chloride, both reactions which are used to characterize phenols (5).

Unusual behavior on melting of the *o*-quinoneimide adduct **3***a* suggested that the above rearrangement might also occur thermally. The yellow compound melted at 148–150°. With increase in temperature, the melt decolorized and partially crystallized. Final remelting occurred at 210–220°, suspiciously similar to the m.p. of rearranged **4***a*. The thermolysis could be conveniently followed by p.m.r. spectroscopy in bromobenzene solvent, in which **3***a* showed methyl singlets at δ 1.00, 1.90, and 2.21 p.p.m. On heating the sample at 139°, these signals diminished in intensity, and the build-up of new signals at δ 1.75, 2.11, and 4.44 p.p.m. was seen. After 20 min the starting signals had been completely removed, and the new signals, in the ratio 3:3:2, were the only ones present. They were found to be identical to those of an authentic sample of **4***a* in bromobenzene. Rearranged **4***a* was recovered in good yield from the thermolysis mixture.

The thermal reaction may proceed through an intramolecular cyclization mechanism, possibly with an initial [1,7] sigmatropic rearrangement to the isomeric phenol **5***a*, which then undergoes cyclization (see Scheme 4). This would presuppose that the *o*-quinoneimide must be in a suitable configuration for interaction, namely with the antipyryl ring *syn* to the carbonyl group. The unusually high field position of the antipyryl *C*-methyl signal of **3***a* at δ 1.52 p.p.m., being shielded by approximately 1 p.p.m. compared with the corresponding group in *para*-quinoneimides, where the signal appears in the range δ 2.49–2.60 p.p.m. (1), would indicate that **3***a* does exist in the ground state configuration shown. Shielding of a proton located above the plane of the carbonyl group is well documented (4*b*).

The proposed initial [1,7] sigmatropic shift is allowed thermally as an antarafacial process by the Woodward–Hoffmann rules (6).

The ease of rearrangement of the *o*-quinoneimides in hydroxylic solvent at or below room temperature suggests the operation of an alternative mechanism, possibly involving a base-catalyzed reaction with an external nucleophile, presumably ethoxide ion (Scheme 5). Some evidence to support a base-catalyzed rearrangement has been obtained. Thus **3***a* appeared to be stable

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

in deuterochloroform solvent, only 8% rearrangement being observed after 3 days at room temperature. However, addition of pyridine to the reaction mixture accelerated the rearrangement since 78% isomerization occurred after a further 3 days. After rearrangement was seen to be complete, **4***a* was isolated in 56% yield.

Experimental

4-Aminoantipyrine (Aldrich) and the starting phenols were purchased from commercial suppliers and were used without further purification. Buffer solution of p*H* 10.4 was prepared by dissolving dry buffer salt (Fisher) in distilled water.

Melting points were taken on a hot stage apparatus and are uncorrected. Microanalyses were performed by Galbraith Laboratories Inc., Knoxville, Tennessee. P.m.r. spectra were recorded on a Varian A-60 spectrometer in deuterochloroform solvent and with tetramethylsilane as an internal standard. I.r. spectra were obtained on a Beckman IR 8 instrument with polystyrene calibration.

Reaction of 4-Aminoantipyrine with p-Cresol

(*a*) To a stirred mixture of 0.35 g (0.0032 mol) of *p*-cresol and 1.1 g (0.0054 mol) of 4-aminoantipyrine in 250 ml of buffer solution was added, in one portion, 21 g (0.064 mol) of potassium ferricyanide. A yellow precipitate immediately formed. The reaction mixture was stirred for 30 min and the solid was filtered off, washed with water, and was allowed to dry in air in the dark. The crude yellow product, 1.16 g, m.p. 29–120°, was recrystallized from 95% ethanol to give 0.25 g of **4***a* as gleaming cream flakes, m.p. 218–222°. Addition of water to the filtrate gave, on standing, further solid, m.p. 210–220°. Both crops had identical spectra and the total yield of **4***a* was 0.38 g (38%). Further recrystallization from ethanol gave the analytical sample, m.p. 224–227°. P.m.r. δ 7.7–6.7 (m, 8H, aromatic), 6.12 (broad s, 1H, removed on addition of D_2O, N*H*), 5.00 (s, 2H, CH_2), 2.81 (s, 3H, NMe), 2.25 (s, 3H, CMe); i.r. ($CHCl_3$) 2.95, 3.05 (NH), 6.02 (C=O).

Anal. Calcd. for $C_{18}H_{17}N_3O_2$: C, 70.34; H, 5.58; N, 13.67. Found: C, 70.44; H, 5.61; N, 13.62.

The product was completely insoluble in 5% aqueous sodium hydroxide, even on heating, and an ethanolic solution showed no noticeable color change on addition of ferric chloride solution.

(*b*) The dried yellow precipitate, prepared as above from 0.31 g (0.0029 mol) of *p*-cresol, 1.1 g (0.0054 mol) of 4-aminoantipyrine, and 20 g (0.061 mol) of potassium ferricyanide in 250 ml of buffer solution, was dissolved in methylene chloride. Addition of petroleum ether (b.p. 100–115°) precipitated 0.17 g of amorphous solid, m.p. 115–140°, whose p.m.r. spectrum was similar to that of unidentified impurities obtained during the preparation of some *p*-quinoneimides (1). The clear yellow filtrate was evaporated and the resulting solid was recrystallized from pentane to give 0.39 g (44%) of yellow **3***a*, m.p. 145–155°. The p.m.r. spectrum indicated the product was an 87:13 mixture of **3***a* and **4***a*. Several recrystallizations from pentane gave pure **3***a*, m.p. 148–150° (resolidifies and remelts 210–220°). P.m.r. δ 8.22–8.00 (m, 2H, vinyl), 7.70–6.85 (m, 6H, aromatic + vinyl), 2.74 (s, 3H, NMe), 2.37 (s, 3H, CMe), 1.52 (s, 3H, antipyryl CMe); i.r. ($CHCl_3$) 5.89, 6.06 μ (C=O).

Anal. Calcd. for $C_{18}H_{17}N_3O_2$: C, 70.34; H, 5.58; N, 13.67. Found: C, 70.40; H, 5.67; N, 13.70.

Reaction of 4-Aminoantipyrine with p-Ethylphenol

To a stirred mixture of 0.35 g (0.0029 mol) of *p*-ethylphenol and 1.2 g (0.0059 mol) of 4-aminoantipyrine in 250 ml of buffer solution was added, in one portion, 20 g (0.061 mol) of potassium ferricyanide. A yellow precipitate immediately formed. The reaction mixture was filtered after 30 min and the yellow solid obtained was dissolved in 95% ethanol. The solution on cooling deposited 0.24 g of **4***b*, m.p. 199–201°. Addition of water to the filtrate gave, on standing, further solid, m.p. 198–200°. The total yield of **4***b* was 0.39 g (42%). Further recrystallization from ethanol gave the analytical sample, m.p. 199–201°. P.m.r. δ 7.7–6.6 (m, 8H, aromatic), 6.35 (broad s, 1H, NH), 5.00 (s, 2H, CH_2), 2.81 (s, 3H, NMe), 2.53 (q, J = 8 Hz, 2H, CH_2CH_3), 1.16 (t, J = 8 Hz, 3H, CH_2CH_3); i.r. ($CHCl_3$), 2.95, 3.05 (NH), 6.02 μ (C=O).

Anal. Calcd. for $C_{19}H_{19}N_3O_2$: C, 71.01; H, 5.96; N, 13.08. Found: C, 71.27; H, 6.10; N, 13.08.

Thermal Rearrangement of **3***a*

A 60 mg (0.0002 mol) sample of **3***a* was dissolved in approximately 0.5 ml of bromobenzene. A p.m.r. spectrum of the solution showed three singlets at δ 1.00, 1.90, and 2.21 p.p.m. (external TMS). The n.m.r. sample tube was placed in a preheated oil bath at 139°. The sample was withdrawn after 10 min and the p.m.r. spectrum was examined. It showed a diminution of the intensities of the above three singlets and the formation of new singlets at δ 1.75, 2.11, and 4.45 p.p.m. These new signals were in the ratio 3:3:2 and subsequent examination of an authentic sample of **4***a* in bromobenzene revealed peaks at identical positions. The ratio of **3***a*:**4***a* was 24:76, as estimated from peak heights. After a further 10 min at 139°, the signals of starting **3***a* were completely removed and **4***a* appeared to be the sole product. Addition of petroleum ether (b.p. 100–115°) to the sample precipitated 48 mg (80%) of crude **4***a*, m.p. 200–214°. A solution of this product in deuterochloroform showed a p.m.r. spectrum identical to that of authentic **4***a*. Further purification by recrystallization from 95% ethanol gave 25 mg (42%) of pure **4***a*, m.p. 217–221°.

Base-catalyzed Rearrangement of **3***a*

A 50 mg (0.00016 mol) sample of **3***a* was dissolved in approximately 0.5 ml of deuterochloroform. The solution was stored in the dark at room temperature. After 3 days, the p.m.r. spectrum showed 8% rearrangement to **4***a*. Pyridine, approximately 0.26 g (0.0032 mol), was added by dropper to the solution. The mixture was stored in the dark and its p.m.r. spectrum was examined at intervals. The observed extent of rearrangement to **4***a* was 14 (3h), 36 (24 h), 60 (44 h), and 78% (70 h). Examination after 6 days showed complete rearrangement to **4***a*. Addition of petroleum ether (b.p. 100–115°) precipitated 28 mg (56%) of **4***a*, m.p. 215–222°.

Grateful acknowledgement is made to the National Research Council of Canada for its generous support of this work.

Arrhenius Parameters for Reaction of *tert*-Butylperoxy Radicals with some Hindered Phenols and Aromatic Amines[1]

JAMES ANTHONY HOWARD AND EDWARD FURIMSKY
Division of Chemistry, National Research Council of Canada, Ottawa, Canada K1A 0R9

Received May 14, 1973

The reaction of *tert*-butylperoxy radicals with some 2,6-di-*tert*-butyl-4-substituted phenols, α-naphthol, α-naphthylamine, and *N*-phenyl-α-naphthylamine has been studied by following the change in radical concentration with time using an e.p.r. spectrometer. Rates of radical decay were first-order in both reactants and were not influenced by the presence of *tert*-butyl hydroperoxide.

Absolute values of the second-order rate constants were measured from −35 to −100° and the preexponential factors and activation energies fell in the range 10^4–10^5 M^{-1} s^{-1} and 0.5–1.0 kcal mol^{-1}. Rate constants for deuterated phenols (OD) and aromatic amines (ND) were an order of magnitude lower than for the corresponding light compounds.

There was no evidence for quantum mechanical tunneling in these hydrogen atom transfer reactions and it would appear that the activation parameters are low because reaction initially involves the formation of a hydrogen bonded peroxy radical – phenol (or aromatic amine) complex, followed by the transfer of a hydrogen atom within the complex.

Les réactions des radicaux peroxy-*tert*-butyliques avec quelques di-*tert*-butyl-2,6 phénols substitués en position 4, α-naphtol, α-naphthylamine et la *N*-phényl-α-naphthylamine ont été étudiées en suivant la variation de la concentration en radicaux avec le temps en utilisant un spectromètre de résonance paraélectronique. Les vitesses de disparition des radicaux sont du premier ordre pour les deux réactifs et ne sont pas influencées par la présence d'hydroperoxyde de *tert*-butyle. Les valeurs absolues des constantes de vitesse de second ordre sont mesurées de −35 à −100°, et les facteurs préexponentiels ainsi que les énergies d'activation sont compris dans l'écart de 10^4–10^5 M^{-1} s^{-1} et 0.5–1.0 kcal mol^{-1}. Les constantes de vitesses pour les phénols deutériés (OD) et les amines aromatiques (ND) sont dans un ordre de grandeur plus faible que pour les composés légers correspondants. Il n'y a pas d'évidence pour un effet tunnel de mécanique quantique dans ces réactions de transfert d'atomes d'hydrogène, et il apparaît que les paramètres d'activation sont bas parce que la réaction initiale implique la formation d'un complexe hydrogène lié à un radical peroxyphénol (ou amine aromatique), suivie par le transfert d'un atome d'hydrogène à l'intérieur du complexe. Introduction

Hindered phenols and aromatic amines (AH) are widely used for the protection of organic materials against atmospheric autoxidation (1–4). These compounds function as antioxidants because they undergo a rapid bimolecular hydrogen atom transfer reaction with a chain propagating alkylperoxy radical (ROO·) to produce a free radical A· which is unable to propagate the chain.

$$\text{[1]} \qquad \mathrm{ROO\cdot} + \mathrm{AH} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \mathrm{ROOH} + \mathrm{A\cdot}$$

There have been several kinetic studies of reaction 1 in solution but they have generally been confined to one temperature (2). In the few cases where absolute values of k_1 were determined over a temperature range, the Arrhenius parameters obtained were unreliable (2). This is because to determine an absolute value for k_1, it is necessary to carry out complete kinetic analyses of the uninhibited and inhibited autoxidations of the substrate (RH) from which ROO· was derived.[2]

In this paper we report the results of a *direct* kinetic e.s.r. study of the reaction of *tert*-butylperoxy radicals with a variety of 2,6-di-*tert*-butyl-4-substituted phenols, aromatic amines, and α-naphthol. Since this work was carried out over a substantial temperature range we are able to report accurate Arrhenius parameters for these reactions.

[1]Issued as NRCC No. 13373.

[2]This means that absolute values of the rate constants for the mutual reaction of ROO· ($2k_t$) and for the reaction of ROO· with RH (k_p) have to be determined in addition to the rate constant ratios $k_p/(2k_t)^{1/2}$ and k_p/k_1.

[2] 
[3] 
Experimental

The apparatus and experimental procedure used to determine bimolecular rate constants for reactions of *tert*-butylperoxy radicals have been described previously (5).

The 2,6-di-*tert*-butyl-4-substituted phenols, α-naphthol, and the aromatic amines were either commercial products or samples which had been prepared previously in our laboratory (6, 7). They were purified before use by recrystallization, sublimation or zone refining. Deuteration of phenolic and amino hydrogens was accomplished by adding a drop of D_2O to a standard solution (*ca.* 0.3 cc) of the undeuterated compound in an e.s.r. tube. The tube was then shaken for periods of time from 1–24 h. Deuteration of phenolic and amino hydrogens is rapid by this technique (8, 9).

Azoisobutane (Merck, Sharpe and Dohme of Canada Ltd), isopentane (Phillips Research Grade), and trichlorofluoromethane (Matheson) were used without further purification. Toluene (Phillips Research Grade) was passed through basic alumina before use.

Results and Discussion

2,6-Di-tert-butyl-4-substituted Phenols

Conventional kinetic studies have shown that overall rates of hydrocarbon autoxidation inhibited by 2,6-di-*tert*-butyl-4-substituted phenols are proportional to the rate of chain initiation and inversely proportional to the phenol concentration (8, 10–14). This implies that reaction of a chain carrying alkylperoxy radical and a phenol is bimolecular. Induction period studies have demonstrated that most of these phenols react with 2 equiv. of peroxy radicals (14, 15). The only exception was 2,6-di-*tert*-butyl-4-chlorophenol (BClP) which, at 65°, scavenged one peroxy radical (15). At the high ratios of peroxy radical to phenol used in the present work and the lower reaction temperatures this phenol behaved like the other phenols and reacted with 2 equiv. of peroxy radicals.

This was demonstrated by following the build-up of the concentration of *tert*-butylperoxy radicals during continuous photolysis of azoisobutane in oxygenated isopentane in the presence of BClP at −100°. The rate of radical production (R_i) was determined in the absence of the phenol and the time taken to reach this rate in the presence of a known concentration of BClP (τ) gave the number of radicals scavenged by each molecule of phenol from $R_i = n[AH]/\tau$. Both 2,6-di-*tert*-butyl-4-methylphenol (BMP) and BClP gave values of n equal to two by this technique.

The overall reaction of a 2,6-di-*tert*-butyl-4-substituted phenol with an alkylperoxy radical can, therefore, be described by eqs. 2 and 3.

The reverse of reaction 3 can be neglected at low temperatures because 4-alkylperoxy-2,6-di-*tert*-butylcyclohexadienones are quite stable at room temperature (15).

Reactions 2 and 3 (assuming a steady state concentration of phenoxy radicals) give the following expression for the rate of disappearance of ROO·

$$\text{I} \qquad \frac{-\mathrm{d}[\mathrm{ROO}\cdot]}{\mathrm{d}t} = \frac{2k_2k_3[\mathrm{ROO}\cdot][\mathrm{AH}]}{k_3 + k_{-2}\dfrac{[\mathrm{ROOH}]}{[\mathrm{ROO}\cdot]}}$$

In the case where $k_3 \gg k_{-2}$ [ROOH]/[ROO·] this rate expression reduces to

$$\text{II} \qquad \frac{-\mathrm{d}[\mathrm{ROO}\cdot]}{\mathrm{d}t} = 2k_2[\mathrm{ROO}\cdot][\mathrm{AH}]$$

Rates of decay of *tert*-butylperoxy radicals (from −37 to −100°) in the presence of a large excess of a 2,6-di-*tert*-butyl-4-substituted phenol (where the 4-substituent was methoxy (BMeOP), *tert*-butyl (BBP), methyl (BMP), chloro (BClP), cyano (BCNP), formyl (BCHOP), carboxy (BCOOHP), or carbo-*tert*-butoxy (BC(O)OP) and the unsubstituted phenol (BP)) in either isopentane, trichlorofluoromethane, or toluene were exactly first-order

For personal use only.

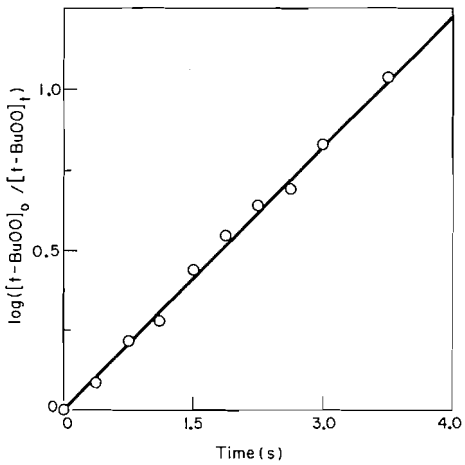

FIG. 1. A first-order plot of log (relative radical concentration) *vs.* time for the disappearance of *tert*-butylperoxy radicals in the presence of 2,6-di-*tert*-butyl-4-methylphenol (1.1×10^{-4} *M*) in isopentane at $-100°$.

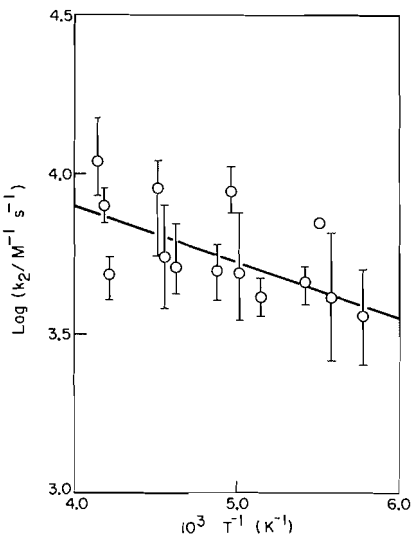

FIG. 2. A plot of log (k_2/M^{-1} s^{-1}) for 2,6-di-*tert*-butyl-4-methylphenol *vs.* the reciprocal of the absolute temperature.

(see *e.g.* Fig. 1). The pseudo first-order rate constants were proportional to the phenol concentration to the first power. The kinetic expression II was, therefore, strictly obeyed for these reactions.

Rates of radical decay were not influenced by the presence of *tert*-butyl hydroperoxide (0.1 *M*) and consequently the reverse of reaction 2 was unimportant.

Average absolute values of k_2, at the highest and lowest temperatures used in this work, are given in Table 1.[3] Plots of log (k_2/M^{-1} s^{-1}) against the reciprocal of the absolute temperature (see *e.g.*, Fig. 2) yielded the Arrhenius parameters listed in Table 1.

TABLE 1. Rate constants and Arrhenius parameters for reaction of *tert*-butylperoxy radicals with 2,6-di-*tert*-butyl-4-substituted phenols

Phenol	10^{-4} (k_2/M^{-1} s^{-1})		log (A_2/M^{-1} s^{-1})	E_2/kcal mol^{-1}
	−37 °C	−98 °C		
BMeOP	2.3	2.1	4.7±0.2	0.4±0.2
BBP	0.70	0.45	4.2±0.2	0.5±0.2
BMP	0.50	0.40	4.6±0.2	0.8±0.2
BP	0.34	0.15	4.3±0.2	1.0±0.15
BClP	0.50	0.40	4.3±0.2	0.5±0.2
BCNP	0.10	0.05	4.0±0.3	1.0±0.3
BCHOP	0.085	0.046	3.7±0.2	0.8±0.2
BCOOHP	0.07	0.025	3.8±0.3	1.0±0.2
BC(O)OBP	0.09	0.035	3.8±0.2	1.0±0.2

Extrapolation of the Arrhenius equation for BMP to 40 and 60° gave k_2 values of 1.1×10^4 and 1.2×10^4 M^{-1} s^{-1}. These values are in good agreement with those estimated for reaction of this phenol with cumylperoxy ($k^{40°} = 1.2 \times 10^4$ M^{-1} s^{-1} (16)), tetralylperoxy ($k^{40°} = 2.75 \times 10^4$ M^{-1} s^{-1} (16); $k^{40°} = 2.8 \times 10^4$ M^{-1} s^{-1} (17); $k^{65°} = 3.6 \times 10^4$ M^{-1} s^{-1} (11)), 9,10-dihydroanthracyl-9-peroxy ($k^{30°} = 1.1 \times 10^4$ M^{-1} s^{-1} (17)), and poly(peroxystyryl)peroxy radicals ($k^{65°} = 2.7 \times 10^4$ M^{-1} s^{-1} (11)). It has been suggested (17) that the rate constant for the reaction of BMP with peroxy radicals decreases in a regular manner with increasing size of the hydrocarbon moiety of the peroxy radical. The similarity between the reactivities of *tert*-butylperoxy and poly(peroxystyryl)peroxy to this phenol suggest that if there is a difference in reactivity between alkylperoxy radicals it is within the limits of error involved in the determination of absolute rate constants.

[3]Only the average rate constants for reaction of *tert*-butylperoxy radicals with 2,6-di-*tert*-butyl-4-substituted phenols, α-naphthol, and the aromatic amines at the highest and lowest temperatures are quoted in this paper. A complete compilation of the values of k_2 and k_7 is available, at nominal charge, from the Depository of Unpublished Data, National Science Library, National Research Council of Canada, Ottawa, Canada K1A 0S2. Copies of these tables can be obtained by writing to this address.

Arrhenius parameters for reaction of most of the phenols with alkylperoxy radicals have not been determined previously. Preexponential factors of $10^{5.6}$–$10^{8.3}$ M^{-1} s^{-1} and activation energies of 3.0–5.6 kcal mol^{-1} have, however, been reported for reaction of BMP with several alkylperoxy radicals (2). More recently Mahoney and DaRooge (17) have calculated an A-factor of $10^{4.46}$ M^{-1} s^{-1} and an activation energy of 0 kcal mol^{-1} for reaction of tetralylperoxy radicals with 2,4,6-tri-*tert*-butylphenol. The A-factors and activation energies that we found for reaction of all the hindered phenols with *tert*-butylperoxy radicals are in good agreement with Mahoney and DaRooge's values. Rate constants for the transfer of a hydrogen atom from a hindered phenol to an alkylperoxy radical are, therefore, characterized by activation parameters that are significantly lower than those usually found for metathesis reactions involving a hydrogen atom (18).

Low activation parameters have been found for other hydrogen atom transfer reactions between oxy radicals (19–22) although the exchange reaction between di-*tert*-butyliminoxyl and di-*tert*-butylhydroxylamine has a substantial activation energy (7 ± 2 kcal mol^{-1}) (23).

It has been suggested that the low activation energies for transfer of a hydrogen atom between two oxy radicals is due to the formation of a hydrogen bonded free radical – molecule complex (24). Reaction of *tert*-butylperoxy radicals with hindered phenols would be represented by reactions 4, 5, and 6.

[4] *tert*-BuOO +  ⇌ *tert*-BuOO····H—O 
1

[5] **1** ⇌ *tert*-BuOO—H····O 
2

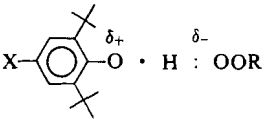
[6] **2** ⇌ *tert*-BuOOH + 
If k_{-4} and $k_{-6} \gg k_5$ the rate controlling step is the transfer of a hydrogen atom within the activated complex and

$$2k_2 = 2k_5k_4/k_{-4}$$

The overall activation energy (E_2) will be lower than for a normal hydrogen atom transfer reaction because of the negative heat of formation of the hydrogen bonded complex (24).

It is conceivable that the hydrogen atom in the hydrogen bonded complex **1** can tunnel through the potential energy barrier between the reactants and the products. Tunneling is possible because the formation of a hydrogen bonded complex between the reactants would be expected to narrow the barrier to reaction. The low activation energy associated with a reaction which involves tunneling would produce a lower than normal preexponential factor.

Linear plots of log k for the reaction of poly(peroxystyryl)peroxy and tetralylperoxy radicals with 2,6-di-*tert*-butyl-4-substituted phenols at 65° against Brown's σ^+ substituent constants (10, 13) have been presented as evidence in support of a dipolar contribution (**3**) to the activated complex for this hydrogen atom transfer reaction.



3

When the values of log $(k_2/M^{-1}\,s^{-1})$ at −37 and −98° were plotted against σ^+ the following correlations were obtained

$$\log (k_2^{-37°}/M^{-1}\,s^{-1}) = 3.5 - 1.00 \times \sigma^+ \quad (r = 0.94) \quad \text{and}$$

$$\log (k_2^{-98°}/M^{-1}\,s^{-1}) = 3.3 - 1.23 \times \sigma^+ \quad (r = 0.91)$$

Since the variations in k_2 with the nature of the 4-substituent are almost certainly due to differences in activation energies it is not surprising

TABLE 3. Rate constants and Arrhenius parameters for reaction of *tert*-butylperoxy radicals with some deuterated 2,6-di-*tert*-butyl-4-substituted phenols (OD)[a]

Phenol	$10^{-4}(k_2/M^{-1}\,s^{-1})$ −34 °C	−97 °C	log $(A_2/M^{-1}\,s^{-1})$	E_2/kcal mol^{-1}
BMeOP	0.19(11)	0.14(14)	3.7±0.2	0.5±0.2
BMP	0.06(11.0)	0.04(24)	4.2±0.3	1.4±0.3
BP	0.015(11)	0.006(20)	3.3±0.2	1.2±0.2
BClP	0.2(4.4)	0.042(10)	5.1±0.5	2.0±0.4
BCNP	0.01(11)	0.003(26)	—	—

[a]The numbers in parentheses give the rate constant ratios k_2^H/k_2^D. Values of k_2^H were determined in the presence of H_2O and may not correspond exactly to the rate constants that can be calculated from the appropriate activation parameters

that the slopes of these correlations (*i.e.*, the ρ^+ values) decrease with an increase in temperature.

Extrapolation of the ρ^+ values to 65° yielded a value of ~ -0.8, lower than experimental values of ρ^+ for poly(peroxystyryl)peroxy (−1.12) and tetralylperoxy (−1.36). The lower ρ^+ value for *tert*-butylperoxy may reflect the lower electronegativity of this radical compared with the secondary alkylperoxy radicals.

Rate constants for hydrogen atom abstraction reactions, which involve a dipolar transition state, should increase when the polarity of the reaction medium is increased (25). However, rate constants for a number of hydrogen atom transfer reactions between oxyl radicals actually *decrease* as the solvent polarity is increased (24, 26). We found that the values of k_2 for BCNP, BP, and BMeOP are lower in trichlorofluoromethane containing acetonitrile (3.8 *M*) than they are in undiluted trichlorofluoromethane (Table 2).

It is well known that hindered phenols can hydrogen bond to acetonitrile (25). It would, therefore, appear that for some hydrogen atom transfer reactions between oxy radicals (especially those which have low activation energies) reactant–solvent interactions overshadow transition state – solvent interactions and the rate constant is decreased rather than enhanced by an increase in the polarity of the medium.

Deuterated 2,6-Di-tert-butyl-4-substituted Phenols

Rates of decay of *tert*-butylperoxy radicals in the presence of deuterated (OD) BMeOP, BMP, BP, BCNP, and BClP in either isopentane or trichlorofluoromethane were also found to obey the kinetic expression II.

Values of k_2 for the undeuterated phenols were identical in the absence and presence of a drop of H_2O which indicated that the only influence D_2O had on the reaction was to deuterate the phenolic hydrogen.

Rate constants[3] and activation parameters for the deuterated phenols are given in Table 3. The numbers in parentheses give the rate constant ratios k_2^H/k_2^D obtained at the highest and lowest temperatures. In all cases a substantial deuterium isotope effect was obtained, the magnitude of which decreased as the temperature was increased. Large primary deuterium isotope effects (~ 10) have been reported for reaction of poly(peroxystyryl)peroxy (8) and tetralylperoxy radicals (11) with BMP at 65°. Several other hydrogen atom transfer reactions between oxy radicals also exhibit substantial isotope effects (26, 27).

Extrapolation of k_2^H/k_2^D ratios for BMP to 65° gave a value of $k_2^H/k_2^D = 5$–6, somewhat lower than experimental values of 10–11 for the secondary alkylperoxy radicals. This difference probably reflects the errors involved in the two methods of determining absolute rate constants rather than to curvature of the Arrhenius plots.

For most of the phenols there was very little difference between A_2^H and A_2^D, and E_2^H and E_2^D. Consequently it was not possible to decide which activation parameter was reponsible for the large isotope effects. Enough kinetic data were, however, accumulated for BMP and BMP(OD) to calculate that $\log(A_2^D/A_2^H) = 0.92$ and $E_2^D - E_2^H = 0.6$ kcal mol^{-1}. The similarity between preexponential factors for BMP and

BMP(OD), in conjunction with the apparent linearity of the Arrhenius plot for BMP (*vide supra*), implies that tunneling does not have an important effect on the activation parameters for transfer of a hydrogen atom between a peroxy radical and a hindered phenol. The difference in the activation energies of 0.6 kcal mol^{-1} is less than would be expected on the basis of a simple zero-point energy effect on the height of the barrier to reaction (8).

α-Naphthol

A kinetic study of the influence of α-naphthol on the 2,2,3,3-tetraphenylbutane initiated autoxidation of 9,10-dihydroanthracene (14) has demonstrated that this phenol behaves like a hindered phenol, *i.e.*, all the α-naphthoxy radicals produced by a reaction analogous to [2] are consumed by reaction with a second peroxy radical [3].

Decays of *tert*-butylperoxy radicals in the presence of α-naphthol and α-naphthol(OD) in isopentane or trichlorofluoromethane accurately obeyed the kinetic expression II and *tert*-butyl hydroperoxide (0.1 *M*) had no effect on rates of radical decay. Absolute values of k_2 for these two compounds were determined over a temperature range[3] *e.g.*, $k_2^H(-74°) = 3.5 \times 10^4\ M^{-1}\ s^{-1}$ and $k_2^H(-105°) = 1.5 \times 10^4\ M^{-1}\ s^{-1}$, and $k_2^D(-74°) = 0.3 \times 10^4\ M^{-1}\ s^{-1}$ and $k_2^D(-105°) = 0.08 \times 10^4\ M^{-1}\ s^{-1}$ and gave the Arrhenius equations

$$\log (k_2/M^{-1}\ s^{-1}) = (6.4 \pm 0.8) - (1.7 \pm 0.6)/\theta$$

and

$$\log (k_2/M^{-1}\ s^{-1}) = (6.4 \pm 0.7) - (2.7 \pm 0.6)/\theta$$

for α-naphthol and α-naphthol(OD), respectively, where $\theta = 2.303RT$ kcal mol^{-1}.

α-Naphthol has approximately the same reactivity to *tert*-butylperoxy radicals at low temperatures as the most efficient hindered phenol studied in this work, BMeOP. The value of A_2 for α-naphthol is about 2 log units larger than for the hindered phenols with a correspondingly larger activation energy. This implies that the entropy of activation is about 10 e.u. less negative for α-naphthol than it is for a hindered phenol.

From Mahoney's work (14) it is possible to calculate a value of $2.0 \times 10^5\ M^{-1}\ s^{-1}$ at 60° for the rate constant for reaction of 9,10-dihydroanthracyl-9-peroxy radicals with α-naphthol[4] which is in satisfactory agreement with the value of $1.9 \times 10^5\ M^{-1}\ s^{-1}$ obtained by extrapolation of the values of k_2 to this temperature.

Replacement of the phenolic hydrogen of α-naphthol with deuterium produced a substantial isotope effect on k_2, *e.g.*, at −74° $k_2^H/k_2^D = 11$ and at −105° $k_2^H/k_2^D = 18$. Again it would appear that tunneling has no influence on this hydrogen atom transfer reaction since log $(A_2^H/A_2^D) = 1.0$ and $E_2^D - E_2^H \sim 1.0$ kcal mol^{-1}.

Aromatic Amines

Kinetic studies of the influence of aromatic amines on hydrocarbon autoxidation at ambient temperatures have established that these compounds can undergo a chain termination reaction by donating a hydrogen atom to a chain propagating peroxy radical (9, 28).

[7] $$ROO\cdot + \diagdown\!\!\diagup NH \xrightarrow{k_7} ROOH + \diagdown\!\!\diagup N\cdot$$

The amino radical formed in reaction 7 may react with a peroxy radical to give nonradical products or undergo an oxygen atom transfer reaction to give an alkoxy radical (RO·) and a nitroxide ($\diagdown\!\!\diagup NO\cdot$).

[10] $$ROO\cdot + \diagdown\!\!\diagup N\cdot \rightarrow \text{Non-radical products}$$

[11] $$ROO\cdot + \diagdown\!\!\diagup N\cdot \rightarrow RO\cdot + \diagdown\!\!\diagup NO\cdot$$

If all the amino radicals are destroyed by reaction 10 the stoichiometric factor n for the aromatic amine – peroxy radical reaction will be two. However, if a significant fraction of the amino radicals undergo reaction 11 or the self reaction 12

[12] $$\diagdown\!\!\diagup N\cdot + \diagdown\!\!\diagup N\cdot \rightarrow \text{Non-radical products}$$

the value of n could be less than 2. Using the induction period method described above n was found to be 2 for α-naphthylamine (AN), *N*-phenyl-α-naphthylamine (PAN), and *N*-phenyl-β-naphthylamine (PBN).

Rates of disappearance of *tert*-butylperoxy radicals were followed from −40 to −110° in the presence of a large excess of AN, β-naphthylamine (BN), PAN, PBN, diphenylamine, and

[4]Using a propagation rate constant of $3.3 \times 10^2\ M^{-1}\ s^{-1}$ at 30° for 9,10-dihydroanthracene and an activation energy of 8.3 kcal mol^{-1} (2).

TABLE 4. Rate constants and Arrhenius parameters[a] for reaction of *tert*-butylperoxy radicals with deuterated and normal α-naphthylamine and *N*-phenyl-α-naphthylamine

Amine	$10^{-4}(k_7/M^{-1}\,s^{-1})$			$\log(A_7/M^{-1}\,s^{-1})$	E_7/kcal mol^{-1}
	−35 °C	−84 °C	−97 °C		
AN	0.15	0.10	—	3.9±0.5	1.0±0.5
AN(ND_2)	0.0065	0.0045	—	2.7±0.5	1.0±0.5
PAN	1.25	—	1.0	5.1±0.5	1.0±0.4
PAN(ND)	0.31	—	0.12	3.8±0.4	0.7±0.4

[a]Per reactive hydrogen.

N,*N*′-diphenyl-*p*-phenylenediamine in either isopentane or trichlorofluoromethane.

Reliable values of k_7 could not be determined for PBN, diphenylamine, and *N*,*N*′-diphenyl-*p*-phenylenediamine. This was because a nitroxide was produced immediately a reaction mixture was photolyzed and the low field line of the nitroxide triplet overlapped the *tert*-butylperoxy signal.

Values of $-d[tert\text{-}BuOO\cdot]/dt$ for AN, PAN, and BN, and the deuterated analogs were accurately first-order in both reactants. Rates of radical decay in the presence of AN and PAN were not influenced by the addition of *tert*-butyl hydroperoxide (0.1 *M*). This implies that α-naphthylamino and *N*-phenyl-α-naphthylamino radicals do not abstract a hydroperoxidic hydrogen at the low temperatures used in this work. *tert*-Butyl hydroperoxide did, however, slow down the rate of disappearance of *tert*-butylperoxy radicals in the presence of BN. This compound must react with peroxy radicals by a mechanism analogous to non-hindered phenols and consequently will not be considered further in this paper.

Absolute values of k_7[3] and Arrhenius parameters per active hydrogen for AN, AN(ND_2), PAN, and PAN(ND) are given in Table 4.

N-phenyl-α-naphthylamine is about 10 times more reactive than α-naphthylamine to *tert*-butylperoxy radicals and has about the same reactivity as BMeOP to this radical. The difference in reactivity between PAN and AN would appear to be because of a difference in entropy of activation rather than to a difference in enthalpy of activation. It is interesting to note that there was no measurable difference between A_7 and A_2, and E_7 and E_2 for PAN and BMeOP.

Rates of disappearance of *tert*-butylperoxy radicals in the presence of AN(ND_2) and PAN(ND) were much slower than they were in the presence of the same concentrations of AN and PBN. The rate constant ratio k_7^H/k_7^D was approximately 20 for AN and 5–6 for PBN.

Experimentally determined values of $\log A_7^D$ were about one log unit less than values of $\log A_7^H$ for both AN and PBN. This difference in preexponential factors is probably the result of experimental error rather than to a larger entropy of activation for the deuterated compound.

Conclusions

The hydrogen atom transfer reaction between the *tert*-butylperoxy radical and 2,6-*tert*-butyl-4-substituted phenols, α-naphthol, α-naphthylamine, and *N*-phenyl-α-naphthylamine is characterized by low Arrhenius parameters (10^4–10^5 $M^{-1}\,s^{-1}$ and 0.5–1.0 kcal mol^{-1}) and moderately large deuterium isotope effects (k^H/k^D = 10–20). In most cases the logarithm of the ratio of the preexponential factors for a deuterated and light compound was ~1.0 with the difference in rate constant being the result of a larger activation energy for the deuterated compound. Arrhenius plots for this reaction would appear to be linear from −100° to +65° which implies that quantum mechanical tunneling does not have an important influence on these reactions. The low activation parameters would appear to be because the reaction involves the formation of a hydrogen bonded free radical – reactant complex followed by the transfer of a hydrogen atom within the complex.

Application of Carbon-13 Nuclear Magnetic Resonance to Conformational Analysis of Trimethylene Sulfites

GERALD W. BUCHANAN[1]
Department of Chemistry, Carleton University, Ottawa, Canada K1S 5B6

J. B. STOTHERS[2]
Department of Chemistry, University of Western Ontario, London 72, Ontario

AND

GORDON WOOD
Department of Chemistry, University of Windsor, Windsor 11, Ontario

Carbon-13 n.m.r. chemical shifts are reported for trimethylene sulfite, 10 alkyl derivatives, and a related 1,3,2-dioxathiane. Data are discussed in terms of possible chair and twist conformations and in some cases the data permit definitive conformational assignments. Results are compared with previous conclusions based on proton n.m.r. and dipole moment measurements. The orientation of the S=O group is shown to have a very pronounced influence on the C-4 and -6 ring carbon shieldings.

On rapporte les déplacements chimiques en r.m.n. ^{13}C du sulfite de triméthylène, de 10 dérivés alkylés et d'une dioxathiane-1,3,2 qui leur est relié. Les donnés sont discutées en termes de conformations chaise et croisée possibles; dans quelques cas les résultats permettent de faire des attributions conformationnelles définitives. Les résultats sont comparés avec des conclusions antérieures basées sur la r.m.n. du proton et sur des mesures de moments dipolaires. On montre que l'orientation du groupe S=O a une profonde influence sur le blindage des C-4 et -6 du cycle. [Traduit par le journal]

Can. J. Chem. 51, 3746 (1973)

Introduction

In recent years considerable effort has been directed towards elucidating the conformations of substituted trimethylene sulfites. The picture appears to be clear for the parent compound in which a chair conformation with an axial S=O group dominates (1, 2). Also a strong preference for the axial orientation ($-\Delta G^\circ_{S=O}$ = 2.1 kcal/mol) has been demonstrated (3). The situation remains doubtful, however, regarding predominant conformations in alkyl substituted materials. From dipole moment (3) and ^1H n.m.r. studies the existence of non-chair conformations for several derivatives has been suggested, particularly for compounds containing *syn*-axial methyl groups at the C-4 and -6 ring positions (4, 5).

It is now well established that ^{13}C n.m.r. chemical shifts are an order of magnitude more sensitive to steric factors than ^1H shifts in favorable cases (6, 7). Thus in an attempt to gain further insight into the geometries of trimethylene sulfites in solution we have obtained the ^{13}C n.m.r. shieldings of 10 alkylated derivatives. To delineate some of the factors affecting the shieldings a related 1,3,2-dioxathiane has been studied. Results are compared with published findings for 1,3-dioxanes (8) and 1,3,2-dioxaphosphorinanes (9).

Results and Discussion

^{13}C n.m.r. shieldings for trimethylene sulfite and 10 alkyl derivatives are presented in Table 1 while data for related systems are collected in Table 2.

Assignments for **1** are apparent from observed integrated intensity ratios. Differences in nuclear Overhauser enhancements for methylene carbons of this type will be minimal. For alkylated materials ring carbon assignments follow directly from empirically established trends of alkyl substitution on carbon resonances (10). In **2**, for example, the downfield shift of 7 p.p.m. for C-4 on replacement of a hydrogen by a methyl is reminiscent of the 9 p.p.m. deshielding effect observed in hydrocarbons (10). The β-deshielding effect on C-5 of similar magnitude is again consistent with the early hydrocarbon findings.

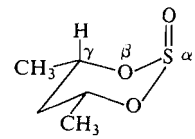
†From ref. 9 (75% v:v solutions in C_6D_6).

For methyl carbons in **5**, **7**, and **8**, assignments were verified by specific ^1H decoupling experiments, since it is known (4) that protons of axial methyl groups in trimethylene sulfites are deshielded relative to their equatorial counterparts. From dipole moments and ^1H n.m.r. (4), compounds **2** and **4** are deemed to be in chair conformations with axial S=O functions. The equatorial methyl carbon shieldings are identical (21.1 ± 0.1 p.p.m.) for these materials. It is interesting to note the similarity with the equatorial methyls in **6**, a compound judged to be entirely in a chair conformation with an *equatorial* S=O grouping. Apparently an equatorial methyl carbon at C-4 or -6 will resonate near 21.1 p.p.m. regardless of the orientation of the S=O moiety.

In striking contrast, employing **4** and **6** as model compounds, it is clear that the orientation of the S=O has a very large influence on the C-4 and -6 ring carbon shieldings. In **4**, where the axial hydrogens on C-4 and -6 are *syn*-axial to the exocyclic oxygen, C-4 and -6 are shielded by *ca.* 9 p.p.m. relative to their counterparts in **6**. Presumably this is another example of the upfield γ steric shift (6, 7, 11, 12, 16).

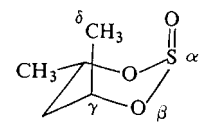


4

In **4** the axial S=O bond is *gauche* with respect to the O—C-4 (O—C-6) bond but in **6** the equatorial S=O will be *anti*. Nonbonded interactions between the axial oxygen in **4** and the axial hydrogens at C-4 and -6 are probably sufficient to perturb the electron distribution about C-4 and -6 and increase their shielding. A theoretical model for the γ effect based on charge polarization has been proposed (12). It is interesting that the magnitude of the upfield shift in the epimeric sulfites is nearly twice that observed in epimeric 4-*t*-butylcyclohexanols (6, 13). For the *cis* isomer of the cyclohexanols the C-3 and -5 ring carbons are shielded by 4.7 p.p.m. relative to the corresponding carbons of the *trans* form. In 1,3 dioxanes (8), where the interatomic distances are somewhat decreased, the steric interactions between an axial CH_3 at C-2 and the axial hydrogens at C-4 and -6 induce an upfield shift of 6.5 p.p.m. in the latter carbon resonances.

Supporting evidence for a predominantly steric origin of the upfield γ shift in **4** is gained from the results for the dioxathiane **12**, which lacks the exocyclic oxygen and is a mixture of rapidly inverting chair forms at room temperature (14). In **12**, C-4 and -6 appear at 74.8 p.p.m. which is reasonably close to those in **6** (73.7 p.p.m.) but 10 p.p.m. less shielded than C-4 and -6 of **4**.

The remaining 4,6-dimethyl trimethylene sulfite **5** is thought to exist as a mixture of a chair form with axial S=O and a non-chair form (4). The 21.0 shielding for the methyl on C-4 indicates an equatorial orientation for this group but the methyl on C-6 appears at measurably lower field at 22.4 p.p.m. If the methyl were



5

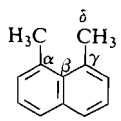
axial it would be *syn*-axial to the exocyclic oxygen and an appreciable steric interaction is expected. For sterically interacting "δ" methyl groups it has recently been found that appreciable deshielding effects are operative (15). A primary example is 1,8-dimethylnaphthalene in which the methyls are deshielded by 6.6 p.p.m. relative to those in the 1,4-dimethyl derivative. Apparently a related deshielding δ effect is responsible for the low field shift of the axial methyl on C-6 of **5**, although in sulfites with an axial S=O group, the possibility of local anisotropic contributions to the shieldings cannot be disregarded.



It is notable that the C-4 methine carbon of **5** is *ca.* 2 p.p.m. upfield from that in **4**. Steric interactions between the axial methyl on C-6 and the axial H on C-4 (γ effect) are likely to be causing this shielding. The magnitude of the effect, however, is only about half of that (3.97 p.p.m.) seen for the axial conformer of methylcyclohexane (10, 16). This may imply some contribution from a form other than a chair in agreement with conclusions based on dipole moment and ^{1}H n.m.r. data.

The monomethyl sulfite **3** is judged from ^{1}H n.m.r. and dipole moments to be a mixture of a chair with equatorial S=O (*b*) and some non-chair form (*c*). If (*b*) were the only contributing conformation then the methyl signal should appear near 21.1 p.p.m. as expected for a pure equatorial substituent. The observed shift of 21.6 p.p.m. implies some contribution from an axial or quasi-axial methyl, since a deshielding δ effect appears to be operative. Notably the C-4 shift of **3** (63.0) is rather similar to that of **2** (64.1) and **4** (64.6). If **3** exists to an appreciable extent in a chair with axial S=O, there will be strong nonbonded interactions between the exocyclic oxygen and the *syn*-axial methyl group. This would be expected to lead to increased shielding at C-4, as observed. Thus, in contrast to earlier interpretations (4), ^{13}C shifts suggest that a chair form (*a*) of **3** is extensively populated. Distinction between (*b*) and (*c*) as minor contributors, however, cannot be made.

In the trimethyl sulfites **7** and **8**, replacement of both hydrogens on C-4 by methyl groups shifts the C-4 resonance substantially downfield as expected from the established trends of alkyl substitution (10). The most striking difference between these isomers, however, is the 10 p.p.m. upfield shift for C-6 of **7** relative to C-6 in **8**. If a chair form with an axial S=O predominates for **7**, then this observation can be explained on the basis of the upfield γ-steric shifts noted earlier. The axial methine proton at C-6 will experience non-bonded interactions with the axial methyl at C-4 and the axial exocyclic oxygen atom. It is interesting to note that relative to **4**, C-6 of **7** is shielded by 4.1 p.p.m. This upfield shift is nearly identical to that observed in an axial methyl substituted cyclohexane (16) and suggests that for **7** a chair conformation with an axial methyl at C-4 is highly populated. In support of this is the 21.2 p.p.m. shift for the methyl at C-6 indicating an essentially pure equatorial disposition. Thus for **7** ^{13}C n.m.r. results suggest that conformation (*a*) predominates and little evidence for a non-chair form (*c*) exists in contrast to conclusions based on ^{1}H n.m.r. and dipole moments.

Compound **8** shows similar dipole moment behavior to **3** and is judged to be a mixture of mostly a chair with equatorial S=O (*b*) and some non-chair form (*c*). The 22.0 p.p.m. shift for the methyl at C-6 of **8** indicates that this function cannot be solely equatorial and therefore some form other than (*b*) must be appreciably populated. Further insight is gained by comparing the C-6 shift of **8** with that of **6**. In **8** C-6 is shielded by 3.4 p.p.m. relative to **6** and accordingly a large contribution from a chair with an axial methyl at C-4 appears likely. The upfield shift, however, is less than that seen for axial methylcyclohexane (10, 16) suggesting minor contributions from either (*a*) or (*c*).

Assuming that **7** exists almost exclusively in conformation (*a*) and **8** is mainly in form (*b*) the shifts of the axial methyls at C-4 can be rationalized on the basis of the previously described deshielding δ effect. In **7** there will be a δ interaction between the axial exocyclic oxygen and the axial methyl at C-4 whereas in the major form of **8** no such interaction will exist. As a result the axial methyl at C-4 of **7** is appreciably deshielded (by 2.4 p.p.m.) relative to its counterpart in **8**.

The tetramethyl substituted sulfite **9** has been assigned a non-chair geometry on basis of ^{1}H

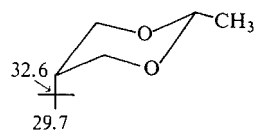
For personal use only.

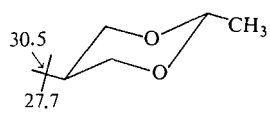
n.m.r. and dipole moments (3, 4). Carbon shieldings for the *gem*-dimethyl groups are distinctly different from those in the predominantly chair forms **7** and **8**. On these grounds ^{13}C n.m.r. results lend support to the earlier conclusions.

The C-4 and -6 shifts of the *t*-butyl sulfites **10** and **11** provide a clue as to their predominant conformations. For **10** the dominant form is no doubt a chair with an equatorial *t*-butyl group and an axial S=O (3, 4). Compound **11**, however, is deemed to be a mixture of *trans*-diaxial chair (*a*) and a twist form (*c*). If **11** had a large component of a *trans*-diequatorial chair (*b*), a considerable deshielding effect relative to **10** should be observed at the C-4 and -6 carbons due to a removal of the *gauche* interaction of the S=O bond with the O—C-4 and O—C-6 bonds. Employing compound **4** as a model for pure axial S=O and **6** for pure equatorial S=O, a difference of near 9 p.p.m. might be expected between **10** and **11**. The observed deshielding in **11**, however, amounts to only 2.4 p.p.m. at C-4 and -6 ruling out extensive contributions from a *trans*-diequatorial chair.

It is interesting to note that the quaternary *t*-butyl carbon and the methyl carbons of **11** are deshielded by *ca.* 1 p.p.m. relative to their counterparts in **10**. By comparison, in *cis*-2-methyl-5-*t*-butyl-1,3-dioxane (**15**), the corresponding carbons are deshielded by 2 p.p.m. relative to those in the *trans*-isomer **16** (8, 17). The epimeric 2-methyl-5-*t*-butyl-1,3,2-dioxaphosphorinanes **13** and **14** (Table 2) show a similar,



15



16

albeit smaller effect which is attributed to the presence of an equilibrium mixture in the *trans*-isomer (9). For an axial substituent at the 5-position of these three classes of compounds no *syn*-axial hydrogens are present, and it appears that the ring oxygen atoms preferentially deshield an axial moiety. If (*a*) were the only contributor to the structure of **11**, a larger deshielding trend close to that of the 1,3-dioxanes would be expected. We conclude therefore that **11** is an equilibrium mixture of about 70% (*a*) with the remaining forms being (*b*) and/or (*c*).

Conclusions

It is clear that ^{13}C n.m.r. constitutes a useful addition to the available methods for examining geometries of trimethylene sulfites. Shieldings at the C-4 and -6 ring carbons combined with those for substituent methyl and *t*-butyl groups give valuable insight into trimethylene sulfite conformation. For C-5 ring carbons no trends consistent with conformational changes are evident. Shieldings at this position reflect the previous observation (4) that association phenomena in any form most strongly perturb the electronic environment about this carbon. The present paper includes additional evidence for an important deshielding δ effect on carbon resonances.

Experimental

Materials

Syntheses for all compounds have been described previously (3, 14).

Spectra

Compounds were examined as 0.1–0.3 *M* solutions in $CDCl_3$ containing TMS as an internal standard. No significant dilution effects on the shieldings were observed over this concentration range. All spectra were obtained at 25.2 MHz most commonly under conditions of complete proton noise decoupling. Except for **11**, a Varian XL-100-15 spectrometer operating in the Fourier Transform mode was employed using 5 mm spinning sample tubes. Compound **11** was examined using a Varian XL-100-12 spectrometer, with spectral accumulations accomplished by a C-1024 time averaging computer on an 8-mm sample tube.

The Isomeric Enol Acetates of Acetylacetone. Evidence for an Unusual Stabilizing Interaction between *cis* Acetyl and Acetoxy Groups

DENNIS V. C. AWANG
Department of National Health and Welfare, Tunney's Pasture, Ottawa, Canada K1A OL2

Received July 23, 1973

The configuration and conformation of the isomeric enol acetates of acetylacetone have been elucidated. P.m.r. shift data obtained by the use of tris(1,1,1,2,2,3,3-heptafluoro-7,7-dimethyl-4,6-octanedionato)-europium(III) ($Eu(fod)_3$) allow assignment of the (*S*)-*cis* conformation to both isomers. The remarkable stability of the isomer having acetyl *cis* to acetoxy is attributed to neighboring group interaction, a rationale consistent with p.m.r. spectroscopic data.

La configuration et la conformation des deux acétates énoliques de l'acétylacétone ont été élucidées. Les déplacements chimiques paramagnétiques de r.m.p. obtenus par l'emploi du tris(1,1,1,2,2,3,3-heptafluoro-7,7-dimethyl-4,6-octanedionato)europium(III) ($Eu(fod)_3$) démontre une conformation (*S*)-*cis* pour les deux isomères. La stabilité remarquable de l'isomère ayant le groupement acétyl en position *cis* par rapport au groupement acétoxy est attribuée à l'interaction des groupements environnants et sa rationalisation est supportée par des données spectroscopiques obtenues par r.m.p.

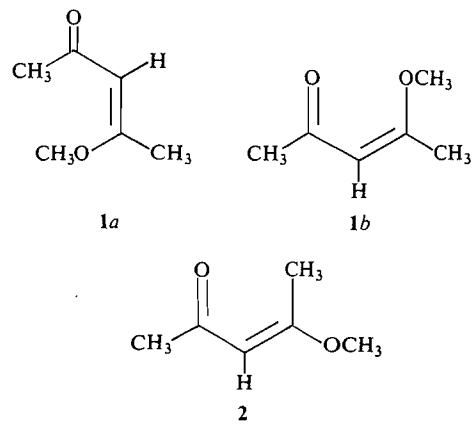
It has been reported (1) that acetylacetone is converted to an enol acetate in good yield when refluxed with isopropenyl acetate in the presence of an acid catalyst. We have repeated this preparation several times and it has been observed to give rise consistently to *two* isomeric monoacetates, hitherto unreported, in close to a 1:1 ratio.[1]

The physical properties of these enol acetates are too similar to permit separation by fractional distillation but the pure liquid isomers can readily be obtained by preparative t.l.c.

The configuration and conformation of the two isomeric methyl enol ethers of acetylacetone have recently been assessed by observation of nuclear Overhauser effects and p.m.r. solvent shift techniques (3); conclusions based on analysis of data collected in the latter study were supported by $Eu(thd)_3$-induced shift data (4).[2] The less stable isomer, having acetyl *cis* to methoxyl adopts the (*S*)-*trans* conformation (**1***a*) and suffers remarkably facile acid-catalyzed isomerization to the other isomer in which the acetyl group is *trans* to methoxyl in an (*S*)-*cis* conformation (**2**). Compound **1** also undergoes ready thermal isomerization to **2**.



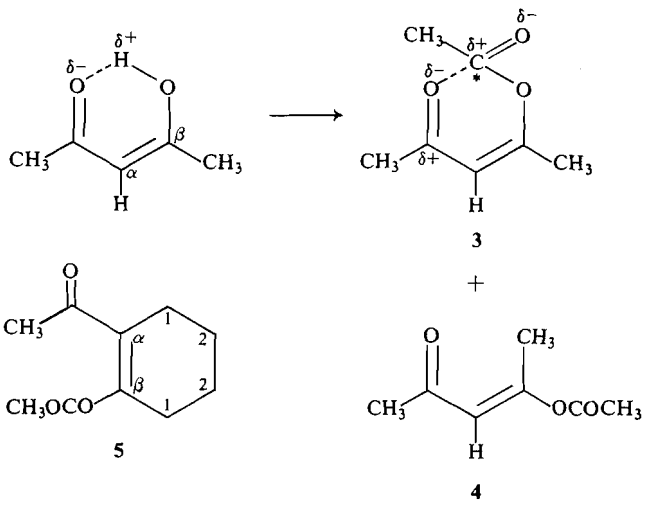
1*a* **1***b*

2

Adoption of the (*S*)-*trans* conformation, generally disfavored by β-disubstituted-α,β-unsaturated acyclic ketones, was attributed to a strong repulsive interaction between *cis* methoxyl and carbonyl in the (*S*)-*cis* conformation (**1***b*) of the less stable enol ether. An analogous situation was expected to exist in the case of the enol acetates of acetylacetone. However, no hope of isolating the acetate corresponding to **1** was seriously entertained, since no mild and relatively neutral method for preparation of enol acetates

[1]Taylor *et al.* (2) have reported a 90% yield of *O*-acetyl derivative from treatment of the thallium(I) salt of acetylacetone with acetylchloride at −78°. However, no spectral data were cited in support of structure.

[2]Tris(2,2,6,6-tetramethyl-3,5-heptanedionato)europium (III), also referred to as tris(dipivalomethanato)europium (III) ($Eu(DPM)_3$).



SCHEME 1

(comparable with the diazomethane method which yields **1**) is yet available.

The configuration and conformation of the isomeric enol acetates were revealed by examination of their p.m.r. spectra utilizing the superior paramagnetic shift reagent, tris(1,1,1,2,2,3,3-heptafluoro - 7,7 - dimethyl - 4,6 - octanedionato)-europium(III) ($Eu(fod)_3$) (5); $Eu(thd)_3$, which was successfully employed in the case of the analogous methyl enol ethers, was of no assistance, presumably because of the reduced Lewis basicity of the enol acetates, allied with a low inherent solubility of the reagent in organic solvents.

As illustrated in Scheme 1, the preferred conformation for both enol acetates of acetylacetone is the (*S*)-*cis*. The increased stability of acetate **3** compared with the analogous enol ether **1** is attributed to a stabilizing attractive interaction between acetyl oxygen and the carbonyl carbon atom of the *cis* acetate group. Table 1 lists Δ_{Eu} values (6), which represent the slopes of the straight lines obtained from plots of δ *vs.* $Eu(fod)_3$/substrate mol ratio; the larger the Δ_{Eu} value the greater the particular proton or set of protons is shifted downfield by the shift reagent.

The assignments made on the basis of $Eu(fod)_3$-induced shifts observed for enol acetate **4** are reinforced by observations of its benzene-induced shifts (3) (Table 2), complexation occurring predominantly at acetyl carbonyl.

The shifts induced by solvent benzene in the proton signals of **3**, however, are not so readily rationalized, being of the same sense and of almost identical value for all protons in the molecule. These enigmatic benzene-induced shifts, the identical Δ_{Eu} values for acetate and acetyl protons,[3] and the fact that the latter two groups of protons exhibit a smaller Δ_{Eu} value than does the vinylic proton, can be explained on the basis of competitive complexation. Involvement of a lone pair of electrons of acetyl oxygen in an electrostatic interaction[4] with the carbonyl carbon of the acetoxy group (as illustrated in Scheme 1) would be expected to reduce the ability of acetyl oxygen to complex with the shift reagent. It is not yet possible to separate electronic from purely steric components. Also the relative values for Δ_{Eu} indicate that when europium is coordinated with either doubly bonded oxygen atom, the methyl protons alpha to the other must be rather less influenced by the ligand than is the vinylic proton.

The fact that the enol acetate (**5**) of 2-acetylcyclohexanone, a cyclic analog of acetate **3**, exists predominantly in the (*S*)-*trans* conforma-

[3]The p.m.r. signal for these protons, under the influence of the shift reagent, is markedly broadened compared with all other signals.

[4]A ^{13}C spectroscopic study bearing upon the nature of this interaction and on conformational variation among some enol derivatives of labile 1,3-diketones will be the subject of a forthcoming publication.

TABLE 1. Δ_{Eu} values for protons of enol acetates of acetylacetone and 2-acetylcyclohexanone

Compound	=CH	$=CCH_3$	$OCOCH_3$	$CCOCH_3$
3	11.6	5.6	7.5	7.5
4	12.0	14.7	5.0	17.5
5[a]	—	—	4.8	12.9

[a]Under the influence of the shift reagent the ring proton pattern is resolved into three broad resonances of relative intensity 1:1:2, corresponding to Δ_{Eu} values of 11.1, 5.6, and 2.8, respectively. Since complexation occurs predominantly at the oxygen atom of the acetyl group, the former resonances are assigned to the methylene protons attached to α-C-1 and -2 carbon atoms; the latter resonance would then be due to the paired β-C-1 and -2 protons.

TABLE 2. Chemical shift displacement[a] of the p.m.r. signals of the enol acetates of acetylacetone and 2-acetylcyclohexanone, induced by benzene solvent

Compound	=CH	$=CCH_3$	$OCOCH_3$	$CCOCH_3$
3	+0.23	+0.25	+0.25	+0.25
4	+0.12	−0.02	+0.40	+0.10
5[b]	—	—	+0.42	+0.01

[a]$\delta_{CCl_4} - \delta_{benzene}$ in p.p.m.
[b]The α-C-1 and -2 protons undergo a positive shift of 0.01 p.p.m. while the β-C-1 and -2 protons are displaced by 0.42 p.p.m. in the same sense.

tion may be explained on the basis of ring constraint in the cyclic compound, preventing rotation about the olefinic bond; such rotation may be necessary for an attractive interaction sufficiently great to counteract the serious 1,3 O–O repulsion that would normally disfavor the (*S*)-*cis* conformation for such molecules.

Experimental

The p.m.r. spectra were recorded using a Varian A-60A spectrometer; spectral grade solvents containing tetramethylsilane (TMS) as internal reference were employed in all cases. The i.r. spectra were obtained with a Perkin-Elmer Model 621 spectrophotometer and u.v. spectra on a Beckman DB spectrophotometer.

Enol acetates **3**, **4**, and **5** were prepared by the method of Hagemeyer and Hull (1) employing commercially available isopropenyl acetate, acetylacetone, and 2-acetylcyclohexanone. The latter two compounds were distilled prior to use.

Enol Acetates 3 and 4

Fractional distillation of the product of reaction of acetylacetone with isopropenylacetate yielded a mixture of isomers **3** and **4**, b.p. 88–90°/6 mm, in a ratio of 9:11, as estimated by integration of the p.m.r. signals of their respective vinylic protons. (No evidence of *C*-acetylation was found.)

The isomers were isolated by preparative t.l.c. on 20 × 20 cm glass plates, precoated with silica gel GF of thickness 1 mm (Fisher), using benzene–ether (9:1). Isomer **4** gives a higher R_f value under these conditions.

Spectral characteristics for **3** are: p.m.r. (CCl_4) δ 5.72 (s, 1H), 2.13 (s, 3H, $=CCH_3$), and 2.00 p.p.m. (s, 6H, $CCOCH_3$; $OCOCH_3$); i.r. ($CHCl_3$) ν 1755 (C=O, ester), 1690 (C=O, ketone), 1655 (?), and 1625 cm^{-1} (C=C); u.v. (95% EtOH) λ_{max} 230 nm (ε 9350). Spectral characteristics for **4** are: p.m.r. (CCl_4) δ 5.98 (s, 1H),[5] 2.25 (d, 3H, $C=CH_3$, $J_{1,3}$ = 1.3 Hz), 2.11 (s, 3H, $OCOCH_3$), and 2.08 p.p.m. (s, 3H, $CCOCH_3$);[6] i.r. ($CHCl_3$) ν 1755 (C=O, ester), 1695 (C=O, ketone), and 1615 cm^{-1} (C=C); u.v. (95% EtOH) λ_{max} 229 nm (ε 6480).

Enol Acetate 5

Enol acetate **5** was obtained pure in 75% yield by fractional distillation of the neutralized reaction product. It had b.p. 95–96°/4.5 mm.

[5]This signal is considerably broadened compared with that of the vinylic proton signal for acetate 3, whose allylic methyl protons are much less strongly coupled and give rise to a sharp singlet under all conditions of observation employed in this study. Its appearance 0.26 p.p.m. downfield from the vinylic proton signal for acetate 3 is probably not significantly due to any deshielding anisotropic effect of the *cis* acetoxy group, since the p.m.r. (60 MHz, CCl_4) signals for the vinylic protons of isopropenyl acetate are coincident. This latter observation prompted Jackman and Wiley (7) to conclude that the acetoxy substituent "prefers those conformations in which the carbonyl group is well removed from *cis*-β-olefinic proton".

[6]These assignments were arrived at by observation of the relative movement of the two signals when very small quantities of the shift reagent were added to the sample solution. No crossover of signals was noted.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Spectral characteristics for **5** are: p.m.r. (CCl_4) δ 2.17 (s, 3H, $CCOCH_3$)[6], 2.13 (s, 3H, $OCOCH_3$),[6] and 2.25 and 1.70 p.p.m. (centers of multiplets, corresponding to 4H each, of α-C-1 and -2, and β-C-1 and -2, respectively); i.r. ($CHCl_3$) ν 1755 (C=O, ester), 1710 (C=O, ketone), 1690 (?), and 1650 cm^{-1} (C=C); u.v. (95% EtOH) λ_{max} 239 nm (ε 7360).

The author acknowledges the excellent technical assistance of Mr. A. Vincent and is grateful to Mr. H. W. Avdovich for recording the p.m.r. spectra.

The Use of Polymer Supports in Organic Synthesis. III.[1] Selective Chemical Reactions on One Aldehyde Group of Symmetrical Dialdehydes

CLIFFORD C. LEZNOFF AND JACK Y. WONG
Department of Chemistry, York University, Downsview, Ontario

Received June 11, 1973

An insoluble polymer support system incorporating a diol functional group was prepared. The symmetrical dialdehydes, terephthalaldehyde and isophthalaldehyde, were attached to the polymer through acetal formation, constituting a unique method of blocking one aldehyde group of symmetrical dialdehydes. The free aldehyde group was reacted with hydroxylamine to give the mono-oximes of the terephthalaldehyde and isophthalaldehyde upon acid cleavage from the polymer. Similarly, the polymer bound aldehydes were reacted with Wittig reagents to give *p*- and *m*-formylstilbenes and 1-*p*- and -*m*-formylphenyl-4-phenyl-1,3-butadienes. The crossed aldol condensation of acetophenone with the symmetrical dialdehydes gave the 3-*p*- and -*m*-formylphenyl-1-phenyl-2-propene-1-ones (formylchalcones) in high yield. The Grignard reaction of phenylmagnesium bromide on the polymer bound aldehyde gave (*p*- and *m*-formylphenyl)phenylcarbinol in quantitative yield. Reduction of the polymer bound free aldehydes with sodium bis(2-methoxyethoxy)-aluminum hydride gave *p*- and *m*-hydroxymethylbenzaldehydes. Similarly the mixed benzoin condensation of polymer bound terephthalaldehyde and isophthalaldehyde gave *p*- and *m*-formylbenzils.

Un support insoluble, à base de polymère possédant un groupe fonctionnel diol, a été préparé. Les dialdéhydes symétriques, téréphthalaldéhyde et isophthalaldéhyde, ont été fixés au polymère sous forme d'acétal constituant ainsi une méthode unique de blocage d'un seul groupe aldéhyde dans les dialdéhydes symétriques. Le groupe aldéhyde libre a été mis en réaction avec l'hydroxylamine pour conduire aux mono-oximes de téréphthalaldéhyde et isophthalaldéhyde, après clivage acide. De la même façon, les aldéhydes fixés au polymère réagissent sur les réactifs de Wittig pour conduire aux *p*- et *m*-formylstilbènes et aux *p*- et *m*-formylphényl-1 phényl-4 butadiènes-1,3. La condensation aldol croisée entre l'acétophénone et les dialdéhydes symétriques conduit aux *p*- et *m*-formylphényl-3 phényl-1 propène-2 ones-1 (formyl chalcones) avec un rendement élevé. La réaction de Grignard entre le bromure de phénylmagnésium et l'aldéhyde fixé au polymère conduit aux (*p*- et *m*-formylphényl)phénylcarbinol avec un rendement quantitatif. La réduction des groupes aldéhydes libres par l'hydrure de sodium bis(méthoxy-2 éthoxy)-aluminium conduit aux *p*- et *m*-hydroxyméthylbenzaldéhydes. De façon semblable, la condensation benzoine mixte du téréphthalaldéhyde et isophthalaldéhyde fixés au polymère conduit aux *p*- et *m*-formylbenzyles. [Traduit par le journal]

Can. J. Chem. **51**, 3756 (1973)

The use of insoluble polymer supports in the synthesis of polypeptides (1), polynucleotides (2), and polysaccharides (3) has been well documented. The general application of insoluble polymer supports to organic synthetic problems has only recently received scattered attention (4). We have previously shown how an insoluble polymer support, containing acid chloride groups (5) can be used as a selective blocking group for completely symmetrical diols and hence the preparation of monotrityl and monotetrahydropyranyl derivatives of symmetrical diols were facilitated (6, 7).

We now describe a procedure in which symmetrical dialdehydes are attached to a modified insoluble Merrifield polymer (**1**) through an acetal linkage of only one aldehyde group, leaving the other aldehyde group available for reaction. This procedure constitutes a unique method of blocking one aldehyde group of a symmetrical dialdehyde.

A suitable modified Merrifield polymer was prepared by reacting a commercially available Merrifield polymer (**1**) (2% cross-linked polystyrene beads with 1.7 mmol of $-CH_2Cl$ groups per gram of resin, obtained from Schwarz/Mann), with the sodium salt of 2,2-dimethyl-1,3-dioxolane-4-methanol in excess 2,2-dimethyl-1,3-dioxolane-4-methanol[2] as solvent to give resin **2**, as shown in Scheme 1. Acid hydrolysis of **2** with dilute HCl in aqueous dioxane (1:1) gave resin **3** containing a vicinal diol functional group

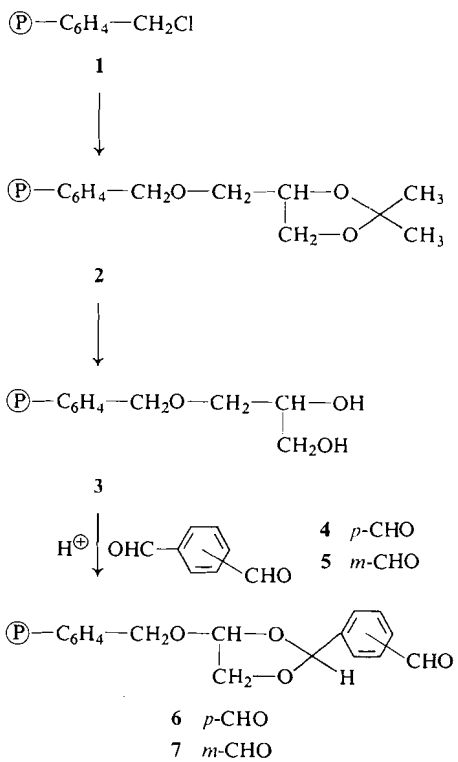
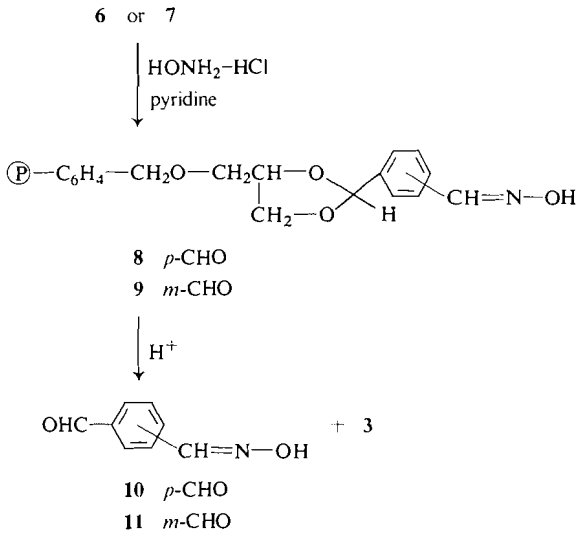
available for acetal formation. The i.r. spectrum of **3** exhibited O—H absorption at 3415 cm^{-1} and C—O absorption at 1058 cm^{-1}.

Resin **3** reacted with excess terephthalaldehyde (**4**) or isophthalaldehyde (**5**) in anhydrous dioxane, containing *m*-benzenedisulfonic acid as a catalyst and magnesium sulfate to absorb the liberated water, to yield resins **6** or **7** containing aldehydes **4** or **5** respectively. The i.r. spectra of resins **6** and **7** exhibited typical aldehyde absorption at 1700 cm^{-1} showing that one aldehyde function did not form an acetal. The use of excess aldehyde ensured that only monoacetal formation would predominate. The amount of aldehyde attached to the polymer was determined by acid hydrolysis of **6** and **7** in aqueous dioxane (1:1) with dilute HCl to yield **4** and **5** respectively. It was thus shown that resin **6** contained 0.34 mmol of **4** per gram and resin **7** contained 0.35 mmol of **5** per gram. Thus the capacities of resins **6** and **7** are very high compared to resins described in earlier publications (1–7).



SCHEME 1



SCHEME 2

Chemical syntheses designed to react with only one aldehyde group of symmetrical dialdehydes are quite rare and have met with success in only a few instances under special conditions (8) and even then difficulties of separation of reagents and products were apparent.

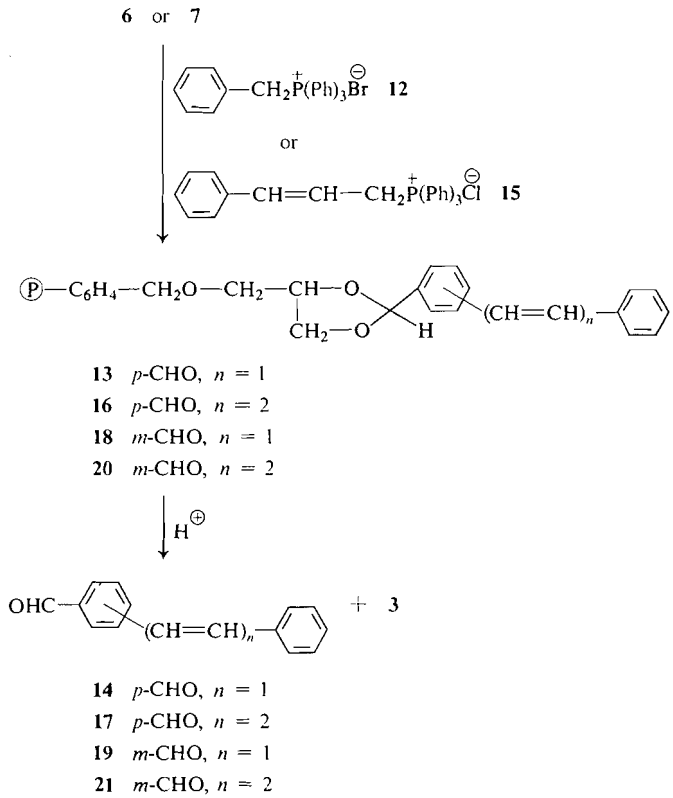
The following chemical reaction types illustrate how resin aldehydes **6** and **7** can be used to prepare largely unknown and poorly accessible compounds containing free formyl groups.

Oxime Formation

For example, the simple mono-oximes of terephthalaldehyde (**4**) and isophthalaldehyde (**5**) are unreported but these derivatives are readily synthesized using resins **6** and **7**.

In a typical reaction sequence as outlined in Scheme 2, resin **6** or **7** and an excess of hydroxylamine hydrochloride in pyridine gave after 24 h the resin oximes **8** or **9**. Acid hydrolysis of **8** or **9** as before gave terephthalaldehyde mono-oxime (**10**) and isophthalaldehyde mono-oxime (**11**) in 86 and 71% yield, respectively.[3] Elemental analysis and mass spectral data were consistent with structures **10** and **11**. Both oximes **10** and **11** exhibited strong parent ions in their mass spectra and a peak at *m/e* 120 indicating the expected loss of a formyl group by α-cleavage. The i.r. spectra

[3]All yields are based on the amount of **4** (or **5**) released from resin **6** (or **7**) upon acid hydrolysis.



SCHEME 3

of **10** and **11** showed characteristic C=O and O—H absorption.[4]

The Wittig Reaction

It was decided to examine the Wittig reaction with the monoprotected dialdehydes **6** and **7** with benzyltriphenylphosphonium bromide and cinnamyltriphenylphosphonium chloride as the products of these reactions, formylstilbenes and 1-formylphenyl-4-phenyl-1,3-butadienes were unknown compounds, difficult to prepare by other methods, and were essential in other studies in this laboratory, involving the photochemistry of diarylpolyenes (9).

Thus reaction of the resin aldehyde **6** and benzyltriphenylphosphonium bromide (**12**) in anhydrous dimethylformamide and sodium methoxide gave resin **13**, as shown in Scheme 3. The i.r. spectrum of resin **13** showed some residual aldehyde absorption at 1692 cm^{-1}. Acid hydrolysis of resin **13** as before gave used resin **3** and crude *p*-formylstilbene (**14**) which on further purification by t.l.c. gave pale yellow needles of **14** in 76% yield. Similarly, the resin aldehyde **6** and cinnamyltriphenylphosphonium chloride (**15**) gave resin **16** which on treatment with acid yielded 1-*p*-formylphenyl-4-phenyl-1,3-butadiene (**17**) in 59% yield.

Likewise, the Wittig reaction of resin aldehyde **7** with **12** gave resin **18** which on acid treatment yielded *m*-formylstilbene (**19**) in 50% yield. Reaction of resin **7** with **15** gave resin **20** which on acid treatment gave 1-*m*-formylphenyl-4-phenyl-1,3-butadiene (**21**) in 27% yield.

The mass spectra of **14**, **17**, **19**, and **21** exhibited parent ions and (M − 29) peaks due to the loss of the formyl group by α-cleavage. The i.r. spectra of **14**, **17**, **19**, and **21** showed absorption for the formyl and olefin moieties. The u.v. spectra of these products showed the characteristic stilbene and 1,4-diphenyl-1,3-butadiene absorption (9).

[4]Full spectral data are described in the Experimental section.

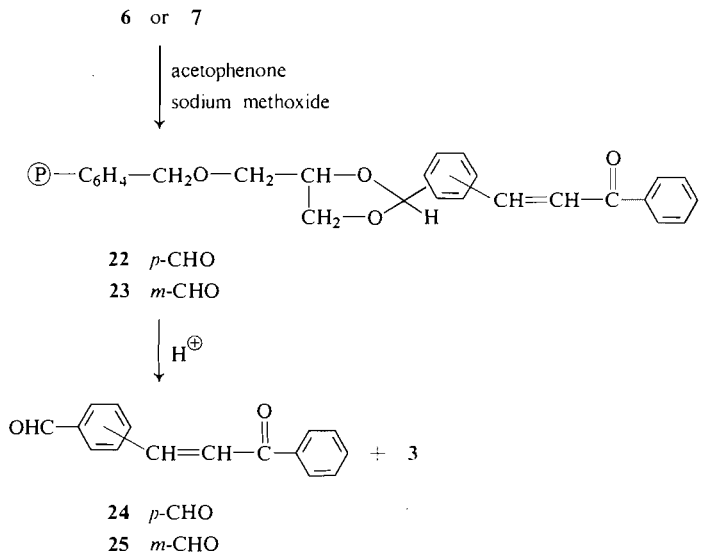

SCHEME 4

The Crossed Aldol Condensation

In experiments designed to test the feasibility of conducting mixed condensation reactions involving the mono-protected symmetrical aldehydes **4** and **5**, the cross aldol condensations of resin aldehydes **6** and **7** with acetophenone were attempted.

Resin aldehydes **6** and **7** were condensed with acetophenone and sodium methoxide in absolute ethanol to yield resin chalcones **22** and **23** respectively. Cleavage of the chalcones from resins **22** and **23** gave the chalcones 3-*p*-formylphenyl-1-phenyl-2-propen-1-one (**24**) (10) and 3-*m*-formylphenyl-1-phenyl-2-propen-1-one (**25**) in 100 and 96% yields respectively[5] as shown in Scheme 4.

The mass spectra of **24** and **25** exhibited parent ions and (M − 29) peaks due to the loss of the formyl group by α-cleavage. The i.r. spectra of **24** and **25** showed typical carbonyl and olefin absorption. The u.v. spectra were typical of chalcones.

The Benzoin Condensation

Attempts at conducting mixed benzoin condensations invariably lead to intractable mixtures of symmetrical benzoins and mixed or crossed benzoins.

It was envisoned that a polymer supported aldehyde could react with excess benzaldehyde under the conditions of the benzoin condensation. The insoluble polymer supported aromatic aldehydes could then react with benzaldehyde to give mixed or crossed benzoins exclusively. All symmetrical benzoin and excess reagents would simply be filtered from the insoluble resin containing the crossed benzoin.

To this end resin aldehyde **6** was treated with benzaldehyde and sodium cyanide in absolute ethanol to give resin **26**, as shown in Scheme 5. Acid cleavage of **26** gave a complex mixture of products which were chromatographed on preparative t.l.c. The major fraction, obtained in only 6% yield, consisted of *p*-formylbenzil (**27**). Similarly, reaction of aldehyde resin **7** with benzaldehyde in a benzoin condensation led to resin **28** which on acid cleavage gave *m*-formylbenzil (**29**) in 4% yield.

The mass spectra of **27** and **29** were very characteristic of benzils and not benzoins and exhibited parent ions and symmetrical cleavage of the α-diketones to give fragment ions at *m/e* 105 and 134 characteristic of the benzoyl group and the formylbenzoyl groups respectively. Furthermore, the i.r. spectra of **27** and **29** exhibited strong carbonyl absorption but a noted absence of O—H absorption. Thus it appears that the crossed benzils **27** and **29** are formed by oxidation of preformed benzoins.

[5]The chalcone **24** was previously obtained in only 30% yield (10).

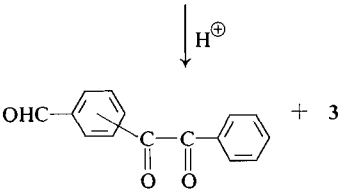
26 *p*-CHO
28 *m*-CHO

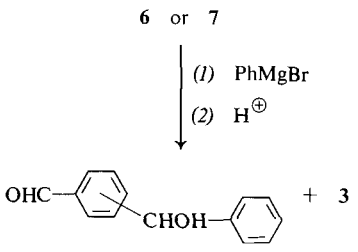


27 *p*-CHO
29 *m*-CHO

SCHEME 5

The Grignard Reaction

The reaction of Grignard reagents with symmetrical dialdehydes would inevitably lead to poorly separable mixtures containing the di-adduct, the mono-addition product, and unreacted starting material. The selective formation of the mono-addition product can be achieved using insoluble polymer supports as outlined in Scheme 6.



30 *p*-CHO
31 *m*-CHO

SCHEME 6

The resin aldehyde **6** was reacted with phenylmagnesium bromide in tetrahydrofuran to yield a resin alcohol which was not isolated, but directly treated with acid to give resin **3** and (*p*-formylphenyl)phenylcarbinol (**30**) (*p*-formylbenzhydrol) in 99% yield. Similarly resin aldehyde **7** was treated with phenylmagnesium bromide to give (*m*-formylphenyl)phenylcarbinol (**31**) (*m*-formylbenzhydrol) in 100% yield.

The mass spectra of **30** and **31** exhibited parent ions and peaks at 105 indicative of the formylphenyl group. The i.r. spectra of **30** and **31** showed C=O and O—H absorption.

Reductions with Metal Hydrides

As shown above, the synthesis of secondary alcohols containing free formyl groups was achieved through the use of the Grignard reaction. An attempt was made to synthesize primary alcohols containing formyl groups by metal hydride reduction of appropriate symmetrical dialdehydes mono-protected by the insoluble resin.

A suspension of resin aldehyde **6** with sodium bis(2-methoxyethoxy)-aluminum hydride in benzene gave a suspension of resin alcohol. The suspension was treated directly with dilute acid to effect cleavage from the polymer of the reaction product and gave *p*-hydroxymethylbenzaldehyde (**32**) (11) in 17% yield[6] as shown in Scheme 7.

[6]The reaction of **6** with lithium aluminum hydride in tetrahydrofuran or sodium borohydride in methanol and subsequent acid cleavage gave no **32** or **33**.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

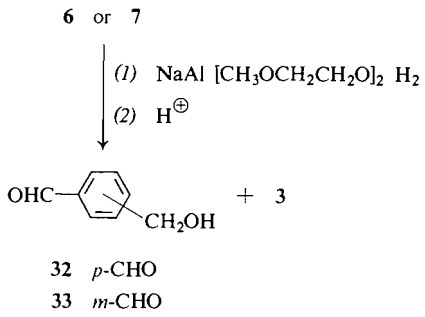

SCHEME 7

Similarly, reaction of resin aldehyde **7** with sodium bis(2-methoxyethoxy)-aluminum hydride gave *m*-hydroxymethylbenzaldehyde (**33**) in 8% yield. The poor yields of **32** and **33** are probably due to ready polymerization of these compounds. The susceptibility of these compounds to polymerization probably accounts for the fact that **33** was previously unrecorded and **32** recorded rarely (11).

The mass spectra of **32** and **33** exhibited parent ions and also showed peaks at *m/e* 107 resulting from loss of the formyl group by α-cleavage. The i.r. spectra of **32** and **33** showed C=O and O—H absorption. The n.m.r. spectra of **32** and **33** were consistent with the assigned structures.

Advantages and Limitations of Organic Synthesis Using Resin 3

The primary advantage of using resin **3** in organic synthesis was shown in the selective high yield formation of the unreported mono-oximes **10** and **11**, the formylstilbenes **14** and **19**, the formylphenyl butadienes **17** and **21**, the formylchalcones **24** and **25**, and the formylbenzhydrols **30** and **31**, from the commercially available symmetrical dialdehydes **4** and **5**. Classical preparations of some of these products from **4** and **5** would invariably lead to poorly separable mixtures of di-adducts, mono-adducts, and starting material (10, 11).[7]

It should be noted that the yields of all products obtained from isophthalaldehyde via resin **7** were slightly but consistently lower than the products from terephthalaldehyde via resin **6**. Thus it appears that steric hindrance of the less accessible meta formyl group in resin **7** plays a role in determining the yields of products derived from this resin.

In an experiment designed to test the quality of the *used* resin **3**, this resin was subjected to the reaction sequence outlined in Scheme 2 using aldehyde **4** and phosphonium salt **12**. Product **14** was obtained once again in 73% yield showing that resin **3** had not deteriorated during the reaction sequence and hence was completely regenerable. The used polymer obtained in the sequence leading to the preparation of monotrityl ethers of symmetrical diols suffered considerable deterioration (6, 7). The recovery in this instance of a completely regenerable polymer constitutes a major step in the *practical* use of polymer supports in organic synthesis.

One limitation to using an acetal linkage to attach molecules to insoluble polymer supports lies in the fact that only reactions conducted under basic conditions can be employed, as are all of the reactions described in this paper. A further limitation results from this same condition, namely that the procedures used for washing the polymer free of excess reactants and reagents cannot employ acid conditions. The Grignard reaction and the metal hydride reductions of resin aldehydes **6** and **7** result in metal salts of resin alcohols. These salts are gelatinous which creates filtering problems. The gelatinous precipitates can be solubilized by acid but of course this procedure causes cleavage of the products from the resin. Thus the Grignard products **30** and **31** were obtained by direct cleavage of the adducts obtained from the Grignard reagent with resin aldehydes **6** and **7**. For this example, this procedure was not a disadvantage as the products were still obtained in high yield but if one wanted the benzhydrol products to remain attached to the polymer for a possible sequential synthesis, the limitation against the use of acid would become serious. The limitation against using acid was more apparent in the syntheses of the hydroxymethylbenzaldehydes **32** and **33** resulting in low yields of these compounds.

The role of solvent in planning organic syntheses on insoluble polymer supports is very important but at times unpredictable. Generally, one likes to do reactions on insoluble resins in solvents that swell the polymer such as pyridine and dimethylformamide. The syntheses of the mono-oximes **10** and **11** in pyridine, and the stilbenes **14** and **19** and the butadienes **17** and **21**

[7]The mono-oxime of *o*-phthalaldehyde is known (12) and was obtained as an oil in 70% yield.

in dimethylformamide in high yields emphasize the importance of a *good* solvent. The formylbenzhydrols **30** and **31**, however, were synthesized in high yield in an only partially acceptable solvent, tetrahydrofuran, while the formylchalcones **24** and **25** were prepared in very high yield in absolute ethanol, a poor solvent for swelling the polymer. Thus, the poor yields of the hydroxymethylbenzaldehydes **32** and **33** obtained from reaction in benzene, a *good* solvent, were probably due to other reasons, although it should be noted that the metal hydride reductions of **6** and **7** in tetrahydrofuran and in methanol, poorer solvents, gave no product and thus the change in solvent (or metal hydride) allowed at least some product to be realized. The poor yields obtained in the benzoin condensation could be due to solvent effects but an attempt to accomplish the benzoin condensation in dimethylformamide, a *good* solvent, resulted in yields of benzils **27** and **29** identical to that in absolute ethanol, a *poor* solvent. Thus the role of solvent is important in organic synthesis on insoluble resins but should not be an inhibiting factor in attempting an organic synthesis.

It has thus been demonstrated that general organic syntheses can be accomplished in high yield on insoluble polymer supports, with recovery of a completely regenerable polymer. Most important of all, because of the high capacity of the insoluble polymer it becomes feasible to react only one aldehyde group of symmetrical dialdehydes with a series of organic reagents in a standard practical procedure, yielding reasonable quantities of products.

The development of further organic synthetic methods using insoluble polymer supports is in progress.

Experimental

All melting points were determined on a Kofler hot stage and are uncorrected. The i.r. spectra were recorded on a Unicam SP1000 i.r. spectrophotometer using KBr discs unless otherwise stated. The u.v. spectra were measured using a Unicam SP800A u.v. spectrometer and benzene as solvent. The n.m.r. spectra were measured on a Varian A60 spectrometer using tetramethylsilane as an internal standard ($\delta = 0$ p.p.m.) and deuterochloroform as solvent. Mass spectra were recorded on a Hitachi-Perkin-Elmer RMU-6 mass spectrometer. The number in brackets after the indicated ion shows the % of the base peak represented by that ion. Silica gel was used for thin- and thick-layer chromatography. Microanalyses were performed by Dr. C. Daesslé of Montreal. Filtering procedures were done under vacuum using a sinter-glass funnel. All the stirring described below was performed using a Fisher magnetic stirrer.

Preparation of Polymer 2

Sodium (2 g) was added to 60 ml of 2,2-dimethyl-1,3-dioxolane-4-methanol (Aldrich Chemical Co.) in a 250 ml round-bottom flask. The mixture was stirred until all the sodium had dissolved. The Merrifield resin (4.87 g) (**1**) (2% cross-linked polystyrene beads with 1.7 mmol of $-CH_2Cl$ groups per gram of resin, obtained from Schwarz/Mann) was then added. The mixture was stirred at room temperature overnight and at 80 °C for 24 h. The resin was collected by filtration and washed three times with dioxane, six times with water, three times with ethanol–water (1:1), three times with ethanol, and three times with dry ether to give 5.88 g of polymer, ν_{max} 1128–1058 cm^{-1} (C—O—C).

Preparation of Polymer 3

Polymer **2** (5.88 g) was suspended in a mixture of dioxane and 1 *M* hydrochloric acid (1:1, 60 ml). The mixture was stirred for 48 h at room temperature. The resin was filtered and washed six times with water, once with acetone, three times with ethanol, and three times with dry ether to give 5.82 g of polymer diol **3**. The i.r. spectrum showed a vicinal diol functional group at ν_{max} 3415 cm^{-1} (OH), 1058 cm^{-1} (C—O—C).

Preparation of Polymer Aldehydes 6 and 7

In a typical procedure, 4.25 g of polymer **3** was suspended in 60 ml of anhydrous dioxane. Excess terephthalaldehyde (**4**) or isophthalaldehyde (**5**) (2 g) and 0.10 g of *m*-benzenedisulfonic acid as catalyst were added. To the mixture was added 2.00 g of anhydrous sodium sulfate to absorb liberated water and the reaction was stirred at room temperature for 48 h under exclusion of moisture ($CaCl_2$, drying tube). The resin was filtered, neutralized with anhydrous pyridine (to prevent cleavage of the aldehyde from the polymer by hydrolysis of the acetal linkage), and filtered twice. Then the resin was washed twice with pyridine–water (1:1), ten times with water (to remove sodium sulfate), three times with ethanol, and at least three times with dry ether. The i.r. spectra of **6** and **7** exhibited typical aldehyde absorption at 1700 cm^{-1}; resin **6**, ν_{max} 1700 cm^{-1}; resin **7**, ν_{max} 1698 cm^{-1}.

Preparation of Mono-oximes 10 and 11

Resin **6** (3.27 g) was suspended in 50 ml of anhydrous pyridine. Excess hydroxylamine hydrochloride (2.50 g) was added. The mixture was stirred at room temperature for 48 h. The resin was filtered and washed three times with pyridine, three times with pyridine–water (1:1), three times with water, three times with ethanol, and three times with dry ether to give the resin **8** (3.43 g). A suspension of 3.43 g of resin **8** and 40 ml of a 1:1 mixture of dioxane and dilute hydrochloric acid was stirred for 48 h at room temperature. The resin was filtered and washed six times with water, once with acetone, three times with ethanol, and three times with ether. The aqueous filtrate was extracted with three aliquots of ether. The combined ether extracts were washed six times with water, dried over Na_2SO_4, and evaporated to give a slightly impure solid which was purified by preparative t.l.c. on silica gel (eluant $CHCl_3$) to give 0.1421 g (86%) of analytically pure terephthalaldehyde mono-oxime (**10**) m.p. 122–127°. No starting terephthalaldehyde **4** was

*Preparation of p-Formylstilbene (**14**) and 1-p-Formylphenyl-4-phenyl-1,3-butadiene (**17**)*

To a solution of benzyltriphenylphosphonium bromide (**12**) (4.00 g) in anhydrous dimethylformamide (60 ml) was added powdered sodium methoxide (2.50 g). After stirring for 5 min, when the solution turned orange, resin **6** (5.77 g) was added to give, after stirring 24 h at room temperature, the resin **13**. Resin **13** was separated by filtration, washed three times with DMF, three times with DMF–water (1:1), three times with water, three times with methanol, and three times with ether. Acid hydrolysis of resin **13** as before and using an identical work-up gave used resin **3** and crude *p*-formylstilbene (**14**). Further purification by preparative t.l.c. on silica gel (eluant 10% $CHCl_3$ – 90% C_6H_6) gave 0.310 g of analytically pure **14**, m.p. 101–105°, in 76% yield and 0.057 g of starting terephthalaldehyde (**4**). I.r. spectrum, ν_{max} (Nujol) 1699, 972 cm^{-1}; mass spectrum, *m/e* 208 (100) (M^+), 179 (30) ($M^+ - CHO$); u.v. spectrum, λ_{max} 335 mμ (ε 33 300).

Similarly, the addition of resin **6** (6.15 g) to the Wittig reagent, cinnamyltriphenylphosphonium chloride (**18**) as described above gave the resin **16**. Acid hydrolysis of **16** and using an identical work-up as before yielded 0.299 g (59%) of analytically pure 1-*p*-formylphenyl-4-phenyl-1,3-butadiene (**17**), m.p. 128, and also 0.088 g of starting aldehyde **4**. I.r. spectrum, ν_{max} (Nujol), 1691, 996 cm^{-1}, mass spectrum, *m/e* 234 (100) (M^+), 205 (100) ($M^+ - CHO$); u.v. spectrum, λ_{max} 347, 362, 379 mμ (ε 39 800, 49 100, 35 100).

Anal. Calcd. for $C_{17}H_{14}O$: C, 87.18; H, 5.98. Found: C, 87.13; H, 5.66.

*Preparation of 1-m-Formylstilbene (**19**) and 1-m-Formylphenyl-4-phenyl-1,3-butadiene (**21**)*

To a solution of benzyltriphenylphosphonium bromide (**12**) (4.00 g) in anhydrous dimethylformamide (60 ml) was added powdered sodium methoxide (2.50 g). After stirring for 5 min, when the solution turned orange, resin **7** (6.07 g) was added to give, after stirring 24 h at room temperature, the resin **18**. Resin **18** was separated by filtration and washed three times with DMF, three times with DMF–water (1:1), three times with water, three times with methanol, and three times with ether. Acid hydrolysis of resin **18** as before and using an identical work-up gave used resin **3** and crude *m*-formylstilbene (**19**). Further purification by preparative t.l.c. on silica gel (eluant 10% $CHCl_3$: 90% C_6H_6) gave 0.239 g of analytically pure **19**, m.p. 104–107°, in 50% yield and 0.100 g of starting aldehyde **5**. I.r. spectrum, ν_{max} (Nujol) 1692, 970 cm^{-1}; mass spectrum, *m/e* 208 (100) (M^+), 179 (100) ($M^+ - CHO$); u.v. spectrum, λ_{max} 300 mμ (ε 26 600).

Anal. Calcd. for $C_{15}H_{12}O$: C, 86.54; H, 5.77. Found: C, 86.86; H, 5.56.

Similarly, the addition of resin 7 (6.49 g) to the Wittig reagent, cinnamyltriphenylphosphonium chloride (**15**), as described above gave the resin **20**. Acid hydrolysis of **20** and using an identical work-up as before yielded 0.147 g (27%) of analytically pure 1-*m*-formylphenyl-4-phenyl-1,3-butadiene (**21**), m.p. 132–136°, and 0.188 g of starting aldehyde **5**. I.r. spectrum, ν_{max} (Nujol) 1690, 990 cm^{-1}; mass spectrum, *m/e* 234 (100) (M^+), 205 (100) ($M^+ - CHO$); u.v. spectrum, λ_{max} 325, 335, 354 mμ (ε 42 100, 45 000, 29 300).

Anal. Calcd. for $C_{17}H_{14}O$: C, 87.18; H, 5.98. Found: C, 87.05; H, 5.56.

*Preparation of Formylchalcones **24** and **25***

Resin **6** (4.31 g) was suspended in 60 ml of absolute ethanol. Excess acetophenone (4.00 g) and sodium methoxide powder (3.50 g) were added. The mixture was stirred at room temperature for 48 h with exclusion of moisture ($CaCl_2$ drying tube). The resin **22** was filtered off and washed three times with ethanol, three times with ethanol–water, three times with water, three times with methanol, and three times with dry ether. Acid hydrolysis of resin **22** as described previously and using an identical work-up gave used resin **3** and crude 3-*p*-formylphenyl-1-phenyl-2-propen-1-one (**24**). Further purification by preparative t.l.c. on silica gel (eluant $CHCl_3$) gave 0.369 g of analytically pure **24**, m.p. 121° (lit. (10) m.p. 125°), in 100% yield. I.r. spectrum, ν_{max} (Nujol) 1600, 1675, 1687 cm^{-1}; mass spectrum, *m/e* 236 (10) (M^+), 207 (8) ($M^+ - CHO$), 105 (90) (benzoyl); u.v. spectrum, λ_{max} 280 mμ (ε 3300).

Similarly, treatment of resin **7** as described above gave the resin **23**. Acid hydrolysis of resin **23** and using an identical work-up as before yielded 0.341 g (96%) of analytically pure 3-*m*-formylphenyl-1-phenyl-2-propen-1-one (**25**). I.r. spectrum, ν_{max} (neat) 1600, 1680, 1690 cm^{-1}; mass spectrum, *m/e* 236 (46) (M^+), 207 (30) ($M^+ - CHO$); u.v. spectrum, λ_{max} 292 mμ (ε 6780).

Anal. Calcd. for $C_{16}H_{12}O_2$: C, 81.36; H, 5.09. Found: C, 81.35; H, 5.38.

*Preparation of Formylbenzils **27** and **29***

The aldehyde resin **6** (4.33 g) was suspended in a mixture of ethyl alcohol, dioxane, and water (1:1:1, 120 ml). To this was added sodium cyanide (2.50 g) in 30 ml of water. The mixture was stirred overnight at 80 °C. Then excess benzaldehyde (4.00 g) was added and the mixture was stirred at 80 °C for another 24 h to give resin **26**. Resin **26** was collected by filtration and washed three times with dioxane–water (1:1), three times with water, three times with ethanol–water (1:1), three times with ethanol, and three times with ether. Acid cleavage of resin **26** as described previously and using an identical work-up gave used resin **3** and a complex mixture of products which were chromatographed on preparative t.l.c. (eluant 5% ether – 95% $CHCl_3$). The yield of 1-*p*-formylbenzil (**27**), as an oil, was 0.0195 g (6%). I.r. spectrum, ν_{max} (neat) 1670–1710 cm^{-1}, broad, (C=O); mass spectrum, *m/e* 238 (3) (M^+), 209 (0.3) ($M^+ - CHO$), 105 (100) (benzoyl), 134 (33) (formylbenzoyl).

Anal. Calcd. for $C_{15}H_{10}O_3$: C, 75.63; H, 4.20. Found: C, 75.71; H, 4.38.

Similarly, reaction of aldehyde resin **7** (5.33 g) with benzaldehyde in a benzoin condensation described above led to resin **28** which on acid cleavage and using an identical work-up gave used resin **3** and a complex mixture of products. Purification by preparative t.l.c. on silica gel (eluant 5% ether – 95% $CHCl_3$) yielded 0.0165 g (4%) of *m*-formylbenzil (**29**), as an oil. I.r. spectrum, ν_{max} (neat) 1670–1705 cm^{-1} (broad) (C=O); mass spectrum, *m/e* 238 (0.6) (M^+), 209 (0.3) ($M^+ - CHO$), 105 (100) (benzoyl), 134 (33) (formylbenzoyl).

Anal. Calcd. for $C_{15}H_{10}O_3$: C, 75.63; H, 4.20. Found: C, 75.57; H, 4.32.

Preparation of Formylbenzhydrols 30 and 31

Phenylmagnesium bromide was prepared as follows. To a solution of magnesium (2 g) and iodine (0.010 g) in 125 ml of anhydrous tetrahydrofuran was added dropwise with stirring bromobenzene (13.2 g) in 20 ml of tetrahydrofuran. The mixture was refluxed for 1 h until all the magnesium had dissolved.

The resin aldehyde **6** (5.57 g) was then reacted with the phenylmagnesium bromide in anhydrous tetrahydrofuran at room temperature for 48 h to give a resin alcohol which was not isolated but directly treated with acid and using an identical work-up as before yielded resin **3** and (*p*-formylphenyl)phenylcarbinol (**30**). Purification by preparative t.l.c. on silica gel (eluant $CHCl_3$) yielded 0.397 g (99%) of analytically pure **30**. I.r. spectrum, ν_{max} (neat) 1695 cm^{-1} (C=O), 3440 cm^{-1} (OH); mass spectrum, *m/e* 212 (23) (M^+), 183 (16) ($M^+ - CHO$), 105 (100) (formylphenyl); u.v. spectrum, λ_{max} (ethanol) 213, 259 mμ (ε 16 900, 16 400).

Anal. Calcd. for $C_{14}H_{12}O_2$: C, 79.24; H, 5.66. Found: C, 78.99; H, 5.47.

Similarly, reacting aldehyde resin **7** (4.63 g) with phenylmagnesium bromide in accordance with the method described above gave a resin alcohol which was directly treated with acid, and using an identical work-up as before yielded resin **3** and (*m*-formylphenyl)phenylcarbinol (**31**). Purification by preparative t.l.c. on silica gel (eluant $CHCl_3$) yielded 0.342 g (100%) of analytically pure (**31**), as an oil. I.r. spectrum, ν_{max} (neat) 1688 cm^{-1} (C=O), 3400 cm^{-1} (OH); mass spectrum, *m/e* 212 (11) (M^+), 183 (0.3) ($M^+ - CHO$), 105 (100) (formylphenyl); u.v. spectrum, λ_{max} (ethanol) 213, 251, 291 mμ (ε 25 100, 12 300; 2620).

Anal. Calcd. for $C_{14}H_{12}O_2$: C, 79.24; H, 5.66. Found: C, 79.23; H, 5.61.

Preparation of p- and m-Hydroxymethylbenzaldehydes (32) and (33)

The aldehyde resin **6** (5.08 g) was suspended in 60 ml of anhydrous benzene. Addition of 20 ml of a 70% solution of sodium bis(2-methoxyethoxy)-aluminum hydride in benzene to the above mixture gave, after stirring for 48 h at room temperature with exclusion of moisture ($CaCl_2$ drying tube), a suspension of a resin alcohol. The suspension was treated directly with dilute acid in a manner described previously to effect cleavage from the polymer of the reaction product. Similar work-up as before and purification by preparative t.l.c. on silica gel (eluant 5% ether – 95% $CHCl_3$) yielded 0.039 g (17%) of analytically pure *p*-hydroxymethylbenzaldehyde (**32**) (11). I.r. spectrum ν_{max} (neat) 1690 (C=O), 3400 cm^{-1} (OH); mass spectrum, *m/e* 136 (4) (M^+), 134 (100) ($M^+ - 2H$), 105 (10) ($M^+ - CH_2OH$); n.m.r. spectrum, 2.42 p.p.m. (1H, OH proton), 4.81 p.p.m. (2H, CH_2 singlet), 8.18–7.35 p.p.m. (4H, four aromatic protons, AB pattern), 10.10 p.p.m. (1H, aldehyde proton, singlet).

Similarly, treatment of aldehyde resin **7** (7.07 g) with sodium bis(2-methoxyethoxy)-aluminum hydride in anhydrous benzene, in a manner identical to that of aldehyde resin **6** as described above, gave a suspension of a resin alcohol. This suspension was treated directly with dilute acid followed by work-up as before. Purification by preparative t.l.c. on silica gel (eluant 5% ether – 95% $CHCl_3$) yielded 0.026 g (8%) of analytically pure *m*-hydroxymethylbenzaldehyde (**33**). I.r. spectrum, ν_{max} (neat) 1695 (C=O), 3440 cm^{-1} (OH); mass spectrum, *m/e* 136 (3) (M^+), 134 (3) ($M^+ - 2H$), 105 (10) ($M^+ - CH_2OH$); n.m.r. spectrum, 3.08 p.p.m. (1H, OH proton), 4.80 p.p.m. (2H, CH_2 protons), 7.88–7.19 p.p.m. (4H, aromatic protons), 10.05 p.p.m. (1H, aldehyde proton, singlet).

Anal. Calcd. for $C_8H_8O_2$: C, 70.59; H, 5.88. Found: C, 70.61; H, 5.90.

A Novel Synthesis of *N*-Styryl Heterocycles

J. ROKACH, Y. GIRARD, AND J. G. ATKINSON
Merck Frosst Laboratories, Kirkland, Quebec

Received March 30, 1973

Reaction of the anions of a variety of 2-carboethoxy *N*-heterocycles with styrene oxide yields directly the *N*-(*trans*-2-styryl)-2-carboxylic acids. The reaction has been shown to proceed through a lactone intermediate which undergoes rapid elimination to form the unsaturated acid. The reaction has been used to alkylate 2-carboethoxy pyrrole, diethyl pyrazole-3,5-dicarboxylate, ethyl indole-2-carboxylate, ethyl benzimidazole-2-carboxylate, and ethyl 2-pyrrolidone-5-carboxylate. Yields were 82, 88, 93.5, 57, and 5% respectively.

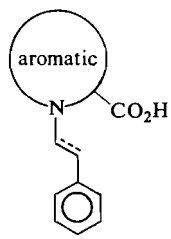
1-(*trans*-2-Styryl)benzimidazole-2-carboxylic acid of m.p. 75–77 °C undergoes an interesting, reversible solid-state transformation to a high melting (255–260 °C), presumably zwitterionic, form.

La réaction d'anions d'une variété de carboéthoxy-2 *N*-hétérocycles avec l'époxide de styrène donne directement les acides *N*-(*trans*-styryl-2) hétérocycles-2 carboxyliques. Le mécanisme de la réaction passe par une lactone intermédiaire qui subit une élimination rapide pour donner ainsi l'acide insaturé. Ont été alkylés par ce procédé le carboéthoxy-2-pyrrole, le dicarboéthoxy-3,5-pyrazole, le carboéthoxy-2-indole, le carboéthoxy-2-benzimidazole et le carboéthoxy-5-pyrrolidone-2 avec des rendements respectifs de 82, 88, 93.5, 57 et 5%.

Il est intéressant de noter que l'acide (*trans*-styryl-2)-1-benzimidazole-2-carboxylique de p.f. 75–77 °C, se transforme réversiblement à l'état solide en un produit de p.f. 255–260 °C, vraisemblablement le zwitterion.

Can. J. Chem. **51**, 3765 (1973)

As part of a synthetic program in our laboratories we required an efficient general synthesis of 2-carboxy *N*-heterocycles substituted on nitrogen with β-styryl and β-phenethyl groups (*e.g.* **1**). Accordingly, we investigated the alkylation of a series of 2-carboethoxy *N*-heterocycles and are reporting the discovery of a novel and efficient synthesis of the desired compounds.



1

Results

Reaction of the ethyl pyrrole-2-carboxylate anion **2** in DMF with 2-phenethyl bromide gave a low yield (<5%) of the desired *N*-alkylation product, **3** (eq. 1). The main course of the reaction probably involved β-elimination to form styrene. A number of experiments served to confirm the initial result and no conditions were found which gave good yields of the desired product. Omote and co-workers (1) have also reported a similar type of reaction between indole and β-phenethyl bromide (or iodide), and obtained trace amounts of *N*-phenethyl indole. Alkylation of the anion **2** with styrene oxide in DMF was then investigated. It was anticipated that the initially formed alkoxide **4** would ring close to form the lactone **5**. Hydrogenolysis of the lactone was expected to lead to the desired phenethyl carboxylic acid **6** (eq. 2). Alkylation did occur, but surprisingly the product directly isolated was found to be 1-(*trans*-2-styryl)-pyrrole-2-carboxylic acid (**7**) (eq. 3).

Using NaH or potassium *t*-butoxide as the base and running the reaction in DMF at 110° for 1–2 h gave rise to an excellent yield (82%) of the product **7**. The elevated temperature was found to be very advantageous as at room temperature the yield was only about 25% after 24 h, and longer reaction times did not substantially improve the yield.

Further investigation with a series of 2-carboethoxy *N*-heterocycles showed that the reaction was of general applicability and that excellent yields of the *N*-(*trans*-2-styryl)-2-

7

carboxylic acids could be readily obtained by this procedure (Table 1). Entry 5 of Table 1 (ethyl 2-pyrrolidone-5-carboxylate) indicates that the reaction is applicable to aliphatic as well as aromatic systems, although in lower yield. As can be seen in the Experimental, a particularly pleasing aspect of the reaction is the purity of the products as isolated directly from the reaction mixture. In all cases, there was no indication of impurities in the crude products as judged by the n.m.r. spectra and t.l.c., and there was little or no improvement in the m.p. upon recrystallization. The *N*-(2-styryl)carboxylic acids thus obtained could be hydrogenated quantitatively to *N*-(2-phenethyl)carboxylic acids (thus completing the original aim of the work in high overall yields).

At the time that our work was nearing completion, a publication by Irwin and Wheeler (2) appeared describing the reaction of the anion of ethyl pyrrole-2-carboxylate with a series of epoxides, and our work confirms and extends the results of these authors. Our assignments agree with those of Irwin and Wheeler (2), and in all cases the *trans* configuration is assigned to the styryl double bond on the basis of the large (~15 Hz) coupling constant between the two protons of the vinyl moiety.

A careful search was made in order to isolate the proposed lactone intermediates of type **5**. In the cases of the indole and benzimidazole compounds (entries 3 and 4, Table 1), it was possible to isolate low yields (~2%) of the lactones directly from the reaction mixture. The major product in each case was still the *N*-(*trans*-2-styryl)-2-carboxylic acid. The lactones were highly crystalline compounds and their structures could be unambiguously assigned on the basis of the i.r. and n.m.r. spectra, the details of which are given in Table 1. The assignment of shifts to the protons H_A and H_B in the lactones is based on the assumption that the *trans* hydrogens will have the larger of the two coupling constants with the tertiary proton H_C. The fact that there is a significant difference in the vicinal coupling constants indicates that

H_C is in fact in a pseudoaxial configuration. Figure 1 shows a photograph of the n.m.r. spectrum of the indole lactone with a proposed configuration for the molecule.

Discussion

The results of Irwin and Wheeler (2) taken with those presently reported show that the reaction of 2-carboethoxy *N*-heterocycles is a

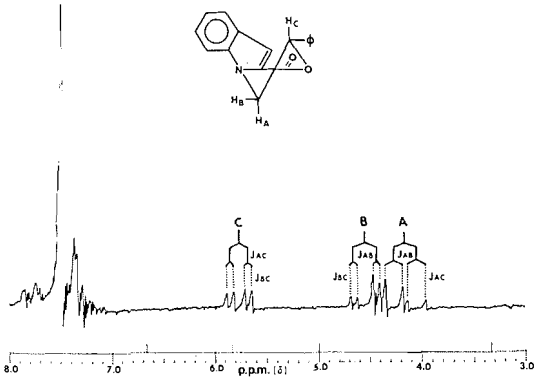

FIG. 1. N.m.r. spectrum of the lactone from the reaction of ethyl indole-2-carboxylate with styrene oxide (60 MHz, $CDCl_3$ solvent).

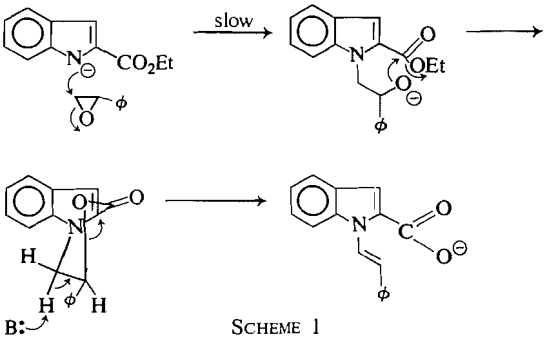

SCHEME 1

generally applicable reaction for the synthesis of 2-carboxy *N*-(β-styryl) compounds. The previous workers employed mainly ethyl pyrrole-2-carboxylate with a variety of epoxides and we have demonstrated, using styrene oxide, that the heterocyclic molecule can be varied considerably.

Irwin and Wheeler had reasonably proposed that the formation of the styryl carboxylic acids must go through a lactone intermediate which then undergoes β-elimination under the basic conditions of the reaction. They were able to isolate a lactone from the reaction with cyclohexene oxide, but this lactone did not undergo the elimination reaction because, as the authors point out, the stereochemistry of the material does not permit a transoid transition state.

We have been able to complete the mechanistic picture by isolation of the lactones from the reaction of styrene oxide with ethyl indole-2-carboxylate and ethyl benzimidazole-2-carboxylate. Both of these lactones, when treated under the conditions of the original reaction, were converted rapidly and in high yields to the styryl carboxylic acids. The ease of the conversion of the lactones to the final product indicates why they are normally isolated in very low yields or not at all.

The mechanistic picture thus derived is shown in Scheme 1 using styrene oxide and ethyl indole-2-carboxylate and is essentially identical to that proposed by Irwin and Wheeler.

Given the demonstrated rapidity of the last step of the scheme and the fact that starting material can be seen by t.l.c. until near the end of the reaction, one can also reasonably propose that the slow step is the initial alkylation by the the epoxide.

The properties of the product derived from ethyl benzimidazole-2-carboxylate and styrene oxide were found to be somewhat unusual and merit some discussion.

The product undergoes decarboxylation with extreme ease and if the work-up is done as usual with HCl, only the decarboxylated product is isolated (Table 1, entry 4). If acetic acid is used, the product can be isolated in good yield. Upon dissolving in organic solvents at room temperature, the acid decarboxylates neatly and quantitatively to 1-(2-styryl)benzimidazole in the time required to run the n.m.r. spectrum. The sodium salt, in contrast, is quite stable, and a satisfactory n.m.r. spectrum could be obtained in DMSO-d_6.

The solid acid of m.p. 75–77°, upon standing for several days at room temperature, undergoes a transformation to a high melting, very insoluble form. There is a concomitant change of the carboxyl band in the i.r. spectrum (KBr) from 1685 (sharp) to 1640 cm^{-1} (broad). Careful treatment with acetic acid regenerates the original form. This indicates that on standing the material is changing from a free acid to a zwitterionic form as shown in Scheme 2.

Experimental

Melting points are uncorrected.

Ethyl benzimidazole-2-carboxylate was prepared according to Copeland and Ray (3). Ethyl 2-pyrrolidone-5-carboxylate and ethyl pyrrole-2-carboxylate were prepared by esterification of the corresponding acids. All the remaining starting materials were commercially available. All new compounds gave correct elemental analysis. The u.v. spectra are collected in Table 2.

N-(trans-Styryl)pyrrole-2-carboxylic Acid

Ethyl pyrrole-2-carboxylate (11.7 g, 0.084 mol) was dissolved in 50 cc dry DMF and sodium hydride powder (2 g, 0.084 mol) added to the stirred solution. When hydrogen evolution had ceased (2–3 h), styrene oxide (14 g, 0.115 mol) was added and the solution warmed at 110–120 °C for 1 h. (Reaction followed by t.l.c. for disappearance of starting material.) The reaction mixture was cooled, ice-water added (~300 cc), the resulting solution extracted with ether, and the water layer cooled and acidified with dilute HCl. The precipitated white solid was filtered, washed with water, and dried, yielding 14.6 g of pure product (82% yield), m.p. 183–184 °C. A sample recrystallized from methanol had m.p. 183–185 °C.

1-(trans-Styryl)pyrazole-3-carboethoxy-5-carboxylic Acid

Diethyl pyrazole-3,5-dicarboxylate (24 g, 0.113 mol) was dissolved in 300 cc dry DMF and potassium *t*-butoxide (13.2 g, 0.116 mol) added to the stirred solution. After 15 min, styrene oxide (18 g, 0.150 mol) was added and the mixture heated at 120 °C for 1–2 h (reaction followed by t.l.c. for disappearance of starting material). The cooled reaction mixture was diluted with ice-water (1000 ml), extracted with ether, and the water layer cooled and acidified with dilute HCl. The precipitated white solid was filtered, washed with water, and dried, yielding 28.4 g of pure product (88% yield), m.p. 165–167 °C, unchanged by recrystallization from methanol.

N-Styrylindole-2-carboxylic Acid

Sodium hydride powder (3.5 g, 0.146 mol) was added to a stirred solution of ethyl indole-2-carboxylate (25 g, 0.132 mol) in 250 ml dry DMF. After the hydrogen evolution had stopped, styrene oxide (30 g, 0.250 mol) was added and the mixture heated at 110 °C for 1½ h. The mixture was cooled, water added, and the solution extracted with ether. The water layer was acidified with excess dilute HCl. The precipitated solid was filtered, washed with water, and dried, yielding 32.5 g (93.5% yield), m.p. 222–224 °C, unchanged on recrystallization from methanol.

In a separate run ethyl indole-2-carboxylate (1.89 g, 10 mmol) and sodium hydride (260 mg, 11 mmol) were heated at 110° with styrene oxide (2.4 g, 20 mmol) and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

the reaction stopped before completion. The reaction was worked-up as above and the ether extracts dried and evaporated to dryness. The residue (1.6 g) was triturated with ether – petroleum ether. The precipitated crystals (50 mg) were filtered to yield the lactone, m.p. 180–182 °C. Recrystallization from methanol did not improve the melting point.

The lactone (45 mg) was dissolved in ½ cc DMF and 19 mg potassium *t*-butoxide (1 equiv.) added and the mixture stirred at room temperature for 15 min. The reaction was diluted with water, acidified, and extracted with ether. The ether solution yielded 40 mg of a yellowish solid, identical by t.l.c. to the acid isolated above. This was recrystallized from methanol, m.p. 218–222 °C, mixed melting point 220–222 °C, with an i.r. spectrum identical to that of the authentic acid.

1-Styrylbenzimidazole-2-carboxylic Acid

To a stirred solution of ethyl benzimidazole-2-carboxylate (3.8 g, 0.020 mol) in 60 ml dry DMF, was added sodium hydride powder (520 mg, 0.022 mol). After 1 h styrene oxide (4.8 g, 0.040 mol) was added and the mixture heated at 110 °C for 2 h. The mixture was cooled, ice-water added, and the mixture extracted with ether. A suspended solid was filtered (30 mg) and proved to be the lactone, m.p. 215–217 °C. The ether extracts were dried and evaporated to dryness and the oily residue (2.6 g) treated with some ether and filtered to yield a further 30 mg of lactone.

The water layer was carefully acidified with acetic acid and the precipitated white solid was dried under vacuum at room temperature to yield the acid (3 g, 57% yield), m.p. 75–77 °C (dec.).

If the acidification is done with HCl, decarboxylation occurs and 1-styrylbenzimidazole is obtained, m.p. 93–94 °C. A sample of the acid recrystallized from cyclohexane similarly yielded the decarboxylated material, m.p. 93–94 °C.

When the acid is stored for a few days the m.p. increases to 255–260 °C and the i.r. spectrum shows a shift in the C=O absorption from 1685 to 1640 cm^{-1}. This compound, treated with AcOH in the cold, regenerates the original form of the acid, m.p. 74–76 °C, and the C=O band is restored to its original position and sharpness.

1-Styryl-2-pyrrolidone-5-carboxylic Acid

Ethyl 2-pyrrolidone-5-carboxylate (1.57 g, 10 mmol) was dissolved in DMF (20 cc) and sodium hydride (260 mg) added. After 1 h a two-fold excess of styrene oxide (2.4 g) was added and the mixture heated at 180 °C for ½ h. Ice-water was added to the cooled reaction mixture which was then extracted with ether. The water layer was acidified with dilute HCl, extracted with ether, and the ether dried and evaporated. The oily residue (350 mg) solidified on standing, m.p. 165 °C ($CHCl_3$).

The Rate of Recombination of H Atoms in the Presence of NH_3

L. TENG[1] AND C. A. WINKLER
Department of Chemistry, McGill University, Montreal, Quebec

Received June 11, 1973

The rate constant for the homogeneous recombination of H atoms in the presence of NH_3, with He as carrier gas, has been determined at 298 °K in a fast flow system, over the pressure range 1.50 to 4.55 Torr, using e.s.r. technique. A value of either 4.00×10^{16} or 5.14×10^{16} $cm^6\ mol^{-2}\ s^{-1}$ was calculated, depending upon the rate constant taken, or estimated, from the literature for the recombination in the presence of helium.

A l'aide d'un système à débit rapide, on a déterminé la constante de vitesse pour la recombinaison homogène d'atomes d'hydrogène en présence de NH_3 en utilisant l'He comme gaz porteur à 298 °K pour des pressions allant de 1.50 à 4.55 Torr. A l'aide de la technique r.p.e., la valeur de cette constante s'est révélée être soit 4.00×10^{16} ou soit 5.14×10^{16} $cm^6\ mol^{-2}\ s^{-1}$ selon la valeur choisie ou estimée, à partir de la littérature, de la constante de vitesse se rattachant à la recombinaison en présence d'hélium.

The recombination of hydrogen atoms has been extensively studied with one of H_2, He, or Ar as the third body, both at room temperature (in flow system) and higher temperatures (in flames or shock tubes) (1). Values of the rate constants were found in the range 3 to 6×10^{15} $cm^6\ mol^{-2}\ s^{-1}$. A few recent investigations have been made in the presence of other inert gases. Measurements at room temperature with N_2 and CO_2 (2), and with H_2O (3), as third bodies yielded values of 3×10^{15} to 9×10^{16} $cm^6\ mol^{-2}\ s^{-1}$ while measurements at higher temperatures (approximately 1550–1900 °K) gave values of 6×10^{14} to 5×10^{15} $cm^6\ mol^{-2}\ s^{-1}$ with the third bodies N_2, $CO + CO_2$, and H_2O (4, 5).

In the present investigation, the recombination of H atoms in the presence of NH_3 has been studied at room temperature using electron spin resonance to determine the H atom concentration. No consumption of NH_3 was observed, in agreement with observations by Kurylo *et al.* (6).

Experimental and Results

Hydrogen atoms were generated by electrode or microwave discharge through a H_2 + He mixture in which the H_2 content was varied in the range 0 to 5%. Hydrogen (99.99%) was passed through a "Deoxo" unit followed by a liquid N_2 trap, then mixed with He (99.995%) which had also been passed through a liquid N_2 trap. From the discharge, the gas mixture passed through a Pyrex tube 26 mm i.d. and 83 cm long, fitted with a movable jet through which NH_3 (99.99%) was added. The inner wall of the Pyrex tube was coated with boric acid to reduce the heterogeneous recombination of H atoms. Pressures were measured at the mid-point of the tube with a McLeod gauge.

The change in H atom concentration was measured with a Varian Model V-4502-12 e.s.r. spectrometer, 100 Kc/s modulation, with a 9 in. magnet, and a Model 4531 multipurpose cavity. The cavity operated in a TE_{012} mode and accepted a sample tube of 11 mm o.d. It was connected to the low-power arm of the microwave bridge. The signal of the e.s.r. was calibrated by determining the maximum extents to which the H atoms reacted with excess HI and HBr (7).

Calculation of Rate Constants

The reactions to be considered are

$$[1] \qquad H + H + NH_3 \xrightarrow{k_1} H_2 + NH_3$$

$$[2] \qquad H + H + He \xrightarrow{k_2} H_2 + He$$

$$[3] \qquad H + \text{Wall} \xrightarrow{k_3} \tfrac{1}{2}H_2 + \text{Wall}$$

The decay of H atoms may be represented by[2]

$$[4] \qquad \frac{-d[H]}{dt} = k_1[NH_3][H]^2 + k_2[He][H]^2 + k_3[H]$$

[1]Postdoctoral Fellow.

[2]It may be assumed that H and H_2, at their low concentrations in these experiments, contribute negligibly as third bodies to atom recombination.

4.50	361	0.41	0.84	2.52	2.75	4.15
4.55	364	0.93	0.84	2.50	2.70	4.06
4.55	364	0.93	2.24	2.50	2.77	3.97
					Av.	4.00 ± 0.09

On integration

$$[5]\quad \ln\frac{[H]_0}{[H]_t} - \ln\frac{k_1[NH_3][H]_0 + k_2[He][H]_0 + k_3}{k_1[NH_3][H]_t + k_2[He][H]_t + k_3} = k_3 t$$

In the absence of NH_3, with known reaction times t_1 and t_2, for which $[H]_{t_1}$ and $[H]_{t_2}$ are determined for given [He]

$$[6]\quad \ln\frac{[H]_{t_2}}{[H]_{t_1}} + \ln\frac{k_2[He][H]_{t_1} + k_3}{k_2[He][H]_{t_2} + k_3} = k_3(t_1 - t_2)$$

or

$$[7]\quad \frac{[H]_{t_2}}{[H]_{t_1}}\left(\frac{k_2[He][H]_{t_1} + k_3}{k_2[He][H]_{t_2} + k_3}\right) = e^{k_3(t_1 - t_2)}$$

For $k_3(t_1 - t_2)$ not in excess of about 0.4

$$[8]\quad \frac{[H]_{t_2}}{[H]_{t_1}}\left(\frac{k_2[He][H]_{t_1} + k_3}{k_2[He][H]_{t_2} + k_3}\right) = k_3(t_1 - t_2) + 1$$

Insertion of the appropriate experimental data into this relation, together with the recently determined value of k_2 (2), permitted the value of k_3 applicable to the present system to be estimated.

When NH_3 was added between the H inlet and the e.s.r. cavity the rate of recombination of H atoms was increased for given values of the pressure and of [He], although the increased flow rate through the tube reduced the extent to which the H atom signal was decreased at the e.s.r. cavity. Several calibration curves were made of the e.s.r. signal against the H atom concentration, determined with the HI or HBr procedure, corresponding to several positions at which NH_3 was added between the H atom inlet and cavity. This allowed values of $[H]_t$ to be calculated in the presence of NH_3 from the change of e.s.r. signal. From the known values of k_2, k_3, $[NH_3]$, [He], and measured values of $[H]_{t_1}$ and $[H]_{t_2}$ for reaction times t_1 and t_2, respectively, the value of k_1 was then calculable from

$$[9]\quad \left(\frac{[H]_{t_2}k_1[NH_3][H]_{t_1} + k_2[He][H]_{t_1} + k_3}{[H]_{t_1}k_1[NH_3][H]_{t_2} + k_2[He][H]_{t_2} + k_3}\right) = 1 + k_3(t_1 - t_2)$$

Rate constants for the recombination of H atoms in the presence of NH_3 are given in Table 1 for a range of pressures from 1.50–4.55 Torr, with various NH_3, He, and H concentrations. The values are corrected for longitudinal diffusion of the hydrogen atoms (8, 9).

The value of k_2 used in the above calculations (2) is approximately one-half that estimated from the results of Kaufman and co-workers (10) for $H + H + H_2$ in conjunction with the ratio of 1.3

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

for the effectiveness of He relative to H_2 (2). If the latter value is used in eqs. 8 and 9, k_3 is changed by less than 5% and the value of k_1 becomes 5.14×10^{16} cm^6 mol^{-2} s^{-1}. From either calculation, it appears that NH_3 has roughly one-half the efficiency of H_2O as a third body for recombination of H atoms.

Molecular Motion in Azulene and the Azulene–(*s*)-Trinitrobenzene Molecular Complex in the Solid State

C. A. FYFE AND G. J. KUPFERSCHMIDT
Department of Chemistry, University of Guelph, Guelph, Ontario

Received December 15, 1972[1]

Molecular motion of azulene in its own molecular crystal and in its complex with trinitrobenzene has been shown from wide-line n.m.r. and spin–lattice relaxation time measurements to occur in the solid state. Calculations of the n.m.r. spectral parameters based on a model where the azulene molecules are reorienting in their molecular planes by 180° jumps give satisfactory agreement with experimental values. The results are discussed with respect to the available X-ray data.

On a montré à l'aide de la r.m.n. large bande et de mesures des temps de relaxation spin–réseau que le mouvement moléculaire de l'azulène dans sa propre structure cristalline ainsi que dans celle de son complexe avec la trinitrobenzène se produit à l'état solide. Les calculs des paramètres spectraux en r.m.n. basés sur un modèle où les molécules d'azulène se réorientent dans les plans moléculaires par des changements de 180° sont en proche accord avec les valeurs expérimentales. On discute des résultats en fonction des données disponibles à l'aide des expériences en rayons-X.

[Traduit par le journal]

Can. J. Chem. 51, 3774 (1973)

Introduction

Several attempts have been made to determine the crystal structure of azulene (1–6). The first investigation was by Günthard and co-workers (1), who suggested the centrosymmetric space group $P2_1/a$ with two molecules in the unit cell. Since azulene is not itself centrosymmetric, a disordered structure was implied. However, subsequent independent investigations by Robertson and Shearer (2) and by Takeuchi and Pepinsky (3) suggested an ordered structure based on the non-centric space group *Pa*. Support for an ordered structure was also claimed from an examination of the external morphology of the crystal (4). However, further work by Robertson and co-workers showed that the structure based on the non-centric space group *Pa* could not be successfully refined, whereas that based on the centric $P2_1/a$ could (5, 6). The occupancy of a single site was the statistical distribution of molecules over two possible sites as shown in Fig. 1, the 'average' occupancy being centrosymmetric. No unusual intermolecular contacts were introduced by the disorder, but the molecular structure was not accurately determined since, because of the overlapping of the three pairs of atoms indicated in Fig. 1, seven other slightly different molecules are possible. Although the molecule drawn in Fig. 1 was considered the most reasonable, there was still a severe limitation to the accuracy of the determination.

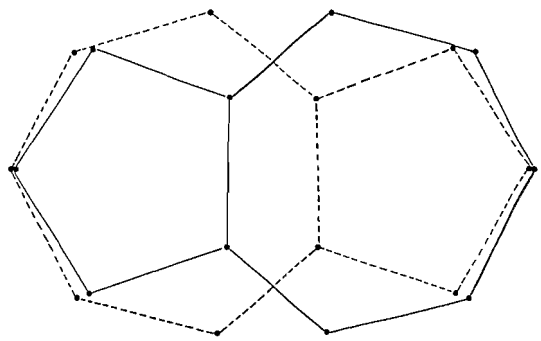

FIG. 1. Schematic representation of the statistical occupancy of a single site in the room temperature azulene crystal as found by Robertson *et al.* (6).

Brown and Wallwork (7) attempted to determine the room temperature structure of the azulene–trinitrobenzene complex but found that 'disorder' in the azulene portion of the molecule prevented refinement, although a structure is given in their paper showing a single orientation of azulene molecules.

The determination of the crystal structure of the complex of azulene with trinitrobenzene was undertaken independently by Hanson (8) as a further attempt to determine the molecular geometry of azulene. In an elegant piece of work,

[1]Revision received July 31, 1973.

For personal use only.

he chose a temperature of −95 °C, and was able to successfully refine the structure at this temperature. The suggested structure involved 93% of the azulene molecules adopting one orientation, and only 7% adopting the alternative orientation by 180° rotation in their molecular planes as shown in Fig. 1.

Several aromatic molecules are known to possess considerable motional freedom in the solid state (9–11) and solid state n.m.r. has proven to be a powerful tool for its investigation. Although the aromatic compounds investigated often show no disorder due to their reorientation because of their high symmetry, there is no *a priori* reason why this must be so.

The purpose of the present work was to determine whether the disorder shown in the case of azulene was of a static or dynamic nature, whether there was any reorientation in the case of the complex, and the relationship of any motional processes to the results of the X-ray structure determinations.

Experimental

Azulene was supplied by the Aldrich Chemical Company and was used without further purification. The complex was prepared by mixing hot equimolar solutions of trinitrobenzene and azulene in toluene. The cooled solution yielded blue-black crystals, m.p. 165–166 °C (lit. (12) 167 °C), which analyzed correctly for a 1:1 complex.

Slow passage n.m.r. spectra were recorded on a Varian H.A. 100A spectrometer with a 15″ magnet. Signal modulation and detection were achieved using a P.A.R. H.R. 8 lock-in amplifier and an H.P. 465A amplifier. Samples were sealed in thin-walled 12 mm o.d. tubes. Temperature variation was achieved using a standard variable temperature accessory, and temperatures were recorded directly using a copper/constantan thermocouple fused into the top of the sample. Several spectra were recorded at each temperature and the average parameters taken.

T_1 measurements on azulene were made with a 30 MHz pulsed spectrometer built from commercial units using a saturation method with a 90° pulse of approximately 2.5 μs. T_1 measurements on the complex were made on a Bruker pulsed spectrometer at 30 MHz using a 90°–τ–90° pulse sequence and a pulse length of 1.5 ms (see acknowledgments).

D.s.c. measurements were made on a Perkin Elmer Differential Scanning Calorimeter, Model 1B (see acknowledgments).

All calculations were performed on the University of Guelph's I.B.M. 360-50 computer using Fortran IV programs.

Results and Discussion

Slow Passage Measurements

The ^{1}H n.m.r. spectrum of solid azulene was found to be temperature dependent (Fig. 2, inset) indicative of some reorientation process. The linewidth and second moment parameters both show a transition, centered at ~310 °K. The anomalous change in the second moment parameters may be an artifact due to saturation, as T_1 in this region is extremely long (see later). The results of calculations of the theoretical second moments for a rigid lattice (13), and for motion (14) between the two alternate sites by 180° jumps, are shown in Table 1 compared with the experimentally observed values, and will be discussed in detail. The second moment ΔH^2 in a rigid lattice can be calculated from the formulation of Van Vleck (13), eq. 1,

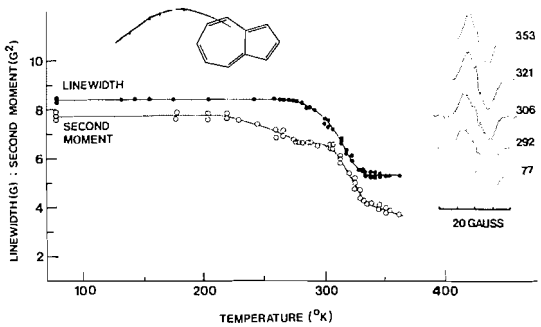

FIG. 2. The temperature dependence of the linewidth (filled circles) and second moment (open circles) parameters of the proton resonance of azulene in the solid state with (inset) representative spectra recorded at the temperatures indicated by the vertical arrows.

$$[1] \quad \Delta H^2 = \frac{9}{16}\gamma^2 h^2 \sum_{i,j} \left(\frac{3\cos^2\theta_{ij} - 1}{r_{ij}^3} \right)^2$$

where r_{ij} is the internuclear distance between atoms i, j and θ is the angle between their internuclear vector and the applied magnetic field. The summation is carried out for all pairs of interactions i, j.

For a polycrystalline sample, the term $(3\cos^2\theta_{ij} - 1)^2$ must be averaged over all the positions of the crystallites becoming 4/5 and yielding [2].

$$[2] \quad \Delta H^2 = \frac{9}{16}\gamma^2 h^2 \sum_{i,j} r_{ij}^{-6}$$

In practice, this interaction is often divided further into an intramolecular contribution from the atoms within a single molecule and an intermolecular contribution from the interactions between the atoms of different molecules. It is possible to calculate the former at least approxi-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

mately from the molecular structure, whereas the latter may only be calculated from a knowledge of the crystal structure or else estimated.

In the case of azulene the molecular structure taken was that considered most probable by Robertson *et al.* (6); hydrogen atoms were generated at a C—H bond length of 1.08 Å by bisecting the ccc angle whose apex was the carbon to which the hydrogen was attached. Calculation of the rigid lattice second moment as described above by the formulation of Van Vleck (13) gives an intramolecular second moment of 4.24 G^2 and an intermolecular second moment of 4.42 G^2, giving a total second moment of 8.66 G^2 compared to the limiting low-temperature second moment of 7.8 G^2. The difference is attributed to the intramolecular second moment being too high. Intramolecular second moments found for polycyclic aromatics are in the range 3.0 ± 0.5 G^2 (21, 22, 24), and the value for the azulene molecule itself in the complex where the coordinates are much better defined is 2.8 G^2. It is thought that the difference in the present case is due to the inherent inaccuracies introduced by the disorder, as discussed in the introduction, and the value found for azulene in the complex was used. There may also be inaccuracies in the intermolecular second moment, but these are liable to be much smaller, as the internuclear distances involved are larger.

In the presence of motion, the term

$$\left(\frac{3\cos^2\theta_{jk} - 1}{r_{jk}^3}\right)^2$$

in eq. 1 must be averaged over the motion. The intramolecular contribution is simplest, since the term r_{jk} remains constant throughout the motion for a rigid molecule such as azulene (not all cases need have this simplification). Gutowsky and Pake (26) have shown that averaging over the motion and then over the powder reduces this term to $(3\cos^2\alpha_{ij} - 1)^2/r_{ij}^6$ where α_{jk} is the angle between the rotation axis and the internuclear vector. The average obtains only for axes of order $\geqslant 3$. In the case of a twofold axis, the term is unchanged as the motion exactly reverses the direction of the internuclear vectors.

For the intramolecular contribution, the term

$$\left(\frac{3\cos^2\theta_{ij} - 1}{r_{ij}^3}\right)^2$$

must again be averaged. In this case, however, the vector r_{ij} changes not only in direction, but also in length. Averaging the above term firstly over all the positions occupied by the two atoms in the reorientation, and then averaging over the powder yields [3].

$$[3]\quad \left\langle\left\langle \frac{3\cos^2\theta_{ij} - 1}{r_{ij}^3}\right\rangle^2\right\rangle = \frac{1}{p^2q^2}\sum_{i=1}^{p}\sum_{j=1}^{q}\frac{1}{r_{ij}^6}\left[\frac{4}{5}\frac{(3\cos^2\theta_{ij} - 1)^2}{2} + \frac{4}{15}(3\cos\theta_{ij}\sin\theta_{ij}\sin\Psi_{ij})^2 + \frac{4}{15}(3\cos\theta_{ij}\sin\theta_{ij}\cos\Psi_{ij})^2 + \frac{1}{15}(3\sin^2\theta_{ij}\cos 2\Psi_{ij})^2 + \frac{1}{15}(3\sin^2\theta_{ij}\sin 2\Psi_{ij})^2\right]$$

Where the summations are made over the N positions occupied by the internuclear vector determined by the p sites occupied by atom i and the q sites occupied by atom j and θ_{ij} and ϕ_{ij} are the polar angles made by the vector ***ij*** with an arbitrary origin. These equations are identical to those deduced by Michel and co-workers (14) and may be used directly in calculations. The averaging for the intramolecular case for a rigid molecule is, in fact, a special case of the more general eq. 3 where the distance r_{ij} does not change. In the present work Van Vleck's formula was modified using [3] for the calculation of both inter- and intramolecular interactions.

Calculation of the theoretical second moment for motion between the two alternate sites leaves the intramolecular second moment unchanged, but causes a drop in the intermolecular contribution to 1.14 G^2, giving a total second moment in reasonable agreement with that experimentally observed.

Although the disorder found crystallographically could theoretically be obtained by rotating the azulene molecule by 180° around an axis in its plane passing through the center of gravity of the molecule (end over end rotation), this possibility is ruled out by the infinitely large repulsive interactions it introduces between the molecule being rotated and the other molecules in the lattice, and in-plane rotation by 180° is thought to be the only reasonable motion.

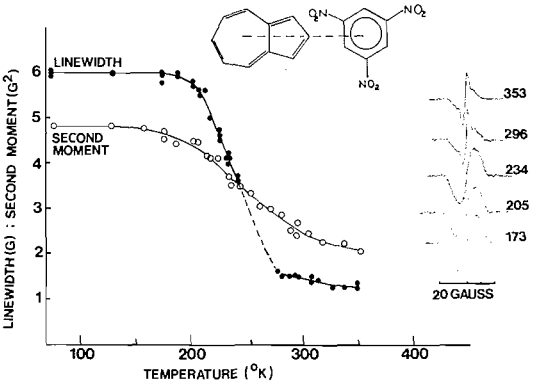

FIG. 3. The temperature dependence of the linewidth (filled circles) and second moment (open circles) parameters of the proton resonance of the azulene–trinitrobenzene molecular complex with (inset) representative spectra recorded at the temperatures indicated by the vertical arrows.

The proton resonance of the complex is similarly temperature dependent (Fig. 3) showing linewidth and second moment changes centered about 250 °K. The discontinuous linewidth change shown in Fig. 3 is due to a change in signal shape. The narrow component in the high-temperature spectra is thought due to the three protons on the trinitrobenzene molecule which will be broadened only slightly as there are no protons 'ortho' to them in the molecule.

The limiting low- and high-temperature second moments are again compared with calculated theoretical values in Table 1. The basic molecular unit taken for the calculation of the intramolecular contribution was a molecule of complex, *i.e.* one azulene and one trinitrobenzene molecule. There is good agreement (Table 1) between the observed low-temperature value and calculated rigid lattice second moment, and tolerable agreement between the limiting high-temperature second moment and the theoretical value calculated for motion of the azulene molecule between two sites related by 180° while the trinitrobenzene molecules are still rigid. There is very little change in the total intramolecular contribution for the complex, since only the interactions between the two rings average.

Calculation of the theoretical second moment based on a model where both the azulene and the trinitrobenzene molecules are moving, the latter round its threefold axis, also yields a value which agrees reasonably well with the observed high-temperature second moment (Table 1). It is not thought possible to distinguish between these two cases from the calculations but it is possible that both molecules could be moving.[2]

The slow passage experiments thus suggest that there is motion of the azulene molecules in both cases. Because discrete positions are shown by the X-ray measurements, the motions must be by 180° 'flips'. The onset of motion occurs at a much lower temperature in the complex.

T_1 Measurements

The spin-lattice relaxation times of azulene and the complex are shown plotted as their logarithms against the reciprocal of absolute temperature in Fig. 4. Both sets are very temperature dependent, indicative of the presence of some reorientation process, in agreement with the results from the slow passage experiments. In the case of the complex, the expected minimum in the curve is found, but azulene itself melts before its minimum is reached. In the case of azulene, T_1 measurements could not be performed below 290 °K due to the very long values of T_1. As indicated above, those large values of T_1 may have caused anomalous values of the second moment parameters because of distortion of the signal shape due to saturation.

Activation Energies

Activation energies calculated from a least-square fit to the linear portions of the T_1 curves are given in Table 2. Also given are the value for azulene from a fit of the modified B.P.P. equation (15, 16) to the linewidth transition, and values for both the azulene and the complex from the Waugh estimate (17) of $37T$, where T is the temperature of the linewidth transition. The overall agreement between all the results is probably fortuitous, as the second methods are considerably more empirical than the T_1 measurements.

That the azulene molecule in complex has a lower activation energy for reorientation than it does in its own molecular crystal suggests certain critical intermolecular contacts have been broken by the layer structure of the complex, and is consistent with results of other systems (11). The reorientation of the azulene molecule in the complex also shows directly that although

TABLE 1. Observed and calculated second moment parameters (in G^2) for azulene and the azulene-trinitrobenzene molecular complex for the various motions indicated for the azulene moieties[a]

Molecule	State	Calculated			Observed	T(°K)
		Intra	Inter	Total		
Azulene	R[b]	3.0±0.5[c]	4.42	7.4 ±0.5	7.8±0.3	<270
	M[b]	3.0±0.5[c]	1.14	4.14±0.5	3.8±0.3	>350
Azulene-trinitrobenzene complex	R[b]	2.46[c]	2.15	4.61±0.5	4.2±0.3	<200
Azulene moving	M[b]	2.45[c]	0.89	3.34±0.5		
Azulene and trinitrobenzene both moving	M[b,d]	2.45[c]	0.54	2.99±0.5	2.2±0.3	>320

[a]For details of the calculations see the text.
[b]R = rigid, M = moving.
[c]In the case of azulene itself, there is no change in the intramolecular contribution to the second moment as the motion is one of 180° flips. In the case of the complex, the intramolecular drops vary slightly because the basic unit considered consists of both components. The contributions from these other interactions are, however, very small.
[d]The author would like to acknowledge the assistance of one of the referees in pointing out this possibility.

the molecule is unsymmetrical, there is no strong localization of the charge transfer interaction at any point in the molecule.

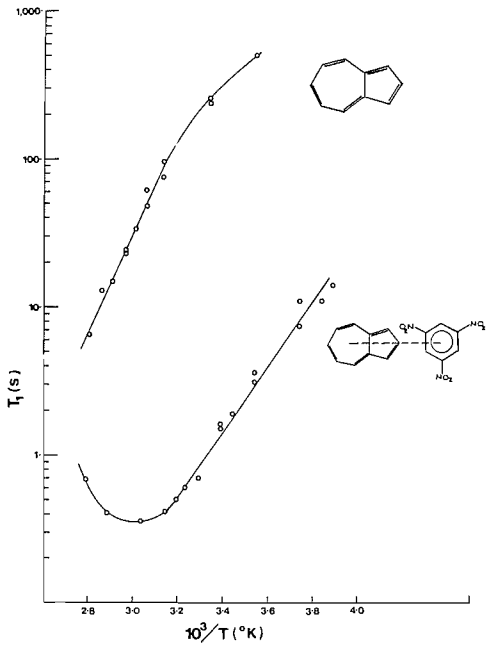

FIG. 4. Spin-lattice relaxation time (T_1, s) of the proton resonance of azulene (upper curve) and the azulene-trinitrobenzene molecular complex (lower curve) plotted as their logarithms against the reciprocal of absolute temperature.

Thermodynamic Results

If there is reorientation of the azulene molecules at room temperature, and if there is no disordered low-temperature phase with an associated zero point entropy, then there should be an order-disorder transition at, or below, the temperature of the n.m.r. linewidth transition, since the latter is the result of a kinetic process.

Accordingly, d.s.c. measurements were made in the appropriate temperature range. These, however, failed to reveal any such transitions although the melting transition was clearly identified. This is thought to be due to the relatively small value of the entropy change involved (R ln 2, in the case of azulene, and half this value for the complex), the relative insensitivity of the apparatus, and the large number of degrees over which transitions of this type typically occur (18). A proper thermodynamic investigation using an adiabatic calorimeter to resolve this point would be of interest.[3]

Conclusions

The azulene molecules in both azulene and its complex with trinitrobenzene are considered to be in dynamic equilibrium between the two alternate sites rotated by 180° as suggested by the

[3]Personal communication from Prof. E. F. Westrum Jr. indicates that his group has recently completed such a study.

TABLE 2. The activation energies (kcal mol^{-1}) for the reorientation processes in azulene and the azulene–trinitrobenzene molecular complex as determined by the methods indicated

	T_1 measurements	B.P.P. approximation	Waugh estimate
Azulene	15.4±0.4	16.2±0.5	11.4
Azulene–trinitrobenzene complex	9.7±0.3	—[a]	9.3

[a]Not applicable due to changes in spectral shape.

X-ray investigation of azulene (6). If a structure determination is found possible for the azulene–trinitrobenzene complex at room temperature, it should show the same type of disorder in the azulene moiety. The low-temperature structure determination of the complex by Hanson (8) is thought to have been done at the low-temperature end of an order–disorder transition involving the azulene molecules. A lower temperature still would perhaps remove the residual 7% of the alternate orientation. Similarly, a structure determination of azulene at some temperature below 270 °K should show only a single occupancy of the sites. The exact temperatures of the transitions will be best determined calorimetrically.

The conclusions from the results here may perhaps be extended to other compounds involving the azulene moiety whose structures have recently been determined (19, 20). Thus, in the case of the organometallic molecule azulene – dimolybdenum hexacarbonyl, the azulene moiety is disordered (19). From the present work, the disorder is thought to be of a dynamic nature, and the bonding between the metal atoms and the azulene weaker and much less localized than in other similar compounds, for example azulene – diiron pentacarbonyl (20) where an ordered azulene structure is found.

Several polycyclic aromatic molecules have now been shown to possess a dynamic, rather than static, structure in the solid state (21–24). A theoretical interpretation of why this should be so, as well as a prediction of the activation energies involved, is currently in progress (25).

The authors would like to acknowledge the financial assistance of the National Research Council of Canada for a grant in aid of research (to C.A.F.) and for a major equipment grant for the purchase of the spectrometer, and also the Research Advisory Board of the University of Guelph. They would also like to thank Dr. J. Stevens for the use of his d.s.c. apparatus and Dr. Pintar and Dr. R. Knispel, University of Waterloo, for the use of their pulse spectrometers and for their assistance in making the T_1 measurements.

On the Aggregation of Bovine Serum Albumin in 0.1 *M* Salt Solutions

NANETTE O. DEL ROSARIO AND SIAO FANG SUN
Department of Chemistry, St. John's University, Jamaica, New York 11439

Received March 29, 1973

The molecular weight of bovine serum albumin at neutral p*H* in 0.1 *M* salt solutions was determined with light scattering measurements. Simultaneously, preferential binding of a salt to the protein was calculated. It was found that the protein aggregates in KI and KSCN, but not in KCl, LiCl, and LiBr solutions. Analysis of the sedimentation behavior has confirmed aggregation as a molecular phenomenon, not an artifact.

Le poids moléculaire de sérum d'albumine de boeuf a été déterminé par diffusion de la lumière à pH neutre dans des solutions contenant 0.1 *M* de sel. Simultanément on a calculé l'attachement préférentiel d'un sel à la protéine. On a trouvé que la protéine forme des aggrégats dans le KI et e KSCN mais pas des solutions de KCl, LiCl et LiBr. L'analyse des patrons de sédimentation a confirmé que l'aggrégation est un phénomène moléculaire et non un artéfact. [Traduit par le journal]

Bovine serum albumin aggregates in 0.1 M NaCl solution below p*H* 4.0 (1–3). It is generally agreed that aggregation is related to molecular expansion. Since at p*H* values above the N → F transition, albumin exists in a compact form, albumin has been assumed to be a non-associating protein. For example, the studies of the binding of Cl^-, I^-, and SCN^- to albumin (4–6) all ignored the aggregation. In this paper we shall demonstrate that at neutral p*H* (*ca.* 5.2) albumin also forms aggregates in the presence of some though not all salts. The molecular weight of albumin at neutral p*H*, ionic strength 0.10 and room temperature was determined and the preferential binding of each salt to the protein was compared, using the technique of light scattering. Supplementary information about aggregation was obtained with sedimentation measurements.

Experimental

Materials

Armour crystalline bovine serum albumin, Lot Nos. A 69908, F 71601, and D 71209, was deionized by Dintzis' method (7). The dimer content varied from 1% to 5% depending upon the lot as judged from sedimentation velocity analyses. No significant differences were detected in light scattering experiments whichever lot was used.

The salts used, KCl, KI, and KSCN were Baker analyzed reagents, while LiCl and LiBr were Matheson, Coleman and Bell reagent grade. Glass-distilled water was used in all the experiments.

Light Scattering

Advantage was taken on the theory of light scattering in multi-component systems that if the light scattering and the refractive index increments are measured on solutions which are at constant chemical potential with the solvent, then the light scattering equation for a multicomponent system may be reduced to an equation similar to a 2-component system (8–10). Thus in a three component system (water-1, protein-2, and salt-3), the plot of $HC_2/\Delta\tau$ *vs.* C_2 would give the true molecular weight M_2, H being the Debye parameter, C_2 the concentration in g/ml and $\Delta\tau$ the excess turbidity of the solution over the solvent. If the solutions are not at constant chemical potential but at constant concentration of the solvent system, then the plot of $HC_2/\Delta\tau$ *vs.* C_2 can only give M_2', the apparent molecular weight of component 2 (protein), not the true molecular weight. Nevertheless the relation between M_2 and M_2' enables one to calculate a quantity $(\partial g_3/\partial g_2)_{T,\mu_1,\mu_3}$ which is the preferential binding of the number of grams of the salt to one gram of the protein on molar or molal basis, g being the number of grams, T the temperature, and μ the chemical potential (8, 10). In order to make use of the multicomponent theory, which we shall discuss in greater detail in latter sections, to analyze data, experiments were carried out with the protein solutions under constant chemical potential of component 3 as well as under constant concentration of component 3. To achieve the condition of constant chemical potential of component 3, the protein solution was dialyzed in equilibrium with the solvent which contained the same concentration of the salt as the protein solution. To achieve the condition of constant concentration of component 3, the solution was not dialyzed, but the concentration of the salt was the same as that of the dialyzed solution and was kept constant for both the solution and the solvent.

Light scattering measurements were made at 546 nm and room temperature using a Brice-Phoenix Dual Photomultiplier Photometer, Model 2000-D. All the solutions were freshly prepared prior to use. In the experiments without dialysis, the solution with the concentration of protein 6.0×10^{-3} g/ml was ultracentrifuged for 30 min at 64 000 r.p.m. with a Spinco L preparative ultracentrifuge and filtered several times using a Millipore filter of porosity 0.22 μ. Turbidity measurements were

TABLE 1. Light scattering data of bovine serum albumin in 0.1 *M* salt solutions

*Of most concentrated protein solution.

first made on this solution and then on the solutions which were diluted by adding the solvent directly into the cell. Mixing was accomplished by swerving, partial inversion and, in some runs, by a micromagnetic stirrer. In the experiments with dialysis, five solutions of different protein concentrations in the range of 1.0×10^{-3} to 6.0×10^{-3} g/ml without ultracentrifugation were filtered several times using the same Millipore filter of same porosity, 0.22 μ. Turbidity measurement was taken with each solution as an independent experiment. The light scattering cell used was D-101 of the semi-octagonal type. The minimum amount of solution required for this cell is 30 ml.

The concentration of filtered bovine serum albumin stock solution was determined by the measurement of optical density in a Cary 14 spectrophotometer using $E_{1cm}^{1\%} = 6.67$ at 279 nm (11). It was also determined by drying the sample in a vacuum oven at 107°. The agreement was good.

Refractive Index Increments

The same solutions used for the light scattering measurements were used for the refractive index increment measurements. The experiments were performed in a Brice-Phoenix differential refractometer, Model BP-2000V at 546 nm, equipped with a Forma temperature control unit to keep the temperature at 25°. The instrument was calibrated with KCl solutions which were prepared from samples, reagent grade, dried in a vacuum oven at 110° over Drierite. The calibration constant was determined using the data of Kruis (12). For the measurements of $(\partial n/\partial C_2)_{T,\mu_1,\mu_3}$, (in which n is the refractive index and C is the concentration in g/ml), one compartment of the differential cell was filled with the dialyzed protein solution and the other compartment with its dialyzate. For the measurements of $(\partial n/\partial C_2)_{T,p,m_3}$, where p is the pressure and m is the concentration in molal, one compartment was filled with the undialyzed protein solution and the other with the solvent (a salt solution).

Measurements of $(\partial n/\partial C_3)_{m_2}$ were taken with a Bausch and Lomb refractometer of Abbe type. The refractive index reading at sodium line was converted to 546 nm using the equation

$$n_x = A + \frac{B}{\lambda_x^2}$$

where

$$A = n_D - 2.8796 \times 10^{-6} B$$

and

$$B = 0.52364 \times 10^{-6}(n_F - n_C)$$

The values of $(n_F - n_C)$ were calculated using the table provided by the manufacturer of the refractometer. The partial specific volume of the protein, $\bar{v}_2$, which was 0.734 ml/g, was taken to be constant for all the solutions, whether for a dialyzed or undialyzed protein (13, 14). The value of $\bar{v}_3$ was determined from the density (15) using graphic methods (16).

Sedimentation Velocity

Sedimentation velocity experiments were carried out with a Spinco Model E analytical ultracentrifuge, equipped with a phase plate and rotor temperature indicator and control (r.t.i.c.) unit. The r.t.i.c. was calibrated according to the method suggested in the manufacturer's manual. The temperature was set at 20° and kept constant. The rotor speed was set at 60 000 r.p.m. for each run and was checked regularly. Photographs were taken at 16 min intervals. The plates were measured with a Nikon comparator Mod 6C. Protein concentrations were about 0.90 g/100 ml.

Results

The differential refractive index and light scattering measurements of this study were undertaken for more than three years. Almost all possible kinds of techniques have been tried. The results reported in this paper were selected from six to twelve determinations of each solution.

Refractive Index Increments

The values of dn/dC_2 for dialyzed as well as undialyzed albumin in salt solutions are listed in Table 1. They are all independent of the protein concentration. A probable error in dn/dC_2 values is in the range of 0.001–0.003 as determined by the least-squares method.

The refractive index increment varies from salt to salt both for dialyzed and undialyzed solutions, but it tends to be invariant between dialyzed and undialyzed solutions for KCl, LiCl, and LiBr. An appreciable change in value was observed between dialyzed and undialyzed proteins for KI and KSCN. We have paid special attention to these two salt solutions, particularly

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

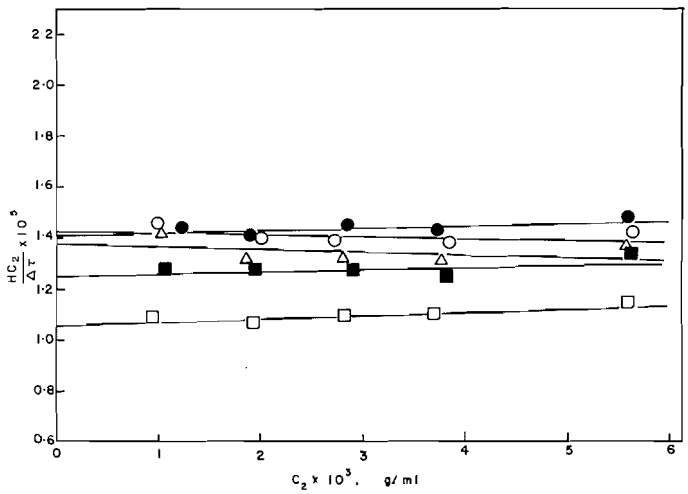

FIG. 1. Turbidity of dialyzed bovine serum albumin in aqueous 0.1 *M* salt solutions: ○, KCl; △, LiCl; ●, LiBr; □, KI; ■, KSCN.

to KI. Among the five salt solutions, KI is supposed to be the least stable. Iodide is easily oxidized to iodine upon standing. For example, color develops for 1 *M* KI solution within 2 h. However, for 0.1 *M* KI solution which we used in this study, the solution was stable for about a week. Our measurements were usually taken on freshly prepared solutions for undialyzed protein and within 24 h for dialyzed protein. Only for the test of reversibility, measurements were taken in 5 days after the solution was prepared. We have checked the amount of iodide in the solvent (0.1 *M* KI) by a conventional method: the solvent was oxidized quantitatively to iodine and the iodine was titrated with thiosulfate. We did not find any loss of iodide in the solvent and we believed that no impurity was developed in KI solution. Since KSCN solution is very stable, we did not perform any analysis on the change of property of this solution.

Dialyzed Bovine Serum Albumin Solutions

Light scattering data for dialyzed bovine serum albumin solutions are plotted in the form of $HC_2/\Delta\tau$ *vs.* C_2 according to Debye equation

$$[1] \qquad \frac{HC_2}{\Delta\tau} = \frac{1}{M_2} + 2BC_2$$

where

$$H = \frac{32\pi^3 n^2 (\partial n/\partial C_2)^2}{3N\lambda^4}$$

In this expression λ is the wavelength *in vacuo* of the light used, in cm, and N is the Avogadro's number. The results are shown in Fig. 1. Although bovine serum albumin is known for its intrinsic anisotropy, depolarization of light scattering by the protein was found to be very small (17). No correction for depolarization was made for $\Delta\tau$.

The slopes, the extrapolated intercepts, and the resulting data are listed in Table 1. The straight lines were determined by the least-squares method. Almost all the experimental points for each solution fall on a straight line. The slopes of most straight lines were expected to be close to zero, since for an isoionic protein or for a protein solution at ionic strength 0.15, the slope is usually found to be near zero (18). Although the slopes were not exactly zero as shown in Fig. 1, the numerical values that we have obtained were not as reliable as those of intercepts. Also the signs of the slopes were not as meaningful as in the case of salt-free protein solutions. The slopes for KI and KSCN were expected to be negative, but they were positive; whereas, negative slopes were obtained with KCl and LiCl which were expected to be positive. In the light scattering study of β-lactoglobulin A in water–methanol mixtures, the slopes were positive with concentration of methanol in volume %: 0, 20, 30, and 40; negative with concentration of methanol 50, 60, and 80, even though no aggregation was found in these solvent mixtures (10). It is for this reason we did not calculate the β factors (*i.e.* β_{22} and β_{23}) from

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

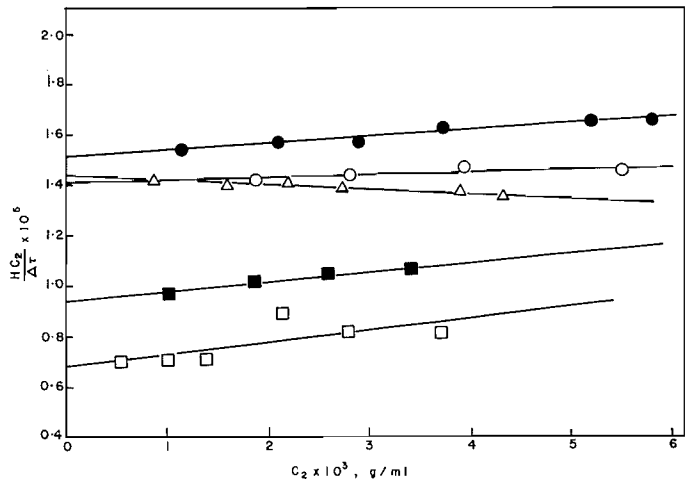

FIG. 2. Turbidity of undialyzed bovine serum albumin in aqueous 0.1 *M* salt solutions: ○, KCl; △, LiCl; ●, LiBr; □, KI; ■, KSCN.

the values of slopes where β's are non-ideality parameters.

Undialyzed Bovine Serum Albumin Solutions

Plots of $HC_2/\Delta\tau$ *vs.* C_2 for undialyzed bovine serum albumin in the same series of salt solutions are illustrated in Fig. 2 and the resulting data are listed in Table 1. The lines in Fig. 2 are similar to those in Fig. 1, but the numerical values of the slopes and intercepts are different. Again the least-squares method was used to determine the slopes and intercepts.

Calculated Data

As we mentioned before, from the plot of $HC_2/\Delta\tau$ *vs.* C_2 for the undialyzed solutions, we obtain the value of $1/M_2'$ (the intercept at $C_2 = 0$), whereas from the plot for the dialyzed solutions, we obtain the value of $1/M_2$. The value of M_2' is the apparent molecular weight of the protein and that of M_2 its true molecular weight. The two quantities, M_2 and M_2', are related in the form (9, 10),

$$[2a] \qquad M_2' = M_2(1 + D)^2$$

where (8)

$$[2b] \qquad D = \frac{(\partial n/\partial g_3)_{T,p,g_2}}{(\partial n/\partial g_2)_{T,p,g_3}} \left(\frac{\partial g_3}{\partial g_2}\right)_{T,\mu_1,\mu_3}$$

or (10)

$$[2c] \qquad D = \frac{(1 - C_3\bar{v}_3)(\partial n/\partial C_3)_{m_2}}{(1 - C_2\bar{v}_2)(\partial n/\partial C_2)_{m_3}} \times \frac{M_3}{M_2}\left(\frac{\partial m_3}{\partial m_2}\right)_{T,\mu_1,\mu_3}$$

The quantity $(\partial g_3/\partial g_2)_{T,\mu_1,\mu_3}$ in eq. 2*b* is the preferential binding of the number of grams of the salt to one gram of the protein on molar basis, whereas the quantity $(\partial m_3/\partial m_2)_{T,\mu_1,\mu_3}$ is the number of moles of the salt bound to a mole of protein on molal basis. The latter quantity can also be converted into $(\partial g_3/\partial g_2)_{T,\mu_1,\mu_3}$, the number of grams of the salt bound per gram of protein on molal basis, using the equation (10)

$$[3] \qquad (\partial g_3/\partial g_2)_{T,\mu_1,\mu_3} = M_3/M_2(\partial m_3/\partial m_2)_{T,\mu_1,\mu_3}$$

Equation 3 is based upon the assumption that

$$(\partial m_3/\partial m_2)_{T,p,\mu_3} \cong (\partial m_3/\partial m_2)_{T,\mu_1,\mu_3}$$

The molal scale is preferred for the reason that the protein volume is not included (19).

Table 2 gives the molecular data for light scattering calculations. In Table 3 are listed all the calculated values: molecular weight, $(\partial m_3/\partial m_2)_{T,\mu_1,\mu_3}$ and $(\partial g_3/\partial g_2)_{T,\mu_1,\mu_3}$.

Time Dependency and Reproducibility

Light scattering and differential refractive index measurements were taken on the protein in 0.1 *M* salt solution after dialysis for 1 night, 2 nights, 4 nights, and 6 nights respectively. It was found that there is virtually no change in the values of $(\partial n/\partial C_2)_{T,\mu_1,\mu_3}$, $\Delta\tau$ and molecular weight for the protein after dialysis for 1 night or 2 nights. This indicates that equilibrium has most likely been reached after dialysis overnight. If, however, dialysis was carried out longer than 2 nights, there was some change in the measured

KSCN	80 000	99	0.120

values. The change followed this pattern: $(\partial n/\partial C_2)_{T,\mu_1,\mu_3}$ decreased, $\Delta\tau$ increased and the overall molecular weight increased. The magnitude of the change depended on the salt. For example, at 0.1 M KCl solution the values of $(\partial n/\partial C_2)_{T,\mu_1,\mu_3}$ were 0.193 (1 day old) and 0.188 (6 days old); the values of $\Delta\tau$ for the protein concentration 0.001 g/ml were 3.206 (1 day old) and 3.251 (6 days old); and the molecular weight as determined from the intercept of the plot $HC_2/\Delta\tau$ *vs.* C_2 was 5% higher for the 6 day-old protein than for the 1 day-old protein. At 0.1 M KI solution, the values of $(\partial n/\partial C_2)_{T,\mu_1,\mu_3}$ were 0.168 (1 day old) and 0.152 (5 days old); $\Delta\tau$ for the protein concentration 0.001 g/ml were 3.424 (1 day old) and 4.037 (5 days old); and the molecular weight increased about 40%.

The reproducibility of light scattering data often poses a problem. There are three major sources of error: C_2, dn/dC_2, and $\Delta\tau$. The error in C_2 is usually due to uncertainty in the dilution. This error is generally not serious, particularly in the determination of molecular weight in our dialyzed solution. (We did not use the dilution technique for the dialyzed solution.) Furthermore, due to the large quantity of solution prepared for the measurements, experimental error in the determination of concentration was minimized. Errors in the determination of dn/dC_2 and $\Delta\tau$ seem to be more serious and they may or may not be in the same direction. If the errors are in the same direction, they may cancel each other or be minimized; for the error of dn/dC_2 was incorporated in the numerator and that of $\Delta\tau$ in the denominator in the term of $HC_2/\Delta\tau$. If the errors are in opposite directions, the overall error increases, and the uncertainty in the determination of molecular weight and preferential binding becomes large.

Molecular weight was more reproducible in some salt solutions than in others. Unexpectedly, the reproducibility of molecular weight determination of bovine serum albumin in 0.1 M LiCl solution was much better than in 0.1 M KCl solution which we used as the reference. The accuracy of the molecular weight in each salt solution was about $\pm 1\,000$ g/mole. The value was estimated from the results of the best two or three runs.

Reversibility

To test the reversibility of changes in molecular weight, light scattering, and differential refractive index measurements were carried out on bovine serum albumin in 0.1 M salt solutions which were dialyzed twice, first against the solvent and then against pure water. Each dialysis was performed in the cold room overnight to make sure that osmotic equilibrium was reached. In the dialysis of the dialyzed protein solution against pure water, the water was changed several times. Figure 3 shows the results of a representative experiment, the reversibility test on bovine serum albumin in 0.1 M KI solution. The molecular weight of bovine serum albumin in water at very low ionic strength is known to be 70 000, almost the same as that in 0.1 M KCl solution. At 0.1 M KI solution, the molecular weight increased to 94 300 (from the y-intercept of line 1, Fig. 3). After the small ions I^- were diffused away from the same salt solution, the molecular weight of the protein came back to 70 000 (from line 2, Fig. 3). This indicates that the effect of KI on the molecular weight of the protein is a reversible process, in agreement with the general behavior of bovine serum albumin in aqueous solutions as observed in other measurements, *e.g.* viscosity (20) and titration (21). This is also in agreement with the current thinking that neutral salts perturb macromolecular structures in a cooperative transition of the order ⇄ disorder type (22).

Sedimentation Velocity

The values of the sedimentation coefficients were corrected to the reference state (water at

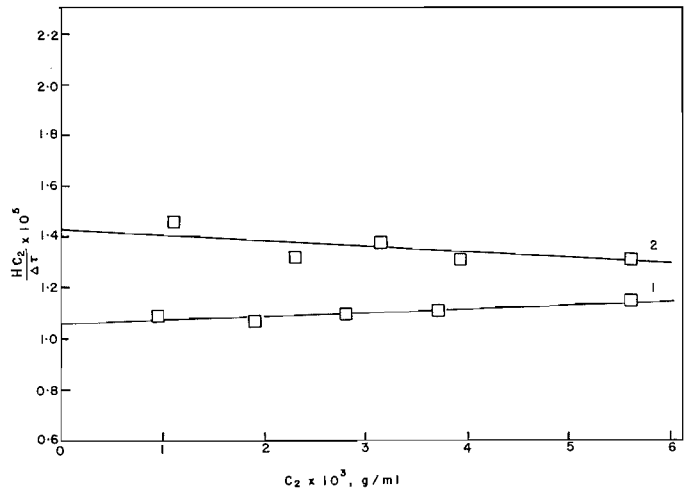

FIG. 3. Test for the reversibility of aggregation of bovine serum albumin in 0.1 *M* KI solution. Line 1, dialyzed solution; line 2, reversed from the dialyzed solution.

20°) according to the following equation

$$S_{20,w} = S_{20,m}\frac{\eta_{20,m}}{\eta_{20,w}}\frac{(1 - \bar{v}\rho)_{20,w}}{(1 - \bar{v}\rho)_{20,m}}$$

where η is the viscosity, ρ the density, and the subscripts m and w refer to the solvent mixture and water, respectively.

The density data were calculated by the equation

$$\rho = \rho_0 + \frac{1 - \bar{v}\rho_0}{100} C$$

where ρ_0 is the density of the solvent and C is the concentration of the protein in g/100 ml. The density of solvent data ρ_0 was obtained from the International Critical Tables and the value of $\eta_{20,m}/\eta_{20,w}$ was determined experimentally.

Assuming that the aggregates are dimers, the percentage of dimer was estimated by dividing the area of the fast component by the total area (14). The Johnson–Ogston effect being small (2), no correction was made for the estimation of the observed areas.

The values of sedimentation coefficient and the percentage of dimer are listed in Table 4. The sedimentation coefficient of albumin is almost identical for KCl, LiCl, LiBr, and KSCN, but is significantly different for KI. The percentage of dimer is the same for KCl, LiCl, and LiBr, higher for KI and KSCN.

TABLE 4. Sedimentation coefficient and percentage of dimer

Salt (0.1 *M*)	$S_{20,w} \times 10^{13}$	% dimer
KCl	4.19	4
LiCl	4.18	4
LiBr	4.19	4
KI	4.31	18
KSCN	4.22	8

Discussion

Several different values of molecular weight of bovine serum albumin have been reported in literature: 69 000 from osmotic pressure measurements (4), 66 500 from ultracentrifuge sedimentation measurements (23) and 66 000 by summing up the individual molecular weights of amino acids that constitute the protein (24). The molecular weight we obtained for the albumin in 0.1 *M* KCl solution which we used as a reference for comparison with other salts is 69 900, within the range of literature values.

Reichmann and Charlwood (1), who also carried out light scattering measurements, reported the molecular weight for the unaggregated bovine serum albumin (at neutral p*H* in 0.10 *M* NaCl solution or at p*H* 1.9 in the presence of 0.10 *M* NaCl) to be 77 000 – 79 000 and for aggregated protein (at p*H* 1.9 in the absence of salt) to be 120 000. Their value of the unaggre-

For personal use only.

gated protein is much higher than ours. It seems that light scattering measurements tend to yield higher values; for example, 77 000 (18) and 72 000 (25).

The values of preferential salt binding for bovine serum albumin are in the order of LiBr < LiCl < KCl < KSCN < KI. The negative values for LiCl and LiBr indicate a deficiency in binding, *i.e.* the Li^+ is not favored over water for interaction in the vicinity of the protein. Scatchard *et al.* (26) have shown that the intrinsic binding constant k_1 and the affinity constant k_2 are both much larger for SCN^- than Cl^- in binding to bovine serum albumin. Using the k values reported by Scatchard *et al.*, Edsall *et al.* (18) have calculated the values of $\bar{\nu}$, the number of these two anions bound per mole of protein. Their value for serum albumin in NaCl solution at ionic strength 0.183 is 10.1, in comparison with our preferential binding in KCl solution at ionic strength 0.1, 12.1. In NaSCN solution at ionic strength 0.183, their value is 24.0, in comparison with ours in KSCN solution at ionic strength 0.1, 99.0. In view of the fact that preferential binding is not binding *per se*, the agreement of the two sets of values is satisfactory.

Preferential binding of salt seems to be related to the weight average molecular weight of the protein. The binding values being relatively low in KCl, LiCl, and LiBr solutions, the protein does not aggregate. The binding values being high in KSCN and KI solutions, the protein does aggregate.

Since the increase in molecular weight of albumin in KI and KSCN solutions is not large, especially in KSCN solution, one might wonder if the aggregations that we believe to be from the light scattering study could be artifacts due to a small quantity of colloidal impurity. Upon examining the sedimentation behavior of the protein in salt solutions, this does not seem to be the case. The percentage of dimer is larger in KI and KSCN than in other salt solutions. It is true that commercially available serum albumin may contain dimers as high as 10% (14), depending upon the lot of preparations, but our comparison was made on the same lot of protein which contained only 4% of dimer. The increase in dimers to 8% in KSCN solution and to 18% in KI solution could not be considered as an artifact.

If we assume the molecular weight of the monomer to be 70 000 and the weight average molecular weight of the mixture of monomer and dimer to be 94 400, then the weight fraction of dimer is 34%. This 34% will be in excess of the 4% dimer already in the monomer. However, the ultracentrifuge data indicate only 14% dimer in excess. Thus there is no quantitative agreement between the two types of experiments. Nevertheless, the qualitative agreement suggests that aggregation behavior in KI and KSCN solutions is most likely a true indication of the protein's behavior.

On the basis of our observations we are led to the following two conclusions: (1) Since, at the same pH (*ca.* 5.4) and same ionic strength (0.1), bovine serum albumin aggregates in KSCN and KI solutions, but not in KCl, LiCl, and LiBr solutions, the ionic strength is not a contributing factor to the aggregation. The usual interpretation that the aggregation of the protein at low pH is a result of electrostatic interaction of residues carrying the same charge seems to be inapplicable here; (2) In view of the reversibility in light scattering measurements, the process of aggregation of bovine serum albumin in salt solutions is equilibrium controlled and not rate controlled.

The assistance of Dr. Tiang Shing Chang in this work is gratefully acknowledged.

Cleavage of the Sulfur–Sulfur Bond in 2,4-Dinitrophenyl-4-substituted-phenyl Disulfides by *trans*-[IrCl(CO) (PPh_3)$_2$]. A Kinetic Study

CHIU T. LAM[1] AND CAESAR V. SENOFF[2]

Departn.ent of Chemistry, University of Guelph, Guelph, Ontario N1G 2W1

Received May 25, 1973

The kinetics of the reaction between *trans*-[IrCl(CO)(PPh_3)$_2$] and a series of 2,4-dinitrophenyl-4-substituted-phenyl disulfides, $YC_6H_4SSC_6H_3(NO_2)_2$ (Y = Br, F, H, CH_3, or CH_3O) have been investigated in toluene between 70 and 90°. These reactions were found to follow simple second order kinetics, rate = k_2[IrCl(CO)(PPh_3)$_2$][$YC_6H_4SSC_6H_3(NO_2)_2$]. The rates of reaction were also found to be insensitive to the nature of the para substituent, Y. This fact together with the observed activation parameters, $\Delta H^{\ddagger} \sim 17$ kcal mol^{-1} and $\Delta S^{\ddagger} \sim -19$ cal mol^{-1} deg^{-1}, have been interpreted as indicating that the initial step in these reactions involves a nucleophilic attack by the iridium atom at the sulfur atom bonded to the 2,4-dinitrophenyl group, followed by the formation of a three-centered transition state. An overall mechanism for these reactions is presented and discussed.

La cinétique des réactions entre le [IrCl(CO)(PPh_3)$_2$]-*trans* et une série de disulfures de dinitro-2,4 phényle et de phényle substitué en position-4 $YC_6H_4SSC_6H_3(NO_2)_2$ (Y = Br, F, H, CH_3 ou CH_3O) a été étudiée dans le toluène entre 70 et 90°. On a montré que ces réactions suivent une cinétique du second ordre où l'équation de vitesse peut s'exprimer ainsi: vitesse = k_2[IrCl(CO)(PPh_3)$_2$][$YC_6H_4SSC_6H_3(NO_2)_2$]. De même, on a montré que la vitesse des réactions était indepéndante de la nature du substituant Y en position para. Ce fait combiné avec les paramètres d'activation observés, $\Delta H^{\ddagger} \sim 17$ kcal mol^{-1} et $\Delta S^{\ddagger} \sim -19$ cal mol^{-1} deg^{-1}, nous ont amenés à considérer que l'étape initiale de ces réactions implique une attaque nucléophile par l'atome d'iridium sur l'atome de soufre relié au groupe dinitro-2,4 phényle, suivie par la formation d'un état de transition à trois centres. On présente et on discute le mécanisme global de ces réactions. [Traduit par le journal]

In recent years the detailed mechanistic aspects of oxidative-addition reactions have been the subject of several reports in the literature (1–9). Particular attention has been focused on the reactions of *trans*-[IrX(CO)(PPh_3)$_2$] (X = Cl, Br, or I) which are capable of undergoing oxidative-addition with a wide variety of addenda (10–15). The results of several investigations related to the reactivity of arenethiols towards low valent transition metal complexes have been reported from this laboratory (3, 16–18) and recently we have extended this work to include a series of 2,4-dinitrodiphenyl-4-substituted-phenyl disulfides (19). These particular organic disulfides were shown to react with *trans*-[IrX(CO)(PPh_3)$_2$] according to eq. 1.

$$[1]\quad 2[IrX(CO)(PPh_3)_2] + 2ArSSAr' \rightarrow [IrX(SAr)(SAr')(CO)(PPh_3)]_2 + 2PPh_3$$

where X = Cl, Br, or I, Ar = a para-substituted benzene ring, and Ar′ = 2,4-dinitrophenyl. We now wish to report the results of a kinetic study of reaction 1 when X = Cl.

Results and Discussion

The preparation and characterization of the products of reaction 1 have been previously reported (19). Representative kinetic data for the reactions studied are shown in Table 1. Kinetic data at various temperatures are summarized in Table 2. These data indicate that the rates of reaction are dependent on the concentration of the substrate, [IrCl(CO)(PPh_3)$_2$], and the concentration of the reacting disulfide. Plots of the pseudo first-order rate constant, k_{obs}, *vs.* [$YC_6H_4SSC_6H_3(NO_2)_2$] were linear with zero intercepts. These plots are shown in Fig 1. and indicate that reaction 1 obeys a simple second-order rate law, equation 2.

$$[2]\quad \frac{-d[IrCl(CO)(PPh_3)_2]}{dt} = k_2[IrCl(CO)(PPh_3)_2][YC_6H_4SSC_6H_3(NO_2)_2]$$

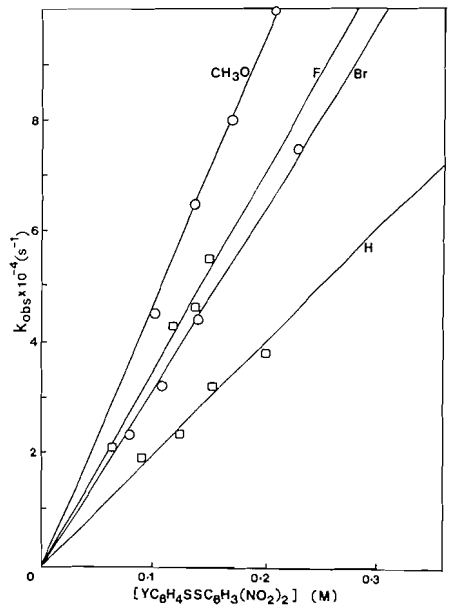

FIG. 1. Plot of k_{obs} *vs.* $[YC_6H_4SSC_6H_3(NO_2)_2]$.

This rate law is similar to that commonly found for oxidative-addition reactions of *trans*-$[IrCl(CO)(PPh_3)_2]$ (13).

Examination of the second-order rate constants given in Table 2 indicates that the rate of reaction 1 is not significantly sensitive to a change in the nature of the para substituent, Y, located on one of the phenyl rings of the incoming disulfide. This behavior is somewhat different from the substituent effect noted for other incoming reactants such as $YC_6H_4CH_2Cl$ (1) and YC_6H_4SH (3) where Y = an electron withdrawing or an electron releasing substituent in the para position.

Assuming a second-order rate, the rates of reaction were also determined at three other temperatures and the activation parameters for reaction 1 were calculated using the Eyring equation, [3]. These parameters are presented in Table 3.

$$[3] \qquad k_2 = \frac{kT}{h} \exp\left(\frac{-\Delta G^{\ddagger}}{RT}\right)$$

It may be noted that the enthalpies and entropies of activation for reaction 1 are insensitive to the nature of the incoming disulfide. Also, $\Delta H^{\ddagger}$ is ~ 8 kcal greater than the corresponding $\Delta H^{\ddagger}$ for the reaction of *trans*-$[IrCl(CO)(PPh_3)_2]$ with

TABLE 3. Activation parameters*

Y†	$\Delta H^{\ddagger}$ (kcal mol^{-1})	$\Delta S^{\ddagger}$ (cal mol^{-1} deg^{-1})

†Y = para substituent in $YC_6H_4SSC_6H_3(NO_2)_2$.

YC_6H_4SH (3) which is a reflection of the greater difficulty to cleave a sulfur–sulfur bond than a sulfur–hydrogen bond by this particular iridium(I) substrate. The enthalpies of activation for reaction 1 also strongly suggest that dissociation of the sulfur–sulfur bond does not occur as a distinguishable step during the course of the reaction. Although the values of $\Delta S^{\ddagger}$ for reaction 1 are somewhat less negative than those reported for the addition of an arenethiol to this iridium(I) substrate (3), they are not inconsistent with the presence of a three-centered transition state.

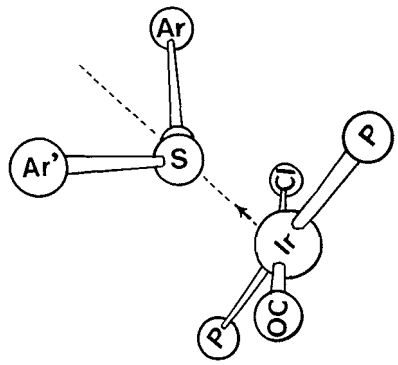
A mechanism which is consistent with the aforementioned kinetic data may now be proposed, *i.e.*,

$$[4]\quad \textit{trans}\text{-}[IrCl(CO)(PPh_3)_2] + ArSSAr' \xrightarrow[\text{slow}]{k_2} [IrCl(SAr)(SAr')(CO)(PPh_3)_2]$$

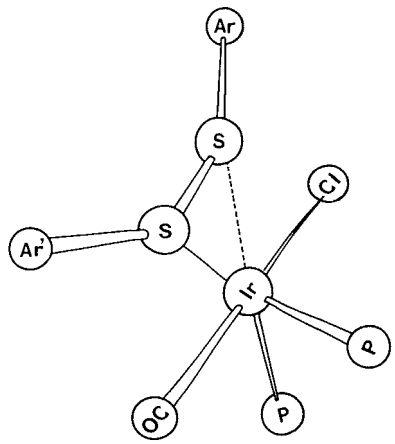
$$[5]\quad [IrCl(SAr)(SAr')(CO)(PPh_3)_2] \xrightarrow{\text{fast}} [IrCl(SAr)(SAr')(CO)(PPh_3)] + PPh_3$$

$$[6]\quad [IrCl(SAr)(SAr')(CO)(PPh_3)] \xrightarrow{\text{fast}} \tfrac{1}{2}\,[IrCl(SAr)(SAr')(CO)(PPh_3)]_2$$

In the rate determining step, [4], the initial process leading to the activated complex may be regarded as a nucleophilic attack by the iridium atom at one of the sulfur atoms of the disulfide. Since the rate of reaction is independent of the nature of the substituent, Y, the iridium presumably attacks at the sulfur atom which is bonded to the 2,4-dinitrophenyl group. In the ground state this particular sulfur atom would be expected to be slightly positive relative to the other sulfur atom in the disulfide by virtue of the two NO_2 substituents. Consequently, the initial process leading to the activated complex may also be regarded as an electrophilic attack by this positive sulfur atom at the iridium atom, since iridium formally loses two electrons during the course of the reaction. If the preferred stereochemistry about the sulfur–sulfur bond is taken into account (20) the iridium complex acting as a nucleophile must initially attack the sulfur–sulfur bond from the "back-side" as shown below.



This will give rise to a three-centered activated complex in which there is formation of two iridium sulfur bonds with concomitant weakening of the sulfur–sulfur bond. This activated complex is shown below and is consistent with



the negative entropies of activation obtained for reaction 1. It is also similar to that previously proposed for other oxidative addition reactions of *trans*-$[IrCl(CO)(PPh_3)_2]$ (1, 3, 4). However, the absence of any substituent effect also suggests that the amount of bond formation between iridium and the SC_6H_4Y portion of the incoming disulfide is significantly less than that

between iridium and the $SC_6H_3(NO_2)_2$ portion of the disulfide in the transition state. This could partially account for the slight increase in entropy in going from an arenethiol to a 2,4-dinitrophenyl-4-substituted-phenyl disulfide as the incoming addendum.

It is interesting to note that the rate determining step in the proposed mechanism ([4]–[6]) is formally an oxidative-addition even though the overall reaction may be regarded as an oxidative-elimination reaction. The inherent tendency of a thiolato ligand to act as a bridging group appears to be the "driving force" leading to the observed dimeric product. The initial oxidative addition product rapidly loses a molecule of triphenylphosphine to form a coordinatively unsaturated five-coordinated species which then rapidly dimerizes to the observed product. At present it is not possible to *unambiguously* assign the stereochemistry associated with those species intervening between the substrate, *trans*-[IrCl(CO)(PPh_3)$_2$], and the product, [IrCl(SAr)(SAr′)(CO)(PPh_3)]$_2$.

Since triphenylphosphine is liberated in reaction 1, the dependence of the rate of reaction on the concentration of added triphenylphosphine was also examined. Kinetic data pertaining to this are given in Table 4 and a plot of k_{obs} *vs.* the concentration of added triphenylphosphine is shown in Fig. 2. These data clearly show that the rate of reaction *increases* with increasing concentration of triphenylphosphine. Consequently, any mechanism which invokes a dissociative step involving triphenylphosphine may be discounted for reaction 1. In addition, the product isolated from the reaction in the presence of added triphenylphosphine is not the same as that isolated from the reaction in the absence of added triphenylphosphine. These particular products exhibit a single ν_{CO} band at about 2055 cm^{-1} (Nujol) which is ~ 10 cm^{-1} lower than that observed for the corresponding [IrCl(SAr)(SAr′)(CO)(PPh_3)]$_2$ complexes. The precise nature of these complexes has not yet been elucidated.

It is noteworthy that the kinetic data presented herein indicate that the iridium(I) substrate acting as a nucleophile initially attacks the sulfur atom bonded to the 2,4-dinitrophenyl group. As a consequence of this interpretation, the previously proposed (3) initial step leading to the activated complex in the reaction between *trans*-IrX(CO)(PPh_3)$_2$ (X = Cl, Br, or I) and HSC_6H_4Y must now be amended to one in which the iridium(I) substrate attacks the *hydrogen atom* of the arenethiol (or an electrophilic attack by hydrogen at iridium). This is not unreasonable in view of the fact that a number of transition metal complexes are capable of being protonated to form well defined hydride derivatives (21).

Experimental

Materials Used and Isolation of Reaction Products

These have been described elsewhere (19).

Kinetic Measurements

The kinetics of reaction 1 were followed spectrophotometrically with a Beckman IR-12 double beam recording spectrophotometer by monitoring the disappearance of the carbonyl peak at 1959 cm^{-1} in the infrared spectrum of the iridium(I) substrate. The kinetic data were obtained under pseudo first-order kinetic conditions using at least a 30-fold excess of the organic disulfide. The initial concentration of the iridium(I) complex was 2.5×10^{-3} *M* while the concentration of disulfide was varied between 0.06–0.2 *M*. Although the product of the reaction between *trans*-$[IrCl(CO)(PPh_3)_2]$ and 4-$O_2NC_6H_4SSC_6H_3(NO_2)_2$ has been isolated and characterized (19), we were not able to measure the rate of this reaction because of the poor solubility of this particular disulfide in toluene.

All kinetic runs were carried out in toluene which had been dried over sodium, degassed, and then saturated with nitrogen. Individual solutions of the iridium(I) complex and the appropriate disulfide used in a given kinetic run were thermostatted for approximately 1 h prior to mixing. The solution containing the disulfide was added to the solution containing the iridium(I) substrate by means of a hypodermic syringe in order to ensure rapid and complete mixing. Aliquots (*ca.*, 0.5 ml) were then withdrawn at fixed intervals of time and the transmittance at 1959 cm^{-1} recorded. Pseudo first-order rate constants were calculated from the slopes of plots of ln A_t *vs.* time where A_t = the absorbance at time, *t*. These plots were found to be linear for at least 60% reaction and the k_{obs} values were reproducible to $\pm 10\%$ or better. Second-order rate constants were calculated from the slopes of plots of k_{obs} *vs.* the concentration of incoming disulfide.

The continued financial support to one of us (C.V.S.) in the form of an operating grant from the National Research Council of Canada is gratefully acknowledged.

Kinetics of Exchange of Dimethylsulfoxide between Hexakis-(dimethylsulfoxide)chromium(III) and Solvent: Pressure Effect and Mechanism

DEBRA LYNN CARLE AND THOMAS WILSON SWADDLE
Department of Chemistry, The University of Calgary, Calgary, Alberta T2N 1N4

Received June 22, 1973

For the exchange of *all six* dimethylsulfoxide (DMSO) ligands in $Cr(DMSO)_6^{3+}$ with perdeuterated DMSO solvent, the first-order rate constant (75°) = 5.5×10^{-5} s^{-1}, while $\Delta H^* = 23.1$ kcal mol^{-1}, $\Delta S^* = -11.8$ cal deg^{-1} mol^{-1}, and $\Delta V^* = -11.3$ cm^3 mol^{-1}. These and other data are indicative of an associative interchange mechanism for substitution in Cr(III) DMSO complexes in DMSO.

Pour l'échange *des six* groupes diméthylsulfoxyde (DMSO) agissant comme ligands dans $Cr(DMSO)_6^{3+}$ par du DMSO prédeutéré agissant comme solvant, la constante de vitesse du premier ordre à 75° est de 5.5×10^{-5} s^{-1} alors que le $\Delta H^* = 23.1$ kcal/mol, le $\Delta S^* = -11.8$ cal deg^{-1} mol^{-1} et le $\Delta V^* = -11.3$ cm^3 mol^{-1}. Ces données et d'autres auraient tendance à montrer que le mécanisme de la substitution du DMSO dans les complexes Cr(III) DMSO est du type d'interchangement associatif.
[Traduit par le journal]

Can. J. Chem. **51**, 3795 (1973)

Introduction

We have recently presented data concerning the effects of pressure on the rates of substitution reactions of some simple cationic chromium(III) (1–3), rhodium(III) (2), and cobalt(III) (4) complexes in aqueous solution, and have argued that the results imply a dissociative interchange (I_d) mechanism in the Co(III) series but an associative interchange (I_a) mechanism for the Rh(III) and Cr(III) reactions. In particular, the effect of pressure on the rate of exchange of $H_2{}^{18}O$ between $Cr(H_2O)_6^{3+}$ and solvent water is characterized by a volume of activation ΔV^* of -9.3 cm^3 mol^{-1}, which, because this reaction involves no development or dissipation of ionic charges and is "symmetrical", constitutes strong evidence for extensive bond-making by the incoming H_2O on going to the transition state.

This leads to the question of whether the proposed associative mechanism for the solvent exchange is peculiar to water as solvent, or whether the mechanism is characteristic of the Cr(III) center and can operate in other solvents having moderate donor properties. The DMSO/$Cr(DMSO)_6^{3+}$ exchange reaction (DMSO = dimethylsulfoxide) provides an appropriate system to examine in the context of this question, since the reaction is conveniently followed by proton magnetic resonance (p.m.r.) techniques using DMSO-d_6 as solvent and $Cr(DMSO\text{-}h_6)_6^{3+}$ as solute (5–7), and also because the molar volume of the DMSO (71.0 cm^3 mol^{-1} for the pure liquid at 20°) is large compared with that of water, so that ΔV^* should be even more sensitive as a mechanistic criterion for solvent exchange in DMSO as compared to water. Furthermore, DMSO is attractive because it differs substantially from water in its solvent properties, being non-protonic and having a dielectric constant of 46.6 at 25° as compared with 78.3 for water.

Experimental

Materials

Dimethylsulfoxide-d_6 (99.5% d_6; Stohler Isotope Co.) was dried over a 4A molecular sieve (Guild Corp.) before use. *P*-Dimethoxybenzene (Matheson, Coleman and Bell) and *p*-dichlorobenzene (Eastman Organic Chemicals) were recrystallized from absolute ethanol before use and dried under vacuum.

Preparation of Hexakis(dimethylsulfoxide)chromium(III) Perchlorate

Chromium(III) nitrate nonahydrate (Fisher Scientific; 4.0 g) in 1.5 ml water was added to 6.0 ml DMSO (Fisher Scientific) and heated at ~65° on the steambath for 2 h. On cooling, a green solid separated, and this was filtered and redissolved in 10.0 ml DMSO on the steambath. Addition of 50 ml 1.0 *M* aqueous $HClO_4$ (*N.B.* concentrated $HClO_4$ solutions must *not* be added to DMSO—explosion hazard!) precipitated a green solid which was redissolved in DMSO and reprecipitated in the same way. The product was recrystallized from about 4 ml hot DMSO and dried under vacuum (0.8 g).

*Standard was *p*-dimethoxybenzene; in all other cases, standard was *p*-dichlorobenzene.

This compound is potentially explosive, and was therefore prepared only in small batches and kept in the dark.

Kinetics

Solutions of $[Cr(DMSO)_6](ClO_4)_3$ and a p.m.r. reference compound (*p*-dimethoxybenzene or *p*-dichlorobenzene) in DMSO-d_6 were prepared by weight. The progress of the reaction at atmospheric pressure was followed by removing samples at appropriate intervals from the solution contained in a closed light-proof vessel in a thermostat (±0.1°), and freezing them until required; the p.m.r. spectra of the thawed samples were then measured with a Varian A-60 spectrometer at 21°, first in chronological order, then in reverse order, and then at random, so as to average out any variations in the spectrometer response with time. The concentration of the freed DMSO-h_6 in each sample was determined by measuring the area or (equally satisfactorily) the height of the DMSO-h_6 resonance (R_t) relative to that of the ring protons in the aromatic standard substance; the equilibrium value R_∞ was obtained from samples which had been thermostatted for at least eight half-lives of the reaction.

Alternatively, the reaction mixture was thermostatted in a p.m.r. tube, which was removed periodically, chilled to 21°, and replaced in the thermostat after its p.m.r. spectrum had been measured; this procedure was less satisfactory than the above (though more economical) because of the significant time-dependence of the response of the spectrometer on some occasions.

The pressure dependence of the reaction rate was measured by removing samples from a pressurized syringe as described previously (4, 8), except that a Hastelloy-B capillary outlet tube was used instead of a tantalum tube. Because DMSO is relatively high-melting, it was necessary to immerse the assembly in the thermostat (75.0 ± 0.1°) as far as the sample valve stem seating to prevent the solution freezing under pressure.

Results

Plots of $\ln(R_\infty - R_t)$ *vs.* time were linear, within the experimental uncertainty, and the first-order rate coefficients k (for the exchange of *all six* DMSO ligands) and their standard deviations are listed in Table 1; the reproducibility of the k values from one run to another was somewhat poorer than suggested by these standard deviations, which might be increased by about 50% accordingly. Rate coefficients k' for the exchange of *single* DMSO ligands are given by $k/6$, *e.g.*, $k' = 0.9_2 \times 10^{-5}\ s^{-1}$ at 75.0° and 1 bar. The nature of the reference solute and the concentration of the complex perchlorate did not affect the values of k seriously. Values of k obtained using the pressure assembly at low pressures corresponded satisfactorily with those obtained at atmospheric pressure, while the value of k listed for 85° (1 bar) agrees well with that obtained in Langford's laboratory (5–7).

An Eyring plot of the data obtained at atmospheric pressure was linear, and gave an enthalpy of activation $\Delta H^* = 23.1 \pm 0.5$ kcal mol^{-1} and an entropy of activation ΔS^* of -11.8 ± 1.5 cal deg^{-1} mol^{-1} for the exchange of *all six* DMSO ligands (or -15.4 ± 1.5 for the exchange of *one* of the six). A plot of $\ln k$ *vs.* pressure was also linear, within the experimental uncertainty, and the corresponding value of ΔV^* was $-11.3 \pm 1.0\ cm^3\ mol^{-1}$.

Discussion

The values of k listed in Table 1 for 75.0°, 1 bar, and various concentrations of $[Cr(DMSO)_6](ClO_4)_3$ are sufficiently close to the weighted mean of $5.5 \times 10^{-5}\ s^{-1}$ to indicate that $Cr(DMSO)_6^{3+}$–ClO_4^- ion pairing is either insignificant or else does not affect the solvent exchange rate appreciably. Ion pairing may indeed be negligible in this system in the concentration range of interest, since Palmer and Watts

(9) found no evidence for ion pairing between $Cr(en)_2Cl_2^+$ and perchlorate in DMSO; it is true that we are concerned here with a tripositive rather than a monopositive cation, but Bott *et al.* (10) have pointed out that the magnitude of the charge on large complex cations is not necessarily a major factor governing their tendency to form ion pairs.

The value of ΔV^* (-11 cm^3 mol^{-1}) indicates a substantial contraction on going from the ground state to the transition state, and, since electrostrictive effects are not involved and the entering and leaving groups are identical, this implies that the mechanism is associative (1–4). This ΔV^* value is somewhat more negative than that (-9.3 cm^3 mol^{-1}) recorded for the $Cr(H_2O)_6^{3+}$–$H_2{}^{18}O$ exchange reaction (1), which is to be expected if the mechanisms are similar because of the larger molecular size of DMSO relative to water—this factor being partially offset by the hydrogen-bonded open structure believed to be present in the solvation sheath in water (2) but necessarily absent in the non-protonic solvent DMSO.

Langford *et al.* (6) have shown that the rate of DMSO–$Cr(DMSO)_6^{3+}$ exchange in DMSO–nitromethane mixtures is virtually independent of the DMSO content of the solvent down to the point where DMSO occupies not more than 0.4 mol fraction of the sites of the solvation sheath, although further increases in the occupancy of the solvation sheath by nitromethane lead to reduced DMSO exchange rates. This is interpreted (6) in terms of the presence of a uniquely firmly bound DMSO molecule in the solvation sheath, this singular DMSO being responsible for the exchange process by an associative mechanism.

This hypothesis is clearly consistent with our mechanistic conclusions based on the volume of activation, and indeed consideration of the non-planar geometry and relatively great bulk of the DMSO ligands of the first coordination sphere leads us to the conclusion that the close approach of the solvating DMSO molecules is impossible except in one specific location. Let us imagine the $Cr(DMSO)_6^{3+}$ ion, arranged so that one C_3 axis of the CrO_6 octahedron is vertical, and suppose that a solvating DMSO molecule moves towards the Cr center down this axis (the faces of the octahedron being the obvious places for closest approach). In order to permit the closest approach of this molecule, the three bulky, O-bonded DMSO ligands associated with this uppermost face must rotate away from the incoming molecule, so directing their methyl groups downward; this in turn will force the other three DMSO ligands to reorient in the same direction (giving an appearance reminiscent of the leaves of a palm-tree). Thus, the side and bottom faces of the octahedron become blocked by the methyl groups, so that the close approach of the solvent molecule down the vertical axis has prevented close approach of any of the other solvating DMSO molecules.

The high degree of ordering inherent in such a process, especially as it proceeds onwards to effect ligand substitution, provides an explanation for the surprisingly strongly negative ΔS^* value for DMSO exchange at the Cr(III) center (-15 cal deg^{-1} mol^{-1} for the exchange of one ligand, *cf.* 0 for water exchange (1)), since the rotational freedom of the DMSO ligands will be severely reduced as the reaction proceeds to the seven-coordinate transition state. This very low entropy of activation is responsible for the slowness of DMSO exchange relative to water exchange (by a factor of 30 at 75° or 14 at 25°, on the basis of the activation parameters (1)), despite the fact that ΔH^* is only 23 kcal mol^{-1} for the DMSO system as compared with 26 for water. The DMSO exchange reaction is about 2×10^3 times slower than the exchange between hexaamminechromium(III) ion and liquid ammonia solvent at 25° (11, 12), but the comparison is not very illuminating since the latter reaction shows a marked dependence of rate upon ammonium and perchlorate ion concentrations, and evidently proceeds *via* the ion pair $\{Cr(NH_3)_5NH_2^{2+}, ClO_4^-\}$.

Lo (13) and Watts (14) have found that the anation of $Cr(DMSO)_6^{3+}$ by various anions X^- (X = Cl, NCS, and N_3) proceeds by an interchange mechanism involving an ion pair:

$$[1]\quad Cr(DMSO)_6^{3+} + X^- \underset{\text{fast}}{\overset{K}{\rightleftharpoons}} \{Cr(DMSO)_6^{3+}, X^-\}$$

$$[2]\quad \{Cr(DMSO)_6^{3+}, X^-\} \underset{\text{slow}}{\overset{k_i}{\longrightarrow}} Cr(DMSO)_5X^{2+} + DMSO$$

The values of k_i at 75° for $X^- = Cl^-$, NCS^-, and N_3^- are about 2×10^{-5}, 2×10^{-4}, and $(5 \text{ to } 6) \times 10^{-3}$ s^{-1} respectively, as compared with our value $k = 5.5 \times 10^{-5}$ s^{-1} for the exchange of all six DMSO ligands with the solvent. Thus, it seems that NCS^- can enter the first

coordination sphere of Cr(III) about 4 times faster, and azide ion some 100 times faster, than the spontaneous exchange of DMSO. This is incompatible with a dissociative interchange (I_d) mechanism, which would require that Cr–DMSO bond-breaking be rate determining in the formation of $Cr(DMSO)_5X^{2+}$. Thus, we have once again an associative interchange (I_a) mechanism, with the various X^- displaying their relative nucleophilic powers towards Cr(III), $Cl^- < NCS^- \ll N_3^-$; this marked dependence of k_i on the nature of X^- is, in any event, contrary to experience with systems which evidently do react by an I_d process (15). The foregoing assumes that the rate of solvent exchange in the ion pair $\{Cr(DMSO)_6^{3+}, X^-\}$ is the same as in the free ion $Cr(DMSO)_6^{3+}$, but this is in accordance with the observations of Duffy and Earley (16) and Monacelli and Viel (17) for aquo-exchange involving ion-paired complex cations in water.

We thank Dr. C. H. Langford for suggesting this topic and for much helpful discussion and advice, Drs. D. W. Watts and D. Lo Siaw-Teck for discussions and exchange of data, and the President's General Research Fund of the University of Calgary for financial assistance.

The *tert*-Butyldimethylsilyl Group as a Protecting Group in Deoxynucleosides

KELVIN K. OGILVIE
Department of Chemistry, University of Manitoba, Winnipeg, Manitoba R3T 2N2

Received June 12, 1973

tert-Butyldimethylsilyl chloride reacts selectively with hydroxyl groups in nucleosides and preferentially with the 5′-hydroxyl of deoxynucleosides. The *tert*-butyldimethylsilyl group can be removed under conditions which do not affect other commonly used acid or base labile protecting groups, yet it is stable to phosphorylation conditions. This allows for the synthesis of a variety of protected deoxynucleosides in good yields and introduces a versatile new protecting group to the nucleoside and nucleotide field.

Le chlorure de *tert*-butyldiméthylsilyle réagit sélectivement avec les groupes hydroxyles des nucléosides et préférentiellement avec les hydroxyl-5′ des désoxynucléosides. Tout en étant stable dans les conditions de phosphorylation, le groupe *tert*-butyldiméthylsilyle peut être enlevé dans des conditions qui n'affectent pas d'autres groupes protecteurs utilisés couramment et qui sont labiles en milieux acide ou basique. Ceci permet d'effectuer, avec de bons rendements, la synthèse d'un grande nombre de déoxynucléosides protégés et d'introduire un nouveau groupement protecteur versatile au domaine des nucléosides et des nucléotides. [Traduit par le journal]

Can. J. Chem. **51**, 3799 (1973)

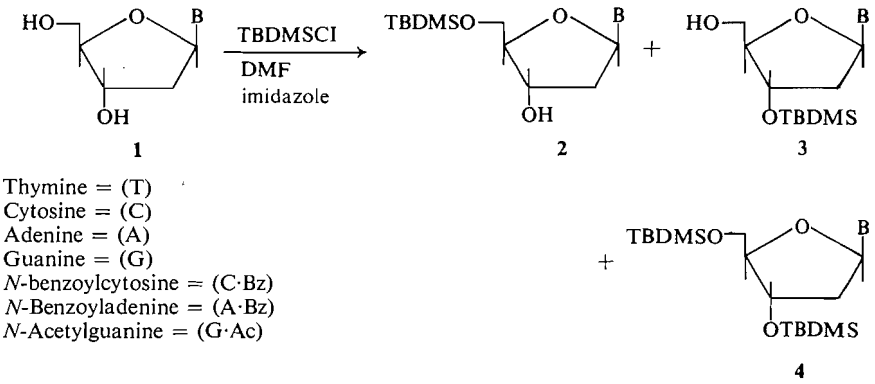
During our investigations into the synthesis and indentification of nucleosides and nucleotides (1, 2) we have been seeking versatile hydroxyl-protecting groups. We describe in this report the use of the *tert*-butyldimethylsilyl (TBDMS) group for protecting hydroxyl functions in deoxynucleosides (3) and the subsequent synthesis of a number of nucleoside derivatives which have not previously been easy to prepare.

tert-Butyldimethylsilyl chloride (TBDMSCL) is prepared by the reaction of *tert*-butyllithium with dichlorodimethylsilane (4). Corey and Venkateswarlu have described the use of TBDMSCL (in DMF at 35 °C in the presence of imidazole) for protecting the hydroxyl groups of a number of alcohols of interest in the synthesis of prostaglandins (5). We have applied these same conditions to the deoxynucleosides and find that: (*a*) TBDMSCL reacts preferentially with the 5′-hydroxyl group; (*b*) the reaction is rapid even at room temperature and the extent of the reaction and distribution of products depends on the amount of imidazole present; (*c*) even in the presence of excess TBDMSCL reaction occurs preferentially with hydroxyl groups and not with amino groups; (*d*) the TBDMS group is stable to phosphorylation conditions; and (*e*) the TBDMS group can be removed with $(n\text{-butyl})_4NF$ in tetrahydrofuran (THF) as described by Corey and Venkateswarlu (5) without affecting other acid or base labile protecting groups on the nucleoside. This has facilitated the preparation of a number of protected nucleosides.

The preparation of the silyl derivatives (Scheme 1) simply requires dissolving the nucleoside, TBDMSCL and imidazole in *N*,*N*-dimethylformamide (DMF). Our initial experiments were carried out at 37 °C. However, we find the reactions are over very quickly (within 30 min) at room temperature with no significant change in yields (Table 1). Further there appears to be little change in product composition for reactions times of 1–24 h.

The amount of imidazole present is important in terms of total yield and also ratio of products (Table 1). We find that for thymidine and *N*-protected nucleosides a ratio of nucleoside: TBDMSCL:imidazole near 1:1.1:2.2 gives the highest yields of 5′-isomers **2**. Reducing the amount of imidazole decreases the total yield of products and increases the ratio of **3**:**2**. Imidazole or other catalyst is essential to the reaction since the absence of imidazole in DMF gives ~5% total yield. However if pyridine is used as solvent in place of DMF, the pyridine also effectively replaces imidazole as catalyst (Table 1). For nucleosides possessing a free amino group the above ratio of reagents generally changes to 1:2.2:4:4 for optimum yields of **2**. However, even under conditions where we obtain di-*O*-silylated nucleosides in



SCHEME 1

*Actual experimental yields. Products isolated by t.l.c.
†In both cases where polysilyated products were isolated the mass spectrum indicated three silyl groups on the nucleoside.

90% yields we seldom isolated trisilylated nucleosides (*N*-substitution). This preference of TBDMSCL for reaction with the hydroxyl groups of nucleosides adds considerable versatility to nucleoside protecting groups and allows easy manipulation of a variety of protecting groups.

We have generally found that nucleosides substituted on the 3′-hydroxyl group move more rapidly on t.l.c. than the 5′-isomers. In our reactions to produce the 5′-TBDMS derivatives we expected, because of the bulk of the silylating agent, that the 5′-isomer would predominate. In six out of the seven cases where we observed two monosilylated products from the reaction of TBDMSCL with a nucleoside (Scheme 1) the slower moving (5′) isomer predominated over the faster moving (3′) isomer (see Tables 1, 2). The exception was deoxycytidine where **3***b* moved slightly slower on t.l.c. than **2***b* in the 8:2 solvent (see Experimental).

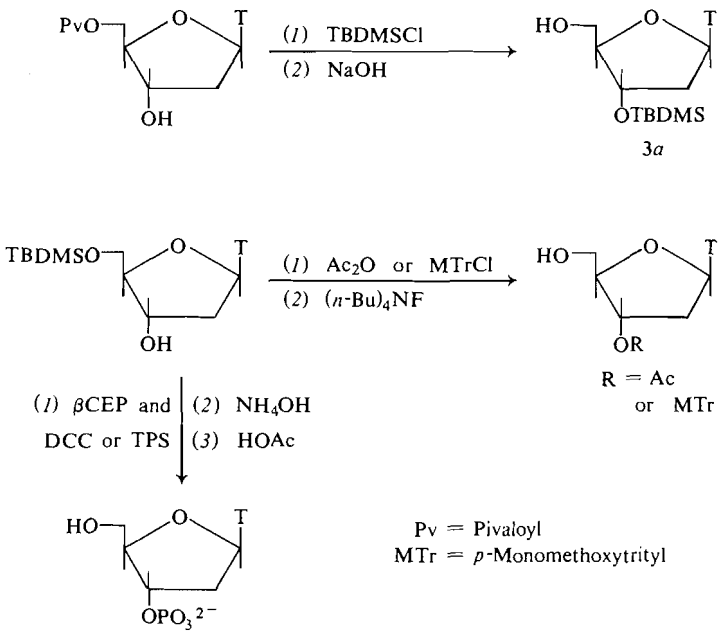
‡8:2 refers to a solvent composed of chloroform:ethanol (8:2, v/v).



SCHEME 2

To confirm the identity of the isomers **2***b* and **3***b*, we prepared **3***b* by an alternate route. $O^{5'}$-Acetyl-*N*-benzoyldeoxycytidine was treated with TBDMSCL followed by removal of the acetyl group with NH_4OH and the benzoyl group with hydrazine hydrate. This produced **3***b* identical to the slower moving product from the reaction of **1***b* with TBDMSCL.

To confirm the identity of the isomers **2***a* and **3***a* of thymidine we treated $O^{5'}$-pivaloylthymidine with TBDMSCL and hydrolyzed the intermediate with 0.5 *N* NaOH. The product was isolated by t.l.c. and found to be identical to the faster moving monosilylated thymidine which is **3***a*. We have detected no isomerization of **2***a* and **3***a* under these conditions. Furthermore **2***a* was reacted in separate experiments with acetic anhydride and monomethoxytrityl chloride (Scheme 2). Removal of the silyl group with $(n\text{-Bu})_4NF$ in THF produced the known compounds $O^{3'}$-acetylthymidine (6) and $O^{3'}$-monomethoxytritylthymidine (1*b*) in 95 and 94% isolated yields respectively.

Further proof of the identities of **2***a* and **3***a* was obtained by phosphorylation and enzymatic analysis of the products. Compound **2***a* was phosphorylated using β-cyanoethylphosphate (βCEP) and either *N*,*N'*-dicyclohexylcarbodiimide (DCC) or triisopropylbenzenesulfonyl chloride (TPS) as condensing agents. Following condensation the protecting groups were removed with 9 *M* NH_4OH at 60 °C for 1 h (βCEP) and 80% acetic acid on a steam bath for 15 min (TBDMS). The yields of thymidine-3′ phosphate (Tp) from the two reactions were 100 and 98% respectively. The product Tp was unaffected by 5′-nucleotidase but was converted to thymidine with alkaline phosphatase. Compound **3***a* was similarly converted to thymidine-5′ phosphate (p.T.) which was hydrolized to thymidine with 5′-nucleotidase. These results not only confirm the identity of **2***a* and **3***a* but demonstrate the stability of the TBDMS group to phosphorylating conditions.

A major advantage of the TBDMS group is its compatibility with other commonly used protecting groups. This has greatly facilitated the preparation of nucleoside derivatives which are otherwise more difficult to obtain. For example the silyl group can be removed (see Table 3) with $(n\text{-Bu})_4NF$ in THF at room temperature for 30 min (5). These conditions do not affect acid labile groups (*e.g.* trityl) base labile protecting groups in general (*O*- or *N*-derivatives) and the β-benzoylpropionyl group in particular. On the other hand the hydrazine hydrate solution which removes *N*-acyl groups and the β-benzoylpropionyl group (7) has no

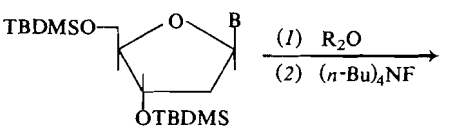
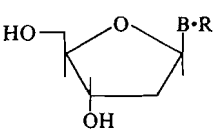
affect on the TBDMS group. Thus treatment of **4***b* and **4***c* with benzoic anhydride and **4***d* with acetic anhydride followed by reaction with $(n\text{-Bu})_4NF$ leads to high yields of *N*-benzoyldeoxycytidine (**5***e*), *N*-benzoyldeoxyadenosine (**5***f*), and *N*-acetyldeoxyguanosine (**5***g*).



4*b–d* R = Benzoyl or Acetyl



5

e; B = C; R = Bz
f; B = A; R = Bz
g; B = G; R = Ac

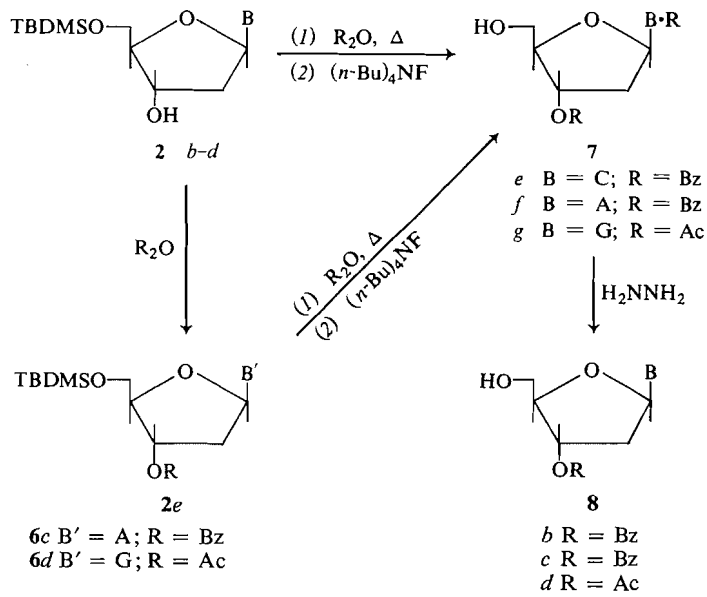
A very useful set of derivatives can easily be obtained as outlined in Scheme 3. Treatment of **2***b* with benzoyl chloride or by heating with benzoic anhydride followed by removal of the silyl group gives **7***e* in 80 and 82% yields respectively. **7***f* and *g* were obtained in a similar fashion in 93 and 86% respectively. We have found that **2***b* reacts with benzoic anhydride in pyridine at room temperature to produce 5′-TBDMS-*N*-benzoyldeoxycytidine (**2***c*) in good yield. This contrasts with **2***c* and *d* which react with benzoic anhydride and acetic anhydride respectively to give preferential *O*-acylation (**6***c* and *d*). The use of excess reagent and gentle heating causes *N*-acylation in these cases as well. Treatment of compounds **7** with hydrazine hydrate solution produces the 3′-acylated derivatives **8** in 90% yields.

Derivatives such as **7** are thus available from the starting nucleosides in two–three steps, two of the steps being ½ h reactions and overall yields being in the 50% range. Existing routes to these compounds usually require more and longer steps and lower overall yields. For example an existing route to **7***e* involves (8) tritylating deoxycytidine (62% yield) followed by benzoylation (71%) and removal of the trityl group (42%) to produce **7***e* in 18.5% overall yield. The acid hydrolsysis of the trityl group also causes hydrolysis of the *N*-glycoside bond in *N*-acylated nucleosides, a problem of particular importance with deoxyadenosine derivatives (9).

One of our goals in the nucleotide area is the development of methods which allow for the rapid identification of isomeric nucleoside and nucleotide derivatives even in very small amounts or from reaction mixtures. To this end we have been employing mass spectrometry (2). We have previously observed different fragmentation patterns from acyl groups of isomeric substituted nucleosides. We had hoped that the TBDMS group would increase the volatility of nucleoside derivatives and give clearly discernable fragmentation patterns from 3′- and 5′-isomeric derivatives. Most importantly, in addition to its use as an identification handle, the TBDMS group is a chemically useful protecting group. Table 4 shows some diagnostically important fragments from the mass spectra of the isomeric compounds **2** and **3**. Clearly fragmentation is significantly different between isomers. The ratio of peaks varies with temperature and with instrument conditions. A full analysis of the spectra of these silylated nucleosides will be presented shortly (10).

A possibility existed that the methyl groups on the TBDMS group of 3′- and 5′-isomers might show different resonances in the n.m.r. However, in the isomeric thymidines no useful distinction could be made with **2***a* having singlets δ ($CDCl_3$) of 0.14 ($(CH_3)_2Si$), 0.92 ($(CH_3)_3CSi$), and 1.91 p.p.m. (5-CH_3) and **3***a* showing singlets at 0.094 ($(CH_3)_2Si$), 0.89 ($(CH_3)_3CSi$), and 1.87 p.p.m. (5-CH_3). These differences are very slight and not considered by us to be of immediate practical use.

We have found most of the silylated nucleo-



SCHEME 3

*Spectra recorded on a Finnigan 1015 mass spectrometer.

sides to be crystalline compounds with sharp melting points. In a few cases initial attempts to induce crystallization have failed and the compounds were obtained as dry solids usually without clear melting points. As crystalline solids the silylated derivatives are stable for at least 10 months but we have detected loss of the protecting group on long standing in aqueous or alcohol solution. Gummy samples in which solvent has been incompletely removed also show deterioration on standing.

In conclusion we have found that TBDMSCL reacts selectively with the hydroxyl groups of nucleosides and preferentially with the 5′-hydroxyl group. Because of the compatibility of the TBDMS group with other acid and base labile protecting groups almost complete manipulation of protecting groups is now possible. The TBDMS group is stable to phosphorylation. The use of the TBDMS group is characterizing isomeric nucleosides and its use in synthesizing oligonucleotides in the ribose series will be described shortly.

Experimental

General Procedures

A detailed description of all our general procedures including solvent purification, chromatography techniques and reagents, phosphorylation procedures, enzyme assays, and analytical and instrumental methods and instruments has been given in detail in ref. 1*a* with the

following exceptions. Thin layer chromatography solvent 8:2 is used in this paper as an abbreviation for a solvent composed of chloroform: ethanol (8:2, v/v). Mass spectra were recorded on a Finnigan 1015 mass spectrometer. *tert*-Butyldimethylsilyl chloride, m.p. 121–125 °C, was prepared according to the method of Sommer and Taylor (4); it is also commercially available from Willow Brook Labs Inc. $(n\text{-Bu})_4NF$ solution was prepared by neutralizing $(n\text{-Bu})_4NOH$ with HF in methanol. After removal of the solvent, benzene–acetonitrile was evaporated from the residue several times. The residue was dried over P_2O_5 and made up to volume in THF (0.5 *M*). After treating a nucleoside derivative with the $(n\text{-Bu})_4NF$ reagent, the solution was usually passed through a short column of Monday DSF-5 silica gel previously prepared on a t.l.c. plate. This procedure removed salts and greatly enhanced subsequent t.l.c. separations of products.

Synthesis of Compounds 2, 3, and 4 from 1

In all cases the nucleoside **1** (1 mmol) TBDMSCL and imidazole were added to 1 ml of DMF and the solution stirred at the desired temperature. At the end of the reaction the solution was applied to three t.l.c. plates developed first in ether and then in chloroform–ethanol (8:2). The separated bands were eluted with ethanol which on concentration yielded the products. Results are listed in Tables 1 and 2. Larger scale reactions were also carried out in a direct scale-up of this procedure. Specific changes for certain nucleosides are as follows.

Thymidine. T.l.c. plates were developed only in ether.

Deoxycytidine. T.l.c. plates were developed in THF. The starting nucleoside was deoxycytidine·HCl.

Deoxyguanosine. During the reactions most of the compound **4***d* precipitates and can be collected by filtration prior to chromatography.

N-Benzoyldeoxycytidine. T.l.c. plates developed only in ether.

N-Benzoyldeoxyadenosine. T.l.c. plates developed twice in ether.

$O^{5'}$-Pivaloyl-$O^{3'}$-TBDMS-thymidine

5′-Pivaloylthymidine (163 mg, 0.5 mmol), TBDMSCL (100 mg, 0.67 mmol), and imidazole (85 mg, 1.25 mol) were dissolved in DMF (0.5 ml) and stirred at 37 °C for 16 h. The solution was applied to two t.l.c. plates developed in ether. The single product band was eluted with ether, solvent was removed at reduced pressure and the residue was crystallized from ethanol to yield 200 mg (91%) of $O^{5'}$-pivaloyl-$O^{3'}$-TBDMS thymidine; m.p. 150–151 °C; $R_f^1(Et_2O)$ 0.53; λ_{max} (EtOH) 208 and 266 nm; parent ion in mass spectrum at *m/e* 440.

Anal. Calcd. for $C_{21}H_{32}N_2O_6Si$: C, 57.24; H, 8.23; N, 6.36. Found: C, 57.11; H, 8.16; N, 6.42.

$O^{3'}$-TBDMS-thymidine (3a)

The above product (100 mg) was dissolved in 1 ml of THF and ethanol (1 ml) and 2*N* NaOH (1 ml) were added. The solution was stirred at room temperature for 6 h. The solution was neutralized with Dowex 50 W-X8 (pyridinium form), concentrated to a small volume and applied to a t.l.c. plate which was developed in ether. The product band and a thymidine band (at the origin) were eluted with ether and ethanol respectively. Thymidine was obtained in a 20% yield. The product **3***a* crystallized from ethanol–water, 55 mg (68%), m.p. 83–85 °C (see Table 2 for properties and analysis).

$O^{5'}$-Acetyl-N-benzoyldeoxycytidine, $O^{3'}$-Acetyl-N-benzoyldeoxycytidine, and $O^{3'}$,$O^{5'}$-Diacetyl-N-benzoyldeoxycytidine

Compound **1***e* (331 mg, 1 mmol) was dissolved in pyridine (5 ml) and acetic anhydride (0.1 ml) was added dropwise to the solution. After 1 h an additional 0.05 ml of acetic anhydride was added and the solution was stirred for a further 3 h. Ethanol (10 ml) was added and the solvents were removed at reduced pressure. The residue was applied to five t.l.c. plates which were developed three times in ethyl acetate. Beautiful separation occurred between the four bands which were eluted with ethanol. On concentration of each of the ethanol solutions the products crystallized from solution and were collected as follows.

The fastest moving material on t.l.c. was $O^{3'}$,$O^{5'}$-diacetyl-*N*-benzoyldeoxycytidine (54 mg, 13%): m.p. 193–194 °C; R_f (EtOAc) 0.36; *m/e* 415; λ_{max} (EtOH) 305 and 260 nm.

Anal. Calcd. for $C_{20}H_{21}N_3O_7$: C, 57.83; H, 5.09; N, 10.12. Found: C, 57.65; H, 5.01; N 10.05.

The next slowest product was $O^{3'}$-acetyl-*N*-benzoyldeoxycytidine (30 mg, 8%): m.p. 180–182 °C; R_f (EtOAc) 0.25; *m/e* 373; λ_{max} (EtOH) 305 and 260 nm.

Anal. Calcd. for $C_{18}H_{19}N_3O_6$: C, 57.90; H, 5.13; N, 11.25. Found: C, 57.85; H, 5.10; N, 11.28.

The second slowest product was $O^{5'}$-acetyl-*N*-benzoyldeoxycytidine (160 mg, 43%): m.p. 165–166 °C; R_f (EtOAc) 0.16; *m/e* 373; λ_{max} (EtOH) 305 and 260 nm.

Anal. Calcd. for $C_{18}H_{19}N_3O_6$: C, 57.90; H, 5.13; N, 11.25. Found: C, 57.82; H, 5.06; N, 11.32.

The slowest moving product on t.l.c. was **1***e* of which 83 mg (25%) was recovered.

$O^{3'}$-TBDMS-deoxycytidine (3b)

$O^{5'}$-Acetyl-*N*-benzoyldeoxycytidine (94 mg, 0.25 mmol), TBDMSCL (75 mg, 0.5 mmol), and imidazole (68 mg, 1 mmol) were added to DMF (0.5 ml) and the solution was stirred for 2 h. Thin layer chromatography showed complete conversion of starting material to a new product R_f (EtOAc) 0.65. The produce was separated from other reactants by passing it through a short column of silica gel (3 × 3.5 cm) with ether. The ether was evaporated and the residue was stirred with 50% NH_4OH in ethanol (4 ml) for 8 h. The solvents were removed at reduced pressure and the residue was dissolved in a solution containing pyridine (2.4 ml), acetic acid (0.6 ml), and hydrazine hydrate (0.1 ml). After 15 h the solvents were removed at reduced pressure and the residue was applied to a t.l.c. plate which was developed first in ether and then in 8:2. The product band was eluted with ethanol which on concentration yielded **3***b* (60%), see Table 2.

A second faster moving nucleoside band was obtained from the t.l.c. plate and was identified as $O^{5'}$-acetyl-$O^{3'}$-TBDMS-deoxycytidine: m.p. 120–122 °C (21%); $R_f^{8:2}$ 0.60; λ_{max} (EtOH) 274, 238 sh.

Anal. Calcd. for $C_{18}H_{29}N_5O_4Si$: C, 53.24; H, 7.62; N, 10.96. Found: C, 52.87; H, 7.55; N, 10.82.

Phosphorylations

Compounds **2***a* and **3***a* (50 mg in each experiment) were phosphorylated with β-cyanoethylphosphate using

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

either dicyclohexylcarbodiimide or triisopropylbenzenesulfonyl chloride as condensing agents using established procedures (1, 11, 12). The β-cyanoethyl group was removed using 9 *M* NH_4OH at 60 °C for 1 h. After removal of solvents the residue was heated on a steam bath for 15 min with 2 ml of 80% acetic acid. The solution was then concentrated at reduced pressure and applied to Whatman 3 mm paper developed in solvent A. Yields are described in the text.

Enzyme Studies

The procedures used for the 5′-nucleotidase and alkaline phosphatase have been described (1*a*). For each analysis 10 $O.D._{.267}$ units of nucleoside monophosphate were used and the product isolated by paper chromatography in solvent A (1*a*). The nucleoside monophosphate (Tp) obtained from **2***a* was resistant to 5′-nucleotidase but yielded thymidine when treated with alkaline phosphatase. From **3***a*, the nucleoside monophosphate (pT) gave thymidine when treated with either 5′-nucleotidase or alkaline phosphatase.

General Procedure for the Synthesis of **5***e–g*

Compound **4** (1 mmol) was dissolved in 5 ml of pyridine and an excess (5 mmol) of the anhydride (benzoic for **4***b* and **4***c* and acetic for **4***d*) was added. The solution was then stirred at room temperature for 24 h for **4***b*, heated on the steam bath for 3 h for **4***c*, and stirred at room temperature for 20 h followed by heating on a steam bath for 1 h for **4***d*. Solvents were removed at reduced pressure and by repeated evaporation of ethanol. $(n\text{-Bu})_4NF$ (2 ml) in THF was added and the solution stirred at room temperature for 30 min. The THF was evaporated and the residue dissolved in ethanol and applied to two t.l.c. plates developed in 8:2. The product band was eluted with ethanol and on concentration of the solvent compounds **5***e–g* were obtained in 94, 92, and 86% yields respectively. The products were identified by comparison to authentic samples prepared by the procedures of Khorana and co-workers (9). The compounds prepared by our procedure were identical (m.p., u.v., chromatography, and mass spectrometry) to those prepared by the Khorana procedure.

$O^{5'}$-TBDMS-$O^{3'}$,N-dibenzoyldeoxycytidine

Procedure (a)

Compound **2***b* (250 mg, 0.73 mmol) was dissolved in 5 ml of pyridine and 1 ml of benzoyl chloride was added. The solution was stirred at room temperature for 3 h, ethanol was added, and the solvents were removed at reduced pressure. The residue was dissolved in ethanol and applied to two t.l.c. plates developed in ether. The major product was eluted with ether and on evaporation of the solvent 350 mg (87%) of a white solid, m.p. 166–167 °C, were obtained: λ_{max} (EtOH) 305, 260, and 231 nm; *m/e* 549; R_f (Et_2O) 0.33, R_f (EtOAc) 0.41.

Anal. Calcd. for $C_{29}H_{35}N_3O_6Si$: C, 63.37; H, 6.41; N, 7.64. Found: C, 63.25; H, 6.40; N, 7.72.

Procedure (b)

Compound **2***b* (341 mg, 1 mmol) and benzoic anhydride (1.35 g, 6 mmol) were dissolved in pyridine (10 ml) and heated on a steam bath for 3 h. The solution was poured into ice and water (400 ml) and allowed to stand overnight. The solid was collected by filtration, dissolved in ethanol, and applied to two t.l.c. plates developed with ether. The product was eluted with ether, which on evaporation yielded 500 mg (91%) of 5′-TBDMS-3′,N-dibenzoyldeoxycytidine.

Procedure (c)

Compound **2***e* (100 mg) was heated with 1 mmol of benzoic anhydride in pyridine (2 ml) for 2 h on a steam bath and worked-up as in (*a*) above to give the desired product in 95% yield.

*$O^{5'}$-TBDMS-N-benzoyldeoxycytidine (**2***e*)*

Compound **2***b* (220 mg, 0.64 mmol) and benzoic anhydride (226 mg, 1 mol) were dissolved in pyridine (2 ml) and stirred at room temperature for 3 h. The solution was applied directly to two t.l.c. plates which were developed first in ether and then in ethyl acetate. Three nucleoside bands were eluted and were identified as **2***b* (40 mg, 14%), **2***e* (160 mg, 56%), and 5′-TBDMS-$O^{3'}$-N-dibenzoyldeoxycytidine (50 mg, 14%).

*$O^{3'}$,N-Dibenzoyldeoxycytidine (**7***e*)*

$O^{5'}$-TBDMS-$O^{3'}$,N-dibenzoyldeoxycytidine (550 mg, 1 mmol) was added to $(n\text{-Bu})_4NF$ in THF (4 ml) and the solution was stirred for 30 min. The solution was passed through a short (2 × 3 cm) column of silica gel which was thoroughly washed with THF. The THF solution was concentrated at reduced pressure and applied to four t.l.c. plates which were developed in ether. The product was eluted with ethanol and, on concentration of the solution, crystallized to give **7***e* (400 mg, 92%): m.p. 218–220 °C; λ_{max} (EtOH) 304, 260, and 232 nm; R_f (Et_2O) 0.20, R_f (EtOAc); *m/e* 435 (8).

*$O^{3'}$-Benzoyldeoxycytidine (**8***b*)*

Compound **7***e* (305 mg, 0.7 mmol) was added to a solution containing pyridine (2.4 ml), acetic acid (0.6 ml), and hydrazine hydrate (0.1 ml) and the resulting solution was stirred for 20 h. Ethanol was added and the solvents were concentrated at reduced pressure and applied to two t.l.c. plates developed first in THF and then in ethanol. The product was eluted with ethanol which on complete evaporation left a white solid (**8***b*, 210 mg, 91%): m.p. dec. > 185 °C; λ_{max} EtOH 273 and 232 nm; R_f (THF) 0.07, R_f (8:2) 0.47; and *m/e* 331.

Anal. Calcd. for $C_{16}H_{17}N_3O_5$: C, 58.07; H, 5.16; N, 12.66. Found: C, 58.01; H, 5.02; N, 12.75.

*$O^{5'}$-TBDMS-$O^{3'}$-benzoyldeoxyadenosine (**6***c*)*

Compound **2***c* (300 mg, 0.82 mmol) and benzoic anhydride (560 mg, 2.47 mmol) were added to pyridine (4 ml) and the solution was stirred at room temperature for 2.5 days. The solution was concentrated at reduced pressure and applied to three t.l.c. plates which were developed in ether yielding three nucleoside bands. These were eluted separately with ethanol and on concentration gave **2***c* (104 mg, 35%) and **6***c* (195 mg, 50%); m.p. 75–76 °C; λ_{max} (EtOH) 260 and 231 nm; R_f (Et_2O) 0.20, R_f (8:2) 0.80; *m/e* 469. Compound **6***c* will crystallize on slow evaporation of an ethanol – water solution.

Anal. Calcd. for $C_{23}H_{31}N_5O_4Si$: C, 58.82; H, 6.65; N, 14.91. Found: C, 59.01; H, 6.62; N, 14.83.

From the above reaction 48 mg of a material R_f (Et_2O) 0.25 was obtained and tentatively identified as $O^{5'}$-TBDMS-$O^{3'}$,N-dibenzoyldeoxyadenosine (λ_{max} (EtOH) 280 and 231 nm; *m/e* 516 (M − 57)).

*$O^{3'}$-N-Dibenzoyldeoxyadenosine (**7***f*)*

(*a*) Compound **2***c* (730 mg, 2 mmol) and benzoic anhydride (1.8 g, 8 mmol) were dissolved in pyridine (10 ml)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

and heated on a steam bath for 2 h. The solution was allowed to stir at room temperature for an additional 12 h whereupon ethanol (10 ml) was added and the solvents were removed at reduced pressure. The dry residue was dissolved in 5 ml of the $(n\text{-Bu})_4$NF solution and stirred for 30 min. The solution was filtered through a short (2 × 3 cm) column of silica gel which was washed with THF. The THF solution was concentrated at reduced pressure and applied to four t.l.c. plates which were developed twice in ethyl acetate. The product was eluted with ethanol and on concentration of the ethanol solution, **7***f* crystallized (850 mg, 93%): m.p. 112–114 °C; λ_{max} (EtOH) 280 and 233 nm; R_f (EtOAc) 0.26, R_f (THF) 0.77, R_f (8:2) 0.84; *m/e* 459.

Anal. Calcd. for $C_{24}H_{21}N_5O_5$: C, 62.74; H, 4.61; N, 15.24. Found: C, 62.66; H, 4.70; N, 15.15.

(*b*) The same general procedure as in (*a*) above gave a 92% yield of **7***f* starting from **6***c*.

*$O^{3'}$-Benzoyldeoxyadenosine (**8***c*)*

(*a*) Compound **7***f* (300 mg, 0.65 mmol) was treated with hydrazine in pyridine – acetic acid as above for **8***b*. The product crystallized from the reaction mixture and was collected by filtration, washed with ether, and dried to give **8***c* (220 mg, 96%). Compound **8***c* crystallized from ethanol: m.p. 264–265 °C; λ_{max}(EtOH) 259 and 232 nm; R_f (EtOAc) 0.12, R_f (THF) 0.63, R_f (8:2) 0.72; *m/e* 355.

Anal. Calcd. for $C_{17}H_{17}N_5O_4$: C, 57.46; H, 4.82; N, 19.71. Found: C, 57.40; H, 4.85; N, 19.65.

(*b*) Compound **8***c* was also obtained from **6***c* in 95% yield by treating **6***c* with $(n\text{-Bu})_4$NF solution in the usual manner.

*$O^{5'}$-TBDMS-$O^{3'}$-Acetyldeoxyguanosine (**6***d*)*

Compound **2***d* (285 mg, 0.75 mmol) and acetic anhydride (1 ml) were added to pyridine (5 ml) and stirred at room temperature for 2 days. The solution had become very viscous and a large amount of precipitate had formed which was collected by filtration and washed successively with pyridine, ether, and hexane. This solid material (190 mg) was pure **6***d*: m.p. dec. > 280 °C; λ_{max} (EtOH) 255 nm; R_f (THF) 0.10, R_f (8:2) 0.55; *m/e* 423. The filtrate and washings were applied to a t.l.c. plate developed in 8:2. An additional 87 mg of **6***d* was obtained.

Anal. Calcd. for $C_{18}H_{29}N_5O_5Si$: C, 51.04; H, 6.90; N, 16.53. Found: C, 49.88; H, 6.86; N, 16.45.

From the above t.l.c. plate 20 mg of a material having R_f (8:2) 0.71; λ_{max} (EtOH) 281, 261, and 255 nm; m.p. 188–189 °C; *m/e* 465, and without further characterization was assumed to be $O^{5'}$-TBDMS-$O^{3'}$,*N*-diacetyldeoxyguanosine.

*$O^{3'}$-N-Diacetyldeoxyguanosine (**7***g*)*

(*a*) The above experiment was repeated except that the solution was heated on a steam bath for 2 h, followed by the addition of ethanol (10 ml), and evaporation of the solvents. The residue was treated with 2 ml of the $(n\text{-Bu})_4$NF solution and following work-up as described for **7***f* (except that t.l.c. plates were developed in 8:2), the product **7***g* was obtained in 86% yield: m.p. 130–132 °C; λ_{max} (EtOH) 280, 260, and 255 nm; R_f (THF) 0.10, R_f (8:2) 0.50; and *m/e* 351.

Anal. Calcd. for $C_{14}H_{17}N_5O_6$: C, 47.86; H, 4.88; N, 19.94. Found: C, 47.80; H, 4.82; N, 19.98.

(*b*) **7***g* was obtained in 90% yield by treating **2***g* with acetic anhydride in pyridine at room temperature and work-up as in (*a*) above.

*$O^{3'}$-Acetyldeoxyguanosine (**8***d*)*

(*a*) Compound **6***d* (85 mg, 0.2 mmol) was treated with 1 ml of the $(n\text{-Bu})_4$NF reagent in the usual manner. The product **8***d* was isolated by t.l.c. in 8:2 in 89% yield: m.p. slow dec. > 225 °C; λ_{max} (EtOH) 255 nm; R_f (THF) 0.00, R_f (8:2) 0.40; and *m/e* 309. This compound has been previously reported in the literature (13), m.p. dec. > 240 °C.

(*b*) Compound **8***d* was also obtained from **7***g* in 92% yield by treating **7***g* with the hydrazine in pyridine – acetic acid reagent.

Irradiation Studies. III. The Products from 4-Phenylterephthalophenone and Their Syntheses[1]

DOUGLAS PAUL THIEMANN,[2,3] DONALD E. PEARSON, AND DAVID JAMES THOENNES[2]
Department of Chemistry, Vanderbilt University, Nashville, Tennessee 37235

Received May 2, 1973

The photoreduction products of the irradiation of 4-phenylterephthalophenone in pyridine – isopropyl alcohol were 4-(4-phenylbenzoyl)benzhydrol (**2**) and the unexpected product, 4-benzoyl-4′-phenylbenzhydrol (**3**). The structures have been confirmed by an independent synthesis of each. A possible mechanism is discussed.

Les produits de la photoréduction obtenus par irradiation de la phényl-4 téréphtalophénone dans un mélange pyridine – propanol-2 sont le (phényl-4 benzoyl)-4 benzydrol (**2**) et le benzoyl-4 phényl-4′ benzydrol (**3**) qui est inattendu. Les structures de ces produits ont été confirmées par des synthèses indépendantes. Un mécanisme possible est discuté. [Traduit par le journal]

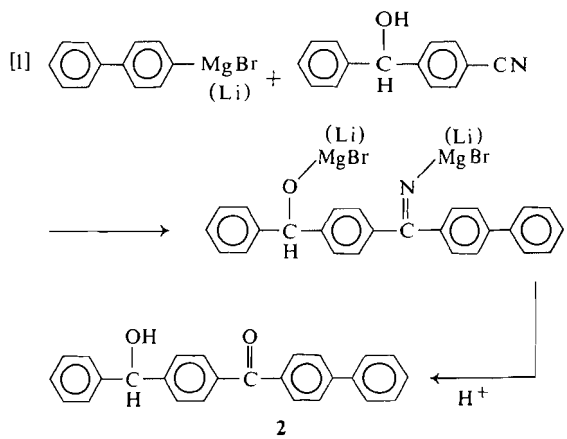
The photoreduction of terephthalophenone and a variety of other aromatic ketones has been studied by Pearson and Thiemann (2) and by other workers (3, 4, 7, 8). Our work on the photochemistry of aromatic ketones included a study of the photoreduction of 4-phenylterephthalophenone (**1**). It was expected that the carbonyl group adjacent to the biphenyl linkage would not undergo photopinacolization, but that the other carbonyl group might be photoreduced in the presence of isopropyl alcohol. For example, 4-phenylbenzophenone does not photoreduce to the pinacol under similar conditions (5).

The stoichiometry of the photoreduction of 4-phenylterephthalophenone (from the amount of acetone produced) indicated that each molecule of diketone **1** had abstracted two hydrogen atoms. Thus, it was thought that the diketone **1** was completely reduced to a polymer similar to that obtained in the case of terephthalophenone (2). However, examination of the i.r. spectrum of the product indicated that approximately 50% of the carbonyl functions still remained. The n.m.r. spectrum at this point indicated the presence of a methinyl hydrogen and hence a CHOH type linkage. The photoreduction product of **1** was tentatively identified as 4-(4-phenylbenzoyl)-benzhydrol (**2**) but the possibility of the isomer, 4-benzoyl-4′-phenylbenzhydrol (**3**) could not be ignored. To confirm the structure of the product, an independent synthesis of both isomers was carried out.

The ketoalcohol **2** was prepared by two slightly different methods. In one case, an excess of the Grignard reagent of 4-bromobiphenyl was allowed to react with 4-cyanobenzhydrol. In the other case, 4-biphenyllithium was prepared from 4-bromobiphenyl and butyllithium and allowed to react with 4-cyanobenzhydrol. These reactions are illustrated in reaction 1.



2

The yield of the lithium reaction was poor. The nitrile appears to be quite resistant to attack by the biphenyllithium, perhaps because the actual species being attacked is the lithium salt of 4-cyanobenzhydrol.

The Grignard method for preparing 4-(4-phenylbenzoyl)benzhydrol is the preferred method because of the superior yield and because the product obtained is considerably purer.

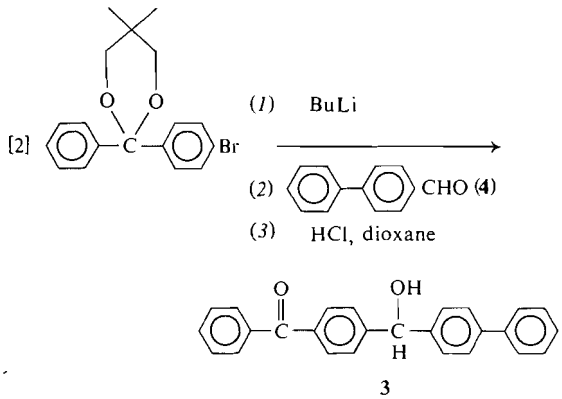
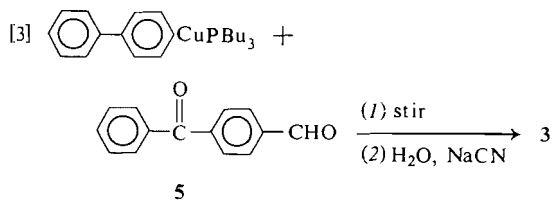
For personal use only.

To obtain the isomeric ketoalcohol **3**, two methods were again developed, the second one a rather elegant and straightforward method avoiding the ketalization of the first method in reaction 2.



The two methyl groups of the protecting ketal in 4-bromobenzophenone neopentylene ketal, above, are chemically nonequivalent and are seen as two distinct singlets, δ 0.86 and 0.97, in the n.m.r.

The second method involved the addition of the biphenylyl-copper(I) directly to the ketoaldehyde **5** in reaction 3.



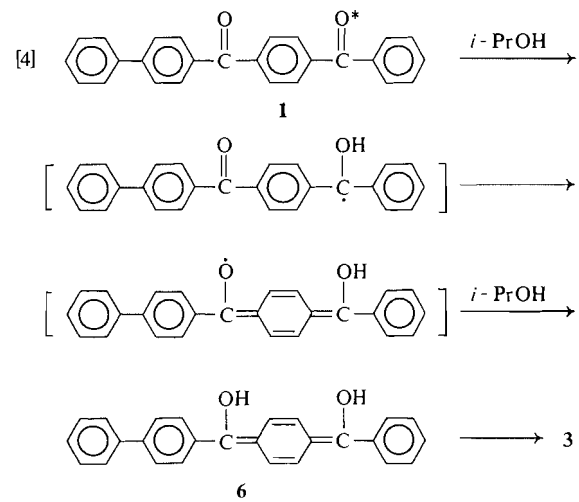
The melting points of the products from both methods were identical, 145–146°, and the yield of the second method, the arylcopper procedure, was 60%.

Results and Discussion

A comparison of the properties of the two isomers, **2** and **3**, and the product obtained on column chromatography of the irradiation mixture of 4-phenylterephthalophenone is given in Table 1.

The mass spectral data and u.v. spectra in Table 1 indicated that a mixture of the two isomers was at hand, an indication supported also by its wide melting point but good analysis. But the 100 MHz n.m.r. spectra truly confirmed the presence of a mixture whereby the two methinyl hydrogen signals, one for each of the isomers, were separate and distinct. From the comparative heights of these two signals obtained from the original crude mixture, the ratio of 4-benzoyl-4′-phenylbenzhydrol (**3**), to 4-(4-phenylbenzoyl)benzhydrol (**2**), was 2:1.

The isolation of the least probable isomer, **3**, in the largest amount is surprising. One possible mechanism is given in reaction 4.



This mechanism is unlikely for several reasons. The intermediate **6** would be expected to give a bright yellow color similar to that of terephthalophenone (2). No color was observed during irradiation. The reduction is slow, and the product is the alcohol, not the pinacol.

The u.v. spectrum of 4-phenylterephthalophenone shows one absorption band at 298 mμ (ε 24 000) and another at 266 mμ (ε 30 000). Both of these are strong and appear to be π–π* bands. No n–π* band was observed. It is suggested that the photoreduction of 4-phenylterephthalophenone proceeds through a π–π* triplet. This is in agreement with the fact that the rate of photoreduction is quite slow. It is thought that the carbonyl next to the biphenyl group is the one which is excited in the π–π* band of lower energy and this accounts for the predominance of photoreduction at this carbonyl. The hydrogen abstracting power of the π–π* triplet is quite low and the rate of photoreduction is slow. Hence, the steady state concentration of ketyl radicals is very low and coupling to give the pinacol would be rare. Instead, the ketyl

radical would abstract a hydrogen atom from the solvent to form the secondary alcohol.

Experimental[4]

Irradiation of 4-Phenylterephthalophenone

4-Phenylterephthalophenone (0.205 g) was weighed into a 10-ml ampoule and 5.00 ml of a standard 80:20 pyridine – isopropyl alcohol solution added. The solution was then degassed with nitrogen, sealed with a serum cap, and irradiated as a stirred solution in a water bath at 25°. The irradiation was carried out using a Sylvania 400 W (H33-1CP), medium-pressure mercury lamp. The outer jacket of this lamp was made of borosilicate glass which cuts out all irradiation below 300 nm. The diketone **1** was not completely soluble in the pyridine solution but was soluble after 50 h of irradiation, the solution becoming a light yellow color. This color was not due to an oxygen-sensitive intermediate such as the one observed in the case of terephthalophenone (2).

After an irradiation period of 350 h, the yellow solution was allowed to stand for several days. During this time, 0.015 g of white platelets which proved to be starting diketone were deposited: m.p. 193–196°; m.p. of diketone **1** is 195°. The solvent was then removed from the irradiated solution and 0.19 g of a yellow crystalline solid was obtained. Chromatography on silica gel using hexane–chloroform gave 0.03 g of diketone **1** and 0.14 g of a white solid which was recrystallized from ethanol and from hexane. The spectral and physical data as compared to those of isomers **2** and **3** indicated that this compound was mainly 4-benzoyl-4′-phenylbenzhydrol (**3**): m.p. 136–138° (softens at 131°); i.r. (KBr) 3430, 1650, 1600, 1310, 1275, 755, 745, and 690 cm^{-1}; n.m.r. ($CDCl_3$) δ 2.9 (s (broad), 1, CHO*H* exchangeable with D_2O), 5.92 (s, 1, C*H*OH), 7.2–7.9 (m, 18, aromatic *H*); the u.v. and mass spectra are given in Table 1.

Anal. Calcd. for $C_{26}H_{20}O_2$: C, 85.69; H, 5.53. Found: C, 85.87; H, 5.54.

Preparation of 4-Cyanobenzhydrol

4-Cyanobenzhydrol was prepared by the reduction of the corresponding ketone with sodium borohydride at room temperature in isopropyl alcohol. After recrystallization from petroleum ether, a 90% yield of 4-cyanobenzhydrol was obtained: m.p. 67.8–69.3; i.r. (Nujol) 3460 (b), 2220, 1045, and 690 cm^{-1}; n.m.r. ($CDCl_3$) δ 3.90 (s (broad), 1, CHO*H*), 5.67 (s, 1, C*H*OH), 7.25–7.40 (d, 9, aromatic *H*).

Anal. Calcd. for $C_{14}H_{11}NO$: C, 80.36; H, 5.30. Found: C, 80.15; H, 5.18.

Preparation of 4-(4-Phenylbenzoyl)benzhydrol (2)

4-Cyanobenzhydrol (3.6 g, 0.017 mol) was treated with a three-fold excess of 4-biphenylmagnesium bromide in dry refluxing ether for 8–10 h. The magnesium complex precipitated and was removed by filtration. This was hydrolyzed with 10% hydrochloric acid and after work-up gave 3.0 g (44%) of 4-(4-phenylbenzoyl)benzhydrol. This was recrystallized from butyl chloride and isopropyl alcohol to give white platelets of **2**: m.p. 145.2–145.9°; i.r. (KBr) 3500 (broad), 1650, 930, 740, and 690 cm^{-1}; n.m.r. ($CDCl_3$) δ 2.8 (s, (broad), 1, CHO*H*), 5.86 (s, 1, C*H*OH), 7.3–7.8 (m, 18, aromatic *H*).

Anal. Calcd. for $C_{26}H_{20}O_2$: C, 85.69; H, 5.53. Found: C, 85.82; H, 5.49.

Preparation of 4-Phenylbenzaldehyde (4)

4-Bromobiphenyl (11.5 g, 0.05 mol) in 75 ml of dry ether was treated with 0.075 mol of butyllithium and the

[4]All melting points are uncorrected and were taken with a Thomas Capillary Melting Point Apparatus. N.m.r. spectra were taken with a Varian A-60 instrument. We are indebted to the National Science Foundation for aid (Grant 1683) in purchasing this instrument. Mass spectra were obtained with a LKB-9000 spectrometer and we are indebted to the National Science Foundation for aid (Grant GU-2057) in purchasing this instrument. I.r. spectra were obtained with a Beckman IR-10. U.v. spectra were obtained with a Cary 14 recording spectrophotometer. Analyses were by Galbraith Laboratories, Knoxville, Tenn.

exchange allowed to proceed at room temperature for 45 min. *N,N*-Dimethylformamide (19 g, 0.26 mol) was added cautiously at 0°. After addition, the solution was maintained at room temperature for 90 min prior to hydrolysis. After normal work-up and recrystallization from cyclohexane, 7.0 g (77%) of 4-phenylbenzaldehyde was obtained as white platelets: m.p. 58–59.5° (ref. 6 p. 401 m.p. 60°); i.r. (neat) 1700, 1600, 830, 750, and 690 cm^{-1}; n.m.r. (CCl_4) δ 7.2–7.9 (m, 9, aromatic *H*), 9.94 (s, 1, C*H*O).

Preparation of 4-Benzoyl-4′-phenylbenzhydrol Neopentylene Ketal (5)

4-Bromobenzophenone was treated with a slight excess of neopentyl glycol and a catalytic amount of *p*-toluenesulfonic acid in refluxing benzene to give a 91% yield of 4-bromobenzophenone neopentylene ketal. Recrystallization from ethanol gave white needles: m.p. 85.8–86.3; n.m.r. (CCl_4) δ 0.86 (s, 3, CH_3), 0.97 (s, 3, CH_3), 3.50 (s, 4, CH_2), 7.1–7.5 (m, 9, aromatic *H*).

Treatment of the above bromo ketal with an equivalent amount of butyllithium gave the corresponding 4-lithio compound which was then allowed to react with 4-phenylbenzaldehyde to give 4-benzoyl-4′-phenylbenzhydrol neopentylene ketal (**5**). Recrystallization from ethanol gave an 82% yield of **5**: m.p. 157.5–158.5; n.m.r. ($CDCl_3$) δ 0.92 (s, 3, CH_3), 0.97 (s, 3, CH_3), 2.33 (s (broad), 1, CHO*H*), 3.59 (s, 4, CH_2), 5.76 (s, 1, CHO*H*), 7.2–7.6 (m, 14, aromatic *H*).

Anal. Calcd. for $C_{31}H_{30}O_3$: C, 82.64; H, 6.71. Found: C, 82.50; H, 6.72.

Preparation of 4-Benzoyl-4′-phenylbenzhydrol (3)

The above ketal was hydrolyzed at room temperature for 48 h in 150 ml of dioxane and 50 ml of 10% hydrochloric acid. Recrystallization from benzene–hexane, from butyl chloride, and from isopropyl alcohol gave white platelets of 4-benzoyl-4′-phenylbenzhydrol: m.p. 145.0–146.0°; n.m.r. ($CDCl_3$) δ 3.0 (s (broad), 1, CHO*H*), 5.92 (s, 1, C*H*OH), 7.2–7.9 (m, 18, aromatic *H*); $u.v._{max}$ (95% ethanol) 257 nm (ε 34 700).

Anal. Calcd. for $C_{26}H_{20}O_2$: C, 85.69; H, 5.53. Found: C, 85.85; H, 5.52.

Alternate Method for Preparation of 4-Benzoyl-4-phenylbenzhydrol (3)

A solution of 4.8 g, 20.6 mmol, of 4-bromobiphenyl in 20 ml of ether was added to a solution of 8.5 ml of 2.45 *M* butyllithium (20.8 mmol) in 50 ml of dry THF and 40 ml of ether at −70° over a period of 2 min. After stirring at −70° for 2 min, the pasty, white slurry was warmed to 0° whereupon the solution cleared. At 0°, tributylphosphine (4.2 g, 20.8 mmol) was added followed by cuprous iodide (4.1 g, 20.8 mmol) giving a green, cloudy solution. To this solution, 4-benzoylbenzaldehyde (2.1 g, 10 mmol) was added in one lot and the mixture stirred at 0° for 1.5 h and at 25° for 1.5 h. *In a hood*, the dark green mixture was treated with water turning it brown and then with 40 ml of 10% aqueous sodium cyanide giving two yellow layers with a film of metallic copper at the interface. The ether phase was separated, washed with more sodium cyanide solution, water, and then dilute hydrochloric acid, water, and then dried with magnesium sulfate. After evaporation, the pale yellow solid, 5.3 g, was triturated with boiling hexane twice to yield 2.6 g of white solid, m.p. 125–139°. Recrystallization from 20 ml of benzene and 30 ml of hexane gave 2.2 g (61%) of white crystals, m.p. 143.5–145.5°. An analytical sample melted at 145–146°.

Anal. Calcd. for $C_{26}H_{20}O_2$: C, 85.69; H, 5.53. Found: C, 85.94; H, 5.74.

The n.m.r. was identical to that of **3** prepared via the lithium exchange reaction.

Received June 7, 1973

The ^{13}C n.m.r. spectra of the 2-acetamido-2-deoxy-D-hexoses and some 3-*O*-acetyl and 1-phosphate derivatives are assigned and discussed. To facilitate the interpretation of the spectra, an initial assignment of the resonances in the spectrum of 2-acetamido-2-deoxy-D-glucose was required. For this purpose, both the 3-^2H and 4-^2H derivatives of this acetamido-hexose were synthesized. These syntheses are reported together with those of 2-acetamido-3-*O*-acetyl-2-deoxy-D-glucose and 2-acetamido-2-deoxy α- and β-D-glucose-1-phosphate. These model compounds were used to study substituent effects related to the 2-acetamido-2-deoxy-D-hexose-containing polysaccharide antigens of *N. meningitidis*.

On explique et on discute des spectres r.m.n. du ^{13}C d'acétamido-2 déoxy-2 D-hexoses et de quelques dérivés *O*-acétyle-3 et phosphate-1. Afin de faciliter l'interprétation des spectres, une attribution initiale des résonances dans le spectre de l'acétamido-2 deoxy-2 D-glucose a dû être effectuée. Dans ce but les dérivés ^2H-3 et ^2H-3 de cet acetamido hexose ont tous deux été synthétisés. Ces synthèses sont rapportées ainsi que celles de l'acétamido-2 *O*-acétyle-3 déoxy-2 D-glucose et de l'acétamido-2 déoxy-2 α- et β-D-glucose phosphate-1. Ces composés modèles ont été utilisés afin d'étudier les effets des substituants reliés au polysaccharide antigène de la *N. meningitidis* contenant l'acétamido-2 déoxy-2 D-hexose.

Introduction

To assist in our structural studies on the hexosamine-containing meningococcal polysaccharide antigens using ^{13}C n.m.r. (1), we required chemical shift data on a number of their monomeric units. Although the ^{13}C spectra of the hexoses have been well documented (2–5), only a preliminary investigation of one of the hexosamines (D-glucosamine hydrochloride) has been reported (6). The two hexosamine-containing meningococcal polysaccharides under investigation were those from Serogroup A and X. The former has been shown to be a partially *O*-acetylated 2-acetamido-2-deoxy-mannose phosphate homopolymer (7) and the latter a 2-acetamido-2-deoxy-glucose phosphate homopolymer (8). Therefore, in addition to the assignment of the resonances in the ^{13}C spectra of the hexosamines, the effects of 3-*O*-acetylation and anomeric phosphorylation of 2-acetamido-2-deoxy-D-glucose were studied. These model compounds and the 3-^2H and 4-^2H derivatives of 2-acetamido-2-deoxy-D-glucose were synthesized. The ^{13}C data for the latter compounds formed the basis of the assignments made in the spectra of the other 2-acetamido-2-deoxy-hexoses and the 3-*O*-acetyl and 1-phosphorylated derivatives of 2-acetamido-2-deoxy-D-glucose. Published data (9) on the equilibrated mixtures of the 2-acetamido-2-deoxy-D-hexoses were also correlated with peak intensities in the spectra to corroborate the assignments.

Results and Discussion

Synthesis

The synthesis of the 3-^2H, 4-^2H, and 3-*O*-acetyl derivatives of 2-acetamido-2-deoxy-D-glucose was accomplished by the initial synthesis of benzyl 2-acetamido-2-deoxy-β-D-glucopyranoside (**1**). This derivative was chosen in order that the reducing sugar could be generated under the mild conditions of hydrogenolysis. Previous methods employed for the synthesis of benzyl glycosides involving acid-catalyzed glycosidation have resulted in either low yields (10) or the formation of an anomeric mixture of glycosides (11) depending on the temperature used. The method described herein involves the Königs-Knorr condensation of 2-acetamido-3,4,6-tri-*O*-acetyl-2-deoxy-α-D-glucopyranosyl chloride with benzyl alcohol; it gave benzyl 2-acetamido-3,4,6-tri-*O*-acetyl-2-deoxy-β-D-glucopyranoside (**2**) in good

yields (85%) from which **1** could be produced in quantitative yields by catalytic deacetylation.

The 3-^{2}H derivative of 2-acetamido-2-deoxy-D-glucose was prepared by the initial oxidation of benzyl 2-acetamido-4,6-*O*-benzylidene-2-deoxy-β-D-glucopyranoside (**5**) using dimethylsulfoxide and acetic anhydride (12). This oxidation gave almost quantitative yields of benzyl 2-acetamido-4,6-*O*-benzylidene-2-deoxy-β-D-*ribo*-hexopyranosid-3-ulose (**8**). Following the

reduction of **8** with sodium borodeuteride and subsequent deacetylation; the benzyl glycosides of the D-*gluco* and D-*allo* epimers were separated by the method of Austin and co-workers (13). Catalytic hydrogenation of the separated benzyl glycosides yielded 3-^{2}H-2-acetamido-2-deoxy-D-glucose and its D-*allo* epimer in the ratio of 2.4:1.0 respectively.

The synthesis of 4-^{2}H-2-acetamido-2-deoxy-D-glucose was performed in a similar manner but the synthesis of the initial 4-ketone proved to be more difficult. Oxidation experiments involving ester blocking groups (14) on C-6 and -3 of **1** resulted in extensive degradation and poor yields of the 4-ketone using both dimethylsulfoxide – acetic anhydride and ruthenium tetroxide (15). The desirability of ether protecting groups was indicated and an attempt to prepare the initial 3-*O*-benzyl ether was made. The benzylation of **5** was attempted using benzyl chloride, but the reaction produced extremely low yields of **6** (10–15%) presumably due to *N*-benzylation (16). Therefore, this route was abandoned. It was discovered eventually that the introduction of an ether group at C-6 was the critical factor involved in obtaining good yields of the oxidation product, presumably avoiding the problem of β-elimination, which is probably promoted by an ester group at C-6. Compound **5** was acetylated at C-3 and the benzylidene group was removed by selective acidic hydrolysis to give crystalline **3**. Compound **3** was tritylated at C-6 to yield crystalline benzyl 2-acetamido-3-*O*-acetyl-6-*O*-trityl-2-deoxy-β-D-glucopyranoside (**4**) which was oxidized using dimethylsulfoxide – acetic anhydride (12) to give excellent yields of benzyl 2-acetamido-3-*O*-acetyl-6-*O*-trityl-2-deoxy-β-D-*xylo*-hexopyranosid-4-ulose (**7**). The 4-ketone (**7**) was reduced with sodium borodeuteride, deacetylated, and detritylated. The benzyl group was removed from the epimeric mixture of glycosides by an identical procedure to that used previously. The resultant 4-^{2}H-2-acetamido-2-deoxy-D-glucose and its D-*galacto* epimer were separated by preparative paper chromatography.

2-Acetamido-3-*O*-acetyl-2-deoxy-D-glucose was prepared by the catalytic hydrogenolysis of **3**, and the α- and β-1-phosphate derivatives were prepared by the method previously reported to yield the crystalline α-1-phosphate derivative (17). Using this method we obtained a mixture of both the α- and β-anomers which were used as an unresolved mixture in the n.m.r. determinations.

^{13}C *Nuclear Magnetic Resonance*

The carbon-13 chemical shifts of the 2-acetamido-2-deoxy-α- and -β-D-hexoses are shown in Table 1. In general the chemical shifts of the individual carbons of each acetamido-hexose can be correlated with the observed chemical shifts of its analogous hexose (4, 5) except for some characteristic differences associated with the introduction of an acetamido group at C-2 of the pyranose ring. Thus the lowest field signals (175.7–176.1 p.p.m.) and the highest field signals (23.2–23.5 p.p.m.) are assigned to the carbonyl and methyl moieties of the 2-acetamido groups. In addition the 2-acetamido group resulted in a substantial upfield shift of the C-2 signal relative to that of their analogous hexoses and enabled C-2 to be assigned quite readily. This displacement of the C-2 resonance was found to be 17.6 p.p.m. for 2-acetamido-2-deoxy-D-glucose; a displacement of considerable magnitude has also been reported for 2-amino-2-deoxy-D-glucose hydrochloride (6). The resonances at 92.1–

96.5 p.p.m. were attributed to the anomeric carbons (C-1) by comparison with the equivalent downfield position of the C-1 resonance in the hexose series (4, 5). The resonances at 62.0 and 61.9 p.p.m. in the spectrum of 2-acetamido-2-deoxy-D-glucose were assigned to C-6 of the β- and α-anomers, respectively, by the appearance of triplets of relative intensity 1:2:1 in the undecoupled spectrum and by their relative intensities. Unequivocal assignment of the remaining resonances (C-3, -4, and -5) in the spectrum of 2-acetamido-2-deoxy-D-glucose were accomplished by utilizing the loss in intensity due to lack of nuclear Overhauser enhancement and the presence of spin coupling to ^2H caused by deuteration (18, 19). A comparison of the spectra of 2-acetamido-2-deoxy-D-glucose and its 3-^2H and 4-^2H derivatives is shown in Fig. 1. These spectra illustrate quite clearly that substitution of deuterium for hydrogen caused the complete collapse of resonances attributable to C-3 and -4 of the α- and β-anomers of 2-acetamido-2-deoxy-D-glucose. Similar disappearances of these signals have been obtained using deuteriated glucose (20). Except for C-4 of 2-acetamido-2-deoxy-D-galactose, which was also assigned by deuterium labelling, all the other assignments in Table 1 were made tentatively by correlation with those assigned for 2-acetamido-2-deoxy-D-glucose and corroborated by comparison with the published data on the hexoses (4, 5).

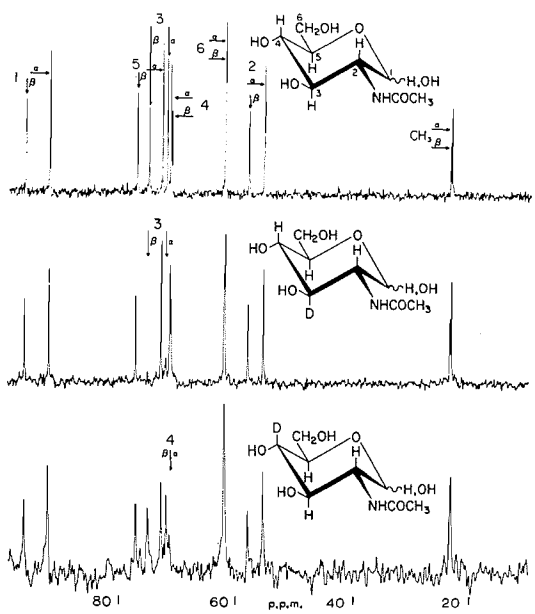

FIG. 1. Comparison of the ^{13}C n.m.r. spectrum of 2-acetamido-2-deoxy-α- and -β-D-glucose with the spectra of its 3-^2H and 4-^2H derivatives.

The dependence of all carbon resonances (with the exception of C-4 for the 1-phosphate and 3-*O*-acetyl derivatives) on the anomeric configuration of the compounds in Table 1 is striking. Similar behavior for C-2 to C-5 has been detected for glucose, galactose, and mannose (4) but the higher resolution available with second generation spectrometers allows observation of a small effect on C-6 (21). It is also noteworthy that the methyl and carbonyl groups of the acetamido moiety on C-2 are sensitive to the anomeric configuration. Thus, all the ^{13}C resonances allow estimates of the dominant anomers at equilibrium which are in qualitative agreement with values determined by more conventional means (9).

Most of the empirical relationships that can be obtained from the chemical shift data on the 2-acetamido-2-deoxy-D-hexoses were found to be similar to those previously found for the analogous hexoses (4). This is not surprising in view of their close structural and conformational relationships. Chemical shift differences due to the change in orientation at the anomeric center, obtained from Table 1, are only marginally different from those obtained from the equivalent hexose data (4), C-1, -2, -3, and -5 being the most affected. It is interesting to note, however, that, although the C-1 anomeric shift difference was the smallest for D-mannose in the hexose series (4), in the case of 2-acetamido-2-deoxy-D-mannose the C-1 signals of the α- and β-anomers are coincident.

Another similarity with the hexose data is the comparison of the overall shielding of the ring carbons as measured by the sum of the observed chemical shifts in each sugar (4). These are recorded in Table 1 and indicate that the α- and β-2-acetamido-2-deoxy-D-hexoses can be placed in the same order as their analogous hexoses. This order has been shown to reflect broadly the differences in conformational stability of the hexoses (4).

The influences of axial groups on the other ring carbons have been studied in derivatives of cyclohexane (22–24), the inositols (25), and the aldohexoses (4, 5). The axial group has been shown to result in changes in chemical shift on the α-carbon to which it is attached, the adjacent β-carbon, and the γ-carbon, but only slightly the

δ-carbon. Table 2 illustrates the effect of the introduction of axial groups to the 2-acetamido-2-deoxy-α- and -β-D-hexoses using the α- and β-D-*gluco* epimers as the reference molecules. The axial acetamido group at C-2 of 2-acetamido-2-deoxy-α- and -β-D-mannose gave shieldings very similar to those found for the axial hydroxyl group on C-2 of mannose (4) except for a significant enhancement in the magnitude of the shielding effect on C-4 (γ-carbon). This enhancement which was approximately 1.0–1.3 p.p.m. could be attributed to the increase in axial shielding of the γ-carbon (4, 25) due to the larger size of the acetamido group when compared to the smaller hydroxyl group at C-2 of D-mannose. However, this enhancement persisted in the opposite situation found in 2-acetamido-2-deoxy-α- and -β-D-galactose, where an axial hydroxyl group at C-4 is situated γ to an equatorial acetamido group on C-2. Obviously in this case the enhancement (1.3 p.p.m.) over the effect found in D-galactose cannot be due to steric factors involving the larger size of the acetamido group and other factors must be invoked.

Substituent effects on the chemical shifts of the ring carbons of 2-acetamido-2-deoxy-D-glucose are listed in Table 3. The differences were obtained by comparison of the spectra of the α- and β-anomers of the substituted and unsubstituted compounds. The introduction of a 3-*O*-acetyl group had a profound effect on the α-carbon (C-3) and also the β-carbons (C-2 and -4); the effect diminishes at the γ-carbons (C-1 and -5). The substituent effect on the α-carbon is well documented for the methyl hexopyranosides (4), 3-*O*-methyl-D-glucose (4, 5) and some *O*-methylated inositols (25). In all cases the α-carbon was considerably deshielded, resulting in a downfield shift of its resonance by 7–10 p.p.m. By comparison, a considerably smaller downfield shift was caused by the 3-*O*-acetyl substitution of 2-acetamido-2-deoxy-D-glucose (3.1 and 1.8 p.p.m. for the α- and β-anomers respectively). However, of considerable interest was the increased shielding of the β-carbons by the *O*-acetyl group when compared to that caused by an *O*-methyl group in aldopyranose molecules. This shift in 2-acetamido-3-*O*-acetyl-2-deoxy-D-glucose of approximately 2.0 p.p.m. is of much greater magnitude than that reported (5) for the equivalent 3-*O*-methyl shift in D-glucose (0.5–1.0 p.p.m.). This could be due to the conformation adopted by the *O*-acetyl group on the pyranose ring (26).

Addition of a phosphate group at C-1 of 2-acetamido-2-deoxy-D-glucose resulted in downfield shifts of the C-1 resonances (0.5 and 1.8 p.p.m. for the β- and α-anomers, respectively) which were smaller than those observed (~2.5 p.p.m.) for substitution at C-2′, -3′, or -5′ of the ribose moiety of nucleosides (27–31). This reflects the special properties of the anomeric center. The deshielding effects of the phosphate group are also considerably smaller than those obtained by the introduction of an anomeric methyl group in the hexoses (4). Unlike the introduction

of an *O*-acetyl group on C-3 of 2-acetamido-2-deoxy-D-glucose the substituent effect of the anomeric phosphate group was not relayed to the adjacent β-carbon (C-2) to any extent, as observed in the ribose series (27–31). This has also been found to be the case with the methyl glycopyranosides (4) where the large substituent effect on C-1 is only relayed to a minimum extent to C-2.

Couplings between ^{31}P and ^{13}C are also manifest in the spectra of the phosphates, Table 1. In the nucleotides the couplings through two bonds ($^2J_{^{31}P-^{13}C}$) were found to be 5 ± 1 Hz (27–31). The two bond couplings for the anomeric 2-acetamido-2-deoxy-D-glucose phosphates also fall within this range. The three bond couplings between ^{31}P and ^{13}C ($^3J_{^{31}P-^{13}C}$) have been shown previously to depend on the dihedral angle between the ^{31}POC and $OC^{13}C$ planes, allowing an estimation of the populations of the possible rotational isomers (27–31). The data in Table 1 ($^3J_{P,C-2} \approx 7$ Hz) indicate that the monomeric phosphates have a strong preference for the extended conformation, C_2-*trans*, as has been found for the corresponding polysaccharides (1).

Experimental

Melting points were determined on a Fisher-Johns apparatus and are uncorrected, and optical rotations were measured at 21 ± 3°. Preparative paper chromatography was carried out on Whatman 3MM paper impregnated with sodium tetraborate using the solvent system (v/v), butan-1-ol – pyridine – water (4 : 6 : 3) (32). T.l.c. was performed on silica gel coated plates with the following solvent systems (v/v): (A) benzene – propan-1-ol (4 : 1) and (B) benzene–acetone (4 : 1). An F and M (model 420) chromatograph was used for g.l.c. analysis using a 10% Neopentylglycol sebacate column at 240°. ^{13}C n.m.r. spectra were recorded in 12 mm tubes at 37° on a Varian XL-100-15 spectrometer operating at 25.16 MHz in the pulsed Fourier transform mode with complete proton decoupling. The computers used in these studies (Varian 620-i and Varian 620-L) allowed aquisition of 4096 and 8192 output data points, respectively, in the transformed spectra. Chemical shifts are reported in parts per million (p.p.m.) downfield from external tetramethylsilane, and deuterium oxide was used as the source of the lock signal. All the 2-acetamido-2-deoxy-hexoses and derivatives were run in deuterium oxide, at concentrations of 100 mg/ml, after having attained their mutarotational equilibria.

Benzyl 2-Acetamido-3,4,6-tri-O-acetyl-2-deoxy-β-D-*glucopyranoside (2)*

Benzyl alcohol (300 ml, 3 mol), previously dried over 3A molecular sieve, was stirred with Drierite (100 g) and mercuric cyanide (84 g) for 1 h in anhydrous benzene before the addition of 2-acetamido-3,4,6-tri-*O*-acetyl-α-D-glucopyranosyl chloride (33) (63 g, 0.17 mol). The suspension was stirred vigorously for 48 h and then poured into chloroform (1 l). The chloroform solution was filtered, extracted with 10% sodium chloride, washed (×3) with water, and dried over anhydrous sodium sulfate. Concentration of the solution, initially at 12 mm Hg and then at 1 mm Hg to remove excess benzyl alcohol gave a syrup that crystallized after dissolution in hot ethanol. Concentration of the mother liquors yielded further product. Recrystallization from ethanol gave crystals (64 g, 85%) of m.p. 168–169° and $[\alpha]_D$ −41° (*c*, 1.0 in methanol). These constants are in close agreement with those quoted in the literature (33).

Benzyl 2-Acetamido-2-deoxy-β-D-*glucopyranoside (1)*

Sodium (20 mg) in methanol (4 ml) was added to a solution of **2** (43.2 g) in methanol (600 ml) and the solution kept for 16 h at 4°. Long colorless needles (21 g, 94%) of **1** were formed having m.p. 206–207° and $[\alpha]_D$ −48.5° (*c*, 1.0 in water). Lit. (11) reports m.p. 207–208° and $[\alpha]_D$ −48.0 (in water for **1**).

Benzyl 2-Acetamido-4,6-O-benzylidene-2-deoxy-β-D-*ribo-hexopyranosid-3-ulose (8)*

Benzyl 2-acetamido-4,6-*O*-benzylidene-2-deoxy-β-D-glucopyranoside (**5**) (11) (10 mmol) in dimethylsulfoxide (70 ml) and acetic anhydride (25 ml) was stirred and allowed to stand at room temperature for 48 h. The reaction mixture was poured into saturated sodium bicarbonate solution (1 l) which caused the precipitation of crude **8**. The precipitate was filtered, washed extensively with cold water, and dried in a vacuum over phosphorus pentoxide. Recrystallization of the residue (3.7 g) from chloroform–acetone gave crystalline **8** (2.7 g, 67%) of m.p. 262–265° (dec.) and $[\alpha]_D$ −65.5° (*c*, 1.0 in dioxane). ν_{max} 1740 (C=O) and 1655 cm^{-1} (—$NHCOCH_3$).

Anal. Calcd. for $C_{22}H_{23}O_6N$: C, 66.49; H, 5.83; N, 3.52. Found: C, 65.93; H, 5.59; N, 3.31.

Benzyl 2-Acetamido-3-^{2}H-2-deoxy-β-D-*gluco- and* -D-*allo-pyranosides*

Crystalline **8** (2.5 g) was stirred in methanol (800 ml) with sodium borodeuteride (800 mg) for 16 h at room temperature. During the reduction the insoluble ketone (**8**) dissolved and then some of the epimeric products began to precipitate. The solution was concentrated to a solid residue, the residue was dissolved in chloroform, and the chloroform solution was washed with dilute acetic acid, water (×3), and dried over anhydrous sodium sulfate. Removal of the sodium sulfate by filtration and concentration of the chloroform solution gave a solid residue (2.3 g) containing the 3-^{2}H derivative of **5** and its D-*allo* epimer. Removal of the benzylidene group was accomplished by heating the residue at 100° in 75% acetic acid until solution was complete (15 mm). The resulting solution was evaporated to dryness and co-evaporated a number of times with water and toluene. The white solid (1.5 g) was dissolved in the minimum amount of water containing several drops of ethanol (total volume 5 ml) which was applied to a column 2.5 × 30 cm of ion-exchange resin (Dowex 1-X2, 200–400 mesh) (OH^- form) which was eluted with water. Fractions (5 ml) were monitored for u.v. absorption (280 mμ). Two peaks were obtained and the corresponding fractions were concentrated to dryness and recrystallized from ethanol. The D-*gluco*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

isomer (500 mg) had m.p. 208–209° and $[\alpha]_D$ −47° (*c*, 1.0 in water). Lit. reports (11) m.p. 207–208° and $[\alpha]_D$ −48 (H_2O). The D-*allo* isomer (300 mg) had m.p. 165–168° and $[\alpha]_D$ −119 (*c*, 1.0 in pyridine). Lit. reports (34) m.p. 156–158° and $[\alpha]_D$ −114° (pyridine).

2-Acetamido-3-^{2}H-2-deoxy-D-*glucose and* -D-*allose*

The epimeric benzyl glycosides above (250 mg) were dissolved separately in ethanol–water (50 ml) and hydrogenated over palladium black (50 mg) for 4 h at room temperature. The solutions were then filtered and concentrated to dryness. The homogeneity of each product was determined by g.l.c. analysis of a small sample of its reduced peracetate (35) using authentic samples of 2-acetamido-2-deoxy-D-glucitol and its D-allitol epimer prepared as described by Gross and Jeanloz (11). Both homogeneous epimers were used without recrystallization for the n.m.r. determinations.

Benzyl 2-Acetamido-3-O-acetyl-2-deoxy-β-D-*glucopyranoside (3)*

Crystalline **5** (7 g) was treated in pyridine (150 ml) with acetic anhydride (10 ml) and the reaction left to stand for 16 h. The solution was poured into ice–water (1.5 l) and a highly crystalline product was filtered off after 30 min. Benzyl 2-acetamido-3-*O*-acetyl-4,6-*O*-benzylidine-2-deoxy-β-D-glucopyranoside (7.6 g, 98%) was obtained directly in an analytically pure state, the physical constants being identical to those reported in the literature (11). Removal of the 4,6-benzylidene group was achieved by heating it with 75% aqueous acetic acid at 100° for 40 min. Concentration of the solution to dryness and co-evaporation with water and toluene left a solid residue which was recrystallized from ethanol–water to give crystals (4.25 g, 70% based on **5**) of m.p. 184–185° and $[\alpha]_D$ −78° (*c*, 2.0 in methanol).

Anal. Calcd. for $C_{17}H_{23}O_7N$: C, 57.76; H, 6.56; N, 3.96. Found: C, 57.68; H, 6.66: N, 3.86.

Benzyl 2-Acetamido-3-O-acetyl-6-O-trityl-2-deoxy-β-D-*glucopyranoside (4)*

A solution of **3** (6 g) in pyridine (100 ml) was stirred with triphenylchloromethane (4.35 g) and left for 3 days at room temperature. T.l.c. analysis in solvent A indicated that the reaction was complete after 2.5 days. The reaction mixture was poured into ice–water and the solid product was allowed to settle after which the supernatant was decanted. The solid was dissolved in chloroform (500 ml) and the chloroform solution was washed (×3) with water and dried over anhydrous sodium sulfate. Concentration of the solution to 30 ml and the addition of light petroleum (b.p. 30–60°) gave crystals of **4** (4.5 g). A further 3 g of **4** was obtained from the mother liquors by an identical procedure. Total yield of **4** was 7.5 g (74%). It had m.p. 122–124° and $[\alpha]_D$ −58° (*c*, 2.0 in chloroform).

Anal. Calcd. for $C_{36}H_{37}O_7N$: C, 72.60; H, 6.22; N, 2.35. Found: C, 72.98; H, 6.36; N, 2.15.

Benzyl 2-Acetamido-3-O-acetyl-6-O-trityl-2-deoxy-β-D-*hexopyranosid-4-ulose (7)*

Crystalline **4** (3 g) was dissolved in dimethylsulfoxide (20 ml) and to this solution was added acetic anhydride (10 ml). The oxidation was left at room temperature and monitored by t.l.c. analysis in solvent B. After 48 h no trace of **4** was detectable and the reaction mixture was poured into ice–water (400 ml). After 10 min the aqueous phase was decanted from an oil which had separated at the bottom of the beaker. The oil was dissolved in chloroform and the chloroform solution was washed with water, dried over anhydrous sodium sulfate, filtered, and concentrated to a syrup (2.7 g). Trituration of the syrup with ether caused it to crystallize and recrystallization from di-isopropyl ether containing a few drops of ethanol gave crystalline **7** of m.p. 165–167° and $[\alpha]_D$ −33.5° (*c*, 2.4 in chloroform). ν_{max} 1760 (C=O), 1740 ($OCOCH_3$), and 1670 cm^{-1} ($NHCOCH_3$).

Anal. Calcd. for $C_{36}H_{35}O_7N$: C, 72.85; H, 5.90; N, 2.36. Found: C, 72.15; H, 6.11; N, 2.18.

2-Acetamido-4-^{2}H-2-deoxy-D-*gluco- and* -D-*galactopyranose*

Crystalline **7** (1.6 g) was dissolved in methanol (50 ml) and sodium borodeuteride (400 mg) was added. The solution was allowed to stand for 16 h and was then concentrated to a solid residue. The residue was dissolved in 80% acetic acid containing a trace of ethanol and the solution was heated at 100° for 30 min. The solution was once more evaporated to a solid residue and the borate was removed by co-distillation with methanol. The solid residue (750 mg) was dissolved in ethanol–water containing a trace of acetic acid and hydrogenated over palladium black (100 mg). Filtration and concentration of the solution followed by g.l.c. analysis of the products as described previously (35) indicated that 2-acetamido-2-deoxy-D-glucose and its D-*galacto* epimer were the sole products of the reduction of **7**. The epimeric mixture of 4-^{2}H-2-acetamido-2-deoxy-hexoses were separated by preparative paper chromatography in solvent C (32). Borate was removed from each fraction by co-distillation with methanol and the syrupy products, shown to be pure by g.l.c. analysis (35), were used in the n.m.r. determinations without crystallization.

2-Acetamido-3-O-acetyl-2-deoxy-D-*glucose*

Crystalline **3** (400 mg) was dissolved in aqueous ethanol and hydrogenated over palladium black catalyst (50 mg). After 16 h the uptake of hydrogen had ceased and the catalyst was removed by filtration. Concentration of the clear filtrate gave a mobile syrup which crystallized on standing. Recrystallization from ethanol–ether (1:2) gave crystals (200 mg, 67%) of m.p. 157–160° having $[\alpha]_D$ +19° (*c*, 1.0 in ethanol; equilibrium).

Anal. Calcd. for $C_{10}H_{17}O_7N$: C, 45.63; H, 6.46; N, 5.32. Found: C, 45.47; H, 6.59; N, 5.38.

Benzyl 2-Acetamido-3-O-benzyl-4,6-O-benzylidene-2-deoxy-β-D-*glucopyranoside (6)*

The benzyl ether was prepared essentially by the method of Croon and co-workers (36) using 2 g of **5** and a reaction time of 8 h. The reaction mixture was filtered, concentrated to small volume, and the 3-*O*-benzyl ether (**6**) was precipitated almost quantitatively by pouring the concentrated solution into ethanol. This was determined by t.l.c. analysis (solvent B) of the mother liquors, which were shown to contain at least one major component having a greater mobility than the 3-*O*-benzyl ether or **5**. The precipitated 3-*O*-benzyl ether (**6**) was recrystallized from pyridine–ethanol (1:1) to give needles (300 mg, 12.3%) of m.p. 283° and $[\alpha]_D$ −97.5° (*c*, 1.0 in pyridine).

Anal. Calcd. for $C_{29}H_{31}O_6N$: C, 71.16; H, 6.33; N, 2.86. Found: C, 70.70; H, 6.48; N, 2.89.

Yields of up to 16% could be obtained by shorter reaction times (4 h).

Hydrolysis of Substituted Diphenylacetaldehyde Ethylene Glycol Cyclic Acetals in Aqueous Hydrochloric Acid[1]

BRUCE L. JENSEN[2] AND RAYMOND E. COUNSELL

Laboratory of Medicinal Chemistry, College of Pharmacy, The University of Michigan, Ann Arbor, Michigan 48104

Received May 24, 1973

The chemistry of DDT and DDD derivatives was explored by studying the steric and electronic effects on the hydrolysis of a variety of substituted diphenylacetaldehyde ethylene glycol cyclic acetals. This investigation demonstrated that *ortho* substituents, *p*-nitro, and *p*-methoxy groups affect the product distribution in different ways. The mechanistic details of this work are discussed.

La chimie des dérivés du DDT et du DDD a été examinée en étudiant les effets électroniques et stériques sur l'hydrolyse d'une variété d'acétals cycliques formés entre l'éthylène glycol et des diphénylacétaldéhydes substitués. Cette étude a démontré que les substituants *ortho* et les groupes *p*-nitro et *p*-méthoxy affectent la distribution des produits de différentes manières. Les détails mécanistiques de ce travail sont discutés. [Traduit par le journal]

Can. J. Chem., **51**, 3820 (1973)

The widespread use of 2,2-di(*p*-chlorophenyl)-1,1,1-trichloroethane (DDT) as a pesticide as well as the more limited use of 2-(*o*-chlorophenyl)-2-(*p*-chlorophenyl)-1,1-dichloroethane (*o,p'*-DDD) as the only clinically approved agent for the treatment of adrenocortical carcinoma has prompted numerous chemical investigations in these classes of compounds (1–12).

Because of the immense biological importance of these compounds, the hydrolysis of cyclic acetals **1** related to DDT and DDD has recently been studied (5, 7, 8, 10, 11). This particularly interesting reaction affords the corresponding benzophenone **2**, diphenylacetaldehyde **3**, and deoxybenzoin **4** in varying proportions. The formation of benzophenones from this reaction has received additional attention and only recently McKinney and co-workers (12) have shown that this conversion probably proceeds via the enol ether **6** and the α-hydroxy aldehyde **7**. Furthermore, the ratio of diphenylacetaldehyde **3** to benzophenone **2** was shown by this group (12) and others (7) to vary considerably depending on the hydrolysis conditions and it was suggested that steric inhibition also influenced this reaction.

The steric dependence of this reaction was explained on the basis by which the benzhydryl carbon can undergo oxidation. By comparing the *p,p'*-, *o,p'*-, and *o,o'*-dichloro systems, McKinney *et al.* demonstrated that steric hindrance to removal of the benzhydryl proton by the *o*-chlorine atom and subsequent steric inhibition of resonance stabilization would influence the progress of this reaction. However, this group made no further attempt to substantiate their

predictions nor were the electronic influences on this reaction explored.

As part of a continuing interest in DDD and DDT compounds, we have investigated the electronic and steric effects on the product distribution when a variety of substituted diphenylacetaldehyde ethylene glycol cyclic acetals **1** were hydrolyzed in boiling 20% aqueous hydrochloric acid. The diphenylacetaldehydes **3***a–h* were obtained commercially or were synthesized from the appropriate benzophenone via Darzen's glycidic ester synthesis. The cyclic acetals **1***a–h* were prepared by treating the diphenylacetaldehydes with ethylene glycol in refluxing benzene containing *p*-toluenesulfonic acid as a catalyst. Aqueous 20% hydrochloric acid was chosen as the hydrolysis medium because of its non-oxidative properties and its inability to form esters with intermediates in the hydrolysis reaction.

G.l.c., i.r., and n.m.r. spectroscopy were employed for characterization of the products and their relative amounts.

Results

G.l.c. analyses for the hydrolysis of the cyclic acetals **1***a–h* in 20% aqueous hydrochloric acid for 6 h are tabulated in Table 1.

TABLE 1. Product distribution and percentages from the hydrolysis of cyclic acetals **1***a–h*

Cyclic acetal **1**	Hydrolysis product (%)		
	Aldehyde **3**	Benzophenone **2**	Deoxybenzoin **4**
a	89	11	0
b	69	31	0
c	100	0	0
d	100	0	0
e	89	11	0
f	88	12	0
g	100	0	0
h	77	4	19

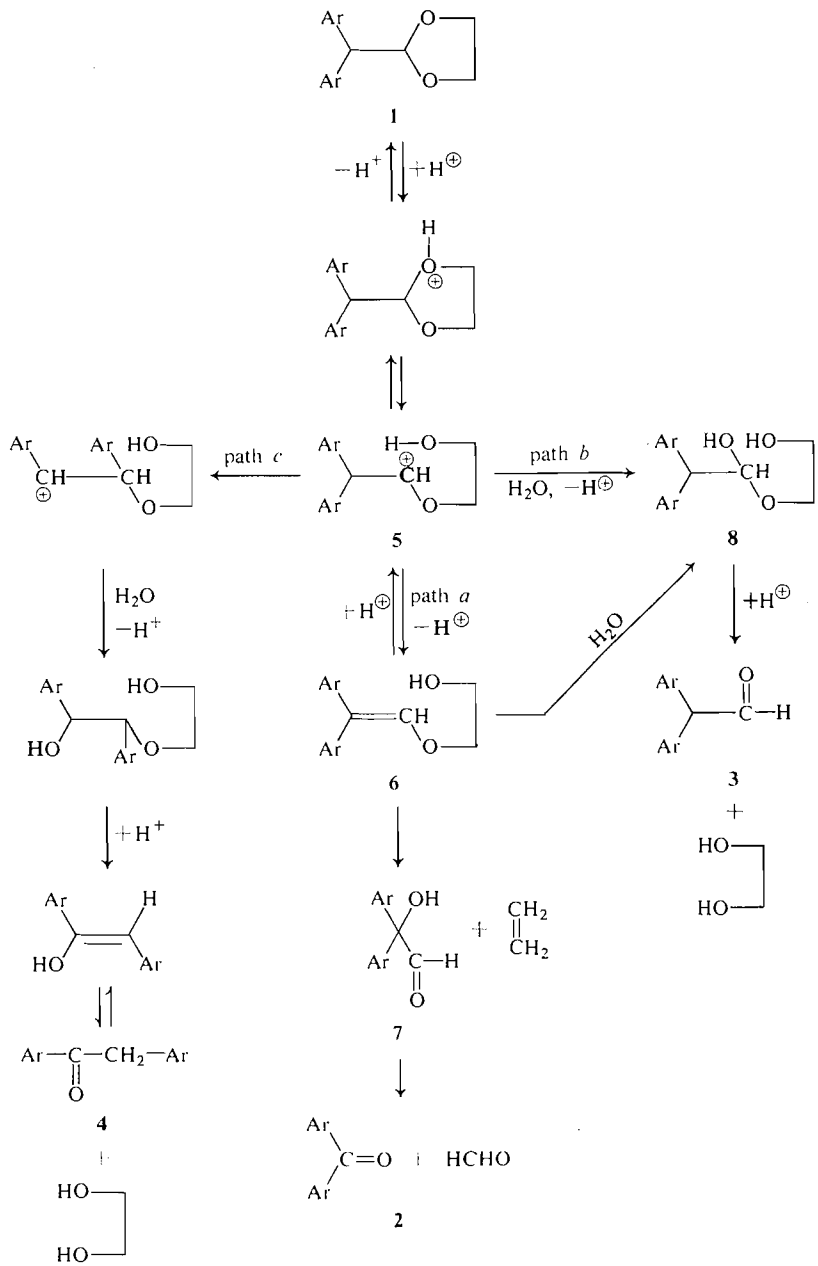
Discussion

From the product distribution shown above, three mechanistic pathways seem to be operative during the hydrolysis of the cyclic acetals **1***a–h* (Scheme 1). Furthermore, the central intermediate structure **6** in this sequence can be used to account for the results obtained. Protonation of an acetal oxygen would give rise to **5**. At this point both steric and electronic factors may influence the course of the reaction.

In cases **1***c–d*, where *ortho* substituents were present, no benzophenones were formed. These results are consistent with McKinney *et al.* findings that steric hindrance to the removal of the benzhydryl proton is probably prevented by *ortho* substituents. Subsequent steric inhibition of resonance stabilization after proton removal would also preclude path *a*. This factor is demonstrated further when *p*-fluoro, -chloro, and -hydrogen substituents are present. These substituents are not capable of steric effects and the small electronic influences of such groups would not be expected to influence the course of the reaction. Thus, in these cases, both pathways *a* and *b* are operative.

In the cases of **1***g–h*, strongly electron releasing and electron withdrawing groups clearly influence the product distribution. Path *c*, which involves an aryl migration, would be favored for **1***h* because of the high migratory aptitude of the *p*-anisyl group (13). The finding that 19% of the hydrolysis products is *p,p'*-dimethoxydeoxybenzoin supported this prediction. As would be expected, no aryl migration product was detected from the hydrolysis of **1***g* since the *p*-nitrophenyl group is a poor migrating group in this carbonium ion rearrangement. Furthermore, only *p,p'*-dinitrodiphenylacetaldehyde (**3***g*), resulting from path *b*, was formed. This result can be explained by the facility by which either **5** or **6** can react with water. The powerful withdrawing effects of the nitro groups would favor the formation of the carbonium ion **5** as opposed to a benzhydryl carbonium ion. Furthermore, the loss of a proton from **5** to give the enol ether **6** would also be favored by the strongly electron withdrawing groups. In either case, the rapid addition of water would afford **8**. An analogous process is the rapidity by which aldehydes and ketones form stable hydrates when electron withdrawing groups are in close proximity to the carbonyl group (14). This mode of addition has been demonstrated further by Tadros *et al.* (11) who have shown that **6** can readily be converted to the corresponding cyclic acetal in concentrated hydrochloric acid.

An additional indication of the substituent effects on the benzhydryl proton in this reaction is also evident from a comparison of the chemical shifts of the benzhydryl proton in the cyclic acetals **1***a–h*. An *o*-chloro substituent shows a strong deshielding effect on the benzhydryl proton when compared with the corresponding



SCHEME 1

para substituents (6). In general, the benzhydryl proton doublet appeared at τ 5.88–5.80 for the acetals having *para* substituents. The one exception was **1***g* whose *p,p'*-dinitro substituents inductively deshield the benzhydryl proton and it appeared at τ 5.52. The most notable deshielding effects by substituents occurred in **1***d* and *c*, whose benzhydryl protons appeared at τ 5.28 and 4.78, respectively. The proton on the adjacent carbon, on the other hand, was virtually unaffected by the substituents. These data correlate well with recent reports (15, 16); a summary of the n.m.r. data for the cyclic acetals **1***a–h* is presented in Table 4.

Experimental

General

Melting points were obtained with a Fisher-Johns melting point apparatus and are uncorrected. Boiling points are uncorrected. The n.m.r. spectra were recorded on a Varian A-60A spectrometer in CCl_4 or $CDCl_3$ with tetramethylsilane as an internal standard. I.r. spectra were determined on a Perkin-Elmer Model 337 spectrophotometer. G.l.c. analyses were performed on a Varian Aerograph Model 90 P (thermal conductivity) gas chromatograph using a 5 ft × 0.25 in. stainless steel column packed with 10% SE 30 on 100/120 mesh Var A port 30 or on a Loenco Model 160 (flame ionization) gas chromatograph using a 6 ft × 0.125 in. stainless steel column packed with 3% OV-17 on 100/120 mesh Chromosorb G. Microanalyses were performed by Spang Microanalytical Laboratories, Ann Arbor, Michigan.

Materials

Preparation of Substituted Diphenylacetaldehydes 3a–h

Diphenylacetaldehyde (*3a*) and *o,o'*-dichlorodiphenylacetaldehyde (*3c*) were commercially available (Aldrich Chemical Company).

Preparation of p,p'-Dimethoxydiphenylacetaldehyde (3h) This compound was prepared according to the method of Tiffeneau and Orekhoff (17).

Preparation of Diphenylacetaldehydes 3b,d–g These aldehydes were obtained from the appropriate benzophenones via Darzen's glycidic ester synthesis according to procedures developed by Horton and co-workers (3) and Counsell *et al.* (8). The general method is illustrated by the preparation of *p,p'*-dinitrodiphenylacetaldehyde (*3g*).

Under an atmosphere of dry nitrogen gas, 57% sodium hydride dispersion (8.0 g, 0.173 mol) was added to a slurry of *p,p'*-dinitrobenzophenone (18) (21.8 g, 0.08 mol) in ethyl chloroacetate (150 ml) over a period of 4 h. The slow addition was accompanied by a gradual increase in temperature. About half way through the addition, gentle boiling was accompanied by a darkening of the color of the solution. After the exothermic reaction subsided, the remaining sodium hydride was added slowly. After the addition, the dark solution was heated for 16 h at 45° and then at 100° for 1 h. The cool reaction mixture was poured into ice-cold 15% aqueous hydrochloric acid (1 l). Ether (500 ml) was added to the mixture and this was stirred thoroughly. The solid which separated was collected by filtration, washed with cold ether and water, and air dried. Recrystallization of this solid from acetone–water (Norit) afforded 12.2 g (42%) of ethyl β,β-di(*p*-nitrophenyl)glycidate as light yellow crystals: m.p. 120–122° (analytical sample m.p. 125–126°); n.m.r. ($CDCl_3$) τ 2.06 (m, 8, Ar*H*), 5.94 (s, 1, C*H*), 5.95 (q, 2, CH_2, J = 7.0 Hz), and 8.94 (t, 3, CH_3, J = 7.0 Hz).

Anal. Calcd. for $C_{17}H_{14}N_2O_7$: C, 56.98; H, 3.93. Found: C, 56.94; H, 3.84.

Ethyl β,β-di(*p*-nitrophenyl)glycidate (6.0 g, 0.016 mol) and sodium carbonate (4.5 g, 0.043 mol) were stirred and refluxed in water (500 ml) for 30 min. The mixture was cooled and filtered. The filtrate was acidified with dilute hydrochloric acid and the resulting precipitate collected by filtration. After washing with water and 95% ethanol and drying, di(*p*-nitrophenyl)glycidic acid (3.0 g, 50%) melted with loss of carbon dioxide at 200–210°.

Under aspirator pressure, di(*p*-nitrophenyl)glycidic acid (2.0 g, 0.006 mol) was heated at 190–210° for 15 min. As the acid melted, evolution of carbon dioxide was vigorous and gradually subsided. The dark oil soon hardened and melted at 65–75°. Extraction of the oil into ether afforded 1.2 g (70%) of *p,p'*-dinitrodiphenylacetaldehyde as orange crystals after drying and evaporation of the ethereal extract. This compound formed hydration products very rapidly and, consequently, had to be used as such for subsequent reactions. Its 2,4-dinitrophenylhydrazone derivative was prepared in ethanol and recrystallized from ethyl acetate – petroleum ether (b.p. 30–60°) and melted at 190–193°.

Physical and analytical data for the substituted diphenylacetaldehydes *3a–h* and their 2,4-dinitrophenylhydrazone (2,4-DNP) derivatives are summarized in Table 2.

Preparation of Substituted Diphenylacetaldehyde Ethylene Glycol Cyclic Acetals **1***a–h*

The general procedure is exemplified by the synthesis of *p,p'*-difluorodiphenylacetaldehyde ethylene glycol cyclic acetal. *p,p'*-Difluorodiphenylacetaldehyde (2.3 g, 0.01 mol), dry ethylene glycol (4 ml), and *p*-toluenesulfonic acid (0.5 g) were refluxed in benzene (100 ml) using a Dean-Stark water trap for 8 h. The solvent was removed *in vacuo* and ice-water (100 ml) was added to the residue. The resulting precipitate was collected by filtration, washed with water, and air dried. Recrystallization of this solid from methanol furnished 1.2 g (43%) of **1***f* as colorless crystals, m.p. 76–78°.

Physical and analytical data for the substituted diphenylacetaldehyde ethylene glycol cyclic acetals **1***a–h* are shown in Table 3. The n.m.r. data for these compounds are tabulated in Table 4.

Product Study

The following general procedure was used for the hydrolysis of **1***a–h* in 20% aqueous hydrochloric acid. Aqueous 20% hydrochloric acid was prepared from 40 ml concentrated hydrochloric acid and 30 ml water. The acetal (1.0 g) was refluxed in 20% aqueous hydrochloric acid (50 ml) for 6 h. The cooled mixture was extracted with chloroform (3 × 35 ml) and the combined extracts were washed with water before drying over sodium sulfate. Filtration and evaporation of the extract left oils which were subjected to g.l.c. analyses. Retention times were compared with authentic samples as well as comparisons of their i.r. and n.m.r. spectras. G.l.c. analyses data are presented in Table 1.

The authors wish to thank Dr. G. Wellman for his assistance on this problem.

Evidence Against a Hydrogen Abstraction Mechanism in the Photorearrangement of Azoxybenzene to 2-Hydroxyazobenzene[1]

DAVID J. W. GOON, N. G. MURRAY, JEAN-PIERRE SCHOCH, AND N. J. BUNCE[2]
Department of Chemistry, University of Guelph, Guelph, Ontario

Received January 22, 1973

In an attempt to distinguish between ionic and free radical mechanisms for the photorearrangement of azoxybenzene to 2-hydroxyazobenzene, aromatic azoxycompounds carrying C—H functions *ortho* to the azoxy linkage have been prepared and irradiated. The failure of these weaker C—H bonds to divert the reaction from its normal course argues against a hydrogen abstraction – hydroxyl transfer mechanism. This conclusion is supported by the observation of a 30-fold increase in quantum yield for 2-hydroxyazobenzene formation on changing from a non-polar to a polar solvent and by the kinetic deuterium isotope effect, which is too small for the primary isotope effect required by the abstraction mechanism. It is concluded that the experimental observations to date may most easily be accommodated in the route originally proposed by Badger and Buttery, where the rearrangement is seen as a substitution by oxygen at the *ortho* ring carbon.

Afin de distinguer entre un mécanisme à caractère ionique et un mécanisme impliquant des radicaux libres lors du photoréarrangement de l'azoxybenzène en hydroxy-2 azobenzène, on a préparé et irradié des composés "azoxy" aromatiques comportant des fonctions C—H en position *ortho* du lien azoxy. Ces liens C—H plus faibles s'étant révélés incapables de dévier la réaction de son cours normal, on en conclut alors qu'un mécanisme impliquant l'enlèvement d'un hydrogène puis transfert du groupe OH ne saurait être considéré. Cette conclusion est d'ailleurs en accord avec l'observation selon laquelle une augmentation (par un facteur de 30) du rendement quantique est enregistrée lors de la formation de l'hydroxy-2 azobenzène lorsque l'on passe d'un solvant non-polaire à un solvant polaire, de même qu'elle est en accord avec l'effet isotopique causé par le deutérium trop faible pour être un effet isotopique primaire qui serait normal pour le mécanisme impliquant l'enlèvement d'un hydrogène. On en conclut alors que les données expérimentales, jusqu'à présent, conduisent au mécanisme proposé à l'origine par Badger et Buttery selon lequel le réarrangement est le résultat d'une substitution par l'oxygène au carbone du cycle en position *ortho*. [Traduit par le journal]

Can. J. Chem., 51, 3827 (1973)

The instability of aromatic azoxy compounds to light has long been recognized as being due to to their transformation into *o*-hydroxyazo compounds (1). The rearrangement apparently proceeds from the $^1\pi,\pi^*$ excited state of the azoxy compound, since Tanikaga *et al.* have shown (2) that no n,π^* band appears in the absorption spectrum of azoxybenzene and that deliberate excitation of the triplet state by photosensitization causes photoreduction as well as oxygen migration. Previously, Badger and Buttery (3) had found that unsymmetrical azoxybenzenes such as **1** rearrange exclusively

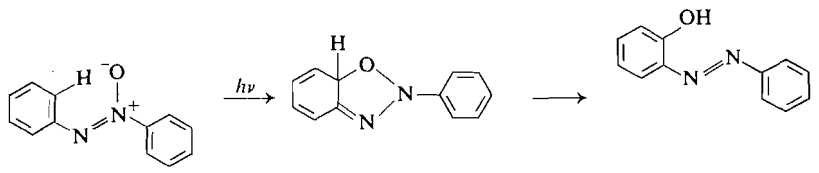
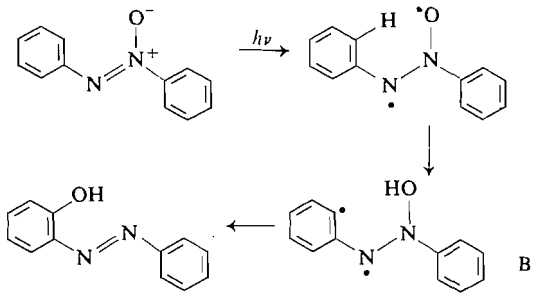


SCHEME 1

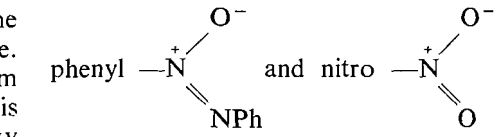
to **2**, where the azoxy oxygen migrates to the aromatic ring farther from its point of departure. They proposed the intramolecular mechanism of Scheme 1, in which the rearrangement is initiated by nucleophilic attack of the azoxy oxygen on the appropriate ring carbon, giving the cyclic intermediate **A**. The intramolecular character of the reaction and the direction of oxygen migration have both been confirmed by ^{18}O (4) and ^{15}N (5) isotopic labelling experiments. All of this work has been reviewed recently (6).

Although the Badger and Buttery mechanism has been widely accepted, to date no other experiments have been carried out to support it and in one study (7), Oae *et al.* have argued that a radical mechanism for the photorearrangement better explains the experimental facts. One possibility for such a mechanism is a radical analog of Scheme 1, although it is questionable whether any distinction can be drawn between an ionic and a radical Scheme 1, since an excited state of azoxybenzene inevitably carries unpaired electrons. Another is the hydrogen abstraction pathway of Scheme 2, in which



SCHEME 2

homolytic hydrogen abstraction from the conveniently situated *ortho* position of the distant aromatic ring is followed by hydroxyl transfer. This route is similar to the mechanism widely accepted (8) for oxygen migration in the photorearrangement of *o*-nitrobenzaldehyde to *o*-nitrosobenzoic acid and is attractive in view of the electronic similarities between the azoxy-



phenyl and nitro groups.

In addition, the crystal structure of an azoxybenzene derivative, 4,4′-azoxyanisole, shows that at least in the solid state, the azoxy group and the distant benzene ring are essentially coplanar, with the oxygen and *o*-hydrogen separated by only 2.3 Å (9). Assuming a comparable excited state geometry, this should facilitate a hydrogen abstraction mechanism.

The purpose of the present study has been to choose between these alternative modes of rearrangement on experimental grounds. We believe that the results presented here allow us to exclude the abstraction mechanism, but we are unable on the present evidence to confirm all the details of the Badger and Buttery mechanism (Scheme 1).

Results and Discussion

In the mechanism of Scheme 2, oxygen migration is preceded by homolytic hydrogen abstraction by oxygen. The ease of reaction should thus parallel the weakness of the C—H bond to be broken, as in typical hydrogen abstractions by free radicals (10), in the photochemical Norrish type II elimination of alkyl ketones (11), and in the intermolecular photoreduction of benzophenone by hydrogen-donating solvents (12). We therefore postulated that if there were available with comparable geometry a C—H bond weaker than the bonds to the distant *ortho* hydrogens, then the more weakly bound hydrogen should be abstracted preferentially. This would divert the arrangement from its usual course. We sought to study systems with the features of **3**, where both the distant *ortho* hydrogen and the benzylic hydrogen are separated from the azoxy oxygen by four intervening atoms. Abstraction of the *ortho* hydrogen gives **4**, the normal product, whereas abstraction of the

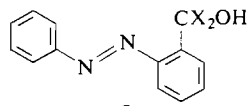
4

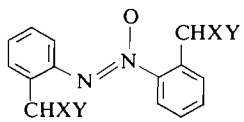


5

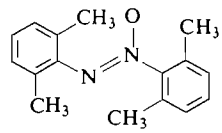
benzylic hydrogen should lead to oxygen insertion at the benzylic site, *viz.* **5**.

Azoxybenzenes with Benzylic Hydrogens: Synthesis

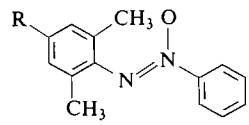
The compounds selected for study were **6**–**11**, all of which were potentially able to undergo both normal and abnormal modes of rearrangement, and **12** and **13** in which the normal rearrangement pathway was blocked.



6 X = Y = H
7 X = Y = CH_3
8 X = H; Y = C_6H_5
9 X = Y = OCH_3
10 X = Y = OC_2H_5
11 XY = O
15 XY = —OCH_2CH_2O—

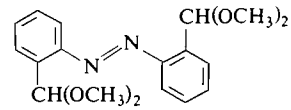


12



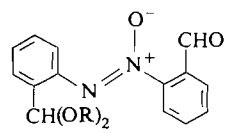
13 R = H
14 R = CH_3

With the exception of the unsymmetrical **13**, which was obtained by oxidation[3] of the condensation product of nitrosobenzene and 2,6-dimethylaniline, all the azoxy compounds were obtained by reduction of appropriate nitro compounds. Most of the nitro compounds were reduced using CH_3OH–NaOH (14), CH_3OH–Na (15), or by metallic thallium (16) giving the azoxy compound directly. For the tetramethyl compound **12**, hitherto difficult to prepare (17), lithium aluminum hydride reduction to the azo compound was followed by peracid oxidation.[4] An attempt to use this route to prepare **9** from *o*-nitrobenzaldehyde dimethylacetal failed because the metal hydride cleaved the acetal function, giving a variety of products including 2,2′-azotoluene but very little of the desired azo compound **16**.

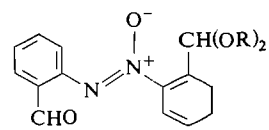


16

A major synthetic problem was the liberation of the azoxybenzaldehyde **11** from its acetals. Carefully controlled hydrolysis of **10** gave the best yield of **11**, but even this was modest (25%); too-vigorous hydrolysis led to destruction of **11** and formation of colorless condensation products as noted previously (19). Very mild conditions gave incompletely hydrolyzed products identified as 2,2′-azoxybenzaldehyde 2-dialkyl acetals; there is still some doubt as to whether these should be represented as **17** or **18**, although we favor **17** slightly. No conclusions



17



18

could be drawn about the position of the azoxy oxygen by comparing the chemical shifts (recorded in the experimental section) of —CHO and —$CH(OCH_3)_2$ in **17** or **18** (R = CH_3) with those of model compounds **9**, **11**, **16**, and 3-hydroxy-2,2′-azobenzaldehyde bisdimethyl acetal (**27**). Mass spectrometry has been used to differentiate between the isomers of simple unsymmetrical azoxy compounds (20), since C—N cleavage occurs more abundantly on the side adjacent to the azoxy oxygen. Although our azoxybenzaldehyde derivatives undergo much more complex fragmentation than the compounds previously studied, the greater abundance of $[C_6H_4CHO]^+$ over $[C_6H_4CH(OR)_2]^+$ lends some support to structure **17** over **18**. In addition, photolysis of small quantities of **17** (R = CH_3 and C_2H_5) did not give hydroxyazo

[3]Oxidation of the 2,6-disubstituted azobenzene gives almost exclusively 2,6-dimethyl-*NNO*-azoxybenzene (**13**) because of steric hindrance (13).

[4]Since completion of this work, the preparation of **12** by oxidation of 2,6-dimethylaniline with AgO has been reported (18).

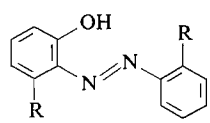
compounds, nor indeed any tractable products; as shown below, this behavior is similar to that of **11**, rather than of **9** and **10** which photorearrange normally. This also favors structure **17** rather than **18**, since **17**, like **11**, has the CHO and N—O functions on adjacent carbon atoms.

Azoxybenzenes with Benzylic Hydrogens: Photolysis

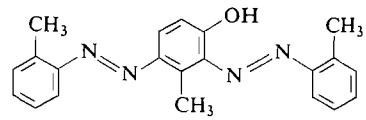
In the first series of experiments, compounds **6–11** were irradiated in benzene solution using Pyrex equipment ($\lambda > 300$ nm). From compounds **6–10** no abnormal products of structure **5** were obtained; instead the expected 2-hydroxyazobenzene was the sole or major product. 2,2′-Azoxybenzaldehyde (**11**) behaved differently; it photolyzed more rapidly and gave a derivative of the abnormal rearrangement product but no hydroxyazo compound. The behavior of compounds **6–10** seems to be inconsistent with a rearrangement pathway initiated by hydrogen abstraction since the alternate C—H bonds available were in all cases weaker than an aromatic C—H bond. In contrast, typical free radical hydrogen abstractors are very unreactive towards aromatic hydrogens (21) but abstract readily from the appropriate positions of toluenes (21), cumenes (21), diphenylmethanes (21), acetals (22), and aldehydes (23). In the following paragraphs the results of the photolyses are examined in more detail.

Photolysis of the dimethyl compound **6** gave a different product mixture according to the conditions. Direct photolysis in dilute benzene solution gave the normal product **19**; using a more concentrated solution, **19** was accompanied by a new photoproduct, a deep red



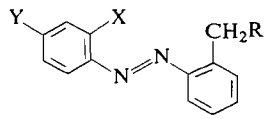
19 R = CH_3
23 R = $CH(CH_3)_2$
24 R = $CH_2C_6H_5$
27 R = $CH(OCH_3)_2$
28 R = $CH(OC_2H_5)_2$

compound whose mass spectrum (M^+ 344) and n.m.r. spectrum indicated a structure with three tolyl rings, one of them hydroxyl substituted. An identical substance was obtained by the action of *o*-toluenediazonium chloride on **19**; since diazonium couplings invariably take place at a free *para* position (24), this suggests **20** as the structure of the new compound.



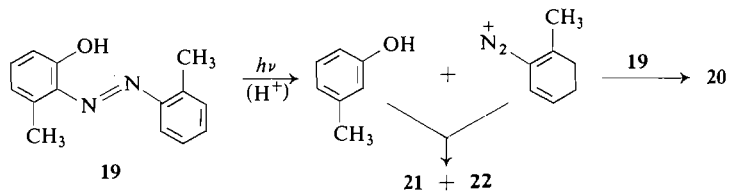
20

An irradiation of **6** was carried out in the presence of benzophenone to determine whether oxygen migration into the side chain could be induced under conditions known (2) to favor hydrogen abstraction. Under these conditions the reaction was much slower but no insertion into the side chain was observed. Instead, the normal product **19** was accompanied by the isomer **21**, previously obtained by Lewis and Reiss (25) as a by-product of the rearrangement of **6** in ethanol. Lewis and Reiss also obtained another isomeric photoproduct, **22**, but we did not observe this in our reactions in benzene.



21 R = H; X = OH; Y = CH_3
22 R = H; X = CH_3; Y = OH
25 R = C_6H_5; X = OH; Y = $CH_2C_6H_5$
26 R = C_6H_5; X = $CH_2C_6H_5$; Y = OH

These abnormal products **20–22** look as though they might arise through the coupling of an *o*-toluenediazonium cation with an appropriate phenol. Lewis and Reiss (25) considered the possibility of fragmentation of **19** on photolysis giving the by-products by the mechanism of Scheme 3 but had to reject this proposal on the grounds that **19** is photostable, an observation which we confirm. In addition, photolysis of azobenzene in a mixture of benzene and phenol gives neither *p*-hydroxyazobenzene (from attack of a benzenediazonium radical or ion on phenol) nor biphenyl (from the action of a phenyl radical on benzene), indicating that C—N bond fission did not occur; indeed, the available evidence (26) suggests that aromatic azo compounds cleave at the N—N rather than the C—N bonds upon irradiation. We currently believe that diazonium ion intermediates are involved as intermediates in the formation of these side products **20–22** but that they are the result of fragmentation of a precursor of **19**



SCHEME 3

rather than of **19** itself. This work is still in progress and will be published elsewhere.

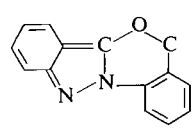
Azoxytoluene **6** has also been photolyzed in quartz equipment in the presence of benzophenone using 2-propanol as the solvent. Under these conditions photoreduction to 2,2′-azotoluene accompanied the photorearrangement, thereby demonstrating that hydrogen abstraction was occurring. Even so, no migration of oxygen into the side chain was observed, implying that hydrogen abstraction was wholly intermolecular (from the solvent).

It was thus concluded that oxygen migration to a side chain methyl group is less facile than insertion into the benzylic bond, despite the higher bond dissociation energy of the latter (27). This conclusion is confirmed by the results of photolysis of **12** and **13**, where the normal rearrangement cannot occur. These compounds do not undergo benzylic insertion; instead they are very photostable, being slowly converted to tar but not to tractable products. A parallel observation has been made previously (25) regarding **14** which suffers no change in electronic spectrum on irradiation. We observed reaction only in **13**, which underwent *cis–trans* photoisomerization.

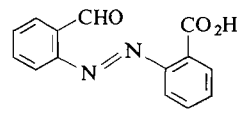
Photolysis of **7** proceeded normally, giving only the expected rearrangement product **23** and a compound believed to be the *cis* isomer of **7** because it reverted to **7** on work-up. A variety of low yield photoproducts was obtained on illumination of azoxydiphenylmethane **8**; of these, three were isolated in quantities sufficient to permit a partial characterization. They are believed to be **24–26**, the analogs of **19**, **21**, and **22** formed on irradiation of **6**.

Irradiation of the acetals **9** and **10** gave the *o*-hydroxyazo compounds, **27** and **28** respectively, together with numerous other low yield products which were incompletely characterized. The products from **9**, which we were unable to purify, had n.m.r. spectra with resonances typical of —CHO and —CO_2CH_3 groups as well as OCH_3, OH, and aromatic C—H linkages, suggesting the possibility of photofragmentation of the acetal group (CHO) and oxygen insertion into the benzylic side chain (CO_2CH_3). In the presence of benzophenone, none of the usual product **27** could be obtained from **9**, but compounds with CHO and CO_2CH_3 groups in their n.m.r. spectra were still observed.

2,2′-Azoxybenzaldehyde photolyzed faster than the other compounds but gave no *o*-hydroxyazo compound. Instead, there was obtained the lactone **29**, a known (19, 28) transformation product of 2′-formylphenylazo-2-benzoic acid (**30**), the expected result of oxygen migration into the benzaldehyde group. While **11** thus



29



30

undergoes the abnormal rather than the normal mode of oxygen migration on photolysis, the greater rapidity of reaction of **11** than of **6–10** and the structural similarity between **11** and *o*-nitrobenzaldehyde, which also photorearranges efficiently (8), suggests the possibility of a change of mechanism in this case.

From this series of experiments we may conclude that while oxygen migration to a benzylic site is possible, as in **11**, or cannot be excluded, as in **9** and **10**, it does not take place as readily as would be predicted on the basis of the hydrogen abstraction mechanism of Scheme 2. Direct competition between abstraction of an aromatic hydrogen and a more weakly bound benzylic hydrogen should have resulted in preferential abstraction at the benzylic site. Scheme 1 is thus more consistent with these observations than Scheme 2, although we must add this reservation: steric factors might make attainment of the transition state for benzylic abstraction less facile than that for aromatic C—H removal, causing the weak benzylic bonds

TABLE 1. Variation with solvent in the quantum yield and deuterium isotope effect for 2-hydroxyazobenzene formation on photolysis of azoxybenzene and its d_{10} analog

Solvent	Φ		k_2[e]	Φ^H/Φ^D
	Relative	Absolute		
95% ethanol	1.00[a]	0.22[c]	1.00[a]	1.26±0.07(6)
100% ethanol	0.875±0.03(8)[b]	0.19	0.84	1.27±0.10(8)[d]
Methanol	0.761±0.04(9)	0.16	0.71	0.98±0.05(4)
Acetic acid	0.998±0.08(7)	0.22	0.99	—
Acetonitrile	0.509±0.03(7)	0.11	0.45	—
10% aqueous acetonitrile	0.764±0.02(7)	0.17	0.72	—
Benzene	0.170±0.01(8)	0.037	0.14	1.25±0.15(6)
Cyclohexane	0.038±0.004(4)	0.008	0.03	—

[a]Assumed; data are for appearance of 2-hydroxyazobenzene.
[b]Number of determinations in parentheses; ± values are statistical deviations (58).
[c]Measured directly; other values calculated from relative Φ.
[d]Data for disappearance of azoxybenzene were 1.37 ± 0.15 (2).
[e]Refers only to mechanism of Scheme 2; see text.

of **6**–**10** and of **12** to be immune towards attack. This kind of argument has been made by Gore and Wheeler (29), who have interpreted anomalies in the electronic spectra of 2,2′-disubstituted azoxybenzenes in terms of steric hindrance to coplanarity. On the other hand, Tanikaga (30) in his study of the *normal* azoxybenzene photorearrangement has presented evidence that steric factors are unimportant in his systems. To try to gain information about the possible influence of steric factors in the azoxybenzene photorearrangement, we carried out a number of experiments using azoxybenzene itself, where steric factors should be unimportant.

Solvent Effects

In the first series of these experiments, the rate of photorearrangement of azoxybenzene was compared in eight solvents of differing polarity. Relative and absolute quantum yields for 2-hydroxyazobenzene formation are given in Table 1. To try to interpret the results obtained, the following analysis was used. Schemes 1 and 2 may both be abbreviated as in eq. 1 in terms of an excited state of azoxybenzene A* and an intermediate I which yields product. Assuming

[1] $$A_0 \underset{k_1}{\overset{h\nu}{\rightleftharpoons}} A^* \xrightarrow{k_2} I \begin{cases} \xrightarrow{k_3} \text{Product} \\ \xrightarrow{k_4} A_0 \end{cases}$$

steady states of A* and I, the quantum yield Φ for product formation is given in eq. 2.

[2] $$\Phi = k_2k_3/(k_3 + k_4)(k_1 + k_2)$$

This expression only simplifies significantly if $k_3 \gg k_4$ when

[2a] $$\Phi \simeq k_2/(k_1 + k_2) \text{ or } k_2 = k_1\Phi/(1 - \Phi)$$

If the abstraction mechanism, Scheme 2, were to represent the reaction pathway, it could be shown that k_3 would indeed be greater than k_4 by the following argument. Since proton transfer reactions are very rapid, it is likely that intermediate B of Scheme 2 would have a long enough lifetime to exchange its proton with the medium; if it now returns to azoxybenzene, the hydrogen atoms of the medium should be incorporated into the starting material. Photolyses of azoxybenzene in CH_3CN–D_2O and of azoxybenzene-d_{10} in ethanol gave no incorporation of the alternate hydrogen isotope into the starting azoxy compound when the irradiations were carried out to partial conversion and the starting material recovered. Thus if Scheme 2 is the mechanism, $k_3 \gg k_4$, and the rates of the abstraction steps (k_2) are proportional to $\Phi/(1 - \Phi)$, assuming that the fluorescence lifetime of azoxybenzene ($1/k_1$) is independent of solvent; this is probably true within the approximations of the above argument (31).

The relative quantum yields of Table 1 thus approximate to relative rate constants (k_2) as applied to Scheme 2. They cannot be applied to Scheme 1, since we have no knowledge of the relative magnitude of k_3 and k_4 if this mechanism is operating. However, the data of Table 1 make it unlikely that Scheme 2 is the proper mechanism, in that a factor of about 30 separates the

quantum yields for cyclohexane and 95% ethanol. This is suggestive of a polar mechanism. Polar media may either increase the rate of formation of the intermediate, or they must promote the breakdown of the intermediate to product rather than to A_0.

Deuterium Isotope Effect

The hydrogen abstraction pathway of Scheme 2 ought to show a moderately large primary deuterium isotope effect for the rate-limiting removal of the strongly bound aromatic hydrogen. Relative quantum yields Φ^H/Φ^D for the rearrangement of azoxybenzene-d_0 and -d_{10} were determined in four different solvents and are reported in Table 1; in each case the isotope effect was very small.

The problem in interpreting this isotope effect is that we may not in this case simply assume that the fluorescent lifetimes of the d_0 and d_{10} compounds will be equal, since the *triplet* excited state lifetimes of aromatic molecules are now well known to be increased by up to a power of 10 by perdeuteration (32). Several theories have been advanced to account for this effect (32), which is known to be due to changes in the rates of radiationless return to the ground state in the protio and deuterio molecules. One possibility (33) is a decrease in the Franck–Condon factor for the deuterio molecule, since T_1 has to overlap with a higher vibrational level of S_0 in the deuterio than in the protio molecule, due to C—D vibrational quanta being smaller than those of C—H. This reduces the probability of radiationless transition and increases the triplet lifetime. Similar considerations should apply to radiationless decay from singlet excited states but less is known about the magnitude of the effect for lack of experimental data. Ideally one would like to measure the fluorescence lifetimes of azoxybenzene-d_0 and -d_{10} experimentally. An attempt to do this was made in collaboration with Dr. W. R. Ware and Mr. T. Nemzek of the University of Western Ontario, using the single photon counting technique, but unfortunately, azoxybenzene was found to be non-fluorescent, an upper limit on Φ_F being about 10^{-4}.

Studies on the aromatic hydrocarbons pyrene and coronene and their perdeuterated analogs have indicated that deuteration has very little effect on the fluorescence lifetimes of these molecules either at 77 °K or at room temperature (34). In private correspondence, Dr. J. L. Kropp of TRW Inc. has suggested that the change in lifetime would not normally exceed ±20% on deuteration. This may not be true of our system however, where almost 80% of all excited singlet molecules are disappearing by non-radiative and non-photochemical processes.

To the extent that we can assume that there is no large deuterium isotope effect on the rate constants for radiationless processes, we believe that the observed small isotope effect is not the result of superimposing a large kinetic isotope effect upon a longer singlet lifetime in the d_{10} system. Taking the mean value from Table 1 of $\Phi^H/\Phi^D = 1.22$, a 20% spread in either direction gives us a likely range of $k^H/k^D = 0.98$–1.46, which is smaller than would have been expected for a primary effect for abstraction from the strong aryl C—H bond. For example, abstraction by oxygen from saturated sites in the type II reaction of aralkyl ketones displays $k^H/k^D = 4.8$ (35), comparable with the isotope effects observed in wholly aliphatic ketones (36) and comparable also with hydrogen abstraction by oxygen in the *t*-butoxy radical (37). For the isotope effect exhibited in the azoxybenzene photorearrangement to be primary, the azoxy oxygen would have to be at least as reactive a hydrogen abstractor as the chlorine atom and far more so than typical oxyradicals (37). Taken together with the evidence already presented, this small isotope effect excludes Scheme 2 as a likely mechanism.[5]

Scheme 1 could accommodate the observed isotope effect in one of two ways: first, if the removal of hydrogen from the Badger and Buttery intermediate A rather than the formation of the intermediate is the slow step in the reaction; second, if the formation of the intermediate is the slow step but the isotope effect being observed is secondary rather than primary. This latter explanation seems less likely in that conversion of sp^2 centers to sp^3 is usually accompanied by an inverse isotope effect $k^H < k^D$ (38), although both normal and inverse secondary deuterium isotope effects have been

[5]The small isotope effect cannot be the result of hydrogen abstraction being either non-rate-determining or reversible ($k_4 > k_3$) from the lack of isotopic exchange in the experiments of the previous section.

observed in electrophilic aromatic substitution (39). At present, we cannot distinguish these possibilities.

Conclusions

Taken together, we believe that the experiments described constitute strong evidence against a hydrogen abstraction mechanism for the azoxybenzene photorearrangement. First, the benzylic C—H bonds of the 2,2′-disubstituted azoxybenzenes are unreactive despite the lower bond dissociation energies of benzylic *vs.* aryl C—H bonds. Second, the rate of reaction increases in polar solvents, suggestive of a polar rather than a radical pathway. Third, the deuterium isotope effect is far too small to be associated with a primary isotope effect for abstraction of the strongly bound aryl hydrogen.

In addition, a $^1\pi,\pi^*$ state is responsible for the azoxybenzene photorearrangement (2), whereas most photochemical hydrogen abstractions *e.g.* of ketones (40) or nitrocompounds (41) proceed from n,π^* states. Although exceptions are known (42, 43), this behavior is suggestive of a mechanism not involving hydrogen abstraction. Lastly, we have found that the photorearrangement of azoxybenzene in styrene solution does not cause polymerization of the styrene, indicating that free radical intermediates are not present.

On all these grounds, we believe that a mechanism involving aromatic substitution, as proposed by Badger and Buttery (3) better accommodates our experimental data than a hydrogen abstraction pathway. A remaining problem is whether the azoxy oxygen attacking the aromatic ring is electron rich, as originally proposed by Badger and Buttery, or electron poor, since the azo linkage is known (44) to be able to stabilize the charge of the intermediates for either nucleophilic or electrophilic substitution at the *ortho* and *para* positions. The literature is unhelpful on the effect of polar substituents on the rate of photorearrangement; Tanikaga (30) found that electron donating or withdrawing substituents at the 4,4′-positions of azoxybenzene alike reduced the efficiency of oxygen migration. We are currently investigating this aspect of the problem and hope to report our findings in a later paper.

Experimental

Irradiations were carried out in an immersion well apparatus, using a Hanovia Model 679A 450 W mercury arc and a cooling well constructed of Pyrex glass to filter out short wave ($\lambda < 300$ nm) radiation. The outer jacket, which was equipped with a reflux condenser, had a volume of 300 ml with the cooling well in place and was constructed with a flat base to permit agitation of the solution by means of a magnetic stirrer. For irradiations carried out in the absence of oxygen, a similar outer vessel was used except that agitation was provided by means of a nitrogen flush through a porosity C sintered glass disc which was positioned near the base of the apparatus, an inlet tube for the nitrogen being sealed into the outer wall of the jacket. Relative rate and quantum yield experiments used the same source and cooling jacket, and were run in corked Pyrex ampoules in batches of eight using a Rayonet "Merry-go-round" apparatus.

Chromatographic separations on columns were run using standard alumina and silica gel adsorbents; preparative t.l.c. was run on 20 × 40 cm plates using a Brinkmann "sandwich" style apparatus or on 20 cm × 1 m plates using a Shandon preparative layer apparatus. The adsorbent was E. Merck Type 7747 silica gel PF_{254} incorporating a fluorescing agent to locate the bands; the developing solvent is indicated in parentheses in the individual procedures. Analytical t.l.c. plates were prepared using the same silica gel adsorbent and occasionally also using J. T. Baker Type 9F alumina. After separation of the reaction mixtures by preparative t.l.c., the bands were scraped off and extracted using a Soxhlet extractor for further purification. For identification of the 2-hydroxyazo compounds, use was made of the characteristic (45) mass spectral fragmentation pattern of azo compounds ($ArN{=}NAr' \rightarrow Ar^+, ArN_2^+, Ar'^+, Ar'N_2^+$) and the well-known (46) low field n.m.r. resonance exhibited by a hydroxyl group situated *ortho* to an azo linkage. Microanalyses on purified samples were carried out either by Mr. H. S. McKinnon of this department or by Dr. C. Daesslé, Montreal.

Solvents were reagent grade materials and were dried and distilled before use. Petroleum ether, b.p. 30–60°, was fractionally distilled to remove high boiling residues. Melting points were run on a Mel-Temp apparatus and are uncorrected. Spectroscopic instruments used included a Pye Unicam SP800 u.v.-visible, Beckman IR5A i.r., Varian Associates A60-A n.m.r., and Varian MAT model CH7 mass spectrometer, which was operated at 70 eV ionizing voltage.

*2,2′-Azoxytoluene (**6**)*

2-Nitrotoluene (British Drug Houses, 0.5 mol) was added over a period of 40 min to a mixture of sodium hydroxide (1 mol) and methanol (100 ml) at reflux. The mixture was heated to reflux for 1 h, cooled, and poured into water (250 ml). The solids were collected by suction, dissolved in benzene, and passed through a 2.5 × 16 cm column of alumina, using benzene as the eluent. Recrystallization from methanol of the material obtained gave 2,2′-azoxytoluene (18 g, 32%): m.p. 57.5–58° (lit. (47) 59°); n.m.r. (CCl_4) δ 2.28, 2.42 (2 singlets, 2 CH_3 groups), 7.0–8.1 (multiplet, 8 ArH).

*Irradiation of **6***

(*a*) A solution of **6** (0.149 g) in benzene (300 ml) was irradiated for 35 min. Evaporation of the solvent and resolution of the residue by preparative t.l.c. (40% benzene in petroleum ether) gave 0.031 g of red solid:

m.p. 70–80°; m.p. after recrystallization from ethanol 92–93.5° (lit. (25) for 2-hydroxy-6,2′-dimethylazobenzene 97°); n.m.r. ($CDCl_3$) δ 2.7 and 2.8 (2 singlets, 2 CH_3 groups), 6.8–8.2 (multiplet, 7 ArH), 14.0 (singlet, OH).

(*b*) A solution of **6** (0.20 g) in benzene (200 ml) was irradiated for 30 min. Evaporation of the solvent and resolution by preparative t.l.c. gave two bands. The more mobile band (97 mg) was **19**, red needles from methanol: m.p. 95–96°; u.v. (EtOH) λ_{max} 395 (sh) (ε 10 000), 335 (21 000), and 240 nm (8500).

Anal. Calcd. for $C_{14}H_{14}N_2O$: N, 12.4. Found: N, 12.4.

The less mobile band (12 mg), a dark brown solid, m.p. 167–169°, was identified as 3-methyl-2,4-bis(*o*-tolylazo)phenol (**20**), having i.r., n.m.r., and mass spectra identical to authentic **20**, prepared in 48% yield by the action of excess *o*-toluenedizaonium chloride on **19** (0.04 g). Data obtained for authentic sample of **20**: m.p. 168–171°; n.m.r. ($CDCl_3$) δ 2.61, 2.70, 3.12 (3 singlets, 3 CH_3 groups), 6.6–8.0 (multiplet, 10 ArH), 14.65 (singlet, OH); u.v. (EtOH) λ_{max} 420 (sh) (ε 5900), 350 (32 000), and 235 nm (11 000); mass spectrum M^+ 344, other prominent peaks at *m/e* 243, 215, 119, 91.

Anal. Calcd. for $C_{21}H_{20}N_4O$: N, 16.3. Found: N, 16.7.

(*c*) Sensitized irradiation: a solution **6** (0.998 g) and benzophenone (4.3 g) in benzene (260 ml) was degassed under reflux using oxygen-free nitrogen,[6] then irradiated for 35 min under nitrogen. The solvent was removed, the residue taken up in ethanol, and a solution of 2,4-dinitrophenylhydrazine (4.7 g) in H_2SO_4–H_2O–EtOH was added. Filtration of the cooled solution afforded benzophenone 2,4-dinitrophenylhydrazone (9.0 g), m.p. 229–230° (lit. (48) 231°). Neutralization of the excess acid, drying, and evaporation afforded a residue which was resolved by preparative t.l.c. (20% benzene in petroleum ether) to give four bands.

Band 1 (13 mg) would not crystallize and was discarded. Band 2 (87 mg), a mixture, was red crystals, m.p. 100–102°, and was further resolved by preparative t.l.c. (petroleum ether) to give two major bands, 2A and 2B. Band 2A (21 mg) had m.p. 86–88°, and on recrystallization from ethanol was identified as **19**: m.p. 94.5–95°; n.m.r. (CCl_4) δ 2.66 and 2.70 (2 singlets, 2 CH_3 groups), 6.7–8.0 (multiplet, 7 ArH), 13.5 (singlet, OH); mass spectrum *m/e* (relative intensity) 226 (M^+) (37), 135 (24), 107 (69), 91 (100). Band 2B (30 mg) was obtained as fine orange needles from ethanol: m.p. 123–124° (lit. (25) for 2-hydroxy-4,2′-dimethylazobenzene (**21**), 126°); n.m.r. (CCl_4) δ 2.36 and 2.60 (2 singlets, 2 CH_3 groups), 6.7–8.0 (multiplet, 7 ArH), 11.1 (singlet, OH); mass spectrum *m/e* (relative intensity) 226 (M^+) (47), 135 (31), 107 (100), 91 (91).

Band 3 (10 mg) was a brown semi-solid. Recrystallization from ethanol gave 1 mg, m.p. 184–185°. This compound is possibly **20**; the mass spectrum showed a probable molecular ion near *m/e* 340.

Band 4 (538 mg) was an orange solid, m.p. 39–43°, and had the n.m.r. spectrum of the starting material. Recrystallization from ethanol gave recovered **6**, 480 mg, m.p. 56–57.5°.

(*d*) Sensitized irradiation using an unfiltered mercury arc: a solution of **6** (0.50 g), and benzophenone (1.0 g) in 2-propanol (300 ml) was degassed and irradiated for 20 min. Resolution of the evaporated reaction mixture by t.l.c. gave 2,2′-azotoluene (107 mg), m.p. 52–54° (lit. (49) 55°); M^+ 210, azoxytoluene (30 mg, estimated by u.v., λ_{max} 312 nm, ε 11 000); and the hydroxyazo compound **19** (34 mg, estimated by u.v.).

Photolysis of ***19***

A solution of **19** (26 mg) in benzene (2.0 ml) was irradiated for 6 h in a 5 ml Pyrex flask equipped with reflux condenser, using an external source. Analytical t.l.c. showed only one spot in the reaction mixture, and passage of the reaction mixture through a short column of silica gel, eluting with benzene, allowed recovery of **19** (22 mg), m.p. 94–96°.

Irradiation of Azobenzene

(*a*) A solution of azobenzene (0.75 g) in benzene (200 ml) was irradiated for 13 h. Evaporation of the solvent and chromatography on alumina (60 g), eluting with benzene, gave *trans*-azobenzene (0.53 g), m.p. 67–68° and *cis*-azobenzene (0.14 g), which changed to *trans* by heating in benzene. No biphenyl could be detected (t.l.c., v.p.c.).

(*b*) A mixture of azobenzene (0.1 g), phenol (2.0 g), and benzene (200 ml) was irradiated for 3 h. After evaporation of the solvent, neutral and acidic extracts were made. The neutral extract contained *cis*- and *trans*-azobenzene (0.09 g) but not biphenyl (t.l.c. analysis, alumina plates), and the colorless acidic material contained only phenol (1.95 g).

*2,2′,6,6′-Tetramethylazoxybenzene (****12****)*

To a solution of lithium aluminum hydride (5.0 g) in dry ether (500 ml) was added in small portions a solution of 2,6-dimethylnitrobenzene (Eastman Kodak, 20 g) in ether (30 ml) and the mixture was heated to reflux for 17 h. After quenching the excess lithium aluminum hydride with ethyl acetate, the organic phase was washed with 2 *M* sulfuric acid, dried, and evaporated. The residue was chromatographed on silica gel (120 g) when 5% benzene in petroleum ether (b.p. 60–80°) eluted 2,2′,6,6′-tetramethylazobenzene (2.0 g), m.p. 46–47° (lit. (50) 47°). Later fractions gave recovered starting material (3.1 g).

The azocompound (1.65 g) was oxidized with 30% H_2O_2 (10 ml) in acetic acid (100 ml) at 60° affording 2,2′,6,6′-tetramethylazoxybenzene in quantitative yield. After recrystallization from methanol, the product was yellow rods, m.p. 89.5–90° (lit. (17) 91°).

Anal. Calcd. for $C_{16}H_{18}N_2O$: C, 75.5; H, 7.1; N, 11.0. Found: C, 75.8; H, 6.8; N, 11.2.

Irradiation of ***12***

A solution of **12** (0.495 g) in benzene was irradiated for 5 h. Evaporation of the solvent and preparative t.l.c. (20% benzene in petroleum) gave the starting material (0.386 g), m.p. 90–91°, as the only isolable material. An irradiation in the presence of benzophenone gave similar results.

[6]Prepared by passing commercial high purity nitrogen through a chromous chloride solution (made from $HgCl_2$ (15 g), zinc dust (5 g), and $CrCl_3$ (5 g) in 200 ml water), then dried by passage through concentrated H_2SO_4 and a tower of granular $CaCl_2$, and finally saturated with benzene to minimize loss of the solvent.

*2,6-Dimethyl-NNO-azoxybenzene (**13**)*

To a solution of nitrosobenzene (1.6 g), prepared by the method of Vogel (51), in ethanol (15 ml), was added a solution of 2,6-dimethylaniline (3.0 ml) in acetic acid (5 ml). The mixture was heated to 80° for 15 min, cooled, washed with base, taken up into ether, dried, and evaporated. The residue was chromatographed on silica gel (60 g) when 30% benzene in petroleum ether, b.p. 60–80°, eluted 2,6-dimethylazobenzene (1.07 g) as a red oil (52), pure by t.l.c.

Anal. Calcd. for $C_{14}H_{14}N_2$: N, 13.3. Found: N, 13.5.

Oxidation of the azo compound (1.03 g) using 30% H_2O_2 (2.0 ml) in acetic acid (15 ml) at 60° for 6 h gave 2,6-dimethyl-*NNO*-azoxybenzene (1.09 g) as a pale yellow oil.

Anal. Calcd. for $C_{14}H_{14}N_2O$: N, 12.6. Found: N, 12.5.

*Irradiation of **13***

A solution of **13** (107 mg) in benzene (75 ml) was irradiated with an external source for 1 h. Evaporation of the solvent and chromatography of the residue on alumina (50 g), eluting with benzene, gave the starting material (98 mg); the n.m.r. spectrum was unchanged from that of the starting material except that the ratio of the two CH_3 resonances was now 91:9.

*2,2′-Azoxycumene (**7**)*

2-Nitrocumene (K and K) was found by n.m.r. to be a mixture of approximately 70% *ortho*, 25% *para*, and 5% *meta* isomers. Resolution was effected on 1.5 g samples using alumina columns (350 g), eluting with benzene–petroleum (15:80), when the first fractions to elute were pure by t.l.c. From two such resolutions a total of 1.65 g of material was obtained[7], n_D^{20} 1.5200 (lit. (53) for *o*-nitrocumene 1.5248; for *m*- 1.5303; for *p*- 1.5369). This material was reduced at reflux for 2 h using thallium[8] (6.1 g) and ethanol (55 ml) (16). After the addition of potassium iodide (6 g) the mixture was stirred for 1 h, filtered and evaporated. The residue, dissolved in benzene, was chromatographed over alumina (30 g) when benzene–petroleum (4:6) eluted the azoxy compound (0.63 g, 44%), an oil which was purified by crystallization from ethanol at −80° and dried *in vacuo* for several hours. N.m.r. (CCl_4) δ 1.22, 1.29 (two doublets, J = 7 Hz, 12H, CH_3), 3.35, 3.45 (two superimposed septets, J = 7 Hz, 2 CH), 7.10–8.30 (multiplet, 8 ArH); mass spectrum (relative intensity) *m/e* 282 (M^+) (<1), and prominent ions at *m/e* 266, 250, 240, 149, 133, 131, 121, 119, 118, 116, 107, 106, 105, 104, 103, 91 (100).

Anal. Calcd. for $C_{18}H_{22}N_2O$: C, 76.55; H, 7.86; N, 9.93. Found: C, 76.43; H, 7.59; N, 10.11.

*Irradiation of **7***

A solution of **7** (0.630 g) in benzene (300 ml) was irradiated under nitrogen for 1 h, during which time the starting material completely reacted (t.l.c.) and was replaced by two major components. Evaporation of solvent and resolution by preparative t.l.c. (20% benzene in petroleum) gave four bands. The most mobile, band 1 (123 mg), a red oil, was a mixture containing one major component, which was isolated pure by running a second preparative plate. Subsequent precipitation from methanol at −80° followed by drying *in vacuo* gave 2-hydroxy-6,2′-diisopropylazobenzene, **23** (60 mg): n.m.r. (CCl_4) δ 1.25, 1.35 (two doublets, J = 7 Hz, 12H, CH_3), 2.91, 3.73 (two septets, J = 7 Hz, 2 CH), 6.75–7.90 (multiplet, 7 ArH), 12.70 (singlet 1H, OH); u.v. (ethanol) λ_{max} 337 (ε 18 500), 248 (8200), and 243 nm (8000); mass spectrum *m/e* (relative intensity) 282 (M^+) (61), 267 (94), 135 (39), 133 (100), 132 (55), 91 (84).

Anal. Calcd. for $C_{18}H_{22}N_2O$: C, 76.55; H, 7.86; N, 9.93. Found: C, 77.21; H, 7.53; N, 10.10.

Band 2 from the t.l.c. resolution (16 mg) was a mixture and could not be resolved further. Band 3 (290 mg) on isolation had the n.m.r. and R_f of the starting material and was presumed to be the *cis* isomer of 7 which on work-up reverted to starting material; band 4 (32 mg) was shown by t.l.c. to be a mixture of at least four compounds and was discarded.

*2,2′-Dibenzylazoxybenzene (**8**)*

2-Nitrodiphenylmethane was prepared from *o*-nitrobenzyl chloride (Aldrich) and benzene–$AlCl_3$ by the method of Geigy and Königs (54). The procedure was modified in that the crude product was partly purified by passage through a 30 g column of alumina before steam distillation. From 6.5 g of benzyl chloride was obtained 6.5 g of partly purified material, 3 g of which was steam distilled to give 1.7 g of 2-nitrodiphenylmethane (pure by t.l.c.). Thallium reduction (16) of this material overnight and the usual work-up gave an oil; this crystallized on standing and was further purified by preparative t.l.c. (benzene–petroleum, 1:1) affording the product (0.60 g), which crystallized from ethanol, 0.48 g: m.p. 53–56°; mass spectrum *m/e* 378 (M^+), see Table 2; n.m.r. (CCl_4) δ 3.99, 4.17 (singlets, two CH_2 groups), 7.0–8.2 (multiplet 18 ArH).

Anal. Calcd. for $C_{26}H_{22}N_2O$: C, 82.50; H, 5.86; N, 7.41. Found: C, 82.56; H, 6.16; N, 7.65.

*Irradiation of **8***

A solution of **8** (0.45 g) in benzene (300 ml) was irradiated for 2 h, after which the solvent was evaporated and the residue resolved by preparative t.l.c. (benzene–petroleum, 1:1). Three major bands were obtained. The most mobile band comprised 50 mg red solid, m.p. 95–105°, not improved by repeated recrystallization from ethanol, and was found to be a mixture by t.l.c. on alumina. Chromatography of band 1 on alumina (20 g), eluting with petroleum containing increasing amounts of benzene (up to 25% v/v), gave three fractions. The most mobile, band 1A (2 mg), red crystals, had m.p. 168–170°; band 1B, red crystals (2 mg), had m.p. 102–105°; band 1C, red crystals (8 mg), had m.p. 130–131°, softened at 121°. The mass spectra of these three compounds, recorded in Table 2, showed that they were all isomers of **8**, consistent with structures **24**–**26**. Too little material was obtained to run n.m.r. spectra, but using the reported (25) method, it was shown that 1C was compound **26** by u.v., since it alone had a pronounced red shift when the spectrum was run in the presence of 10^{-2} *M* potassium

[7]The purified *o*-nitrocumene discolored rapidly upon exposure to air, so it and the subsequent cumyl derivatives were handled and stored under nitrogen.

[8]Molten commercial thallium (British Drug Houses) was poured into water and washed with ethanol.

TABLE 2. Mass spectral fragmentation patterns of compounds **8**, **24**, **25**, and **26**

	Relative abundance of ion			
m/e	**8**	Band 1A	Band 1B	Band 1C (**26**)

151	5	14	7	4
150	9	3	8	7

hydroxide (see Table 3). Hence 1A and 1B were **24** and **25**, though not necessarily respectively. Attempts to find free (compound **26**) and chelated (**24** and **25**) hydroxyl stretching frequencies in the i.r. were unsuccessful due to lack of material, though there was some indication of a free hydroxyl group in 1C (ν_{max} (CS_2) 3550 cm^{-1}).

Band 2 from the preparative t.l.c. plate was starting material (200 mg), while band 3 (red oil 80 mg) was a mixture by t.l.c. Attempts to obtain pure materials from this fraction were unsuccessful.

2-Nitrobenzaldehyde Dimethyl Acetal (34)

2-Nitrobenzaldehyde (Aldrich, 0.1 mol) was dissolved in a mixture of methanol (100 ml) and concentrated hydrochloric acid (1.5 ml). After 17 h at room temperature, the solution was basified with sodium methoxide, evaporated down, and water added. Extraction with ether, followed by evaporation of the organic phase gave the acetal (94%) as a colorless or yellow oil: n.m.r. (neat liquid) δ 3.33 (singlet, 6H, OCH_3), 5.95 (singlet, 1 CH), 7.31–7.95 (multiplet, 4 ArH).

2,2′-Azoxybenzaldehyde Bisdimethyl Acetal (9)

The acetal **34** was reduced by the method of Bamberger (15) using sodium and methanol. The crude azoxy compound was recrystallized from ethanol giving **9** (65%), m.p. 52–56° (lit. (15) 59°). When the reaction time was prolonged in order to improve the conversion, further reduction occurred. Fractional crystallization gave **9** (20%), together with 2,2′-azobenzaldehyde bisdimethylacetal (**16**) (13%): m.p. 142–143° (lit. (55) 144°); n.m.r. (CCl_4) δ 3.25 (singlet, 12H, OCH_3), 6.27 (singlet, 2CH), 7.25–7.85 (multiplet, 8 ArH).

Anal. Calcd. for $C_{18}H_{22}N_2O_4$: C, 65.43; H, 6.71; N, 8.48. Found: C, 65.48; H, 6.90; N, 8.44.

An attempt to prepare **9** by lithium aluminum hydride reduction of **34** to **16** followed by oxidation was unsuccessful. A reaction using **34** (0.06 mol) gave a crude reduction product (6.9 g) which was partly resolved by chromatography on silica gel. The least polar material, a red solid (0.25 g), eluted with 20% benzene in petroleum, n.m.r. (CCl_4) δ 2.16 (singlet), 7.2 (multiplet), area ratio 3:4. Oxidation with hydrogen peroxide in acetic acid gave a pale solid (0.24 g), m.p. 56–57.5°, undepressed by admixture with authentic 2,2′azoxytoluene (**6**), and with an identical n.m.r. Intermediate fractions from the column were red and had n.m.r. resonances characteristic of CHO, aromatic, OCH_3, and CH_3 protons, but were all mixtures. These were followed by unreacted **34** (2.5 g). The last fraction, removed from the column with methanol crystallized from methanol as orange plates (0.10 g), m.p. 139–141° with n.m.r. identical to **16** described above.

Anal. for $C_{18}H_{22}N_2O_4$: Found: C, 65.42; H, 6.64; N, 8.50.

Mass spectrum *m/e* 330 (M^+ absent), prominent peaks at *m/e* 282, 268, 267, 251, 237, 236, 235, 221, 194, 159, 130.

The best route to **9** was thallium reduction of **34**.

TABLE 3. Ultraviolet absorptions in ethanol of the products of irradiation of **8**

Compound	Neutral solution		10^{-2} *M* KOH	
	λ_{max} (nm)	log ε	λ_{max} (nm)	log ε
Band 1A	340	4.22	338	4.12
	243	3.80	243	3.84
	237	3.76	236	3.80
Band 1B	342	4.33	338	4.21
	245	3.84	246	3.89
	240	3.84	240	3.89
Band 1C (**26**)	376 sh	4.19	441	4.01
	334	4.31	325	4.11
	245	3.99	242	4.05
	240	3.93		

After the usual work-up, **9** was obtained as orange crystals from ethanol (64%): m.p. 54–56° (lit. (15) 59°); n.m.r. (CCl_4) δ 3.22, 3.24 (two singlets, 12H, OCH_3), 5.60, 5.90 (two singlets, 2 CH), 7.08–7.84 (multiplet, 8 ArH); u.v. (ethanol) λ_{max} 232 (log ε 4.0) and 307 nm (3.9).

Anal. Calcd. for $C_{18}H_{22}N_2O_5$: C, 62.41; H, 6.40; N, 8.09. Found: C, 62.79; H, 6.52; N, 8.07.

Irradiation of ***9***

A solution of **9** (1.00 g) in benzene (300 ml) was irradiated for 8 h. After removal of solvent, the residue was resolved by preparative t.l.c. (chloroform) to give three bands.

The most mobile band, band 1, was orange (439 mg), m.p. 82–84° after several recrystallizations from ethanol, and was identified as 3-hydroxy-2,2′-azobenzaldehyde bisdimethylacetal (27): n.m.r. (CCl_4) δ 3.50, 3.52 (two singlets, 12H, OCH_3), 6.07, 6.48 (two singlets, 2 CH), 7.00–8.14 (multiplet, 7 ArH), 12.76 (singlet, OH).

Anal. Calcd. for $C_{18}H_{22}N_2O_5$: C, 62.48; H, 6.39; N, 8.07. Found: C, 62.65; H, 6.48; N, 8.08.

Bands 2 and 3 were incompletely resolved and were further separated by t.l.c. Band 2 (54 mg) was starting material. Band 3 (34 mg) was an oil: n.m.r. (CCl_4) δ 3.30, 3.40, 3.50 (singlets OCH_3?), 3.80, 3.87 (singlets, $COOCH_3$?), 5.57, 5.62, 5.74, 6.23 (singlets CH), 6.7–7.7 (multiplet ArH). This substance was a mixture and could not be resolved further.

A second irradiation gave, in addition to **27**, various other poorly resolved and incompletely characterized materials whose n.m.r. spectra showed resonances typical of aromatic, —CHO, $\diagdown\!\!\diagup$CH, —$COOCH_3$, —OCH_3 and hydrogen bonded —OH groups. When the irradiation was carried out under nitrogen and in the presence of benzophenone, three products were obtained, but none could be obtained pure. Their n.m.r. spectra all showed the presence of —CHO protons, but low field resonances characteristic of hydrogen-bonded OH groups were absent.

*2,2′-Azoxybenzaldehyde Bisdiethyl Acetal (**10**)*

2-Nitrobenzaldehyde was converted to its diethylacetal in 91% yield: n.m.r. (neat) δ 1.10 (triplet, J = 7 Hz, 6H, CH_3), 3.50 (quartet, J = 7 Hz, 4H, CH_2), 5.84 (singlet, 1 CH), 7.16–7.74 (multiplet, 4 ArH). Thallium reduction (16) of the acetal gave the azoxycompound **10** (42%), m.p. 70–72°. A better yield was obtained by reduction of the acetal with sodium and methanol (15); after recrystallization of the crude product from ethanol the yield of **10** was 65%: m.p. 73–75° (lit. (15) 76°); n.m.r. (CCl_4) δ 1.13 (triplet, J = 7 Hz, 12 H, CH_3), 3.4 (two close quartets, J = 7 Hz, 8H, CH_2), 5.90, 6.17 (two singlets, CH), 7.2–8.0 (multiplet, 8 ArH). The mass spectrum showed a very small M^+ (*m/e* 402), first major peak *m/e* 384.

Anal. Calcd. for $C_{22}H_{30}N_2O_5$: C, 65.65, H, 7.51; N, 6.96. Found: C, 65.81; H, 7.57; N, 6.92.

Irradiation of ***10***

A solution of **10** (1.00 g) in benzene (300 ml) was irradiated for 1 h. Evaporation of solvent and resolution of the residue by t.l.c. (chloroform) gave four bands. Band 1 (131 mg) was a mixture: n.m.r. (CCl_4) δ 1.20 (two triplets, area 103, CH_3), 3.6 (two quartets, area 63, CH_2), 5.86, 6.00, 6.15, 6.43 (singlets areas 5:3:5:2, CH), 7.15–8.06 (multiplet, area 59, ArH), 12.36, 12.74 (two singlets, areas 1:4, OH). Recrystallization from petroleum ether, b.p. 30–60°, then from ethanol gave the major component; m.p. 85–86°; mass spectrum *m/e* (relative intensity) 402 (M^+ absent), 356 (2), 328 (20), 327 (100), 312 (20), 311 (31), 284, (47), 253 (80), 237 (71), 151 (31), 120 (7).

Anal. Calcd. for **28**, $C_{22}H_{30}N_2O_5$: C, 65.65; H, 7.51; N, 6.96. Found: C, 65.38; H, 7.83; N, 6.98.

Band 2 from the t.l.c. plate (646 mg) was starting material, m.p. 72.5–74°, after crystallization from petroleum. Band 3 (156 mg), an oil, appeared to be the *cis* isomer of the starting material, since on recrystallization it was converted to **10**, m.p. 71–73°. Band 4, a red oil (32 mg), was unidentified; its n.m.r. spectrum was similar to that of **10** and had no low field resonances typical of hydrogen-bonded OH protons.

*2,2′-Azoxybenzaldehyde Bisethylene Acetal (**15**)*

2-Nitrobenzaldehyde was converted to its ethyleneacetal (90%), n.m.r. (neat): δ 3.90 (singlet, 4H, CH_2), 6.47 (singlet, 1 CH), 7.3–8.0 (multiplet, 4 ArH). The acetal was reduced by the thallium and ethanol method

For personal use only.

(16) to give the azoxy compound **15** as yellow needles from ethanol (66%): m.p. 103.5–104.5°; n.m.r. ($CDCl_3$) δ 3.95 (close multiplet, 8H, CH_2), 6.30, 6.48 (two singlets 2H, CH), 7.24–8.30 (multiplet, 8 ArH). The mass spectrum showed M^+ (*m/e* 342) and other prominent ions at *m/e* 296, 253, 234, 192, 177, 163.

Anal. Calcd. for $C_{18}H_{18}N_2O_5$: C, 63.13; H, 5.30; N, 8.19. Found: C, 62.61; H, 5.37; N, 8.00.

*2'-Formylphenyl-ONN-2-azoxybenzaldehyde Dimethyl Acetal (**17**), R = CH_3*

The bisdimethylacetal **9** (1.95 g) was dissolved in warm methanol (50 ml), then water (20 ml) and concentrated hydrochloric acid (1 ml) were added with stirring. After 2 min, the solution was diluted with water (50 ml) and extracted with chloroform. The organic phase was washed ($NaHCO_3$), dried ($MgSO_4$), and evaporated, and the residue recrystallized from ethanol to give the compound (0.52 g) as tan crystals: m.p. 59–60°; n.m.r. ($CDCl_3$) δ 3.30 (singlet, 6H, OCH_3), 5.95 (singlet, 1 CH), 7.26–8.10 (multiplet, 8 ArH), 10.44 (singlet, 1 CHO); u.v. (EtOH); λ_{max} 308, 248, and 214 nm (ε undetermined but smaller for the 308 nm band); mass spectrum *m/e* (relative intensity) 300 (M^+ absent), 246 (26), 233 (52), 220 (38), 193 (28), 180 (100), 151 (6), 150 (12), 149 (44), 119 (32), 105 (48), 91 (72), 77 (86).

Anal. Calcd. for $C_{16}H_{16}N_2O_4$: C, 63.99; H, 5.37; N, 9.33. Found: C, 64.00; H, 5.45; N, 9.23.

From a 1 h irradiation of this substance (0.255 g) in benzene, only starting material (94 mg) could be recovered.

*2'-Formylphenyl-ONN-2-azoxybenzaldehyde Diethyl Acetal (**17**), R = C_2H_5*

To a solution of **10** (1.0 g) in glacial acetic acid (3 ml) and acetonitrile (2 ml) cooled in an ice-bath was added water (0.75 ml) and 0.2 *M* hydrochloric acid (0.7 ml). After 2 min, water (10 ml) was added dropwise. Extraction into chloroform and treatment of the organic phase as above gave an oil (0.61 g) which was purified by preparative t.l.c. (benzene) to give the azoxy compound as a yellow oil (0.54 g) which crystallized at −80° from petroleum: m.p. 37–38.5°; n.m.r. (CCl_4) δ 1.12 (triplet, J = 7 Hz, 6H, CH_3), 3.53 (quartet, J = 7 Hz, 4H, CH_2), 6.13 (singlet, 1 CH), 7.17–8.23 (multiplet, 8 ArH), 10.48 (singlet, 1 CHO); mass spectrum *m/e* 328 (M^+ absent), major peaks at *m/e* 311, 237, 211, 208, 134, 105. Only very minor peaks were present at *m/e* 179, 180.

Anal. Calcd. for $C_{18}H_{20}N_2O_4$: C, 65.84; H, 6.14; N, 8.53. Found: C, 65.66; H, 6.13; N, 8.65.

*2,2'-Azoxybenzaldehyde (**11**)*

After several unsuccessful attempts to hydrolyze the acetals **9**, **10**, and **15**, the most successful procedure was the following modification of Bamberger's method (19).

The bisdiethylacetal **10** (2.0 g) was dissolved in glacial acetic acid (7 ml) with the minimum amount of heating. The yellow solution was cooled in ice, and water (1.5 ml) and 2 *M* hydrochloric acid (1.4 ml) were added. A white emulsion formed; this clarified on shaking, and after < 30 s, the solution began to turn brown. After a further 2.5 min, water (9 ml) was added dropwise with shaking (a white precipitate formed after 6 ml had been added), and the mixture was kept at 0° for 15 min more before suction filtration. The crude solid was taken into chloroform, washed ($NaHCO_3$), dried ($MgSO_4$), and the solution concentrated to < 10 ml for purification by t.l.c. (chloroform). The one major band afforded 1.8 g of crude solid, yellow needles (0.31 g) from ethanol[9]: m.p. 113–114° (lit. (19) 118°); n.m.r. ($CDCl_3$) δ 6.97–8.33 (multiplet, 8 ArH), 10.45 (singlet, 2 CHO); mass spectrum M^+ (*m/e* 254).

Anal. Calcd. for $C_{14}H_{10}N_2O_3$: C, 66.13; H, 3.96; N, 11.02. Found: C, 65.30; H, 3.92; N, 10.88.

The poor analysis is probably because **11** decomposes to a considerable extent in a few days at the ambient temperature.

*Irradiation of **11***

(*a*) In benzene: a solution of **11** (0.769 g) in benzene (300 ml) was irradiated for 20 min by which time a yellow solid was present. The solvent was removed and the residue (including the yellow substance) was resolved by preparative t.l.c. (chloroform) to give two major bands, neither of them red. Band 1 (225 mg) crystallized from ethanol as tan needles, m.p. 109–110°, and had the same n.m.r. spectrum as **11**. Band 2 (26 mg) was **29**, colorless crystals from chloroform–ether: m.p. 288–290° (lit (19) 294°); i.r. ($CHCl_3$) ν_{max} 1690 cm^{-1}; mass spectrum *m/e* (relative intensity) 236 (M^+) (100), 208 (38), 179 (33), 76 (37).

(*b*) In isopropanol: a solution of **11** (0.296 g) in isopropanol (300 ml) was irradiated for 1 h. Evaporation and t.l.c. resolution as above gave two colorless bands. Band 1 (6 mg) was unidentified; band 2 (36 mg) was starting material, tan needles from ethanol, m.p. 105–110°.

Quantum Yield Determinations

Azoxybenzene, m.p. 35–36°, was prepared by the method of Lachman (14): u.v. (ethanol) λ_{max} 231 (ε 9560), 267 (7990), and 323 nm (15 800), ε < 140. Irradiation in benzene and resolution by preparative t.l.c. (benzene–petroleum, 1:1) gave 2-hydroxyazobenzene, red needles from ethanol: m.p. 79–80° (lit. (56) 81°); u.v. (ethanol) λ_{max} 244 (ε 8110), 325 (16 800), 375 nm (8250), ε_{410} = 4480. For the quantum yield measurements, solutions of azoxybenzene in 95% ethanol and of the modified ferrioxalate actinometer described by Kurien (57) were irradiated simultaneously using a Rayonet "Merry-go-round". A filter solution (5 cm) of $NiSO_4 \cdot 6H_2O$ (90 g/l) and $CoSO_4 \cdot 7H_2O$ (48 g/l) was used to restrict the absorption of light to the region 300–330 nm where both azoxybenzene and the actinometer absorb strongly. Samples were withdrawn during the irradiation and analyzed by u.v. (Bausch and Lomb, Spectronic 70); ferrous phenanthroline formation was monitored at 510 nm (ε 11 000) and 2-hydroxyazobenzene formation at 410 nm. Knowing the quantum yield (1.10) for ferrous ion formation in the actionometer, the ratio of the initial slopes of the plots of ferrous phenanthroline and 2-hydroxyazobenzene formation with time gave the quantum yield for 2-hydroxyazobenzene formation as 0.217 ± 0.015 (11 runs).[10] Deviations were calculated by the usual method (58).

[9]It is important not to heat solutions of **11** any more than necessary, or decomposition results.

[10]NOTE ADDED IN PROOF: The quantum yield for this reaction has been determined (61) as ~0.008 in 95% ethanol. At present, we see no cause for discrepancy between our results and theirs. We wish to thank Dr. Jaffé for sending us a copy of his paper before publication.

Solvent Effect on Photoreactivity of Azoxybenzene

Solutions (about 7×10^{-5} *M*) of azoxybenzene in various solvents were irradiated simultaneously using the "Merry-go-round". Aliquots of the reaction mixture were withdrawn at intervals, and the formation of 2-hydroxyazobenzene was followed by monitoring the absorbance at 410 nm. First-order rate constants were evaluated by plotting log $(A_\infty - A_0)/(A_0 - A_t)$ against time, first-order kinetics being followed for better than one half-life. From the results obtained were calculated the data of Table 1.

Azoxybenzene-d_{10}

Thallium reduction (16) of nitrobenzene-d_5 (Stohler Isotope Chemicals) gave the azoxycompound as yellow needles from ethanol (36% after two recrystallizations): m.p. 34.5–36°; mass spectrum *m/e* (relative intensity) 208 (M^+) (37), 192 (5), 157 (6), 110 (11), 98 (8), 96 (24), 83 (100), 70 (18), 68 (16), 54 (30).

Anal. Calcd. for $C_{12}D_{10}N_2O$: N, 13.45. Found: N, 13.41.

Deuterium Isotope Effect for Azoxybenzene Photorearrangement

Solutions of azoxybenzene and azoxybenzene-d_{10} were irradiated simultaneously and first-order rate constants for 2-hydroxyazobenzene formation at 410 nm (in one experiment for azoxybenzene disappearance, monitored at 265 nm) were obtained as described above. The data are summarized in Table 1.

Irradiation of Azoxybenzene-d_{10} in Ethanol

A solution of azoxybenzene-d_{10} (302 mg) in 95% ethanol (300 ml) was irradiated for 1.5 h. The solvent was evaporated and the residue resolved by preparative t.l.c. (20% benzene in petroleum). Azoxybenzene-d_{10} (187 mg), m.p. 34.5–35°, and 2-hydroxyazobenzene-d_9 (89 mg), m.p. 79–80°, were obtained. After reservation of a sample of azoxybenzene-d_{10} for mass spectrometry, 185 mg was dissolved in fresh 95% ethanol (300 ml), and irradiated for a further 1.5 h. Azoxybenzene-d_{10} (57 mg) and 2-hydroxyazobenzene-d_9 (85 mg) were recovered. Several mass spectra were run on the starting sample of azoxybenzene-d_{10} and on each of the recovered samples, and the ratios of the peaks at *m/e* 206, 207, 208 were compared: starting material, $(4.9 \pm 0.2):(6.9 \pm 0.2):100$; first recovered sample, $(4.9 \pm 0.4):(6.1 \pm 0.3):100$; second recovered sample, $(4.5 \pm 0.1):(6.9 \pm 0.2):100$.

Irradiation of Azoxybenzene in CH_3CN–D_2O

A solution of azoxybenzene (305 mg) in dry (59) acetonitrile (300 ml) and deuterium oxide (20 ml) was irradiated for 1 h. Work-up as above gave azoxybenzene (60 mg) and 2-hydroxyazobenzene (77 mg). Several mass spectra were run to compare the ratio of the peaks at *m/e* 198 and 199 in the starting and recovered azoxybenzene samples: starting material, $100:(14.5 \pm 0.3)$; recovered sample, $100:(14.3 \pm 0.3)$.

Fluorescence Measurements

Using a Farrand Mark I fluorometer no fluorescence could be observed from azoxybenzene (10^{-3}–10^{-5} *M*) or azoxybenzene-d_{10} in purified ethanol, methanol, or hexane solutions. Ethanol and hexane solutions were also examined by Dr. W. R. Ware and Mr. T. Nemzek of the University of Western Ontario using the single photon counting technique (60), but again, no emission was observed.

Irradiation of Azoxybenzene in Styrene

Solutions of azoxybenzene (0.10 g) in styrene (30 ml) from which the stabilizer had been removed were irradiated in corked ampoules for 6 h using the Merry-go-round. The solutions were poured into methanol and the weight of polystyrene determined. From two experiments the weight of polymer was 0.01 and 0.01 g; in control experiments where the azoxybenzene was omitted the weight was 0.50 and 0.55 g.

We wish to thank the National Research Council of Canada for their generous financial support of this work. We also express thanks to Dr. J. L. Kropp of the Systems Group of TRW Inc. for a helpful correspondence concerning the effects of deuteration on the singlet lifetimes of aromatic hydrocarbons, to Dr. R. D. McAlpine formerly of this department for discussions on the same subject, to Dr. W. R. Ware and Mr. T. Nemzek of the University of Western Ontario for their kindness in making fluorescence measurements on azoxybenzene, and to Dr. A. McKillop of the University of East Anglia for correspondence on the proper method of purifying the thallium metal for reducing aromatic nitrocompounds.

Metabolites of *Cyathus helenae*. A New Class of Diterpenoids

WILLIAM A. AYER AND HUBERT TAUBE
Chemistry Department, University of Alberta, Edmonton, Alberta T6G 2E1

Received June 4, 1973

Allocyathin B_3 and cyathin A_3, metabolites of the bird's nest fungus *Cyathus helenae* Brodie are shown to possess structures **2***a* ⇄ **3***a* and **5***a* ⇄ **6***a*, respectively. In the solid state allocyathin B_3 exists in the hydroxyketone form **2***a*, while cyathin A_3 is in the hemiketal form **6***a*. In each case acetylation gives the diacetyl derivative of the hydroxyketone form whereas treatment with methanolic HCl gives an internal ketal. Allocyathin B_3 and cyathin A_3 have been correlated by hydrogenation to the common product **13***a*, and by transformation of each to the aldehyde **12***a*. These compounds are representatives of a new class of diterpenoids. Their biogenesis from geranylgeranyl pyrophosphate is discussed.

On a montré que l'allocyathine B_3 et la cyathine A_3, deux métabolites du champignon *Cyathus helenae* Brodie ("nid d'oiseaux") possèdent respectivement les structures **2***a* ⇋ **3***a* et **5***a* ⇋ **6***a*. A l'état solide, l'allocyathine B_3 existe sous la forme hydroxycétone **2***a* alors que la cyathine A_3 existe sous la forme d'un hémiacétal **6***a*. Dans chacun des cas, l'acétylation a conduit au dérivé diacétylé de la forme hydroxycétone alors que le traitement par HCl dans le méthanol a conduit à un acétal interne. L'allocyathine B_3 et la cyathine A_3 ont conduit toutes deux par hydrogénation au seul produit **13***a* et par transformation à l'aldéhyde **12***a*. Ces composés sont les membres d'une nouvelle classe de diterpénoïdes. On discute de leur biogénèse à partir du pyrophosphate de géranylgéranyle.

[Traduit par le journal]

Can. J. Chem., **51**, 3842 (1973)

In 1965 H. J. Brodie discovered a new bird's nest fungus of the genus *Cyathus* growing in the Rocky Mountains of Alberta. The species was given the designation *Cyathus helenae* (1). Subsequently, Brodie and co-workers succeeded in growing the fungus in liquid culture and showed that the metabolites possessed antibiotic activity (2). At the same time we reported on the isolation and preliminary characterization of some of the metabolites (2). We now wish to present a detailed account[1] of the studies leading to the elucidation of the structure of two of the diterpenoid components of the "cyathin complex".

The isolation procedure previously reported (2) was based mainly on a combination of column and thin-layer chromatography (t.l.c.) on the ethyl acetate extract obtained from the culture broth. A material with R_f 0.4 (silica gel G, chloroform–methanol 9:1) which appeared chromatographically pure was obtained and called cyathin A_3. However, careful inspection of the n.m.r. spectrum of the acetyl derivative indicated that this material consisted of two components: a compound A and its dihydro derivative B.[2]

Chromatography on silica gel impregnated with silver nitrate, a standard technique (4) for separating compounds with differing degrees of unsaturation, proved to be successful in separating A from B. The R_f values for the system 10% silver nitrate – silica gel, Skellysolve B – acetone (2:3), are 0.51 for A and 0.60 for B. This difference allows easy separation of the two components by preparative t.l.c. (p.t.l.c.). The molecular formula of A is $C_{20}H_{28}O_3$, that of B, $C_{20}H_{30}O_3$; the name cyathin A_3 has been retained for compound B and compound A is called allocyathin B_3 conforming to the system of nomenclature devised earlier (2).

The chemistry of allocyathin B_3 will be discussed first, since an exhaustive study of spectra of this compound and two key derivatives, *O*,*O*-diacetylallocyathin B_3 and "allocyathin B_3 methyl ketal", allowed an unambiguous solution of the structural problem.

Allocyathin B_3 has the composition $C_{20}H_{28}O_3$ as determined by high resolution mass spectrometry (h.r.m.s.).[3] The i.r. spectrum in chloroform displays hydroxyl absorption and a broad band of medium intensity at 1650 cm^{-1}. This absorption band, which is assigned to an α,β-unsatu-

[1]A preliminary report of some of these findings has appeared (3).

[2]In most preparations, B was the major component; in a few instances, however, A predominated.

[3]Because of the small quantities of pure material available, most of the molecular formulas in this series have been determined by high resolution mass spectrometry.

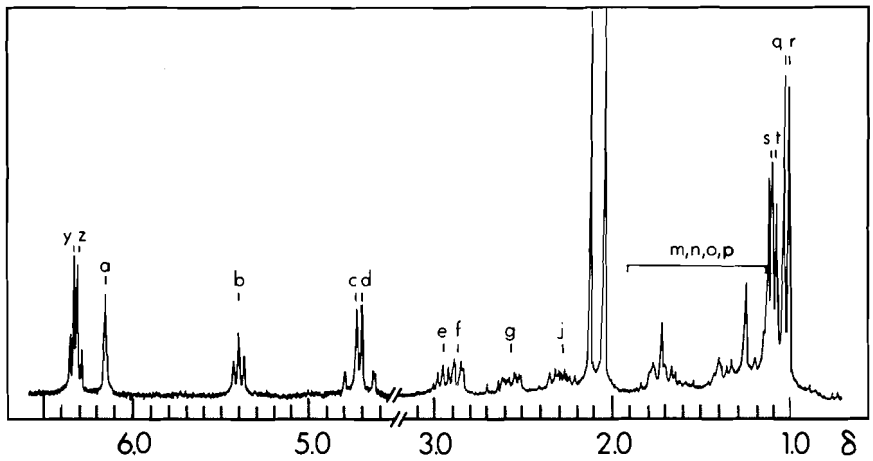

FIG. 1. Nuclear magnetic resonance spectrum (220 MHz) of *O,O*-diacetylallocyathin B_3 in $CDCl_3$.

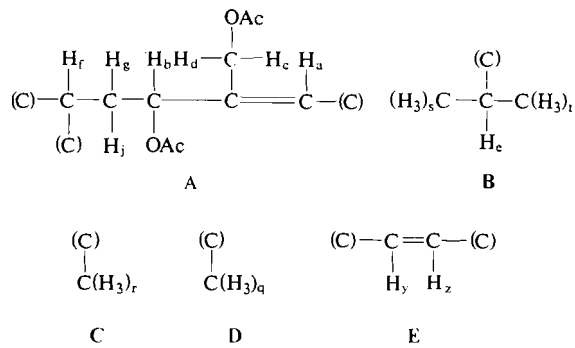
rated carbonyl group, appears in the same position in the solid-phase spectrum in which it is much stronger and sharper. The decreased intensity in solution indicates that the carbonyl group is partially in a hemiketal form as will be discussed later. A weak but sharp band at 3060 cm^{-1} indicates olefinic hydrogen(s). The u.v. spectrum has a somewhat unsymmetrical maximum at 235 nm with ε 5000 (shown to result from two overlapping chromophores). The c.d. spectrum displays a positive maximum at 327 nm with a dichroic absorption (Δε) of +1.6, assigned to the n–π* transition of an α,β-unsaturated carbonyl group. The n.m.r. spectrum of allocyathin B_3 (100 MHz) has but one readily analyzable (5) feature: an AB quartet centered at δ 6.26 with $\Delta\nu = 7$ Hz and $J = 5$ Hz; the remainder of the spectrum is poorly defined (tautomerism?) and was of limited value in the structural study.

Acetylation of allocyathin B_3 gave an *O,O*-diacetyl derivative as indicated by a molecular weight increase of 84 a.m.u. ($C_{20}H_{28}O_3 \rightarrow C_{24}H_{32}O_5$), 3-proton singlets in the n.m.r. at δ 2.05 and 2.12, and i.r. absorption at 1745 cm^{-1}. The i.r. spectrum also shows absorption at 1685 and 1655(sh) attributed to an α,β-unsaturated carbonyl system. The u.v. spectrum (isooctane) shows maxima at 325 (ε 140), 254 (ε 4800), and 225 nm (ε 9000). The maxima at 325 and 225 nm are assigned to the n–π* and π–π* transitions of the α,β-unsaturated carbonyl; the 254 nm absorption, as shown below, is due to a cyclopentadiene moiety. A strong c.d. maximum at 330 nm (Δε +4.1) further confirms the presence of an α,β-unsaturated carbonyl. Nuclear magnetic resonance spectra determined at 100 and 220 MHz (Fig. 1 and Table 1) using both $CDCl_3$ and C_6D_6 as solvents proved to be extremely revealing. Part structures **A**, **B**, **C**, and **D**, where (C) indicates a carbon atom bearing no hydrogen, were apparent.



Proton f at δ 2.87 ($CDCl_3$) has two vicinal couplings, an equatorial–axial type coupling of 3 Hz with proton g and an axial–axial like coupling of 10.5 Hz with j. Protons g (δ 2.56) and j (δ 2.27) show, besides the above mentioned coupling, a mutual geminal coupling of 14 Hz and each a vicinal coupling of 6.5 Hz with proton b. Besides these, proton b (δ 5.39) has only weak couplings (~0.5 Hz), better observed in the case of cyathin A_3, with protons a, c, and d. The nonequivalent protons c (δ 4.75) and d (δ 4.68) are geminally coupled (14.5 Hz) and are each further split by an allylic coupling of 1.5 Hz with proton a. Proton a, which must be olefinic since it resonates at low field (δ 6.15), displays

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

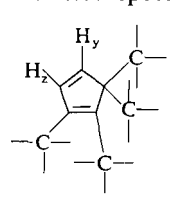
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

only the above-mentioned small couplings and consequently is located at the other end of the isolated spin system **A**. Protons b, c, and d must be located on carbon atoms bearing acetoxyl groups since the nonacetylated compound does not show signals at these shift values.

Proton e (δ 2.96) gives rise to a septet (the outer two lines are not always apparent) which has typical acyclic vicinal coupling (7 Hz) (5). Nuclear magnetic double resonance (n.m.d.r.) experiments show that e is coupled to a pair of doublets, s and t, at δ 1.12 and 0.99. Only part structure **B**, an isolated isopropyl group, is consistent with this pattern.

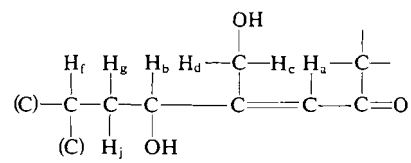
Three-proton singlets at δ 1.04 and 1.00 are due to quaternary methyl groups **C** and **D**. Part structure **E** is revealed by the isolated AB quartet at δ 6.34 and 6.31. The coupling constant of 5.5 Hz is in the range expected for olefinic coupling in a five-membered ring (6). The observed chemical shifts indicate the presence of a cyclopentadiene rather than a cyclopentene moiety (ref. 5*a*, p. 188: δ 6.42 and 5.60, respectively). The remaining four protons give rise to a very complex signal pattern in the region δ 1.9–1.1. Since all spin systems mentioned above appear to be isolated systems, this pattern suggests an isolated ABCD-system of two adjacent methylene groups.

When allocyathin B_3 is treated with methanolic HCl at room temperature it is transformed into a compound $C_{21}H_{30}O_3$. The transformation is accompanied by loss of the n–π* c.d. band at 326 nm and is conveniently monitored in this way. The net reaction is one of methylation and corresponds to the transformation of a hydroxy ketone (or hemiketal) to an internal half methyl ketal. The i.r. spectrum (CCl_4) of this derivative is considerably better defined than that of the diacetyl derivative or the parent compound, possibly a reflection of the more rigid conformation. The i.r. spectrum shows hydroxyl absorption (3620, 3470 cm^{-1}), olefinic C—H stretching (3100, 3050 cm^{-1}), and lacks carbonyl absorption. Ultraviolet and c.d. spectra confirm the absence of carbonyl absorption although both spectra display an absorption band centered at *ca.* 255 nm: the c.d. spectrum has a minimum at 252 (Δε −3.6), the u.v. spectrum a maximum at 256 nm (ε 4200). The u.v. spectrum is in good agreement with that expected for a 5,5-dialkylcyclopentadiene bearing two alkyl substituents.[4] Consequently we may expand part structure **E** to **F**.



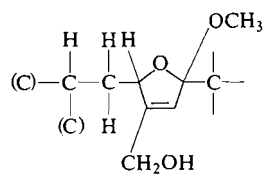
F

This part structure is compatible with the n.m.r. spectra, since protons y and z are coupled only to each other and the additional olefinic proton is accounted for in **A**. The mass spectrum of the ketal, unlike that of the parent compound, is completely dominated by an intense peak at *m/e* 141 corresponding to the ion $C_7H_9O_3$ (h.r.m.s.) which contains *all three oxygen atoms of the ketal.* This shows that the three oxygens in allocyathin B_3 are located on six contiguous carbon atoms. Since two oxygens are accounted for in part structure **A** and the third is incorporated into an α,β-unsaturated ketone, the carbonyl group must be attached to the carbon carrying proton a. Part structure **A** may thus be expanded to **G**. Since it is the secondary hydroxyl

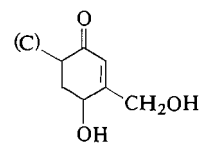


G

which is involved in ketal formation (see below), part structure **H** follows for the methyl ketal.



H



I

It seemed unlikely that the unsaturated carbonyl system **G** was part of a six-membered ring (as in **I**) since much higher extinction coefficients would then be expected for the π–π* transition than are observed. It is also difficult to rationalize

[4]Published examples (7) indicate that 5,5-dialkylcyclopentadienes absorb at about 250 nm and that each further alkyl substituent contributes an increment of 3–4 nm. Extinction coefficients are in the range 3000–4500.

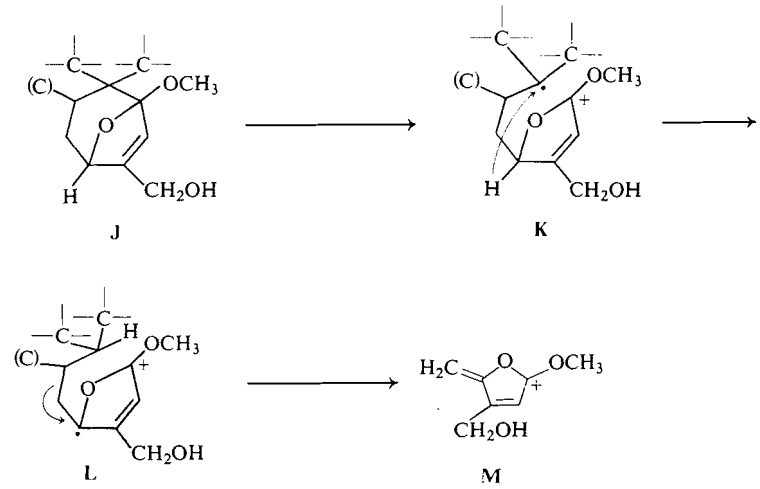

SCHEME 1

the formation of the *m/e* 141 ion on the basis of a ketal derived from a system such as **I**. Such an ion may, however, readily be accounted for (Scheme 1) if the original carbocyclic ring is (at least) seven-membered. α-Cleavage (**J** → **K**) followed by hydrogen shift (five-membered transition state **K**) and cleavage (**L**) yields the highly resonance-stabilized ion **M**.

The n.m.r. spectrum of the ketal (Table 2) is similar to that of the diacetyl derivative. Noteworthy is the fact that the splitting pattern for proton b (δ 4.72) has changed considerably. Nuclear magnetic double resonance experiments show that the couplings with j and g are now only 3 Hz and <1 Hz, respectively. This coupling pattern is reminiscent of that displayed by protons attached to the bridgehead carbon in bicyclo[2.2.1] systems (*5a*).

The acetyl derivative of allocyathin B_3 methyl ketal was prepared in order to provide unequivocal evidence that it is indeed the secondary hydroxyl group which is involved in ketal formation. The n.m.r. spectrum (C_6D_6) shows a single three proton singlet at δ 1.59 confirming monoacetylation; the methylene protons, c and d, of the primary alcohol underwent a downfield shift of 0.4 p.p.m., a typical "acylation shift" (ref. *5b*, p. 122) for primary alcohols, whereas signal b was not shifted.

The low chemical shifts of protons e and f in the various n.m.r. spectra suggest that part structures **B** and **G** are attached to **F** as in **N** or **O**.[5] Twenty-four of the 28 protons and 17 of the 20 carbon atoms are accounted for in the expanded part structures **C**, **D**, and **O** (or the alternative **N**). The functionality defined dictates a tricyclic system. The remaining three carbons must be attached to the carbonyl carbon, to the carbon bearing proton f, and, possibly, to the saturated carbon of the cyclopentadiene moiety. The only structural possibilities remaining at this point are shown in Scheme 2.

Structures **P**, **Q**, and **R** have a double bond at a bridgehead carbon and thus contradict Bredt's rule. Attempts to build molecular models strengthened the view that these structures could be excluded. Structures **S** and **T** (in each case two positional isomers possible on cyclopentadiene ring) may be disregarded since the n.m.r. spectra lack signals in the region typical of cyclopropyl protons, *i.e.*, between δ 1.0 and 0.0, and because of the stability of allocyathin B_3 to acid conditions (ketal formation). Structure **U** has a methylene group α to the carbonyl. The corresponding protons should give rise to signals between δ 3.0 and 2.0. Since this is not observed,

[5]Attachment of either of the carbons bearing proton e or f to the carbonyl group in **G** could also account for such shifts. However, if the carbon carrying proton f were attached to the carbonyl carbon a six-membered ring would result and this has been shown to be unlikely. The fact that the chemical shifts of protons e and f remain essentially unchanged after ketalization also serves to exclude the possibility that they are α to the carbonyl.

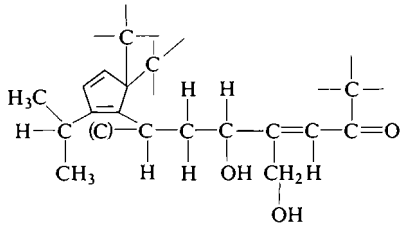
N



O

this structure is ruled out. The same reasoning applies to **V**. Moreover, **V** contains two isolated methylene groups which should give rise to two discernible AB quartets. Such is not the case. Structure **W** then remains as a unique solution to the structural problem. At this stage it was not possible to completely define the relative stereochemistry of allocyathin B_3. At the same time that the studies described here were in progress, we had initiated with others in these laboratories an X-ray crystallographic study of cyathin A_3. Shortly after structure **W** (= **2***a* without stereochemical implication) had been deduced for allocyathin B_3 and consequently structure **5***a* (without stereochemical implication) for cyathin A_3 (see below) the X-ray structure determination was completed (8) and revealed that crystalline cyathin A_3 exists in the internal hemiketal form **1** (=**6***a*) with the relative stereochemistry shown in **1**. We have arbitrarily selected H-5 (H_f in the discussion above) to be situated on the β-face of the molecule and shall adhere to that convention throughout the paper. Recent work (8) has shown that **1** also represents the absolute configuration of cyathin A_3. Since allocyathin B_3 has been correlated with cyathin

A_3 (see below), **2***a* ⇄ **3***a* represents the absolute stereochemistry of allocyathin B_3. The keto form (**2***a*) of allocyathin B_3 possesses four chiral centers and has the 5*R*, 6*R*, 9*S*, 11*R* configuration according to the Cahn, Ingold, Prelog notation (9). In cyathin A_3 the configuration is 5*R*, 6*R*, 9*R*, 11*R* (8).

We may now assign structure **2***b* to the diacetyl derivative of allocyathin B_3 (*O*,*O*-diacetylallocyathin B_3), **3***b* to allocyathin B_3 methyl ketal, and **3***c* to *O*-acetylallocyathin B_3 methyl ketal.

The presence of the cyclopentadiene moiety in allocyathin B_3 was further confirmed by formation of a Diels–Alder adduct. When a benzene solution of **2***b* and maleic anhydride was heated to 70° the crystalline adduct **4** was formed in good yield. The n.m.r. spectrum shows the typical coupling pattern expected for a bicyclo-[2.2.1]heptene system; in particular, H-1 is coupled to H-1′ by 4.5 Hz (*exo* coupling) proving that the adduct has the expected *endo* configuration (ref. 5*a*, p. 289). We are unable to determine

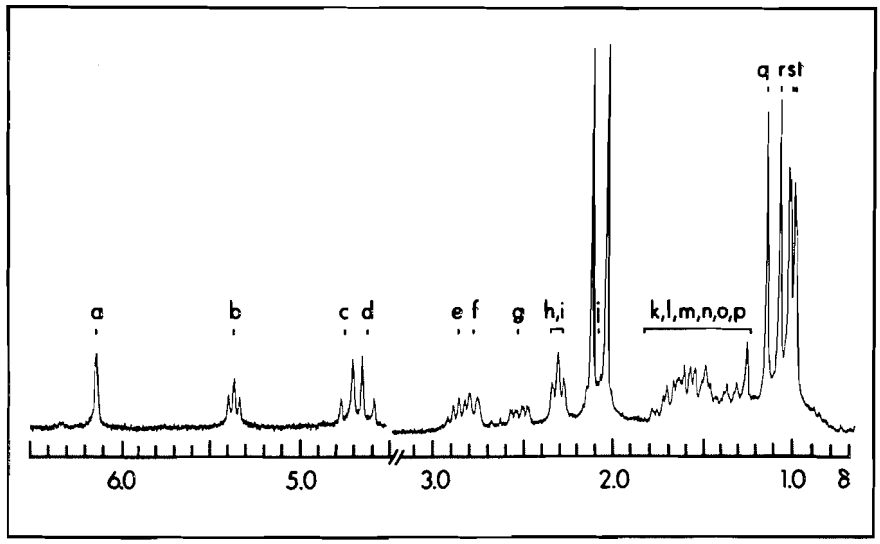

FIG. 2. Nuclear magnetic resonance spectrum (220 MHz) of *O,O*-diacetylcyathin A_3 in $CDCl_3$.

the configuration at C-1 and -4 (*i.e.*, whether addition has occurred to the α or the β face).

In contrast to allocyathin B_3, cyathin A_3 crystallizes in the hemiketal form as is evidenced by the solid phase i.r. spectrum which lacks absorption in the 1750–1650 cm^{-1} region. The i.r., u.v., and c.d. spectra taken in solution display absorption bands which are assigned to an α,β-unsaturated carbonyl group; however the 1650 cm^{-1} band is, as in allocyathin B_3, only of medium intensity and consequently cyathin A_3 appears to exist in solution as an equilibrium mixture of the tautomeric forms **5***a* and **6***a*.

O,O-Diacetylcyathin A_3 (**5***b*) was prepared in the same way as *O,O*-diacetylallocyathin B_3 (**2***b*). No rearrangement occurred during acetylation, since under mild alkaline hydrolysis conditions (K_2CO_3 – aqueous CH_3OH) **5***b* could be converted back to **5***a*. In fact we have noticed that simple storage of **5***b* in methanol will effect the same conversion. The spectroscopic data obtained with **5***b* are similar to those obtained for **2***b*, except for those features which are associated with the cyclopentadiene chromophore. The more characteristic features are: i.r. maximum at 1690 cm^{-1} with a shoulder at 1670 cm^{-1}; u.v. maximum (isooctane) at 323 nm (ε 130), shoulder at 225 nm (ε 8700), assigned to n–π* and π–π* transitions of the α,β-unsaturated carbonyl system, respectively; c.d. maximum at 330 nm (Δε +2.73). The n.m.r. spectra (Fig. 2 and Table 3) lack the AB quartet in the δ 6.0–6.5 region; instead, they display two additional unresolved signals in the δ 1.2–1.8 region for the two protons on C-1 and signals for another two protons at ~δ 2.3 attributable to the allylic protons at C-2 (the coupling pattern for this multiplet could not be analyzed). The remaining protons give chemical shifts and coupling patterns similar to those of **2***b*, with the exception that the signal for H-10α (axial proton j) is obscured by that of the allylic methylene at C-2.

The methyl ketal **6***b* formed almost instantaneously when cyathin A_3 was treated with dilute methanolic hydrochloric acid. Ketal formation is reversible since cyathin A_3 can be recovered after mild acid hydrolysis. The spectroscopic data for **6***b* is in complete agreement with the assigned structure (see Tables 2 and 3). The most characteristic feature of the n.m.r. spectrum is the narrow multiplet at δ 4.79 ($CDCl_3$) for the bridgehead proton H-11 (proton b) shown to be coupled to H-10α (3 Hz) and H-10β (~0.5 Hz) by n.m.d.r. experiments. The acetyl derivative **6***c* was formed in the usual manner and displayed the expected properties (see Tables 2 and 3).

During the investigation of these compounds we frequently encountered complications when reactions were conducted under alkaline conditions (*e.g.*, attempted hydrolysis of *O*-acetyl derivatives with hydroxide catalysis). When this observation was followed up by control experiments it was found that the epimeric conjugate

addition products **7***a* and *b* were formed in a ratio of about 4:1 when cyathin A_3 was allowed to stand overnight in dilute methanolic potassium hydroxide. The R_f values of the two products differed sufficiently to allow separation by p.t.l.c. The predominant isomer was obtained in pure form, the minor one in a purity of only ~70% (estimated by n.m.r. spectroscopy). The major epimer **7***a* has the molecular composition $C_{21}H_{34}O_4$ (h.r.m.s.); the u.v. (no maxima near either 290 or 230 nm), c.d. (weak negative minimum at 290 nm, $\Delta\varepsilon$ −0.05), and i.r. spectra (extremely weak carbonyl absorption at 1690 cm^{-1}) all indicate that the adduct exists almost exclusively in the hemiketal form. The n.m.r. spectrum ($CDCl_3$) shows a three-proton singlet at δ 3.36 for the methoxyl group and a relatively narrow multiplet at δ 4.27 for H-11. No assignments can be made with respect to coupling patterns and chemical shifts of H-2, -5, -10, and -13 as together they give rise to a complex signal in the region δ 2.4–2.1. The minor epimer **7***b* was characterized only by its i.r. spectrum (no carbonyl absorption) and n.m.r. spectrum (see Table 3) which exhibits a pattern similar to that of **7***a* (on which it is superimposed, since **7***a* is the impurity in the sample of **7***b*).

Acetylation of **7***a* at 50° for 1.5 h gave the monoacetyl derivative **8**. The i.r. spectrum of **8** shows hydroxyl absorption at 3380 and 3580 cm^{-1}, and acetoxyl absorption at 1743 cm^{-1} with a very weak shoulder at ~1690 cm^{-1} (keto tautomer). The n.m.r. spectrum shows an acetyl methyl signal at δ 2.09; protons H-15a and H-15*b* are shifted downfield by about 0.6 p.p.m. relative to **7***a*. These data establish that **8** exists mainly in the hemiketal form and that it is the primary hydroxyl group which is acetylated.

The diacetyl derivative **9** was prepared by heating **8** with acetic anhydride – pyridine – benzene under reflux for several hours. The presence of the keto group was revealed by the u.v. (maximum at 282 nm, ε 150), c.d. (298 nm, $\Delta\varepsilon$ −1.9), and i.r. spectra (strong absorption at 1696 cm^{-1}). The n.m.r. spectrum ($CDCl_3$) displays two acetyl signals (δ 2.10 and 2.09). The signals for the protons at C-13 appear at somewhat lower field than those of **7***a* and **8** and give rise to an AB quartet centered at δ 2.94 with $\Delta\nu = 26$ Hz and $J = 13$ Hz. The signal for H-11 is shifted downfield by 0.75 p.p.m. (δ 5.02) when compared with the corresponding signal in **7***a* or **8** and appears as a clean doublet of doublets with coupling constants of 11 Hz (presumably due to axial–axial type coupling with H-10α) and 4 Hz (axial–equatorial type coupling with H-10β). The configuration at C-12 has not been established.

All attempts to hydrogenate allocyathin B_3 (or one of its derivatives) selectively to cyathin A_3 (or one of its derivatives) met with failure. It was therefore necessary to correlate the two series via a common hydrogenation product. Under various hydrogenation conditions (10) cyathin A_3 methyl ketal (**6***b*) was transformed,

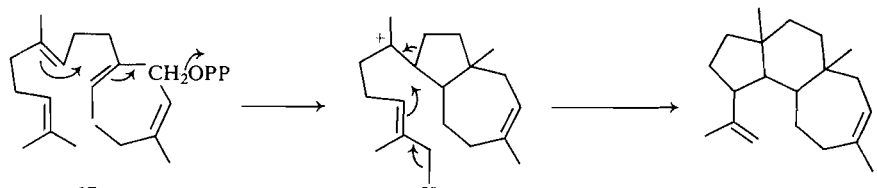
in varying degree, to three different products (each possibly consisting of a pair of C-12 epimers). These are assigned structures **10** (product of normal hydrogenation), **11** (hydrogenolysis and hydrogenation), and **12** (allylic rearrangement). Assignments **10** and **11** must be considered tentative as they were arrived at only on the basis of mass and i.r. spectroscopy. When 5% Pd–C was used as catalyst aldehyde **12***a* was the predominant product. As shown by h.r.m.s., it is isomeric with the starting material; the aldehyde function is apparent from the i.r. (2710 and 1725 cm^{-1}) and n.m.r. spectra (δ 9.64, $J = 2$ Hz). The assignment of configuration at C-12 is based on the coupling pattern of H-12 (δ 2.53), revealed by decoupling experiments: $J_{12,13a} = 9$, $J_{12,13b} = 4$, $J_{12,15} = 2$, and $J_{12,11} < 0.5$ Hz. The latter value allows us to assign the *endo* configuration (β) to H-12 and *exo* configuration (α) to the aldehyde function. When allocyathin B_3 methyl ketal (**3***b*) was subjected to hydrogenation using 5% Pd–C as catalyst the products were **10**, **11**, and the *endo* aldehyde **12***b*. The *endo* aldehyde **12***b* differed in R_f value and i.r. spectrum from the epimeric **12***a*. When **12***b* was allowed to stand in methanol containing sodium carbonate it isomerized to **12***a*, identical (t.l.c. behavior, i.r. spectrum) with that obtained from cyathin A_3. The different product distribution (**12***a* *vs.* **12***b*) is attributed to slight variations in p*H* during the different hydrogenations.

In another series of experiments, cyathin A_3 and allocyathin B_3 were subjected to hydrogenation. Reproducible results were obtained using ethyl acetate as solvent, 5% Pt–C as catalyst, and traces of sodium bicarbonate as a buffer. Under these conditions crystalline dihydrocyathin A_3 (**13***a*) is formed in good yield from cyathin A_3. Crystalline **13***a* exists in the hemiketal form as shown by the solid-phase i.r. spectrum (no carbonyl absorption); in solution both hemiketal and keto forms are present in equilibrium since fairly substantial carbonyl absorption bands are observed in the i.r., u.v., and c.d. spectra. Due presumably to this equilibrium the n.m.r. spectrum is poorly defined. The diacetyl derivative **13***b* also crystallizes readily. The ketonic absorption is much stronger in the various spectra (see Table 2) and the n.m.r. spectrum (C_6D_6) is well defined. Proton H-11 resonating at δ 4.86 shows couplings of 11, 11, and 4 Hz assigned to interactions with H-10α, H-12, and H-10β, respectively. The large coupling indicates a *trans*-coplanar relationship between H-11 and H-12. If we assume that ring C occupies a twist chair conformation (11) with the axis carbon at C-6 (this being the only carbon that carries two substituents) and further assume that the chiral center C-11 was not inverted during the hydrogenation we conclude that H-12 must be *trans* to H-11 and consequently occupies the α position. This conformation places all substituents in energetically favorable positions (11), those at C-6 into isoclinal and those at C-5, -11, and -12 into equatorial positions. The remaining n.m.r. data are summarized in Table 3 and indicate that hydrogenation has occurred stereoselectively from the α side to produce only one epimer. This may be due to the fact that it is the hemiketal form of cyathin A_3 which actually undergoes hydrogenation. The α side is the more freely accessible *exo* side of the bicyclo-[3.2.1] system. When allocyathin B_3 is subjected to the same hydrogenation conditions as cyathin A_3 it appears that the Δ^{12} bond is hydrogenated selectively. Assignment of structure **14** to this intermediate product remains tentative as it was characterized only by its u.v. spectrum which displays a typical cyclopentadiene chromophore at 253 nm. Under somewhat more vigorous conditions the cyclopentadiene moiety is also reduced. A major product (the desired **13***a*) and a minor one (presumably **15***a*, due to 1,4 addition) were formed in a ratio of ~3:1 along with traces of unidentified compounds. Separation of the two isomers was effected by p.t.l.c., although in one instance this was not necessary since the major product crystallized selectively.

The usual spectroscopic characteristics of the major product and its diacetyl derivative were obtained and compared with those of dihydrocyathin A_3; they are identical within the limits of experimental error. In particular, m.p.'s were the same, mixture m.p.'s were undepressed, solid-phase i.r. spectra were identical for both the parent compound and the diacetyl derivative and the richly detailed n.m.r. spectra and the o.r.d. and c.d. spectra of the diacetyl derivatives were superimposable.

The hydrogenation experiments serve to confirm the relationship between cyathin A_3 and allocyathin B_3 and thus establish structure **1** (without stereochemical implications) for cyathin A_3. Since, on the other hand, the full structure of cyathin A_3 (including absolute stereochemistry) has been established by X-ray crystallog-



SCHEME 3

raphy, these experiments also serve to establish the complete structure of allocyathin B_3 as **2***a*, provided we make the reasonable assumption that the chiral centers C-5, -6, -9, and -11 are not altered during the hydrogenation.[6]

The molecular formulas of the cyathins together with the fact that they contain five *C*-methyl group equivalents suggested at an early stage that they belong to the diterpenoid group of natural products (12). The carbon skeleton **16**, for which we suggest the name cyathane, does not appear to have been encountered previously among the diterpenes (13). It may also be noted that allocyathin B_3 is one of the very few cyclopentadienes that have been isolated from natural sources. Geranylgeranyl pyrophosphate (**17**) is regarded as the biogenetic precursor of the cyclic dieterpenoids (14). The carbon skeleton of the cyathins may be derived from geranylgeranyl pyrophosphate as illustrated in Scheme 3, or by variations on this theme. Various oxidative and reductive processes lead to the individual cyathins. Recent work has led to the elucidation of the structures of two additional members of this family of compounds (15) and to their correlation with cyathin A_3 and allocyathin B_3.

Experimental

High resolution mass spectra were recorded on an A.E.I. model MS-9 mass spectrometer, i.r. spectra on a Perkin-Elmer model 421 dual grating spectrometer, u.v. spectra on a Cary model 14M spectrophotometer, c.d. and o.r.d. spectra (only the $[\alpha]_D$ values are reported here) on a Jasco model 5 spectropolarimeter, and 100 MHz n.m.r. spectra on a Varian HA-100 spectrometer. A Varian HR-220 spectrometer at the Ontario Research Foundation, Sheridan Park, Ontario, was used to measure the 220 MHz n.m.r. spectra of **2***b* and **5***b*. Melting points were determined on a Leitz-Wetzlar hot-stage or a Fisher-Johns melting point apparatus. The various data obtained with these instruments are reported in Tables 1, 2, and 3.

Plates for t.l.c. were prepared with equipment available from DESAGA Heidelberg. Ordinary t.l.c. plates were prepared with Silica Gel G (E. Merck, Darmstadt) to which 1% Electronic Phosphor (General Electric, Cleveland) was added. Argentated silica gel was prepared by mixing Silica Gel G (45 g) with $AgNO_3$ (5 g in 100 ml water). For analytical t.l.c., the thickness of the layers varied from 0.3–0.5 mm, for p.t.l.c. from 0.5–0.7 mm. In p.t.l.c. compounds were detected by viewing under shortwave (254 nm) u.v. light (ordinary t.l.c.) or longwave (325 nm) u.v. light after the plates were sprayed with 0.2% solution of ethanolic 2′,7′-dichlorofluorescein in 95% ethanol. In the case of analytical t.l.c. spraying with 30% H_2SO_4 and heat charring served as an alternative method. The chromatograms were developed with $CHCl_3$–MeOH 9:1 (system A, to separate polar substances) or Skellysolve B – acetone 3:1 (system B, to separate less polar substances) unless otherwise specified.

Unless otherwise noted, acetylations were carried out by using an "acetylation solution" prepared from 0.16 ml pyridine and 0.08 ml acetic anhydride made up to 1 ml with benzene. When acetylation was complete (as indicated by t.l.c.) excess reagents were usually removed by "purging" with benzene, *i.e.*, evaporating the mixture at reduced pressure, dissolving the residue in benzene, evaporating, and repeating the process 2–3 times. Solvents were usually evaporated under reduced pressure (water aspirator) with the aid of a rotary evaporator at a bath temperature of 40–50°. Skellysolve B refers to Skelly Oil Company light petroleum, b.p. 62–70°.

Separation of Allocyathin B_3 (A) and Cyathin A_3 (B)

Cyathin A_3 – mixture (240 mg), isolated as reported previously (2), was applied to two t.l.c. plates each supporting a layer of 0.05 × 20 × 100 cm of 10% $AgNO_3$ – silica gel. The plates were developed with Skellysolve B – acetone 2:3, sprayed with a 0.2% solution of 2′,7′-dichlorofluorescein in ethanol, and viewed under longwave u.v. light to locate the zones containing allocyathin B_3 and cyathin A_3. The zones were scraped off and eluted with ether (250 ml). After evaporation, 79 mg allocyathin B_3 and 117 mg cyathin A_3 were obtained. Cyathin A_3 crystallized after trituration with acetone and could be further purified by recrystallization from benzene or benzene–cyclohexane mixtures.

Anal. Calcd. for $C_{20}H_{30}O_3$: C, 75.43; H, 9.50. Found:

[6]The hydrogens on the two centers which could conceivably be inverted (double bond migration on the catalyst surface) during hydrogenation, C-5 and -11, both give rise to well-defined n.m.r. signals. Since these signals are very similar in both series, it is considered unlikely that cyathin A_3 and allocyathin B_3 differ at either or both of these chiral centers.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

C, 75.37, 75.46; H, 9.59, 9.68%. Further characterization is described in Tables 2 and 3.

Allocyathin B_3 could only be crystallized after it had been subjected to an acetylation–deacetylation procedure, as described below, with further purification by p.t.l.c. at each stage. Allocyathin B_3 was then recrystallized from Skellysolve B – benzene. Characterization of allocyathin B_3 and its derivatives is described in Tables 1 and 2.

Preparation of O,O-Diacetylallocyathin B_3 (2b)

Allocyathin B_3 (19 mg) was treated with acetylation solution (1 ml) for 4.5 h at 45°. The usual work-up followed by p.t.l.c. (system B) yielded *O,O*-diacetylallocyathin B_3 (13 mg). When the reaction mixture was worked-up after 1 h, the monoacetyl derivative (C-15 hydroxyl acetylated) was the major product.

Methanolysis of O,O-Diacetylallocyathin B_3

O,O-Diacetylallocyathin B_3 (102 mg) was dissolved in methanol (10 ml) and K_2CO_3 (6.5 mg) was added. As judged by t.l.c., deacetylation occurred immediately. This material yielded crystalline allocyathin B_3 after evaporation, removal of salts, and p.t.l.c.

Preparation of Allocyathin B_3 Methyl Ketal (3b)

To a solution of allocyathin B_3 (31 mg) in methanol (20 ml) was added a saturated solution of HCl in methanol (1 ml). After 0.5 h the solution was neutralized with Na_2CO_3 (800 mg), insoluble material removed by filtration, and the solvent evaporated. The residue was dissolved in ether, filtered, and evaporated to give crude product (28 mg). Purification by p.t.l.c. (system B) yielded pure allocyathin B_3 methyl ketal (20 mg) which could not be obtained in crystalline form.

Preparation of O-Acetylallocyathin B_3 Methyl Ketal (3c)

Allocyathin B_3 methyl ketal (20 mg) was treated with a solution of pyridine (0.16 ml) and acetic anhydride (0.08 ml) in dichloromethane (1 ml) for 1 h at 30° and then for 0.5 h at 40°. The crude product was purified by p.t.l.c. (system B) to give *O*-acetylallocyathin B_3 methyl ketal which could not be crystallized but was used directly for spectroscopic measurements.

Preparation of Diels–Alder Adduct 4

A solution of maleic anhydride (3.25 mg, 0.033 mmol) in benzene (0.13 ml) was added to *O,O*-diacetylallocyathin B_3 (13 mg, 0.033 mmol) in a 5-ml conical flask. The flask was heated to ~70° for 19 h. Evaporation of the solvent left crude adduct (18 mg), which was purified by p.t.l.c. (solvent system Skellysolve B – acetone, 2:1) to yield crystalline **4** (6 mg).

Preparation of O,O-Diacetylcyathin A_3 (5b)

Crystalline cyathin A_3 (20 mg) was treated with a solution of pyridine (0.16 ml) and acetic anhydride (0.08 ml) in dichloromethane (1.0 ml) for 0.5 h at 26° (monoacetylation), and for 10 h at 35° (diacetylation, as judged by t.l.c.). The usual work-up yielded crude product (20 mg) as a nearly colorless gum. Purification by p.t.l.c. (system B), followed by molecular distillation at 105–120°/0.02–0.2 mm gave pure *O,O*-diacetylcyathin A_3 (15 mg) which could not be induced to crystallize.

Hydrolysis of O,O-Diacetylcyathin A_3

O,O-Diacetylcyathin A_3 (23 mg) was treated at room temperature with a solution of 2% K_2CO_3 in 80% aqueous methanol (1.5 ml) for 0.5 h. The reaction mixture was then diluted with water (2 ml), extracted with ether (25 ml), and washed with water until neutral. Evaporation of the dried ($MgSO_4$) extract yielded a product which was identical with cyathin A_3 according to t.l.c., mass, and i.r. spectra.

Preparation of Cyathin A_3 Methyl Ketal (6b)

Crystalline cyathin A_3 (20 mg), dissolved in methanol (10 ml), was treated with a saturated solution of HCl in methanol (10 drops) for 0.5 h. The solution was then neutralized with Na_2CO_3 (120 mg) and the solvent evaporated. The residue was taken up in ether, the suspension filtered, and the ether evaporated to yield cyathin A_3 methyl ketal (22 mg) which showed a single spot on t.l.c.

Hydrolysis of Cyathin A_3 Methyl Ketal

Cyathin A_3 methyl ketal (40 mg) was dissolved in acetone – water – concentrated HCl (20:2:1) (23 ml) and kept for 18 h at 32°. The solution was neutralized with Na_2CO_3, filtered, and most of the acetone evaporated. The resulting aqueous suspension was extracted with ether, dried ($MgSO_4$), filtered, and evaporated to give crude product (36 mg). Purification by p.t.l.c. (system A) gave cyathin A_3 (11 mg) which crystallized upon trituration with acetone. Identity was established by t.l.c. and i.r. spectrum (KBr pellet).

Preparation of O-Acetylcyathin A_3 Methyl Ketal (6c)

Cyathin A_3 methyl ketal (20 mg) was treated with a solution of pyridine (0.16 ml) and acetic anhydride (0.08 ml) in dichloromethane (1 ml) for 1.25 h at 26° and for 1 h at 40°. The usual work-up yielded *O*-acetylcyathin A_3 methyl ketal which crystallized upon storage in the refrigerator.

Preparation of Methanol Adducts 7a and 7b

Cyathin A_3 (20 mg) was dissolved in a solution of 2% KOH in methanol (1.0 ml) and allowed to stand for 17 h at room temperature. The solution was concentrated under a nitrogen stream and subjected to p.t.l.c. (system A) to yield crude **7a** (17.5 mg) and crude **7b** (3.7 mg). Crude **7a** was subjected once more to purification by p.t.l.c. and obtained in pure form as judged by t.l.c. and n.m.r. Crude **7b** was chromatographed (p.t.l.c.) twice more but could only be obtained in a purity of *ca.* 70% (as judged by n.m.r., the remaining 30% being **7a**).

Preparation of 8

The major adduct **7a** (17 mg) was treated with acetylation solution (1 ml) for 1.5 h at 40° and 1.5 h at 50°. The usual work-up yielded crude **8** (20 mg) with which the data listed in Table 2 were obtained.

Preparation of 9

The monoacetyl derivative **8** (20 mg) was dissolved in acetylation solution (1 ml) and heated under reflux for 24 h. The usual work-up yielded crude product (18 mg). Purification by p.t.l.c. (system B) yielded **9** (11 mg), which could not be crystallized.

Hydrogenation of Cyathin A_3 Methyl Ketal

Crystalline cyathin A_3 (30 mg) dissolved in methanol (60 ml) was treated with a saturated solution of HCl in methanol (1 ml) for 0.5 h. Dry Na_2CO_3 (1 g) was added, the mixture stirred until the solution was neutral, and the insoluble material filtered off. Palladium–charcoal (5%,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

50 mg) was added to the filtrate and the mixture stirred in an atmosphere of hydrogen for 0.5 h at room temperature. The catalyst was removed by filtration and the solvent evaporated. The residue was taken up in ether, filtered, and the solvent evaporated. The crude product (28 mg) consisted mainly of two components, alcohol **10** and aldehyde **12***a*, along with trace amounts of **11** (the latter identified by t.l.c.). The aldehyde (12 mg) and the alcohol (7 mg) were separated by p.t.l.c. (system B). No attempt was made to isolate **11**. Alcohol **10** could not be crystallized. Aldehyde **12***a* crystallized spontaneously after evaporation of the solvent from the appropriate chromatographic fraction and was recrystallized from Skellysolve B.

Hydrogenation of Allocyathin B_3 Methyl Ketal

Allocyathin B_3 methyl ketal (purified by p.t.l.c., 10 mg), dissolved in methanol (20 ml), was hydrogenated over 5% Pd–C (20 mg) at atmospheric pressure and room temperature for 17 min. The catalyst was filtered off and the solvent evaporated. The crude product (9 mg) was separated by p.t.l.c. (system B) and found to be a mixture of **10** (1 mg), **11** (3 mg), and **12***b* (1 mg).

Aldehyde **12***b* isomerized to **12***a* when allowed to stand in a saturated solution of Na_2CO_3 in methanol (1 ml) for 28 h at room temperature. The solvent was evaporated, the residue taken up in ether, filtered, and evaporated. The i.r. spectrum and t.l.c. characteristics of the product were indistinguishable from those of aldehyde **12***a* obtained from cyathin A_3. The small amount (~0.5 mg), however, precluded attempts at recrystallization.

Hydrogenation of Cyathin A_3

Cyathin A_3 (30 mg), 5% Pt–C (15 mg), and $NaHCO_3$ (30 mg) in ethyl acetate (30 ml) were hydrogenated at room temperature and atmosphere pressure for 10 min. Catalyst and undissolved $NaHCO_3$ were removed by filtration and the solvent was evaporated to give a crude hydrogenation product (35 mg). Crystallization from benzene yielded 12,13-dihydrocyathin A_3 (**13***a*) (10 mg). The mother liquors contained mainly **13***a* and this material was used for acetylation (see below).

Hydrogen of Allocyathin B_3

(a) "Incomplete" Hydrogenation

In an exploratory experiment, allocyathin B_3 (4 mg), 5% Pt–C (5 mg), and $NaHCO_3$ (4 mg) were suspended in ethyl acetate (4 ml) and hydrogenated at room temperature and atmospheric pressure for 5 min. Catalyst, $NaHCO_3$, and solvent were removed and the crude product investigated by u.v. and mass spectroscopy which indicated that 11,12-dihydroallocyathin B_3 (**14**) had formed.

(b) "Complete" Hydrogenation

Crystalline allocyathin B_3 (10.4 mg), 5% Pt–C (10 mg), and $NaHCO_3$ (10 mg) were suspended in ethyl acetate (10 ml) and hydrogenated at room temperature and atmospheric pressure for 30 min. Filtration and evaporation yielded crude product (11.2 mg) which consisted mainly of **13***a* and **15***a*. This material was subjected to p.t.l.c. (system A) and **13***a* (6.7 mg) and **15***a* (2.6 mg), both slightly impure, were obtained. In a separate hydrogenation experiment involving allocyathin B_3, 1,2,12,13-tetrahydroallocyathin B_3 (12,13-dihydrocyathin A_3, **13***a*) crystallized directly from the hydrogenation product. Identity of this product with that obtained from cyathin A_3 was established by means of t.l.c., m.p., mixed m.p., and i.r. spectroscopy.

Preparation of 13b

(a) From Cyathin A_3

Crude **13***a* (residue from the crystallization, 20 mg) was treated with acetylation solution (1 ml) at 50° for 10 h. The usual work-up gave a crude product (24 mg) which was combined with material of similar purity obtained in a separate experiment (7 mg) and subjected to p.t.l.c. (system B). In this way the diacetyl derivative **13***b* (12.7 mg) was obtained. It crystallized from ether and could be recrystallized from Skellysolve B.

(b) From Allocyathin B_3

1,2,12,13-Tetrahydroallocyathin B_3 (the material described under the heading "Hydrogenation of Allocyathin B_3", 6.7 mg) was treated with acetylation solution (0.7 ml) at 50° for 17 h. The usual work-up followed by p.t.l.c. (system B) gave the diacetyl derivative **13***b* (6.2 mg) which crystallized from ether. Identity between this material and material derived from cyathin A_3 was established by t.l.c., m.p., mixed m.p., and u.v., o.r.d., c.d., i.r., and n.m.r. spectroscopy.

Preparation of 15b

15*a* (2.6 mg) was treated with acetylation solution (0.3 ml) at 50° for 17 h. The usual work-up yielded crude product (2.6 mg) which was purified by p.t.l.c. (system B) to give **15***b* (0.8 mg). This material crystallized when triturated with ether.

We wish to thank Professor Harold J. Brodie, Department of Botany, University of Alberta, for drawing this problem to our attention and for the help and instruction in microbiological techniques that he and Dr. B. N. Johri provided. We also wish to acknowledge the contributions of our colleague, the late Dr. A. D. Allbutt, to the early stages of this work. The financial support provided by the National Research Council of Canada is gratefully acknowledged.

Reactivity of the Thallium(I) Salts of 3-Hydroxy-1,3,5(10)-estratrien-17-one and 1,3,5(10)-Estratriene-3,17β-diol. Preparation of 17-Oxoestra-1,3,5(10)-trien-3-yl 2′-Acetamido-3′,4′,6′-tri-*O*-acetyl-2′-deoxy-β-D-glucopyranoside[1]

ALENKA PAQUET AND DONALD S. LAYNE
Department of Biochemistry, University of Ottawa, Ottawa, Canada K1N 6N5

Received April 12, 1973

Thallium(I) salts of estrone and 17β-estradiol were prepared in high yields by the reaction of estrone or 17β-estradiol with thallium(I) ethoxide. Both compounds were found to be reactive intermediates for alkylation and acylation of the steroid. The preparation and characterization of 17-oxoestra-1,3,5(10)-trien-3-yl 2′-acetamido-2′-deoxy-β-D-glucopyranoside by reaction of the thallium(I) salt of estrone with 2-trifluoroacetamido-3,4,6-tri-*O*-acetyl-2-deoxy-β-D-glucopyranosyl bromide is described.

Les sels de thallium(I) de l'estrone et de l'estradiol-17β ont été préparés avec de bons rendements par réaction de l'estrone ou de l'estradiol-17β avec l'éthylate de thallium(I). On a trouvé que les deux composés sont des intermédiaires réactifs pour l'alkylation et l'acylation du stéroide. On décrit la préparation et la caractérisation de l'acétamido-2′ déoxy-2′ β-D-glucopyranoside de l'oxo-17 estratriène-1,3,5(10)yle par réaction du sel de thallium(I) de l'estrone avec le bromure du trifluoroacétamido-2 tri-*O*-acétyl-3,4,6 déoxy-2 β-D-glucopyranosyle. [Traduit par le journal]

Can. J. Chem., **51**, 3855 (1973)

Since the initial recognition (1) that steroid glucuronides were present in human and animal excreta, many syntheses of these compounds have been reported (2). In the past 10 years evidence has accumulated that steroid glucuronides may be important in determining the transport as well as the rate and route of excretion of hormonally active steroids (2). In addition, glucosides, galactosides, and *N*-acetylglucosaminides of the estrogens have been found in tissues of the human and other animals (3, 4). These findings have focused attention on the physiological importance of steroid glycosides and on improved methods for their preparation. These latter have almost exclusively been concerned with increasing the yields obtained in the standard Koenigs–Knorr synthesis, and Bernstein and his collaborators (5, 6) have achieved yields of up to 70% of extrogen glucuronides and *N*-acetylglucosaminides by the use of cadmium carbonate as a catalyst in this reaction.

We have been interested in the development of syntheses which might be adaptable to the preparation, for use in physiological studies, of glycosides of radioactive steroids of high specific activity. Both the Koenigs–Knorr and the modified Helferich synthesis (7) are cumbersome for this purpose, and furthermore, in our hands, the yields obtained by Bernstein's procedure (5, 6) were highly variable, being extremely dependent on the source, purity, and crystalline state of the cadmium carbonate used. We therefore explored the use of thallium(I) salts of the phenolic steroid estrogens as intermediates in glycoside synthesis, using the procedures which have been described by Taylor, McKillop, and their coworkers (8, 9) for the preparation of derivatives of several other classes of compounds.

The thallium(I) salts of estrone and the 3-monothallium(I) salt of 17β-estradiol were prepared in practically quantitative yields by the reaction of the respective steroids with thallium(I) ethoxide. In initial experiments to explore the reactivity of these salts, it was found that their reaction with acyl or alkyl halides led to the facile formation of the corresponding acyl or alkyl derivatives of the steroids. The 3-acetates and 3-benzoates of both estrone and 17β-estradiol, as well as the 3-methyl and 3-benzyl ethers of these steroids, were obtained in yields of the order of 90%. The convenience and effectiveness of the procedure might well make it preferable in some instances to the usual methods of preparing these steroid derivatives, in similar yields, by the use of the appropriate anhydride or halide in pyridine (ref. 10 p. 30 and ref. 11).

The thallium(I) salt of estrone **1** was converted

into various glycosides in several solvent systems. The reaction gave low yields when chlorinated solvents (chloroform, dichloromethane) were used. High yields, which were reproducible, were obtained in benzene. Only a limited number of relatively easily available sugar derivatives were investigated in the present work. The reaction of the thallium(I) salt of estrone **1** with 2,3,4,6-tetra-*O*-acetyl-α-D-glucopyranosyl bromide produced only a 16% yield of the glycoside **6**, while the analogous reaction with 2,3,4,6-tetra-*O*-acetyl-α-D-galactopyranosyl bromide failed, as did the reaction with methyl 2,3,4-tri-*O*-acetyl-1-bromo-1-deoxy-α-D-glucopyranuronate. However, when the highly reactive 2-trifluoracetamido-3,4,6-tri-*O*-acetyl-2-deoxy-αD-glucopyranosyl bromide (**12**) was used (12), the reaction proceeded rapidly at room temperature and yielded 86% of pure 17-oxoestra-1,3,5(10)-trien-3-yl 2′-trifluoroacetamido-3,4,6-tri-*O*-acetyl-2-deoxy-β-D-glucopyranoside (**7**). Removal of acetyl groups from this product yielded the free amine **8** in crude form which was then either submitted to selective *N*-acetylation (13) by acetic anhydride in ethanolic solution or was fully acetylated with acetic anhydride in pyridine. The glycoside **9** obtained by the latter procedure was de-*O*-acetylated by treatment overnight at 0° with dry ammonia in chloroform–methanol (14). The 17-oxoestra-1,3,5(10)-trien-3-yl 2′-acetamido-2′-deoxy-β-D-glucopyranoside (**10**) obtained was compared with that synthesized by a conventional Koenigs–Knorr synthesis from estrone and 2-acetamido-3,4,6-tri-*O*-acetyl-α-D-glucopyranosyl chloride in acetone in the presence of 1 *M* NaOH and cadmium chloride. The two compounds had identical i.r. spectra and there was no depression of the melting point on mixing of the two.

The fact that, in a 30 min reaction time at room temperature with the thallium(I) salt of estrone an 86% yield of glycoside was obtained, whereas the less reactive sodium salt of estrone gave a much lower yield of 26% under the same conditions, indicates that 2-trifluoroacetamido-3,4,6-tri-*O*-acetyl-2-deoxy-α-D-glucopyranosyl bromide (**12**) is a very reactive glycosylating agent for the phenolic hydroxyl group of the steroid. The trifluoracetyl group can be easily introduced or removed under mild conditions, and it has therefore often been used (12, 15, 16) in nucleoside and glycoside syntheses involving 2-deoxy-2-amino sugars. The use of the trifluoracetyl as a non-participating group to avoid the formation of an oxazoline ring has been described by Strachan *et al.* (17) and discussed by Meyer zu Reckendorf *et al.* (18).

The β-D-anomeric linkage of the steroid glycosides synthesized in this work was established by the application of Klyne's rule (19).

The formation, by way of the thallium(I) salts, of ethers, esters, and glycosides of the phenolic hydroxyl group of the estrogens proceeds rapidly at room temperature under neutral conditions. The easy removal by filtration of precipitated thallium(I) halide makes the work-up simple and convenient as compared to previously reported methods (ref. 10 p. 204 and refs. 11 and 24).

Experimental

The following procedures were used unless otherwise stated. Melting points were determined on a Thomas-Hoover Capillary melting point apparatus and i.r. spectra on a Unicam SP200 spectrometer in chloroform solution or Nujol. Nuclear magnetic resonance spectra were determined on a Varian HA-100 or a Varian T-60 spectrometer in deuterochloroform or in dimethylsulfoxide solution, with tetramethylsilane as internal standard. Specific rotations were measured on a Perkin-Elmer 141 polarimeter in chloroform or methanol. T.l.c. was carried out on plates of Silica gel H and column chromatography on Silica gel 60 (70–230 mesh, ASTM). Both adsorbents were obtained from Merck, Darmstadt.

Thallium(I) Salt of Estrone ***1***

(i) Method using Benzene–ethanol as Solvent

Thallium(I) ethoxide (20) (250 mg) was added slowly with stirring to a suspension of 267 mg of estrone in a mixture of 4 ml of benzene and 2.5 ml of ethanol. Within a few minutes estrone was dissolved and another white crystalline precipitate appeared. The reaction mixture was left overnight at 4° and was then filtered to yield 426 mg (91%) of **1**.

(ii) Method using Ethanol as Solvent

Thallium(I) ethoxide (270 mg) was added with stirring to a solution of 270 mg of estrone in hot ethanol. A white crystalline product was separated by filtration. A further 150 mg of thallium(I) ethoxide in ethanol was added to the mother liquor and the crystalline product was again removed by filtration. The total yield was 368 mg (78%) of the thallium(I) salt of estrone **1**, m.p. 188–195° (dec.).

addition of 10 ml of ether a white crystalline solid was separated by filtration. A yield of 1.734 g (98%) of **1′** was obtained: m.p. (dec.) 180–200°; $[\alpha]_D^{25}$ +27.4° (*c*, 1.66 in pyridine). Analysis: drying under elevated temperature to remove solvent resulted in decomposition, precluding valid elemental analysis.

3-Acetoxyestra-1,3,5(10)-trien-17-one (2) and 3-Benzoyloxyestra-1,3,5(10)-trien-17-one (3). 3-Acetoxy-17β-hydroxyestra-1,3,5(10)-triene (2′) and 3-Benzoyloxy-17β-hydroxyestra-1,3,5(10)-triene (3′)

The thallium(I) salt of the steroid was suspended in benzene and a slight excess of acetylchloride or of benzoyl chloride in benzene solution was added slowly with stirring. The reaction vessel was kept in cold water during the addition. The inorganic precipitate was filtered off, washed with benzene, and the washings were added to the filtrate which was washed with a 10% (w/v) aqueous solution of sodium carbonate and then with 5% hydrochloric acid and with water. The organic layer was dried over sodium sulfate and concentrated. The following esters were obtained in crystalline form (>90%) by this procedure: **2**, m.p. 124° (lit. (21) 125°); **3**, m.p. 216° (lit. (21) m.p. 218°); **2′**, m.p. 134–136° (lit. (22) 136–138°); **3′**, m.p. 193° (methanol–water) (lit. (23) 192–193°) (methanol–water). The i.r. spectra of chloroform solutions were in accord with these structures.

3-Methoxyestra-1,3,5(10)-trien-17-one (4) and 3-Benzyloxyestra-1,3,5(10)-trien-17-one (5). 3-Methoxy-17β-hydroxyestra-1,3,5(10)-triene (4′) and 3-Benzyloxy-17β-hydroxyestra-1,3,5(10)-triene (5′)

The 3-monothallium(I) salt of steroid (100 mg) was dissolved in 2 ml of dimethylsulfoxide and a slight excess of methyl iodide or benzyl bromide was added. After 10 min 5 ml of chloroform and a small amount of Celite were added. The inorganic precipitate was filtered off and washed with chloroform. The filtrate and washings were combined and concentrated by evaporation, aqueous methanol was added, and the crystalline precipitate was separated by filtration and recrystallized from methanol–water. The following ethers were obtained: **4** (92%), m.p. 165° (lit. (24) m.p. 161–162°); **5** (80%), m.p. 134° (lit. (21) m.p. 136°); **4′** (94%), m.p. 96–98° (fuse), 118–120° (melting) (lit. (23) m.p. 97–98°); **5′** (94%), m.p. 83° (lit. (23) m.p. 82–84°). Infrared spectra in chloroform were in accord with these structures.

Etherifications in Dimethylformamide

The thallium(I) salt of estrone (100–110 mg) was dissolved in dimethylformamide and a slight excess of methyl iodide or of benzyl bromide was added. The reaction mixture was heated with stirring at 70° for 3 h in the methylation reaction and at 55° for 4 h in the benzylation reaction. The inorganic precipitate was removed by filtration through a pad of Celite and was washed with chloroform. The washings were added to the filtrate, which was concentrated by evaporation. Crystalline products **4** and **5** were obtained in the yields over 90%.

17-Oxoestra-1,3,5(10)-trien-3-yl 2′,3′,4′,6′-Tetra-O-acetyl-β-D-glucopyranoside (6)

2,3,4,6-Tetra-*O*-acetyl-α-D-glucopyranosyl bromide (**11**) (411 mg) was added in two portions to a suspension of 470 mg of the thallium(I) salt of estrone **1** in 10 ml of benzene. The reaction mixture was stirred at room temperature for 3 days. The inorganic precipitate was removed by filtration. After evaporation and separation of a small amount of unreacted steroid, 97 mg of glycoside **6** was obtained (16%), m.p. 139–141° (lit. (5, 7) m.p. 140–142°).

17-Oxoestra-1,3,5(10)-trien-3-yl 2-Trifluoroacetamido-3′,4′,6′-tri-O-acetyl-2-deoxy-β-D-glucopyranoside (7)

(i) From the Thallium(I) Salt of Estrone

The thallium(I) salt of estrone (650 mg) was added in small portions to a solution of 634 mg of 2-trifluoroacetamido-3,4,6-tri-*O*-acetyl-2-deoxy-α-D-glucopyranosyl bromide (**12**) in 10 ml of dry benzene. The reaction mixture was stirred at room temperature for 30 min. The inorganic product was removed by filtration through a Celite pad and washed with benzene. The filtrate and washings were combined and washed with a small amount of water, dried over sodium sulfate, and evaporated to dryness. On crystallization from dichloromethane–ether–hexane 865 mg of crude material yielded 765 mg (86%) of **7**: m.p. 203–205°; $[\alpha]_D^{27}$ +51° (*c*, 0.5 in chloroform). These constants remained unchanged on further crystallization. Infrared (chloroform) ν_{max} 1720–1745, 1545, 1510, 1200–1250, and 1180 cm^{-1}; n.m.r. (Varian HA-100, $CDCl_3$) 7.22 (H-1 and N—H; 2 protons, spacing 20 Hz), 6.75 (H-2, -4; 2 protons, m, 12 Hz), broad signal from 5.4 to 5.02 (H-1′, -3′, -4′, 3 protons), 4.2 (Hs-6′ and H-2′; 3 protons; m, spacing 16 Hz), 2.06, 2.0 and 1.99 (3 acetates, 9 protons, 3 singlets) and 0.84 δ (C-18 methyl group; 3 protons, singlet).

Anal. Calcd. for $C_{32}H_{38}F_3NO_{10}$: C, 58.80; H, 5.86; N, 2.14. Found: C, 58.57; H, 6.03; N, 2.08.

(ii) From the Sodium Salt of Estrone

To a solution of 296 mg of the sodium salt of estrone (prepared from sodium methoxide and estrone in methanol) in benzene 471 mg of bromide **12** was added in three portions. The reaction mixture was stirred at room temperature for 3 days and the inorganic material was then removed by filtration. The filtrate and washings were washed with a small amount of water, dried over sodium sulfate, and evaporated to dryness. During the evaporation 88 mg of unreacted steroid was separated. The residue was chromatographed on a column containing 10 times its weight of silica gel. Benzene eluates gave 172.6 mg (26%) of crystalline **7** (m.p. 200–203°). Further eluates contained a mixture of unreacted steroid and of a partly decomposed sugar component and were not further investigated.

17-Oxoestra-1-3-5(10)-trien-3-yl 2′-Amino-2′-deoxy-β-D-glucopyranoside (8)

A solution of 200 mg of glycoside **7** in 15 ml of chloroform and 30 ml of methanol was saturated with dry ammonia at 0° and allowed to stand at room temperature for 7 days. The solution was evaporated under reduced pressure to an oily residue. Water was added and the product was isolated by extraction into chloroform – isopropyl alcohol (3 : 2). Evaporation gave 100 mg (76%) of amorphous material **8**: $[\alpha]_D^{24}$ +59° (*c*, 0.2 in methanol); i.r. ν_{max} 3500–2800, 1720, and 1497 cm^{-1}.

17-Oxoestra-1,3,5(10)-trien-3-yl 2′-Acetamido-3′,4′,6′-tri-O-acetyl-2′-deoxy-β-D-glucopyranoside (9)

Compound **7** (100 mg) was converted into 17-oxoestra-1,3,5(10)-trien-3-yl 2′-amino-3′4′6′-trihydroxy-2′-deoxy-β-D-glucopyranoside (**8**) by means of ammonia as described above, and the crude product was dissolved in pyridine and acetylated by the addition of 3 ml of acetic anhydride. The reaction mixture was allowed to stand overnight at room temperature. After work-up 88 mg of *O,N*-acetate **9** was obtained (96%). The product was chromatographed on a column containing 50 times its weight of silica gel. Chloroform eluates contained 80 mg (87%) of **9** as a white amorphous solid: $[\alpha]_D^{24}$ +70° (*c*, 0.129 in chloroform) $[M]_D$ +419°, $[M]_D$ calcd. +351° for β-D-glycosidic linkage ($[M]_D$ of methyl 3,4,6-tri-*O*-acetyl-*N*-acetyl-glucosaminide −75.8°, $[M]_D$ of estrone +427°); i.r. ν_{max} 1720–1760, 1545–1510, 1200–1250, 1180 cm^{-1}; n.m.r. (Varian HA-100) 7.1 (1 proton; d; $J_{1,2}$ = 8 Hz), 6.8 (H-2, -4; 2 protons, m, spacing 10 Hz), 5.7 (N—H; 1 proton; d, J = 9 Hz), broad signal from 5.53 to 5.02 (H-1′, -3′, -4′; 3 protons), 4.2 (H-2′, Hs-6′; 3 protons; m, spacing 13 Hz), 3.89 (H-5′, 1 proton; m over 14 Hz), 2.86 (H-6; 2 protons, m, spacing 12 Hz), 2.06, 2.03, 2.01 (3 acetates, 9 protons, 3 singlets), 1.93 (*N*-acetate; 3 protons; singlet), and 0.89 δ (C-18 methyl; 3 protons; singlet).

17-Oxoestra-1,3,5(10)-trien-3-yl 2′-Acetamido-2′-deoxy-β-D-glucopyranoside (10)

(i) By Selective Acetylation of the Free Amine 8

A solution of 90 mg of **8** in 2 ml of absolute ethanol was treated with 0.02 ml of acetic anhydride. After 2 h at room temperature the solvents were removed under vacuum, the residue was dissolved in a 5% (v/v) solution of ethanol in benzene, and filtered through twice its weight of silica gel. The crude product was crystallized from aqueous methanol to yield 45 mg (45%) of **10**: m.p. 225° (softening), 228–230°; $[\alpha]_D^{25}$ +130° (*c*, 0.1 in methanol); i.r. (Nujol) ν_{max} 3500–2800, 1728, 1680, 1510 cm^{-1}.

Anal. Calcd. for $C_{26}H_{35}NO_7$ $1\frac{1}{2}$ CH_3OH: C, 63.32; H, 7.92; N, 2.68. Found: C, 63.05; H, 7.63; N, 2.82.

(ii) By Selective De-O-acetylation of the Fully Acetylated Glycoside 9

A solution of 60 mg of 17-oxoestra-1,3,5(10)-trien-3-yl 2′-acetamidoacetyl-2′-deoxy-β-D-glucopyranoside (**9**) in 3 ml of chloroform and 10 ml of methanol was saturated with dry ammonia at 0° and allowed to stand at 0° overnight. The product was extracted into chloroform – isopropyl alcohol (3:2). After the addition of water to the reaction mixture 43 mg of crude material was obtained. Crystallization from ethanol–water yielded 40 mg (85%) of **10**.

Investigation of the Polymers Formed in Reactor Irradiated Aniline and Pyridine

MAHMOUD F. BARAKAT[1] AND FAWZI M. ABDELKERIM[2]
Nuclear Chemistry Department, Atomic Energy Authority, Cairo, Egypt

Received February 27, 1973

In reactor irradiated aniline or pyridine most of the radiocarbon generated by the $^{14}N(n,p)^{14}C$ reaction was found preferentially localized in a polymer-like material, brown in color, frequently lustrous and constituting 15–30% of the initial amount of the irradiated material. This stimulated us to try to obtain an idea about the chemical groupings existing in these highly radioactive materials and thereafter to deduce their possible formation pathways.

By comparing the i.r. spectra of these polymers with those of the corresponding pure compounds it was possible to detect some changes in the spectra on polymerization and consequently it was possible to identify some basic structural groups existing. Based on these findings some polymerization reaction mechanisms have been suggested. In general, polymer formation was assumed to take place through the formation of polymerization centers produced by the rupture of the aromatic rings to give highly unsaturated fragments and radicals. These are capable of adding different radicals and fragments formed in the irradiated material by radiolysis or by the action of energetic recoil atoms. Cross linking between individual polymer chains was observed. The preferential localisation of ^{14}C in the polymer fraction could be attributed to the great capacity of the recoil atoms to form reactive secondary species such as $^{14}CH_3^{\cdot}$, $^{14}CH_2^{\cdot\cdot}$, or $^{14}CH^{\cdot\cdot\cdot}$ which participate in polymer formation.

L'aniline ou la pyridine irradiée dans un réacteur où la majorité des radiocarbones produits provient de la réaction $^{14}N(n,p)^{14}C$, se retrouve préférentiellement, comme il a été trouvé, sous forme d'un produit du type polymère, de couleur brunâtre souvent reluisant et comportant 15–30% de la quantité initiale du matériel irradié. Cette constatation nous a alors amené à rechercher les différents groupements chimiques présent dans ces produits hautement radioactifs et par suite à en déduire les différentes voies possibles de formation.

En comparant les spectres i.r. de ces polymères avec ceux des espèces pures correspondantes, il fut possible de déceler certains changements dans les spectres à la suite de la polymérisation et par suite il fut possible d'identifier quelques groupes structuraux présents. En se basant sur ces données, quelques mécanismes de réactions de polymérisation furent entrevues. En général, la formation des polymères semble se produire à la suite de la formation de centres de polymérisation découlant de la rupture des cycles aromatiques pour donner des fragments hautement insaturés ainsi que des radicaux. Ceux-ci sont capables d'additionner différents radicaux et différents fragments formés dans le matériel irradié par radiolyse ou à la suite de l'action d'atomes très énergétiques. On a aussi observé la formation de ponts entre différentes chaînes polymériques individuelles. On a attribué la localisation préférentielle du ^{14}C dans la fraction contenant le polymère à la grande facilité des atomes énergétiques à former des espèces réactives secondaires telles $^{14}CH_3^{\cdot}$, $^{14}CH_2^{\cdot\cdot}$ ou $^{14}CH^{\cdot\cdot\cdot}$ qui participent à la formation des polymères.

Can. J. Chem., **51**, 3860 (1973)

Introduction

Reactor irradiation of systems containing organic nitrogen frequently leads to the transformation of a relatively small fraction of the irradiated material into a lustrous polymer-like material, brown in color, and containing the greater fraction of the induced carbon-14 activity (1–5). The non-polymeric fraction produced consists essentially of the labelled parent material together with some other ^{14}C-labelled synthetic products. Although numerous publications have appeared dealing with the mechanism of formation of the different radioactive chemical species present in the non-polymeric fraction resulting from the reactions of the newly born carbon recoils with the molecules of the irradiated materials (6–13), not much is known about the nature, properties, and structures of the highly radioactive polymeric products obtained. This stimulated us to study some of these polymers in order to get an idea about the chemical groups

No. of molecules polymerized per each ^{14}C atom in polymer $\times 10^{-5}$	1.9	2.0	1.2	0.8

*The complementary part was found in the non-polymeric fraction.

existing in them and then attempt to deduce the possible mechanisms of their formation.

In a previous publication (14) it was shown by the use of i.r. spectroscopy that the polymers formed in reactor irradiated benzene or toluene in the presence of AlN, used as a source of nitrogen for carbon recoils generation, have a polystyrene-like structure. Further clarification of the nature of the polymerization processes, particularly those in which recoil carbons participate, requires a systematic study of the polymers formed in different irradiated media.

In the present work the polymers formed in reactor irradiated aniline and pyridine have been isolated, purified, and investigated by i.r. absorption spectroscopy. The i.r. spectra of the polymers were compared with those of the corresponding pure compounds in order to identify and interpret the changes in the different absorption bands which occur on polymerization. Based on these findings some mechanisms have been proposed for the formation of these polymers.

Experimental

Chemicals

All chemicals used were obtained from British Drug Houses and were of AnalaR grade. Aniline was twice distilled under reduced pressure, dried for several days over KOH pellets, and then repeatedly purified by fractional distillation. The fraction collected at 184 °C was used. Pyridine was also dried over KOH pellets and then repeatedly distilled using a fractionating column. The fraction collected at 115.5 °C was used. Purity of the target materials was tested by the refractive indices and also by analytical g.l.c. of microliter samples at elevated equipment sensitivity.

Preparation of Targets and Irradiation

Quartz ampoules, half filled with the organic materials to be irradiated, were attached to a high vacuum line and were sealed under vacuum as described in a previous publication (13). Irradiations were carried out in the 2 MW research reactor of the Atomic Energy Authority (Egypt). The irradiation conditions are given in Table 1. The maximum sample temperature during irradiation did not exceed 80 °C. After irradiation the samples were kept for several months before being opened and used.

Separation and Analysis of the Polymeric Products

The non-polymeric fraction consisting of all volatile components in the aniline samples, irradiated using either of the two different thermal neutron fluxes, was distilled off after the addition of the following carriers: diethylamine, benzene, toluene, *p*-xylene, *N*-methylaniline, *o*-toluidine, and *N*-ethylaniline as described before (12). The dark brown solid polymer remaining in the distilling flask was taken up in ethanol or chloroform and analyzed by t.l.c. using silica gel G uniformly spread on glass plates. Before use the plates were activated by heating at 150 °C for 2 h. Pure benzene was used as a solvent and iodine vapor was used to detect the spots on the chromatograms. It was found that a well defined dark brown polymer spot remained at the starting point, while some other faintly colored spots were found with R_f values consistent with those of some of the carriers added before separating the polymer by distillation. Consequently, the polymeric fraction in irradiated aniline was purified by t.l.c. using several plates. After developing the plates the pure polymer was collected by scraping followed by elution from the support material by carbon tetrachloride. After evaporation of the solvent the specific activity of the polymer was determined. The solution of the polymer in chloroform was used for the i.r. spectrophotometric analysis.

In the case of pyridine it was found that sample II, irradiated with the higher thermal neutron flux, had been completely transformed into a brown solid polymeric material. When pulverized, this was transformed into a pale yellow powder soluble in chloroform. Using a 14% solution of methanol in benzene as a solvent in the analysis of the polymer sample by t.l.c., it was found that in addition to the main polymer spot remaining at the starting point of the chromatogram, three other very faint

For personal use only.

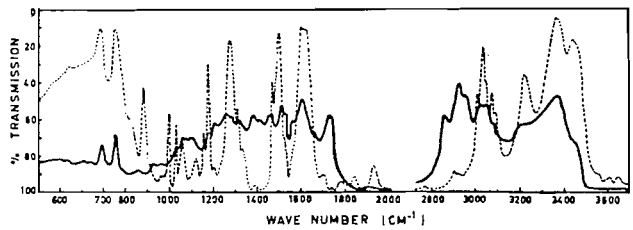

FIG. 1. The i.r. spectrum of the ^{14}C-labelled polymer separated from reactor irradiated aniline (solid line) and that of pure liquid aniline (dotted line).

spots were obtained with R_f values 0.54, 0.69, and 0.88 respectively. The polymer in the other pyridine sample (I) was taken up in pyridine, after the removal of the non-polymeric volatile fraction by distillation, and analyzed by t.l.c. In addition to the main polymer spot remaining at the starting point, a very faint spot was found on the chromatogram with R_f 0.52. As in the case of aniline, the purified pyridine polymer was used for radioactivity measurements and also for obtaining the i.r. spectra.

The i.r. spectra were measured using a fully automatic double beam i.r. spectrophotometer (UR10) Carl Zeis, Jena, with KBr prism (600–700 cm^{-1}), NaCl prism (700–2000 cm^{-1}), and a LiF prism for the region 2700–3800 cm^{-1}. Slit program 4 was used in the measurements. The polymer spectra were measured using thin polymer films deposited on KBr plates by evaporation of small amounts of the chloroform solution of the polymers. The reference spectra of pure liquid aniline or pyridine were recorded using liquid cells with 0.03 mm thickness.

Radioactivity measurements were made by ignition of samples using a dry combustion apparatus followed by measuring the activity of radioactive carbon dioxide formed using the internal flow-monitoring gas counter (15).

Results and Discussion

Table 1 shows that the extent of polymer formation increased with increasing the neutron flux; it is also seen that about 10^5 molecules of the irradiated liquids were transformed into the polymer for each carbon-14 recoil atom formation event. This shows that polymer formation in the strong reactor irradiation field occurs mainly as a radiation effect, probably through free radical or ion-molecule reactions (16). In these reactions carbon recoils preferentially participate. This is explained by their interaction with molecules or molecular fragments which initiate or participate in these reactions finally leading to polymer formation.

Examination of the i.r. spectra of the polymers separated from the two irradiated aniline samples revealed their remarkable identity. This indicates that increasing the irradiation time or neutron flux affects only the quantity of the polymer, as deduced from the observed increase of the polymer yield, and not its composition. Comparing the i.r. spectrum of the polymer formed in the irradiated aniline sample I with that of pure liquid aniline (Fig. 1), one observes the characteristic bands of the phenyl ring of aniline in both spectra, *i.e.* at 1508 and 1610 cm^{-1} due to the aromatic C—C stretching vibrations and also at 3030 and 3060 cm^{-1} due to aromatic C—H stretching vibrations. Moreover, the bands due to the C—H out of plane deformation vibrations of the monosubstituted aromatic ring appeared nearly at the same positions in both spectra, *i.e.* at 695 and 750 cm^{-1} in the polymer spectrum and at 692 and 755 cm^{-1} in the pure liquid aniline spectrum (17, 18). This indicates that additional substitution in the phenyl ring of aniline did not play an important part in the polymerization. On the other hand, remarkable changes were found to occur in the characteristic bands of the amino group of aniline. Thus, the $—NH_2$ deformation vibration band at 1630 cm^{-1} (19, 20) completely disappeared while the phenyl—NH_2 stretching vibration band at 1280 cm^{-1} (19, 21) were found to decrease in intensity. A similar decrease was also observed in the symmetric and antisymmetric $—NH_2$ stretching vibration bands appearing at 3355 and 3435 cm^{-1} (19). At the same time, a new band appeared at 1530 cm^{-1} which could be assigned to the —NH bending vibrations of a secondary aromatic amine (22). In addition, a new weak band appeared at 1250 cm^{-1} which could be due to the —NH group of a secondary aromatic amine (19, 21, 22). From all these changes it seems reasonable to conclude that the primary aromatic amino group in aniline transformed into a secondary one on polymerization.

In the spectrum of the polymer separated from irradiated aniline, two new bands appeared at 1390 and 1465 cm^{-1} due to the symmetric and antisymmetric bending vibrations of CH_3 groups,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

For personal use only.

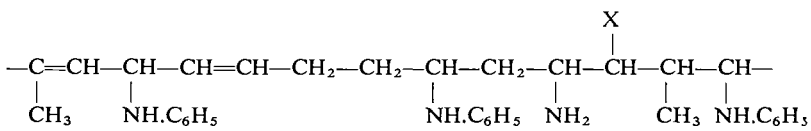
in addition to the new band appearing at 1450 cm^{-1} due to the bending vibrations of CH_2 groups (23, 24). The presence of CH_2 and CH_3 groups could be further confirmed by the presence of the two new bands at 2920 and 2955 cm^{-1}, which are due to the antisymmetric stretching vibrations of CH_2 and CH_3 groups respectively (23, 24). Moreover, a new band appeared at 2845 cm^{-1} due to the CH_2 and/or CH_3 symmetric stretching vibrations. The very small shoulder at 740 cm^{-1} could be assigned to the rocking vibrations of CH_2 groups present in a long chain consisting of more than four carbon atoms (23). It is worth mentioning that the weak, but well defined, band observed at 850 cm^{-1} and normally assigned to the wagging vibrations of trisubstituted olefinic groups (25), probably indicates the presence of unsaturated branched aliphatic chains in the polymer. Moreover, the shoulder appearing at 1660 cm^{-1} indicates the possible presence of aliphatic C=C bonds (23) while the band appearing at 1200 cm^{-1} indicates the presence of tertiary branching in the polymer (23, 26).

The band appearing at 1730 cm^{-1} due to the carbonyl group stretching vibrations is probably an indication of the occurrence of some oxidation in the polymer during the chemical treatment that followed reactor irradiation (27, 28).

From the above mentioned interpretations of spectral data it is evident that the polymer contains anilide groups attached to aliphatic carbon chains which contain some double bonds and are possibly branched. Some residual $-NH_2$ groups could still be present in the polymer. In fact, a probable structure of an individual polymer chain could be represented by the following empirical formula:



The end groups are likely to be CH_2=CH— or CH_3— groups. Cross linking between individual polymer chains could be through the point X.

The foregoing discussions lead to the assumption that polymer formation occurs in two successive steps. In the first step, rupture of the phenyl rings takes place with the formation of highly reactive unsaturated radicals shown in eq. 1 and/or smaller fragments of similar composition.

[1] 
This need not be due entirely to the strong irradiation field in the reactor but also could occur as a result of the collisions occurring between energetic recoil carbons and the phenyl ring carbons without stabilization of the formed intermediates (2, 14). All products formed in this way could be considered as good centers for initiating and promoting polymer formation. In the second step, "building up" of the polymer takes place through the addition to the above-mentioned unsaturated fragments of different radicals, such as $H^{\cdot}$, $CH^{\cdot\cdot\cdot}$, $CH_2^{\cdot\cdot}$, $CH_3^{\cdot}$, $C_6H_5^{\cdot}$, and $C_6H_5NH^{\cdot}$, formed as a result of the fragmentation processes occurring in the molecules of the irradiated material. It is possible to assume that the latter radicals are formed with greater probability due to the ease with which the lone pair of electrons on nitrogen are displaced towards the phenyl ring leaving the nitrogen atom positively charged (29) and thus facilitating hydrogen removal from the amino group of aniline. The absence of absorption bands at 790 cm^{-1}, normally attributed to the presence of disubstitution in the benzene nucleus, probably indicates that anilide and/or phenyl radicals are the only aromatic radicals involved in polymer formation. Further building up of the polymer could occur both by addition to end groups and by cross linking of individual straight polymer chains, either directly or through $-CH_2$ linkages.

The preferential localization of carbon-14 in the polymer may be explained by the fact that the energetic recoil carbons, present as atoms, ions, or free radicals such as $^{14}CH^{\cdot\cdot\cdot}$, $^{14}CH_2^{\cdot\cdot}$, or $^{14}CH_3^{\cdot}$, readily participate in or act as initiators of the addition reactions leading to the formation of polymer chains as indicated above. The absence of disubstituted benzene in the polymer indicates that the well-known insertion reaction of carbon recoils in C—H bonds probably leads

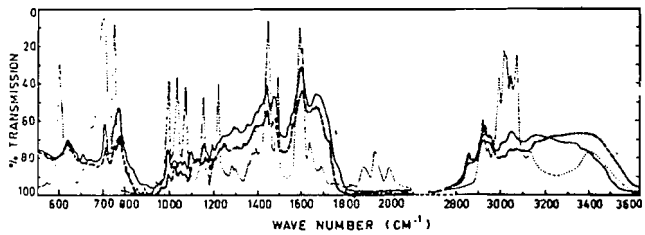


FIG. 2. The i.r. spectra of the ^{14}C-labelled polymer separated from irradiated pyridine sample I (dashed line), pyridine sample II (solid line), together with the i.r. spectrum of pure liquid pyridine (dotted line).

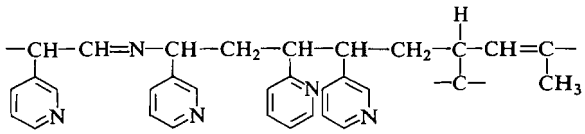
to intermediates that abstract hydrogen more readily to form different labelled toluidines (12) rather than interacting with different fragments to form a polymeric product. The reason for this somewhat unexpected behavior could not be explained on the basis of the present data.

Considering the i.r. spectra of pure liquid pyridine and of the polymer separated from reactor irradiated pyridine, both shown in Fig. 2, it is possible to observe the bands at 710 and 775 cm^{-1} which can be assigned to the C—H out of plane deformation vibrations of 3-substituted pyridine (30, 31). The shoulder appearing at 750 cm^{-1} may be attributed to the C—H out of plane deformation vibrations of 2-substituted pyridine (30, 31) present in small amounts relative to 3-substituted pyridine. The presence of 3- and 2-substituted pyridyl groups in the polymer could be further confirmed by observing the bands appearing at 1475 and 1595 cm^{-1} normally assigned to the ring stretching vibrations of 3- and 2-substituted pyridine (30, 32). The characteristic C—H stretching vibrations of the aromatic ring were observed at 3010 and 3050 cm^{-1}. The combination and overtone bands appearing in the regions 1800–2000 and 2900–2950 cm^{-1}, in the pure pyridine spectrum, completely disappeared in the polymer spectrum. Instead of the latter bands, two new bands appeared at 2925 and 2955 cm^{-1} which are normally assigned to the antisymmetric stretching vibrations of CH_2 and CH_3 groups respectively. The presence of these groups could be further confirmed by observing the bands at 2850 cm^{-1} due to the symmetric stretching vibrations of CH_2 and CH_3 groups. At the same time, the shoulder at 1390 cm^{-1} could be due to CH_3 symmetric bending vibrations while the band at 1440 cm^{-1} may be assigned to the antisymmetric bending vibrations of CH_2 or CH_3 groups.

In the polymer spectrum, shown in Fig. 2, a new band appeared at 1670 cm^{-1}. This could be assigned, most likely, to —C=N— group (33). The same band could also indicate the presence of a carbonyl group in a straight carbon chain containing double bonds (34, 35). The band appearing at 1197 cm^{-1} probably indicates the presence of aliphatic branched chains (23).

From the foregoing interpretation of spectral data it seems possible to conclude that the polymer formed in irradiated pyridine consists mainly of pyridyl groups attached in the 3- or 2-positions to aliphatic carbon chains, that are probably branched, represented as follows:



Similar to the case of the polymer formed in irradiated aniline, the formation of the polymer in irradiated pyridine probably took place in two steps. The first involves the pyridine ring rupture, more likely through the breaking of a C—N bond, which is less stable than the C—C bond (29), according to the reaction shown in eq. 2.

[2] 
This is followed by the "building up" step in which the different radicals formed in the irradiated matrix, such as H', C_5H_4N', CH_2'', etc., add to the double bonds of the highly unsaturated radicals or fragments formed in the first step.

It is important to note that, in the spectrum of the polymer formed in pyridine sample I, the intensity of the band appearing at 2925 cm^{-1}, due to the aliphatic CH_2 stretching vibrations, is greater than the intensity of the band appearing at 3050 cm^{-1}, due to the aromatic CH stretching vibrations, whereas in the spectrum of the polymer separated from the other pyridine

sample (II) the contrary could be observed. This should indicate that the aliphatic/aromatic ratio is greater in the first product than in the second one, *i.e.* aromatization of the aliphatic straight chain takes place gradually as the irradiation time increases. Furthermore it is possible to observe that the shoulder at 1660 cm^{-1}, normally attributed to aliphatic C=C bond stretching vibrations (23), apparent in the spectrum of the polymer separated from pyridine sample I, disappeared completely in the spectrum of the polymer separated from sample II. These findings are in reasonable agreement with the abovementioned polymer formation mechanism and indicate that saturation of the double bonds in the primarily formed straight carbon atom chains occurs as the irradiation time increases. The observed preferential addition of pyridyl radicals in the β position could be explained on the basis of the well-known fact that positions 3 and 5 are points of high electron density in the pyridine nucleus (29), and consequently reaction is easiest with the π electrons of the double bonds through these positions.

The preferential localization of ^{14}C in the polymers formed in pyridine could be explained on the same basis as in the case of aniline.

Finally, it should be clear that it is practically very difficult to put forward a definite structure for the polymers formed in reactor irradiated organic systems. In the present study, it was only possible to suggest some empirical formulae and some probable mechanisms leading to the formation of such high specific activity products.

Internal Substitution of 5α-Lanostane on C-5, C-6, and C-8[1]

O. E. EDWARDS AND Z. PARYZEK[2]

Division of Biological Sciences, National Research Council of Canada, Ottawa, Canada K1A 0R6

Received January 5, 1973[3]

Thermolysis of 3β-acetoxy-11-oxolanostan-7α-yl azidoformate gave the cyclic carbamate of 3β-acetoxy-5α-amino-11-oxolanostan-7α-ol (9%) and the corresponding 6α-amino (52%) derivative. 3β-Acetoxy-11-oxolanostan-7β-yl azidoformate gave the cyclic carbamate of 3β-acetoxy-6α-amino-11-oxolanostan-7β-ol (52%) and the corresponding 6β-amino (26%) and 8β-amino (7%) derivatives. Some features of the ^{13}C.m.r. and c.d. spectra of the above compounds and related steroids are described.

La thermolyse de l'azidoformate-7α, d'acétoxy-3β-oxo-11 lanostanyle conduit au carbamate cyclique de l'acétoxy-3β amino-5α-oxo-11 lanostanol-7α (9%) et au dérivé amino-6α (52%) correspondant. L'azidoformate-7β de l'acétoxy-3β oxo-11 lanostanyle fournit le carbamate cyclique de l'acétoxy-3β amino-6α-oxo-11-lanostanol-7β (52%) et les dérivés amino-6β (26%) et amino-8β (7) correspondants. On décrit aussi quelques caractéristiques des spectres ^{13}C.m.r. et c.d. des composés mentionnés plus haut ainsi que d'autres stéroides qui leur sont reliés. [Traduit par le journal]

Can. J. Chem., **51**, 3866 (1973)

Two skeletons related to lanostane which are of exceptional interest are those of the cucurbitacins (**1**) (1) and of the fusidanes (protostanes) **2** related to probable intermediates in the biosynthesis of lanosterol (2). We attempted to produce good yields of substituted lanostanes which might be converted to compounds with these skeletons.

Attempts to produce compounds with the cucurbitane skeleton have been made by ApSimon and Rosenfeld (3), Guest and Marples (4), and Levy and Lavie (5), by the action of Lewis acids on 9α,11α-oxidolanostane derivatives. No migration of the 10-methyl group was observed. However, since we had obtained efficient migration of the 10-methyl group to C-9 during deamination of a 9α-amino-11-keto steroid (6) we hoped to extend this to deamination of 9α-amino-3β-acetoxylanostan-11-one (**3**) and 8β-amino-3β-acetoxylanostan-7-one (**4**).

Attempts to prepare a 9β,11β-oxidolanostane derivative from which the 9α-amino-11-ketone might be prepared (6) have so far failed in this laboratory (7) and in that of Marples (4).

Since approach of external reagents to the α-face of a 9,11 double bond in lanostane derivatives is somewhat impeded by the 14α-methyl group, an approach using intramolecular cyclization appeared to be one of the most promising alternatives for substituting C-9. Curran and Angier (8) had obtained a 45% yield of the oxazolidinone **5** by pyrolysis of 1-adamantanyl azidoformate, and Kreher and Kühling (9) had shown that thermal decomposition of hexahydrobenzyl azidoformate gave a 3:1 ratio of the oxazolidinone **6** and the tetrahydro-1,3-oxazin-2-one (**7**). Breslow and coworkers (10) and Lwowski (11) found that the insertion factor for different types of CH bonds was in the ratio tertiary–secondary–primary = 30:10:1. Hence we had reason to hope that the nitrene produced from the 7α-azidoformate **8**

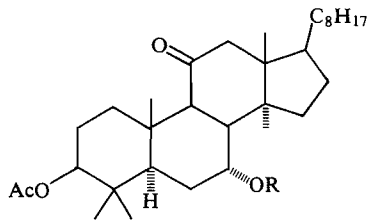
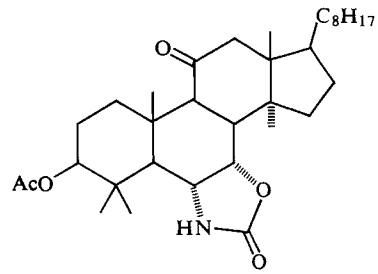
would preferentially attack the 5α- and 9α-CH bonds.[4]

Dihydrolanosterol was converted via 3β-acetoxy-7,11-dioxolanost-8-ene to a mixture of 3β-acetoxy-11-oxolanostan-7α-ol (**9**, R = H) and the corresponding 7β-alcohol (12*a*, 13). Phosgene converted the alcohols to the chloroformates, then sodium azide in dimethyl formamide transformed these to the desired azidoformates.

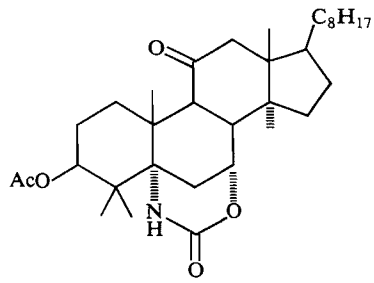
A solution of the 7α-azidoformate **8** in carbon tetrachloride in a sealed tube was maintained at 140–142° for 2 h. By this time the azide group had disappeared (i.r.) and a mixture of at least five products had formed. These were separated by column chromatography and preparative t.l.c., and the four major components characterized. The main product (52%) clearly arose from insertion into the 6α-CH bond. Its i.r. spectrum (ν_{max} ($CHCl_3$) 1760 cm^{-1}) was characteristic of an oxazolidinone. In addition a new low-field hydrogen (δ 3.83; triplet, $J_{5,6}$ = 10.6 Hz; $J_{6,7}$ = 5 Hz) was present in its p.m.r. spectrum and the coupling constants were as expected for a 6α orientation. Hence we assign it structure **10**. Its ^{13}C.m.r. spectrum is described below.



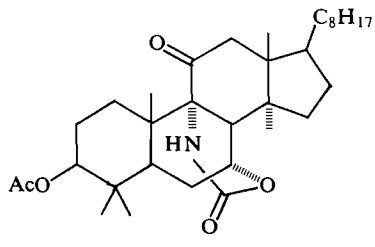
9



10



11



12

[4]The only related work for lanostane skeleton seems to be functionalization of C-32 (14α-methyl) by photolysis of the 7α-nitrite or action of lead tetraacetate–iodine on the 7α-alcohol (12).

TABLE 1.

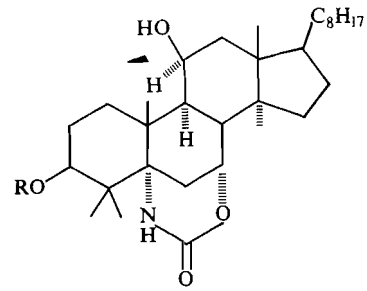
*In dioxane.
†In $CDCl_3$; ^{13}C.m.r. signal relative to TMS = 0.

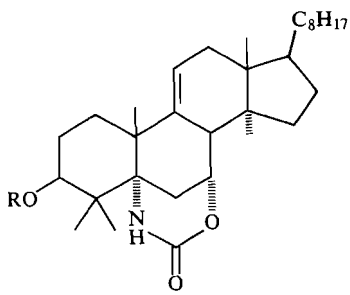
The next most abundant nitrogen-containing product was a tetrahydro-1,3-oxazinone (ν_{max} ($CHCl_3$) near 1690 cm^{-1}). It gave no low-field p.m.r. signals other than the ones for the 3- and 7-hydrogens, since it was the product of attack on C-5 or C-9. We had anticipated that the u.v. spectrum would distinguish these, since the nπ* transition for ketone carbonyls with axial electronegative substituents such as methoxyl, halogen, and azide (6, 14) groups is at wavelength longer and of higher intensity than that of the unsubstituted ketone. Since the unknown product and 3β-acetoxy-11-ketolanostane had very similar absorption (Table 1) it appeared that the compound has structure **11**. On the other hand c.d. evidence appeared to demand the alternate structure **12** with a 9α substituent (see below). However its ^{13}C.m.r. (see below) was consistent with the 5-substituted structure, and chemical transformations confirmed that it was indeed **11**.

The compound was very resistant to acid or alkaline hydrolysis. Meerwein's reagent converted it to an imino ether. Treatment of this ether with base only hydrolyzed the 3-acetoxy group, while acid hydrolysis gave back the tetrahydrooxazinone. The tetrahydrooxazinone was inert to nitrosyl chloride or dinitrogen tetroxide, so direct deamination was not possible. Hence an indirect proof of structure was used.

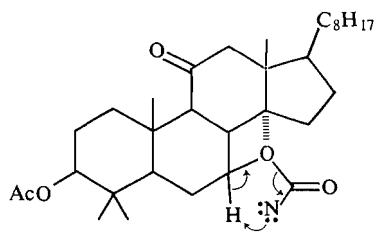
Sodium borohydride reduced the ketone carbonyl and hydrolyzed the 3-acetoxy group. The resulting diol was transformed by pivaloyl chloride into a monopivaloyloxy derivative. Dehydration of this with thionyl chloride – pyridine gave a trisubstituted olefin without disturbing the cyclic urethane group. It must therefore have structure **14**, proving the intermediates to be **13** (R = H or pivaloyl) and the original tetrahydrooxazinone to be **11**.



13



14



15

The third product characterized was the simple urethane of the 7α-alcohol, presumably formed by abstraction of hydrogen from other molecules by the *triplet* state of the nitrene. The fourth product was 3β-acetoxylanosta-7,11-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

dione. It seems likely that this arose by thermal fragmentation of the nitrene as illustrated in **15**.

The yield of **11** was roughly 9%. Hence other factors were overriding the discrimination factor mentioned earlier. It seems certain that the azide decomposition to nitrene and the insertion of the nitrene into saturated CH bonds are independent events. Hence the observations of Breslow and co-workers (10) regarding the reaction of ethyl azidoformate with 2-methylbutane imply that ethoxycarbonyl nitrene survives numerous collisions with primary CH bonds before it reacts. Thus in the lanostane cases the *nitrene* rotamer ratios are large factors in determining which CH bonds will be attacked. A family of rotamers roughly represented by **16** must be the most highly populated one. This would account for the relatively high yield of 6α-substituted product. This also has the potential of giving insertion into the 5-CH bond, but the low yield of **11** despite the tertiary nature of the hydrogen, indicates that approach to the CH bond is impeded by the 4α-methyl group and the 6α-hydrogen.

A second family of rotamers represented by **17** does not participate to any extent, since it would permit insertion into the 5- and 9-CH bonds with equal facility.

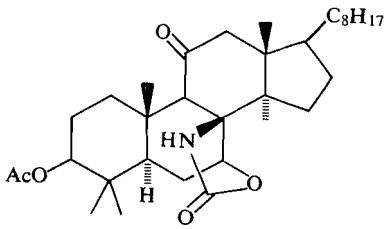
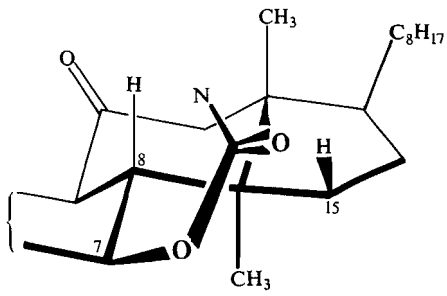
a 6α-amino

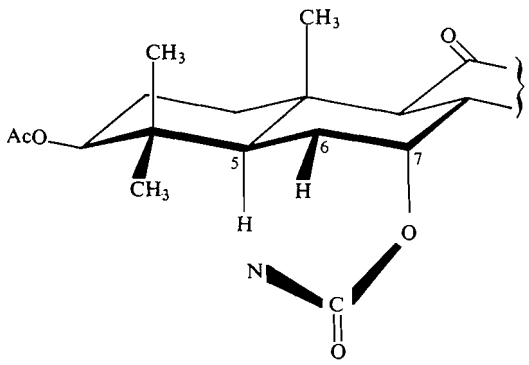
b 6β-amino



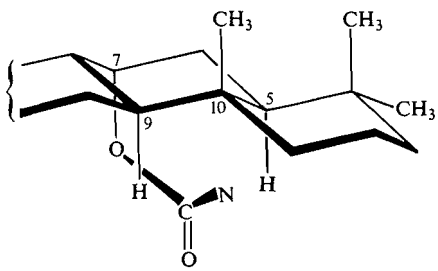
20



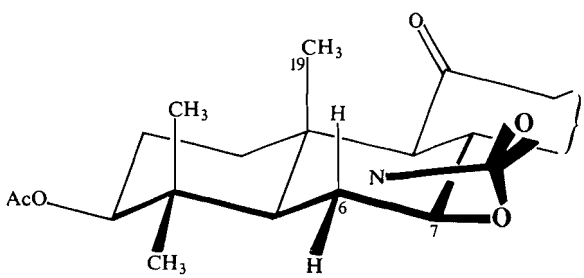
21



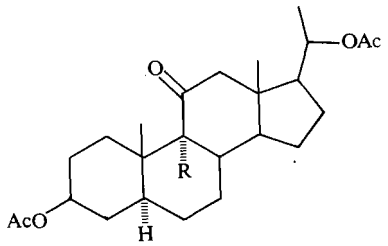
16



17



22



23

Photolysis of the 7α-azidoformate in methylene chloride appeared to give a more complex mixture than the thermolysis, hence this was not pursued further.

In a manner analogous to that for the 7α isomer, 3β-acetoxy-11-oxolanostan-7β-ol was converted to the azidoformate **18**. Thermolysis at 140° converted this to a mixture of at least three compounds. Again, products of insertion into the C-6 hydrogen bonds (**19**) predominated (78%) with the ratio of 6α to 6β insertion being at least 2:1. The 6α isomer was identified by the fact that the axial 6β-hydrogen and the 7α-hydrogen gave rise to two triplets with $J = 10$ centered at δ 3.65 and 3.99 in its p.m.r. spectrum. The product of insertion into the C-8–hydrogen bond (**20**) was only formed in 7% yield.

The product ratios are again accounted for on the basis of nitrene rotamers and non-bonded repulsion in the transition state. Examination of models showed that only rotamer **21** enables formation of a three-center cyclic transition state for insertion into the C-8—H bond. Because of repulsive interaction with the 15β hydrogen this rotamer is unfavorable, hence the low yield of **20**. Rotamer **22** appears to be the only one permitting close-enough approach to the 6-hydrogens for insertion. To account for the higher percentage of insertion into the 6α-CH bond we suggest that repulsive interaction of the β-hydrogen with C-19, as the transition state for insertion develops, raises its energy relative to that of the 6α case.

The proton-decoupled ^{13}C.m.r. spectrum of **11**, in comparison with those of 9-substituted steroidal molecules (**23**, R = $NHCOCH_3$ or $NHCOOCH_3$) supported the 5-substituted structure. In the models an upfield shift of *ca.* 5 p.p.m. was noted for the carbonyl carbon, relative to the corresponding 11-ketone with no substituent on C-9 (Table 1) (see ref. 15). In contrast the carbonyl of **11** had no such displacement (Table 1). A 5 p.p.m. upfield shift of C-3 in the spectrum of **11** was observed. This too is more consistent with substitution on C-5 rather than on the more remote C-9.

As mentioned above, the c.d. spectrum of **11** corresponded well with that of the 9α-amido-11-ketopregnane models **23** (Table 1). However we now must conclude that the presence of the acylamino group on C-5 in a positive octant is the source of the sizeable positive ΔΔε for **11**.

The failure to obtain the 9-substituted derivative and the low yield of the 8-substituted one, discourages this approach to cucurbitanes and protostanes. However substitution of C-9 from an 11α-azidoformate remains an interesting possibility.

Experimental

Infrared spectra were taken on a Perkin-Elmer model 257 grating spectrophotometer, with chloroform as solvent; p.m.r. spectra were determined using a Varian A-60-A spectrometer using deuteriochloroform as solvent and TMS as internal reference; ^{13}C.m.r. spectra were obtained using a Varian XL-100 Fourier transform spectrometer using external TMS in deuteriochloroform as reference; u.v. spectra were recorded using a Cary model 11 spectrophotometer and o.r.d–c.d. spectra on a Durrum-Jasco model ORD-5 spectropolarimeter, all in 95% ethanol. Thin-layer chromatography was done using silica gel. Rotations were for solutions in chloroform with concentrations near 10 g/l.

Materials

Crude lanosterol (Sigma Chemical Co.) was converted into 3β-acetoxylanostan-7,11-dione, which was reduced catalytically to 3β-acetoxy-11-oxolanostan-7α-ol (12) or with sodium borohydride, to 3β-acetoxy-11-oxolanostan-7β-ol (12).

3β-Acetoxy-11-oxolanostan-7α-yl Chloroformate

3β-Acetoxy-11-oxolanostan-7α-ol (153 mg) was dissolved in 15 ml of benzene. To this was added 108 mg of phosgene–pyridine complex (16) and the mixture stirred at room temperature for 25 min. The benzene solution was washed three times with cold water, dried with sodium sulfate, and evaporated. The 167 mg of oily residue crystallized in the presence of *n*-pentane. Two recrystallizations from *n*-hexane gave 130 mg of the chloroformate: m.p. 128–132°; ν_{max} 1770, 1726, and 1700 cm^{-1}; $[\alpha]_D$ +21°.

Anal. Calcd. for $C_{33}H_{53}O_5Cl$: C, 70.12; H, 9.45; Cl, 6.30. Found: C, 70.29; H, 9.60; Cl, 6.13.

3β-Acetoxy-11-oxolanostan-7α-yl Azidoformate (8)

To a solution of 472 mg of 3β-acetoxy-11-oxolanostan-7α-yl chloroformate in 30 ml of dimethylformamide was added 800 mg of sodium azide. The mixture was stirred for 3 h at 50 °C, 5 ml of water was then added and the product extracted into benzene. The benzene layer was washed three times with water, dried over magnesium sulfate and evaporated. The 474 mg of residue was recrystallized from methanol. The azidoformate had m.p. 123–125°; ν_{max} 2185, 2135, 1720, and 1700 cm^{-1}; $[\alpha]_D$ +2°.

*Thermolysis of 3β-Acetoxy-11-oxolanostan-7α-yl Azidoformate (**8**)*

A solution of 905 mg of **8** in 50 ml of carbon tetrachloride in a sealed tube was maintained at 140–142° for 1 h, 45 min. The cooled solution was washed with sodium bicarbonate solution, dried over magnesium sulfate, and distilled. The residual oil was adsorbed onto a column of 120 g of neutral alumina, grade III. The column was eluted with benzene, benzene–ether mixtures, ether, and ether–methanol mixtures. The main products are listed in the order of their emergence:

3β-Acetoxylanostan-7,11-dione

The crude fraction (47 mg) after purification by t.l.c. gave 40 mg m.p. 216–218° (lit. (12) 223–224°). Its i.r. and n.m.r. spectra were identical with those of authentic 3β-acetoxylanostan-7,11-dione.

*Carbamate of 3β-Acetoxy-11-oxolanostan-7α-ol (**9**, R = $CONH_2$)*

Crude weight 58 mg. T.l.c. purification followed by recrystallization from methanol gave a product with m.p. 235–240°. It had ν_{max} 3540, 3430, 1725, 1700, and 1585 cm^{-1}; ν_{max} 293 nm (ε 51); p.m.r. signals at δ 5.29 (broad singlet, 7β-H), 5.07 (s, NH), 4.69 (t, 3α-H); ^{13}C.m.r. signals at 208.6 (C-11), 171.1 (3β-O*C*OCH$_3$), 155.9 (O*C*ONH), 80.5 (C-3), and 72.0 (C-7) p.p.m.; $[\alpha]_D$ +18°.

Anal. Calcd. for $C_{33}H_{55}NO_5$: C, 72.62; H, 10.16; N, 2.57. Found: C, 72.78; H, 9.97; N, 2.50.

*Cyclic Carbamate of 3β-Acetoxy-6α-amino-11-oxolanostan-7α-ol (**10**)*

The 478 mg needed only recrystallization from ethanol – methylene chloride to give **9** m.p. 258–262°. It had ν_{max} 3500, 3300, 1760, 1735, and 1702 cm^{-1}; p.m.r. signals at δ 6.76 (s, NH), 4.60 (d, J = 5 Hz, 7β-H), 4.44 (t, J = 7 Hz, 3α-H), 3.83 (broad q, J_1 = 10 Hz, J_2 = 5 Hz, 6β-H); ^{13}C.m.r. signals at 210.6 (C-11), 170.7 (3β-OCOCH$_3$), 158.9 (OCONH), 79.4 (C-7), and 55.8 (C-6); $[\alpha]_D$ +27°.

Anal. Calcd. for $C_{33}H_{53}O_5N$: C, 72.89; H, 9.82; N, 2.58. Found: C, 72.73; H, 10.00; N, 2.53.

*Cyclic Carbamate of 3β-Acetoxy-5α-amino-11-oxolanostan-7α-ol (**11**)*

The crude product (119 mg) was purified by preparative t.l.c. followed by recrystallizations from acetone and ethanol – methylene chloride. It then gave a single spot on t.l.c. and gave sharp spectra. However its m.p. still had the range 278–292° unaltered on further recrystallization. It had ν_{max} 3340, 1725, and 1690 cm^{-1}; λ_{max} 296 nm (ε 34); and p.m.r. signals at δ 5.87 (s, NH), 5.10 (broad, 3α-H), 4.67 (broad singlet, 7β-H); $[\alpha]_D$ +18°. It gave ^{13}C.m.r. signals at 211.0 (C-11), 170.6 (3β-O*C*OCH$_3$), 153.6 (O*C*ONH), 74.9 (C-3), 74.4 (C-7), and 64.2 (C-5) p.p.m.

Anal. Calcd. for $C_{33}H_{53}O_5N$: C, 72.84; H, 9.82; N, 2.58. Found: C, 72.69; H, 9.98; N, 2.49.

In a larger run the yields were: **9**, 7%; **10**, 50%; **11**, 9%.

*3β-Acetoxy-11-oxolanostan-7β-yl Azidoformate (**18**)*

Phosgene was bubbled into a solution of 1.34 g of 3β-acetoxy-11-oxolanostan-7β-ol and 0.8 ml of pyridine in 70 ml of benzene for 1.5 h. The reaction mixture was washed three times with water, dried over magnesium sulfate, then the solvent removed under reduced pressure. The crude chloroformate was dissolved in 6 ml of dry dimethylformamide. After addition of 1.3 g of sodium azide the mixture was heated at 55–60° for 4 h. Water was added to the cooled solution, the product extracted into benzene, and the benzene washed three times with water. The benzene layers gave 1.53 g of crude crystalline azidoformate. After recrystallization from acetone–methanol it had m.p. 141–146°; ν_{max} 2185, 2135, 1725, and 1705 cm^{-1}; $[\alpha]_D$ +34°.

Anal. Calcd. for $C_{35}H_{53}O_5N_3$: C, 69.32; H, 9.34; N, 7.35. Found: C, 69.14; H, 9.51; N, 7.32.

*Thermolysis of **18***

A solution of 720 mg of **18** in 50 ml of carbon tetrachloride in a sealed tube was kept at 140–142° for 70 min. It was then washed with sodium bicarbonate solution, dried, and distilled. The residue was given a preliminary purification by chromatography on alumina (activity III), then separated into two main fractions by preparative t.l.c. The one with higher R_f was rich in oxazolidinone **20** while the more polar one contained a mixture of the two epimeric oxazolidinones **19**. These were separated by fractional crystallization from methanol – methylene chloride and ethanol–chloroform mixtures.

*Cyclic Carbamate of 3β-Acetoxy-6α-amino-11-oxolanostan-7β-ol (**19a**)*

This had m.p. 268–276°; ν_{max} 3440, 1758, 1730, and 1705 cm^{-1}; p.m.r. signals at δ 6.58 (s, NH), 4.40 (t, J = 8 Hz, 3α-H), 3.99 (t, J = 10 Hz, 7α-H), 3.65 (t, J = 10 Hz, 6β-H); $[\alpha]_D$ +54°.

Anal. Calcd. for $C_{35}H_{53}O_5N$: C, 72.89; H, 9.82; N, 2.58. Found: C, 72.88; H, 10.02; N, 2.51.

*Cyclic Carbamate of 3β-Acetoxy-6β-amino-11-oxolanostan-7β-ol (**16b**)*

This had m.p. 307–313°; ν_{max} 3460, 1755, 1730, and 1705 cm^{-1}; p.m.r. signals at δ 5.78 (s, NH), 4.60 (t, J = 8 Hz, 3α-H), 4.32 (multiplet, 6α- and 7α-H); $[\alpha]_D$ +90°.

Anal. Calcd. for $C_{35}H_{53}O_5N$: C, 72.89; H, 9.82; N, 2.58. Found: C, 72.74; H, 9.99; N, 2.50.

*Cyclic Carbamate of 3β-Acetoxy-8β-amino-11-oxolanostan-7β-ol (**20**)*

The 45 mg of product was recrystallized from methanol – methylene chloride to give **17**, m.p. 315–320°. It had ν_{max} 3490, 1755, 1730, and 1715 cm^{-1}; p.m.r. signals at δ 5.34 (s, NH), 4.67 (t, J = 7 Hz, 3α-H), 4.42 (t, J = 8 Hz, 7α-H); $[\alpha]_D$ +46°.

Anal. Calcd. for $C_{33}H_{53}O_5N$: C, 72.89; H, 9.82; N, 2.58. Found: C, 72.67; H, 9.68; N, 2.37.

*Partial Hydrolysis of **11***

A solution of 203 mg of carbamate **11** and 115 mg of potassium hydroxide in 5 ml of ethanol and 0.5 ml of dioxane was refluxed for 15 min. After dilution with water, the mixture was extracted with chloroform. The 190 mg of crystalline product melted at 245–248° and gave n.m.r. signals at δ 6.70 (NH), 4.58 (7β-H), 3.86 (3α-H); ν_{max} 3600–3100, 3450, 1705, 1685 cm^{-1}. This is consistent with the 3β-hydroxy-11-keto carbamate.

*11β-Hydroxy-3β-pivalate (**13**) (R = pivaloyl)*

A solution of 100 mg of the 3β-hydroxy-11-keto car-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

bamate in 2 ml of methanol was refluxed gently while 95 mg of sodium borohydride was added in 15-mg portions over a period of 16 h.

The reaction mixture was diluted with water then extracted with chloroform. The dried ($MgSO_4$) chloroform layers gave 96 mg of product giving one spot on a t.l.c. plate (chloroform–ethanol, 10:1). This was dissolved in 2 ml of pyridine, 0.2 ml of pivaloyl chloride added then the mixture left for 18 h at room temperature. After addition of ice water, the product was extracted into benzene. The benzene solution was washed with dilute hydrochloric acid, sodium bicarbonate solution, then with water, dried ($MgSO_4$), and distilled. The residue was purified by preparative t.l.c. (10:1 chloroform–ethanol) giving 70 mg of crystalline solid. After recrystallization from methanol – methylene chloride it had m.p. 302–312° and gave one spot on a t.l.c. plate (10:1 $CHCl_3$—EtOH). It had ν_{max} 3605, 3440, 1725, and 1690 cm^{-1} and gave n.m.r. signals at δ 5.40 (NH), 4.85 (3α-H), 4.56 (7α-H), and 4.29 (11α-H).

Anal. Calcd. for $C_{36}H_{61}NO_5$: C, 73.55; H, 10.46; N, 2.38. Found: C, 73.51; H, 10.74; N, 2.33.

*3β-Pivaloyloxy-5α-lanost-9(11)-ene-5α(N),7α(O)-carbamate (**14**)*

The 3β-pivaloyloxy-11β-hydroxy carbamate (**13**) (R = pivaloyl) (65 mg) was dissolved in 0.5 ml of pyridine and the solution cooled to 5 °C. After addition of 0.03 ml of thionyl chloride the mixture was left at 5 °C for 15 min. After dilution with ice water the product was extracted into benzene, the benzene layers washed with water, dilute acid, sodium bicarbonate solution, and water, dried and distilled. The 64 mg of crystalline product after one recrystallization from ethanol had m.p. 282–288°; $[\alpha]_D$ +25°; and ν_{max} 3440, 3040, 1725, and 1700 cm^{-1}. It gave n.m.r. signals at δ 5.48 (NH), 5.42 (11-H), 4.83 (3α-H), 4.65 (7β-H).

Anal. Calcd. for $C_{36}H_{59}NO_4$: C, 75.88; H, 10.44; N, 2.46. Found: C, 75.76; H, 10.51; N, 2.39.

*3β,20β-Diacetoxy-9α-methoxycarbon-amido-5α-pregnan-11-one (**23**, R = $NHCOOCH_3$)*

A mixture of 126 mg of 3β,20β-diacetoxy-9α-aminopregnane-11-one (6), 1 ml of methyl chloroformate, and 3 ml of pure chloroform was refluxed gently for 5 days. The solution was taken to dryness under reduced pressure, the residue dissolved in methylene chloride, and the solution filtered through a short column of neutral alumina (Activity I). The 160 mg of crystalline product was recrystallized repeatedly to give a m.p. 228–230°; $[\alpha]_D$ +71°; ν_{max} 3450, 1730, and 1505 cm^{-1}. It gave p.m.r. signals at δ 5.38 (NH), 4.90 (broad, 2H, C*H*OAc), 3.83 (OCH_3), 2.1 (6H, OAc); and ^{13}C.m.r. signals at 205.4 (C-11); 170.8 and 170.5 (3β- and 20β-O*C*OCH_3); 156.2 (N-*C*OCH_3); 72.9 and 72.4 (C-3 and C-20); and 66.8 (C-9) p.p.m.

Anal. Calcd. for $C_{27}H_{41}NO_7$: C, 65.96; H, 8.41; N, 2.85. Found: C, 65.89; H, 8.51; N, 2.56.

*3β,20β-Diacetoxy-9α-acetamido-5α-pregnane-11-one (**23**, R = $NHCOCH_3$)*

A solution of 86 mg of 3β,20β-diacetoxy-9α-aminopregnan-11-one (6) in 1.3 ml of acetic anhydride was heated at 130° for 2h. The product crystallized from the hot solution. After cooling, 83 mg of crystals were collected by filtration. These were recrystallized from ethanol – methylene chloride to give the *N*-acetyl derivative, m.p. 324–332°; $[\alpha]_D$ +67°; ν_{max} 3450, 1725, 1682, and 1505 cm^{-1}. It gave p.m.r. signals at δ 6.02 (NH), 4.76 broad (3α- and 20α-H), 2.13 ($NCOCH_3$), 2.05 ($OCOCH_3$), 1.20 (C-19), and 0.61 (C-18); and ^{13}C.m.r. signals at 204.8 (C-11); 170.9, 170.0, 169.7 (3β- and 20β-O*C*OCH_3 and *N*-*C*OCH_3); 73.1 and 72.4 (C-3 and C-20); 67.0 (C-9) p.p.m.

Anal. Calcd. for $C_{27}H_{41}NO_6$: C, 68.18; H, 8.69; N, 2.94. Found: C, 68.06; H, 8.82; N, 3.01.

*3β-Acetoxy-11-oxolanostan-7α-yl Carbamate (**9**, R = $CONH_2$)*

Aqueous ammonia (28%, 0.5 ml) was added to a stirred ice-cold solution of 3β-acetoxy-11-oxolanostan-7α-yl chloroformate in 1 ml of tetrahydrofuran. After 3 h at 0° water was added and the product extracted into chloroform. The 99 mg of crystalline product was recrystallized from methanol giving the carbamate with m.p. 237–240° and ν_{max} 3540, 3435, 1725, 1700, 1585, and 1400 cm^{-1}. It gave n.m.r. signals at δ 5.17 (7β-H), 5.04 (NH_2), and 4.58 (3α-H).

Anal. Calcd. for $C_{33}H_{55}NO_5$: C, 72.62; H, 10.16; N, 2.57. Found: C, 72.69; H, 10.22; N, 2.61.

Received May 14, 1973

The ^{13}C n.m.r. chemical shifts of some monofunctional keto- and hydroxy-steroids were monitored as a function of the concentration of added shift reagent, $Pr(fod)_3$ or $Eu(fod)_3$, and the observed induced shifts were fitted to the geometric quantities in the one-term pseudocontact shielding equation. The correlation between experimental and calculated shifts was quantitative for all carbons except those closest to the complexing site, where contact interactions are most noticeable. With $Pr(fod)_3$ the carbonyl and hydroxyl carbons and the alpha carbons usually had to be excluded from the calculations in order to optimize the correlation between predicted and observed induced shifts for the remaining nuclei and to derive reasonable adduct geometries. With $Eu(fod)_3$, contact shifts were also noticeable at the beta carbons and the europium shift reagents are therefore less useful in ^{13}C n.m.r. spectroscopy. It is shown that the application of shift reagents, in conjunction with off-resonance decoupling, permits the assignment of practically all carbon chemical shifts of the steroids studied.

Les spectres r.m.n. du carbone-13 des céto et hydroxy stéroides monofunctionnels sont étudiés en fonction de la concentration des réactifs paramagnétiques de déplacement chimique, $Pr(fod)_3$ et $Eu(fod)_3$. Les déplacements induits observés sont ajustès aux quantités géométriques de l'équation pseudocontact. Si on néglige les 3 carbones les plus proches du métal pour $Pr(fod)_3$ et les 5 carbones les plus proches pour $Eu(fod)_3$, la correlation entre les déplacements expérimentaux et les déplacements calculés sont excellents. On peut interpréter l'observation de correlation dans le cas des carbones proche du métal en terme d'une interaction contact entre ces carbones et le metal. Nous suggérons que pour ces systèmes $Pr(fod)_3$ est le meilleur reactif pour l'observation des déplacements pseudocontact. Nous montrons comment on peut utiliser le réactif paramagnétique avec le couplage liens-résonance pour alterner les déplacements chimiques de tous les carbones des stériodes etudiés.

Can. J. Chem., **51**, 3874 (1973)

It is now well established (1–8) that lanthanide induced shifts are quantitatively reproduced by the one-term pseudocontact shielding eq. 1 for axially symmetric complexes.

$$[1] \qquad \Delta_i = C(1-3\cos^2\theta_i)/R_i^3$$

However, the success of eq. 1 in the lanthanide series is more likely the result of conformational averaging in solution (9) than due to the formation of axially symmetric shift reagent – substrate adducts, since there is no evidence of axial symmetry in the solid state (10–12). In addition to the dipolar shifts there is, however, evidence of contact interactions at the nuclei closest to the complexing site (2, 7, 8, 13).

The value of quantitative applications of eq. 1 in ^{13}C n.m.r. spectroscopy has already been demonstrated with the complete assignment of the carbon resonances of borneol (2, 7) and isoborneol (7). In order to assess the utility of the lanthanide shift reagents for spectral assignments of larger molecules we studied the effects of $Pr(fod)_3$ and $Eu(fod)_3$ on the ^{13}C n.m.r. chemical shifts of a series of monofunctional keto and hydroxy steroids.

Results and Discussion

The ^{13}C chemical shifts for the hydroxy and keto steroids are given in Table 1. Most signals could be assigned by comparison with c.m.r. spectra of steroids reported by Roberts and coworkers (18). The remaining assignments are based on the shift reagent studies described below. We return to these assignments after a discussion of the shift reagent results.

The $Pr(fod)_3$ induced shifts are given in Table

*Cholesterol.

2, together with the differences between observed and calculated induced shifts. The results in Table 2 fully justify the use of eq. 1 in the lanthanide series. The correlation between observed shifts and the geometric quantities $(1-3\cos^2\theta)/R_i^3$ is essentially quantitative for all carbons outside the C—(C—OH)—C and C—(C=O)—C moieties, if these closest carbons are omitted from the calculations, and the corresponding metal–oxygen distances are found to be of the order of magnitude (*ca.* 2.5 Å) expected from X-ray crystallographic studies of shift reagent – substrate adducts (10, 12). The lack of agreement between calculation and experiment for the carbons closest to the lanthanide metal is most likely due to contact interactions. If the induced shifts for the C—(C—OH)—C and C—(C=O)—C fragments were excluded from the calculations the predicted upfield shifts for the carbonyl carbons were far too small, whereas the predicted shifts for the hydroxyl carbons were somewhat too large, with the exception of 3β-hydroxyandrostane (Table 2). If the shifts for the C—(C—OH)—C, and C—(C=O)—C fragments were included in the calculations excellent agreement with experiment was achieved for the carbonyl, as well as the hydroxyl carbons (Table 3). However, the fit for the remaining carbons deteriorated and the Pr—O distances became unrealistically long for the ketones and too short for the hydroxides. Not surprisingly optimization of the fit of eq. 1 to the observed shifts leads to geometries which best reproduce the experimental values for the carbons which experience the largest shifts. Because of their $1/R^3$ dependence the induced shifts for carbons close to the functional group decrease more rapidly than those for more remote carbons. Contact interactions reinforcing the pseudocontact shifts, as for the hydroxyl carbons, will increase this difference and result in an apparent decrease of the Pr—O bond lengths. Contact shifts opposing the pseudocontact shifts, as for the carbonyl carbons, decrease this difference and cause an apparent increase of the Pr—O distances.

Contact interactions are also noticeable at the alpha carbons, especially if they are tertiary or quaternary. The observed induced shifts for the quaternary carbons alpha to the hydroxyl carbons are lower than the induced shifts for secondary alpha carbons and lower than the calculated pseudocontact shifts. Similarly with the ketosteroids the induced shifts for tertiary and quaternary alpha carbons are significantly smaller than those of the secondary alpha carbons and smaller than the predicted values (Tables 2 and 3).

It was considerably more difficult to correlate $Eu(fod)_3$ induced carbon chemical shifts with the geometric quantities in eq. 1. With this shift reagent contact interactions seem to extend to the beta carbons and it was usually necessary to

‡Positive residuals ΔΔ, if significant, denote upfield contact shifts.

exclude at least one of the beta carbon shifts from the calculations to assure convergence and to find reasonable adduct geometries (Table 4). The induced shifts for tertiary and quaternary alpha carbons contain particularly large contact contributions. For instance, the signal of C-14 in 15-ketoandrostane was shifted upfield by $Eu(fod)_3$, *i.e.* the contact shift exceeded the pseudocontact shift in this case. Sample results with $Eu(fod)_3$ are found in Table 4. Figure 1 shows a comparison of optimized Pr and Eu metal coordinates relative to four of the steroids. In view of the sensitivity of the lanthanide metal locations to contact shifts the Pr and Eu coordinates are considered as satisfactorily close.

$Pr(fod)_3$ and $Eu(fod)_3$ induce contact shifts of opposite sign. With $Pr(fod)_3$ upfield contact shifts are observed for hydroxyl carbons, downfield shifts for the carbonyl carbons and also for tertiary and quaternary alpha carbons in both types of steroids. $Eu(fod)_3$ caused downfield contact shifts for hydroxyl carbons and upfield shifts for all tertiary and quaternary alpha carbons. The predicted pseudocontact shifts for the carbonyl carbons agreed well with the observed induced shifts, which is undoubtedly due to a

fortuitous cancellation of upfield and downfield contact shifts. A change of sign of the contact shifts on going from Pr to Eu has also been observed in shift reagent studies of borneol and isoborneol (8), of quinoline (13) and studies of

isotropic shifts induced by the tripositive ions Pr^{3+} and Eu^{3+} (19).

As mentioned at the beginning most signals could be assigned by comparison with related steroids studied by Roberts and co-workers (18). Their assignments are supported by the present shift reagent results, with the exception of the chemical shifts for carbons 12 and 16 of cholesterol which have to be interchanged (*vide infra*). It is shown in this section that the combined application of lanthanide shift reagents and off-resonance decoupling permits an independent assignment of practically all ^{13}C chemical shifts of any of the steroids. 3-Ketoandrostane may serve as an example of the A-ring-substituted steroids. The off-resonance decoupled spectrum, before or after addition of shift reagent, allows one to distinguish primary, secondary, tertiary, and quaternary carbons. Qualitatively the lanthanide induced shifts are expected to decrease in the order

$$3 > 2 \sim 4 > 1 \sim 5 > 6 \sim 10 \sim 19 > 7 \sim 8 \sim 9 \sim 11 > 12 \sim 13 \sim 14 \sim 18 > 15 \sim 16 \sim 17$$

Combined with the results of off-resonance decoupling experiments this leads to the series

CH_3 $19 > 18$

CH_2 $2 \sim 4 > 1 > 6 > 7 \sim 11 > 15 \sim 16 \sim 17$

CH $5 > 8 \sim 9 > 14$

C $10 > 13$

and to reasonably certain assignments for carbons 1, 3, 5, 6, 10, 12, 13, 14, 18, and 19. A least-squares fit of the pseudocontact equation to the induced shifts for these carbons confirmed these assignments and distinguished carbons 8 and 9 (Table 5). Carbons 15, 16, and 17 cannot be assigned from the shift reagent results alone. However, by comparison with the chemical shifts of C-1 and C-12 the lowfield signal has to be due to C-17 and carbons 15 and 16 can then be distinguished on the basis of the predicted induced shifts. The induced shifts for C-15 and C-16 are close, but these assignments are supported by the results for the other A-ring-substituted steroids (Table 2). The signals of C-2 and C-4, and those of C-7 and C-11 cannot be distinguished on the basis of the lanthanide induced shifts and have been assigned according to Roberts (18).

The assignment of the carbon chemical shifts in D-ring-substituted steroids is exemplified by 17-ketoandrostane. Qualitatively the induced shifts are expected to decrease in the order

CH_3 $18 > 19$

CH_2 $16 > 15 \sim 12 > 11 > 7 > 6 > 1 \sim 4 > 2 \sim 3$

CH $14 > 8 \sim 9 > 5$

C $13 > 10$

leading to rather unambiguous assignments for carbons 5, 6, 7, 10, 11, 13, 14, 16, 17, 18, and 19. The resonances for the pairs of carbons 1/4, 2/3, 8/9, and 12/15 remain to be distinguished. The chemical shift of C-4 has to be close to that of C-6, and C-1 and C-4 are assigned accordingly. A least-squares fit of eq. 1 to the induced shifts for these carbons led to the unequivocal assignment of C-12 and C-15, and of C-8 and C-9 (Table 5); C-2 and C-3 cannot be assigned unambiguously from the induced shifts and were assigned according to Roberts (18).

With the exception of C-12 and C-16 in cholesterol the c.m.r. chemical shifts assigned on the basis of lanthanide induced shifts agree with the assignments made by Roberts and co-workers (18) for related steroids. The induced shifts for carbons 12 and 16 in cholesterol as well as the other A-ring-substituted steroids are unambiguous evidence (Table 2) that the downfield signal is due to C-12 and the upfield peak due to C-16. This is not unreasonable since the C-12 chemical shift is expected to be close to that of C-1 due to the structural similarities about the two sites. In addition, the C-12 resonance now moves upfield on going from the A-ring ketones and hydroxides to the 17-ketone similar to the upfield shift of C-6 upon introducing a keto group into position 4. Thus the assignments of C-12 and C-16 for all cholestane derivatives in reference 18 have to be reversed.

Conclusions

The quantitative correlation between the pseudocontact eq. 1 and the observed chemical shifts induced in the ^{13}C n.m.r. spectra of the keto and hydroxy steroids is further evidence for the $(1-3\cos^2\theta_i)/R_i^3$ dependence of the dipolar shifts induced by the lanthanide shift reagents. However, the unrealistic adduct geometries required to reproduce the observed induced shifts for the

closest carbons, and the lack of agreement between observation and predictions based on acceptable metal–oxygen bond lengths, are clear evidence of contact interaction at the carbons closest to the complexing site. The $Eu(fod)_3$ induced contact shifts are larger and noticeably further along the carbon chain than the $Pr(fod)_3$ induced contact shifts. For this reason $Pr(fod)_3$ is the more useful shift reagent in ^{13}C n.m.r. spectroscopy. Finally, it was demonstrated that the combined application of off-resonance decoupling and lanthanide shift reagents permits the assignment of practically all carbon chemical shifts of the steroids studied.

Experimental and Calculations

The hydroxy and keto steroids were available in the laboratory. $Pr(fod)_3$ and $Eu(fod)_3$ were purchased from Norell Chemical Co. and used without further purification. The ^{13}C n.m.r. spectra of the steroids were recorded as 0.2 *M* solutions in $CDCl_3$. For every substrate 0.5 *M* shift reagent solutions in $CDCl_3$ were freshly prepared. All manipulations of shift reagents were carried out as quickly as possible but no special precautions were taken to exclude moisture. Five aliquots of the shift reagent solutions were added to the steroids to reach a maximum shift reagent – substrate concentration ratio of 0.5. All ^{13}C n.m.r. spectra were recorded on a Bruker HX 90 n.m.r. spectrometer equipped with a Nicolet 1083 instrument computer for Fourier transform spectroscopy. The probe temperature was 37 °C.

The chemical shifts before and after addition of shift reagent were plotted against the sums of the shifts in each spectrum, which were scaled from zero to unity. The "observed induced shifts Δ_{obs}" reported in Tables 2 and 4 are the slopes in these plots (14, 15). The root-mean-squares deviations of the experimental points from the lines were of the order of 0.05 p.p.m. The steroidal carbon coordinates used in the calculations were those for androsterone (16) and 3β-chloro-5-androsten-17β-ol (17), as determined by X-ray crystallography. The oxygen coordinates were calculated assuming standard bond lengths and angles. The lanthanide metal position relative to the substrate and the fit between observed and calculated induced shifts were optimized as described previously (6). Briefly, the method consists of expanding the pseudo-contact eq. 1 in a Taylor series in the proportionality constant *C* and three Cartesian coordinates for the lanthanide atom. The sum of the squares of the deviations is then minimized iteratively by a linear least-squares fit of the expanded equation to the observed induced shifts. The minimum was usually located after five or six iterations, depending on the starting parameters. The calculations were performed on the IBM 360 computer at the Université de Sherbrooke, with programs written in Fortran IV language.

Studies on Metal Hydroxy Compounds. XIV. Thermal Analyses, Calorimetry, and Decomposition Kinetics of Heterocationic Hydroxy Chloride Compounds

AH-DONG LEU,[1] PALEPU RAMAMURTHY,[2] AND ETALO A. SECCO[3]
Chemistry Department, St. Francis Xavier University, Antigonish, Nova Scotia

Received June 25, 1973

Studies were carried out on two series of mixed metal hydroxy chloride compounds of the type $x\text{Me(OH)}_2.y\text{MCl}_2$ where Me = Cd, Cu and M = Mn, Co, Ni, Cu, Zn, Cd, Mg, or Ca.

Thermal analyses for the Cd–M series reveal that the initial mode of decomposition involves a dehydroxylation step with a concomitant metathetical reaction between MCl_2 and CdO. The compound $CdCl_2.2CdO$ is formed and decomposes at higher temperature leading to the eventual volatilization of $CdCl_2$. The kinetics of thermal decomposition follow a simple first-order rate equation. The sole exception to this general pattern of behavior is the Cd–Zn compound.

The initial mode of thermal decomposition of the Cu–M series compounds follows a parallel pattern described for the Cd–M series. The kinetic data for the Cu–M series are fitted into three groups: (*i*) phase boundary control embracing the contracting sphere and contracting plate model equations, (*ii*) A-E type equation with $n = 2$, and (*iii*) first-order rate equation.

On a étudié deux séries de hydroxychlorures métalliques du type mixte $x\text{Me(OH)}_2.y\text{MCl}_2$ où Me = Cd, Cu et M = Mn, Co, Ni, Cu, Zn, Cd, Mg ou Ca.

Des analyses thermiques pour la série Cd–M ont montré que le mode initial de décomposition implique une déshydroxylation avec une réaction de double décomposition concomitante entre MCl_2 et CdO. Le composé $CdCl_2.2CdO$ est formé et se décompose à des températures plus élevées en entraînant la volatilisation éventuelle du $CdCl_2$. La cinétique de la décomposition thermique obéit à une équation de vitesse du premier ordre. La seule exception à ce type général de comportement est le composé Cd–Zn.

Le mode initial de décomposition thermique de la série Cu–M suit un processus parallèle à celui décrit pour la série Cd–M. Les données cinétiques pour la série Cu–M sont résumées en trois groupes: (*i*) contrôle topochimique quand la réaction commence à la surface extérieure du solide et progresse en trois dimensions (modèle d'une sphère contractante) ou quand la réaction progresse en deux dimensions (modèle d'une lame contractante); (*ii*) équation du type A-E avec $n = 2$ et (*iii*) équation de vitesse du premier ordre. [Traduit par le journal]

Can. J. Chem., **51**, 3882 (1973)

Introduction

An earlier study on metal basic halides involving the cadmium derivative (1) showed that the reaction between CdO and $CdCl_2$ in aqueous solution gave a solid compound of composition CdOHCl, *viz.*

$$[1]\quad CdO_{(s)} + CdCl_{2(s)} + H_2O_{(l)} \xrightarrow{\sim 80\,^\circ C} 2\,CdOHCl_{(s)}$$

When NaCl was used instead of $CdCl_2$ under similar conditions a white precipitate (2) was again obtained whose composition was found to be $Na_2Cd(OH)_2Cl_2$, *i.e.*,

$$[2]\quad CdO_{(s)} + 2\,NaCl_{(s)} + H_2O_{(l)} \xrightarrow{\sim 80\,^\circ C} Na_2Cd(OH)_2Cl_{2(s)}$$

The existence of such mixed metal hydroxychloride compounds prompted us to extend the previous studies reported on bivalent metal hydroxyhalides (1, 3, 4) and mixed metal hydroxides (5) to assess the effect of a different metal halide presence on the thermal stability and decomposition kinetics of a given hydroxide.

This paper contains results on thermal analyses, calorimetry, and decomposition kinetics on two series of mixed metal hydroxychloride compounds of the type $x\text{Me(OH)}_2.y\text{MCl}_2$ where Me = Cd or Cu and M = Mn, Co, Ni, Cu, Zn, Cd, Mg, or Ca.

Experimental

Preparation

All compounds used in this study were prepared in this laboratory. The mixed-Cu compounds were obtained by following the known procedure of Feitknecht and Maget (6) whereas the mixed-Cd compounds were prepared by digesting CdO in an aqueous solution of metal chloride,

MCl_2, at 75–80 °C for 2–4 days. Two-fold excess of MCl_2 over CdO ensured complete consumption of the oxide.

All chemicals used, except CdO, were commercially supplied reagent grade material. The CdO was obtained from the decomposition of cadmium basic oxalate (7) which had the desired property of higher reactivity compared to the commercially available reagent grade oxide (1).

The precipitates were filtered and washed thoroughly with distilled water and then dried at 110 °C overnight.

The identities of the Cu–M compounds were confirmed by the available X-ray diffraction patterns (6) and in an indirect manner by correlating the thermogravimetric analysis with the X-ray patterns of the solid residues. All compounds were determined to be in the constant atomic relationship $MCl_2.3Cu(OH)_2$ except for Ca which was $CaCl_2.4Cu(OH)_2$.

The new Cd–M compounds were identified by elemental quantitative analysis.

Elemental Quantitative Analysis

All chemicals used were at least of reagent grade. Aqueous solutions were prepared with water distilled in a Pyrex distillation apparatus. The glassware was cleaned with acidic cleaning solution followed by thorough rinsing; the volumetric glassware was also soaked in hot alkaline disodium ethylenediamine tetra-acetate (EDTA) solution and then rinsed thoroughly.

The mole ratio of the two cations, x and y in the compound, $xCd(OH)_2.yMCl_2$, was determined by EDTA titration (8–10) initially for a known or standard solution in two steps: (*a*) masking and demasking agents present (8, 9); (*b*) masking and demasking agents absent. The volume V_a consumed in step (*a*) corresponded to the presence of one cation while V_b concerned in (*b*) corresponded to both cations. V_a and V_b represented the measured mole ratio of the cations which was then compared to the known value of the standard solution. The method giving a discrepancy of $< 2\%$ was deemed satisfactory for analysis of the unknown solution containing the prepared compound.

The Cl content of each compound was determined by the Volhard method (11) and the OH content was obtained from the weight loss due to the dehydroxylation in TG.

Instrumental Analysis

The heating and cooling curves, calorimetric measurements, and isothermal kinetic traces were obtained as previously described (4). The heating rate used was usually 20 °C/min and an ambient atmosphere of dry N_2 (Matheson Prepurified Grade with a stated impurity of 0.003% O_2) at a flow rate of 2 SCFH was maintained during all experiments.

The X-ray diffraction traces of the samples were recorded on a Norelco X-ray diffractometer unit using CuK_α or MoK_α radiation (12); the identities of the residues were confirmed by the available X-ray diffraction patterns (13).

Results and Discussion

Elemental Quantitative Analysis

The cation mole ratio results of the standard solutions as determined in our analytical procedure incorporated errors ranging from 0.24% to 1.53%. Using the nearest integer ratio ($x:y$) along with the Cl analysis and the OH content from TG weight loss, the empirical formula for each compound of the type $Cd_kM_l(OH)_mCl_n$ was found and is presented in Table 1.

The k and l values in $Cd_kZn_l(OH)_mCl_n$ could not be determined quantitatively because of the difficulty in the separation of Cd and Zn. With prior knowledge of the compound $Zn_5(OH)_8Cl_2$ (14) the mixed compound was assumed to be $Cd_kZn_l(OH)_8Cl_2$ where $k + l = 5$. All evidence from thermal analysis and X-ray diffraction of intermediate products supports the assignment of $k = 1$ and $l = 4$, *i.e.* $CdZn_4(OH)_8Cl_2$.

Thermogravimetry

The results of TG are presented in Table 2; the proposed over-all decomposition reaction and steps are those which best fit the observed weight loss. The intermediate and final products were further confirmed by X-ray diffraction and correlated with DTA curves.

Cd–M Compounds

The first step in the decomposition reaction occurs, as expected, via dehydroxylation which can be represented by the general overall equation

*Onset and terminal temperatures.
†A, dehydroxylation; B, disproportionation of $CuCl_2$; C, volatilization of Cu_2Cl_2 and partial chlorination of oxide; D, E, volatilization of $CdCl_2$, $CaCl_2$, respectively; F, dehydroxylation and dechlorination.

[3] $$Cd_kM_l(OH)_mCl_{n(s)} \rightarrow aCdO_{(s)} + bMO_{(s)} + cCdCl_{2(s)} + dH_2O_{(g)}$$

where M = Cu, Co, Mg, Mn, Ni, and Zn. The coefficients are related as follows, $a + c = k$; $b = l$; $m = 2d = a + b + d$; $2c = n$. The second weight loss process for all compounds, excepting Cd–Cu, is assigned to the volatilization of $CdCl_2$; the Cd–Cu compound weight loss is best fitted to Cu_2Cl_2 volatilization.

Cu–M Compounds

The first step in the decomposition of the Zn, Ni, and Co compounds involves dehydroxylation to yield CuO, metal chloride, and water, *i.e.*

[4*a*] $$MCl_2.3Cu(OH)_{2(s)} \rightarrow MCl_{2(s)} + 3CuO_{(s)} + 3H_2O_{(g)}$$

This reaction is followed immediately by the metathetical reactions of the chloride with CuO where no weight loss is involved, *i.e.*

[4*b*] $$MCl_{2(s)} + CuO_{(s)} \rightarrow CuCl_{2(s)} + MO_{(s)}$$

The second and third steps in the heating curve are due to disproportionation of $CuCl_2$ and subsequent volatilization of Cu_2Cl_2 (15). The higher observed weight loss for the volatilization of Cu_2Cl_2 shown in Table 2 is due to partial chlorination of CuO as previously reported (15).

The Cd and Ca compounds undergo simple dehydroxylation with no ensuing metathetical reaction, *i.e. viz.* [4*a*]. The second step is the volatilization of the chloride which in the case of $CaCl_2$ was incomplete up to 900 °C.

$MgCl_2.3Cu(OH)_2$ decomposed via simultaneous dehydroxylation and dechlorination, *i.e.*

[5] $MgCl_2.3Cu(OH)_{2(s)} \rightarrow MgO_{(s)} + 2CuO_{(s)} + \frac{1}{2}Cu_2Cl_{2(l)} + \frac{1}{2}Cl_2 + 3H_2O_{(g)}$

which is followed by volatilization of Cu_2Cl_2.

Differential Thermal Analysis

The DTA results are presented in Table 3 and these thermal effects are interpreted in terms of processes consistent with the TG data.

Cd–M Compounds

Two or three endotherms were observed in the heating curves of this series. The first endotherm is dehydroxylation according to [3] which is followed by the $CdCl_2$ melting endotherm between 555–575 °C if the amount of $CdCl_2$ exceeded CdO by the mole ratio 1:2 (16). The final endotherm 665–695 °C observed in all compounds, excepting Cd–Zn, originates in the decomposition of $CdCl_2.2\,CdO$ (16). The absence of this latter endotherm in $CdZn_4(OH)_8Cl_2$ implies the absence of CdO in the product, *i.e.* $CdCl_2.4Zn(OH)_2$, confirming the earlier interpretation that $Zn_5(OH)_8Cl_2$ is more properly represented by $ZnCl_2.4\,Zn(OH)_2$.

The cooling curve for the residue from each decomposed compound, from 800 °C to room temperature, exhibited exotherms characteristic of $CdCl_2$–CdO presence with two exceptions, Cd–Zn and Cd–Cu compounds. $CdZn_4(OH)_8Cl_2$ showed the $CdCl_2$ fusion exotherm only. On the other hand $CdCu_2(OH)_4Cl_2$ showed two exotherms, 480 °C and 440 °C, associated with the Cu_2Cl_2–$CdCl_2$ binary system of solid solution with minimum melting point (24). Although the latter two exotherm temperature peaks could be mistaken for the temperatures normally observed for Cu_2Cl_2 solidification and the $\gamma \rightarrow \beta$ transi-

$Cd_4Mn(OH)_7Cl_3$	280–320	5	first order	28.7±0.3	9.3
$CdCl_2.3Cu(OH)_2$	280–315	5		48±3	17.7
$ZnCl_2.3Cu(OH)_2$	300–350	6	$-\ln(1-\alpha) = (kt)^2$	34±1	11.8
$NiCl_2.3Cu(OH)_2$	340–380	6	$1-(1-\alpha)^{\frac{1}{2}} = kt$	36±1	12.1
$CoCl_2.3Cu(OH)_2$	320–355	6	$1-(1-\alpha)^{\frac{1}{2}} = kt$	34±1	11.2
$MgCl_2.3Cu(OH)_2$	400–430	6	$1-(1-\alpha)^{\frac{1}{2}} = kt$	74±2	22.6
$CaCl_2.4Cu(OH)_2$	335–360	6	$1-(1-\alpha)^{1/3} = kt$	66±4	22.2

tion, the exotherm profiles differed significantly in both instances.

Cu–M Compounds

The heating trace up to 700 °C for Cu–Ni and Cu–Co compounds revealed two endotherms corresponding to simultaneous dehydroxylation and metathetical reactions according to [4*a*] and [4*b*] followed by disproportionation of $CuCl_2$. On cooling, two exotherms at 460 °C and 420 °C are identified with fusion and structural transition in Cu_2Cl_2, respectively (15).

Two endotherms appeared on heating $ZnCl_2.3Cu(OH)_2$. The first endotherm consisted of a doublet described by [4*a*] and followed by $ZnCl_2$ melting and the metathetical reaction 4*b*. Cooling the residue revealed two exotherms at 440 and 420 °C involving Cu_2Cl_2 transitions.

$CdCl_2.3Cu(OH)_2$ showed two endotherms on heating; these endotherms correspond to dehydroxylation via [4*a*] and melting of $CdCl_2$. The solidification exotherm of $CdCl_2$ was confirmed on cooling.

Only one endotherm was observed on heating $MgCl_2.3Cu(OH)_2$ described by reaction 5, involving simultaneous dehydroxylation and $CuCl_2$ disproportionation. The cooling curve of the residue revealed the two exotherms characteristic of Cu_2Cl_2.

The heating trace of $CaCl_2.4Cu(OH)_2$ displayed one endotherm due to dehydroxylation analogous to [4*a*].

Reaction Kinetics Data

The recorded weight loss *vs.* time trace was converted to decomposition fraction, α, *vs.* time plot according to the overall reactions 3, 4*a*, or 5. The experimental α, t, data were processed through all the known solid state kinetic rate equations. The best linear fit between the data and the rate expressions over the maximum reaction fraction $\alpha \sim 0.90$ and over the temperature range studied are presented in Table 4. The fitting of the data to a particular rate expression was straightforward and clear-cut in each case.

Cd–M Compounds

The kinetic data for all compounds, except Cd–Zn, were fitted to simple first-order kinetics; $CdZn_4(OH)_8Cl_2$ rate data fit the second-order rate law presented in its integrated form (17) by

$$1/(1-\alpha) = 1 + kt \qquad [6]$$

The activation energy, E_a, values of all Cd–M compounds fall within the range 25–32 kcal/mol which compare with 26.3 kcal/mol for $Cd(OH)_2$. The striking similarity in E_a values suggests a fundamentally similar decomposition mechanism and activated complex state. The fundamental step for a first-order dehydroxylation rate is visualized as an OH abstraction by a highly mobile H species.

The E_a value for the dehydroxylation reaction in the Ni, Mg, and Mn compounds is lower than its respective ΔH value. The observation that $E_a < \Delta H$ is at variance with current rate theory (18) and the literature of endothermic decomposition reactions (19). Recently, Fichte and Flanagan (20) reported a similar result, *i.e.* $E_a < \Delta H$, and have cited Somorjai and Lester's discussion on evaporation processes (21) to illustrate that the condition $E_a > \Delta H$ is not a necessary condition for solid-state dehydration reactions. However we are inclined to assign our result of $E_a < \Delta H$ to concomitant secondary

TABLE 5. Heats of decomposition and values of ΔH_f^0

Compound	Temperature range (°C)*	Heat of Decomposition ΔH_w	Heat of Decomposition ΔH_c†	$-\Delta H_f^0$ (kcal/mol)
Cd $Cu_2(OH)_4Cl_2$	220–315	11.8	23.6±1.7	‡
Cd $Zn_4(OH)_8Cl_2$	195–270	6.8	27.4±0.7	668
$Cd_9Ni_4(OH)_{20}Cl_6$	265–400	‡	101±1	‡
$Cd_3Co(OH)_6Cl_2$	270–385	6.3	18.8±0.4	464
$Cd_7Mg_2(OH)_{14}Cl_4$	300–415	‡	48.3±1.9	‡
$Cd_4Mn(OH)_7Cl_3$	310–430	‡	35.0±1.8	‡
Zn $Cl_2.3Cu(OH)_2$	255–350	12.1	36.3±0.3	405
Ni $Cl_2.3Cu(OH)_2$	300–415	11.7	35.0±0.5	395
Cd $Cl_2.3Cu(OH)_2$	240–355	11.7	35.0±0.2	413
Co $Cl_2.3Cu(OH)_2$	280–370	12.0	36.0±1.0	398
Mg $Cl_2.3Cu(OH)_2$	400–530	14.7	44.0±1.0	482
Ca $Cl_2.4Cu(OH)_2$	270–370	13.0	42.0±0.4	612

*Onset and terminal temperatures.
†All determinations were done in triplicate; ΔH_c values are given with their average deviation; ΔH_w, heat of decomposition in kcal/mole of H_2O formed; ΔH_c, heat of decomposition in kcal/mole of compound decomposed; ΔH_f, heat of formation of the hydroxychloride compound.
‡Unable to calculate because of unknown secondary effects.

endothermic solid-state effects, such as metathetical reactions, etc.

The Arrhenius pre-exponential term, A, values are less than 10^{13}. Since $A = [10^{13}Q^*/Q]$ where Q^* and Q from absolute rate theory represent the complete partition functions of the activated complex, excluding the reaction coordinate, and of the reactant, respectively then $Q^* < Q$ implies that the complex is more restricted in its modes of freedom relative to the reactant. Cordes' analysis (22) for a bimolecular first-order reaction yields a predicted A range 10^9–10^{11} which spans the interval of A values cited in Table 4.

Cu–M Compounds

The compounds can be classified on the basis of their reaction kinetics into three groups.

(*i*) Phase boundary control with the kinetic data for $CaCl_2.4Cu(OH)_2$ fitting the contracting sphere model, *viz.*

$$[7] \qquad 1 - (1 - \alpha)^{1/3} = kt$$

and the kinetic data for $NiCl_2.3Cu(OH)_2$, $CoCl_2.3Cu(OH)_2$, and $MgCl_2.3Cu(OH)_2$ fitting the contracting plate model, *viz.*

$$[8] \qquad 1 - (1 - \alpha)^{\frac{1}{2}} = kt$$

(*ii*) The Avrami–Erofeyev (A–E) type equation with $n = 2$, *viz.*

$$[9] \qquad -\ln(1 - \alpha) = kt^2$$

as found for $ZnCl_2.3Cu(OH)_2$.

(*iii*) First order rate kinetics as observed for $CdCl_2.3Cu(OH)_2$.

The activation energy E_a values range from 34 to 74 kcal/mol. This wide range of values and compared to 18 kcal/mol for $Cu(OH)_2$, strongly suggests different mechanisms and activated complex configurations for $Cu(OH)_2$ dehydroxylation. This feature is a striking contrast to the apparently similar mechanism of dehydroxylation in the $Cd(OH)_2$ compounds.

The interpretation of the Arrhenius pre-exponential term A values parallels the analysis given above in an earlier report (23).

Calorimetric Measurements

The calorimetric results are presented in Table 5 according to the overall eqs. 3 and [4] for Cd–M and Cu–M compounds, respectively for the temperature range cited; the heat of formation of each compound is included.

The values of ΔH per mole of H_2O formed are lower for all the heterocationic Cd hydroxychlorides relative to the analogous value for $Cd(OH)_2$. On the other hand, the heterocationic Cu compounds exhibited slightly higher values for ΔH per mole of H_2O formed relative to that for $Cu(OH)_2$. The thermal stability of each heterocationic compound is greater than its parent hydroxide as evidenced by the higher decomposition temperature. It also can be concluded that the presence of the bivalent metal chloride MCl_2 has had a positive effect on strengthening the Cu—OH bond whereas the presence of MCl_2 in $Cd(OH)_2$ has significantly weakened the Cd—OH bond.

For personal use only.

This study emphasizes the dependence of thermal stability of hydroxy-compounds on two distinct parameters: (*i*) a kinetic factor, related to the separation of OH groups and identified by the decomposition temperature range, and (*ii*) a thermodynamic factor, intimately linked to OH bond strength as indicated by the value of ΔH per mole of H_2O formed.

Etude par resonance magnetique des mouvements moléculaires dans l'acrylonitrile solide

BUU BAN
Laboratoire de Photophysique Moléculaire, Faculté des Sciences, 91, Orsay

ET

C. CHACHATY
Service de Chimie-Physique, C.E.N. de Saclay, B.P. N°2, 91, Gif sur Yvette

Reçu le 12 mars 1973

Les transitions de phase et les mouvements moléculaires de l'acrylonitrile solide et de son homologue deutérié CH_2=CDCN ont été étudiés entre 100 °K et le point de fusion (191 °K) par r.m.n. large bande et par des mesures du temps de relaxation T_1. La phase I (164° < T < 191 °K) est piégée sous forme métastable par refroidissement rapide de l'acrylonitrile à 77 °K. Elle donne la phase II stable entre 113 °K et 164 °K par recuit prolongé à 155–160 °K. Le passage de la phase II à la phase III, stable aux plus basses températures, s'effectue à 113 °K. La phase III peut être considérée comme rigide au-dessous de 105 °K. La phase II est caractérisée par un mouvement de libration des molécules autour d'un axe passant par l'azote et le milieu de la double liaison vinylique. En phase I, l'acrylonitrile effectue un mouvement de réorientation d'ordre deux autour de cet axe avec une énergie d'activation de 4.2 kcal mol^{-1}.

On a étudié également, par r.p.e., les mouvements moléculaires des radicaux péroxyles produits par addition d'oxygène sur les radicaux préalablement formés par irradiation γ à 77 °K. La variation de l'anisotropie de g avec la température ne présente aucune discontinuité aux transitions de phases et l'énergie d'activation de réorientation est seulement de 0.65 kcal mol^{-1} ce qui suggère qu'il s'agit de radicaux macromoléculaires dont on n'observe que la rotation interne.

Phase transitions and molecular motions in solid acrylonitrile and its deuterated homologue CH_2=CDCN, have been studied between 100 and 191 °K (m.p.) by wide line n.m.r. and by T_1 relaxation time measurements. Phase I (164 °K < T < 191 °K) is trapped and becomes metastable by quick cooling of acrylonitrile at 77 °K. It changes into the phase II, stable between 113 °K and 164 °K by a long duration annealing at 155–160 °K. The phase II → phase III transition occurs at 113 °K. It may be assumed that phase III, stable below this temperature, is rigid at T < 105 °K. Phase II may be characterized by a rotational oscillation of molecules around an axis defined by the N atom and the middle of the vinyl double bond. In phase I, acrylonitrile molecules undergo a binary reorientation motion around this axis with an activation energy of 4.2 kcal mol^{-1}. The motion of peroxy radicals, trapped in acrylonitrile has been also studied by e.s.r. These radicals were produced by oxygen addition to free radicals previously formed by γ irradiation of acrylonitrile at 77 °K. The g anisotropy variation with temperature, shows no discontinuities at phase transitions, the activation of reorientation of peroxy radicals being 0.65 kcal mol^{-1}. This result suggests that we are dealing in fact with macroradicals, the internal rotation of which is only observable in a solid matrix.

Can. J. Chem., **51**, 3889 (1973)

Introduction

L'acrylonitrile est le premier monomère vinylique dont la polymérisation amorcée par irradiation γ en phase solide, à basses températures, a été observée (1, 2). Tout de suite la question s'est posée de savoir si cette réaction n'a lieu qu'au point de fusion à 191 °K, où si elle se produit réellement en phase solide.

La calorimétrie (3) a permis une mise en évidence directe de la polymérisation en phase solide. Des mesures effectuées par cette méthode sur le monomère non irradié ont en outre montré l'existence d'une transition de phase à 160 °K. La diffraction de rayons X (4) indique que l'acrylonitrile possède en fait trois phases stables entre 77 °K et 191 °K: phase I entre 164 et 191 °K, phase II entre 113 °K et 164 °K, phase III en dessous de 113 °K.

Nous nous sommes donc proposés d'étudier par r.m.n. large bande et par relaxation nucléaire les mouvements moléculaires qui se produisent dans ces trois phases. Des mesures complémentaires de résonance paramagnétique électronique ont été effectuées pour étudier les mouvements de réorientation des radicaux libres formés par irradiation γ de ce monomère.

Conditions experimentales

L'acrylonitrile a été purifié par distillation en atmosphère d'azote, après séchage sur tamis moléculaire, puis dégazé et scellé sous vide. Nous avons utilisé également des échantillons d'acrylonitrile monodeutérié $CH_2{=}CD{-}CN$, le taux de deutériation en α du groupe CN étant d'environ 95%.

Les mesures de r.m.n. large bande ont été effectuées sur un spectromètre JEOL JNM W40 fonctionnant à 40 MHz. La température de l'échantillon était régulée à $\pm 1°$, au-dessus de 100 °K, par un jet d'azote gazeux refroidi. Quelques mesures à $T \leqslant 100$ °K ont été faites à 16 MHz à l'aide d'un spectromètre VARIAN V 4502 utilisable aussi bien en r.p.e. qu'en r.m.n. large bande grâce à l'adjonction d'une unité radiofréquence V 4210 A. Pour les expériences de r.p.e., les mesures du facteur g ont été effectuées par rapport à un échantillon de référence, en utilisant une cavité double V 4532 et en déterminant la valeur du champ magnétique à l'aide d'une sonde à résonance protonique Varian F8.

Le temps de relaxation T_1 des protons a été mesuré par écho de spin, à l'aide d'un spectromètre fonctionnant à 25 MHz, réalisé à l'Institut d'Electronique de la Faculté des Sciences d'Orsay. Nous avons utilisé la méthode des séquences 90°, τ, 90° pour $T_1 > 7$ s et la méthode de Carr et Purcell (5) pour $T_1 < 7$ s. Le système de variation thermique permettait de contrôler la température à ± 0.1 °K.

Resultats et interpretation

(1) Identification des phases

La variation de la largeur totale et du second moment de l'acrylonitrile normal en fonction de la température sont données sur la Fig. 1.

(*i*) Les portions (*a*) représentent les variations à température décroissante. Le prolongement du palier de la phase I vers les basses températures ($T < 164$ °K) indique que cette phase est "piégée" à basse température.

(*ii*) Les portions (*b*), celles à température croissante de 103 °K à 153 °K. Vers 153 °K on assiste à des variations irréversibles, le second moment varie brusquement de 5.5 G^2 à 7.5 G^2. Ceci indique le dépiégeage de la phase I métastable et l'apparition de la phase II, stable entre 115 et 164 °K.

(*iii*) Après ce recuit à 153 °K, les variations de la largeur de raie et du second moment en fonction de la température croissant de 103 °K à la température de fusion, sont représentées sur les portions (*c*).

La fig. 5 donne les variations de la largeur de raie et du second moment de l'A.N. monodeutérié, après recuit à 150–160 °K, en fonction de la température croissante.

La Fig. 6 représente la variation du temps de relaxation spin réseau T_1, pour un échantillon

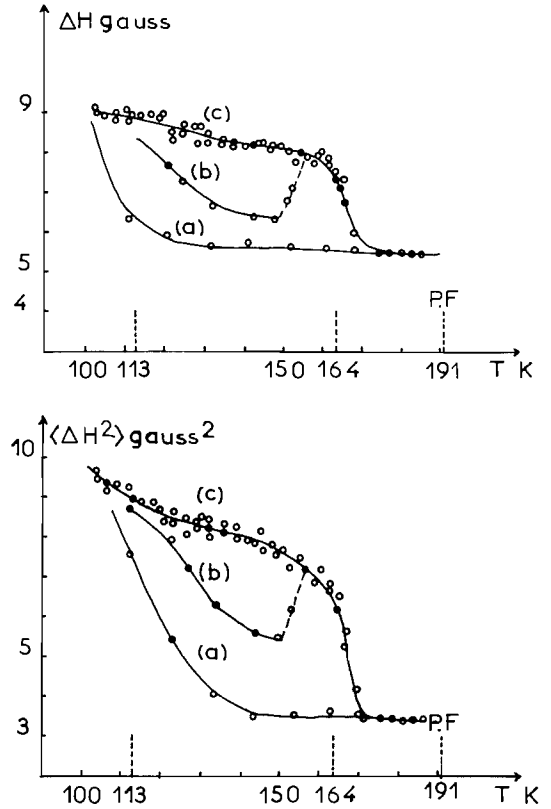

FIG. 1. Variation de la largeur (ΔH) et du second moment ($\langle \Delta H^2 \rangle$) du spectre de l'acrylonitrile normal en fonction de la température: (*a*) refroidissement progressif; (*b*) réchauffement jusqu'à 153 °K; (*c*) variation réversible avec la température jusqu'à 160 °K puis réchauffement jusqu'à 191 °K (P.F.).

après recuit à 153 °K en fonction de l'inverse de la température.

Les courbes $T_1 = f(T^{-1})$ présentent des variations nettes au voisinage de 113 °K et 164 °K confirmant ainsi l'existence des transitions de phases solide–solide à ces températures trouvées par d'autres techniques (3, 4): la phase III est située dans le domaine de températures inférieures à 113 °K; la phase II, obtenue après recuit à 153 °K est comprise entre 113 °K et 164 °K, et la phase I, comprise entre 164 °K et le point de fusion. La diminution du second moment vers 113 °K est moins brusque que celle vers 164 °K indiquant ainsi pour le premier cas une transition ordre–désordre libérant progressivement les mouvements moléculaires, et pour le deuxième cas une transition thermodynamique libérant brusquement les mouvements moléculaires (transition du 1er ordre).

(2) Etude par R.M.N. des mouvements moléculaires

(a) Acrylonitrile normal

Pour préciser les mouvements moléculaires se produisant dans chaque phase, nous devons connaître les données cristallographiques correspondantes. Or seules sont connues celles de la phase I (4). En supposant cette phase rigide la formule de Van Vleck (6) permet de calculer le second moment théorique:

$$[1]\quad \langle \Delta H^2 \rangle^{\text{rig}} = \frac{6}{5} I(I+1) g^2 \beta^2 N^{-1} \sum_{i<j} r_{ij}^{-6}$$
$$= 6.856\,\text{G}^2(\text{intra}) + 2.628(\text{inter})$$
$$= 9.48\,\text{G}^2$$

les distances interprotons étant calculées sur ordinateur IBM 360/91 d'après les données de Renaud (4) et de Reddy *et al.* (7). Pour la contribution intermoléculaire la sommation $\sum_{i<j} r_{ij}^{-6}$ s'effectue sur toutes les distances des protons situés à l'intérieur d'une sphère de 10 Å de rayon. A l'extérieur de cette sphère la sommation est remplacée par une intégrale dont la contribution est d'ailleurs négligeable (10^{-4} G^2).

En passant de la phase I à la phase III, on peut admettre que la géométrie de la molécule demeure invariante. Seule change alors la contribution intermoléculaire qui passe d'une valeur théorique de 2.63 G^2 à 3.2 G^2 si l'on admet une contraction volumique de l'ordre de 10%, ce qui nous donne un second moment total de 10 G^2. Le second moment experimental à 105 °K est de 9.5 G^2, donc très proche de la valeur théorique, ce qui indique que la phase III est rigide à cette température. A la transition III → II, $\langle \Delta H^2 \rangle$ n'est plus que de 9 G^2 et continue à décroître à mesure que l'on élève la température, sans atteindre de palier jusqu'à la transition II → I.

La décroissance du second moment dans les phases III et II peut être attribuée à des mouvements de libration d'amplitude de plus en plus grande. Etant donné la géométrie de la molécule, nous envisageons comme axe de libration, l'axe Δ passant par l'azote et par le milieu de la double liaison C=C (fig. 2). Ce choix est dicté par un "libre volume de rotation" maximum autour de cet axe ainsi que par un mouvement d'inertie plus faible ($I = 1.89 \times 10^{-39}$ g cm^2) que celui relatif aux axes N≡C ($I = 3.72 \times 10^{-39}$ g cm^2) et C=C ($I = 12 \times 10^{-39}$ g cm^2).

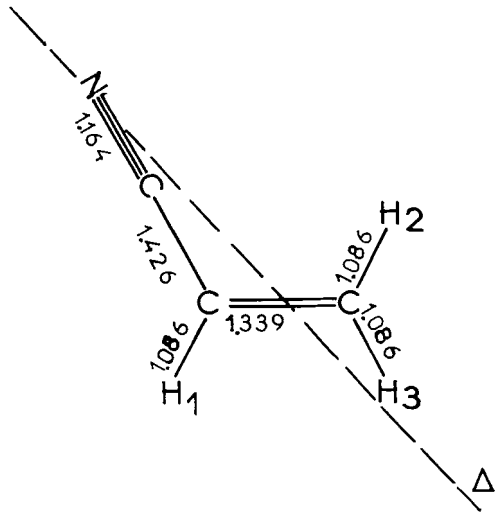

FIG. 2. Structure de la molécule d'acrylonitrile.

En outre l'axe Δ est pratiquement parallèle au vecteur moment dipolaire de la molécule (8) et à l'arête C de la maille cristalline de la phase I.

Le second moment intramoléculaire dans le cas d'une libration d'amplitude α est donné par la relation (9):

$$[2]\quad \langle \Delta H^2 \rangle^{\text{lib}} = \frac{3}{2} I(I+1) g^2 \beta^2 N^{-1} \sum_{i<j} B_{ij}$$

avec

$$B_{ij} = \frac{4}{5}\left[1 - \frac{3}{4}(1 - J_0^2(\alpha)) \sin^2 2\gamma_{ij} - \frac{3}{4}(1 - J_0^2(2\alpha)) \sin^4 \gamma_{ij}\right] r_{ij}^{-6}$$

γ_{ij} étant l'angle que fait la droite joignant les noyaux i, j avec l'axe de libration et α l'amplitude de libration. L'angle γ_{23} que fait l'axe Δ avec le vecteur interatomique $\overrightarrow{r_{23}}$, calculé à partir des données de Reddy (7) est de 41° 41′ (Fig. 2).

La fig. 3 donne la variation du second moment avec l'amplitude de libration α, calculée en admettant que le terme intermoléculaire se réduit dans la même proportion que le terme intramoléculaire donné par la relation 2. On constate ainsi que la décroissance de $\langle \Delta H^2 \rangle$ de 9 à 6 G^2 en phase II correspond à une variation d'amplitude de libration de 15° à 45° autour de l'axe Δ.

Pour préciser le mouvement de la phase I, nous avons envisagé des mouvements de réorientation d'ordre deux autour des liaisons N≡C, C=C et de l'axe Δ. La contribution intramolé-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

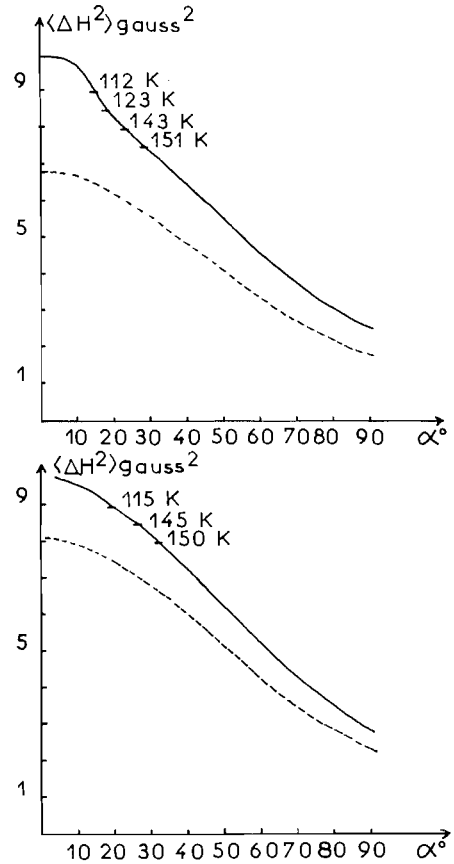

FIG. 3. Variation du second moment (---, intra, — total) en fonction de l'amplitude de libration de l'acrylonitrile normal (diagramme supérieur) et de l'acrylonitrile α deutérié (diagramme inférieur).

culaire au second moment se calcule alors d'après la formule de Eades (10):

$$[3]\quad \langle \Delta H^2 \rangle_{\text{intra}}^{\text{réor}} = \frac{6}{5} I(I+1) g^2 \beta^2 N^{-1} \times \sum_{i<j} (1 - 3\cos^2 \gamma_{ij} \sin^2 \gamma_{ij}) r_{ij}^{-6}$$

tandis que la contribution intermoléculaire se calcule en "projetant" les noyaux sur l'axe de réorientation. Nous obtenons ainsi pour les axes:

$$\text{N}\equiv\text{C},\ \langle \Delta H^2 \rangle_{\text{réor}} = 3.031\ \text{G}^2(\text{intra}) + 1.320\ \text{G}^2(\text{inter}) = 4.35\ \text{G}^2$$

$$\text{C}=\text{C},\ \langle \Delta H^2 \rangle_{\text{réor}} = 6.646\ \text{G}^2(\text{intra}) + 1.87\ \text{G}^2(\text{inter}) = 8.52\ \text{G}^2$$

$$\Delta,\ \langle \Delta H^2 \rangle_{\text{réor}} = 1.986\ \text{G}^2(\text{intra}) + 1.329\ \text{G}^2(\text{inter}) = 3.31\ \text{G}^2$$

La valeur 4.35 G^2 ne correspond à aucune valeur expérimentale; remarquons que la valeur 8.52 G^2 est égale à celle trouvée expérimentalement vers 125 °K (phase II), il serait alors tentant de caractériser la phase II par un mouvement de réorientation d'ordre deux autour de la liaison C=C, mais nous avons précédemment exclu cette éventualité à cause de l'encombrement stérique du réseau. D'autre part l'absence de palier du second moment dans la phase II rend difficile l'attribution d'un mouvement de réorientation (11) à cette phase.

Le second moment calculé pour la rotation de la molécule autour de l'axe Δ est par contre en excellent accord avec la valeur de 3.3 ± 0.1 G^2 obtenue pour la phase I. Renaud (4) pense qu'il y a diffusion des molécules en phase I, mais un tel mouvement, s'il existe n'affecterait qu'une très faible proportion des molécules puisqu'il ne parait pas influer sur le second moment.

(b) Acrylonitrile α deutérié

Dans tout le domaine de température étudié, le spectre r.m.n. de l'acrylonitrile ordinaire est un triplet (fig. 4). Une telle structure est difficilement interprétable à partir des données que l'on a sur l'interaction dipolaire entre les protons de cette molécule. On sait en effet que l'on peut observer un triplet dans le cas de trois protons équidistants (12) mais dans celui de l'acrylonitrile, la distance entre les protons géminaux H_2

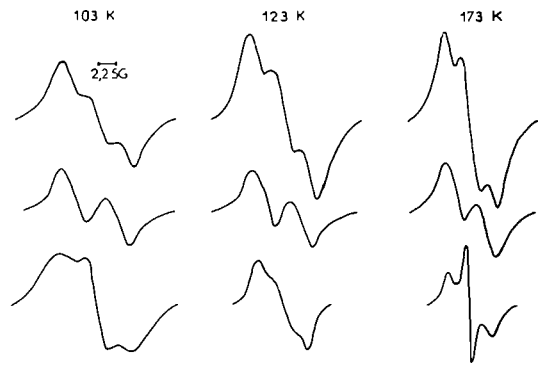

FIG. 4. Spectres r.m.n. de l'acrylonitrile: 1ère ligne, acrylonitrile normal, 2ème ligne, acrylonitrile deutérié, 3ème ligne, acrylonitrile normal irradié à 77 °K (dose 2 Mrads).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

et H_3 (1.88 Å) est nettement plus faible que $d(H_1H_2) = 3.069$ Å et $d(H_1H_3) = 2.425$ Å. On pourrait éventuellement attribuer l'existence de la bande centrale à une certaine proportion de molécules en réorientation rapide, mais cela n'est en général observé qu'au voisinage des points de transition ou dans le cas de phases métastables.

Ceci nous a amenés à effectuer les mêmes expériences sur le produit monodeutérié CH_2CD—CN. Les spectres présentent une structure de doublet comme l'on s'y attend (voir fig. 4). Cette structure persiste pratiquement jusqu'au point de fusion. La variation de la largeur ΔH du doublet et du second moment en fonction de la température est représentée sur la fig. 5. Nous allons d'abord étudier la variation de ΔH en fonction des mouvements moléculaires envisagés pour l'A.N. normal.

Pour un réseau rigide, la largeur du doublet relatif aux protons géminaux H_2 H_3 sera (13):

$$[4] \qquad \Delta H_{rig} = \frac{3}{2} g\beta r^{-3} = 6.3\ \text{G}$$

La largeur expérimentale à 103 °K est de 4.5 G, la différence de 1.8 G avec la valeur théorique pour un réseau rigide correspond sans doute en grande partie à l'élargissement dipolaire des raies qui tend à rapprocher les sommets du doublet.

La diminution de la largeur du doublet devient sensible à partir de 115 °K. Dans le cas d'une paire de noyaux qui se réorientent rapidement entre deux directions extrêmes faisant entre elles un angle 2β, cette réduction est donnée par la relation (14):

$$[5] \qquad \rho = |1 - 3\sin^2\beta|$$

l'angle β étant lié aux angles α et γ définis plus haut par la relation

$$[6] \qquad \sin\beta = \sin\alpha \sin\gamma$$

prenons par exemple, $\alpha = 30°$, γ étant égal à 41°, 41′ on a $\beta = 19°$, 30′, $\rho = 0.67$ et donc $\Delta H = 4.2$ G. L'examen des figs. 1, 3, et 5 indique que cette valeur de α correspond à $T \sim 150$ °K. La valeur expérimentale de ΔH est de 3.8 G pour CH_2=CD—CN à cette température (fig. 5), donc en assez bon accord avec la valeur calculée plus haut si l'on considère l'élargissement des raies.

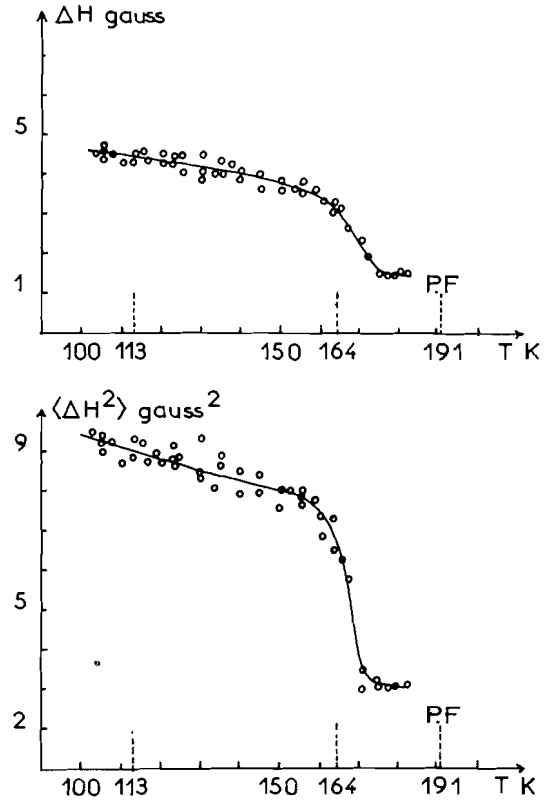

FIG. 5. Variation de ΔH et de $\langle \Delta H^2 \rangle$ en fonction de la température, pour l'acrylonitrile α deutérié.

La largeur du doublet diminue rapidement au voisinage de la transition II → I, à 164 °K, pour atteindre une valeur de 1.5 G en phase I. Dans l'hypothèse d'une réorientation de l'acrylonitrile autour de l'axe binaire Δ, en phase I, la largeur du doublet peut être encore calculée par la relation (5) dans laquelle β devient égal à γ puisque $\alpha = 90°$, et l'on obtient $\Delta H_{réor} = 2.07$ G comparable à la valeur expérimentale de 1.5 G.

Comme pour l'A.N. normal, nous avons calculé sur l'IBM 360/91 les seconds moments suivant la formule de Van Vleck (6) pour un échantillon polycristallin:

$$[7] \quad \langle \Delta H^2 \rangle = \frac{6}{5} I(I+1) g^2\beta^2 N^{-1} \sum_{i<j} r_{ij}^{-6} + \frac{8}{15} S(S+1) g_D{}^2\beta^2 N^{-1} \sum_{i<k}{}' r_{ik}^{-6}$$

La sommation $\sum_{i<j}$ s'effectue sur les protons i et j, $\sum'_{i<k}$ sur les protons i et les deuterons k dont $S = 1$ et $g_D = 0.8573$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Pour la phase I supposée rigide

$$\langle \Delta H^2 \rangle_{rig} = 8.114\ G^2(\text{intra}) + 1.401\ G^2(\text{inter}) = 9.52\ G^2$$

Il est à remarquer que dans le second moment intramoléculaire, la contribution des protons géminaux est de loin la plus importante (8.08 G^2).

En admettant, comme précédemment, une contraction volumique de 10% lorsqu'on passe de la phase I à la phase III, nous trouvons un second moment intermoléculaire de 1.7 G^2 et donc un second moment global de 9.8 G^2, en bon accord avec la valeur de 9.4 G^2 obtenue à 103 °K.

Pour un mouvement de réorientation du vecteur r_{23} entre deux positions extrêmes faisant un angle 2β, le second moment devient (14):

$$[8] \quad \langle \Delta H^2 \rangle = \left| 1 - \frac{3}{4} \sin^2 2\beta \right| \langle \Delta H^2 \rangle_{rig}$$

ce qui nous donne pour l'angle $\beta = 19°30'$ envisagé précédemment pour $T = 150$ °K, $\langle \Delta H^2 \rangle = 7.96\ G^2$.

La fig. 3 donne la variation de $\langle \Delta H^2 \rangle_{lib.}$ en fonction de l'amplitude de libration α, calculée à partir de la relation (2) avec un terme supplémentaire relatif au deutéron, en supposant comme précédemment que les contributions intra et intermoléculaires varient dans la même proportion. Pour $\alpha = 30°$ on obtient ainsi $\langle \Delta H^2 \rangle_{lib.} = 6.79\ G^2$ (intra) + 1.42 G^2 (inter) = 8.21 G^2. Les relations 8 et 3 donnent donc des résultats très voisins, proches de la valeur expérimentale de $8 \pm 0.2\ G^2$, obtenue vers 150 °K.

Quand la molécule de $CH_2{=}CD{-}CN$ se réoriente autour de l'axe binaire Δ, en phase I, la relation de Eades (10) s'écrit:

$$[9] \quad \langle \Delta H^2 \rangle_{intra}^{réor} = \frac{6}{5} I(I+1) g_H{}^2 \beta^2 \times \frac{1}{2}(1 - 3\cos^2 \gamma_{23} \sin^2 \gamma_{23}) r_{23}{}^{-6} + \frac{8}{15} S(S+1) g_D{}^2 \beta^2 \times \frac{1}{3} \sum_{i=2,3} (1 - 3\cos^2 \gamma_{1i} \sin^2 \gamma_{1i}) r_{1i}{}^{-6}$$

La contribution intermoléculaire étant calculée en projetant les vecteurs intermoléculaires sur l'axe Δ, le second moment global devient:

$$\langle \Delta H^2 \rangle_{réor} = 2.11\ G^2(\text{inter}) + 0.887\ G^2(\text{inter}) = 3.0\ G^2$$

en excellent accord avec le résultat expérimental (fig. 5).

Les résultats relatifs à l'acrylonitrile deutérié recoupent donc bien ceux obtenus pour l'acrylonitrile normal et confirment l'hypothèse d'une libration (phase II) puis d'une rotation (phase I) de cette molécule autour de l'axe Δ.

(3) Temps de relaxation spin réseau

La variation du temps de relaxation spin–réseau T_1 en fonction de l'inverse de la température ($T^{-1} \times 10^3$) indique que dans les phases I et II (fig. 6), les mouvements moléculaires contribuent efficacement à la relaxation spin–réseau.

Pour un mouvement moléculaire pas trop lent, comme c'est le cas ici, et caractérisé par un temps de corrélation unique à une température donnée, la théorie de Bloembergen, Purcell, et Pound (15) revue par Kubo et Tomita (16) donne:

$$[10a] \quad T_1{}^{-1} = C\left\{\frac{\tau_c}{1 + \omega_0{}^2\tau_c{}^2} + \frac{4\tau_c}{1 + 4\omega_0{}^2\tau_c{}^2}\right\}$$

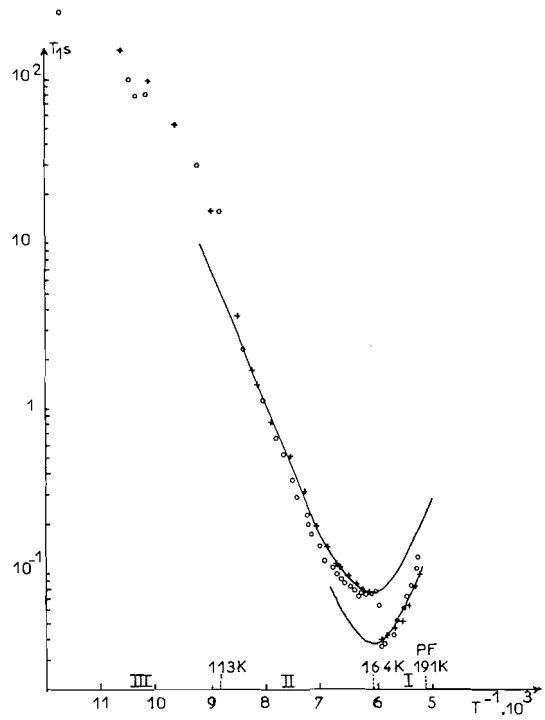

FIG. 6. Temps de relaxation spin réseau en fonction de la température: (+ + +) acrylonitrile normal, (○○○) acrylonitrile α deutérié. Le tracé continu correspond aux valeurs théoriques de T_1 calculées d'après les formules 10*a* et 11 (voir texte).

Si d'autre part τ_c suit la loi d'Arrhenius

[11] $$\tau_c = \tau_0 e^{E/kT}$$

les parties linéaires de la courbe $T_1 = f(T^{-1})$ permettent de calculer les énergies d'activation des mouvements moléculaires.

Pour l'A.N. normal, ces énergies sont de 4.2 et 3.7 kcal mol^{-1} respectivement pour les phases I et II.

La phase II possède un temps de relaxation minimum $T^{II}{}_{1\ min} = 78$ ms vers 163 K, le temps de corrélation correspondant est $\tau_c = 0.6158/\omega_o = 3.9 \times 10^{-9}$ s, le coefficient C de la formule 10*a* étant égal à $(\omega_0/1.425\ T^{II}{}_{1\ min}) = 1.4 \times 10^9\ s^{-2}$.

La variation brusque de T_1 vers 164 °K (fig. 6) s'explique bien par la transition de phase II → I qui libère le mouvement de réorientation de la molécule autour de l'axe binaire Δ comme nous avons vu dans la section 2.

Dans la phase I le temps de relaxation possède un minimum $T^{I}{}_{1\ min} = 38$ ms vers 164 °K.

Pour un mouvement de réorientation autour d'un axe binaire, le temps de relaxation spin réseau peut être décrit par la formule approchée (voir l'appendice pour les détails de calcul):

[10*b*] $$T_1^{-1} = \frac{3}{5}\gamma^4\hbar^2 I(I+1)N^{-1} \times \sum_{i<j}^{N} r_{ij}^{-6} \sin^2 2\gamma_{ij} \times \left\{\frac{\tau_c}{1+\omega_0^2\tau_c^2} + \frac{4\tau_c}{1+4\omega_0^2\tau_c^2}\right\}$$

Dans ce calcul de T_1 nous avons négligé la corrélation entre les mouvements des vecteurs internucléaires r_{12}, r_{13}, et r_{23}, c'est-à-dire supposé que la relaxation longitudinale est régie par une seule exponentielle.

Nous avons effectivement observé pour $T_1 > 7$ s que l'aimantation nucléaire décroit exponentiellement, par contre la méthode du "τ null" de Carr et Purcell (5), utilisée pour $T_1 < 7$ s ne permet pas de savoir si la décroissance est exponentielle ou non. Cependant, nous pensons que notre approximation n'est pas trop mauvaise, car la contribution essentielle à la relaxation provient du mouvement de r_{23}, $r_{23}{}^{-6}$ étant beaucoup plus grand que $r_{12}{}^{-6}$ et $r_{13}{}^{-6}$.

En ne considérant que la contribution intramoléculaire, nous trouvons d'après la relation 10*b* un T_1 théorique de:

$$T^{I}{}_{1\ min} = \frac{\omega_o}{1.425C} = 47\ \text{ms}$$

Cette valeur est supérieure à la valeur expérimentale 38 ms, ceci est dû sans doute à ce que nous avons négligé la relaxation croisée et la contribution intermoléculaire. Pour tenir compte de cette dernière contribution nous employons la relation (15):

[12] $$T_{1\ min} = \frac{\omega_0}{1.425C} = \frac{\omega_0}{1.425\gamma^2\langle\Delta H^2\rangle_{mod}}$$

où $\langle\Delta H^2\rangle_{mod}$ est le second moment modulé par le mouvement:

$$\langle\Delta H^2\rangle_{mod} = \langle\Delta H^2\rangle_{rig} - \langle\Delta H^2\rangle_{réor} = 10\ G^2 - 3.3\ G^2 = 6.7\ G^2$$

la formule 12 donne alors $T^{I}{}_{1\ min} = 35$ ms en bon accord avec la valeur expérimentale. Les courbes continues des fig. 6 et 7 sont calculeés à partir des relations 10*a* et 11, avec les valeurs

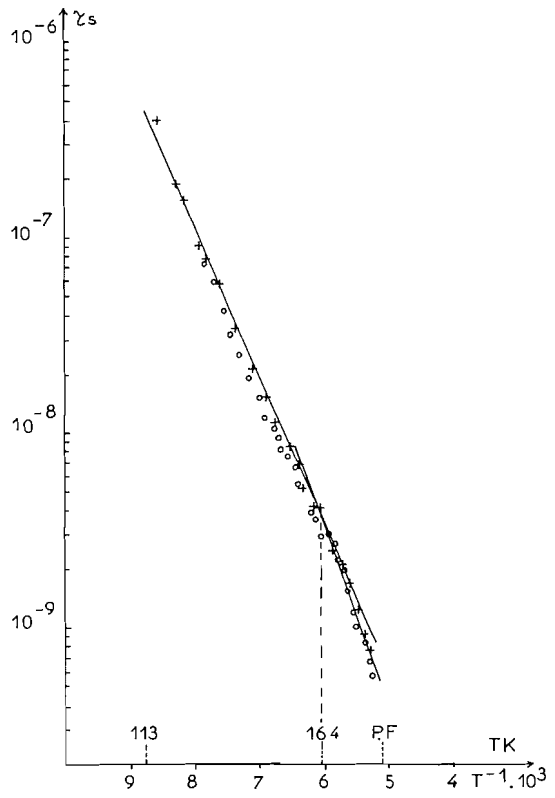

FIG. 7. Temps de corrélation de réorientation de l'acrylonitrile normal (+++) et de l'acrylonitrile deutérié (○○○).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

experimentales de C et E relatives à l'A.N. normal.

L'allure générale des courbes $T_1 = f(T^{-1})$ et $\tau_c = f(T^{-1})$ (figs. 6 et 7), relative à l'A.N. α-deutérie est analogue à celle relative à l'A.N. normal. Ceci est prévisible quand on se rappelle que $\gamma_H/\gamma_D = 6.5$ et que les quantités $r_{DH_2}{}^{-6}$ et $r_{DH_3}{}^{-6}$ sont négligeables devant $r_{H_2H_3}{}^{-6}$.

Pour l'A.N. α-deutérié les énergies d'activation sont légèrement plus grandes que celles pour l'A.N. normal, respectivement de 4 kcal mol^{-1} et de 5 kcal mol^{-1} dans les phases II et I; et les T_1 minima sont légèrement plus petits (respectivement 72 ms et 35 ms dans les phases II et I).

Dans la phase I le $T_{1\,min}$ calculé d'après (10*b*) sera de

$$T^{I}{}_{1\,min} = \frac{\omega_0}{1.425C} = 39 \text{ ms}$$

tandis que la formule 12 avec:

$$\langle \Delta H^2 \rangle_{mod} = 9.8\ G^2 - 3.0\ G^2 = 6.8\ G^2$$

nous donne $T^{I}{}_{1\,min} = 34$ ms en bon accord avec la valeur expérimentale.

Remarquons cependant que l'hypothèse d'un τ_c unique à chaque température n'est pas tout à fait réaliste. L'étude par l'absorption diélectrique (17) en phase I montre en effet l'existence d'une distribution des temps de corrélation. Malheureusement l'absence des mesures du temps de relaxation spin réseau suivant le champs tournant $T_{1\rho}$ et des mesures de T_1 avec différentes fréquence ν_0 ne nous permet pas d'aller plus loin dans notre analyse.

(4) R.M.N. de l'acrylonitrile irradié

Les mesures à basses températures sont rendues difficiles par la longueur du temps de relaxation T_1 qui devient non négligeable par rapport à la durée normale d'enregistrement d'un spectre. Le procédé le plus efficace pour réduire T_1 consiste à irradier le composé étudié pour y former des radicaux libres (18). Nous avons tenté d'appliquer cette méthode à l'acrylonitrile en supposant que la polymérisation ne progresse rapidement qu'au voisinage du point de fusion, en phase I. Pour un échantillon refroidi rapidement à 77 °K et irradié à des doses de 1 à 2 Mrads, nous avons constaté que la phase I piégée ne donne pas la phase II par recuit à 150 °K, ce qui suggère que le polymère déjà présent dans la matrice inhibe la transition phase métastable → phase stable.

Si l'on recuit préalablement à l'irradiation le monomère de façon à obtenir la phase II puis au refroidissement la phase III, on constate que le second moment relatif à la phase II varie de 7 G^2 à 3 G^2 entre 113 et 164 °K (fig. 8) alors qu'il est compris entre 9 G^2 et 6.5 G^2 pour le monomère non irradié. Cela confirme l'existence d'un polymérisation à ces basses températures, qui contribue à désorganiser le réseau.

En outre, on observe à la transition II → I (fig. 4) la croissance quasi instantanée d'une raie étroite ($\Delta H = 0.3$ G), superposée au spectre normal, et caractéristique de certaines polymérisations en phase solide (19) attribuable à la réorientation rapide des molécules dans les défauts du réseau créés par les chaînes croissantes de polymère (19). L'amplitude de cette raie atteint une valeur limite en quelques minutes. Ce

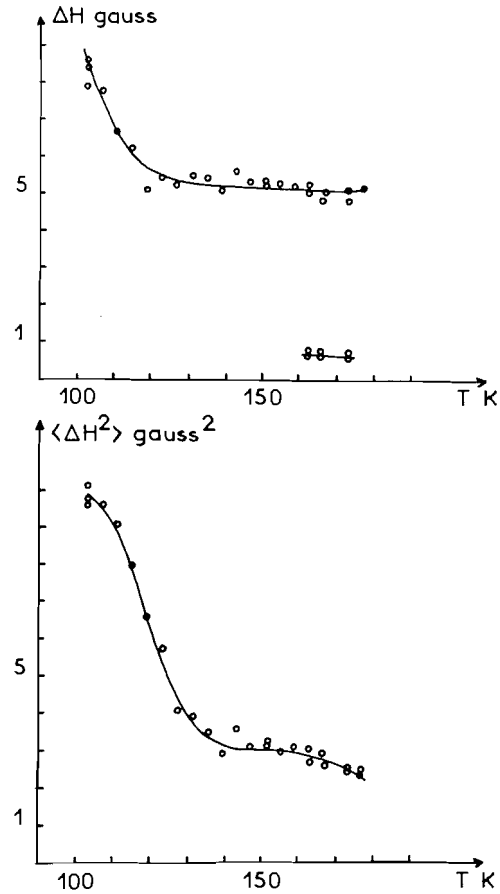

FIG. 8. Variation de ΔH et de $\langle \Delta H^2 \rangle$ avec la température pour l'anylonitrile normal irradié à 77 °K (dose 2 Mrads) après recuit à 153 °K.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

fait est à rapprocher des résultats de mesures calorimétriques de Tal'Roze et coll. (20) qui ont mis en évidence une durée de croissance des chaînes de l'ordre de 30 s à la transition II → I (qu'ils situent à 157 °K et non à 164 °K).

(5) Résonance paramagnétique électronique

La résonance paramagnétique électronique des radicaux provenant de l'irradiation γ de l'acrylonitrile a fait l'objet de plusieurs travaux (21–24). Selon Bensasson et coll. (21, 22) le radical $CH_3\dot{C}H$—CN est initialement formé à 77 °K. Il disparaît au réchauffement par addition sur le monomère et formation du radical macromoléculaire ~~CH_2—$\dot{C}H$—CN (21, 22). Bol'shakov et coll. (24) ont proposé une interprétation différente du spectre de R.P.E. qu'ils attribuent à la présence des radicaux CH_3—$\dot{C}H$—CN et CH_2=$\dot{C}$—CN, ne participant pas à la polymérisation, qui serait donc exclusivement ionique. La réduction du second moment des spectres de ces radicaux leur a permis de mesurer une énergie d'activation de réorientation qu'ils supposent égale à celle des molécules de la matrice. Cette méthode nous paraît contestable car la contribution relative des différents radicaux au second moment peut varier avec la température du fait de leur vitesse différente de recombinaison. En outre le terme prédominant du second moment provient du couplage isotrope des protons, invariant avec la réorientation globale d'un radical.

Pour éviter ces difficultés, nous avons irradié l'acrylonitrile en présence d'oxygène et réchauffé les échantillons jusqu'à peroxydation complète des radicaux.

L'échantillon était alors trempé à 77 °K et subissait par la suite un traitement analogue à celui effectué par les expériences de r.m.n.

La structure des spectres r.p.e. des radicaux peroxyles ne dépend que de l'anisotropie du tenseur g, approximativement axial selon la liaison O—O·. En matrice rigide à 77 °K, la position des singularités correspondant aux valeurs principales de g (fig. 9) nous donne $g_{\parallel} = 2.0360$, $g_{\perp} = 2.00285$ et $g_{iso} = 2.0139$. La réduction progressive de l'anisotropie de g avec la température permet de mesurer le temps de corrélation de réorientation d'un radical (25). Cette méthode a été précédemment appliquée au cas de radicaux peroxyles (26, 27). et nous allons brièvement en rappeler le principe.

Pour un mouvement de réorientation isotrope,

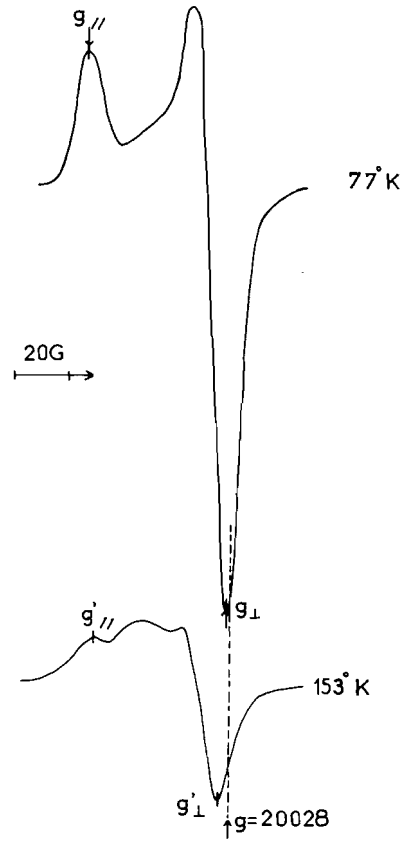

FIG. 9. Spectres r.p.e. des radicaux peroxyles piégés dans l'acrylonitrile.

les singularités $g_{\parallel}$ et $g_{\perp}$ convergent progressivement vers la position correspondant à $g_i = 1/3\,(g_{\parallel} + 2\,g_{\perp})$ le déplacement de la singularité $g_{\parallel}$ étant le plus facilement mesurable. En présence d'un mouvement de réorientation, de temps de corrélation τ_c, la position de cette singularité est donnée par la relation (25, 26):

$$[13]\quad g_{\parallel}'^2 = S + (g_{\parallel}^2 - S)\frac{2}{\pi}\arctan\frac{\tau_c}{T_2}$$

avec

$$S = \frac{1}{3}(g_{\parallel}^2 + 2g_{\perp}^2)_{rig}$$

T_2 étant le temps de relaxation dipolaire électronique que l'on peut déduire de la largeur homogène des raies, déterminée à partir de leur largeur réelle par des expériences de saturation progressive. Cette méthode n'étant pas applicable puisque les signaux ne se saturent pas pour le champ radiofréquence maximum dont nous disposons ($H_1 \sim 1$ G), nous avons évalué T_2 à

5×10^{-8} s d'après des études analogues effectuées sur d'autres monomères vinyliques (28).

On peut également déterminer τ_c à partir de la relation (13), en mesurant le second moment des spectres dont la valeur théorique est (29):

$$[14] \quad \langle \Delta H^2 \rangle = \frac{{H_0}^2}{5}\left(\varepsilon_{\parallel}'^2 + \frac{8}{3}\varepsilon_{\perp}'^2 + \frac{4}{3}\varepsilon_{\parallel}'\varepsilon_{\perp}'\right) + \frac{\lambda^2}{4}$$

avec

$$\varepsilon_{\parallel}' = \frac{g_{\parallel}'}{g_0} - 1 \qquad \varepsilon_{\perp}' = \frac{g_{\perp}'}{g_0} - 1 = \frac{1}{2}(3\varepsilon_i - \varepsilon_{\parallel})$$

H_0 étant le champ de résonance de l'échantillon de référence, correspondant dans le cas présent à $g_0 = 2.0028$. λ est la largeur gaussienne des raies égale en moyenne à 6 G dans le domaine de température étudié. A 77 °K en matrice rigide, la valeur théorique de $\langle \Delta H^2 \rangle$ pour $H_0 = 3280$ G est de 599 G^2. Entre 77 et 180 °K, le second moment expérimental décroît d'une manière continue de 610 G^2 à 500 G^2.

La variation de τ_c avec la température permet de mesurer l'énergie d'activation de réorientation. La comparaison des résultats obtenus par mesure du déplacement du pic $g_{\parallel}'$ et par mesure du second moment, permet d'évaluer la largeur de la distribution des énergies d'activation (27). Dans le cas présent les résultats obtenus par les deux méthodes coïncident ce qui indique une distribution étroite des temps de corrélation. On a obtenu ainsi $E = 0.65 \pm 0.05$ kcal mol^{-1} avec un terme préexponentiel $\tau_0 = (2.3 \pm 0.4)\ 10^{-2}$ $T_2 \sim 10^{-9}$ s (fig. 10).

L'énergie d'activation est donc très inférieure à celle trouvée par écho de spin pour la réorientation des molécules de la matrice en phase II ($E = 3.7$ kcal mol^{-1}) et correspond plus vraisemblablement à la rotation du groupement peroxyle qu'à la réorientation globale du radical. Ce résultat, joint au fait que la variation de l'anisotropie de g et celle de $\langle \Delta H^2 \rangle$, ne présentent aucune discontinuité au voisinage des transitions de phase suggère que les radicaux dont on a observé la peroxydation sont en fait des macroradicaux conformément à l'interprétation de Bensasson et coll. (21, 22) et non des radicaux monomères tels que CH_3 $\dot{C}H$—CN ou $CH_2{=}\dot{C}$—CN comme le proposent Bolshakov et coll. (24), ce qui n'exclut pas d'ailleurs la prédominance d'un mécanisme ionique de polymérisation (24).

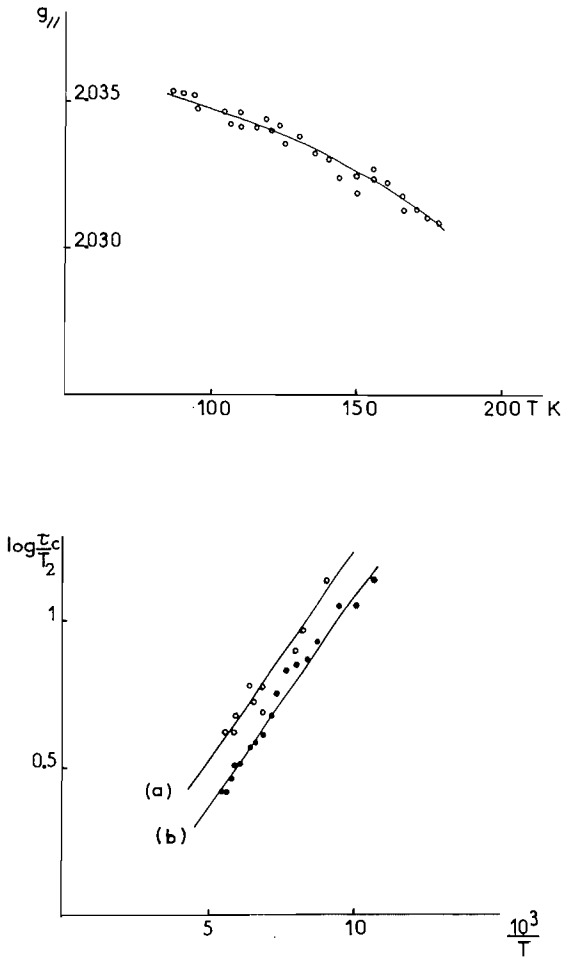

FIG. 10. Diagramme supérieur: variation de $g_{\parallel}'$ avec la température; Diagramme inférieur: temps de corrélation de réorientation des radicaux peroxyles en fonction de $1/T$: (*a*) calculés à partir de $\langle \Delta H^2 \rangle$ (relations 13 et 14); (*b*) calculés à partir de $g_{\parallel}'$ déterminé directement sur les spectres.

Les auteurs remercient vivement M. Guibé, Maître de Recherche à l'Institut d'Electronique de la Faculté des Sciences d'Orsay, qui a eu l'obligeance de mettre à leur disposition un spectromètre à écho de spin, ainsi que M. Truong, Ingénieur au C.N.R.S., pour son aimable coopération expérimentale. Ils remercient également M. Herbert, Ingénieur au C.E.A., qui a bien voulu synthétiser l'acrylonitrile deutérié, ainsi que l'un des rapporteurs de cet article, pour ses remarques et suggestions, qui nous ont été très utiles.

Appendice

Nous partons de la relation, pour une paire de noyaux (11):

$$[1]\quad T_1^{-1} = \frac{3}{2}\gamma^4\hbar^2 I(I+1)\{J^{(1)}(\omega_0) + J^{(2)}(2\omega_0)\}r^{-6}$$

Les fonctions densité spectrale $J^{(k)}$ étant des transformées de Fourier des fonctions d'auto corrélation

$$[2]\quad J^{(k)}(\omega_k) = \int_{-\infty}^{\infty} \langle F^{(k)}(t)F^{(k)}(t+\tau)\rangle\, e^{-i\omega_0\tau}\, d\tau$$

avec les fonctions aléatoires (30)

$$[3]\quad F^{(1)}(t) = (1 + im)n \qquad F^{(2)}(t) = (1 + im)^2$$

l,m,n étant des cosinus directeurs du vecteur internucléaire $\boldsymbol{r}$ par rapport à un système d'axes fixes $S(\boldsymbol{X},\boldsymbol{Y},\boldsymbol{Z})$ avec $\boldsymbol{Z}||\boldsymbol{H}_0$. Nous repérons $\boldsymbol{r}$ dans un système $S'(\boldsymbol{X}',\boldsymbol{Y}',\boldsymbol{Z}')$ lié à la molécule par $\boldsymbol{r} = r(\sin\gamma\boldsymbol{X}' + \cos\gamma\boldsymbol{Z}')$, avec $\boldsymbol{Z}'$ pris parallèle à l'axe de réorientation Δ. Le système S'est relié au système S par des angles d'Eluler θ,φ,ψ et le passage de S' à S se fait par la matrice

$$[4]\quad M = \begin{vmatrix} \cos\varphi\cos\psi - \sin\varphi\sin\psi\cos\theta & -\cos\varphi\sin\psi - \sin\varphi\cos\psi\cos\theta & \sin\varphi\sin\theta \\ \sin\varphi\cos\psi + \cos\varphi\sin\psi\cos\theta & -\sin\varphi\sin\psi + \cos\varphi\cos\psi\cos\theta & -\cos\varphi\sin\theta \\ \sin\psi\sin\theta & \cos\psi\sin\theta & \cos\theta \end{vmatrix}$$

Compte tenu de (4), (3) s'écrit:

$$[5]\quad \begin{aligned} F^{(1)}(t) &= \{\sin^2\gamma\sin\theta\sin 2\psi + \sin 2\gamma\cos\theta\cos\psi \\ &\quad + i[\sin^2\gamma\sin 2\theta\sin^2\psi - \cos^2\gamma\sin 2\theta + \sin 2\gamma\cos 2\theta\sin\psi]\}e^{i\varphi}/2 \\ F^{(2)}(t) &= \{\sin^2\gamma\cos^2\psi - \sin^2\gamma\sin^2\psi\cos^2\theta - \cos^2\gamma\sin^2\theta + \tfrac{1}{2}\sin 2\gamma\sin 2\theta\sin\psi \\ &\quad + i[\sin^2\gamma\cos\theta\sin 2\psi - \sin 2\gamma\sin\theta\cos\psi]\}e^{i2\varphi} \end{aligned}$$

Soit $p(\psi,t)$ la probabilité de trouver $\boldsymbol{r}$ dans l'orientation ψ à l'instant t et $p(\psi',t)$ la probabilité de trouver $\boldsymbol{r}$ dans l'orientation ψ' à l'instant t. Supposons qu'il y a équiprobabilité pour que $\boldsymbol{r}$ passe de ψ' à ψ et de ψ à ψ'

$$W_{\psi\to\psi'} = W_{\psi'\to\psi} = W$$

nous aurons les équations d'évolution suivantes

$$[6]\quad \frac{dp(\psi,t)}{dt} = -Wp(\psi,t) + Wp(\psi',t) \qquad \frac{dp(\psi',t)}{dt} = Wp(\psi,t) - Wp(\psi',t)$$

A un instant quelconque t il est évident que

$$p(\psi,t) + p(\psi',t) = 1$$

par suite (6) a comme solution

$$[7]\quad p(\psi,t) = \frac{1}{2}(1 + Ce^{-t/\tau_c}) \qquad p(\psi',t) = \frac{1}{2}(1 - Ce^{-t/\tau_c})$$

$\tau_c = (2W)^{-1}$ étant défini comme temps de corrélation.

Nous définissons les probabilités conditionnelles suivantes: $P(f,i,\tau)$: probabilité de trouver $\boldsymbol{r}$ dans une orientation f à l'instant $t+\tau$, sachant qu'à l'instant t $\boldsymbol{r}$ se trouve dans l'orientation i. Comme il y a quatre combinaisons possibles pour le couple (f,i)

$$P(\psi,\psi,\tau) = p(\psi,\tau) \text{ avec } p(\psi,0) = 1 \text{ en prenant } t = 0$$

$$[8]\quad \begin{aligned} P(\psi',\psi',\tau) &= p(\psi',\tau) \text{ avec } p(\psi',0) = 1 \\ P(\psi',\psi,\tau) &= p(\psi',\tau) \text{ avec } p(\psi',0) = 0 \\ P(\psi,\psi',\tau) &= p(\psi,\tau) \text{ avec } p(\psi,0) = 0 \end{aligned}$$

compte tenu de (7), (8) devient alors

$$P(\psi,\psi,\tau) = P(\psi',\psi',\tau) = \frac{1}{2}(1 + e^{-\tau/\tau_c})$$

$$P(\psi',\psi,\tau) = P(\psi,\psi',\tau) = \frac{1}{2}(1 - e^{-\tau/\tau_c})$$

Dans le calcul des fonctions d'auto corrélation nous devons tenir compte de ces quatre possibilités

$$\langle F^{(k)}(0)F^{(k)}(\tau)\rangle = \sum_{(f,i)=\psi,\psi'} F^{(k)}(0)p(i,0)F^{(k)}(f,i,\tau)P(f,i,\tau)$$

et les fonctions de densité spectrale deviennent

$$J^{(1)}(\omega_0) = A\frac{\tau_c}{1 + \omega_0{}^2\tau_0{}^2}$$

$$J^{(2)}(2\omega_0) = B\frac{\tau_c}{1 + 4\omega_0{}^2\tau_c{}^2}$$

avec

$$A = \frac{1}{16}\{\sin^2\gamma\sin\theta(\sin 2\psi' - \sin 2\psi) + \sin 2\gamma\cos\theta(\cos\psi' - \cos\psi)^2 + \sin^2\gamma\sin 2\theta(\sin^2\psi' - \sin^2\psi) + \sin 2\gamma\cos 2\theta(\sin\psi' - \sin\psi)^2\}$$

$$B = \frac{1}{4}\sin^2\gamma(\cos^2\psi' - \cos^2\psi) - \sin^2\gamma\cos^2\theta(\sin^2\psi' - \sin^2\psi) + \frac{1}{2}\sin 2\gamma\sin 2\theta(\sin\psi' - \sin\psi)^2 + \sin^2\gamma\cos\theta(\sin 2\psi' - \sin 2\psi) - \sin 2\gamma\sin\theta(\cos\psi - \cos\psi')^2\}$$

Pour un échantillon polycristallin nous devons moyenner A et B dans tout l'espace, et en posant $\psi' - \psi = \alpha$ nous obtenons

$$T_1{}^{-1} = \frac{3}{20}\gamma^4\hbar^2 I(I+1)[\sin^4\gamma(1 - \cos 2\alpha) + \sin^2 2\gamma(1 - \cos\alpha)] \times \left\{\frac{\tau_c}{1 + \omega_0{}^2\tau_c{}^2} + \frac{4\tau_c}{1 + 4\omega_0{}^2\tau_c{}^2}\right\} r^{-6}$$

rappelons que γ étant l'angle que fait $\boldsymbol{r}$ avec l'axe de réorientation Δ.

Dans le cas où Δ est un axe binaire

$$T_1{}^{-1} = \frac{3}{10}\gamma^4\hbar^2 I(I+1)\sin^2 2\gamma \times \left\{\frac{\tau_c}{1 + \omega_0{}^2\tau_c{}^2} + \frac{4\tau_c}{1 + 4\omega_0{}^2\tau_c{}^2}\right\} r^{-6}$$

En supposant qu'il n'y a pas de relation de phase entre les mouvements des divers $\boldsymbol{r}_{ij}$, nous pouvons écrire

$$T_1{}^{-1} = \frac{3}{5}\gamma^4\hbar^2 I(I+1)N^{-1}\sum_{i<j}\sin^2 2\gamma_{ij} r_{ij}{}^{-6} \times \left\{\frac{\tau_c}{1 + \omega_0{}^2\tau_c{}^2} + \frac{4\tau_c}{1 + 4\omega_0{}^2\tau_c{}^2}\right\}$$

Chain Length Determination of Fatty Acids by Raman Spectroscopy

CHARLES H. WARREN AND DONALD L. HOOPER
Department of Chemistry, Dalhousie University, Halifax, Nova Scotia

Received June 15, 1973

For saturated long chain fatty acids, as for hydrocarbons, the odd order "accordion mode" vibrations are Raman active. These "accordion mode" vibrations have been used to provide qualitative and quantitative analysis of mixtures of acids in the range C_{12}–C_{24}.

Pour les acides gras à longue chaîne de même que pour les hydrocarbures, les vibrations d'ordre impaire du "type accordéon" sont actives en Raman. Ces vibrations ont été utilisées pour analyser qualitativement et quantitativement des mélanges d'acides de C_{12} à C_{24}.

[Traduit par le journal]

Can. J. Chem., **51**, 3901 (1973)

The room temperature infrared spectrum of a long chain fatty acid in the solid phase exhibits in the region 1180–1350 cm^{-1} a characteristic "progression" of bands spaced about 20 cm^{-1} apart. The number of bands in such a progression, assigned to the —CH_2— wagging motion, has been correlated with the number of $-CH_2-$ units in the hydrocarbon chain of the fatty acid. This correlation has been used (1) as the basis of an infrared method of chain length determination, although this region of the spectrum is partially obscured by the 1307 cm^{-1} peak attributed to the C—O—H linkage of free acids. This peak is, of course, not present in the spectrum of the alkali metal salt of a fatty acid, and in general more reliable results are obtained (2) by conversion of the fatty acid to the soap. Even if this is done, it is difficult to identify the components of a mixture of acids having different chain lengths, as there are many absorption peaks for each chain length, some of which may overlap the peaks of other chain lengths. Quantitative analysis of chain length distribution of such a mixture is almost impossible.

Schaufele *et al.* (3) have reported that the Raman scattering spectra of short chain polymethylenes show a series of bands below 600 cm^{-1} whose frequency varies inversely with chain length. These Raman active transitions arise from the longitudinal acoustical vibration (l.a.) of the carbon skeleton and the overtones of l.a. They are represented as the symmetric longitudinal accordion-like motion of an extended zig-zag carbon chain (Fig. 1). The Raman wavenumber shifts $\Delta\tilde{\nu}$ for these vibrations are approximately linear in (m/n) where m is the order of the vibration and n is the number of carbon atoms in the chain. The fundamental l.a. vibration ($m = 1$) is the most intense of the series observed for a particular chain length, with the intensities of the overtones approximately proportional to $(1/m)$. Only overtones corresponding to odd values of m are observed, as to a first approximation, even values of m correspond to vibrations that give no change in the molecular polarizability.[1] For each chain length, n, there are only a limited number of frequencies intense enough for observation and these frequencies are different from the frequencies observed for other chain lengths. For very long chain hydrocarbons the frequency differences are sufficiently great to allow identification of different hydrocarbons in a mixture.

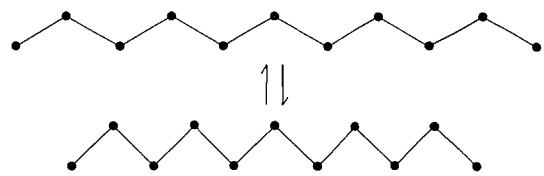

FIG. 1. The l.a. accordion mode of an extended normal hydrocarbon molecule.

As the carboxyl group of a fatty acid should act as only a small perturbation on the accordion-like motion of the hydrocarbon chain, a Raman investigation of fatty acids should give a simple relation between the wavenumber shifts of l.a. modes and the chain length with the possibility of using this correlation in the identification of acids. We wish to report such an investigation for the fatty acids in the range of chain lengths

[1]This selection rule will be relaxed slightly for fatty acids since the replacement of one methyl group of the polymethylenes by a carboxyl group reduces the symmetry of the molecule.

(C_{12}–C_{24}) of the acids derived from natural oils. The results indicate the possibility of using the l.a. modes for both qualitative and quantitative analysis of fatty acid mixtures.

Experimental

The fatty acids used in this investigation were commercial samples used without further purification after a g.l.c. check of the purity. Raman spectra were recorded for each acid in the solid state at room temperature. The polycrystalline powder, pressed into a small pellet, was placed on a Spex 180° viewing platform. The 4880 Å line (*ca.* 800 mW) of a Carson Model 101 Argon-ion laser was used as the incident light source, and light scattered at 180° to the incident radiation was collected and focussed on the entrance slit (*ca.* 3 cm^{-1}) of a Spex 1401 double monochromator containing two 1200 lines/mm gratings blazed at 5000 Å. A photon counting detection system consisting of a Bendex Channeltron Photon counter tube and an SSR amplifier–discriminator and ratemeter was used to provide the output to the recorder. Some of the spectra were also recorded in digital form through the use of an interface which couples the monochromator and the associated photon detection system to a Wang 700C programmable calculator. The interface and capability of the resulting system have been previously described (4). The spectral data in digital form were stored on a Wang 710 Disc Drive. The advantages of this latter method are that background and frequency correction, digital smoothing and peak location can be performed automatically.

Raman spectra were also recorded for mixtures of fatty acids. These mixtures were prepared by weighing out the individual components, melting them together, and then pressing the cooled mixture into a pellet.

A high background scattering is frequently encountered in the Raman spectra of polymeric samples (5, 6). The background intensity decays with time and does not reappear when the laser is temporarily extinguished provided the sample is kept in the same position. This phenomenon was observed with a number of our samples. Although the decay rate varies from sample to sample it was found that satisfactory spectra could be obtained after the samples were illuminated with the incident laser light for approximately 30 min. There was no evidence of any sample deterioration by the laser and the spectra were reproducible.

Results and Discussion

Figure 2 shows the 0–600 cm^{-1} portion of the Raman spectrum of a typical saturated straight chain fatty acid. Although there is a sloping baseline resulting from background scattering, the l.a. frequencies corresponding to $m = 1, 3, 5$ are observed.[2] The wavenumber shifts measured from such spectra are accurate to ± 2 cm^{-1} and in each case the frequency observed for a fatty acid is similar to, but slightly shifted from, the corresponding frequency in the hydrocarbon of the same chain length.

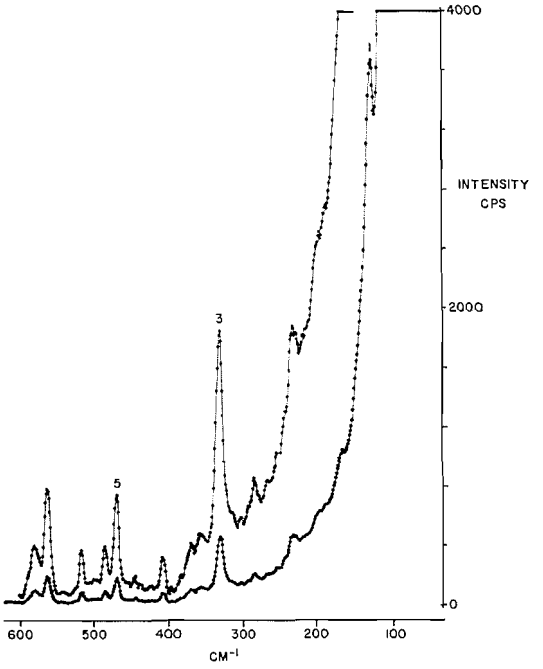

FIG. 2. Raman scattering by crystalline $C_{20}H_{40}O_2$.

Schaufele *et al.* showed that the frequencies of the accordion modes for finite polymethylene chains could be fitted to a polynomial in (m/n) of the form

$$[1] \quad \Delta\tilde{\nu} = A_1 + A_2(m/n) + A_3(m/n)^2 + ... + A_7(m/n)^6$$

For small values of m/n the linear term is sufficient, but for $m/n > \sim 0.08$ the higher order terms in m/n must be included. The observed l.a. modes for the fatty acids were also found to obey an equation of the form [1] with values of the parameters A_1–A_7 determined from a least squares treatment of the experimental frequencies. Figure 3 shows the dependence of frequency on the ratio (m/n) for the l.a. modes of fatty acids. The least squares treatment of the data enabled us to verify the assignment of some of the less intense overtones. Table 1 compares the observed frequencies for the C_{12}–C_{24} acids with those calculated from eq. 1. The simplest application of both Fig. 3 and Table 1 would be in the identification of a single fatty acid. Since the fundamental and the overtones ($m = 3, 5$) are generally observed, the presence of all three

[2]In a number of the longer chain acids, overtones corresponding to $m = 2, 4, 6$ were observed, but with an intensity much less than that of the odd overtones.

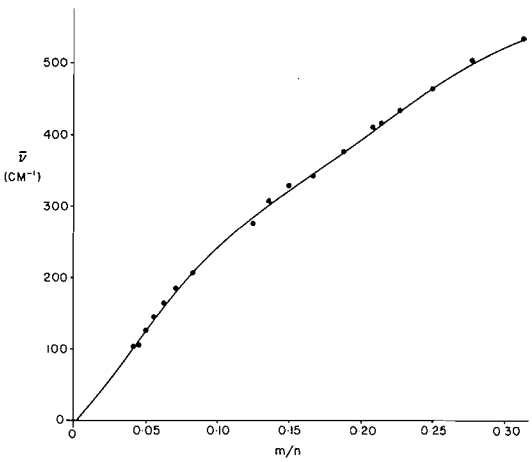

FIG. 3. Low frequency Raman bands plotted as a function of m/n.

TABLE 1. Longitudinal acoustical accordion mode frequencies of straight chain fatty acids

		$\Delta\bar{\nu}$(cm^{-1})

bands could be used to confirm the estimate of chain length, even in the presence of impurities.

Figure 4 shows part of the Raman spectrum observed for a mixture of myristic, palmitic, and stearic acids. The labelled peaks in this figure correspond to the $m = 3$ transition of each fatty acid. For detection of the components of a mixture of chain lengths, the fundamental l.a. frequencies could be used, but their relatively greater intensity is obscured by the very strong Rayleigh line. The overtones corresponding to $m = 5$ transitions are so much weaker that for a multicomponent mixture these peaks are almost lost in background noise.

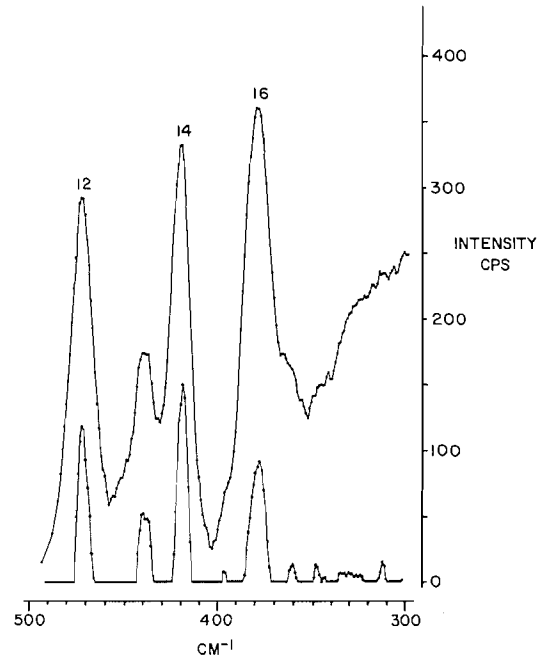

FIG. 4. Observed $m = 3$ overtones (upper curve) for a mixture of $C_{12}H_{24}O_2$, $C_{14}H_{28}O_2$, and $C_{16}H_{32}O_2$. The lower curve represents the negative of the second derivative of the upper curve.

Comparison of the ratio of peak heights in the spectra of mixtures of palmitic and stearic acid with the ratio of mole fractions of the two acids showed an approximate linear relation between the two ratios, but the difficulty of measuring accurate peak heights above a sloping baseline introduces considerable error if this method were to be used for the quantitative analysis of mixtures. The problem of the sloping base line was minimized by measuring the negative portion of the 2nd derivative spectrum, which is also illustrated in Fig. 4. The second derivative spectrum is obtained from the original digitized spectrum (4) by using the procedure of Savitsky and Golay (7, 8). Although the second derivatives of peaks wouldn't be expected to be strictly proportional to the peak height, a much better linear relation was found between the ratios of the second derivatives of the palmitic and stearic $m = 3$ peaks and the mole fraction ratios in our mixtures of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

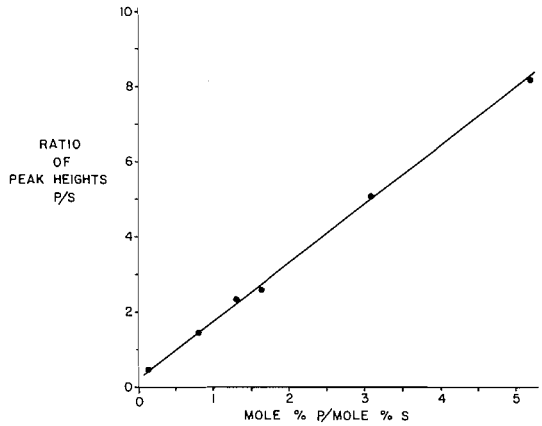

FIG. 5. Ratio of the 2nd derivative peak heights of the $m = 3$ overtones *vs.* the ratio of their mole percentages for mixtures of palmitic and stearic acids.

the two acids. Figure 5 illustrates this relation, which is linear to within experimental error. If second derivative spectra are used, quantitative analysis by the Raman method is both accurate and straightforward.

The superiority of the Raman over infrared methods of chain length determination has been demonstrated. No derivative formation is required, mixtures may be analyzed as well as single acids, and the percentage of each acid in a mixture is easily determined. This should be of interest to those interested in the chain length determination of acids derived from naturally occurring oils, most probably as an adjunct to the different chromatographic methods of analysis.

Spectrum, Kinetics, and Radiation Chemical Yield of Solvated Electrons in Hexamethylphosphoric Triamide

ERIC A. SHAEDE AND LEON M. DORFMAN
Department of Chemistry, The Ohio State University, Columbus, Ohio 43210

AND

GARRY J. FLYNN AND DAVID C. WALKER
Department of Chemistry, The University of British Columbia, Vancouver 8, British Columbia

Received June 29, 1973

The spectrum, yield, and kinetics of solvated electrons in hexamethylphosphoric triamide were investigated by the pulse radiolysis method. The optical absorption band is in the infrared with a maximum at 2200 ± 100 nm. The molar absorptivity at this maximum is (3.2 ± 0.5) × 10^4 M^{-1} cm^{-1}, and the oscillator strength for the transition is estimated to be $f = 0.7 \pm 0.2$. A free ion yield of $G(e_s^-) = 2.3 \pm 0.4$ solvated electrons/100 eV was determined from the observed yields of anthracene and pyrene radical anions formed by electron attachment.

Kinetic studies provided values of the rate constants for the reaction of solvated electrons with anthracene and N_2O. The decay mechanism of the solvated electrons in the absence of added solutes was found to be complex, and the half-life (in the range of 2 to 50 μs) was dependent on experimental conditions. A second transient species, absorbing at wavelengths below 500 nm, was observed but not identified. In solutions containing bromide ion the species Br_2^- was observed. The pulse radiolysis of stable solutions of e_s^-, formed by dissolving sodium metal in HMPA, is also reported.

On a étudié le spectre, le rendement ainsi que la cinétique d'électrons solvatés dans le triamidure d'hexaméthyl phosphore (HMPA) à l'aide de la méthode de radiolyse par pulsations. La bande d'absorption optique se situe dans l'infrarouge avec un maximum se trouvant à 2200 ± 100 nm. La capacité d'absorption molaire à ce maximum est de (3.2 ± 0.5) × 10^4 M^{-1} cm^{-1} et la force de l'oscillateur pour la transition est évaluée à $f = 0.7 \pm 0.2$. Un rendement en ion libre de $G(e_s^-) = 2.3 \pm 0.4$ électrons solvatés/100 eV a été déterminé à partir des rendements observés pour la formation, par fixation d'un électron, d'anions radicalaires de l'anthracène et du pyrène.

Des études cinétiques ont permis d'obtenir les constantes de vitesse pour la réaction d'électrons solvatés avec l'anthracène et le N_2O. Le mécanisme de disparition des électrons solvatés en absence de solutés ajoutés s'est révélé complexe et le temps de demi-vie (variant de 2 à 50 μs) est dépendant des conditions expérimentales. Une seconde espèce transitoire, absorbant à des longueurs d'onde inférieures à 500 nm, a été observée mais n'a pu être identifiée. Dans des solutions contenant l'ion bromure, on a observé la présence de l'espèce Br_2^-. On discute aussi de la radiolyse par pulsations des solutions stables de e_s^-, formées par dissolution de sodium métallique dans du HMPA.

Can. J. Chem., **51**, 3905 (1973)

Introduction

Information about the physical characteristics of solvated electrons, with particular attention to the optical properties in solvents (1–4) of widely differing molecular structure and dielectric behavior, is useful in assessing the validity of theoretical models (5) which have been postulated to describe these species. Hexamethylphosphoric triamide (HMPA) is a particularly interesting solvent since it is a liquid of moderately high dielectric constant which solvates negative ions extremely weakly and positive ions very strongly (6). Studies of the chemical behavior of solvated electrons by pulse radiolysis of pure liquids may have general implications in many areas of chemistry because of the possible role of these species as intermediates in reactions such as the Birch reduction, in electrochemical processes, and in electron transfer reactions. Information about the ability of a solvent to stabilize electrons, and about the reactivity of these species toward other materials, is thus of interest.

HMPA, $[(CH_3)_2N]_3PO$, is an aprotic solvent with a macroscopic dielectric constant of 30 at 20 °C and a large dipole moment (5.3 D at 25 °C). Alkali metals dissolve in HMPA to form relatively stable solutions of solvated electrons that are characterized by an optical absorption band in the infrared (7, 8) and by narrow e.s.r.

lines (9, 10). There is evidence that solvated electrons may be produced in HMPA at the surface of a noble metal cathode by electrolysis of LiCl solutions (11).

There have been two recent studies on various aspects of solvated electrons formed by pulse radiolysis of HMPA (12, 13) which suggest the absorption band occurs at $\lambda > 1500$ nm. We report here a pulse radiolysis investigation of the physical and chemical properties of solvated electrons in which the wavelength range studied covers the region of the absorption band maximum. Some of the results are in general qualitative agreement but are substantially different in certain important respects from those already published (12, 13).

Experimental

Pulse radiolysis experiments utilized 4 MeV electrons from a Varian V7715A electron linear accelerator. The details of the apparatus have been described earlier (14). Pulse widths ranged from 10 to 1200 ns with a dose rate of about 10^{19} rad s^{-1}. Transient optical absorption measurements involved the use of one of several photomultiplier tubes (RCA 7200, 7102, 1P28) for wavelengths below 1200 nm, and an indium antimonide photodiode with fast response circuitry (4) for wavelengths between 800 and 2300 nm. The 10–90% risetime of the fast infrared detector was about 100 ns with a somewhat longer 1% settling time. For some experiments where time resolution of about 5 ns was required, a photomultiplier system (RCA 1P28 or HTV 196) with a 2 ns risetime was used with a Fairchild 777V dual beam oscilloscope. A Tektronix 545 dual beam oscilloscope was also used. A 500W xenon arc which could be flashed in synchronization with the electron pulse was used as light source. In the majority of the experiments Suprasil quartz cells with a 20 mm optical path contained the samples; sometimes with two light passes were used. Thin Vitrosil cells (3 mm) allowed for measurements in the infrared region to nearly 2300 nm where the solvent absorption was great. Bausch and Lomb high intensity grating monochromators were utilized for wavelength selection over the entire spectral region. Appropriate Corning glass filters were placed in the optical path before the cell to prevent photolysis of the solutions and in front of the monochromator to eliminate second order and scattered light. A 0.1 M aqueous KSCN solution saturated with nitrous oxide was used for dosimetry. The transient species absorbing at 500 nm was monitored and the value (15) of $G\varepsilon^{500} = 4.2 \times 10^4\ M^{-1}\ cm^{-1}$ molecule $(100\ eV)^{-1}$ was used to calculate the absorbed dose in water. As a secondary dosimeter, hydrated electrons were observed in pure water samples at 715 nm where $G\varepsilon^{715}$ was taken (ref. 16, p. 42) to be $5.0 \times 10^4\ M^{-1}\ cm^{-1}$ molecule $(100\ eV)^{-1}$. The dose absorbed by the HMPA samples was obtained by correcting for the relative electron densities of water and HMPA. Pulse to pulse reproducibility of the accelerator was generally better than $\pm 5\%$ of the mean. The two dosimetry methods gave results within 10% of each other and an average of the values was used in the calculations.

Purification of HMPA involved stirring Dow Chemical Company "Dorcol" brand HMPA with metallic sodium under vacuum until a dark blue solution of solvated electrons had been formed. The sodium solution was then fractionally distilled under vacuum, vacuum fractionated and the middle portion collected in an evacuated flask equipped with a Teflon stopcock. Samples were then prepared by re-distilling the HMPA from the storage flask directly into the radiolysis cells under vacuum. The samples were finally subjected to a multiple freeze–thaw procedure to remove residual traces of dissolved oxygen.

All chemicals used as scavengers were analytical reagent grade or better. Pyrene and anthracene were Aldrich "Gold Label" zone refined grade rated at 99.9+% purity. Nitrous oxide was purified by trap-to-trap distillation on a vacuum line and solutions were prepared by freezing measured quantities into the radiolysis cells. The concentration of dissolved N_2O was then calculated from an empirical solubility relationship (17).

Results and Discussion

Transient Absorption Spectra

Figure 1 shows the spectrum obtained from measurements of the optical absorption at the end of 400 or 500 ns electron pulses in pure HMPA over the wavelength range 300–2300 nm. The data represent the results of several series of experiments using both the 3 mm and 20 mm optical pathlengths with appropriate normalization. The inset of Fig. 1 is a representative example of the quality of the transient signals used in the spectral mapping. It was obtained at 2150 nm with a 3 mm optical path using a 500 ns pulse. 2300 nm represents the long wavelength limit of our detection capability as a result of solvent absorption and decrease in emission intensity of the light source.

A single species contributed the absorbance over the wavelength range from 500 to 2300 nm as is evident from the fact that the decay characteristics of the transient absorptions were identical over this wavelength range. This infrared absorption band may be assigned fairly confidently to the solvated electron because of the following observations. The lifetime of the absorption was drastically reduced by even trace amounts of oxygen, nitrous oxide, pyrene, and anthracene, all of which are good electron scavengers. Radical anions of the aromatic compounds were formed in the scavenging process. The spectrum of Fig. 1 is furthermore very similar to that reported for solvated electrons in sodium solutions in HMPA over the

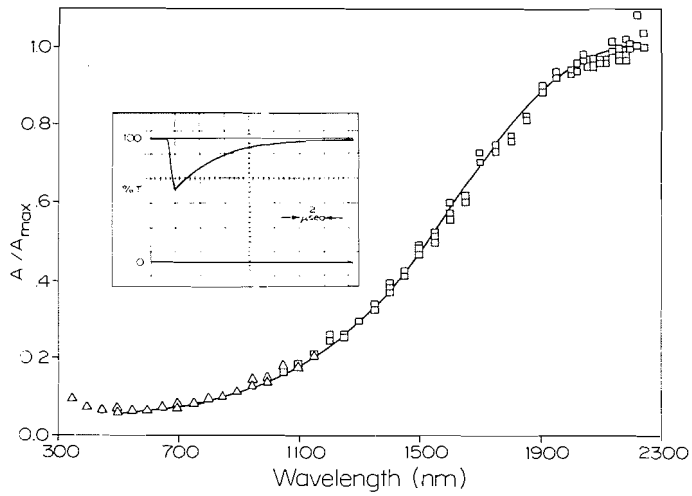

FIG. 1. Absorption spectrum of e_s^- in HMPA produced by pulse radiolysis. □, 3 mm cell, 500 ns pulse and InSb diode detector; △, 40 mm path length, 400 ns pulse and photomultiplier detector (normalized over the region 900–1150 nm). A_{max} represents the absorbance at 2200 nm. At $\lambda < 500$ nm another species, in addition to e_s^-, also contributes to the absorption. Inset: typical oscilloscope trace at 2150 nm using InSb detector.

wavelength range 1000–2300 nm (8) when these two spectra are normalized at 1500 nm.

We conclude that the maximum of the absorption is at 2200 ± 100 nm. The data shown in Fig. 1 strongly suggest that the maximum is at 2200 nm or at a slightly longer wavelength. The maximum is so near our long wavelength detection limit (2300 nm) as to preclude an unequivocal determination of λ_{max} directly. A confirmation of the value of λ_{max} may, however, be obtained independently by an extrapolation of data for the binary solution HMPA–ethylenediamine, as had been done with various ethers (4). λ_{max} for the binary solutions changes monotonically between the maxima for the pure liquids. Extrapolation to pure HMPA, as in Fig. 2, gives $\lambda_{max} = 2150 \pm 100$ nm in agreement with the value from Fig. 1.

Below 500 nm at least one other species contributes to the absorbance. By using nitrous oxide to remove the electron absorption, the contribution of e_s^- below 500 nm was shown to decrease over the wavelength range 500 to 300 nm.

Despite its substantial dielectric constant, HMPA apparently solvates electrons only very weakly as is evident from the transition energy of only 0.57 eV at the absorption band maximum. In this regard, HMPA seems similar to dimethylsulfoxide, another strongly polar, aprotic solvent, which solvates electrons very weakly, giving rise to a near-infrared absorption band

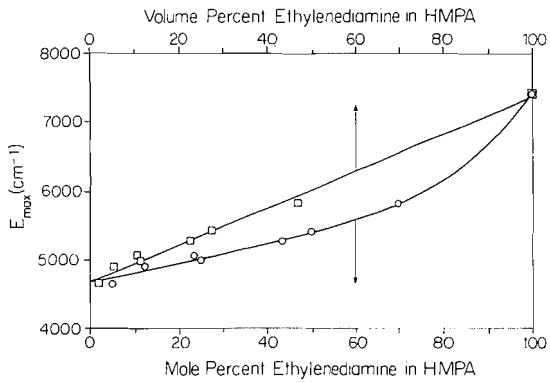

FIG. 2. Absorption maximum of the solvated electron in the binary liquid system ethylenediamine–HMPA. The energy of the band maximum (units of cm^{-1}) is plotted against (*i*) mol % ethylenediamine, ○; and (*ii*) vol % ethylenediamine, □. The extrapolation to pure HMPA gives $\lambda_{max}^{HMPA} = 2150$ nm.

(18). The absorption band shape in HMPA also closely resembles that observed for solvated electrons produced by pulse radiolysis in several weakly polar aprotic ethers (4) and low temperature glassy hydrocarbons (19). Very weak solvation of electrons in HMPA may be rationalized by considering the fact that the positive end of the P=O dipole is diffused over the three dimethylamine groups. Furthermore, the molecule is so bulky that cavities already present in the liquid, or induced by the excess electrons, will necessarily be quite large, thereby con-

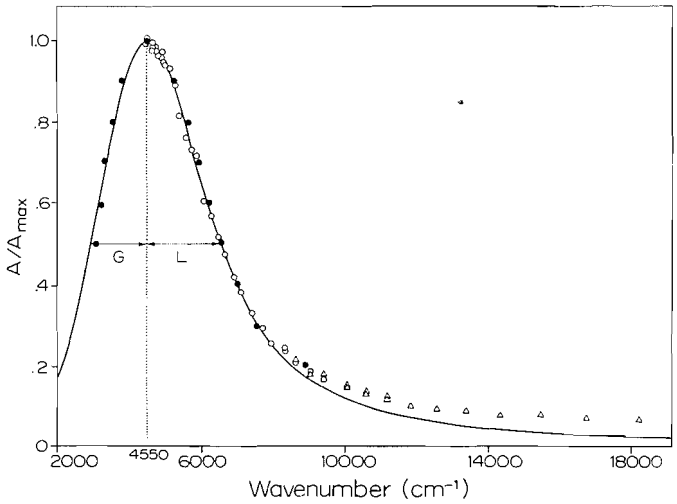

FIG. 3. Combined Gaussian-Lorentzian fit to the observed absorption spectrum plotted on an energy scale. Data same as Fig. 1 plus the published data for Na solution in HMPA (8) represented by ●, the filled circles. G and L represent half of the independently variable "half-widths" for the functions described in the text and give the half-width for the total absorption band of only 3600 cm^{-1} (0.45 eV).

ferring an extended charge distribution commensurate with the infrared absorption band. If a calculation of the vacancy size in the liquid is made for a tetrahedral configuration of four dipole-oriented HMPA molecules, it is found to be a hole of radius 5 Å. Indeed, any fit of a continuum-cavity model requires a cavity radius of about 4 Å for this band. This large cavity size may be contrasted with calculated radii between 1–2 Å for solvated electrons in water and alcohols.

It has been shown (20) that a Gaussian–Lorentzian shape function may be used to curve-fit solvated electron absorption band data. In Fig. 3 the function

$$y(\bar{\nu}) = \exp\left\{-\frac{\ln 2(\bar{\nu}_m - \bar{\nu}_i)^2}{(H_{1/2}{}^G)^2}\right\} \quad \text{for } \bar{\nu}_i < \bar{\nu}_m$$

$$y(\bar{\nu}) = \frac{(H_{1/2}{}^L)^2}{(H_{1/2}{}^L)^2 + (\bar{\nu}_i - \bar{\nu}_m)^2} \quad \text{for } \bar{\nu}_i > \bar{\nu}_m$$

is shown fitted to the data from Fig. 1 plotted on an energy scale taking $\bar{\nu}_m = 4550\ cm^{-1}$ corresponding to $\lambda_{max} = 2200$ nm as reference point. $H_{1/2}{}^G$ and $H_{1/2}{}^L$ are the independently variable "half-widths" for the Gaussian and Lorentzian functions shown as *G* and *L* in Fig. 3. Also included in Fig. 3 is the spectrum obtained by Brooks and Dewald (8) for the sodium solution in HMPA over the wavelength range 1000–3200 nm. The data indicate that the presence of sodium does not perturb the spectrum either with respect to shape on the high energy side or to the position of λ_{max}. Below 1000 nm other species besides e_s^- contribute to the absorption in sodium solutions. The deviation of the solvated electron spectrum from the Lorentzian function in the high energy region has recently been noticed in several amines and ethers (4).

The half-width of the absorption band in HMPA is 3600 cm^{-1} (0.45 eV) as is evident from Fig. 3. This value is similar to that in tetrahydrofuran (4), but smaller than that observed for many other solvated electron bands. Half-widths in the range from 0.7 to 1.5 eV are generally found for e_s^- in alcohols, water, and amines. The electron band in ammonia is narrower at half-height, with $W_{1/2} = 3100\ cm^{-1}$ (0.39 eV) (20).

Mal'tsev *et al.* (12) and Nauta and van Huis (13) have both observed the tail of the absorption band over the spectral range 500 to 1500 nm which they attributed to e_s^-. When their data are compared with that of Fig. 1 the shape coincides quite well for ref. 13 (but rather poorly for ref. 12) when normalized at 1500 nm; but the absolute intensities differ considerably.

The other species which contributed to the transient absorption in pulse-irradiated HMPA at wavelengths below 500 nm was not identified. It was substantially longer lived than the absorption of the solvated electron, as noted previously (13), but its decay was complex and kinetic data

suggested it may have been involved in the decay mechanism of the solvated electron. Low concentrations of hydrogen, water, or methanol had no observable effect on this transient absorption, nor on that due to e_s^-. Addition of bromide ion led to the formation of Br_2^- which masked the absorption below 500 nm. Addition of N_2O or O_2 to remove the electron absorption did not lead to a sufficiently simplified system to permit a spectral assignment.

Molar Absorptivity and Oscillator Strength of e_s^- Band

When pyrene (Py) or anthracene (An) were present in pulse irradiated HMPA the corresponding radical anion absorption bands shown in Fig. 4 were produced. These bands are very similar to those published for the mononegative ions in tetrahydrofuran (21) with peaks at 495 and 740 nm for Py^- and An^- respectively. The maximum molar absorptivities of the anions were taken to be the same as measured in tetrahydrofuran, assuming no solvent dependence, namely $5.0 \times 10^4\ M^{-1}\ cm^{-1}$ for pyrene and $1.0 \times 10^4\ M^{-1}\ cm^{-1}$ for anthracene. Direct comparison of the e_s^- absorption at 1000 nm in pure HMPA with the radical anion absorption in the same sample, after the addition in vacuo of small amounts of An or Py, established $\varepsilon = (4.75 \pm 0.4) \times 10^3\ M^{-1}\ cm^{-1}$ for e_s^- in HMPA at 1000 nm. Using the measured ratio of 6.7 ± 0.4 for the absorbance at 2200 nm to that at 1000 nm the molar absorptivity at the band maximum was calculated to be $\varepsilon = (3.2 \pm 0.5) \times 10^4\ M^{-1}\ cm^{-1}$.

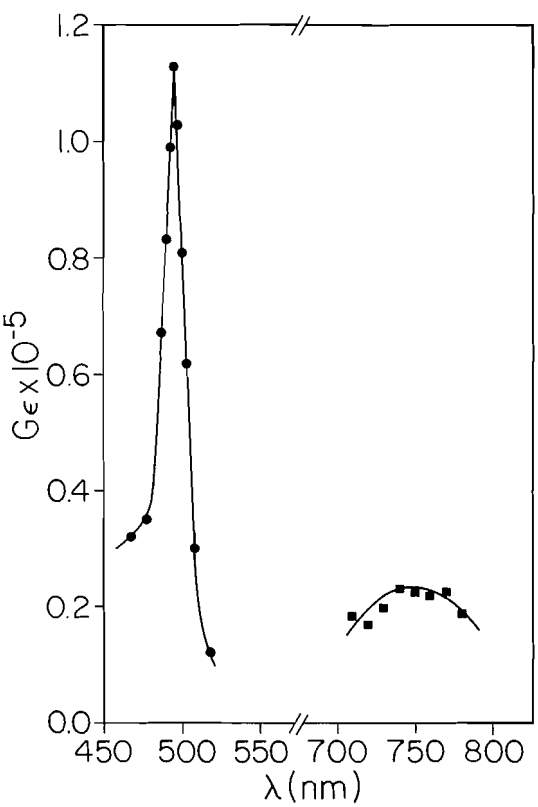

FIG. 4. Radiation produced transients observed at (*i*) 470–520 nm for $(2.6 \pm 0.1) \times 10^{-3}\ M$ pyrene and (*ii*) 710–780 nm for $6.3 \pm 0.5) \times 10^{-4}\ M$ anthracene in HMPA. The species are attributed to the aromatic negative ions.

Integration of the area under the total absorption band, as simulated by the Gaussian–Lorentzian function in Fig. 3, using the relationship

$$f = 4.3 \times 10^{-9} \int_{\bar{\nu}=0}^{\bar{\nu}=\infty} \varepsilon(\bar{\nu})\, d\bar{\nu}$$

(this does not take into account corrections for the refractive index of the liquid (22)), gives a value for the oscillator strength $f = 0.7 \pm 0.2$ for e_s^- in HMPA. This large oscillator strength is in accord with similar determinations for other solvated electrons (ref. 16, p. 40, ref. 23).

Yield of Solvated Electrons

No fast geminate decay of the solvated electron absorption could be observed with the fastest available time resolution of 5 ns. This is probably to be expected for a liquid of such high dielectric constant in which the Onsager escape radius is quite small resulting in a short lifetime for geminate ion-pairs. Since the electron decay half-life is several microseconds it can be assumed that the absorption observable after 5 ns corresponds almost entirely to the free ion yield.

For various scavenger concentrations the radiation yields presented in the Table were obtained. At these concentrations the electron absorption band was completely eliminated. Since the yield is nearly independent of concentration when this was $> 10^{-4}\ M$ it can be accepted that quantitative conversion of the free electrons to anions was occurring at these concentrations. (Py^- formed by scavenging geminate electrons at 0.1 M could have undergone charge neutralization in lieu of e_s^- in the spurs. No fast decay of Py^- was observed on a 5 ns

TABLE 1. Radiation yield of aromatic anions from anthracene (An) and pyrene (Py) at various concentrations for ~1 krad pulses

	Solute	Yield
Anthracene	$(6\pm2)\times10^{-5}$ *M*	$G(An^-)$ 1.9±0.4
	$(6.3\pm0.5)\times10^{-4}$ *M*	2.3±0.4
Pyrene	$(3.2\pm0.3)\times10^{-4}$ *M*	$G(Py^-)$ 2.1±0.4
	$(2.6\pm0.1)\times10^{-3}$ *M*	2.3±0.4
	$(1.2\pm0.1)\times10^{-1}$ *M*	2.4±0.4

time scale.) Addition of ~0.1 *M* N_2O to samples containing $<10^{-3}$ *M* Py or An resulted in reduction to ~5% in initial yield of the aromatic anions observed. This suggests that the aromatic cations Py^+ or An^+ do not contribute to the absorption at 495 nm or 740 nm in this system. Based on the data given in Table 1 we conclude that for the free ion yield $G(e_s^-) = 2.3 \pm 0.4$ in HMPA.

This yield is in good agreement with the value of 2.4 ± 0.3 measured by Nauta and van Huis (13) but twice as large as $G(e_s^-) = 1.2$ reported by Mal'tsev *et al.* (12). A yield of 2.3 is somewhat higher than would be expected simply on the basis of previously demonstrated empirical correlations between the free ion yield and a liquid's static dielectric constant (24). This probably stems from a rather high mobility of the solvated electrons in HMPA due to its nearly spherical shape (25) which could lead to a higher than normal escape probability. In addition, steric screening of the positive counter-ion and the strongly aprotic nature of the liquid may cause relatively inefficient charge neutralization processes in HMPA. However, this free-ion yield is substantially lower than $G(N_2)$ from γ-irradiated N_2O solutions of HMPA (26).

Our $G\varepsilon$ values are about twice as large as those estimated by Nauta and van Huis (13) and more than ten times those reported at 1600 nm by Mal'tsev *et al.* (12). One possible explanation for the low $G\varepsilon$ values found in the latter studies is the fact that they used comparatively long radiation pulses during which a significant fraction of their solvated electrons would have decayed. This explanation is supported by their four-fold increase in $G(e_s^-)$ on addition of ~0.2 *M* Br^- (12).

Kinetic Studies

(i) Decay of e_s^-

The lifetime of the solvated electron in pure irradiated HMPA was found to increase with decreasing dose per pulse and to be sensitive to sample purification and preparation techniques. Using low dose pulses (~300 rad) in a carefully deoxygenated sample first half-lives approaching 50 μs could be achieved. Analysis of the e_s^- decays (for various doses) showed them to arise from mixed first- and second-order processes with the second-order components always having $k \sim 2 \times 10^{10}\ M^{-1}\ s^{-1}$. This is consistent with the anticipated reactions involved

$$[1] \qquad e_s^- + X \xrightarrow{k_1} [X^-]$$

$$[2] \qquad e_s^- + e_s^- \xrightarrow{2k_2} [e_2^{2-}]$$

$$[3] \qquad e_s^- + S^+ \xrightarrow{k_3} [S]$$

where X represents species contributing to all decays which are not second-order in e_s^- including impurities and other radiation products, and S^+ is the solvent counter-ion or its decomposition product.

In an attempt to decide if radiation-produced species contributed to [1], some experiments were performed on the pulse radiolysis of blue solutions of Na metal dissolved in HMPA which already contained substantial (but unknown) concentrations of solvated electrons (presumably in equilibrium with Na^-). Typical oscilloscope traces are shown in Fig. 5 from which it is clear that the radiation pulse creates additional solvated electrons but that the overall processes lead to a net loss in the concentration of e_s^-. Furthermore, the net loss is comparable in magnitude to the radiation yield of solvated elec-

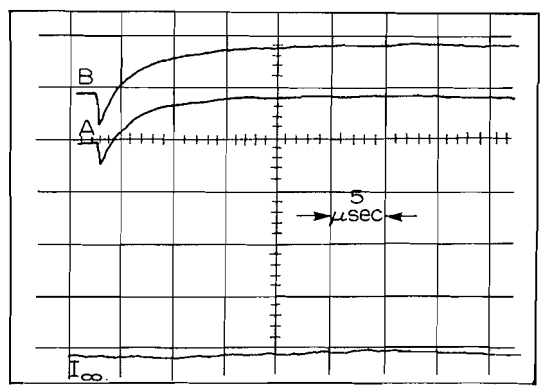

FIG. 5. Effect of electron pulses on a solution of Na in HMPA at 750 nm. The second pulse, B, followed 10 s after the first and showed that the pulses give an initial increase in e_s^- concentration, but a net permanent loss of the species. Similar results were found at 1550 nm.

For personal use only.

trons. If only reactions 2 and 3 were involved the initial and final concentrations of e_s^- would have been the same. The Na solutions obviously do not contain impurities with which e_s^- reacts, so that one must conclude that other radiation-produced species, such as free radicals, contribute significantly to e_s^- decay according to reaction 1.

(ii) Kinetic Studies with Anthracene and Nitrous Oxide

For solutions containing anthracene at 6×10^{-5} M the rate of electron decay, observed at 1000 nm, corresponded almost exactly to the rate of build-up of absorption due to An^- at 740 nm. Representative traces for a solution containing $(6 \pm 2) \times 10^{-5}$ M anthracene are shown in Fig. 6*a* and *b*. The absorption at 740 nm (Fig. 6*b*) includes a contribution from e_s^- (equal to that shown in Fig. 6*a* multiplied by the ratio of extinction coefficients of e_s^- at 740 and 1000 nm obtained from Fig. 1). On applying this correction the rate constant for formation of An^- was evaluated to be $(1.7 \pm 0.2) \times 10^6$ s^{-1} from the linear plot of log $(A_{2.5} - A_t)$ against time, where $A_{2.5}$ is the absorbance 2.5 μs after the pulse (plateau value) and A_t the absorbance at time t. The data of Fig. 6*a* were shown to correspond to a first-order decay with $k = (1.5 \pm 0.2) \times 10^6$ s^{-1}. From these one calculates the rate constant for reaction 4;

$$[4] \qquad e_s^- + An \xrightarrow{k_4} An^-$$

to be $k_4 = (3 \pm 1) \times 10^{10}$ M^{-1} s^{-1}.

A solution of 8×10^{-4} M N_2O in HMPA was made by condensing into the cell a known quantity of N_2O (the solubility of N_2O in HMPA having been measured (17) to be 1.85×10^{-4} M mm^{-1}). For this solution the rate of reaction 5.

$$[5] \qquad e_s^- + N_2O \xrightarrow{k_5} [N_2O^-]$$

was evaluated in two ways. Firstly, by measuring the steady state absorbance of e_s^- at 1000 nm during a constant dose-rate 700 ns pulse, which gave a pseudo first-order rate constant of $(1.2 \pm 0.3) \times 10^7$ s^{-1}. Secondly, by analysis of the pseudo first-order decay following the pulse, the value $(1.1 \pm 0.3) \times 10^7$ s^{-1} was obtained. These correspond to $k_5 = (1.4 \pm 0.4) \times 10^{10}$ M^{-1} s^{-1}. It may be noted that this is about three-fold larger than the analogous reaction in water (27) and thus seems contrary to the reported lower mobility of e_s^- in HMPA (12).

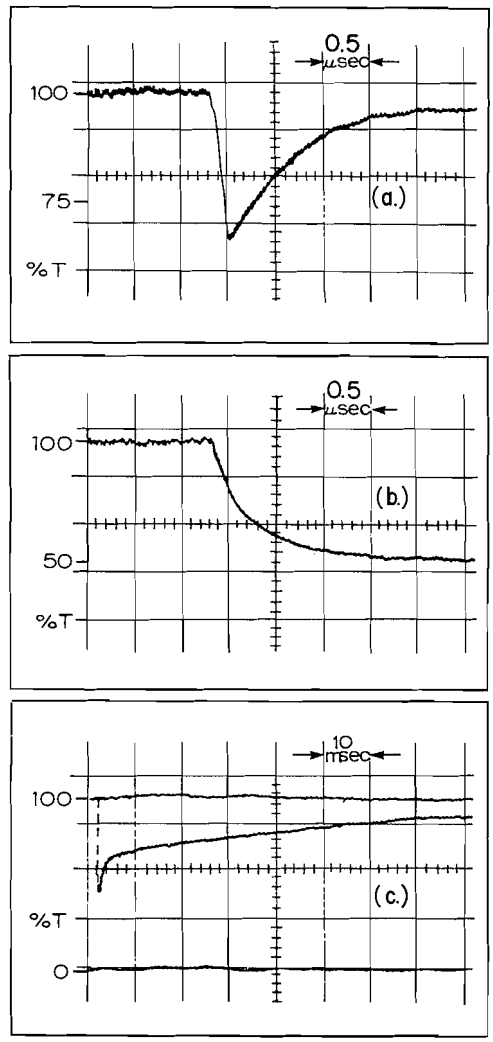

FIG. 6. (*a*) Decay of absorption due to e_s^- at 1000 nm in a solution containing $(6 \pm 2) \times 10^{-5}$ M anthracene in HMPA following a 200 ns pulse. (*b*) Build-up of the absorption due to An^- at 740 nm for the same solution as in (*a*). (*c*) Decay of absorption due to An^- at 750 nm in a solution containing $(6.3 \pm 0.5) \times 10^{-4}$ M anthracene in HMPA.

In dilute solutions of anthracene (or pyrene) to which small concentrations of N_2O were also added, the initial yields of the aromatic anions were substantially smaller than in the absence of N_2O; but the decay rate of An^- (or Py^-) was essentially unchanged. This is consistent with a competition between reactions 4 and 5 for e_s^-, and it also means that there is no charge exchange between An^- and N_2O or between N_2O^- and An. By contrast, in the presence of some oxygen the Py^- decay rate was greatly

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

enhanced implying that an interaction between the aromatic anions and O_2 does occur.

The decay processes of the aromatic anions in the absence of a second solute were not investigated in detail but showed two distinct decay regions, as can be seen for An^- in Fig. 6*c*. The faster decay step occurs over microseconds and probably results from neutralization with the radiation-produced counter-ions; but a substantial second portion of the decay is very slow, extending over tens of milliseconds.

Solutions Containing Bromide Ions

The presence of 0.14 *M* LiBr, or 0.17 *M* NaBr, in pulse irradiated HMPA resulted in a 35% increase in the yield of solvated electrons, to $G(e_s^-) = 3.1 \pm 0.4$. Bromide ions also increased the electron's lifetime significantly, thereby corroborating the probable involvement of reaction 3 in electron decay. In these solutions a new absorption band with $\lambda_{max} \sim 360$ nm was observed, which is similar to that found in aqueous Br^- solutions and attributed to Br_2^- (28). The yield of Br_2^- from a 10^{-2} *M* Br^- solution was about half that from the 0.14 *M* solution but the absorbance found at 360 nm all grew-in during the radiation pulse and was certainly complete in $< 10^{-6}$ s. Evidently the species scavenged have alternative fates involving fast reactions.

For the NaBr solutions, the spectrum was carefully studied over the region 700 to 1000 nm in search of contributions from species such as Na^- which have been observed at ~750 nm in sodium solutions in HMPA (8) and which were reported in pulse radiolysis (12). At the end of the pulse the absorption spectrum for a 0.17 *M* NaBr solution was identical to that shown in Fig. 1 for pure HMPA in this wavelength region. However, some 30 μs after the radiation pulse, when ~97% of the solvated electrons had decayed, there was some evidence of an absorption band with a maximum near 750 nm. The intensity of this new band was very small and probably amounted to less than 5% of the initial electron absorption in this region.

Br_2^- is believed to be formed in water when Br^- scavenges the oxidizing species which result from positive ion decay, and by analogy we assume this happens in HMPA also. From the measured absorbance at 360 nm for the 0.14 *M* solution of LiBr in HMPA, one calculates $G\varepsilon = 21\,000\ M^{-1}\ cm^{-1}$ molecule $(100\ eV)^{-1}$. This value reduces to a value for Br_2^- of 15 000 when appropriate correction is made for the absorbance of e_s^- at 360 nm. It would be reduced further (to ~12 000) if the second transient species shown in Fig. 1 to absorb at 360 nm was also present in the irradiated Br^- solutions. There is controversy regarding the magnitude of $\varepsilon_{Br_2^-}^{360}$ with values of either 8 200 or 12 000 $M^{-1}\ cm^{-1}$ reported for aqueous solutions (29). Thus $G(Br_2^-)$ may have a value of 1.2 or 1.8 for 0.14 *M* Br^- in HMPA. These values are much lower than the corresponding $G(e_s^-) = 3.1 \pm 0.4$ in the same solution but are significantly larger than the increased yield of electrons caused by the presence of Br^-. It is possible that even at the highest Br^- concentration all the available oxidizing species were not scavenged. Perhaps the low yield of Br_2^- and the very slow decay of part of the An^- absorption together suggest that there are rapid alternative decay paths available to the primary HMPA positive ions, only some of which give rise to reaction with Br^- and An^-.

We are grateful for support of this research by the U.S. Atomic Energy Commission (at the Ohio State University) and the National Research Council of Canada (at the University of British Columbia and for a Graduate Scholarship to G.J.F.). We are also most grateful to Mr. John Richter for the continued maintenance and improvement of the pulse radiolysis apparatus, and are indebted to Dr. F. Y. Jou for obtaining the absorption data in HMPA–EDA which helped to determine λ_{max} for HMPA.

Organic Sulfur Mechanisms. 14. Kinetic Resolution in the Reaction of a Sulfene with an Amine

JAMES FREDERICK KING, SOO-KHOON SIM, AND SHIU-KANG LAURENCE LI

Department of Chemistry, University of Western Ontario, London, Ontario N6A 3K7

Received May 30, 1973

The reaction of camphor-10-sulfonyl chloride (**1**) with menthylamine (**2**) is shown by deuterium exchange experiments to proceed principally via the sulfene and the kinetic resolution first observed by Read and Storey (1) demonstrated to arise in the sulfene trapping step. This work constitutes the first authenticated kinetic resolution by a sulfene and also provides new kinetic evidence complementary to earlier work for the existence of a sulfene in the reaction of an alkanesulfonyl chloride with an amine. Evidence is also presented that a small but clearly detectable amount of "unexchanged" product in the deuterium exchange reactions arises via a direct displacement of the amine on the sulfonyl chloride; no kinetic resolution in this latter process was detectable.

Des expériences d'échange du deutérium ont permis de montrer que la réaction du chlorure de camphre-10 sulfonyle (**1**) avec la méthylamine (**2**) passe principalement par l'intermédiaire du sulfène et que la résolution cinétique observée la première fois par Read et Storey (1) se produit lors de l'étape de captage du sulfène. Ce travail fait état de la première résolution cinétique authentique par un sulfène et apporte une preuve cinétique supplémentaire aux travaux antérieurs de l'existence d'un sulfène lors de la réaction d'un chlorure d'alcane sulfonyle avec une amine. La preuve est également faite qu'une faible mais aisément détectable quantité de produit "non échangé" lors des réactions d'échange du deutérium provient d'un déplacement direct de l'amine sur le chlorure de sulfonyle; aucune résolution cinétique pour ce dernier processus n'a pu être mise en évidence. [Traduit par le journal]

Can. J. Chem., **51**, 3914 (1973)

Introduction

In 1930 Read and Storey (1) reported that (+)-camphor-10-sulfonyl chloride (**1**) effected a measure of kinetic resolution with racemic menthylamine (**2**) and with its stereoisomers isomenthylamine and neomenthylamine. With equimolar amounts of $\mathbf{1}_+$ and $\mathbf{2}_\pm$, for example, the recovered menthylamine hydrochloride contained about twice as much of the (+)-isomer as the (−)-isomer.[1] In 1968, Okamoto *et al.* (2) extended this work to include six more primary amines (with which relatively little resolution was observed) and carried out rate studies designed to yield the activation parameters for the reactions of the enantiomeric menthylamines. To this end these authors measured the rate of reaction of $\mathbf{2}_-$ with $\mathbf{1}_+$ and then estimated the rate of the reaction of the dextrorotatory amine, $\mathbf{2}_+$, with $\mathbf{1}_+$ from the measured rate of $\mathbf{2}_-$ with $\mathbf{1}_+$ taken with the extent of the kinetic resolution of the racemic menthylamine with the (+)-sulfonyl chloride. Such a method of estimation is justified only if the product ratios and rate ratios are both determined in the same stage of the reaction. This would be the case if, as seemed reasonable to the Japanese authors, the reaction of **1** were to take place by a mechanism involving direct attack of the amine on the sulfur of the sulfonyl group, as has been proposed for the reaction of *arenesulfonyl* chlorides. *Alkanesulfonyl* halides, at least those with α-hydrogens, have been found in our experience to react with amines with the formation of a sulfene as a short-lived intermediate; furthermore, in the cases examined the rate-determining and product-forming steps were *different* (3) and hence the work of Okamoto *et al.* (2) would probably require correction. We were reinforced in our expectation that a sulfene might be an intermediate in these reactions by the knowledge that the reaction of **1** with triethylamine gives a chlorosulfine ("camphorchlorosulfoxide") by a process believed to involve a sulfene (4, 5).

It appeared to us worthwhile to perform a

[1]Throughout this paper we designate the signs of the rotation of enantiomeric reagents by a subscript sign, *e.g.* $\mathbf{2}_-$ refers to (−)-menthylamine, $\mathbf{1}_+$ to (+)-camphor-10-sulfonyl chloride, and $\mathbf{2}_\pm$ to (±)-menthylamine, etc. For the diastereomeric products in this paper two consecutive subscript signs suffice to indicate each diastereomer unambiguously. The first sign refers to the sign of the parent camphor-10-sulfonic acid (or sulfonyl chloride) and the second gives the sign of the parent menthylamine. Hence for the four diastereomers symbolized by **3** ($\mathbf{3}_{+-}$, $\mathbf{3}_{-+}$, $\mathbf{3}_{++}$, $\mathbf{3}_{--}$), the first refers to that obtained from $\mathbf{1}_+$ and $\mathbf{2}_-$, the second to that from $\mathbf{1}_-$ and $\mathbf{2}_+$, and so on.

simple test for the intermediacy of a sulfene, since this could provide the first example of an authenticated kinetic resolution via a sulfene and might perhaps also provide a way of gaining further insight into the difficultly accessible problem of the detailed mechanism of the reaction of sulfenes with amines and related sulfene traps. On the other hand, if the major part of the reaction should prove to be a direct displacement on the sulfur, it would be the first such reaction of a basic amine with an alkanesulfonyl chloride bearing a α-hydrogen and could provide new information about the direct displacement *vs.* sulfene processes.

Results and Discussion

Evidence for the Sulfene Reaction

(+)-Camphor-10-sulfonyl-10,10-d_2 chloride ($\mathbf{1}c_+$) was prepared by repeated reactions of (+)-camphor-10-sulfonyl chloride with triethylamine and D_2O followed by regeneration of the chloride with PCl_5. The first of these reactions gives the monodeuteriated product, $\mathbf{1}b_+$, showing that sulfene was generated from **1** with triethylamine and D_2O. Reaction of the dideuteriated sulfonyl chloride, $\mathbf{1}c_+$ with a 10-fold molar quantity of (−)-menthylamine ($\mathbf{2}a_-$) gave the appropriate sulfonamide (**3**) in which the ratio of the mono- to dideuteriated compounds was about 83:14. Using the protiated sulfonyl chloride $\mathbf{1}a_+$ and (−)-menthylamine-d_2 ($\mathbf{2}c_-$) the sample of **3** contained mono- and undeuteriated amides in the ratio 92:8. Though it is evident that more than 80% of the product (and hence at least some of the kinetic resolution) arises in the sulfene reaction, the presence of "unexchanged"[2] sulfonamide would allow the possibility that some of the product (and hence, again, part of the kinetic resolution) comes from a direct displacement on sulfur by the amino nitrogen. As is shown in the subsection entitled *The Direct Displacement Reaction*, however, we have found that, in fact, there is little or no kinetic resolution in the direct displacement process in this case.

The Stereoselectivity of the Separate Steps of the Sulfene Process

Since it would appear that essentially all of the kinetic resolution arises via the elimination–addition (*i.e.* sulfene) mechanism, we turn to the question of how much of the kinetic resolution arises in the formation of the sulfene and how

[2]"Unexchanged" amide refers to the CD_2-amide (3*c*) obtained from the CD_2-sulfonyl chloride (1*c*) and to the CH_2-amide (3*a*) from the CH_2-chloride (1*a*). It is almost certain that at least part of the "unexchanged" product arises by reaction of the sulfene with the amine with uptake of a hydrogen isotope of the same kind as was lost in the sulfene formation, *i.e.*, some of the "unexchanged" amide is formed in a sulfene reaction with an unobservable hydrogen exchange.

much in the trapping step. Intuitively it would seem that the sulfene trapping step would be the one giving most of the resolution but the possibility of some resolution occurring in the first stage, which gives sulfene and menthylamine hydrochloride, cannot be dismissed without evidence. If the (+)-amine, for example, were to react faster than the (−)-amine and *if* the excess (+)-amine hydrochloride so formed were relatively slow to donate a hydrogen to the (−)-amine, then the concentration of the free (−)-amine would exceed that of the free (+)-amine and kinetic resolution could ensue even if the rate constants for trapping of the sulfene by the two amines were the same. The slow hydrogen transfer required by this supposition might conceivably arise if there were either (*a*) very rapid precipitation of the amine hydrochloride or perhaps (*b*) tight aggregation of the hydrochloride. The former is excluded in the present instance, however, by the fact that in this case the amine hydrochloride, uniquely in our experience, does not precipitate from benzene or toluene solution.

In the absence of information about how readily the proton is transferred from the (+)-hydrochloride to the (−)-amine under these conditions, we answered the question of how much kinetic resolution arises in each of the two steps of the reaction simply by measuring each directly, *i.e.*, by (*a*) determining the rate constants for the reaction of $\mathbf{1}a_+$ with $\mathbf{2}a_+$ and $\mathbf{2}a_-$, respectively, and (*b*) measuring the stereoselectivity of the second step under conditions in which the sulfene is generated by an achiral base and hence without any possibility of kinetic resolution in that step.

For the reaction of $\mathbf{1}a_+$ with $\mathbf{2}a_+$ and $\mathbf{2}a_-$ in toluene at −10° we obtained good second-order plots for >60% reaction, from which we calculated the rate constants, 2.49×10^{-2} and 2.41×10^{-2} M^{-1} s^{-1} for $\mathbf{2}a_+$ and $\mathbf{2}a_-$, respectively. These results clearly show that virtually no kinetic resolution could arise in the sulfene forming step, even in the unlikely circumstance of a complete absence of any kind of proton exchange between the amines and their hydrochlorides. Okamoto *et al.* (2) measured the rate of the reaction of $\mathbf{1}a_+$ and $\mathbf{2}a_-$ in toluene at somewhat lower temperatures and higher concentration and obtained slightly curved rate plots; extrapolation of their data to −10° gives a rate constant of 2.8×10^{-2} M^{-1} s^{-1} in fair agreement with our value. It is evident from the above results (which confirm the reasoning given in the Introduction) that there is no relationship between the ratio of the above rate constants (for the reactions of $\mathbf{2}a_+$ and $\mathbf{2}a_-$) and the product ratios, and that the procedure of Okamoto *et al.* for estimating the rate constant for the reaction of $\mathbf{2}a_+$ on the assumption of such a relation is therefore incorrect.

In order to measure the stereoselectivity in the second step without any complications arising in the first step, it was necessary to find an achiral base which reacts at a sufficiently fast rate to be the principal reagent effecting dehydrohalogenation of **1**. 1,4-Diazabicyclo[2.2.2]octane (DABCO) was found to react with $\mathbf{1}a_+$ in toluene at −10° using 2-propanol as the sulfene trap, with a rate constant of 2.26×10^{-1} M^{-1} s^{-1}, *i.e.* almost 10 times that for either of the menthylamines. In a reaction of $\mathbf{1}a_+$ with DABCO and $\mathbf{2}a_\pm$ (molar ratio 1:4:2) in toluene at −10°, in which virtually all of the sulfene would be formed by reaction of $\mathbf{1}a_+$ with DABCO, we observed a product ratio $\mathbf{3}a_{+-}/\mathbf{3}a_{++}$ of 1.9. In the absence of DABCO, using the same conditions and quantities, exactly the same product ratio was obtained.

It is clear that the kinetic resolution discussed here arises more or less entirely in the reaction of the chiral sulfene with chiral traps; this work constitutes the first demonstration that sulfenes show sufficient discrimination in their reaction with enantiomers to be able to lead to significant kinetic resolution. As has been noted already by Okamoto *et al.* (2), there is a measure of consistency in the stereochemistry of the amine which reacts faster with the sulfene derived from $\mathbf{1}a_+$; in each case the faster reacting enantiomer of menthylamine, neomenthylamine, and isomenthylamine has the configuration shown in **4**. Okamoto *et al.* point out that this is the *R* configuration and that the faster reacting enantiomer had the *R* configuration in three of their four other cases which showed any resolution at all and in which the absolute configuration was known. In our view the use of the Cahn–Ingold–Prelog descriptors (which are not based on, and only approximately correlated with, effective steric bulk) is less appropriate than merely ordering the groups attached to the carbon bearing the amino group as large, medium, and small (L, M, and S). Assuming that the methine bearing the isopropyl group is "larger" in the present sense than the methylene, this leads to the representation **5** for the faster reacting enantiomer of each

For personal use only.

of the menthylamines. The other amines studied by Okamoto *et al.* all show such low stereoselectivities[3] (3% or less) that it is doubtful if their results with these compounds can be of much value in determining the geometry of the sulfene trapping reaction. The consistency shown in the reactions of the three diastereomeric menthylamines suggests that the observed kinetic resolution ought to be explicable in simple conformational terms, but in our view the mechanism of the addition of amines to sulfenes is not sufficiently well understood to warrant such an explication at present.

The Rate–Product Discrepancy, Nonreciprocal Kinetic Resolution, and the Intermediacy of a Sulfene

In the above subsection it is noted that the ratio of the measured rate constants differs from the ratio of the products. It was pointed out a number of years ago by Ingold and co-workers (7, 8) that such a rate–product discrepancy *requires* the presence of an intermediate (see also refs. 9 and 10); in the present instance this intermediate may be identified as the sulfene. Although evidence from deuteration experiments for the involvement of sulfene has already been presented, corroboration is not unwelcome.

It is of interest that although we have presented kinetic evidence for the intermediacy of sulfene before (3), our previous method is inapplicable in the present case. We had previously shown that the rate of the reaction of methanesulfonyl chloride, triethylamine and 2-propanol (which leads to isopropyl methanesulfonate) was independent of the 2-propanol concentration, thereby requiring the presence of an intermediate which reacts with the alcohol in a fast second step. With the reaction of **1***a* and **2***a*, **2***a* is the sulfene generating base as well as the trap and the reaction is first order in **2***a*; this circumstance no longer allows the sulfene mechanism and, for example, the direct displacement process to be differentiated by the kinetic order of the reaction. The observation of the rate–product discrepancy, however, does allow such a distinction, and hence is complementary to our earlier study (3).

Very closely related to the rate–product discrepancy is the phenomenon that we have named "nonreciprocal kinetic resolution" which, as we have recently pointed out (11), arises in the reaction of **1***a* and **2***a*. The defining feature of nonreciprocal kinetic resolution is that the stereoselectivity[3] of the reaction of, say, $\mathbf{A}_{\pm}$ with $\mathbf{B}_{+}$ is *different* from that of $\mathbf{B}_{\pm}$ with $\mathbf{A}_{+}$. In the present case we found a stereoselectivity of about 30% in the reaction of $\mathbf{1}_{+}$ with $\mathbf{2}_{\pm}$ (in ageement with previous reports (1, 2)), whereas with $\mathbf{1}_{\pm}$ and $\mathbf{2}_{-}$ there was little or no stereoselectivity ($1 \pm 1\%$) (11). It can be shown that under pseudo first-order conditions the product ratio from the reaction of $\mathbf{1}_{\pm}$ with $\mathbf{2}_{-}$ gives the ratio of the measured rate constants (11) and hence, that as means of demonstrating the presence of an intermediate, the rate–product discrepancy and nonreciprocal kinetic resolution are identical in their essential argument but are quite different experimentally: the former requires kinetic measurements but can be used with achiral reagents; the latter requires that a chiral intermediate react with a chiral reagent but dispenses with measurement of rates. The use of kinetic resolution promises to be of considerable value in a number of ways in the study of reaction mechanisms, but the topic is sufficiently extensive that we shall defer further discussion to a later account.

Practical Synthetic Application of Kinetic Resolution via Sulfenes

The purpose of the present study was primarily, of course, mechanistic and only peripherally concerned with the practical problem of resolution of racemic modifications. Except for enzymic processes, kinetic asymmetric transformations (of which kinetic resolution is an example) have found relatively little practical application in the resolution of racemic materials. In the course of this work we required a sample of (+)-menthylamine, the "unnatural" enantiomer, and in fact to obtain our first sample we used the partially resolved mixture as our starting material for the resolution via the tartrates (12). The resolution was completed without difficulty but there was no clear evidence that this route is any more efficient than starting with $\mathbf{2}_{\pm}$. Cursory examination of the mixture of diastereomeric sulfonamides (**3**) obtained by reaction with $\mathbf{1}_{+}$ did not lead to any easy method for separating the components; recrystallization gradually leads to enrichment in the originally less abundant isomer (derived from $\mathbf{2}_{+}$) but the process in our hands was slow.

A spectacular illustration of the practical use-

[3]Percent stereoselectivity is defined (6) as $100(D_1 - D_2)/(D_1 + D_2)$, where D_1 and D_2 refer to the yields of the diastereomers produced in the greater and lesser amounts, respectively.

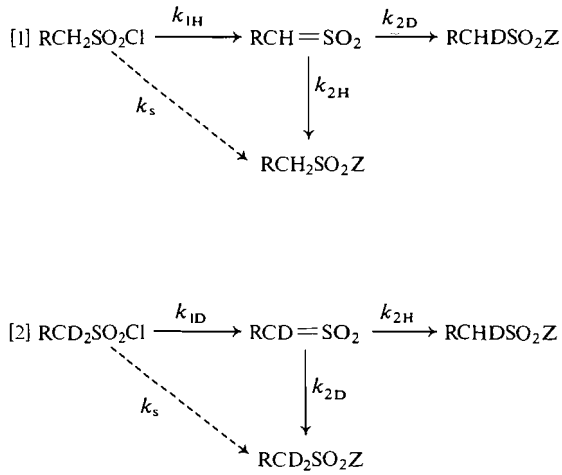
fulness of kinetic resolution was recently described by Wiesner *et al.* (13), who found that one enantiomer of their synthetic relay for the total synthesis of the alkaloid delphinine reacted more or less *quantitatively* with $\mathbf{1}a_-$ and pyridine leaving the desired "natural" enantiomer essentially uncontaminated with the enantiomer of the unnatural configuration. Since **1***a* reacts with a mixture of pyridine and piperidine-*d* (which like the delphinine relay is a cyclic secondary amine) to give the monodeuteriated sulfonamide, it seems highly likely that the remarkable resolution achieved by Wiesner *et al.* occurred via the sulfene.

The Direct Displacement Reaction

Although, as is noted above, the deuterium labelling experiments indicate that at least 80% of the product is formed by the sulfene mechanism, there is some "unexchanged" product generated; from $\mathbf{1}a_+$ and $\mathbf{2}c_-$ this amounts to about 8% of the total and with $\mathbf{1}c_+$ and $\mathbf{2}a_-$ there is 13 to 14% "unexchanged" sulfonamide (**3***c*). This raises the question of whether there is another, concurrent mechanism and if there is, what is its stereoselectivity?

One straightforward explanation for these data is that there is simply a non-sulfene mechanism, presumably a direct displacement on sulfur, which contributes to a small but significant extent. Such a mechanism has been accepted for a long time as the mechanism of reaction of arenesulfonyl chlorides (see ref. 14 and the earlier work cited therein) and presumably operates with other sulfonyl chlorides lacking α-hydrogens. Though the possibility has been raised (15, 16), clear evidence for its incursion in the reaction of amines with those alkanesulfonyl chlorides that bear α-hydrogens has been lacking. We wish to show here that our data for the reaction of **1** and **2** are *not* consistent with any mechanism that we have been able to devise in which all of the product is formed via the sulfene but are in good agreement with a sulfene process together with a small contribution by a direct displacement mechanism. Deuterium labelling experiments (some of which have been mentioned above) and a determination of the rate constant for the reaction of $\mathbf{1}c_+$ with $\mathbf{2}a_-$ ($7.36 \times 10^{-3}\ M^{-1}\ s^{-1}$) are consistent with the following approximate values relating the parameters in Scheme 1: $k_{1H}/k_S = 30$, $k_{1H}/k_{1D} = 3.3$, $k_{2H}/k_{2D} = 1.15$, and $k_{1D}/k_S = 9$; *i.e.* with menthylamine about 3% of the reaction of $\mathbf{1}a_+$



SCHEME 1

and 10% of the reaction of $\mathbf{1}c_+$ proceed via the direct displacement process.

In contrast to the ease with which our experiments may be accommodated by assuming a small amount of direct displacement, a number of difficulties arise if we attempt to account for the data exclusively on the basis of the sulfene processes (indicated by the solid arrows in Scheme 1). A portion of the "unexchanged" product can, and indeed must, arise by uptake during the trapping step of some of the hydrogen isotope released into the medium by the formation of the sulfene from the sulfonyl chloride. In the present experiments there were 10 mol of amine (each with two hydrogens) for each mol of sulfonyl chloride (each releasing one hydrogen) and hence, if there were no kinetic isotope effect in the trapping step, 5% of the product would be "unexchanged" product formed by such a process. But we have observed that starting with *either* $\mathbf{1}a_+$ or $\mathbf{1}c_+$ the amount of "unexchanged" product is greater than 5%, and hence this mechanism is not sufficient to account for all of the "unexchanged" material. Further, a kinetic isotope effect in the trapping step would not help matters since to the extent that it would allow a proportion of unexchanged product greater than 5% for one reaction, it would require a corresponding amount less than 5% for the other.

A variation in the above mechanism has been discussed earlier (16) but for the reasons which follow it seems to us unlikely to be of significance in the present system. This mechanism

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

postulates that the sulfene trapping step is sufficiently fast that the hydrogen recently abstracted from the sulfonyl chloride has not had sufficient time to diffuse very far from the reaction site and hence there is a higher *local* concentration of the isotope originally on the sulfonyl chloride in the vicinity of the sulfene trapping reaction than in the body of the reaction as a whole. In such a scheme the factor deciding the ratio of "unexchanged" product to exchanged in, say, reaction 1 is not the overall ratio of active hydrogen to active deuterium as determined by the ratios of the starting materials but rather the average effective ratio of available protons to deuterons while the sulfene trapping process is taking place. We shall designate this "effective ratio of H to D" by x and hence the ratio of "unexchanged" to exchanged product in [1] is $(RCH_2SO_2Z/RCHDSO_2Z)_1 = k_{2H}x/k_{2D}$.

Similarly, if we designate the corresponding "effective ratio of D to H" in reaction 2 as x', then $(RCD_2SO_2Z/RCHDSO_2Z)_2 = k_{2D}x'/k_{2H}$.

It seems likely that in the reaction medium used for these experiments (methylene chloride) simple diffusion is the principal mechanism by which the hydrogen recently abstracted from the sulfonyl chloride departs from the site of sulfene formation. Further, the diffusion rates for the amine or ammonium salt will be much the same whether protiated or deuteriated, and therefore it seems likely that x and x' would be approximately equal. This leads to the approximation $(RCD_2SO_2Z/RCHDSO_2Z)_2 \approx k_{2D}x/k_{2H}$ and hence to eq. 3.

$$[3]\quad \frac{(RCH_2SO_2Z/RCHDSO_2Z)_1}{(RCD_2SO_2Z/RCHDSO_2Z)_2} \approx \left(\frac{k_{2H}}{k_{2D}}\right)^2$$

From the data already presented above, in the reactions of $\mathbf{1}c_+$ and $\mathbf{2}a_-$, and $\mathbf{1}a_+$ and $\mathbf{2}c_-$, the left side of eq. 3 is numerically equal to $8/90 \div 14/83 = 0.53$ or $k_{2H}/k_{2D} = 0.73$. In other words, in order to account for the amounts of "unexchanged" product from $\mathbf{1}a_+$ and $\mathbf{1}c_+$ on the basis of the "local concentration effect", there must be a distinct inverse isotope effect in the sulfene trapping step.

Such an isotope effect, however, does not show up in the reaction of this sulfene with menthylamine. This was shown by treating $\mathbf{1}a_+$ and $\mathbf{1}c_+$ each with a mixture obtained by combining equal quantities of $\mathbf{2}a_-$ and $\mathbf{2}c_-$ (*i.e.* an equilibrium mixture of $\mathbf{2}a_-$, $\mathbf{2}c_-$, and $\mathbf{2}b_-$ with the last predominating). The respective amounts of RCH_2SO_2Z and $RCHDSO_2Z$ from $\mathbf{1}a_+$ were 56 and 41%, and of RCD_2SO_2Z and $RCHDSO_2Z$ from $\mathbf{1}c_+$ were 50 and 47%. It is clear simply from inspection of these results that there is no inverse isotope effect in the addition of menthylamine to the sulfene. (Alternatively, referring to eq. 3, these data yield a different value for k_{2H}/k_{2D} which, in effect, means that eq. 3 is not valid and hence that the "local concentration effect" does not account for the "unexchanged" products in the reactions of $\mathbf{1}a_+$ and $\mathbf{1}c_+$ with menthylamine.) Participation of the "local concentration effect" to some extent is not excluded by these results but as is mentioned above the data can be satisfactorily rationalized without using the hypothesis at all.

This leads us to return to the conclusion that the "unexchanged" product comes partly from a direct displacement process, and thereby raises a further question: is there any stereoselectivity in the direct displacement reaction of **1** and **2**? It would appear, in fact, that within the precision of our method, there is no significant kinetic resolution in this reaction. This conclusion is derived as follows. In the reaction of $\mathbf{1}c_+$ with the "other" enantiomer of menthylamine, *i.e.* $\mathbf{2}a_+$, the "unexchanged" material constituted 13% of the total; this, within experimental uncertainty, is the same as that found with $\mathbf{2}a_-$. This implies that k_1/k_S in the reaction with $\mathbf{1}_+$ is the same for $\mathbf{2}a_+$ and $\mathbf{2}a_-$. As has been mentioned in an earlier subsection, k_1, the rate of sulfene formation, is (except, of course, for the 3% direct displacement) given by the measured rate of chloride ion formation, and this was found to be virtually the same for $\mathbf{2}a_-$ and $\mathbf{2}a_+$ with $\mathbf{1}a_+$. It follows that the values of k_S for the reactions of $\mathbf{2}a_-$ and $\mathbf{2}a_+$ with $\mathbf{1}_+$ must also be about the same, *i.e.* there is no kinetic resolution detectable (by this means) in the direct displacement reaction path.

The conclusions drawn above led us to wonder if the low levels of stereoselectivity observed by Okamoto *et al.* (2) might arise because these bases were reacting by a direct displacement mechanism rather than a sulfene process. Reaction of one of these amines, (±)-1-phenylethylamine, with $\mathbf{1}c_+$, however, led to incorporation of roughly 80% of one protium equivalent at C-10 (as judged by n.m.r.), indicating that the sulfene reaction is also the major process with this amine, and hence that the low stereoselectivity observed does not arise because of a completely different

mechanism from that which operates with menthylamine.

Experimental

I.r. spectra were recorded in carbon tetrachloride or chloroform solution on a Beckman IR-10 or IR-20A instrument. The n.m.r. spectra were run in deuteriochloroform on a Varian HA-100, A-60, or T-60 spectrometer with tetramethylsilane as internal standard. Mass spectra were obtained with a Varian M-66 mass spectrometer. The methylene chloride, toluene, and dioxane used as reaction solvents were stored over molecular sieves and found by analysis with an Aquatest Automatic Karl Fischer titrator to contain < 50 p.p.m. of water. Melting points were determined on a Gallenkamp melting point apparatus and are uncorrected. Ether and toluene extracts were dried over anhydrous magnesium sulfate. Methylene chloride extracts were dried by washing with saturated sodium chloride solution then passing through a small plug of cotton wool. Solvents were removed from solutions with a rotary evaporator in conjunction with a water aspirator.

Camphor-10-sulfonyl Chlorides $\mathbf{1}a_+$ *and* $\mathbf{1}a_\pm$

These compounds were prepared according to the method of Smiles and Hilditch (17). Treatment of (+)-camphor-10-sulfonic acid (Aldrich Chemical Co.) (20 g, 86 mmol) with thionyl chloride (43 g, 360 mmol) gave 19 g (76 mmol, 88%) of (+)-camphor-10-sulfonyl chloride. Recrystallization from cyclohexane yielded colorless plates, m.p. 66–67°; lit. (17) m.p. 67–68°.

In a similar manner, $\mathbf{1}a_\pm$ was prepared from (±)-camphor-10-sulfonic acid (18) in 80% yield, m.p. 83–84.5°; lit. (17) m.p. 81–83°.

The n.m.r. spectrum ($CDCl_3$) showed bands at δ 2.70–1.50 (m, 7H), 1.15 (s, 3H), 0.95 (s, 3H), and the C-10 methylene protons appeared as an AB quartet (δ_A 4.33 1H, δ_B 3.80 p.p.m. 1H, J = 14 Hz).

(+)-Camphor-10-sulfonyl-10-d_2 Chloride $\mathbf{1}c_+$

To a solution of (+)-camphor-10-sulfonyl chloride ($\mathbf{1}a_+$) (5.0 g, 20 mmol) in dioxane (20 ml) was added slowly by means of a dropping funnel a solution of triethylamine (15 ml), D_2O (15 ml), and dioxane (10 ml). The resulting solution was stirred for ½ h and then evaporated to dryness. The residue was taken up with CH_2Cl_2 and then treated with excess of phosphorus pentachloride (15 g, 72 mmol). The solution was washed with water until the washing was neutral. Solvent removal gave 4.5 g (18 mmol, 90%) of crude sulfonyl chloride $\mathbf{1}b_+$.

The n.m.r. spectrum showed partial deuteration at C-10 (δ 4.33, 0.74H; 3.80, 0.36H).

Further treatment of $\mathbf{1}b_+$ with triethylamine and D_2O followed by regeneration of the sulfonyl chloride with PCl_5 (four more cycles) gave 1.55 g (6.2 mmol, 31%) of product, $\mathbf{1}c_+$; the n.m.r. spectrum $(CDCl)_3$ showed almost complete absence of the absorption at δ4.33 and 3.80, corresponding to a maximum amount of about 10% of the monodeuteriated sulfonyl chloride ($\mathbf{1}b_+$).

Menthylamines $\mathbf{2}a_\pm$ *and* $\mathbf{2}a_-$

(±)-Menthylamine ($\mathbf{2}a_\pm$) (b.p. 120/155 mm) and (−)-menthylamine ($\mathbf{2}a_-$) (b.p. 100/14 mm) were prepared from the corresponding form of menthol following the method of Sandborn (19) and Andres and Andreef (20). Oxidation of (−)-menthol with sodium dichromate gave 79% yield of menthone, b.p. 142° 110 mm, lit. (19) b.p. 209°. Treatment of (−)-menthone with hydroxylamine acetate yielded menthone oxime in 64% yield. (−)-Menthylamine ($\mathbf{2}a_-$) was obtained in 95% yield by reducing the menthone oxime with sodium in ethanol. The hydrochloride of (−)-menthylamine had $[\alpha]_D$ −36.4° (H_2O); lit. (12) $[\alpha]_D$ −36.6° (H_2O).

(−)-Menthylamine-d_2 ($\mathbf{2}c_-$*)*

(−)-Menthylamine ($\mathbf{2}a_-$) (3.8 g, 25 mmol) dissolved in ether was shaken for ½ min or more with four batches of D_2O (5 ml each) in a separatory funnel. The solvent was then evaporated and the menthylamine distilled under reduced pressure (b.p. 120/150 mm). The deuterium content of the deuterated amine was determined by n.m.r. to be > 1.96 atom D/mol.

(+)-Camphor-10-sulfonyl-(−)-menthylamide ($\mathbf{3}a_{+-}$*)*

To a solution of (−)-menthylamine ($\mathbf{2}a_-$) (380 mg, 2.5 mmol) in CH_2Cl_2 was added a solution of (+)-camphor-10-sulfonyl chloride ($\mathbf{1}a_+$) (132 mg, 0.53 mmol) in CH_2Cl_2. The solution was kept at room temperature for 4 h. It was then washed twice with 1 *N* HCl solution and then with H_2O. After solvent removal, 180 mg (0.48 mmol, 90% yield) of crude sulfonamide $\mathbf{3}a_{+-}$ was obtained. Recrystallization from ether–pentane gave colorless needles, m.p. 137–138°, $[\alpha]_D$ −27.8° (benzene); lit. (1) m.p. 139° $[\alpha]_D$ −28.0 (benzene).

The n.m.r. spectrum ($CDCl_3$) showed the amine proton as a doublet at δ 5.15 (1H); the methylene protons at C-10 appeared as an AB quartet: δ_A 3.40 (1H), δ_B 3.04 (1H), J_{AB} = 14 Hz. The remaining protons appeared as complex multiplets at 2.40–0.80 p.p.m. (m, 32H).

The i.r. spectrum ($CHCl_3$) showed absorption at 3280 (NH), 1738 (C=O), 1310, and 1130 cm^{-1} (SO_2). The mass spectrum gave a molecular ion peak at *m/e* 369.

(+)-Camphor-10-sulfonyl-(+)-menthylamide ($\mathbf{3}a_{++}$*)*

Following the procedure described for the preparation of $\mathbf{3}a_{+-}$, the title compound was obtained from $\mathbf{1}a_+$ (126 mg, 0.5 mmol) and $\mathbf{2}a_+$ (115 mg, 1 mmol) in 78% yield. Recrystallization from 1:1 ether–pentane gave colorless needles, m.p. 142–143° $[\alpha]_D$ +61° (benzene). The enantiomer (−)-camphor-10-sulfonyl-(−)-menthylamide ($\mathbf{3}a_{--}$) is reported (1) to have m.p. 143° and $[\alpha]_D$ −60.1° (benzene).

The n.m.r. spectrum ($CDCl_3$) showed the amine proton as a doublet at δ 5.15 (1H); the two hydrogens on C-10 appeared as an AB quartet: δ_A 3.50 (1H), δ_B 3.00 (1H), J_{AB} = 14 Hz. The remaining protons appeared as a complex multiplet at 2.40–0.80 (32 H). The i.r. spectrum ($CHCl_3$) showed absorption at 3260 (NH), 1730 (C=O), 1310 and 1130 cm^{-1} (SO_2). The mass spectrum showed a parent ion peak at *m/e* 369.

Deuterium Exchange in the Reaction of Camphor-10-sulfonyl Chloride with Menthylamine

These reactions were carried out as described above for the preparation of (+)-camphor-10-sulfonyl-(−)-menthylamide ($\mathbf{3}a_{+-}$).

(a) $\mathbf{1}a_+$ *with* $\mathbf{2}c$

(+)-Camphor-10-sulfonyl chloride ($\mathbf{1}a_+$) (110 mg, 0.44 mmol) and (−)-menthylamine-d_2 ($\mathbf{2}c_-$) (665 mg, 4.2 mmol) in CH_2Cl_2 (6 ml) gave 152 mg (0.42 mmol, 93% yield) of (+)-camphor-10-sulfonyl-(−)-menthylamide-10-

For personal use only.

d ($3b_{+-}$). The n.m.r. spectrum ($CDCl_3$) showed partial deuteriation at C-10. The mass spectrum showed peaks at *m/e* 369 and 370, corresponding to 8% $3c_{+-}$ and 92% $3b_{+-}$. Control spectra of natural abundance sulfonamide ($3a_{+-}$) and of the same deuteriated sulfonamide sample at different times indicated that the error in these percentage compositions (and those which follow) is about ± 1 or slightly less. Intensity contributions from natural isotopes were calculated as described by Hamming and Foster (21).

(b) $1c_+$ *with* $2a_-$

(+)-Camphor-10-sulfonyl-10-d_2 chloride ($1c_+$) (69 mg, 0.3 mmol) with (−)-menthylamine ($2a_-$) (418 mg, 3 mmol) gave 78 mg (0.21 mmol, 78% yield) of the sulfonamide (3_{+-}). The n.m.r. spectrum showed protium incorporation at C-10 corresponding to roughly one hydrogen per molecule. The mass spectrum showed peaks at *m/e* 369, 370, and 371 corresponding to 3% $3a_{+-}$, 83% $3b_{+-}$, and 14% $3c_{+-}$.

A sample of partial deuteriated sulfonamide (containing mostly $3b_{+-}$) was allowed to stand with $2a_-$ in CH_2Cl_2 solution for 20 h at room temperature. The mass spectrum of the recovered material was identical within experimental error to that obtained prior to treatment with $2a_-$.

(c) $1c_+$ *with* $2a_+$

(+)-Camphor-10-sulfonyl-*10*-d_2 ($1c_+$) (30.4 mg, 0.12 mmol) and (+)-menthylamine (2_+) (187 mg, 1.2 mmol), obtained as described below, gave 30 mg (0.08 mmol, 67% yield) of the sulfonamide (3_{++}). The n.m.r. spectrum showed protium incorporation corresponding to uptake of roughly one protium atom at C-10 per molecule. The mass spectrum showed peaks at *m/e* 369, 370, and 371 corresponding to 4% $3a_{++}$, 83% $3b_{++}$, and 13% $3c_{++}$.

(d) $1a_+$ *with an Equimolar Mixture of* $2a_-$ *and* $2c_-$

(+)-Camphor-10-sulfonyl chloride ($1a_+$) (125 mg, 0.5 mmol) and 775 mg (5 mmol) of a mixture obtained by mixing equimolar amounts of (−)-menthylamine ($2a_-$) and (−)-menthylamine-d_2 ($2c_-$) gave 207 mg of sulfonamide (3_{+-}). The mass spectrum showed peaks at *m/e* 369 and 370 corresponding to 58% $3a_{+-}$ and 42% $3b_{+-}$.

(e) $1c_+$ *with an Equimolar Mixture of* $2a_-$ *and* $2c_-$

(+)-Camphor-10-sulfonyl-*10*-*d* chloride ($1c_+$) (127 mg, 0.5 mmol) and 805 mg (5.2 mmol) of the same equimolar mixture of $2a_-$ and $2c_-$ as used above gave 258 mg of sulfonamide (3_{+-}). The mass spectrum showed peaks at 369, 370, and 371 corresponding to 3% $3a_{+-}$, 47% $3b_{+-}$, and 50% $3c_{+-}$.

Kinetic Resolution Experiments

(a) (+)-Camphor-10-sulfonyl Chloride ($1a_+$*) with (±)-Menthylamine (*$2a$*)*

In a typical experiment, a solution of $1a_+$ (130 mg, 0.5 mmol) in toluene (10 ml) was mixed with a solution of $2a_\pm$ (156 mg, 1.0 mmol) in toluene (15 ml) at −10°. The homogeneous solution was kept at −10 ± 0.2° for 2 h and then allowed to warm up. It was then extracted twice with 1 *N* HCl solution, washed with water and dried. Solvent removal gave 149 mg (0.40 mmol, 81% yield) of a mixture of (+)-camphor-10-sulfonyl-(−)-menthylamide ($3a_{+-}$) and (+)-camphor-10-sulfonyl-(+)-menthylamide ($3a_{++}$). In the n.m.r. spectrum, the C-10 methylene proton signals as well as the amide proton signals of the two diastereomers were sufficiently separated to allow integration which showed the mixture to contain 65% of **3** and 35% of **4** corresponding to 30% stereoselectivity. The specific rotation ($[\alpha]_D$ +2.9° (benzene)) of the sulfonamide mixture showed a stereoselectivity of 30.8%.

The aqueous solution from the acid extraction was made basic with 6 *N* NaOH solution. The menthylamine liberated was extracted twice with CH_2Cl_2. The organic layer was then dried and solvent removed. The menthylamine obtained was treated with concentrated HCl giving 93 mg (0.49 mmol, 97%) of menthylamine hydrochloride. Its specific rotation $[\alpha]_D$ +10.6° (water) corresponded to a stereoselectivity of 30%.

(b) (±)-Camphor-10-sulfonyl Chloride ($1a_\pm$*) with (−)-Menthylamine (*$2a_-$*)*

A solution of $1a_\pm$ (252 mg, 1 mmol) in toluene (10 ml) was mixed with a solution of $2a_-$ (154 mg, 1 mmol) in toluene (5 ml) at −10°. After being kept at −10 ± 0.2° for 2 h, the solution was worked-up following the procedure described previously. The crude toluene extract after washing with HCl solution and evaporation of solvent was a mixture of $1a_\pm$ (50%), $3a_{+-}$ (25%), and $3a_{--}$ (25%) as shown by n.m.r. spectroscopy.

This mixture was then dissolved in 1,2-dimethoxyethane. The unreacted sulfonyl chloride was hydrolyzed with 6 *N* NaOH solution. After acidification, the solvent was evaporated and the residue taken up with CH_2Cl_2. After washing with H_2O, drying, and solvent removal, 160 mg (0.43 mol, 86%) of a mixture (as shown by n.m.r.) of $3a_{+-}$ (50%) and $3a_{--}$ (50%) was obtained. The optical rotation of the sulfonamide mixture ($[\alpha]_D$ −44.2° (benzene)) corresponded to stereoselectivity of 1%.

(c) (+)-Camphor-10-sulfonyl Chloride ($1a_+$*) with DABCO and (±)-Menthylamine (*$2a_\pm$*)*

A solution of $1a_+$ (124 mg, 0.5 mmol) in toluene (10 ml) was mixed with a solution of $2a_\pm$ (156 mg, 1 mmol) and 1,4-diaza[2.2.2]bicyclooctane (DABCO) (230 mg, 2 mmol) in toluene (5 ml) at −10°. The solution was kept at −10 ± 0.2° for 2 h and then allowed to warm to room temperature. It was extracted twice with 1 *N* HCl solution, then with H_2O and dried. Removal of solvent left 140 mg (0.38 mmol, 76%) of crude sulfonamide mixture estimated by n.m.r. to contain 65% $3a_{+-}$ and 35% $3a_{++}$, corresponding to a stereoselectivity of 30%.

Resolution of (±)-Menthylamine ($2a_\pm$*)*

The partially resolved menthylamine (0.37 g, 214 mmol) recovered from a reaction of $1a_+$ with excess $2a_\pm$ was treated with an equimolar quantity of (+)-tartaric acid in warm alcohol. After solvent removal, the crude menthylamine hydrogen tartrate was recrystallized (five times) from water to give 64 mg (0.2 mmol, 8.3%) of (+)-menthylamine-(+)-hydrogen tartrate, m.p. 166–167°, $[\alpha]_D$ + 37.6° (H_2O), lit. (12) m.p. 168°, $[\alpha]_D$ + 37.1° (H_2O)). This provided a sample of seeds for future fractional recrystallizations of material obtained by reaction of (+)-tartaric acid with (±)-methylamine (not partially resolved). The free $2a_+$ was obtained by extraction of a basified aqueous solution of the tartrate with CH_2Cl_2, followed by removal of the solvent and distillation under reduced pressure.

Kinetic Measurements

A stock solution of $1a_+$ (or $1c_+$) in toluene was prepared by dissolving a known weight of 1_+ in toluene. The

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

initial concentration of the solution was determined by titration of chloride with silver nitrate solution (0.025 *N*) after the solution was allowed to react with the base solution for an interval of at least 10 half-lives.

A stock solution of base about ten times as concentrated as the substrate solution was also prepared by dissolving the calculated amount of base in toluene. The concentration of the base was determined by titration with standard HCl solution (0.1 *N*).

For rate measurement, 5 ml of the substrate solution and 5 ml of base solution kept in separate flasks were immersed into the constant temperature (±0.2°) compartment of the "Kryothermat KT-62" as described previously (3). After ½ h, when both solutions reached the desired temperature (−10° the two solutions were mixed as quickly as possible. Timing was started at the beginning of the mixing. After the appropriate time interval, the reaction was quenched with 2 ml of cold saturated formic acid in toluene. The resulting solution was then extracted twice with 20 ml of water and the combined aqueous solution was titrated with silver nitrate solution (0.025 *N*).

The rate constants were obtained from the slope of a plot of $\log [b - 2x)/(a - x)$ *vs.* t, where b is the initial concentration of base, a the initial concentration of $\mathbf{1}_+$ and x the amount of reaction after time t. At least five points in the range from 10% to at least 60% reaction were measured to construct the plots. For the reaction of $\mathbf{1}_+$ with DABCO and 2-propanol, the procedure was the same except that the 2-propanol was mixed with the base, and $\log [(b - x)/(a - x)$ vs. t was plotted to obtain the rate constant.

Reaction of (+)-Camphor-10-Sulfonyl-10-d_2 Chloride ($\mathbf{1}c_+$) with (±)-1-Phenylethylamine

(+)-Camphor-10-sulfonyl-*10-d_2* chloride ($\mathbf{1}c_+$) (160 mg, 0.63 mmol) was added to a solution of (±)-1-phenylethylamine (766 mg, 6.3 mmol) in CH_2Cl_2 (13 ml) and the mixture left for 4½ h. It was then washed with 1 *N* HCl and water, and dried. Removal of the solvent left an essentially quantitative yield of the sulfonamide (mixture of diastereomers). The n.m.r. spectrum showed peaks at the appropriate positions in the range 2.5–3.5 p.p.m. corresponding in intensity to roughly 80% of one protium in C-10. The positions of the C-10 methylenes in the fully protiated diastereomeric sulfonamides were obtained by examining the n.m.r. spectra of the crude product obtained similarly from $\mathbf{1}a_+$. The intensities of these two C-10 AB quartets were approximately the same, indicating that under these conditions there is little or no kinetic resolution in the reaction, *i.e.* the result is much the same as that observed by Okamoto *et al.* (2) for the reaction in benzene at 27–30°.

Reaction of (+)-Camphor-10-Sulfonyl Chloride ($\mathbf{1}a_+$) with Piperidine-d and Pyridine

Piperidine (4 ml) was dissolved in D_2O (5 ml) and then extracted with CH_2Cl_2 (10 ml). The CH_2Cl_2 layer was shaken for ½ min with four more batches of D_2O (5 ml) and then passed through a plug of cotton wool into a 50-ml flask. Fractional distillation gave piperidine-*d* (1.2 ml).

To a solution of piperidine-*d* (1 ml, 860 mg, 10 mmol) in pyridine (2 ml) was added (+)-camphor-10-sulfonyl chloride (125 mg, 0.5 mmol). After 3½ h at room temperature, the mixture was taken up in ether, washed twice with 3 *N* HCl and once with water, and dried. Removal of the solvent gave 118 mg of product which except for the region 2.5–3.5 p.p.m. was identical with that obtained by similar treatment of ordinary (protiated) piperidine. The 2.5–3.5 p.p.m. region in the spectrum of the amide from the ordinary piperidine shows an AB quartet δ_A 2.72, δ_B 3.28, J = 14 Hz with a large unresolved peak at 3.22 p.p.m. (due to the nitrogen-bearing methylenes of the piperidine) superimposed. The product from the reaction with piperidine-*d* showed only a small residue of the AB quartet and a new peak at 2.75 p.p.m. appropriate to a CHD replacing a CH_2 group; the corresponding peak expected at ~3.25 p.p.m. was obscured by the large peak at 3.22 p.p.m. A control experiment with piperidine-*d* and the natural-abundance sulfonpiperidide showed that no significant deuterium uptake occurs after formation of the amide.

We thank the National Research Council of Canada for financial support of this work.

Reduction of 5α-Cholestan-3-one with Water as a Hydrogen Donor in the Presence of Precipitated Metals[1]

MASAYOSHI ISHIGE, MICHIO SHIOTA, AND YUKIKO IDENO
Chemical Laboratory, Ochanomizu University, Otsuka, Bunkyo-ku, Tokyo, Japan

Received April 26, 1973

Reduction of 5α-cholestan-3-one with various precipitated metals using water as a hydrogen donor was investigated. Precipitated cobalt in *t*-BuOH and nickel in dioxane afforded 5α-cholestan-3α-ol favorably. Some multi-component precipitated metals were found to show high activity.

On a examiné la réduction de la 5α-cholestanone-3 par divers métaux précipités et utilisant de l'eau comme donneur d'hydrogène. Du cobalt précipité dans le *t*-BuOH et du nickel dans la dioxanne mènent favorablement au 5α-cholestanol-3α. On a trouvé que quelques métaux précipités contenant plusieurs composants possèdent une grande activité. [Traduit par le journal]

Introduction

Some information has been given on the features of the reduction catalyzed by precipitated nickel (1–4), which is performed by heating organic substrates with water in the presence of precipitated nickel (ppt-Ni in abbreviation).[2] One of the unique characteristics of this reaction is the fact that water is used as a hydrogen donor. In comparison with the studies on the utility and mechanism of the reaction, the stereochemistry has been examined to a lesser extent. Furthermore, the slowness of the reaction often presents difficulties, especially when the dioxane–water mixed solvent is used.

With the purpose of studying this reduction method further, we investigated the reactivity and stereochemistry in the reduction of 5α-cholestan-3-one using various ppt-metals. The condition under which the formation of 5α-cholestan-3α-ol was favored was also examined.

Experimental

A. Precipitated Metals

1. Ppt-Ni[3]

A mixture of zinc dust (10 g) and distilled water (*ca.* 3 ml) in an Erlenmeyer flask was heated to 80 °C. An aqueous solution (10 ml) containing 4.04 g of nickel chloride (hexahydrate), pre-heated at 80 °C, was added to the hot zinc dust mud at once with vigorous shaking. A violent ion-exchange reaction was stopped by cooling with water after about 2 min. The deposited solid was collected on a filter paper by suction, washed successively with water, ethanol, and ether, and then dried on a filter paper. The ppt-Ni thus obtained contains about 1 g of nickel, supported on zinc metal and zinc compounds.

2. Ppt-Co and Ppt-Cu[3]

Instead of nickel chloride, 4.04 g of cobalt(II) chloride (hexahydrate) and 2.86 g of copper(II) chloride (dihydrate) were used with 10 g of zinc for the preparation of ppt-Co and ppt-Cu respectively, by the procedure described above.

3. Ppt-metals of Multi-component System

Ppt-Ni–Co (2:1) and ppt-Ni–Cu (2:1)[4] were prepared by using a mixture of 2.69 g of nickel chloride and either 1.34 g of cobalt(II) chloride or 0.95 g of copper(II) chloride. Ppt-Ni–Co–Cu (2:1:1) was prepared from a mixture of 2.02 g of nickel chloride, 1.01 g of cobalt(II) chloride, and 0.72 g of copper(II) chloride.

Other ppt-metals were also prepared from the mixture of the corresponding metal chlorides as follows: ppt-Ni–Co (10:1), 3.67 g of nickel chloride and 0.37 g of cobalt(II) chloride; ppt-Ni–Cu (10:1), 3.67 g of nickel chloride and 0.26 g of copper(II) chloride; ppt-Ni–Mn (10:1), 3.67 g of nickel chloride and 0.31 g of manganese(II) chloride (tetrahydrate); ppt-Ni–Co–Cu (20:2:1), 3.51 g of nickel chloride, 0.35 g of cobalt(II) chloride, and 0.12 g of copper(II) chloride; ppt-Ni–Co–Mn (20:2:1), 3.51 g of nickel chloride, 0.35 g of cobalt(II) chloride, and 0.15 g of manganese(II) chloride; ppt-Ni – Co – Cr (20:2:1), 3.51 g of nickel chloride, 0.35 g

[1]Presented in part at the 28th Annual Meeting of the Chemical Society of Japan in Tokyo, Japan, April 1973.

[2]The ppt-Ni itself possesses no ability to catalyze the ordinary hydrogenation with hydrogen gas. However, the acid or alkali treatment of ppt-Ni leads to Urushibara nickel catalysts; *cf.* ref. 5.

[3]It has been shown that various kinds of ppt-metals are obtainable as the result of the different combinations of the source materials used and the procedures employed. In this work, we adopted the ordinary types of ppt-Ni, -Co, and -Cu prepared by the simplified procedure; see footnote 2, pp. 29–60.

[4]The numerals in parentheses denote the ratio of atom numbers of the metals based on the metal chlorides used as source materials of each ppt-metal. The representation of zinc ratio is ignored.

For personal use only.

of cobalt(II) chloride, and 0.20 g of chromium(III) chloride (hexahydrate).

B. Reduction

1. Reduction with Ppt-metals (Tables 1 and 2)

A mixture of 18 mg of 5α-cholestan-3-one, 3 ml of an organic solvent, 0.1 ml of water, and 0.20 g of each ppt-metal was kept at 80–83 °C for 20 h in a sealed tube.

2. Reduction with Ppt-metals of Higher Activity (Table 3)

Each sealed tube containing 0.200 g of ppt-metal and 1.00 ml portion of the solution prepared from 5α-cholestan-3-one (180 mg), *t*-BuOH (10 ml), and H_2O (1.00 ml) was kept at 80 ± 0.1 °C for 65 min.

C. Analysis

The reaction mixture was analyzed by gas chromatography after trimethylsilylation of the resulting sterols with *N,O*-bis(trimethylsilyl)acetamide. The gas chromatograms were taken on Shimadzu GC-4APF instrument by using a glass column packed with 1.5% Silicone OV-17 on silanized Shimalite W (80–100 mesh, 4 mm ϕ × 3 m) under the following conditions: column temperature, *ca.* 250 °C; carrier gas, nitrogen; flow rate, *ca.* 0.91 ml/s; detector, HFID.

Results and Discussion

Effect of Organic Solvents on the Reaction

Effect of organic solvents on the reactivity and stereoselectivity on the reduction of 5α-cholestan-3-one with ppt-Ni is shown in Table 1. It was found that the ketone was much more readily reduced to corresponding sterols in a protic solvent than in an aprotic solvent. The effect of the alcohols used on the relative reactivity was found to be in the following order; *n*-BuOH > *i*-PrOH > *t*-BuOH. Methanol and ethanol as solvents were undesirable because of low solubility of the substrate in these solvent–water systems. The alcohols probably play a dual role, serving both as a solvent and as a hydrogen donor, since the steroid ketone was hydrogenated in anhydrous *t*-BuOH to some extent. However, from the fact that the reduction occurred much faster in *t*-BuOH–H_2O than in *t*-BuOH alone, it may be concluded that coexistence of water and the alcohol is greatly responsible for the acceleration of the reaction.

TABLE 1. Solvent effect on the reduction of 5α-cholestan-3-one with ppt-Ni*

Solvent†	Ketone reacted (%)	Composition of the products (%) 3α-ol	3β-ol
Isopropyl alcohol	89	42	58
n-Butyl alcohol	95	48	52
t-Butyl alcohol	82	39	61
Dioxane	15	59	41
Tetrahydrofuran	5	38	62

*The results in Tables 1–3 were reproducible within 3% error with respect to the ketone reacted and within 2% error with respect to the composition of the products.

†Each organic solvent is used by mixing it with a given amount of water required for the reduction.

In aprotic solvents, such as dioxane and tetrahydrofuran, the reaction proceeded very slowly.

With regard to stereoselectivity of the products, the results were not so different in *i*-PrOH, *t*-BuOH, and tetrahydrofuran (39–42% with respect to 3α-ol). *n*-Butyl alcohol was, however, slightly favorable for the formation of 3α-ol. It was observed that dioxane characteristically favored the formation of 3α-ol rather than 3β-ol.

General Aspects of the Activities of Ppt-metals

It was previously suggested that ppt-metal with higher activity would be obtainable by a proper combination of metals (2, 3). Thus, we have prepared ppt-metals of multi-component systems and applied them to the reduction of 5α-cholestan-3-one. The results of representative experiments in *t*-BuOH–H_2O (listed in Table 2) show the relative activities of ppt-metals in the following order: Ni – Co – Cu (2:1:1) > Ni–Co (2:1) ≃ Ni–Cu (2:1) ≃ Ni > Co > Cu. The result indicates that coexistence of cobalt and copper with nickel may effectively promote the activity of nickel catalyst, though cobalt or copper itself contributes slightly to the change in activity of nickel.

However, it must be pointed out that the activity of each ppt-metal depends on the reaction conditions. In dioxane–H_2O, the order of relative activities alters as follows: Cu > Ni – Co – Cu (2:1:1) ≃ Ni–Cu (2:1) ≃ Ni ≃ Ni–Co (2:1) > Co. From the facts, it is inferred that some metals are sensitively deactivated by dioxane and others are not;[5] for instance, cobalt is strongly poisoned by dioxane, whereas copper is hardly deactivated by it. As for the dependence of activity on solvents, nickel seems to rank between the two.

Preparation of Ppt-metals of Higher Activity

A suitable combination of metals with nickel

[5]Generally, the reduction was markedly retarded by a trace of chromium as a contaminant in 5α-cholestan-3-one; cobalt was the most strongly deactivated of all the metals used, while the activity of copper was hardly influenced.

TABLE 2. Activities and stereoselectivities of various ppt-metals in the reduction of 5α-cholestan-3-one in the mixed solvents of *t*-BuOH–H_2O and dioxane–H_2O

Solvent	Ppt-metal	Ketone reacted (%)	Composition of the products (%) 3α-ol	3β-ol
t-BuOH–H_2O	Ni	82	39	61
	Co	53	68	32
	Cu	47	28	72
	Ni–Co (2:1)	85	38	62
	Ni–Cu (2:1)	83	39	61
	Ni–Co–Cu (2:1:1)	90	36	64
Dioxane–H_2O	Ni	15	59	41
	Co	3	51	49
	Cu	43	39	61
	Ni–Co (2:1)	12	58	42
	Ni–Cu (2:1)	15	49	51
	Ni–Co–Cu (2:1:1)	15	62	38

was extensively explored to increase the catalytic activity of ppt-metal.

The data in Table 3 show the promotion in relative activity of ppt-Ni – Cu and Ni – Co – Cu, and, especially, of ppt-Ni–Mn and Ni–Co–Mn.

Though the precipitation of manganese by the ion-exchange reaction with zinc would not be expected, it is inferred that the inclusion of some manganese in precipitates may occur during the course of the preparation of ppt-Ni–Mn and ppt-Ni–Co–Mn, because manganese clearly contributes to the promotion of activity of both ppt-Ni–Co–Mn and Urushibara-Ni, Co,Mn-A which is prepared by the removal of zinc and zinc compounds from ppt-Ni–Co–Mn with acetic acid. This result also suggests that the catalytic activity of ppt-metal is largely dependent on the nature of the crystallite of nickel but not on zinc.

The addition of chromium was unfavorable for the increase of the catalytic activity of nickel.

TABLE 3. The results of the reduction of 5α-cholestan-3-one using various ppt-metals with higher activity

Ppt-metal	Ketone reacted (%)	Composition of the products (%) 3α-ol	3β-ol
Co	Trace	—	—
Ni	Trace	—	—
Ni–Co (10:1)	12	35	65
Ni–Cu (10:1)	32	33	67
Ni–Mn (10:1)	56	35	65
Ni–Co–Cu (2:1:1)	32	36	64
Ni–Co–Cu (20:2:1)	31	29	71
Ni–Co–Mn (20:2:1)	60	33	67
Ni–Co–Cr (20:2:1)	7	36	64

Relation between Metal and Stereoselectivity

It should be noted that the 3α-ol was favorably produced in *t*-BuOH–H_2O in the presence of ppt-Co (68%) (Table 2). On the other hand, ppt-Cu was the least selective for the formation of 3α-ol under the same reaction condition. In the *t*-BuOH–H_2O system, little difference in selectivity between other ppt-metals was observed in the formation of 3α-ol.

The intrinsic nature of cobalt to give favorably the 3α-ol proved to be invariable even in the conversion of ppt-Co to Urushibara-Co-A by acid treatment; for example, the hydrogenation of 5α-cholestan-3-one with Urushibara-Co-A in *t*-BuOH at 35 °C for 4 h under the hydrogen pressure of 100 kg/cm^2 gave 5α-cholestan-3α-ol (61% yield, m.p. 188–189 °C) and 5α-cholestan-3β-ol (39% yield, m.p. 140–141.5 °C). This result provides an example of the favorable formation of 3α-ol in 5α-steroid by the catalytic hydrogenation under the practically neutral condition.[6]

[6]The catalytic hydrogenation of 5α-cholestan-3-one with Urushibara-Ni-A in dioxane at 72–75 °C afforded 3α-ol in 62% yield. In *t*-BuOH, the formation of 3α-ol was not favored (38%) (6). These results were similar to those obtained with ppt-Ni.

TABLE 4. Reduction by refluxing 5α- and 5β-cholestan-3-one with water in the presence of ppt-Ni*

Substrate	Solvent	Ketone reacted (%)	Composition of the products (%)	
			3α-ol	3β-ol
5α-Cholestan-3-one	*t*-BuOH–H_2O	100	40	60
	Dioxane–H_2O	68	48	52
5β-Cholestan-3-one	*t*-BuOH–H_2O	80	*ca.* 100	—
	Dioxane–H_2O	44	99	1

*Reaction condition: substrate, 90 mg; ppt-Ni, 1.0 g; organic solvent, 5 ml; water, 0.5 ml; reaction time, 7 h.

As compared with the reactions in *t*-BuOH–H_2O, a general tendency to increase the selectivity of 3α-ol was observed in dioxane–H_2O in the presence of various ppt-metals (Table 2). However, in the cases with ppt-Cu and ppt-Ni–Cu (2:1), the trend was not so conspicuous as in other cases. When ppt-Co was used in dioxane–H_2O, the proportion of 3α-ol was decreased markedly.

Reduction of 5α- and 5β-Cholestan-3-one by Refluxing with Water in the Presence of Ppt-Ni

5α- and 5β-Cholestan-3-one were hydrogenated to the corresponding sterols by refluxing in *t*-BuOH–H_2O or dioxane–H_2O in the presence of ppt-Ni. The results are summarized in Table 4.

The composition of the products from 5α-cholestan-3-one in refluxing *t*-BuOH–H_2O was similar to that described in Table 2. 5β-Cholestan-3-one gave exclusively the 3α-ol.

In refluxing, a long reaction time was required for the completion of the reaction as compared with the case in a sealed tube. The reasons may be attributable mainly to the loss of generated hydrogen gas and to the deactivation of nickel by oxygen in the air.

The reduction with ppt-Co under reflux was not conducted effectively. This result may also be attributed to the fact that ppt-Co is sensitive to catalyst poisons.

It was observed that 3β-acetoxy-5α-cholestan-6-one was not reduced by this method. This fact may indicate that reduction by this method may be influenced by the steric environment at C-6.

The Interaction of Sulfite Ion with 2,4,6-Trinitrobenzaldehyde: Kinetic, Equilibrium, and Proton Magnetic Resonance Studies

NEVEN MARENDIC AND ALBERT RICHARD NORRIS
Department of Chemistry, Queen's University, Kingston, Ontario

Received June 4, 1973

Sulfite ion reacts with 2,4,6-trinitrobenzaldehyde in aqueous solution of ionic strength 0.14 *M* to yield a 1:1 σ-complex at low sulfite concentrations and a 2:1 σ-complex at high sulfite concentrations. The visible absorption characteristics of these two σ-complexes as well as equilibrium constants and relevant thermodynamic parameters for their formation have been determined. P.m.r. studies demonstrate that two isomeric forms of the 1:1 σ-complex occur in aqueous dimethylsulfoxide solution and two isomeric forms of the 2:1 σ-complex occur in water. In both the 1:1 and the 2:1 complexes isomers are found which contain sulfite ion attached to the C-1 carbon and one of the isomeric 2:1 σ-complexes is postulated to exist in *cis* and *trans* forms. Observations are presented concerning the kinetics of the very rapid formation of the 1:1 σ-complex in water.

L'ion sulfite réagit avec la trinitro-2,4,6 benzaldehyde en solution aqueuse de force ionique 0.14 *M* pour donner un complexe 1:1 à des concentrations faibles de sulfite et un complexe 2:1 à des concentrations élevées de sulfite. On a déterminé les caractéristiques d'absorption de ces deux complexes ainsi que les constantes d'équilibres et les paramètres thermodynamiques se rapportant à leur formation. Des études en r.m.p. ont montré que deux formes isomériques du complexe 1:1 se forment en solution aqueuse de sulfoxyde de diméthyle et que deux formes isomériques du complexe 2:1 se forment dans l'eau. On a trouvé dans les deux complexes 1:1 et 2:1 des isomères qui contiennent l'ion sulfite relié au carbone C-1. De même on admet que l'un des complexes 2:1 isomériques existe sous des formes *cis* et *trans*. On présente aussi des observations se rattachant à la cinétique de formation très rapide du complexe 1:1 dans l'eau. [Traduit par le journal]

Can. J. Chem., **51**, 3927 (1973)

Introduction

In an earlier paper describing our observations concerning the reaction of sulfite ion with 1,3,5-trinitrobenzene (1) we reported the visible absorption characteristics of the 1:1 σ-complexes of sulfite ion with 2,4,6-trinitrotoluene and 2,4,6-trinitrobenzaldehyde. Since that time information has become available concerning the visible absorption characteristics and p.m.r. spectra of a number of 1:1 and 2:1 sulfite ion – 1-X-2,4,6-trinitrobenzene σ-complexes (X = H, HO, CH_3O, NH_2, $NHCH_3$, $NH(C_6H_5)$, $N(CH_3)_2$, and $N(CH_3)(C_6H_5)$) (2–4), but no further data have been published concerning the sulfite ion – 2,4,6-trinitrobenzaldehyde reaction. In connection with kinetic studies of 1:1 complex formation in the reactions of sulfite ion with a number of 1-X-2,4,6-trinitrobenzenes (X = H, NH_2, $NHCH_3$, and $N(CH_3)_2$), and as part of a study involving the σ-complex formation reactions of 2,4,6-trinitrobenzaldehyde (5) we have investigated in more detail the sulfite ion – 2,4,6-trinitrobenzaldehyde reaction. The visible absorption characteristics of the 1:1 and 2:1 σ-complexes, equilibrium constants, and relevant thermodynamic parameters for the formation of the 1:1 and 2:1 σ-complexes, the p.m.r. spectra of the 1:1 and 2:1 σ-complexes, and observations regarding the kinetics of formation of the 1:1 σ-complex in aqueous solution are now reported.

Experimental

(1) Reagents

Sodium sulfite and potassium nitrate were both A. R. grade reagents (Fisher Scientific) and were used as received. 2,4,6-Trinitrobenzaldehyde (Aldrich Chemical Co.) was purified by carbon black treatment in benzene–ethanol solution, recrystallized several times from ethanol, and dried *in vacuo* over phosphorus(V) pentoxide, m.p. 119.0–119.5 °C. All other reagents used were A.R. grade or better.

Doubly distilled and deionized water was boiled for approximately 30 min to remove dissolved gases then allowed to cool to room temperature and stored under a nitrogen atmosphere. Absolute ethanol was purified by distillation from magnesium turnings in an atmosphere of nitrogen.

A 2,4,6-trinitrobenzaldehyde stock solution ($\sim 2 \times 10^{-3}$ *M*) was prepared by dissolving a weighed amount of dried compound in a known volume of ethanol. Solutions of 2,4,6-trinitrobenzaldehyde used in the kinetic and equilibrium studies were freshly prepared prior to use by appropriate dilution (usually 1–100 ml) of an aliquot of

the stock solution with 0.14 M aqueous potassium nitrate solution.

Sodium sulfite and potassium nitrate stock solutions were always prepared immediately before use. The composition of the stock sodium sulfite solution was determined each time by iodimetric titration (6). Sodium sulfite solutions used in the kinetic and equilibrium studies were prepared by dilution of aliquots of the stock solution with 0.14 M aqueous potassium nitrate solution. The pH's of the stock solutions and the solutions used in the equilibrium and kinetic studies were checked with a pH meter and, if required, adjusted to a particular pH value by the addition of small amounts of 2×10^{-3} M sodium hydroxide or hydrochloric acid. The amount of added acid or base was generally so small that neither the concentration nor ionic strength of the solutions was affected by this procedure.

(2) Procedures

(a) Equilibrium Studies

In most instances a 1.0-cm cell containing 1.50 ml of 2,4,6-trinitrobenzaldehyde test solution (approximately 2×10^{-5} M) at an ionic strength of 0.14 M (KNO_3), a second cell containing 2–3 ml of sodium sulphite solution of desired concentration and ionic strength 0.14 M (KNO_3), and a syringe were placed in the thermostatted cell holder of the spectrophotometer and allowed to stand for 20 min in order to reach thermal equilibrium. A 1.50-ml sample of the sodium sulphite solution was then quickly transferred by syringe to the cell containing the 2,4,6-trinitrobenzaldehyde solution; the solution was thoroughly mixed, allowed to stand for approximately 2 min, and its spectrum recorded. When solutions of low sulfite ion concentration were required 10.0 ml of aqueous potassium nitrate solution was placed in a 5.0-cm cell and the cell and contents allowed to come to thermal equilibrium with the thermostatted cell compartment. Small volumes of the sodium sulfite and 2,4,6-trinitrobenzaldehyde stock solutions were then added by means of microliter syringes, the solution was mixed thoroughly and its spectrum recorded. Changes in the concentrations of sodium sulfite and 2,4,6-trinitrobenzaldehyde as a result of dilution were taken into account where necessary.

(b) Stopped-flow Kinetic Studies

Solutions containing 2,4,6-trinitrobenzaldehyde (at approximately 2×10^{-5} M) and sodium sulfite were prepared immediately prior to the kinetic run by dilution of known volumes of the corresponding stock solutions with 0.14 M aqueous potassium nitrate solution. Before each run the drive syringes were rinsed three times with the appropriate solution, filled to capacity, and allowed 20 min to reach thermal equilibrium with the bath. In the course of the kinetic measurements the concentration of 2,4,6-trinitrobenzaldehyde was generally kept constant and therefore, only the sodium sulfite solutions were changed. Each time this was done the drive syringe was flushed thoroughly with the new sodium sulfite solution before being filled for the kinetic run.

For the most part the kinetic runs were monitored by following the change in absorbance at 460 nm. In some runs absorbance changes at 500 and 580 nm were also recorded. Traces on the storage oscilloscope of absorbance *vs.* time were recorded photographically when at least two consecutive runs gave identical traces. The kinetic curves were then transferred from the photographs to cm-graph paper and the values of absorbance as a function of time read from the graph paper used to construct plots of $\ln (A_\infty - A_t)$ *vs.* time; (A_∞ and A_t refer to absorbances at times infinity and t, respectively). The slopes of the $\ln (A_\infty - A_t)$ *vs.* time plots yielded pseudo first-order rate constants k_{obs}. As a check on this procedure values of k_{obs} were also calculated using absorbance values read directly from the photographs. Values of k_{obs} obtained by using the two methods were, within experimental error, generally the same. Although more time-consuming the first method had the advantage of yielding accurate absorbance values at a larger number of times. As a result, the k_{obs} values calculated using this method generally had lower error limits associated with them.

(c) Proton Magnetic Resonance Studies

Solutions in aqueous dimethylsulfoxide (30% v/v water) were prepared by dissolving 2,4,6-trinitrobenzaldehyde in dimethylsulfoxide and mixing this solution with the required amount of aqueous sodium sulfite solution. The concentration of 2,4,6-trinitrobenzaldehyde was kept constant (0.10–0.15 M) while the concentration of sodium sulfite was varied over the range 0.10–2.0 M.

Solutions in water were prepared either by dissolving solid 2,4,6-trinitrobenzaldehyde directly in an aqueous sodium sulfite solution or by dissolving 2,4,6-trinitrobenzaldehyde in carbon tetrachloride and shaking this solution with a concentrated aqueous solution of sodium sulfite. The recorded spectra were independent of the method of preparation of the solutions. The concentration of 2,4,6-trinitrobenzaldehyde was kept constant (0.10–0.12 M) and the sodium sulfite concentration varied over the range 0.10–1.2 M.

All chemical shifts are quoted relative to internal tetramethylsilane (TMS).

(3) Instruments

Optical measurements in the equilibrium studies were carried out on a Cary 14 recording spectrophotometer using matched silica cells of 1.0- and 5.0-cm path lengths. Temperature in the cells was maintained constant to ± 0.1 °C by circulating water from a constant temperature bath through a specially designed cell holder in the spectrophotometer.

Proton magnetic resonance spectra were recorded on a Bruker HX-60 spectrometer employing the HDO peak in aqueous solution and the TMS peak in aqueous dimethylsulfoxide solution as the "internal lock". The probe temperature was generally about 20 °C.

Kinetic measurements were carried out on a Durrum-Gibson stopped-flow spectrophotometer. A closed circuit temperature control system utilizing an Ultra Kryomat TK30D constant temperature bath kept the temperature in the valve-block, drive syringes, and observation cell constant to within ± 0.1 °C. Temperature-jump or conventional stopped-flow cells of 2.0-cm path length were used. Minimum "dead times" of the two cells were 10 and 2 ms, respectively. For most of the kinetic runs the normal mode of operations of the stopped-flow spectrophotometer was modified so as to yield an oscilloscope trace of absorbance as a function of time rather than percent transmission as a function of time.

TABLE 1. Proton magnetic resonance data for 2,4,6-trinitrobenzaldehyde and the sulfite ion – 2,4,6-trinitrobenzaldehyde complexes formed in aqueous dimethylsulfoxide and water. Relative intensities of the resonances are in parentheses

Compound	Solvent[a]	Chemical shifts (p.p.m.) H_a	H_α	H_β

trans		0.17 (1)	1.27 (1)	4.05 (1)

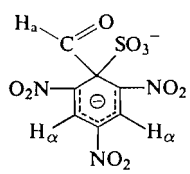
[a]Solvent designations: A, aqueous dimethylsulfoxide 30% (v/v water); B, water.

Measurements of p*H* were carried out with an EIL Model 23A p*H* meter which is capable of measuring the p*H* with an accuracy of ±0.02 p*H* units. Calibration of the p*H* meter with standard buffer solutions of p*H* 7.40 ± 0.02 and p*H* 10.00 ± 0.02 at 25 °C was performed prior to each measurement.

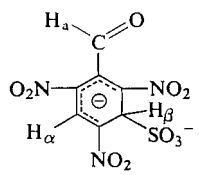
Results and Discussion

In aqueous dimethylsulfoxide (30% v/v water) 2,4,6-trinitrobenzaldehyde shows resonance absorbances at τ −0.52 and 0.83 (both singlets, ratio 1:2). The resonance absorbances characteristic of the complexes generated in this medium were found at τ −0.38 (singlet), −0.18 (singlet), 1.72 (singlet), 1.82 (doublet), and 4.08 p.p.m. (doublet). No changes were observed in the number of resonance absorbances or in the relative intensities of the absorbances over a period of at least a day at room temperature.

The observed spectra are consistent with the solutions containing, in addition to free 2,4,6-trinitrobenzaldehyde, only the two isomeric 1:1 σ-complexes **1** and **2**. Assignments of the reso-



1



2

nance absorbances of the hydrogens in these two complexes, as given in Table 1, are based by analogy with the chemical shifts observed in other related 1:1 σ-complexes. The assignment of the ring H_α and H_β protons in **2** is consistent with the observed chemical shifts in the 1:1 sulfite ion complexes of 1,3,5-trinitrobenzene, 2,4,6-trinitroanisole, picramide, and *N*-methyl- and *N*,*N*-dimethylpicramide (2). The smaller upfield shift of the H_α resonance in complex **1** as compared to the upfield shift of the H_α resonance in complex **2** has previously been observed in the corresponding complexes of 2,4,6-trinitroanisole with both cyanide ion and methoxide ion (7–12). The observation that the aldehyde proton in **1** is upfield from the aldehyde proton in **2** is also consistent with the chemical shifts observed for the hydrogens of the methoxyl groups in the corresponding complexes (the C-1 and -3 complexes) of cyanide ion and methoxide ion with 2,4,6-trinitroanisole (7–12).

Over the range of sodium sulfite concentrations employed in the experiments the two 1:1 σ-complexes **1** and **2** were present at approximately equal concentrations and no evidence could be found for the formation of any 2:1 σ-complexes. The increased stability of 1:1 as compared to 2:1 sulfite ion – 1-X-2,4,6-trinitrobenzene σ-complexes in aqueous solutions of high dimethylsulfoxide content has been attributed to better solvation by dimethylsulfoxide than by water of the charge-delocalized 1:1 σ-complex (4, 13).

Complex **1** is the first 1:1 σ-complex of sulfite ion with a 1-X-2,4,6-trinitrobenzene (X other than H) in which addition has been shown to occur at the C-1 position. In all previous adducts investigated only addition at C-3 (or -5) was observed.

In aqueous solutions at low sulfite ion concentrations p.m.r. spectra recorded immediately on mixing show, in addition to resonances attrib-

For personal use only.

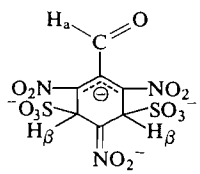
uted to the parent 2,4,6-trinitrobenzaldehyde, eight resonance absorbances located at τ −0.18, −0.05, 0.17, 1.27, 1.45, 3.95, 4.05, and 4.13 p.p.m. All the resonance absorbances appear to be singlets. In marked contrast to what is observed in the case of aqueous dimethylsulfoxide solutions the pattern of resonance absorbances observed in water undergoes fairly rapid changes with time. These changes are always more rapid at higher temperatures and/or higher sulfite ion concentrations. Intermediate spectra show absorbances at τ 0.35 (often, but not invariably) and at τ 1.58 while the final spectra showed in all cases only a single resonance absorbance at τ 1.58.

The number and the positions of the initial resonance absorbances observed could be consistent with solutions containing either a mixture of the complexes **2**, **3**, and **4** or a solution consisting of complex **3** and the *cis* and *trans* isomers of **4**. In view of the large excess of sulfite ion to



3 **4**

2,4,6-trinitrobenzaldehyde normally present in solution, the large equilibrium constant associated with 2:1 σ-complex formation in aqueous solution (*vide infra*) and the apparent insensitivity of the relative intensities of the various resonances attributable to the complexes to changes in sulfite ion concentration over the range 0.10–1.20 *M*, the experimental data seem more in accord with the latter possibility, *i.e.* under all conditions the solutions are thought to contain only 2:1 σ-complexes.

Assignments of the resonance absorbances of the hydrogens in complex **3** and the *cis* and *trans* isomers of **4** are given in Table 1.

For complex **3** the chemical shifts of the H_β protons are comparable to those found for the sulfite-containing 2:1 complexes of 1,3,5-trinitrobenzene, 2,4,6-trinitroanisole, picramide, and *N*-substituted picramides (2). No covalency change occurs at the C-1 position in complex **3** so the small upfield shift ($\Delta\tau = 0.44$) of the aldehyde hydrogen in the complex relative to the aldehyde hydrogen in the parent 2,4,6-trinitrobenzaldehyde must reflect primarily the increase in negative charge density in the C-1 position of complex **3**.

All the protons attributed to the *cis* and *trans* isomers of **4** show upfield shifts relative to the resonance absorbances of the parent compound. The shifts are largest ($\Delta\tau = 3.32$ and 3.22) for the H_β protons and smallest for the H_α protons ($\Delta\tau = 0.54$ and 0.72). The positions of the resonance absorbances of the H_β protons of **4** in water are very close to those observed for the H_β protons of **2** in aqueous dimethylsulfoxide. The aldehyde hydrogens of the two isomers show larger upfield shifts ($\Delta\tau = 0.57$ and 0.79) than that observed for the aldehyde hydrogen in complex **3** consistent with the fact that a covalency change occurs at the C-1 position of both the *cis* and *trans* forms of **4** but not at the C-1 position of **3**. Though coupling between H_α and H_β protons was observed for complex **2**, coupling between the H_α and H_β protons in the *cis* and *trans* forms of **4** could not be observed.[1] As a result definite assignments of the H_a, H_α, and H_β protons to the *cis* and *trans* forms of **4** is not possible, nor is it possible at this stage to say whether the *cis* or the *trans* isomer is the preferred species at equilibrium. In any event the preference of the *cis* form over the *trans* form (or *vice versa*) under the reaction conditions necessary to obtain the p.m.r. spectra is slight.

Even at the lowest concentrations of sulfite ion that could be used in order to obtain the p.m.r. spectra of the complexes formed in aqueous solution (~0.09 *M*) there was no evidence for the existence of 1:1 σ-complexes such as **1** or **2**. Crampton (2) has previously reported on the increased stability, relative to the 1:1 complexes, of 2:1 complexes of sulfite ion with 1,3,5-trinitrobenzene, 2,4,6-trinitroanisole, and picramide in aqueous solution. The presence of 2:1 but not 1:1 complexes suggests that the 2:1 complexes, which have far more localized charges than the 1:1 complexes, are considerably more strongly solvated by water than are the 1:1 complexes.

Complex **4** is the first 2:1 σ-complex of sulfite ion with a 1-X-2,4,6-trinitrobenzene for which addition has been shown to occur at both the

[1]Coupling between H_α and H_β protons can be resolved in the 1:1 sulfite ion – 1,3,5-trinitrobenzene complex but not in the 2:1 sulfite ion – 1,3,5-trinitrobenzene complex (2).

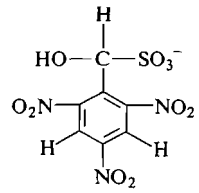
C-1 and the -3 (or -5) position. Previously reported 2:1 σ-complexes between sulfite ion and a variety of 1-X-2,4,6-trinitrobenzenes all possessed structures similar to that observed for complex **3** *i.e.* addition had occurred only at the C-3 and -5 positions (4, 13).

The failure to detect addition of sulfite ion at an X-substituted carbon in other 1-X-2,4,6-trinitrobenzene 1:1 and 2:1 σ-complexes has been ascribed to two causes. One is steric strain effect associated with the addition of a sulfite ion at a carbon already bearing a large substituent X; the other is a specific solvation effect which arises because the sulfite ion in the complex still carries a formal negative charge and consequently must still be extensively solvated. Neither steric strain effects nor the solvation requirements of the 1:1 σ-complexes would be expected to be much different in complexes in which X = CHO as compared to those in which X = O^-, OCH_3, $NHCH_3$, and $N(CH_3)_2$. Other factors must also be important then in determining the point of addition of the sulfite ion. The electron withdrawing effect of the aldehyde group may be one such factor. Thus cyanide ion, which would be expected to have less stringent solvation requirements and give rise to much smaller steric strain effects than sulfite, reacts with 2,4,6-trinitrobenzaldehyde to yield only the C-1 complex even at low temperatures (5). It might be argued that, in the special case for which X = COH and the anion is sulfite ion, the electron withdrawing effect of the aldehyde group together with better solvation and coplanarity with the ring of the para nitro group and the possible release of steric compression (4, 13) in the C-1 complex (**1**) relative to the parent compound might partially offset the more favorable steric and solvation requirements of the C-3 complex (**2**). As a result both isomeric complexes are observed.

If this argument is correct the relative proportions of the two isomeric 1:1 σ-complexes **1** and **2** present in the system should be strongly solvent dependent and the existence of 1:1 C-1 complexes should occur only in those cases in which X is strongly electron withdrawing and the anion is small. These ideas are currently being tested.

The nature of the species formed as a result of the decomposition of complexes **3** and **4** is not known. The resonance absorbances at τ 1.58 could possibly be assigned to ring hydrogens in a compound such as **5**, but no effort was made to isolate such a species from the final reaction mixtures.



5

Aqueous solutions containing both 2,4,6-trinitrobenzaldehyde ($\sim 2 \times 10^{-5}$ *M*) and sodium sulfite (10^{-4}–10^{-2} *M*) in the p*H* range 7.50–10.0 are red in color though neither component alone absorbs in the region 370–700 nm under these conditions.

Studies of the visible absorption spectra of solutions containing a fixed concentration of 2,4,6-trinitrobenzaldehyde (typically $\sim 2 \times 10^{-5}$ *M*) and a variable concentration of sodium sulfite indicate the existence of two equilibria involving 2,4,6-trinitrobenzaldehyde and sulfite ion. The first is dominant at sulfite concentrations below 1.3×10^{-3} *M* while the second becomes apparent at sulfite concentrations above 1.3×10^{-3} *M* and is complete in solutions containing from 0.60–0.80 *M* sodium sulfite. Further changes in the visible absorption spectra are not observed as the concentration of sodium sulfite is increased above 0.80 *M*. Typical absorption curves are shown in Fig. 1. Sharp isosbestic points are observed at 480 and 527 nm at all temperatures over the range 0–50 °C.

The absorption characteristics of the species formed at sulfite concentrations $< 1.3 \times 10^{-3}$ *M* (λ_{max} 458 nm, shoulder mid point at 540 nm) are similar to those reported for the 1:1 σ-complexes of sulfite ion with 1,3,5-trinitrobenzene, 2,4,6-trinitrotoluene, 2,4,6-trinitroanisole, and picramide (1, 2, 14). The absorption characteristics of the species formed at high sulfite ion concentrations (λ_{max} 500 nm) are similar to those reported for a number of 2:1 sulfite ion complexes of 1-X-2,4,6-trinitrobenzenes, X = H, CH_3O, NH_2, $NHCH_3$, and $N(CH_3)_2$ (2). The positions of the absorption maxima are independent of temperature over the range 0–50 °C.

The above observations suggest that the two equilibria in solution are associated with the reversible formation of 1:1 and 2:1 sulfite

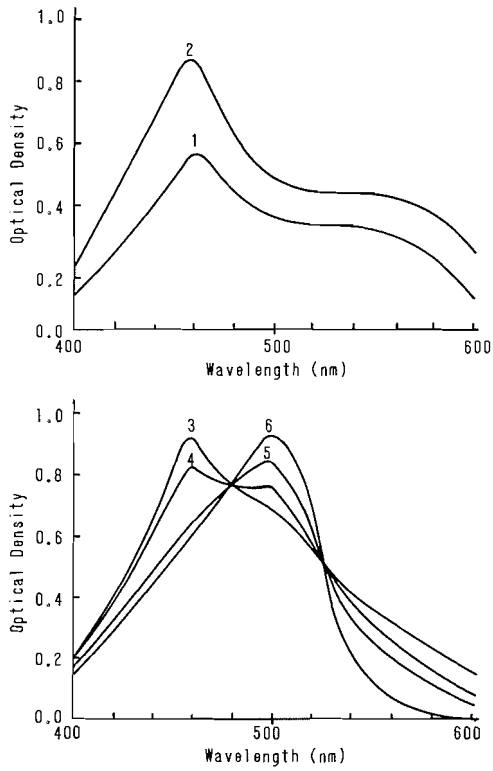


FIG. 1. Absorption spectra of 2,4,6-trinitrobenzaldehyde (1.0×10^{-5} *M*) in water containing the following molarities of sodium sulfite: (*1*) 0.0001; (*2*) 0.003; (*3*) 0.025; (*4*) 0.05; (*5*) 0.10; (*6*) 0.60. *T*, 24.0 °C. Ionic strength for all solutions but (*6*) 0.14 *M* (KNO_3).

ion – 2,4,6-trinitrobenzaldehyde σ-complexes. Schematically the processes can be formulated as

[1] 2,4,6-Trinitrobenzaldehyde + $SO_3^{2-} \rightleftharpoons C_1$

and

[2] $C_1 + SO_3^{2-} \rightleftharpoons C_2$

where K_1 and K_2 are the equilibrium constants associated with the formation of the 1:1 and 2:1 complexes, respectively.

The 1:1 stoichiometry of the 2,4,6-trinitrobenzaldehyde – sulfite ion complex formed at fixed 2,4,6-trinitrobenzaldehyde concentrations ($\sim 1 \times 10^{-5}$ *M*) and concentrations of sulfite ion in the range 1.0×10^{-4} to 1.3×10^{-2} *M* was established through the use of the graphical test method reported by Coleman, Varga, and Mastin (15) and by the use of the method of continuous variations (16).

Absorbance data for solutions of fixed initial concentrations of 2,4,6-trinitrobenzaldehyde ($[A_0]$) and sodium sulfite ion concentrations 1.0×10^{-3} to 1.30×10^{-4} *M*, when plotted in the form $[A_0]$/absorbance *vs.* $1/[B_0]$ (where $[B_0]$ is the initial sodium sulfite concentration), gave excellent straight lines from whose slopes and intercept values of the equilibrium constant for 1:1 σ-complex formation (K_1) and molar extinction coefficients (ε_1) of the complex at the wavelength at which absorbances were recorded were calculated (Benesi-Hildebrand (B–H) method (17)). Values of K_1 and ε_1 determined at a number of different temperatures and wavelengths are tabulated in Table 2. The excellent linearity of the B–H plots, the non-dependence of K_1 on wavelength, and the constancy of ε_1 as a function of temperature offer further evidence that only a single 1:1 σ-complex is being studied under the quoted reaction conditions. The results of the p.m.r. studies suggest that the 1:1 complex could be either **1** or **2**. Unfortunately, the visible absorption data cannot be used to differentiate between these two possibilities (4, 13, 14).

At any wavelength the molar extinction coefficient of the 2:1 σ-complex formed between 2,4,6-trinitrobenzaldehyde and sulfite ion could be found directly since conversion of 2,4,6-trinitrobenzaldehyde to the 2:1 complex was complete at high sulfite concentrations. Employing molar extinction coefficients (ε_2) found in this manner and known K_1 and ε_1 values the concentration of the 2:1 complex and the equilibrium constant for formation of the 2:1 complex could be calculated for solutions of different initial concentrations of sodium sulfite and 2,4,6-trinitrobenzaldehyde. Values of ε_2 and K_2 obtained in this way are tabulated in Table 3. The K_2 values are independent of the wavelength at which absorbance data are recorded while the values of ε_2, like the values of ε_1, are, within experimental error, temperature independent.

Mean values of the equilibrium constants K_1 and K_2 and mean molar extinction coefficients ε_1 and ε_2 at the wavelengths of maximum absorption (458 and 500 nm, respectively) at different temperatures are given in Table 4.

Enthalpies of formation ($\Delta H°$) and entropies of formation ($\Delta S°$) associated with both 1:1 and 2:1 σ-complex formation were obtained from plots of log K_1 and log K_2 *vs.* $1/T$. Relevant values are -2.41 ± 0.16 kcal mol^{-1} and 11.36 ± 1.05 cal deg^{-1} mol^{-1} and -8.53 ± 0.10 kcal mol^{-1} and -21.80 ± 2.36 cal deg^{-1} mol^{-1} for

the $\Delta H°$ and $\Delta S°$ of formation of the 1:1 and 2:1 complexes respectively. The errors in $\Delta H°$ and $\Delta S°$ are based on a "least squares" treatment of the data in the log K *vs.* $1/T$ plots.

The values of $\Delta H°$ and $\Delta S°$ for formation of the 1:1 sulfite ion – 2,4,6-trinitrobenzaldehyde σ-complex differ from the $\Delta H°$ and $\Delta S°$ values reported for formation of the 1:1 sulfite ion – 1,3,5-trinitrobenzene σ-complex. The lack of published thermodynamic data for the formation of other 1:1 and 2:1 sulfite ion – 1-X-2,4,6-trinitrobenzene complexes precludes any detailed analysis of the thermodynamic parameters at this time.[2] The large values of $\Delta H°$ and $\Delta S°$ associated with the formation of the 2:1 σ-complex may reflect the better solvation by water of the charge-localized 2:1 complex than the charge-delocalized 1:1 complex.

Stopped-flow techniques were employed to study the kinetics of the sulfite ion – 2,4,6-trinitrobenzaldehyde. These studies, which were

[2]Kinetic and thermodynamic studies of the formation of the 1:1 sulfite ion complexes of picramide, *N*-methylpicramide, and *N*,*N*-dimethylpicramide have been completed . The results of these studies have been submitted for publication (A.R. Norris and P. J. Sheridan).

carried out over a range of sodium sulfite (2.6×10^{-5} to 1.12×10^{-3} M) and 2,4,6-trinitrobenzaldehyde (9.7×10^{-6} to 2.0×10^{-5} M) concentrations, at different temperatures (10.0 to 35.0 °C) and in solutions of varying pH (7.50–10.00), indicated there were always two reactions taking place in solution. The first was a very fast reaction ($t_{1/2} < 5$ ms) which, under all the experimental conditions we were able to employ, was complete in too short a time to allow for any detailed study of its rate dependence on various reaction parameters. The absorption spectrum of the species formed at the completion of this first reaction could be recorded however, and was identical in all respects to that of a 1:1 sulfite ion – 2,4,6-trinitrobenzaldehyde complex. The second reaction which was characterized by values of $t_{\frac{1}{2}}$ in the range 50–100 ms could be more extensively studied. At all reaction temperatures the rate of this reaction was found to be independent of the initial concentration of 2,4,6-trinitrobenzaldehyde, independent of pH over the range 7.5–10.0[3] and linearly dependent on the initial concentration of sulfite ion at low concentrations of sodium sulfite, but independent of sulfite concentration at high sodium sulfite concentrations. The absorption spectrum of the species present at the termination of this reaction was also characteristic of 1:1 sulfite ion – 2,4,6-trinitrobenzaldehyde complex.

The kinetic observations seem compatible with the following scheme

$$\text{TNBA} + \text{SO}_3^{2-} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \text{A} \qquad [3]$$

$$\text{TNBA} + \text{SO}_3^{2-} \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} \text{B} \qquad [4]$$

where the first equilibrium is established much more rapidly than the second, but in which $k_1/k_{-1} \ll k_2/k_{-2}$. A and B are formulated as isomeric 1:1 σ-complexes differing only in the position of addition of the sulfite ion. The formation of 1:1 σ-complexes of methoxide ion with 2,4,6-trinitroanisole has been shown to follow the above reaction scheme with the C-3 adduct being the kinetically favored species and the C-1 adduct being the thermodynamically favored species (18). While p.m.r. studies of the sulfite ion – 2,4,6-trinitrobenzaldehyde reaction in aqueous solution have to be carried out under conditions such that only the isomeric 2:1 σ-complexes are formed, the isomeric 1:1 σ-complexes **1** and **2** were observed as stable entities in aqueous dimethylsulfoxide solution and may be presumed to exist as well in aqueous solution under appropriate conditions.

The lack of accurate rate constants for the second reaction over a wide range of low sulfite ion concentrations renders a detailed analysis of kinetic data in terms of the proposed scheme unwarranted at this time. The data that are available suggest k_2 has a value (at 25°) in the range 9×10^4 M^{-1} s^{-1}. This rate constant is very close to that reported by Bernasconi and Bergstrom (19) for the formation of the 1:1 sulfite ion – 1,3,5-trinitrobenzene complex and is in the range of the specific rate constants observed for 1:1 σ-complex formation between sulfite ion and picramide, *N*-methylpicramide, and *N*,*N*-dimethylpicramide.[4] For each of these four reactions sulfite ion attacks at a hydrogen-bearing ring carbon. Studies using the T-jump technique are in progress in an attempt to obtain more extensive and more reliable kinetic data for both the fast and very fast reactions.

Financial support by the National Research Council of Canada is gratefully acknowledged.

[3]Separate studies were carried out to ensure that under the experimental conditions used in the kinetic and equilibrium experiments there were no complications due to the interaction of hydroxide ion and 2,4,6-trinitrobenzaldehyde. These studies indicated that over the temperature range 0–50 °C the formation of the hydroxide ion – 2,4,6-trinitrobenzaldehyde complex was only important at pH values greater than 10. Relevant thermodynamic, spectroscopic, and kinetic data associated with the 1:1 hydroxide ion – 2,4,6-trinitrobenzaldehyde σ-complex are $K = 5.0 \times 10^3$ M^{-1} at 25.0 °C (based on equilibrium studies), $\varepsilon_{430} = 2.0 \pm 0.1 \times 10^4$ M^{-1} cm^{-1}, $\varepsilon_{530} = 1.3 \pm 0.1 \times 10^4$ M^{-1} cm^{-1}, $k_1 = 5.2 \times 10^2$ M^{-1} s^{-1} and $k_{-1} = 0.1$ s^{-1}. All values are quoted for solutions of ionic strength 0.14 M (KNO_3).

Water Soluble Steroids with Catalytic Substituents II. Synthesis of 3β-(4(5)-Imidazolyl)-5α-androstane-11β,17β,-diamine and Comparison of its Catalytic Properties with Those of 17β-(4(5)-Imidazolyl)-5α-androstane-3β,11β-diamine

J. Peter Guthrie and Yasutsugu Ueda

Department of Chemistry, University of Western Ontario, London, Ontario

Received May 7, 1973

3β-(4(5)-Imidazolyl)-5α-androstane-11β,17β-diamine, **15**, has been synthesized in a multistep process from adrenosterone, **2**, starting with lithium ammonia reduction to give 11α,17β-dihydroxy-5α-androstan-3-one, **3**, which was converted to its diacetate, **4**. Ethynylation at the 3 keto group gave the ethynyl triol **5**, purified as its 11,17-diacetate **6**. Acid catalyzed rearrangement of **6** gave 3-acetyl-5α-androst-2-ene-11α,17β-diol diacetate, 7. This was hydrogenated, and then subjected to base catalyzed hydrolysis and equilibration to give crystalline 3β-acetyl-5α-androstane-11α,17β-diol, **9**, which was converted to 3β-acetoxyacetyl-5α-androstane-11α,17β-diol, **10**, using lead tetraacetate. After hydrolysis to the triol, **11**, the Weidenhagen reaction led to formation of 3β-imidazolyl-5α-androstane-11α,17β-diol, **12**. Finally oxidation to the dione, **13**, formation of the dioxime, **14**, and hydrogenation give **15**. As expected **15** is a better catalyst than 17β-(4(5)-imidazolyl-5α-androstane-3β,11β-diamine, **1**, for the hydrolysis of aryl esters of acids with hydrophobic substituents, but the effect is small. With **1** there is a marked electrostatic rate enhancement or retardation when charged groups are present on the aryl esters; this effect is much smaller for **15**.

La synthèse de l'(imidazolyl-4(5))-3β androstane-5α diamine-11β,17β, **15**, a été réalisée en plusieurs étapes à partir de l'adrénostérone, **2**, qui, soumis à une réduction avec du lithium dans l'ammoniaque, a donné le dihydroxy-11α,17β androstan-5α one-3, **3**, lequel a été converti en diacétate, **4**. L'éthynylation du groupe céto-3 a conduit à l'éthylnyl triol **5**, que l'on purifie en formant de diacétate-11,17 **6**. Le réarrangement catalysé par l'acide de **6** a conduit à l'acétyl-3 androst-5α ène-2 diol diacétate-11α,17β, **7**. Ce dernier composé fut hydrogéné, puis soumis à une hydrolyse basique et à une équilibration pour donner l'acétyl-3β androstane-5α diol-11α,17β, **9**, cristallin qui a été transformé en acétoxyacétyl-3β androstane-5α diol-11α,17β, **10**, en utilisant du tétraacétate de plomb. Après hydrolyse pour obtenir le triol, **11**, la réaction de Weidenhagen a conduit à la formation d'imidazolyl-3β androstane-5α diol-1α,17β, **12**. Finalement le produit **15** fut obtenu par oxydation de **12** en dione **13** suivie par la formation du dioxime **14** et par hydrogénation de ce dernier composé. Comme prévu, **15** est un meilleur catalyseur que l'(imidazolyl-4(5))-17β androstane-5α diamine-3β,11β, **1**, pour l'hydrolyse des esters aryles d'acides possédant des substituants hydrophobes, mais l'effet est faible. Avec le composé **1**, on a noté une augmentation ou une diminution electrostatique dans la vitesse lorsque des groupes chargés sont présents dans les esters aryles; cet effet est beaucoup plus faible pour **15**. [Traduit par le journal]

Can. J. Chem., **51**, 3936 (1973)

Recently (1) we reported the synthesis of 17β-imidazolyl-5α-androstane-3β,11β-diamine, **1**, a water soluble steroid with a potentially catalytic substituent. We have investigated the kinetics of the reactions of this steroid with several aryl esters of acids which contain hydrophobic substituents, and found a rate enhancement attributable to hydrophobic binding between substrate and catalyst (2). Koshland and co-workers have proposed (3–6) a theory of "orbital steering" as a source of a large fraction of enzymic rate enhancements; this theory states that a reaction is greatly accelerated if the reactant atoms are held in close proximity and in the optimum relative orientation for reaction. Koshland and co-workers estimate (3, 5) that for lactonization the orientation effect is at least 10^4 in rate. There has been considerable controversy over the concept of orbital steering (7–9). Nevertheless it is clear that some reactions at least are much faster when they are intramolecular and the reactant atoms are held close together. Examination of space filling models convinced us that although the 17β-imidazolyl group in **1** is quasi-equatorial and can act as a catalyst for the hydrolysis of its substrates, the imidazole nitrogen-3 is not optimally oriented, being too high above the plane of the molecule. A 17α-imidazole would be much worse since the nitrogen lone pair would be directed almost parallel to the plane of the molecule and would not readily react with any hydrophobically bound substrate.

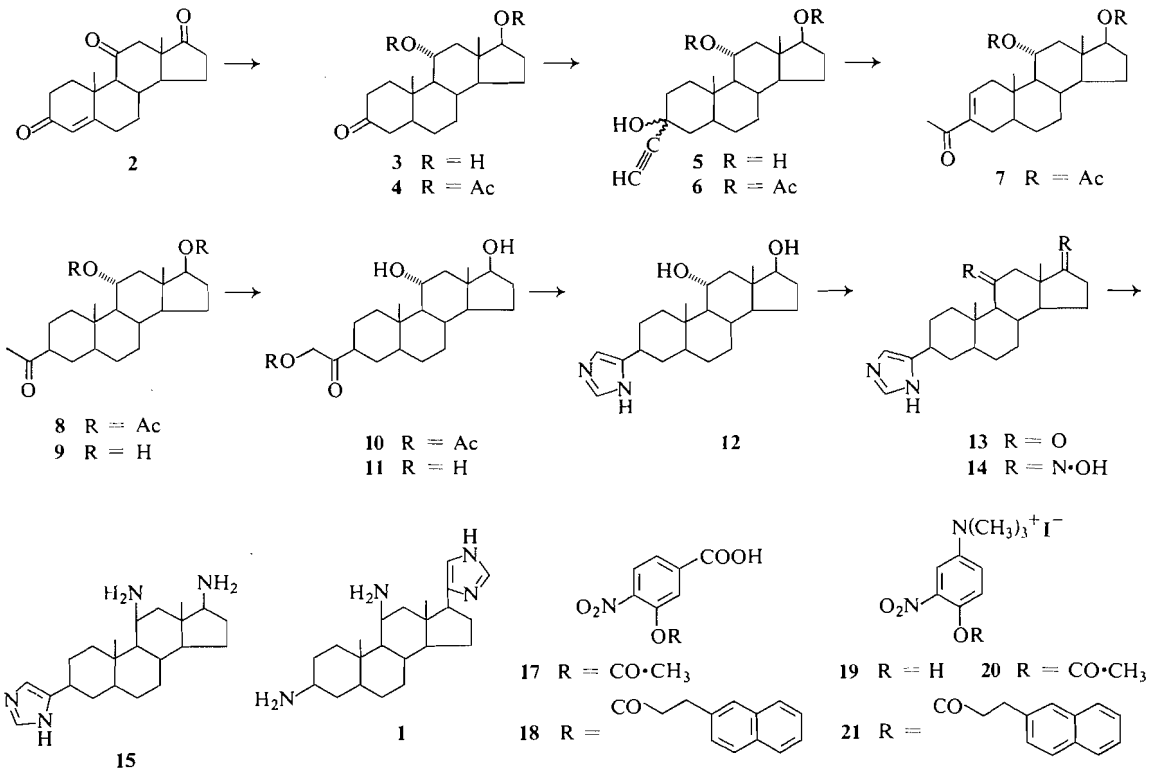
For personal use only.



SCHEME 1

A 3β-imidazole would however be truly equatorial and better positioned to react with a substrate which was also in contact with the lower surface of the steroid.

It seemed to us of considerable interest to determine how sensitive the imidazole catalyzed ester hydrolysis was to the orientation of the imidazole group. Accordingly we have prepared 3β-(4(5)-imidazolyl)-5α-androstane-11β,17β-diamine, **15**. We wish to report the synthesis of this compound, and some investigations of its catalytic properties, relative to **1**.

Results and Discussion

Synthesis

The approach used is outlined in Scheme 1. Adrenosterone, **2**, could be reduced with lithium in liquid ammonia to the desired 3-oxo-5α-androstane-11α,17β-diol, **3**, albeit in modest yield. Major by-products were the triol and 3,17-dioxo-5α-androstane-11α-ol which presumably results from formation of the 17-enolate. At best only 45% yield of **3** was obtainable. Compound **3** was converted to the diacetate **4**, for which the stereochemistry at C-5 could be established unambiguously by ^{13}C n.m.r. spectroscopy. The chemical shift of the C-19 signal differs by 10 p.p.m. depending on whether the A–B ring junction is *cis* or *trans* (10) and can be predicted for either stereochemistry on the basis of previous studies of the ^{13}C spectra of steroids (10, 11). The diacetate **4** was then treated with the lithium acetylide – ethylenediamine complex in 1:1 benzene – dimethylacetamide. The crude product, mostly **5**, was acetylated to give the diacetate **6**; the acetylation was monitored by t.l.c. and stopped before significant amounts of triacetate formed. Compound **6** was purified and then converted to **7** by heating with strongly acidic ion exchange resin; hydrogenation of **7** led to **8**. Basic hydrolysis of **8** gave **9** and will[1] also lead to equilibration at C_3; the preferred orientation of an acetyl group has been shown to be equatorial (12). Lead tetraacetate oxidation of **9** produced **10** in good yield. Unfortunately **10** could not be used directly for production of

[1]Equilibrium is established in 49 h at 56° with 0.1 *M* sodium methoxide (12); the conditions used in this work (11 h at reflux with 0.35 *M* sodium methoxide) should also give complete equilibration.

TABLE 1. Rate constants for hydrolysis of esters[a]

Ester	Background rate (no catalyst) k_{obs} (min^{-1})	Catalyzed rate k_2[b] (M^{-1} min^{-1}) Imidazole	**15**	**1**	Hydrophobic effect **15**	**1**	Electrostatic effect **15**	**1**	k_{rel}[c] **15**	**1**	k_{rel}^{15}/k_{rel}^{1}
16	0.000854	26.0	24.3	25.5	—	—			0.935	0.980	0.954
17	0.000716	56.9	58.7	305			1.10[f]	5.47[f]	1.03	5.36	0.192
18	0.000666	55.7	180	700	3.14[d]	2.34[d]			3.23	12.6	0.256
20	0.00469	247	123	90.0			0.532[g]	0.372[g]	0.497	0.365	1.40
21	0.00428	316	370	234	2.4[e]	2.1[e]			1.2	0.740	1.62

[a]In aqueous solution, 0.62 M acetonitrile, ionic strength = 0.097 M (KCl), 0.00996 M Tris buffer, pH 7.9; temperature = 25.0 ± 0.1 °C.
[b]Observed pseudo first-order rate constant, corrected for the background rate, divided by the total concentration of catalyst.
[c]k_2 for the steroidal imidazole divided by k_2 for imidazole.
[d]k_{rel} for **18** divided by k_{rel} for **17**.
[e]k_{rel} for **21** divided by k_{rel} for **20**.
[f]k_{rel} for **17** divided by k_{rel} for **16**.
[g]k_{rel} for **20** divided by k_{rel} for **16**.

the imidazole compound **12** but had to be hydrolyzed to **11** with some attendant loss of material. Then conversion of **11** to **12** went in essentially quantitative yield, using the modified conditions for the Weidenhagen (13, 14) synthesis devised (1) for the preparation of **1**. Overall yields for the introduction of the imidazole group were 12% (yield of **11** from **4**). The worst losses were suffered in the oxidation–hydrolysis sequence from **8** to **11**. The diol **12** could be transformed first to the dione **13** and then to the dioxime **14** almost quantitatively. Unfortunately the hydrogenation to give **15** proceeded with difficulty and in mediocre yield. The n.m.r. spectrum of **15** showed that the desired stereochemistry had been obtained, since the methyne proton on C-11 had $\Delta\nu_{\frac{1}{2}} = 10$ Hz, as expected for an equatorial hydrogen, and the methyne proton on C-17 had $\Delta\nu_{\frac{1}{2}} = 8.5$ Hz, as expected for a 17α proton.[2]

Kinetics

p-Nitrophenyl acetate, **16**, and substrates **17**–**21** were used with both **1** and **15** in order to compare the catalytic efficiencies of the two steroidal imidazoles with the results shown in the Table 1. In order to compare the various reactions, it is desirable to correct for differences in inherent reactivity of the substrates and catalysts. For each substrate, calculating k_{rel}, the relative rate constant for a steroidal imidazole with imidazole as standard, corrects for any differences in intrinsic reactivity of the substrates. Since *p*-nitrophenyl acetate, **16**, shows a relative rate of 0.94 with **15** and 0.98 with **1**, we conclude that the intrinsic reactivity of the steroidal imidazoles is virtually identical to that of imidazole. Imidazole is well known (16) to act as a nucleophilic catalyst for the hydrolysis of aryl esters; we assume that the steroidal imidazoles are also acting as nucleophilic catalysts. Any deviations of k_{rel} from unity must represent a stabilizing or destabilizing influence present in the transition state for these more complicated substrates but absent for **16**. The ratio of k_{rel} values for **18** to **17** or **21** to **20** should cancel the effects of the charged leaving group and give a measure of the magnitude of the hydrophobic interaction between the naphthyl ring and the α surface of the steroid. This treatment shows that there is a rate enhancement of about two-fold on adding a naphthyl group as hydrophobic binding moiety. Furthermore the rate enhancements are in both cases slightly larger for **15** than for **1** indicating that indeed the 3β-imidazole is more accessible than the 17β imidazole. Figure 1 shows the geometry of the intermediate formed after attack of the imidazole on the ester carbonyl and before expulsion of phenoxide. This drawing is based on CPK space filling models which show the steroid and aromatic rings in

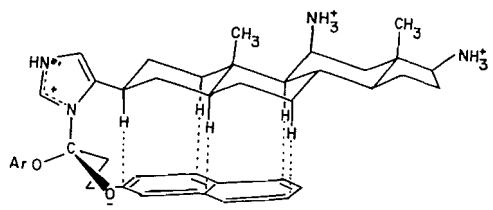

FIG. 1. Geometry of intermediate formed after attack of the imidazole on the ester carbonyl and before expulsion of phenoxide.

[2]Using the empirical relations (15) $\nu_{\frac{1}{2}} = J_{AX}+J_{BX}$ and observed values of J or $\Delta\nu_{\frac{1}{2}}$ (15, 18).

van der Waals' contact. However for the substrates tested so far the effect is very small. The ratio of k_{rel} values for **17** to **16** or **20** to **16** should provide an estimate of the effect of the charged substituent on the leaving group. These electrostatic effects are small for **15** but considerably larger for **1**. Inspection of space filling models shows that for **1** the charged substituents are closer to the 11β-ammonium group than they are in **15**, and that in fact very close contact between the carboxylate of **17** or **18** and the 11β-ammonium is quite possible and requires no obvious crowding or distortion.

This small orientational effect may result from the flexibility of the substrates **18** and **21**, a flexibility introduced so that the carbonyl carbon can become covalently bonded to the imidazole nitrogen while the hydrophobic side chain is in contact with the α surface of the steroid; examination of molecular models showed that two methylene groups was the minimum required (see Fig. 1). However this flexibility will doubtless decrease the sensitivity of the catalytic effect to small changes in orientation. For less flexible substrates we may hope to see a greater effect and experiments in this direction are now under way.

Experimental

Melting points were determined on a Thomas Hoover capillary melting point apparatus and are uncorrected. Infrared spectra were recorded with a Beckman IR-20A spectrometer. Nuclear magnetic resonance spectra were obtained with Varian T-60 or HA-100 spectrometers. Chemical shifts were recorded in p.p.m. downfield from internal tetramethylsilane for the neutral compounds in organic solvents and from internal sodium 2,2-dimethyl-2-silapentane-5-sulfonate for the water soluble compounds in D_2O. Mallinckrodt Silicic Acid (100 mesh) No. 2847 and neutral silica, silicAR CC-7 (100–200 mesh) No. 7083 were used for column chromatography. E. Merck Silica Gel G.F.-254 No. 7730 was used for t.l.c. and Silica Gel P.F.-254, No. 7747 was used for preparative layer chromatography. Imidazole containing compounds were detected using the Pauly reagent (17). Dowex 50 W (50–100 mesh) was washed thoroughly, cycled several times from sodium form to acid form, and finally converted to the acid form and dried *in vacuo* over $CaCl_2$. Linde 4A molecular sieves were used for solvent drying. During work-up, organic extracts normally were washed with saturated aqueous sodium chloride solution, dried over anhydrous sodium sulfate, and evaporated to dryness *in vacuo*.

11α,17β-Dihydroxy-5α-androstan-3-one (3)

A solution of adrenosterone, **2** (Upjohn Company, m.p. 218–220°, 10.0 g) in dioxane (500 ml, dried over molecular sieves) was added to a solution of lithium (3.0 g) in anhydrous liquid ammonia (3 l) over a period of 20 min with good stirring. After stirring another 20 min, the blue color was discharged by the addition of solid ammonium chloride and the ammonia was allowed to evaporate under a nitrogen atmosphere. Water was added to the residue; the product was extracted with methylene chloride three times, and the organic extracts were dried and evaporated. Crystallization of the residue from methanol gave 11α,17β-dihydroxy-5α-androstan-3-one, **3** (2.0 g). The crystallization mother liquor was subjected to column chromatography on silicic acid; elution with chloroform methanol (98:2) gave another 2.5 g of **3**. Total yield of **3** was 4.5 g (45%): m.p. 183–185 °C; n.m.r. ($CDCl_3$) δ 0.78 (3H, s, C_{18}-Me), 1.15 (3H, s, C_{19}-Me), 3.3 ~ 4.2 p.p.m. (2H, overlapping signals from $C_{11\beta}$-H, and $C_{17\alpha}$-H) (lit. (18) δ 0.78 (C_{18}-Me), 1.14 (C_{19}-Me), 3.96 (C_{11}-βH), 3.66 (C_{17}-αH)); i.r. (KBr disc) 3230 (OH), 1715 cm^{-1} (ketone). Major byproducts were isolated by column chromatography (mentioned above) and identified as 11α-hydroxy-5α-androstane-3,17-dione: m.p. 193–195 °C, (lit. (19) 194–195 °C); i.r. ($CHCl_3$) 3450 (—OH), 1730 (5-membered cyclic ketone), 1700 cm^{-1} (ketone); n.m.r. ($CDCl_3$) δ 0.93 (3H, s, C_{18}-Me), 1.17 (3H, s, C_{19}-Me), 4.0 p.p.m. (1H, br s $\Delta\nu_{\frac{1}{2}}$ = 12 Hz, $C_{11\beta}$-H) and 5α-androstane-3β,11α,17β-triol: m.p. 241–243 °C; n.m.r. ($CDCl_3$) δ 0.73 (3H, s, C_{18}-Me) 0.95 (3H, s, C_{19}-Me), 3.4–4.2 p.p.m. (3H, overlapping signals from $C_{3\alpha}$-H, $C_{11\beta}$-H, and $C_{17\alpha}$-H). Calculated δ, using Zürcher's (20) values: 0.76 (C_{18}-Me) and 0.94 (C_{19}-Me).

11α-17β-Dihydroxy-5α-androstan-3-one Diacetate (4)

Compound **3** (7.9 g) in anhydrous pyridine (30 ml) was acetylated using acetic anhydride (15 ml) at room temperature overnight. Crystallization of the product from ethanol gave 7.7 g of **4**: m.p. 192–193 °C; i.r. ($CHCl_3$) 1710 (ketone and ester), 1240 cm^{-1} (acetate); n.m.r. ($CDCl_3$) δ 0.86 (3H, s, C_{18}-Me), 1.10 (3H, s, C_{19}-Me), 1.96 (3H, s, —OAc), 2.01 (3H, s, —OAc), 4.66 (1H, br t, J = 7 Hz, $C_{17\alpha}$-H), 5.2 p.p.m. (1H, m, $C_{11\beta}$-H) (lit. (18) δ 0.86 (C_{18}-Me), 1.11 (C_{19}-Me), 4.62 (C_{17}-αH), 5.17 (C_{11}-βH)), ^{13}C n.m.r. ($CDCl_3$) δ 11.90 (C-19), 12.70 (C-18).

3ξ-Ethynyl-5α-androstane-3ξ,11α,17β-triol 11,17-Diacetate (6)

Lithium acetylide ethylenediamine (55 g, 0.55 mol; Foote Mineral Company) was placed in a nitrogen-flushed flask, followed by 385 ml of 1:1 benzene – *N,N*-dimethylacetamide (21). To it a solution of diacetate, **4** (21.4 g, 55 mmol) in 150 ml of the same solvent mixture was added dropwise over a period of 15 min at room temperature with stirring. After stirring 2 h under a nitrogen atmosphere, cold water (200 ml) was added slowly under ice-cooling with vigorous stirring and organic materials were extracted with ethyl acetate (3 × 200 ml). The organic layer was washed with 6 *N* HCl (4 × 200 ml), dried and evaporated, yielding 17.7 g of crude **5**, which was acetylated in anhydrous pyridine (100 ml) – acetic anhydride (18 ml) at room temperature. The acetylation was followed by t.l.c. ($CHCl_3$–CH_3OH 98:2) and stopped by pouring the reaction mixture slowly with stirring into cold 2 *N* H_2SO_4 (720 ml) before appreciable amounts of the triacetate formed. T.l.c. analysis of the crude product ($CHCl_3$–CH_3OH 98:2) showed, in addition to **6** as major component, *ca.* 10% of triacetate and *ca.* 20% of **4**. Crystallization from ethanol gave 8.7 g of **6**, containing a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

small amount of impurity (t.l.c. analysis) which was presumed to be the C-3 epimer. Column chromatography of the mother liquors on silicic acid (200 g) with chloroform as eluant gave triacetate and 4.5 g of **6**. Total yield of **6** was 13.2 g (31.8 mmol, 58% based on **4**). An analytical sample, recrystallized from ethanol showed a single spot on t.l.c.: m.p. 218–218.5°; i.r. (KBr) 3480 (OH), 3250 (C≡C—H), 2120 (C≡C), 1740, 1715 cm^{-1} (ester); n.m.r ($CDCl_3$) δ 0.83 (3H, s, C_{18}-Me), 0.90 (3H, s, C_{19}-Me), 1.97 (3H, s, OAc), 2.00 (3H, s, OAc), 2.48 (1H, s, ethynyl-H), 4.67 (1H, br t, J = 8 Hz, $C_{17\alpha}$-H), 5.19 p.p.m. (1H, m, $C_{11\beta}$-H).

Anal. Calcd. for $C_{25}H_{30}O_5$: C, 72.08; H, 8.71. Found: C, 71.99; H, 8.82.

3α-Ethynyl-5α-androstane-3β,11α,17β-triol triacetate, isolated as a by-product of the preparation of **6**, was identified on the basis of its n.m.r. spectrum: n.m.r. ($CDCl_3$) δ 0.84 (3H, s, C_{18}-Me), 0.93 (3H, s, C_{19}-Me), 1.99 (3H, s, OAc), 2.02 (6H, s, 2 OAc), 2.61 (1H, s, ethynyl-H) 4.65 (1H, br t, J = 8 Hz, $C_{17\alpha}$-H) 5.2 p.p.m. (1H, m, $C_{11\beta}$-H).

3-Acetyl-5α-androst-2-ene-11α,17β-diol Diacetate (7)

A stirred mixture of **6** (12.9 g, 31 mmol), glacial acetic acid (12.4 ml), and Dowex 50W (23.5 g) was heated at reflux under a nitrogen atmosphere for 12 h (22). After cooling the reaction mixture, the resin was filtered off and washed with methanol until the filtrates were clear. The combined filtrates and washings were evaporated to dryness. Crystallization of the residue from ethanol gave 4.7 g of 7. The mother liquor was acetylated in pyridine (20 ml) – acetic anhydride (10 ml) at room temperature overnight. Crystallization from ethanol of the residue after work-up gave 1.8 g of **7**. The mother liquor was purified by column chromatography on silicic acid (100 g), eluting with benzene – diethyl ether (97:3) to give another 3.4 g of 7 as a white solid. Total yield of **8** was 9.9 g (77% based on **6**). An analytical sample was obtained by recrystallization from methanol: m.p. 172–173 °C; i.r. ($CHCl_3$) 1730 (ester), 1660 cm^{-1} (C=C—C=O); n.m.r. ($CDCl_3$) δ 0.80 (3H, s, C_{18}-Me), 0.85 (3H, s, C_{19}-Me), 2.00 (1H, s, two —OAc), 2.25 (3H, s, C_3-acetyl-Me), 4.63 (1H, br t, J = 7 Hz, $C_{17\alpha}$-H), 5.2 (1H, m, $C_{11\beta}$-H), 6.7 p.p.m. (1H, br, C_2-H); u.v. λ_{max} (CH_3OH) 233 (ε 1.1 × 10^4), 300 nm (ε ≃ 70).

Anal. Calcd. for $C_{25}H_{36}O_5$: C, 72.08; H, 8.71. Found: C, 72.44; H, 8.77.

3β-Acetyl-5α-androstane-11α,17β-diol (9)

A suspension of **7** (9.5 g, 22.6 mmol) and 5% palladium–carbon catalyst (1.9 g) in ethanol (500 ml) containing 0.5 ml of pyridine (23) was hydrogenated at 1 atm and 25 °C until t.l.c. showed no u.v. absorbing spot. The catalyst was filtered off, washed with ethanol and the filtrate was evaporated to dryness, yielding 9.3 g of **8** as a pale yellow syrup: n.m.r. ($CDCl_3$) δ 0.83 (3H, s, C_{18}-Me), 0.90 (3H, s, C_{19}-Me), 1.98 (3H, s, —OAc), 2.03 (3H, s, —OAc), 2.13 (3H, s, acetyl-Me), 4.67 (1H, br t, J = 7 Hz, $C_{17\alpha}$-H), 5.2 p.p.m. (1H, m, $C_{11\beta}$-H). Without any purification crude **8** (9.3 g) in methanol (200 ml) containing 15 ml of 5 *N* sodium methoxide in methanol was heated at reflux under a nitrogen atmosphere for 11 h. The reaction mixture was extracted with ethyl acetate after addition of saturated sodium chloride and the organic phase was dried and evaporated. Crystallization from ethyl acetate gave 4.65 g of **9**. Another 1.23 g of crystalline **9** was obtained from the crystallization mother liquor by repeating the above procedure (hydrolysis–crystallization). Total yield of crystalline **9** 5.88 g (17.6 mmol, 78% based on 7). An analytical sample was obtained by crystallization from 95% ethanol: m.p. 186.5–187.5 °C; i.r. ($CHCl_3$) 3600 (—OH), 1690 cm^{-1} (ketone); n.m.r. ($CDCl_3$) δ 0.74 (3H, s, C_{18}-Me), 0.93 (3H, s, C_{19}-Me), 2.12 (3H, s, acetyl-Me), 3.5 (1H, m, $C_{17\alpha}$-H), 4.0 p.p.m. (1H, m, $C_{11\beta}$-H).

Anal. Calcd. for $C_{21}H_{34}O_3$: C, 75.40; H, 10.25. Found: C, 75.32; H, 10.18.

3β-Acetoxyacetyl-5α-androstane-11α,17β-diol (10)

To a mixture of crystalline **9** (5.01 g, 15 mmol) and lead tetraacetate (9.31 g, 21 mmol, British Drug Houses Ltd.) in benzene–methanol (95:5) (210 ml) boron trifluoride – diethyl ether complex (27.9 ml) was added dropwise over a period of 5 min with stirring under ice-cooling and a nitrogen atmosphere (24). After stirring at room temperature for 4 h, the starch iodide test for lead tetraacetate was negative. Water was added to the reaction mixture; the products were extracted with ethyl acetate. The organic phase was washed with saturated aqueous sodium chloride, saturated aqueous sodium bicarbonate, and then dried and evaporated.

The residue was rinsed with diethyl ether to yield 3.43 g of **10** as a white powder. The filtrate was evaporated to dryness and purified by column chromatography on neutral silica (50 g) eluted with chloroform-methanol (98:2) giving another 1.33 g of **10**. Total yield of **10** (powder) was 4.76 g (12.1 mmol, 81% based on **9**). The n.m.r. spectrum showed the presence of a small amount of an impurity of unknown constitution, which was more conveniently removed after the next step. An analytical sample was obtained by recrystallizing 10 times from 95% ethanol: m.p. 183–183.5 °C; i.r. ($CHCl_3$) 3600 (—OH), 1735, 1715 cm^{-1}; n.m.r. ($CDCl_3$) δ 0.70 (3H, s, C_{18}-Me), 0.93 (3H, s, C_{19}-Me), 2.15 (3H, s, OAc), 4.71 (2H, s, —CH_2-in the acetoxyketone), 3.5–4.2 (2H, m, overlapping signals from $C_{11\beta}$-H and $C_{17\alpha}$-H).

Anal. Calcd. for $C_{23}H_{36}O_5$: C, 70.37; H, 9.25. Found: C, 70.08; H, 9.23.

3β-Glycolyl-5α-androstane-11α,17β-diol (11)

A mixture of 2 *N* methanolic potassium hydroxide (12 ml) and water (4 ml) was slowly added to **10** (4.60 g) in methanol (240 ml) under ice-cooling and a nitrogen atmosphere. The solution was allowed to attain room temperature and let stand for 2.5 h. The excess of base was neutralized with acetic acid, most of the solvent was removed *in vacuo*, water was added to the residue, the products were extracted with ethyl acetate and the organic phase was dried and evaporated, yielding 3.95 g of crude **11** as a white solid which showed two spots on t.l.c. Column chromatography on 90 g of silica gel (neutral) with chloroform–methanol (98:2) as eluant yielded **11** (1.90 g) as a white solid and 1.50 g of a mixture of **12** and an unknown material which was not identical with either **10** or **9**, but identical with the unknown impurity in crude **10** based on n.m.r. data (in $CDCl_3$ δ 3.40 (s), 4.07 p.p.m. (s)). An analytical sample of **10** was obtained by recrystallization from acetone: m.p. 180–181°; n.m.r. ($CDCl_3$) δ 0.75 (3H, s, C_{18}-Me), 0.97 (3H, s, C_{19}-Me), 3.5–4.2 (2H, m, overlapping signals from $C_{11\beta}$-H and $C_{17\alpha}$-H),

Anal. Calcd. for $C_{21}H_{34}O_4$: C, 71.96; H, 9.78. Found: C, 71.42; H, 9.75.

3β-Imidazolyl-5α-androstane-11α,17β-diol (12)

To a solution of **10** (1.86 g, 5.3 mmol) in 95% ethanol (145 ml) was added formalin (Shawinigan 37% formaldehyde) (9.1 ml) and a solution of cupric acetate monohydrate (2.18 g), water (5.5 ml), and concentrated ammonia (31.5 ml). The solution was refluxed for 4 h, at which time t.l.c. ($CHCl_3$–CH_3OH 80:20) showed that the reaction was over. The reaction mixture was allowed to cool and after addition of saturated aqueous sodium chloride, the product was extracted with ethyl acetate until the extracts were Pauly negative (17). The combined extracts were washed with 1 *M* aqueous ammonium hydroxide, dried and evaporated, yielding 1.9 g of **12** as a white powder. An analytical sample was obtained by recrystallization from methanol–water: m.p. 272° (dec.); n.m.r. (pyridine) δ 1.02 (3H, s, C_{18}-Me), 1.08 (3H, s, C_{19}-Me), 3.55 (3/2H, s, $\frac{1}{2}CH_3OH$), 3.8–4.6 p.p.m. (2H, m, overlapping peaks from $C_{11\beta}$-H and $C_{17\alpha}$-H).

Anal. Calcd. for $C_{22}H_{34}O_2N_2 \cdot \frac{1}{2}CH_3OH$: C, 72.15; H, 9.69; N, 7.48. Found: C, 72.59; H, 9.78; N, 7.30.

3β-Imidazolyl-5α-androstane-11,17-dione (13)

Crude **12** (1.83 g, 5.1 mmol) was dissolved in a mixture of 2 *N* aqueous sulfuric acid (25.5 ml) and acetone (51 ml), to which was added 10 ml of Jones' reagent (2 *M* in chromium trioxide, 3.3 *M* in sulfuric acid) dropwise with stirring. The reaction mixture was allowed to stir at room temperature for 2 h, at which time t.l.c. ($CHCl_3$–CH_3OH 80:20 showed that there was no remaining starting material. Concentrated ammonia was added to basify the reaction mixture and the product was extracted with ethyl acetate. The ethyl acetate extracts were dried and evaporated, yielding 1.78 g (5.03 mmol, 98.5%) of crude **13** as a pale yellow solid, which was crystallized from methanol: m.p. 278 °C (dec.); i.r. (KBr) 1725 (C_{17}-ketone), 1690 cm^{-1} (C_{11}-ketone); n.m.r. ($CDCl_3$) δ 0.80 (3H, s, C_{18}-Me), 1.03 p.p.m. (3H, s, C_{19}-Me); n.m.r. (D_2O using the monohydrochloride of **14**), δ 0.73 (3H, s, C_{18}-Me), 0.95 (3H, s, C_{19}-Me), 7.1 (1H, s, 5 (4) H of imidazolium ring), 8.5 p.p.m. (1H, s, 2H of imidazolium ring).

3β-Imidazolyl-11,17-bisoximido-5α-androstane (14)

A mixture of crude **13** (1.5 g) and hydroxylamine hydrochloride (3.0 g) in 90% aqueous pyridine (30 ml) was heated at reflux for 12 h. After cooling the reaction mixture, the pyridine was removed *in vacuo* thoroughly, 1 *N* aqueous sodium hydroxide (50 ml) was added to the residue and the product was extracted with ethyl acetate until the extracts were Pauly negative. The ethyl acetate extracts were dried and evaporated, giving quantitative recovery of crude **14** as a pale yellow powder. Crystallization from methanol–water gave colorless crystalline **14**. An analytical sample was obtained by recrystallization from methanol–water: m.p. 300 °C (dec.); i.r. (KBr) 3600, 3400, 1630 cm^{-1} (C=N in oxime); n.m.r. (CD_3CO_2D) δ 0.90 (3H, s, C_{18}-Me), 1.15 p.p.m. (3H, s, C_{19}-Me).

Anal. Calcd. for $C_{22}H_{32}O_2N_4$: C, 68.72; H, 8.39; N, 14.57. Found: C, 68.81; H, 8.39; N, 14.23.

3β-Imidazolyl-5α-androstane-11β,17β-diamine (15)

Crystalline **14**, (576 mg, 1.5 mmol) was dissolved in methanol (6 ml) and 1 *N* aqueous hydrochloric acid (1.5 ml) was added: evaporation gave the monohydrochloride of **14** as a white powder. This monohydrochloride was dissolved in glacial acetic acid (15 ml) and hydrogenated over PtO_2 (200 mg) at 450 p.s.i. and room temperature for 48 h. The hydrogenation was interrupted and PtO_2 (200 mg) and 3 *N* HCl (0.33 ml) were added. The hydrogenation was continued under the same conditions for 70 h. The hydrogenation was interrupted again and PtO_2 (200 mg) and 3 *N* HCl (0.25 ml) were added; hydrogenation was continued under the same conditions for 70 hours. After filtering off the catalyst and washing thoroughly with glacial acetic acid, the filtrates and washings were combined and evaporated to dryness. The residue was chromatographed on neutral silica (20 g), eluting first with 10% 1 *M* ammonia in methanol – 90% chloroform, then with 15% 1 *M* ammonia in methanol – 85% chloroform. Pooling appropriate fractions gave 161 mg of **15**. A second column chromatography of this material on neutral silica (5 g) eluting with 10% 1 *M* ammonia in methanol – 90% $CHCl_3$ gave 105 mg of **15** as a pale yellow syrup. This material dissolved in methanol – *n*-propanol was treated with 3 *N* HCl (0.295 ml) and evaporated to dryness yielding 132 mg of the trihydrochloride of **15**, a white powder. This trihydrochloride of **15** was dissolved in the minimum amount of boiling methanol, *n*-propanol was added to the boiling methanol solution and methanol was driven off at the boiling point until an abundant precipitate had formed. This operation was repeated several times for an analytical sample and a sample for kinetic studies: m.p. > 350 °C; n.m.r. (D_2O) 100 MHz, δ 1.04 (6H, s, C_{18} and C_{19}-Me), 3.24 (1H, br t, J = 8.5 Hz, $C_{17\alpha}$-H), 3.55 (1H, t, J = 7.0 Hz, $\frac{1}{2}CH_3CH_2$-CH_2OH), 4.05 (1H, br s, $\Delta\nu\frac{1}{2}$ = 10 Hz, $C_{11\alpha}$-H), 7.23 (1H, s, 5 (4) H of imidazolium ring), 8.60 p.p.m. (1H, s, 2H of imidazolium ring).

Anal. Calcd. for $C_{22}H_{39}N_4Cl_3 \cdot \frac{1}{2}C_3H_7OH.3/2H_2O$: C, 53.96; H, 8.87; N, 10.71. Found: C, 54.09; H, 8.87; N, 10.40.

Substrates for Kinetics

p-Nitrophenyl acetate (Eastman, m.p. 75–77°) was used without further purification. 4-Hydroxy-3-nitrophenyl trimethylammonium iodide, **19**, was prepared according to the procedure of Bruice *et al.* (25), m.p. 220–221° (lit. (25) m.p. 220°).

3-Acetoxy-4-nitrobenzoic Acid

To a stirred solution of 3-hydroxy-4-nitrobenzoic acid (Aldrich, m.p. 231–237°, 0.915 g) and triethylamine (1.01 g) in DMF (5 ml) was added acetic anhydride (0.51 g). After stirring 1 h at room temperature, 1 *N* HCl (30 ml) was added, and the mixture was extracted with diethyl ether (3 × 30 ml). The combined extracts were washed with water (twice), dried (Na_2SO_4), and evaporated. The residue (1.02 g) was crystallized from 95% ethanol, m.p. 187–188°.

Anal. Calcd. for $C_9H_7NO_6$: C, 48.01; H, 3.09. Found: C, 47.97; H, 3.09.

3-(3-(2-Naphthyl)propanoyloxy)-4-nitrobenzoic Acid (18)

3-(2-Naphthyl)propionic acid (prepared from 2-naph-

thaldehyde (26)) (1.0 g) in dry DMF (5 ml), was cooled in an ice bath, treated with triethylamine (0.48 ml) and then ethyl chloroformate (0.53 ml), and stirred 5 min. To this stirred mixture was added a solution of 3-hydroxy-4-nitrobenzoic acid (0.92 g) and triethylamine (0.96 ml) in dry DMF (4 ml). The ice bath was removed and the mixture was stirred 30 min, then poured into 1 *N* HCl (30 ml) and extracted into ethyl acetate (30 ml). The organic layer was washed with water (three times) and saturated aqueous sodium chloride (once), dried (Na_2SO_4), and evaporated. The residue was purified by preparative layer chromatography (Merck Silica Gel PF 254) using 95:5:1 benzene – ethanol – acetic acid as solvent and crystallized from benzene–cyclohexane, m.p. 186–188°.

Anal. Calcd. for $C_{20}H_{15}NO_6$: C, 65.75; H, 4.15. Found: C, 66.24; H, 4.21.

4-Acetoxy-3-nitrophenyltrimethylammonium Iodide (20)

To a suspension of **19** (0.972 g) in DMF (6 ml) was added triethylamine (0.303 g). After 30 min stirring, acetic anhydride (0.306 g) was added and the mixture was stirred 1 h, and then evaporated to dryness. Crystallization from 1:1 ethanol–water gave 0.745 g **20**, m.p. 152–157° (dec.). Recrystallization gave material of m.p. 154–156.5° (dec.) (lit. (25) m.p. 151–155°).

4-(3-(2-Naphthyl)propanoyloxy)-3-nitrophenyltrimethylammonium Iodide (21)

To a suspension of **19** (0.324 g) in DMF (1 ml) was added triethylamine (0.202 g) and the mixture was stirred 30 min at room temperature. Then to this stirred solution was added the mixed anhydride formed by stirring 3-(2-naphthyl)propanoic acid (0.200 g) in trifluoracetic anhydride (0.210 g) for 30 min at room temperature. The combined reaction mixture was stirred 20 min at room temperature and evaporated to dryness *in vacuo*. The residue was crystallized from 95% ethanol to give 0.385 g of **21**. After three recrystallizations, it had m.p. 158–160°.

Anal. Calcd. for $C_{22}H_{23}N_2O_4I$: C, 52.18; H, 4.58. Found: C, 52.20; H, 4.50.

Kinetics

Esters were added as solutions in acetonitrile from a microliter syringe to buffer containing imidazole or steroid in 1-cm cuvettes of 3 ml or 1 ml capacity and the solutions mixed by inverting the stoppered cuvettes. Appearance of phenolate ion was followed at 400 nm for **16**, **20**, and **21** and at 420 nm for **17** and **18**. Solutions were brought to the desired calculated ionic strength with KCl. p*H* was determined at the end of each run. Pseudo first-order rate constants were calculated from first order plots which were linear to at least 3 half-lives.

We gratefully acknowledge financial support from the National Research Council of Canada, and a generous gift of adrenosterone from the Upjohn Company, Kalamazoo, Mich. We wish to thank Dr. J. B. Stothers of this department for the ^{13}C n.m.r. spectra.

Biosynthesis of Lycomarasmin

C. R. POPPLESTONE AND A. M. UNRAU
Department of Chemistry, Simon Fraser University, Burnaby 2, British Columbia

Received April 2, 1973

Cultures of *Fusarium oxysporum Schl. emend. Sny. et Hans. f. lycopersici (Sacc.) Sny. et Hans.* grown on a liquid medium with glucose as the principal carbon source produce, among other products, the phytotoxin lycomarasmin. Acid hydrolysis of lycomarasmin results in the formation of aspartic acid, glycine, and pyruvic acid. Tracer studies showed that glycine-U-^{14}C, L-serine-U-^{14}C, DL-aspartic acid-4-^{14}C, DL-alanine-1-^{14}C, and glucose-U-^{14}C served as relatively efficient precursors of the lycomarasmin molecule. DL-Aspartic acid-4-^{14}C was incorporated into the 4-carbon fragment without label scrambling. Glycine was found to be the most efficient precursor of the 2-carbon fragment while glucose afforded the most efficient and direct route for the 3-carbon fragment.

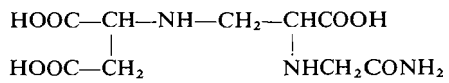
Des cultures de *Fusarium oxysporum Schl. emend. Syn. et Hans. f. lycopersici (Sacc.) Syn. et Hans.* se développant sur un médium liquide avec comme source principale de carbone, le glucose, ont produit plusieurs composés dont la phytotoxine, lycomarasmine. L'hydrolyse acide de la lycomarasmine a conduit à la formation d'acide aspartique, de glycine et d'acide pyruvique. Des études avec des éléments marqueurs ont montré que la glycine-U^{14}C, la L-serine-U^{14}C, l'acide DL-aspartique-4-^{14}C, la DL-alanine-1-^{14}C et le glucose-U-^{14}C sont des précurseurs relativement efficaces de la molécule de lycomarasmine. L'acide DL-aspartique-4-^{14}C a été incorporé dans le fragment du carbone-4 sans aucun mélange du marqueur. La glycine s'est révélée être le précurseur le plus efficace du fragment carbone-2 alors que la glucose représente le chemin le plus efficace et le plus direct pour l'obtention du fragment carbone-3.
[Traduit par le journal]

Can. J. Chem., **51**, 3943 (1973)

Introduction

Lycomarasmin, the structure of which was determined in 1962 (1), is a phytotoxin produced by various strains of *Fusarium*. At least two other wilt toxins are produced by *Fusarium oxysporum, f. lycopersici*, one of which is fusaric acid (2). The biosynthesis of this pyridine alkaloid has been established (3, 4). Topical application of fusaric acid and lycomarasmin results in rapid wilting and necrosis of leaves. Whether the wilting symptoms exhibited by infected plants, particularly during high transpiration stress, is directly due to the systemic presence of these alkaloids or due to tylosis is not entirely clear. It is known that high concentrations of these wilt toxins are only produced in still cultures (5). Time course studies have shown that lycomarasmin made its first appearance in 40-day-old culture filtrates, after which the amount of lycomarasmin rose steadily at least until the 85th day (5).

The structure of lycomarasmin (**1**) indicates that at least some parts of the molecule could well be derived from simple amino acids or their deaminated keto analogs. A subdivision of the molecule into its apparent structural units gives rise to a series of well-known metabolic intermediates all of which could conceivably serve as immediate biogenetic precursors. Thus, acid hydrolysis of lycomarasmin gives rise to aspartic acid, pyruvic acid, and glycine (1), some or all of which might serve as building units. We now wish to describe labelling experiments which would either unequivocally determine the actual precursors or at least significantly narrow down the possible alternatives.



1

Experimental

Growth Conditions of Fungus

Fusarium oxysporum Schl. emend. Sny. et Hans. f. lycopersici (Sacc.) Sny. et Hans., Strain n. 5414, kindly supplied by Dr. S. Naef-Roth, Institut fur Spezielle Botanik der Eidgenossischen Technischen Hochschule, Zurich, was used in all experiments. Stock cultures were maintained on potato dextrose agar slants.

Culture media was inoculated by transferring the mycelium to 2-l Erlenmeyer flasks containing 500 ml modified Richards' medium (6) and maintained (still culture) at 25 °C in the dark. Lycomarasmin was isolated, after requisite growth intervals, from the culture filtrates according to the procedure described by Hardegger *et al.* (1), m.p. 225–228° (dec.)(lit. (1) 227–229°), $[\alpha]_D^{25}$ −48° (6).

Radioisotopic Techniques

(a) Radioactive Materials and Adminstration

DL-Aspartic acid-1-^{14}C, DL-alanine-1-^{14}C, L-serine-U-^{14}C, glycine-U-^{14}C, glycine-2-^{14}C, D-glucose-U-^{14}C, D-glucose-6-^{3}H, and L-aspartic acid-2,3-^{3}H were obtained from the International Chemical and Nuclear Corporation, California, and New England Nuclear, Massachusetts.

An aqueous solution of each radioactive tracer was prepared in a standard volumetric flask and sterilized for 30 min at 130 °C. Aliquots of the appropriate solution were administered to cultures which had been growing for 2–4 months using a sterilized hypodermic syringe fitted with a 12 in. needle. The solution containing the radioactive compound was injected into the culture medium below the mycelial pad.

(b) Assay of Radioactivity

Aqueous solutions of amino acids were counted in a scintillator solution consisting of naphthalene (100 g) and 2,5-diphenyloxazole (PPO) (5 g) dissolved in dioxane (1 l).

Toluene solutions of the 2,4-dinitrophenylhydrazone derivative of pyruvic acid were counted in a scintillator solution consisting of PPO (4 g) and POPOP (50 mg) per liter of toluene.

Lycomarasmin, crystallized to constant activity, was dissolved in 0.02 *N* sodium hydroxide and counted as previously described for amino acids.

Radioactivity of $^{14}CO_2$ was assayed using the procedure described by Jaffray and Alvarez (7). The radioactivity in the samples was assayed in a Beckman LS 200B automatic liquid-scintillation counter under the specified conditions. Background corrections were made and the observed counting rate was converted to an absolute value.

Acid Hydrolysis of Lycomarasmin

Lycomarasmin (100 mg) dissolved in 6 *N* hydrochloric acid (5 ml) was heated in a sealed tube for 7 h at 140–150 °C. After cooling, the solution was transferred to a 50-ml flask and connected to the vacuum pump via a Dry Ice – acetone cold trap (−78 °C). The flask was warmed carefully to completely remove the solvent (the remaining residue contained amino acids) and the condensate in the trap added to a solution of 2,4-dinitrophenylhydrazine (50 mg) in hot 6 *N* hydrochloric acid (5 ml). The resulting solution was heated on a water bath for 5 min and then stored at 4 °C for 15 h during which time the 2,4-DNPH derivative of pyruvic acid crystallized. The derivative was collected (centrifugation), dissolved in a solution (5 ml) of 2 *N* sodium carbonate, and filtered to remove unreacted reagent. The filtrate was carefully acidified with 50% hydrochloric acid and the resulting precipitate collected. The 2,4-DNPH derivative was washed with 1–2 ml of water and dried under vacuum (27 mg, 28%), m.p. 215–217 °C, mixture m.p. 214–216 °C.

The residue of amino acids was, after addition of water (10 ml), again concentrated to dryness *in vacuo* to effect removal of residual HCl. The mixture of amino acids was dissolved in water (2–3 ml) and separated using a Dowex 1 (×8) acetate column (1 × 10 cm). Glycine was eluted with water (35 ml) and aspartic acid with 0.5 *N* acetic acid (60 ml).

Each fraction was evaporated to dryness. The residues were dissolved in water (2–3 ml) and, after addition of charcoal, filtered through a 2-mm layer of Celite 535. The filtrate was concentrated to a small volume (1–3 ml) upon which the amino acid crystallized by the addition of ethanol (1–5 ml). For aspartic acid, glacial acetic acid (0.5 ml) was also added. Each amino acid was crystallized to constant activity and counted as described.

Aqueous Hydrolysis of Lycomarasmin

Lycomarasmin (200 mg), suspended in water (7 ml), was heated in a sealed tube for 2½ h at 200 °C. After cooling, the solution was removed and transferred to a 50 ml-flask and evaporated to dryness under vacuum. An aqueous solution of the residue was decolorized with charcoal. After filtering through a pad of Celite, the mixture of amino acids was partially separated on a Dowex 1 (×8) acetate column (1 × 10 cm). Glycine and alanine were eluted with water (35 ml) and aspartic acid with 0.5 *N* acetic acid (60 ml). Aspartic acid was crystallized as described previously.

The mixture of alanine and glycine was resolved on a Dowex 50 (×8) (H^+) column (8). The amino acids were eluted with 1 *N* hydrochloric acid at a rate of 8 ml/h and collected in 10-ml fractions in which glycine was eluted first followed by alanine. The fractions containing the individual amino acids, as detected by paper chromatography, were combined and evaporated to dryness *in vacuo*. Residual HCl was removed from the samples by elution with water through a Dowex 1 (×8) (acetate) column and the amino acids crystallized from aqueous ethanol to constant activity.

Paper Chromatography

Amino acids were identified by paper chromatography (Whatman No. 1) using the following three different solvent systems: (*i*) pyridine – acetic acid – water 50:35:15, (*ii*) pyridine–water 65:35, and (*iii*) phenol–water (1).

Skeletal Degradation of Amino Acids and Malic Acid

The chemical degradation of amino acids and malic acids for localization of radioactivity was carried out according to published procedures (9).

Results and Discussion

As a first approach toward determining the biogenetic origin of the lycomarasmin molecule, cultures of *F. lycopersici* were inoculated with ^{14}C-labelled amino acids and the specific activity of the toxin determined. This was followed by hydrolytic cleavage of the alkaloid and comparison of specific activities of the hydrolysis products.

As a regular procedure, the still cultures were maintained at 25° in the dark for 7 weeks after which 50 μCi of ^{14}C-labelled amino acid was distributed between six cultures. Two series of experiments were performed in which the cultures were harvested after 5- and 24-h contact with the labelled compounds. Crystalline lycomarasmin was isolated using a published isola-

TABLE 1. Specific activity of lycomarasmin

Precursor administered	Specific activity of precursor $\times 10^{-9}$ (d.p.m./mmol)	Specific activity of lycomarasmin $\times 10^{-4}$ (d.p.m./mmol)		Dilution $\times 10^{6}$	
		5 h	24 h	5 h	24 h
Glycine-U-^{14}C	242	0.22	3.34	110	7.3
L-serine-U-^{14}C	278	0.64	3.25	43	8.6
DL-Aspartic acid-4-^{14}C	4.66	0.17	1.67	2.7	0.3
DL-Alanine-1-^{14}C	7.24	0.10	2.01	7.2	0.4

tion procedure (1). The specific activities of the toxin and hydrolysis products of labelled toxin are shown in Tables 1, 2, and 3.

The results in Table 1 indicate that the administered ^{14}C-labelled amino acids can serve as relatively efficient precursors. The label distribution observed in Tables 2 and 3 can be explained in terms of known enzymatic interconversions of the respective amino acids, and will be considered in some detail in the succeeding sections concerned with the incorporation of specific precursors.

TABLE 2. Specific activity of hydrolysis products of 5 h ^{14}C-labelled lycomarasmin

Precursor	Specific activity $\times 10^{-3}$ (d.p.m./mmol)		
	Glycine	Aspartic acid	Pyruvic acid (as 2,4-DNPH)
Glycine-U-^{14}C	0.54	0.31	1.52
L-Serine-U-^{14}C	2.20	0.74	3.78
DL-Aspartic acid-4-^{14}C	<0.1	0.61	1.05
DL-Alanine-1-^{14}C	<0.1	0.10	1.12

TABLE 3. Specific activities of hydrolysis products of 24 h ^{14}C-labelled lycomarasmin

Precursor	Specific activity $\times 10^{-4}$ (d.p.m./mmol)		
	Glycine	Aspartic acid	Pyruvic acid (as 2,4-DNPH)
Glycine-U-^{14}C	1.04	0.37	1.54
L-Serine-U-^{14}C	0.97	0.44	1.44
DL-Aspartic acid-4-C^{14}	0.07	1.12	0.41
DL-Alanine-1-^{14}C	0.05	0.99	0.97

TABLE 4. Specific activities of hydrolysis products of lycomarasmin from cultures inoculated with glycine-2-^{14}C

Hydrolysis product	Specific activity $\times 10^{-4}$ (d.p.m./mmol)
Glycine	7.75
Aspartic acid	1.83
Pyruvic acid	4.04

Glycine-U-^{14}C, Glycine-2-^{14}C, and Serine-U-^{14}C Labelling Experiments

In the case of the 2-carbon and 3-carbon fragments, label distribution might be expected on the basis of the glycine–serine interconversion via the biological aldol–retro–aldol reaction. Glycine may be incorporated as such or may be deaminated and the generated glyoxylate in turn condensed with a suitable 3-carbon fragment.

Incorporation of glycine and serine-U-^{14}C into the 4-carbon fragment (aspartic acid) can occur via the pathway glycine → serine → pyruvate $\xrightarrow{CO_2}$ oxaloacetate → aspartate.

A labelling experiment with specifically labelled glycine-2-^{14}C was designed to establish the origin of the 2-carbon fragment. Six cultures, 10 weeks old, were labelled for 48 h with 100 μCi glycine-2-^{14}C. The isolated lycomarasmin had a specific activity of 1.67×10^{5} d.p.m./mmol and the specific activities of the hydrolysis products are shown in Table 4.

The glycine was degraded by oxidation with ninhydrin and carbon 1, counted as CO_2, was found to contain 28% of the label and carbon 2, counted as the dimedone derivative of formaldehyde, contained 72% of the label. This distribution of label can be rationalized on the basis of randomization of label in the TCA cycle and regeneration of glycine by transamination of glyoxylate from the glyoxylate cycle. Despite

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

this randomization of label, glycine-2-^{14}C was incorporated with relatively high efficiency into the 2-carbon fragment.

In view of the results of the labelling experiments with uniformly labelled glycine and serine and also with specifically labelled glycine, it is reasonable to propose that glycine is a prime precursor to the 2-carbon fragment. These experiments do not however yield unequivocal information as to whether glycine participates as such or is first deaminated to glyoxylate before condensation with the 3-carbon fragment.

Aspartic Acid-4-^{14}C, Aspartic Acid-2,3-^{3}H, and Alanine-1-^{14}C Labelling Experiments

The experimental results (Tables 1 and 3) indicate that aspartate can serve as the 4-carbon source and may also contribute to the 3-carbon fragment. The reason for the relatively low specific activity of the lycomarasmin from the aspartic acid-4-^{14}C labelling experiment may be attributed to the generally accepted high biological lability of this amino acid. It is significant to note that almost 70% of the label which is incorporated into lycomarasmin enters the 4-carbon fragment and 25% into the 3-carbon fragment while very little activity ($\sim$5%) enters the 2-carbon fragment. The observed incorporation of label into the 3-carbon fragment could readily occur via fumarate ($C_4 \equiv C_1$) → malate → oxaloacetate → phosphoenolpyruvate(PEP) → 3-hydroxypyruvate → serine.

Both D- and L-isomers of alanine can be used as the sole carbon source for several species of *Fusaria* (10). Incorporation of label from alanine-1-^{14}C into aspartate (the 4-carbon fragment) could occur via pyruvate → oxaloacetate → fumarate. Oxaloacetate thus derived by carboxylation may give rise to PEP which can eventually give rise to 3-hydroxypyruvate via a similar pathway as indicated for aspartic acid and so enter the 3-carbon fragment.

The low distribution (2.5%) of label from alanine-1-^{14}C into the 2-carbon fragment is of the same magnitude as that observed for aspartic acid-4-^{14}C (5%). Based on the assumption that the label from both these compounds enters the 3-carbon fragment by a similar pathway, these results suggest that their conversion into a suitable 3-carbon source does not proceed past 3-hydroxypyruvate to any significant extent since conversion of this compound into serine would, as has been shown, lead to incorporation of label into C-1 of glycine. The low level of ^{14}C that was incorporated in glycine indicates that the glyoxylate cycle is operative at an accordingly low level.

In order to differentiate between the two possibilities of the 4-carbon fragment being derived directly from either fumarate or aspartate, aspartic acid isolated from lycomarasmin was first degraded by deamination to malic acid followed by decarboxylation to acetaldehyde.

The total carboxyl activity of malic acid and also the activity at C-1 were determined in separate experiments, and the activity at C-4 obtained by difference.

Table 5 shows the distribution of ^{14}C in the carbon atoms of aspartic acid (specific activity = 1.12×10^4 d.p.m./mmol) obtained from lycomarasmin isolated from cultures which had been labelled 24 h with DL-aspartic acid-4-^{14}C. The distribution is expressed as a percentage of the total activity detected.

The overall pattern therefore strongly suggested that the entry of C-1, -2, -3, and -4 of aspartic acid occurs mainly as an intact (or at least isotopically identically reconstituted) carbon chain into the 4-carbon component of lycomarasmin.

The relatively specific incorporation of aspartic acid-4-^{14}C therefore eliminates the possibility of direct participation of fumarate and suggests that aspartate may be incorporated directly or as oxaloacetate. With a view to differentiating between these two possible precursors, a feeding

experiment with L-aspartic acid-2,3-^{3}H was performed.

L-Aspartic acid-2,3-^{3}H (1000 μCi) was distributed equally between six cultures. It was found necessary to extend the feeding period to 14 days in order to increase the incorporation of ^{3}H to a measurable quantity for subsequent degradation experiments. Lycomarasmin (200 mg) was added as carrier during the work-up procedure to give a final yield of 250 mg which on acid hydrolysis gave 114 mg of aspartic acid and 60 mg glycine. The results of this feeding experiment are summarized in Table 6. It was not found possible to determine the specific activity of the 2,4-DNPH derivative of pyruvic acid due to severe color quenching in the tritium channel.

Aspartic acid isolated from lycomarasmin was degraded in a similar way as in the previous experiment, with the exception that acetaldehyde was further degraded by the iodoform reaction to give C-2 as formate. Degradation of the isolated aspartic acid by the sequence described resulted in only 1.5% of the label of malate being detected in the formic acid derived from C-2 of aspartate. It was not possible to determine the activity of the iodo-form because of quenching in the tritium channel. This low level of activity at C-2 is most probably the result of this amino acid undergoing transamination at a faster rate than its direct incorporation into lycomarasmin and the experiment does not, therefore, conclusively differentiate the participation of aspartate from that of oxaloacetate.

The tritium from aspartic acid-2,3-^{3}H can be incorporated into the 2-carbon fragment (glycine) via a slow but sufficiently operative glyoxylate cycle particularly over the necessary extended feeding period. This observation is in accord with the slow ^{14}C incorporation from aspartate and alanine described above. The somewhat higher incorporation of tritium is attributable to the longer feeding period employed in this experiment.

The biogenetic reaction sequence involved, followed by the requisite chemical degradations are summarized in Scheme 1.

D-*Glucose-U-*^{14}*C and* D-*Glucose-6-*^{3}*H Labelling Experiments*

Based on our previous findings that aspartic acid and glycine furnish the carbon atoms for the 4- and 2-carbon fragments respectively, possibilities for the origin of the 3-carbon fragment are a 3-carbon amino acid such as serine, or 3-carbon compounds derived from glucose such as 3-hydroxypyruvate, phosphoenolpyruvate or pyruvate. With a view to determining the participation of the latter three compounds a labelling experiment with glucose-U-^{14}C was carried out.

D-Glucose-U-^{14}C (180 mCi/mmol, 500 μCi) was distributed between six 10-week-old cultures and the lycomarasmin isolated after a 24 h labelling period. The specific activities of lycomarasmin and the hydrolysis products have been divided by 10 before entry into Table 7 for comparison purposes with those from the amino acid labelling experiments, in which 50 μCi of each amino acid was fed.

The results in Table 7 suggest that either glucose is a more immediate precursor of the 3-carbon fragment than the amino acids or that it penetrates to the site of synthesis more easily. However, previous analytical studies of the culture medium have shown that the organism is depleted in glucose after 30 days growth (11) thus largely eliminating the possibility that glucose serves as an immediate precursor at such a time. External application of ^{14}C-labelled amino acids results in their dilution by the relatively large pool of unlabelled amino acids in the medium (11) prior to their transport to the site of synthesis resulting in relatively low specific activity of lycomarasmin. Glucose, on the other hand, will undergo rapid catabolism inside the cells resulting in production of numerous 2- and 3-carbon compounds and provided they undergo transamination near the site of synthesis, the specific activity of lycomarasmin will be relatively high. Unless this transamination process occurs near the site of synthesis, the release of the freshly derived amino acids into the general amino acid pool would consequently give specific activities not

too different from direct administration of labelled amino acids.

Cochrane *et al.* (12) supplied *F. oxysporum* with glucose-U-^{14}C and subsequently demonstrated that less than 5% of the glucose label remains in the medium. The present finding of a relatively higher incorporation of glucose into lycomarasmin as compared with the amino acids may therefore simply indicate that permeability barriers exist.

Nevertheless, the relatively high incorporation of activity in the 3-carbon fragment (pyruvate) suggests that this part of the molecule is relatively efficiently derived from glucose.

It was reasoned that the information gained from a dual labelling experiment with D-glucose-U-^{14}C-6^{3}H would elucidate the mechanism by which the 4-carbon fragment condenses with the 3-carbon fragment.

For the detection of tritium in the 3-carbon fragment, it was found necessary to count this fragment as alanine rather than pyruvic acid because of the intense color quenching caused by the 2,4-DNPH derivative. For this reason, the lycomarasmin was subjected to aqueous hydrolysis giving glycine, alanine, and aspartic acid. It was also necessary to extend the feeding period to 40 h in order to increase the incorpora-

tion of ^{14}C and ^{3}H to a measurable quantity for the calculation of the $^{3}H/^{14}C$ ratio.

The results of this dual labelling experiment in which 500 μCi of D-glucose-U-^{14}C and 1000 μCi of D-glucose-6-^{3}H were distributed between six cultures are summarized in Table 8. During the work-up procedure 50 mg carrier lycomarasmin were added to give a final yield of 330 mg. Each $^{14}C/^{3}H$ ratio was divided by the $^{14}C/^{3}H$ ratio of the original glucose to give the ratio that would have been obtained if the $^{14}C/^{3}H$ ratio in the glucose had been 1:1 before entry into Table 8.

Consideration of the pathway by which the 3-carbon fragment is derived from glucose leads to the prediction that retention of ^{3}H at C-3 will result in a $^{14}C/^{3}H$ ratio comparable to the initial value, *i.e.*, 1:1 corrected. Similarly, loss of one tritium atom at C-3 will result in a ratio of about 2:1, corrected. The observed value of $^{14}C/^{3}H$ in alanine derived from pyruvic acid is 9.5:1 corrected, showing a substantial loss of tritium which cannot be explained by the loss of one tritium atom. This loss of tritium can, however, be rationalized on the basis of the tritium atoms (at C-6 in the original glucose) undergoing relatively rapid chemical or biological exchange before incorporation into lycomarasmin. This could occur by the pathway PEP → pyruvate → oxaloacetate → PEP → 3-carbon fragment of lycomarasmin.

Summary

The experimental results described herein indicate that metabolites occupying rather key positions in well established metabolic cycles serve as efficient precursors of the different parts of the wilt toxin. The administered glycine-2-^{14}C was primarily incorporated without extensive label randomization; however, the results do not unequivocally distinguish between the participation of either glycine or glyocylate, or both. Feeding of aspartic acid-4-^{14}C showed that the entry of C-1, -2, -3, and -4 of aspartate occurs mainly as an intact carbon chain into the 4-carbon fragment of lycomarasmin, although experiments with aspartic acid-2,3-^{3}H were inconclusive in differentiating between the participation of oxaloacetate from that of aspartate.

The labels from alanine-1-^{14}C and aspartic acid-4-^{14}C were incorporated to only a small extent into the 2-carbon fragment of lycomarasmin indicating the conversion of these compounds does not proceed past 3-hydroxypyruvate. Taken in conjunction with results from a glucose-U-^{14}C feeding experiment, the above experiments indicate that the probable precursor of the 3-carbon fragment is a compound readily derived from glucose such as phosphoenolpyruvate. From a mechanistic approach, the condensation of aspartate, phosphoenolpyruvate and glycine could directly lead to the formation of the wilt toxin.

A Rapid Route to Hex-1-enopyran-3-uloses[1]

BERT FRASER-REID, D. L. WALKER,[2] S. Y-K TAM,[3] AND N. L. HOLDER[4]

Chemistry Department, University of Waterloo, Waterloo, Ontario

Received June 18, 1973

Whereas the pseudo-axial 3-hydroxyl group of allal derivatives is known to be inert to manganese dioxide oxidation, the equatorial counterpart in glucal derivatives is shown to be readily oxidized. Thus glucal is converted to the 6-*O*-triphenylmethyl ether or 6-*O*-benzoyl ester to promote solubility in chloroform, and the derivatives are oxidized in that solvent in 12 h or less.

Acetonation of glucal is readily accomplished in 45 min using 2,2-dimethoxypropane and *p*-toluenesulfonic acid in dimethylformamide; the product may be oxidized directly either with manganese dioxide or dipyridine chromium oxide. Thus it is possible to obtain 1–3-g quantities of the crystalline acetonated enone from triacetyl glucal (via deacetylation, acetonation, and oxidation) in 3–4 h.

If the acetonation medium stands for 2 h methyl 2,3-dideoxy-4,6-*O*-isopropylidene-α-D-*erythro*-hex-2-enopyranoside is obtained. The mechanism of its formation in the reaction medium is discussed.

Alors que le groupe hydroxy-3 pseudo-axial des dérivés allal est reconnu inerte vis-à-vis de l'oxydation par le bioxyde de manganèse, on montre que le groupe équatorial des dérivés glucal est rapidement oxydé. Ainsi, le glucal est transformé en dérivé triphénylméthoxy-6 ou benzoxy-6 afin d'augmenter sa solubilité dans le chloroforme et les dérivés sont oxydés dans ce solvant en douze heures ou moins.

L'acétonation du glucal est aisément réalisé en 45 min à l'aide du diméthoxy-2,2 propane et l'acide *p*-toluènesulfonique dans la diméthyl formamide; le produit peut être directement oxydé avec du bioxyde de manganèse ou avec le complexe dipyridine oxyde de chrome. Il est possible à partir du glucal triacétylé d'obtenir en 3–4 heures des quantités de 1–3 g de l'énone acétoné sous forme cristalline (par l'intermédiaire de la déacétylation, de l'acétonation et de l'oxydation).

Si le milieu réactionnel de l'acétonation est maintenu durant 2 h, on obtient le didéoxy-2,3 *O*-isopropylidène-4,6 α-D-érythro hexèno-2 pyrannoside de méthyle. On discute le mécanisme de sa formation.

Can. J. Chem., **51**, 3950 (1973)

In pursuing our interest in the chemistry of carbohydrate conjugated enones (1) we need to have an assortment of dihydro γ-pyrone type molecules such as **1** which (*a*) are obtainable from readily available materials and, in addition, may be equipped with either (*b*) acid- or (*c*) base-labile protecting groups, the choice being dictated by our ultimate designs for the molecule. Existing routes (2) do not fill requirements (*a*) and (*c*). The parent substance **7***d* has been synthesized recently (3) but the sensitivity of this substance to acid (*vide infra*) indicates that it would not likely survive conditions for preparing derivatives such as **1***a*.

Glucal (**2***a*) seemed to be a precursor via which all three requirements could be met but we were mindful of Collins' experience (2*b*) that the allylic alcohol in compound **3** was not oxidized by manganese dioxide. Having ourselves encountered anomalies in the oxidation of epimeric allylic alcohols (4) we were interested to see

SCHEME I

whether the equatorial alcohol in **4** would respond differently from its axial counterpart in **3**. We report herein the results of this study.

Given the failure of **3** to be oxidized by manganese dioxide, the appropriate candidate for testing was the equatorial isomer **4***a*. However attempts to prepare this substance from glucal (**2***a*) in the usual way with benzaldehyde and zinc chloride (5) did not give useful amounts of the material. Therefore the method of Evans *et al.* (6) was tried.

Glucal (**2***a*) was treated with α,α-dimethoxytoluene in the presence of *p*-toluenesulfonic acid at room temperature. A plethora of products was given, one of which was recognizable from t.l.c. and subsequently by isolation as olefin **5***a*. The conversion must be a highly efficient process, since **5***a* was formed in appreciable amounts (t.l.c.) very early in the reaction, even though considerable starting material remained unreacted.

The conversion of **4***a* → **5***a* is reminiscent of the well-known process in which acetylated glycals are transformed into hex-2-enopyranosides by acidified alcohols (7). Unfortunately we were unable to develop conditions that would provide for a viable synthetic process, **2***a* → **5***a*. Prolonged standing at room temperature and/or heating of the reaction mixture caused extensive decomposition.

For the rearrangement of the acetylated glycals, the favored mechanism invokes anchimeric assistance by the acetyl groups and therefore would be inoperable for the conversion of **4***a* → **5***a*. Conceivably, the process could be facilitated by formation of the mixed hemiacetal **6**, as outlined in Scheme 1.[5] Interestingly, the only other case, to our knowledge, in which a glycal with a free hydroxyl group at carbon-3 has been successfully rearranged to an hex-2-enopyranoside also involved ketal-type solvent. Ferrier and Prasad, upon treating D-glucal with boron trifluoride in dimethoxymethane also obtained **5***c* (8).

Acetonation of glucal proved to be more controllable than the foregoing benzylidination. Thus glucal (**2***a*) obtained from triacetyl glucal **2***b* (9) was treated with 2,2-dimethoxypropane in dimethylformamide, acidified to p*H* 3 with *p*-toluenesulfonic acid. After 45 min a mixture was obtained from which **4***b* could be separated chromatographically as an oil in 44% yield (from **2***b*). When the reaction was allowed to go for 2 h, two other substances, R_f 0.62 and 0.27, had formed in addition to **4***b* (R_f 0.43). The fastest running substance was isolated as a syrup and was assigned structure **5***b* because of the similarity of its n.m.r. spectrum to that of well-known **5***a*. The syrupy material (**5***b*) and **5***a* were deblocked separately by treatment with *p*-toluenesulfonic acid in dry methanol to afford the same diol **5***c*, which was converted to the known di-*O*-*p*-nitrobenzoate **5***d* (8).

Compound **4***b* underwent manganese dioxide oxidation smoothly in 2–3 days to give the crystalline ketone **1***b* in 73% yield. Alternatively the oxidation could be accomplished in 15 min (77% yield) using dipyridine chromium oxide in methylene chloride (10).

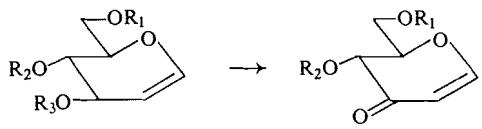
It could be estimated from the n.m.r. spectrum that the 45 min acetonation product contained >90% of **4***b*. Therefore in practice the crude acetonation product was oxidized directly. Furthermore, if **2***b* was deacetylated by the methanol–water–triethylamine method and the oxidation done with the chromium oxide complex (10), it was possible to obtain 1–3 g (~20%) quantities of crystalline **1***b* from **2***b* in 3–4 h, without purification of intermediates.

The foregoing success meant that the equatorial alcohol in glucal derivatives, unlike the axial alcohol in the previously reported allal derivatives (2), would respond to manganese dioxide treatment. An obvious limitation is that the derivative must be soluble in chloroform.

[5]We are indebted to a referee for this suggestion.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

This can readily be arranged by taking advantage of the high reactivity of the primary alcohol as has been done in the preparation of 6-*O*-*p*-toluenesulfonyl-D-glucal (11). Thus glucal **2***a* was furnished with either the base-labile benzoyl group (**2***c*) or the acid-labile triphenylmethyl group (**2***d*), and the material in each case was oxidized to the enones **7***a* and *b*, respectively. The former is a crystalline material, the latter is crystallized as the acetate **7***c*.



2 **7**

a $R_1 = R_2 = R_3 = H$ *a* $R_1 = PhCO$; $R_2 = H$
b $R_1 = R_2 = R_3 = Ac$ *b* $R_1 = Ph_3C$; $R_2 = H$
c $R_1 = PhCO$; $R_2 = R_3 = H$ *c* $R_1 = Ph_3C$; $R_2 = Ac$
d $R_1 = Ph_3C$; $R_2 = R_3 = H$ *d* $R_1 = R_2 = H$

In practice crystalline triacetal glucal (**2***b*) was deacetylated, and the crude glucal was treated with a 10% deficiency of the reagent. The unreacted glucal was extracted from the chloroform solution with water and the chloroform-soluble material was usually oxidized directly (particularly when preparing a small amount (1–2 g) of the enone), thereby postponing chromatographic separation until the final step.

Unfortunately attempts to remove the blocking group from **7***a* (with dilute base) or **7***b* (with dilute acid) to obtain the free parent enone **7***d* were unsuccessful. In both cases the enone was destroyed, judging from the n.m.r. spectrum. Deep-seated degradation of **7***b* by acid was indicated by the formation of formaldehyde.

The spectral data of these enones compare well with those of its congeners reported previously (2). In **1***b* for example, H-1 and H-2 are doublets ($J_{12} = 6$ Hz) at δ 7.26 and 5.43, respectively. The former signal in **1***a* and **7***a–c* is of course obscured by the aromatic protons. It is interesting to note that the u.v. absorption of **1***b* occurs at very much longer wavelength than that of other enones (2*c*). In the hex-2-enopyranosid-4-uloses (1*b*) and hex-3-enopyranosid-2-uloses (1*c*) the absorption in ethanol has λ_{max} at ~220 nm (ε ~9000). In **1***b* however, the absorption shows λ_{max} at 260 nm (ε 8048) which corresponds favorably with the maximum (263 nm) reported for related 2,3-dihydro-2,6-dihydro-4-pyrones (12).

We verified that compound **3** was inert to the conditions under which the glucal derivatives (**4**, **2***c* and *d*) reacted with manganese dioxide. Nickon and co-workers reported some time ago, that in some steroidal allylic alcohols, the axial epimer was less readily oxidized than the equatorial (13). In the present case the difference is more dramatic, since **3** was still unchanged after 2 weeks while **4** and **2***c* and *d* were oxidized in 0.5–3 days. A similar anomaly was noted by us in the resistance of an axially-disposed allylic alcohol in the anomers of some pent-2-enopyranosides (3). An attempt is being made by us to determine the reason for the absolute resistance of these axial alcohols. However, *the phenomenon is not general for axial allylic alcohols in carbohydrate molecules*, since 5*c* and its carbon-4 epimer were oxidized with equal readiness. Similarly hex-3-enopyranosides are oxidized to the same 2-ketone regardless of the orientation of the carbon-2 hydroxyl group.

Experimental

Melting points were determined on a Fisher-Johns heating stage and are uncorrected. Elemental analyses were performed by Chemalytics Inc., Tempe, Arizona 85281 and Microanalyses Laboratory, Toronto, Ontario. The n.m.r. spectra ($CDCl_3$, TMS) were determined on a Varian T-60 spectrometer, the *J* values quoted being the spacing measured directly from the spectra. Infrared spectra were determined on a Beckman model I.R.-10 spectrometer using 0.1-mm sodium chloride solution cells (chloroform as solvent). Ultraviolet spectra were obtained from a Beckman DBG Grating Spectrophotometer and a Cary Recording Spectrophotometer Model 14 (methanol as solvent). Mass spectra were measured with a CEC model 21-110B double focusing instrument at an i.p. of 70 eV. Optical rotations were determined on a Carl Zeiss model LEP nür 370740 Lichtelektusches Praizisionpolarimeter at 23 °C.

Thin-layer chromatography was performed on glass plates coated with silica gel (HF-254, E. Merck) to a thickness of 0.3 mm. Unless otherwise stated the chromatograms were developed in petroleum ether (30–60°) – ethyl acetate (1:1), dried, viewed under u.v. light, and then sprayed with concentrated sulfuric acid. For column chromatography E. Merck Silica Gel (0.063–0.20 mm 70–230 mesh, A.S.T.M.) was used.

The procedure for manganese dioxide oxidation was as described previously (1).

The glucal **2***a* used for the preparations below was usually the crude non-crystalline material obtained by deacetylation of triacetyl glucal (9) **2***b* by one of the following methods: (*A*) Triacetyl glucal **2***b* (25 g) was dissolved in absolute methanol (400 ml) and stirred for 3 h with anhydrous sodium carbonate (25 g). The solids were removed by filtration and the filtrate was evaporated leaving a thick syrup. (*B*) Triacetyl glucal **2***b* was dissolved in a minimum amount of methanol–water–triethylamine

mixture (5:4:1) and when t.l.c. showed the reaction to be complete (1–1½ h) the solution was poured into excess chloroform. The aqueous layer was isolated and washed twice with chloroform and then evaporated. Persistent traces of triethylamine could be removed by dissolving the residue in water and stirring with a small amount of acidic ion-exchange resin.

*1,2-Dideoxy-4,6-O-isopropylidene-*D*-arabino-hex-1-enopyranose*, **4***b*

To a solution of crystalline glucal (**2***a*) (2.0 g; 13.7 mmol) in dry dimethylformamide (50 ml) was added 2,2-dimethoxypropane (8 ml, 5 mol equiv.). The mixture was acidified to p*H* 3 (test paper) with *p*-toluenesulfonic acid and allowed to stand at room temperature for 45 min when t.l.c. visualized with iodine vapor showed appreciable amounts of a new substance **4***b*, R_f 0.43. The reaction was quenched with saturated sodium bicarbonate solution and extracted with chloroform (3 × 50 ml). The dried (Na_2SO_4) chloroform layer upon evaporation yielded an oily residue (1.7 g). N.m.r. analysis indicated that **4***b* constituted ~90% of this residue. A faster running substance **5***b*, R_f 0.62 (*vide infra*), was also detected by t.l.c. Compound **4***b* was isolated by silica column chromatography using petroleum ether – ethyl acetate (1:1) as eluant. Pure **4***b* (1.1 g, 44% yield) was isolated as an oil. Significant n.m.r. features were: δ 1.50 and 1.55 (pair of singlets, 6, $(CH_3)_2C$); 4.80 (q, 1, J_{12} = 6.0, J_{23} = 2.0 Hz, H-2); 6.37 (q, 1, J_{12} = 6, J_{13} = 2.0 Hz, H-1). The oil was characterized as its *p*-nitrobenzoate m.p. 111.5–112°; $[\alpha]_D^{23}$ −131.9° (*c*, 1.23 in chloroform).

Anal. Calcd. for $C_{16}H_{17}O_7N$: C, 57.31; H, 5.11; N, 4.18. Found: C, 57.35; H, 5.16; N, 4.26.

*1,2-Dideoxy-4,6-O-isopropylidene-*D*-erythro-hex-1-enopyran-3-ulose*, **1***b*

(*i*) The oily product (0.6 g) from 45-min acetonation of glucal was dissolved in 300 ml of chloroform and stirred with 9 g of activated manganese dioxide for 3 days. Removal of the manganese dioxide by filtration and evaporation of the filtrate afforded only an oily residue which crystallized on standing yielding 0.44 g of **1***b* (73% yield) after recrystallization from ether.

(*ii*) A portion (0.28 g) of the crude acetonation product and 2.4 g of dipyridine chromium(VI) oxide (10) in methylene chloride (10 ml) were stirred at room temperature for 15 min. The solution was filtered and the filter cake was washed with ether. The filtrate was evaporated to dryness and traces of pyridine removed by codistillation with toluene. Crystallization of the residue as in (*i*) afforded 0.22 g (77% yield) of **1***b*.

(*iii*) Glucal **2***a* (crude oil from deacetylation of 20 g of triacetyl glucal **2***b*) was dissolved in 180 ml of dried dimethylformamide and treated with dimethoxypropane (30 ml) and *p*-toluenesulfonic acid (~3.3 g) to achieve p*H* ~3. The reaction was quenched after 45 min with saturated sodium bicarbonate and worked up as described above. The oil from the dried chloroform extract (8.5 g) was dissolved in 320 ml of dried methylene chloride and freshly prepared dipyridine chromium oxide (70 g) was added in one lot while maintaining vigorous stirring with a mechanical stirrer. After 15 min the solution was filtered through celite and the filtrate was evaporated to a small volume and then diluted with ether and washed successively with 10% sulfuric acid (to remove pyridine), sodium bicarbonate, and water. The ether layer afforded an oil which crystallized readily from ether, to give **1***b* (2.9 g, 21% from **2***b*): R_f 0.4; m.p. 104–105°; $[\alpha]_D^{23}$ +206.57° (*c*, 5.0 in $CHCl_3$); I.r. ($CHCl_3$) ν_{max} 1700, 1600 (α,β-unsaturated ketone) 1250, 1060 (C═C—O—C), 1195 cm^{-1} ($(CH_3)_2C$); u.v. (ethanol) λ_{max} 260 nm (ε 8048); n.m.r.: δ 1.5 (s, 6, $(CH_3)_2C$), 3.8–4.3 (m, 4, H-4, H-5, H-6, H-6′), 5.43 (d, 1, J_{12} = 6.0 Hz, H-2), and 7.26 (d, 1, J_{12} = 6.0 Hz, H-1).

Anal. Calcd. for $C_9H_{12}O_4$: C, 58.69; H, 6.57. Found: C, 58.64; H, 6.40.

*Methyl 2,3-Dideoxy-4,6-O-isopropylidene-*α*-*D*-erythro-hex-2-enopyranoside*, **5***b*

The oily acetonation product of crude glucal (3.6 g) was oxidized by manganese dioxide as described above to give a solid residue (2.6 g). T.l.c. showed ketone **1***b* (R_f 0.40), and faster (R_f 0.62) and slower (R_f 0.27) running substances, the latter being in trace amounts. The mixture was chromatographed on a silica column and eluted with petroleum ether – ethyl acetate (1:1), whereby the material of R_f 0.62 was recovered as a mobile oil (0.280 g) $[\alpha]_D^{23}$ +54.6° (*c*, 2.20 in chloroform); n.m.r. H-1, H-2, H-3 at δ 4.90, 5.70, and 6.07, respectively; J_{12} = 10.0 Hz. For the known analog **5***a*, the corresponding values are 5.0, 5.84, and 6.1, respectively.

A portion of the oil (0.140 g) was dissolved in dry methanol (5 ml) and *p*-toluenesulfonic acid (0.025 g) was added. T.l.c. indicated the disappearance of **5***b* after 5 min. The solution was diluted with dry methanol (20 ml) and neutralized with barium carbonate. The solids were removed by filtration, and the filtrate poured into water and extracted with ether. The aqueous layer was evaporated to dryness and the residue converted to the di-*O*-*p*-nitrobenzoate **5***d* for comparison with an authentic specimen,[6] m.p. and mixture m.p., 170–171°.

*1,2-Dideoxy-4-O-acetyl-6-O-triphenylmethyl-*D*-erythro-hex-1-enopyran-3-ulose*, **7***c*

The syrupy glucal **2***a* from 25 g (0.092 mol) of **2***b* (method *A*) was dissolved in a mixture of pyridine (300 ml) and methylene chloride (100 ml), and trityl chloride (30 g, 0.108 mol) was added to the stirred solution at room temperature. After 2 days, the mixture was poured into ice water, extracted with chloroform, and the organic layer was washed with sulfuric acid, sodium bicarbonate, and then dried with sodium sulfate. Evaporation of the solvent yielded a thick oil which, after chromatography on a silica column, afforded 30 g (84% from **2***b*) of **2***c*. (The need for chromatography at this stage could be obviated by working on 2–5-g quantities of **2***b* and by using a deficiency of trityl chloride.) Crude **2***c* (15 g) was dissolved in chloroform (1500 ml) and stirred with manganese dioxide (60 g). The reaction was finished in 8 h and the solids were removed by filtration. The filtrate afforded **7***b* (13 g 85% from **2***c*) as an oil, which was acetylated with pyridine (120 ml) and acetic acid anhydride (20 ml). Customary work-up afforded **7***c* which crystallized from ether, m.p. 143.5–144.5°; $[\alpha]_D^{23}$ +230.9° (*c*, 1.55 in $CHCl_3$).

[6]We are indebted to Professor R. J. Ferrier for an authentic sample of **5***d*.

Anal. Calcd. for $C_{27}H_{24}O_5$: C, 75.68; H, 5.65. Found: C, 75.47; H, 5.67.

*6-O-Benzoyl-1,2-dideoxy-*D*-erythro-hex-1-enopyran-3-ulose*, *7a*

Crystalline glucal **2***a* (2.0 g, 1.37 mmol) was dissolved in pyridine (100 ml) and methylene chloride (50 ml). The solution was cooled in a Dry Ice – acetone bath to −76° and benzoyl chloride (1.7 ml, 1.47 mmol) in 20 ml methylene chloride was added dropwise over 1 h. At this time the solution was poured into ice water and the product extracted into methylene chloride and processed in the usual way. The resulting oil (3 g) was treated with manganese dioxide (14 g) in chloroform (200 ml). After 12 h the solution was filtered, the filtrate was evaporated, and the product was chromatographed eluting with petroleum ether – ethyl acetate (1:1). Compound **7***a* (0.95 g, 26%) was obtained by crystallization from cold ethanol, m.p. 94–95°; $[\alpha]_D^{23}+207.2°$ (*c*,1.16 in chloroform).

Anal. Calcd. for $C_{13}H_{12}O_5$: C, 62.90; H, 4.87. Found: C, 62.73; H, 5.10.

We express our gratitude to the National Research Council of Canada, Bristol Laboratories, and the University of Waterloo for the financial support that made this work possible.

The Question of Conformational Restriction in the *trans*-Cyclononene Ring of Caryophyllene[1]

E. W. WARNHOFF AND V. SRINIVASAN
Department of Chemistry, University of Western Ontario, London, Ontario
Received September 18, 1972[2]

The possibility that the barrier to rotation of the *trans* double bond within the nine-membered ring of caryophyllene might be high enough to prevent the interconversion of conformers **2** and **3** near room temperature has been examined. Contrary to earlier reports, it has been found that two *trans* epoxides are formed on peracid epoxidation of caryophyllene and hence both conformers are present. Attempts to determine whether **2** and **3** are interconverting near room temperature were inconclusive.

On a étudié la possibilité selon laquelle la barrière à la rotation de la double liaison *trans* à l'intérieur du cycle à neuf membres du caryophyllène puisse être suffisamment élevée pour empêcher l'interconversion des conformères **2** et **3** à température ambiante. Contrairement aux rapports antérieurs, on a trouvé que deux époxydes *trans* sont formés lors de l'époxydation du caryophyllène par un peracide, confirmant ainsi la présence des deux conformères. Les essais afin de déterminer si **2** et **3** peuvent s'interconvertir à température ambiante n'ont pas permis d'en venir à une conclusion.
[Traduit par le journal]

Can. J. Chem., **51**, 3955 (1973)

Introduction

There has been considerable interest in the existence of stable conformational isomers due to restricted rotation in medium ring cycloalkenes and in this regard our attention was drawn some time ago to the sesquiterpene caryophyllene. In the voluminous chemical literature on this molecule (1), certain observations suggested the possibility of severe restriction to rotation of its *trans*-cyclononene double bond about the attached single bonds to carbon. This possibility acquired increased interest when it was found by Cope *et al.* that both *trans*-cycloöctene and *trans*-cyclononene could be resolved (2, 3). Although racemization of these resolved cycloalkenes merely requires rotation about the single bonds of these molecules, in particular 180° rotation of the *trans* double bond, optically active *trans*-cycloöctene was only slowly racemized at 132° ($t_{1/2}$ = 122 h) (4). On the other hand, *trans*-cyclononene was not optically stable at room temperature and had a half life of about four minutes at 0° (3). However, the barrier to rotation of the *trans* double bond of caryophyllene (**2** ⇌ **3**) about the single bonds *a* could be higher than that of *trans*-cyclononene.[3]

Among the earlier recorded observations possibly indicative of restricted rotation is the formation of two nitrosochlorides from isocaryophyllene (**13**) with the *cis* endocyclic double bond, whereas caryophyllene gave a single nitrosochloride (5). All three nitrosochlorides were formed by addition to the trisubstituted double bond since each gave the same compound on reaction with benzylamine. A second and more significant finding was that the reaction of isocaryophyllene (**13**) with monoperphthalic acid gave approximately equal amounts of two isomeric oxides, **16** and **17**, of the *cis* endocyclic double bond, while caryophyllene afforded a

[1]Presented in part at the Symposium on the Chemistry of Natural Products, Vancouver, B.C., June 1968.
[2]Revision received August 23, 1973.

[3]The *trans*-fused cyclobutane ring and its attached exocyclic methylene group remove some of the freedom of rotation in the cyclononene ring of caryophyllene, but on the other hand the H—H repulsive non-bonded interactions during rotation might be less serious for caryophyllene than for *trans*-cycloöctene. The balance of angle and torsional strain and non-bonded interactions for the two molecules is not obvious. Since interconversion of **2** and **3** must occur by movement of one substituent on the double bond through the "hole" in the nine-membered ring, the probability of 180° rotation about bonds *a* in **2** or **3** relative to the same rotation in *trans*-cyclononene will be halved by the presence of the allylic methyl group which cannot pass through the "hole".

single pure oxide, **4**,[4] of the *trans* endocyclic double bond in 82% yield after recrystallization. "Careful examination of the product from caryophyllene showed no indication of a second oxide" (7). The *cis* endocyclic double bond of the less rigid isocaryophyllene not only has greater freedom to change from one extreme conformation to the other (**14** ⇌ **15**), but in **14** and **15** and each intermediate conformation both sides of the double bond are exposed. However, as pointed out by Barton and co-workers (6), that arrangement of the nine-membered ring of caryophyllene with the least angle and torsional strain and fewest repulsive non-bonded interactions has the plane of the endocyclic double bond perpendicular to the plane of the cyclobutane ring. There are two such conformers, **2** and **3**, in each of which only one face of the π-bond is exposed to attack, the other side being *completely* shielded by the rest of the molecule. Consequently, each conformer can only give rise to a single endocyclic 1,2-epoxide. While the above observations might merely have been reflections of the less sensitive analytical techniques available at the time, the possibility of restricted rotation merited investigation.

If, as suggested by the foregoing discussion, only a single oxide (**4**) were formed from caryophyllene, there would be, *a priori*, three possible explanations: (*a*) Conformers **2** and **3** are interconvertible by rotation about bonds *a* and appreciable amounts of each are present at room temperature. One (**2**) reacts faster with peracid (*ca.* 10–50 times) than the other but slower than the **2** ⇌ **3** interconversion. (*b*) Conformers **2** and **3** are interconvertible by rotation about bonds *a*, but conformer **2** is present in great excess (*ca.* 50:1 or greater) and rates of epoxidation of both conformers are nearly the same. (*c*) Conformers **2** and **3** are not interconvertible by rotation and caryophyllene is actually only conformer **2**. The first two conceivable explanations for the reported formation of only one oxide seemed unreasonable after examination of Stuart–Briegleb and Dreiding models of **2** and **3**. Hence, explanation (*c*) was implicated. At the time the work described herein was done, the chemistry of caryophyllene did not raise any serious obstacle to this interpretation since, in any acid-catalyzed reaction of the molecule, there was always the possibility of prior isomerization to isocaryophyllene (a known reaction; also *trans*-cyclononene is easily isomerized to *cis*-cyclononene by acid (8)) from which products could arise.[5] Nor was explanation (*c*) excluded by the total synthesis of *dl*-caryophyllene (9) since the relative stereochemistry of the boldface methyl and C_1-hydrogen in the key intermediate **18** was unknown.

However, since this work was completed, Nickon *et al.* (10) have described a mechanistic study which *requires* the presence of both conformers **2** and **3** in caryophyllene and hence excludes the possibility of caryophyllene existing *only* in conformation **2**. When **1** was cyclized in D_2SO_4 to caryolan-1-ol-9-d_1 (**19**) and clov-2-ene-9-d_1 (**20**), the deuterium atom in **19** was entirely β and that in **20** was entirely α. This result is only consistent with stereospecific anti addition of D^+ and $=CH_2$ to the *trans* endocyclic double bond (**2** → **20** and **3** → **19**) (10). Control experiments showed that isocaryophyllene, although formed, did not give caryolanol or clovene under the conditions used. Although yields of **19** and **20** were not given, this study in conjunction with the previous discussion implies, but does not prove, that conformers **2** and **3** are interconvertible near room temperature.

Results and Discussion

After initial attempts to observe changes in the n.m.r. spectrum of caryophyllene at higher and lower temperatures were inconclusive (see Experimental), our investigation of restricted rotation centered on the determination of whether only one epoxide was indeed produced in the reaction of this sesquiterpene with peracid. For this purpose a sample of caryophyllene was carefully purified to a minimum of 97% caryophyllene (see Experimental).[6] When equimolar

[4]The determination of the stereochemistry of this monoepoxide is described in ref. 6.

[5]For example, the observation that oxidation of caryophyllene with hydrogen peroxide plus vanadium pentoxide gave in addition to **4** about 10% of caryolan-1,9β-diol (**19**, OH for D), a cyclization product expected from **5**, was ambiguous since (*a*) the purity of the caryophyllene was not established, (*b*) there was no proof that the caryolan-1,9β-diol originated from an epoxide, (*c*) the presence of some *cis* oxide **16** was not excluded, (*d*) the product was subjected to an acid treatment, and (*e*) the course of the acid-catalyzed cyclization of **16**, which might lead to caryolan-1,9β-diol if not concerted, has not been investigated.

[6]The remaining ~3% consisted of traces of at least five other compounds.

quantities of this caryophyllene and monoperphthalic acid were allowed to react at 4° in ethereal solution, the crude product obtained in 98.5% yield gave four spots on t.l.c. corresponding in increasing order of polarity to ~0.5% isocaryophyllene, 2% of recovered caryophyllene, 94% of monoepoxide, and 2–3% of bisepoxide.[7] Direct crystallization of a portion of the crude product from methanol gave the well known monoepoxide **4**, m.p. 63.5–64°, $[\alpha]_D$ −79.4°, in 65–72% yield. However, the i.r. and n.m.r. spectra and the optical rotation ($[\alpha]_D$ −46°) of the crude product revealed the presence in the monoepoxide fraction of another unidentified component amounting to about 20% of the crude oxidation product.

The unknown compound was concentrated in the crystallization mother liquors from removal of successive crops of **4**. Material of m.p. 29–31° (single t.l.c. spot) containing approximately equal amounts of **4** and its companion was obtained. Further attempts to separate these compounds by low temperature crystallization and g.l.p.c. were unsuccessful[8] and therefore the mixture was used for further experiments. The most obvious differences in the n.m.r. spectra (Fig. 1) of pure monoepoxide **4** and the mixture are the additional singlet methyl peak at δ 1.23, the additional olefinic absorption at δ 5.09, and the extra *gem*-dimethyl peaks at δ 0.95 and 0.97.

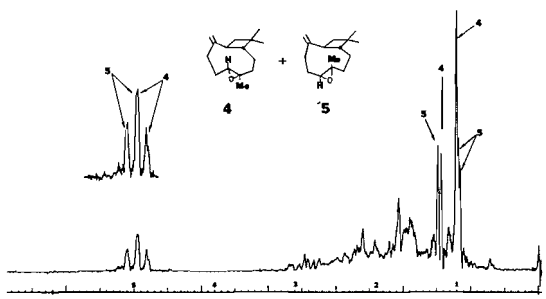

FIG. 1. Nuclear magnetic resonance spectrum of caryophyllene oxide mixture (**4** + **5**) in $CDCl_3$ solution at 60 MHz.

[7]Caryophyllene monoxide reacts much slower than caryophyllene with peracid. A sample of monoxide oxidized under the same conditions gave only about 40% of bisepoxide after 24 h at 4°.

[8]In metal g.l.p.c. columns caryophyllene oxide undergoes a variety of reactions (11). In an all glass apparatus the mixture apparently survived unchanged but no separation was obtained with the silicone SE-30 and neopentyl glycol succinate columns used.

The i.r. spectrum of the mixture did not contain carbonyl or hydroxyl absorption. That the unknown component is not either of the two *cis* epoxides **16** ($[\alpha]_D$ −7°) or **17** ($[\alpha]_D$ +23°) (7) can be seen from the distinguishing n.m.r. peaks listed in Table 1 and from the calculated optical rotation ($[\alpha]_D$ +80°) of the unknown. Nor has epoxidation occurred at the exocyclic methylene group of caryophyllene since the n.m.r. spectrum of the mixture lacks allylic methyl absorption and the ratio of olefinic protons to the rest is 2:22. Therefore, the unknown component was an oxide, most likely the missing *trans* monoepoxide **5**, and proof of this was provided in the following manner.

In the hope of obtaining separable derivatives, the exocyclic methylene group of the mixture of two epoxides was oxidized with permanganate, but the two keto epoxides formed were likewise inseparable in our hands. However, in the n.m.r. spectrum of the mixture the peaks which did not correspond to those of the known keto epoxide (**4** with =O in place of $=CH_2$) were different from the peaks of the two isocaryophyllene keto epoxides (**16** and **17** with =O in place of $=CH_2$) (see Table 1). The calculated optical rotation ($[\alpha]_D$ +187° in MeOH) was also different from that of the isocaryophyllene keto epoxides ($[\alpha]_D$ −72° and −13° in MeOH) (7).

Finally, the OsO_4-catalyzed hydroxylation of the epoxide mixture was resorted to because it was known that the only significant product of this reagent with the known caryophyllene oxide **4** was Treibs' 119° glycol **8***a* (12), and therefore any other products from the hydroxylation of the oxide mixture must have arisen from the other oxide. To facilitate separation the crude mixture of glycols obtained was subjected to mild acetylation with acetic anhydride – pyridine at room temperature. The crude acetylation product which had two major t.l.c. spots, R_f 0.55 and 0.40, and a minor spot at 0.15, was separated into components by preparative t.l.c. The least polar product, R_f 0.55, was found to be the diacetate of Treibs' 119° diol (**8***b*).

The other major component (R_f 0.40), a beautifully crystalline diol monoacetate of m.p. 159°, therefore, had come from the other unknown oxide. Saponification gave a diol, m.p. 136°, which was not identical with the diols (m.p. 130 and 196°) obtained from either of the isocaryophyllene oxides **16** and **17** (13). The diol contained a secondary hydroxyl group (ready

TABLE 1. Distinguishing n.m.r. data (δ) for the *cis*- and *trans*-caryophyllene oxides and keto oxides in $CDCl_3$ solution at 60 MHz

Isomer	Nuclear magnetic resonance data (δ)		
	gem-diMe	C_4-Me	$=CH_2$
trans-Oxide **4**	1.00 (2Me)	1.19	4.87, 4.97

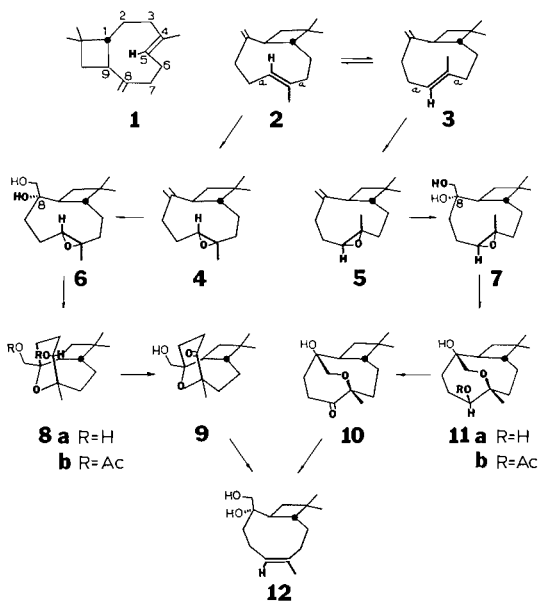
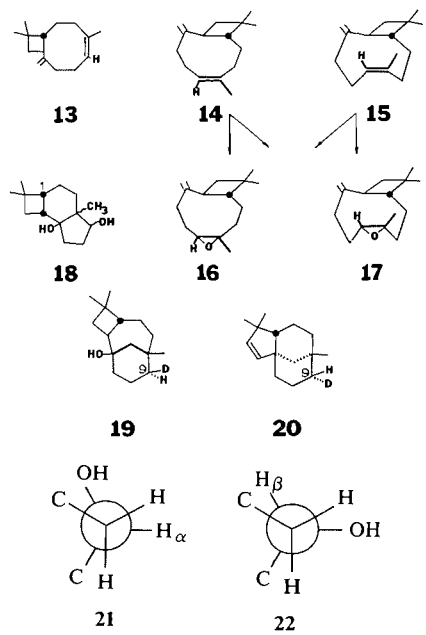
cis-Keto oxide **16** (=O for $=CH_2$)	1.02, 1.07	1.41	—
cis-Keto oxide **17** (=O for $=CH_2$)	1.01, 1.11	1.24	—

acetylation at room temperature, $\Delta\delta \sim 1.2$ p.p.m. for C*H*OH → C*H*OAc, oxidation to ketone) and a tertiary hydroxyl group (not acetylated at room temperature; 159° monoacetate not oxidized by chromic acid – pyridine). The hydroxyl groups were not vicinal since the diol did not react with $NaIO_4$. In addition the diol contained a methylene group attached to an ethereal oxygen (δ 3.87 (2H), not shifted on acetylation). The only structure that will account for the features without carbon skeleton rearrangement is **11***a*, resulting from intramolecular attack of the initial 1,2-diol **7** on the epoxide ring. This structure was confirmed in the following way. Oxidation of the diol with chromic acid – pyridine gave the hydroxy ketone **10**. On Wolff–Kishner reduction the α-alkoxy ketone **10** underwent





reductive elimination to the unsaturated 1,2-diol **12**, m.p. 92°, which proved to be identical with that obtained from Treibs' 119° glycol by the same sequence of reactions (12). Therefore, there has been no carbon skeleton rearrangement either in the formation of the unknown oxide or its reaction with OsO_4. Because of this identity the configuration of C-8 is the same in both the 119 and 136° glycols. This stereochemistry has been convincingly shown to be that resulting from α-attack of OsO_4 on the exocyclic methylene group (12). Consequently the stereochemistry of the 136° glycol must be that shown in **11***a*. Closure of the oxide ring by attack of the primary hydroxyl group on the epoxide ring with inversion can only lead to a relatively strain-free *cis*-

[4.3.2] system if the methyl configuration at the epoxide ring is β[9] (same side as the reference H at C-1) as in **5** and **7**. In what is apparently the most stable conformation of **11***a* and *b* the configuration of the secondary oxygen function must be β to account for the small width at half-height (7–8 Hz) of the n.m.r. signal due to the α-hydrogen (see **21**) on the carbon atom bearing the acetate; if this hydrogen were β as in (**22**), there would be an ~anti vicinal CH_2 coupling and a larger half-width (~15–25 Hz). Since the *cis* oxide **16** has been proved to be absent from our caryophyllene epoxidation product, the stereostructure of **11***a* for the 136° glycol could only result from the other *trans* epoxide **5** and therefore the presence of **11***a* constitutes proof of the formation of **5** during the epoxidation of caryophyllene and likewise proof of the existence of conformer **3** in caryophyllene.

The further question of whether the two conformers **2** and **3** are interconvertible near room temperature was probed by examining the dependence of the ratio of the two epoxides **4** and **5** on solvent, temperature, and peracid when monoepoxidation was carried to completion under conditions not affecting the oxides. The ratios of monoepoxides **5**:**4** (calculated by integration of the olefinic n.m.r. absorption) from the following sets of conditions: perbenzoic acid – benzene, 25° (15:85); perbenzoic acid – chloroform – tetraethylammonium benzoate buffer, 5° (17:83);[9] monoperphthalic acid – ether, −30° (22:78); and hydrogen peroxide – benzonitrile – potassium bicarbonate – methanol, 25° (hetrogeneous) (21:79) were not sufficiently different for any conclusions to be drawn regarding conformational interconversion. At present the best, although weak, evidence for interconversion at room temperature is the variable temperature n.m.r. study (see Experimental).

Experimental

For instruments and general procedures see ref. 12.

Purification of Caryophyllene (1)

Crude clove oil (*Eugenia caryophyllata*) terpene residue (~1.5 l) obtained from Fritsche Bros., Toronto, from which the phenol esters had been removed by saponification was fractionally distilled through a 60-cm vacuum-jacketed spinning band column at 10 Torr, and fractions of 10–15 ml were collected. The fractions having b.p. 109–110° (10 Torr) and $[\alpha]_D$ −9.46° to −9.04° (neat) were combined (250 ml) and refractionated. Each 10-ml fraction was examined by t.l.c. developed in petroleum ether (b.p. 60–80°). Typical R_f values were isocaryophyllene 0.96, caryophyllene 0.82, and humulene 0.70.[10] Later distillation fractions (56 g) containing only caryophyllene and humulene by t.l.c. analysis were combined in 100 ml of petroleum ether (b.p. 30–60°). The colorless solution was washed 10 times with 10-ml portions of aqueous $AgNO_3$ (60 g dissolved in 100 ml). This treatment removed all of the humulene (15) together with some of the caryophyllene. The petroleum ether solution of **1** was washed with water, dried over $MgSO_4$ and then percolated first through a column of 120 g of silica gel (B.D.H. for chromatography) and finally through a column of 100 g of neutral alumina (Woelm) with the aid of additional petroleum ether to remove any traces of oxygenated impurities.[11] Distillation gave a total of 39.1 g of **1**, b.p. 136–136.5° (15 mm), $[\alpha]_D^{21}$ −15.0° (*c*, 2.60 in chloroform) with only a very faint odor. T.l.c. showed less than ~0.5% of an impurity corresponding in R_f to isocaryophyllene **13**. G.l.p.c. analysis of the caryophyllene indicated it be 97% pure, the remaining impurities being small amounts of at least five compounds. To determine whether these trace compounds were being formed from **1** in the g.l.p.c. apparatus, another carefully fractionated sample of caryophyllene, $[\alpha]_D^{23}$ −15.2° (*c*, 5.03 in chloroform) from a different source, *Strobilanthopsis linifolia*,[12] was also analyzed on the same g.l.p.c. column and apparatus. From the fact that the two samples give different amounts of partly different g.l.p.c. peaks (Table 2),[13] at least most of the peaks are not due to artifacts but correspond to impurities in the samples. Furthermore the proportion of compounds in the *Eugenia* caryophyllene showed no change when the injection block temperature was varied from 207 to 240°. Even at an injection block temperature of 290°, there was still 96.5% caryophyllene and only traces (totalling 0.16%) of three new g.l.p.c. peaks appearing together with very slight variations in the other peaks.

Variable Temperature N.m.r. Study

The p.m.r. spectrum of caryophyllene in both CS_2 and $CDCl_3$ solution was examined at 100 MHz from +50° down to −90°. The 100 MHz spectra at −20°, −40°, −60°, −70°, and −90° were similar but differed slightly from that taken at +30° in that there was (*i*) a slight bulge on the high field side of the overlapping *gem*-dimethyl

[9]Chloroform solutions of perbenzoic acid on standing apparently generate enough strong acid (HCl?) to catalyze further reactions of the epoxides **4** and **5** to more polar (t.l.c.) products. These side reactions, which are responsible for the incorrect result reported on p. 82 of ref. 13, are suppressed by the addition of benzoate anion buffer to the epoxidation mixture.

[10]Miller and Kirchner (14) first noted that these sesquiterpenes could be readily separated by t.l.c. After partial charring caryophyllene gave a beautiful deep indigo color.

[11]On standing in air pure **1** develops traces of oxygenated impurities which remain at the application point on t.l.c. in petroleum ether.

[12]Kindly provided by Y. Hikino, Dr. R. E. Williams, and Professor P. de Mayo.

[13]We would like to thank Drs. J. B. DiGiorgio, T. Swartz, and A. Nickon for these g.l.p.c. analyses.

TABLE 2. G.l.p.c. analyses of caryophyllene samples[a]

Peak	% from *Eugenia*	% from *Strobilanthopsis*	E:S	Relative retention time
A	0.03	0.03	1:1	0.77
B	0.52	0.23	2.3:1	0.83
C	Absent	0.72	—	0.88
D	0.29	0.16	1.8:1	0.92
Caryophyllene	97.07	98.69		1.00
E	0.30	Absent	—	1.90
F	1.79	0.16	11.2:1	2.30

[a]Golay Castorwax column at 150°, injection block 240°, 20 p.s.i. He pressure.

peaks, (*ii*) a slight bulge on the high field side of the narrow absorption at δ 1.60, (*iii*) the highfield peak of the exocyclic methylene group was better resolved, and (*iv*) two new broad peaks appeared adjacent to the two exocyclic methylene peaks (see Fig. 2). While these changes can be interpreted in terms of the two conformers **2** and **3** being "frozen out" on the n.m.r. time scale and having small chemical shift differences for certain protons, the lack of better separation makes such an interpretation ambiguous.

*Epoxidation of Caryophyllene (**1**)*

To a solution of 7.420 g (36.4 mmol) of 97% pure caryophyllene in 5 ml of ether chilled in an ice bath was added 100 ml of an ice cold ethereal solution of monoperphthalic acid (16) containing 36.3 mmol of peracid. The reaction was kept at ~5° for 9 h when no peracid remained. The decanted ethereal solution was washed twice with water, twice with aqueous Na_2CO_3 solution, and dried over $MgSO_4$. Removal of solvent left 7.860 g (98.5%) of colorless viscous oil, $[\alpha]_D^{20}$ −46.0° (*c*, 2.15 in chloroform). Quantitative t.l.c. with petroleum ether (b.p. 60–80°) gave three spots with R_f 0.95 (<0.5% of **13**), 0.78 (~2% of **1**), and 0.00 (oxygenated products). T.l.c. with the more polar system ethyl acetate – petroleum ether (15:85) gave three spots with R_f 1.00 (**1** + **13**), 0.77 (94% of monoepoxides), and 0.25 (~3% of bis-epoxides).

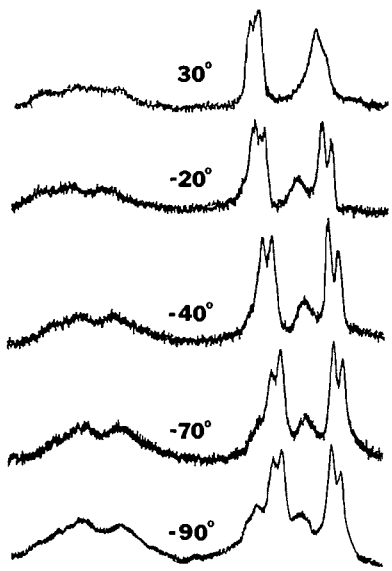

FIG. 2. Variable temperature n.m.r. spectra of the olefinic proton absorption of caryophyllene in $CDCl_3$ solution at 100 MHz.

Recrystallization of the crude product from 12 ml of methanol yielded 5.167 g (68.5%) of large colorless crystals of **4**, $[\alpha]_D^{20}$ −72.1° (*c*, 2.18 in chloroform) and mother liquor *A* (see below). Further recrystallization from methanol raised the melting point to 63.5–64°, $[\alpha]_D^{20}$ −79.4° (*c*, 2.32 in chloroform) (lit. (17) m.p. 64°, $[\alpha]_D$ −68°).[14]

From recrystallization mother liquor *A* above, a second crop of 1.345 g of less pure **4** was removed. The 1.34 g of colorless oil $[\alpha]_D^{20}$ 0° (*c*, 2.26 in chloroform) remaining in the mother liquors of the second crop was recrystallized twice from methanol and once from petroleum ether (b.p. 30–60°) without appreciable change in composition (n.m.r., $[\alpha]_D$). The thrice recrystallized material (775 mg) had m.p. 29–31° with a few small crystals not melting until 48°, $[\alpha]_D$ 0° (*c*, 2.46 in chloroform). Comparison of the integrated n.m.r. peaks at δ 4.87 (from **4**) and 5.09 (from **5**) (Fig. 1) gave a ratio of 4:5 of 50:50. The *calculated* optical rotation of **5** from these data is $[\alpha]_D^{19}$ +80° (chloroform). Attempted zone refinement in a narrow tube did not change the composition. I.r. peaks at 1280 and 1070 cm^{-1} are moderately intense in the spectrum of **5** but weak or missing from that of **4**.

Integration of the δ 4.85 and 5.10 n.m.r. peaks in the crude epoxidation product from various reactions (ether, monoperphthalic acid, ~5°) gave the amount of **5** formed as 16–20%.

*Permanganate Oxidation of Epoxides **4** + **5***

To a solution of 2.075 g (9.43 mmol) of a mixture of epoxides **4** + **5** (~1:1) in 25 ml of acetone and 1 ml of water was added with stirring (magnetic bar) 4.08 g of powdered $KMnO_4$ in small portions during 1.5 h. Extraction with ether after dissolution of the MnO_2 in H_2SO_4

[14]That **4** was stable to phthalic acid under the epoxidation conditions was proved by allowing a mixture of 300 mg of **4**, 50 mg of phthalic acid, and 20 ml of ether to stand at 4° for 25 h. Work up gave 286 mg (95%) of pure **4** (i.r. and t.l.c.).

gave 1.315 g (~63%) of colorless oil. Chromatography on alumina (Woelm basic, activity II) gave a total of 765 mg (36% from **4** + **5**) of almost pure liquid keto oxide mixture, $[\alpha]^{25}$ −71° (*c*, 1.96 in chloroform). The n.m.r. spectrum of a sample of the keto oxide mixture not containing any **4** or **5** had two peaks corresponding to the methyl group on the epoxide ring at δ 1.18 and 1.30. Integration gave 23–36% of keto epoxide **5** (=O for $=CH_2$) in various fractions. Calculation of the optical rotation of keto epoxide **5** (=O for $=CH_2$) from the n.m.r. integrations and the $[\alpha]_D$ −148° (*c*, 1.95 in chloroform) of pure keto epoxide **4** (=O for $=CH_2$) gave $[\alpha]_D^{25}$ +187° (chloroform or methanol).[15] Attempts to separate the two keto epoxides by chromatography were unsuccessful.

*OsO_4 Hydroxylation of Epoxides **4** + **5***

A solution of 867 mg (3.94 mmol) of the 1:1 mixture of **4** + **5** in 4 ml of ether was added to an ice cold solution of 989 mg (3.90 mmol) of OsO_4 in 2 ml of ether plus 2 ml of pyridine. After 127 h the reaction mixture was worked up by evaporation of solvent, reflux with ethanol – mannitol – sodium hydroxide, and extraction with ether after aqueous dilution. The partially crystalline product (809 mg, 81%) was acetylated at room temperature with 2 ml of acetic anhydride and 5 ml of pyridine for 23 h. Work-up gave 895 mg of partially crystalline product whose t.l.c. (ethyl acetate – petroleum ether (b.p. 60–80°), 50:50) had three spots R_f 0.55, 0.40, and 0.15.[16] This acetylation product was combined with another 786 mg from a similar reaction. Recrystallization from ether – petroleum ether gave 560 mg of felted needles of **11***b* (R_f 0.40) contaminated with the diol of R_f 0.15. The material (1.13 g) from the mother liquor was chromatographed on four preparative t.l.c. plates developed in ethyl acetate – petroleum ether (b.p. 60–80°), 15:85.

Extraction of the least polar zone gave 631 mg (37% based on OsO_4 product) of pure oily Treibs' glycol diacetate **8***b*, R_f 0.55. Saponification of the acetate with methanolic KOH produced 471 mg (99%) of Treibs' glycol **8***a*, which after one recrystallization from chloroform – petroleum ether had m.p. 116–119° (lit. (17) m.p. 119°) undepressed by an authentic specimen.

From the middle thick layer zone and the 560 mg of impure **11***b* from recrystallization of the crude acetylation mixture above, there was obtained by further t.l.c. and recrystallization from ether – petroleum ether (b.p. 60–80°) 685 mg (40% based on OsO_4 product) of colorless needles of pure monoacetate **11***b*, m.p. 158–159°; $[\alpha]_D^{19}$ +18.0° (*c*, 1.90 in chloroform); ν_{max} 3598 and 3420 (OH), and 1725 cm^{-1} (ester C=O).

Anal. Calcd. for $C_{17}H_{28}O_4$ (296.4): C, 68.89; H, 9.52. Found: C, 69.06; H, 9.96.

When a mixture of 26 mg of monoacetate **11***b*, 30 mg of CrO_3 and 1 ml of pyridine was allowed to stand for 39 h, the **11***b* was recovered quantitatively on passage of the reaction mixture through alumina in methylene chloride.

[15]The optical rotations of the keto epoxides are the same within 1–2% in methanol and chloroform.

[16]In one reaction there was a faint fourth spot, R_f 0.25, perhaps due to **7** because it was removed by $NaIO_4$ treatment.

*136° Glycol **11***a*

Saponification of 165 mg (0.56 mmol) of monoacetate **11***b* in 10 ml of methanol containing 200 mg of NaOH gave 130 mg (92%) of solid diol **11***a* (single t.l.c. spot). Three recrystallizations from ether – petroleum ether gave colorless felted needles which rearranged above 120° to short hexagonal prisms melting at 135–136°, $[\alpha]_D$ 0.0° (*c*, 0.91 in chloroform), ν_{max} 3448 cm^{-1} (OH).

Anal. Calcd. for $C_{15}H_{26}O_3$ (254.3): C, 70.82; H, 10.29. Found: C, 70.94; H, 10.34.

Glycol **11***a* (20 mg) was unchanged on standing with 40 mg of $NaIO_4$ in 2 ml of methanol and 0.5 ml of water at room temperature for 6.5 h.

*Hydroxy Ketone **10***

A solution of 162 mg (0.64 mmol) of 136° diol **11***a* in 2.3 ml of pyridine was added at room temperature to the orange complex of 107 mg (1.07 mmol) of CrO_3 in 1 ml of pyridine. After 20 h at room temperature, the reaction mixture was diluted with methylene chloride and passed through a short column of alumina (Woelm neutral, activity IV) to yield 159 mg of crude ketone containing ~20% of **11***a*. Preparative t.l.c. and recrystallization from ether – petroleum ether (b.p. 60–80°) gave colorless needle-like prisms of **10**, m.p. 82–83°; $[\alpha]_D$ +2° (*c*, 0.45 in chloroform); ν_{max} 3570 and 3448 (OH), and 1701 cm^{-1} (seven-ring ketone C=O).

Anal. Calcd. for $C_{15}H_{24}O_3$ (252.3): C, 71.39; H, 9.57. Found: C, 71.11; H, 9.55.

*Wolff–Kishner Reduction of Hydroxy Ketone **10***

To a solution of 37 mg (0.14 mmol) of hydroxy ketone **10** in 3 ml of triethylene glycol were added 1.5 ml of hydrazine hydrate (85%) and six KOH pellets. The mixture was refluxed (oil bath 145°) for 2 h, after which the excess hydrazine hydrate was distilled. The temperature of the oil bath was raised to 200° and maintained there for 4.5 h. Dilution with water and extraction with ether gave 20 mg (60%) of colorless oil, which on t.l.c. in ethyl acetate gave a single spot of the same R_f 0.70 as **12** obtained from Wolff–Kishner reduction of **9** (12). The oil crystallized on chilling and was recrystallized once from petroleum ether (b.p. 30–60°) to give small crystals, m.p. 87–90° undepressed on admixture with **12**, m.p. 91–92°, from **9**.

Alkyl Inductive Effects on Molecular Ionization Potentials. XVI. Esters

LEONARD S. LEVITT, HARRY F. WIDING, AND BARBARA W. LEVITT
Department of Chemistry, College of Science, University of Texas, El Paso, Texas 79968

Received June 25, 1973

Correlation of molecular ionization potentials, E_I, with Taft's alkyl inductive substituent constants, $\sigma_{I(R)}$, has now been extended to include the esters. It is found that three series of esters, the formates, acetates, and methyl alkanoates, fall on three separate straight lines in accord with the general equation $E_I = E_0 + a_I\sigma_{I(R)}$, where E_0 is the intercept and a_I the slope. The average standard error for the three lines is 0.024 eV with an average correlation coefficient of 0.992, showing that the alkyl substituent exerts an inductive influence on the electron density at the site suffering the electron loss: a lone pair on either the carbonyl or alkoxy oxygen atom. Evidence is deduced for the site of electron expulsion and a prediction is made concerning the site of vapor phase protonation of esters and carboxylic acids. E_I values presently not available experimentally are predicted for several esters.

La corrélation entre les potentiels d'ionisation moléculaire, E_I, et les constantes de Taft traitant de l'effet inductif de substituants alcoyles, $\sigma_{I(R)}$, a maintenant été étendue aux esters. On a trouvé que trois séries d'esters, les formates, les acétates et les méthyl alcanoates, se retrouvent sur trois lignes droites séparées, ce qui est en accord avec l'équation générale $E_I = E_0 + a_I\sigma_{I(R)}$ où E_0 est l'ordonnée à l'origine et a_I la pente. L'erreur standard moyenne pour les trois lignes est égale à 0.024 eV et le coefficient moyen de corrélation à 0.992, montrant que le substituant alcoyle exerce un effet inductif sur la densité électronique au site subissant la perte d'électrons: une paire libre soit sur l'atome oxygène carbonyle ou soit sur l'oxygène du groupe alcoxy. On présente des preuves en faveur du site où se produit l'expulsion d'électrons; de même on fait une prédiction concernant le site de protonation en phase vapeur d'esters et d'acides carboxyliques. Les valeurs de E_I qui ne sont pas encore expérimentalement accesibles, sont prédites pour plusieurs esters. [Traduit par le journal]

Can. J. Chem., **51**, 3963 (1973)

We demonstrate in this paper that the ionization potentials of various series of carboxylate esters are linearly correlated with Taft's alkyl inductive substituent constants, σ_I (1).

A huge body of data relating to many physical properties of organic molecules has been correlated with different sets of substituent constants, such as σ_I, σ^* (2), and Hammett's original (3) σ and its offshoots. The ionization energies of the alcohols (4*a*), ethers (4*b*), thiols (4*c*), thioethers (4*d*), alkyl halides (4*e*), ketones (4*f*), carboxylic acids (4*g*), copper acetylacetonates (4*h*), amines (4*i*), nitriles (5), nitroalkanes (5), *n*-alkanes (6), alkenes (7), alkynes (8), and disulfides (9) have recently been shown to be linear functions of both the inductive and polar substituent constants.

Assuming the validity of Koopmans' theorem (10) which identifies the first adiabatic ionization energy with the energy of the highest occupied molecular orbital, the electron must be lost from a non-bonding lone pair on one of the oxygens of the carboxyl group (11). This may be represented by the following equation

$$R{-}CO_2{-}R' \xrightarrow{E_I} R{-}\overset{+}{C}O_2{-}R' + e^-$$

Evidence will be given later in this paper pertaining to *which* oxygen is the probable site of electron loss. It is quite apparent that electron-releasing alkyl groups should increase the electron density at the relatively electronegative carboxyl group and consequently facilitate ionization of the molecule. A similar effect should manifest itself in a greater basicity, the greater the electron density at the carboxyl group, as in the case of alcohols (12).

The $\sigma_{I(R)}$ values and the experimentally determined (13) photoionization potentials of three series of esters, HCOOR, MeCOOR, and RCOOMe are given in Table 1.

Good correlations are obtained when the E_I values are plotted *vs.* σ_I for the corresponding R groups of the three series of esters. The equations for the regression lines are given by the following

$$E_{HCO_2R} = E_0 + a_I\sigma_{I(R)}$$

$$E_{MeCO_2R} = E_0' + a_I\sigma_{I(R)}$$

$$E_{RCO_2Me} = E_{HCO_2Me} + a_I\sigma_{I(R)}$$

The slopes, a_I, are found to be 20.79, 15.99, and 12.84 eV, respectively, for the formates, acetates, and methyl alkanoates. It should be pointed out that only the methyl alkanoate line (RCO_2Me),

has its intercept essentially at the E_I value of the hydrogen-substituted ester (methyl formate, 10.82 eV). The intercepts for the other two lines, E_0 and E_0', on the other hand, do not correspond to their hydrogen-substituted analogs because these would be carboxylic acids (not esters) and this effect will be discussed later in this paper. The three intercepts are, respectively, 11.76, 10.99, and 10.83 eV, and therefore we can write:

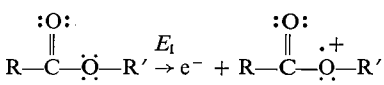
$$E_{HCO_2R} = 11.76 + 20.8\sigma_{I(R)} \pm 0.02 \text{ eV}$$

$$E_{MeCO_2R} = 10.99 + 16.0\sigma_{I(R)} \pm 0.02 \text{ eV}$$

$$E_{RCO_2Me} = 10.83 + 12.8\sigma_{I(R)} \pm 0.03 \text{ eV}$$

the corresponding correlation coefficients being 0.990, 0.989, and 0.997. These correlations once again demonstrate that the effect of alkyl substituents on the electron density of the atom which loses the electron, is essentially an inductive effect. Comparing the last two columns of Table 1 it is readily seen that the calculated and experimental E_I values are in excellent agreement. Calculated estimates are also given in the Table for HCO_2t-Bu, $MeCO_2t$-Bu, and t-$BuCO_2Me$, for which PI or PES values have not yet been obtained. Although the a_I constants have eV units, they are analogous to the reaction constants, ρ_I, and constitute measures of the susceptibility of the reaction sites to substituent effects. The a_I values observed here may be compared to those observed in the correlations of the E_I values of alcohols (4*a*) (37.5), ethers (4*b*) (28.0), ketones (4*f*) (14.0), and carboxylic acids (4*g*) (15.4).

The carboxylic acids, upon vapor phase ionization, lose an electron from the non-bonding lone pair of the carbonyl oxygen (4*g*). In the case of the esters, however, the electron loss, evidently, is from the non-bonding lone pair of the alkoxy oxygen. This can be seen by comparing the a_I value of the alkyl acetates (16.0) with that of the methyl alkanoates (12.8), which shows that a change in the alkyl substituent on the alkoxy oxygen has a larger inductive effect than a corresponding change of the alkyl group on the carbonyl group. It is for this reason, the non-equivalence of the inductive effects of the R groups in the two different positions, that a plot of $\sum\sigma_{I(R)}$ *vs.* E_I does *not* give a straight line for the esters in general; instead three separate lines are obtained for the three classes of esters discussed here. Thus we can rewrite the ionization equation, shown above, as



Since we have stressed throughout this entire series of papers that ionization occurs at the atom with the highest electron density (presumably due to interelectron repulsions), this implies, in our present case, that the gas phase protonation of esters should occur at the alkoxy oxygen (the most basic site) (12*a*, *b*), whereas carboxylic acids should be protonated on the carbonyl oxygen (4*g*). In a very recent study (12*c*) of gas phase proton affinities of esters and acids, this question could not be resolved; but both esters and acids are protonated on the carbonyl oxygen atom in solution (14). It seems quite possible, in view of the apparent near-equivalence of electron density at the two oxygens, that the protonation site varies for different esters depending on the magnitude of σ_I for R and R′. Furthermore, the a_I

value for the formates is closer to that for ethers than are those for the other esters, and this may indicate that *only* the formates, with no polarizable alkyl group nearby to increase the electron density at the carbonyl oxygen, suffer the electron loss and vapor phase protonation at the alkoxy oxygen. In accord with this view is the fact that the a_I values of the other two series of esters are very close in value to those of the ketones and carboxylic acids.

The site of protonation in solution may or may not correspond to the gas-phase protonation due to solvation energies and entropies, etc. For example, a study (15) of the gas phase proton affinities of NH_3 and methylamines indicated a different order of basicity than that which is observed in solution.

Effect of Electron Scavenger on the γ-Radiolysis of Gaseous Propane at High Densities

MASARU NISHIKAWA, YOH-ICHI YAMAGUCHI, KAZUO FUJITA, KAZUNORI KON, AND TETSURO OKAMOTO

Department of Pure and Applied Sciences, University of Tokyo, 3-8-1, Komaba, Meguro, Tokyo, Japan

Received December 28, 1972[1]

Hydrogen formation from γ-radiolysis of gaseous propane at 120 ± 1 °C was studied as the function of density in the range from 0.1 to 0.5 g/ml. $G(H_2)$ gradually decreased with density from 8.0 at 0.12 g/ml towards the liquid-phase value of 6.4 at room temperature. $G(H_2)$ in the presence of SF_6 showed similar decrease from 3.9 to 3.0. The decrease was discussed in comparison to the abrupt drop in G-values from the radiolysis of ammonia at high density (11). The separation distances of ion–electron pairs were estimated from the analysis of the electron scavenging reaction.

Les rendements en hydrogène ont été mesurés par γ-radiolyse du propane à 120 ± 1 °C à des densité allant de 0.1 a 0.5 g/ml avec et sans SF_6. La diminution des rendements dans les deux cas avec la densité est plus faible que dans le cas de la radiolyse d'ammoniac gazeux. Les reactions d'électrons avec SF_6 sont analysés selon un modèle théorique, et les distances séparant les paires ion–électron sont estimés.

Can. J. Chem., **51**, 3966 (1973)

Although radiation chemistry of propane has been studied repeatedly both in liquid and gas phase (1), much less attention has been paid to the intermediate phase of high density gas. For example, it appears that the yields of hydrogen in this region, with and without electron scavengers, have not yet been reported. The difference in the yield in the presence and absence of electron scavengers is usually considered to represent the contribution of dissociative neutralization to the product formation. It is of some interest to see how the importance of such a process changes with density. Furthermore, the kinetic analysis of electron scavenging reactions in this region is expected to yield information related to the electron thermalization distances. Thus the study of gaseous propane radiolysis at high densities appears appropriate. We wish to report here the results of such a study with both ends in view, using SF_6 as the scavenger.

Experimental

Takachiho Research Grade propane was purified by storing with hydrogen over platinum on alumina catalyst for several days in order to eliminate olefinic impurities, and then by bulb-to-bulb distillation. Matheson Research Grade propane (99.98% min) was used without further purification for some of the runs; the results agreed within experimental errors. SF_6 used was Matheson Research Grade as received except for bulb-to-bulb distillation. The method of sample preparation in general, irradiation and dosimetry were described previously (2). However, a metal valve (Hoke Packless Valve) was used at the inlet of sample gases into the irradiation cells in order to avoid adsorption and/or contamination of gases by the stopcock grease for low-concentration runs.

Doses were approximately 7×10^{18} eV/g (^{60}Co-γ) for most samples except where dose *vs.* yield relationship was tested. The dose rate was 2.39×10^{18} eV/g h at the start of the study. The yield of hydrogen was determined by combustion over cupric oxide furnace at about 350 °C.

Results and Discussion

Figure 1 shows the variation of $G(H_2)$ from propane radiolysis at 120 ± 1 °C (T_{cr} of propane = 95.6 °C) upon addition of SF_6 at different densities. The values at $d = 0.50$ g/ml were for liquid propane at 20 ± 2 °C. The shape of the curves clearly indicates the density dependence of the efficiency of electron scavenging reactions.

It has been a well known fact that the yield of a product produced in a charge scavenging reaction increases linearly with the square root of the scavenger concentration in the lower concentration range (3, 4). Hummel has treated this problem theoretically and obtained an equation which shows such a square root dependence (5):

$$G(P) = f\{G_{fi} + G_{gi}(A[S])^{1/2}\}$$

where $G(P)$, G_{fi}, and G_{gi} represent the yields of a product, free and geminate ions, respectively,

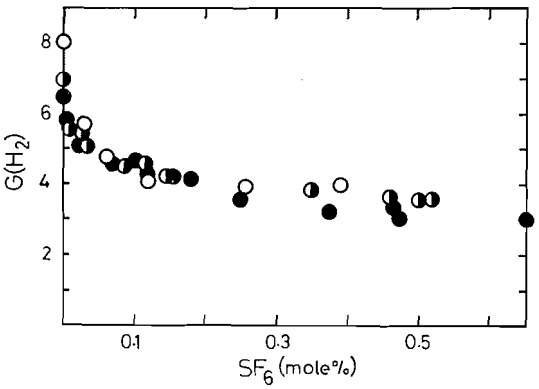

FIG. 1. Dependence of hydrogen yields on the concentration of SF_6 in the radiolysis of propane at 120 °C at different densities; ○, 0.12 ± 0.01 g/ml; ◑, 0.35 ± 0.01 g/ml; ●, 0.50 g/ml (iquid phase, 20 ± 2 °C).

[S] is the concentration of the scavenger, A is a scavenging efficiency parameter, and f is the efficiency of formation of the product from charge scavenging.

The depression of hydrogen yields $\Delta G(H_2)$ upon addition of SF_6 when plotted against the square root of SF_6 concentration was shown to conform to such an expression except at the lowest density studied, 0.12 g/ml (Fig. 2). The failure of the square root model at this density may be because the behavior of thermalizing electrons in that density region deviates seriously from that in the condensed medium, *i.e.*, the diffusive motion. The intercepts $(\Delta G(H_2)_0)$ obtained in Fig. 2 are identified with $f \cdot G_{fi}$. Then, by assuming the maximum depression of hydrogen yield observed in Fig. 1 as $f(G_{fi} + G_{gi})$,[2] one can calculate the ratio G_{fi}/G_{tot}. Assuming further a Gaussian distribution of the separation distances of ion–electron pairs (r), and with the use of the equation (6):

$$G_{fi}/G_{tot} = \int_0^\infty (4r^2/\pi^{1/2} \cdot b^3) \exp(-r^2/b^2 - r_c/r)dr$$

[2]A referee suggested to use the empirical equation found by Schuler's group (16) in order to obtain $f \cdot G_{gi}$. However, the validity of the equation is not proved in the present system, nor did the plot according to the equation yield meaningful figures even in the liquid propane at room temperature. High mobility of electrons expected in the present system might be related to the failure. The assumption $f(G_{fi} + G_{gi}) = \Delta G(H_2)_{max}$ has been used by Fujisaki *et al.* (1*a*). Further, the shape of the curves in Fig. 1 and the fact that $\Delta G(H_2)_{max}$ of the present study is the largest so far found may justify the use of the assumption at least as the zeroth order approximation.

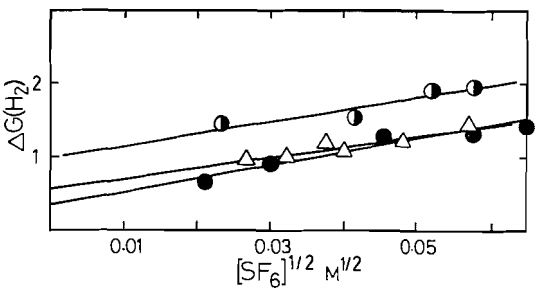

FIG. 2. Decrease of hydrogen yields in the radiolysis of propane at various densities as functions of the square root of the molar concentration of SF_6; ◑, 0.35 ± 0.01 g/ml; △, 0.42 ± 0.01 g/ml; ●, 0.50 g/ml (liquid phase, 20 ± 2 °C).

one obtains the value of b which is the most probable value of r. Values of b thus calculated, and the product of b and the gas density d are listed in Table 1 together with the values of other parameters. These b and $b \cdot d$ values agree reasonably well to those determined in a similar experiment using N_2O as the electron scavenger (8)[3]. Further, the $b \cdot d$ values are in fair agreement with that obtained from the electrical measurement in the liquid at 183 °K, 59×10^{-8} g/cm^2 (7). A gradual increase in $b \cdot d$ with density confirms a previous observation (8). The agreement of $b \cdot d$ values obtained with different electron scavengers, if not fortuitous, is significant, since $b \cdot d$ is considered to be the most meaningful parameter related to the efficiency of the electron energy loss process in a medium (6). At the present time we do not intend to explain the observation except a speculative argument given elsewhere (8).

The slopes of the square-root plot (Fig. 2) together with $\Delta G(H_2)_{max} - \Delta G(H_2)_0$ $(= f \cdot G_{gi})$ at a given density give the A values listed in Table 1. A values decrease with the increase in density. The trend is somewhat different from that observed with N_2O as the scavenger. The reason for this discrepancy is not obvious at present.

The variation with density of $G(H_2)$ from pure propane and from C_3H_8–SF_6 (*ca.* 0.7 mol %) are shown in Fig. 3. The values for the liquid phase obtained in this work were 6.4 and 3.0 in the absence and presence of SF_6, which are higher than the corresponding values, 4.8 and 2.5 (0 °C), of Fujisaki *et al.* (1*a*). Lower values of the latter may be due to the higher total dose used in

[3]Preliminary results indicated otherwise when we quoted the present work in ref. 8.

their work. Robinson and Freeman reported still lower values of 4.6 and 1.8 at 183 °K using N_2O (9). Our maximum $\Delta G(H_2)$ in the liquid phase is larger than either of them.

$G(H_2)$ from pure propane is seen to decrease gradually with density. This is in contrast to the abrupt drop in $G(H_2)$ from ammonia radiolysis that takes place at lower densities than those studied in this work (10). However, a similar gradual change was observed in the case of ethane (11) and butanes (12). The difference can be explained in terms of differences in the neutralization process at high densities in ammonia and in hydrocarbons. We proposed that in gaseous ammonia at high densities ion–ion neutralization ($NH_4^+ + NH_2^-$) prevails, which does not lead to hydrogen formation, over that between ion–electron ($NH_4^+ + e^-$) (10). Formation of solvated electrons in supercritical ammonia was recently observed with approximately constant yield above $d \simeq 0.2$ g/ml (13). Ward observed that they rapidly react with NH_2 forming NH_2^- which in turn reacts rapidly with NH_4^+ in liquid ammonia (14). The fact that sharp decrease in $G(H_2)$ begins in the density region where solvation of electrons becomes important is an indirect evidence for the proposed mechanism. Then, in hydrocarbons where solvated electrons are not produced except at very low temperatures (15), it seems obvious that the neutralization remains between ions and electrons throughout the density range and that such a sharp change in the yield cannot occur.

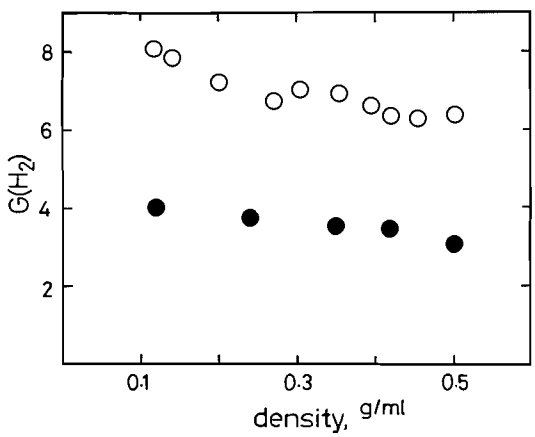

FIG. 3. Dependence of hydrogen yields from propane radiolysis on the gas density; ○, no additive; ●, ≃ 0.7% SF_6.

The gradual decrease in the contribution of the neutralization process to H_2 formation with density might be ascribed to the cage effect and to the deactivation of excited states formed upon neutralization in view of the results of isotopic analysis of hydrogen (1*a*). However, this analysis also shows that the change in the composition of hydrogen from gas to liquid phase radiolysis is rather complicated. Therefore it is not warranted in this work to speculate further the relative importance of the conceivable causes for the over-all decrease of $G(H_2)$ such as deactivation of excited ions and molecules, and the cage effect.

Mercury(II) Complexes of L-Cysteine Methyl Ester

GEORGE A. NEVILLE[1] AND MATHS BERLIN
The Institute of Hygiene, University of Lund, Magle Stora Kyrkogata 12, S-223 50 Lund, Sweden
and
Organic Chemistry 2, Chemical Center, Box 740, University of Lund, S-220 07 Lund 7, Sweden

Received May 30, 1973

The mercurial complexation of L-cysteine methyl ester hydrochloride with mercury(II) nitrate, chloride, and acetate has been investigated at low p*H*. Bis(methyl L-cysteineato)mercury(II) hydrochloride hydronitrate monohydrate, following isolation and extensive characterization, was shown to be the substance reported in the literature as the dihydrochloride sesquihydrate complex. The preparation and properties of bis(methyl L-cysteineato)mercury(II) dihydrochloride monohydrate are reported for the first time. The properties and structural features of the complexes are discussed mainly in the context of investigations utilizing infrared, ^{1}H- and ^{13}C-n.m.r. spectroscopy.

La complexation du chlorhydrate de l'ester méthylique de la L-cysteine par le nitrate, le chlorure et l'acétate de mercure(II) a été étudiée en fonction de bas p*H*. On a montré après isolement et caractérisation que le chlorhydrate hydronitrate monohydraté de bis(méthyl L-cysteineato) de mercure(II) est en réalité le produit rapporté dans la littérature comme étant le complexe dichlorhydrate sesquihydraté. La synthèse ainsi que les propriétés du dichlorhydrate monohydraté de bis(méthyl L-cysteineato) de mercure(II) sont rapportées pour la première fois. Les propriétés ainsi que les caractéristiques structurales des complexes sont décrites surtout en fonction des études effectuées à l'aide de la spectroscopie i.r. et de la r.m.n. ^{1}H et ^{13}C. [Traduit par le journal]

Can. J. Chem., **51**, 3970 (1973)

Introduction

Few mercury complexes of amino acids have been isolated and subjected to structural characterization in spite of the long known affinity of this element for such substrates and its use in analytical biochemistry. In the course of work undertaken to investigate the nature of some mercurial complexes of interest for toxicological investigations of biotransport and biotransformation, mercury(II) complexes of L-cysteine methyl ester were obtained whose properties were found to be at variance with those reported in the literature. During potentiometric study of the interaction of cysteine methyl ester hydrochloride with various metal ions, Porter, Perrin, and Hay (1) isolated a complex by the use of mercury(II) nitrate which they reported to be bis-(methyl L-cysteineato)mercury(II) dihydrochloride sesquihydrate. Reinvestigation and extension of this work has revealed that the reported complex contains both nitrate and chloride ions and that it differs in the solid state from the dihydrochloride complex prepared separately and now authenticated. This paper describes the preparation of the 2:1 complexes of cysteine methyl ester hydrochloride from mercury(II) nitrate, chloride, and acetate and an investigation of their properties by infrared, ^{1}H- and ^{13}C-n.m.r. spectroscopy and X-ray diffraction.

Results and Discussion

X-Ray diffraction confirmed the crystalline nature of the products and served admirably to differentiate between the closely related *bis*-(methyl L-cysteineato)mercury(II) hydrochloride, hydronitrate monohydrate, and the dihydrochloride monohydrate. The complexes were obtained as thin needles, approx. 0.5 × 0.02 mm for the chloride–nitrate complex and less than half this size in the case of the dichloride complex. Because better crystals could not be grown for crystallographic analysis, the $\sin^2\phi$ values from X-ray diffraction have been submitted to the Depository of Unpublished Data.[2]

[1]1972 Centennial Fellow of the Medical Research Council of Canada. Present address: Health and Welfare Canada, Tunney's Pasture, Ottawa, Canada K1A 0L2.

[2]$\sin^2\phi$ data for the X-ray powder diffraction patterns and band frequencies for the infrared spectra of bis-(methyl L-cysteineato)mercury(II) hydrochloride, hydronitrate monohydrate, and of the corresponding dihydrochloride monohydrate are available upon request, at a nominal charge, from the Depository of Unpublished Data, National Science Library, National Research Council of Canada, Ottawa, Canada K1A 0S2.

The presence of an infrared band at 1365 cm^{-1} which occurs in the range 1380–1350 cm^{-1} usually associated with asymmetric NO_3 stretching (2), suggested the presence of inorganic nitrate in the complex prepared according to the conditions reported by Porter *et al.* (1). This band is absent in the complex prepared from L-cysteine methyl ester hydrochloride and mercury(II) chloride. Attempts to verify the presence of nitrate ion by laser Raman spectroscopy and obtain complementary information of ν(SH), ν(C—S), and other modes failed due to rapid degradation of the sample in the laser beam. Complete microanalysis established the stoichiometry of the complex prepared with mercury(II) nitrate and showed it to have the composition $(C_4H_9NO_2S)_2ClHgNO_3 \cdot H_2O$ consistent with the presence of one nitrate ion. Porter's reported composition, $C_8H_{18}Cl_2HgN_2O_4S_2$ 1.5 H_2O appears to have been based solely on analysis for C and H, and no other infrared bands were reported for the complex apart from ν(H_2O) 3450, 3650, ν(NH) 3000, δ(NH) 1576, and ν(CO) 1745.

The infrared spectra obtained for the chloride–nitrate and dichloride complexes may be compared in Fig. 1. Although each complex is hydrated it appears from band contours and observed frequencies for ν(OH) that water is less strongly hydrogen bonded in the chloride–nitrate complex than in the dichloride complex. Neither complex shows the combination band of medium strength near 2000 cm^{-1} which is so striking in the parent substance, but each complex shows a broad ν(N—H) band centered near 2900 cm^{-1} characteristic of substituted ammonium ion interaction with simple anions (3). The dihydrochloride complex shows typical fine structure[2] for substituted ammonium chloride salts on the low frequency side (2650–2200 cm^{-1}) of the ν(N—H) band. In contrast, the hydrochloride hydronitrate complex shows evidence of both chloride interaction by weak shoulder development at 2300 cm^{-1} and nitrate interaction resulting in the ν(N—H) band being less broad and more highly shouldered near 2900 cm^{-1}. Little data is available on ν(Hg—S), but from values reported for this mode in $Hg(SCN)_2$ (278 cm^{-1}) and $Hg(SCN)_4^{2-}$ (239 cm^{-1}) (4) and in CH_3SHgCH_3 (333 cm^{-1}) (5), it would appear that the broad band near 365 cm^{-1} in both the hydrochloride hydronitrate complex and the dihydrochloride complex may be due to ν(Hg—S).

The results of n.m.r. spectroscopic study of the complexes and parent substance in D_2O solution are summarized in Tables 1 and 2. Horsley and Sternlicht (6) have investigated the dependence of methylene ^{13}C and proton chemical shifts on p*D* of various amino acids. Horsley *et al.* (7) have also examined natural abundance ^{13}C spectra of amino acids. In the range p*D* 0–2, the very small variation in chemical shift can be ignored in relation to the very much larger shifts induced by the presence of a paramagnetic element like mercury. Because ^{13}C chemical shifts reflect primarily the local charge density, the large downfield shift (~4 p.p.m.) for the methylene carbon atoms in the mercury complexes of cysteine methyl ester (Table 2) indicates that sulfur is bonded to mercury. The relatively smaller ^{13}C downfield shifts for the methine and carboxyl carbons relative to the parent substance appear to arise solely from the operation of the inductive effect. In solution, therefore, these complexes do not appear to have other possible ligands, amino or carboxy, engaged in mercurial complexation as might be found in chelated structures.

The proton n.m.r. spectral results (Table 2), obtained from the same solutions used for ^{13}C study, are consistent with the ^{13}C results in showing the same relative order for chemical shift, $CH > CH_3 > CH_2$, and a marked downfield shift for the methylene protons of the mercury complexes relative to the parent compound. The practically invariant ^{13}C and ^{1}H frequencies for the methyl ester afford an internal check on the relative frequencies for other groups within the complexes and parent compound. The observed equivalence for the methylene protons in both the parent substance and the complexes precludes the measurement of separate vicinal coupling constants and the determination of relative rotameter populations.

Attempts were made to study bonding in the solid state of these complexes by means of electron spectroscopy for chemical analysis (ESCA), but decomposition of the samples on platinum foil even at −100 °C prevented this. Degradation of the samples was indicated during scanning by deterioration of the mercury signal and by the development of multiple mercury bands indicating the formation of mercury in other oxidation states.

The degree of hydration of the complexes was established from the microanalyses for H and O. For these complexes, in which the hydrogen

content is low, the oxygen analysis is the best determinant. The percent drying loss (50°/HV) does not appear to be a satisfactory means for determining extent of hydration in these mercurial complexes. Attempts were made to determine the degree of hydration by means of differential scanning calorimetry, using nylon capsule liners. The complexes were found to be thermally labile, the thermal degradation being unreproducible and seemingly dependent on both starting temperature and rate of heating. Substances containing both mercury and sulfur are usually notorious for study by thermometric techniques (8).

Experimental

Instrumentation

X-ray diffraction powder patterns were obtained using Guinier-Hägg cameras from samples mixed with KCl (BDH, Analar).

Infrared spectra were measured with a Perkin–Elmer Model 621 spectrometer using fluorolube mulls and NaCl windows from 4000–1340 cm^{-1} and Nujol mulls with caesium iodide windows from 1340–200 cm^{-1}.

^{13}C-n.m.r. spectra were obtained with a Varian XL-100 spectrometer following accumulation and Fourier transformation of signals in both proton decoupled and coupled modes. Proton spectra were obtained with a Varian A-60A spectrometer. The parent substance and dihydrochloride complex dissolved readily in D_2O (5 ml) giving solutions at pD 2.6 and 2.1, respectively. The hydrochloride hydronitrate complex required the addition of two drops of trifluoroacetic acid for dissolution resulting in pD of 1.3. The pD of the other solutions was adjusted to 1.3 by addition of TFA, but no spectral changes were observed on charge of pD. The pH of D_2O solutions was measured with a glass electrode and pH meter, and the measurements were converted to pD values as directed by Gutfreund (9).

Microanalyses

Microanalyses were performed by Alfred Bernhardt, Mikroanalytische Laboratorium, 5251 Elbach über Engelskirchen, Fritz-Pregl-Strasse 14–16, W. Germany. Appropriate separatory processes were employed to eliminate the interference of mercury with the C, H, and Cl determinations. Sulfur was analyzed by a reductive process.

Preparations of Complexes

Bis(methyl L-cysteineato)mercury(II) Hydrochloride Hydronitrate Monohydrate

To L-cysteine methyl ester hydrochloride (0.350 g, 0.002 mol, Sigma 98%) in water (10 ml) was added dropwise with magnetic stirring, a solution of mercury(II) nitrate monohydrate (0.343 g, 0.001 mol, BDH Analar) in water (20 ml). (Two drops of conc. HNO_3 were added to the mercury(II) nitrate to dissolve the salt.) No turbidity or crystallization occurred upon addition of the $Hg(NO_3)_2$ contrary to the observations of Porter *et al.* (1). The mixture (p$H \sim 1.0$) was subjected to rotary evaporation (20 mm Hg, 60°) to obtain a fluffy white solid. The solid was recrystallized from a minimum volume of hot 95% ethanol. On cooling, the solution produced a mass of extremely fine needles which required the addition of more ethanol for collection by filtration. The solid was washed with acetone and dried over NaOH pellets *in vacuo*. The yield was 0.46 g or 38%.

To a solution of L-cysteine methyl ester hydrochloride (0.875 g, 0.005 mol, Sigma 98%) in warm (50–60°) 95% ethanol (30 ml), a solution of mercury(II) nitrate monohydrate (0.855 g, 0.0025 mol, BDH Analar) in warm water (10 ml), containing a few drops of conc. HNO_3,

was added dropwise with magnetic stirring. Immediate precipitation was followed by fairly rapid dissolution. On cooling, the solution gave a voluminous, semi-immobilized fibrous product. More ethanol was added to facilitate collection of the solid which was washed with acetone and dried over NaOH pellets *in vacuo* (20 mm Hg, 25°). The yield of product was 1.40 g or 47%.

X-ray diffraction showed the solid to be identical with the product obtained under aqueous conditions. The product gave a positive chloride test after dissolution in dilute nitric acid. Mass spectra featured mercurial cluster peaks at *m/e* 461, 372, 357, 327, 313, and 202 based on the 202 Hg isotope.

Anal. Calcd. for $(C_4H_9NO_2S)_2ClHgNO_3 \cdot H_2O$ (m.w. 586.46): C, 16.38; H, 3.44; O, 21.83; N, 7.17; Cl, 6.05; Hg, 34.21; S, 10.93. Found: C, 16.26; H, 3.15; O, 21.85 and 21.63; N, 7.09; Cl, 5.89; Hg, 34.04; S, 10.77.

Bis(methyl L-cysteineato)mercury(II) Dihydrochloride Monohydrate

(a) Using Mercury(II) Chloride

To a warm solution (50–60°) of L-cysteine methyl ester hydrochloride (0.875 g, 0.005 mol, Sigma 98%) in 95% ethanol (30 ml) was added dropwise with magnetic stirring a warm solution of mercury(II) chloride (0.678 g, 0.0025 mol, BDH Analar) in 95% ethanol (10 ml). The instantly formed precipitate dissolves fairly rapidly to give a solution from which massive crystallization of white, feathery solid is obtained within a half hour of the addition. Additional ethanol was used to loosen and transfer the solid during collection. The solid was washed with acetone and dried several hours over NaOH pellets *in vacuo* (20 mm Hg, 25°). The yield was 1.16 g or 41%.

The product gave a positive chloride test after dissolution in dilute nitric acid. X-Ray diffraction patterns and infrared spectra showed the product to be different from that prepared with mercury(II) nitrate. Mass spectra showed mercurial cluster peaks at *m/e* 371, 313, and 202 (reported for ^{202}Hg isotope) and base peak at *m/e* 160.

Anal. Calcd. for $(C_4H_9NO_2S)_2HgCl_2 \cdot H_2O$ (m.w. 559.91): C, 17.16; H, 3.60; O, 14.29; N, 5.00; Cl, 12.67; Hg, 35.83; S, 11.45; H_2O, 3.22. Found: C, 17.21; H, 3.67; O, 14.34; N, 5.14; Cl, 12.37; Hg, 35.75; S, 11.26, and % drying loss (50°/HV), 3.18.

(b) Using Mercury(II) Acetate

To a warm solution (50–60°) of L-cysteine methyl ester hydrochloride (0.875 g, 0.005 mol, Sigma 98%) in 95% ethanol (30 ml) was added dropwise with magnetic stirring a solution (25–30°) of mercury(II) acetate (0.798 g, 0.0025 mol, BDH Analar) in methanol (10 ml). (The use of ethanol and higher alcohols and methanolic solutions at higher temperature results in the rapid formation of a yellow precipitate identified by X-ray diffraction as mercury(II) oxide.) Precipitation occurred instantly on mixing but dissolved fairly quickly except towards the end of the addition when very finely divided solid began to accumulate. No further crystallization occurred at room temperature, but a massive, immobilized solid was obtained with ordinary refrigeration consisting of very thin, glistening needles.

During filtration of the cold mixture, most of the solid redissolved, however; a small portion (Fr. A) was collected, washed with 95% ethanol and set to dry. The mother liquor was treated with diethyl ether until just turbid (no turbidity produced with acetone) and returned to the refrigerator. Within 15 min, the mixture was immobilized by a mass of feathery, silk-like solid. The solid (Fr. B) was collected, washed with ether – 95% ethanol (1:1 and dried over NaOH pellets *in vacuo*. X-ray diffraction patterns showed fractions A and B were identical and that the product of this reaction was identical to that obtained using mercury(II) chloride. The overall yield was 41%.

We are indebted to Prof. Börje Wickberg (Organic Chemistry, Lund Institute of Technology) for provision of laboratory space. The stimulus and advice of Prof. Bengt Aurivillius and of Dr. Karin Aurivillius (Inorganic Chemistry, Lund Institute of Technology) in matters related to crystal growing and crystallography is much appreciated as well as the determination of numerous powder diffraction patterns by Christer Hansson. We are grateful to Dr. Ragnar Larsson (Inorganic Chemistry, University of Lund) for infrared and ESCA instrumentation, for stimulating discussions related to their application and to Börje Folkesson for his careful ESCA investigations. We are particularly indebted to Prof. Sture Forsén (Physical Chemistry, University of Lund) for the availability of n.m.r. instrumentation and to Dr. Torbjörn Drakenberg for determining n.m.r. spectra. It is a pleasure to recognize Prof. Stig Sunner (Thermochemistry, University of Lund) as a major advocate of the Lund Chemical Center as an interdisciplinary center for chemical research and to acknowledge his interest and discussions of thermometric investigations performed by Bengt Falk. The Medical Research Council of Canada is generously thanked for the award of a Centennial Fellowship to G.A.N.

Kinetics of the Reaction of Nickel(II) and 2,2′-Bipyridine in Ethanol

M. L. SANDUJA AND W. MACF. SMITH
Department of Chemistry, Queen's University, Kingston, Ontario

Received June 15, 1973

The kinetics of formation of the monobipyridine complex of nickel(II) in ethanol has been studied with stopped-flow methods over the temperature range 7 to 35 °C. The value of the second order rate constant k_f at 25 °C of 6.6×10^{-3} M^{-1} s^{-1} and the values of $\Delta H^{\ddagger}$ (10.1 ± 1.0 kcal mol^{-1}) and of $\Delta S^{\ddagger}$ (-7.3 ± 3.4 cal deg^{-1} mol^{-1}) are close to the corresponding values for ethanol exchange on nickel(II) and suggest that the mechanism is dissociative interchange. However the difference in the values of the kinetic parameters of this reaction and those previously reported for the reactions involving the chemically similar phenanthroline imply a degree of ligand specificity for the reactions in ethanol which is considerably larger than is the case for reactions in water and methanol and that a common I_d mechanism with monodentate formation being rate controlling is not applicable to both reactions.

La cinétique de formation du complexe monobipyridine de nickel(II) dans l'éthanol a été étudiée à l'aide de méthodes à débit interrompue dans l'intervalle de températures allant de 7 à 35 °C. La valeur de la constante de vitesse du second ordre k_f à 25 °C (6.6×10^{-3} M^{-1} s^{-1}) et les valeurs de $\Delta H^{\ddagger}$ (10.1 ± 1.0 kcal mol^{-1}) et de $\Delta S^{\ddagger}$ (-7.3 ± 3.4 cal deg^{-1} mol^{-1}) sont proches des valeurs correspondantes pour l'échange de l'éthanol sur le nickel(II) et suggèrent que le mécanisme est du type échange mutuel dissociatif. Cependant la différence dans les valeurs des paramètres cinétiques de cette réaction et celles précédemment rapportées pour des réactions avec la phénanthroline (qui est chimiquement similaire) implique un degré de spécificité du coordinat pour les réactions dans l'éthanol beaucoup plus élevé que pour les réactions dans l'eau et dans le méthanol. De plus cette différence implique qu'un mécanisme I_d commun, où la formation d'un monocoordinat serait l'étape déterminant la vitesse, n'est pas applicable aux deux réactions. [Traduit par le journal]

Can. J. Chem., **51**, 3975 (1973)

To expand information about the kinetic behavior of nickel(II) in non-aqueous solvents we have investigated the reactions of nickel(II) with several ligands in ethanol. Our results for the reactions involving 1,10-phenanthroline have been reported (1). We considered that our data were consistent with a mechanism which was dissociative interchange (I_d) (2) although the kinetic parameters deviated significantly from those reported by Breivogel (3) for ethanol exchange on nickel(II) and the rate constant for the reaction was somewhat higher than would be anticipated on the basis of a simple I_d mechanism and a magnitude for the association constant for the encounter pair based on the Fuoss–Eigen relation (4) for an uncharged ligand and a solvated nickel(II) ion. We report here on the reaction of nickel(II) with 2,2′-bipyridine, a ligand which is analogous to phenanthroline in its bidentate nature, its coordinating atoms, and high association constant involving nickel(II), but differing in the decreased rigidity of its structure which has been considered to be a possible source of difference in kinetic behavior.

Experimental

Experimental procedures including treatment of ethanol and preparation and handling of solutions of nickel perchlorate and perchloric acid were as previously reported (1). The 2,2′-bipyridine (Fisher reagent) was used without further purification. Lithium perchlorate (K and K laboratories) and lithium nitrate (Fisher reagent) apart from drying over silica gel and Drierite were used without further purification. Kinetic measurements were made with a model D-150 Durrum-Gibson stopped-flow spectrophotometer and spectrophotometric measurements relating to equilibria with a Beckman DK1 spectrophotometer.

The majority of kinetic runs involved solutions in which the concentration of nickel(II) perchlorate was 2.0×10^{-3} M and that of bipyridine 2.0×10^{-5} M, but for some runs the concentration of nickel(II) was 4.0×10^{-3} or 6.0×10^{-3} M and that of bipyridine 4.0×10^{-5} M. As in the previous work a trace of perchloric acid ($\sim 4 \times 10^{-7}$ M) was added to the solution used in the kinetic runs to avoid possible complications associated with solvolysis of nickel(II). The spectrophotometric properties of the slightly acidified solutions of bipyridine were identical with those of solutions to which no acid was added. At higher acidities at λ 300 and 310 nm there is a marked increase in absorbance to a value which remained substantially constant over concentrations of perchloric acid ranging from 2.2×10^{-3} to 7.9×10^{-3} M (the highest concentration investigated) over which range the monoprotonated form is presumably

the dominant species. At λ 300 nm, the wavelength used to monitor the course of the reaction, the extinction coefficient of the complex is approximately 3.6-fold greater than that of bipyridine. That complexing was complete under the conditions of the kinetic runs was confirmed by the fact that an increase of 3.6-fold in the concentration of nickel(II) over 2.0×10^{-3} M at constant concentration of bipyridine of 2.0×10^{-5} M yielded no significant increase in absorbance. In the majority of kinetic runs the only electrolyte present was the reactant nickel perchlorate and the trace of perchloric acid. Some runs were made with addition of one of sodium perchlorate, tetrabutyl ammonium perchlorate, lithium perchlorate, and lithium nitrate which if present in completely dissociated form would have yielded an ionic strength of 0.050.

The data were interpreted as previously described (1) on the assumption, which is supported by the data given below, that the reaction

$$[1]\qquad Ni^{2+} + bipy \xrightarrow{k_f} Ni(bipy)^{2+}$$

is second order overall. Since the initial concentration of nickel(II) was in substantial excess over that of bipyridine (100-fold in most runs) the reaction is pseudo first order and the slope of the line of regression for the plot of log $(A - A_\infty)$ against time was identified with $-k_f[Ni]_0/2.303$ where $[Ni]_0$ represents the initial concentration of nickel(II). The absorbance A was obtained from a photographic record of oscilloscope traces of absorbance against time.

Results and Discussion

Values for the rate constant (k_f) with 95% confidence limits and a summary of the conditions for the kinetic runs are given in Table 1. The values under I represent the ionic strength corresponding to complete dissociation of the nickel perchlorate and any other added electrolyte. The data for 25 °C imply no significant dependence of k_f on the concentration of reactant. It also appears that the rate is not sensitively dependent on the concentration of perchlorate, sodium, lithium, or tetrabutyl ammonium ions or on the concentration of nickel(II). Runs were carried out at 25 °C with addition of 1 and 2 wt. % of water and these indicated a significant increase in rate constant to the values 8.6 ± 0.47 and 7.6 ± 0.64 M^{-1} s^{-1}. Values for the parameters implied by the data from runs with no added electrolyte are $\Delta H^{\ddagger} = 10.1 \pm 1.0$ kcal mol^{-1} and $\Delta S^{\ddagger} = -7.3 \pm 3.4$ cal deg^{-1} mol^{-1}.

The values of the kinetic parameters for the reaction of bipyridine with nickel(II) are significantly different from those for the reaction involving phenanthroline (1) which are $\Delta H^{\ddagger} = 15.9 \pm 1.0$ kcal mol^{-1} and $\Delta S^{\ddagger} = 15.4 \pm 3.2$ cal mol^{-1} deg^{-1} whereas they approach those obtained by Breivogel for solvent exchange on nickel(II) in ethanol (3) which are $\Delta H^{\ddagger} = 10.8 \pm 1.5$ kcal mol^{-1} and $\Delta S^{\ddagger} = -4 \pm 5$ cal mol^{-1} deg^{-1}. Also the value of k_f at 25 °C of 6.6×10^3 M^{-1} s^{-1} for the reaction of bipyridine with nickel(II) may be contrasted with the value of 31×10^3 M^{-1} s^{-1} for the reaction of phenanthroline in ethanol. At lower temperatures the values of k_f for the two reactions approach and at higher temperatures they diverge; k_f (phen)/k_f (bipy) is ~2.2 at 7 °C and ~5.7 at 35 °C.

The interchange mechanism involving a bidentate ligand may be summarized as

$$[2]\qquad \begin{aligned} NiS_6^{2+} + L &\overset{K_0}{\rightleftharpoons} NiS_6^{2+}\cdot L \\ NiS_6^{2+}\cdot L &\underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} NiS_5\cdot L^{2+} + S \\ NiS_5L^{2+} &\xrightarrow{k_2} NiS_4L^{2+} + S \end{aligned}$$

where $NiS_6^{2+}\cdot L$ represents the encounter pair (outer complex) between solvated nickel(II) and the entering ligand L and $NiS_5\cdot L^{2+}$ represents

an intermediate monodentate (inner) complex. On the basis of this mechanism

$$[3] \qquad k_f = K_0 k_1 \frac{k_2}{k_{-1} + k_2}$$

For reactions involving nickel(II) and uncharged ligands in water k_f is approximately the same for mono- and bidentate ligands (5) which is consistent with the assumption that $k_2 \gg k_{-1}$, that k_1 is rate controlling, and that $k_f = k_1 K_0$. Using estimates for K_0 based on the Eigen–Fuoss relation, the value implied for k_1 is of the same order as that of the rate constant for solvent exchange. The ratio $R = (4/3)\, k_f/K_0 k_s$ has been proposed (6) as a convenient measure of whether the mechanism is of such simple dissociative interchange character where k_s is the rate constant for solvent exchange on the nickel(II) ion. For reactions of nickel(II) in water, R ranges in value from 0.2 to 0.6 for mono- and bidentate ligands when a value for the separation of centers, a, in the encounter complex is assigned a value of 5 Å. Assuming a value of 9 Å for a for the reactions of nickel(II) in ethanol the value for K_0 implied by the Eigen–Fuoss relation is 1.8 M^{-1}. Using this value for K_0 and Breivogel's value of 11×10^3 s^{-1} for k_s, the rate constant for ethanol exchange on nickel, yields values for R of 0.33 for the reaction involving bipyridine and 1.6 for the reaction involving phenanthroline. In view of the uncertainty in the value adopted for K_0, the somewhat high value for the reaction involving phenanthroline should not be considered as definitely ruling out an essentially dissociative interchange mechanism, but the value of k_f for the reaction of bipyridine is sufficiently smaller than that of phenanthroline to imply real differences in the details of the two reactions.

Considering the similarity of the ligands it is unlikely that the difference in the value of k_f is a reflection of differences in K_0. The closeness of the values of the kinetic parameters for the reaction involving bipyridine and those involving ethanol exchange, along with appreciation that the temperature coefficient for K_0 must be small, tempts one to consider that the reaction involving bipyridine is "normal", *i.e.* of simple I_d character with $k_f = K_0 k_1$, and that the reaction involving phenanthroline is "abnormal". The high values of k_f and its temperature coefficient (and so for $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$) for the reaction involving phenanthroline relative to those for the reaction involving bipyridine might be the consequence of phenanthroline reacting via both an I_d pathway and one involving relatively large values for the energy and entropy of activation. In view of the correspondence in values of the thermodynamic parameters for the reactions of solvated nickel(II) with solvent and with bipyridine, the difference in values of the parameters for the reactions involving phenanthroline and bipyridine, and the relatively high value of k_f (phenanthroline) relative to k_s (solvent exchange), such a hypothesis seems preferable to one which considers k_{-1}/k_2 larger for the bipyridine reaction than for the phenanthroline reaction, as has been suggested by Chattopadhyay and Coetzee (6) for the corresponding reactions in dimethyl sulfoxide.

Admittedly, however, the uncertainty in the values of K_0 and the possibility of competition between the steps with rate constants k_{-1} and k_2 where bidentate ligands are involved do complicate the interpretation of our data. Information about the reactions of uncharged unidentate ligands would be free of the second complication and would assist assessment of the nature of ligand specificity in the various reactions of nickel(II) in ethanol.

The Synthesis of Songorine: A Simplified Synthesis of the Aromatic Intermediate

KAREL WIESNER, PAK-TSUN HO, DING CHANG, YIU KUEN LAM, CONNIE SHII JEOU PAN, AND WU YUN REN

Natural Products Research Center, University of New Brunswick, Fredericton, New Brunswick

Received June 21, 1973

A simple conversion of the previously described (1) tricyclic ester **1** into the pentacyclic songorine intermediate **21** is described. The process is stereospecific and it operates in an overall yield of 7.8%.

On présente une méthode simple pour transformer l'ester tricyclique **1** décrit précédemment en intermédiaire pentacyclique **21** de la songorine. Le procédé est stéréospécifique et effectué avec un rendement global de 7.8%. [Traduit par le journal]

Can. J. Chem., **51**, 3978 (1973)

We have described recently (1) a simple synthesis of the tricyclic ester **1** via the sequence **i** → **ii** → **iii** → **iv** → **1**. Compound **1** was then converted to the benzene sulfonyl aziridine **v** which selectively rearranged on acetolysis to compound **vi**.

The conversion of the tricyclic ester **vi** to the desired songorine intermediate **21** was also published in a preliminary report (1*b*, 2). Since large amounts of the intermediate **21** were required we wished to develop the synthetic process to a maximum of simplicity and efficiency. It turned out that the section of the synthesis between **vi** and **21** is the only one which could be fundamentally improved. The differential manipulation of the functions in compound **vi** required some five steps which might be eliminated by a suitable modification of the process.

Such a modification was indeed found, but it was necessary to abandon compound **vi** and to go back to the tricyclic ester **1** as starting material. Consequently we wish to describe in the present paper in detail the preferred and simplified route to the intermediate **21**. The overall yield in this new stereospecific conversion of **1** to **21** is 7.8% and thus this process provides a reliable platform for the continuation of the synthesis.

The tricyclic ester **1** was reduced with lithium aluminum hydride to the primary alcohol **2** and this compound was oxidized with *N*,*N*′-dicyclohexylcarbodiimide, dimethylsulfoxide, and pyridine in anhydrous benzene (3) to the aldehyde **3** in excellent yield.[1] The side chain destined to form ring A of songorine with its substituent was attached next. The aldehyde **3** was treated with an excess of the Grignard reagent prepared from 1-bromo-3-benzyloxybutane (4) in ether. A mixture of diastereoisomers represented by the formula **4** was obtained in a quantitative yield.

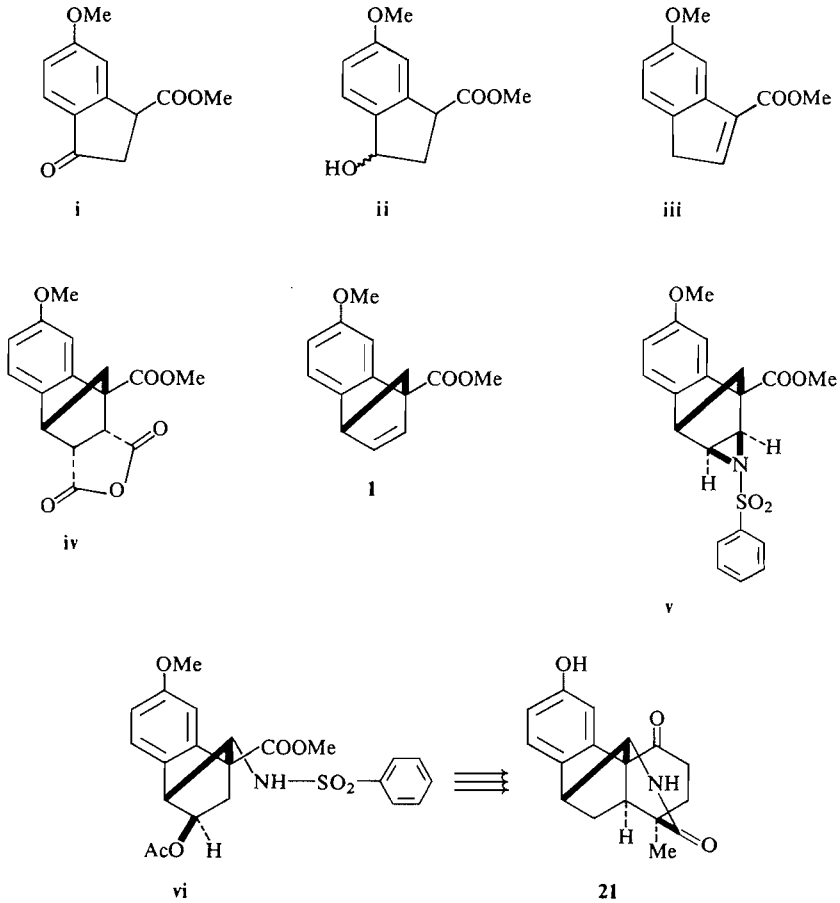
The oily mixture **4** was now converted to the *exo* benzenesulfonyl aziridine by treatment with an excess of benzenesulfonyl azide in benzene. The aziridine was quite unstable and it was consequently immediately subjected to acetolysis. Acetic acid and sodium acetate were added to the reaction mixture and stirring was continued at room temperature for several days. The crystalline mixture of diastereoisomers represented by the formula **5** was obtained in a yield of 84%. The mixture appeared to consist mainly of two components which differed in the configuration of the hydroxyl marked by the asterisk in formula **5**. For characterization the two components were separated by preparative t.l.c. and recrystallized for analysis. They were obtained in approximately equal quantities.

The aziridine rearrangement was completely regiospecific and the desired "compound" **5** was the only product detected in the reaction mixture. This clearly is due to the powerful influence of the aromatic methoxyl which increases the migratory aptitude of the bond in the *para* position.[2]

At this stage it was necessary to perform a reductive cleavage of the sulfonamide group and to replace it by an *N*-acetyl group. One of the subsequent steps in the synthesis involves the

[1] All spectral data for all compounds are recorded in the Experimental. They are mentioned in the Discussion only when specially relevant.

[2] For a full discussion of the influence of substituents on aziridine rearrangements see ref. 1*a*.



SCHEME 1

closure of ring A by an aldol condensation and the yield of this reaction is excellent if the nitrogen is blocked by acetylation but poor in the presence of the acidic sulfonamide group. The mixture of diastereoisomers **5** was reduced with an excess of $LiAlH_4$ in refluxing dioxane and the product was immediately acetylated with acetic anhydride and pyridine. The diastereoisomeric mixture **6** was obtained in a yield of 85%. The two major components of the mixture epimeric on the carbon marked by the asterisk in formula **6** were again isolated for characterization by preparative t.l.c.

The next task was to prepare the material for the closure of ring A by converting it into the diketone **9**. Fortunately, it turned out that the required partial hydrolysis of **6** to **7** proceeded with complete selectivity and practically quantitatively. The diastereoisomeric mixture **7** was converted into the diols **8** by hydrogenolysis and further into the mixture of the two epimeric diketones **9** by oxidation with chromium trioxide in pyridine. Both epimers **9** were crystalline and they were obtained in approximately equal quantities. They both showed in the i.r. spectrum a five-membered ketone at 1750 cm^{-1} and in the n.m.r. spectrum four methyl singlets. (β-epimer: τ 6.17 (—OCH_3), 7.84 (—$\overset{\overset{O}{\|}}{C}$—$CH_3$), 7.87 ($O$—$\overset{\overset{O}{\|}}{C}$—$CH_3$), and 7.94 p.p.m. ($N$—$\overset{\overset{O}{\|}}{C}$—$CH_3$)).

The mixture of the two diketones **9** was subjected to an aldol condensation in refluxing methanolic potassium carbonate. The two epimers **10** were obtained as a crystalline mixture in a yield of 88% and they were separated for

SCHEME 2

characterization by preparative t.l.c. The configuration of the hydroxyl in the two epimers **10** was assigned by n.m.r. spectroscopy. The aromatic hydrogen marked by the asterisk in formula **10** produces a narrow doublet at τ 3.24 p.p.m. in the β- and τ 2.87 p.p.m. in the α-epimer. This is due to the close proximity of this hydrogen and the ring A substituent in the α-epimer.[3]

[3]In the case of the epimeric pair **10** the assignment of configuration was corroborated by a complete X-ray structure analysis performed by Dr. J. F. Blount (Hoffmann-La Roche, Nutley, New Jersey) on a heavy atom derivative of the β-epimer of compound **16**. A chemical proof of this configuration was the observation of an $N \rightarrow O$ acetyl migration in the course of the preparation of this derivative (*cf.* ref. 2).

The operation which faced us now was the stereospecific addition of a one carbon element in the β position of the α,β-unsaturated ketone system of **10** and the ring closure of this new function with the nitrogen. The method which we have developed for related systems, *i.e.*, the addition of cyanide (5), turned out to be useless in the present case since the cyanide ion added selectively *anti* to the nitrogen.

The problem was finally solved as follows. Photoaddition of vinyl acetate to the mixture of the two epimers **10** gave two epimers of compound **11**. For characterization they were separated by preparative t.l.c. and the α-epimer was crystalline. The configuration of the acetoxy group in both epimers **11** is tentative and there is no evidence for it apart from *a priori* considerations of more favorable geometry and orbital overlap. On the other hand the peculiar regiospecificity of the photoaddition and the stereochemistry of the cyclobutane ring are certain from subsequent transformations and n.m.r. spectroscopy. The most remarkable feature in the n.m.r. spectra of both epimers **11** is the extremely high field position of the carbon–methyl group singlet. (β-Epimer, τ 9.70 p.p.m.;

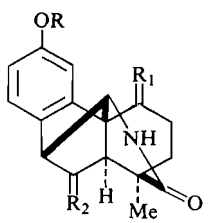
α-epimer, τ 9.66 p.p.m.). This is due to the shielding effect of the anisole ring on the methyl group and is only possible if the stereochemistry of the entire skeleton is as indicated in the formula **11**.

Saponification of "compound" **11** with methanolic potassium hydroxide gave a quantitative yield of the two epimers represented by formula **12**. They were oily and were separated for characterization by preparative t.l.c. The n.m.r. spectra of both compounds showed an aldehydic proton (β-epimer, τ −0.17 p.p.m.; α-epimer, τ −0.24 p.p.m.) and it was thus clear that after the hydrolysis of the acetoxy group the resulting alcohol opened by a reverse aldol reaction. Inspection of the n.m.r. spectra allowed also an unambiguous configurational assignment to the skeleton. Both epimers still showed a singlet for the carbon–methyl group at an abnormally high field (β-epimer, τ 9.54 p.p.m.; α-epimer, τ 9.50 p.p.m.). Consequently the AB *cis* stereochemistry of the photoadduct was preserved after the base catalyzed ring opening with simultaneous equilibration of the AB ring junction. We must therefore assume that this steric arrangement is more stable than the desired AB *trans* configuration. The operations which had to be executed at this point involved the shortening of the group R_1 in formula **12** by one carbon, epimerization of the AB ring junction and ring closure of the group R_1 with the nitrogen. The two epimers **12** were converted by enol acetylation to the two epimeric acetates **13**. These compounds were oxidized by osmic acid – periodate (6) to the noraldehydes **14** and oxidized further by the Jones method, followed by esterification with diazomethane to the acetoxy esters **15**. All these transformations were executed in excellent yields and the oily products were separated for characterization into the individual epimers by preparative t.l.c. The high-field methyl singlets in the n.m.r. spectra of these intermediates indicated that all of them had the same AB *cis* configuration. The structure and configuration of the β-epimer of compound **16** was furthermore rigorously confirmed when Dr. J. F. Blount, Hoffmann La Roche, Nutley, New Jersey, performed an X-ray analysis on a heavy atom derivative of this material (*cf.* ref. 2).

Mild alkaline hydrolysis of the epimers **15** yielded the hydroxy esters **16** and these were finally oxidized by the Jones method to the single crystalline diketo ester **17**, the synthesis of which was thus fully stereospecific.[4]

Ketalization of the diketone **17** with ethylene glycol and *p*-toluenesulfonic acid in benzene gave a quantitative yield of the crystalline ketal **18** which still showed the carbonyl maximum of the five-membered ring B ketone (1750 cm^{-1}) in the i.r. spectrum.

Finally the stage was set for the closure of the nitrogen ring. In compound **18**, of course, ring formation between the ester group and the nitrogen is sterically impossible because of the *cis* fusion of the rings A and B. However, we believed that in a solution sufficiently basic to enolize to a small extent the hydrogen next to the ring B ketone a certain amount of the AB *trans* isomer will be formed by reprotonation of the enolate ion. This material will then have opportunity to cyclize by lactam formation. Once cyclization occurs the system will be locked permanently and will be unable to go back to a *cisoid* derivative. This in fact turned out to be correct. The ketal ester **18** was heated under reflux with methanolic sodium methoxide and the beautifully crystalline lactam **19** was obtained in a yield of 80%. The i.r. spectrum of compound **19** showed carbonyl maxima at 1750 and 1675 cm^{-1} for the ketone and lactam and very significantly the carbon–methyl group singlet in the n.m.r. spectrum showed a normal expected chemical shift (τ 8.66 p.p.m.). In the *cisoid* ketal ester **18** the same carbon–methyl group singlet is located at τ 9.43 p.p.m.



19 R = Me; R_1 =  ; R_2 = =O

20 R = Me; R_1 =  ; R_2 = H_2

21 R = H; R_1 = =O; R_2 = H_2

SCHEME 4

[4]Since $LiAlH_4$ reductions of the ring A keto group in the songorine skeleton are known to yield stereospecifically "natural" β-hydroxy derivatives it is clear that the configuration of the ring A hydroxyl will also present no problems in the future. The ketone **17** was obtained not only from the mixture of the two epimers **15** but also from each epimer separately.

Wolff–Kishner reduction of compound **19** proceeded with no difficulty and yielded 89% of the highly crystalline ketal **20**.[5] Finally heating of the ketal **20** under reflux in a mixture of hydrobromic and acetic acid gave the high melting crystalline phenol **21** in an 86% yield. The process described in the present communication can supply very simply and efficiently the aromatic intermediate not only for songorine, but also if suitable modifications are introduced for a variety of other diterpene alkaloids. The chief advantage of the method is that it automatically provides the typical substitution pattern in rings A and B of delphinine type alkaloids simultaneously with the construction of the skeleton. This is an advantage which obviously is not fully utilized in the case of songorine.

The question remains whether the process described is the simplest and most efficient one possible. We do not believe this to be the case. It will probably turn out to be feasible to find a one carbon anionic reagent which will add to the α,β-unsaturated ketone **10** with the correct stereochemistry. Thus it should be possible to proceed from compound **10** directly to products of the type **16**. However, while we plan to return to these experiments in the future the present form of the synthesis is already highly satisfactory for our present purposes.

Experimental

*Reduction of the Ester **1** to the Alcohol **2***

To a cold stirred mixture of $LiAlH_4$ (3 g) in anhydrous ether (120 ml), a solution of the ester **1** (9.96 g) in anhydrous ether (110 ml) was added dropwise. The reaction mixture was stirred for 1 h at room temperature, and worked up by careful addition of wet ether (1000 ml) and then of 10% aqueous sodium hydroxide (2 ml). The white precipitate was filtered and the filtrate was evaporated to give 8.56 g of the pure alcohol **2** as an oil homogeneous in t.l.c.

Mol. Wt. Calcd. for $C_{13}H_{14}O_2$: 202. Found (mass spectroscopy): 202.

I.r. ($CHCl_3$): 3625 cm^{-1} (hydroxyl); n.m.r. ($CDCl_3$): τ 3.18 (m, 2H, vinylic protons), 5.71 (s, 2H, methylene of primary alcohol), 6.26 (s, 3H, aromatic methoxyl), 7.73 p.p.m. (q, 2H, apex protons).

*Oxidation of **2** to the Aldehyde **3***

Trifluoroacetic acid (1.76 ml) was added to a solution of the primary alcohol **2** (8.46 g), *N,N'*-dicyclohexylcarbodiimide (26 g), anhydrous dimethylsulfoxide (70 ml) and pyridine (3.54 ml) in benzene (80 ml). The solution was stirred for 12 h at room temperature and diluted with ether (300 ml) and *n*-hexane (700 ml). A solution of oxalic acid (7.96 g) in methanol (53 ml) was added slowly with stirring in order to destroy the excess of diimide and the white precipitate was removed by filtration. The filtrate was washed several times with a saturated sodium chloride solution, dried over anhydrous magnesium sulfate and evaporated to dryness. Chromatography of the yellow residue on silica gel and elution with benzene yielded 7.12 g (85%) of the oily aldehyde **3** homogeneous in t.l.c.

Mol. Wt. Calcd. for $C_{13}H_{12}O_2$: 200. Found (mass spectroscopy): 200.

I.r. ($CHCl_3$): 2950, 2848, 2740, 1725 cm^{-1} (aldehyde); n.m.r. ($CDCl_3$): τ −1.28 (s, 1H, aldehyde), 3.10 (m, 2H, vinylic protons), 6.02 (m, 1H, benzylic bridgehead proton), 6.23 (s, 3H, aromatic methoxyl), 7.25 p.p.m. (d, 2H, apex protons).

*Preparation of the Alcohol **4***

A solution of 1-bromo-3-benzyloxybutane (4) (14.6 g, two-fold excess) in absolute ether (200 ml) was added dropwise to a warm stirred mixture of magnesium turnings (1.5 g) in absolute ether (20 ml) in a nitrogen atmosphere. When the addition of the bromide solution was complete, reflux was maintained for about ½ h.

A solution of the aldehyde **3** (6 g) in absolute ether (120 ml) was added dropwise under reflux to the well-stirred Grignard solution. When the addition was completed, the reaction mixture was heated under reflux in a nitrogen atmosphere for 12 h. After cooling, ether (500 ml) was added and the unreacted magnesium metal was removed. A 10% aqueous ammonium chloride solution (200 ml) was added to the reaction mixture under stirring. After removal of the aqueous layer, the ether solution was washed with water, dried, and evaporated to dryness. The residue was chromatographed on silica gel, using ether–benzene (v/v 1:9) as eluant. The yield of the oily alcohol **4** was quantitative (10.6 g).

Mol. Wt. Calcd. for $C_{24}H_{28}O_3$: 364.2031. Found (high resolution mass spectroscopy): 364.2039.

I.r. ($CHCl_3$): 3615, 3415 cm^{-1} (hydroxyl); n.m.r. ($CDCl_3$): τ 3.06 (m, 2H, vinylic protons), 5.45 (q, 2H, benzylic protons), 5.60 (unresolved m, 1H, hydrogen unshielded by secondary hydroxyl), 6.27 (s, 3H, aromatic methoxyl), 8.75 p.p.m. (d, 3H, methyl protons).

*Preparation of the Rearranged Compound **5***

A solution of the unsaturated compound **4** (10 g) and an excess of benzenesulfonyl azide (20 g) in anhydrous benzene (50 ml) was stirred for 6 days at room temperature. Sodium acetate (6 g) and glacial acetic acid (70 ml) were added in one portion and the mixture was stirred for 5 days at room temperature. The reaction mixture was diluted with chloroform (1000 ml) and washed with saturated aqueous sodium bicarbonate (2 × 200 ml), followed by saturated aqueous sodium chloride. The organic layer was dried over anhydrous magnesium sulfate. Evaporation of the solvent gave a yellow residue which was subjected to chromatography on silica gel. Elution with benzene–ether (8:2) gave 13.6 g (84%) of the crystalline product **5**.

This material was a mixture (1:1) of two epimers, when analyzed by t.l.c. on silica gel using benzene–ether (7:4)

[5]In a derivative similar to **19** (R_1 = —OH, R_2 = =O) desulfurization of a thioketal and Wolff–Kishner reduction yielded the same ring B desoxy compound in both cases in a high yield.

(*ii*) α-Epimer, m.p. 167.5–168 °C.

Anal. Calcd. for $C_{32}H_{37}O_7NS$ (mol. wt. 579): C, 66.29; H, 6.43; N, 2.42. Found (mass spectroscopy 579): C, 66.14; H, 6.42; N, 2.54. The mass spectra of both epimers were identical.

I.r. ($CHCl_3$): 3455 (hydroxyl), 3375 (NH), 1740 cm^{-1} (acetate); n.m.r. ($CDCl_3$): τ 2.91 (d, J = 8 Hz, 1H, hydrogen *meta* to aromatic methoxyl), 2.99 (d, J = 2.5 Hz, 1H, hydrogen *ortho* to aromatic methoxyl), 3.37 (q, J = 8 Hz, J = 2.5 Hz, 1H, hydrogen *ortho* to aromatic methoxyl), 4.11 (d, 1H, —N(H)—), 5.33 (m, 1H, proton unshielded by acetoxyl), 5.85 (m, 1H, proton unshielded by hydroxyl), 6.98 (broad s, 1H, benzylic bridgehead proton), 7.89 p.p.m. (s, 3H, acetoxy methyl).

Conversion of Compound **5** *to the N-Acetyl Amide* **6**

To a stirred solution of compound **5** (13 g) in anhydrous dioxane (400 ml), an excess of $LiAlH_4$ (15 g) was added in one portion. The mixture was refluxed under nitrogen for 27 h. After cooling, the excess of hydride was decomposed by careful addition of wet ether (600 ml) and of 10% aqueous sodium hydroxide (6 ml). The white precipitate was removed by filtration and washed with tetrahydrofuran (8 × 100 ml). The combined filtrates were evaporated under reduced pressure to give 8.84 g of material which was immediately acetylated with acetic anhydride (20 ml) and anhydrous pyridine (80 ml) for 24 h at room temperature. Most of the solvent was evaporated *in vacuo* and the residue was dissolved in chloroform (1500 ml). The chloroform solution was washed with dilute hydrochloric acid, dilute aqueous sodium bicarbonate, and water. After drying over magnesium sulfate, evaporation gave a yellow residue which was chromatographed on silica gel. Elution with ether–benzene (3:7) yielded 9.98 g (85%) of the *N*-acetyl amide **6** as a thick oil. For analysis, the two epimers were separated by preparative t.l.c.

(*i*) β-Epimer (larger R_F value).

Mol. Wt. Calcd. for $C_{30}H_{37}O_7N$: 523.2570. Found (high resolution mass spectroscopy): 523.2566.

I.r. ($CHCl_3$): 3461 (NH), 1738 (acetate), 1678 cm^{-1} (amide); n.m.r. ($CDCl_3$): τ 4.63 (m, 1H, proton deshielded by acetoxyl), 5.26 (m, 1H, proton deshielded by acetoxyl), 6.25 (s, 3H, aromatic methoxyl), 6.68 (broad s, 1H, benzylic bridgehead proton), 7.91 (s, 3H, acetoxy methyl), 7.94 (s, 3H, acetoxy methyl), 7.99 (s, 3H, —N(C=O)—CH_3), 8.84 p.p.m. (d, 3H, methyl).

(*ii*) α-Epimer (smaller R_F value).

Mol. Wt. Calcd. for $C_{30}H_{37}O_7N$: 523.2570. Found (high resolution mass spectroscopy): 523.2557. The mass spectrum was identical with the mass spectrum of the β-epimer.

I.r. ($CHCl_3$): 3462 (NH), 1737 (acetate), 1678 cm^{-1} (amide); n.m.r. ($CDCl_3$): τ 4.45 (m, 1H, proton deshielded by acetoxyl), 5.21 (m, 1H, proton deshielded by acetoxyl), 6.26 (s, 3H, aromatic methoxyl), 6.59 (broad s, 1H, benzylic bridgehead proton), 7.90 (s, 6H, two acetoxy methyl), 7.99 (s, 3H, —N(C=O)—CH_3), 8.81 p.p.m. (d, 3H, methyl).

Selective Hydrolysis of the Diacetate **6** *to the Hydroxyacetate* **7**

The diacetate **6** (9 g) was dissolved in methanolic potassium carbonate (400 ml, p*H* 8.5) and the reaction mixture was stirred at room temperature. The course of the reaction was followed by t.l.c. In this case the reaction was allowed to proceed for 16 h, after which time the reaction mixture was neutralized with 5% hydrochloric acid (2 ml) and poured into saturated aqueous sodium chloride (600 ml). It was extracted with chloroform (5 × 200 ml) and the combined extracts were washed with saturated sodium chloride, dried, and evaporated to dryness. The hydroxyacetate **7** (8.16 g) was isolated as the sole product and the yield was quantitative. A small portion (100 mg) of the material was taken out and the two epimers separated by preparative t.l.c. (methanol–ether 4:96) as colorless foam homogeneous in t.l.c. Ratio of the epimers was 1:1.

(*i*) β-Isomer (larger R_F value).

Preparation of the Acetoxy Diol 8

To a solution of the benzyloxy ether **7** (8 g) in methanol (200 ml), 10% palladium on charcoal (1 g) was added. The mixture was hydrogenated at atmospheric pressure and room temperature overnight. The catalyst was filtered off and washed with methanol. The methanolic solution was evaporated under reduced pressure and the diol **8** (6.4 g) was obtained as a colorless foam in a quantitative yield. For analysis, the two epimers were separated by preparative t.l.c.

(*i*) β-Epimer (larger R_F value).

Mol. Wt. Calcd. for $C_{21}H_{29}O_6N$: 391.1995. Found (mass spectroscopy): 391.2001.

I.r. ($CHCl_3$): 3610, 3460 (hydroxyl), 3400 (NH), 1731 (acetate), 1670 cm^{-1} (amide); n.m.r. ($CDCl_3$): τ 2.16 (d, J = 9 Hz, 1H, —N—H), 4.62 (m, 1H, proton unshielded by acetoxyl), 5.75 (d, J = 9 Hz, 1H, apex proton), 6.20 (s, 3H, aromatic methoxyl), 6.85 (broad s, 1H, benzylic bridgehead proton), 7.91 (s, 3H, acetoxy methyl), 7.98 (s, 3H, —N—C(=O)—CH_3), 8.82 p.p.m. (d, 3H, methyl).

(*ii*) α-Epimer (smaller R_F value).

Mol. Wt. Calcd. for $C_{21}H_{29}O_6N$: 391.1995. Found (mass spectroscopy): 391.2001. The mass spectra of both epimers were identical.

I.r. ($CHCl_3$): 3610 (hydroxyl), 3408 (NH), 1733 (acetate), 1670 cm^{-1} (amide); n.m.r. Preparation of the Diketone 9

A solution of the diol **8** (6.4 g) in pyridine (40 ml) was added slowly at room temperature to a stirred solution of chromium trioxide (7 g) in pyridine (50 ml). The mixture was stirred for 2 days at room temperature after which time it was diluted with ether (400 ml) and chloroform (100 ml). The brown precipitate was filtered and washed with ether. The combined filtrates were washed with dilute hydrochloric acid, 10% aqueous sodium bicarbonate and finally with water. Evaporation of the solvent and removal of the yellow color by filtration through a short neutral alumina column (100 g, activity grade II) gave 5.1 g (80%) of the diketone **9** as white crystals. The two epimers were separated by preparative t.l.c. (ether–methanol 9:1) and recrystallized for analysis. The ratio of the epimers was 1:1.

(*i*) β-Epimer (larger R_F value), m.p. 115°.

Preparation of the α,β-Unsaturated Ketone 10

A solution of the diketone **9** (8.8 g) in saturated methanolic potassium carbonate (200 ml) was refluxed for 10 h in a nitrogen atmosphere. The mixture was neutralized by careful addition of dilute hydrochloric acid. Most of the solvent was removed *in vacuo* and the residue was suspended in saturated aqueous sodium chloride (300 ml). The aqueous phase was extracted with methylene dichloride (4 × 200 ml) and the combined extracts were washed with saturated sodium chloride and dried over anhydrous magnesium sulfate. After evaporation of the solvent, the ketone **10** was obtained by crystallization from ether–chloroform. The yield was 6.62 g (88%). This crystalline material was a mixture (1:1) of two epimers when examined by t.l.c. on silica gel using chloroform–ether–methanol (70:30:6) as developing solvent. For analysis, samples of the two epimers were obtained by preparative t.l.c. and crystallized from ether.

(*i*) β-Epimer (larger R_F value), m.p. 205°.

Preparation of the Photoadduct ***11***

To a solution of the α,β-unsaturated ketone **10** (15 g) in freshly distilled tetrahydrofuran (2000 ml), a great excess of distilled vinyl acetate (1000 ml) was added. The solution was irradiated continuously with a 400 W Hanovia Mercury lamp (Pyrex was used as filter) at −20° for 12 h under nitrogen. After evaporation of the solvent, the photoadduct **11** was purified by crystallization from ether. 7.4 g of the crystalline photoadduct was obtained and chromatography of the mother liquor on silica gel gave another 9.52 g. The yield was thus 16.92 g (89%). For analysis, the two epimers were separated by preparative t.l.c. on silica gel. The α-epimer crystallized from ether (m.p. 254–256°) while the β-epimer when pure remained a white foam. Both epimers were homogeneous in t.l.c.

(*i*) β-Epimer.

Oxidation of ***16*** *to the Diketone* ***17***

Compound **16** (6.24 g) dissolved in acetone (80 ml) was oxidized at 0° with a slight excess of Jones' reagent for 2 h. The reaction mixture was poured into water and the product was extracted with chloroform. The chloroform solution was washed with water and dried over anhydrous magnesium sulfate. Evaporation of the solvent gave 5.18 g (83%) of the diketone **17** which was crystallized from ether–chloroform as white crystals homogeneous in t.l.c. in several solvent systems. An analytical sample was prepared by recrystallization from ether, and melted at 109°.

Anal. Calcd. for $C_{21}H_{23}O_6N$ (mol. wt. 385): C, 65.45; H, 6.02; N, 3.64. Found (mass spectroscopy, 385): C, 65.41; H, 6.09; N, 3.63.

I.r. ($CHCl_3$): 3450 (NH), 1750 (five-membered ketone), 1725 (ester), 1710 (six-membered ketone), 1680 cm^{-1} (amide); n.m.r. ($CDCl_3$): τ 2.98 (d, J = 7 Hz, 1H, —N(H)—), 5.33 (d, J = 7 Hz, 1H, apex proton), 4.03 (broad s, 1H, benzylic bridgehead proton), 6.20 (s, 3H, aromatic methoxyl), 6.23 (s, 3H, —C(=O)—OCH_3), 8.03 (s, 3H, —N(—C(=O)—CH_3)—), 9.40 p.p.m. (s, 3H, tertiary methyl shielded by benzene ring).

Preparation of the Keto Ketal ***18***

The diketone **17** (5.18 g) was dissolved in anhydrous benzene (300 ml) to which ethylene glycol (2 ml) and *p*-toluenesulfonic acid (850 mg) were added. The solution was heated under reflux for 1½ h with a water separator. The cooled reaction mixture was worked up by the usual procedure. The ketal **18** was crystallized from ether and melted at 245°. The yield was quantitative.

Anal. Calcd. for $C_{23}H_{27}O_7N$: C, 64.32; H, 6.33; N, 3.26. Found: C, 64.29; H, 6.32; N, 3.29.

I.r. ($CHCl_3$): 3410 (NH), 1750 (five-membered ketone), 1720 (ester), 1670 cm^{-1} (amide); n.m.r. ($CDCl_3$): τ 5.93 (m, 4H, dioxolane hydrogen), 6.20 (s, 3H, aromatic methoxyl), 6.25 (s, 3H, —C(=O)—OCH_3), 8.00 (s, 3H, —N(—C(=O)—CH_3)—), 9.43 p.p.m. (s, 3H, tertiary methyl shielded by benzene ring).

Cyclization of Compound ***18*** *to the Keto Lactam* ***19***

A solution of the keto ester **18** (5.71 g) in absolute methanol (50 ml) was added to a solution of sodium methoxide prepared by dissolving sodium metal (2 g) in absolute methanol (50 ml). The mixture was heated under reflux for 26 h in a nitrogen atmosphere. Most of the methanol was removed *in vacuo* and the residue was dissolved in ice water (200 ml). The solution was extracted with chloroform (4 × 150 ml) and the combined extracts were washed with water, dried, and evaporated to dryness. Crystallization of the solid residue from chloroform–ether gave the pure lactam **19**, m.p. 264°. The yield was 3.75 g (80%).

Anal. Calcd. for $C_{20}H_{21}O_5N$: C, 67.59; H, 5.96; N, 3.94. Found: C, 67.55; H, 5.87; N, 3.97.

I.r. ($CHCl_3$): 3400 (NH), 1750 (ketone), 1675 cm^{-1} (lactam); n.m.r. ($CDCl_3$): τ 5.80 (m, 4H, dioxolane hydrogen), 6.23 (s, 3H, aromatic methoxyl), 8.66 (s, 3H, tertiary methyl).

Wolff–Kishner Reduction of the Keto Lactam ***19***

A mixture of the lactam **19** (3.6 g), 95% hydrazine (48 g), hydrazine dihydrochloride (9.6 g) and triethylene glycol (150 ml) was heated at 130° (oil bath temperature) for 4 h with stirring. Potassium hydroxide pellets (13 g) were added in portions with stirring and the temperature was gradually raised to 190° (oil bath). The solution was stirred at that temperature for 5 h. The whole process was operated in a nitrogen atmosphere. After cooling, saturated aqueous sodium chloride (200 ml) was added and the mixture was extracted with chloroform (4 × 200 ml). The chloroform extracts were washed with water, dried, and evaporated to dryness. The pure reduction product **20** (3.1 g, 89%) was obtained by crystallization from ether and it melted at 233°.

Anal. Calcd. for $C_{20}H_{23}O_4N$ (mol. wt. 341): C, 70.36;

H, 6.79; N, 4.10. Found (mass spectroscopy, 341): C, 70.49; H, 6.80; N, 4.06.

I.r. ($CHCl_3$): 3400 (NH), 1665 cm^{-1} (lactam); n.m.r. ($CDCl_3$): τ 3.63 (broad s, 1H, —NH), 5.80 (m, 4H, dioxolane hydrogen), 6.20 (s, 3H, aromatic methoxyl), 6.46 (broad s, 1H, apex proton), 6.83 (m, 1H, benzylic bridgehead proton), 8.76 p.p.m. (s, 3H, tertiary methyl).

Preparation of the Phenol ***21***

A solution of compound **20** (2.6 g) in 48% hydrobromic acid (50 ml) and glacial acetic acid (35 ml) was refluxed for 4 h under nitrogen. After cooling, water was added and the product was extracted with methylene dichloride. Evaporation of the solvent yielded 1.82 g (86%) of the highly crystalline phenol **21**. The analytical sample was prepared by recrystallization from chloroform–methanol to a constant melting point of 301° (dec.).

Mol. Wt. Calcd. for $C_{17}H_{17}O_3N$: 283.1214. Found (high resolution mass spectroscopy): 283.1208.

I.r. ($CHCl_3$): 3500–3300 (OH and NH), 1718 (ketone in six-membered ring), 1655 cm^{-1} (lactam); n.m.r. ($CDCl_3$—CD_3OD): τ 3.12 (d, J = 8 Hz, 1H, aromatic hydrogen), 3.13 (d, J = 3 Hz, 1H, aromatic hydrogen), 3.52 (q, J = 8 Hz, J = 3 Hz, 1H, aromatic hydrogen), 6.43 (broad s, 1H, apex proton), 6.67 (m, 1H, benzylic bridgehead proton), 8.82 p.p.m. (s, 3H, tertiary methyl).

The generous support of the National Research Council of Canada, Ottawa, and the Hoffmann-La Roche Company, Nutley, New Jersey and Dorval, Quebec, is gratefully acknowledged.

Unusual Reactivity Differences in the Decalone Series

CIRILL SCHMIDT

Department of Chemistry, University of Prince Edward Island, Charlottetown, Prince Edward Island

Received May 17, 1973

It was found that an 8α-axial substituent in a 2α,5α,9β-trimethyl-1,4-decaldione system exercises an extraordinary steric hindrance in the reduction of the 1-keto group. Therefore the 4-keto group was reduced in the three compounds **7***b*, **13**, and **22** with complete selectivity. In the absence of such a substituent the 1-keto group is reduced in preference to the 4-keto group (1, 5) with almost complete selectivity. An interplay of 1,3-diaxial and 1,3-*peri*-diequatorial interactions is involved to explain the unusual stereochemical behavior in these compounds. The blocking effect of the 8α-axial group was found to be independent of its own polarity. The steric preference of the reductions does not seem to be influenced by variously located double bonds in the decaline system.

On a trouvé qu'un substituant axial en position 8α de la triméthyl-2α,5α,9β décaldione-1,4 excerce un effet stérique extraordinaire sur la réduction du groupe cétonique en position 1. Une sélectivité complète en faveur de la réduction du groupe cétonique en position 4 a donc été observée lors de la réduction des composés **7***b*, **13** et **22**. En l'absence d'un tel substituant, le groupe cétonique en position 1 est réduit de préférence à celui en 4 (1, 5) avec une sélectivité presque complète. Une combinaison d'interactions diaxiales-1,3 et *péri*-diéquatoriales-1,3 est invoquée pour expliquer la stéréochimie inhabituelle de ces réductions. L'influence du groupe axial en 8α est indépendant de sa polarité. Il apparait que la préférence stérique des réductions ne serait pas influencée par la présence de doubles liaisons dans le système décalinique. [Traduit par le journal]

Can. J. Chem., **51**, 3989 (1973)

In the course of our synthetic studies toward decanortriterpenes we encountered a number of unprecedented selective reductions in the decalin series. The results of these reactions revealed an interesting interplay of several 1,3-interactions leading to a peculiar stereochemical behavior which might be relevant to the field of terpene synthesis.

The reduction of *trans*-diketone **1** (1) with $LiAlOC(CH_3)_3H$ in tetrahydrofuran led to the formation of ketone alcohol **2** in 80% yield, as evidenced by a one proton doublet at $\tau = 6.07$, $J = 8$ Hz. In retrospective this result can be readily rationalized.

An axial approach of the hydride ion to C-4 is impeded by a 1,3-diaxial interaction in the transition state as in the reduction of 6-keto steroids (2). In addition to that interference, the 4-keto group in **1** is also shielded by a 1,3-*peri*-diequatorial interaction. The seriousness of the latter stereochemical effect could be compared to an $A^{(1,3)}$ strain (3*b*) pertinently documented by the fact that the 6-β-hydroxy isomer **4** is favored relative to the 6-α-hydroxy derivative **3** (3*a*).

As a result of these two 1,3 interactions at the 4-keto group in diketone **1** the reduction takes place preferentially at the 1-keto group by an uninhibited axial attack from the α side.

It could be assumed that the special steric hindrance at C-4 in diketone **1** might be attributed at least partially to a particular conformation imposed on the structure by the $\Delta^{(7,8)}$ double bond. Such a conformational distortion (4, 5) must however be of small importance in this instance since the saturated diketone **5** was also reduced preferentially at C-1 leading to ketone alcohol **6**.

Since we wished to retain the keto group at C-1 we decided to increase the steric hindrance in its immediate vicinity. Therefore the acetate **7***b* was prepared from the corresponding alcohol **7***a* (1).

According to the well-known stereochemistry of the Diels–Alder transition state (6) the 8-hydroxyl and the 8-acetoxy groups in compounds **7***a* and **7***b* respectively are axial since the ring junction could be assigned as *trans* on the basis of previous chemical evidence (1, 7).

To our satisfaction and surprise we found that the 1-keto group was completely inert in acetate **7***b* when it was reduced with a large excess of sodium borohydride in methanol at room temperature in 24 h. Thus ketone alcohol **8** was formed in virtually quantitative yield by the reduction of the 4-keto group. A comparison of the chemical behavior of compounds **1**, **5**, and **7***b* suggests that the apparent cause of this remark-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

able reversal of steric preference must be the axial acetoxy group at C-8 in acetate **7***b*.

In order to study the influence of the size of the 8-axial substituent on the reactivity of the 1-keto group we prepared the diol ketone **9** by methanolysis of acetate **8**. It is to be mentioned that during the methanolysis of acetate **8** to diol ketone **9** the 8-axial OH might have been converted to the corresponding equatorial isomer via a reversible retroaldol condensation. However, this possibility can be excluded by recognizing that the coupling constants of the triplet corresponding to H_8 in compounds **7***b*, **8**, **9**, and **10** remain unchanged ($J_{AX} = J_{BX} = 2.5$ Hz). An equatorial OH at the same position would require an axial hydrogen at C-8 giving rise to a coupling constant of approximately 10 Hz.

It was found that compound **9** was reduced in 1 h with $NaBH_4$ in methanol at room temperature to the triol **10**. This oily compound was characterized in terms of crystalline triketone **11** to which it was oxidized with Jones' reagent. However, it would be unjustified to attribute this large increase in reactivity entirely to the difference in size of OH relative to the acetoxy group in compounds **9** and **8** respectively. It is believed that complexing between the borohydride and the 8-hydroxy group might have preceded the attack of a hydride ion on the 1-keto group in ketone diol **9**. Such an intramolecular reduction might have been responsible for the fast reduction of the 1-keto group in compound **9**.

The assumption that in the transition state of these reductions a crucial 1,3-diaxial interaction is involved can be supported by one of our compounds in which positions 1 and 8 were actually linked together. When the diol ketone **9** was treated in liquid ammonia with sodium *o*-methoxyphenylacetylide the cyclic vinyl ether **12***a* was formed as evidenced by appropriate n.m.r. data and the presence of only one acetylable hydroxyl (**12***a* → **12***b*). Such a cyclic compound is possible only if the relative position of substituents at C-1 and C-8 is *cis* in the decalin system. This finding corroborates the assumption that the nucleophile encounters a critical 1,3-diaxial interaction when it attacks the 1-keto group from an α-axial direction. For the addition of alcohols to acetylenes in alkaline conditions numerous examples can be cited (8).

The triketone **11** was most conveniently obtained by the oxidation of diketone alcohol **7***a* with Jones' reagent. It is noteworthy that compound **11** exhibited a double carbonyl peak (1740, 1725 cm^{-1}) attributable to a *cisoid* 1,3-diketone (9) in addition to the normal peak at 1703 assigned to the 4-keto group.

Since we wished to investigate the reactivity of the 1-keto group in this system further, triketone **11** was reacted with a large excess of ethylene glycol in the presence of boronfluoride ethereate and methylene chloride at room temperature. As suspected from the previous results a monoketal, **13**, was obtained in almost quantitative yield.

The fact that in compound **13** the 4-keto group was not ketalized can be understood in terms of a 1,3-diaxial and a 1,3-*peri*-diequatorial interaction already invoked in connection with the reduction previously discussed **1** → **2**. Since in the i.r. of **13** the double carbonyl band characteristic of 1,3-dicarbonyls disappeared, either the 1-keto group or 8-keto group is ketalized. Rigorous proof of structure **13** will be presented after derivatives **14**, **15**, and **16** are discussed.

The reduction of diketone ketal **13** in methanol with sodium borohydride at room temperature in 8 h led to a quantitative yield of alcohol **14**. A one proton multiplet at $\tau = 5.50$, $J = 4.5$, 9.5, and 6 Hz, showed that the 4-keto group was reduced in compound **13**. These coupling constants corroborate the equatorial assignment of H_4, since an axial hydrogen at C-4 should have been indicated by two coupling constants of approximately 10 Hz. A similar argument can be used for the stereochemical assignment of the same hydrogen in compound **8** thus confirming the β-axial position of the 4-hydroxyl group in both compounds.

The ring juncture in triketone **11** and diketone ketal **13** was assigned with the help of double irradiation experiments in their 220 MHz n.m.r. Irradiating at the position of the 5-methyl group located the hydrogen on C-5. When the latter proton was irradiated the low field doublet corresponding to the hydrogen on C-10 was affected. The coupling constant in both cases was found to be 10.6 Hz corresponding to a *trans*-diaxial arrangement.

As far as the ring junction in compounds **11** and **13** is concerned a *trans* isomer and two *cis* conformations should be considered. The relative stereochemistry of the methyls at C-5 and C-9 is *trans*, since the precursor of these compounds originated from a Diels–Alder reaction (1, 7). The well established transition state of the latter reac-

tion is known to place the substituents at these positions in a *trans* relative position (6). The two *cis* conformations for triketone **11** are depicted as formulae **17** and **18**.[1] A *trans*-diaxial arrangement of H_5 and H_{10} is compatible only with structure **11** but not with **17** or **18**. The 1-keto group in compound **14** could be reacted only under vigorous conditions. Refluxing of **14** in tetrahydrofuran for 8 h with an excess of bromomagnesium *o*-methoxyphenylacetylide led to adduct **15**. After hydrogenation of **15** and refluxing in 85% formic acid the olefin **16** was formed. In the n.m.r. of **16** a three proton singlet at $\tau = 8.2$ clearly indicates the presence of a methyl group situated on a double bond. The structure of **16** clarifies the location of the dioxolane group in compound **13** at C-8 since an olefinic methyl

[1]The stereochemistry at C-2 in formulae **17** and **18** was drawn undefined since it is irrelevant for this argument.

could not have formed in this sequence if the 8-keto group had been unprotected.

The stereochemical assignment for **13**, **14**, and **15** is completely certain since the structure of **16** was also elucidated by X-ray crystallography and will be published in connection with some other work (10). The stereochemical assignment of the 4-β-hydroxyl in compounds **14** and **15** is also firmly established by the crystallographic structure determination. Since the energy difference between *trans*- and *cis*-9-methyldecalones is quite small (11) we had to corroborate our stereochemical assignments by the most reliable methods available.

Although in compound **14** the 8-axial substituent was incorporated in a dioxolane ring the deceleration of reactivity at C-1 was just as pronounced as in the case of acetate **7***b*. It can be summarized therefore, that all compounds presented here which carry an oxygenated 8-axial substituent exhibit this remarkable blocking effect with the exception of ketone diol **11** which contains an axial OH only.

It was thought to be desirable to replace the oxygenated group by a neutral methyl substituent in position 8 and examine the question whether this phenomenon is due to electronic effects or to steric hindrance only. Thus, the Diels–Alder adduct **19** was prepared in a yield of 85% from piperylene and 2,6-dimethylbenzoquinone. *A priori* two products, **19** and **20**, could have formed. As in numerous other Diels–Alder additions only one of the possible adducts, **19**, could be isolated (6). The structural proof for the location of the methyl group in ring A of adduct **19** is outlined in Scheme 1[2] and it is self-explanatory.

A clearly resolved one proton doublet in the n.m.r. of keto alcohol **25** at $\tau = 5.76$ ($J = 8$ Hz) indicates that the less hindered 4-keto group was ketalized in dioxolane **23**. Baeyer–Villiger oxidation led to the ε-lactone **28**, which was converted without isolation to the more stable γ-lactone **29** after methanolysis. Bromination of ketone lactone **30** with 1 mol of bromine in acetic acid led to the bromoketone **31**. The elimination of HBr in dimethylformamide in the presence of LiBr and Li_2CO_3 gave the α,β-unsaturated ketone **32** which contained two olefinic hydrogens but no n.m.r. signal corresponding to a methyl group situated on a double bond. Therefore it was shown that the methyl group in ring A of adduct **19** was not attached to C-5, thus excluding compound **20** while proving structure **19** for the Diels–Alder adduct formed.

The stereochemistry of diketone **22** is represented as **33**. Because of the isomerization **21** → **22** = **33** the ring juncture can be assigned *trans* in the latter compound. The chemical shift of the angular methyl and one of the methyl doublets change by 0.39 and −0.22 p.p.m. respectively as a result of isomerization from the *cis* diketone **21** to its *trans* isomer **22**. The second methyl doublet is not affected and it is assigned to the 2-methyl group. It follows from the stereochemistry of the Diels–Alder transition state that the 8-methyl group must be *trans* to the angular methyl (6). Consequently the 8-methyl group is axial in compound **22** = **33** and can be used in this study.

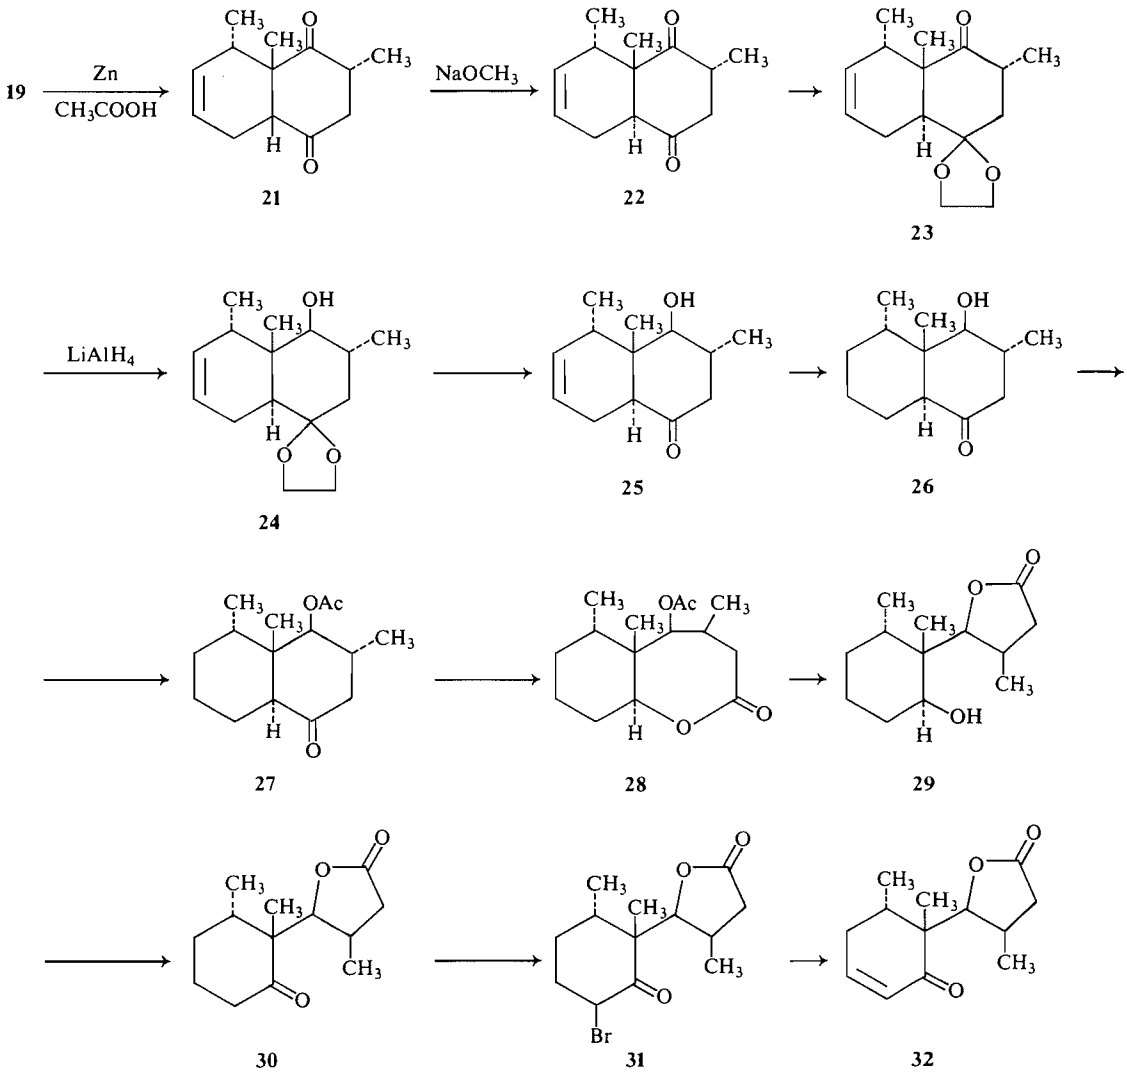
With an excess of sodium borohydride in methanol the diketone **22** = **33** was reduced at room temperature in 18 h to the ketone alcohol **34**. Further reduction to the diol **35** could be achieved only by refluxing in THF with $LiAlH_4$ for 15 h producing a two component mixture. It should be mentioned that compounds **8**, **14**, and **34** were all treated with a large excess of sodium borohydride under the same conditions as described previously but they were recovered unchanged. Therefore, it was concluded that the low reactivity of the 1-keto group in **7***b*, **13**, and **22** = **33** is due to steric hindrance rather than to electric effects and it is caused by the 8-axial group which transmits its effect by a 1,3-diaxial interaction arising in the transition state.

In relation to our data we should mention that the rate of saponification of *trans*-1α-decalyl acid succinate was found to be 14 times slower than that of the *trans*-2β isomer (12). The ester group is present in both compounds in an axial position but the *trans*-1α-isomer contains an extra 1,3-diaxial interaction to which the rate decrease was attributed.

The influence of the decalin system on these saponification rates is impressive in spite of the fact that the site of reaction ($^-OH + RCOOR \rightarrow RCO^-(OH)OR$) (13) is removed from the decalin ring by two atoms.

In the reduction of our 1-decalones by sodium borohydride the stereochemical influence of the

[2]It should be mentioned that prior to undertaking the rather elaborate degradation, diol **35** was subjected to dehydrogenation. The product was, however, an unidentified trimethylnaphthaline indicating that a rearrangement interfered with the structure elucidation.



SCHEME 1

decaline ring must be two atoms closer to the site of reaction than in the cases of saponification cited (11*a*, p. 236 and 12).

Due to this and to the larger size of the 8-axial substituent involved in the 1,3-diaxial interaction of the transition state, the 1-keto group in compounds 7*b*, **13**, and **33** is inert at room temperature with sodium borohydride in methanol. It is pertinent to mention that *trans*-2α,9β-dimethyl-1-decalone (15) and a similarly substituted decalone (16) lacking an 8-α-substituent exhibited facile reactivity at the 1-keto group.

It is unlikely that the $\Delta^{(6,7)}$ double bond would exert a pronounced decelerative effect on the 1-keto group, by conformational transmission (4, 5), since all three compounds 7*b*, **13**, and **33** showed qualitatively the same steric hindrance at the 1-keto group, although a double bond was present only in compound **33**.

From the data presented here it appears that the 8-α-axial-decalin effect is a special case of 1,3-diaxial interaction which could be utilized to protect the 1-keto group of the *trans*-decalin system under the conditions described.

In summary the compounds discussed here add further examples of the decalin type to the interesting cases discussed by Sandris and Ourisson (14) in which 1,3-interactions drasti-

cally change the stereochemical behavior of cyclohexanes and terpenes.

Experimental[3]

trans-1β-Hydroxy-2α,5α,9β-trimethyl-7-octal-4-one (2)

To a solution of 7.32 g of diketone 1 in dry tetrahydrofuran (200 ml) 10.27 g of $LiAlOC(CH_3)_3H$ was added in 2 h. The reaction mixture was stirred magnetically at room temperature for 12 h, then it was poured on ice. The solution was extracted with ether (4 × 300 ml). After washing with water and drying ($MgSO_4$) the solution concentrated to dryness. The crystalline residue was recrystallized from benzene–chloroform giving 6.10 g of pure ketone alcohol **2** (yield 83%, m.p. 108–112°). The mother liquor contained some diol, it was therefore freed from all solvents and oxidized with Jones' reagent in acetone (25 ml) furnishing 0.50 g of diketone **1**. An analytical sample of the ketone alcohol **2** was prepared by recrystallizing from benzene–chloroform: m.p. 115°; mass spectrum (70 eV) *m/e* (relative intensity) 208 (30, parent peak), 193 (10), 175 (8), 150 (20), 135 (100); i.r. ($CHCl_3$) 3650, 2950, 1710, 1460, 1360, 1240, 1050, 990, 980, 840 cm^{-1}; u.v.$_{max}$ (96% C_2H_5OH) 215 mμ (ε 350); n.m.r. at 60 MHz ($CDCl_3$) τ 9.1 (s, 3, angular methyl), 9.00 (d, 3, J = 6 Hz, CH—CH_3), 8.93 (d, 3, J = 6 Hz, CH—CH_3), 6.07 (d, 1, J = 8 Hz, C*H*OH), 4.43 (m, 2, olefinic protons).

Anal. Calcd. for $C_{13}H_{20}O_2$: C, 74.96; H, 9.68. Found: C, 74.98; H, 9.65.

trans-2α,5α,9β-Trimethyl-1,4-decaldione (5)

A solution of diketone **1** (250 mg) in methanol (30 ml) was hydrogenated for 18 h at a pressure of 30 p.s.i. in the presence of 30 mg of PtO_2. After filtration and evaporation a t.l.c. homogeneous crystalline product was obtained (250 mg, yield quantitative). An analytical sample was obtained by recrystallizing from benzene–pentane: m.p. 99–101°; i.r.($CHCl_3$) 2980, 1720, 1475, 1380, 1160, 1100, 1020 cm^{-1}; u.v. end absorption; n.m.r. at 60 MHz ($CDCl_3$) τ 9.14 (s, 3, angular methyl), 9.03 (d, 3, J = 6 Hz, CH—CH_3), 8.90 (d, 3, J = 6 Hz, CH—CH_3); mass spectrum (70 eV) *m/e* (relative intensity) 208 (100, parent), 193 (50), 180 (20), 137 (80).

*trans-1β,4β,8α-Trihydroxy-2α,5α,9β-trimethyldecalin (**10**)*

A solution of 300 mg of ketone diol **9** in methanol (10 ml) was stirred at room temperature for 1 h with 150 mg of $NaBH_4$. The reaction mixture was poured on water (50 ml) and extracted with chloroform (4 × 50 ml). After washing the extracts with water, the dried ($MgSO_4$) solution was evaporated to dryness. The oily material (280 mg, 90%) resisted all attempts to crystallize it but appeared homogeneous in t.l.c., mass spectrum (70 eV) *m/e* (relative intensity) 228 (10, parent peak), 210 (20), 192 (15), 174 (5), 159 (100); i.r. ($CHCl_3$) 3450, 2950, 1450, 1400, 1300, 1170, 1020, 970, 915, 870 cm^{-1}; u.v. end absorption; n.m.r. at 60 MHz ($CDCl_3$) τ 9.00 (d, 6, J = 6 Hz, 2-methyl and 5-methyl), 8.83 (s, 3, angular methyl), 6.00 (t, 1, $J_{AX} = J_{BX}$ = 2.5 Hz, C*H*OH), 5.6 (m, 2, two C*H*OC).

The triol **10** (270 mg) was dissolved in acetone (5 ml) and titrated with Jones' reagent. The reaction mixture was poured on water (30 ml) and extracted with chloroform (4 × 30 ml). After drying ($MgSO_4$) and evaporation the crystalline material (230 mg) was identified as the already characterized triketone **11**.

*trans-2α,5α,9β-Trimethyldecal-1,4,8-trione (**11**)*

To a solution of 65 g of diketone alcohol **7***a* in acetone (600 ml) 120 ml of Jones' reagent (17) was dripped in 1 h while cooling with ice water and stirring with a mechanical stirrer. The permanently brown solution was stirred at room temperature for 1 h. Then the reaction mixture was poured on ice water and extracted with ether (4 × 1 l). The combined ether extracts were washed in succession with water, diluted $NaHCO_3$ solution, and water again. The dried ($MgSO_4$) solution was evaporated to dryness *in vacuo* giving 60 g (92%) of t.l.c. homogeneous crystalline triketone. An analytical sample was prepared by recrystallization from benzene–pentane: m.p. 115–117°C mass spectrum (70 eV) *m/e* (relative intensity) 222 (100, parent peak), 207 (10), 194 (50); i.r. ($CHCl_3$) 2950, 1740, 1725, 1703, and 1454 cm^{-1}; u.v.$_{max}$ (96% C_2H_2OH) 218 mμ (ε 678), 290 (113); n.m.r. at 220 MHz ($CDCl_3$) τ 8.90 (d, 3, J = 6 Hz, CH*C*H_3), 8.87 (d, 3, J = 6 Hz, CH*C*H_3), 8.71 (s, 3, angular methyl), 8.50 (m, 1), 8.11 (m, 2), 7.87 (m, 1), 7.68 (m, 1), 7.21 (m, 2), 6.75 (d, 1, J = 10.6 Hz, H_{10}, superimposed on a one proton multiplet). Irradiation of the CH_3—CH at 8.90 showed that H_5 was buried at 8.11. When the latter position was irradiated the doublet at 6.75 was affected. The coupling constant J = 10.6 Hz is compatible with a *trans* diaxial relationship between H_5 and H_{10}.

*3aβ,4,5,6,6aα,7,8,9,9a,10β-Decahydro-2-o-methoxyphenyl-3aβ,6β-dihydroxy-4α,7α,10β-trimethylnaptho-1,8-bc Pyran (**12***a*)

In 1 l of magnetically stirred liquid ammonia sodium amide was prepared from 5.97 g of sodium catalyzed with $Fe(NO_3)_3$. After the complete disappearance of the blue color a solution of 16 g of *o*-methoxyphenylacetylene in dry tetrahydrofuran (30 ml) was dripped to the solution in 10 min. Then the reaction mixture was stirred magnetically for 1 h. The dihydroxyketone **9** (11.70 g) dissolved in dry tetrahydrofuran (30 ml) was dripped to it in ½ h. The liquid ammonia solution was stirred for 6 h. After the addition of NH_4Cl (10 g) the ammonia was allowed to evaporate. To the residue ether (0.5 l) was added and while stirring and cooling with ice, water (100 ml) was dripped in. After separation the water layer was extracted with ether (4 × 0.5 l).

The ether solution was evaporated to dryness. Next the excess *o*-methoxyphenylacetylene was precipitated. The residue was dissolved in 96% C_2H_5OH (50 ml) then 5% $Ag(NH_3)_2OH$ was dripped in to it until no more precipitate was formed (a sample of filtrate was checked). After filtering and washing the precipitate with alcohol and ether the filtrate was diluted with water (100 ml) and extracted with ether (4 × 100 ml). The ether extracts were washed with saline and dried ($MgSO_4$). After evaporation the t.l.c. homogeneous material crystallized (14.8 g, yield 80%) m.p. 208–215°. An analytical sample was prepared by recrystallizing from benzene–pentane: m.p. 218–220°, mass spectrum (70 eV) *m/e* (relative intensity) 358 (80), 340 (15), 325 (50), 307 (20), 298 (15), 279 (10), 210 (100); i.r. *trans-1α-(o-Methoxyphenylethynyl)-1β,4β-dihydroxy-8,8-ethylenedioxy-2α,5α,9β-trimethyldecalin (**15**)*

203 ml of 2.95 M CH_3MgBr solution (Arapahoe) was dripped into a solution of 82.3 g of *o*-methoxy-phenylacetylene in dry tetrahydrofuran (1 l). The addition was carried out in ½ h with ice cooling in an atmosphere of dry N_2 while stirring. The 2-l, three-neck flask was equipped with a mechanical stirrer, reflux condenser ($CaCl_2$ drying tube), dripping funnel, and an opening for the continuous introduction of dry N_2. The reaction mixture was allowed to stir for 20 min at room temperature then it was refluxed for 10 min. Then it was cooled down to 5° and a solution of 42 g of compound **14** in dry THF was added in ½ h. The reaction mixture was then refluxed for 8 h under a stream of anhydrous nitrogen. The reaction mixture was poured on ice then it was diluted with 1 l of chloroform and the emulsion was filtered on celite. The clear filtrate was extracted with chloroform (3 × 0.5 l). The combined chloroform extracts were washed with water then dried ($MgSO_4$). After evaporation the residue was examined by t.l.c. indicating the complete disappearance of starting material and the presence of the acetylene and the product only. The residue was then dissolved in 300 ml of ethanol and while stirring 0.4 g mol of Ag-$(NH_3)_2OH$ (prepared in ½ l of distilled water) was dripped into it in 20 min. The yellow acetylene precipitate was filtered on a Buchner funnel. The precipitate was washed with ½ l of ether. The filtrate was extracted with ether (4 × 0.5 l). After drying ($MgSO_4$) and evaporation the residue was dissolved in 1 l of $CHCl_3$ and dried again ($MgSO_4$). After evaporation the oily residue was dissolved in 100 ml of benzene and allowed to crystallize and 38 g of crystalline **15** was collected (yield 65%), m.p. 95°. An analytical sample was prepared by recrystallizing from benzene–pentane, m.p. 100°; mass spectrum (70 eV) *m/e* (relative intensity) 400 (5, parent peak), 382 (100), 364 (100), 349 (80), i.r. ($CHCl_3$) 3300, 2850, 1580, 1470, 1440, 1240, 1100, 1010, 980, 940, 900 cm^{-1}; u.v.$_{max}$ (96% C_2H_5OH) 209 mμ (ε 20 600), 219 (18 000), 247 (12 000), 257 (12 850), 291 (5150), 301 (6000): n.m.r. at 60 MHz ($CDCl_3$) τ 9 (d, 3, J = 6 Hz, CH—CH_3), 6.17 (s, 3, CH_3O), 6 (m, 5, O—CH_2—CH_2—O and CHOH), 3.0 (m, 4, aromatic protons).

*trans-1-(2-o-Methoxyphenylethyl)-4β-formoxy-2,5α,9β-trimethyl-1-octal-8-one (**16**)*

Twenty grams of Nef adduct **15** was hydrogenated for 24 h in methanol (300 ml) in the presence of 300 mg of 5% Pd–charcoal. After filtration the methanol was com-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

pletely removed. Spectroscopic examination by n.m.r. and u.v. indicated the complete disappearance of the starting material. According to t.l.c. only one product was present, which was refluxed in 85% formic acid (100 ml) for 8 h. The reaction mixture was poured into water (500 ml) and extracted with ether (4 × 500 ml). The ether extracts were washed successively with saline, 5% sodium bicarbonate, and saline. The dried ($MgSO_4$) ether extracts were evaporated to dryness. T.l.c. showed the presence of one major product and a minor product in such minute quantities that we were unable to characterize it. The major compound was obtained by crystallizing from benzene–pentane (16 g, yield 87%, m.p. 120°). An analytical sample was prepared by recrystallizing from benzene–pentane: m.p. 130°; mass spectrum (70 eV) *m/e* (relative intensity) 370 (4, parent peak), 352 (2), 324 (30), 306 (70), 291 (100), 249 (55); i.r. ($CHCl_3$) 2950, 1720 (broad), 1600, 1480, 1450, 1230, 1160, 1040, 830 cm^{-1}; u.v.$_{max}$ (96% C_2H_5OH) 224 mμ (ε 7850), 273 (1990), 279 (1850): n.m.r. at 60 MHz ($CDCl_3$) τ 9.03 (d, 3, J = 6 Hz, CH—CH_3), 8.37 (s, 3, angular methyl), 8.20 (s, 3, =C—CH_3), 6.17 (s, 3, CH_3O) 4.50 (m, 1, C*H*OCOH), 3.00 (m, 4, aromatic protons), 1.9 (s, 1, OCO*H*).

*cis-1,4,4a,5,8,8a-Hexahydro-2,8α,8aβ-trimethyl-1,4-dioxonaphthalene (**19**)*

2,6-Dimethylbenzoquinone (20 g) and piperylene (100 g, 95:5 *trans–cis* mixture) were refluxed for 24 h in benzene (500 ml). After evaporating the excessive piperylene and benzene the reaction mixture was distilled *in vacuo* at 0.7 mm Hg using a short Vigreux column. The first fraction boiling at 20–100°/0.7 mm Hg contained a few per cent of quinone which crystallized in the column. After its complete evaporation the distillation was interrupted and the crystalline material was removed. The product distilled at 100–105°/0.7 mm Hg, giving 26 g (85%) of product whose gas chromatographic purity was found to be better than 95%; i.r. ($CHCl_3$) 3050, 2950, 1685, 1610, 1450, 1360, 1350, 1200, 1050, 900 cm^{-1}; u.v.$_{max}$ (96% C_2H_5OH) 242 mμ (ε 11 500); n.m.r. ($CDCl_3$) τ 9.26 (d, 3, J = 6 Hz, 8-methyl), 8.66 (s, 3, 8a-methyl), 8.08 (s, 3, 2-methyl), 4.52 (m, 2, olefinic), 3.45 (m, 1, H_3). Characterized as its monosemicarbazone, m.p. 196–200°.

Anal. Calcd. for $C_{14}H_{19}ON_3$: C, 64.35; H, 7.33; N, 16.08. Found: C, 64.33; H, 7.35; N, 1610.

*cis-2α,8α,9β-Trimethyl-6-octal-1,4-dione (**21**)*

A solution of adduct **19** (60 g) in acetic acid (200 ml) and water (200 ml) was heated at 55° with zinc dust (40 g) while stirring for 12 h. Acetone (500 ml) was poured into the cool solution and after filtration the solution was concentrated *in vacuo*. The residue was dissolved in ether, extracted with diluted sodium bicarbonate solution, then with water. The dry solution ($MgSO_4$) was concentrated to dryness. This oily product (58 g, 95%) crystallized after two days. An analytical sample was obtained by recrystallizing from benzene–hexane: m.p. 43°; i.r. ($CHCl_3$) 2950, 1710, 1455, 1000 cm^{-1}; u.v. end absorption; n.m.r. ($CDCl_3$) τ 9.27 (d, 3, J = 6 Hz, 8-methyl), 8.83 (d, 3, J = 6 Hz, 2-methyl), 8.67 (s, 3, angular methyl), 4.44 (m, 2, olefinic protons).

Anal. Calcd. for $C_{13}H_{18}O_2$: C, 75.69; H, 8.80. Found: C, 75.71; H, 8.78.

*trans-2α,8α,9β-Trimethyl-6-octal-1,4-dione (**22**)*

Five g of *cis*-diketone **21** dissolved in methanol (50 ml) was refluxed for 3 h in the presence of a catalytic amount of sodium methylate. After the addition of acetic acid (0.2 ml) the methyl alcohol was removed *in vacuo*. The residue was dissolved in chloroform (100 ml) and washed with diluted sodium bicarbonate solution. Then the solution was dried ($MgSO_4$) and evaporated to dryness. The crystalline product (5 g) was homogeneous according to t.l.c. An analytical sample was prepared by recrystallizing from benzene–hexane: m.p. 95 °C; i.r. ($CHCl_3$) 2950, 1710, 1460, 1050, 850 cm^{-1}; u.v. end absorption; n.m.r. ($CDCl_3$) τ 9.09 (d, 3, J = 6 Hz, 8-methyl), 9.06 (s, 3, angular methyl), 8.86 (d, 3, J = 6 Hz, 2-methyl), 4.36 (m, 2, olefinic protons).

Anal. Calcd. for $C_{13}H_{18}O_2$: C, 75.69; H, 8.80. Found: C, 75.67; H, 8.79.

*trans-4,4-Ethylenedioxy-2α,8α,9β-trimethyl-6-octal-1-one (**23**)*

Diketone **22** (10 g), ethylene glycol (7 ml), and *p*-toluene sulfonic acid (80 mg) were refluxed for 24 h in benzene using a Dean–Stark head for the removal of water. The benzene solution was washed with diluted $NaHCO_3$ solution then with saline twice. After the removal of benzene a colorless, t.l.c. homogeneous oil (10.7 g, 88%) was obtained: i.r. ($CHCl_3$) 2950, 1715, 1460, 1299, 1176, 1156, 1111, 1053, 1003 cm^{-1}; u.v. end absorption; n.m.r. ($CDCl_3$) τ 9.25 (d, 3, J = 6 Hz, CH—CH_3), 8.89 (d, 3, J = 6 Hz, CH—CH_3), 8.73 (s, 3, angular methyl), 6.02 (m, 4, O—CH_2—CH_2—O), 4.42 (m, 2, olefinic protons). Characterized in terms of alcohol **7**.

*trans-1β-Hydroxy-4,4-ethylenedioxy-2α,8α,9β-trimethyl-6-octalin (**24**)*

A solution of monoketal ketone **23** (10 g) in dry tetrahydrofuran (25 ml) was added dropwise to a stirred suspension of $LiAlH_4$ (10 g) in dry tetrahydrofuran (100 ml) at room temperature. It was then refluxed for 24 h under anhydrous conditions. The reaction mixture was decomposed with cold water. After filtration and washing the inorganic material was washed with ether. The filtrate was extracted with ether (3 × 10 ml) then the combined extracts were washed with saline and dried ($MgSO_4$). A crystalline residue was obtained on evaporation of the ether (9.1 g, 90%). An analytical sample was prepared by recrystallizing from benzene–pentane: m.p. 106–107°; i.r. ($CHCl_3$) 3660, 2950, 2900, 1460, 1120, 1050, 980 cm^{-1}; u.v. end absorption: n.m.r. ($CDCl_3$) τ 8.75–9.08 (m, 9, methyls), 6.04–6.3 (m, 5, C*H*OH and O—CH_2—CH_2—O), 4.41 (m, 2, olefinic protons).

*trans-1β-Hydroxy-2α,8α,9β-trimethyl-decal-4-one (**26**)*

The unsaturated keto alcohol **25** (5 g) was hydrogenated in methanol (75 ml) using 10% Pd-on-charcoal (200 mg) at 20 p.s.i. for 20 h at room temperature. After filtering the catalyst and evaporation a crystalline, t.l.c. homogeneous product (4.8 g, 96%) was obtained. An analytical sample was obtained by recrystallizing from benzene – petroleum ether: m.p. 129–131°; i.r. ($CHCl_3$) 3600, 3480, 2950, 1710, 1460, 1200 cm^{-1}; u.v. end absorption; n.m.r. ($CDCl_3$) τ 9.05 (s, 3, angular methyl), 8.95 (d, 3, J = 6 Hz, CHCH_3), 8.84 (d, 3, J = 6 Hz, CHCH_3), 5.82 (d, 1, J = 8 Hz, CH—OH).

Anal. Calcd. for $C_{13}H_{22}O_2$: C, 74.24; H, 10.54. Found: C, 74.27; H, 10.55.

*trans-1β-Acetoxy-2α,8α,9β-trimethyl-decal-4-one (**27**)*

A solution of the saturated keto alcohol **26** (1 g) in 7 ml of acetyl chloride was refluxed for 3 h. (Acetic anhydride and pyridine at room temperature failed to esterify keto alcohol **26**.) After evaporating the excess acetyl chloride *in vacuo* a colorless oil was obtained which was dissolved in ether (20 ml) and was successively washed with sodium bicarbonate and saline. The combined extracts were dried ($MgSO_4$) and concentrated *in vacuo*. The colorless oil (1.1 g, 94%) appeared to completely homogeneous in t.l.c.; i.r. ($CHCl_3$) 2950, 1739, 1710, 1460, 1200, 950 cm^{-1}; u.v. end absorption; n.m.r. ($CDCl_3$) τ 9.00 (s, 3, angular methyl), 8.90 (d, 3, J = 6 Hz, two CH—CH_3), 7.87 (s, 3, $OCOCH_3$), 4.46 (d, 1, J = 8 Hz, CH—$OCOCH_3$). The acetoxy ketone **27** was characterized in terms of crystalline γ-lactone **29**.

*3-Methyl-4-hydroxy-4-(1-6β-hydroxy-1β,2α-dimethylcyclohexyl)-1-butanoic Acid γ-Lactone (**29**). Baeyer–Villiger Oxidation Followed by Methanolysis **27** → **28** → **29***

Trifluoroacetic anhydride (20 ml) was stirred in a round-bottomed flask at 0–5 °C and then 98% hydrogen peroxide (2.7 ml) was added dropwise in 10 min. The reagent was stirred for 2 h then a solution of keto acetate **27** (900 mg) in trifluoroacetic acid (5 ml) was added to it dropwise in 30 min at 0–5°. The reaction mixture was allowed to react at the same temperature for 2 h then it was poured on ice and the product was extracted with ether (4 × 100 ml). After washing the combined ether extracts with saline the solution was dried ($MgSO_4$) and concentrated *in vacuo*. The crude ε-lactone (**28**) was saponified without isolation in 20 ml of methanol containing sodium methylate (380 mg) at room temperature in 18 h. After neutralizing with 10% H_2SO_4 the product was extracted with ether (4 × 70 ml). With saline the combined extract was washed, then it was dried ($MgSO_4$). On evaporation *in vacuo* the residue crystallized. After recrystallization from benzene – petroleum ether 460 mg of γ-lactone **29** (64% based on keto acetate **27**) was obtained: m.p. 123–124°; i.r. ($CHCl_3$) 3580, 3450, 2950, 1770, 1460, 1180 cm^{-1}; u.v. end absorption; n.m.r. ($CDCl_3$) τ 9.02 (s, 3, angular methyl), 8.90 (d, 3, J = 6 Hz, CHCH_3); 8.77 (d, 3, J = 6 Hz, CHCH_3), 6.17 (m, 1, CH—OH), 5.69 (d, 1, J = 5 Hz, CHOCO).

Anal. Calcd. for $C_{13}H_{22}O_3$: C, 68.99; H, 9.80. Found: C, 69.01; H, 9.78.

*3-Methyl-4-hydroxy-4-(1-1β,2α-dimethyl-6-oxocyclohexyl)butanoic Acid γ-Lactone (**30**)*

A solution of hydroxy-γ-lactone **29** (400 mg) dissolved in acetone (10 ml) was oxidized with Jones' reagent. The reaction mixture was then poured on water (50 ml) and extracted with ether (4 × 50 ml). The combined ether extracts were washed with 5% $NaHCO_3$ then with saline. After drying ($MgSO_4$) and evaporation a crystalline residue was obtained. Recrystallizing from benzene – petroleum ether gave 310 mg (77%) of ketone **30**: m.p. 99–100°; i.r. ($CHCl_3$) 2950, 1780, 1710, 1450, 1180, 1000 cm^{-1}; u.v. end absorption; n.m.r. ($CDCl_3$) τ 8.96 (d, 6, J = 6 Hz, two CH—CH_3), 8.78 (s, 3, angular methyl), 5.45 (d, 1, J = 3 Hz, CHOCO).

Anal. Calcd. for $C_{13}H_{20}O_3$: C, 69.61; H, 8.99. Found: C, 69.63; H, 8.97.

*3-Methyl-4-hydroxy-4-(1-1β,2α-dimethyl-6-oxocyclohex-4-enyl)butanoic Acid γ-Lactone (**32**)*

The keto lactone **30** (500 mg) dissolved in acetic acid (5 ml) was brominated with 1 equiv bromine (357 mg) dissolved in 8 ml of acetic acid. The bromine solution was added at 0–5° in 20 min and the reaction mixture was allowed to stand for 2 h at room temperature. After diluting with water (100 ml) the product was extracted with ether (4 × 50 ml). The combined extracts were washed in succession with saline, 5% sodium bicarbonate, and saline. Drying ($MgSO_4$) was followed by evaporation *in vacuo*. The light brown oil (600 mg) appeared to be homogeneous in t.l.c.; i.r. ($CHCl_3$) 2950, 1780, 1725, 1460 cm^{-1}. Without further isolation the bromoketone lactone **31** was subjected to elimination.

Lithium bromide (480 mg) and lithium carbonate (800 mg) were stirred in dry dimethylformamide under a nitrogen atmosphere at 120–125° for 30 min. The bromo compound 31 (600 mg) dissolved in dimethylformamide (20 ml) was added to above reagent after cooling, then the reaction mixture was stirred for 2 h at 120–125°. After pouring the solution on ice and acetic acid the product was extracted with methylene chloride (4 × 70 ml). The organic phase was washed with sodium bicarbonate and saline in succession. After drying ($MgSO_4$) and evaporation an oily product was obtained which was purified by preparative thick layer chromatography on silica gel developing with benzene. Then the sample was microdistilled at approximately 105°/0.3 mm Hg (310 mg, 62%): mass spectrum (70 eV) *m/e* (relative intensity) 222 (15 parent peak), 207 (25), 182 (100), 140 (70); i.r. ($CHCl_3$) 2950, 1780, 1680, 1455, 1200, 1000 cm^{-1}; $u.v._{max}$ (96% C_2H_5OH) 228 mμ (ε 11 100), n.m.r. ($CDCl_3$) τ 8.87 (d, 6, J = 6 Hz, two CHCH_3), 8.83 (s, 3, angular methyl), 5.6 (d, 1, J = 4 Hz, CHOCO), 4.02 (d, 1, J = 11 Hz, HC=CH—C=O), 3.08 (m, 1, CH=CH—C=O).

Anal. Calcd. for $C_{13}H_{18}O_3$: C, 70.24; H, 8.16. Found: C, 70.36; H, 8.22.

*trans-4β-Hydroxy-2α,8α,9β-trimethyl-6-octal-1-one (**34**)*

To a solution of diketone **22** = **33** (4.5) in methanol (100 ml) and water (6 ml) sodium borohydride (750 mg) was added while stirring at 5–10° in 1 h. The reaction mix-

ture was then stirred overnight at room temperature. After pouring the solution on ice and water (200 ml) extraction was carried out with ether (4 × 150 ml). The combined ether extracts were washed with saline then dried ($MgSO_4$) and evaporated to dryness. On standing overnight the residue crystallized (4.3 g, 95%). An analytical sample was obtained by recrystallizing from benzene – petroleum ether; m.p. 95°; i.r. ($CDCl_3$) 3630, 3540, 2950, 1710, 1640, 1460, 1350, 1000, 970 cm^{-1}; u.v. end absorption; n.m.r. ($CDCl_3$) τ 9.08 (d, 3, J = 5 Hz, $CHCH_3$), 8.95 (d, 3, J = 6 Hz, $CHCH_3$), 8.73 (s, 3, angular methyl), 6.03 (m, 1, $CHOH$), 4.46 (m, 2, olefinic protons).

Anal. Calcd. for $C_{13}H_{20}O_2$: C, 74.96; H, 9.68. Found: C, 74.98; H, 9.68.

An attempt was made to reduce ketone alcohol **34** further under the same conditions as described for compound **8**. However only the starting material **34** was recovered.

trans-1,4-Dihydroxy-2α,8α,9β-trimethyl-6-octalin (35)

A solution of ketone alcohol **34** (1 g) in dry tetrahydrofuran (35 ml) was refluxed and stirred with $LiAlH_4$ (0.8 g). Samples withdrawn every 3 h showed that the CO i.r. band disappeared only after 15 h. The reaction mixture was then decomposed by the addition of water. After filtering on a Büchner funnel and washing with ether the product was extracted with ether (4 × 100 ml). The combined ether extracts were washed with water, dried ($MgSO_4$) and evaporated to dryness (0.85 g, 84%). According to t.l.c. the oily product consists of two closely related isomers which could not be separated. Mass spectrum (70 eV) *m/e* (relative intensity) 210 (20, parent peak), 192 (35), 177 (100), 159 (15); i.r. ($CHCl_3$) 3640, 3530, 2960, 1460, 1250, 1200, 1150 cm^{-1}; u.v. end absorption; n.m.r. ($CDCl_3$) τ 9.1–8.6 (methyl signals), 6.0–6.1 (CH—OH) signals).

The diol mixture was oxidized with Jones' reagent to the crystalline diketone **22** = **33** in terms of which it was characterized.

For financial assistance the National Research Council of Canada and the Research Corporation are acknowledged. The technical assistances of Mrs. E. Schmidt and Mr. C. Dube are greatly appreciated. Mr. S. Sabnis is thanked for carrying out the last reactions of Scheme 1. The University of Prince Edward Island is thanked for financial support also. Special thanks are due to Professor Z. Valenta for helpful discussion.

Thermal explosion limits have been measured in the temperature range 285–351 °C for methyl isocyanide and at 351 °C for mixtures of methyl isocyanide and methyl cyanide. We suggest that the methyl isocyanide isomerization is potentially the best reaction system against which to test thermal explosion theories, but at the present time certain kinetic, thermochemical, and thermodynamic data are not available with sufficient accuracy.

Les limites d'explosion thermique ont été évaluées dans l'intervalle de température allant de 285–351 °C pour l'isocyanure de méthyle et à 351 °C pour des mélanges isocyanure de méthyle et cyanure de méthyle. Le système réactionnel impliquant l'isomérisation de l'isocyanure de méthyle est, comme nous le suggérons, possiblement le meilleur système pour la vérification des théories d'explosion thermique; cependant, certaines données cinétiques, thermochimiques et thermodynamiques ne peuvent être présentement obtenues avec une précision suffisante. [Traduit par le journal]

Can. J. Chem., **51**, 4001 (1973)

Precise experimental tests of thermal explosion theory (1) require an exothermic reaction for which the mechanism and Arrhenius parameters are sufficiently well established to give accurate estimates of rates under explosive conditions. Typically the rates required will be at least an order of magnitude greater than those determined in kinetic investigations; in addition, the thermal conductivity of each gas mixture used, the heat of reaction, and the effect of diluents must be known. Few reactions meet these demanding requirements; those used recently have been either complex reactions (2) or of uncertain mechanism (3, 4). We suggest that the thermal isomerization of methyl isocyanide would be an ideal reaction for testing thermal explosion theory, including the effects of convection and reactant consumption, and now report some exploratory experiments designed to test this proposal.

The thermal isomerization of methyl isocyanide to methyl cyanide is exothermic to about 14.7 kcal mol^{-1} (5) and has been the subject of extensive kinetic studies because of its importance as a reaction against which to test theories of unimolecular reaction. The reaction is exceptionally clean and is almost entirely free of side reactions (6–8); in addition, the stability of the product and its thermodynamic similarity to the reactant molecule make it useful as a diluent and as a model molecule for admission studies.

Explosion limits were found by conventional techniques (2, 9) using a 1170-cc spherical Pyrex vessel equipped with a 0.0025-cm diameter thermocouple positioned in the center to monitor the temperature rise, and a rapid-response pressure transducer at the entry tube to measure the pressure in the vessel. In the subcritical region, the reaction was clean in the sense that the products were completely condensable, although we found one small side product (<1%) having the same retention time as ethyl cyanide; in the critical region, however, noncondensables were formed, except in the 3:1 dilution case described below. Since the observed explosion pressures were well into the fall-off region for the isomerization, the rate-constant data for 1–100 Torr at 230 °C (6) were represented as

$$[1] \quad \log_{10} k = -4.4266 + 0.7820 \log_{10} p - 0.09861 (\log_{10} p)^2$$

with p in Torr and the rate constant k_T at the experimental temperature and pressure was esti-

*For definitions of B and δ_c, see ref. 10; heat capacity data required for calculation of B taken from ref. 11.
†These are values for CH_3CN, estimated by extrapolating viscosity data of Craven and Lambert (12) and f_{obs} values of Vines and Bennett (13), and it is assumed that the thermal conductivity of CH_3NC is the same (*cf.* also ref. 6); our own measurements at 25 °C for CH_3CN and CH_3NC, respectively, give λ_0 values of 21.8 × 10^{-6} and 22.5 × 10^{-6} cal cm^{-1} °C^{-1} s^{-1}, with β values of 120 and 30% atm^{-1}, supporting this assumption reasonably well.
‡Calculated for a temperature rise ΔT = 40 °C, and using thermodynamic constants for CH_3CN.
§Calculated by substituting p_c into eq. 1 to get the rate constant at 230 °C, and then assuming an activation energy of 36500 cal mol^{-1}.

mated using the low-pressure activation energy of 36.5 ± 0.2 kcal mol^{-1} (6); this uncertainty in E introduces a shift of ±(0.15–0.20) in the calculated values of the critical initial rate parameter δ_c (10) at the test temperatures.

Table 1 presents explosion limit data for methyl isocyanide. The predicted values of δ_c and of ΔT_{max}, allowing for reactant consumption but ignoring convection and diffusion, are 4.1–4.3 and 40–50 °C, respectively (10); above 300 °C, the agreement is excellent, considering the nature of the extrapolation for k_T. At 300 °C and below, the large values of δ_c appear to be associated with convective processes. Figure 1 shows three just-critical temperature and pressure recordings for different cases. In Fig. 1*a*, the observed temperature at the center rises discontinuously, implying that explosion commenced elsewhere in the vessel; this effect is just discernible at 300 °C, but at higher temperatures there is no discontinuity in the temperature trace *cf.* Fig. 1*b*. The onset of these convective effects seems to be associated with Rayleigh numbers >400 and causes the maximum observed temperature rises (ΔT_{max}) to be rather low, as would be expected (4, 9).

The model calculations (10) also predict that if B (the dimensionless adiabatic temperature rise) is less than 14, an explosion proper will not occur because of excessive reactant consumption during the induction period. This is clearly shown in Fig. 1*c* where an inflection occurs, but the temperature rise dies because of reactant consumption, in this case at a value of $\Delta T \approx 225$ °C; there is also no sudden rise in the transducer plot, unlike the normal explosion cases. These

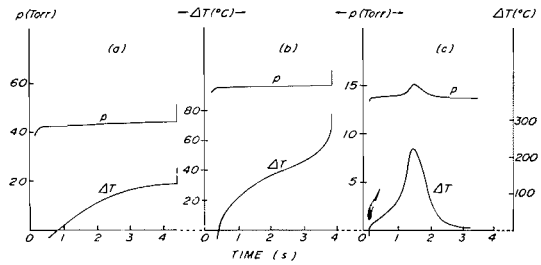

FIG. 1. Temperature and pressure traces in three just-critical experiments: (*a*) pure CH_3NC, T = 284.6 °C, initial pressure = 43.0 Torr; (*b*) pure CH_3NC, T = 311.9 °C, initial pressure = 14.8 Torr; and (*c*) mixture, CH_3NC + $3CH_3CN$, T = 350.7 °C, initial pressure = 13.8 Torr.

traces were obtained with a 3:1 CH_3CN–CH_3NC mixture, giving a B value of about 10 on the assumption that the two molecules have identical heat capacities; the data for this and for a 1:1 mixture are presented in Table 2, where it is seen that although Fig. 1*c* shows the expected behavior at low B, agreement with predicted critical parameters is poor. Reexamination of the model calculations (10) reveals that under these conditions, severe concentration gradients would also occur near threshold (10*b*) and therefore the simple theory without diffusion is inadequate in this regime.

We conclude therefore that this reaction shows considerable promise of being the best one against which to make precise tests of thermal explosion theory, once the following improved experimental data have been provided: (*i*) heats of formation of CH_3NC and CH_3CN; (*ii*) kinetic rate data, in the absence of self-heating, at much

The Densities, Viscosities, and Diffusion Coefficients of Solutions of Mono-, Di-, and Triethylamine in Water

A. N. CAMPBELL AND S. Y. LAM

Department of Chemistry, University of Manitoba, Winnipeg, Manitoba R3T 2N2

Received January 18, 1973[1]

The densities, relative viscosities, and diffusion coefficients of the binary systems, monoethylamine–water, diethylamine–water, both at 25 °C, and triethylamine–water at 17 °C, slightly below its lower critical solution temperature, were investigated experimentally.

Densities were determined with Ostwald–Sprengel type pycnometers and viscosities by means of Cannon and Fenske viscometer. The diffusion coefficients of the amines in aqueous solution were obtained by the Stokes diaphragm cell method. Monoethylamine has the highest diffusion rate. Plotting D *vs.* c and extrapolating to $c = 0$ gives an apparent D^0 which, for all three amines, is notably smaller than the value given by the Nernst model.

Les densités, les viscosités relatives et les coefficients de diffusion des systèmes binaires, monoéthylamine–eau et diéthylamine-eau à 25 °C et du système triethylamine–eau à 17 °C, légèrement en dessous de sa plus basse température de solution cinétique ont été étudiés expérimentalement.

Les densités ont été déterminées à l'aide d'un pycnomètre de type Ostwald–Sprengel, les viscosités à l'aide d'un viscosimètre de Cannon et Fenske. Les coefficients de diffusion des amines en solutions aqueuses ont été obtenus par la méthode de la cellule à diaphragme de Stokes.

La monoéthylamine a la plus haute vitesse de diffusion. En reportant D en fonction de c et en extrapolant pour la valeur $c = 0$ on obtient pour les trois amines une valeur de D^0 nettement plus faible que la valeur donnée par le modèle de Nernst. [Traduit par le journal]

Can. J. Chem., **51**, 4005 (1973)

Introduction

This work deals principally with the determination of the diffusion coefficients, in water, of mono-, di-, and triethylamine. Viscosities of binary mixtures of the amines and water were also measured, since viscosity is necessary in the study of diffusion. The temperature chosen for the investigation of the completely miscible systems monoethylamine–water and diethylamine–water was 25 °C. Since we found that mixtures of monoethylamine and water containing more than about 70 mol% amine boiled at 25 °C, measurements were not extended beyond this upper limit of concentration. For the system triethylamine–water, the temperature of investigation was 17 °C, since the two components are completely miscible at this temperature. Both triethylamine–water and diethylamine–water have lower critical solution temperatures, *i.e.* the mutual solubility decreases with rising temperature. This common behavior is presumably determined by the same pattern of molecular interaction in solution.

Experimental

Water of specific conductance of the order of 1×10^{-6} ohm^{-1} cm^{-1} was obtained by passing ordinary distilled water through an ion exchange column with a mixed bed of ion-exchange resins. The amines were the best com-

For personal use only.

mercial products. Triethylamine and diethylamine were refluxed with sodium and with sodium hydroxide pellets and distilled. The fractions used distilled at 88.8 ± 0.5 and 55.7 ± 0.5 °C for triethylamine and diethylamine, respectively. Weighed samples of the distilled amines neutralized the theoretical quantities of hydrochloric acid within ±0.2%, using methyl red as indicator. Monoethylamine was used without further purification.

Preparation and Analysis of Solutions

Aqueous stock solutions of known concentrations of triethylamine and of diethylamine were prepared by mixing conductivity water and amine in known masses. The densities were determined and hence the compositions of the stock solutions were known in weight percent, mole percent, molality, and molarity. A stock solution of approximately 70 mol% monoethylamine was prepared in the same way. Because of the volatility of monoethylamine, however, the concentrations of the dilute solutions prepared by diluting this stock solution were obtained volumetrically, by adding excess of standard HCl and back titrating with standard NaOH, using methyl red as indicator. The densities of these diluted solutions were also determined.

Density Measurements

Densities were determined with Ostwald-Sprengel type pycnometers, of approximately 25 ml capacity.

Viscosity Measurements

Viscosities were measured with a Cannon and Fenske (1) type viscometer, with a run time of about 400 s. It was calibrated with water at 17 and 25 °C. The run times were reproducible within 0.05%.

Diffusion Measurements

Diffusion coefficients were measured by the Stokes magnetically stirred diaphragm cell method (2). A slight modification of the Stokes cell was made. Instead of the rubber stoppers used by Stokes, the necks of the cell were closed with a capillary bore stopcock at the bottom and with a fine capillary plug at the top.

In order to keep the diaphragm in the degassed condition, in all subsequent transfers of solution or solvent to and from the cell compartments, special side-hole pipettes recommended by Janz and Mayer (3) were used. Since the amine solutions had smaller densities than that of water, the former were placed in the upper compartment. The duration of the pre-diffusion run was determined by the Gordon criterion (4), $t = 1.2l^2/D$, where D is the diffusion coefficient and l the thickness of the frit.

The stirring rate within the cell was 60 r.p.m., sufficiently rapid to prevent the formation of layers of stagnant solution in the vicinity of the cell diaphragm, since Stokes (2) reported that any rate between 25 and 80 r.p.m. was sufficient. The diaphragm cell constant was obtained at 25 °C by using approximately 1 M potassium chloride solution in the lower compartment and pure water in the upper. The cell constant was redetermined after every three runs and the cell constant for each experimental run obtained by interpolation.

With an analytical error less than 0.2%, a precision of about ±0.5% is to be expected in the integral diffusion coefficient. The concentrations of the solutions were kept above 0.05 M, because, as pointed out by Stokes (2), surface transport in the diaphragm could lead to considerable errors below this concentration.

Results

Densities and Relative Viscosities

The experimental results are to be found in the Depository of Unpublished Results.[2] From the densities, the partial molar volumes have been obtained by the method of intercepts and these are reproduced graphically in Figs. 1 and 2. The viscosities are expressed graphically as functions of mole fraction and of volume fraction of amine in Fig. 3.

Diffusion Coefficients

The experimental results are to be found in Depository, or, in full detail, in the Ph.D. thesis of S. Y. Lam. (5).

Figure 4 gives graphical representation of differential diffusion coefficients as functions of concentration.

We also attempted to fit the experimental diffusion coefficients to the Hartley–Crank equation (6–8) but, as one of the referees has pointed out, there is some doubt whether the Hartley–Crank equation is really applicable to these hydrophobic solutes, we have relegated the cal-

culations and graphs to the Depository of Unpublished Data.

Summary

Of the ethylamines, monoethylamine has the highest derived diffusion coefficient at infinite dilution. Examination of diffusion data in the literature indicates an increase of about 25% in numerical value when the temperature increases by 10°. Even allowing for this, however, the derived diffusion coefficient of triethylamine is still the smallest. The Nernst limiting values are higher than the corresponding derived values and this is not surprising, since the Nernst values are calculated by regarding the diffusing entities as "aminium" and hydroxyl ions; the mobility of the hydroxyl ion is exceptionally high.

While the viscosities of all three systems are practically the same in the regions dilute with respect to water and to amine (the viscosities of all three pure amines are practically the same), a pronounced maximum viscosity occurs at volume fraction 0.5 for di- and triethylamine (the two systems which are known to exhibit partial miscibility under appropriate conditions). A similar maximum occurs at volume fraction 0.4, for monoethylamine.

The values of D, the integral diffusion coefficient, were plotted against c, the concentration of amine. The calculated Nernst limiting values are: $D° = 2.002 \times 10^{-5}$ for monoethylamine at 25 °C; 1.640×10^{-5} for diethylamine at 25 °C; and 1.192×10^{-5} for triethylamine at 17 °C.

To calculate these limiting values, it is necessary that the limiting ionic conductances should be known and these we have recently determined (9). It is not surprising that the curves do not extrapolate to the values of D^0, since the calculation assumes complete ionization and this is never attained with weak electrolytes like the ethylamines, except perhaps at a theoretically infinite dilution.

The shapes of the curves of Fig. 4, despite the fact that the temperatures are not all the same, show considerable similarity. They all show a distinct minimum. Though this minimum does not occur exactly at the composition corresponding to the maximum in viscosity, there is an obvious connection; other things being equal, the more viscous the medium, the more slowly the particle will diffuse.

In general, the diffusion coefficients decrease from monoethylamine to triethylamine. At the minimum, the magnitudes of the diffusion coefficients rounded off to powers of ten, diminish from about 1×10^{-5} cm^2/s for monoethylamine, to 0.1×10^{-5} cm^2/s for diethylamine, to 0.01×10^{-5} cm^2/s for triethylamine, and this is low in comparison with the values found for most substances, which are of the order of 1×10^{-5} cm^2/s.

Krichevskii and Tsekhanskaya (10) also found the diffusion rate of triethylamine to be low.

Electron Spin Resonance Studies in Aqueous Solution: Fragmentation of Radical Intermediates Derived from β-Amino Alcohols

TERRY FOSTER AND PAUL RONALD WEST

Department of Chemistry, University of Victoria, Victoria, British Columbia

Received June 18, 1973

In acidic aqueous solution, oxidation of the β-amino alcohols $R_3\overset{+}{N}CH_2CH_2OH$, I, and $R_3\overset{+}{N}CH_2CHOHCH_3$, II, (R = H, alkyl) using the Ti(III)–H_2O_2 flow technique gave the radicals $R_3\overset{+}{N}CH_2\dot{C}HOH$, and $R_3\overset{+}{N}CH_2\dot{C}OHCH_3$. The spectrum of $(CH_3)_2\overset{+}{N}HCH_2\dot{C}OHCH_3$ shows restricted rotation about the C_1—C_2 bond assigned to intramolecular hydrogen bonding.

Under neutral conditions, oxidation of I gave the spectrum of $\cdot CH_2CHO$, and of II the acetonyl radical $\cdot CH_2COCH_3$. It is proposed that elimination occurs by deprotonation of the abstraction radical in a hydrogen-bonded conformation, followed by rapid fragmentation to yield the α-carbonyl radical.

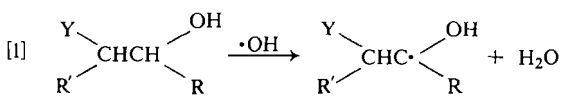
En solution aqueuse acidique, l'oxydation des β-amino alcools $R_3\overset{+}{N}CH_2CH_2OH$, **1**, et $R_3\overset{+}{N}CH_2CHOHCH_3$, **II** (R = H, alcoyle) en utilisant le système Ti(III)–H_2O_2 a conduit aux radicaux $R_3\overset{+}{N}CH_2\dot{C}HOH$ et $R_3\overset{+}{N}CH_2\dot{C}OHCH_3$. Le spectre de $(CH_3)_2\overset{+}{N}HCH_2\dot{C}OHCH_3$ a révélé une rotation limitée autour du lien C_1—C_2 attribuable à un enchaînement par liaison hydrogène intramoléculaire.

Dans des conditions neutres, l'oxydation de **I** a conduit au $\cdot CH_2CHO$ alors que l'oxydation de **II** a conduit au radical acétonyle, $\cdot CH_2COCH_3$. On suggère que l'élimination s'effectue par déprotonation du radical d'abstraction dans une conformation comportant une liaison hydrogène, puis par fragmentation rapide pour donner le radical α-carbonyle. [Traduit par le journal]

Can. J. Chem., **51**, 4009 (1973)

Introduction

In reaction with the hydroxyl radical, many alcohols **1** undergo preferential hydrogen atom abstraction at the α (carbinol) carbon (eq. 1).

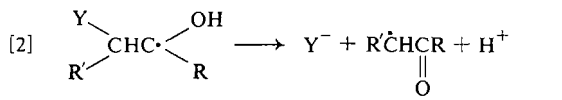


[1]

R, R′ = H, alkyl

1 **2**

The secondary radicals **2** have been detected by e.s.r. spectroscopy during radiolysis of aqueous solutions (1), photolysis of alcohols containing hydrogen peroxide (2), and by use of the Ti(III)–H_2O_2 reaction in a rapid flow system (3). When the alcohol bears certain β substituents (notably Cl, Br, and OH), radical **2** may undergo a polar elimination process generating an α-carbonyl radical **3** and losing the substituent Y^- (eq. 2) (4, 5).



[2]

2 **3**

Acid-catalysis of the elimination of hydroxide ion during oxidation of 1,2-ethanediol (**1** R, R′ = H, Y = OH) was demonstrated in photolysis studies (2), and in the Ti(III)–H_2O_2 experiments (4) by e.s.r. observation of radical **5** (eq. 3).

[3]

4 **5**

By way of confirmation, a recent pulse radiolysis study indicated this elimination was complete at p*H* 1.0 immediately following a 5 μs pulse (6).

In the p*H* 4.0–7.0 range, however, only the abstraction radical **4** was detected in the e.p.r. and pulse radiolysis work. It has been suggested that the rate of the uncatalyzed elimination (eq. 2), was too slow at high steady-state radical concentrations to compete with bimolecular termination (7). Indeed, continuous γ irradiation of neutral aqueous solutions of 1,2-ethanediol containing added H_2O_2 (7) or N_2O (8) revealed a chain reaction that produced acetaldehyde. It was proposed that at these lower radical concentrations, elimination did occur and that radical **5** propagated the chain. Furthermore, e.s.r. spectra of α-carbonyl radicals **3** were recorded at p*H* 4.6 for 1,2-propanediol oxidation (**1** R = H, R′ = CH_3, Y = OH) and under neutral conditions for 2,3-butanediol (**1** R, R′ = CH_3,

Y = OH) (5). The observation of deoxy sugars as products of the photolysis (9) and radiolysis (10) of neutral aqueous solutions of carbohydrates was also rationalized by the same reaction sequence (reactions 1, 2).

An apparent change in this established mechanism of elimination has been reported in the case of quaternary *N*-methyl derivatives of 2-aminoethanol. Electron spin resonance studies on the γ irradiation of crystalline choline chloride (**1** R, R′ = H, Y = $(CH_3)_3\overset{+}{N}$—) (11), and on the oxidation of its aqueous solutions in the Ti(III)–H_2O_2 systems (5) both assigned $(CH_3)_3\overset{+}{N}\cdot$ as the only observed fragmentation or elimination radical. Homolysis of the β C—N bond was proposed to account for cation radical formation (eq. 4). Interest in the solid state radiolysis arose from the efficient chain production of acetaldehyde and trimethylamine hydrochloride (G = 55 000) (12, 13).

$$[4]\quad (CH_3)_3\overset{+}{N}CH_2\dot{C}HOH \rightarrow (CH_3)_3\overset{+}{N}\cdot + CH_2{=}CHOH \rightleftharpoons CH_3CHO$$

In solution at pH 1.0, 2-hydroxyethyltriethylammonium chloride (**1** R, R′ = H, Y = $(CH_3CH_2)_3\overset{+}{N}$—) also gave the cation radical spectrum (5). However, under the same conditions other 2-aminoethanol derivatives (Y = $\overset{+}{N}H_3$, $CH_3\overset{+}{N}H_2$, $(CH_3)_3\overset{+}{N}H$) gave only the abstraction radicals **2**. The results are unexpected in view of the usual tendency of a quaternary nitrogen substituent to be eliminated as the amine moiety, just as predicted on the basis of the previously observed elimination reactions (reaction 2).

In this paper we report an e.s.r. study on the oxidation of both 2-aminoethanol (**1** R, R′ = H, Y = $\overset{+}{N}H_3$) and 1-amino-2-propanol (**1** R = CH_3, R′ = H, Y = $\overset{+}{N}H_3$) and related *N*-alkyl derivatives, in both acidic and neutral solution. Conditions are established under which the established polar radical elimination pathway (reaction 2) is operative for these substrates.

Experimental

General

For the aqueous flow experiments, a Varian E-6S X-band e.s.r. spectrometer was equipped with a commercial all-quartz two-entry T-mixing chamber (Varian model E-249) having a specified mixing volume of 2.5×10^{-3} ml. The flat sample cell is an integral part of the device, providing a total reacting volume to the view point of 0.080 ml. Flow rates for the two reactant solutions of 150 ml per min were generated by gravity feed, and controlled by a water aspirator applied to the exit tubing. A Gilmont #13 "Compact" flowmeter was inserted in each stream. Hyperfine splitting constants (h.f.s.) were measured to ±0.1 G, and g values to ±0.0002 employing Fremy's salt (a_N = 13.0 G, g = 2.0055) as a standard (14). Alternatively, direct comparison was made to the $\cdot CH_2OH$ radical (a_{CH_2} = 17.57 G, g = 2.0032) generated during the flow experiment by addition of a large excess of methanol as co-substrate (15).

pH measurements (to ±0.1 units) were made on all reactant and effluant solutions. Water from the building supply was routinely used after determining that its substitution for distilled water made no detectable change in the nature or quality of the spectra that were obtained. Commercially available aminoalcohols and inorganic reagents were of Fisher Certified Reagent or Aldrich reagent grade unless otherwise specified. In the amine syntheses, n.m.r. spectra were recorded on a Perkin–Elmer R12A instrument employing CCl_4 solvent and TMS as internal standard, or D_2O with TMS external.

Flow Experiments

(a) Acidic Conditions

In the oxidation of the aminoalcohols at pH 2.0, one reactant stream contained 0.02 M titanium(III) chloride (Fisher Reagent, 20% solution) adjusted to pH 2.0 with concentrated sulfuric acid; and the other stream contained 0.1 M hydrogen peroxide (Fisher Certified, 30% solution), and 0.5 M alcohol substrate, acidified to pH 2.0 with concentrated sulfuric acid. All solutions were deaerated with oxygen-free nitrogen gas for at least 15 min prior to reaction. Titanium(III) stock solution was not added until after degassing to minimize oxidation of the metal ion.

(b) Neutral Conditions

After deaerating a 0.02 M solution of disodium ethylenediaminetetraacetate, titanium(III) chloride was added to a final concentration of 0.02 M; and the pH adjusted to 7.5 with concentrated NH_4OH (d = 0.880). The second solution was made 0.5 M in organic substrate, 0.1 M in hydrogen peroxide, and adjusted to pH 7.5 with concentrated sulfuric acid. It should be noted that a reduction in the pH of the effluant solution to pH 6.5–7.0 is observed. (In this work we have ensured that the results reported at pH 2.0 for the abstraction radicals do not qualitatively change in the range 1.5–2.5 unless specified. Similarly eliminations reported at pH 7.0 have been verified in the range 6.0–8.0.)

(c) Reduction with the Formic Acid Radical ·COOH

The reduction of chloroacetone $ClCH_2COCH_3$ and the aminoketone $(CH_3)_2NCH_2COCH_3$ via the oxidation of formic acid was carried out using an all-glass mixing device that allows the simultaneous mixing of three reactant streams. The design has been previously described by Norman and co-worker (16). In these experiments, one stream contained 0.02 M titanium(III) chloride and 0.5 M formic acid, the second 0.1 M hydrogen peroxide, and the third 0.5 M organic substrate. All solutions were adjusted to pH 2.0 prior to reaction.

TABLE 1. Hyperfine splitting constants for the radicals $R_3\overset{+}{N}CH_2\dot{C}HOH$;* R = H, CH_3, $HOCH_2CH_2$

	Aminoalcohol	a_{CH_α}	$a_{CH_2\beta}$	a_N	a_{OH}	a_{NH^+}
6	$\overset{+}{N}H_3CH_2CH_2OH$	18.0	11.6	10.5	1.0	—†
7	$CH_3\overset{+}{N}H_2CH_2CH_2OH$	18.6	11.0	11.0	1.0	0.8(2H)

9	$(CH_3)_3\overset{+}{N}CH_2CH_2OH$	19.7	8.5	13.6	1.8	—
10	$\overset{+}{N}H_2(CH_2CH_2OH)_2$	18.5	10.9	11.0	1.1	1.1(2H)
11	$\overset{+}{N}H(CH_2CH_2OH)_3$	19.1	9.7	11.9	1.2	1.2(1H)

*g-Values of all radicals were 2.0032 ± 0.0002.
†No further resolved splitting, line width 0.5 G.

(d) Spectral Simulation

A program (QCPE 160) was used that allowed simulation of two or more radicals with different g-value and line width.[1]

Preparation of Aminoalcohols

(i) 2-Hydroxyethyltriethylammonium Chloride

2-Chloroethanol (40.0 g, 0.5 mol) and triethylamine (25.0 g, 0.25 mol) were heated under reflux for 7 h. On cooling, two layers formed. The lower layer, containing the desired quaternary salt and excess 2-chloroethanol, was washed repeatedly with ether, and the resulting syrup recrystallized from ethanol–ether to yield 30 g (0.18 mol; n.m.r. (D_2O): 8.76 (9H, t, J = 7.5 Hz), 5.67 (6H, q, J = 7.5 Hz), 5.77 (2H, m), and 5.10 (2H, m).

(ii) 2-Hydroxypropyltrimethylammonium Chloride

A solution of *N,N*-dimethylamino-2-propanol (50.0 g, 0.49 mol) in 500 ml of absolute ethanol was heated under reflux (Dry Ice – acetone condenser) while chloromethane was bubbled through the mixture until an aliquot no longer showed $(CH_3)_2N$–n.m.r. absorption. After cooling the reaction mixture (Dry Ice – acetone), anhydrous ether was added until precipitation ceased. Recrystallization (ethanol–ether) and vacuum desiccation (10 h) gave the hygroscopic salt (69 g, 0.45 mol), m.p. 163–165° (lit. (17) 165°); n.m.r. (D_2O): 6.90 (9H, s), 8.86 (3H, d, J = 7.0 Hz), 6.59 (s) and 6.78 (d, J = 0.5 Hz) total 2H, and 5.65 (1H, m).

(iii) 1-(N-methylamino)-2-propanol and 1-(N-methyl,N-(2-hydroxypropyl)-amino)-2-propanol

Both amines were isolated from the reaction of propylene oxide and methylamine. Propylene oxide (40 g, 0.7 mol) and methylamine (28 g, 0.33 mol), the latter added as the 40% aqueous solution, were heated under reflux for 30 min. On distillation (1 atm) 1-(*N*-methylamino)-2-propanol was collected at 148–150° (10 g, 0.11 mol); n.m.r. (D_2O): 7.83 (3H, s), 8.97 (2H, d, J = 7.0 Hz), 7.62 (2H, d, J = 7.0 Hz), and 6.23 (1H, sextet, J = 7.0 Hz). 1-(*N*-methyl,*N*-(2-hydroxypropyl)amino)-2-propanol was collected at 225 °C (28 g, 0.19 mol); n.m.r. (D_2O): 8.41 (6H, d, J = 7.0 Hz), 5.57 (2H, sextet, J = 7.0 Hz), and 7.17 (7H, m, CH_3—N and CH_2). Prolonged reflux led to increased yields of *tertiary* amine, but no attempt to optimize the yields of the respective amines has been made.

(iv) N,N-Dimethylamino-2-propanone

The reaction of bromoacetone with aqueous dimethylamine by the method of Craig *et al.* (18) gave *N,N*-dimethylamino-2-propanone in 40% yield, b.p. 115° (lit. (18) 114°); n.m.r. (CCl_4): 7.79 (6H, s), 7.07 (2H, s), and 7.94 (3H, s).

Results

2-Aminoethanol and Related Compounds

(i) Hydrogen Abstraction Radicals

In acidic aqueous solution, all the aminoalcohols under consideration are in the protonated form. The deactivating effect of a $-\overset{+}{N}(R)_3$ substituent (R = alkyl or H) on hydrogen abstraction by the electrophilic OH radical is consistent with the exclusive observation of the radicals $R_3\overset{+}{N}CH_2\dot{C}HOH$ at pH 2.0. In Table 1, the hyperfine splitting constants (h.f.s.) for a series of these abstraction radicals show a pattern of low β hydrogen h.f.s. constants (10–13 G) and relatively large β nitrogen splitting (10–12 G).[2] In the case of the radical $CH_3\overset{+}{N}H_2CH_2\dot{C}HOH$, we report for the first time the resolution of the NH and OH h.f.s. constants for radicals of this type. The fine structure consists of a doublet (a_{OH}(1H) = 1.0 G) of triplets ($a_{NH_2^+}$ (2H) = 0.8 G) recorded in a spectrum with line width <0.1 G. In the pH range indi-

cated no other resonances are observed for these compounds, while signal intensity is near the maximum observed using the flow technique. In particular repeated attempts to observe the radical $(CH_3)_3\overset{+}{N}\cdot$ from choline chloride oxidation ($R_3\overset{+}{N}$— = $(CH_3)_3\overset{+}{N}$—) were unsuccessful.[3]

(ii) Secondary Elimination Radicals

(a) Acetaldehyde Radical $\cdot CH_2CHO$

Oxidation of the aminoalcohols **6–8** and **10** (Table 1) at p*H* 6.5–7.5 (effluant) provided spectra dominated by the $\cdot CH_2CHO$ radical. Previously unreported in neutral aqueous solution, this species has spectral parameters unchanged from those at p*H* 1.0 (4), namely $a_{CH_2}(2H) = 19.0$ G, $g = 2.0045$, and a line width of 1.0 G. In addition, one detects weaker resonances from the radicals **12–14** associated with generation of $\cdot CH_2CHO$ in aqueous solution (5).[4]

$\cdot CH_2CH(OH)_2$ $HOCH_2\dot{C}HOH$ $O{=}CHCH_2CH_2\dot{C}HOH$

12 **13** **14**

At p*H* 6.5–7.5, spectra of sufficient intensity to interpret have not yet been observed for triethanolamine **11** and the quaternary ion $(CH_3)_3\overset{+}{N}CH_2CH_2OH$, **9**. However, for all of the compounds **6–11**, the abstraction radical spectrum (*e.g.* $R_3\overset{+}{N}CH_2\dot{C}HOH$) does *not* persist under conditions where $\cdot CH_2CHO$ and related species are detected (p*H* > 5.0).

(b) Fragmentation of $(CH_3CH_2)_3\overset{+}{N}CH_2\dot{C}HOH$

At p*H* 1.6, the triethyl quaternary ion $(CH_3CH_2)_3\overset{+}{N}CH_2CH_2OH$ gave an intense spectrum attributed to $(CH_3CH_2)_3\overset{+}{N}\cdot$ ($a_N(1) = 20.2$ G, $a_{CH_2}(6H) = 22.1$ G) as previously reported (5).[5] At p*H* 2.5–4.0, a complex spectrum appeared dominated by the radical $\cdot CH_2CH(OH)_2$ **12** ($a_{CH_2}(2H) = 22.4$ G, $a_{CH}(1H) = 18.7$ G, $g = 2.0025$); with weaker lines clearly assigned to the species $HOCH_2\dot{C}HOH$ **13** ($a_{CH_2}(2H) = 9.4$ G, $a_{CH}(1H) = 18.0$ G, $a_{OH}(1H) = 1.0$ G, $g = 2.0032$) and $O{=}CHCH_2CH_2\dot{C}HOH$ **14** ($a_{CH}(1H) = 15.2$ G, $a_{CH_2}(2H) = 20.2$, γCH_2 splitting unresolved, $g = 2.0032$). In striking contrast to choline, no spectra of simple abstraction radicals are identified at p*H* 1.5–2.5.

1-Amino-2-Propanol and Related Compounds

(i) Hydrogen Abstraction Radicals

In Table 2, h.f.s. constants are given for the radicals $R_3\overset{+}{N}CH_2\dot{C}OHCH_3$ (R = H, alkyl) observed during the oxidation of the corresponding alcohols at p*H* 2.0–4.5. In the spectra from **16–18**, the N—H hydrogen splittings are again resolved, but no splitting due to the OH group can be detected. However, at p*H* 2.0 in water, no splitting due to hydroxyl hydrogen is detected for the radical $(CH_3)_2\dot{C}OH$ a good model for **16–18**. In the spectra of **17** and **18** severe broadening of the central lines of the β-hydrogen triplet creates the impression of a single (doublet) splitting. Indeed this apparent anomaly in the spectrum from **17** led us to examine the oxidation of **18**. Computer simulation shows the spectra to be compatible with splitting from two β-hydrogens only if the central lines of each triplet are assigned a higher line width (0.8 G) than the remaining resonances. The phenomenon is analyzed in terms of hindered rotation (see Discussion).

(ii) Secondary Elimination Radicals

At p*H* 6.5–7.5, the dominant signal from **15–18** was the acetonyl radical $\cdot CH_2COCH_3$ ($a_{CH_2}(2H) = 19.7$ G, $a_{CH_3}(3H) = 1.1$ G, $g = 2.0042$). The central quartet is resolved, but has a line width twice as great as the wing multiplets. The drastic simplification of the spectrum makes evident in each case a weaker spectrum of radicals of the type $\cdot CH_2CHOHCH_2\overset{+}{N}R_3$ ($g = 2.0025$), mostly appearing as an unresolved quartet with broadened center lines ($a(3H) = 22.7 \pm 0.5$ G). Only in the case of $\overset{+}{N}H_3CH_2CHOH\dot{C}H_2$ was further resolution possible ($a_{CH_2}(2H) = 22.4$ G, $a_{CH}(1H) = 24.0$ G). The line width of the wing resonances was still 1.3 G, evidently due to an unresolved γ hydrogen splitting (compare $\cdot CH_2CHOHCH_3$, $a_{CH_3}(3H) = 0.8$ G) (19). However, referring to $\cdot CH_2$-

[3]Simulated spectra of the $(CH_3)_3\overset{+}{N}CH_2\dot{C}HOH$ species with low percentage intensities of the resonances from $(CH_3)_3\overset{+}{N}\cdot$ ($a_{CH_3}(9H) = 28.6$ G, $a_N(1) = 20.3$ G) were used to evaluate the experiments.

[4]In neutral solution, we suggest ·OH addition to $CH_2{=}CHOH$ in the continuing secular equilibrium is the likely source of **12** and **13** with **14** arising from $\cdot CH_2CHO$ addition to the enol as previously suggested (5).

[5]The lack of observation of $(CH_3)_3\overset{+}{N}\cdot$ from choline oxidation in this work must then be attributed to not achieving the exact conditions of the earlier study (5).

TABLE 2. Hyperfine splitting constants for the radicals $R_3\overset{+}{N}CH_2\dot{C}OHCH_3$;* R = H, CH_3, $CH_2CH(CH_3)OH$

	Aminoalcohol	$a_{\beta CH_3}$	$a_{\beta CH_2}$	a_N	a_{N-H^+}
15	$\overset{+}{N}H_3CH_2CHOHCH_3$	21.3	11.6	9.7	—†
16	$CH_3\overset{+}{N}H_2CH_2CHOHCH_3$	21.9	11.0	11.0	1.0(2H)
17	$(CH_3)_2\overset{+}{N}HCH_2CHOHCH_3$	21.7	9.9‡	12.5	1.4(1H)
18	$(CH_3CHOHCH_2)(CH_3)\overset{+}{N}HCH_2CHOHCH_3$	21.5	9.8‡	12.5	1.4(1H)

*g-Values were 2.0032 ± 0.0002.
†No further splitting was resolved.
‡The center lines of the triplet splitting are broadened and detected only in the outer multiplets.

$CHOHCH_2OH$ as a model ($a_{CH_2}(2H)$ = 22.3 G, $a_{CHOH}(1H)$ = 24.6 G) (5), the above assignment seems appropriate.

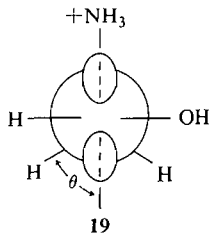
Both at p*H* 2.0 and at p*H* 7.0, oxidation of the quaternary cation $(CH_3)_3\overset{+}{N}CH_2CHOHCH_3$ gives the same spectrum, assigned as $(CH_3)_3\overset{+}{N}CH_2CHOH\dot{C}H_2$ (a(3H) = 22.7 ± 0.5, g = 2.0025).

Reduction of α-Substituted Ketones

The oxidation of formic acid (0.5 *M*) in the presence of the aminoketone cation, $(CH_3)_2\overset{+}{N}HCH_2COCH_3$ was undertaken as a route to the anomalous abstraction radical from alcohol **17** via one-electron reduction of the carbonyl group by $\cdot CO_2H$. At p*H* 2.0, reduction did occur to give a weak spectrum of the desired abstraction radical, but also an equal intensity of the acetonyl radical. At p*H* 4.0 only the radical $\cdot CH_2COCH_3$ was observed. When chloroacetone replaced the aminoketone as substrate, acetonyl radical was again the sole species observed at p*H* 4.0. Evidently the intermediate anion radical eliminates the β substituent in a process closely akin to the eliminations from alcohol abstraction radicals (see Discussion).

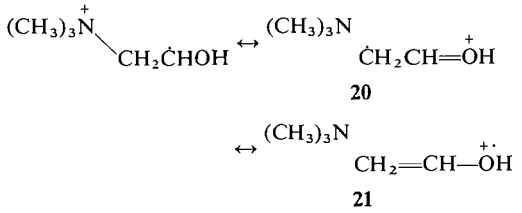
Discussion

The anomalously low β h.f.s. constants that are observed for organic π radicals of the type $YCH_2\dot{C}HX$ have been analyzed by Norman and co-workers (20) in a wide-ranging general treatment. Observing that the phenomenon was restricted to cases where Y was an electron acceptor and X had an available electron pair, he proposed a preferred conformation of the radical that gained stabilization as a result of this substitution pattern. Employing the radical $\overset{+}{N}H_3CH_2\dot{C}HOH$ from 2-aminoethanol as an example, the conformation **19** with dihedral angle θ = 60° is consistent with the observed value of $a_{\beta CH_2}(2H)$ = 11.6 G. In some instances, even lower



19

βCH_2 h.f.s. constants are observed; for example $a_{CH_2}(2H)$ = 8.5 G for the choline derived radical $(CH_3)_3\overset{+}{N}CH_2\dot{C}HOH$. Further lowering beyond that predicted by **19** is attributed to the electron delocalization shown in structures **20** and **21**, a model that suggests planarity



20 **21**

at the α-carbon and a distortion from tetrahedral geometry at the β-carbon (20). Furthermore, the relatively large β-nitrogen h.f.s. constants are accommodated. Such stabilization would make **19** a preferred conformation.

In the present work, further examples of low β-hydrogen and large β-nitrogen h.f.s. values are noted in the radicals $CH_3\dot{C}OHCH_2\overset{+}{N}H_3$ and $CH_3\dot{C}OHCH_2\overset{+}{N}H_2CH_3$ (Table 2, **15**, **16**). More-

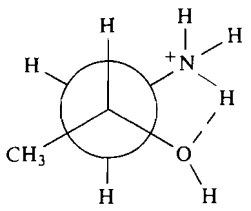
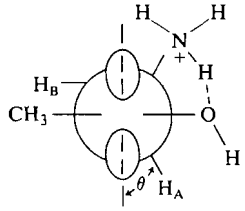
over radicals of the type $R_2NHCH_2\dot{C}OHCH_3$ (Table 2, **17**, **18**) have marked broadening of the center lines of β-hydrogen triplets. In consequence we suggest an additional factor that plays a role in determining radical conformation where intramolecular hydrogen-bonding is possible.

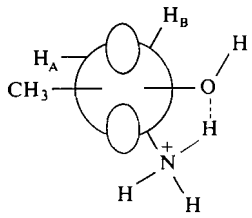
Consider $\overset{+}{N}H_3CH_2CHOHCH_3$, having as one preferred conformation the hydrogen bonded form **22** prior to hydrogen abstraction. One predicts then conformers **23** and **24** will result if intramolecular hydrogen bonding continues as a significant factor in the radical. By focussing



22



23



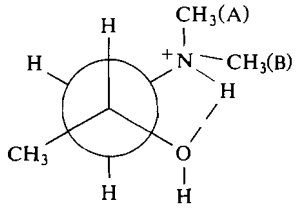
24

attention on one of the β hydrogens, H_A, we can project a value of $a_{\beta CH_2}$ for conformation **23**. Applying the McConnell relationship (eq. 5),

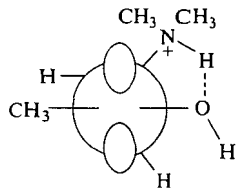
$$[5] \qquad a_H = B_0 + B\cos^2\theta$$

we set $B_0 \simeq 0$ and $B = 42.6$ following the basic approach taken by Norman and co-workers (20).[6] Then with $\theta = 30°$, $a_{H_A} = 31.95$. In conformation **24**, we assume $\theta = 0$ for H_A yielding $a_{H_A} = 0$ in the approximation. For equal but preferred population of just these two conformations, one predicts $a_{CH_2}(2H) = 15.98$ G. Clearly, the observed value ($a_{CH_2}(2H) = 11.6$) is somewhat lower, just as often noted for the alternative hypothesis based on conformation **19** (20). In the hydrogen-bonded model, the further depression in $a_{\beta CH_2}$ is ascribed to distortion of the β carbon tetrahedral geometry towards planarity by net displacement of the amino group toward C-α, energetically compensated for by retention of the optimum hydrogen-bonding between $\overset{+}{N}H_3$ and OH.

The hypothesis accommodates the observation of a selective line broadening in the 1-(*N*,*N*-dimethylamino)-2-propanol abstraction radical.[7] We propose **25** as the stable conformation of the substrate leading to **26** as one conformation of the radical.[8] First, the n.m.r. spectrum of the cation **25** in aqueous hydrochloric acid (p*H* 2.0)

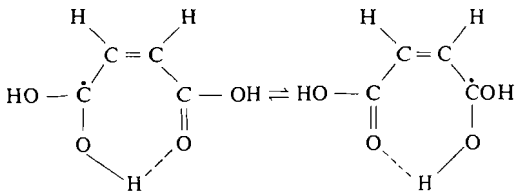


25



26

shows two distinct *N*-methyl resonances at 6.47 (CH_3(A)) and 6.37 (CH_3(B)), each split by a single proton ($\overset{+}{N}$—H, $J = 2$ Hz). Secondly, the magnitude of the $\overset{+}{N}$—H splitting (e.s.r.) for **26** ($a_{NH}^{+} = 1.4$ G) is compatible with direct interaction of the hydrogen with the oxygen atom bonded to the alpha carbon. For example, in the maleic acid reduction radical **27**, the bridging hydrogen has $a_H(1) = 1.1$ G, and is not exchange broadened at p*H* 1.0 (21).



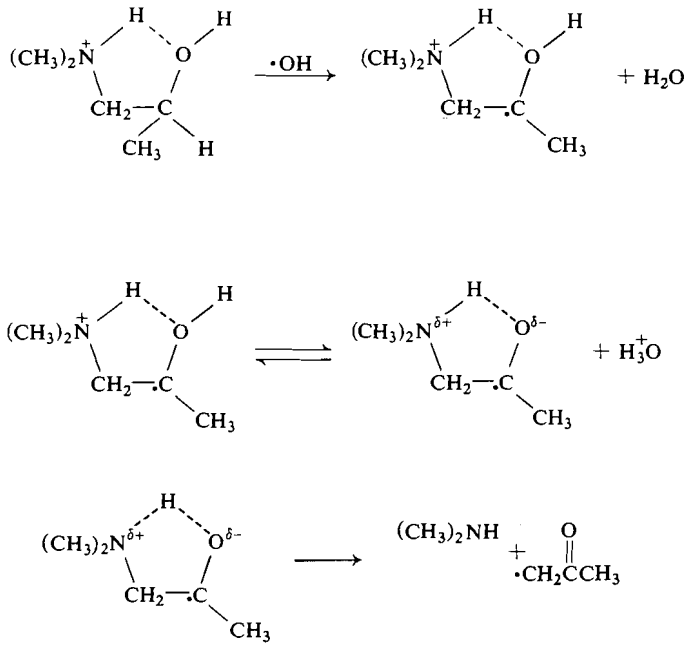
27

Indeed, both the observation of large β-nitrogen h.f.s. and $\overset{+}{N}H$ splitting throughout the series of radicals from the aminoalcohols is consistent with population of hydrogen-bonded conformations. Broadening of the center line of the triplets is compatible with slow interconversion

[6]Calculated from $a_{CH_3} = 21.3$ G in $CH_3\dot{C}OHCH_2\overset{+}{N}H_3$ with $\langle\cos^2\theta = 1/2\rangle$ for a freely rotating methyl group.

[7]The authors acknowledge a referee's suggestions in interpretation of this phenomenon.

[8]In analogy to **23** and **24**, an equivalent enantiomeric conformation exists.



SCHEME I

of the equivalent conformers on the e.s.r. time scale.

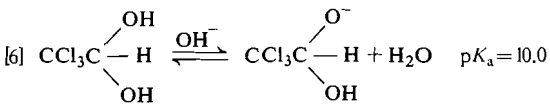
In support of the interpretation we note that the phenomenon is observed for two distinct substrates and that one of the radicals $(CH_3)_2\overset{+}{N}HCH_2\dot{C}OHCH_3$ has been generated by an independent route (reduction of *N,N*-dimethylamino-2-propanone).

Clearly for radicals such as $CH_3OCH_2\dot{C}HOCH_3$, only the Norman analysis in terms of conformations of the type **19** is appropriate (20). We propose that *in addition* conformations of the type **23** and **24** are populated in the aminoalcohols and contribute to lowered β-hydrogen h.f.s. values. For highly hindered cases, restricted rotation in the radical can be observed as a line broadening effect.

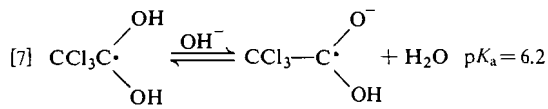
Elimination Processes in β-Aminoalcohol Abstraction Radicals

The observation of α carbonyl radical spectra in the p*H* range 6.5–7.5 is compatible with deprotonation of an abstraction radical, followed by rapid fragmentation of its conjugate base. The sequence is outlined in Scheme I for $(CH_3)_2\overset{+}{N}HCH_2\dot{C}OHCH_3$ adopting the proposed intramolecularly hydrogen-bonded conformation.

For the mechanism to be operative, it is clearly necessary that the pK_a of the abstraction radical be markedly lower than that of the amine precursor. Presently available data from e.s.r. studies during irradiation of alcohols indicate that the pK_a of an α-alcohol radical is lower by from 4–8 units in comparison with that of the alcohol substrate (22). For instance, 2-propanol has pK_a = 17.1, while $(CH_3)_2\dot{C}OH$ has pK_a 12.03. Even more striking is the acidity of $(CF_3)_2\dot{C}OH$, pK_a = 1.7. Similarly, chloral hydrate and



[6] $CCl_3C(OH)_2H \rightleftharpoons CCl_3C(O^-)(OH)H + H_2O$ pK_a = 10.0



[7] $CCl_3C(OH)_2\cdot \rightleftharpoons CCl_3C(O^-)(OH)\cdot + H_2O$ pK_a = 6.2

its abstraction radical show the same trend (reactions 6, 7) (23). Moreover, the effect of an electron-withdrawing $R_3{}^+N$-group on alcohol radical acidity should be comparable to that of the CCl_3 group. For example, betaine, $(CH_3)_3\overset{+}{N}—CH_2COOH$ (pK_a = 1.83) is a stronger acid

than acetic acid, CH_3COOH ($pK_a = 4.75$). By analogy, then, the abstraction radical from $(CH_3)_2\overset{+}{N}HCH_2CHOHCH_3$ ($pK_a = 9.3$) will have a pK_a value at least as low as 6.0. Elimination is clearly in evidence in solutions $pH \geqslant 6.0$.[9]

Using pulse radiolysis Henglein and co-workers have observed the conversion of the 1,2-dihydroxyethyl radical $CH_2OH\dot{C}HOH$ to acetaldehyde radical $\cdot CH_2CHO$ at pH 8.5 (reaction 8) (6).

$$[8]\quad HOCH_2\dot{C}HOH \overset{OH^-}{\rightleftharpoons} HOCH_2\dot{C}HO^- \rightarrow \cdot CH_2CHO + OH^-$$

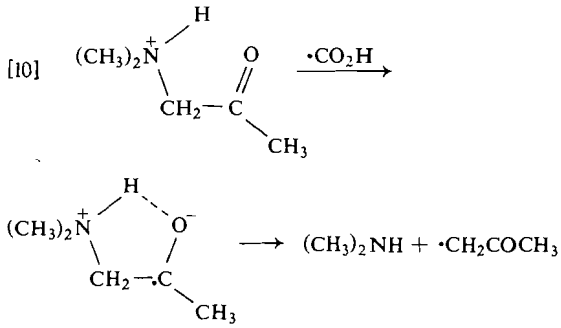
We consider the β-aminoalcohol radical elimination to be an analogous reaction via the conjugate base of the initial abstraction radical. In summary, e.s.r. observation of a significant steady state population of the α-carbonyl radicals at pH 7.0 probably reflects a significantly faster rate of elimination of the deprotonated radical than of the acid form at pH 2.0. If such is the case then under *in vivo* conditions (*e.g.* pH 7.3), radicals from biologically important 2-aminoethanol derivatives (serine, choline) may eliminate in competition with repair even by efficient hydrogen transfer agents.

The observation of the acetonyl radical from reduction of *N*,*N*-dimethylamino-2-propanone is fully consistent with the proposed elimination. First, Fessenden and co-worker have demonstrated that the reducing radical $\cdot CO_2H$ is not active in direct deamination reactions that would yield the α-carbonyl radical directly (*e.g.* reaction 9) (24).

$$[9]\quad \cdot CO_2H + (CH_3)_2\overset{+}{N}HCH_2COCH_3 \not\rightarrow \cdot CH_2COCH_3 + (CH_3)_2NH + CO_2 + H^+$$

Observation of the $\cdot CH_2COCH_3$ species at higher acidity than in aminoalcohol oxidation can be understood in terms of direct formation of the deprotonated intermediate **28** by electron transfer to the carbonyl group (21). Fragmentation is then assumed to occur before the protonation equilibrium can be established (eq. 10).

[10]



Spectra of $R_3N\cdot^+$ in Quaternary Cation Oxidation

Spectra of sufficient intensity to analyze were not achieved for $(CH_3)_3\overset{+}{N}CH_2CHOHCH_3$ oxidation at pH 1.0 and 7.0 or for choline cation oxidation at pH 7.0. At pH 1.0 only the radical $(CH_3)_3\overset{+}{N}CH_2\dot{C}HOH$ was observed from choline. However, for both cations at pH 1.0 and 7.0 we have observed that trimethylamine hydrochloride and acetone or acetaldehyde, respectively, are the major products of photolysis of their aqueous solutions containing H_2O_2 (25). Accordingly, further efforts to identify the elimination radicals by e.s.r. particularly at pH 7.0 are being made prior to speculation on the mechanism in these instances.

In the case of $(CH_3CH_2)_3\overset{+}{N}CH_2CH_2OH$, the radical $(CH_3CH_2)_3\overset{+}{N}\cdot$ was observed at pH 1.6. However, at pH 2.5–4.0 the spectra of $\dot{C}H_2$-$CH(OH)_2$ and associated species were recorded, with no trace of cation radical remaining. By analogy to previous considerations (5) we postulate the usual heterolysis (reaction 11). In order to accommodate

$$[11]\quad (CH_3CH_2)_3\overset{+}{N}CH_2\dot{C}HOH \rightarrow [(CH_3CH_2)_3\dot{N}\ \ \dot{C}H_2CH{=}\overset{+}{O}H] \rightarrow (CH_3CH_2)_3\overset{+}{N}H + \dot{C}H_2CHO$$

the appearance of the cation radical at pH 1.6, either a change in mechanism (homolysis of the C—N bond) (reaction 4) or electron-transfer from the amine to the radical in a cage reaction is required (reaction 12).

$$[12]\quad (CH_3CH_2)_3N: + \dot{C}H_2CH{=}\overset{+}{O}H \rightarrow (CH_3CH_2)_3\overset{+}{N}\cdot + CH_2{=}CHOH$$

[9]Clearly if elimination from the deprotonated form were highly favored kinetically, reaction could be observed at a pH one or two units lower than the actual pK_a.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Clearly the protonated amine is not an oxidizable species, so only transfer from the amine is viable. *Tertiary* amines are readily oxidized, *e.g.* tri-*n*-propylamine in acetonitrile at $E_p = -0.87$ V (26). Henglein has recently measured the reducing potential of the *neutral* acetaldehyde radical $\dot{C}H_2CHO$ as -0.75 V by polarographic current measurements during pulse irradiation (6). If one admits only a modest increase in reducing potential for the protonated form $\dot{C}H_2\overset{+}{C}HOH$ in close proximity to the amine, an electron transfer is clearly possible. Walling and El-Taliawi (27) have demonstrated reduction of $\dot{C}H_2COCH_3$ by ferrous ion in the Fenton reagent oxidation of acetone (reaction 13), another example of reduction of α-carbonyl radicals.

[13] $\cdot CH_2COCH_3 + Fe^{II} \rightarrow \bar{C}H_2COCH_3 + Fe^{III}$

We favor the electron-transfer as preferable to postulating a complete change in mechanism over such a narrow range of p*H*, but clearly more examples of such cation radical generation would be desirable.

The authors acknowledge the generous support of the University of Victoria Committee on Research Leave and Travel and the National Research Council of Canada in operating grants. An N.R.C.C. equipment grant made possible the e.s.r. spectrometer installation. The assistance of Dr. A. Tweedale (University of Victoria Computing Center) with the spectral simulation program was much appreciated.

The authors appreciate the helpful comments of Professor R. O. C. Norman who read the manuscript.

Mutual Solubilities of Hydrocarbons and Water at 0 and 25 °C

JIRI POLAK AND BENJAMIN C.-Y. LU

Department of Chemical Engineering, University of Ottawa, Ottawa, Canada K1N 6N5

Received July 23, 1973

Mutual solubilities of 14 paraffinic and 6 aromatic hydrocarbons and water were determined experimentally at 0 and 25 °C. The solubilities are generally smaller at 0 than at 25 °C except the solubilities of paraffins in water which are larger at 0 than at 25 °C. The coefficients of the Redlich–Kister equation were evaluated from the experimental data and correlated as a function of molar volume of liquid hydrocarbons and group contributions. The correlation allows calculation of the mutual solubilities of paraffinic and aromatic hydrocarbons and water at 0 and 25 °C from the knowledge of the molar volume of liquid and the contribution of their component groups.

On a déterminé expérimentalement à 0 et à 25 °C la solubilité mutuelle de l'eau et de 14 hydrocarbures paraffiniques et de 6 hydrocarbures aromatiques. La solubilité est généralement plus faible à 0 qu'à 25 °C à l'exception de la solubilité des paraffines dans l'eau qui est plus grande à 0 qu'à 25 °C. Les coefficients de l'équation Redlich–Kister ont été évalués à partir de données expérimentales et reliés en termes d'une fonction du volume molaire des hydrocarbures liquides et des contributions des groupes. Cette relation permet le calcul de la solubilité respective des hydrocarbures paraffiniques et aromatiques et de l'eau à 0 et à 25 °C à partir de la connaissance du volume molaire du liquide et de la contribution des groupes qui les composent. Introduction

The mutual solubilities of liquid hydrocarbons and water are quite low, generally in the order of parts per million by weight. Nevertheless, hydrocarbons and water are not completely insoluble and even the minute amounts dissolved are of interest and importance.

From the practical point of view, a knowledge of the solubilities of hydrocarbons in water is necessary for evaluating the impact of oil spills, as hydrocarbons are the main constituents of the crude oil and oil products. The data on the solubilities of water in hydrocarbons are useful in the evaluation of the amount of water dissolved in oil and oil products.

The experimental data on the mutual solubilities of hydrocarbons and water obtained from simultaneous determinations at different temperatures are useful to the understanding of the solution behavior of these compounds.

Experimental

Materials

Most of the liquid hydrocarbons used in this investigation were pure grade reagents (99%+), with the exception of 3-methylhexane which was technical grade (95%+), and were supplied by Phillips Petroleum Co. Toluene was spectroquality reagent grade and was obtained from Matheson, Coleman and Bell, *o*- and *p*-xylenes were pure grade and supplied by Eastman Organics. All hydrocarbons were purified by shaking three times with distilled water, in the amount of 5 parts of water per part of hydrocarbon, in a separatory funnel to remove trace amounts of soluble components and emulsifiers which might be present.

Dodecane was olefin-free (99% pure) and was obtained from Matheson, Coleman and Bell. It was distilled under vacuum to remove traces of low boiling components which might interfere with the gas chromatographic analysis. Distilled water was used throughout this work.

Apparatus and Technique

Approximately 50 ml of hydrocarbon together with 50 ml of distilled water were placed in a 125 ml Hypo-vial, which was closed with a Teflon coated rubber septum and placed in a constant-temperature water bath. In this investigation, the bath was maintained at 0 ± 0.02 °C and at 25 ± 0.01 °C. Two methods were used to equilibrate water with hydrocarbons. Initially, the system under consideration was stirred using a magnetic stirrer for 24 h. The vial was then left in the bath for at least 3 days to ensure the separation of the layers. However, it was subsequently found that when the components were allowed to remain in contact for a sufficiently long period of time (2–4 days) without stirring, the solubility also reached a constant value. For the majority of the experimental determinations, the vials were therefore kept in the thermostat without stirring for at least 7 days before samples were taken for analysis. An excellent agreement was obtained between the results of the two methods.

Determination of the Solubility of Hydrocarbons in Water

In this case, the sample of the bottom (water rich) layer must be taken for analysis. For this reason, the vials were placed in the bath with their necks down. To collect the sample, the vial was taken out of the bath, and dried with tissue; then the septum was pierced with the hypodermic needle of a 30 ml syringe. A second needle, connected to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

a compressed air source, was then introduced to push the liquid into the syringe. A sample about 15 ml was taken for each analysis, with the exact amount determined by weighing. The sample was placed in a 15 ml Hypo-vial, which was filled beforehand with approximately 2 ml of dodecane solution containing a known amount of benzene or toluene (whenever benzene interfered with the hydrocarbon during the analysis, toluene was used instead). The Hypo-vial was then closed with a Teflon coated rubber septum.

The vial was closed and hand shaken for 5 min and then, after the water and hydrocarbon layers had separated, 0.1 to 2 μl (depending on the solubility) of the dodecane layer was injected into a Hewlett–Packard model 5750B chromatograph equipped with a flame ionization detector and a model 3373B integrator. The samples were analyzed using a 6 ft long, 1/4 in. diameter stainless steel column packed with 3% Carbowax 20M on Chromosorb T, 30/60 mesh.

The temperature of the chromatographic oven was initially maintained at 80 °C. After the peaks of hydrocarbon and benzene or toluene had been integrated, the oven temperature was increased to 220 °C and kept there for about 8 min to remove all of the relatively high boiling dodecane. The temperature was then lowered to 80 °C and after stabilization the next sample was analyzed. Each analysis took about 20–30 min. The temperature of the injection port and the detector was kept at 220 °C. Between repeated analyses of unknown samples prepared as described above, the known-composition standard solutions of dodecane with hydrocarbon and benzene (toluene) at approximately the same concentrations, and treated the same way as the unknown samples (*i.e.* shaken with the same amount of water), were analyzed. In this manner, the ratio of the response factors of hydrocarbon and benzene (toluene) was determined and the amount of hydrocarbon could be calculated.

Determination of the Solubility of Water in Hydrocarbons

The water–hydrocarbon mixture was equilibrated in a similar manner but with the vial opening at the top during the equilibration. After equilibrating for at least 7 days, the vial was lifted partially from the bath and the septum was thoroughly washed with methanol and dried. Approximately 15 ml of the hydrocarbon layer was taken into a syringe after pressurizing the vial with dry air and injected into a titrimeter vessel (with the exact amount determined by weighing of the syringe), and titrated. A Metrohm model E452 Karl Fischer titrator equipped with a 10 ml buret was used. Commercial stabilized Karl Fischer reagent (Fisher Scientific Co.) was diluted to a titer of about 0.15 mg H_2O/ml. The reagent was frequently standardized with sodium tartrate.

An excess amount of the Karl Fischer reagent was always added to ensure the fast reaction of the small amount of water. The standardized methanol was then added in such an amount so that the titration was always completed by the Karl Fischer reagent.

For measurements at 0 °C ethylene glycol was added to the water bath. Precautions were taken to prevent contamination of the samples with glycol. In some cases after the measurements were made at 0 °C the same vials were again thermostated at 25 °C; subsequently measured solubilities agreed within experimental error with those obtained for the fresh samples.

All measurements of the solubility of hydrocarbons in water were repeated at least twice, some, such as *n*-hexane, as many as 10 times. The determinations of the solubility of water in hydrocarbons were repeated at least three times.

The precision of the measurements of the solubility of hydrocarbons in water is in the mean ±1.7%; for solubilities which are under 5 p.p.m., it is ±4%. The precision of the solubilities of water in hydrocarbons is ±3.1% at 25 °C and ±4.7% at 0 °C.

Results and Discussion

The experimentally determined solubilities are listed in Table 1 along with some experimental values available in the literature for 25 °C. Hardly any definitive conclusions can be drawn from this comparison. The experimental data reported from different sources are usually quite different, with the discrepancy in values being much larger than the quoted precision.

For the solubilities of hydrocarbons in water, for example, for *n*-hexane, which is only slightly soluble, the three most recently reported values (1–3) vary from 9.5–18.3 p.p.m. Probably because of the magnitude of their solubilities, the agreement for aromatics is generally better. The results from this investigation for paraffinic hydrocarbons are in most cases larger than those obtained by McAuliffe (2). For the solubilities of water in hydrocarbons the values obtained in this investigation are generally lower than those published for paraffins and close to the values listed for aromatics.

In the literature, most of the solubility data are reported at 25 °C. Little is known about the temperature dependence of the solubility of hydrocarbons in water. The work of Nelson and de Ligny (3) partially confirms our findings of higher solubilities of paraffins in water at 0 °C than at 25 °C. Their experimentally determined values indicated an increase in the solubility with a decrease in temperature for *n*-pentane from 25 to 4 °C and for *n*-octane from 25 to 5 °C. On the other hand, their results for *n*-hexane and *n*-heptane indicated a decrease in the solubility from 25 to about 4 °C. Although in some cases, such as *n*-hexane, the change of solubility with temperature is within experimental error, in other cases, such as heptane and octane, the difference seems to be definite.

The available data in the literature on the solubility of water in hydrocarbons show a decline with a decrease in temperature (4–6) which is in agreement with the findings of this investigation.

Correlation of the Solubilities

The mixture of hydrocarbon (HC) and water (w) represents a typical binary system with partially miscible components. The condition for equilibrium between two liquid phases may be expressed in terms of the fugacities

$$[1] \qquad f_{HC} = \bar{f}_{HC}$$

$$[2] \qquad f_w = \bar{f}_w$$

where the bar denotes the hydrocarbon rich phase. Because $f_i = x_i\gamma_i f_i^0$

$$[3] \qquad x_{HC}\gamma_{HC} = \bar{x}_{HC}\bar{\gamma}_{HC}$$

$$[4] \qquad x_w\gamma_w = \bar{x}_w\bar{\gamma}_w$$

In these equations, x is the liquid mole fraction, γ is the Raoult's law activity coefficient and f^0 is the standard state fugacity. The subscripts HC, w, and i refer to hydrocarbon, water, and component i, respectively.

It has been shown by Leinonen *et al.* (7) that the coefficient K in the Redlich–Kister equation,

$$[5] \qquad g^E = x_{HC}(1 - x_{HC})\,K$$

can be correlated with the molar volumes and other structural parameters of the dissolved hydrocarbon molecule. In eq. 5, g^E is the molar excess Gibbs free energy. Equation 5, which allows the calculation of K from only one experimental value for solubility of each component, implies that the g^E curve is symmetrical. Unfortunately this does not hold for the hydrocarbon–water systems.

A further expansion of eq. 5 yields

$$[6] \quad g^E = RTx_{HC}(1 - x_{HC})[A + B(1 - 2x_{HC})]$$

To determine the parameters A and B, a pair of points such as the mutual solubilities is needed. From eq. 6 together with eqs. 3 and 4 the following expressions are derived:

$$[7] \quad A[(1 - x_{HC})^2 - \bar{x}_w{}^2] + B[-6x_{HC} + 9x_{HC}{}^2 - 4x_{HC}{}^3 + 6(1 - \bar{x}_w) - 9(1 - \bar{x}_w)^2 + 4(1 - \bar{x}_w)^3] = \ln\left(\frac{1 - \bar{x}_w}{x_{HC}}\right)$$

and

$$[8] \quad A[x_{HC}{}^2 - (1 - \bar{x}_w)^2] + B[3x_{HC}{}^2 - 4x_{HC}{}^3 - 3(1 - \bar{x}_w)^2 + 4(1 - \bar{x}_w)^3] = \ln\left(\frac{\bar{x}_w}{1 - x_{HC}}\right)$$

in which x_{HC} and $\bar{x}_w$ are, respectively, the solubilities of hydrocarbon in water and water in hydrocarbon, expressed in mole fractions. The parameters A and B were calculated by solving eqs. 7 and 8 simultaneously.

The calculated A and B values, like the parameter K of eq. 5 (1), display a dependence on the hydrocarbon liquid molar volume and other molecular parameters as shown in Figs. 1 and 2. To correlate coefficients A and B, and therefore the solubilities, the following equations were used:

$$[9] \qquad A = C_{A_1}V_i + \sum_{i=2}^{7} C_{A_i}n_i$$

$$[10] \qquad B = C_{B_1}V_i + \sum_{i=2}^{7} C_{B_i}n_i$$

In these equations V_i is the liquid molar volume, expressed in terms of $cm^3\ g\ mol^{-1}$, and n_i is the

number of the groups i present in the molecule. Values of the coefficients C_{A_i} and C_{B_i} are given in Table 2. The groups were chosen in such a way as to express the molecules concerned in terms of a minimum number of groups. The contributions attributed to the individual groups are listed in Table 2 as C_{A_i} and C_{B_i} for $i = 2$ to 7. In this table, all the bonds shown as free are connected to atoms other than hydrogen. As an example, the value of A for 2,2,4-trimethylpentane at 25 °C ($V_i = 166.07$ cm^3 g-mol^{-1}) is obtained as follows

$$A = 0.02306 \times 166.07 + 5 \times 2.97571 + 0.32934 + (-2.44926) + (-5.31870) = 11.2695$$

Similarly, $B = 3.6453$. Based on these values, the solubility of 2,2,4-trimethylpentane in water is calculated to be 2.11 p.p.m. and the solubility of water in 2,2,4-trimethylpentane to be 77.0 p.p.m.

In the calculation at 25 °C, the molar volumes were calculated from the densities ($d_{25°}$) listed in ref. 8. At 0 °C, the method of ref. 9 was adopted using $d_{25°}$ as the reference density.

From the coefficients (group contributions) given in Table 2, and a knowledge of the molar volume and molecular groups, the values of A and B can be obtained. Thus, the mutual solubilities of hydrocarbons and water can be calculated by means of eqs. 7 and 8. Because of the very low values of the solubilities, $x_{HC} \approx 1/\gamma_{HC}$, and at the limiting condition, where $x_{HC} \to 0$, $\ln \gamma_{HC} = A + B$. Therefore

$$[11] \qquad x_{HC} = \frac{1}{e^{(A+B)}}$$

Similarly

$$[12] \qquad \bar{x}_w = \frac{1}{e^{(A-B)}}$$

The calculated results obtained from these equations were compared with those obtained from eqs. 7 and 8 and the difference was found to be very small. For this reason, eqs. 11 and 12 are recommended for calculating solubilities from the known A and B values for their simplicity.

A comparison of the experimental and calculated solubilities at 25 °C is given in Table 3. A similar comparison has been done for 0 °C. The average deviations are 10.88% for the solubilities of hydrocarbons in water and 7.59% for the solubilities of water in the hydrocarbons.

It should be mentioned that eq. 6 was arbitrarily chosen to express the dependence of the excess Gibbs free energy on the liquid phase composition. Other expressions, such as the van Laar equation, may be used in a similar manner. The van Laar equation was actually tried in this investigation. Apart from the fact that the calculation of the van Laar parameters is more difficult due to the nonlinear nature of the equation there appears to be practically no difference between the correlation based on the parameters of eq. 6 and the van Laar equation. This is a consequence of the low solubility values and the nature of the limiting γ values.

Since γ's are expressed in terms of A and B, which are functions of the group contributions, our correlation is thus linked with two other works.

It has been shown by Deal, Derr, and coworkers (10–12) that the limiting values of the

activity coefficients for a homologous series of solutes in a fixed or homologous series of solvents are, with a good approximation, a function of the group of the molecules involved.

Similarly Irmann (13) has shown that for a wide variety of hydrocarbons and their halogen derivatives, the logarithm of $1/S$, where S is the solubility of the organic material, can be calculated as the sum of atomic and structural parameters. The fact that $1/S$ is related to $1/x$ links his correlation with the one presented in this work.

A ^{19}F Nuclear Magnetic Resonance Study of Polymeric Fluoroanions of Tin(IV) and Titanium(IV)

P. A. W. DEAN

Department of Chemistry, University of Western Ontario, London, Ontario

Received July 16, 1973

Fluorine n.m.r. has been used to demonstrate the existence of fluorine-bridged polymeric fluoroanions of tin(IV) and titanium(IV) in liquid sulfur dioxide solution. In the system TiF_4–$(Pr_2^nNH_2)_2TiF_6$ the species formed are: $Ti_2F_{11}^{3-}$; a species $(TiF_5)_n^{n-}$, which has a structure consisting of *cis* fluorine-bridged TiF_6 octahedra and is most probably $Ti_2F_{10}^{2-}$; $Ti_2F_9^-$; other fluorine-bridged polymers. The spectra of $(TiF_5)_n^{n-}$ and $Ti_2F_9^-$ are complex due to the effects of magnetic nonequivalence; the spectrum of $(TiF_5)_n^{n-}$ has been analyzed in detail. Both $Sn_2F_{11}^{3-}$ and $(SnF_5)_n^{n-}$, which has a structure like $(TiF_5)_n^{n-}$, are formed in SnF_4–$(Pr_2^nNH_2)_2SnF_6$.

La r.m.n. du fluor a été utilisée pour démontrer en solution liquide d'anhydride sulfureux l'existence de fluoroanions de l'étain(IV) et du titanium(IV) polymériques comportant des ponts fluor. Dans le système TiF_4–$(Pr_2^nNH_2)_2TiF_6$ les espèces présentes sont: $Ti_2F_{11}^{3-}$; une espèce $(TiF_5)_n^{n-}$ qui possède une structure composée d'octaèdres TiF_6 pontés de manière *cis* au fluor et qui est probablement $Ti_2F_{10}^{2-}$; $Ti_2F_9^-$; d'autres polymères comportant des ponts fluor. Les spectres de $(TiF_5)_n^{n-}$ et de $Ti_2F_9^-$ sont complexes principalement à cause des effets de nonéquivalence magnétique; le spectre de $(TiF_5)_n^{n-}$ est décrit en détail. Les deux espèces $Sn_2F_{11}^{3-}$ et $(SnF_5)_n^{n-}$, qui possède une structure identique à $(TiF_5)_n^{n-}$, sont formées dans le système SnF_4–$(Pr_2^nNH_2)_2SnF_6$.

Can. J. Chem., **51**, 4024 (1973)

Introduction

Fluorine-bridging occurs in crystalline stannic fluoride (1) and in some organotin fluorides in the solid state (2). The structure of solid titanium tetrafluoride is presently unknown, but it is also thought to involve fluorine-bridging (3). The occurrence of discrete fluorine-bridged polymeric fluoroanions of tin(IV) and titanium(IV) would therefore seem possible also. However, no such anions have been reported for tin(IV) and the situation for titanium(IV) is unclear. A continuous variation study (4) of the binary system TiF_4–TiF_6^{2-} in acetone provided evidence for the existence of species of empirical formula $Ti_2F_9^-$ and TiF_5^-, and could not rule out the possibility that complexes of the type $[(TiF_4)_xF]_n^{n-}$ occur, but the extent of polymerization and solvation of these anions and hence their structures could not be determined (5). Similarly an anion of the empirical formula $Ti_2F_9^-$, but of unknown structure, was thought to be formed in the system arene – TiF_4 – HF (6).

We now report ^{19}F spectroscopic data for the systems TiF_4–TiF_6^{2-} and SnF_4–SnF_6^{2-} in liquid sulfur dioxide. These data provide evidence for the occurrence and structures of polymeric fluoroanions of tin(IV) and titanium(IV).

Results and Discussion

The System TiF_4–$(Pr_2^nNH_2)_2TiF_6$ in SO_2

Titanium tetrafluoride itself is insoluble in SO_2, but solutions of TiF_6^{2-} dissolve TiF_4 up to $TiF_4/TiF_6^{2-} = 3$. In the region where $TiF_4/TiF_6^{2-} \lesssim 1$ this reaction is noticeably exothermic at room temperature, the solvent boiling; larger amounts of TiF_4 dissolve less vigorously. When $TiF_4/TiF_6^{2-} \gtrsim 1$ initial complete dissolution is followed, in a period of *ca.* 10 min, by formation of small amounts of insoluble crystalline material. In all cases the solutions are colorless.

The ^{19}F n.m.r. spectra of the TiF_4–TiF_6^{2-} solutions show broad lines at room temperature, presumably due to relatively rapid fluorine exchange. At low temperatures, however, fine structure is observed. Figure 1*a* shows the spectrum of a solution with $TiF_4/TiF_6^{2-}/SO_2 = 1/3.2/36$, measured at $-80°$. In addition to the singlet -89.6 p.p.m. below $CFCl_3$, which is due to TiF_6^{2-}, there is also observed a doublet of quintets, *1*, a doublet of doublets, *2*, and a multiplet, *3*, of at least 11 lines, the relative intensities of resonances *1*, *2*, and *3* being 2:8:1. By analogy with the ^{19}F n.m.r. spectrum of $Ta_2F_{11}^-$ (7), resonances *1*, *2*, and *3* may be assigned to the $Ti_2F_{11}^{3-}$ anion **1**.

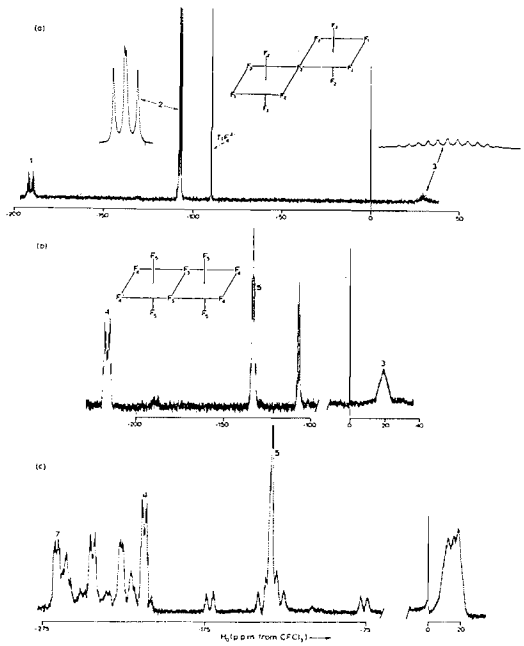

FIG. 1. (*a*) The 56.4 MHz ^{19}F n.m.r. spectrum of a solution with $TiF_4/TiF_6^{2-}/SO_2 = 1.0/3.2/36$, measured at $-80°$. (*b*) The 56.4 MHz ^{19}F n.m.r. spectrum of a solution with $TiF_4/TiF_6^{2-}/SO_2 = 1.0/1.1/12$, at $-80°$. (*c*) The 58.3 MHz ^{19}F n.m.r. spectrum of the supernatant liquor in a mixture with $TiF_4/TiF_6^{2-}/SO_2 = 1.6/1.0/14$, at $-70°$.

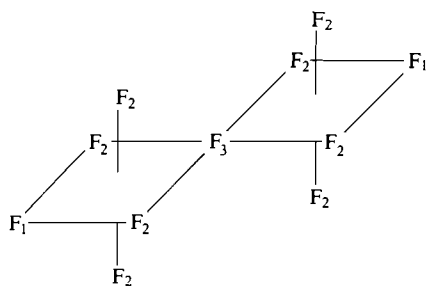


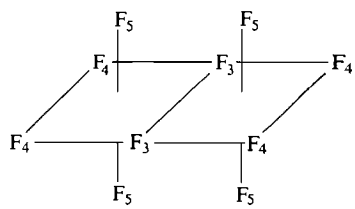
1

The chemical shifts and coupling constants for this ion are given in Table 1. Since $J_{13} \approx J_{23}$, the signal due to F_3, which should be a triplet (by coupling to the two fluorines F_1) of nonets (by coupling to the eight fluorines F_2) will appear theoretically as a 15 line multiplet with intensities 1:8:28:48:86:102:121:156:121:102:86:48:28:8:1. Eleven of these lines are observed experimentally, with approximately the correct relative intensities. The $Ti_2F_{11}^{3-}$ anion must be formed according to the overall equation

$$3TiF_6^{2-} + TiF_4 \rightarrow 2Ti_2F_{11}^{3-}$$

As the relative amount of TiF_4 is increased towards $TiF_4/TiF_6^{2-} = 1$, new signals appear in the spectrum, and the amounts of $Ti_2F_{11}^{3-}$ and TiF_6^{2-} in solution diminish. The new resonances, labelled *3*, *4*, and *5* in Fig. 1*b*, are, respectively, a broad line, a complex symmetrical multiplet, and an apparent quintet. The intensities 3:4:5 are in the constant ratio 1:2:2, and the total intensity *3* + *4* + *5* is at a maximum, relative to the rest of the spectrum, at $TiF_4/TiF_6^{2-} = 1$. In at least some of the region between $\frac{1}{3} < TiF_4/TiF_6^{2-} < 1$, *e.g.* when $TiF_4/TiF_6^{2-} = \frac{1}{2}$, the signals *3*, *4*, and *5* are observed at the same time as the resonances of TiF_6^{2-} and $Ti_2F_{11}^{3-}$.

Since the species responsible for *3*, *4*, and *5* reaches its maximum relative concentration when $TiF_4/TiF_6^{2-} = 1$, it must be of the form $(TiF_5)_n^{n-}$. As is the case for SbF_5 (8), the 1:2:2 intensities of *3*, *4*, and *5* are explicable only in terms of dimers or higher polymers consisting of MF_6 octahedra linked via *cis* fluorine-bridges. For the exact formulation $(TiF_5)_n^{n-}$ the fluorine-bridged ions must be cyclic as in the case of $Ti_2F_{10}^{2-}$, **2**, the $(TiF_5)_n^{n-}$ anion is favored on the basis of further evidence (*vide infra*).



2

The position and relative intensity of resonance *3* show that it is due to the bridging fluorine F_3. The spectrum of the $Ti_2F_{11}^{3-}$ ion (*vide supra*) suggests that those fluorines giving rise to signals at lowest field are *trans* to a bridging fluorine. Resonance 4 is therefore assigned to F_4; this assignment is borne out by a detailed analysis of the spectrum (*vide infra*). Thus the signal labelled *5* must be from F_5.

We have analyzed the spectrum of $(TiF_5)_n^{n-}$ using the approximation,[1] previously employed

[1]Thus must be recognized as an approximation since a small coupling *between* linked octahedra is a distinct possibility; a coupling of 1.5 Hz has been observed (18) between the terminal fluorines on the two octahedra in $[F_4O\,^{183}WFWOF_4]^-$.

TABLE 1. ^{19}F n.m.r. spectral parameters for polymeric fluoroanions of titanium(IV)

for a detailed analysis of the spectrum of SbF_5 (9), that the resonances of F_4 and F_5 can be simulated by considering the coupling between fluorines in a single octahedral MF_6 unit. Within this unit, the spectrum depends on six coupling constants, $J_{33'}$, J_{34}, $J_{34'}$, J_{35}, $J_{44'}$, and J_{45}; J_{55} does not affect the spectrum. As in the case of SbF_5 (9), analysis of the spectrum was achieved by generating theoretical spectra using the general n.m.r. spectral program LAOCN3 of Bothner-By and Castellano (10), calculating a line shape as the sum of the Lorenzian curves for the individual theoretical transitions, and comparing the plotted theoretical spectrum with the observed spectrum. The observed chemical shifts are widely separated so that the spin system can be described as $AA'M_2XX'$, any second order effects in the spectrum arising almost entirely from the presence of magnetic nonequivalence in the TiF_6 unit.

The resonance due to F_5 is expected to be a triplet (by a coupling of J_{45} to the two fluorines F_4) of triplets (by coupling of J_{35} to the two fluorines F_3). The resonance *5* (Fig. 1*b*) appears to be a quintet with a splitting of 42 Hz, indicating $J_{45} \approx J_{35} \approx 42$ Hz. The resonance from F_4 is shown in Fig. 2*a*. The theoretical treatment indicates that the splitting between the two largest lines of the F_4 multiplet is $|J_{34} + J_{34'}|$. This splitting is found to be 180 Hz. It is highly unlikely that this, by coincidence, is equal to the sum of the two analogous coupling constants in $Ti_2F_{11}^{3-}$ ($J_{23} = 44$ Hz; $J_{13} = 135$ Hz), so J_{34} and $J_{34'}$ were set at 45 and 135 Hz (both

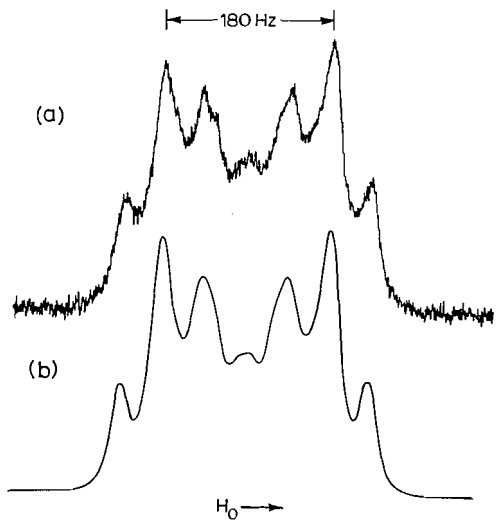

FIG. 2. (*a*) The resonance due to F_4 of $(TiF_5)_n^{n-}$ in the −80° 56.4 MHz ^{19}F n.m.r. spectrum of a solution with $TiF_4/TiF_6^{2-}/SO_2 = 1.0/1.1/12$. (*b*) The calculated spectrum for F_4 of $(TiF_5)_n^{n-}$.

with the same sign) as trial values. Since we find that the frequency between the two outermost lines is $\{|J_{34} + J_{34'}| + 2|J_{45}|\}$, J_{45} can be determined as 41 Hz and, hence, from the "quintet" of F_5, $J_{35} = 44$ Hz. With the values J_{34}, $J_{34'}$, J_{45}, and $J_{34} = \pm 45$, ± 135, 41, and 44 Hz, $J_{33'}$ and $J_{44'}$ were varied over the range 0–300 Hz and 0–80 Hz, respectively,[2] and the

[2]*cis* couplings between terminal fluorines in titanium fluoro-complexes have been reported in the range 31–52 Hz.

linewidth was also varied, until the shapes of the center of the multiplet and of the shoulders on the lines closest the center were best reproduced. Only a small range of values for $J_{33'}$, $J_{44'}$ and the linewidth produced *both* the central resonance *and* the shoulders. Having the best values for $J_{33'}$ and $J_{44'}$ for fixed values of the other four coupling constants, J_{34} (and thus $J_{34'}$), $J_{33'}$, and $J_{44'}$ were allowed to vary over ± 5 Hz until the closest fit was found. At this point a charge of ± 2Hz in any one coupling constant produced a noticeably poorer fit. In Fig. 2 the best theoretical spectrum, having a line width of 23 Hz, is compared with the experimental spectrum. The best values of the coupling constants are given in Table 1, which also lists the chemical shift data for $(TiF_5)_n^{n-}$ (as $Ti_2F_{10}^{2-}$). Of particular interest among the coupling constants calculated are the small sizes of $J_{33'}$ and $J_{44'}$. For transition metal species no couplings of the same type as $J_{33'}$ have been reported. However, the magnitude of $J_{44'}$, the smallest coupling reported between *cis* terminal fluorines bound to Ti(IV),[2] is consistent with the argument of Dyer and Ragsdale (11) that *cis*- coupling between terminal fluorines depends on the angle between these. In the present case the angle F_4—Ti—F_4 should be greater than 90°, as is the angle between the corresponding halogen atoms in $Ti_2Cl_{10}^{2-}$ (12), VF_5 (13), NbF_5 (14), and TaF_5 (14), whereas in other complexes which have been investigated, the F—Ti—F angles were probably 90° or less (see, for example, ref. 11).

The ^{19}F n.m.r. spectra of the supernatant liquor above mixtures with $1 < TiF_4/TiF_6^{2-} < 3$ are exceedingly complicated (we noted earlier that small amounts of insoluble material are formed in this range). A typical example, the −70° spectrum of a mixture where $TiF_4/TiF_6^{2-}/SO_2 = 1.6/1.0/14$, is shown in Fig. 1*c*. We are unable, at present, to assign many of the resonances in these spectra, though we can determine the types of species giving rise to them (*vide infra*). As TiF_4/TiF_6^{2-} approaches 3, the resonances in the region from 0 to 250 p.p.m. below $CFCl_3$ diminish in intensity, the signals *4* and *5* of $(TiF_5)_n^{n-}$ disappearing first. Concurrently, the resonance labelled *7* in Fig. 1*c*, and a broadened quintet-like resonance at ϕ 18.1, increase in intensity, until, at $TiF_4/TiF_6^{2-} \sim 3$ or in the supernatant liquor of a mixture with $TiF_4/TiF_6^{2-} > 3$, these two resonances comprise the bulk of the spectrum as is shown in Fig. 3.

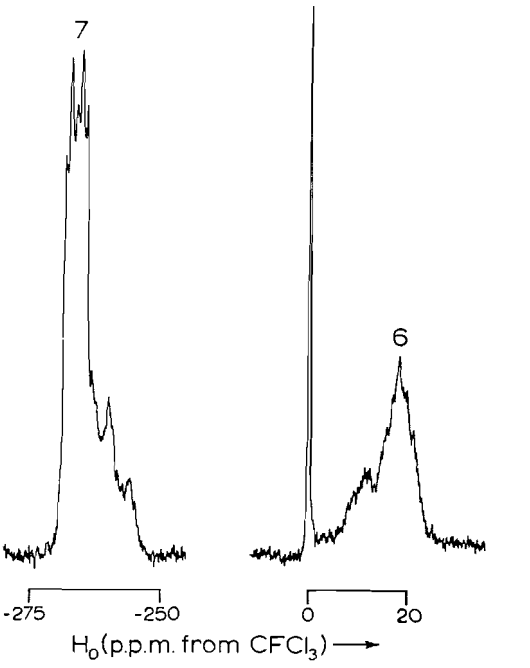

FIG. 3. The 58.3 MHz ^{19}F n.m.r. spectrum of the supernatant liquor in a mixture with $TiF_4/TiF_6^{2-}/SO_2 = 5.0/1.0/36$, at −60°.

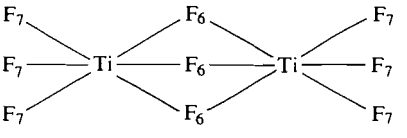
By a consideration of the spectra of $Ti_2F_{11}^{3-}$ and $(TiF_5)_n^{n-}$ (see above), the symmetrical downfield multiplet *7* can reliably be assigned to terminal fluorines, and the "quintet", *6*, to bridging fluorines. The relative intensities of *6* and *7* are 1:2 and the intensities of these signals relative to others in the spectrum is not constant, so that *6* and *7* alone must arise from one species. Assuming that the titanium will remain six-coordinate, as in $Ti_2F_{11}^{3-}$ and $(TiF_n)^{n-}$ (*vide supra*), a single formulation is possible for a species where the number of terminal fluorines is twice the number of bridging fluorines, *i.e.* it is $Ti_2F_9^-$, having a face-joined bioctahedral structure, represented by **3**.



3

This formulation is consistent with resonances *6* and *7* reaching their maximum intensity at $TiF_4/TiF_6^{2-} = 3$, as $Ti_2F_9^-$ would be formed according to the overall equation

$$3\ TiF_4 + TiF_6^{2-} \rightarrow 2\ Ti_2F_9^-$$

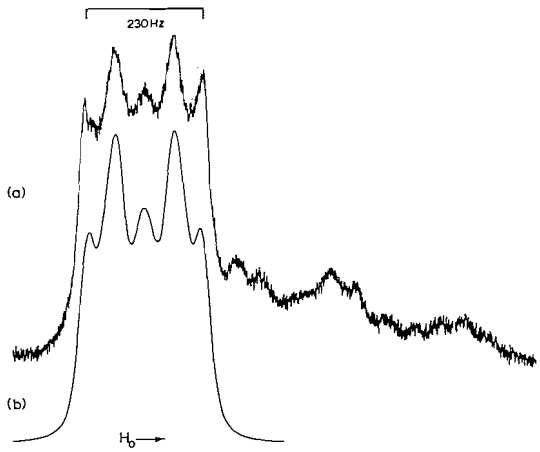


FIG. 4. (*a*) The resonance due to F_7 of $Ti_2F_9^-$ in the $-60°$ 58.3 MHz ^{19}F n.m.r. spectrum of the supernatant liquor in a mixture with $TiF_4/TiF_6^{2-}/SO_2 = 5.0/1.0/36$. (*b*) Theoretical spectrum for F_7 of $Ti_2F_9^-$ generated using $J_{66'} = 10, J_{67} = \pm 47, J_{67'} = \pm 132, J_{77'} = 25$ Hz, and a linewidth of 40 Hz.

The unusually-shaped multiplet[3] due to F_7 is shown in greater detail in Fig. 4*a*. Since this signal appears as five broadish resonances it is not sensible to attempt an analysis of the spectrum by the method used for $(TiF_5)_n^{n-}$ (*vide supra*) which would require values for four coupling constants, $J_{66'}$, J_{67}, $J_{67'}$, and $J_{77'}$. However, we have values of the analogous coupling constants for $(TiF_5)_n^{n-}$, *i.e.* for $J_{33'}$, J_{34}, $J_{34'}$, and J_{44}, and, using values close to these, the essential features of the resonance 7 can be reproduced, as shown in Fig. 4*b*. The fit of experimental is not perfect but is certainly good enough to confirm that the signal 7 is due to F_7 of $Ti_2F_9^-$ and to suggest that corresponding couplings in $(TiF_5)_n^{n-}$ and $Ti_2F_9^-$ have similar values. The chemical shifts of $Ti_2F_9^-$ are given in Table 1.

Since a four-membered  ring exists in $Ti_2F_9^-$, it could clearly exist in $Ti_2F_{10}^{2-}$ and on this basis we suggest that the species $(TiF_5)_n^{n-}$ is most probably the dimer **2**. If so, the series $Ti_2F_{11}^{3-}$, $Ti_2F_{10}^{2-}$, and $Ti_2F_9^-$ is the only one reported in which corner-, edge-, and face-bound bioctahedra are known for the same metal, oxidation state and halogen. In any event the complex resonances appearing in the spectra of mixtures with $1 < TiF_4/TiF_6^{2-} < 3$, *e.g.* Fig. 1*c*, can now be assigned to trimers or higher polymers as (*i*) they are not due to the 1:1 species, (*ii*) they do not arise from the dimeric $Ti_2F_9^-$ ion.

The chemical shifts in Table 1 deserve further comment. The spectra of all three dimeric species have in common relatively low field resonances for terminal fluorines and surprisingly high field shifts for the bridging fluorines. The latter phenomenon has also been noted by other workers (7) for $Ta_2F_{11}^-$, $Nb_2F_{11}^-$, and some related ions. This situation resembles that found in the ^{17}O n.m.r. spectrum of the dichromate ion (15) where the signal of the bridging oxygen occurs 784 p.p.m. above that of the terminal oxygens. For $Cr_2O_7^-$ the chemical shift difference has been interpreted (16) in terms of different double-bond characters in the two types of Cr—O bonds: the terminal oxygens can readily double-bond to the chromium, whereas the bridging oxygen, due to a bent Cr—O—Cr linkage, cannot. Presumably the same explanation applies in the present case: there is convincing evidence for partial double-bonding between titanium(IV) and terminal fluorides (ref. 17 and references cited therein), and the formation of bent Ti—F—Ti linkages in

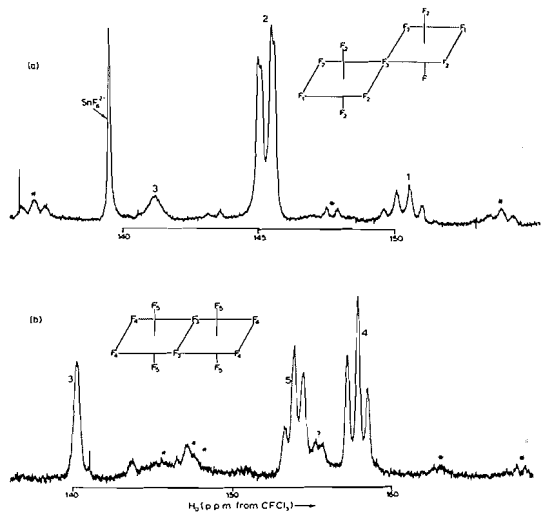

FIG. 5. (*a*) The 94.1 MHz ^{19}F n.m.r. spectrum of a solution with $SnF_4/SnF_6^{2-}/SO_2 = 1.0/3.0/26$, measured at $-60°$. (*b*) The 94.1 MHz ^{19}F n.m.r. spectrum of a solution with $SnF_4/SnF_6^{2-}/SO_2 = 1.0/1.0/11$, at $-60°$. (The starred resonances are $^{117/119}Sn$ satellites.)

[3]We were unable to prepare a sample free of the resonances overlapping and on the high field side of that due to F_7.

TABLE 2. ^{19}F n.m.r. spectral parameters for polymeric fluoroanions of tin(IV)

Ion	Fluorine assignment[a]	Chemical shift[b] (p.p.m.)	Average[c] tin–fluorine coupling constant (Hz)	Fluorine–fluorine coupling constants (Hz)
$Sn_2F_{11}^{3-}$	1	150.6	?	$J_{12} = 46 \pm 1$
	2	145.1	1638 ± 10	$J_{13} < 10$
	3	141.2[d]	?	$J_{23} = 11 \pm 1$
$Sn_2F_{10}^{2-}$	3	140.4[e]	~1340	J_{34} small
	4	158.1[f]	1950 ± 20	$J_{34'}$ small
	5	154.2[g]	~1690	$J_{45} = 58 \pm 1$

[a]For numbering scheme and method of assignment see text.
[b]Relative to internal $CFCl_3$; at $-60°$, $(Pr^n_2NH_2)_2SnF_6$ in SO_2 resonates at: 137.8 (11% solution); 139.8 (38% solution).
[c]Average of $J(^{119}Sn—F)$ and $J(^{117}Sn—F)$; for SnF_6^{2-} at $-60°$, $J(^{119}Sn—F) = 1604 \pm 4$ Hz.
[d]Width at half height ~55 Hz.
[e]Width at half height ~48 Hz.
[f]Width of components at half height ~25 Hz.
[g]Width of components at half height ~36 Hz.

$Ti_2F_9^-$, $Ti_2F_{10}^{2-}$, and probably $Ti_2F_{11}^{3-}$ also, is expected to restrict multiple-bonding between Ti(IV) and the bridging fluorines considerably.

The System SnF_4–$(Pr^n_2NH_2)_2SnF_6$ in SO_2

Stannic fluoride will dissolve in SO_2 solutions of SnF_6^{2-} only up to $SnF_4/SnF_6^{2-} = 1$. The dissolution of the insoluble SnF_4 is slower than that of TiF_4 in TiF_6^{2-} solutions and not noticeably exothermic.

Fine structure can be observed in the low temperature ^{19}F n.m.r. spectra of the SnF_4–SnF_6^{2-} solutions. Figure 5*a* shows the $-60°$ spectrum of a solution with $SnF_4/SnF_6^{2-}/SO_2 = 1.0/3.0/26$. In addition to a signal from SnF_6^{2-} with its appropriate $^{117/119}Sn$ satellites, the spectrum also shows three resonances, labelled *1*, *2*, and *3* in Fig. 5*a*, having relative intensities 2:8:1. In addition, the $^{117/119}Sn$ satellites of resonance *2* are observed, but those of resonances *1* and *3* are not seen, presumably due to their weakness and/or broadness. The resonances *1*, *2*, and *3* are attributed to the $Sn_2F_{11}^{3-}$ anion with structure **1**. The most intense absorption is a distorted doublet of doublets, which may be assigned to the fluorines F_2 coupled to the neighboring terminal fluorine F_1 and the bridging fluorine F_3. The fluorines F_1 are coupled to four nearest fluorines F_2, and their resonance appears as a quintet distorted towards *2*; evidently J_{13} is small (< 10 Hz) as no further splitting of the quintet is observed. The resonance *3* should be a nonet by coupling to the eight equivalent fluorines F_2, but no fine structure is observed in *3*. The n.m.r. parameters for $Sn_2F_{11}^{3-}$ are given in Table 2. The order of the chemical shifts of F_1, F_2, and F_3 is the same as found in $As_2F_{11}^-$ (19) and $Sb_2F_{11}^-$ (20), but the spread of the spectrum (9.4 p.p.m.) is smaller than that for either $As_2F_{11}^-$ (64 p.p.m. (19)) or $Sb_2F_{11}^-$ (42–49 p.p.m. (9, 20)). Thus even though J_{12} and J_{23} for $Sn_2F_{11}^{3-}$ are smaller than for the analogous Group V dimers, the spectrum of the tin(IV) ion shows greater second-order distortions than do the spectra of either of the other two at the same frequency.

The low-temperature n.m.r. spectrum of a solution with $SnF_4/SnF_6^{2-} = 1$ consists essentially of three resonances, labelled *3*, *4*, and *5* in Fig. 5*b*, together with their $^{117/119}Sn$ satellites. Resonance *3* is a broad singlet, *4* a relatively sharp triplet (slightly distorted towards 5 by second order effects) and *5* a broad distorted triplet; *3*, *4*, and *5* have intensities 1:2:2. As in the case of $Ti_2F_{10}^{2-}$ (see earlier) this spectrum must be interpreted in terms of an $(MF_5)_n^{n-}$ ion with a cyclic structure of *cis* linked MF_6 octahedra. The simplest such ion would be $Sn_2F_{10}^{2-}$ with structure **2**. The types of species occurring in the TiF_4–TiF_6^{2-} system (see above), coupled with the well-known (21) similarity between the chemistries of tin(IV) and titanium(IV), would suggest that $(SnF_5)_n^{n-}$ is, in fact, $Sn_2F_{10}^{2-}$, and it will be referred to as such for further discussion.

By comparison with the spectrum of SbF_5 (9), the resonances *3*, *4*, and *5* may be assigned to fluorines F_3, F_4, and F_5 of **2**. Like the spectra of $Ti_2F_{10}^{2-}$ and SbF_5 (9), the spectrum of $Sn_2F_{10}^{2-}$ should show the effects of magnetic

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

nonequivalence. The only obvious manifestation of these effects is the broadness of triplet 5 compared with triplet 4. Presumably the simplicity of the spectrum in Fig. 5*b* is a result of J_{45} being much larger than either J_{34} or $J_{34'}$.

The n.m.r. spectral parameters for $Sn_2F_{10}^{2-}$ are given in Table 2. Of particular interest is the sizeable $^{117/119}Sn$ coupling to the bridging fluorines F_3. This coupling, apparently the first of its type unambiguously identified for a non-transitional element, is of comparable size to many tin–terminal fluorine couplings (see, for example, ref. 22).

Experimental

Reagents

Di-*n*-propylammonium hexafluoro-stannate(IV) and -titanate(IV) were prepared as previously reported (23). Titanium tetrafluoride (Ozark–Mahoning Co.) was purified by sublimation at ~150° in an all-quartz apparatus and used as soon as possible after purification. Sulfur dioxide (Matheson of Canada Ltd., anhydrous grade) was dried by standing over 3A Molecular Sieves in the gas phase. Stannic fluoride (Ozark–Mahoning Co.) was used as received.

^{19}F Nuclear Magnetic Resonance Spectra

The n.m.r. spectra were obtained using Varian DA-60 or HA-100 spectrometers modified as reported earlier (24).

Sample Preparation

Samples were made up in well-dried all-glass vessels consisting of a mixing chamber which was open at the top via $\frac{1}{4}$ in. o.d. tubing and had a sidearm leading via a fine sinter to an n.m.r. tube. In a drybox, appropriate amounts of solid reactants were weighed into the mixing chamber, and the apparatus was closed by a detachable top. The apparatus was attached to a calibrated all-glass vacuum line and evacuated. Appropriate amounts of SO_2 and $CFCl_3$ were condensed into the mixing vessel. The apparatus was then sealed off at the $\frac{1}{4}$ in. tubing and allowed to warm to room temperature. Reaction of TiF_4–TiF_6^{2-} mixtures was rapid (a few minutes for complete dissolution) but that of SnF_4–SnF_6^{2-} mixtures was slower. In the case of $SnF_4/SnF_6^{2-} = 1$, warming to 40° for several hours was necessary to obtain complete dissolution of the SnF_4. The solution was now transferred via the sinter to the n.m.r. tube, and the mixing vessel and sidearm washed with SO_2 to ensure as complete a transfer of material as possible to the n.m.r. tube. The sample in the n.m.r. tube was frozen in liquid nitrogen and the tube sealed, thus separating it from the rest of the apparatus. Samples prepared in this manner were stable for long periods at room temperature. The ^1H n.m.r. spectra showed no evidence for decomposition of the cation.

We thank the National Research Council of Canada for generous financial assistance. We are also grateful to Mrs. H. Schroeder of the University of Western Ontario and Mr. J. I. A. Thompson of McMaster University for expert technical assistance in obtaining the n.m.r. spectra, and to Dr. S. Castellano, of the Mellon Institute, Pittsburgh, for providing a copy of his n.m.r. spectra plot program NMRPLOT.

Hydrogen–Water Deuterium Exchange over Graphon Supported Group VIII Noble Metals[1]

NORMAN HENRY SAGERT AND RITA MARY LOUISE POUTEAU

Research Chemistry Branch, Atomic Energy of Canada Limited, Whiteshell Nuclear Research Establishment, Pinawa, Manitoba R0E 1L0

Received June 25, 1973

Specific activities of Group VIII noble metals supported on Graphon have been determined for hydrogen–water deuterium exchange. Metal surface areas, which are required to calculate specific activities, were measured by hydrogen chemisorption, and by reaction of hydrogen with chemisorbed oxygen. For the second triad metals, ruthenium, rhodium, and palladium, and in the temperature range 140 to 225 °C, the variation of activity was Ru < Rh > Pd. For the third triad metals, osmium, iridium, and platinum, the variation of activities was Os < Ir < Pt in the same range of temperature. Apparent activation energies were measured over this temperature range, and orders of reaction with respect to hydrogen and water were measured at 160 °C (200 °C for Pt). From these data, activation energies for the surface exchange reaction were calculated. In the second triad the activation energies decrease slightly with increasing atomic number, but in the third triad they decrease quite markedly with increasing atomic number. A good correlation was obtained between the activation energy for surface exchange and the thermionic work function of the metal. This supports our earlier suggestion that Graphon is able to donate electrons to the metal and thus lower the activation energy for the surface exchange.

L'activité spécifique de métaux nobles du groupe VIII fixés sur Graphon a été déterminée pour l'échange de deutérium H_2–HDO. La superficie de la surface métallique, qui est nécessaire lors du calcul des activités spécifiques, a été évaluée à l'aide de la chemisorption de l'hydrogène ainsi qu'à l'aide de la réaction de l'hydrogène avec de l'oxygène chemisorbé. Pour la seconde triade de métaux, ruthénium, rhodium et palladium, et dans l'intervalle de températures allant de 140 à 225 °C, la variation d'activité a été dans l'ordre Ru < Rh > Pd. Pour la troisième triade de métaux, osmium, iridium et platine, la variation d'activité a été dans l'ordre Os < Ir < Pt dans le même intervalle de températures. Les énergies apparentes d'activation ont été mesurées pour cet intervalle de températures alors que l'ordre des réactions par rapport à l'hydrogène et à l'eau a été déterminé à 160 °C (200 °C pour le Pt). A partir de ces données, on a calculé pour les réactions d'échange se faisant en surface les énergies d'activation. Dans la seconde triade, les énergies d'activation diminuent légèrement selon l'ordre croissant des numéros atomiques, alors que dans la troisième triade elles diminuent selon l'ordre croissant des numéros atomiques d'une façon assez marquée. Une bonne corrélation a été obtenue entre l'énergie d'activation pour l'échange en surface et la fonction du travail thermionique du métal. Ce fait est en accord avec nos suggestions antérieurs voulant que le Graphon est capable de donner des électrons au métal et ainsi diminuer l'énergie d'activation nécessaire à l'échange en surface. [Traduit par le journal]

Can. J. Chem., **51**, 4031 (1973)

Introduction

Group VIII metals have been shown to be good catalysts for most hydrogenation, dehydrogenation, and hydrogenolysis reactions. This is partly, if not entirely, because they are able to adsorb hydrogen in its atomic form (1). However, it has not been easy to compare activities over a number of these metals because the results are complicated by varying heats of reaction, varying selectivities, and self poisoning. Isotopic exchange reactions offer a partial solution to this problem as there is a very small heat of reaction, and no large chemical difference between reactants and products. However, isotopic exchange reactions involving hydrocarbons can still be affected by self poisoning from side reactions, or indeed, from the main reaction if many hydrogen atoms are stripped from a single carbon atom (2).

Hydrogen–water deuterium isotope exchange is a reaction which does not involve such complications (3, 4). Moreover it is a sterically simple or "facile" reaction (5), so that in studying it over a series of metals the electronic, or chemical, effects should predominate over geometric effects. The reaction is very slow over unpromoted metals of the first triad, iron, cobalt, and nickel (6), but was found to take place with acceptable rates over metals of the second and third triads of Group VIII, the

TABLE 1. Properties of the graphon supported catalysts

Metal	Impregnating solution	Calculated site area (10^{-20} m^2)	Metal surface area (m^2 kg^{-1})	Metal dispersion (%)
1% Pd	$(NH_4)_2PdCl_6$	8.8	890	53
1% Rh	$RhCl_3$	8.4	890	48
1% Ru	$RuCl_3 \cdot 1$–$3H_2O$	11.0	260	18
0.5% Pt	H_2PtCl_6	8.9	240	52
1% Ir	H_2IrCl_6	8.6	820	84
1% Os	H_2OsCl_6	11.7	(800)	(85)

so-called noble metals. Therefore the reaction was studied over these six metals, ruthenium, rhodium, palladium, osmium, iridium, and platinum. To compare activities in a meaningful way, rates should be compared per unit surface area of exposed metal. In recent years methods have been developed for measuring surface areas of noble metals by selective chemisorption (7, 8) and by surface titrations (9). These methods may not be accurate to better than $\pm 30\%$, but they are generally reproducible to $\pm 10\%$.

Earlier work (4) indicated that support effects could be important. In this work the support chosen was Graphon, a highly graphitized carbon black. We previously suggested (4) that, for metals with work functions higher than 4.6 eV, some donation of electrons to the metal from the Graphon occurs. We have tested this hypothesis by using metals of varying work function.

Experimental

Apparatus and Procedure

Rates were measured in a flow system at atmospheric pressure, as previously described (4, 5). The HD concentrations were measured either by gas chromatography or with a Consolidated 21-621 mass spectrometer fitted with a continuous inlet. The mass spectrometer was calibrated for HD by equilibrating hydrogen with water of known deuterium content. In addition, the correction for H_3^+ was measured by passing deuterium-free H_2 through the mass spectrometer. This hydrogen was generated from the action of finely divided calcium on water containing only 1.6 p.p.m. deuterium. Argon was used as a diluent to reduce the partial pressure of hydrogen (4). Catalysts were reduced *in situ* with hydrogen at 300 °C for 18 h, and thereafter were kept overnight at 180 °C in flowing hydrogen. Generally several hours of conditioning in a hydrogen–water flow were necessary before reproducible results could be obtained after the initial reduction. If catalysts were kept in flowing hydrogen at 180 °C overnight their activity remained stable.

The total surface area of the Graphon support has been reported previously (4). Metal surface areas were measured by Boudart's hydrogen titration technique (9), by electron microscopy (5) and, for Pt, Ir, and Ru, by hydrogen chemisorption. For area measurements, catalysts were reduced under the same conditions used in the catalytic studies. They were then evacuated for 16 h to 2×10^{-4} Nm^{-2} and either a hydrogen chemisorption isotherm was measured, or a titration was done. Water isotherms were measured volumetrically at 27 °C. Corrections were made for the adsorption of water vapor in an empty cell.

Materials

Sources and methods of purifying water, D_2O, hydrogen, and argon have been described (4, 5). The preparation of the 0.5% platinum on Graphon catalysts was described previously (4). Because of their lower activities, the other catalysts were prepared as 1% metal on Graphon by impregnation with an appropriate compound (Table 1). Graphon was wetted with a solution containing the required amount of metal and the slurry was evaporated to dryness. The catalysts were then dried overnight at 100 °C.

Results

Metal surface areas of the catalysts are given in Table 1. These were calculated from the amount of hydrogen taken up using the stoichiometry proposed by Benson and Boudart (10).

[1] $$PtO + \tfrac{3}{2}H_2 \rightarrow PtH + H_2O$$

The number of sites measured in this way agreed with the number estimated from hydrogen chemisorption to within 20%, which was considered adequate for our purposes. From the number of sites, surface areas were calculated using the site areas listed. Relative site areas were estimated by averaging the site areas of crystal faces with high densities of atoms (28). The absolute site area of platinum was taken as 8.9×10^{-20} m^2 (11). The titration gave more reproducible results for the number of sites so this number was used. However, for osmium the Boudart titration did not seem to work and hydrogen chemisorption gave very low amounts adsorbed. Therefore, the surface area of osmium was estimated from the electron micrographs,

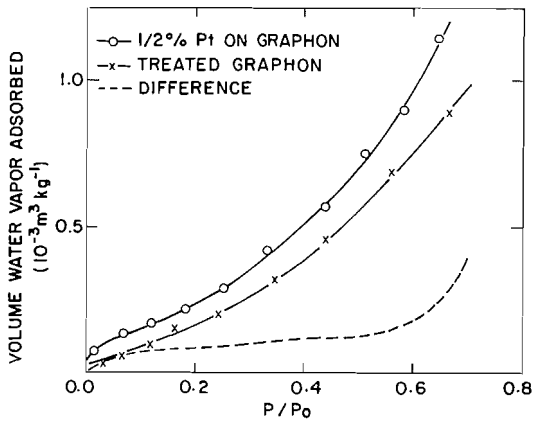

FIG. 1. Water adsorption isotherms for ½% Pt on Graphon catalyst and HCl treated Graphon measured at 27° C.

and the value in Table 1 is bracketed because it is considerably less accurate. Electron micrographs of other catalysts yielded surface areas agreeing with those obtained chemically to within ±50%, assuming spherical particles. In fact the particles were usually somewhat elongated.

Water vapor isotherms were measured at 27 °C for all catalysts, and Fig. 1 shows the results obtained with the platinum catalyst. We attempted to estimate the amount of water adsorbed on the platinum by measuring a water isotherm over Graphon which had been treated as the catalysts, apart from substituting HCl for the equivalent amount of chlorine in the impregnating compound. Untreated Graphon took up no water at all at relative pressures (P/P_0) smaller than 0.5. As a crude approximation, the difference between the water adsorbed on the treated Graphon and the water adsorbed on the catalyst was taken as that adsorbed on the platinum. A type II isotherm was observed which did not turn up until P/P_0 was greater than 0.5. Although the adsorption is primarily physical, the flat portion of the isotherm was well enough defined so that the Langmuir isotherm is obeyed for $P/P_0 < 0.5$. If the area of the water molecule is 1.06×10^{-19} m^2 (12), the metal surface areas, measured by hydrogen titration, imply a full water monolayer on the metal at 1.25×10^{-4} m^3 kg^{-1}, so that the plateau corresponds to $\theta_{H_2O} = 1.0$. However, low water coverages for the catalyst as a whole were calculated previously from kinetic data (4). This suggests that most of the water adsorbed on the support takes part in the reaction. In the present work, the reaction orders were measured in a region of intermediate water coverage at 160 °C or at 200 °C where P/P_0 equals 0.03_7 or 0.015, respectively.

The reaction rate coefficient, k, in moles of HD per kilogram of catalyst per second is given by eq. 2 (3–6) for water containing less than 5% deuterium.

$$[2] \qquad k = \frac{F}{(\alpha+\gamma)W} \ln \frac{n_e - n_0}{n_e - n}$$

F is the hydrogen flow rate in mol^{-1}, W is the catalyst weight in kg, α is the reciprocal of the equilibrium constant for reaction 3 and γ is the ratio of hydrogen pressure to water pressure.

$$[3] \qquad HDO + H_2 \rightleftarrows H_2O + HD$$

The n's represent HD concentrations, respectively at equilibrium (n_e), before reaction (n_0), and after reaction (n). The rate coefficient, k, would be the initial rate of reaction 3 in the forward direction if experiments could be done with pure HDO and H_2 (3, 4). Equation 2 is analogous to equations developed by Harris (13), and used by Kemball (14) in studies of the exchange of D_2 with hydrocarbons. Further consideration of the derivation of eq. 2 makes it clear that the rate is in moles of HD produced, not D_2 as earlier stated (4, 5). References in our earlier papers to D_2 should be taken as referring to HD. Previously we have shown that, with this type of catalyst, the rate is not controlled by internal or external diffusion (4).

Specific rates, or activities, were obtained by dividing the rate coefficient, k, by the surface area of the metal per kg of catalyst as given in Table 1. These specific rates are shown in Fig. 2 as a function of temperature, plotted in the Arrhenius form. All the data shown were obtained with a hydrogen pressure of 78.0 kN m^{-2} and a water pressure of 23.7 kN m^{-2}, and were calculated from plots of $\ln(n_e - n_0)/(n_e - n)$ against W/F. Table 2 summarizes the specific rates at 160 °C, the apparent activation energies, E_{app}, defined as $\partial \ln k/\partial(1/T)$ at constant pressure, and the reaction orders with respect to water and hydrogen. Reaction orders were defined as $(\partial \ln k/\partial \ln P_{H_2})_{T,P_{H_2O}}$ and were obtained from double logarithmic plots of k against pressure, where the pressure was usually varied over about one order of magni-

†$a = 1 - \theta_{H_2O}$, $b = \frac{1}{2}(1 - \theta_H)$.

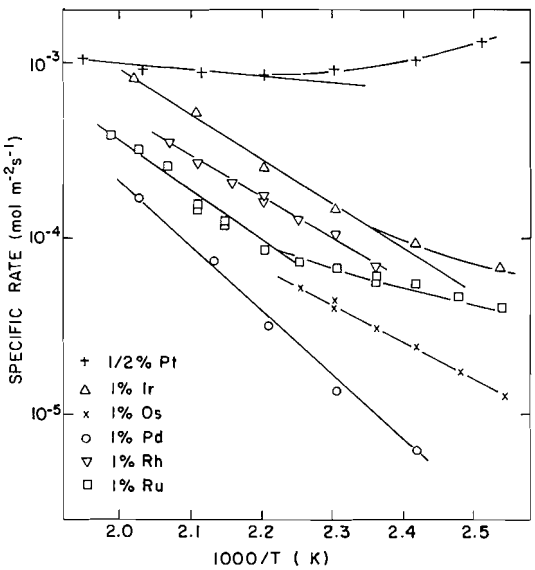

FIG. 2. Arrhenius plots of specific rates, measured with $P_{H_2} = 78.0$ kN m^{-2} and $P_{H_2O} = 23.7$ kN m^{-2}.

tude. Over this relatively small range of pressure, straight lines were obtained so that the rate expression could be written as

$$[4] \qquad k = k^1 P_{H_2O}{}^a P_{H_2}{}^b$$

Sandler (15) has shown that for the ortho–para hydrogen conversion, which follows a rate law in which the rate is proportional to the hydrogen pressure to the nth power, the apparent activation energy (E_{app}) is related to the true activation energy (E_0) by eq. *5a*

$$[5a] \qquad E_0 = E_{app} + n\lambda_{H_2}$$

where λ_{H_2} is the heat of desorption of H_2. Eley (16) later confirmed this and showed that n equaled $(1 - \theta)$ where θ is the surface coverage. Following these authors, it is easily shown that, for the rate expression in eq. 4, the true surface activation energy, E_0, and the apparent activation energy, E_{app}, are related by eq. *5b*

$$[5b] \qquad E_0 = E_{app} + b\lambda_{H_2} + a\lambda_{H_2O}$$

where λ_{H_2} and λ_{H_2O} are the heats of desorption of hydrogen and water respectively. Furthermore a equals $(1 - \theta_{H_2O})$ and $2b$ equals $(1 - \theta_H)$. Heats of desorption of hydrogen from ruthenium and osmium were required and these were taken as 105 kJ mol^{-1} (ref. 1, pp. 74–86). The heat of desorption of water was taken as 50 kJ mol^{-1}, about 10% greater than the heat of vaporization, in accordance with the results of Cole (17). It is easily shown that the form of hydrogen dependence used in eq. *5b* is correct even if a dissociative mechanism is involved in hydrogen adsorption. This also follows from Sandler's general derivation using the Freundlich isotherm. Considering the approximations involved the values of E_0 may not be valid to better than ±10 kJ mol^{-1}.

Figure 3 shows specific rates at 160 °C and E_0's plotted against periodic group number. Specific rates rise steadily for the third triad metals of group VIII, but peak at Rh for the second triad metals. This pattern would be the same at any of the temperatures investigated, although the shape of the curves would be different. A number of correlations of E_0 with various metallic properties were attempted. The best, shown in Fig. 4, was the correlation with the thermionic work functions selected by Bouwman and Sachtler (18). More scatter is noted when E_0 is plotted against the photoelectric work functions of the same authors.

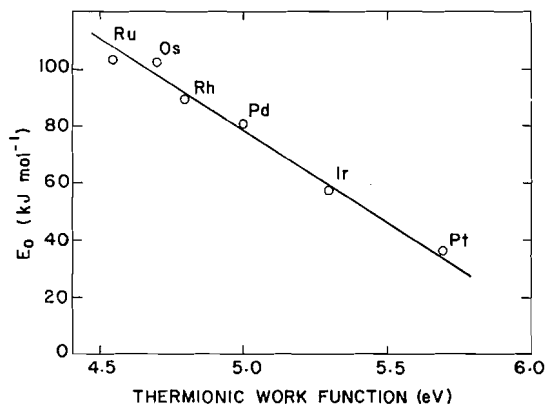

FIG. 4. Correlation of chemical activation energy with the thermionic work functions selected by Bouwman and Sachtler (ref. 18).

Discussion

The mechanism previously proposed for hydrogen–water exchange over platinum supported on alumina (3) and Graphon (6) is summarized below. It involves the adsorption of hydrogen and water vapor at different sites, I and II respectively.

[6] $H_2(g) + 2\,(I) \rightleftarrows 2H_{ads}$

[7] $HDO(v) + (II) \rightleftarrows HDO_{ads}$

[8] $H_{ads} + HDO_{ads} \rightleftarrows H_2O_{ads} + D_{ads}$

[9] $H_{ads} + D_{ads} \rightleftarrows HD\,(g) + 2(I)$

[10] $H_2O_{ads} \rightleftarrows H_2O\,(v) + (II)$

Reaction 8 is taken to be rate limiting, and this leads (3, 4) to the rate expression:

[11] $$k = k_8K_7K_{10}\theta_{H_2O}\theta_H$$

where k_i is the forward rate constant for reaction i and K_i is the equilibrium constant for equilibrium i. If equilibria are maintained between the gas and the surface, the product K_7K_{10} will be a constant corresponding to the isotope effect for adsorption of HDO relative to H_2O. Thus the ratio will be close to unity. Therefore

[12] $$k = k_8\theta_{H_2O}\theta_H$$

Reaction 8 may consist of a number of steps. Hallaba and Abdel-Wahab (19) have adopted the original suggestion of Farkas (20) that reaction 8 consists of the fast formation of a hydroxide film, followed by slow reduction of that film. However, if the adsorption of water does not affect adsorption of hydrogen, it is impossible to distinguish such a sequence kinetically from a single step reaction.

Taking reaction 9 as rate determining leads (4) to eq. 13

[13] $$k = k_9K_7K_8K_{10}\theta_H^2$$

As the reaction over all the metals showed some dependence on water pressure and a dependence on hydrogen pressure less than 0.5, it is unlikely that reaction 9 is rate determining. Conversely, if the rate of water adsorption were rate limiting, then

[14] $$k = k_7K_{10}\theta_{H_2O}$$

This case is not clearly excluded, because the high hydrogen pressures result in a weak dependence of rate on hydrogen pressure, *i.e.* a full hydrogen coverage is usually maintained. However for osmium and ruthenium a measurable dependence of rate on hydrogen pressure was observed. For these catalysts water adsorption–desorption is clearly not the rate determining step, and by implication it is unlikely for the other metals as well. Therefore the rate equation is taken as eq. 12 with chemical exchange rate-determining.

Our previous study (4) on platinum at lower temperatures indicated that exchange took place with water which was weakly bonded to the platinum, and that, kinetically, the water coverage was low. This work suggests that the water coverage on the metal is fairly high. The apparent contradiction may be resolved if we postulate that much of the water adsorbed on the support is kinetically equivalent to water adsorbed on the metal. Since Graphon untreated with chloride adsorbs little water, it would seem that the chloride forms the hydrophilic sites on the surface. The chloride is formed from decomposing particles of chloroplatinic acid, so it is reasonable to assume that most of the hydrophilic sites are formed close to the metal particles. The water adsorbed on these sites then participates in the reaction in a manner similar to that suggested by Rolston for alumina supported platinum (3).

From the experimental orders, obtained by fitting data to the empirical eq. 4, and the apparent activation energies, we can use eq. 5*b* to calculate and compare the true activation energies (E_0). These are taken to be activation energies for the surface exchange, reaction 8, although it is recognized that with different metals, reaction 8 may be broken down into a number of different steps, which may vary with the different metals.

We are now in a position to make some comparisons of activity patterns for this reaction as a function of the position of the metal in the periodic table (Fig. 3*a*). For the third triad metals, osmium, iridium, and platinum, specific activity rises steadily as the atomic number increases. For the second triad metals, ruthenium, rhodium, and palladium, the specific activity passes through a small maximum at rhodium in position 2 of group VIII. This pattern is remarkably similar to that observed by Dalla Betta *et al.* (21) for the hydrogenation of cyclopropane, a reaction termed facile by Boudart *et al.* (22). The activity pattern is very different for reactions such as the hydrogenolysis of ethane, where activities fall steeply in each triad with increasing atomic number (21). It is interesting to note that the hydrogenation of cyclopropane and of many olefins does not require dissociative chemisorption and may well proceed through π-bonded intermediates (21, 23). These reactions are usually facile as well. Thus the activity pattern observed suggests that hydrogen–water exchange is a facile reaction and that water may be not dissociatively bonded to the surface. The bonding may be by electron donation from p orbitals of the oxygen to the unfilled d bands of the metal (ref. 1, p. 219).

The chemical activation energies, E_0, fall as the atomic number rises in each triad, although the fall is much more noticeable in the third triad, (Fig. 3*b*). If our suggestions about the mechanism are correct, then E_0 corresponds to E_8, (eq. 12) and thus E_8 is lowered on the more noble metals of higher atomic number. Correlations of E_0 with various properties such as percentage d-band character, and metallic radius were attempted, but these only gave correlations within each triad. However, all the E_0's were well correlated with the thermionic work functions (Fig. 4). The slope of the line in Fig. 4 indicates that for each kJ mol^{-1} that the work function is raised, E_0 is lowered by 0.67 kJ mol^{-1}. The validity of this correlation is somewhat tentative, largely because of the great variations in reported work functions. However, we have taken a set of thermionic work functions collected by Bouwman and Sachtler (18). If the set of photoelectric work functions at 373 °A collected by the same authors (18) is used, in conjunction with their own recent value for palladium of 5.1 eV (24), a good correlation is obtained with a slope of -0.8. However, work functions are notoriously sensitive to variations in purity and surface structure. Thus the quantitative nature of the correlation is extremely tentative. It seems reasonably well established however that platinum has a higher work function than the other metals. As a point of reference, it should be noted that a recent determination of the gas phase equivalent to reaction 8 gives an activation energy of about 85 kJ mol^{-1} (25). The presence of a surface would alter this value, but nevertheless it is quite close to that observed over metals of low work function.

We have suggested (4) that the high work function of platinum and iridium relative to Graphon (4.5 eV) leads to significant negative charging of the metal, and consequently to a metal–hydrogen bond more polarized in the sense $M^{\delta+}$–$H^{\delta-}$. Such polarization should lower E_8. Similar electron donation has recently been postulated for the alkali metal promotion of supported ruthenium ammonia synthesis catalysts (26). This is our preferred interpretation in the light of our earlier work on carbon sup-

For personal use only.

ported Graphon, in which the activation energies for surface exchange fell with increased graphitizing temperature of the support. However, it is possible that the lower E_0's on iridium and platinum are due to properties of the metal alone, rather than to a metal–support interaction. Further work on unsupported metals, presently in progress, should show whether or not this is the case. Another alternative interpretation is that over the catalysts with the highest rates, the mechanism is changing to one where the adsorption–desorption of water is rate determining. In this case eq. 14 shows that we would be measuring E_7. The value of E_7, corrected for the order of the reaction and heat of adsorption, would be the activation energy for water adsorption which should be small. However, for reaction 7 to be rate determining, reaction 8 would have to be in equilibrium. Thus E_8 should have fallen to a value even lower than that quoted. Therefore this interpretation would not invalidate our conclusions about E_8.

No correlation was established between the reaction orders with respect to water and either the specific activity or the activation energy for surface exchange. On the other hand, some correlation was noted in the order with respect to hydrogen. For dissociative hydrogen adsorption Eley's approach equates b with $\frac{1}{2}(1 - \theta_H)$. Thus the hydrogen atom coverages are all unity with exception of the two least noble metals ruthenium ($\theta_H = 0.6 \pm 0.2$) and osmium ($\theta_H = 0.2 \pm 0.2$). For these two Graphon supported metals, the calculated hydrogen coverages are definitely lower than unity. This would account for the difficulty we encountered in measuring osmium surface areas by the usual techniques. No such difficulty has been noted by Sinfelt and co-workers using silica supported ruthenium and osmium (8, 27). Possibly this low hydrogen coverage results from an interaction between Graphon and the metal.

In summary, we have shown that the pattern of specific activities for hydrogen–water deuterium exchange is very similar to that for cyclopropane hydrogenation. Thus our hydrogen–water exchange is probably a "facile" reaction and shows much less variation in specific rate than does a demanding reaction such as ethane hydrogenolysis. In contrast to cyclopropane hydrogenation, however, surface activation energies fall for metals of higher work function. This may be truly a property of the metal, or it may result from a support effect whereby electrons are donated to the metal.

We thank W. M. Thurston, General Chemistry Branch, CRNL, for preparation and analysis of the deuterium-free water. E. E. Sexton of the Materials Science Branch, WNRE, took the electron micrographs. We also thank G. G. Strathdee, J. H. Rolston, and H. C. Chen for useful discussions.

Dielectric Loss of Adsorbed Polar Molecules[1]

T. McMULLEN

Department of Chemistry, St. Francis Xavier University, Antigonish, Nova Scotia

Received February 27, 1973

A theory of the dielectric susceptibility of polar gases adsorbed on ionic solids is presented. The rotational oscillator model of an adsorbed polar molecule is used, and dielectric loss is assumed to occur by phonon emission and absorption. For linear coupling of the rotational oscillator to the lattice vibrations, an exact solution is found using diagrammatic perturbation theory at finite temperature. In this model, appreciable loss is only found if the density of phonon states near the classical oscillator frequency is reasonably large, and it is suggested that this is to be expected in situations where the rotational oscillator model is valid. The method can be extended to more complex adsorbate–lattice interactions.

On présente une théorie traitant de la susceptibilité diélectrique de gaz polaires adsorbés sur des solides ioniques. On utilise le modèle d'oscillateur de rotation d'une molécule polaire adsorbée. De même, on suppose que la perte diélectrique se produit par émission et par absorption d'un phonon. En ce qui a trait au couplage linéaire de l'oscillateur de rotation avec les vibrations du réseau, on a trouvé une solution exacte en utilisant la théorie de perturbation graphique à température fixée. Dans ce modèle, on a trouvé une perte appréciable seulement lorsque la densité des états du phonon proches de la fréquence de l'oscillateur classique est suffisament grande; on propose que cet état doit prévaloir dans les situations où le modèle d'oscillateur de rotation est valide. La méthode peut être appliquée à des interactions réseauproduit adsorbé plus complexes. [Traduit par le journal]

Can. J. Chem., **51**, 4038 (1973)

Introduction

The interpretation of measurements of the dielectric behavior of adsorbed species (1) is a difficult task, and only the simplest of adsorbate–adsorbent systems as yet permit any sort of detailed description. Small polar molecules physically adsorbed on the surface of an ionic crystal form such a system, and have been investigated both experimentally (1, 2) and theoretically (1, 3). Often, it is assumed that a frequency dependent dielectric constant can be assigned separately to the adsorbed phase. This fundamental idealization permits one to ignore the effect of the field due to polarization induced in the solid when calculating the susceptibility of the adsorbed phase. The adsorbed molecules can be regarded simply as moving in a potential due to the surface in response to the applied field.

We will make this idealization here, and consider the dielectric susceptibility of an isolated small polar molecule adsorbed on the surface of an ionic crystal, such as hydrogen chloride on sodium chloride. The problem of assigning a dielectric constant to the adsorbed phase has been discussed previously (3), and we suppose that a reasonable "experimental" value of this susceptibility is available.

The rotational oscillator model of a small polar adsorbed molecule was introduced by Kurbatov (4), and its development has been reviewed by McIntosh (1). The most recent treatment is that of McMullen and McIntosh (3) who use a correlation function approach to determine the frequency dependent susceptibility. These authors introduce dielectric loss by proposing a "strong collision" type of approximation with a phenomonological mean free time. This mechanism, as the authors point out, does not seem to be a particularly realistic model of the physical system, and there seems to be no way of determining their relaxation time from first principles. It is this defect we wish to rectify in the present article by constructing a more detailed model of the interaction between the rotational oscillator and the vibrating crystal lattice of the adsorbent.

Dielectric loss is due to energy dissipation to the lattice vibrations. The oscillating electric field causes the adsorbed polar molecule to oscillate. The polar molecule is bound to the ions of the substrate, and thus exerts a force on these ions as it moves. This causes the adsorbate lattice itself to vibrate, and the phonons generated

carry energy away from the adsorbed molecule, and so indirectly from the oscillating electric field. Creation of additional phonons can, of course, be regarded as heating the lattice.

To describe this process we use the language of Green functions at non-zero temperature (5). This formalism provides a convenient and general approach, and allows us to include temperature effects. An approximation to the coupling of the adsorbed molecule to the lattice will be introduced in Section 3 which makes the problem exactly soluble, but corresponds to ignoring the temperature dependence of the susceptibility. Nevertheless, this approximation describes a tightly bound "true" rotational oscillator which makes only small excursions from equilibrium, and is applicable to rotational oscillators at low temperatures. Also, the main purpose of the present article is to outline an approach to the problem, and an exactly soluble model best serves this purpose.

Dielectric Susceptibility

Previous treatments of the rotational oscillator model of an isolated rotational oscillator on a surface have assumed a classical oscillator. In order to treat the interaction with the quantized lattice vibrations we use a quantized oscillator. The assumptions used in constructing the quantized oscillator model are essentially identical with those used in the classical model, and need no comment here. The quantum mechanical analog of the classical correlation function expression for the susceptibility (ref. 3, p. 1009) is needed and will be derived in this section.

The Hamiltonian of the crystal and N point dipoles in an electric field may be written as

$$H - \sum_{i=1}^{N} \boldsymbol{\mu}_i \cdot \boldsymbol{E}$$

where $\boldsymbol{\mu}_i$ is the dipole moment operator of the ith dipole, and the field is

$$\boldsymbol{E}(t) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} d\omega e^{-i\omega t} \boldsymbol{E}(\omega)$$

The dipole moment of the N oscillators is

$$[1] \qquad \boldsymbol{M}(t) = \left\langle \sum_i \boldsymbol{\mu}_i(t) \right\rangle$$

where $\langle\rangle$ indicates the trace over the canonical density matrix $\rho_0 = \exp\{\beta(\Omega - H)\}$ (the chemical potential of oscillators is zero, and $\beta = 1/kT$) characterizing the system at $t = -\infty$ before the field is switched on adiabatically.

Equation 1 is written in the Heisenberg picture. Changing to the interaction picture defined by the perturbation due to the field, and retaining only the terms

$$1 - i \int_{-\infty}^{t} dt' \sum_{i=1}^{N} \boldsymbol{\mu}_i(t') \cdot \boldsymbol{E}(t')$$

in the expansion of the time development operator, we find, to lowest order in $\boldsymbol{E}$

$$[2] \quad \boldsymbol{M}(t) = i \int_{-\infty}^{t} dt' \sum_{ij} \langle [\boldsymbol{\mu}_j(t') \cdot \boldsymbol{E}(t'), \boldsymbol{\mu}_i(t)] \rangle$$

([,] indicates the commutator of the two operators) if we take $\sum_i \langle \boldsymbol{\mu}_i \rangle = 0$. Writing M^E and μ_i^E for the components of $\boldsymbol{M}$ and $\boldsymbol{\mu}_i$ in the field direction, the frequency-dependent susceptibility of the dipoles is

$$[3] \qquad \chi(\omega) \equiv \frac{M^E(\omega)}{E(\omega)} = -i \sum_{ij} \int_0^{\infty} dt e^{i\omega t} \langle [\mu_i^E, \mu_j^E(t)] \rangle$$

This equation is the quantum analog of the classical expression for the susceptibility; the classical correlation function is replaced by the retarded commutator $-i\langle[\mu_i^E, \mu_j^E(t)]\rangle\theta(t)$ where $\theta(t)$ is the unit step function. The relation between the susceptibility and the dielectric constant is given in ref. 3.

If the dipole moments of the dipoles are permanent and of identical magnitude μ, the operator μ_i^E is μ times the operator giving the angle between the dipole orientation and the field direction, and can be expressed in terms of the angular displacement of the ith dipole from equilibrium. It is convenient to rewrite [3] as

$$[4] \quad \chi(\omega) = -2 \sum_{ij} \int_0^{\infty} dt e^{i\omega t} \operatorname{Im} \langle \mu_i^E(t) \mu_j^E \rangle$$

Since we do not know the actual adsorption sites, let us consider the dipoles to be adsorbed on a NaCl lattice as shown in Fig. 1. They are located along the lines joining positive and negative ions so that there are four equilibrium orientations, all equally populated. If a coordinate system is chosen so that the x and y axes lie along the equilibrium directions, if θ, ϕ indicate the field direction, and if $\phi_i = 0, \pi/2, \pi, 3\pi/2$ gives the equilibrium orientation of the ith dipole while x_i measures the angular devia-

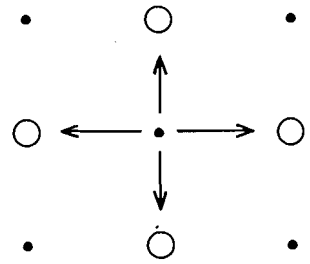

FIG. 1. The equilibrium positions of dipoles adsorbed on the (100) surface of a NaCl lattice.

tion from this position, we have

$$[5]\quad \mu_i^E = \mu \sin\theta\,[\cos(\phi - \phi_i)\cos x_i + \sin(\phi - \phi_i)\sin x_i]$$

The adsorbent consists of very many surfaces oriented at random to the field direction, however, and we must average over all angles θ,ϕ to obtain

$$[6]\quad \langle \mu_i^E(t)\mu_j^E\rangle = \frac{\mu^2}{3}[\cos\Delta_{ij}\langle\cos x_i(t)\cos x_j\rangle - \sin\Delta_{ij}\langle\sin x_i(t)\cos x_j\rangle + \sin\Delta_{ij}\langle\cos x_i(t)\sin x_j\rangle + \cos\Delta_{ij}\langle\sin x_i(t)\sin x_j\rangle]$$

where

$$\Delta_{ij} \equiv \phi_i - \phi_j$$

Trigonometric functions of operators are defined by their power series. Recognizing that equal time correlation functions are real, [4] and [6] give

$$[7]\quad \chi(\omega) = -\tfrac{2}{3}\mu^2 \sum_{ij}\int_0^\infty dt e^{i\omega t} \times \mathrm{Im}\{\cos\Delta_{ij}[\langle x_i(t)x_j\rangle + \tfrac{1}{4}\langle x_i^2(t)x_j^2\rangle + \ldots] + \tfrac{1}{2}\sin\Delta_{ij}[\langle x_i^2(t)x_j\rangle - \langle x_i(t)x_j^2\rangle + \ldots]\}$$

This is an expansion in increasing order correlation functions, and presumably for small displacements from equilibrium the higher order correlations can be neglected. If the oscillator is assumed to be tightly bound

$$[8]\quad \chi(\omega) \simeq -\tfrac{2}{3}\mu^2 \sum_{ij}\int_0^\infty dt e^{i\omega t} \times \mathrm{Im}\{\cos\Delta_{ij}\langle x_i(t)x_j\rangle\}$$

an approximation which is essentially that used to obtain equation 36 of ref. 3.

All dipoles are equivalent to the one at, say, $j = 0$, and ϕ_j can be arbitrarily chosen as zero so that [8] becomes

$$[9]\quad \chi(\omega) = -\tfrac{2}{3}N\mu^2 \sum_i \cos\phi_i \int_0^\infty dt e^{i\omega t} \times \mathrm{Im}\langle x_i(t)x_0\rangle$$

If surface coverage is so low that the dipoles do not interact with each other, then $\langle x_i(t)x_0\rangle = 0$ for $i \neq 0$, and we have the simple result

$$[10]\quad \chi(\omega) = -\tfrac{2}{3}N\mu^2 \int_0^\infty dt e^{i\omega t}\,\mathrm{Re}\{-i\langle x(t)x\rangle\}$$

where the subscript zero has been suppressed.

Oscillator on a Rigid Lattice

An isolated oscillator on a rigid lattice should give the $1/\tau_0 \to 0$ limit of the result given on p. 1009 of ref. 3. The Hamiltonian of an isolated rotational oscillator which does not interact with the adsorbate lattice vibrations:

$$[11]\quad H_{osc}^0 = p^2/2I + \tfrac{1}{2}k_0x^2$$

may, with the aid of the annihilation operator

$$[12]\quad c \equiv \frac{1}{\sqrt{2I\omega_c}}(I\omega_c x + ip)$$

where $\omega_c = \sqrt{k_0/I}$ is the classical oscillator frequency, be rewritten as

$$[13]\quad H_{osc}^0 = \omega_c(c^\dagger c + \tfrac{1}{2}),\quad \hbar = 1$$

On defining the "field" operator

$$[14]\quad \theta \equiv c + c^\dagger$$

for this oscillator, we have as well

$$[15]\quad x = \frac{1}{\sqrt{2I\omega_c}}\theta$$

Let us define the free time ordered Green function for the oscillator as

$$[16]\quad G_0(t) \equiv -i\langle(\theta(t)\theta^\dagger)_+\rangle$$

where $(\ )_+$ indicates the usual time ordering operator: that is

$$[17]\quad (A(t_1)B(t_2))_+ \equiv \begin{cases} A(t_1)B(t_2) & t_1 > t_2 \\ B(t_2)A(t_1) & t_1 < t_2 \end{cases}$$

if A and B are boson creation or annihilation operators (there is a sign change on reversing if A and B are fermion operators). The Green function is introduced as a time ordered product simply because it is easier to evaluate ground state expectation values of time ordered operator

products than, say, ordinary products. Since in [10] $t > 0$ it can be rewritten

$$[18]\quad \chi(\omega) = -\frac{N\mu^2}{3I\omega_c}\int_0^\infty dt e^{i\omega t}\,\mathrm{Re}\,G_0(t)$$

Using [14], G_0 is simple to evaluate, since

$$\langle (c(t)c)_+\rangle = \langle (c^\dagger(t)c^\dagger)_+\rangle = 0$$

and, with the aid of

$$c^\dagger(t) = \exp\{iH_{osc}{}^0 t\}\, c^\dagger \exp\{-iH_{osc}{}^0 t\}$$

$$[19]\quad \langle (c^\dagger(t)c)_+\rangle = \begin{cases}\langle c^\dagger c\rangle e^{i\omega_c t} & t > 0\\ \langle cc^\dagger\rangle e^{i\omega_c t} & t < 0\end{cases}$$

Similarly

$$[20]\quad \langle (c(t)c^\dagger)_+\rangle = \begin{cases}\langle cc^\dagger\rangle e^{-i\omega_c t} & t > 0\\ \langle c^\dagger c\rangle e^{-i\omega_c t} & t < 0\end{cases}$$

The creation and annihilation operators satisfy the commutation law $[c,c\dagger] = 1$, and $\langle c\dagger c\rangle$ is just the expectation value of the number of quanta present at the appropriate temperature

$$[21]\quad \langle c^\dagger c\rangle = \frac{\mathrm{Tr}\, e^{-\beta H^0_{osc}} c^\dagger c}{\mathrm{Tr}\, e^{-\beta H^0_{osc}}} = \frac{1}{e^{\beta\omega_c} - 1}$$

Thus

$$[22]\quad G_0(t) = -i\{e^{-i\omega_c t} f^{\pm}(\omega_c) + e^{i\omega_c t} f^{\mp}(\omega_c)\} \qquad t \gtrless 0$$

where

$$[23]\quad f^{\pm}(\omega) \equiv \pm\,[1 - e^{\mp\beta\omega}]^{-1}$$

so that after performing the time integral in [18]

$$[24]\quad \chi(\omega) = \frac{N\mu^2}{3I}\frac{1}{\omega_c{}^2 - \omega^2}$$

in agreement with ref. 3 as $1/\tau_0 \to 0$. The classical and quantum results are identical, as expected, since the possibility of tunneling has been ignored.

Oscillator–Phonon Coupling

The preceding treatment gives no loss; the susceptibility given by [24] is purely real. This happens, of course, because there is no means of dissipating energy from the field. If the oscillator is coupled to a deformable, rather than rigid, adsorbent lattice, energy from the field can be dissipated. The field causes the oscillator to oscillate, and its motion in turn sets the lattice vibrating, and the phonons so created carry away energy, essentially in the form of heat. Thus, our model must be supplemented in two ways; we must know how the oscillator is coupled to the phonons, and we must know something about the phonons themselves.

The lattice modes required are those of a crystal with a surface. Surface phonons can occur, and have been investigated (6 and references therein), and certainly an adsorbed molecule samples the vibrational modes at the surface. As we will see shortly, these modes should be determined, not for a clean surface, but for a surface plus an adsorbed molecule at its equilibrium orientation. These modes can be found and used in the following calculations. However, surface mode frequencies typically differ from bulk mode frequencies by a factor of only about $\frac{1}{2}$, and the translational symmetry of the bulk crystal leads to particularly simple expressions for ion displacements. Consequently, we make here the simplifying, although unnecessary, assumption that the lattice vibrations are those of the bulk lattice, and take for the Hamiltonian of the lattice

$$[25]\quad H^0{}_{latt} = \sum_{q\lambda}\omega_{q\lambda}(a_{q\lambda}{}^\dagger a_{q\lambda} + \tfrac{1}{2})$$

where $a_{q\lambda}$ annihilates a phonon of the λth mode and wavevector $\boldsymbol{q}$, and $\omega_{q\lambda}$ is the corresponding phonon frequency (7). A correct treatment would replace the quantum numbers $q\lambda$ with ones describing the true normal modes, although the form of $H^0{}_{latt}$ would remain unaltered.

The displacement from equilibrium of the bth ion in the lth unit cell is given by

$$[26]\quad \boldsymbol{\eta}_{l,b} = \sum_{q\lambda}(2\omega_{q\lambda}N_c M_b)^{-1/2}\, e^{i\boldsymbol{q}\cdot\boldsymbol{R}_l{}^0}\boldsymbol{\varepsilon}_{qb\lambda}\phi_{q\lambda}$$

where N_c is the number of unit cells, M_b the mass of the bth ion, $\boldsymbol{R}_l{}^0$ the position vector locating the lth cell, and

$$[27]\quad \phi_{q\lambda} = a_{q\lambda} + a^\dagger{}_{-q\lambda}$$

the phonon field operator. Sums over $\boldsymbol{q}$ are restricted to the first Brillouin zone throughout.

When the polar molecule is placed on the clean surface of the crystal at orientation x, there is an energy of interaction $u(x,\boldsymbol{\eta}_{l,b})$, which can be expanded as

$$u(x,\boldsymbol{\eta}_{l,b}) = u(0,0) + x\frac{\partial u}{\partial x} + \sum_{l,b}\boldsymbol{\eta}_{l,b}\cdot\frac{\partial u}{\partial \boldsymbol{\eta}_{l,b}} + \tfrac{1}{2}x^2\frac{\partial^2 u}{\partial x^2} + \tfrac{1}{2}\sum_{\substack{l,b\\ l',b'}}\boldsymbol{\eta}_{l,b}\cdot\frac{\partial^2 u}{\partial\boldsymbol{\eta}_{l,b}\,\partial\boldsymbol{\eta}_{l',b'}}\cdot\boldsymbol{\eta}_{l',b'} + \tfrac{1}{2}\sum_{l,b}x\cdot\frac{\partial^2 u}{\partial x\,\partial\boldsymbol{\eta}_{l,b}}\cdot\boldsymbol{\eta}_{l,b} + \cdots$$

where all derivatives are evaluated for x and all $\eta_{l,b}$ zero. The second term is zero, since $x = 0$ is the equilibrium orientation. The third describes the change induced in the equilibrium ion positions, and the fifth the change in the ion frequencies. We suppose that these two terms are included when determining the phonons. The fourth term is the harmonic potential $\frac{1}{2}k_0x^2$ of the dipole on the rigid lattice, and the sixth the interaction term of interest to us. Higher terms will be neglected.

In order to construct an explicit expression for this sixth term, the interaction of the oscillator with the phonons, the adsorption site and orientation of the adsorbed molecule must be known. Let us suppose that the oscillator is a point dipole located at the mid-point of the line joining a positive adsorbent ion to a negative one (Fig. 2). When the ions are at their equilibrium positions ($\eta_{l,b} = 0$), the potential acting on the rotational oscillator is $V(x) = \frac{1}{2}k_0x^2$. If the ions move, this is altered. The dipole's equilibrium orientation is different, and the force constant likely changes. That is, the potential is now $\frac{1}{2}k(\eta_{l,b})[x - \xi(\eta_{l,b})]^2$ where $k(\eta_{l,b} = 0) = k_0, \xi(0) = 0$. Presumably k and ξ depend only on the positions of the neighboring ions, which we call 1 and 2, and we may expand

$$[28] \quad k(\eta_{l,b}) = k_0 + \boldsymbol{\eta}_1 \cdot \boldsymbol{k}_1 + \boldsymbol{\eta}_2 \cdot \boldsymbol{k}_2 + \ldots$$

with

$$\boldsymbol{k}_1 \equiv \frac{\partial k}{\partial \boldsymbol{\eta}_1} \qquad \boldsymbol{k}_2 = \frac{\partial k}{\partial \boldsymbol{\eta}_2}$$

and

$$[29] \quad \xi(\eta_{l,b}) = \boldsymbol{\eta}_1 \cdot \boldsymbol{\xi}_1 + \boldsymbol{\eta}_2 \cdot \boldsymbol{\xi}_2 + \ldots$$

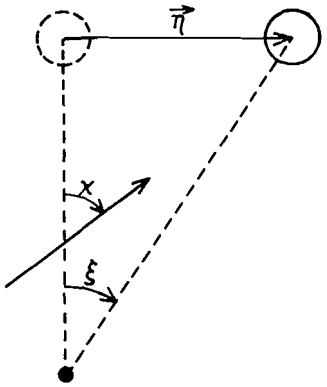

FIG. 2. Dipole on a deformed lattice.

where

$$\boldsymbol{\xi}_1 = \frac{\partial \xi}{\partial \boldsymbol{\eta}_1} \qquad \boldsymbol{\xi}_2 = \frac{\partial \xi}{\partial \boldsymbol{\eta}_2}$$

This gives for the change in potential seen by the oscillator on moving the ions from their equilibrium positions

$$[30] \quad \Delta V \equiv \tfrac{1}{2}k(\eta_{l,b})[x - \xi(\eta_{l,b})]^2 - \tfrac{1}{2}k_0x^2 = -k_0\boldsymbol{\xi}_1 \cdot x\boldsymbol{\eta}_1 - k_0\boldsymbol{\xi}_2 \cdot x\boldsymbol{\eta}_2 + \tfrac{1}{2}\boldsymbol{k}_1 \cdot x^2\boldsymbol{\eta}_1 + \tfrac{1}{2}\boldsymbol{k}_2 \cdot x^2\boldsymbol{\eta}_2 + \ldots$$

For small displacements of the ions (that is, low temperatures and weak coupling to the oscillators) the higher powers of ionic displacements can be neglected. In addition, let us suppose that the oscillator only makes small angular excursions from equilibrium as well, and retain only the first order terms in x. It is easy to formally include more $\boldsymbol{\eta}_{l,b}$'s, and write the interaction between a single rotational oscillator and the lattice as

$$[31] \quad H' = \sum_{l,b} \boldsymbol{g}_{l,b} \cdot \boldsymbol{\eta}_{l,b} x$$

where $\boldsymbol{g}_{l,b} = -k_0\,\boldsymbol{\xi}_{l,b}$. Using [15] and [26],

$$[32] \quad H' = \sum_{q\lambda} g_{q\lambda}\phi_{q\lambda}\theta$$

with

$$[33] \quad g_{q\lambda} \equiv \sum_{l,b} \frac{1}{\sqrt{4I\omega_c\omega_{q\lambda}N_cM_b}}\, e^{i\boldsymbol{q}\cdot\boldsymbol{R}_l^0}\boldsymbol{\varepsilon}_{qb\lambda} \cdot \boldsymbol{g}_{l,b}$$

The quantity $g_{q\lambda}$ measures the strength of the coupling between the rotational oscillator and the phonon of wavevector $\boldsymbol{q}$ and mode λ. The strongest coupling is to the optic modes, in which the positive and negative ions vibrate 180° out of phase, rather than to the acoustic modes, where they move in phase. We will see later, however, that this is not the only factor that determines which phonons are important in causing dielectric loss. Energy is also important, for the rotational oscillator tends to resonate with phonons of the same frequency.

Oscillator on a Vibrating Lattice

A single rotational oscillator interacting with an adsorbate lattice is described by the Hamiltonian

$$[34] \quad H = H^0 + H'$$

where the non-interacting part is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

[35] $$H^0 = H^0_{\text{osc}} + H^0_{\text{latt}}$$

In this situation, the susceptibility given by [10] becomes

[36] $$\chi(\omega) = -\frac{N\mu^2}{3I\omega_c}\int_0^\infty dt e^{i\omega t}\,\text{Re}\,G(t)$$

where

[37] $$G(t) = -i\langle(\theta(t)\theta^\dagger)_+\rangle$$

in contrast to [18] and [16]. The difference between [37] and [16] is the Hamiltonian; the operators are in a Heisenberg picture, and develop in time according to $\theta(t) = \exp\{iHt\}\theta \exp\{-iHt\}$ where in [37] H is given by [34], whereas in [16] H is just the H^0_{osc} of [13]. G_0 is the free Green function of the oscillator, and G is the true Green function.

The techniques for evaluation of thermodynamic Green functions such as [37] are by now well known, and are given in the books by Fetter and Walecka (5) or Abrikosov *et al.* (8). The methods have their origin in quantum field theory, although the extension to non-zero temperature (the thermodynamic Green function) was developed for the solid state many-body problem. They provide a very convenient way of handling the interactions of many particles, such as the large number of phonons in the present problem.

G is evaluated by exploiting the formal similarity of the time development operator exp $\{-iHt\}$ and the canonical density operator exp $\{-\beta H\}$ which, with $\tau = -i\beta$, may be written exp $\{iH\tau\}$. Let us generalize the definition [37] to imaginary time arguments in the interval $(-\tau,\tau)$ of the imaginary t-axis by specifying $-\tau$ as the "earliest time" and τ as the "latest time". This defines the ordering operation $(\ )_+$ for imaginary times in this interval. It is just a generalization, for it can be shown that $G(t)$ for real times is given by analytic continuation from $(0,\tau)$ for positive times and from $(-\tau,0)$ for negative times. There is a branch cut in the complex t-plane along the real axis. It turns out that $G(t)$ is periodic in the interval $(-\tau,\tau)$ and can be expanded as a Fourier series

[38] $$G(t) = \frac{1}{\tau}\sum_n G(\omega_n)e^{-i\omega_n t} \qquad \omega_n = \frac{2\pi n}{\tau}$$

where the sum runs over $n = 0, \pm1, \pm2, \ldots$. The existence of this series enables us to conveniently evaluate the required $G(t)$, continue to real time, and find the susceptibility from [36]. Rather than do this directly, however, it is easier to proceed somewhat differently.

The real part of $G(t)$ is, for $t > 0$

[39] $$\begin{aligned}\text{Re}\{-i\langle\theta(t)\theta^\dagger\rangle\} &= \tfrac{1}{2}\{-i\langle\theta(t)\theta^\dagger\rangle \\ &\quad + i\langle\theta\theta^\dagger(t)\rangle\} \\ &= -\frac{i}{2}\langle[\theta(t),\theta^\dagger]\rangle\end{aligned}$$

since θ is hermitian, and [36] may be rewritten as

[40] $$\chi(\omega) = -\frac{N\mu^2}{6I\omega_c}G^R(\omega)$$

using the expansion

[41] $$G^R(t) = \frac{1}{2\pi}\int_{-\infty}^{\infty} d\omega e^{-i\omega t}G^R(\omega)$$

where

[42] $$G^R(t) = -i\langle[\theta(t),\theta^\dagger]\rangle\theta(t)$$

That is, we have returned to [3] in order to find a concise and convenient expression for $\chi(\omega)$. The new function $G^R(t)$ is called the retarded Green function, as opposed to the time-ordered function [37]. We have pointed out that it is $G(t)$ which is convenient to evaluate, or more precisely the Fourier transform $G(\omega_n)$. The convenience of [40] is simply this: $G^R(\omega)$ is just the analytic continuation of $G(\omega_n)$ from the points ω_n to just above the real ω-axis; the appropriate continuation has been shown to be unique (9). This is the same thing as saying that $G(t)$ for positive times is the analytic continuation of $G(t)$ from $(0,\tau)$ so that using [40] instead of [36] merely saves Fourier transforming to the t-variable and then back again.

The procedure we now use for finding $G(\omega_n)$ is well known, and will only be outlined briefly. The t variable is considered to be in $(0,\tau)$ throughout. We change states and operators from the Heisenberg picture to the interaction picture defined by H', and so can write

[43] $$\begin{aligned}e^{-iHt} &\equiv e^{-iH^0t}U(t,0) \\ e^{-\beta H} &= e^{-iH^0\tau}U(\tau,0)\end{aligned}$$

where

[44] $$U(t,0) = \exp\left(-i\int_0^t dt'H'(t')\right)_+$$

Then

[45] $$G(t) = -i\langle(\theta(t)\theta^\dagger U(\tau,0))_+\rangle_0/\langle U(\tau,0)\rangle_0$$

where $\langle\rangle_0$ indicates the trace over the unper-

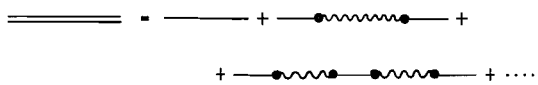

FIG. 3. The expansion of $G(t)$. G_0 is represented by a straight line, D_0 by a wiggley line, and $g_{q\lambda}$ by a dot. The double line represents G.

turbed density operator $e^{-\beta H^0}$. $U(\tau,0)$ is next expanded in powers of H', and the generalized (to non-zero temperatures) Wick's theorem (5) applied. The various terms in the expansion of numerator and denominator of [45] are most easily represented pictorially (*e.g.* Fig. 3); terms of odd order in H' vanish, unlinked diagrams cancel, and in order $2m$ there are precisely $(2m)!$ topologically equivalent diagrams. Hence, since $g_{-q\lambda} = g_{q\lambda}{}^*$:

$$[46]\quad G(t) = \sum_{m=0}^{\infty} \sum_{q_1\lambda_1} \cdots \sum_{q_m\lambda_m} |g_{q_1\lambda_1}|^2 \times |g_{q_2\lambda_2}|^2 \cdots |g_{q_m\lambda_m}|^2 \times \int_0^\tau dt_1 \cdots \int_0^\tau dt_{2m} G_0(t - t_{2m}) \times D^0{}_{q_m\lambda_m}(t_{2m} - t_{2m-1}) \times \cdots \times G_0(t_3 - t_2) D^0{}_{q_1\lambda_1}(t_2 - t_1) G_0(t_1)$$

where G_0 is as defined in [16], but with an imaginary time argument, and

$$[47]\quad D^0{}_{q\lambda}(t) = -i\langle \phi_{-q\lambda}(t) \phi^\dagger{}_{-q\lambda} \rangle_0$$

is the propagator for phonons of wavevector q and mode λ. $G_0(t)$ and $D^0{}_{q\lambda}(t)$ can be expanded in Fourier series as was $G(t)$ in [38]. Inserting these expansions in [46] we find

$$[48]\quad G(\omega_n) = \sum_{m=0}^{\infty} \sum_{q_1\lambda_1} |g_{q_1\lambda_1}|^2 \cdots \sum_{q_m\lambda_m} |g_{q_m\lambda_m}|^2 \times [G_0(\omega_n)]^{m+1} D^0{}_{q_1\lambda_1}(\omega_n) \cdots D^0{}_{q_m\lambda_m}(\omega_n)$$

The series sums to

$$[49]\quad G(\omega_n) = \frac{G_0(\omega_n)}{1 - G_0(\omega_n)\Pi(\omega_n)}$$

where

$$[50]\quad \Pi(\omega_n) = \sum_{q\lambda} |g_{q\lambda}|^2 D^0{}_{q\lambda}(\omega_n)$$

is the self energy of the rotational oscillator in this model.

$G_0(t)$ and $D^0{}_{q\lambda}(t)$ are easily found by the arguments following [20], since the operators involved now develop in time under the unperturbed Hamiltonian H^0, and

$$[51]\quad G_0(\omega_n) = \frac{2\omega_c}{\omega_n{}^2 - \omega_c{}^2}$$

$$[52]\quad D^0{}_{q\lambda}(\omega_n) = \frac{2\omega_{q\lambda}}{\omega_n{}^2 - \omega_{q\lambda}{}^2}$$

Thus, we have found $G(\omega_n)$, and since $G^R(\omega)$ is its analytic continuation to just above the real axis

$$[53]\quad G^R(\omega) = G(\omega + i\eta) = \frac{2\omega_c}{\omega^2 - \omega_c{}^2\left[1 + \frac{2}{\omega_c}\Pi(\omega + i\eta)\right]}$$

where η is a positive infinitesimal. $\Pi(\omega)$, and hence $G(\omega)$, has a branch cut along the real axis.

If ω_c, $g_{q\lambda}$, and $\omega_{q\lambda}$ are known, the susceptibility is given by combining [40], [53], [50], and [52]. The form of the result [53] is a general one, irrespective of the coupling between the oscillator and the phonons. Even if the coupling is nonlinear (or if there is phonon–phonon scattering), a self-energy $\Pi(\omega)$ can still be defined, although only for linear coupling is it given by [50]. The self-energy has both a real and an imaginary part, making $\chi(\omega)$ complex, and giving dielectric loss.

It is convenient to introduce the dimensionless weighted density of states

$$[54]\quad \alpha^2(\omega)F(\omega) \equiv \sum_{q\lambda} \frac{|g_{q\lambda}|^2}{\omega_{q\lambda}} \delta(\omega - \omega_{q\lambda})$$

where $F(\omega)$ is the usual phonon frequency distribution

$$[55]\quad F(\omega) \equiv \frac{1}{N_c} \sum_{q\lambda} \delta(\omega - \omega_{q\lambda})$$

and $\alpha(\omega)$ an "averaged" oscillator–phonon coupling. (This trick has been used elsewhere; a rather similar example is found in ref. 10.) The self energy may, using this, be written

$$[56]\quad \Pi(\omega) = \int_{-\infty}^{\infty} d\omega' \alpha^2 F(\omega') \frac{2\omega'}{\omega^2 - \omega'^2}$$

where to shorten the notation $\alpha^2(\omega)F(\omega)$ has been written $\alpha^2 F(\omega)$. $\alpha^2 F$ is zero except along a finite portion of the positive real axis, and $\Pi(\omega)$ has a cut extending along this portion. In addition, the denominator of [53] may have a zero on the real axis outside this cut, but elsewhere on the physical sheet $G(\omega)$ is analytic.

On separating the real and imaginary parts of the self-energy, [53] can be written

$$[57] \qquad G^R(\omega) = 2\omega_c \frac{\omega^2 - \omega_c^2 - 2\omega_c \operatorname{Re}\Pi(\omega) + 2i\omega_c \operatorname{Im}\Pi(\omega + i\eta)}{[\omega^2 - \omega_c^2 - 2\omega_c \operatorname{Re}\Pi(\omega)]^2 + [2\omega_c \operatorname{Im}\Pi(\omega + i\eta)]^2}$$

where, from [56]

$$[58] \quad \operatorname{Re}\Pi(\omega) = -\int_{-\infty}^{\infty} \omega' d\omega' \alpha^2 F(\omega') \left[\frac{1}{\omega' + \omega} + \frac{1}{\omega' - \omega}\right]$$

$$[59] \quad \operatorname{Im}\Pi(\omega + i\eta) = -\pi\omega[\alpha^2 F(\omega) + \alpha^2 F(-\omega)]$$

(In [58] $\int$ indicates that the principle value is to be taken). If an appropriate form for $\alpha^2 F$ is available (see, *e.g.*, ref. 10), that is, if the coupling and the lattice phonon spectrum are known, [58] and [59] can easily be evaluated, numerically if necessary. If we now set

$$[60] \qquad \Delta(\omega) \equiv \frac{2}{\omega_c} \operatorname{Re}\Pi(\omega)$$

$$[61] \qquad \Gamma(\omega) \equiv 2\omega_c \operatorname{Im}\Pi(\omega + i\eta)$$

then

$$[62] \quad \chi(\omega) = -\frac{N\mu^2}{3I} \frac{\omega^2 - \omega_c^2[1 + \Delta(\omega)] + i\Gamma(\omega)}{\{\omega^2 - \omega_c^2[1 + \Delta(\omega)]\}^2 + \{\Gamma(\omega)\}^2}$$

It is $\Gamma(\omega)$, that is, the imaginary part of Π, that determines the energy dissipation. The real part Δ merely shifts the frequency from that of the isolated oscillator ω_c, and $\omega_c\sqrt{1 + \Delta(\omega)}$ can be regarded as the effective classical oscillator frequency seen by an applied field of frequency ω. Δ is normally negative at lower frequencies, for the effective moment of inertia of the oscillator increases as it starts to drag part of the lattice along. If $G^R(t)$ is calculated, Γ acts as a damping factor governing the time rate of decay of a quantum of energy added to the oscillator.

Simple Phonon Model

In this section we attempt to gain some insight into the formula [62] by choosing the simplest possible model for $\alpha^2 F$, a model which is certainly only qualitatively valid. In a crystal with two atoms per unit cell, there are six phonon modes, three optic modes in which the two different ions move in opposite directions (*i.e.* 180° out of phase) and three acoustic modes in which the two ions move in phase near $q = 0$. Each group of three consists of a longitudinal and two transverse branches. (The phonon spectrum of sodium chloride has recently been measured by inelastic neutron scattering (11).)

The measuring frequencies used experimentally have been much lower than the typically THz frequencies of the optic modes, so that although the dipole is likely coupled most strongly to the optic modes, they do not, from [59], contribute to Γ in the frequency range of interest. They can provide a more or less frequency independent contribution to Δ, but it is the loss that is of interest here. Consequently, we include only the acoustic modes. Even assuming that the dipole is only coupled to the two ions in the unit cell at the origin, the resulting

$$[63] \quad g_{q\lambda} = \frac{1}{\sqrt{4I\omega_c\omega_{q\lambda}}} \left(\frac{\boldsymbol{\varepsilon}_{q1\lambda} \cdot \boldsymbol{g}_{01}}{\sqrt{M_1}} + \frac{\boldsymbol{\varepsilon}_{q2\lambda} \cdot \boldsymbol{g}_{02}}{\sqrt{M_2}}\right)$$

requires the polarization vectors in addition to the phonon dispersion curve. This author is unaware of any simple model that can be used to evaluate [63] directly, and it probably requires a calculation for the specific material of interest, as in the approach of Bergersen *et al.* (10). The detailed structure of $\alpha^2 F$ is likely not important, however. It would be very optimistic to suppose that dielectric measurements are a *sensitive* probe of surface phonons. Thus, let us assume that $\alpha^2 F$ is proportional to a constant effective coupling to acoustic phonons α_a^2 times the density of acoustic phonon states as given by the Debye model (*e.g.* Ziman 1964)

$$[64] \qquad \alpha^2 F(\omega) = 9\,\alpha_a^2 \omega^2/\omega_D^3$$

where ω_D is the Debye frequency for (all) the acoustic modes. This gives

$$[65] \qquad \Gamma(\omega) = -18\pi\alpha_a^2\omega_c(\omega/\omega_D)^3$$

and

$$[66] \quad \Delta(\omega) = -24\frac{\alpha_a^2}{\omega_c}\left[1 + 3(\omega/\omega_D)^2 + \tfrac{3}{2}(\omega/\omega_D)^3 \ln\left|\frac{\omega_D - \omega}{\omega_D + \omega}\right|\right]$$

Using these in [62], we find an explicit expression for $\chi(\omega)$ in this simple model, and this appears very different in form from the result of McMullen and McIntosh (3). However, as illustrated in Figs. 4 and 5, the resulting plots of

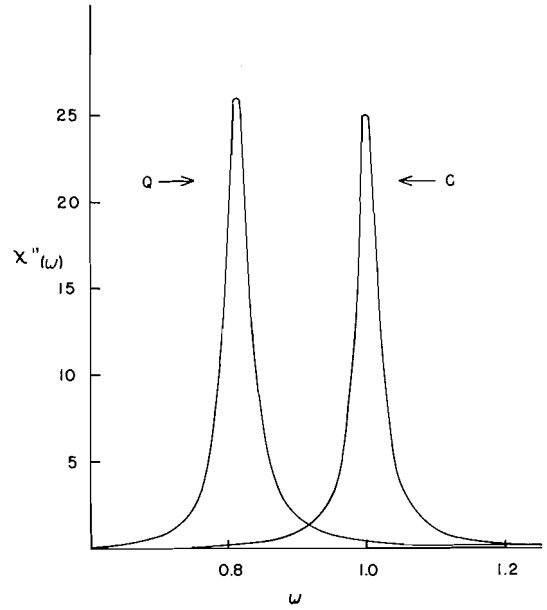

FIG. 4. The real part of the susceptibility as a function of frequency. Curve Q is the present result with $\alpha_a = 0.1$ and $\omega_D = 2\omega_c$. Curve C is the classical result of ref. 3 with $\tau_0 = 50$. Frequency is expressed in units of ω_c, and susceptibility in units of $N\mu^2/3I\omega_c^2$.

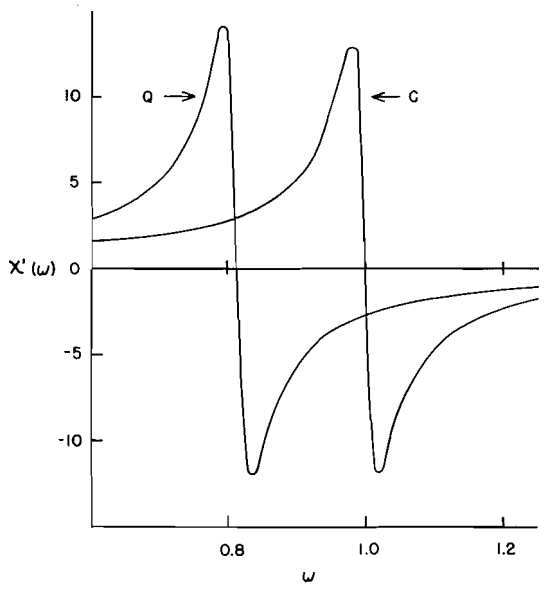

FIG. 5. The imaginary part of the susceptibility. Labels and units are as in Fig. 4.

the susceptibility are quite similar except for the frequency shift caused by $\Delta(\omega)$. In these figures, no serious attempt has been made to adjust the parameters to match peak height and width, and $\alpha_a = 0.1$ is likely an upper limit for any imaginable physical system.

Γ, due to its $(\omega/\omega_D)^3$ dependence, is almost vanishingly small in the frequencies (up to GHz, see *e.g.* ref. 1) usually employed experimentally in dielectric measurements. If ω_c is very much less than $\omega_D \sim 10^{12}$ s^{-1} the loss peak looks very much like a δ-function, and experimental loss peaks at MHz or GHz frequencies, of course, don't. This indicates that anharmonic terms in the oscillator–phonon coupling are very important, and that higher powers of x should be retained in [30] in order to properly describe the system if loss occurs at these frequencies. That is, the conditions for validity of the true rotational oscillator model are not very well satisfied. It is easy to demonstrate that this is to be expected, for if a dipole is a rotational oscillator at temperature T, $\frac{1}{2}k_0x^2 \gtrsim \beta^{-1}$ for x about 1 radian. Using a reasonable estimate of the moment of inertia of hydrogen chloride, we find

$$\beta\omega_c \gtrsim \sqrt{\frac{100\ ^\circ\mathrm{K}}{T}} \qquad [67]$$

as a necessary condition for rotational oscillations. Unless ω_c is high, that is, of the order of thermal energies, the adsorbed molecule is something between a free Debye rotator and a rotational oscillator.

Discussion

The dielectric susceptibility of a tightly bound rotational oscillator (one which makes only small excursions from its equilibrium orientation) has been calculated. It has not been necessary to introduce a phenomenological relaxation time as was done previously (3). Instead, a self energy appears naturally in the theory, and can be evaluated exactly in the simple model used. This self energy depends on the coupling of the adsorbed molecule to the substrate lattice and on the properties of the lattice phonons. The latter can be presumed known, for they can be independently measured by inelastic neutron scattering (11). The coupling must be derived from knowledge (or assumption) about the nature of the adsorption site and the

For personal use only.

forces between adsorbate and adsorbent. Thus, dielectric loss experiments are best regarded as measuring these forces, and the intention of this article has been to take a step toward making this measurement quantitative.

In addition, we have found that a "pure" rotational oscillator shows very little dielectric loss at frequencies much below typical phonon frequencies. It seems unlikely that an isolated adsorbed molecule will exhibit true resonance absorption at low frequencies. It should be emphasized, however, that in some systems the experimental results cannot be explained on the basis of a Debye rotator model, but show resonance behavior (1). It will be interesting to extend the present theory to non-linear couplings to find temperature dependent self energies, for even if the "pure" rotational oscillator model of this paper does not occur, the improved theory may realistically describe adsorbate–adsorbent systems in a microscopic way.

Discussions with B. Bergersen, R. L. McIntosh, D. A. Pink, and especially J. P. Carbotte were very helpful in clarifying the ideas presented here.

The Radiolysis of Water Vapor at Very High Dose Rates. I. Hydrogen Yields from H_2O, H_2O–HCl, and H_2O–HBr Mixtures[1]

A. W. Boyd, C. Willis,[2] and O. A. Miller

Physical Chemistry Branch, Chalk River Nuclear Laboratories, Atomic Energy of Canada Limited, Chalk River, Ontario

Received June 22, 1973

The plateau yields of hydrogen from the Febetron radiolysis of mixtures of water vapor with up to 8 mol% of HCl or HBr are $G(H_2) = 7.9 \pm 0.2$ and $G(H_2) = 4.6 \pm 0.2$ with 1 mol% SF_6. These yields are consistent with $G(H) = 7.45$ in pure water vapor and $G(H) = 4.15$ in water vapor with SF_6. In the Febetron radiolysis of pure water vapor at 2×10^{27} eV g^{-1} s^{-1} and densities of $\sim$1 mg ml^{-1} $G(H_2) = 1.65 \pm 0.05$ from 164 to 190 °C. This yield is reduced to $G(H_2) = 0.90 \pm 0.05$ on the addition of 1 mol% SF_6. Using a second order equivalent rate constant for the disappearance of the OH radicals in water vapor at 1 mg ml^{-1} of 2×10^{10} M^{-1} s^{-1} these yields are consistent with rate constant values for the reactions $H + OH (+H_2O) \rightarrow H_2O$, $OH + OH (+H_2O) \rightarrow H_2O_2$, and $H + H (+H_2O) \rightarrow H_2$, of $1.7 \pm 0.1 \times 10^{10}$ M^{-1} s^{-1}, $1.5 \pm 0.5 \times 10^9$ M^{-1} s^{-1}, and $3 \pm 1 \times 10^8$ M^{-1} s^{-1}, respectively.

Le rendement au palier en hydrogène lors de la radiolyse avec une Febetron de vapeur d'eau mélangée à des quantités allant jusqu'a 8 mol % de HCl ou HBr est $G(H_2) = 7.9 \pm 0.2$. Il devient $G(H_2) = 4.6 \pm 0.2$ lors de la présence supplémentaire de 1 mol % de SF_6. Ces rendements sont cohérents avec ceux obtenus pour la vapeur d'eau pure, $G(H) = 7.45$ et $G(H) = 4.15$ en présence de SF_6. Dans la radiolyse avec un Febetron de la vapeur d'eau pure à 2×10^{27} eV g^{-1} s^{-1} et aux densités 1 mg ml^{-1} $G(H_2) = 1.65 \pm 0.05$ entre 164 et 190 °C. Ce rendement est ramené à $G(H_2) = 0.90 \pm 0.05$ lors de l'addition de 1 mol % de SF_6. En utilisant une constante de vitesse équivalente au second ordre de 2×10^{10} M^{-1} s^{-1} pour la disparition des radicaux OH dans la vapeur d'eau à une densité de 1 mg ml^{-1}, ces rendements sont cohérents avec ceux des réactions $H + OH (+H_2O) \rightarrow H_2O$; $OH + OH (+H_2O) \rightarrow H_2O_2$; $H + H (+ H_2O) \rightarrow H_2$ en prenant pour constantes de vitesse respectivement les valeurs $1{,}7 \pm 0.1 \times 10^{10}$ M^{-1} s^{-1}; $1.5 \pm 0.5 \times 10^9$ M^{-1} s^{-1} et $3 \pm 1 \times 10^8$ M^{-1} s^{-1}.

Can. J. Chem., **51**, 4048 (1973)

Introduction

This paper gives the results of yield measurements from the Febetron radiolysis of pure water vapor and mixtures of water vapor with HCl and with HBr. The following paper (1) gives the results of both yield and isotope effect measurements from the Febetron radiolysis of H_2O–D_2O vapor mixtures.

This work was undertaken for two main reasons. The first of these is the difference in the radiolytic H atom yields derived from different low dose rate irradiations of water vapor. The total hydrogen yields from the radiolysis of water vapor with a few mole percent of alkanes or alcohols vary by little more than a G unit and have a maximum value of $G(H_2) = 9$ (ref. 2, Table 13 and references contained therein). Since the unimolecular decomposition of water vapor to hydrogen has a yield of $G(H_2) = 0.45$ (2) the H atom yield is not more than $G(H) = 8.5$. The exchange yield observed in the radiolysis of D_2–H_2O and H_2–D_2O mixtures is $G(HD) = 13.1 \pm 0.3$ (3) and this has been interpreted as a measure of the H atom yield. An obvious source of uncertainty in these systems is the neutralization reaction. We can specify neither the positive nor the negative ion involved and moreover they may well be different in the different mixtures. These uncertainties arise from the relative slowness of ion-neutralization reactions in low intensity experiments. Many ion–molecule reactions can occur before neutralization and only extremely low concentrations of products or impurities are required to change the identities of the ions which finally are neutralized (4). At Febetron intensities however because of high ion concentrations the ion neutralization reactions are very rapid and we can often specify with considerable certainty the identities of the ions in the neutralization process.

It is obviously of interest then to determine

the hydrogen yield from the Febetron radiolysis of water vapor. Ideally we should use the same systems as those used at low dose rates but interpretation of these systems is very complex at Febetron dose rates. For example at low dose rates in H_2O–c–C_6H_{12} mixtures the H atoms act simply as in reaction 1. At Febetron intensities the high radical concentrations reduce the yield by reactions 2–6 and make it difficult to obtain a precise H atom yield (5). We require then a scavenger which leads to H_2 yields that are unambiguous. Hydrogen chloride and hydrogen bromide react rapidly with both H atoms and OH radicals and the radical product of these reactions (Cl or Br atoms) react relatively slowly with H atoms. Also the radiolytic behavior of HCl and HBr at high dose rates is well established (6).

[1] $$H + C_6H_{12} \rightarrow H_2 + C_6H_{11}$$

[2] $$H + H + M \rightarrow H_2 + M$$

[3] $$H + OH + M \rightarrow H_2O + M$$

[4] $$OH + C_6H_{12} \rightarrow H_2O + C_6H_{11}$$

[5] $$H + C_6H_{11} + M \rightarrow C_6H_{12} + M$$

[6] $$H + C_6H_{11} \rightarrow H_2 + C_6H_{10}$$

The second reason for our present work is the possibility of establishing rate constants for reactions 3 and 7 in water vapor.

[7] $$OH + OH + M \rightarrow H_2O_2 + M$$

The rate constant for the second order disappearance of OH radicals in water vapor at 1 atm has been determined by Gordon and Mulac (7). Their value, which is largely the sum of $k_3 + 2k_7$ is $2 \times 10^{10}\ M^{-1}\ s^{-1}$. We could expect the hydrogen yield from H atom reactions in pure water vapor at Febetron intensities will be controlled mainly by reactions 2, 3, and 7. Reaction 2 is known to be slow relative to reactions 3 and 7 (8) therefore the observed hydrogen yield should be a function of the ratio of reactions 3 and 7.

Experimental

Irradiations and Dosimetry

The irradiations were done with a Febetron 705.[3] The samples were contained in quartz cells heated in a furnace as described in ref. 9. The mean absorbed dose in the cells using nitrous oxide dosimetry with $G(N_2) = 12.4$ (6, 10, 11) was 1×10^{20} eV g^{-1} per pulse. This dose is independent of density over the range of densities in these irradiations. The mean dose rate was $\sim 2 \times 10^{27}$ eV g^{-1} s^{-1}. The stopping power corrections in going from N_2O to H_2O, HCl, and HBr are 1.143, 0.925, and 0.76, respectively (6).

Materials and Analyses

The water was pre-irradiated and triply distilled. To free the water of dissolved gases it was injected from a micro-pipette into a liquid nitrogen cooled evacuated bulb through a rubber septum and then subjected to several freeze–pump–thaw cycles. The hydrogen bromide and hydrogen chloride were purified as described in ref. 6. The sulfur hexafluoride was purified by freeze–pump–thaw cycles.

The volume of radiolytic gas noncondensible at 77 °K was measured with a McLeod gauge and its composition was determined by mass spectrometry.

Results

H_2O–HCl, H_2O–HBr

The hydrogen yields from H_2O–HCl mixtures with and without 1 mol% SF_6 are shown in Fig. 1. These yields were calculated using the total energy absorbed in the mixture by both the H_2O and HCl but not by SF_6. The hydrogen yield from pure HCl is $G(H_2) = 8.0 \pm 0.2$ (6). Therefore the plateau yield of $G(H_2) = 7.9 \pm 0.2$ in Fig. 1 corresponds to the sum of the unimolecular hydrogen yield plus the hydrogen atom yield from pure water assuming all the hydrogen atoms react with HCl to give hydrogen.

The hydrogen yields from H_2O–HBr mixtures with and without 1 mol% SF_6 are shown in Fig. 2. These were calculated in the same way as in the H_2O–HCl mixtures. As the yield of hydrogen from pure HBr is $G(H_2) = 9.8 \pm 0.2$ (6) the plateau yield from H_2O–HBr mixtures $G(H_2) = 8.0 \pm 0.2$ must be decreased by 1 to 2%.

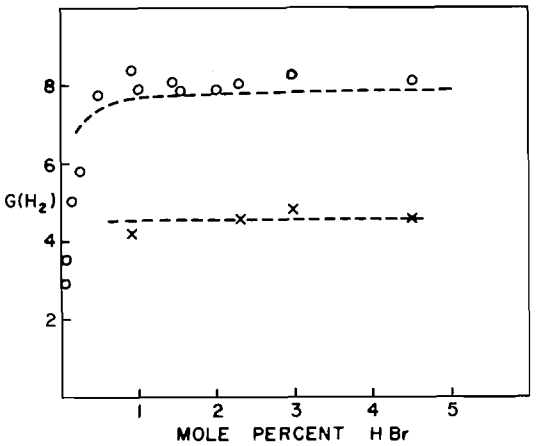

FIG. 2. Hydrogen yields from the Febetron radiolysis of water vapor – HBr mixtures. 2×10^{27} eV g^{-1} s^{-1}, 1×10^{20} eV g^{-1}, 160 °C, 1000 Torr. ○, H_2O–HBr; ×, H_2O – HBr – 1 mol% SF_6; ---, calculated; see discussion.

H_2O, H_2O–SF_6

The yields of hydrogen from the radiolysis of pure water vapor at temperatures from 164 to 400 °C and at doses in the range 1×10^{20} to 3×10^{20} eV g^{-1} are listed in Table 1. The yield in mixtures of water vapor with 1 mol% SF_6 at 164 °C, 1 mg ml^{-1}, 2×10^{27} eV g^{-1} s^{-1}, 1×10^{20} eV g^{-1} is $G(H_2) = 0.91 \pm 0.02$ based on three determinations. This yield was calculated using only the energy deposited in the water.

Discussion

H_2O–HCl, H_2O–HBr

The best values of the total hydrogen yields extrapolated to zero concentration of the additives from Figs. 1 and 2 appear to $G(H_2) = 7.9 \pm 0.2$ and $G(H_2) = 4.6 \pm 0.2$ in the presence of an electron scavenger. Taking the unimolecular yield of hydrogen from reaction 8 to be 0.45 (2) the yields of H atoms from water

[8] $$H_2O \rightsquigarrow H_2 + O$$

vapor are $G(H) = 7.45$ and $G(H) = 4.15$ in the presence of SF_6. The decrease with the addition of SF_6 $\Delta G(H_2) = 3.3$ is in very good agreement with the ion pair yield in water vapor as $W = 30 \pm 0.1$ eV (12–14).

We shall assume that the relative primary ion yields under our conditions are the same as the ion abundances determined by low pressure mass spectrometry. Combining these abundances with the above experimental yields and ion molecule reaction rates (ref. 2, Tables 2 and 9 and references contained therein) gives the following principal reactions for radical formation in water vapor.

[9] $$H_2O \rightsquigarrow H_2O^+ + e \qquad G = 2.7$$

[10] $$H_2O \rightsquigarrow H + OH^+ + e \qquad G = 0.6$$

[11] $$H_2O^+ + H_2O \rightarrow H_3O^+ + OH$$

[12] $$OH^+ + H_2O \rightarrow H_3O^+ + O$$

[13] $$H_3O^+ + nH_2O \rightarrow [H(H_2O)_{n+1}]^+$$

[14] $$[H(H_2O)_{n+1}]^+ + e \rightarrow H + (n+1)H_2O$$

[15] $$H_2O \rightsquigarrow H + OH \qquad G = 3.55$$

[8] $$H_2O \rightsquigarrow H_2 + O \qquad G = 0.45$$

The total yields then are $G(H) = 7.45$, $G(OH) = 6.25$, $G(O) = 1.05$, and $G_{H_2} = 0.45$. It would appear that no hydrogen atoms result from neutralization in the presence of SF_6. It might be argued that there are two H atoms per neutralization in H_2O–HCl or H_2O–HBr mixtures and that this yield is reduced to one on the addition of SF_6. This would mean, then, a dissociative excitation yield of less than one. Moreover, at low dose rates the energy available for neutralization does not appear to be sufficient to give 2 H atoms (3). Thus with SF_6, reaction 13 should be replaced by a reaction such as [16].

[16] $$[H(H_2O)_{n+1}]^+ + SF_6^- \rightarrow HF + SF_5 + (n+1)H_2O$$

The yields in this system are then $G(H) = 4.15$, $G(OH) = 6.25$, $G(O) = 1.05$, and $G_{H_2} = 0.45$.

It is clear that our values for the hydrogen produced by abstraction from the hydrogen halides support the low dose rate radiolysis values for hydrogen obtained by abstraction

§Using E_a = 5.2 kcal mol^{-1}.

from organic additives in water vapor. The yield of hydrogen or H atoms from dissociative excitation should be independent of dose rate. Even at Febetron dose rates neutralization of H_2O^+ or OH^+ reactions 17 and 18 will not

[17] $$H_2O^+ + e \rightarrow H + OH$$

[18] $$OH^+ + e \rightarrow O + H$$

compete with reactions 11 or 12 due to the high values of k_{11} and k_{12} (ref. 2, Tables 2 and 9) and the high concentration of H_2O. As discussed in the Introduction the identities of the ions in reaction 13 are expected to be dependent on dose rate and the nature of the additive. Certainly more extensive clustering of the positive ion will occur at the low dose rates as well as electron attachment to O_2. Despite these changes it appears that the H atom yield formed by ionic processes is close to the ion pair yield in both our hydrogen halide mixture and the low dose rate organic mixtures. We shall show in the following section that the reduction in the H_2 yield from the Febetron radiolysis of pure water vapor on the addition of SF_6 is also consistent with one H atom per neutralization.

We shall also discuss later the dependence of the H_2 yield on the concentrations of HCl and HBr.

H_2O, H_2O–SF_6

The observed yields of hydrogen in pure water vapor and water vapor – SF_6 mixtures are made up of the unimolecular hydrogen yield $G(H_2)$ = 0.45 and the net result of all the reactions of H atoms, OH radicals, and O atoms during and following the Febetron pulse. The yields of these species resulting from reactions 8–16 have been given in the preceding section.

The rate constants at 160 °C for the reactions of radicals and molecules that appear to be relevant at our conditions are listed in Table 2. It obviously cannot be assumed that the observed H_2 yields are a function of the primary yields and the rate constants of reactions 3 and 7 only. To determine the contributions of all these reactions to the hydrogen yield we have used the computer program of Schmidt (29). The input data are the primary yields and concentrations, the rate constants of the reactions, the total dose, and the length and shape of the electron pulse. The resulting calculated values include the concentration and yield of each species as a function of time and the contribution of each reaction. By using a range of values for each of k_2, k_3, and k_7 we were able to obtain calculated H_2 yields which agreed with the observed yields in both pure H_2O and H_2O containing SF_6. These values and the contributions of the other reactions are listed in Table 3. A measure of the uncertainty in the derived values of k_2, k_3, and k_7 rate constants is given by the results listed in Table 4. It can be seen that the observed hydrogen yields in both water vapor and water vapor – SF_6 mixtures can be

$k_3 = 1.3 \times 10^{10}$ $2k_7 = 7 \times 10^9$	1.78	1.09	1.95	1.14	2.15	1.23	2.28	1.28	2.46	1.34

fitted by the following range of values: $k_2 = 3 \pm 1 \times 10^8$ M^{-1} s^{-1}, $k_3 = 1.7 \pm 0.1 \times 10^{10}$ M^{-1} s^{-1}, and $2k_7 = 3 \pm 1 \times 10^9$ M^{-1} s^{-1}.

These values of k_3 and k_7 are of course based on $k_3 + 2k_7 = 2 \times 10^{10}$ M^{-1} s^{-1} (7). There is no value reported for k_2 under our conditions but the above range of values is consistent with what is known. Ham *et al.* (15) have determined the rate constant for H atom recombination with H_2 as the third body over the temperature range 77 to 300 °K and obtain a rate constant of $8.3 \pm 0.4 \times 10^{-33}$ cm^6 molecule^{-2} s^{-1} at 298 °K. This value and the calculated values of Shui and Appleton (16) together indicate a rate constant of 6×10^{-33} cm^6 molecule^{-2} s^{-1} at 160 °C (1×10^8 M^{-1} s^{-1} in H_2 at 1 atm). Thrush (8) puts an upper limit of 10 on the ratio k_{H+H+H_2O}/k_{H+H+H_2} at 300 °K.

The other major reactions occurring are [19]–[22]. The uncertainties in the first two of these are believed to be within ±50% and changes of this order in k_{19} and k_{20} do not change the calculated value of $G(H_2)$ by more than the experimental uncertainties in the

observed yields. There is no reported value of k_{21}, k_{22}, or k_{23} though their ratios are known (19) and Baulch *et al.* (30) recommend a value of 1×10^{10} M^{-1} s^{-1} for k_{21}. However changing k_{21} or k_{22} by a factor of four changes the calculated value of $G(H_2)$ by less than 5%.

The increase in $G(H_2)$ with temperature is most probably due to the temperature dependence of reaction 3, the major reaction of H atoms. The activation energies of reactions 19–22 should be small. We are now in a position to calculate the concentration dependence of the hydrogen yields from the radiolysis of the water vapor – hydrogen halide mixtures. The rate constants for the reactions occurring in these mixtures, in addition to those in Table 2, are listed in Table 5.

The hydrogen yields calculated using the computer program are shown by the broken lines in Figs. 1 and 2. The agreement between the calculated and observed values is in general within the experimental errors. We have discussed the relation of the uncertainties in the rate constants in Table 2 to the calculated $G(H_2)$ values for water vapor. There are also uncertainties in the rate constants for the atom recombination reactions in Table 5, *i.e.* [34], [36], [40], and [42].

To determine if limits can be set on these rate constants or those previously discussed *e.g.* k_2, k_3, the contributions of each reaction to the hydrogen yield in the water vapor – hydrogen halide mixtures have been calculated for different concentrations. The results are shown in Table 6.

At low concentrations *i.e.* 0.2 and 1 mol% HCl and 0.2 mol% HBr the calculated hydrogen yield can be seen to be dependent on a large number of rate constants. There are large uncertainties in k_{34}, k_{36}, k_{40}, and k_{42} and in k_2 and k_7. It is thus very difficult to set limits on these uncertainties by comparison of the calculated and observed yield at these concentrations.

At 6 mol% HBr the contributions of reactions 41 and 42 are so small that even a factor of 10 increase in k_{41} and k_{42} would not affect the calculated hydrogen yield. This shows that practically all the H atoms react as in [38] and that the observed hydrogen yield is a true measure of the H atom yield from water vapor. In 6 mol% HCl the calculated yield is slightly lower than the observed yield. This difference cannot be accounted for by any reasonable changes in k_{34} or k_{37}. The results can however be used to set an upper limit on k_{36}. Assuming that its contribution cannot be more than 0.3 G units $k_{36} \leqslant 3 \times 10^9$ M^{-1} s^{-1}.

Conclusions

The yields of hydrogen from the Febetron radiolysis of water vapor – HCl and water vapor – HBr mixtures $G(H_2) = 7.9 \pm 0.2$ are in agreement with those from the low dose rate radiolysis of water vapor – alkane mixtures. In both systems the hydrogen yields are reduced by approximately 3 G units on the addition of an electron scavenger. Since the ion pair yield in water vapor is 3.3 there is a yield of an H atom per neutralization.

The yields of hydrogen from pure water vapor and water vapor with an electron scavenger are $G(H_2) = 1.65$ and $G(H_2) = 0.90$. Taking the unimolecular yield of hydrogen to be $G_{H_2} = 0.45$ the yields of hydrogen resulting from the reactions of hydrogen atoms are $G(H_2) = 1.2$ in pure water vapor and $G(H_2) = 0.45$ in the presence of an electron scavenger. These yields are consistent with one H atom per neutralization. From these yields a set of rate constants for the reactions for the recombination of H atoms and OH radicals can be derived, *i.e.*

$$H + OH + (H_2O) \rightarrow H_2O$$
$$k = 1.7 \pm 0.1 \times 10^{10}\ M^{-1}\ s^{-1}$$

$$OH + OH + (H_2O) \rightarrow H_2O_2$$
$$2k = 3 \pm 1 \times 10^{9}\ M^{-1}\ s^{-1}$$

$$H + H + (H_2O) \rightarrow H_2$$
$$k = 3 \pm 1 \times 10^{8}\ M^{-1}\ s^{-1}$$

Comparison of the observed hydrogen yields in water vapor – HCl mixtures with those calculated from the H atom yields and the reaction rate constants leads to an upper limit of $3 \times 10^{9}\ M^{-1}\ s^{-1}$ for the reaction

$$H + Cl\ (+H_2O) \rightarrow HCl$$

The Radiolysis of Water Vapor at Very High Dose Rates. II. Isotope Effects in the Hydrogen Yield from H_2O–D_2O Mixtures[1]

A. W. Boyd, C. Willis,[2] and O. A. Miller

Physical Chemistry Branch, Chalk River Nuclear Laboratories, Atomic Energy of Canada Limited, Chalk River, Ontario

Received June 22, 1973

The isotope effect in the formation of hydrogen has been measured for H_2O–D_2O mixtures (10–90% H_2O, 0.5–1.0 mg ml^{-1}, 412–138 °C) with and without 1 mol% SF_6 at 2×10^{27} eV g^{-1} s^{-1}. The values of α ((H/D) radiolytic hydrogen/(H/D) H_2O–D_2O) for the reactions of hydrogen atoms are in the range 3–6 varying with H/D ratio of the substrate. Consideration of possible mechanisms for these large α values leads to the conclusions that reaction of the hydrogen atoms to form hydrogen involves the substrate and that the species H_3O may be formed as an intermediate.

L'effet isotopique dans la formation d'hydrogène a été mesuré pour des mélanges H_2O–D_2O (10–90% H_2O. 0.5–1.0 mg ml^{-1}, 412–138 °C) en présence et en absence d'une mol % de SF_6 à 2×10^{27} eV g^{-1} s^{-1}. Les valeurs de α ((H/D) hydrogène radiolytique /(H/D) H_2O–D_2O) pour les réactions des atomes d'hydrogène varient de 3 à 6 en fonction du rapport H/D du substrat. L'étude des mécanismes possibles pour ces grandes valeurs de α amène à conclure que la réaction des atomes d'hydrogène pour former l'hydrogène fait intervenir le substrat et que les espèces H_3O peuvent se former comme intermédiaires.
[Traduit par le journal]

Can. J. Chem., **51**, 4056 (1973)

Introduction

The results in the preceding paper (1) are consistent with a total H atom yield of $G(H) = 7.45$ and a yield of one H atom per neutralization both in irradiated pure water vapor and water vapor – hydrogen halide mixtures. They support the H atom yields derived from the low dose rate irradiations of water vapor – alkane mixtures (2) but provide no explanation for the high yields of $G(HD) = 13.1$ obtained in low dose rate irradiations of H_2O–D_2 and D_2O–H_2 mixtures (3).

However the results in ref. 1 do show that there is a measurable, consistent hydrogen yield from the Febetron radiolysis of water vapor that does not change over a considerable range of absorbed dose and temperature (at least below 250 °C). We have carried out a study of the isotope effects in this hydrogen yield both as a further study of radiolytic isotope effects in water (4) and in the hope that the results might resolve the high exchange yields.

Experimental

The methods of sample preparation, irradiation, dosimetry, and measurements of the total hydrogen formed were the same as those described in ref. 1.

The H_2, HD, and D_2 contents of the hydrogen were determined with a calibrated CEC-21-610 mass spectrometer. The calibration was done with mixtures of H_2 and D_2 equilibrated on a platinum filament at 900–950 °C (see ref. 4 for details).

Both the H_2O (isotopic D content 150 p.p.m.) and D_2O (isotopic purity 99.58%) were preirradiated and triply distilled.

Results

The values of α as a function of H_2O concentration[3] at a dose rate of 2×10^{27} eV g^{-1} s^{-1}, 160 °C, and a vapor density of 1 mg ml^{-1} are shown in Fig. 1 for H_2O–D_2O vapor mixtures with and without 1 mol% SF_6. It can be seen that there is a large isotope effect in both the pure system and that containing the electron scavenger.

The total hydrogen yields for the same mixtures and conditions are shown in Fig. 2. The yields are constant and can be taken to be G (total hydrogen) $= 1.65 \pm 0.15$ in H_2O–D_2O and G(total hydrogen) $= 0.90 \pm 0.15$ in H_2O–D_2O, 1 mol% SF_6 over the whole range of H_2O concentration.

The α values and total hydrogen yields from the irradiation of 66.6 mol% H_2O – 33.3 mol% D_2O mixtures at temperatures from 138–412 °C are listed in Table 1.

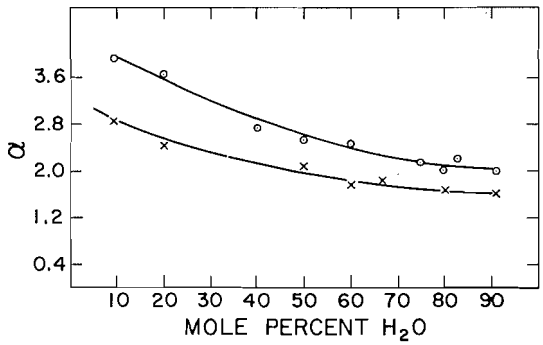

FIG. 1. Measured isotope effects in the total yield of hydrogen from H_2O–D_2O vapor irradiations. Dose 1×10^{20} eV g^{-1}; average dose rate 2×10^{27} eV g^{-1} s^{-1}, 1000 Torr, 160 °C, (vapor density 1 mg/ml). ○, H_2O–D_2O; ×, H_2O–D_2O + 1 mol% SF_6.

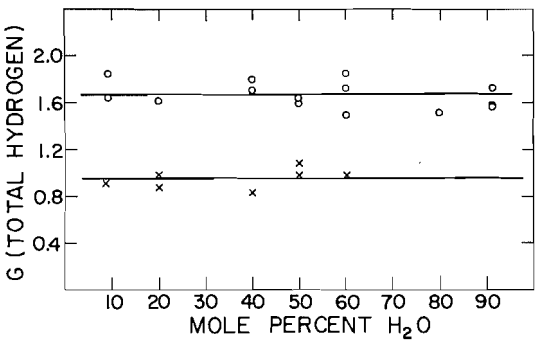

FIG. 2. Hydrogen yields from H_2O–D_2O vapor irradiations. Dose 1×10^{20} eV g^{-1}; average dose rate 2×10^{27} eV g^{-1} s^{-1}; 1000 Torr, 160 °C. ○, H_2O–D_2O; ×, H_2O–D_2O + 1 mol% SF_6.

Correction for Unimolecular H_2 Yield

The observed hydrogen yields in Fig. 2 are made up of the unimolecular yield of hydrogen and the hydrogen resulting from the reactions of hydrogen atoms. The value of the former which is assumed to be due to reaction 1 is the same in both H_2O and D_2O and has the value $G_{H_2} = G_{D_2} = 0.45$ (2).

[1] $$H_2O \rightsquigarrow H_2 + O$$

If this molecular yield is correctly represented by reaction 1 then approximately one-third of the hydrogen in pure water and one-half the hydrogen in water vapor containing 1 mol% SF_6 must be produced with no isotope effect. The observed α values in Fig. 1 were corrected to obtain the isotope effect in the reactions of H atoms as follows. The amounts of radiolytic H_2, HD, and D_2 from reaction 1 were calculated from the isotopic content of the H_2O–D_2O mixture. This isotopic content was calculated assuming that $K = (HDO)^2/(H_2O)(D_2O) = 4$. This is the maximum value that K can have and the minimum must be greater than 3.74, the value at 25 °C (5). Both values give the same concentrations of H_2O, HDO, and D_2O within 2% in our mixtures. These amounts of H_2, HD, and D_2 from [1] were subtracted from the total amounts of H_2, HD, and D_2 formed. Corrected α values were then calculated using the remaining concentrations of H_2, HD, and D_2. These corrected α values are shown in Fig. 3. As can be seen the corrected α values vary from $\alpha \approx 3$ for high H_2O to $\alpha \gtrsim 6$ for high D_2O and are practically the same in the presence and absence of SF_6.

Discussion

Isotope Effects in the Formation of H Atoms

The inference to be drawn from the identity of the corrected α values with and without SF_6, that is with and without ionic contributions, is that the separation factors for atom production by ionic and non-ionic processes are equal. At first sight this would appear to be in conflict with low dose rate observations. Johnson and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 84.22.46.98 on 09/08/12

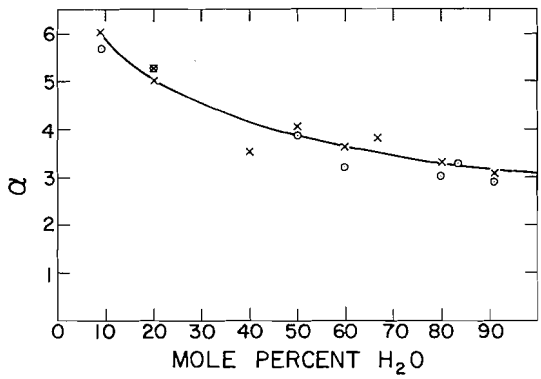

FIG. 3. Isotope effects in the reactions of hydrogen atoms from H_2O–D_2O vapor irradiations. Dose 1×10^{20} eV g^{-1}; average dose rate 2×10^{27} eV g^{-1} s^{-1}, 1000 Torr, 160 °C. ○, H_2O–D_2O; ×, H_2O–D_2O + 1 mol% SF_6.

Simic (6) irradiated H_2O–D_2O vapor mixtures at 140 °C in the presence of 1.5 mol% propane at 10^{16} eV g^{-1} s^{-1}. Under these conditions all the H and D atoms from the water vapor abstract a H atom from the propane and any isotope effect in their formation is reflected in the yields of H_2 and HD. They used mixtures with and without SF_6 and corrected for the unimolecular contribution to the yields by the same method as we have used above. They obtained $\alpha = 1.1 \pm 0.1$ for the formation of hydrogen atoms by dissociative excitation and $\alpha = 2.1 \pm 0.4$ for the formation of hydrogen atoms by neutralization reactions.

The results in ref. 1 indicate that the yield of H atoms from dissociative excitation of H_2O is independent of dose rate over the range 10^{16} to 10^{28} eV g^{-1} s^{-1}. We would expect therefore that there should be no effect of dose rate on any isotope effect in the dissociative excitation of HOD. Indeed, it is difficult to envisage an intensity effect if dissociative excitation is a simple Franck–Condon controlled, "vertical" excitation process. Thus Johnson and Simic's value of $\alpha = 1.1 \pm 0.1$ should be valid at Febetron dose rates. However as discussed in ref. 1 the ionic processes which lead to the formation of H atoms will be different at the two dose rates. The probable reaction sequences are:

10^{27} eV g^{-1} s^{-1}

[2] $H_2O \rightarrow H_2O^+ + e$

[3] $H_2O^+ + H_2O \rightarrow H_3O^+ + OH$

[4] $H_3O^+ + nH_2O \rightarrow [H(H_2O)_{n+1}]^+$

[5] $[H(H_2O)_{n+1}]^+ + e \rightarrow H + (n+1)H_2O$

10^{16} eV g^{-1} s^{-1}

[2] $H_2O \rightarrow H_2O^+ + e$

[6] $e + O_2 + H_2O \rightarrow O_2^- + H_2O$

[3] $H_2O^+ + H_2O \rightarrow H_3O^+ + OH$

[7] $H_3O^+ + \begin{pmatrix} H_2O \\ C_3H_8 \end{pmatrix} \rightarrow [?]$

[8] $[?]^+ + O_2^- \rightarrow H + [?]$

Although reactions 5 and 8 both give one H atom there may be different isotope effects in these reactions.

As discussed above within our experimental error we do not see any difference in the α values with or without 1 mol% SF_6 and it therefore seems most reasonable to assume that there is no isotope effect in the formation of H atoms either by dissociative excitation or ionic processes in the Febetron irradiations, in other words α is close to unity for both processes.

Mechanism of the Isotope Effect

From the above discussions and the results of the calculations described in ref. 1 the isotope effect observed appears to arise from radical reactions, essentially reactions 9–14. The contributions of the other reactions to the hydrogen yield are so small that it is unlikely that they can produce any sizeable effect.

[9] $H + H + H_2O \rightarrow H_2 + H_2O$

[10] $H + OH + H_2O \rightarrow 2\,H_2O$

[11] $O + OH \rightarrow O_2 + H$

[12] $H + O_2 + H_2O \rightarrow HO_2 + H_2O$

[13] $H + HO_2 \rightarrow H_2 + O_2$

[14] $H + HO_2 \rightarrow 2\,OH$

Measurements of the isotope effect for reactions 9 and 12 have been reported but with third bodies other than H_2O. The ratio of k_{H+H+H_2}/k_{D+D+D_2} given by Ham *et al.* is 1.4 (7). This is in agreement with the calculations of Roberts and Bernstein (8). Bennett and Blackmore (9) however, report a value of 0.8 for this ratio. For the ratio k_{H+O_2+M}/k_{D+O_2+M} in reaction 12 Baldwin *et al.* (10) obtain 0.86 at 500 °C, M = H_2, and Clyne and Thrush (11) obtained 0.7 ± 0.2 at 293 °K and 0.9 ± 0.2 at 244 and 225°K, M = Ar, and 0.6 ± 0.2 at 293°K, M = He.

Reaction 9 is significantly slower than the other reactions. This means that hydrogen atoms will only react to form hydrogen by reaction

9 when few OH radicals remain unreacted and therefore these H atoms have a single reaction channel. No isotope effect due to the rate of this reaction then will be reflected in the hydrogen produced. This, coupled with the small α values observed for this reaction with other third bodies, suggests that there should be little preference for a change in the H/D ratio due to reaction 9. From the previous work discussed above, the isotope effect due to reaction 12 is expected to be small and if anything in the opposite direction to our overall observed α values.

Thus, if the observed isotope effect is to be explained by reactions 9–14, the explanation must reside in reactions 10, 11, 13, and 14. Reactions 11, 13, and 14 are very fast and consequently must have very small activation energies and a small isotopic dependence of their rate constants. For reaction 10 to account for the observed α values it is required that $k_{10H} < 3k_{10D}$. This seems very unlikely in view of the observed isotope effects in reactions 9 and 12. More significantly this inequality would result in a markedly lower total hydrogen yield with increasing D_2O concentration, in direct contrast to the observed consistency of that yield over the entire composition range studied. Furthermore, the yields as a function of temperature for 66.6% H_2O – 33.3% D_2O agree very well with those for 100% H_2O (1).

We have made extensive calculations, of the type described in ref. 1, to try and fit the radical mechanism to explain the observed α values and at the same time the constant total hydrogen yield. We varied each of the significant rate constants by a factor of four about the best value given in the tables. Although it was possible to obtain an α value ≈ 3, approximately constant over the concentration range, this gave a decrease in the total hydrogen yield as the concentration of D_2O was increased. We were unable to fit a mechanism to an increasing α value from 3–6 with a constant total hydrogen yield.

It seems, therefore, that the observed α values cannot be explained by primary processes nor by the simple radical mechanism discussed above.

An alternative mechanism which can possibly account for the α values is isotopic exchange with the substrate during the formation of hydrogen by reaction 9, and possibly reaction 13. This can schematically be envisaged as, for example

[9′] $$H + H + D_2O \rightarrow HD + HDO$$

Immediately this would explain the independence of the total hydrogen yield on the H_2O–D_2O ratio.

For a reaction of the type [9′] we must postulate a first step of the form of reaction 15

[15] $$H + H_2O \rightarrow H_3O$$
$$D + H_2O \rightarrow H_2DO$$
$$H + HDO \rightarrow H_2DO$$
$$\text{etc.}$$

This could be followed either by reaction 16 or reaction 17

[16] $$H + H_2DO \rightarrow H_2 + HDO$$
$$D + H_2DO \rightarrow H_2 + D_2O$$
$$\text{etc.}$$

[17] $$H_3O + H_2DO \rightarrow H_2 + H_2O + HDO$$
$$D_3O + HD_2O \rightarrow HD + 2\,D_2O$$
$$\text{etc.}$$

What we mean these reactions to imply is association of the H atom or D atom with the substrate, for example H···HDO, and that when the associated atom reacts by [16] or [17] the molecules of association are intimately involved in the complex which decomposes to give hydrogen with preferential elimination of H_2 (or HD) rather than HD (or D_2). We do not necessarily mean to imply a complete equivalence of the three hydrogen atoms in the associated atom system, H_3O, etc.

The existence of an H_3O species is not a new suggestion. From mass spectroscopic measurements it has been suggested that H_3O can be formed with an appreciable lifetime (12). Also on the basis of simple thermodynamic cycles both $H(H_2O)$ and $H(NH_3)$ have predicted stabilities of at least 5–10 kcal mol^{-1} (13). More generally, chaperone mechanisms for three body reactions of the type

$$A + B \rightarrow AB$$
$$AB + A \rightarrow A_2 + B$$

implicitly require an associated atom of the type H_3O, etc.

Any significant involvement of reactions 18 or 19

[18] $$H + D_2O \rightarrow HDO + D$$

[19] $$H + D_2O \rightarrow HD + OD$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 84.22.46.98 on 09/08/12
For personal use only.

or isotope variations of these reactions appears to be ruled out by their high activation energies, 19–22 kcal (3), and the small temperature dependence of our observed α values.

We cannot distinguish between reactions 16 and 17 on the basis of the increase from $\alpha \approx 3$ to $\alpha \approx 6$ on going from high to low H_2O/D_2O ratios. At high H_2O concentrations the α value is dependent on k_{16}/k_{16a} or k_{17}/k_{17a}, at high D_2O concentrations α is largely dependent on k_{16b}/k_{16c} or k_{17b}/k_{17c}. We would expect that if $k_{16b}/k_{16c} > k_{16}/k_{16a}$ then $k_{17b}/k_{17c} > k_{17}/k_{17a}$.

[16a] $H + H_2DO \rightarrow HD + H_2O$

[17a] $H_3O + H_2DO \rightarrow HD + 2H_2O$

[16b] $D + HD_2O \rightarrow HD + D_2O$

[16c] $D + HD_2O \rightarrow D_2 + HDO$

[17b] $D_3O + HD_2O \rightarrow HD + 2D_2O$

[17c] $D_3O + HD_2O \rightarrow D_2 + HDO + D_2O$

This mechanism provides a possible explanation of the high exchange yields of Bibler and Firestone (3), *i.e.*, $G(HD) = 13.1 \pm 0.3$ in the radiolysis of both D_2–H_2O and H_2–D_2O mixtures. This high HD yield could be due to the contributions of reactions 15 and 20 in D_2–H_2O mixtures and of reactions 15 and 21 in H_2–D_2O mixtures.

[15] $D + H_2O \rightarrow H_2DO$

[20] $D_2 + H_2DO \rightarrow HD + D + HDO$

[20a] $D_2 + H_2DO \rightarrow D_2 + D + H_2O$

[15] $H + D_2O \rightarrow HD_2O$

[21] $H_2 + HD_2O \rightarrow HD + H + HDO$

[21a] $H_2 + HD_2O \rightarrow H_2 + H + D_2O$

This mechanism requires that the stability of H_3O be great enough to survive several thousand encounters with H_2O before reacting with H_2. This could be possible if only vibrational de-excitation of the initially formed associated atom occurred in the collisions with H_2O. There will also be D atoms in D_2–H_2O mixtures and H atoms in H_2–D_2O mixtures from reactions 22 and 22a.

[22] $D_2 + OH \rightarrow HDO + D$

[22a] $H_2 + OD \rightarrow HDO + H$

To account for the observed increase of $G(HD) \approx 6.7$ by this mechanism requires then the ratios k_{20}/k_{20a} and k_{21}/k_{21a} be approximately equal and less than unity. Their values are of course dependent on the chain length. It would appear that these requirements are possible but we cannot say more on the basis of our present knowledge.

Conclusions

It is difficult to explain the observed α values of 3–6 for the hydrogen found in the Febetron radiolysis of H_2O–D_2O vapor mixtures without assuming H atoms react with involvement of the substrate and presumably the formation of a hydrogen atom water molecule complex. That this complex should be H_3O is supported by mass spectrometric evidence (12) and thermodynamic considerations (13).

Isotope effects in the reactions of H_3O may explain the high exchange yields in H_2O–D_2O or D_2O–H_2O radiolysis as well as the α values reported in this paper.

It is of interest that there are also kinetic data supporting the formation of the analogous radical NH_4 in H atom – ammonia mixtures. Back and Terao (14) have obtained a value for the rate constant for the recombination of NH_2 radicals of $4 \times 10^{10}\ M^{-1}\ s^{-1}$. We have shown (15) that in 1 atm of NH_3 the rate constant for the reaction between NH_2 and H atoms to form NH_3 is $\approx 10 k_{NH_2+NH_2}$. We have also shown (15) that in 1 atm of NH_3 the rate constant for the removal of H atoms by propene is $\approx 0.5 k_{H+NH_2}$. The resulting values of k_{H+NH_2} and $k_{H+C_3H_6}$ are $\sim 4 \times 10^{11}$ and $1 \times 10^{10}\ M^{-1}\ s^{-1}$, respectively. The former is much larger than could be reasonably expected and the latter is almost certainly less than $10^9\ M^{-1}\ s^{-1}$ (16, 17). A possible explanation of both these anomalies is that the rate constants obtained are for the reactions of NH_4 with NH_2 and C_3H_6.

The Rotational Oscillations of Tetrahydrofuran in Tetrahydrofuran Clathrate Hydrate[1]

D. D. KLUG AND E. WHALLEY

Division of Chemistry, National Research Council of Canada, Ottawa, Canada

Received June 8, 1973

The absorptivity of tetrahydrofuran clathrate hydrate in the range 70–7 cm^{-1} has been measured at several temperatures in the range 17–80 K. There are two broad bands with maxima at 25 and 38 cm^{-1} which are due to the rotational oscillations of tetrahydrofuran molecules in their cages. The integrated absorptivity yields an effective dipole moment for the oscillation of 1.63 D, which is close to the gas-phase value. The negative second moment of the absorptivity yields the contribution 0.105 $\pm$ ~0.007 to the low-frequency refractive index, in good agreement with a less accurate value from dielectric measurements. The orientational disorder of the water molecules causes a distribution of potentials hindering the rotational oscillations of the guest molecules, and a detailed analysis of the shapes of the bands yields directly the distribution of force constants for the oscillations.

La capacité d'absorption du clathrate hydraté de tétrahydrofuranne entre 70 et 7 cm^{-1} a été mesurée pour des températures variant de 17 à 80 K. Il y a deux bandes larges avec des maxima à 25 et 38 cm^{-1} qui sont causées par les oscillations de rotation des molécules de tétrahydrofuranne dans leur environnement. La valeur de la capacité d'absorption a permis d'évaluer le moment dipolaire effectif à 1.63 D ce qui est une valeur proche de celle de la phase gazeuse. La valeur du second moment négatif de la capacité d'absorption a apporté une contribution de 0.105 $\pm$ 0.007 à l'indice de réfraction à base fréquence, ce qui est en accord avec la valeur moins précise obtenue par mesures diélectriques. Le désordre d'orientation des molécules d'eau provoque une distribution de potentiels perturbant les oscillations de rotation des molécules-hôtes. Une analyse détaillée de la forme des bandes a permis d'obtenir directement la distribution des constantes de force pour les oscillations.

Introduction

The intensity of absorption by the intermolecular translational and rotational motions of molecules in molecular crystals is not well understood in detail, in contrast with the intensity of absorption due to the translational motion of ions, which is understood in reasonable detail in simple salts (1). The dipole absorption arises, of course, from rotational motions of permanent dipole moments and from induction of dipole moments due to intermolecular interaction.

The only reasonably accurate intensities due to rotational vibrations so far reported appear to be on carbonyl sulfide (2), chlorine and bromine cyanide (3), ice (4, 5), hydrogen chloride and bromide (6) (the translational vibrations were included in these measurements), and hydrogen cyanide (7). The three studies on hydrogen-bonded systems concluded that the librating dipole was appreciably less than that in the vapor, presumably because of incompletely understood polarization occurring in the crystals, whereas those on chlorine and bromine cyanides and on carbonyl sulfide gave good agreement with the calculated intensities based on gas-phase dipole moments. Thus, although non-hydrogen-bonded crystals appear to be reasonably well understood, only three examples have been studied.

Absorption by induced moments is well understood in crystalline hydrogen (8), which has been studied in great detail from many points of view. The sum of the intensities of the two translational vibrations in solid carbon dioxide (9) agrees well with that expected for quadrupole – induced dipole moments (10) but the ratio of intensities is 1.5 instead of 5.4 as calculated, perhaps because of uncertainties in the normal coordinates used in the theory. The integrated intensity of the translational vibrations in α-nitrogen (11) is only one fourth of that expected for quadrupole-induced moments. The integrated absorption due to the translational vibrations of ice is about 1/16 of that expected for dipole- and quadrupole-induced dipole moments (12), and that of crystalline chlorine is about 1/35 of that calculated for quadrupole-induced dipole moments (13). It must be

concluded that absorption due to induced moments is not well understood at all except in the simplest molecules.

The main purpose of this paper is to further our understanding of the intensities of intermolecular vibrations by reporting the absorptivity of the rotational vibrations of the guest molecule in a solid in which there is little coupling of the rotational vibrations. The rotational vibrations of tetrahydrofuran in its clathrate hydrate have been studied mainly for the following reason. Tetrahydrofuran clathrate hydrate, which has structure II and is ideally $C_4H_8O \cdot 17H_2O$ (14), has an infrared polarizability derived from dielectric measurements (15) that corresponds to a contribution of 0.11 ± 0.05 to the low-frequency refractive index and that is not due to the water molecules. This has been attributed by Davidson (15) to the rotational oscillations of the tetrahydrofuran molecules in their cages, and a frequency of about 20 cm^{-1} was deduced from an approximate treatment. One of the purposes of the present measurements was to verify this absorption and determine from it the infrared contribution to the low-frequency refractive index.

Because the tetrahydrofuran molecules are far enough apart that coupling between the rotational oscillations of neighbors is small (see Section 3 of Results), the restoring force is due almost entirely to the interaction between the guest and the water molecules in the cage wall and so something can be learned about these from the frequencies. In addition, since the water molecules in the clathrate are orientationally disordered, the forces between the guest and the cage may vary from cage to cage, and the breadth of the bands extrapolated to 0 K should be a measure of the effect of the orientational disorder on these forces. Rotational oscillations of some molecules in clathrates have been observed previously (16–19), but none in clathrate hydrates, except one report of the detection of low-frequency absorption in ethylene oxide clathrate hydrate (20), and no integrated intensities have been reported except an approximate estimate of the intensity of hydrogen chloride in β-quinol clathrate (16).

Experimental methods

Eastman Kodak tetrahydrofuran was refluxed over and distilled from calcium hydride, and was supplied by Dr. S. R. Gough.

Tetrahydrofuran clathrate hydrate was prepared by freezing in a shallow Teflon cup solutions that had about 1% more tetrahydrofuran than in the ideal stoichiometric composition, to guard against possible loss by evaporation. It was held, along with a few drops of tetrahydrofuran that was not in contact with the sample to ensure a saturated atmosphere, for at least 24 h at 0 C in an ice bath to allow complete conversion (21), and was then cooled to ~100 K in the cold gas from rapidly boiling liquid nitrogen. The surface of the hydrate was scraped level with the rim of the cup using a cooled razor blade, and the thickness of the sample plus the base of the cup was measured to ±25 μm by a cooled micrometer. The sample thickness was obtained from this measurement and the thickness of the base of the cup measured at the same temperature. The sample thicknesses were uniform to ±25 μm and covered the range 0.58 to 1.32 mm.

The sample was covered with a cap that was wedged to prevent interference fringes and was mounted, using silicone grease to improve thermal contact, in the cold finger of a Sulfrian Cryogenics liquid-helium-cooled optical Dewar fitted with wedged polyethylene windows. The sample was cooled to the required temperature in the range 17–80 K by pumping liquid helium from the reservoir through a tube in the cold finger. The temperature of the cup was measured by a chromel–constantan thermocouple attached to it by a screwed copper ring, using silicone grease to increase thermal contact, and was kept to ±1 K of the required temperature. The thermocouple e.m.f. was measured to ±0.1 μV by a Cambridge Vernier potentiometer and was calibrated at the temperature of boiling liquid nitrogen, hydrogen, and helium.

Sulfur hexafluoride hydrate (22) containing more than 90% hydrate and less than 10% ice was supplied to us by Dr. S. R. Gough and Dr. D. W. Davidson. The fine powder that was supplied was pressed into discs of the required thickness in the range 1–2 mm at 195 K under a pressure of about 300 bar, and these were placed in the Teflon cups.

The spectrometer was an R.I.I.C. lamellar grating LR-100 interferometer operating in the range 70–4 cm^{-1} using vitreous silica (23) or the crossed-transmission-grating low-pass filters supplied with the instrument. The spectra at temperatures >17 K were taken with a Unicam SP-50 Golay cell, and the 17-K spectra were taken with a Texas Instruments doped-germanium bolometer fitted with cold wedged crystal quartz and cold black polyethylene filters. The spectrometer was evacuated to about 50 μm Hg except for the sample chamber which was isolated from the optical chamber by a wedged polyethylene window and was purged with dry air. A resolution of 0.9 cm^{-1} was used for all samples at 17 K and 0.45 cm^{-1} for all other samples, with scan times of 35 or 70 min. The background run for each sample was taken at the sample temperature with the cap placed on the base of the empty Teflon cup. Triangular apodization was used in processing the spectra.

In calculating the absorptivity, the reflection loss from the various surfaces was allowed for. The background spectra were obtained with the base of the wedged cap in contact with the base of the cup in an attempt to remove interference fringes. But intereference fringes due to the base of the cup were obtained except at the lowest frequencies, showing that complete optical contact

between the base of the cup and the cap was not obtained. In the sample configuration, it was assumed that the sample was in good contact with the base of the cup, but, by analogy with the observations of the preceding sentence, not with the cap. Above about 20 cm^{-1}, the effect of errors in these assumptions, such as uncertain gaps and differences between the refractive index of the sample and the cup, might cause an error in the absorptivity of $\sim$1 cm^{-1}, compared with the standard deviation of duplicate runs (see below) of $\sim$1 cm^{-1}. The reflection error falls below $\sim$20 cm^{-1} because the effect of the gap decreases with increasing wavelength.

Results and Discussion

The absorptivity of tetrahydrofuran clathrate hydrate at various temperatures is shown in Fig. 1. The 17-K spectrum was obtained from the average of four spectra and four backgrounds on each of two samples 0.635 and 0.584 mm thick and three spectra and three backgrounds on a sample 1.32 mm thick. The spectrum consists of two broad absorption bands centered at 25 and 38 cm^{-1}. The standard deviation of the absorptivity for duplicate runs on the sample averaged at several frequencies was $\sim$0.5 cm^{-1}, and the standard deviation for the three sets of spectra averaged at several frequencies in the region of overlap was $\sim$0.6 cm^{-1}. The spectra at temperatures higher than 17 K were the average of two or more spectra on samples of different thicknesses.

The apparent absorptivity of the compressed powder of sulfur hexafluoride clathrate hydrate, which also has structure II (22), is largely due to scattering from the interfaces of the particles it was made from, and it is not clear that any absorption was detected. It has, however, no absorption comparable to that of the two strong bands in tetrahydrofuran hydrate. These two bands are therefore due to the rotational oscillations of tetrahydrofuran.

The tetrahydrofuran molecule appears to be nearly planar in the equilibrium configuration but with a small barrier to pseudorotation, and the polar axis appears to be a principal axis of inertia (24). The equilibrium configuration appears to be of C_2 symmetry, but is not far from the planar C_{2v}. It is enclosed in cages which on the average have the symmetry T_d but which depart from the average symmetry due to the disorder of the orientations of the water molecules. A tetrahydrofuran molecule in an average cage will by symmetry oscillate about the principal axes if its symmetry is taken as C_{2v}. However, in a real disordered cage it will not in general oscillate about its principal axes and the normal coordinates of the oscillations are not known. This is of no consequence for the treatment of Sections 1 and 2 of Results. In Section 3 of Results, the average interaction constants for rotations about the principal axes, which is zero by the average symmetry if the molecule is C_{2v}, will be assumed to hold for all cages.

(1) Integrated Absorptivity

There are three degrees of rotational freedom per molecule, and these can be characterized by small rotational displacements θ_x, θ_y, θ_z about the three principal axes of inertia. In general, a normal vibration will consist of the coupled oscillations of neighboring molecules. The tetrahydrofuran molecules are contained in the hexakaidecahedral cages whose centers are 7.40 Å apart (25). The main mechanism for the coupling of the rotational vibrations of molecules in neighboring cages is the dipole–dipole interaction. Maximum coupling occurs when the dipoles are in line, and the coupling constant is then

$$[1] \qquad \frac{\partial^2 V}{\partial\theta_1\partial\theta_2} = \pm\frac{2\mu^2}{r^3}$$

where θ_1 and θ_2 are the displacements in the same plane of the dipolar axes of the molecules from the line of the cage centers, and the polarization of the intervening water molecules is neglected. Since the centers of the cages are 7.40 Å apart the coupling constant from eq. 1 is $\pm$13 ferg rad^{-2}.[2] This value is an upper limit because the dipoles will usually be less favorably oriented and because the intervening water molecules will be polarized. It is therefore much smaller than the rotational force constants due to interaction with the cage, which are 600 and 450 ferg rad^{-2} for rotation about the two nonpolar axes (see below), and so coupling between neighboring molecules can be neglected.

The normal coordinates Q_1, Q_2, and Q_3 for the rotational vibrations of a molecule are related to the moment-of-inertia-reduced rotational displacements ϕ_x, ϕ_y, ϕ_z about the principal axes by the matrix relation

$$[2] \qquad \mathbf{Q} = \mathbf{L}\boldsymbol{\phi}$$

where $\mathbf{Q}$ and $\boldsymbol{\phi}$ are the vectors representing the normal and reduced rotational coordinates and

[2] 1 ferg = 10^{-15} erg.

L is the transformation matrix. Because the kinetic energy T can be written

$$[3] \qquad 2T = \tilde{\dot{Q}}\dot{Q} = \tilde{\dot{\phi}}\dot{\phi}$$

where $\tilde{Q}$ is the transpose of Q, the matrix **L** is orthonormal. The integrated intensity of absorption of normal vibration i of a polycrystal is (26)

$$[4] \qquad A_i = \frac{(n^2 + 2)^2}{9n}\frac{N\pi}{3c^2}\left(\frac{\partial\mu}{\partial Q_i}\right)^2$$

where n is the refractive index excluding the effects of the band being considered, N the number density of molecules, c the speed of light, and μ the dipole moment of the crystal.

If the refractive index is the same for all bands to a sufficient approximation, the sum of the integrated intensities is proportional to $\tilde{\boldsymbol{\mu}}_Q\,\boldsymbol{\mu}_Q$ where $\boldsymbol{\mu}_Q$ is the vector with components $|\partial\boldsymbol{\mu}/\partial Q_1|$, etc. But

$$[5] \qquad \boldsymbol{\mu}_Q = \boldsymbol{L}^{-1}\,\boldsymbol{\mu}_\phi$$

where $\boldsymbol{\mu}_\phi$ is the vector with components $\partial\boldsymbol{\mu}/\partial\phi_{\alpha i}$, etc., $\alpha = x, y,$ or z, and i denotes the particular molecule so that

$$[6] \qquad \tilde{\boldsymbol{\mu}}_Q\boldsymbol{\mu}_Q = \tilde{\boldsymbol{\mu}}_\phi\,\tilde{\boldsymbol{L}}\boldsymbol{L}\boldsymbol{\mu}_\phi$$

Since **L** is orthonormal, eq. 6 implies that

$$[7] \qquad \tilde{\boldsymbol{\mu}}_Q\boldsymbol{\mu}_Q = \tilde{\boldsymbol{\mu}}_\phi\boldsymbol{\mu}_\phi$$

and so

$$\tilde{\boldsymbol{\mu}}_Q\boldsymbol{\mu}_Q = \sum_{\substack{\alpha=x,y,z\\ i}}\left(\frac{\partial\mu}{\partial\phi_{\alpha i}}\right)^2 = N\sum_{\alpha=x,y,z}\frac{{\mu_\alpha}^2}{I_\alpha}$$

where $\boldsymbol{\mu}_\alpha$ is the dipole moment of the ith molecule perpendicular to the α principal axis, I_α the moment of inertia about that axis. The integrated intensity of absorption is therefore independent of the coupling of the motions about the principal axes. This is a special case of a more general sum rule due to Gordon (27).

The translational vibrations, which are active because of induced moments, can be included in this treatment. The measured absorption includes them, but the spectrum of sulfur hexafluoride hydrate suggests that they are much weaker than those due to the permanent moment, and for present purposes they can be neglected. The reason for this can be seen qualitatively from the following crude arguments. For rotational vibrations $(\partial\mu/\partial Q)^2$ is of the magnitude μ^2/mr^2 where μ is the dipole moment, m the mass of an atom, and r an intramolecular distance. Since μ is of the magnitude er where e is the electronic charge, the intensity is proportional to a quantity like e^2/m. For the translational vibrations in which the activity is due to induction of a dipole in neighboring molecules,

$$[8] \qquad \left(\frac{\partial\mu}{\partial Q}\right)^2 = \frac{\alpha^2}{M}\left(\frac{\partial E}{\partial a}\right)^2$$

where α is the polarizability of a molecule, E is the electric field of the permanent dipole, a is a typical intermolecular distance, and M is a molecular weight. α is of the magnitude r^3 and $(\partial E/\partial a)^2$ is of the magnitude e^2r^2/Ma^8.

It follows that $(\partial\mu/\partial Q)^2$ is of the magnitude $e^2(r/a)^8/M$. The ratio of intensities of permanent and dipole-induced moments is therefore of the magnitude $(r/a)^8\ m/M$. Since r/a is the ratio of typical intra- and intermolecular distances, it is about 1/2, and m/M is 1/2 or less, so the ratio of intensities is of the magnitude $(1/2)^9$. The induced intensity is therefore of the magnitude of 0.002 of the intensity due to the rotation of the permanent dipole, and it can be neglected.

For tetrahydrofuran, one of the principal axes is, according to the pure rotational microwave absorption of the vapor (24), within experimental error coincident with the polar axis. Rotation about this axis will therefore not be observed in the infrared. If the polar axis is the z axis, it follows that the total integrated absorption A is

$$[9] \qquad A = \frac{(n^2 + 2)^2}{9n}\frac{N\pi}{3c^2}\mu^2\left(\frac{1}{I_x} + \frac{1}{I_y}\right)$$

independent of the actual form of the normal vibrations, if n can be taken as independent of wave number. The limiting low- and high-frequency refractive indexes of the clathrate on either side of the absorption band differ by 0.105 (see below). Since the limiting low- and high-frequency refractive indexes are about 1.76 and 1.87, the limiting low- and high-frequency values of $(n^2 + 2)^2/9n$ are 1.795 and 1.64, and to a sufficient accuracy the actual values can be replaced by the mean.

Since the water molecules in the clathrates are orientationally disordered, there are no selection rules governing their infrared activity, and the water molecules in the clathrate should absorb in a manner similar to that of ice I (28). Un-

For personal use only.

fortunately, the absorption in the sulfur hexafluoride clathrate is obscured by scattering. However, the absorption is relatively small and can be allowed for accurately enough as follows.

The absorption of ice in this region is due to the acoustic vibrations, and if the correlation of the orientations of the molecules is neglected, the absorption is predicted to follow the formula (28)

$$[10] \quad K(\nu) = 3\pi^2(\varepsilon_0 - \varepsilon_\infty)\{(\varepsilon_0 + 2)/(\varepsilon_\infty + 2)\} \times \varepsilon_0^{-1/2}\nu_D^{-3}\nu^4$$

where ε_0 and ε_∞ are the limiting low- and high-frequency permittivities of the translational band and ν_D is the Debye frequency expressed in wave numbers. This formula is not well obeyed by ice Ih for two main reasons. The first is that inadequate account was taken of the effect of the local correlation of the molecular orientations (29), leading to an error of a factor of about 5 in the absorptivity (30), and the Debye distribution of frequencies, which was assumed in deriving eq. 10, is not exactly obeyed, and this causes an absorptivity at the higher frequencies that is not exactly proportional to the fourth power of the frequency. The formula has not, therefore, been used directly, but has been used to scale the absorptivity of ice to that of the clathrate by adjusting ε_0 and ε_∞ using the Clausius–Mossotti relation and the densities of ice and the empty clathrate, and adjusting the Debye frequency according to the relation

$$\nu_D \propto \rho v^3$$

where ρ is the density and v the speed of sound, and

$$v \propto \rho^{-1/2}$$

According to this treatment, using 0.809 g cm^{-3} for the density of the empty clathrate from the unit cell parameters (14), the absorptivity of the empty clathrate is 0.76 of that of ice I. The absorptivity so obtained using absorptivities of ice I reported by Whalley and Labbé (28) and some unpublished values of Klug's, is plotted in Fig. 1 as curve I.

The difference between the absorptivity due to ice and the total absorptivity is that due to the tetrahydrofuran, and this is plotted in Fig. 2 for the 17-K spectrum. The absorption below 7 cm^{-1} was obtained by extrapolating a graph of log K *vs* log ν and is shown as a broken line

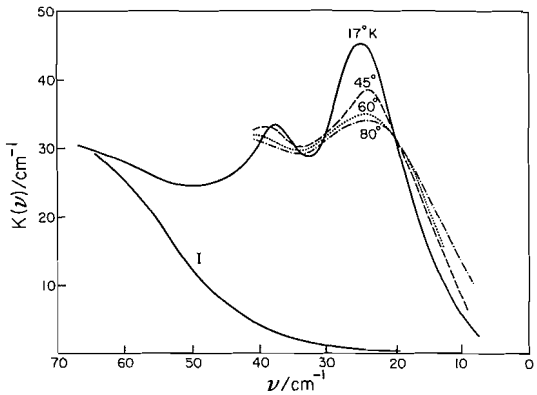

FIG. 1. Absorptivity of tetrahydrofuran clathrate hydrate at several temperatures. The curve labelled I is the presumed absorptivity due to the translational lattice vibrations of the ice framework as calculated in Section 1 of Results section.

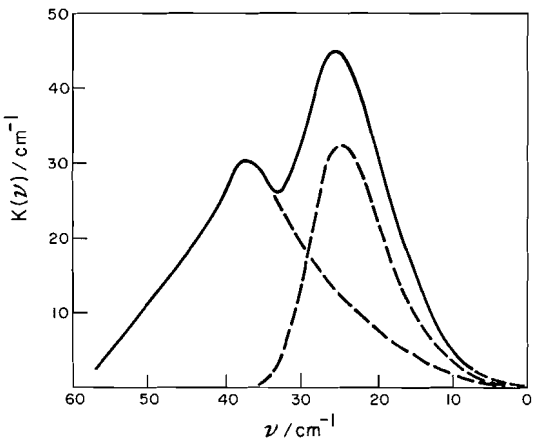

FIG. 2. Absorptivity due to the tetrahydrofuran in tetrahydrofuran clathrate hydrate at 17 K, obtained from the 17-K spectrum in Fig. 1 and the presumed absorptivity of the ice framework. The broken line indicates the resolution into the bands illustrated in Figs. 4 and 5.

in Fig. 2. The integrated absorptivity of the 17-K spectrum obtained using the trapezoidal rule is 420 $\pm$ ~40 cm mmol^{-1}. About half the quoted uncertainty is due to the uncertainty of the absorptivity of the empty clathrate and was obtained by assuming that the adsorptivity of the empty clathrate could be the arithmetic mean of the absorptivity as calculated above and the actual absorptivity of ice I. The other half of the quoted uncertainty is due to the uncertainty in the sample thickness and the reflection losses, and the reproducibility of the spectrometer.

The effective dipole moment μ_{eff} calculated from eq. 9 and the integrated absorptivity, as-

suming that

$$I_x = 209.2 \times 10^{-40} \text{ g cm}^2$$

$$I_y = 118.1 \times 10^{-40} \text{ g cm}^2 \quad (24)$$

where the x axis is perpendicular to the "plane" of the ring, and the y axis is in the "plane",

$$N = 1.62 \times 10^{21} \text{ cm}^{-3} \quad (14)$$

$$n = 1.82 \quad (15)$$

is

$$\mu_{\text{eff}} = 1.63 \pm \sim 0.08 \text{ D}$$

In the gas phase, the tetrahydrofuran molecule undergoes pseudorotation, and its dipole moment depends strongly on its pseudorotation quantum number. In the zero level it is 1.75 D, and in the second and third levels it falls to the value 1.52 D (24). The pseudorotation is either quenched or greatly damped in the clathrate (see Section 6 of Results), and so the appropriate gas-phase dipole moment to compare with the measured transition moment is not obvious. Dipole moments measured in solution range from 1.63 to 1.84 D (31), and it is not clear which is the most appropriate. The agreement, nevertheless, between the effective and directly measured moments is reasonably close.

(2) Contribution to the Low-frequency Refractive Index

The contribution Δn to the low-frequency refractive index due to these bands is given by the Kramers–Kronig relation

$$[11] \qquad \Delta n = (2\pi)^{-2} \int_{\text{band}} K\nu^{-2} \, d\nu$$

The integral for the spectrum of Fig. 2, which is corrected for ice absorption, was evaluated using the trapezoidal rule, and yielded

$$\Delta n = 0.105 \pm \sim 0.007$$

where the error is an estimated standard error from the uncertainty of the ice absorption as described in Section 1 (contribution ± 0.002) and the remaining causes of the uncertainty of the absorptivity (contribution $\pm \sim 0.006$). The value agrees much better than expected with the 0.11 ± 0.05 from dielectric measurements (15).

(3) Detailed Analysis of the Band

The spectrum appears to consist of two broad bands centered at about 25 and 38 cm^{-1} having a ratio of frequencies of 1.52. They are presumably due to the oscillation of the tetrahydrofuran molecules about two axes perpendicular to the polar axis. If the oscillations were about the principal axes with equal force constants, the ratio of frequencies, which is 1.52, would be equal to the square root of the inverse ratio of the principal moments of inertia, which is 1.33. As was argued at the beginning of this section the oscillations in the average cage are about principal axes, and since the most probable cage is the average one, the ratio of frequencies must depart from the expected value due to the unequal force constants for rotation about the two active axes. The axis perpendicular to the plane will be labelled x and that in the plane will be labelled y. The effect of the moments of inertia is to make the oscillations about the axis of higher moment (x) have the lower frequency and lower integrated area. It appears from Fig. 2 that this could be true only if the high-frequency band is much broader than the low-frequency band. It will be shown later that this is probably so. If this conclusion is accepted, then the force constants for rotation about the x and y axes are 465 and 606 ferg rad^{-2} from the peak frequencies. A more detailed analysis of the bands as described below changes these force constants slightly.

The source of the potential energy restricting rotation can be investigated by means of these frequencies. The barrier arises of course from the interaction of the tetrahydrofuran with the water molecules in the cage. The main sources of the interaction are the dispersion, repulsive, and electrostatic forces.

The electrostatic forces can be shown to be unimportant as follows. If an electric field E making an angle θ to the equilibrium dipole direction of the tetrahydrofuran molecule is present, it contributes a term $\mu E \cos\theta$ to the force constant. According to Davidson (32), the average dipolar field in a large cage in the structure II hydrate is about 15 kesV cm^{-1}. If θ is zero, this contributes a term 24 ferg rad^{-2} which is $<5\%$ of the force constants, and contributes only about $2\frac{1}{2}\%$ to the frequency. Even a field that is several times larger than the average field would contribute a force constant much smaller than that observed. It follows that the main barrier to reorientation is not the electrostatic field of the water molecules. It must be due therefore to their repulsive and van der Waals attractive forces.

Since the molecule is in a tetrahedral (symmetry of the average cage T_d) cage and has, at

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

least approximately, C_{2v} symmetry, it is in a stationary potential with respect to small rotational displacements about axes perpendicular to the polar axis when it is aligned either way along the four 3-fold or the three 2-fold axes. There are therefore at least 14 orientations of the polar axis at which the potential energy of the molecule is in a minimum with respect to rotations of the polar axis. Since tetrahydrofuran has at most a 2-fold axis, when the tetrahydrofuran molecule is aligned along a 3-fold (C_{3v}) axis there are at least 3 orientations about the polar axis at which the potential energy is a minimum. Likewise, when it is aligned along a 2-fold axis of the tetrahedron, there must be at least 2 orientations at which the potential energy is a minimum. In addition, the molecule has a pentagonal ring, and there are at least 5 possible orientations of this ring about the axis perpendicular to it. It is clear that an accurate analysis of the potential minima of tetrahydrofuran in the cage would be a formidable task, and cannot be attempted with the data we have.

Something about the periodicity of the potential function of the polar axis can, however, be learned from a simple model. The tetrahydrofuran molecule is replaced by an axially symmetric molecule which imitates it in an appropriate way, and considered to be in a potential of the form

$$V = V_0(1-\cos n\theta) \qquad [12]$$

where n is the periodicity of the potential. Small oscillations in this potential have a frequency ν in wave numbers given by

$$\nu = (n/2\pi c)(V_0/I)^{1/2} \qquad [13]$$

where I is the appropriate moment of inertia. When the geometric mean frequency and moment of inertia are inserted into eq. 13, the value

$$n^2V_0 = 7.7 \text{ kcal mol}^{-1} \qquad [14]$$

is obtained.

The temperature dependence of the dielectric relaxation time suggests that a suitably weighted average barrier height $2V_0$ is 0.92 kcal mol^{-1} (15). From this value and eq. 14

$$n = 4.1$$

This suggests that the potential energy is a minimum when the polar axis coincides with the crystallographic trigonal axes. The dipole moment then points into the center of a hexagonal ring (or alternatively in the opposite direction).

(4) Breadth of the Bands

The bands are very broad even at 17 K. To determine if they appear to be approaching zero width at 0 K, the absorptivity at several frequencies at the lower end of the bands is plotted against temperature in Fig. 3. It is clear that unless a major change occurs below 17 K, the bands are very broad at 0 K. The breadth is therefore due largely to a variation in the force constant from cage to cage.

This variation can arise from several factors as follows:

(*i*) The tetrahydrofuran molecule occupies a number of nonequivalent minima in the cage.

(*ii*) The van der Waals, repulsive, and other nonelectrostatic forces vary from cage to cage because of the orientational disorder of the water molecules.

(*iii*) The electrostatic field in the cages varies from cage to cage because of the disorder of the water molecules.

(*iv*) The coupling between neighboring tetrahydrofuran molecules produces a band of vibrations, each member of which will be active because of the disorder.

(*v*) Anharmonicity.

The contributions *ii–iv* cause an essentially temperature-independent width, while the first and last cause a temperature-dependent width. The intermolecular coupling and electrostatic contribution can be immediately eliminated as the discussion in Sections 1 and 3 shows them to

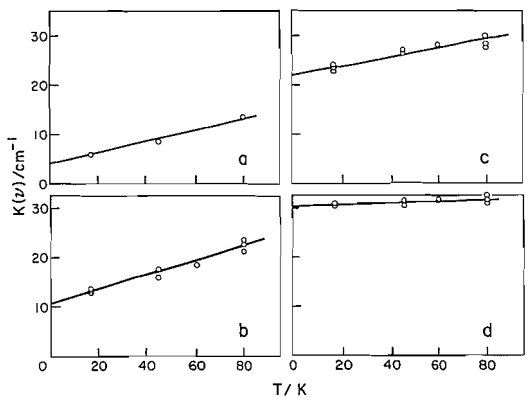

FIG. 3. Absorptivity at several temperatures at several frequencies in the low-frequency part of the band. The frequencies of the four plots are *a*, 10 cm^{-1}; *b*, 14 cm^{-1}; *c*, 18 cm^{-1}; *d*, 20 cm^{-1}.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

be too small unless the fields are much bigger than those Davidson calculated.

The tetrahydrofuran molecule almost certainly occupies several minima and if some of them do not become unoccupied until well below 17 K, the breadth can be understood. There is, however, no independent evidence of this effect.

Little is known about the effect of orientations on the van der Waals and repulsive forces of a water molecule with other molecules. The van der Waals forces depend upon the polarizabilities of the molecules in a simple model, and since the polarizability of a water molecule is almost independent of orientation (33, 34), the van der Waals forces should be nearly independent of the orientation. On the other hand, the hydrogen atoms in the wall of the cage which encloses a tetrahydrofuran molecule, which take part in hydrogen bonds O—H---O, can be attached to either oxygen atom subject only to the requirements of the ice rules. The hydrogen atoms therefore occupy one of two positions about 0.7 Å apart. The repulsive potential due to the interactions of these hydrogen atoms with the hydrogen atoms of tetrahydrofuran, which is likely to be approximately of the form $Ae^{-\rho r}$, where A and ρ are constants and r the hydrogen–hydrogen distance, will depend on the hydrogen atom positions, and it seems likely that the width of the band is dominated by this effect. The anharmonicity of the potential of tetrahydrofuran as a function of orientation and of the interaction of the tetrahydrofuran with the water molecules cannot explain the temperature-independent width at 0 K.

It seems clear that the main source of the breadth of the bands is the distribution of the repulsive forces, although other forces may contribute. If this is true, then information about the distribution of potential constants can be obtained from the spectrum.

Let us assume that each oscillator has its characteristic force constant k and effective moment of inertia I, so that its wave number is given by

$$\nu^2 = k/4\pi^2c^2I$$

If each oscillator has the same integrated absorption intensity, as it should since the same dipole moment is oscillating in all vibrations, then a plot of K against ν^2, as given in Fig. 4 which is derived directly from Fig. 2, is a plot of the distribution $g(k/4\pi^2c^2I)$ of the values of

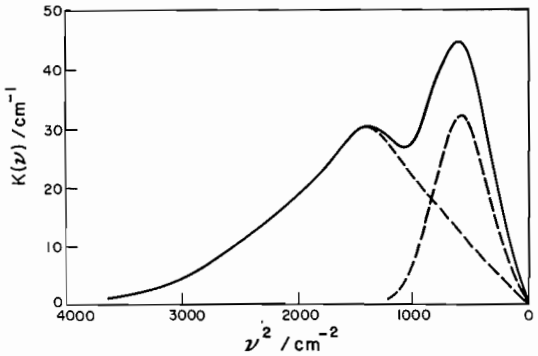

FIG. 4. Absorptivity of tetrahydrofuran in tetrahydrofuran clathrate hydrate, as shown in Fig. 2, replotted against the square of the wave number. The broken line shows the spectrum resolved into two bands assuming that they are related to one another by a multiplicative constant.

$k/4\pi^2c^2I$ against $k/4\pi^2c^2I$. If we further assume that the distribution of k/I in one of the bands that compose the spectrum is the same as the distribution of $\alpha k/I$ in the other, where α is a constant that allows for the differences in force constants and moments of inertia, then the two bands can be resolved as shown in Fig. 4. This resolution yields the superposed curves of $g(\alpha k/I)$ against $\alpha k/I$ for the two bands in Fig. 5, where $\alpha = 4\pi^2c^2$ for the 25 cm^{-1} band and $0.43 \times 4\pi^2c^2$ for the 38 cm^{-1} band. This

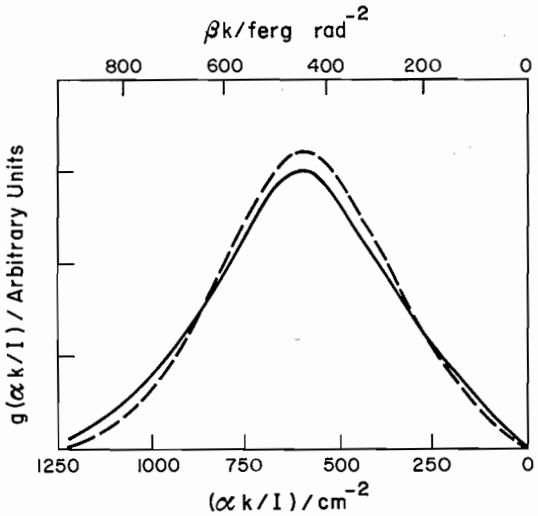

FIG. 5. The density of the quantity $\alpha k/I$ or βk for the two bands of Fig. 4. The scale of the abscissa at the bottom represents $\alpha k/I$ where α is $4\pi^2c^2$ for the 25 cm^{-1} band and $0.43 \times 4\pi^2c^2$ for the 39 cm^{-1} band. The scale of the abscissa at the top represents βk where β is 1 for the 25 cm^{-1} band and 1.34 for the 38 cm^{-1} band.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

particular fit is, of course, not unique but is consistent with the assumption that $g(\alpha k/I)$ is the same for the two bands. The mean force constants for the high- and low-frequency bands respectively are 600 and 450 ferg rad^{-2} and the widths at half height are about 580 and 400 ferg rad^{-2}. The distribution of force constants is indicated by the upper abscissa of Fig. 5, where β is 1 for the 25 cm^{-1} band and 1.34 for the 38 cm^{-1} band.

This resolution of the two bands can be translated into a resolution of the two bands in the spectrum of $K(\nu)$ against ν, and the resolved bands are shown in Fig. 2. The ratio of areas of the two bands is 1.69, compared with the expected value of 1.77 if the oscillations occur about principal axes. Within the limitations of the (partly arbitrary) analysis therefore, the oscillations occur about principal axes.

The two bands can be assigned in the reverse order, when the ratio of force constants for rotation about the x and y axes would be about 4. The curve of Fig. 2 would then be resolved so that the low-frequency band had the higher area, and the distribution of force constants in the two bands would be less simply related. Although this assignment cannot be rigorously eliminated, it seems less probable.

(5) Effect of Temperature on the Breadth of the Bands

The bands broaden greatly as the temperature is increased. This could be due to

(*i*) limited life-time of the excited vibrational states due to transitions to lower states, and interaction with lattice vibrations,

(*ii*) limited life-time due to reorientation of the molecules,

(*iii*) increasing occupancy of the higher potential minima which would have different force constants.

The reorientation time at 88 K is ~11 ps (35), which corresponds to a half width of ~0.5 cm^{-1}, and so this reorientation does not contribute appreciably to the width even at 80 K. The relaxation does, however, contribute appreciably to the absorptivity at low frequencies. From the dielectric data at 88 K (35), the absorptivity at 5 cm^{-1} due to the relaxation would be about 3.5 cm^{-1} if the (important) effects of inertia were neglected. The actual absorptivity would be less than this, but nevertheless it contributes an important part of the observed absorptivity at low frequencies and 80 K.

Some of the broadening is undoubtedly due to the life-time of the states due to interaction with the lattice vibrations, and no doubt increasing occupancy of higher potential minima contributes also.

(6) Pseudorotation in the Clathrate

The tetrahydrofuran molecule undergoes pseudorotation in the gas phase, and the energy levels have been obtained from spectra taken at room temperature (36). At 17 K, the tetrahydrofuran molecules are mainly in the lowest few pseudorotational levels, and transitions below ~20 cm^{-1} might be observable in the clathrate if pseudorotation occurs. The number of tetrahydrofuran molecules per unit area of the sample is similar in the clathrate samples used in this work and the samples (36) used for the gas spectra. Unfortunately, there appears to be no way of reliably predicting the intensities. No features attributable to pseudorotation were observed in the clathrate spectra. It follows that either the pseudorotation is quenched or the bands are too weak to be observed, because either they are intrinsically weak or they are broadened by the interaction with the cage.

Summary

(*1*) The far-infrared spectrum of polycrystalline tetrahydrofuran clathrate hydrate contains two broad bands centered at 25 and 38 cm^{-1}, that are due to the rotational oscillations of the tetrahydrofuran molecule.

(*2*) The integrated absorptivity of the bands yields a value for the oscillating dipole moment of 1.63 $\pm$ 0.08 D, which is close to the gas-phase and solution values.

(*3*) The negative second moment of the band about zero frequency yields the contribution to the low-frequency refractive index of 0.105 $\pm$ ~0.007, which agrees with the less accurate value from the dielectric properties.

(*4*) The bands are due to rotations about the principal axes perpendicular to the polar axis, and yield force constants for rotation about the axes perpendicular to the plane of the ring and in the plane of 600 and 450 ferg rad^{-2}, respectively.

(*5*) The great breadths of the bands at low temperatures is due mainly to a variation of force constants from cage to cage. This occurs mainly because the orientational disorder of the water molecules results in a variation of the

hydrogen(water)–hydrogen(tetrahydrofuran) interaction.

(*6*) If the distribution of force constants for rotation about the two principal axes is assumed to be similar, an internally consistent resolution of the two bands can be obtained.

(*7*) The pseudorotation of tetrahydrofuran, which occurs in the isolated molecule, is either quenched in the clathrate hydrate due to the interaction with the cage wall or is too weak to be observed.

An Electron Spin Resonance Study of the Reaction of Nitrogen Dioxide with Metal Acetylacetonates

WILLIAM H. WOLODARSKY, JOSHUA FANIRAN,[1] AND JEFFREY K. S. WAN
Department of Chemistry, Queen's University, Kingston, Ontario

Received June 18, 1973

The reaction of nitrogen dioxide with several metal acetylacetonates was studied by electron spin resonance. Those metal complexes that have stable lower oxidation state (*i.e.* Cu(II), Fe(III), Co(III), and VO(II)) react to form iminoxy radicals, while those metals not readily reduced (*i.e.* Zn(II), Cr(III), and Ce(III)) do not give iminoxy radicals. On the basis of the e.s.r. results, a simple mechanism was proposed to account for the formation of iminoxyacetylacetone radicals. A low temperature study of the e.s.r. spectra of the iminoxy-Cu(II)hexafluoroacetylacetonate suggested that a π-complex is formed between the organic radical and the Cu(II) compound.

La réaction du bioxyde d'azote avec plusieurs acétylacétonates de métaux a été étudiée à l'aide de la résonnance de spin électronique. Les complexes métalliques qui possèdent les plus bas états d'oxydation stables (*i.e.* Cu(II), Fe(III), Co(III) et VO(II)) réagissent pour former des radicaux iminoxy alors que les métaux qui ne sont pas facilement réduits (*i.e.* Zn(II), Cr(III) et Ce(III)) ne donnent pas ces radicaux iminoxy. En se basant sur les résultats r.s.e., on propose un mécanisme simple tenant compte de la formation des radicaux iminoxyacétylacétone. Une étude des spectres r.s.e. à basse température de l'iminoxy-Cu(II) hexafluoroacétylacétonate a suggéré qu'un complexe-π se forme entre le radical organique et le composé du Cu(II). Introduction

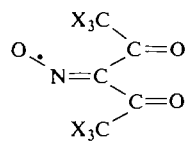
Metal acetylacetonates are complexes with a partially covalent metal–oxygen bond (1). As such their reactions are often described as analogous to aromatic systems; the central hydrogen atom of the chelate ring can be replaced by a variety of groups under apparently electrophilic conditions (2). The reaction of nitrogen dioxide or its dimer with metal acetylacetonates has been studied with a view toward isolating and identifying products (3). Thus, in an excess of nitrogen dioxide, the acetylacetonates of Cu(II), Ni(II), Pt(II), and Al(III) yield the corresponding 3-nitro derivatives. Although it has been established (4) that the reaction of nitrogen dioxide with the acetylacetone ligands alone leads to the formation of stable iminoxy radicals such as



few e.s.r. studies had been reported on the system with metal acetylacetonates. In addition, there is a possibility that the organic iminoxy radical may form a molecular complex with the metal acetylacetonates. For example, the Cu(II)-hexafluoroacetylacetonate has recently been the subject of some interest, concerning its electron-acceptor properties. Zelonka and Baird (5) have reported the preparation of the molecular complex between Cu(II)hexafluoroacetylacetonate and di-*tert*-butyl nitroxide radical. The structure of the complex, however, was not studied in detail by e.s.r. spectroscopy.

In this paper we wish to report an e.s.r. investigation of the reaction of nitrogen dioxide with several metal acetylacetonates at room temperature. A detailed e.s.r. analysis of the low temperature spectra obtained in the Cu(II)hexafluoroacetylacetonate system reveals the molecular association in the form of a π-bonding between the organic iminoxy radical and the Cu(II) complex.

Experimental

Electron spin resonance spectra were recorded with an X-band Varian V4502 spectrometer using 100 kHz modulation and auxiliary equipment. The g values were measured relative to DPPH ($g = 2.0036$) as the standard.

Nitrogen dioxide (Matheson) was purified by bubbling oxygen through the liquid at 0 °C. This was repeated until the frozen nitrogen dioxide was pure white. Phosphorus pentoxide was added as a drying agent and the sample was refrigerated at −10 °C in a darkened vessel.

TABLE 1. Electron spin resonance parameters of iminoxy radicals formed from the reaction of nitrogen dioxide with metal acetylacetonates in chloroform

Metal complex	A_N (G)	$A_X^{(CX_3)}$ (G)	Metal splitting (G)	g value	Line width (G)
$Cu(acac)_2$	27.5 ± 0.1*		$A_{Cu} = 78 \pm 2$	2.0044 ± 0.0002*	2.0
$Cu(trifluoroacac)_2$	27.5	5.0(F)	$A_{Cu} = 70 \pm 2$	2.0039	2.0
$Cu(hexafluoroacac)_2$	30.0	5.3(F)	$A_{Cu} = 52 \pm 2$	2.0038	0.7
$VO(acac)_2$	27.5	—	$A_V = 105 \pm 5$	—	2.0
$Co(acac)_3$	27.5	0.4(H)	—	2.0044	0.05
$Fe(acac)_3$	27.5	—	—	—	2.0

*The errors reported here are the standard deviation among separate measurements. The overall accuracy of these values is limited by the accuracy of the field-dial in the spectrometer.

All solvents used were purified by conventional methods. Oximinoacetylacetone was prepared by the method of Wolff and co-workers (6), and recrystallized twice from cyclohexane and identified by i.r. All metal acetylacetonates were supplied by PCR, Inc. or by Alpha Inorganic, and were used after recrystallization purification. Bis-(3-nitroacetylacetonate)Cu(II) was prepared by the method of Djordjeric and co-workers (3).

Solutions of metal acetylacetonates were normally prepared at a concentration less than 0.01 M. In a typical experiment nitrogen dioxide in the amount of about 8×10^{-7} mol was distilled into a previously degassed solution contained in a 3 mm tubing. The sample tube was then sealed off under a vacuum of 10^{-5} Torr for e.s.r. study. Low temperature studies at 77 °K were carried out to obtain further information from the anisotropy of the g and hyperfine coupling values.

Results and Discussion

The reaction of nitrogen dioxide at room temperature with Cu(II), VO(II), Fe(III), and Co(III) acetylacetonates yielded organic radicals whose hyperfine splittings and g values are consistent with the iminoxy acetylacetone radical (4). The e.s.r. parameters of these observed radicals are given in Table 1.

The cupric and vanadium complexes are paramagnetic and therefore their e.s.r. spectra are superimposed on the organic free radical spectra. Ferric complexes, although paramagnetic, have very broad lines at room temperature and thus the spectrum of the ferric complex could not be observed. One interesting feature of the iminoxy radical spectra derived from the metal complexes is that the hyperfine splitting of the methyl protons is not observed due to line-broadening. This effect may arise from the interaction of the metal with the organic radical since addition of Cu(II) complex to the iminoxy radical derived alone from the ligand causes the immediate disappearance of the proton splittings with simultaneous broadening of the ^{14}N lines. The nature of this interaction will be shown later as due to molecular association in the form of a π-complex.

An oxidation-reduction mechanism was proposed to account for the formation of the iminoxy radicals

$$[1] \quad M(acac)_n + (NO_2)_2 \rightarrow M(acac)_{n-1} + NO(acac) + \dot{N}O_3$$

The reactive species could be $NO^+NO_3^-$ with NO^+ attacking the central carbon atom. In each case the nitroso derivative (NO(acac)) rearranges to the oxime which is then further oxidized to the iminoxy radical by nitrogen dioxide. Evidence for the metal reduction in reaction 1 was provided by the fact that those metal complexes (Cu(II), Fe(III), Co(III), and VO(II)) having stable lower oxidation states react to give the iminoxy radicals, while those metal complexes, such as Zn(II), Cr(III), and Ce(III), which are not readily reduced do not lead to iminoxy radical formation.

That substitution occurring at the central hydrogen atom of the chelate ring is proved by the fact that Cu(3-nitroacac)$_2$ does not yield an iminoxy radical. Evidence has also been presented (4) that the precursor of these iminoxy radicals is probably the corresponding oxime formed by rearrangements of the intermediate nitroso compounds. For example, experiments have been carried out to show that oxidation of oximinoacetylacetone by nitrogen dioxide gives the iminoxy acetylacetone radical. Wolodarsky and Wan (7) have demonstrated that iminoxy radicals derived from tri- or hexafluoroacetylacetone may have two conformations depending upon the solvent. However, in the present metal complex systems, the conformers are not observed as the lines are broadened beyond resolution of the isomer fine structures.

Further experiments were carried out to investigate the possibility of molecular association

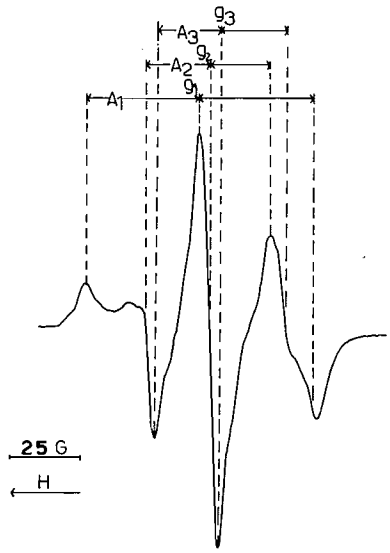

FIG. 1. The low temperature (77 °K) e.s.r. spectrum of the iminoxyacetylacetone radical in chloroform.

between the metal complexes and the organic iminoxy radicals. The low temperature (77 °K) spectrum of the iminoxy radical in the absence of metal complexes is presented in Fig. 1. The analysis of this powder spectrum gives the following results: $g_1 = 2.0023 \pm 0.0002$, $g_2 = 2.0043$, $g_3 = 2.0063$, $a_1 = 39.1 \pm 0.08$ G; $a_2 = 21.9$ G; $a_3 = 21.9$ G. Taking the $a_{iso} = 27.6$ G from the room temperature isotropic spectrum, it is apparent that $a_{\parallel} = 11.5$ G and $a_{\perp} = -5.7$ G. Fortunately the principle values of the hyperfine and g tensors of the iminoxy radical derived from γ irradiated single crystal of dimethylglyoxime have been analyzed in details by Miyagawa and Gordy (8). It is possible to relate the principle axes of the dimethylglyoxime radical to the powder spectrum of the iminoxyacetylacetone radical: $g_z = 2.0023 \pm 0.0002$, $g_y = 2.0043$, $g_x = 2.0063$, $a_z = 11.5 \pm 0.08$ G; $a_y = -5.7$ G; $a_x = -5.7$ G; where the x, y, z axes are defined similar to that in the dimethyl glyoxime radical (8) and for our purpose the z-axis is taken approximately 120° from the C=N and —N—O bonds, *i.e.* along a sp^2 lobe, and the x-axis is perpendicular to the molecular framework. Since the hyperfine tensor is axially symmetric with the maximum value along the z-axis, it appears that the electron density is concentrated in the sp^2 orbital of the nitrogen. Taking the average values of $B_0 = 18.4$ G and $A_0 = 595$ G for nitrogen (9), $c_{2p}{}^2 = 0.312$ and $c_{2s}{}^2 = 0.046$. The total spin density on the nitrogen is therefore equal to 0.358 in the uncomplexed iminoxyacetylacetone radical.

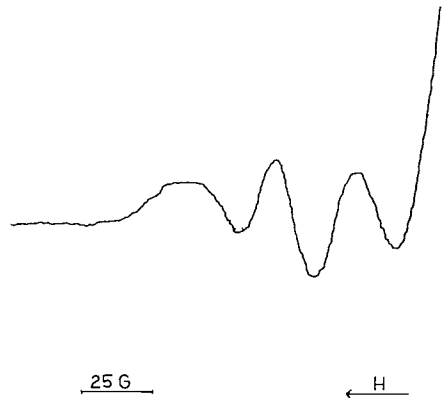

FIG. 2. The low temperature (77 °K) e.s.r. spectrum of the iminoxyacetylacetone radical in chloroform with the presence of Cu(II)hexafluoroacetylacetonate. The Cu(II) spectrum is not shown here.

The low temperature (77 °K) spectrum of the same iminoxyacetylacetone radicals in the presence of Cu(II)hexafluoroacetylacetonate is given in Fig. 2. Several other metal complexes were used but only the Cu(II)hexafluoroacetylacetonate afforded the least overlap between the metal lines and the nitrogen triplet splittings. It was established that the Cu(II) spectrum was not changed significantly in the presence or absence of the iminoxy radicals. However, in the presence of the Cu(II) complex, the iminoxy radical yielded the following spectral parameters: $g_z = 2.0015 \pm 0.0002$, $g_y = 2.0050$, $g_x = 2.0097$, $a_z = 9.8 \pm 0.08$ G; $a_y = -7.2$ G; $a_x = -2.7$ G. The hyperfine tensor is not axially symmetric but can be broken into two tensors

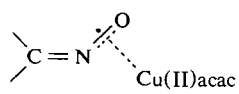
$$\begin{vmatrix} 9.8 & & \\ & -7.2 & \\ & & -2.7 \end{vmatrix} = \begin{vmatrix} 11.4 & & \\ & -5.7 & \\ & & -5.7 \end{vmatrix} + \begin{vmatrix} -1.6 & & \\ & -1.5 & \\ & & 3.0 \end{vmatrix}$$

one of which is symmetric about the z-axis and the other being symmetric about the x-axis. These can be taken as indicative of electron density in the sp^2 and p_x orbitals, respectively. Using the same average values of B_0 and A_0 (9), the iminoxy radical in the presence of the Cu(II) complex gives the following spin density on the nitrogen: $c_{2p_z}{}^2 = 0.310$, $c_{2p_x}{}^2 = 0.082$, and $c_{2s}{}^2 = 0.050$. In comparing these data with those

for the uncomplexed iminoxy radicals given above, it is apparent that the electron spin has penetrated the $2p_x$ orbital, which is perpendicular to the molecular framework, presumably as a result of some interaction with the Cu(II) complex. The same conclusions can be drawn when different solvent such as dichloromethane was used instead of chloroform.

It should be pointed out that the value of $c_{2p_z}{}^2$ is less certain since the z-component of the anisotropic tensor was determined from a section of the radical spectrum (Fig. 2) that overlapped to a small extent with the Cu(II) spectrum. The value for the $c_{2p_x}{}^2$, however, is more reliable since it was derived from A_x and A_y which were obtained from the section of spectrum where overlap was minimal.

On the basis of the e.s.r. results, the nature of the interaction between the organic iminoxy radical and the Cu(II) complex is most likely the formation of the π-complex:



The increase in the value of g_z for the complexed iminoxy radical from 2.0063 to 2.0097 suggests that there is some degree of orbital mixing between the organic radical and the metal. It is not known at the present time why this π-bonding is preferred over the structure involving the mixing of the σ-orbital of the iminoxy radical with the $d_z{}^2$ orbital of the Cu(II).

The research is supported by the National Research Council of Canada.

Unusual Long-Range Spin–Spin Coupling in Norbornane-2,3-diones. Proton Magnetic Resonance Spectrum and X-Ray Structure Analysis of 6-*endo*-Bromo-1,5,5-trimethylnorbornane-2,3-dione

G. F. Hambly, Jeanette Leitch, Peter Yates, and S. C. Nyburg

Lash Miller Chemical Laboratories, University of Toronto, Toronto, Ontario M5S 1A1

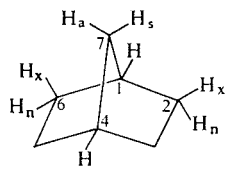
Received June 29, 1973

Several norbornane-2,3-diones show in their proton magnetic resonance spectra an unusual long-range spin–spin coupling, $^4J_{46x} = 1.0$–1.5 Hz. An X-ray structure analysis of 6-*endo*-bromo-1,5,5-trimethylnorbornane-2,3-dione shows that the norbornane framework deviates only slightly from mirror symmetry. This makes it unlikely that the unusual coupling in the norbornane-2,3-diones is due to distortion of the norbornane framework and lends credence to the view that it is due to substituent effects.

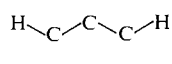
Plusieurs norbornanedione-2,3 possèdent dans leur spectre r.m.n. du proton un couplage spin–spin à longue distance qui est inusité $^4J_{46x} = 1.0$–1.5 Hz. Une analyse par rayons-X de la structure de l'endo-bromo-6 triméthyl-1,5,5 norbornanedione-2,3 montre que le squelette du norbornane devie très peu de la symétrie par rapport à un miroir. Ce résultat implique qu'il est peu probable que le couplage inusité soit dû à une distortion du squelette du norbornane et amène à croire qu'il est dû à des effets de substituants.
[Traduit par le journal]

Can. J. Chem., **51**, 4076 (1973)

Three types of long-range proton couplings (^4J) have been generally recognized in the p.m.r. spectra of norbornane derivatives (**1**), *viz.* J_{14} (1.0–1.6 Hz), J_{2x6x} (1.0–1.8 Hz), and J_{2n7a} (1.7–4 Hz) (1). Each of these is associated with an approximately planar W geometry of the two



1



2

protons and a three carbon atom chain (**2**) (2). Theoretical arguments have been advanced to account for the occurrence of significant long-range proton coupling in systems with this geometry (1). Although long-range coupling has been observed in four-bond systems involving three sp^3 carbon atoms with other geometries, the coupling constants are usually appreciably smaller (≤ 0.5 Hz) (1, 3, 4).[1]

It is therefore of considerable interest that Gagnaire and Rassat and their co-workers (5, 6) have observed a fourth type of significant long-range coupling (J_{13x}) in the case of the two norbornane-2,3-diones **3** ($J_{46x} > 1$ Hz) and **4** ($J_{46x} = +1.1$ Hz),[2] where the four-bond systems corresponding with those referred to above might be expected to show gross deviation from the coplanar W geometry **2**. We ourselves (7) have made similar observations in the case of the norbornane-2,3-diones **5**–**9**, whose spectra all show significant coupling of the H_1–H_{3x} type (Table 1).

In considering the origin of this unusual long-range coupling, which has not been detected in the spectra of simple norbornanes or norborn-

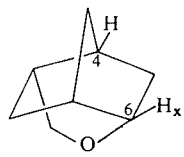
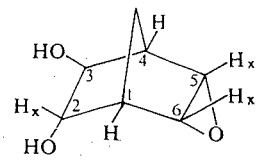
10 R = CH_3, X = H

anones, it occurred to us that it might arise because of appreciable skewing of the α-diketone groups as a result of dipole–dipole interaction (8).[3] Such skewing could result in a conformation in which H_4 and H_{6x} much more closely approach the planar W geometry **2** than they do in simple norbornanes and norbornanones, where distortion of the norbornane framework is expected to be small (10).

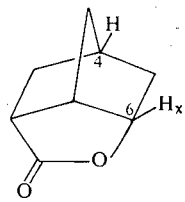
We were encouraged in this view by the circumstance that the spectra of the 2-diazo 3-ones (7) corresponding to the 2,3-diones **5**–**8** gave no evidence of analogous H_4–H_{6x} coupling, which could be attributable to replacement of a skewed α-diketone function by a planar α-diazo ketone function. Further, significant long-range coupling constants have been reported for analogous proton pairs in the more complex norbornane derivatives **11**–**13** (11–13) (Table 1), and it could be postulated that the additional ring in each of these compounds distorts the geometry in such fashion as to favor a closer than usual approach to the planar W arrangement for the coupled protons.[5]



11



12



13

An X-ray crystallographic examination of compound **8** was therefore undertaken to determine whether evidence could be obtained for a skewed dicarbonyl system in the crystalline state. The structure and dimensions of **8** are shown in Figs. 1 and 2.

A quantitative estimate of the distortion of the norbornane framework can be obtained by checking this for mirror symmetry. An undistorted skeleton will have a mirror plane through C(7) and the mid-points of the bonds C(2)—C(3) and C(5)—C(6). This can be checked by a best molecular fit routine (14) in which the best fit is found between the molecule itself and its mirror image, the atoms matched being the mirror image of C(1) with the original C(4), etc. In this way we can place the molecules of reasonably accurately known structure containing the norbornane framework (but without additional distortion due to further bridging) in order of deviation from mirror symmetry.

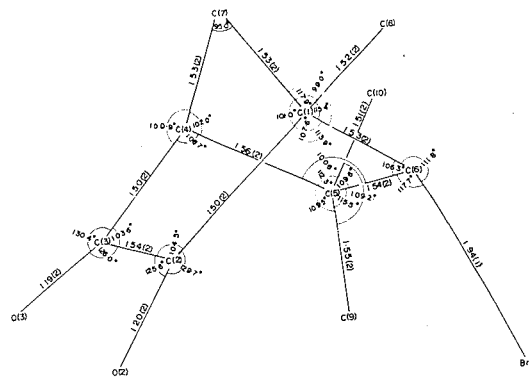


FIG. 1. Dimensions of molecule.

[3]Such a skewing has been invoked to interpret the electronic spectrum and circular dichroism of camphorquinone (**10**) (9), whose crystal structure has recently been determined by Silverton and Bright (9*b*) (see footnote 4).

[4]We thank Dr. L. Tsai, U.S. National Institutes of Health, for informing us of these results before publication.

[5]It is recognized that additional factors would have to be involved in the case of **12**, since no significant J_{15x} was observed.

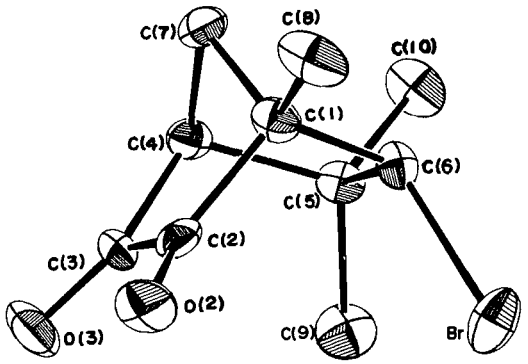

FIG. 2. ORTEP plot of molecule showing 15% probability ellipsoids.

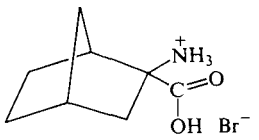
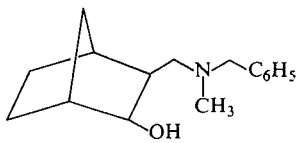
The quantitative estimate we use is the sum of the squares of the distances between the atoms in their best fitting positions. Amongst known structures we find the most closely symmetric ($\sum d^2 = 0.0079$ Å^2) is the hydrobromide salt of



14

(−)-2-*exo*-aminonorbornane-2-carboxylic acid, **14** (15), and the most distorted ($\sum d^2 = 0.0703$ Å^2) is 3-*exo*-(*N*-benzyl-*N*-methylaminomethyl)-2-*endo*-norbornanol, **15** (16). Altona and Sundaralingam (10) also give the latter as the most distorted norbornane nucleus in a known structure.



15

The present molecule lies between these extremes ($\sum d^2 = 0.0107$ Å^2) but clearly nearer the undistorted end of the range. Further evidence of lack of distortion is provided by the close planarity of that part of the molecule containing the α-diketo-group, namely C(1), C(2), C(3), C(4), O(2), and O(3). This system is closely coplanar, the maximum deviation from the plane being that of atom C(2), $d = 0.027$ Å. The only other structure analysis known to us of a molecule containing the α-diketo group is that of camphorquinone (**10**) (9*b*). In this molecule there is also remarkably little skewing of the α-diketo group. Thus in the present structure the dihedral angle C(2)C(3)C(4)/C(1)C(2)C(3) is 1.73° and in the two crystallographically independent molecules of camphorquinone it is 0.1° and 2.9°. The α-diketo groups in these molecules have therefore closely similar conformations.

Amongst molecules of norbornane type of known structure we find that the bond lengths at C(7) are inversely correlated with the C(1)—C(7)—C(4) bond angle and the present molecule fits in well with this trend. A similarly good fit is found for C(1)—C(2), C(3)—C(4), C(4)—C(5), and C(6)—C(1) lengths which are inversely correlated with the sum of the bond angles at C(1) and C(4).

A virtually undistorted molecule such as the present one has a three carbon atom chain (**2**) (C(4)—C(6)) in which the hydrogen atoms at C(4) and C(6) are not at all coplanar with the carbon atoms ($d = 0.96$ and 0.35 Å, respectively). Although it is possible that the molecule is more distorted in solution, the crystal structure makes it unlikely that there is a large angle of skew and suggests that this is not a major factor in the occurrence of the unusual long-range couplings in **3**–**9**. It is more probable that the major factor is a substituent effect (1), as previously suggested (5), arising from the presence of electronegative substituents at each of the carbon atoms bearing the coupled protons.[6] In each case one of these is the strongly electron-withdrawing α-dicarbonyl functions; the absence of significant H_4–H_{6x} coupling in the case of the 2-diazo 3-ones corresponding to the 2,3-diones **5**–**8** may be attributable to the reduced electronegativity of this substituent.

Experimental

Compound **5** was prepared by the method of Meinwald, Gassman, and Hurst (17). Compounds **6**–**9** were prepared and purified by standard methods (7, 18). For X-ray analysis of **8** the crystal data are:
Orthorhombic, $a = 11.40(1)$, $b = 11.58(2)$, $c = 8.39(1)$ Å, $V = 1073$ Å^3; space group $P2_12_12_1$, $\rho_o = 1.48$, $Z = 4$, $\rho_c = 1.51$ (20 °C; CuKα, $\lambda = 1.542$ Å).

Intensity data were collected in 2θ-scan mode by a Canberra-automated Picker diffractometer using filtered CuKα radiation. Out of 1055 measured intensities 754 were observed on the basis $I > \sqrt{2}\sigma(I)$ where $\sigma(I) =$

[6]It must be noted, however, that Barfield and Chakrabarti (1) have suggested on a tentative basis that introduction of electronegative substituents at the terminal carbon atoms of a planar W system (**2**) gives rise to a negative shift of the corresponding $^4J_{HH}$. Since it has been shown in the case of **4** that J_{46x} is positive (6), the present proposal requires a substituent effect in the opposite sense.

(peak + background)$^{1/2}$. No absorption corrections were made.

Phases were first assigned from the Br positions and subsequent analysis was uneventful. Full matrix anisotropic least squares refinement was carried out taking e.s.d.s in F_o as $\sigma(F) = ((\sigma(I)/(\mathrm{Lp}))^2 + 0.02F_o^4)^{1/2}/2F_o$ where Lp is the Lorentz polarization correction and using scattering factors of Cromer and Mann (19). After all non-hydrogen parameters had been refined four (non-methyl) hydrogen atoms were located on the final electron density difference map but those associated with the methyl groups were more diffuse. The positions chosen for these were those giving the highest electron density difference compatible with tetrahedral stereochemistry and a C—H bond length of 1.08 Å. These hydrogens were included in the final calculation of F_c giving them the same anisotropic temperature factors as the carbon atoms to which they were attached. The final residual for observed reflections was 0.072.[7]

Positional and thermal parameters are given in Tables 2 and 3 and a dimensioned molecule and an ORTEP plot in Figs. 1 and 2.

[7]Table of F_o and F_c values is available at a nominal charge from the Depository of Unpublished Data, National Science Library, National Research Council of Canada, Ottawa, Canada K1A 0S2.

We thank the National Research Council of Canada for support of this work.

Lanthanide Induced Shifts in the Proton Magnetic Resonance Spectra of Cyclic Amines

DONALD L. HOOPER AND ALZBETA KARDOS
Chemistry Department, Dalhousie University, Halifax, Nova Scotia

Received June 11, 1973

Complex formation between europium tris(dipivalatomethane), $Eu(DPM)_3$, and cyclic amines is not accompanied by inversion of the amine configuration, even for 2-alkyl and 2,6-dialkylpiperidines, where inversion of the amine configuration accompanies formation of the usual amine derivatives. There is, however, a steric effect of C-2 or C-6 substitution, in that the magnitude of the lanthanide induced shifts is sharply reduced.

Lors de la formation de complexes entre l'europium tris(dipivalatométhane), $Eu(DPM)_3$, et des amines cycliques, aucune inversion de la configuration de l'amine ne fut observée même dans le cas d'alcoyl-2 ou de dialcoyl-2,6 pipéridines où l'inversion de la configuration de l'amine accompagne la formation des dérivés usuels de l'amine. Cependant, un effet stérique provenant de la substitution en C-2 ou C-6, fut observé et se traduit par une légère réduction de l'ampleur des déplacements chimiques induits par la lanthanide. [Traduit par le journal]

Can. J. Chem., **51**, 4080 (1973)

Determination of the configuration of cyclic amines from analysis of p.m.r. spectra is often complicated by the small chemical shift differences between a number of closely coupled protons. The magnitude of these chemical shift differences can be increased in the spectra of *N*-acetyl and *N*-nitroso derivatives; however, unless the cyclic amine is symmetrically substituted, hindered rotation about the N—CO or N—NO bonds can lead to even more complex spectra. In the case of the simple 2-alkyl and 2,6-dialkylpiperidines, where the alkyl groups are known to be equatorial, formation of the *N*-acetyl derivative forces inversion of the configuration with the alkyl groups becoming axial (1). Similarly, formation of the *N*-carbothionic acid derivatives by reaction with carbon disulfide is accompanied by inversion of configuration (2).

The power of lanthanide "shift reagents" (3) in the simplification of complex spectra has been well established and the assignment of configuration to substituted piperidines should be straightforward. The magnitude of a lanthanide induced chemical shift (l.i.s.) is a function of both the distance to a particular proton from the lanthanide atom at the center of the complex and of the angle between the principal magnetic axis of the complex and a line drawn joining the lanthanide atom to the proton, with the result that for a cyclic system such as a cyclohexanol addition of a "shift reagent" separates the signals of axial and equatorial protons at a particular carbon as well as those of protons at different carbon atoms (4). There remains, however, the possibility of a steric effect when the complex is formed between a piperidine with bulky substituents close to the nitrogen atom and the already bulky lanthanide complex which acts as the "shift reagent". Steric effects on complex formation have been postulated for other substrates, *e.g.* to explain the much greater l.i.s. observed (5) for the *trans* conformation compared with the *cis* conformation of *O*-dimethyl and *O*-diisobutyl esters of methylthiocarbamic acid.

We have measured lanthanide induced shifts for 2% solutions in $CDCl_3$–TMS of the substituted piperidines listed in Table 1, with the molar ratio of europium tris(dipivalatomethane), $Eu(DPM)_3$, to amine varying from 0.00 to 0.30. The $Eu(DPM)_3$ was a single fresh sample stored over P_2O_5 in a desiccator before use. A steric effect is observed, but it is not inversion of the ring configuration. At low values of the ratio, $[Eu(DPM)_3]/[amine]$, the p.m.r. signals corresponding to the C-2 and C-6 protons are somewhat broadened and the chemical shift differences increased, however, the characteristic spin coupling constants are still observed, indicating that the configuration has not changed. With increasing relative concentration of $Eu(DPM)_3$ the broadening of signals obscures all the fine structure, nevertheless graphs of the magnitude of the lanthanide induced shift versus molar ratio $[Eu(DPM)_3]/[amine]$ are linear over the range studied. Thus inversion of configura-

TABLE 1. Slopes of graphs of lanthanide induced chemical shifts for some substituted piperidines *vs.* molar ratio of $Eu(DPM)_3$ to amine in $CDCl_3$–TMS solution

Compound	Slope (p.p.m.)			
	NH	C_6-H(eq)	C_6-H(ax)	CH_3
3-Methylpiperidine	55	18.0	17.0	5.0
2-Methylpiperidine	51	15.0	9.6	7.8
2-Ethylpiperidine	35	12.3	—*	2.5†
2-Propylpiperidine	36	11.5	—*	0.6†
2,6-Dimethylpiperidine	29.5	—	2.8	3.3

*Obscured by alkyl signals.
†Terminal CH_3 of the alkyl group.

tion has not occurred even at high $Eu(DPM)_3$ concentrations.

Table 1 lists the slopes of some of these l.i.s. *vs.* molar ratio graphs. As the slope of such a graph is the magnitude of the lanthanide induced shift which would be observed for a 1/1 molar ratio of "shift reagent" and substrate, a comparison of the slopes for corresponding protons in a series of similar molecules measures any steric effect on complex formation. The observed reduction in the l.i.s. with increasing substitution at C-2 and C-6 could mean either a change in the geometry of the complex, for example, an increase in the separation of the europium and nitrogen atoms bonded in the complex, or a reduction in the equilibrium constant for complex formation. Calculation of the geometry, using the McConnell equation is not likely to be meaningful, as the broadening observed for the signals of C-2 and C-6 protons quite probably is caused by a contact contribution to the l.i.s., as well as the pseudo-contact term for which the McConnell equation applies.

For the range of $Eu(DPM)_3$/amine concentrations used in this work, the p.m.r. signals of the other piperidine ring protons were to a large extent, complex multiplets, or were observed by alkyl signals. However, it would be expected that any effect reducing the value of the equilibrium constant for complex formation would reduce the observed l.i.s. for all protons in the substrate molecule.

The use of lanthanide induced shift measurements will lead to a proper assignment of the configuration of cyclic amines, but only if due consideration is paid to the number and size of substituents close to the nitrogen atom and their effect on the value of lanthanide induced shifts.

The authors acknowledge financial support by the National Research Council of Canada and thank Dr. T. P. Forrest for the gift of samples of the cyclic amines used in this work.

Organic Sulfur Mechanisms. 15. The Stereochemistry of α-Hydrogen Exchange in the Simple Cyclic Sulfoxide 1,3 Dihydrobenzo[*c*]thiophene 2-Oxide

JAMES FREDERICK KING AND JOHN RICHARD DU MANOIR

Department of Chemistry, University of Western Ontario, London, Ontario

Received July 25, 1973

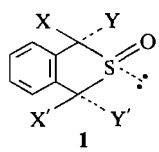
In NaOD–D_2O at 5.0° the α-hydrogens *trans* to the oxygen in 1,3-dihydrobenzo[*c*]thiophene 2-oxide (**1**) exchange 67 times faster than the *cis*. The *cis* hydrogens in turn exchange slightly faster than the *faster* of the α-hydrogens of the methylene group in benzyl methyl sulfoxide. Treatment of **1** with methyllithium followed by rapid quenching with DCl leads to a predominantly *cis*-monodeuterated product. It is also shown that the hydrogen removal in the lithiation step involves loss of the *cis* hydrogen and that the lithiation of **1** is much faster than that of benzyl methyl sulfoxide. Comparison of these results with the Rauk–Wolfe–Csizmadia nonempirical calculations on α-sulfinyl carbanions indicates that current theoretical understanding is as yet incomplete.

Dans le NaOD–D_2O à 5.0°, les hydrogènes-α *trans* par rapport à l'oxygène dans l'oxyde-2 de dihydro-1,3 benzo[*c*]thiophène (**1**) s'échangent 67 fois plus rapidement que les hydrogènes *cis*. Les hydrogènes *cis*, à leur tour, s'échangent légèrement plus vite que le plus rapide des hydrogènes-α du groupe méthelène dans le sulfoxyde de benzyle et de méthyle. La réaction de **1** avec du méthyllithium arrêtée brusquement par du DCl à conduit majoritairement à un composé *cis* monodeutérié. On montre aussi que l'enlèvement d'un hydrogène lors de l'étape de lithiation implique la perte de l'hydrogène *cis*, et que la lithiation de **1** est beaucoup plus rapide que celle du sulfoxyde de benzyle et de méthyle. La comparaison de ces résultats avec les calculs non-empiriques de Rauk–Wolfe–Csizmadia sur les carbanions α-sulfinyles montre que l'interprétation théorique courante est encore à ce stade-ci incomplète.

[Traduit par le journal]

Can. J. Chem., **51**, 4082 (1973)

Asymmetric induction in reactions involving α-sulfinyl carbanions and related species has been much studied in recent years (1–18), though a truly predictive theoretical description of these reactions for practical use has not as yet been elaborated. In the hope of contributing to the development of such a rationale we describe our observations with 1,3-dihydrobenzo[*c*]thiophene 2-oxide (**1**), a simple cyclic sulfoxide in which the asymmetric induction derives entirely from one prochiral sulfur atom and in which a number of the steric features of these reactions can be seen very easily.



1

a X = Y = X′ = Y′ = H
b X = X′ = H; Y = Y′ = D
c X = X′ = D; Y = Y′ = H
d X (or X′) = D; Y = Y′ = X′ (or X) = H
e X (or X′) = H; Y = Y′ = X′ (or X) = D
f X = Y = X′ = Y′ = D

The n.m.r. spectrum of **1***a* in $CDCl_3$ shows an AB quartet, δ_A 4.13, δ_B 4.28 p.p.m., J = 16 Hz, due to the diastereotopic hydrogens of the mutually enantiotopic methylene groups. When **1***a* is treated with NaOD in D_2O, the quartet is first quickly replaced by a 1:1:1 triplet at δ 4.12 (J = 2.2 Hz) which after increasing in area to become close to half of that of the original AB quartet subsequently gradually disappears entirely; these results signify a rapid exchange of the lower field protons followed by much slower exchange of the epimeric hydrogens. The stereochemistry of the α-hydrogens is assigned by "shift reagent" experiments, which have been shown by recent studies (19) to provide an apparently reliable method for determining the configuration of hydrogens in cyclic sulfoxides. Addition of $Eu(dpm)_3$ to the solution of **1***a* gave a very strong downfield shift of the higher field signal and a smaller shift of the lower field component of the AB quartet. The higher field proton (which is the slower exchanging one in D_2O) is therefore *cis* (*syn*-periplanar (18)) to the oxygen[1]

[1]The geometry of **1** is not known precisely. A fully planar skeleton (in which the dihedral angle of the *cis* and *trans* hydrogens with the oxygen would be 0° and 120°, respectively) would have the least angle strain but eclipsing interactions along the C—S bonds could distort the system from full planarity, though not beyond the ±30° limits of the Klyne–Prelog descriptors.

TABLE 1. Hydrogen–deuterium exchange in the lithiation–acidification of sulfoxide **1**

Starting material			Isotopic composition of product (%)	Change in deuterium content (at. % excess deuterium)			Stereochemistry of exchange (from n.m.r.)
Major component	Isotopic composition (%)	Quenching acid*		From mass spectrum	From D analysis	From n.m.r.	
1*a*	d_0 100	DCl	d_0 14.7 d_1 71.7 d_2 12.8 d_3 0.2 d_4 0.5	12.5 increase	12.3 increase	13.7 increase	*cis* (88%) *trans* (12%)
1*b*	d_0 0 d_1 6.0 d_2 79.0 d_3 12.6 d_4 2.4	DCl	d_0 0 d_1 3.1 d_2 11.3 d_3 62.2 d_4 23.3	11.7 increase	10.6 increase	11.9 increase	*cis*†
1*c*	d_0 0 d_1 10.6 d_2 71.6 d_3 12.6 d_4 5.1	HCl	d_0 11.9 d_1 63.6 d_2 20.8 d_3 2.8 d_4 0.8	12.0 decrease	11.3 decrease	10.7 decrease	*cis*†
1*f*	d_0 0 d_1 0 d_2 0 d_3 5.3 d_4 94.6	HCl	d_0 0 d_1 0 d_2 17.9 d_3 77.0 d_4 5.1	12.7 decrease	13.4 decrease	13.9 decrease	*cis* (93%) *trans* (7%)

*The lithio derivatives of **1***a* and *b* were also quenched with HCl, and those of **1***c* and *f* with DCl. The product was in each case indistinguishable from starting material except with **1***c* (and DCl), which showed a slight increase (2.5% by n.m.r. 1.5% by deuterium analysis) in the amount of deuterium; the apparently exceptional behaviour of **1***c* probably arises from the presence of a significant proportion of *cis* hydrogens in the starting material (note particularly the relatively high proportion of d_1 sulfoxide).

†The n.m.r. spectra show the *cis* exchange to be much the more important, but do not appear to warrant a more quantitative interpretation.

and the low-field, more rapidly exchanged proton (in D_2O), *trans* (*anti*-clinal) to the oxygen. Quantitative n.m.r. studies gave the following pseudo-first-order rate constants for the exchange in 0.1 *M* NaOD in D_2O at 5°: $k'_{trans} = 2.2 \times 10^{-3}\ s^{-1}$, $k'_{cis} = 3.3 \times 10^{-5}\ s^{-1}$, $k'_{trans}/k'_{cis} = 67$. Under the same conditions with benzyl methyl sulfoxide, we found for the faster hydrogen of the methylene group $k' = 3.1 \times 10^{-5}\ s^{-1}$, slightly less than that of the slower hydrogens in **1***a*.

Durst and Fraser and their co-workers (7) have shown that the relative rates of exchange of the two diastereotopic methylene hydrogens in benzyl methyl sulfoxide are altered by changing base or solvent. We have obtained a similar result with **1**; with an equimolar amount of methyllithium in tetrahydrofuran at 0° followed by rapid quenching with DCl in D_2O, **1***a* gave principally the *cis*-monodeuterated sulfoxide **1***d*.

For the reactions with NaOD in D_2O, both the principle of microscopic reversibility and the fact that one may readily isolate a fairly pure sample (>70%) of **1***b* by simple exchange of **1***a*, require that the proton abstraction and deuteron addition proceed with the same stereochemistry, *i.e.* that a *trans* hydrogen be removed and the deuteron enter *trans* (to the oxygen). With the methyllithium reaction the disposition of the deuterium in the product gives information about the stereochemistry (preferentially *cis*) of the *quenching* step only; the experiments summarized in Table 1 show the proton *removal* step to be preferentially *cis* as well. For example, compound **1***b* (in which the deuterium atoms are *trans* to the oxygen) on lithiation followed by quenching with DCl gave chiefly the trideuterated product (**1***e*), thereby showing that the lithiation abstracted one of the protium atoms (which are *cis* to the oxygen). In addition, quenching of the lithio derivative of **1***b* with HCl gave back essentially unchanged **1***b*, as expected. That the above results did not derive from a deuterium isotope effect was shown by the corresponding experiments starting with **1***c*, which has the deuterium atoms *cis* to the oxygen. With **1***c* lithiation proceeds with abstraction of a deuteron as shown by trapping with (*i*) HCl to give principally the monodeuterated product

(**1***d*) and (*ii*) with DCl to give back **1***c*; it is evident that the preference for removal of a *cis* hydrogen is more than sufficient to outweigh completely any favouring of the *trans* hydrogens arising from a primary kinetic isotope effect.

The process of lithiation and quenching of **1** thus proceeds with overall retention of configuration at the α-carbon. Very recently Viau and Durst (16) have found similar retention of configuration in the exchange of the benzylic hydrogen of benzyl *t*-butyl sulfoxide by reaction with methyllithium followed by quenching with water. The analogous reaction of benzyl methyl sulfoxide, however, is not as clearcut. It has been reported that the reaction of butyllithium followed by water proceeds with overall inversion of configuration (17, 18) but the work of Viau and Durst (16) implies that retention is the major process; the reported stereoselectivities for the deprotonation step, however, are apparently not large (16, 17) even if there is disagreement as to their magnitude. It seems likely that the comparatively low stereoselectivity observed in the deprotonation of benzyl methyl sulfoxide derives from the high conformational mobility of that molecule (relative to **1** or benzyl *t*-butyl sulfoxide), which allows either of the diastereotopic hydrogens to become easily oriented in a conformation favorable for deprotonation.

Inspection of the data in Table 1 shows that in addition to the principal results discussed above, there are formed in these reactions significant amounts of multiexchanged products. The origin of these materials is not established but it seems likely that they arise at least in part from reaction of more than one molecule of alkyllithium. When 2 equiv. of methyllithium were used instead of 1.1 (as in the experiments in Table 1), **1***a* gave a product in which about 1.5 hydrogens per molecule were exchanged. It is also conceivable that some of the anomalous products could have arisen by base-catalyzed exchange in the aqueous medium during quenching but experiments using different rates of addition of acid or different stirring speeds during quenching gave no support for this notion.

With **1***b* and *c*, which contain both α-protium and α-deuterium atoms, there is a possibility of intermolecular hydrogen scrambling prior to quenching. When **1***a* was treated with methyllithium and then with **1***f* and the mixture allowed to stand for 10 min before quenching with HCl, the n.m.r. spectrum of the recovered sulfoxide showed CH_2 and CHD peaks of roughly equal intensity, indicating extensive exchange of the hydrogens. When the addition of **1***f* was followed by immediate quenching, however, the scrambling was almost completely suppressed; since the latter conditions more closely approximate those used to obtain the data in Table 1, it is unlikely that intermolecular hydrogen exchange prior to quenching is of any importance in those experiments. With **1***a* and *f*, of course, such exchange is impossible; it was found that the composition of the product was essentially the same with either a rapid quench or a 10 min wait before quenching but the recovered material in the former case was less discoloured and more readily obtained crystalline.

It has been noted above that the reaction of **1** in aqueous medium is faster than that of benzyl methyl sulfoxide. The cyclic sulfoxide (**1**) is also more reactive to methyllithium than benzyl methyl sulfoxide, as was shown by a competition experiment in which methyllithium, **1***a*, and benzyl methyl sulfoxide in the molar ratio 2:1:2 were mixed and quenched with DCl as before; the n.m.r. spectrum of the product showed that **1** was extensively exchanged whereas the benzyl methyl sulfoxide was apparently unaltered.

Rauk, Wolfe, and Csizmadia (4) have reported nonempirical calculations on the dependence on geometry of the energy of formation of an α-sulfinyl carbanion. Their calculations indicate that in the planar conformation of **1** the *anti*-clinal anion (which is close to the lower energy maximum) would be formed more readily than the *syn*-periplanar anion (which lies about halfway up the higher energy maximum). This corresponds to our observations in aqueous medium, but because the *syn*-periplanar species corresponds to a region of maximum slope, any prediction on this basis is highly suspect without precise knowledge of the geometry of the molecule. The results with methyllithium, of course, since they are opposite to those found with NaOD in D_2O cannot be similarly explained. It is perhaps conceivable that the conformation of **1** is altered from that in D_2O to give an "envelope" conformation with the oxygen quasi-axial; this could give dihedral angles appropriate (according to the m.o. calculations) to the faster exchange of the hydrogens *cis* to the oxygen, but this hypothetical alteration of conformation is not readily accounted for and certainly would not have been predicted.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Much more disquieting, however, is the fact that the m.o. calculations do not appear to be consistent with the comparatively slow rate of reaction of benzyl methyl sulfoxide in *either* reaction medium, even though conformations calculated to be much more favorable than those accessible to **1** (and its anion) would appear to be readily available.

The Rauk–Wolfe–Csizmadia calculations specifically omit solvation and other "external" effects, except insofar as these can be accounted for on the basis of conformational changes; it is highly unlikely that all of the medium effects observed to date, especially those found with comparatively rigid systems such as that used in the present study, can be thus explained. It would appear then that the theoretical calculations are not in themselves sufficient to enable prediction of the ease of formation of α-sulfinyl carbanions under the varying conditions commonly employed and that further work, both experimental and theoretical, seems in order.

Experimental

Melting points were determined on a Kofler hot stage and are uncorrected. The i.r. spectra were obtained with a Beckman IR-20A spectrophotometer using chloroform as solvent and sodium chloride cells. Unless otherwise stated, the n.m.r. spectra were determined on a Varian HA-100 spectrometer with $CDCl_3$ as solvent. The mass spectra (m.s.) were obtained on a Varian M-66 instrument; the correction tables of Hamming and Foster (21) were used when estimating isotopic composition from the mass spectrum. Deuterium analyses were performed by Josef Nemeth, Urbana, Ill. Magnesium sulfate (anhydrous) was used as the drying agent for organic solutions.

1,3-Dihydrobenzo[c]thiophene 2-Oxide (1a)

To a rapidly stirred solution of sodium metaperiodate (25.7g, 0.12 mol) in water (230 ml) was added dropwise molten 1,3-dihydrobenzo[c]thiophene (14.8 g, 0.11 mol) (22). The mixture was stirred at room temperature for 1 h, then cooled to 0° for 3 h. The white precipitate (sodium iodate) was removed by filtration and washed with cold water. The filtrate and washings were extracted three times with methylene chloride. The extracts were dried and the solvent evaporated to give yellow crystals (16.4 g). The crude product was dissolved in ether and filtered through neutral alumina to remove the coloured impurities. The ether was evaporated and the crystalline residue recrystallized from benzene–pentane to give colourless plates, m.p. 89–91° (15.6 g, 93.5%); i.r.: 1040(s) and 1485, 1210, and 1125 cm^{-1} (all weak); n.m.r.: AB quartet (4H), δ_A 4.13 and δ_B 4.28 (J = 16 Hz), singlet 7.35 p.p.m. (4H); with $Eu(dpm)_3$ shift reagent 0.3 equiv AB quartet δ_A 6.92 and δ_B 5.73 p.p.m.

Anal. Calcd. for C_8H_8OS: C, 63.13; H, 5.30; S, 21.06. Found: C, 63.35; H, 5.49; S, 21.18.

trans-1,2-cis-1,3-1,3-Dihydrobenzo[c]thiophene-1,3-d_2 2-Oxide (1b)

To a stirred, ice-cooled solution of NaOD in D_2O (10 ml, 0.1 *N*) was added 5 mmol of sulfoxide **1***a* (0.76 g). This solution was stirred at 0° for 60 min, then quenched with 0.1 *N* HCl (12 ml). The aqueous solution was extracted twice with methylene chloride. The extracts were dried and solvent removed to give a quantitative yield of crystalline sulfoxide. Recrystallization from benzene–pentane gave colourless plates, m.p. 89–90°; n.m.r.: triplet 4.12 p.p.m. (1:1:1, J = 2.2 Hz, 2H), singlet 7.35 p.p.m. (4H). With 0.3 equiv $Eu(dpm)_3$ shift reagent, the triplet is shifted to 6.87 p.p.m. The isotopic composition was estimated from the peaks at *m/e* 152 to 156: d_0, 0; d_1, 6.0; d_2, 79.0; d_3, 12.6; d_4, 2.4%, average 26.4 at. % excess deuterium.

Anal. Calcd. for $C_8H_6D_2OS$: 25.00 at. % excess deuterium. Found: 25.50 at. %.

1,3-Dihydrobenzo[c]thiophene-1,1,3,3-d_4 2-Oxide (1f)

A solution of the sulfoxide **1***a* (1 g) in 0.1 *N* NaOD (25 ml) was warmed to 50° for 1 h. The reaction was quenched with 0.5 *N* HCl (10 ml) and extracted with methylene chloride. The extracts were dried and solvent evaporated to give crystalline product (1.0 g, 98%). Recrystallization from benzene–pentane gave colourless plates, m.p. 90–91°. The n.m.r. indicated quantitative exchange of the methylene protons; the m.s. showed: d_3, 5.3; d_4, 94.6%; average 49.3 at. % excess D.

Anal. Calcd. for $C_8H_4D_4OS$: 50.00 at. % excess deuterium. Found: 47.85 at. %.

cis-1,2-cis-1,3-1,3-Dihydrobenzo[c]thiophene-1,3-d_2 2-Oxide (1c)

The tetradeuterated sulfoxide **1***f* (400 mg) was dissolved in aqueous sodium hydroxide (10 ml, 0.1 *N*) at 0° and allowed to react for 3 h. Upon quenching with 0.5 *N* HCl (4 ml), the solution was extracted with methylene chloride and the extracts were dried and solvent evaporated to give crystalline sulfoxide (391 mg, 99%). Recrystallization from benzene–pentane gave colourless plates (340 mg, 86%), m.p. 89–90.5°; n.m.r. triplet 4.25 p.p.m. (1:1:1, J = 2.2 Hz, 2H), singlet 7.31 p.p.m. (4H). With 0.3 equiv $Eu(dpm)_3$ shift reagent, the triplet is shifted to 5.81 p.p.m.; m.s.: d_0, 0; d_1, 10.6; d_2, 71.6; d_3, 12.6; d_4, 5.1%; average, 26.5 at. % excess deuterium.

Anal. Calcd. for $C_8H_6D_2OS$: 25.00 at. % excess deuterium. Found: 24.90 at. %.

Measurement of Deuterium Exchange Rates in Aqueous Medium

1,3-Dihydrobenzo[c]thiophene 2-Oxide (1a)

The rate of exchange of the hydrogens *trans* to the oxygen was much faster than the exchange rate of the *cis* hydrogens, so that the exchange of either set could be studied separately. In both cases, a solution of sulfoxide (10.00 mmol, 0.40 *N*) in 0.10 *N* NaOD–D_2O (25.00 ml) was prepared at 5.0° and 2-ml aliquots were withdrawn at appropriate intervals (2 min for the *trans* hydrogens or 60 min for the *cis* hydrogens). The samples were quenched in HCl (1 ml, 0.5 *N*) and the partially exchanged sulfoxide recovered by extraction with methylene chloride. The crude samples were recrystallized from benzene–pentane. The n.m.r. of each was then recorded on a Varian T-60 instrument equipped with a signal-lock device. The

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

samples were run in $CDCl_3$–TMS with an equal weight of Eu(fod)$_3$ shift reagent. Percent exchange for the *trans* hydrogens was determined by comparing the integral for the *trans* hydrogens with that of the aromatic hydrogens. The slope (obtained by the method of least squares) of a plot of log (100 − % exchange) *vs.* t was divided by 2.303, thereby giving directly the rate constant for the exchange of each *trans* hydrogen. The corresponding rate constant for the *cis* hydrogens was obtained similarly from the integral of the signal due to the *cis* hydrogens. The pseudo-first-order rate constants so obtained were $k_{trans} = 2.2 \times 10^{-3}$ s^{-1}, $k_{cis} = 3.3 \times 10^{-5}$ s^{-1}, and $k_{trans}/k_{cis} = 67$.

Benzyl Methyl Sulfoxide

The rate difference between the diastereotopic benzylic hydrogens of benzyl methyl sulfoxide was not sufficiently large to allow determination of the individual rates in the same way as had been used with **1** and a modified procedure was required. A solution (20 ml) of benzyl methyl sulfoxide (8.00 mmol, 0.40 *N*) in 0.10 *N* NaOD–D_2O at 5.0° was prepared. Aliquots (2 ml) were withdrawn and quenched at suitable intervals (2 h for the fast exchange or 12 h for the slow exchange) and the sulfoxide isolated and recrystallized from petroleum ether (b.p. 30–60°). The n.m.r. spectra were recorded on a Varian T-60 spectrometer and the total amount of exchange determined from the integration. The rates of exchange of the two hydrogens were calculated from a plot of log [100 − % exchange] as a function of time. The slower exchange rate was determined directly from the linear part of the graph and the best slope extrapolated back to $t = 0$. The differences between this line and the curve for the faster exchanging proton were plotted as a function of time to give a linear slope from which the faster rate was calculated. The pseudo-first-order rates thus determined were $k_1 = 3.1 \times 10^{-5}$ s^{-1}, $k_2 = 1.4 \times 10^{-6}$ s^{-1}, and $k_1/k_2 = 22$.

α-Exchange of 1,3-Dihydrobenzo[c]thiophene 2-Oxide by the Lithiation and Quenching Procedure

Typically, the sulfoxide (1 mmol) was dissolved in 30 ml tetrahydrofuran (freshly distilled from calcium hydride) under nitrogen and the solution cooled to 0°. Methyllithium (1.1 mmol, in ether) was then added to the rapidly stirred solution through a serum cap, using a hypodermic syringe. The resulting yellow solution was rapidly quenched (within 10 s) with DCl–D_2O (1 ml, *ca.* 4 *N*) or aqueous HCl (5 ml, 0.5 *N*). This mixture was quickly worked up by diluting with water and extracting twice with methylene chloride. The extracts were dried and solvent evaporated. The residue was transferred immediately to a thick layer silica gel plate and developed with ethyl acetate. The first band above the baseline was isolated, treated with decolourizing carbon, and crystallized from benzene–pentane. Recrystallization gave colourless plates with sharp melting points with about 50% recovery or better. The product analyses are shown in Table 1.

The following experiments were carried out to determine the effect of varying some of the reaction conditions. (*i*) When the sulfoxide (**1***a*) was treated under conditions identical to those given above except that the DCl was added 10 min after addition of the methyllithium, the recovered product after recrystallization (~30%) showed the presence of 12 at. % excess deuterium by n.m.r.; m.s.: d_0, 19.2; d_1, 68.0; d_2, 11.9; d_3, 0.5; d_4, 0.4%; average 11.9 at. % excess deuterium. (*ii*) With **1***a* and 2 mmol of methyllithium (1.34 ml, 1.5 *M*) and otherwise identical conditions as those used to obtain the data in Table 1 the n.m.r. spectrum of the product (24 mg, 15%) showed the presence of 19 at. % excess deuterium (*i.e.* about 1.5 deuterium atoms per molecule); m.s. showed d_0, 4.0; d_1, 60.2; d_2, 31.5; d_3, 3.9; d_4, 0.4%; average 17.1 at. % excess deuterium. (*iii*) Sulfoxide **1***a* (76 mg, 0.5 mmol) in tetrahydrofuran (40 ml) was treated at 0° with methyllithium (0.5 mmol) and the mixture allowed to stand for 10 min. Then **1***f* (78 mg, 0.5 mmol) dissolved in tetrahydrofuran (5 ml) was added and the mixture allowed to stand for 10 min. Work-up as above yielded an oily product (127 mg, 83%) which was purified by t.l.c. (developing with methylene chloride). The n.m.r. spectrum showed considerable exchange manifest by a decrease in the AB quartet pattern of the methylene group and a sizeable CHD signal (roughly the same area as the CH_2 signal). When the above experiment was repeated except that the addition of **1***f* was followed immediately (3 or 4 sec later) by acid quenching, the n.m.r. spectrum of the product (137 mg, 87%) indicated much diminished (< 5%) formation of the CHD products.

Competition of Sulfoxide 1a and Benzyl Methyl Sulfoxide for Methyllithium

Sulfoxide **1***a* (152 mg, 1 mmol) and benzyl methyl sulfoxide (308 mg, 2 mmol) were dissolved in 40 ml tetrahydrofuran (freshly distilled from calcium hydride) under nitrogen. (This ratio of the two sulfoxides gives a 1:1 ratio of benzylic hydrogens α to the sulfinyl groups). This solution was cooled to −78° and 1 mmol of methyllithium (0.67 ml, 1.5 *M*) in ether was added through a serum cap (hypodermic syringe). The resulting yellow solution was quenched within 10 s with DCl–D_2O (1 ml, *ca.* 4 *N*). This was quickly worked up by diluting with water and extracting twice with methylene chloride. The extracts were dried, treated with decolourizing carbon, and the solvent evaporated to give a yellow oil (417 mg, 90%). The n.m.r. of the crude product showed no detectable impurities. From the integration, it was deduced that the ratio of deuterium incorporation for **1***a* *vs.* benzyl methyl sulfoxide was 11 to 1.

We thank Dr. M. C. Woods for aid and advice on the "shift reagent" experiments, Professors R. R. Fraser and T. Durst (University of Ottawa) for helpful discussions and unpublished information, and the National Research Council of Canada for financial support.

An Electron Spin Resonance Method for Monitoring the Progressive Replacement of Fluorine by Alkoxy Groups in Perfluorobenzophenone[1]

FREDERICK PETER SARGENT AND MARSHALL GRANT BAILEY

Research Chemistry Branch, Atomic Energy of Canada Limited, Whiteshell Nuclear Research Establishment, Pinawa, Manitoba R0E 1L0

Received July 6, 1973

The use of electron spin resonance (e.s.r.) to follow the course of a chemical reaction which does not involve paramagnetic intermediates is reported. The principle of the method is the conversion of the reaction product into a paramagnetic species which may be characterized by e.s.r. In the present example, photoconversion of ketones into radical anions is used to follow the successive displacement of fluorine from perfluorobenzophenone.

On rapporte l'utilisation de la résonnance paramagnétique électronique (r.p.e.) pour établir la nature du chemin suivi par une réaction chimique qui n'implique pas d'intermédiaires paramagnétiques. Le principe de la méthode est de transformer le produit de la réaction en une espèce paramagnétique caractérisable par r.p.e. A titre d'exemple, on utilise la photoconversion de cétones en radicaux anions pour examiner les déplacements successifs du fluor en perfluorobenzophénone.

[Traduit par le journal]

Can. J. Chem., 51, 4088 (1973)

Introduction

Displacement of fluorine from highly fluorinated aromatic compounds is well known and is an important synthesis route for many partly fluorinated compounds (1). During our studies (2) of the photochemistry of perfluorobenzophenone, $(C_6F_5)_2CO$, henceforth referred to as PFB, a simple method for demonstrating and monitoring the successive replacement of fluorine by methoxide groups in basic methanol solutions was discovered. This replacement process is generalized in eqs. 1 and 2.

[1] $$C_nF_m + CH_3O^- \rightarrow C_nF_{m-1}OCH_3 + F^-$$

[2] $$C_nF_p(OCH_3)_q + CH_3O^- \rightarrow C_nF_{p-1}(OCH_3)_{q+1} + F^-$$

The method involves photoconversion of the ketone into its radical anion (3, 4). The number of fluorines replaced may be deduced from the changes in the e.s.r. spectra.

Experimental

The e.s.r. spectra were obtained with a Varian V-4500 spectrometer. The magnetic field sweep was calibrated with aqueous solutions of Fremy's salt assuming a_N to be 13.0 G. All chemicals were reagent grade and were used as received. Solutions of methoxide were prepared by dissolving freshly cut pieces of sodium in methanol. The photolyses were performed in the sample cavity of the e.s.r. spectrometer with a 100-W, compact-arc, medium-pressure, mercury lamp.

Results and Discussion

A methanolic solution containing 0.1 mol/kg PFB and 1 mol/kg methoxide was prepared by mixing. Aliquots of this were taken at various times after mixing and photolyzed *in situ* in the e.s.r. spectrometer. The spectrum shown in Fig. 1 was observed immediately after mixing. This closely resembles that reported by Brown and Williams (5), the interpretation being given in Table 1. We also assign this spectrum to the radical anion of 4,4'-dimethoxyoctofluorobenzophenone, $(C_6F_4OMe)_2CO$. The presence of this ketone shows that the two *para* fluorines of PFB which have a hyperfine splitting of 8.36 G (2), have been replaced by methoxy groups which do not give a resolvable hyperfine splitting, in the e.s.r. spectrum of the anion.

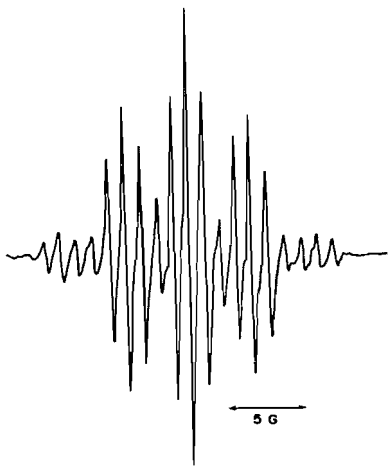

FIG. 1. The e.s.r. spectrum observed during the photolysis of solutions of methoxide and perfluorobenzophenone immediately after mixing.

TABLE 1. The e.s.r. hyperfine splitting (G) for the observed spectra. The numbers in parentheses are the number of equivalent fluorine nuclei

	Position	
Spectrum	*ortho*	*meta*
Fig. 1	4.57 (4)	1.14 (4)
Fig. 2	4.65 (2)	0.87 (4)
Fig. 3	5.90 (1)	1.6 (2)

Photolysis of an aliquot of the mixture 1 h after mixing gave the spectrum shown in Fig. 2 and described in Table 1. The prominent features of the spectrum are a triplet of quintets. These originate from an anion containing only six fluorine atoms. The four fluorines of 0.87 G were assigned to the *meta* positions. The remaining two fluorine nuclei are clearly at *ortho* positions but the spectra do not indicate which positions. From steric considerations, this radical was assigned to the ketyl of 2,2′,4,4′-tetramethoxyhexafluorobenzophenone. The presence of this ketone shows that after the two *para* fluorines are substituted, two *ortho* fluorines are replaced by methoxide.

Photolysis of an aliquot of the mixture 1 week after mixing gave the spectrum shown in Fig. 3 and Table 1. The major features of this are a doublet of triplets which would arise from three fluorine nuclei, two of which are equivalent. The latter have a hyperfine splitting of 1.58 G and undoubtedly occupy *meta* positions. The remaining fluorine with splitting of 5.9 G must originate from an *ortho* position. Therefore this spectrum shows the presence of a heptamethoxytrifluorobenzophenone. The sharp central features of the spectrum in Fig. 3 arise from residual tetramethoxyhexafluorobenzophenone.

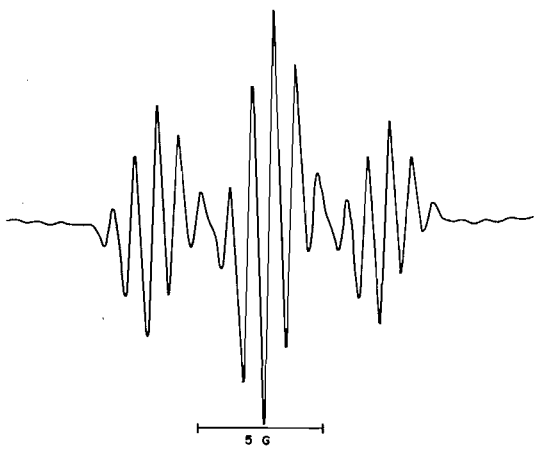

FIG. 2. The e.s.r. spectrum observed during the photolysis of solutions of methoxide and perfluorobenzophenone 1 h after mixing.

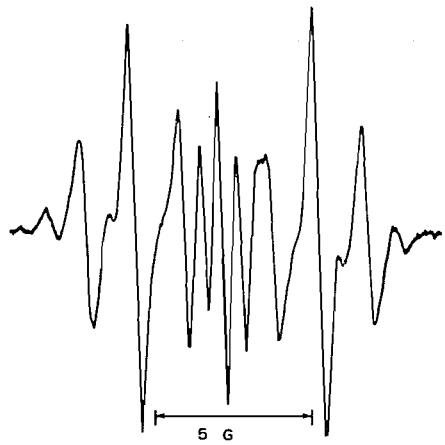

FIG. 3. The e.s.r. spectrum observed during the photolysis of solutions of methoxide and perfluorobenzophenone one week after mixing.

When solutions of PFB and methoxide were mixed and continuously photolyzed, similar changes are observed. Therefore the successive nucleophilic replacement of fluorine by methoxy groups are not affected by the photolysis. The latter merely serves as a probe to determine the progress of the reaction.

Summary

The observations reported demonstrate the use of e.s.r. to follow the successive replacements of fluorine in perfluorobenzophenone by methoxy groups. The principle of the method is the conversion of the products of a chemical reaction into a paramagnetic species which may be characterized by e.s.r. This conversion may be made by any means suitable to the system under study. In the present example, the well-known photoconversion of ketones to radical anions (3, 4) was used. Other methods could involve radiolysis, thermolysis, electrolysis, the reaction with alkali metals, or oxidation–reduction reactions.

Carbonium Ion Rearrangement with Retention at the Migration Terminus

FERRERS R. S. CLARK AND JOHN WARKENTIN
Department of Chemistry, McMaster University, Hamilton, Ontario

Received July 13, 1973

The isomeric 7-*t*-butylbicyclo[2.2.1]hept-2-en-7-ols afford isomeric dienes (7-methyl-7-(2′-propenyl)-bicyclo[2.2.1]hept-2-enes) by Wagner–Meerwein rearrangement on treatment with thionyl bromide or acid. Methyl migration in the nonclassical 7-*t*-butylbicyclo[2.2.1]hept-2-en-7-yl cation intermediate occurs with a substantial *syn* preference, in sharp contrast to the *anti* preference exhibited in capture of similar cations by external nucleophiles. The result is interpreted in terms of a steric factor.

Les *t*-butyl-7 bicyclo[2.2.1]heptène-2 ols-7 isomériques conduisent aux dienes isomériques (méthyl-7 (propènyl-2′)-7 bicyclo[2.2.1.]heptène-2) à l'aide d'un réarrangement Wagner-Meerwein lorsque l'on traite les alcools avec du bromure de thionyle ou de l'acide. La migration du méthyl dans le cation intermédiaire non-classique *t*-butyl-7 bicyclo[2.2.1.]heptène-2 yle-7 se produit préférentiellement de manière *syn*, ce qui est en désaccord avec la préférence *anti* manifestée lors de la fixation de cations similaires par des nucléophiles externes. On explique ce résultat par l'intervention d'un facteur stérique.

Can. J. Chem., 51, 4090 (1973)

Rearrangements involving migration of an atom or a group from one quaternary carbon atom to another through a carbocation intermediate generally proceed with net inversion of the migration terminus. There are exceptions to this generalization, notably cases in which geometric constraints are such as to effectively rule out migration to one face of the cation center. A 6,2-hydride shift in a bicyclo[2.2.1]-hept-2-yl cation (eq. 1) probably involves the *endo* face of the cationic center,[1] regardless of

[1] 
whether the cation originated from *exo* or *endo* precursor. For stepwise reaction (eq. 1) the stereochemical course of migration, with respect to C-2, should be defined without reference to the identity of the starting isomer, since such identity is lost prior to rearrangement. In rearrangement of the cation, the substituent "leaving" C-2 is C-1; the bond order between C-1 and C-2 decreasing as a consequence of 6,2-hydride transfer. The stereochemical outcome at the migration terminus is therefore retention of configuration (2). The stereochemical outcome of 6,2-migration concerted with C—X heterolysis would be defined in terms of precursor structure in the usual way, *exo* and *endo* precursors having rearranged with inversion and retention, respectively.

The mechanistic similarity between intramolecular rearrangement and nucleophilic substitution at saturated carbon is generally recognized. This similarity extends to nonclassical cation systems in which either reaction involves a nominal leaving group consisting of part of the molecular framework, held to the migration terminus (or the site of substitution) of the ion by a partial bond. Bicyclo[2.2.1]hept-2-yl cations are captured with a strong *exo* preference, even if *exo* approach is hindered by a 7-methyl substituent (3–5). Rearrangement of such cations, by 2,3-hydride transfer (6) or alkyl migration (7, 8), is also highly *exo* selective. Similarly, all 7-norbornenyl cations studied to date react faster with nucleophiles at the *anti*-C_7 face than at the *syn* face. The preference for inversion, which is very high in the 7-unsubstituted (9–11) and the 7-ethyl cations (12), becomes less pronounced in cases where the 7-substituent is a good electron donor, such as *p*-anisyl (13) or alkoxy (14, 15). Intramolecular attacks at C-7 of such ions, by migration of a group from a 7-substituent to C-7, should show analogous preferences. In a case of hydride transfer (eq. 2) migration was, in fact, highly

[1]Although *endo–endo* migration has not been established in the unsubstituted system, it has been demonstrated in the 2-carboxy-3-methyl-5-norbornyl cation (1).

1:**2** = 1:1	HOAc, 10% H_2SO_4, 22.5°, 3 h	4.9	4.9	74	13[f]

[a]A mixture of the two alcohols gave only one bromide on treatment with $SOBr_2$ in Et_3N. The (*E*)-configuration was assigned, on the basis of its n.m.r. spectrum.
[b]A zero means that the material in question was not detectable by g.l.p.c.; *i.e.*, $< \sim 2\%$.
[c]Plus starting material.
[d]Each isomer separately gave the results shown.
[e]An unidentified material (**8**, 27%) was present. The total yield is based on the assumption that **8** is an isomer of the dienes.
[f]The mixture contained **8** (11%), another unidentified product **9** (5%), and materials, probably polymeric, which were not extracted into petroleum ether. The yield was estimated assuming that **9** is also an isomer of the dienes.

[2] 
anti selective (16) and the authors concluded that a nonclassical ion must be an intermediate.[2] Although there are no reported cases of alkyl migrations to C-7 of 7-norbornenyl cations, one would predict the analogous preference for inversion at C-7; that is, for *anti* migration. Therefore it came as a surprise to us when we found a marked *syn* preference in such a process.

Results and Discussion

Treatment of the isomeric (*Z*)- and (*E*)-7-*t*-butylnorbornen-7-ols (**1** and **2**, respectively) with thionyl bromide in refluxing CCl_4, with acetic acid, and with acetic acid containing sulfuric acid gave the results listed in Table 1. Gross structures of the isomeric dienes, (*E*)- and (*Z*)-7-methyl-7-(2′-propenyl)bicyclo[2.2.1]hept-2-enes (**3** and **4**, respectively) followed from elemental analysis, from their characteristic norbornene-like p.m.r. spectra, and from their interconversion in acid with concurrent formation of ether (**5**). Assignment of stereochemistry to **3** and **4** rests on the 8% nuclear Overhauser effect (n.O.e.) found on irradiation of the 7-methyl signal of **3** while observing the vinyl signal.[3] Diene **4** did not show a corresponding, measurable n.O.e. The analogous n.O.e. value in a model for **3**, (*E*)-7-acetoxy-7-methylnorbornene, was 5%.

The results in Table 1 are consistent only with reaction mechanisms involving the nonclassical 7-*t*-butylbicyclo[2.2.1]hept-2-en-7-yl cation as intermediate. A common intermediate is indicated in the fact that **1** and **2** give the same mixture of **3**, **4**, and **5**.[4] That the intermediate is a nonclassical ion is suggested by much analogy (18), for all known norborn-2-en-7-yl cations, with the possible exception of the 7-*p*-anisyl (13), the 7-*p*-dimethylaminophenyl (13), and some 7-alkoxy analogs (14, 15), all of which derive

[2]If a nonclassical ion mechanism is correct, then either isomer of the substrate would give the same product and the stereochemistry of the migration step is correctly described as inversion at the migration terminus. The authors (16) called their stereochemistry retention; which focuses attention on the substrate rather than on the immediate precursor of the rearranged ion.

[3]Average of six measurements. The separation between methyl and C-2,3 vinyl hydrogens that corresponds to a n.O.e. value of 8% is about 3 Å (17).

[4]Rows 4 and 6, 5 and 7, or 8 of Table 1.

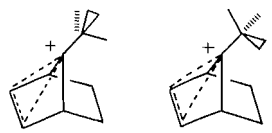
[3] 
conjugative stabilization from the 7-substituent which the *t*-butyl group cannot provide, are best described as nonclassical ions. The greater reactivity of **2**, relative to that of **1**, is in keeping with anchimeric assistance to rate-determining formation of the nonclassical 7-*t*-butylbicyclo-[2.2.1]hept-2-en-7-yl cation. Since the formal leaving group in subsequent rearrangement of that ion is the bridging etheno group, the stereochemistry at the migration terminus is retention of configuration. A rationale for this preference is discussed below.

Equilibration of dienes **3** and **4**, which must occur by the reverse of the Wagner–Meerwein rearrangements which formed them, is slow in acetic acid. This means that the initial diene ratio is determined largely by kinetics. The thermodynamic diene ratio appears to be close to 1:1, as expected on the basis of the small difference between the steric requirements at the *syn* and *anti* faces (15). Formation of ether (**5**) in the more acidic media is readily accounted for by either or both of the pathways of eq. 3.

We now turn to discussion of the stereochemistry of methyl migration. Electronic interaction energies, from simple LCAO calculations (6), favor the inversion mode for similar migrations. The facts that external nucleophiles prefer *anti* approach and that hydride transfer (eq. 2) shows the same selectivity suggest that the reversal in the present case is not stereoelectronically determined. It is also unlikely that thermodynamics favors *syn* migration, for both steric and electronic effects in the product cations should favor the cation resulting from *anti* migration. The reasons for this prediction are the above-mentioned lesser hindrance at the *syn* face and the fact that stabilization by π-electron bridging, although quite small in ions of the type resulting from *anti* migration (19), must be absent altogether in the ion from *syn* migration.

We suggest that a steric factor, operating at the transition state for *anti* migration, opposes and dominates over a favorable electronic factor for that process. Electronically favorable geometries for the cation intermediate must be those which permit delocalization into neighboring π and σ bonds. Two such geometries, differing in the way conjugation is achieved between C—C bonds of the *t*-butyl group and the electron deficient orbital at C-7, are illustrated below.



6 **7**

These conformations are also those necessary for migration to C-7 with good overlap; **6** leading to the transition state for *anti* migration and **7** leading to that for *syn* migration. Geometry **6**, in which a methyl group is placed directly over the ethano bridge, probably involves substantial non-bonded interactions which must increase in magnitude as the transition state for *anti* migration is reached; first, because CH_3 moves toward C-7 and second, because C-7 moves closer to C-5,6 as the homoallylic conjugation is destroyed. On the other hand, migration from conformation **7** involves the migrating CH_3 group in a relatively open area; C-7 swinging away from C-2,3 as migration progresses. Concurrent flattening of the developing isopropyl substituent probably prevents the development of strong nonbonded repulsions on the other side. A similar steric factor, preventing the ready attainment of certain conformations, has been invoked to account for reactions of norbornen-7-one and norbornan-7-one with diazomethane (20) or dimethylsulfoxonium methylide (21) and for the ratio of hydrogen migration to ring enlargement in acetolysis of 7-arylsulfonyloxymethylbicyclo[2.2.1] systems (22).

Whatever the reasons for the surprising

stereochemistry discussed above, it is clear that the very useful general rules for the stereochemistries of nucleophilic and electrophilic substitutions at saturated carbon do allow for exceptions. Brown and Lane (23) recently published an example of electrophilic substitution with inversion. Our example can be considered a case of nucleophilic substitution with retention.

Experimental

Product Analyses

Crude products were analyzed by g.l.p.c. using a Carbowax 20M column (15% on 60–80 mesh Chromosorb W, 10 ft × 1/4 in.) in a Varian Aerograph A90-P3 instrument equipped with thermal conductivity detector, with helium as the carrier gas. The thermal conductivities of products **3**, **4**, and **5** were assumed to be identical and ratios of products were obtained by triangulation of peaks in the g.l.p.c. traces. Pure samples of **3** and **4** collected from the column were neither interconverted nor hydrated to **5** on reinjection. Similarly, **5** passed through the column unchanged.

(E)- and (Z)-7-t-Butylbicyclo[2.2.1]hept-2-en-7-ol (1 and 2)

Synthesis, separation and spectra of these compounds have been published (24).

Reaction with Thionyl Bromide

A solution of **1** and **2** (**1**:**2** = 1:1.8, 0.470 g, 3.01 mmol) in carbon tetrachloride (2 ml) was added to a stirring solution of thionyl bromide (1.35 g, 6.50 mmol) in 15 ml of carbon tetrachloride. The resulting solution, protected against moisture, was refluxed in the dark for 2.5 h before it was cooled and poured into water (150 ml). The CCl_4 layer, after washing with water, drying, and evaporation of the solvent gave a yellow oil (0.357 g, 84%) which was found (g.l.p.c.) to contain, in addition to a trace of solvent, only dienes **3** and **4** in the ratio **4**:**3** = 15.8:1. At 118° and 52 ml min^{-1}, **3** and **4** were eluted in 6.5 and 8.0 min, respectively.

Reactions in Acetic Acid

A solution of **1** and **2** (1:1 ratio, 200 mg) in acetic acid (10 ml) was unchanged (p.m.r.) after 20 h at room temperature.

Alcohol **1** (11.5 mg) in acetic acid (0.50 ml) was heated in a sealed tube for 3 h at 83°. The solution was poured into water and the resulting mixture was extracted with petroleum ether (b.p. 30–42°). Washing of the hydrocarbon extract with dilute aqueous bicarbonate, drying and concentration gave a colorless oil (11.2 mg) which contained (g.l.p.c.) only **1**, the starting material.

Alcohol **2** (7.2 mg) in acetic acid (0.50 ml) was treated as described above for **1**. The same work-up gave a colorless oil (7.4 mg) which contained solvent, starting material (83%) and **3** (17%), but not **4**.

A solution of **1** and **2** (1:1 ratio, 200 mg) in 10 ml of acetic acid was sealed under vacuum into a heavy-walled tube. After 2 h at 140 ± 5°, the mixture was cooled and worked-up as described above. Both alcohols were absent and the ratio of dienes was **3**:**4** = 3.6:1.

Data pertaining to reactions in acetic acid at 108° (Table 1) were obtained by procedures analogous to that described above.

Reactions in Acetic Acid Containing Sulfuric Acid

A solution of **2** (117.8 mg, 0.795 mmol) in acetic acid containing 2% by volume of concentrated (95.5% minimum) sulfuric acid (50 ml), at 22.5°, turned orange about 1 min after mixing. After 6 h at that temperature the solution was added to water (75 ml) and the resulting solution was extracted with low-boiling petroleum ether (20 ml). The water layer was neutralized with sodium bicarbonate before reextraction with petroleum ether. The combined extract was washed with dilute bicarbonate and with water before it was dried and concentrated to give a sweet-smelling yellow oil (92.7 mg).

The exactly analogous procedure with alcohol **1** (58.6 mg) gave the same yellow oil (52.1 mg). Analysis by g.l.p.c. gave identical traces for the two samples; their composition is shown in Table 1. Relative retention times were: unknown **8**, 0.25; **3**, 0.31; **4**, 0.38; unknown **9**, 0.51 and **5**, 1.0. Proton magnetic resonance of **5** (Varian T-60, δ, CCl_4, TMS): 3.86 (t, 1, H—C_2—O); 1.14 (s, 3, $C(CH_3)_2$), 1.04 (s, 3, $C(CH_3)_2$), individual methyl groups of the *gem* dimethyl component not assigned; 0.96 (s, 3, C_7-CH_3); 0.7–2.25 (overlapping multiplets, 8, CH_2 and bridgehead).

In a similar experiment, a mixture of **1** and **2** (**1**:**2** =

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

1:1, 0.660 g, 1.08 mmol) was dissolved in acetic acid containing 10% by volume of sulfuric acid (10 ml). The solution, which turned black in 5 min, was worked up as described above after 3 h at 22.5°. An oil (77 mg) was obtained which was gas chromatographed on SE30 (20% on Chromosorb W, 60–80 mesh, 5 ft × 1/4 in., 125°, 42 ml min^{-1}). This column did not separate **3** from **4** but gave their combined percentage as 9.8. Three other components were separated from the dienes, as indicated in Table 1. The carbowax column described above separated **3** and **4** clearly to give small peaks of roughly equal area. The numbers 4.9% in Table 1 were obtained by dividing 9.8% by two rather than by triangulating the small, resolved diene peaks. Spectra and analyses pertaining to **3** and **4** are in Table 2.

Nuclear Overhauser Effects

Samples for n.O.e. studies were prepared as follows. A solution of the compound in carbon tetrachloride, containing TMS to serve as internal lock, was filtered through fine sintered glass into a carefully cleaned n.m.r. tube sealed to a ground joint. The tube was then transferred to a vacuum line and put through five degassing cycles, with the pressure below 5 μ in each cycle, before it was sealed.

(*E*)-7-Methylbicyclo[2.2.1]hept-2-en-7-yl acetate, the reference compound for the n.O.e. studies, was made by acetylating the known (22) (*E*)-7-methylbicyclo[2.2.1]-hept-2-en-7-ol with acetyl chloride in tetrahydrofuran containing pyridine. Spectra of the product agreed with those reported by Erman (22).

This work was supported by the National Research Council of Canada. We are indebted to Mr. Brian Sayer, Dr. R. A. Bell, and Dr. J. K. Saunders for the n.O.e. measurements.

Electron Spin Resonance Study of the Cation Radicals of 1,5-Dihydronaphthyridine and Di-*N*-methyl-1,5-Naphthyridine

PAUL D. SULLIVAN AND WILLIAM W. PAUDLER[1]

Department of Chemistry, Ohio University, Athens, Ohio 45701

Received June 5, 1973

The e.s.r. spectra of the cation radicals 1,5-di-*N*-methylnaphthyridine (**1**) and 1,5-dihydronaphthyridine (**2**) in trifluoroacetic acid have been reported and analyzed. The splitting constants of **2** are unequivocally assigned by comparison of the spectra of several partially deuterated derivatives. The methyl proton splitting constant of **1** is thought to be low in comparison with other similar radicals and possible reasons for this anomaly are discussed.

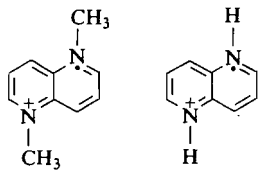
On rapporte et analyse les spectres r.p.e. des cations radicaux di-*N*-méthyl-1,5 naphtyridine (**1**) et dihydro-1,5 naphtyridine (**2**) dans l'acide trifluoroacétique. Les constantes de couplages de **2** sont attribuées sans équivoque par comparaison avec les spectres de plusieurs dérivés partiellement deutériés. On croit que la constante de couplage du proton du groupe méthyle de **1** est faible par comparaison avec d'autres radicaux similaires et les raisons possibles pour cette anomalie sont discutées.

[Traduit par le journal]

Can. J. Chem., **51**, 4095 (1973)

Introduction

Recent studies have described the synthesis of the diquaternary di-*N*-alkylated naphthyridine salts (1, 2). It was also observed (2) that the zinc reduction of an aqueous solution of di-*N*-methyl-1,5-naphthyridine difluorosulfonate gave a green solution which was attributed to the formation of the cation radical **1**. The e.s.r. spectrum of the



1 **2**

radical was not obtained, nor have the resolved spectra of any cation radicals derived from naphthyridines previously been observed to the best of our knowledge. It is the purpose of this paper to report the analysis of the e.s.r. spectra of the cation radicals of 1,5-dihydronaphthyridine (**2**) and of di-*N*-methyl-1,5-naphthyridine (**1**) and to describe some attempts to prepare cation radicals from other naphthyridines.

Experimental

The naphthyridines studied were synthesized as previously described (1). The cation radicals were prepared by reduction of the naphthyridines with zinc dust in trifluoroacetic acid (TFA) (3, 4). The reaction was carried out under vacuum in an inverted U-tube and the radical concentration was varied by dilution until the best e.s.r. spectrum was obtained. The e.s.r. spectra were measured on a Varian E-15 spectrometer in a dual cavity using a sample of the perylene radical anion as a secondary standard. Computer simulations of the experimental spectra were carried out as previously described (5).

Results and Discussion

Intense, well resolved e.s.r. spectra (line width 50 mG) attributed to the radical cation **1** were obtained when the diquaternary salt was reduced with zinc dust in TFA. The parent 1,5-naphthyridine, under the same reducing conditions, also gave a well resolved e.s.r. spectrum of the dihydronaphthyridine cation radical (**2**). The intensity was, however, considerably decreased over that of **1** and the radical decayed slowly (half-life 15 min) at room temperature. The analysis of the spectrum was considerably simplified due to the availability of some selectively deuterated 1,5-naphthyridines (6). Thus, the e.s.r. spectra of the cation radicals of 4,8-dideuterio-1,5-dihydronaphthyridine and 2,6-dideuterio-1,5-dihydronaphthyridine together with 1,5-dideuterionaphthyridine (formed in deuterated trifluoroacetic acid) served to unequivocally analyze the spectra in terms of the splitting constants shown in Table 1. Computer simulations of the spectra showed excellent agreement with the experimental results. By analogy with the results for **2** the spectrum of **1** was readily

[c]Methyl group proton splittings.
[d]Obtained from refs. 7 and 8.
[e]Calculated from McLachlan-HMO method with $h_N = 1.30$ $k_{CN} = 0.95$, the splitting constants obtained from $a_{CH}{}^H = \rho_C{}^\pi Q_{CH}{}^H$ and $a^N = \rho_N{}^\pi Q_{N(CH)}{}^N$ where $Q_{CH}{}^H = 27$ G, $Q_N{}^N = 25$ G.

analyzed and the splitting constants are also shown in Table 1. For comparison purpose Table 1 also includes the e.s.r. spectral parameters for the 1,5-naphthyridine anion radicals (7–8) and also the calculated parameters obtained from a McLachlan-HMO calculation using previously suggested parameters for the nitrogen atom and carbon–nitrogen bond (9). The calculated values are in reasonable agreement with the experimental parameters.

It is instructive to compare the results for **1** and **2** with those for similar compounds which can be found in the literature (see Table 2). The quantities of interest are the change in the nitrogen splitting constant on methyl substitution, the ratio of the nitrogen splitting to the NH proton splitting ($a^N/a_{NH}{}^H$) in the protonated compounds, and the ratio of the nitrogen splitting to the methyl splitting ($a^N/a_{NCH_3}{}^H$) in the *N*-methyl compounds. As can be seen in Table 2 the nitrogen splitting constant usually increases by 15 to 30% upon methyl substitution, and in this regard radicals **1** and **2** behave normally. For the protonated compounds the $a^N/a_{NH}{}^H$ ratio is usually slightly less than one (except for the hydrazine cation radical) and again **2** is normal in this regard. For the *N*-methyl compounds the ratio $a^N/a_{NCH_3}{}^H$ is usually slightly greater than one and clearly **1** is anomalous in this respect. The only other reported cation radical which shows an anomalous ratio of this magnitude is the tetrakis(dimethylamino)ethylene cation radical, but in this compound there is considerable steric hindrance to rotation about the C—N bond and the molecule is presumably able to relieve this strain by adopting a non-planar configuration. In radical **1**, there will be a steric interaction between the methyl group and the peri protons but it seems unlikely that such an interaction could cause such a large deviation. The lack of any temperature dependence of the splitting constants also argues against a steric effect. A better explanation might perhaps lie in the effect of charge and charge distributions on the methyl group splitting constant and clearly further investigation is called for on this point.

Several other di-*N*-alkylated naphthyridine salts (1,6-, 1,7-, and 1,8-) were reacted with zinc in TFA in an effort to produce their corresponding cation radicals. However, no e.s.r. signals were detected. This is not unexpected in the case of the 1,6- and 1,8-derivatives since these compounds do not belong to the class of radicals known as violenes (11) as do the 1,5- and 1,7-derivatives. It is, therefore not possible to write favorable valence bond structures which allow the unpaired electron to be localized onto both nitrogen atoms for the 1,6- and 1,8-derivatives. The 1,7-compound does however belong to the violene class and should show an extra stability towards the formation of a cation

TABLE 2. Comparison of results for various cation radicals

	Splitting constant (G)

The Addition of Hypobromous Acid to Δ^4-Steroids

PETER MORAND AND ALENKA POLAKOVA-PAQUET
Department of Chemistry, University of Ottawa, Ottawa, Canada K1N 6N5

Received July 12, 1973

The addition of hypobromous acid to 4-cholesten-3β-yl acetate (**1**) has been found to result in the formation of a significant amount of 4β-bromo-5α-cholestane-3β,5-diol 3-acetate (**3**) as well as of 5-bromo-5α-cholestane-3β,4β-diol 4-acetate (**2***a*). Evidence is presented in support of the structure proposed for the former and confirmation of the structure of the latter, about which there is disagreement, is adduced. The conversion of **2***a* to 4-cholestene-3β,19-diol 3-acetate (**9**) by treatment with lead tetraacetate and subsequent opening of the 4β,19-oxide ring is described.

L'addition de l'acide hypobromeux à l'acétate de cholestène-4 yl-3β (**1**) a conduit à la formation d'une quantité significative d'acétate-3 du bromo-4β cholestane-5α diol-3β,5 (**3**) et d'acétate-4 du bromo-5 cholestane-5α diol-3β,4β (**2***a*). On apporte des preuves en faveur de la structure proposée pour le premier et pour confirmer la structure du dernier, autour de laquelle il existe un désaccord. On décrit la transformation de **2***a* en acétate-3 de cholestène-4 diol-3β,19 (**9**) par traitement avec du tétraacétate de plomb ainsi que l'ouverture subséquente du cycle oxyde-4β,19. Introduction

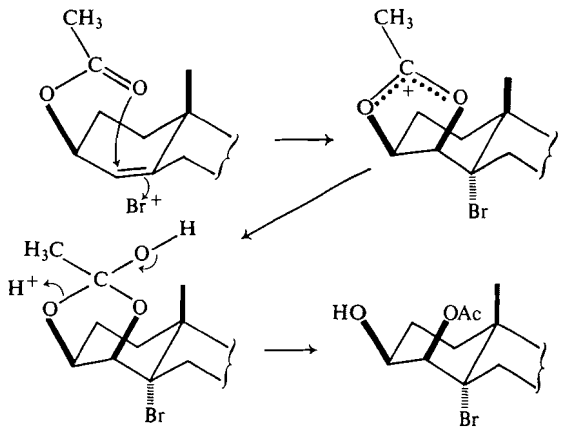
As part of our investigation of approaches to the synthesis of the A/B-ring system of strophanthidin (1) we were interested in the conversion of readily available 3-oxo-Δ^4-steroids into 19-oxygenated derivatives. A key transformation in this sequence involves the addition of hypobromous acid to the 4,5-double bond after reduction of the C-3 ketone group and subsequent acetylation to the 3β-acetoxy derivative. This reaction was first reported by Collins (2) on 4-cholesten-3β-yl acetate (**1**) and the product isolated was identified as 4α-bromo-5β-cholestane-3β,5-diol 3-acetate (**4**, see Scheme 2). In a subsequent paper (3) evidence is presented to exclude the known bromohydrin **2***b*, with similar physical constants, as an alternative structure. However, Julia and Fürer (4) have concluded that the compound obtained must be 5-bromo-5α-cholestane-3β,4β-diol 4-acetate (**2***a*). Their proposed structure easily accounts for the isolation of the ketone **7** and of the 4β,5β-epoxide **6***a* by oxidation of **2***a* followed by treatment with base. The same compounds are reported by Collins (3) who invokes the rearrangement of the bromohydrin **4** during the course of oxidation. Although Collins reported an alternative synthesis of the bromohydrin **4** by treatment of 5β-cholest-3-en-5β-ol with acetyl hypobromite, Julia and Fürer have argued that, under the reaction conditions, allylic rearrangement is likely to occur, resulting in the formation of 5-bromo-5α-cholestane-3β,4β-diol 4-acetate (**2***a*). Recent work in our laboratory on the allylic rearrangement of Δ^6-5α-hydroxy steroids under mild acidic conditions (5) supports this assumption.

The formation of a compound with an acetoxy group at C-4 instead of the bromohydrin **2***b* by the addition of hypobromous acid to 4-cholesten-3β-yl acetate (**1**) has been rationalized (4) by considering the participation of the 3β-acetoxy group in the α-side addition of the bromonium ion to the double bond (see scheme 1). This is consistent



SCHEME 1

with the observed (6) neighboring group participation of the C-3 acetoxy group in the opening of a 4α,5α-epoxide and the preference for the 4β- over the 3β-position by an acetoxy group (7).

For personal use only.

The results reported here confirm the structure proposed by Julia and Fürer for the disputed compound. Furthermore, we have found that a second substance, formed during the reaction, can be isolated and its structure has been elucidated. The synthesis of 4-cholestene-3β,19-diol 3-acetate (**9**) from 5-bromo-5α-cholestane-3β,4β-diol 4-acetate (**2***a*) is also described.

Results and Discussion

When 4-cholesten-3β-yl acetate (**1**) was treated with *N*-bromosuccinimide and perchloric acid, two compounds were isolated in yields of 46 and 14%, respectively. The major product had a higher melting point (156–157°) than reported by either Collins (2) (147°) or Julia and Fürer (4) (148°). Its n.m.r. spectrum, which was not reported by these authors, indicated (8) a *trans* A/B-ring junction (half-band width of 11 Hz for the 3α-proton signal) and an equatorial proton at C-4 (τ 4.40, J_{ae} = 2.0 Hz). Treatment of this compound with potassium hydroxide in aqueous methanol and subsequent oxidation gave a substance identified as 4β,5-oxido-5β-cholestan-3-one (**6***a*) on the basis of its melting point (9) and the expected optical rotatory dispersion (o.r.d.) curve (10). There seems to be little doubt, therefore, that the compound isolated by Collins (2, 3) and by Julia and Fürer (4) is 5-bromo-5α-cholestane-3β,4β-diol 4-acetate (**2***b*).

The second product isolated from the reaction mixture was identified as 4β-bromo-5α-cholestane-3β,5-diol 3-acetate (**3**) on the basis of its elemental analysis, spectral properties and chemical reactions. The i.r. spectrum indicated the presence of acetoxy and hydroxy groups. In the n.m.r. spectrum, a broad signal at τ 4.60 (half-band width of 12 Hz) and a doublet centered at τ 5.6 (J_{ae} = 2.0 Hz) were observed. The former could be attributed to an axial proton at C-3 and the latter to an equatorial proton (8) at C-4.

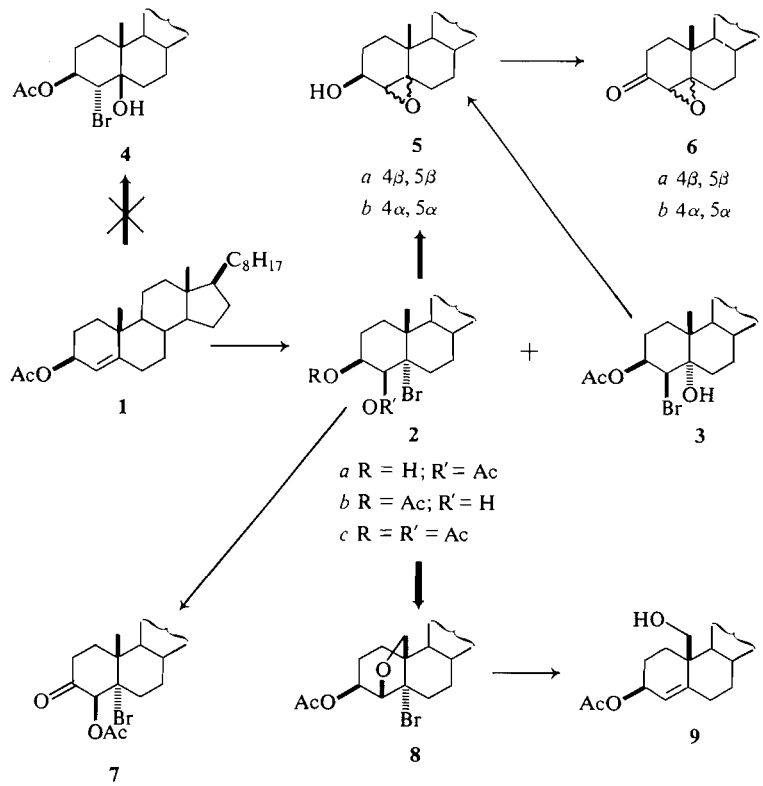
Whereas the major product **2***a* was converted into the diacetate **2***c* on treatment with acetic anhydride in pyridine at room temperature, the second product was unchanged under these conditions. Similarly, while **2***a* was easily oxidized with Jones' reagent (11) to the ketone **7**, the lower yield product was recovered unchanged when subjected to these reaction conditions. However, when the latter was treated with base, the product isolated was identified as 4α,5-oxido-5α-cholestan-3β-ol (**5***b*) on the basis of its n.m.r. spectrum which exhibited a broad signal centered at τ 6.15 (3α-proton) and a singlet (12) at τ 7.20 (4β-proton in a 4α,5α-epoxide). Oxidation of this alcohol **5***b* gave 4α,5-oxido-5α-cholestan-3-one (**6***b*) whose structure was confirmed by the "reversed Cotton effect" observed in its o.r.d. curve (10).

The formation of 4β-bromo-5α-cholestane-3β,5-diol 3-acetate (**3**) implies β-side attack of bromonium ion on the 4,5-double bond with subsequent diaxial opening of the cyclic intermediate by hydroxide ion to give the bromohydrin **3**. In this reaction sequence the participation of the 3β-acetoxy group is excluded and this substituent therefore remains unchanged in the product isolated. It appears that the addition of hypobromous acid is less stereospecific in Δ^4-steroids than in Δ^5-steroids where formation of the analogous 6β-bromo-5α-hydroxy derivatives has never been detected (13). The increased accessibility of the β-side of the molecule in Δ^4-steroids has been observed (14) in other types of reactions involving the double bond.

Treatment of 5-bromo-5α-cholestane-3β,4β-diol 4-acetate (**2***a*) with lead tetraacetate under the conditions reported by Julia and Lorne (15) gave a mixture of many products which could not be separated. By modifying the reaction conditions (see Experimental) it was possible to isolate two products in yields of 25 and 17%, respectively.

The substance obtained in lower yield was identified as 4β,5-oxido-5β-cholestan-3β-ol acetate (**5***a*, acetate) on the basis of the n.m.r. spectrum which showed a singlet at τ 7.82 (acetate group), a doublet (12) centered at τ 6.80 (4α-proton of 4β,5β-epoxide), and a multiplet at τ 4.80 (C-3 proton). The formation of an analogous epoxide has also been observed (16) in the reaction of 5α-bromo-6β-hydroxy steroids with lead tetraacetate but it is not clear what mechanism is involved in its formation.

The structure of the major product is considered to be 5-bromo-4β,19-oxido-5α-cholestan-3β-ol acetate (**8**) on the basis of its elemental analysis, spectral properties, and the fact that it was easily converted to 4-cholestene-3β,19-diol 3-acetate (**9**) by treatment with zinc dust in dimethylformamide. The i.r. spectrum showed a low intensity band at 1490 cm^{-1} assigned (17) to the C—H scissoring of the protons in the methylene group of the oxide ring. Similarly, the n.m.r. spectrum indicated the presence of a methylene



SCHEME 2

group adjacent to an ether linkage (quartets at τ 5.80, 5.82, 6.19, 6.35) as well as of an equatorial acetoxy group.

Julia and Lorne (15) have postulated a cyclic intermediate involving the *cis* hydroxy and acetoxy groups at C-3 and C-4, respectively (as shown earlier) to rationalize the formation of the 4β,19-oxide. The direct participation of an adjacent methoxy group has also been reported (16) in the reaction of steroidal alcohols with lead tetraacetate.

Experimental

Melting points were determined on a Hoover Uni-Melt apparatus and are uncorrected. Infrared and n.m.r. spectra were recorded on a Beckman IR-8 i.r. spectrophotometer and on a Varian V-4302 60 Mc spectrometer, respectively. A Durrum-Jasco automatic spectropolarimeter, Model ORD-5, and a Perkin-Elmer 141 recording polarimeter were used to determine optical rotatory dispersion curves and optical rotations, respectively. Microanalyses were performed by G. Daesslé, Organic Microanalyses, Montreal. SilicaR (200–300 mesh) was used as an adsorbant for column chromatography. Silica gel G (according to Stahl) was used as adsorbant for t.l.c. and sulfuric acid was used as spraying agent. In working up the products of reactions the organic extracts were washed with dilute HCl solution and/or $NaHCO_3$ solution, dried over anhydrous $MgSO_4$, and evaporated to dryness under reduced pressure.

Addition of Hypobromous Acid to 4-Cholesten-3β-yl Acetate (1)

To a solution of 4-cholesten-3β-yl acetate (**1**) (18) (m.p. 82–84°, $[\alpha]_D$ +9.5°, 6.30 g, 1.48 mmol) in dioxane (120 ml), *N*-bromosuccinimide (4.2 g) and 0.2 *N* $HClO_4$ (23 ml) were added with stirring at a temperature of 10°. After maintaining these conditions for 1.5 h, water (100 ml) was added and the solid (7.45 g) which precipitated was collected by filtration. Crystallization from acetone gave two crops (3.21 and 0.50 g, 46%) of *5-bromo-5α-cholestane-3β,4β-diol 4-acetate* (**2***a*): m.p. 156–157° (lit. (2, 4) m.p. 147 and 148°); $[\alpha]_D$ +27° (*c*, 0.4 in $CHCl_3$); n.m.r. ($CDCl_3$) τ 7.88 (singlet, 4β-OAc), 5.15 (multiplet, 3α-H, $w_{\frac{1}{2}}$ = 11 Hz), 4.40 (doublet, 4α-H, J_{ae} = 2.0 Hz); i.r. ($CHCl_3$) 3590 (—OH), 1735 (—$OCOCH_3$) cm^{-1}.

The mother liquors from the above crystallization were taken to dryness and an aliquot (200 mg) was chromatographed using benzene as eluant. In this manner a crystalline substance (52 mg), identified as 4β-*bromo*-5α-*cholestane-3β,5-diol 3-acetate* (**3**), was isolated. Crystallization from acetone gave an analytical sample (50 mg) which exhibited m.p. 152–154°; $[\alpha]_D$ −10° (*c*, 0.2 in $CHCl_3$); n.m.r. ($CDCl_3$) τ 7.80 (singlet, 3β-OAc), 5.60 (doublet, 4α-H, J_{ae} = 2.0 Hz), 4.60 (multiplet, 3α-H, $w_{\frac{1}{2}}$ = 12 Hz); i.r. ($CHCl_3$) 3420–3500 (—OH), 1735 (—$OCOCH_3$) cm^{-1}. In a subsequent experiment, the yield of **3** increased to 28% when it crystallized directly from the mother liquors.

Anal. Calcd. for $C_{29}H_{49}O_3Br$: C, 66.26; H, 9.39; Br, 15.25. Found: C, 66.24; H, 8.93; Br, 15.51.

Reactions of 5-Bromo-5α-cholestane-3β,4β-diol 4-Acetate (2a) and of 4β-Bromo-5α-cholestane-3β,5-diol 3-Acetate (3)

(*i*) *Acetylation*

Treatment of 5-bromo-5α-cholestane-3β,4β-diol 4-acetate (**2a**) (31 mg) with acetic anhydride (0.2 ml) and pyridine (0.4 ml) and working up in the usual way gave pure *5-bromo-5α-cholestane-3β,4β-diol diacetate* (**2c**) (16 mg) after crystallization from ether. It had m.p. 149.5–151°; $[\alpha]_D$ +24° (*c*, 0.21 in $CHCl_3$) (lit. (4) m.p. 149.5–150.5°, $[\alpha]_D$ +25°).

When 4β-bromo-5α-cholestane-3β,5-diol 3-acetate (**3**) was treated under the same acetylating conditions, it was recovered unchanged.

(*ii*) *Oxidation*

5-Bromo-5α-cholestane-3β,4β-diol 4-acetate (**2a**) (11.4 mg) in acetone (0.4 ml) was treated with Jones' reagent (0.05 ml) and left standing at room temperature for 2 h. Excess isopropyl alcohol was then added and, after working up in the usual way, pure *5-bromo-4β-hydroxy-5α-cholestan-3-one acetate* (7) (8.0 mg) was obtained with m.p. 128–129°; $[\alpha]_D$ +100° (lit. (3) m.p. 117–122° (capillary), 126–127° (dec.); $[\alpha]_D$ +99° and (4) m.p. 124–125°; $[\alpha]_D$ +91°).

4β-Bromo-5α-cholestane-3β,5-diol 3-acetate (**3**) (10.0 mg) was recovered unchanged when an attempt was made to oxidize this compound under the conditions described above.

(*iii*) *Epoxidation and Oxidation*

To a suspension of **2a** (40.5 mg) in methanol (2.0 ml) was added 1.0 ml of KOH solution (1.2 g of KOH in 1.5 ml of H_2O and 12 ml of CH_3OH) and the reaction mixture was refluxed for 0.5 h. Water (2.0 ml) was then added, the methanol removed under reduced pressure, and the organic material extracted with chloroform. Working up in the usual way gave *4β,5-oxido-5β-cholestan-3β-ol* (**5a**) as a foamy solid (30.8 mg). The i.r. spectrum indicated the absence of acetate and the presence of an hydroxy group (3600–3500 cm^{-1}); n.m.r. ($CDCl_3$) τ 6.82 (doublet, 4α-H, J_{ae} = 2.0 Hz), 5.90 (multiplet, 3α-H, $w_{\frac{1}{2}}$ = 10 Hz). Oxidation of this alcohol in acetone (2.0 ml) with Jones' reagent (0.03 ml) at 0° and then allowing to stand at room temperature for 0.3 h gave, after usual work-up, a crude product which was purified by chromatography. Elution with benzene gave a solid which, on crystallization from ether, yielded pure *4β,5-oxido-5β-cholestan-3-one* (**6a**): m.p. 115–117° (lit. (4) m.p. 113–114°); o.r.d. (dioxane) $[\Phi]_{450}$ +750°, $[\Phi]_{338}$ +6750°, $[\Phi]_{332}$ +6500°, $[\Phi]_{327}$ +6670°, $[\Phi]_{285}$ −6410°.

Treatment of **3** (48.0 mg) with base under the conditions described above gave *4α,5-oxido-5α-cholestan-3β-ol* (**5b**) as a foamy solid (39.6 mg). No acetate absorption was observed in the i.r. spectrum but the presence of an hydroxyl group (3600–3500 cm^{-1}) was indicated; n.m.r. ($CDCl_3$) τ 7.20 (singlet, 4β-H), 6.15 (multiplet, 3α-H, $w_{\frac{1}{2}}$ = 11 Hz). Oxidation of this alcohol (10.0 mg) in the manner already described gave crude *4α,5-oxido-5α-cholestan-3-one* (**6b**) (7.6 mg) which could be purified by crystallization from ether. It had m.p. 118–121° (lit. (2) m.p. 123–124.5°); $[\Phi]_{450}$ −360°, $[\Phi]_{337}$ −6550°, $[\Phi]_{331}$ −6450°, $[\Phi]_{327}$ −6800°, $[\Phi]_{282}$ +9150°.

5-Bromo-4β,19-oxido-5α-cholestan-3β-ol Acetate (8)

Lead tetraacetate (8.0 g, previously dried over P_2O_5) and $BaCO_3$ (1.0 g) were added to cyclohexane (180 ml) and this mixture was heated under reflux for 0.3 h. 5-Bromo-5α-cholestane-3β,4β-diol 4-acetate (**2a**) (0.50 g, 9.5 mmol) was then added and refluxing continued for an additional 18 h. After cooling the reaction mixture, the insoluble material was removed by filtration through celite and the filtrate was worked up in the usual way. The oily product (0.48 g) was chromatographed on silica gel using benzene as eluant. The first fraction (102 mg) could be crystallized from ether (80 mg, 17%) and this substance was identified as *4β,5-oxido-5β-cholestan-3β-ol acetate*: m.p. 85–90°; $[\alpha]_D$ −18° (*c*, 0.1 in $CHCl_3$) (lit. (9) m.p. 89–90°, $[\alpha]_D$ −21 ± 1°); n.m.r. ($CDCl_3$): τ 7.82 (singlet, 3β-OAc), 6.80 (doublet, 4α-H, J_{ae} = 4.0 Hz), 4.80 (multiplet 3α-H, $w_{\frac{1}{2}}$ = 16 Hz).

Further elution with benzene gave 5-bromo-4β,19-oxido-5α-cholestan-3β-ol acetate (**8**) (127 mg, 25%). An analytical sample, obtained by crystallization from benzene–methanol exhibited m.p. 154–156°; $[\alpha]_D$ −2° (*c*, 0.13 in $CHCl_3$); n.m.r. ($CDCl_3$) τ 7.90 (singlet, 3β-OAc), 6.35, 6.19, 5.82, 5.80 (quartet, —OCH_2—, J_{AB} = 3.0 Hz), 4.30 (multiplet, 3α-H, $w_{\frac{1}{2}}$ = 11 Hz); i.r. ($CHCl_3$) 1490 (—OCH_2—) cm^{-1}.

Anal. Calcd. for $C_{29}H_{47}O_3Br$: C, 66.52; H, 9.05; Br, 15.26. Found: C, 66.30; H, 8.73; Br, 15.05.

Further fractions were obtained in non-crystalline form, mostly as mixtures (t.l.c.), and these were not submitted to further separation and identification.

4-Cholestene-3β,19-diol 3-Acetate (9)

Zinc dust (325 mg) was added in small portions over a period of 0.3 h to a stirred solution of 5-bromo-4β,19-oxido-5α-cholestan-3β-ol acetate (**8**) (32 mg, 0.06 mmol) in DMF (3.2 ml) at 50°. These conditions were maintained for another 4.0 h and the reaction mixture was then cooled and the zinc removed by filtration through celite. Working up in the usual way gave a crude product (27 mg) which crystallized from methanol as 4-cholestene-3β,19-diol 3-acetate (**9**) (15 mg): m.p. 116°; $[\alpha]_D$ +20° (*c*, 0.1 in $CHCl_3$); n.m.r. ($CDCl_3$): τ 8.0 (singlet, 3β-OAc), 6.45, 6.35, 6.15, 5.90 (quartet, —OCH_2—, J_{AB} = 5.0 Hz), 4.75 (multiplet, 3α-OAc, $w_{\frac{1}{2}}$ = 8.0 Hz), 4.35 (singlet, 4-H).

Ring C Functionalized Diterpenoids. Part I. The Hypoiodite Reaction as a Route to Ring C Functionalized Kauranes and Phyllocladanes

ALAN JAMES MCALEES AND ROBERT MCCRINDLE[1]

Chemistry Department, University of Guelph, Guelph, Ontario N1G 2W1

Received July 26, 1973

16β-*ent*-17-Kauranol (**1***a*), the corresponding C-19 ester (**1***b*), and 16β,17-phyllocladanol (**2**), on reaction with lead tetraacetate – iodine in refluxing cyclohexane, suffered intramolecular attack mainly at C-11. Thus **1***a* gave as major products the 11-en-17-ol (**3***a*) and the 11β-iodo-12β,17-ether (**4***a*), along with minor amounts of the 9,11-en-12β,17-ether (**5**), the 11β,17-ether (**6***a*), and, resulting from attack at C-12, the 12β,17-ether (**7**). The phyllocladanol **2** gave the 11β,17-ether (**8**) and the 9,11-en-12β,17-ether (**9**). The assignment of structures **6***a*, **7**, and **8** to the ethers rests on their conversion with ruthenium tetroxide into the corresponding lactones, **10**, **11**, and **12**.

L'*ent*-16β Kauranol-17 (**1***a*), l'ester C-19 correspondant (**1***b*) et le phyllocladanol-16β,17 (**2**), subissent une attaque intramoléculaire principalement au site C-11 lorsqu'ils sont reflués dans le cyclohexane en présence de tétraacétate de plomb–iode. Ainsi, **1***a* a donné, comme produits majeurs, l'ène-11 ol-17 (**3***a*) et l'éther-12β,17 iodo-11β (**4***a*), en même temps que des petites quantités d'éther-12β,17 ène-9,11 (**5**), d'éther-11β,17 (**6***a*) ainsi que d'éther-12β,17 (**7**) résultant de l'attaque en C-12. Le phyllocladanol **2** a conduit à l'éther-11β,17 (**8**) et à l'éther-12β,17 ène-9,11 (**9**). L'attribution des structures **6***a*, **7** et **8** aux éthers est basée sur leur transformation à l'aide du tétroxyde de ruthénium en lactones correspondantes, **10**, **11** et **12**. [Traduit par le journal]

Can. J. Chem., **51**, 4103 (1973)

In connection with work on carbonium ion rearrangements in the tetracyclic diterpenoid field, we have been exploring routes to 13-substituted atisiranes and 12-substituted kauranes and beyeranes. An additional incentive for these studies has been the discovery of a wide range of natural products with ring C functionality. Compounds of this type include alkaloids derived from atisirene (1–4) and rearranged atisirenes (aconitine) (5), kaurenes (6–9) and modified kauranes (10,11) (including gibberellins (12,13) and alkaloids (14–16)), and beyeranes (17). No synthetic approaches to such systems have been reported apart from that of Coates and Bertram (18) for the beyerane type. The present paper deals with the introduction of substituents into ring C of kauranes and phyllocladanes. In subsequent papers, routes to analogously substituted atisanes and beyeranes will be described.

The considerable synthetic utility of the hypoiodite reaction of alcohols, which usually results in attack at a δ-carbon atom, has been reviewed (19). We have now applied this reaction to the *ent*-kauranols **1***a* and *b*, and to the phyllocladanol **2**, in which the *endo* carbinol functions are ideally situated for intramolecular attack on ring C. Since *ent*-kauren-19-oic acid (**13***a*), accompanied by trachylobanic acid, is readily obtainable from the common sunflower (20), our first experiments were carried out using the kauranol ester **1***b*, which was prepared by hydroboration–oxidation of methyl *ent*-kauren-19-oate (**13***b*).

[1]To whom correspondence should be addressed.

Results

A mixture of ester **1***b*, 1 g-equiv. of iodine, excess lead tetraacetate, and calcium carbonate in refluxing cyclohexane was irradiated with a tungsten lamp, the reaction being allowed to proceed for 1.5 h although the color of the iodine had disappeared after 35–40 min. Thin layer chromatography of the reaction mixture after work-up indicated the presence of at least four products, the most polar pair of which had very similar R_f values. On standing in solution or on warming on the water bath during the removal of solvent under vacuum, the color of iodine appeared, suggesting that HI was being eliminated from a reaction product and subsequently undergoing air oxidation. Accordingly, the mixture was treated with pyridine and then reexamined by t.l.c., which showed the disappearance of the most polar product and an increase in the intensity of the neighbouring spot. The three main products in this later mixture were then

separated by column chromatography over alumina and then preparative t.l.c.

The most polar "product" in fact proved to be a mixture of methyl 17-hydroxy-*ent*-kaur-11-en-19-oate (**3***b*) and starting material with the former predominating. Pure **3***b* (*vide infra*) had m.p. 105–107.5° and $\nu_{OH}(CCl_4)$ 3637 cm^{-1}, the primary nature of the alcohol function being confirmed by the n.m.r. spectrum (τ 6.47, 2 H-17, d, $J \sim 7$ Hz) which also revealed the presence of the 11,12 double bond, H-11 appearing at τ 4.43 (dd, J = 10 and 3.4 Hz) and H-12 at τ 4.08 (apparent dd with additional broadening, J_{obs} = 10 and 5.5 Hz) (*cf.* ref. 9.).

The principal product of intermediate polarity **4***b*, m.p. 107–109°, lacks hydroxyl absorption in the i.r. and is rather unstable, the color of iodine appearing on storage at room temperature, either in the solid state or in solution. The resulting inference that **4***b* is an iodoether is supported by its n.m.r. spectrum, which shows multiplets at τ 5.63 (dd, H-12, J = 8 and 4.5 Hz) and 5.95–6.35 (complex m, H-11 + 2 H-17), and by its reaction with zinc and acetic acid in diethyl ether to give **3***b*. The stereochemistry at C-11 and ring size of the ether in **4***b* are assigned by analogy with the corresponding product (**4***a*) obtained from **1***a* and discussed below.

The n.m.r. spectrum of the least polar principal product (**6***b*, m.p. 153–155°) has resonances at τ 6.07 (narrow m, H-11), 6.22, and 6.66 (each broadened d, 2 H-17, J_{obs} = 10 Hz), indicating that it is an ether. The assignment of structure **6***b* is based on the finding that oxidation of the related compound **6***a* with ruthenium tetroxide gives a δ-lactone (*vide infra*).

In subsequent investigations, we turned to 16β-*ent*-17-kauranol (**1***a*)[2] since the minor products of the hypoiodite reaction of this compound are more tractable than those from **1***b* and since important peaks in the n.m.r. spectra of products from the latter are partly obscured by the carbomethoxy resonance. The reaction of **1***a* was carried out as indicated above for **1***b* except that the reaction was stopped soon after

[2]When the hypoiodite reaction of **1***b* was repeated using excess iodine to ensure complete consumption of starting material and conversion of any **3***b* formed to **4***b* (see Discussion), the resulting mixture contained two new products, the acetates **4***c* and **6***c*. As these had very similar R_f values on t.l.c., they were separated by hydrolysis to the corresponding alcohols, **4***d* and **6***d*, respectively, followed by preparative t.l.c. Acetylation of **4***d* and **6***d* with acetic anhydride – pyridine regenerated **4***c* and **6***c*.

(10 min) the color of the iodine had disappeared. Thin-layer chromatography of the reaction mixture indicated the presence of three major products, the more polar pair having very similar R_f values. As before, the color of iodine appeared when the mixture was allowed to stand at room temperature and treatment with pyridine led to the disappearance of the most polar major product with concommitant buildup of the product with similar R_f value. Column chromatography over alumina of the mixture remaining after pyridine treatment led to separation of the two major products and to partial resolution of the minor products, which were further purified by t.l.c.

The more polar major "product" proved to be a mixture of **3***a*: m.p. 162–163°; $\nu_{OH}(CCl_4)$ 3639 cm^{-1}; τ 9.20, 9.13, 9.08 (all s, quaternary C—CH_3's), 6.43 (d, 2 H-17, J = 7.2 Hz), 4.41 (dd, H-11, J = 9.5 and 3.5 Hz), and 4.07 (apparent dd with additional broadening, H-12, J_{obs} = 10 and ~6 Hz); and starting material (**1***a*) in which the former predominated.

The less polar major product, **4***a*, m.p. 110–110.5°; τ 9.19, 9.14, 9.01 (all s, quaternary C—CH_3's), 6.33–5.95 (complex m, 2 H-17 + H-11), and 5.62 (dd, H-12, $J_{12,11}$ = 8 Hz, $J_{12,13}$ = 4.8 Hz), decomposes slowly in the solid state or in solution with the appearance of the color of iodine and reacts with zinc and acetic acid in ether to give **3***a* in high yield. Reaction of **4***a* with lithium aluminum hydride gives an ether (**7**) in high yield plus a little **3***a*. The ether (**7**) was identical with one of the minor products of the hypoiodite reaction of **1***a* and the elucidation of its structure is discussed below. The iodine atom in **4***a* is assigned the 11β-configuration rather than 11α on the basis of the observed coupling constants and on the finding that the C-10 methyl resonance position is not markedly altered on going from **4***a* to **7** (9.01 and 9.10, *cf.* C-10 methyl resonance in **6***a* at τ 9.03).

By careful preparative t.l.c. two minor products,[3] which were slightly less polar than **4***a* and did not show clearly on the original analytical plate, were isolated. The assignment of structure **5** to the more polar of these, m.p. 86–89°, is based on the n.m.r. spectrum which shows peaks at τ 6.73 (dd, βH-17, J_{obs} ~3.5 and ~9 Hz), 6.05 (t, αH-17, J_{obs} ~8.5 Hz), 5.42 (apparent dd, H-12, J_{obs} ~3.5 and ~7 Hz), and 4.85 (d, H-11, J_{obs} ~3.5 Hz). Examination of models of **5** shows that βH-17 lies in the shielding zone of the 9,11-double bond and hence should resonate at higher field than αH-17. The second minor product was obtained as an oil which ran as a single spot on analytical t.l.c. but failed to crystallize. The n.m.r. spectrum of this impure material showed it to be essentially identical with the main product (**7**) of reaction of iodoether **4***a* with lithium aluminum hydride. The compound (**7**) thus obtained could be crystallized, although with some difficulty, and had m.p. 41.5–43.5°, its formulation as an ether being sustained by peaks at τ 6.1–6.5 (complex m, 2 H-17) and 5.6–5.9 (complex m, H-12) in its n.m.r. spectrum. This resonance pattern differs markedly from that observed for the ether **6***b* previously obtained from the kauranol ester **1***b*. Examination of models of 16β-*ent*-17-kauranol (**1***a*) and of the 11β,17-(**6**) and 12β,17-(**7**) ethers in the light of the suggested mechanism of the hypoiodite reaction (19) indicated that both five- and six-membered ring ethers might be

[3]A further minor product, **4***e*, was isolated from the mixture obtained in a subsequent hypoiodite reaction of **1***a* under the same conditions as before.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

formed from **1**. This examination also suggests that the lone proton α to the ether function should have larger coupling constants with neighbouring protons in the tetrahydrofuran (**7**) than in the tetrahydropyran (**6**). This is consistent with the observation of a relatively narrow multiplet for H-11 in **6***b* and a much broader multiplet for H-12 in **7**. However, as it was desirable to have more conclusive evidence for the nature of the cyclic ether functions in these compounds, we decided to attempt the oxidation of the ethers to the corresponding lactones using ruthenium tetroxide (21, 22). Thus, a catalytic quantity of a solution of RuO_4 in carbon tetrachloride was added to the impure ether (**7**), isolated from the hypoiodite reaction of **1***a*, in the same solvent and the resulting mixture was stirred vigorously at room temperature with excess of an aqueous solution of sodium periodate. The progress of the reaction was followed by t.l.c. When all the starting material had disappeared (10 days), t.l.c. indicated the presence of two products and a trace of polar material. After separation by preparative t.l.c., the major and less polar product, the γ-lactone **11**, had m.p. 170–171°; $\nu_{C=O}(CCl_4)$ 1778 cm^{-1}; τ 6.82–7.33 (m, H-13 + H-16) and 5.00–5.28 (m, H-12). The minor product had m.p. 175–176°; τ 6.97–7.55 (m, H-13 + H-16), 5.52 (narrow m, H-11); and $\nu_{C=O}(CCl_4)$ 1749 cm^{-1}, which suggests that it is the δ-lactone **10** and that the impurity in the tetrahydrofuran (**7**) obtained by the hypoiodite reaction of **1***a* is 11β,17-oxido-16β-*ent*-kaurane (**6***a*). This was confirmed by the preparation of **6***a* from **1***a* and the subsequent oxidation of the former with ruthenium tetroxide – sodium periodate to **10** (*vide infra*).

The hypoiodite reaction of 16β,17-phyllocladanol (**2**), obtained by hydroboration–oxidation of phyllocladene, under the same conditions as those used for **1***a* gave a mixture which again liberated iodine on standing. Treatment with pyridine as before gave a mixture which appeared to contain three principal components (t.l.c.), all appreciably less polar than starting material. These were readily separated by preparative t.l.c.

The least polar and main product had m.p. 71.5–73° and lacked hydroxyl absorption in the infrared. The n.m.r. spectrum showed peaks at τ 6.60 and 6.27 (each broadened d, 2 H-17, $J_{obs} = 10$ Hz) and 5.65 (m, H-11). The close similarity of this portion of the n.m.r. spectrum to the same region in the spectra of **6***a* and *b* suggested the formulation of this product as 11β,17-oxido-16β-phyllocladane (**8**). This was confirmed by the oxidation of **8** to **12**, which had m.p. 188–189°; $\nu_{C=O}(CCl_4)$ 1754 and 1745 cm^{-1}; and τ 5.10 (m, H-11).

The "product" of intermediate polarity was obtained as an oil which appeared uniform on analytical t.l.c. but the complexity of the methyl region of the n.m.r. spectrum showed it to be a mixture. Absorption in the low-field region of the n.m.r. spectrum suggested the presence of ether(s), accordingly, the mixture was oxidized with ruthenium tetroxide – sodium periodate. The resulting mixture appeared to contain at least four components (t.l.c.) which we have not attempted to separate due to shortage of material.

The most polar product isolated from the hypoiodite reaction of **2** is the ene-ether **9**, m.p. 82–87°. The n.m.r. spectrum of the latter, from which its structure was deduced, is very similar to that of **5**, showing peaks at τ 6.77 (dd, βH-17, $J_{obs} \sim 9$ and ~ 4 Hz), 6.05 (t, αH-17, $J_{obs} \sim 9$ Hz), 5.44 (broadened dd, H-12, $J_{obs} \sim 3.5$ and ~ 6 Hz), and 4.83 (d, H-11, $J_{obs} \sim 3.5$ Hz).

Discussion

The hypoiodite reaction of an alcohol can be envisaged as involving the formation of an oxygen radical (Scheme 1; **i** → **ii**) which may subsequently abstract a suitably disposed hydrogen atom, usually from a δ-carbon atom via a six-membered ring transition state, to give a carbon radical (Scheme 1; **iii**) (19). The carbon radical can then react with an iodine atom to give an iodohydrin (**iii** → **iv**). If the carbon atom originally attacked is a methylene carbon, the resulting iodohydrin (**iv**) may react further by the pathways outlined in Scheme 1.

Examination of models of 16β-*ent*-17-kauranol (**1***a*) and 16β,17-phyllocladanol (**2**) indicates that the derived oxygen radicals should be able to abstract a β-hydrogen from either C-12 (δ-carbon) or C-11 (ε-carbon). It has been suggested (19) that reaction is most favoured if the distance between the centers of the oxygen atom and the carbon atom from which hydrogen is abstracted lies in the range 2.5–2.7 Å, and if a linear transition state (—O · · · H · · · C—) is possible. On this basis, it would appear that attack at C-11 should occur more readily than attack at C-12 (*cf.* **14**–**17**). This conclusion is confirmed by the

nature of the products isolated from **1***a* (or *b*) and **2**.

The C-12 radical from **1***a* should suffer attack by an iodine atom to give the 12α-iodide preferentially (*cf.* **15**).[4] This iodine atom would then be suitably disposed to undergo intramolecular displacement in an S_N2 or S_H2 process (Scheme 1; **iv** → **v**, **vii**; $n = 1$) with formation of the tetrahydrofuran **7** (**15**). Alternatively, the 12α-iodide from **1***a* might lose HI with the formation of an 11,12 double bond (Scheme 1; **iv** → **viii** etc.; $n = 1$), leading eventually to **3***a*, **4***a*, and **5**. However, the low yield of **7** from **1***a* suggests that initial abstraction of a hydrogen atom from C-12 is not of major importance.

The C-11 radical from **1***a* should undergo attack by iodine from the β face (*cf.* **14**) to give the 11β-iodide (**18***a*) in which the iodine is not suitably disposed to undergo an S_N2 or S_H2 displacement with formation of the tetrahydropyran, **6***a* (Scheme 1; **iv** → **v**, **vii**; $n = 2$). However, this axial iodide (**18***a*) should suffer ready elimination of HI to give **3***a*. Elimination to give a 9,11 double bond is not favourable since H-9 is *cis* to the 11β-iodine (*cf.* elimination of 11β-tosylate in ref. 9). It would thus appear likely that the unstable products of the hypoiodite reaction of **1***a* and *b*, which disappear on treatment with pyridine, are the 11β-iodides, **18***a* and *b*, respectively. However, we still have to explain the formation of the tetrahydropyrans **6***a* and *b*, the latter having been obtained in fair yield from a prolonged reaction, while only traces of the former were present in a reaction which was stopped soon after the color of iodine had disappeared. From this it was inferred that these ethers are probably formed by reaction of **1***a* or *b* with lead tetraacetate alone (23), a pathway which will gain in importance after consumption of all or most of the available iodine. This was confirmed by repeating the hypoiodite reaction of **1***a* and continuing the reflux for 3h. Thin-layer chromatography of the product after work-up now showed a distinct spot of somewhat greater R_f than the iodoether (**4***a*). This product proved to be **6***a*, m.p. 123–125°; τ 6.22 and 6.61 (each d, 2 H-17, J_{obs} = 10.5 Hz) and 6.07 (narrow m,

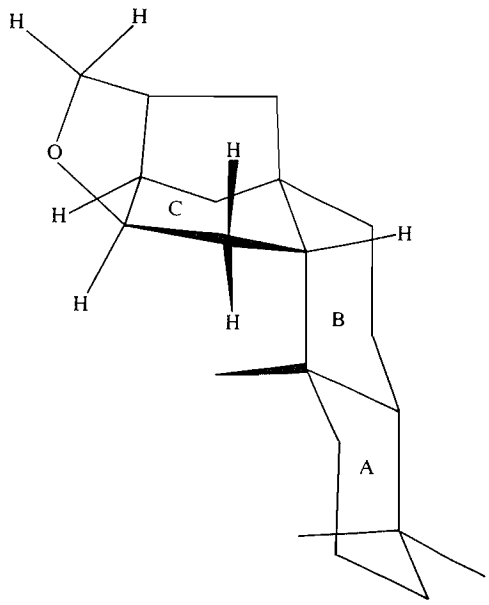
14



15

[4]We have considered various conformations for this compound, including the possibility of a full boat ring C, but that drawn, with this ring flattened, appears preferable. The presence of an 11α- or 11β-iodo substituent (see later) should enhance the preference for this conformation.

8*a* R = CH_3
8*b* R = CO_2CH_3

H-11), which, on oxidation with ruthenium tetroxide – sodium periodate, gave the lactone **10**. Further, reaction of **1***a* with lead tetraacetate alone (23) in refluxing cyclohexane for 24 h gave almost pure **6***a*, supporting the contention that the hypoiodite reaction of the former proceeds mainly via hydrogen abstraction from C-11.

The remaining products from **1***a* may arise via the oxygen radical derivable from **3***a* (Scheme 1; **viii** → **x**, **xi**; $n = 1$). Indeed, **3***a*, under the same reaction conditions as **1***a*, gives a high yield of **4***a*. This iodoether (**4***a*) does not appear to be a precursor of **5** since the former was recovered from attempts to eliminate HI with base (pyridine at room temperature or sodium methoxide in refluxing methanol–THF). This would suggest that H-9 is *cis* to the iodine at C-11, supporting the assignment of the 11β configuration to the latter. The ene-ether (**5**) may therefore arise via oxidation of the C-11 radical to a carbonium ion followed by proton elimination (Scheme 1; **ix** → **xii** → **xi**; $n = 1$). This con-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

clusion is reinforced by the observation of an increased yield of **5** in the prolonged hypoiodite reaction of **1***a*. It should therefore be possible to prepare **5** from **3***a* by reaction with lead tetraacetate alone.

Similar arguments to those presented above may be applied to explain the products of the hypoiodite reaction of 16β,17-phyllocladanol (**2**). Thus the C-11 radical derived from **2** would be expected to give the 11α-iodide (*cf.* **16**), which, in contrast to the case above, is suitably oriented to undergo S_N2 or S_H2 displacement with formation of **8** (**16**) which is in fact the principal product. Elimination of HI is probably less favourable in this case than for **18***a* (*b*) since the 11α-iodine is equatorial in the most stable (chair) conformation of ring C. As before, H-9 is *cis* to the iodine so that elimination of HI should give a $\Delta^{11,12}$ intermediate from which the ene-ether **9** may subsequently be derived as outlined for **5** above. It is perhaps surprising that no iodo-ether (**17** with I in place of 11α-H) was isolated, since this product would be expected to resist HI elimination by analogy with **4***a*.

The C-12 radical derived from **2** could probably attach iodine on either the α or the β side (*cf.* **17**), the former intermediate being expected to give an ether (**17**) via an S_N2 or S_H2 process, while the latter could be a precursor of **9** and other products. Unfortunately, the quantity of starting material available has precluded a study of the minor products of the hypoiodite reaction of **2**.

Experimental

Melting points were determined on a Kofler hot-stage apparatus and are uncorrected. For analytical and preparative t.l.c. chromatoplates were spread with Kieselgel G. (Merck). Alumina (Fisher) and silica gel (Baker) used for column chromatography were 80–200 and 40–140 mesh, respectively. Lead tetraacetate (British Drug Houses) was dried for several hours at 0.02 mm Hg and cyclohexane was distilled from calcium hydride immediately before use. Light petroleum was of b.p. 60–80°. Microanalyses were by Mr. S. McKinnon, Guelph. Infrared solution spectra were recorded in carbon tetrachloride on a Beckmann I.R. 12 spectrophotometer, and p.m.r. spectra on a Varian Associates A-60A spectrometer, in carbon tetrachloride unless otherwise stated.

Methyl ent-Kauren-19-oate and Methyl ent-Trachyloban-19-oate from Helianthus annuus

The literature method (20) was modified to the following. Mature, dried sunflower heads were ground after removal of the seeds (courtesy of the local bird population) and the resulting powder (5 kg) was packed into a large chromatography column. Elution with ether until no further material was extracted afforded an oil (300 g) containing *ent*-kaurenoic and *ent*-trachylobanic acids. A considerable proportion of unwanted material in this mixture was conveniently separated from the acids by dry column chromatography over silica gel (900 g) using light petroleum (1500 ml) as the developing solvent. The acid-enriched fraction thus obtained (35 g) was then subjected to column chromatography over silica gel (600 g). Elution with ethyl acetate – light petroleum (1:99; 500 ml) gave most of the material less polar than the desired acids; ethyl acetate – light petroleum (1:49; 500 ml) gave initially a mixture of acids and some less polar material, and subsequently, the acids plus more polar material; and finally ethyl acetate – light petroleum (3:97 → 1:19; 1500 ml) eluted the remainder of the acids along with more polar material. The last two sets of fractions were combined (28 g) and esterified with diazomethane, and the esters were chromatographed over 12% silver nitrate – silica gel in batches of 7 g of mixture to 250 g of adsorbent. Elution with ethyl acetate – light petroleum mixtures of gradually increasing polarity (0 → 1:49) gave methyl *ent*-trachyloban-19-oate (8 g) and methyl *ent*-kauren-19-oate (14 g).

Hydroboration–Oxidation of Methyl ent-Kauren-19-oate

Boron trifluoride etherate (1.80 g) in diglyme (5 ml) was added dropwise with stirring to a mixture of methyl *ent*-kauren-19-oate (2.00 g) and sodium borohydride (0.36 g) in diglyme (35 ml) under nitrogen at room temperature. The mixture was stirred under nitrogen for a further 2 h, then water (2 ml) was added, followed by 3 *N* sodium hydroxide solution (4 ml) and 30% hydrogen peroxide (8 ml). After stirring overnight, the mixture was poured into water (300 ml) and extracted with ether (3 × 75 ml). The combined ether extracts were dried (Na_2SO_4) and evaporated to give an oil which was chromatographed on alumina (45 g), elution with ethyl acetate – light petroleum (1:9) giving pure methyl 17-hydroxy-16β-*ent*-kauran-19-oate (1.47 g); m.p. 120–122°; ν_{OH} 3638 cm^{-1}, after crystallization from hexane.

Anal. Calcd. for $C_{21}H_{34}O_3$: C, 75.41; H, 10.25. Found: C, 75.28; H, 10.51.

The Hypoiodite Reaction of Methyl 17-Hydroxy-16β-ent-kauran-19-oate

A mixture of lead tetraacetate (5.75 g) and calcium carbonate (3.0 g) was stirred for 10 min in refluxing cyclohexane (200 ml), then the kauranol (**1***b*, 1.47 g) and iodine (0.60 g) were added and refluxing was continued while the mixture was irradiated with a 150 W tungsten lamp. After 40 min the color of the iodine had virtually disappeared. The reaction was allowed to proceed for a total of 1.5 h then the mixture was cooled, filtered, and the insoluble material washed with ether, the ether washings being combined with the filtrate. The filtrate was washed successively with sodium thiosulfate solution, water, and brine, and dried over Na_2SO_4. On standing, the initially clear, colorless solution turned light brown due to the liberation of iodine. Filtration and evaporation *in vacuo* on the water bath gave a dark residue (2.01 g), t.l.c. of which (ethyl acetate – light petroleum, 1:9) indicated the presence of four principal components. The dark product was dissolved in pyridine (10 ml) and left overnight at room temperature, after which it was poured into

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

ether and the ether solution washed successively with water, sodium thiosulphate solution, water, and brine, then dried over Na_2SO_4. Filtration and evaporation of the ether gave an oil (1.80 g) which liberated iodine very slowly and which showed the presence of only three of the original four main spots on t.l.c., the most polar component in the original mixture having disappeared. The oil was chromatographed on alumina (45 g) and eluted with ethyl acetate – light petroleum mixtures ($0 \rightarrow 1:9$) and finally with ethyl acetate alone. This separated the principal components, which were further purified by preparative t.l.c. using 1:9 ethyl acetate – light petroleum for the ether (**6***b*) and iodoether (**4***b*) and 1:3 ethyl acetate – light petroleum for the kaurenol (**3***b*). The least polar principal product (**6***b*; 0.195 g, 13.3%), on crystallization from methanol, had m.p. 153–155°; τ 9.27 (s, 3 H-20), 8.85 (s, 3 H-18), 6.42 (s, O—CH_3), 6.60 and 6.22 (each broadened d, 2 H-17, J_{obs} = 10 Hz), and 6.07 (narrow m, H-11).

Anal. Calcd. for $C_{21}H_{32}O_3$: C, 75.86; H, 9.70. Found: C, 75.90; H, 9.82.

The iodoether (**4***b*; 0.410 g, 20.3%), after crystallization from hexane, had m.p. 107–109°; τ 9.21 (s, 3 H-20), 8.88 (s, 3 H-18), 6.41 (s, O—CH_3), 5.95–6.35 (complex m partly obscured by O—CH_3 resonance, 2 H-17 + H-11) and 5.63 (dd, H-12, J = 4.5 and 8 Hz). Since this product decomposed slowly in the solid state and the color of iodine appeared in the solvent in the course of attempted crystallization, it was not analysed.

On crystallization from hexane, the kaurenol (**3***b*; 0.400 g, 27.4%) isolated above had m.p. 103–105.5°. Comparison with pure material (*vide infra*), m.p. 105–107.5°, ν_{OH} 3637 cm^{-1}, suggested that the former contained a little of the starting alcohol (**1***b*). The n.m.r. spectrum of pure **3***b* shows peaks at τ ($CDCl_3$) 9.26 (s, 3 H-20), 8.83 (s, 3 H-18), 6.47 (d, 2 H-17, $J \sim 7$ Hz), 6.39 (s, O—CH_3), 4.43 (dd, H-11, J = 10 and 3.4 Hz), and 4.08 (broadened dd, H-12, J_{obs} = 10 and ~5.5 Hz).

Anal. Calcd. for $C_{21}H_{32}O_3$: C, 75.86; H, 9.70. Found: C, 75.75; H, 9.61.

Reaction of Methyl 11β-Iodo-12β,17-oxido-16β-ent-kauran-19-oate with Zinc and Acetic Acid

The iodoether (**4***b*; 0.218 g) was dissolved in dry ether (10 ml), acetic acid (1 ml) and zinc dust (0.20 g) were added and the mixture was stirred overnight at room temperature. Thin-layer chromatography (ethyl acetate – light petroleum, 3:17) showed the presence of a single product with the same R_f as methyl 17-hydroxy-16β-*ent*-kaur-11-en-19-oate (**3***b*). The reaction mixture was filtered, shaken with excess potassium hydroxide solution, and dried over Na_2SO_4. Filtration and evaporation of the solvent left a solid residue (0.159 g) which gave pure **3***b* on crystallization from hexane.

The Hypoiodite Reaction of 1b using Excess Iodine

When the hypoiodite reaction of **1***b* was carried out as above but using double the amount of iodine, t.l.c. showed that all of the starting material had been consumed and a new spot of lower R_f than **4***b* was clearly evident. After work-up as outlined above, followed by column chromatography over alumina, this new "product" was isolated as a viscous oil whose n.m.r. spectrum showed it to be a mixture, peaks at τ ~8 and ~5 suggesting the presence of secondary acetate(s). The oil was subjected to mild hydrolysis (2 h reflux in dilute 1:1 aqueous methanolic NaOH and the mixture of two alcohols thus obtained was readily separated by preparative t.l.c. (ethyl acetate – light petroleum, 3:17).

The more polar alcohol (**6***d*), on crystallization from hexane had m.p. 169–171°; ν_{OH} 3628 cm^{-1} (free; concentration, 2 mg/ml. Contrast **4***e*); τ ($CDCl_3$) 9.06 (s, 3 H-20), 8.82 (s, 3 H-18), 6.47 and 6.05 (each broadened d, 2 H-17, J_{obs} = 10 Hz), 6.37 (s, O-CH_3), 6.07 (narrow m, H-11), and 5.78 (m, H-12); *cf.* n.m.r. spectrum of **6***b*.

Anal. Calcd. for $C_{21}H_{32}O_4$: C, 72.38; H, 9.26. Found: C, 72.29; H, 9.25.

On crystallization from hexane, the less polar alcohol (**4***d*) had m.p. 162–165°; ν_{OH} 3624 cm^{-1} (free; concentration, 2.0 mg/ml. Contrast **4***e*); τ ($CDCl_3$) 8.88 and 8.82 (both s, quaternary C—CH_3's), 6.33 (s, O—CH_3), 6.18 (main peak of m; minor peaks to higher and lower fields obscured; 2 H-17), and 5.77–6.0 (m, H-11 + H-12); *cf.* n.m.r. spectrum of **4***b*.

Anal. Calcd. for $C_{21}H_{32}O_4$: C, 72.38; H, 9.26. Found: C, 72.12; H, 9.26.

Treatment of the alcohols **6***d* and **4***d* with acetic anhydride – pyridine (3 h on steam bath followed by 18 h at room temperature) gave the corresponding acetates, **6***c* and **4***c*.

The former, on crystallization from hexane, had m.p. 103–104°; τ 9.20 (s, 3 H-20), 8.83 (s, 3 H-18), 8.02 (s, OCOCH_3), 6.52 and 6.02 (each broadened d, 2 H-17, J_{obs} = 10.5 Hz), 6.37 (s, O—CH_3), 6.12 (narrow m, H-11), and 4.92 (m, H-12).

Anal. Calcd. for $C_{23}H_{34}O_5$: C, 70.74; H, 8.78. Found: C, 70.64; H, 9.05.

On crystallization from hexane, **4***c* had m.p. 137.5–140°; τ 9.10 (s, 3 H-20), 8.87 (s, 3 H-18), 8.03 (s, OCOCH_3), 6.37 (s, O—CH_3), 5.83 to ~6.33 (m, H-12 + 2 H-17), and 4.87 (dd, H-12, J = 4.5 and 2.7 Hz). (Contrast last with low-field dd observed for **4***a*, *b*, and *e*).

Anal. Calcd. for $C_{23}H_{34}O_5$: C, 70.74; H, 8.78. Found: C, 70.82; H, 8.91.

The Hypoiodite Reaction of 16β-ent-17-Kauranol (24)

A mixture of lead tetraacetate (11.68 g) and calcium carbonate (6.0 g) was stirred in refluxing cyclohexane (250 ml) for 10 min and **1***a* (2.50 g) and iodine (1.13 g) were then added, stirring and heating being continued while the mixture was irradiated as before. After about 40 min, most of the iodine color had disappeared, and when, during a further 10 min, no visible change in the faint pink color of the solution occurred, the mixture was allowed to cool and the solution was filtered. The solid residue was washed with ether, and the combined filtrate and washings were shaken in succession with sodium thiosulfate solution, water, and brine, and dried over Na_2SO_4. The initially clear, colorless solution thus obtained darkened on standing due to the liberation of iodine. Filtration and evaporation of the solvents gave a dark oil which appeared to contain three major components (t.l.c.). The oil was dissolved in pyridine (10 ml) and left overnight at room temperature. The resulting mixture was taken up in ether, and this solution washed successively with sodium thiosulfate solution, water, and brine, and dried over Na_2SO_4. Thin-layer chromatography of the material remaining after filtration and evaporation of solvent showed that the most polar major spot had disappeared. This mixture (2.56 g) was now

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

subjected to column chromatography over alumina (60 g), elution being performed with ethyl acetate – light petroleum mixtures, and the resulting fractions were further purified by preparative t.l.c. as follows.

Elution of the column with light petroleum and with ethyl acetate – light petroleum (1:199) gave a complex mixture (0.235 g) containing eight or nine components (t.l.c.). This mixture was not examined further.

Elution with ethyl acetate – light petroleum (1:99) gave a mixture containing **7**, **5**, and **4*a***. Preparative t.l.c. of this mixture was carried out with ethyl acetate – light petroleum (3:97; run four times). The sample of **7** (106 mg, 4.3%) thus obtained was an oil which appeared as a uniform, single spot on t.l.c. but which would only solidify partly on attempted crystallization from methanol, or on sublimation at 80–90°/0.02 mm Hg. Pure **7** was obtained by reduction of **4*a*** with lithium aluminum hydride (*vide infra*).

On crystallization from methanol–water, **5** (101 mg, 4.1%) had m.p. 86–89°; τ 9.15, 9.07, 8.91 (all s, quaternary C—CH_3's), 6.73 (dd, βH-17, J_{obs} ~3.5 and ~9 Hz), 6.05 (t, αH-17, J_{obs} ~8.5 Hz), 5.42 (broadened dd, H-12, J_{obs} ~3.5 and 7 Hz), and 4.85 (d, H-11, J_{obs} ~3.5 Hz).

Anal. Calcd. for $C_{20}H_{30}O$: C, 83.86; H, 10.56. Found: C, 83.99; H, 10.88.

Pure iodoether (**4*a***) was obtained on elution of the column with ethyl acetate – light petroleum (3:197) and combined with material purified by preparative t.l.c. of preceding and subsequent column fractions to give a total of 0.717 g (20.1%), m.p. 110–110.5° on crystallization from methanol. The n.m.r. spectrum of **4*a*** shows peaks at τ 9.19, 9.14, 9.01 (all s, quaternary C—CH_3's), 6.33–5.95 (complex m, 2 H-17 + H-11), and 5.62 (well resolved dd, H-12, J = 8 and 4.8 Hz; relative peak heights, high field → low field, 21:20:14.5:14).

Anal. Calcd. for $C_{20}H_{31}IO$: C, 57.97; H, 7.54. Found: C, 57.96; H, 7.65.

Fractions eluted with ethyl acetate – light petroleum (3:97 → 9:191) contained a mixture of at least seven components (0.201 g) according to analytical t.l.c. and were not examined further on this occasion (*vide infra*).

Elution with ethyl acetate – light petroleum (1:19) then more polar mixtures gave **3*a*** plus a small amount of more polar material. Most of the **3*a*** was isolated by direct crystallization from hexane and the remainder recovered from the mother liquors by preparative t.l.c. using ethyl acetate – light petroleum (1:9). This product (0.904 g, 36.4%) had m.p. 160–161.5°. Comparison of its n.m.r. spectrum with that of **3*a*** prepared from **4*a*** (*vide infra*) suggested that it contained a little **1*a***.

As indicated above, column fractions of polarity between those containing **4*a*** and **3*a*** contained a complex mixture of compounds. On one occasion, when the hypoiodite reaction of **1*a*** was repeated using the same conditions as before, a fraction which contained a component slightly less polar than **3*a*** was obtained. Preparative t.l.c. (ethyl acetate – light petroleum, 1:19; run five times) and crystallization from hexane gave **4*e***, which had m.p. 103.5–104.5; ν_{OH} 3566 cm^{-1} (intramolecular hydrogen bond; concentration, 1.5 mg/ml. Contrast **4*d*** and **6*d***); τ 9.14 (6H), 8.98 (both s, quaternary C—CH_3's), ~6.35–6.78 (broad m, H-12 + O*H*), 6.00 to ~6.4 (complex m, 2 H-17), and 5.76 (dd, H-11, J = 9 and 6 Hz) (*cf.* n.m.r. spectrum of **4*a***); and sublimes readily at 80°/0.01 mm Hg.

Anal. Calcd. for $C_{20}H_{32}O_2$: C, 78.90; H, 10.59. Found: C, 79.27; H, 10.49.

Reaction of 11β-Iodo-12β,17-oxido-16β-ent-kaurane (4a) with Zinc and Acetic Acid

Zinc dust (2.0 g) and glacial acetic acid (2 ml) were added to a solution of **4*a*** (0.547 g) in dry ether (30 ml) and the resulting mixture was stirred for 24 h at room temperature. The mixture was filtered and the filtrate washed with excess potassium hydroxide solution, dried over Na_2SO_4, filtered, and evaporated to leave a white solid (0.388 g) which ran as a single spot on t.l.c. (ethyl acetate – light petroleum, 1:9). Crystallization from hexane gave pure **3*a***, m.p. 162–163°; ν_{OH} 3639 cm^{-1}; τ 9.20, 9.13, 9.08 (all s, quaternary C—CH_3's), 6.43 (d, 2 H-17, J = 7.2 Hz), 4.41 (dd, H-11, J = 9.5 and 3.5 Hz), and 4.07 (broadened dd, H-12, J ~10 and ~6 Hz).

Anal. Calcd. for $C_{20}H_{32}O$: C, 83.27; H, 11.18. Found: C, 82.98; H, 11.25.

Reduction of 4a with Lithium Aluminum Hydride

The iodoether **4*a*** (200 mg) in ether (100 ml) was refluxed overnight with lithium aluminum hydride (100 mg). Fresh lithium aluminum hydride (100 mg) was then added and heating continued for a further 20 h. The mixture was cooled and ethyl acetate (5 ml) added, followed by water (0.2 ml), 15% NaOH (0.2 ml), and water (0.6 ml) with continuous stirring. The resulting granular precipitate and the solvent were removed to give an oil. Thin-layer chromatography of this oil (ethyl acetate – light petroleum, 1:9) indicated the presence of two products which were separated by preparative t.l.c. (same solvent) and identified as **3*a*** (0.022 g) and **7** (0.107 g). The latter crystallized from methanol only on cooling to 0–5° and had m.p. 41.5–43.5° (with some softening around 36°); τ 9.17, 9.10 (6H) (both s, quaternary C—CH_3's), 6.1–6.5 (complex m, 2 H-17), and 5.6–5.9 (complex m, H-12).

Anal. Calcd. for $C_{20}H_{32}O$: C, 83.27; H, 11.18. Found: C, 83.48; H, 11.18.

Ruthenium Tetroxide Solution in Carbon Tetrachloride

This solution was prepared according to a literature method (22) by oxidation of RuO_2 with aqueous sodium periodate and extraction of the RuO_4 formed into CCl_4. The resulting solution contained ~1.5 mg RuO_4/ml.

Oxidation of Impure 12β,17-Oxido-16β-ent-kaurane (7) with Ruthenium Tetroxide – Sodium Periodate.

Impure ether **7** [0.156 g; from $Pb(OAc)_4$–I_2 reaction of **1*a***] in carbon tetrachloride (10 ml) was stirred vigorously with sodium periodate (1.0 g) and water (10 ml), and ruthenium tetroxide solution (2 ml) added. The light yellow RuO_4 solution turned brown-black immediately on mixing with the substrate. After 2 days' stirring at room temperature, t.l.c. (ethyl acetate – light petroleum, 1:9) indicated that **7** was reacting rather slowly so more RuO_4 solution (3 ml) and sodium periodate (1.0 g) in water (10 ml) were added. Fresh sodium periodate (1.0 g) was added after 5 and 8 days of reaction. After 10 days, t.l.c. indicated that all of the starting material had been consumed and that two more polar products had been formed. The aqueous and carbon tetrachloride layers were separated and ethanol (1 ml) was added to the latter to destroy any RuO_4 present. Evaporation of the solvent gave a product darkened by ruthenium residues. This was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

taken up in ethyl acetate and passed through a short alumina column to give a colorless solution which on evaporation yielded a mixture (0.107 g) of **10** and **11**. These were separated by preparative t.l.c. in ethyl acetate – light petroleum (1:19, run eight times). The major, less polar product, **11**, on crystallization from hexane, had m.p. 170–171°; $\nu_{C=O}$ 1778 cm^{-1}; τ 9.17, 9.08 (6H) (both s, quaternary C—CH_3's), 6.82–7.33 (m, H-13 + H-16), 5.00–5.28 (m, H-12).

Anal. Calcd. for $C_{20}H_{30}O_2$: C, 79.42; H, 10.00. Found: C, 79.71; H, 10.32.

The minor, more polar product (**10**) had m.p. 175.5–176° on crystallization from hexane and $\nu_{C=O}$ 1749 cm^{-1}; τ 9.14, 9.10, 8.98 (all s, quaternary C—CH_3's), 6.97–7.55 (m, H-13 + H-16), 5.52 (narrow m, H-11).

Anal. Calcd. for $C_{20}H_{30}O_2$: C, 79.42; H, 10.00. Found: C, 79.50; H, 10.30.

Hydroboration–Oxidation of Phyllocladene

The procedure was analogous to that used in the hydroboration–oxidation of *ent*-kaurene (24). On crystallization from hexane, the product (**2**) had m.p. 136–146°; τ ($CDCl_3$) 9.18, 9.14, 9.09 (all s, quaternary C—CH_3's), 6.28 (d, 2 H-17, J = 7 Hz).

Anal. Calcd. for $C_{20}H_{34}O$: C, 82.69; H, 11.80. Found: C, 82.63; H, 11.49.

The Hypoiodite Reaction of 16β-Phyllocladan-17-ol (2)

The phyllocladanol (**2**; 0.476 g) and iodine (0.214 g) were added to a mixture of lead tetraacetate (3.0 g) and calcium carbonate (1.5 g) in cyclohexane (50 ml) which had been refluxing and stirring for 10 min. After about 30 min irradiation with a 150 W tungsten lamp, the color of the iodine had disappeared. The mixture was cooled and worked up as outlined for **1***a* and *b*. Thin-layer chromatography of the product (0.70 g) which liberated iodine on standing, showed the presence of three principal components with similar polarities and several minor ones. Treatment with pyridine (3 ml) and work-up as before gave an oil (0.591 g), t.l.c. of which (ethyl acetate – light petroleum, 1:19) indicated that the three major products had survived but that two minor products (one slightly more polar than the most polar major component and one slightly less polar than the least polar major component) had disappeared. The mixture was then separated into five fractions by preparative t.l.c. (ethyl acetate – light petroleum, 1:19).

The least polar fraction (0.056 g) contained a mixture of products less polar than **8** and has not been examined further.

The second fraction (**8**; 0.183 g, 38.7%), on crystallization from methanol had m.p. 71.5–73°; τ 9.16 (6H), 8.67 (both s, quaternary C—CH_3's), 6.60 and 6.27 (each broadened d, 2 H-17, J = 10 Hz), and 5.65 (m, H-11).

Anal. Calcd. for $C_{20}H_{32}O$: C, 83.27; H, 11.18. Found: C, 83.50; H, 11.23.

The third fraction was obtained as an oil which could not be induced to crystallize although it appeared as a single spot on t.l.c. The n.m.r. spectrum showed it to be a mixture, at least five individual peaks being detectable in the methyl region. The lower field portion of the n.m.r. spectrum showed a multiplet similar to that due to 2 H-17 in **8**, but including additional peaks which partly obscured the lower field doublet, and a multiplet at τ 5.6–5.95. The last two features resemble the H-12 multiplet of **7** and the H-12 and H-11 multiplets of **4***a* (or *b*). Finally, a weak multiplet was discernible at τ 4.4–4.65. The ruthenium tetroxide oxidation of this mixture resulted in complete consumption of the substrate but a poor yield of a complex mixture was obtained. It has not been investigated further.

The fourth fraction (**9**; 0.065 g, 13.8%) could not be persuaded to solidify in the presence of solvent but had m.p. 82–87° after sublimation at 80°/0.01 mm Hg. The n.m.r. spectrum shows peaks at τ 9.16, 9.12, 8.86 (all s, quaternary C—CH_3's), 6.77 (dd, βH-17, J_{obs} ~9 and ~4 Hz), 6.05 (t, αH-17, J_{obs} ~9 Hz), 5.44 (broadened dd, H-12, J_{obs} ~3.5 and ~6 Hz), and 4.83 (d, H-11, J ~3.5 Hz).

Anal. Calcd. for $C_{20}H_{30}O$: C, 83.86; H, 10.56. Found: C, 83.73; H, 10.87.

Oxidation of 11β,17-Oxido-16β-phyllocladane (8) with Ruthenium Tetroxide – Sodium Periodate

Ruthenium tetroxide solution (2 ml) was added to a mixture of **8** (0.141 g) in carbon tetrachloride (10 ml), sodium metaperiodate (1.0 g), and water (10 ml), and the mixture stirred rapidly at room temperature. Fresh sodium periodate (1.0 g) and water (10 ml) were added on the third and eighth day. After a total of 10 days, all the starting material had disappeared (t.l.c.; ethyl acetate – light petroleum, 1:9) and a single, more polar product had formed. Work-up as for **7** gave a solid (**12**; 0.132 g) which had m.p. 188–189° on crystallization from hexane; $\nu_{C=O}$ 1754 and 1745 cm^{-1}; τ ($CDCl_3$) 9.15 (6H), 8.80 (both s, quaternary C—CH_3's), 5.10 (m, H-11).

Anal. Calcd. for $C_{20}H_{30}O_2$: C, 79.42; H, 10.00. Found: C, 79.47; H, 9.90.

The Prolonged Hypoiodite Reaction of 16β-ent-Kauran-17-ol (1a)

The hypoiodite reaction of **1***a* (1.31 g) was conducted as before [0.60 g I_2, 4.00 g $Pb(OAc)_4$, 2.00 g $CaCO_3$] except that irradiation with stirring and heating were continued for 3 h. Work-up and column chromatography of the mixture were carried out as already described to give, in addition to the previously isolated products (**3***a*, **4***a*, **5**) the ether **6***a* (0.233 g, 17.9%) which, on crystallization from methanol, had m.p. 123–125°; τ 9.17, 9.13, 9.03 (all s, quaternary C—CH_3's), 6.61 and 6.22 (each d, 2 H-17, J = 10.5 Hz), 6.07 (narrow m, H-11).

Anal. Calcd. for $C_{20}H_{32}O$: C, 83.27; H, 11.18. Found: C, 83.15; H, 11.30.

The yield of **5** obtained in this instance (0.180 g, 13.9%) was markedly greater than that obtained in the previous run on **1***a* (4.1%).

Oxidation of 11β,17-Oxido-16β-ent-kaurane (6a) with Ruthenium Tetroxide – Sodium Periodate

The mother liquors from successive crystallizations of **6***a* were collected (0.113 g) and oxidized with ruthenium tetroxide solution (2 ml) and aqueous sodium periodate as before. Work-up gave a mixture (0.083 g) which contained one major component, one slightly less polar minor component and a trace of polar material. Separation was accomplished by preparative t.l.c. (ethyl acetate – light petroleum, 1:19; run eight times) when the major component proved to be **10** and the minor one **11**.

Reaction of 16β-ent-Kauran-17-ol (1a) with Lead Tetraacetate

A mixture of **1***a* (0.062 g) and lead tetraacetate (0.500 g)

in cyclohexane (50 ml) was refluxed for 24 h. The resulting mixture was cooled and filtered and the solvent evaporated to give an oil (0.066 g) which crystallized readily on standing. Thin-layer chromatography suggested the presence of a single product less polar than the starting material, and the n.m.r. spectrum showed it to be essentially pure **6***a*.

The Hypoiodite Reaction of 16β-ent-Kaur-11-en-17-ol (3a)

The hypoiodite reaction of **3***a* (0.100 g), iodine (0.045 g), lead tetraacetate (0.50 g), and calcium carbonate (0.50 g) in cyclohexane (50 ml) was complete (t.l.c.) in about 30 min. Work-up as described earlier gave an oil (0.145 g) which solidified on standing. Analytical t.l.c. (ethyl acetate – light petroleum, 3:97; run four times) showed the presence of one major product, one less polar minor product, and traces of polar material. Preparative t.l.c. (same solvent) and crystallization from methanol gave the major component, **4***a* (0.107 g).

We thank the National Research Council of Canada for an operating grant.

Smiles Rearrangement in Hydrazonyl Systems: Extension of a Recent 4*H*-1,3,4-Benzoxadiazine Synthesis

ARTHUR J. ELLIOTT

Department of Chemistry, McMaster University, Hamilton, Ontario

AND

MARTIN S. GIBSON, MARGARET M. KAYSER, AND GORDON A. PAWELCHAK

Department of Chemistry, Brock University, St. Catharines, Ontario[1]

Received July 13, 1973

Hydrazonyl aryl ethers derived from hydrazonyl halides $Ar_1CBr{=}NNHC_6H_3XY$ (2, 4) and (*a*) *o*- and *p*-nitrophenols or (*b*) pentachlorophenol undergo a facile base-catalyzed Smiles rearrangement to *N*-aroyl-*N'*,*N'*-diarylhydrazines typified by:

$$Ar_1C(OAr_2){=}NNHC_6H_3XY \rightarrow Ar_1CONHNAr_2C_6H_3XY$$

e.g. **6** → **7**, **8** → **9**, **10** → **11**.

If the 2-substituent X is Br or F and the 4-substituent Y is electron attracting, the *N*-aroyl-*N'*,*N'*-diarylhydrazines can be cyclized under basic conditions to 4-aryl-4*H*-1,3,4-benzoxadiazines by displacement of X, *i.e.* **7** → **13**, **9** → **14**. However, in the analogous cyclization of *N*-benzoyl-*N'*-(2,4-dibromophenyl)-*N'*-pentachlorophenylhydrazine (**11**), chlorine rather than bromine is displaced and the migrating ring ($Ar_2 = C_6Cl_5$) in **10** → **11** becomes the benzene ring of the benzoxadiazine, *i.e.* **11** → **15**.

Independent syntheses of two 4-aryl-4*H*-1,3,4-benzoxadiazines (**13***a* and **14**), from 7-bromo-2-phenyl-4*H*-1,3,4-benzoxadiazine (**5***a*) and *o*- and *p*-fluoronitrobenzene respectively, are reported.

Les ethers hydrazonyl aryle dérivés des halides hydrazonyl $Ar_1CBr{=}NNHC_6H_3XY$ (2, 4) et (*a*) *o*-, *p*-nitrophénol ou (*b*) pentachlorophénol subissent une simple réarrangement de Smiles à catalisation alkaline pour donner *N*-aroyle-*N'*,*N'*-diarylhydrazines tels que:

$$Ar_1C(OAr_2){=}NNHC_6H_3XY \rightarrow Ar_1CONHNAr_2C_6H_3XY$$

e.g. **6** → **7**, **8** → **9**, **10** → **11**.

Si le 2-substituant X est du Br ou du F et le 4-substituant Y est un groupe attirant les electrons, les *N*-aroyle-*N'*,*N'*-diarylhydrazines peuvent cycliser dans des conditions alkalines de façon pour donner 4-aryle-4*H*-1,3,4-benzoxadiazines par le déplacement du X, *i.e.* **7** → **13**, **9** → **14**. Cependant, dans le cyclisation analogue de *N*-benzoyl-*N'*-(2,4-dibromophényle)-*N'*-pentachlorophényl hydrazine (**11**), le chlore plûtot que le brome est déplacé et l'anneau migrateur ($Ar_2 = C_6Cl_5$) en **10** → **11** devient l'anneau benzoic de la benzoxadiazine, *i.e.* **11** → **15**.

On présente aussi les deux synthèses indépendantes de **13***a* et **14**, les 4-aryle-4*H*-1,3,4-benzoxadiazines à partir de 7-bromo-2-phényle-4*H*-1,3,4-benzoxadiazine (**5***a*) et *o*-, *p*-fluoronitrobénzene respectivements.

Can. J. Chem., **51**, 4115 (1973)

A recent synthesis of 4*H*-1,3,4-benzoxadiazines employs various hydrazonyl bromides (**1**), where X = Br or F and Y = Br or NO_2, as starting materials (1). These are converted by reaction with sodium acetate to the corresponding *N*-acetyl-*N'*-aroyl-*N*-arylhydrazines (**3**), presumably by way of hydrazonyl acetates (**2**) though the latter are not isolated. Compounds **3**, on base treatment, give **4** by nucleophilic displacement of the substituent X; in some cases, a subsequent deacetylation (**4** → **5**) is observed under the reaction conditions (Scheme 1). This synthesis supplements the alternative synthesis due to Huisgen and Fleischmann (2).

In order to examine reactions of the type **2** → **3**, a less labile migrating group is required. To this end a number of phenoxy derivatives have been synthesized in which the electron deficiency of the phenoxy ring is controlled by choice of substituents. It was anticipated that if base-catalyzed rearrangement of these compounds were possible, it would lead to *N*-aryl derivatives analogous to **3**. Such an *O* → *N* aryl transfer would provide analogy for the *O* → *N* acyl transfer proposed in **2** → **3** and would represent a Smiles rearrangement (3) on a hydrazonyl skeleton as template. It was hoped further that some of these *N*-aryl derivatives

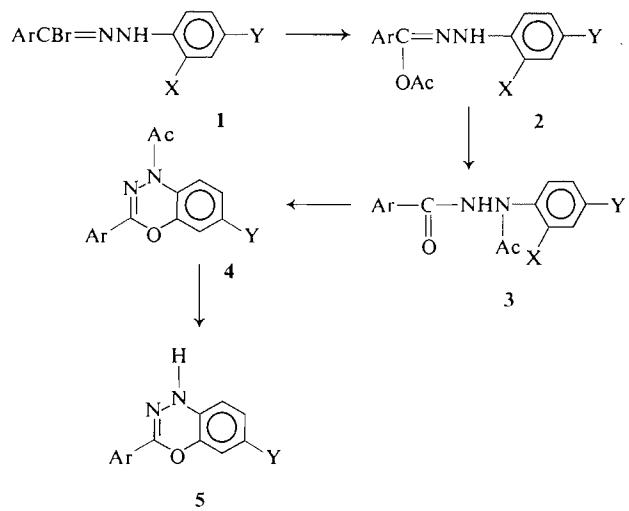

SCHEME 1

would be useful intermediates for syntheses of 4-aryl-4*H*-1,3,4-benzoxadiazines and so permit generalization (1) of the recent benzoxadiazine synthesis typified by **3** → **4**.

Certain of our observations, noted below, are germane to the thermal isomerisation (Chapman rearrangement) of aryl hydrazonyl ethers (aryl hydrazonates), which has recently been the subject of communications from other laboratories (4).

For convenience, the readily available nitrophenols have been principally used in this study. First, equivalent amounts of hydrazonyl bromide **1***a* and *p*-nitrophenol were stirred together in ethanol with added triethylamine at room temperature to give hydrazonyl *p*-nitrophenyl ether **6***a*. The latter rearranged smoothly in boiling ethanol–triethylamine to the corresponding hydrazide **7***a*. The mass spectra of **6***a* and **7***a* proved interesting. Only **6***a* lost the elements of *p*-nitrophenol on electron impact, an observation in agreement with structure **6***a* (*m/e* 350 for ^{79}Br isotope, 12% of base peak). Further examination of the mass spectrum of **6***a*, and correlation with that of **7***a*, permitted assignment of peaks at *m/e* 384 and 370 to the rearranged compound **7***a*, *i.e.* assignment after allowing for $O \rightarrow N$ aryl transfer. There was no evidence for reverse aryl migration in the mass spectrum of **7***a*.

Other hydrazonyl halides (**1***b–h*), similarly treated with *p*-nitrophenol and triethylamine, gave the corresponding hydrazonyl *p*-nitrophenyl ethers (**6***b–h*). Each of these ethers rearranged to the corresponding hydrazide **7** in refluxing ethanol–triethylamine, generally within a few minutes. Compounds (**6***d* and *f*) which contained electron-attracting groups in the *N*-aryl ring, required longer reaction times for complete rearrangement, reflecting the decreased nucleophilicity of the appropriate nitrogen atom in such compounds (Scheme 2).

Studies were then extended to *o*- and *m*- nitrophenols. It was found that *o*-nitrophenol and hydrazonyl halides (**1***a* and *g*) gave the corresponding hydrazonyl *o*-nitrophenyl ethers (**8***a* and *g*) and that these rearranged smoothly to the corresponding hydrazides (**9***a* and *g*) in boiling ethanol–triethylamine. Under similar conditions, the hydrazonyl aryl ether from **1***a* and *m*-nitrophenol was recovered, and more forcing conditions resulted in decomposition. The last compound examined was hydrazonyl aryl ether **10** from **1***a* and pentachlorophenol; this compound rearranged in boiling ethanol–triethylamine to give hydrazide **11**, though the latter compound was not obtained in an analytically pure condition (Scheme 3).

At this stage, in order to obtain some indication that the base-catalyzed rearrangement was intramolecular, the hydrazonyl ethers **6***g* and **8***a* were rearranged in admixture. Intramolecular rearrangement would give **7***g* and **9***a* respectively, whilst an intermolecular rearrangement, for example resulting from dissociation and recombination, would provide in addition **7***a* and **9***g*. The choice of compounds **6***g* and **8***a* was based

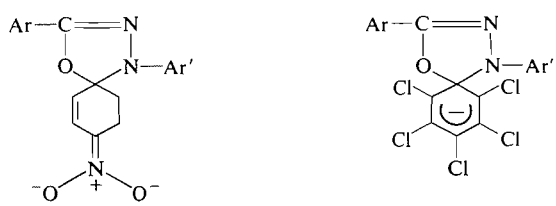
SCHEME 3

on similar reactivity, good yields on rearrangement, and ease of separation and identification of the possible products. The mixture produced by rearranging **6***g* and **8***a* in admixture under these conditions contained, within the limits of detection chromatographically, only **7***g* and **9***a*.

Our view is that these rearrangements are intramolecular and proceed through a five-membered cyclic transition state, *e.g.* **12** (Scheme 4). In the cases where the migrating group is *o*- or *p*-nitrophenyl, the transition state is stabilized by delocalisation involving the NO_2 group. No such delocalisation is possible in the case of *m*-nitrophenyl and, under the reaction conditions employed, no rearrangement occurs. In the case of pentachlorophenyl, the ring is sufficiently electron deficient for inductive stabilization of



12

the minus charge on the migrating ring to allow rearrangement to proceed.

The thermally-induced or Chapman rearrangement of hydrazonyl aryl ethers to *N*-aroyl-*N'*,*N'*-diarylhydrazines, rather than the isomeric *N*-aroyl-*N*,*N'*-diarylhydrazines, is of some current interest (4).

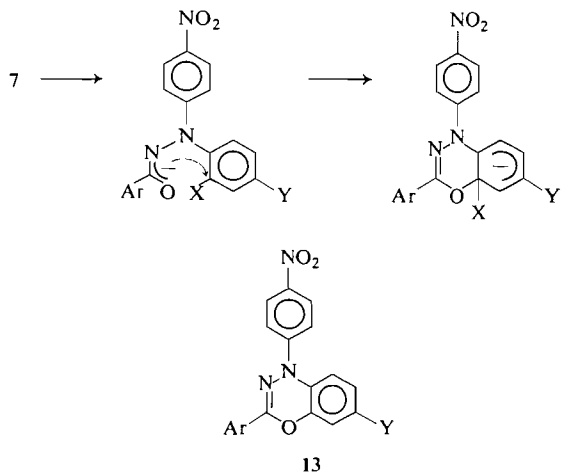
[1] $Ar_1C(OAr_2) = NNHAr_3 \rightarrow Ar_1CONHNAr_2Ar_3$

Rearrangement occurs readily at 200°. Our investigations have not encompassed these conditions but we have noted that no detectable rearrangement (t.l.c.) occurs, *e.g.*, during m.p. determination of **6***a* (118°). Part of the evidence for structural assignment to the products from thermal rearrangement of hydrazonyl aryl ethers comes from hydrolysis to the corresponding *N*,*N*-diarylhydrazines and it has been pointed out that this would provide a useful route to such hydrazines. Whilst this is undoubtedly true, it may be difficult to achieve hydrolysis successfully with more heavily substituted compounds (5). In particular, no success attended our efforts with **9***a* under normal conditions.

Extension of the previously reported 4*H*-1,3,4-benzoxadiazine synthesis (1) was the next objective. The cyclization of a series of the foregoing hydrazides (**7***a–f*) was effected by boiling with an equivalent amount of sodium hydroxide in dimethylformamide–triethylamine mixture for several hours. In most cases, the desired product (**13***a–f*) was isolated chromatographically, the yields ranging from 25–96%.

The presence of electron-withdrawing groups in the *N*-aryl rings and of electron-releasing groups in the *C*-aryl ring would be expected to aid the cyclization. This appears to be so, except for the case of **7***d*. However, in this case, competitive hydrolysis by sodium hydroxide of the ester function would replace an electron withdrawing ethoxycarbonyl group by carboxylate anion and cyclization would then be expected to take place reluctantly, if at all; the benzoxadiazine isolated (**13***d*, 25%) is that derived from the unhydrolyzed hydrazide **7***d* (Scheme 5).

Comparison of **7***a* with **7***e* shows that changing the leaving group from bromine to fluorine results in smoother cyclization and increased yield of the benzoxadiazine **13***a*. In fact **7***e* is converted entirely to benzoxadiazine **13***a* and the yield (96%) represents the material obtained after work-up. In view of this, the mechanism favored for the reaction **7** → **13** is analogous to



SCHEME 5

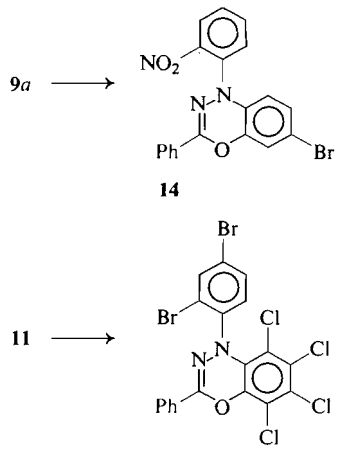
that proposed earlier for the cyclization **3** → **4**, except that the *p*-nitrophenyl substituent is not as labile as an acetyl group and is not removed under the reaction conditions, *i.e.* the reaction corresponding to **4** → **5** is not observed (1). The anionic species derived from **7**, or possibly the zwitterionic conjugate acid, is thought to attack the 2-position of the appropriate *N*-aryl ring to form the heterocyclic ring by nucleophilic displacement of halogen.

The structure of **13***a* was confirmed by an alternative synthesis. When **5***a* and *p*-fluoronitrobenzene were boiled together in acetonitrile–triethylamine for 4 h, **13***a* was obtained in 66% yield.

The cyclization of *N*-benzoyl-*N'*-(2,4-dibromophenyl)-*N'*-*o*-nitrophenylhydrazine (**9***a*) posed the alternatives of cyclization by displacement of bromine or by displacement of nitro group. When **9***a* was treated as for the foregoing hydrazides, only **14** was obtained; there was no evidence of other cyclized product (t.l.c.). This oxadiazine was also synthesized from **5***a* and *o*-fluoronitrobenzene.

The cyclization of *N*-benzoyl-*N'*-(2,4-dibromophenyl)-*N'*-pentachlorophenylhydrazine (**11**) posed similar alternatives. In earlier work on synthesis of 4*H*-1,3,4-benzothiadiazines (**6**) it had been noted that no benzothiadiazine formation occurred when compounds (**1**, X = Cl) were treated with potassium thioacetate, though reaction was successful when X = F, Br, or I. However, more heavily chlorinated aromatic rings do undergo nucleophilic displacement of chlorine, and the reactions are synthetically

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.



SCHEME 6

useful (7). In the event, **11**, was cyclized to **15** by displacement of chlorine, with no evidence of other cyclized product (t.l.c.) (Scheme 6).

The present work establishes that aryl hydrazonyl ethers substituted such that the *O*-aryl ring is sufficiently electron deficient, undergo a facile base-catalyzed Smiles rearrangement to give the corresponding *N*-arylhydrazide, *e.g.* **6** → **7**, **8** → **9**, **10** → **11**. The *N*-arylhydrazides thus available are, for given substituents X and Y, eminently suitable intermediates for synthesis of 4-aryl-4*H*-1,3,4-benzoxadiazines. In many cases, the aryl group migrating in the Smiles rearrangement becomes the 4-aryl substituent in the benzoxadiazine finally produced, *e.g.* **6** → **7** → **13**, **8** → **9** → **14**. However, this is not necessarily so, as shown by the conversion **10** → **11** → **15** in which the aryl group migrating in the Smiles rearrangement is finally incorporated as the benzene ring of the benzoxadiazine ring system.

Experimental

General procedures follow those described previously (1). Mass spectra were determined with an AEI-MS30 double beam double focussing mass spectrometer, unless otherwise stated.

Hydrazonyl Halides: Preparation of **1***h* (*8*)

A mixture of *N*-cinnamoyl-*N'*-phenylhydrazine (12.0 g, 0.05 mol), phosphorus pentachloride (11.9 g, 0.055 mol) and dry ether (100 ml) was boiled under reflux for 78 h. The brown solution was cooled and treated with an ethereal solution of phenol until no further reaction was observed. Ethanol was then added and ether was removed by concentration *in vacuo*. The solid was filtered off and crystallized from ethanol to give *N*-α-*chlorocinnamylidene-N'-phenylhydrazine* (**1***h*) as plates (5.8 g, 45%), m.p. 150–151°.

Anal. Calcd. for $C_{15}H_{13}ClN_2$: C, 70.18; H, 5.07; N, 10.92. Found: C, 70.06; H, 5.08; N, 10.74.

Compound **1***h* gave an intense red coloration when heated with phenylhydrazine in ethanol.

Preparation of Hydrazonyl Aryl Ethers

As general procedure, the hydrazonyl halide (0.01 mol) and the phenol (0.01 mol) were stirred in ethanol (EtOH) or acetonitrile (MeCN) containing triethylamine (NEt_3, 0.02 mol) at room temperature, usually for 2 h. The product was collected by (*a*) filtration or (*b*) dilution of the reaction mixture with water followed by filtration, and then washed, dried and purified by crystallization.

Hydrazonyl Aryl Ethers from **1***a*

Compound **1***a* (9) (4.33 g), *p*-nitrophenol (1.39 g), EtOH (30 ml), and NEt_3 (2 ml) gave *N*-α-(*p-nitrophenoxy*)-*benzylidene-N'-(2,4-dibromophenyl)hydrazine* (**6***a*) (3.44 g, 70%) as yellow prisms, m.p. 100–101° or yellow needles, m.p. 117–118° (from ethanol); n.m.r. (CCl_4) δ 8.25 (s, NH), 8.3 (A) and 7.2 (B) (A_2B_2q, J = 8 Hz), and 7.9–7.35 (m, 8H); mass spectrum *m/e* 493/491/489 (M^+), 477/475/473, 463/461/459, 412/410, 411/409, 400/398/396, 354/352/350 ($M^+ - HOC_6H_4NO_2$), 344/342/340, 274/272, 252/250/248 ($Br_2C_6H_3NH$), 225/223/221, 171/169, 139 ($HOC_6H_4NO_2$), 105, 103, and 77. Low intensity peaks at *m/e* 388/386/384, 374/372/370, and 372/370/368 are attributable to rearranged material. A mass spectrum obtained using an AEI-MS902 spectrometer (200–300°) showed some differences, notably reduced intensity of peak *m/e* 354/352/350 and increased intensities of peaks due to rearranged material.

The compound did not undergo detectable rearrangement (t.l.c.) during m.p. determination.

Anal. Calcd. for $C_{19}H_{13}Br_2N_3O_3$: C, 46.44; H, 2.65; Br, 32.59; N, 8.55. Found: C, 46.5; H, 2.7; N, 8.6.

Compound **1***a* (2.0 g), *m*-nitrophenol (0.64 g), EtOH (25 ml) and NEt_3 (1 ml) gave the corresponding *hydrazonyl aryl ether* (1.24 g, 55%) as yellow prisms, m.p. 117–118° (from ethanol).

Anal. Found: C, 46.5; H, 2.9; Br, 32.5; N, 8.5.

Similarly, **1***a* (4.33 g), *o*-nitrophenol (1.39 g), EtOH (25 ml) and NEt_3 (2 ml) gave **8***a* (3.97 g, 81%) as yellow prisms, m.p. 106° or yellow needles, m.p. 122–124° (from ethanol).

Anal. Found: C, 46.6; H, 2.6; Br, 32.8; N, 8.6

Compound **1***a* (4.33 g), pentachlorophenol (2.66 g), EtOH (30 ml), and NEt_3 (1 ml) gave **10** (5.2 g, 84%) as colorless needles, m.p. 165° (from ethanol).

Anal. Calcd. for $C_{19}H_9Br_2Cl_5N_2O$: C, 36.86; H, 1.46; N, 4.53. Found: C, 37.1; H, 1.7; N, 4.7.

Hydrazonyl Aryl Ethers from **1**, *b–h*

Compound **1***b* (10) (4.64 g), *p*-nitrophenol (1.39 g), EtOH (25 ml), and NEt_3 (2 ml) gave **6***b* (4.73 g, 90%) as yellow needles, m.p. 143–144° (from ethanol – ethyl acetate).

Anal. Calcd. for $C_{20}H_{15}Br_2N_3O_4$; C, 46.06; H, 2.88; N, 8.06. Found: C, 45.99; H, 2.88; N. 8.03.

Compound **1***c* (1) (4.67 g), *p*-nitrophenol (1.39 g), EtOH (30 ml), and NEt_3 (2ml) gave **6***c* (4.4 g, 84%) as yellow needles, m.p. 151° (from *t*-amyl alcohol – benzene).

Anal. Calcd. for $C_{19}H_{12}Br_2ClN_3O_3$: C, 43.39; H, 2.28; N, 7.99. Found: C, 43.8; H, 2.5; N. 7.9.

Compound **1***d* (1) (2.13 g), *p*-nitrophenol (0.69 g), EtOH (20 ml), and NEt_3 (0.5 ml) gave **6***d* (1.49 g, 62%) as needles, m.p. 145° (from ethanol).

Anal. Calcd. for $C_{22}H_{18}BrN_3O_5$: C, 54.55; H, 3.72; Br, 16.53; N, 8.68. Found: C, 54.5; H, 3.7; Br. 16.7; N, 8.7.

Compound **1***e* (6) (3.72 g), *p*-nitrophenol (1.39 g), MeCN (30 ml), and NEt_3 (1ml) gave **6***e* (3.85 g. 90%) as yellow needles. m.p. 115° (from benzene–hexane).

Anal. Calcd. for $C_{19}H_{13}BrFN_3O_3$: C, 53.02; H, 3.02; N, 9.77. Found: C, 53.22; H, 3.14; N, 9.68.

Compound **1***f* (11) (3.99 g), *p*-nitrophenol (1.39 g), EtOH (30 ml), and NEt_3 (1 ml) gave **6***f* (3.8 g, 83%) as yellow plates, m.p. 192° (from toluene).

Anal. Calcd. for $C_{19}H_{13}BrN_4O_5$: C, 49.89; H, 2.84; Br, 17.51; N, 12.25. Found: C, 50.0; H, 3.0; Br, 17.3; N, 12.4.

Compound **1***g* (8) (2.3 g), *p*-nitrophenol (1.39 g), EtOH (60 ml), and NEt_3 (2 ml) gave, after 3 h, **6***g* (1.2 g, 36%) as yellow needles, m.p. 138–139° (from ethanol) (lit. (4*c*) m.p. 134°).

Anal. Calcd. for $C_{19}H_{15}N_3O_3$: C, 68.47; H, 4.50; N, 12.61. Found: C, 68.68; H, 4.59; N, 12.43.

Similarly, **1***g* (2.3 g), *o*-nitrophenol (1.39 g), EtOH (60 ml), and NEt_3 (2 ml) gave, after 3 h, **8***g* (1.5 g, 45%) as yellow needles, m.p. 122–123° (from ethanol).

Anal. Found: C, 68.12; H, 4.44; N, 12.65.

Compound **1***h* (1.4 g), *p*-nitrophenol (0.75 g), EtOH (25 ml) and NEt_3 (1 ml), stirred overnight, gave **6***h* (0.5 g, 25%) as pale orange needles, m.p. 182–183° (from ethanol).

Anal. Calcd. for $C_{21}H_{17}N_3O_3$: C, 70.19; H, 4.74; N, 11.70. Found: C, 70.06; H, 4.85; N, 11.52.

N-Aroyl-N′,N′-diarylhydrazines by Smiles Rearrangement of Hydrazonyl Aryl Ethers

As general procedure, the hydrazonyl aryl ether in 1:1 EtOH–NEt_3 mixture was boiled under reflux for 15 min. In some cases, the product separated on cooling; otherwise solvents were removed *in vacuo* and the product was crystallized.

Compound **6***a* (0.5 g, 0.001 mol) in EtOH (5 ml) and NEt_3 (5 ml) gave *N-benzoyl-N′-(2,4-dibromophenyl)-N′-p-nitrophenylhydrazine* (7*a*) (0.34 g, 68%) as prisms, m.p. 215–216° (from benzene); i.r. (KBr) 1645 cm^{-1} (C=O); n.m.r. (DMSO-d_6) δ 11.4 (s, NH), 8.0 (A) and 6.65 (B) (A_2B_2q, J = 9Hz), and 7.9–7.3 (m, 8H); mass spectrum *m/e* 493/491/489 (M^+), 477/475/473, 463/461/459, 412/410, 411/409, 395/393, 388/386/384 (M^+ – PhCO), 374/372/370 (M^+ – PhCON), 372/370/368 (M^+ – $PhCONH_2$), 344/342/340, 342/340/338, 309/307, 263/261/259, 246/244, 199, 166, 121, 106, 105, 104, 103 and 77.

Anal. Calcd. for $C_{19}H_{13}Br_2N_3O_3$: C, 46.44; H, 2.65; Br, 32.59; N, 8.55. Found: C, 46.3; H, 2.6; N, 8.4.

Similarly, **8***a* (0.5 g) in EtOH (5 ml) and NEt_3 (5 ml) gave **9***a* (0.32 g, 64%) as yellow needles, m.p. 200–201° (from benzene–hexane).

Anal. Found: C, 46.4; H, 2.9; Br, 32.8; N, 8.8.

The isomeric hydrazonyl *m*-nitrophenyl ether did not rearrange under these conditions, even after 2 h, nor when boiled under reflux in 2,6-lutidine for 1 h. Under more vigorous conditions (DMF–NEt_3) decomposition ensued.

Compound **6***b* (3 g) in EtOH (15 ml) and NEt_3 (15 ml) gave **7***b* (2.5 g, 83%) as cream needles, m.p. 235° (from ethanol – ethyl acetate).

Anal. Calcd. for $C_{20}H_{15}Br_2N_3O_4$: C, 46.07; H, 2.88; Br, 30.71. Found: C, 46.04; H, 3.01; Br, 30.89.

Compound **6***c* (0.5 g) in EtOH (5 ml) and NEt_3 (5 ml) gave **7***c* (0.32 g, 64%) as cream needles, m.p. 235° (from reaction mixture).

Anal. Calcd. for $C_{19}H_{12}Br_2ClN_3O_3$: C, 43.39; H, 2.28; N, 7.99. Found: C, 43.4; H, 2.4; N, 8.0.

Compound **6***d* (0.5 g) in EtOH (5 ml) and NEt_3 (5 ml) gave, after 2 h, **7***d* (0.31 g, 62%) as pale yellow prisms, m.p. 119° (from benzene–hexane).

Anal. Calcd. for $C_{22}H_{18}BrN_3O_5$: C, 54.55; H, 3.72; Br, 16.53; N, 8.68. Found: C, 54.7; H, 3.9; Br. 16.5; N, 8.6.

Compound **6***e* (2.15 g) in MeCN (15 ml) and NEt_3 (15 ml) gave **7***e* (1.9 g, 88%) as needles, m.p. 214–216° (from benzene).

Anal. Calcd. for $C_{19}H_{13}BrFN_3O_3$: C, 53.02; H, 3.02. Found: C, 53.15; H, 3.10.

Compound **6***f* (0.5 g) in EtOH (5ml) and NEt_3 (5 ml) gave, after 2 h. **7***f* (0.41 g, 82%) as yellow prisms, m.p. 286° (trituration with boiling hexane–toluene).

Anal. Calcd. for $C_{19}H_{13}BrN_4O_5$: C, 49.89; H, 2.84; Br, 17.51; N, 12.25. Found: C, 50.2; H, 2.8; Br, 17.7; N, 12.35.

Compound **6***g* (0.5 g) in EtOH (10 ml) and NEt_3 (5 ml) gave, after 1 h, **7***g* (0.3g, 60%) as cream needles, m.p. 173–174° (from benzene) (lit. (4*c*) m.p. 178–180°).

Anal. Calcd. for $C_{19}H_{15}N_3O_3$: C, 68.47; H, 4.50; N, 12.61. Found: C, 68.85; H, 4.45; N, 12.61.

Similarly, **8***g* (0.5 g) in EtOH (10 ml) and NEt_3 (5 ml) gave, after 1 h, **9***g* (0.3 g, 60%) as yellow needles, m.p. 171–172° (from benzene).

Anal. Found: C, 68.24; H, 4.38; N, 12.60.

Compound **6***h* (0.3 g) in EtOH (15 ml) and NEt_3 (5 ml) gave, after 2 h. **7***h* (0.17 g, 57%) as yellow needles, m.p. 155–156° (from benzene, then from ethanol).

Anal. Calcd. for $C_{21}H_{17}N_3O_3$; C, 70.19; H, 4.74; N, 11.70. Found: C, 70.38; H, 4.89; N, 11.79.

Compound **10** (0.5 g) in EtOH (5 ml) and NEt_3 (5 ml) gave, after 1 h, **11** (0.4 g, 80%) as needles, m.p. 248–249° (from hexane).

Anal. Calcd. for $C_{19}H_9Br_2Cl_5N_2O$ (mol. wt. 618.5): C, 36.86; H, 1.46; N, 4.53. Found (620, vapor pressure, acetone): C, 39.2; H, 1.9; N, 4.5.

Rearrangement of 6g and 8a in Admixture

T.l.c. (silica gel, $CHCl_3$) of reference mixtures of **7***g* (R_f 0.33), **7***a* (R_f 0.39), **9***g* (R_f 0.51), and **9***a* (R_f 0.60) showed that **7***a* and **9***g* were each detectable in mixtures containing **7***g* (49.5% w/w), **7***a* (0.5%), **9***g* (0.5%), and **9***a* (49.5%).

A mixture of **6***g* (0.3 g) and **8***a* (0.3 g) in EtOH (15 ml) and NEt_3 (5 ml) was boiled under reflux for 1 h and the mixture of rearranged products was isolated by evaporation of solvents *in vacuo*. T.l.c. showed that **7***g* and **9***a*, but not **7***a* and **9***g*, were present. The mixture was chromatographed to yield **9***a* and **7***g*; these compounds were identified after crystallization by correlation (i.r., t.l.c., mixture m.p.) with reference samples. The eluates collected between **9***a* and **7***g* were evaporated and examined by t.l.c.; there was no indication of the presence of **7***a* or **9***g*.

Attempted Debenzoylation of 9a

Attempts to debenzoylate **9***a* by hydrolysis (24 h

For personal use only.

reflux with 1:1 ethanol – concentrated HCl) or by ethanolysis (12 h reflux with 5–6% ethanolic sodium ethoxide) were unsuccessful; **9***a* was recovered.

Preparation of Substituted 4H-1,3,4-Benzoxadiazines from N-Aroyl-N′,N′-diarylhydrazines

As general procedure, equivalent amounts of the *N*-aroyl-*N*′,*N*′-diarylhydrazine and sodium hydroxide were dissolved in a mixture of dimethylformamide (DMF) and NEt_3 and boiled under reflux for 6 h. The solution was cooled, poured into excess 5% acetic acid, and the solid was collected, washed with water, and dried. Except where directly crystallized, the crude products were chromatographed on Florisil (toluene as eluant) and the fraction containing the fluorescent product was collected.

Compound **7***a* (4.91 g, 0.01 mol), sodium hydroxide (0.4 g, 0.01 mol), DMF (25 ml), and NEt_3 (5 ml) yielded *7-bromo-4-p-nitrophenyl-2-phenyl-4H-1,3,4-benzoxadiazine* (**13***a*) (1.2 g, 29%) as yellow-orange needles, m.p. 221–222° (from benzene). The yield was improved in a subsequent experiment (79%, 10 h).

Anal. Calcd. for $C_{19}H_{12}BrN_3O_3$: C, 55.61; H, 2.93; N, 10.24. Found: C, 54.97; H, 2.90; N, 10.09.

Compound **7***e* (2.15 g), sodium hydroxide (0.2 g), DMF (25 ml), and NEt_3 (5 ml) also gave **13***a* (2.0 g, 97%) as needles, m.p. 221–222° (direct crystallization from benzene); mixture m.p. (with above sample) 221–222°.

Compound **7***b* (1.3 g), sodium hydroxide (0.1 g), DMF (15 ml) and NEt_3 (5 ml) gave **13***b* (0.8 g, 73%) as orange needles, m.p. 179–180° (from ethanol – ethyl acetate).

Anal. Calcd. for $C_{20}H_{14}BrN_3O_4$: C, 54.55; H, 3.18; Br, 18.18. Found: C, 54.26; H, 3.35; Br, 18.48.

Compound **7***c* (2.6 g), sodium hydroxide (0.2 g), DMF (25 ml), and NEt_3 (5 ml) gave **13***c* (0.8 g, 36%) as yellow needles, m.p. 267–268° (from benzene).

Anal. Calcd. for $C_{19}H_{11}BrClN_3O_3$: C, 51.29; H, 2.47; N, 9.45. Found: C, 51.29; H, 2.54; N, 9.80.

Compound **7***d* (1.21 g), sodium hydroxide (0.1 g), DMF (15 ml), and NEt_3 (2 ml) gave **13***d* (0.26 g, 25%) as yellow-orange prisms, m.p. 217° (from toluene).

Anal. Calcd. for $C_{22}H_{17}N_3O_5$: C, 65.51; H, 4.22; N, 10.42. Found: C, 65.66; H, 4.14; N, 10.31.

Compound **7***f* (4.57 g), sodium hydroxide (0.4 g), DMF (25 ml), and NEt_3 (5 ml) gave **13***f* (2.3 g, 62%) as red prisms, m.p. 288° (direct crystallization from DMF).

Anal. Calcd. for $C_{19}H_{12}N_4O_5$: C, 60.64; H, 3.19; N, 14.89. Found: C, 60.56; H, 3.31; N, 14.73.

Compound **9***a* (4.91 g), sodium hydroxide (0.4 g), DMF (25 ml), and NEt_3 (5 ml) gave **14** (1.1 g, 27%) as red needles, m.p. 163° (from benzene–hexane).

Anal. Calcd. for $C_{19}H_{12}BrN_3O_3$: C, 55.61; H, 2.93; Br, 19.51. Found: C, 55.49; H, 2.84; Br, 19.58.

Compound **11** (3.09 g), sodium hydroxide (0.2 g), DMF (15 ml), and NEt_3 (5 ml) gave **15** (1.8 g, 62%) as yellow needles, m.p. 215–216° (from benzene–hexane).

Anal. Calcd. for $C_{19}H_8Br_2Cl_4N_2O$ (mol. wt. 582): C, 39.16; H, 1.37; N, 4.81. Found (577, vapour pressure, benzene): C, 39.45; H, 1.45; N, 4.82.

Alternative Syntheses of 13a and 14 from 5a (1)

Compound **5***a* (1) (0.3 g), *p*-fluoronitrobenzene (0.14 g), NEt_3 (5 ml), and MeCN (15 ml) were boiled together under reflux for 4 h. Solvents were removed *in vacuo* and the residue was washed with water and dried. Crystallization from benzene gave **13***a* (0.24 g, 60%), m.p. and mixture m.p. 221–222°.

An analogous experiment in which *o*-fluoronitrobenzene (0.14 g) replaced the *p*-isomer gave, after crystallization from hexane–toluene, **14** (0.20 g, 50%), m.p. and mixture m.p. 162–163°.

Detection of Reversible Reactions in Solution Using Group Enthalpies of Transfer. Formation of Benzaldehyde Hemiacetals in Methanol[1]

RICHARD FUCHS, THOMAS M. YOUNG, AND RANDOLPH F. RODEWALD
Department of Chemistry, University of Houston, Houston, Texas 77004

Received July 23, 1973

The enthalpies of transfer from methanol to dimethylformamide for a wide variety of aromatic compounds are additive properties of the groups present within the molecules. Values of $\Delta\Delta H_s$ fail to be additive for benzaldehydes by an amount of energy which increases with increasing electron withdrawing power of the substituent. Nuclear magnetic resonance studies indicate that this results from hemiacetal formation in methanol, which varies from nil for *p*-dimethylamino-, *p*-hydroxy-, and *p*-methoxybenzaldehyde to 71% for the *p*-nitro compound. The non-additivity of group $\Delta\Delta H_s$ values can indicate that specific interactions are occurring with a solvent, even though no stable product can be isolated.

Les enthalpies de transfert du méthanol à la diméthylformamide pour un grand nombre de composés aromatiques sont des propriétés additives des groupes présents dans les molécules. Les valeurs de $\Delta\Delta H_s$ ne sont pas additives pour les benzaldéhydes à cause d'une quantité d'énergie qui augmente lorsque le pouvoir d'attraction des électrons par le substituant augmente. Des études r.m.n. ont montré que cette relation dépend de la formation d'hemiacétal dans le méthanol, dont le pourcentage varie de zéro pour le *p*-diméthylamino-, le *p*-hydroxy- et le *p*-méthoxybenzaldéhyde à 71% pour le dérivé *p*-nitro. La non-additivité des valeurs de $\Delta\Delta H_s$ pour un groupe peut alors montrer qu'il existe des interactions spécifiques avec un solvant même si aucun produit stable ne peut être isolé. [Traduit par le journal]

Can. J. Chem., **51**, 4122 (1973)

Recently the enthalpies of solution (ΔH_s) of a large number of aromatic compounds were measured in methanol (MeOH) and in *N*,*N*-dimethylformamide (DMF) (1, 2). From the ΔH_s values enthalpies of transfer ($\Delta\Delta H_s$) (MeOH → DMF) were determined. The important observation was made that values of $\Delta\Delta H_s$ are additive functions of the substituent groups present, regardless of the relative positions of each group on the aromatic ring. Small deviations from additivity exceeding the experimental error occurred in cases such as *o*-nitroaniline and *o*-nitrophenol, where intramolecular hydrogen bonding is known to occur. Some of the group enthalpies of transfer determined (in kcal/g group wt.) are C_6H_5, −0.3; Cl, −0.1; NO_2, −0.8; $COCH_3$, −1.0; OH, −1.7; $N(CH_3)_2$, −0.5; OCH_3, −0.6; and CH_3, +0.03. The individual group $\Delta\Delta H_s$ values were discussed (2) in terms of the greater dipole moment, hydrogen bond acceptor ability, and solvent–solvent association forces of DMF (relative to MeOH), and the resulting more exothermic dipole–dipole, dipole – induced dipole, and hydrogen bonding interactions with polar, polarizable, and hydrogen bond donating groups, respectively. The group $\Delta\Delta H_s$ values show some correlation with the changes in ^{19}F chemical shifts caused by the same groups in *m*-substituted fluorobenzenes, when the compounds are transferred from a "normal" aprotic solvent to a "weakly protonic" solvent such as methanol (3). Comparisons (2) of the $\Delta\Delta H_s$ values for aromatic and aliphatic compounds with the limited number of $\Delta\Delta G$ values available (4) suggest that, as in the case of ions (5), free energies of transfer among solvents other than water are largely determined by the enthalpy contribution. Thus the enthalpy of transfer is a meaningful indication of the change in solvation that a molecule, group, or ion undergoes upon transfer from one solvent to another. The observation of additivity of group $\Delta\Delta H_s$ values in many molecules permits the calculation of $\Delta\Delta H_s$ for other molecules, provided that the appropriate group values are known.

Results and Discussion

The enthalpies of solution of a series of *m*- and *p*-substituted benzaldehydes in methanol and in *N*,*N*-dimethylformamide, and the resulting enthalpies of transfer [$\Delta\Delta H_s = \Delta H_s(\text{DMF}) - \Delta H_s(\text{MeOH})$] are listed in Table 1. In the final column are apparent $\Delta\Delta H_s$ values for the aldehyde group, based on the observed $\Delta\Delta H_s$ for the compound less the group enthalpies of transfer

§Solid compounds at 25°.

for the benzene ring and the substituent. Benzaldehyde has a dipole moment (2.78 D) only slightly less than that of acetophenone (2.96 D) (6). Since the exothermic enthalpy of transfer of the acetyl group (−1.0 kcal/g group wt.) has been attributed (2) mainly to the larger dipole–dipole interaction with DMF than with methanol, an aldehyde group $\Delta\Delta H_s$ of perhaps −0.7 to −1.0 might be anticipated. A value of −0.8 is, in fact, found (within experimental error) for the three benzaldehydes with strongly electron releasing substituents, *p*-$N(CH_3)_2$, *p*-OH, and *p*-OCH_3. Slightly less negative values are calculated for the *p*-CH_3 and unsubstituted members, and increasingly positive values are found as the electron withdrawing character of the substituents increases: *p*-Cl < *m*-Cl < *m*-NO_2 < *p*-NO_2. Rather similar values of ΔH_s(DMF) are observed for the liquid aldehydes, −0.25 to −0.08 kcal/mol, whereas the range is 1.53 to −0.92 in methanol, with the values becoming less endothermic with increasing electron withdrawal. A similar trend exists with the solid aldehydes, with the possible exception of the *p*-OH compound.

It therefore appears that enthalpies of solution of benzaldehydes possessing electron withdrawing substituents are more exothermic (or less endothermic) in methanol than might be expected. This thermal effect might be attributed to an exothermic reaction of the aldehydes occurring in methanol, such as uncatalyzed hemiacetal formation, and, possibly, to the greater solvation of the reaction product than of the reactants by methanol. We were surprised that the entire heat effect in the calorimetric measurements was released within 1–2 min, in view of the somewhat slower rates of hemiacetal formation reported for acetaldehyde (7).

The p.m.r. spectra of *p*-dimethylamino-, *p*-methoxy-, *m*-chloro-, and *p*-nitrobenzaldehyde in methanol and in dimethylformamide were examined. The first two aldehydes showed similar peaks in both solvents, including the aldehydic (formyl) proton about 9.9 p.p.m. downfield from TMS, but the second two had an additional singlet in methanol, absent in DMF, at 3.6 p.p.m. due to methoxy protons of the hemiacetal. The hemiacetal α-proton and presumably the hydroxyl proton are masked by the hydroxyl proton of neat methanol at 4.8 p.p.m. *p*-Nitrobenzaldehyde had peak areas in the formyl/methoxy proton ratio of 0.29/0.71 × 3, leading to the conclusion that 71% of the original aldehyde exists in methanol solution as the hemiacetal. This is confirmed by the formyl/aromatic proton ratio of 0.28/4, which indicates that over 70% of the aldehyde has been converted to another substance. The $(CH_3)_2N$— and CH_3O— compounds had formyl/substituent proton ratios of 1/5.9 and 1/2.9, respectively, indicating that no appreciable amount of aldehyde has been diverted in either case by reaction with methanol.

Using the reasonable assumption that the enthalpy of reaction for the formation of hemiacetal, and the difference in enthalpy of solvation of reactants and products are the same for all of the benzaldehydes, one may use the apparent —CHO

group enthalpies of transfer (Table 1, last column) to calculate the percentage of hemiacetal formed from the other benzaldehydes. The $\Delta\Delta H_s$ value for the aldehyde group (MeOH → DMF) is −0.8 kcal/g group wt. Apparent group $\Delta\Delta H_s$ values may differ from this in an amount directly dependent on the amount of hemiacetal formation. *p*-Nitrobenzaldehyde differs from this by 3.6 − (−0.8) = 4.4 kcal, due to a 71% conversion to hemiacetal. A 100% conversion would have led to a discrepancy of 4.4/0.71 = 6.2 kcal. From these considerations the following amounts of hemiacetal formation in methanol may be calculated: *m*-NO_2, 65%; *m*-Cl, 31.5%; *p*-Cl, 13%; H, 3.7%; and *p*-CH_3, 2.1%. Relative equilibrium constants may be calculated for the hemiacetal forming reactions, assuming a constant methanol concentration; $K = k$[hemiacetal]/[aldehyde]. From the equilibrium constants for the *p*-NO_2, *m*-NO_2, *m*-Cl, *p*-Cl, H, and *p*-CH_3 systems a satisfactory Hammett equation plot of log K *vs.* σ can be constructed. From the plot log K values for the *p*-OCH_3, *p*-OH, and *p*-$N(CH_3)_2$ systems can be estimated, and from these the percent of hemiacetal formation can be derived, even though the amount of hemiacetal formation (*p*-OCH_3, 1.1%; *p*-OH, 0.7%; *p*-$N(CH_3)_2$, 0.06%) is too small to affect, within experimental error, the enthalpies of solution of these aldehydes in methanol.

The average of two p.m.r. determinations of the formyl and hemiacetal peak areas for *m*-chlorobenzaldehyde indicates hemiacetal formation to the extent of 33%. Because the addition of methanol to aldehydes is an equilibrium, the reaction may proceed to a slightly greater extent in the dilute calorimetric solutions than in the relatively concentrated n.m.r. solutions.

The true enthalpy of transfer of *p*-nitrobenzaldehyde may be calculated from the following group values: —NO_2, −0.8; —C_6H_4—, −0.3; —CHO, −0.8 = −1.9 kcal/mol. The measured value of 3.6 kcal/mol corresponds with 71% formation of hemiacetal. The difference in the two values results from enthalpies of reaction, of desolvation of reacting aldehyde and methanol, and of solvation of hemiacetal. Group $\Delta\Delta H_s$ values are not available for the latter term, but it is believed that the enthalpies of desolvation of reactants and of solvation of the product approximately cancel, leaving the enthalpy of reaction as the principal contributing term.

Experimental

The calorimetric method used was that previously described (2, 8). Sample concentrations were in the range of 10^{-4} to 10^{-3} *M*. Liquid samples were introduced using a microliter syringe. The methanol and DMF were reagent grade materials which were dried with 3A and 4A molecular sieve, respectively. The aldehydes were commercial samples which were freshly purified via the bisulfite addition products, and recrystallized or distilled. Physical constants were in agreement with literature values.

N.m.r. spectra were obtained with a Varian T-60 spectrometer, using solutions which were about 5% aldehyde by weight, with tetramethylsilane added.

Conclusions

In a series of *m*- and *p*-substituted benzaldehydes the amount of hemiacetal formation increases with the electron withdrawing power of the substituent. This behavior was initially recognized by variations in the apparent enthalpy of transfer of the aldehyde group. Group $\Delta\Delta H_s$ values constitute a potentially general method for detecting reactions of solutes with solvents, even in systems such as the present one, where no isolable product is formed.

Influence of Lewis Acids on the Diels–Alder Reaction. V. The Reaction of Furan with Dimethyl Acetylenedicarboxylate[1,2]

A. W. McCulloch, D. G. Smith, and A. G. McInnes

Atlantic Regional Laboratory, National Research Council of Canada, Halifax, Nova Scotia

Received July 10, 1973

The Diels–Alder addition of furan to dimethyl acetylenedicarboxylate (DMAD) affords a monoadduct **1**. The position and steric course of further addition of furan to the latter are temperature dependent. At temperatures of 50° or below addition occurs mainly at the activated double bond to give *endo-endo* **4** and *endo-exo* **5** diadducts. At 100° addition occurs at the less substituted double bond of the monoadduct to give analogous *endo-endo* **7** and *endo-exo* **9** diadducts; further addition of furan to the latter at 100° affords four triadducts **12–15**. The configurations of all these products were determined by p.m.r. and assignments confirmed by simulation of the spectra.

$AlCl_3$ causes enormous rate enhancement of the Diels–Alder additions of furan to DMAD and to the activated double bond of the monoadduct. In the presence of the Lewis acid the predominant diadduct formed is the *endo-exo* isomer **5**.

L'addition du type Diels–Alder du furanne sur l'acétylènedicarboxylate de diméthyle (DMAD) conduit au produit de monoaddition **1**. La position et le mécanisme stérique d'additions supplémentaires du furanne sur le produit **1** dépendent de la température. A 50 °C ou en-dessous l'addition se produit principalement sur la double liaison activée pour donner des produits de double addition *endo-endo* **4** et *endo-exo* **5**. A 100 °C, l'addition se produit sur la double liaison la moins substituée du produit de monoaddition pour donner les produits de double addition analogues *endo-endo* **7** et *endo-exo* **9**; des additions supplémentaires du furanne sur ces derniers produits à 100 °C conduisent à quatre produits de triple addition **12–15**. Les configurations de tous ces produits ont été déterminées par r.m.n. et les attributions ont été confirmées par simulation des spectres.

Le $AlCl_3$ entraîne une augmentation enorme de la vitesse d'addition du type Diels–Alder du furanne sur le DMAD et sur la double liaison activée du produit de monoaddition. En présence de l'acide de Lewis, le produit majeur de double addition formé est l'isomère *endo-exo* **5**.

Introduction

In the course of our studies of $AlCl_3$ acceleration of the Diels–Alder reactions of heterocyclic dienes with acetylenic dienophiles (1–3) we have investigated the reaction of furan with dimethyl acetylenedicarboxylate (DMAD). This communication details the results of our studies on both the thermal and $AlCl_3$-promoted reactions of these addends.

The reaction of furan with DMAD involves initial formation of a monoadduct **1** which can then function as a dienophile. Further addition of furan can occur at the more substituted double bond of **1** to give a diadduct of type **2** or at the less substituted double bond to give a diadduct of type **3**. There are three possible configurations of **2**, namely *endo-endo* **4**, *endo-exo* (or *exo-endo*) **5**, and *exo-exo* **6**, and four possible configurations of **3**, namely *endo-endo* **7**, *exo-endo* **8**, *endo-exo* **9**, and *exo-exo* **10**.[3]

The temperature dependence of the thermal reaction of furan and DMAD was the subject of a recent paper by Slee and LeGoff (4). These workers found that at room temperature the major product (90%) was **5** with only 6% **4**, while at 100° the chief products were **7** (4.3%) and **9** (27.0%). They also isolated a triadduct of type **11** (3.7%) from the reaction at higher temperature, but did not establish its stereochemistry.

As has been pointed out by Martin and Hill in their review of the stereochemistry of the

[1]NRCC No. 13459.

[2]Presented in part at the 55th Canadian Chemical Conference of the Chemical Institute of Canada, Quebec City, Quebec, June, 1972.

[3]The system which we have adopted to define stereochemistry in **2** is that originally used by Stockman (17), in which the relationship of the ring-juncture substituents to the two bridged rings are denoted, reading from left to right. We have used this system also to define the stereochemistry of **3** (and the triadducts **11**), where the ring-juncture substituents are hydrogen atoms. In these cases the most heavily substituted ring is placed to the left.

Diels–Alder reaction, in practically all additions using norbornene type dienophiles the diene is subject to "steric approach control" by the dienophile. A considerable body of experimental evidence indicates that, with the exception of systems having a heavily substituted bridge, approach of the diene is preferred at the bridged face of the dienophile (5). If this rule is applicable to the Diels–Alder additions of furan to the oxanorbornadiene **1**, formation of diadducts **6**, **8**, and **10** will be highly improbable; the observed formation of **4**, **5**, **7**, and **9**, on the other hand, is consistent.

Compounds **1** (6–8) and **4** (6, 9, 10) are well authenticated; both have also been reported as products of the photochemical reaction of furan with DMAD (11).[4] Slee and LeGoff were the first to report the isolation of **5**, **7**, and **9** (4).

Results and Discussion

Thermal Reaction

We have investigated the initial phases of the thermal reaction at three temperatures (25, 50, and 100°). At each temperature the reaction was carried out in a sealed tube and was monitored by p.m.r. Typical results are given in Table 1. These serve to illustrate the features noted below.

(*a*) Initially the reactants are converted to **1** and little diadduct is formed.

(*b*) At room temperature further addition of a second molecule of furan to the more substituted double bond of **1** occurs to give diadducts **4** and **5**; isomer **5** is formed faster than **4**.[5]

(*c*) At 50° or in the initial stages of reaction at 100° equilibration occurs, resulting in a gradual buildup of isomer **4** relative to **5**.[6]

(*d*) The combination of furan and **1** to give **7** and **9** is slow, and significant amounts of these products are observed only at higher reaction temperatures (> 50°) and longer reaction times. Isomer **9** is formed faster than **7**. It was not possible to monitor the reaction for a subsequent buildup of **7** relative to **9**, since addition of a third molecule of furan to these compounds was competitive.

We have repeated the preparative scale reaction at 100° (18 h), carried out by Slee and LeGoff (4), and have also isolated **1** (4.5%), **4**

[4]It seems probable that these compounds are actually products of the thermal reaction, and the yields of **1** and **4** reported are consistent with this. Formation of these compounds by a photoaddition process would be contrary to the Woodward–Hoffman rules (12).

[5]Our results from a series of reactions at room temperature (Table 1) indicate that after 25 days approximately 50% diadduct was formed with a **5** to **4** ratio of 3:1. These findings conflict with those of Slee and LeGoff who report 90% formation of **5** after 5 weeks, with only 6% **4** (a ratio of 15:1!). However they observed crystallization of the product while our reactions remained homogeneous. This suggests that an equilibrium exists between **1**, **4**, and **5**, and that removal of **5** from solution by precipitation drives the equilibrium in solution towards further formation of this isomer.

[6]We have also monitored the retrogression of **5**. Under the conditions used (50° in C_6D_6) we observed approximately 80% retro reaction during the first 5 days; with increasing time we again observed slow formation of **4** and as expected an increasing **4**:**5** product ratio. Independent experiments showed that at 50° retrogression of **5** occurs at least 10 times faster than that of **4**.

*The yields, based on furan, were calculated by integration of the appropriate olefinic and/or bridgehead proton signals in the p.m.r. spectra. Reactions were carried out in sealed p.m.r. tubes.

(3.0%), **7** (15.4%), and **9** (26.6%). In addition we obtained as products not one, but *four* triadducts of type **11**, the stereochemistry of which we have established, on the basis of p.m.r. spectral evidence (see below) as *endo-endo-endo-endo* **12**, *endo-endo-endo-exo* **13**, *endo-exo-endo-endo* **14**, and *endo-exo-endo-exo* **15**. It is noteworthy that the latter four products must be formed by addition of furan to the less substituted double bond of the *endo-endo* **7** and *endo-exo* **9** diadducts. In accord with the principles controlling addition described by Martin and Hill (5) only these 4 out of a possible 16 triadducts of type **11** would be expected. Thus **12** (1.5%) and **13** (2.7%) arise through addition of furan to **7**, while **14** (4.2%) and **15** (6.1%) are formed by addition of furan to **9**. The relative yields of the four triadducts reflect both the predominance of **9** over **7** (**14** + **15** > **12** + **13**) and the preferred initial formation of an *endo-exo* ring juncture (**15** and **13**) over one that has *endo-endo* stereochemistry (**14** and **12**).

Although detailed kinetic studies would be a necessary prerequisite for understanding the mechanisms of the Diels–Alder associations discussed above and summarized in Scheme 1 it is still possible to draw some conclusions.

At the outset it should be emphasized that equilibration between **1**, **4**, and **5** has been demonstrated experimentally. Since it is known that adducts of furan generally undergo relatively facile retrogression, it seems likely that under the reaction conditions used diadducts **7** and **9** or any of the four triadducts could undergo retrogression–equilibration. However, since this has not been proved, use of the terms "kinetic" and "thermodynamic" is inappropriate to a discussion of the present products.

Addition of furan to **1** can in theory take place in eight ways. Figure 1 illustrates the transition states for these additions, analogous to those envisaged by Herndon and Hall for the dimerization of cyclopentadiene (13). We shall limit our discussion to the observed additions, that is, those satisfying the rule of steric control, leading to products **4**, **5**, **7**, and **9**. These four reactions are homocompetitive. The preferred initial formation of diadducts **4** and **5**, arising by addition at the more substituted double bond of **1**, is to be expected due to the presence of electron-attracting substituents in the dienophile (14).

As we have seen the formation of **9** is preferred to that of **7** (Table 1). There are no carbonyl substituents at the site of addition in the dienophile so that no secondary orbital overlap is possible. Similarly, production of **5** is preferred over that of **4** (Table 1). This parallelism suggests that the role of secondary attractive forces in the latter case is negligible. While this would be contrary to the ideas of Woodward and Hoffmann (12), it is in accord with the suggestion of Herndon and Hall who have proposed that such interactions between centres which are not bonded in the product may be relatively unimportant and that the stabilities of *endo* and *exo* transition states are governed predominantly by geometrical overlap of the π-orbitals at the primary centers where bond formation is in process (13).

The additions of furan to **1** (to give **9** and **7**), **7** (to give **12** and **13**), and **9** (to give **14** and **15**) are analogous to the Diels–Alder addition of furan to maleic anhydride which yields *endo* (kinetic) and *exo* (thermodynamic) adducts (15). The primary product formed in each case (**9**, **13**, and **15**) corresponds to the *endo* adduct; its formation obeys the Alder *endo* rule. However,

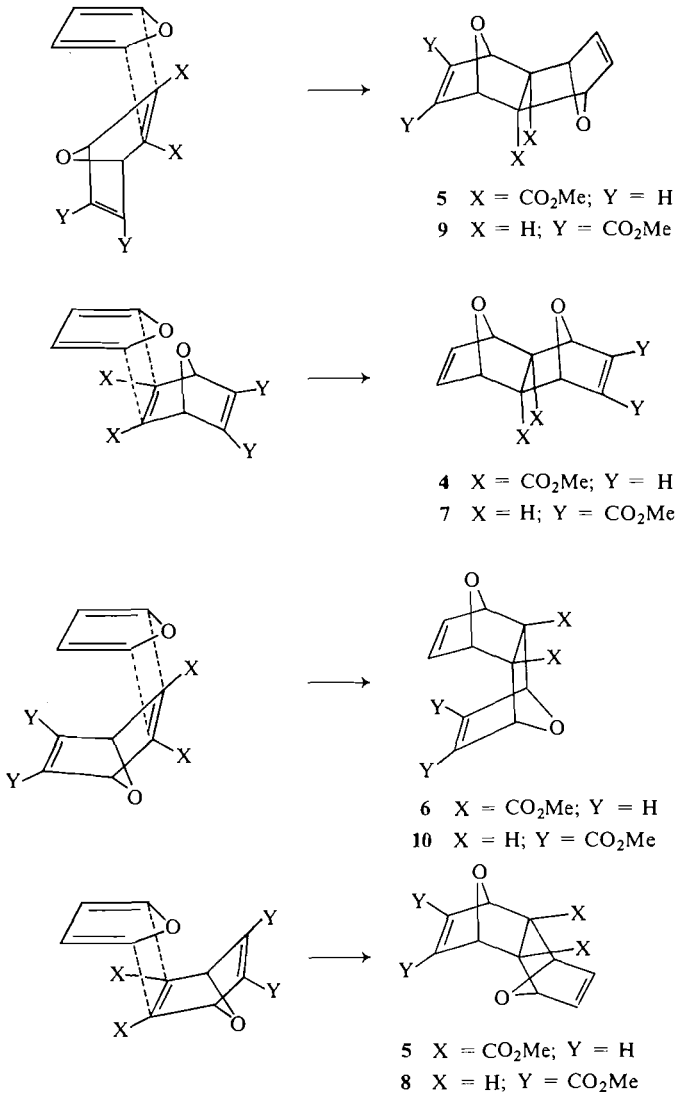

FIG. 1. Addition of furan to **1**.

addition to give **5** is contrary to the Alder *endo* rule,[7] which by definition requires maximum overlap involving the double bonds of activating substituents in the dienophile (14). The same conclusion was reached by Slee and LeGoff (4). In contrast, formation of diadduct **4** obeys the *endo* rule.

$AlCl_3$-promoted Reaction

Anhydrous $AlCl_3$ had a two-fold effect on the reaction of furan with DMAD at room temperature. In the first place it caused an enormous enhancement (approximately $\times 10^4$) in the rates of the Diels–Alder additions of furan to both DMAD and **1**, in common with our results on other Diels–Alder additions of furans to acetylenic esters (3). Secondly, the kinetically favored **5** was by far the major diadduct produced; only a trace of **4** could be detected and no addition occurred at the less substituted double bond of **1**. For example, a reaction mixture 0.4 *M* in furan and 0.2 *M* in DMAD and $AlCl_3$ (in CH_2Cl_2) showed at least 30% conversion of DMAD to

[7]Isomer **5** could in theory arise by an *endo* addition process (see Fig. 1), but this would involve invalidation of the rule of steric approach control (5).

adduct (**1** and **5**) in only 1 min at room temperature, the molar ratio of **1** to **5** being *ca.* 4:1. Negligible reaction occurred at the same concentration level in 30 min in the absence of the Lewis acid. After 1 h at room temperature the isolated yields (based on DMAD) of **1** and **5** were 20 and 22%, respectively. As expected considerable diene polymerization occurred. The monoadduct acid **16** was obtained as a by-product (6.6%), presumably arising by work-up hydrolysis of **1**.

It was established independently that neither **4** nor **5** dissociate appreciably (> 10%) to **1** and furan in the presence of an equimolar amount (0.2 *M* in CH_2Cl_2) of $AlCl_3$ for 1 h at room temperature. Consequently **5** is isolated in the $AlCl_3$-promoted reaction as the predominant diadduct since this kinetically-controlled product forms a reasonably stable complex with the Lewis acid, thus inhibiting retrogression and subsequent equilibration. This behavior is similar to that which we have observed previously with monoadducts of pyrroles and other furans with DMAD which also form complexes with $AlCl_3$ (1, 2).

Previous work in this laboratory and by other workers (16) indicates that in $AlCl_3$-promoted Diels–Alder reactions the role of the Lewis acid is to lower the enthalpy of activation. Consequently, the fact that the reaction of the addends in the presence of $AlCl_3$ produces predominantly **5** would seem to imply that the activation energy for the formation of the latter is lowered to a greater extent than in the case of **4**.

Proton Magnetic Resonance Spectra

No systematic analysis of the p.m.r. spectra of **1**, **4**, **5**, **7**, and **9** has been carried out. We have therefore analyzed the 60 MHz spectra of these compounds, and also of the acid **16** and the four triadducts **12**–**15**. The parameters were checked by means of simulation of the spectra using a Varian Spectrosystem 100. In all cases the experimental and simulated spectra were superposable within experimental error. The relevant parameters are detailed in Tables 2–4.

Monoadducts 1 and 16 (Table 2)

The olefinic and bridgehead protons of **1** form an AXX′A′ system in which the signals appear as deceptively simple triplets (*cf.* ref. 11). Analysis necessitated observation of two outer low-intensity lines, symmetrically placed on each side of each "triplet", and was carried out in the same way as reported for the very similar spectrum for the four ring hydrogens of furan (18, 19). Values of $J_{5,6}$, $J_{1,4}$, and of $(J_{1,5} + J_{1,6})$ (the spacing between the apparent outer lines of each triplet) are obtainable directly from the spectrum.

The olefinic and bridgehead protons of the asymmetric compound **16** (in benzene-d_6) comprise an XABY system in which the X and Y parts appear as slightly broadened triplets. In this case it was possible to obtain independent values for $J_{1,6}$ (1.9 Hz) and $J_{1,5}$ (0.2 Hz) directly from the spectrum.

Diadducts 4 and 5 (Table 2)

The stereochemistry of **4** and **5** can be established from their spectra on the basis of symmetry arguments. Isomer **4** possesses C_{2v} symmetry and as a result its p.m.r. spectrum consists of two superposed equivalent AXX′A′ systems for the identical pairs of bridgehead and olefinic protons. In contrast, isomer **5** has only C_s symmetry and consequently the bridgehead and olefinic protons of one bridged ring are not equivalent to the corresponding protons of the other ring. The p.m.r. spectrum of **5** thus consists of two independent AXX′A′ systems. The AXX′A′ systems of **4** and **5** appear in each case, as in **1**, as pairs of deceptively simple triplets. The sub-spectra were analyzed in a manner similar to that of **1**.

Diadducts 7 and 9 (Table 3)

The differing ring-juncture stereochemistry of isomers **7** and **9** is readily established from the multiplicity of the signals in their spectra for the bridgehead (H_5H_8) and ring-juncture (H_9H_{10}) protons. In the case of **7** the *endo-endo* configuration requires that the dihedral angles between these protons be close to 90°, resulting in near absence of coupling (20–22).[8] In contrast, the *endo-exo* configuration of **9** requires a dihedral angle of approximately 45°, resulting in a significant $J_{5,10}$ (4.9 Hz). The four ring hydrogens ($H_5H_6H_7H_8$) of **7** give rise to an AXX′A′ system as before, with a pair of deceptively simple triplets. Analysis of this system was carried out in the same way as for **1**, **4**, and **5**.

In the case of **9** we observe a six-spin system

[8]Since the ring-juncture hydrogens in both **7** and **9** are *endo* to the ring carrying the ester groups, the signal for bridgehead hydrogens (H_1H_4) appears as a singlet in the spectrum of each isomer.

for $H_5H_6H_7H_8H_9$ and H_{10}. Absence of coupling between the olefinic (H_6H_7) and ring-juncture (H_9H_{10}) hydrogens, however, allows the deceptively simple triplet observed for the former (due to their coupling with the bridgehead hydrogens) to be analyzed as before. The bridgehead and ring-juncture hydrogens ($H_5H_{10}H_9H_8$) comprise essentially a separate AXX'A' subsystem with the signal for H_9H_{10} appearing as a deceptively simple quartet. Once again, observation of low-intensity wings symmetrically disposed about the centroid of the "quartet" allows analysis of the system. The separation between the apparent outer lines of the "quartet" is equal to $J_{5,10} + J_{5,9}$ ($J_{AX} + J_{AX'}$).

Triadducts 12–15 (Table 4)

The p.m.r. spectra of all four compounds clearly establish the general structure **11**, as each compound shows a signal for only *two* olefinic hydrogens.

The elucidation of the configurations of the four isomers was based essentially on the arguments outlined above in confirming the ring-juncture stereochemistry of **7** and **9**. The signal for the bridgehead hydrogens (H_1H_4) on the ring carrying the ester groups was observed in all cases as a singlet, confirming (as in the cases of **7** and **9**) that the neighboring ring had been added from the bridged face of the dienophile. In addition, a similar mode of addition of the second furan molecule results in virtual absence of coupling between H_9H_{10} and $H_{13}H_{14}$ in the triadducts. The signal for the olefinic hydrogens (H_6H_7) always appeared as a deceptively simple triplet, allowing partial analysis of the AXX'A' sub-spectrum for $H_5H_6H_7H_8$. The neighboring bridgehead hydrogens (H_5H_8) appeared either as a "triplet" (if the C_{13-14} ring juncture was *endo–endo*) or as a very broad multiplet (if the C_{13-14} ring juncture was *endo-exo*, involving additional coupling of $H_5H_8$with H_{13} and H_{14}). In the latter case $H_{13}H_{14}$ appeared as a deceptively simple "quartet" (*cf.* H_9H_{10} in **9**). The remaining ring-juncture relationships were readily deduced on the basis of the multiplicity ("quartet" or singlet) of the signals for the ring-juncture ($H_{11}H_{12}$) and bridgehead (H_9H_{10}) hydrogens.

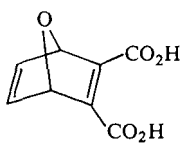
The spectrum of compound **14** can be interpreted on the basis of either *endo-exo-endo-endo* or *endo-endo-exo-endo* stereochemistry. However, although the latter could arise via the *endo-endo* diadduct **7**, its formation would be contrary to the principle of steric approach control which governs these additions. Hence, this triadduct is concluded to be the expected *endo-exo-endo-endo* isomer.

Infrared and Mass Spectra

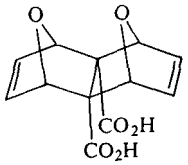
Diadducts **4**, **5**, **7**, and **9**, and all four triadducts show in their i.r. spectra *two* strong absorptions (1716–1720 and 1737–1745 cm^{-1}) in the carbonyl region (see Experimental). This may be attributed to steric interaction between the two ester groups. This effect can be observed on the i.r. time scale, whereas averaging prevents observation of separate methoxyl resonances by p.m.r. There are only very slight differences in the spectra of isomers; for example, the absorptions of **12–15** at 1600–1750 cm^{-1} are essentially identical. A medium-intensity C=C stretching vibration absorption (1635–1639 cm^{-1}) is observed in the spectra of all compounds carrying carbomethoxyl substituents on a double bond. The base peak in the mass spectra of all the adducts was observed at *m/e* 68 ($C_4H_4O^+$), reflecting the tendency of these molecules to undergo retrogression with loss of furan.

Reaction of Furan with Acetylenedicarboxylic Acid

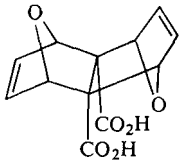
In view of our results it seemed pertinent to reexamine the corresponding reaction of furan and acetylenedicarboxylic acid. A diadduct was first isolated by Diels and Alder (10), but it was not until recently that Kallos and Deslongchamps (9) on chemical grounds established that it was the *endo-endo* isomer **18** and not the alternative *endo-exo* **19** as reported by Stockmann (17). However, in both of the latter studies the only material examined was that which crystallized from the ethereal reaction solution. No attempt was made to determine whether **18** was the product of kinetic or thermodynamic control, or for that matter to establish whether it was in fact the only diadduct formed. We repeated the reaction and confirmed that the material which crystallized from solution was **18** by converting it to **4** with diazomethane. Reaction solutions (solvent ether, furan 8 *M*, acetylenedicarboxylic acid 4 *M*) were then monitored by p.m.r. (temperature 36°). Characteristic signals were obtained for **17** ("triplets" at average δ 7.10 and 5.73), **18** ("triplets" at average δ 6.62 and 5.18), *and* **19** ("triplets" at average δ 6.68, 6.40, 5.06, and 4.60). After 1 h (≪10% addends reacted) the



17



18



19

molar ratio of **19** to **18** was approximately 2:1, whereas at the end of 24 h (*ca.* 20% addends reacted) this ratio had changed to 1:4 and **18** had started to crystallize from solution, thus driving the equilibrium in solution towards its further formation.

Experimental

The p.m.r. spectra were obtained on a Varian A-60A spectrometer equipped with a V-6058 spin decoupler, using $CDCl_3$ as solvent (unless stated otherwise) and tetramethylsilane as internal standard. Spectral simulations were carried out using a Varian Spectrosystem 100. The i.r. spectra were recorded on a Perkin-Elmer 521 spectrometer and the mass spectra on a Dupont-CEC 21-491 spectrometer.

Reaction of Furan and DMAD

Monitoring of Reactions

Forward Reaction. Mixtures of furan (272 mg, 0.004 *M*) and DMAD (284 mg, 0.002 *M*) were sealed in p.m.r. tubes which were then immersed in constant temperature baths maintained at 25, 50, or 100°. The reactions were monitored by p.m.r. and the yields of products (based on furan) calculated from the integrated intensities of the signals for the ring hydrogens of the unreacted furan and the olefinic and bridgehead hydrogens of the products. The results are summarized in Table 1.

Retrogression of diadduct 5. A saturated solution of **5** in benzene-d_6 was sealed in a p.m.r. tube which was then immersed in a constant temperature bath maintained at 50°. The reaction was monitored by p.m.r. and the product composition measured on the basis of integrated intensities as above. A retrogression of 80% was observed in 5 days.

Diadduct **4** underwent only 25% retrogression to furan and **1** in 3 h at 100° (toluene solution).

Reaction of Furan and DMAD at 100°

Furan (22.7 g, 0.334 *M*) and DMAD (14.2 g, 0.100 *M*) were placed in a 100 ml stainless steel vessel of a "Baskerville" high pressure autoclave. The reaction temperature was maintained at approximately 100° for 20 h. The product was a highly viscous orange syrup (35.5 g), totally soluble in $CHCl_3$. This was chromatographed on Mallinckrodt silicic acid (100–150 mesh). Elution with chloroform afforded:

(*a*) The monoadduct **1** as a yellow oil (0.95 g, 4.5%). ν_{max} ($CHCl_3$) 1733, 1640, 1600 cm^{-1}.

(*b*) *Endo-exo* diadduct **9** as a colorless solid (7.40 g, 26.6%). Recrystallization from EtOH gave colorless rosettes, m.p. 118–120° (lit. 120–122° (4)). Highest molecular ion at *m/e* 246 (7%); base peak at *m/e* 68; prominent ions at *m/e* 217 (5%), 153 (8%), 150 (33%), and 119 (17%). ν_{max} ($CHCl_3$) 1739, 1717, 1639 cm^{-1}.

(*c*) *Endo-endo* diadduct **4** eluted with diadducts **9** and **7**. Estimated yield (from p.m.r.) 3%.

(*d*) *Endo-endo* diadduct **7** as a colorless solid (4.29 g, 15.4%). Recrystallization from EtOH gave colorless prisms, m.p. 158–160° (lit. 157–159° (4)). Highest molecular ion at *m/e* 246 (3%); base peak at *m/e* 68; prominent ions at *m/e* 217 (9%), 153 (26%), 150 (34%), and 119 (17%). ν_{max} ($CHCl_3$) 1737, 1716, 1637 cm^{-1}.

(*e*) *Endo-exo-endo-exo* triadduct **15** as a colorless solid (2.10 g, 6.1%).[9] Recrystallization from EtOH gave colorless needles, m.p. 188–192° (dec.) but dependent on rate of heating (lit. 213–215° (4)). Highest molecular ion at *m/e* 246 (3%); base peak at *m/e* 68; prominent ions at *m/e* 217 (8%), 153 (20%), 150 (33%), 119 (10%), and 94 (12%). ν_{max} ($CHCl_3$) 1740, 1718, 1639, 1603 cm^{-1}.

Elution was now continued with 2% MeOH–$CHCl_3$. Separation of the triadduct fractions so obtained was carried out by repeated preparative t.l.c. on silicic acid (2% MeOH–$CHCl_3$ as eluant). This afforded, in order of their elution:

(*a*) *Endo-endo-endo-exo* triadduct **13** as a colorless solid (0.94 g, 2.7%). Recrystallization from EtOH gave colorless prisms, m.p. 182–186° (dec.), dependent on rate of heating. Highest molecular ion at *m/e* 346 (1%); base peak at *m/e* 68; prominent ions at *m/e* 278 (7%), 249 (3%), 246 (6%), 217 (9%), 153 (27%), 150 (29%), 119 (7%), 95 (30%), and 94 (12%). ν_{max} ($CHCl_3$) 1739, 1719, 1636, 1602 cm^{-1}.

(*b*) *Endo-exo-endo-endo* triadduct **14** as a colorless solid (1.44 g, 4.2%). Recrystallization from EtOH gave colorless flakes, m.p. 227–229° (dec.). Highest molecular ion at *m/e* 246 (4%); base peak at *m/e* 68; prominent ions at *m/e* 217 (8%), 185 (5%), 153 (12%), 150 (46%), 119 (9%), and 94 (9%). ν_{max} ($CHCl_3$) 1740, 1718, 1639, 1602 cm^{-1}.

(*c*) *Endo-endo-endo-endo* triadduct **12** as a colorless solid (0.52 g, 1.5%). Recrystallization from EtOH gave colorless needles, m.p. 267–269° (dec.). Highest molecular ion at *m/e* 346 (2%); base peak at *m/e* 68; prominent ions at *m/e* 278 (1%), 249 (4%), 246 (6%), 218 (38%), 217 (10%), 185 (5%), 153 (28%), 150 (28%), 119 (6%), and 94 (15%). ν_{max} ($CHCl_3$) 1739, 1718, 1635, 1602 cm^{-1}.

Reaction of Furan and DMAD in the Presence of $AlCl_3$

A solution of DMAD (5.68 g, 0.04 *M*) in CH_2Cl_2 (50 ml) was added to a stirred suspension of anhydrous $AlCl_3$ (5.32 g, 0.04 *M*) in CH_2Cl_2 (100 ml) to give a yellow-green solution. To this was now added a solution of furan (5.44 g, 0.08 *M*) in CH_2Cl_2 (50 ml). During the initial stages of addition of the diene (external cooling by cold water bath) the temperature rose from 20 to 30° and a dark red gum was deposited. Stirring was continued for 1 h at room temperature. The dark red solution was

[9]This was the triadduct isolated, but not identified, by Slee and LeGoff (4).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

poured into and shaken vigorously with cold water. The aqueous phase was separated and extracted with CH_2Cl_2 and the combined CH_2Cl_2 solutions dried (Na_2SO_4) and evaporated to give a viscous dark red oil (9.51 g). The product was chromatographed over silicic acid using $CHCl_3$ as eluant. This afforded, in order of their elution from the column:

(*a*) Unreacted DMAD (681 mg, 12.0%), identified by p.m.r.

(*b*) Monoadduct **1** (1.70 g, 20.2%) as a yellow oil.

(*c*) Monoadduct acid **16** (0.52 g, 6.6%), after extraction of the impure solid fractions with hot petroleum ether (b.p. 60–80°). Recrystallization from petroleum ether gave colorless needles, m.p. 86–87°. Highest molecular ion at *m/e* 196 (16%); base peak at *m/e* 68; prominent ions at *m/e* 150 (11%), 139 (18%), 136 (18%), 119 (28%), and 44 (29%). ν_{max} ($CHCl_3$) 1730, 1683, 1627 cm^{-1}.

(*d*) *Endo-exo* diadduct **5** as a colorless solid (2.4 g, 21.6%). Recrystallization from EtOH gave colorless prisms, m.p. 114–115° (dec.) (lit. 120–122° (4)). ν_{max} ($CHCl_3$) 1745, 1725, 1604 cm^{-1}.

(*e*) *Endo-endo* diadduct **4** was indicated by p.m.r. Estimated yield (from p.m.r.) 1.5%.

Compound **4** was isolated from the products of a thermal reaction, by fractional crystallization from EtOH, as colorless plates, m.p. (dec.) 147–149° (lit. 154–156° (9), 148° (10)); ν_{max} ($CHCl_3$) 1745, 1720, 1602 cm^{-1}.

We wish to thank Mrs. M. G. Flack and Mr. J. Van Ingen for valuable technical assistance. Thanks are also due to Mr. P. F. Seto for the i.r. spectra.

Structure of the Second Coordination Sphere of Transition Metal Complexes. IV. Solvent Effects

D. R. EATON AND K. L. CHUA

Department of Chemistry, McMaster University, Hamilton, Ontario

Received May 3, 1973

The participation of various solvents in the second coordination sphere of Co(II) pyrazolylborate has been investigated. Equilibrium constants relative to carbon tetrachloride as a second sphere ligand have been obtained. The ability of a solvent to participate in the second sphere depends predominantly on its dipole moment and it is concluded that Van der Waals forces are responsible for outer sphere binding.

La participation de différents solvants à la seconde sphère de coordination du pyrazolylborate de Co(II) a été étudiée. Les constantes d'équilibres relatives au tétrachlorure de carbone en tant que coordinat de la seconde sphère ont été obtenues. La possibilité pour un solvant d'intervenir dans la seconde sphère dépend essentiellement de son moment dipolaire et il a été conclu que les forces de Van der Waals sont responsables des liaisons extérieures à la sphère. [Traduit par le journal]

Can. J. Chem., **51**, 4137 (1973)

We have previously reported n.m.r. structural studies of the weak second sphere complexes formed between coordinately saturated Co(II) trispyrazolylborate compounds and other ligands present in solution (1, 2). These studies have also been extended to include the structures of ion pairs formed by analogous trispyrazolylmethane complexes (3). The motivation underlying this research is the belief that the efficiency of ligand exchange processes depends intimately on the ability of a metal complex to hold incoming ligands in a second coordination sphere where they are readily available for further reaction (4). The efficiency of a sequence of such ligand exchange reactions determines the overall efficiency of homogeneous catalysis. The Co(II) trispyrazolylborates comprise a particularly favorable substrate system for studies of this kind since the strongly bound tridentate ligands cannot be replaced by the monodentate ligands added which, if they are going to interact at all, can therefore only occupy positions in the second coordination sphere. Further, the large magnetic anisotropy of these Co(II) complexes give rise to dipolar shifts in the n.m.r. spectra of surrounding molecules and hence provides a probe to investigate the structure of such a second sphere. Previous studies have demonstrated that anions tend to prefer to occupy positions close to the three-fold axis of the chelate whereas neutral molecules such as aniline and pyridine are located perpendicular to this axis and have preferred orientations which may or may not be favorable for a subsequent ligand exchange reaction. It is apparent that the solvent plays a part in determining the detailed structure of the second sphere. Thus it was argued previously (3) that anions occupy positions on the symmetry axis because the more favorable positions perpendicular to the axis are preferentially taken by the dipolar solvent molecules. Similarly the observed n.m.r. shifts of neutral molecules depend strongly on the solvent used, indicating competition between added ligands and solvent molecules for the limited number of places in the second sphere. The present note reports some further studies with Co(II) trispyrazolylborates aimed at clarifying solvent effects.

The crux of the method used for studying second sphere structure lies in the equation (5)

$$\Delta\nu_0 = -\text{constant}\frac{(3\cos^2\theta - 1)}{r^3}(\chi_{\parallel} - \chi_{\perp})$$

which relates the dipolar n.m.r. shift of a magnetic nucleus to its position in space relative to the cobalt chelate. Unfortunately this equation (the detailed form of which has been discussed recently (6)) cannot be used directly since it is impossible to disentangle $\Delta\nu_0$ from the equilibrium constant K of a reaction

$$X + L \rightleftharpoons XL$$

which determines the fraction of the ligand L complexed to the chelate X. Only the product $K\Delta\nu_0$ is experimentally accessible (1). This

limitation determined the strategy of the present experiments. We wish to determine the relative tendencies of different solvents to occupy positions in the second sphere, *i.e.* the relative values of K for the above equilibrium. The direct approach would be to observe the dipolar shifts of the solvent molecules. Unfortunately not all solvents contain hydrogen or other nuclei suitable for n.m.r. experiments and even if they do the observed shifts will depend on both K and $\Delta\nu_0$ which will both vary from solvent to solvent. We have therefore adopted the procedure of measuring the extent to which a given solvent will displace a common ligand from the second coordination sphere.

Aniline was chosen as the common ligand and carbon tetrachloride as the common solvent. Previous results have shown that the aniline shifts are larger in carbon tetrachloride than in other solvents indicating that carbon tetrachloride has the least tendency to displace aniline from the second coordination sphere. Aliquots of solvent were therefore added to a standard solution of aniline plus Co(II) trispyrazolylborate in carbon tetrachloride and the n.m.r. shifts of the aniline protons measured as a function of the concentration of added solvent. Plots of data obtained in this way are shown in Fig. 1. These plots refer to the ortho proton of aniline. Other positions behave similarly but the shifts are somewhat smaller. In order to determine the isotropic shift due to the second sphere interaction, which is defined as the difference between free ligand frequency and complexed ligand frequency it is necessary to determine the aniline chemical shifts in the various mixtures used. The data shown in Fig. 1 were therefore corrected appropriately, using as calibration curves plots of the chemical shifts of aniline in carbon tetrachloride plus added solvent. Consider the equilibria

[1] $$XS + L \rightleftharpoons XL + S \qquad K_1$$

and

[2] $$XS + S' \rightleftharpoons XS' + S \qquad K_2$$

in which X represents the Co(II) complex, L is aniline, S is carbon tetrachloride, and S′ the added solvent. The observed n.m.r. shift is the weighted average of the shift for complexed and that for free aniline, *i.e.*

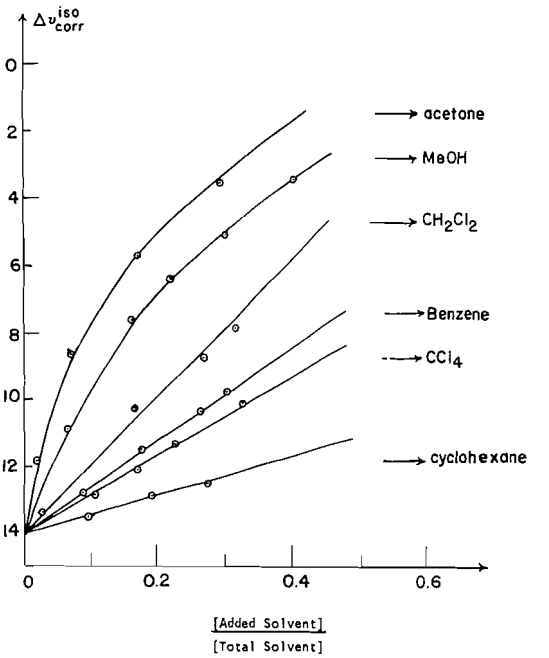

FIG. 1. Chemical shifts of the *ortho* protons of aniline in the presence of Co(II) pyrazolylborate and added solvents. Shifts in Hz at 100 MHz.

$$\Delta\nu = \frac{[XL]}{[XL] + [L]}\Delta\nu_0$$

where $\Delta\nu_0$ is the frequency of complexed aniline. Assuming the degrees of association of L and S′ in eqs. 1 and 2 are small it may be readily shown that

[3] $$\Delta\nu = \frac{K_1 x}{S + K_1 l}\Delta\nu_0$$

and

[4] $$\Delta\nu' = \frac{K_1 x}{S + K_1 l + K_2 S'}\Delta\nu_0$$

where $\Delta\nu$ is the aniline shift in the absence of a second solvent, $\Delta\nu'$ is the shift in the presence of the second solvent, x is the concentration of cobalt complex (assumed to be small), l is the concentration of aniline, S is the concentration of carbon tetrachloride, and S' that of the added solvent. Part of the difference between $\Delta\nu$ and $\Delta\nu'$ is due to the dilution of the solution on adding the second solvent. It is therefore appropriate to compare the shift produced by adding the second solvent ($\Delta\nu'$) with that produced by adding an equal amount of carbon tetrachloride

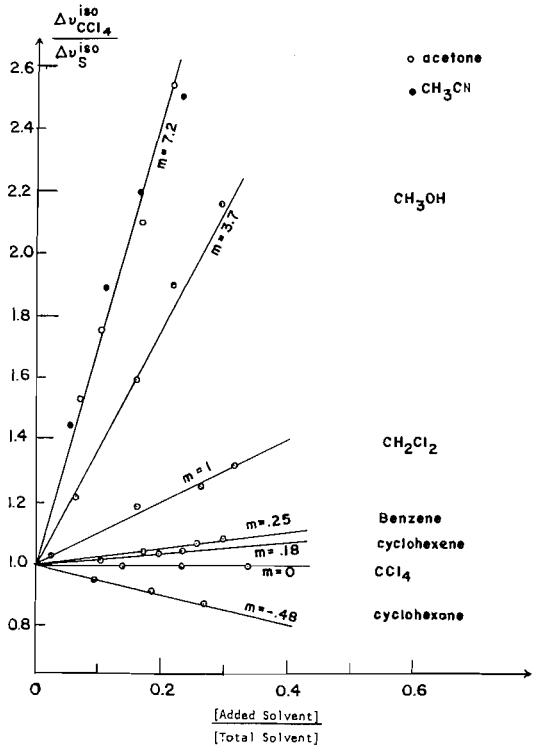

FIG. 2. Relative chemical shifts in carbon tetrachloride and different solvents. m is the slope of the line.

($\Delta\nu''$). Substitution in eq. 4 together with the approximation that $S \gg S'$, x, and l gives[1]

$$\frac{\Delta\nu''}{\Delta\nu'} = 1 + (K_2 - 1)\frac{S'}{S}$$

Plots of $\Delta\nu''/\Delta\nu'$ *vs.* the mole fraction of S' should therefore be linear with slopes equal to $(K_2 - 1)$. Such plots are shown in Fig. 2 for several solvents and the resulting values of (K_2) are collected in Table 1.

It is concluded from the data of Table 1 that the interactions responsible for binding in the second coordination sphere are essentially Van der Waals forces. The equilibrium constant clearly increases with the dipole moment of the ligand. Ligands for which hydrogen bonding with the nitrogen of the first sphere pyrazolyl ligands would be feasible do not appear to have anomalously high positions in the series. All of the non-polar molecules show a relatively small tendency to form second sphere complexes. Cyclohexane proves to be a somewhat worse second sphere ligand than carbon tetrachloride. The above conclusion is consistent with the values of 2–3 kcal previously obtained for the enthalpy of formation of the aniline second sphere complex (1). Perhaps the most significant point though is that the range of equilibrium constants obtained shows that there are very marked preferences for different molecules in the second coordination sphere, which must be reflected in the ease of substitution in the first sphere.

[1]A derivation of this expression for the relative chemical shifts is available at a nominal charge, from the Depository of Unpublished Data, National Science Library, National Research Council of Canada, Ottawa, Canada K1A 0S2.

Thermodynamic Properties of Cyclopentanol + *p*-Dioxane Mixtures at 25 °C[1]

S. C. ANAND,[2] J.-P. E. GROLIER,[3] OSAMU KIYOHARA,[4] and G. C. BENSON
Division of Chemistry, National Research Council of Canada, Ottawa, Canada K1A 0R6

Received July 19, 1973

Excess enthalpies, excess volumes, and total vapor pressures were measured for cyclopentanol + *p*-dioxane mixtures at 25 °C. The method of Barker was used to calculate vapor–liquid equilibria and excess Gibbs free energies from the vapor pressure results. A comparison with results (from the literature) for the systems cyclohexane + cyclopentanol and cyclohexane + *p*-dioxane indicates that the excess thermodynamic properties of cyclopentanol + *p*-dioxane mixtures arise primarily from the disruption of the structure of the *p*-dioxane solvent.

Les enthalpies d'excès, les volumes d'excès et les pressions de vapeur totales ont été mesurés à 25 °C pour des mélanges cyclopentanol + *p*-dioxane. La méthode de Barker a été utilisée pour calculer les équilibres liquide–vapeur et les énergies libres de Gibbs d'excès. Une comparaison de nos résultats avec ceux de la littérature, pour les mélanges cyclohexane + cyclopentanol et cyclohexane + *p*-dioxane, fait apparaître que les propriétés thermodynamiques d'excès des mélanges cyclopentanol + *p*-dioxane résultent principalement de la rupture de la structure du solvant *p*-dioxane, dans ces mélanges.

Can. J. Chem., 51, 4140 (1973)

Previous publications (1–4) from our laboratory have described the measurement of various thermodynamic properties for a number of binary systems formed by mixing cycloalkanols with other organic solvents. For the most part these have been nonpolar cycloalkanes, but some systems have involved the polar solvent acetone. From the point of view of thermodynamic behavior and theories of mixtures, the system cyclopentanol + *p*-dioxane is an interesting subject for study, since, although the dipole moment of *p*-dioxane is relatively small, the *p*-dioxane molecule has high local electric fields which lead to strong proton accepting character.

Experimental

Materials

Both of the components were purified in an F & M preparative gas chromatograph (Model 775). Care was taken to avoid exposure of the purified materials to moist air. Before the *p*-dioxane was used in the vapor–liquid equilibrium studies, it was vacuum distilled over anhydrous ferrous sulfate and stored under its own vapor in a dark flask to inhibit its decomposition to peroxide. The usual chemical methods (5) failed to show the presence of peroxide in freshly prepared samples. The vapor pressures of samples from separate preparations agreed within ±0.01 Torr; however after a period of 3 or 4 days the vapor pressure at 25 °C increased by about 0.1 Torr and remained constant for a number of days thereafter. Chemical analysis of these older samples revealed traces of peroxide, thus it appears that a slight conversion to peroxide occurred even in the absence of light. Only freshly prepared samples of *p*-dioxane were used for the vapor–liquid studies.

Physical properties of the purified components are compared with values from the literature (6–10) in Table 1. In most cases the agreement is good.

Apparatus and Techniques

A modified form of Van Ness dilution calorimeter (11) was used to determine the enthalpies of mixing. The error of the enthalpy results is estimated to be less than ±0.5% over most of the concentration range. Volumes of mixing were determined in a dilution dilatometer which has been described previously (12); the uncertainty in the value for an equimolar mixture is estimated to be less than ±0.002 $cm^3\ mol^{-1}$.

Equilibrium vapor pressures of mixtures of known total composition were determined by the static method in a cell similar to that used by Singh and Benson (13). The pressure at 25.000 ± 0.001 °C was measured to ±0.005 Torr with a quartz spiral gauge which was calibrated by comparison with a mercury manometer. The distribution of material between the vapor and liquid phases was computed by a modified form of Barker's analysis (1, 14). The empirical expression

$$[1] \qquad X^E = x_1(1 - x_1) \sum_{j=1}^{n} a_j(1 - 2x_1)^{j-1}$$

was used to represent the concentration dependence of the molar excess Gibbs free energy G^E at constant temperature. The values of the n coefficients a_j in eq. 1 were determined by an iterative calculation which minimized the sum of the squares of the deviations between calculated and observed values of the pressure. The analysis

was repeated with increasing values of n and the minimum number of coefficients needed to give an adequate representation of the results was determined. Since only total compositions were known directly, it was necessary at each iteration to calculate the mole fraction of cyclopentanol x_1 in the liquid by allowing for the material present in the vapor phase (1). The vapor pressure of *p*-dioxane is much larger than that of cyclopentanol, hence only the second virial coefficient for *p*-dioxane ($B_{22} = -1720$ cm^3 mol^{-1}, estimated from the correlation of O'Connell and Prausnitz (15)) was used in correcting for imperfection of the vapor phase. The validity of this approximation was confirmed by further calculations employing rough estimates of the virial coefficients B_{11} and B_{12}. These led to values of G^E which did not differ significantly from those reported in this paper.

Results

Vapor pressures of *p*-dioxane, measured at temperatures in the range 14–51 °C, are listed in Table 2. These values are represented by the Antoine form

$$[2]\quad \log_{10}(p/\text{Torr}) = 7.50915 - 1559.92/[236.88 + (t/°\text{C})]$$

with a standard error of estimate equal to 0.10 Torr. At 30 °C this equation leads to a pressure of 46.14 Torr, in excellent agreement with the lower of the two values observed most recently by Byer *et al.* (16). It has been reported that some of the physical properties of *p*-dioxane (viscosity (17), dielectric constant (18)) show an anomaly at about 26 °C in their temperature dependence curves, and this has been attributed to the existence of a boat form for *p*-dioxane at higher temperatures. A plot of $\log_{10} p$ against the reciprocal of the absolute temperature, for the present results shows no evidence of a change in slope around 26 °C.

The results of the vapor–liquid studies of cyclopentanol (1) + *p*-dioxane (2) mixtures are summarized in Table 3, where p is the observed pressure, x_1 and y_1 are the mole fractions of cyclopentanol in the liquid and vapor phases, and G^E is the molar excess Gibbs free energy of the liquid phase. The experimental values of the molar excess enthalpies H^E and of the molar excess volumes V^E are given in Tables 4 and 5.

$$[4] \qquad TS^E = H^E - G^E$$

is also shown in Fig. 1.

Discussion

Cyclopentanol + p-dioxane mixtures show positive deviations from Raoult's law. In Fig. 1, the curves for H^E, G^E, and TS^E are positive throughout the whole concentration range and are nearly symmetrical about $x_1 = 0.5$. The values of H^E are relatively large compared to those for mixtures of p-dioxane with other polar solvents. Negative excess enthalpies have been reported for p-dioxane + chloroform (19) and a sigmoid-shaped curve was found for p-dioxane + water (20). Negative excess enthalpies have also been reported for mixtures of p-dioxane with carbon tetrachloride (21) and benzene (22) but positive values were observed with cyclohexane (20, 23). The excess Gibbs free energy is negative for mixtures of p-dioxane with chloroform (19) and positive for mixtures with water (20), carbon tetrachloride (24), benzene (24), and cyclohexane (20). It appears from these findings that the tendency for p-dioxane to form a complex with other molecular species depends very much on the nature of the other species.

Chemical association theories have been fairly successful in explaining the thermodynamic behavior of mixtures of p-dioxane with chloroform (19), benzene (24), and carbon tetrachloride (24). In all of these systems there is a strong interaction between unlike species in the mixture and the excess entropy is negative; in some cases the existence of a stable compound has been confirmed by solid–liquid phase diagrams (25, 26). However, in view of the large positive values found for the excess entropy of the present system, it is very unlikely that a chemical association theory could be used to explain and correlate its thermodynamic properties.

It is instructive to compare the thermodynamic properties of cyclopentanol + p-dioxane mixtures with those of cyclohexane + cyclopentanol (3) and of cyclohexane + p-dioxane (20, 23, 24, 27, 28). Considering equimolar mixtures, the excess enthalpy of cyclopentanol + p-dioxane is of similar magnitude to the sum of the H^E values for the other two systems. The excess enthalpy of cyclohexane + cyclopentanol comprises contributions from dispersion forces and the disruption of hydrogen bonds; that for cyclohexane + p-dioxane comprises contributions from dispersion forces and the breakup of electrostatic interactions (mainly quadrupole) between p-dioxane molecules. Rather surprisingly the excess enthalpy of cyclohexane + p-dioxane is roughly twice as large as that for cyclohexane + cyclopentanol. Thus it may be inferred that the breakup of structure in p-dioxane makes a very important contribution to H^E when mixtures are formed with other solvents. The fact that the H^E and TS^E curves for cyclopentanol + p-dioxane are slightly skewed towards mixtures rich in cyclopentanol suggests that the positional and orientational disorder resulting from the breakup of the p-dioxane structure is somewhat greater than that resulting from the disruption of the hydrogen-bonded alcohol structure.

The excess volume of a mixture is also the resultant of a number of competing effects (29, 30). For the present system, the breakup of the structures of both cyclopentanol and p-dioxane will contribute positive terms to V^E; heterogeneous complex formation and the fitting of one solvent into the structure of the other will make negative contributions. The value of V^E for an equimolar cyclopentanol + p-dioxane mixture is roughly twice as large as that for cyclohexane + cyclopentanol but only about one half of the value for cyclohexane + p-dioxane. These results again point to the important role played by the breakup of the p-dioxane structure in

determining the excess thermodynamic properties of the present system. It appears that the contribution to V^E from this effect is more important than the contribution from the disruption of hydrogen bonds and that contributions from complex formation and interstitial solution are relatively of much less significance.

We are indebted to Mr. C. J. Halpin and Mr. P. J. D'Arcy for their capable assistance in all phases of the experimental work.

Oxidative Addition of 3,5-Dinitrobenzoyl Chloride to *trans*-Chlorocarbonylbis(dimethylphenylphosphine)iridium(I)

ALBERT RICHARD NORRIS AND JOHANNES ANTONIUS VAN KESSEL

Department of Chemistry, Queen's University, Kingston, Ontario

Received July 18, 1973

Trans-[IrClCO{$(CH_3)_2C_6H_5P$}$_2$] undergoes oxidative addition with 3,5-dinitrobenzoyl chloride in benzene, ether, and benzene–ether mixtures to yield two isomeric Ir(III) complexes containing the 3,5-dinitrobenzoyl group σ-bonded to the metal via the acyl carbon atom. The structures and properties of these two complexes are described.

Le composé [IrClCO{$(CH_3)_2C_6H_5P$}$_2$]-*trans*, subit une addition oxydative en présence du chlorure de dinitro-3,5 benzoyle dans le benzène, l'éther et des mélanges benzène–éther, pour conduire à deux complexes isomériques de Ir(III) contenant le groupe dinitro-3,5 benzoyle lié au métal par un lien σ via l'atome de carbone du groupe acyle. On décrit les structures et les propriétés de ces deux complexes.

Introduction

Many metals are known to form complexes containing σ-bonded alkyl and aryl groups (1), but relatively few complexes are known which contain a metal center σ-bonded either directly, or through one or more atoms, to an aromatic ring containing one or more nitro groups (2–9).

Metal complexes containing σ-bonded nitroaromatic compounds with nitro groups on the ring in 2,4-, 3,5-, and 2,4,6-positions are of particular interest to us in connection with studies of the reactions of bases and nitroaromatic compounds (10, 11). Of prime interest is the effect of the metal center (plus ligands) on both the modes of reaction (12) and the rates of reaction of the base and the nitroaromatic compound. In addition, valuable information on the characteristics of metal ligand bonds could, in principle, be obtained from proton magnetic resonance studies of such complexes since the chemical shifts of the hydrogens in the nitroaromatic compounds are very sensitive to the electron density in the ring (12, 13).

As an extension of earlier studies involving the oxidative addition of picryl chloride to Pt{$(C_6H_5)_3P$}$_3$ and Pt{$(C_6H_5)_3As$}$_3$ (5), we have investigated the oxidative addition reactions (14) of a number of 1-X-2,4-dinitro-, 1-X-3,5-dinitro-, and 1-X-2,4,6-trinitrobenzenes (X = Cl, CO_2H, SO_2Cl, COCl, CN, and $CONH_2$) with *trans*-$IrClCOL_2$ (L = $(C_6H_5)_3P$ and $(CH_3)_2C_6H_5P$). The preparation and properties of two isomeric Ir(III) complexes resulting from the oxidative addition of 3,5-dinitrobenzoyl chloride to *trans*-[IrClCO{$(CH_3)_2C_6H_5P$}$_2$] are reported here.

Experimental

Reagents

Eastman 3,5-dinitrobenzoyl chloride was purified by sublimation under vacuum at 40–50 °C. The melting point, determined in a sealed glass capillary on a Gallenkamp melting point apparatus, was 68.0–68.5 °C. Literature melting point, 69.5 °C (15).

Dimethylphenylphosphine (Maybridge Research Chemicals) was purified by vacuum distillation at 12.5 mm mercury and 70 °C. The compound was stored and handled under an atmosphere of dry nitrogen.

Chloroiridic acid ($H_2IrCl_6{\cdot}xH_2O$, Alfa Inorganics and Johnson, Matthey and Mallory Ltd.) was used without purification.

Thiophene-free benzene (Fisher Certified or "Baker Analyzed" Spectrophotometric Reagent) was refluxed over sodium wire, then distilled and stored under a dry nitrogen atmosphere. Fisher certified methanol and ethanol were purified by the Grignard method described by Vogel (16), then distilled and stored under dry nitrogen. All other solvents were A.R. grade or better and were usually stored over Linde 4A Molecular Sieve. For operations under nitrogen solvents were thoroughly degassed with dry nitrogen immediately prior to use.

All other reagents used were A.R. grade or better and were used without further purification.

Equipment

Ultraviolet–visible absorption spectra were recorded on Unicam SP 800 and Cary 14 spectrophotometers using matched optical glass cells of 1.0 cm pathlength. Spectra were recorded at approximately 25.0 °C. When a spectrum was required on a solution containing an oxygen- or water-sensitive compound, one of the cells was stoppered with a serum cap or a plug of silicone rubber and alternately evacuated and filled with dry nitrogen several times. Transfer of the solution, itself prepared in an atmosphere of dry nitrogen, was accomplished by means of a hypodermic syringe.

Infrared spectra were recorded on Beckman IR-10 and Perkin–Elmer 180 double beam grating spectrophotometers. Samples were run as Nujol or hexachlorobutadiene mulls or in solution using matched solution cells

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

equipped with either KBr or CaF_2 windows. A polystyrene film was used to calibrate the spectra recorded on the IR-10. All frequencies reported are believed to be accurate to $\pm 5\ cm^{-1}$.

Nuclear magnetic resonance spectra were recorded on a Bruker HX-60 spectrometer. The proton resonance absorbance of tetramethylsilane (TMS) was used as an internal lock and all proton chemical shifts are quoted relative to internal TMS. Phosphorus-31 peak positions were determined by an INDOR technique. Trimethylphosphite (−141 p.p.m. from 85% H_3PO_4) was used as a standard and all phosphorus-31 chemical shifts are quoted relative to 85% H_3PO_4. Concentrations of the solutions were of the order of 5–10% by weight. In those cases in which spectra were recorded on solutions containing oxygen- or water-sensitive compounds, an n.m.r. tube fitted with a serum cap was alternately evacuated and filled with dry nitrogen prior to introduction of the solution via a hypodermic syringe. Chemical shifts and coupling constants are believed accurate to $\pm 0.01\ \tau$ and 0.5 Hz, respectively.

Except as noted, melting points were determined between glass plates on a Nalge melting point apparatus. The melting points are uncorrected.

All operations involving the handling of 3,5-dinitrobenzoyl chloride and chloroiridic acid were carried out as much as possible in a dry box constructed of Plexiglass. A dry atmosphere was maintained in the box by using a Fisher pressure-vacuum air pump to circulate air from the box through tubes filled with silica gel and Linde 4A Molecular Sieve. Trays of phosphorus(V) pentoxide were kept inside the box and changed as required.

Analyses of the new compounds were carried out by Galbraith Laboratories, Inc. (Knoxville, Tenn.) and by the Analytical Services Section, Department of Chemistry, Stanford University.

Preparations

Preparation of Hydridodichlorocarbonylbis(dimethylphenylphosphine)iridium(III) (Configuration I)

The procedure followed was essentially that reported by Deeming and Shaw (17) though our yields were highly variable if their procedure was followed exactly. We obtained the highest yield of product if the chloroiridic acid was used as soon as possible after receipt of a new shipment, the reaction solution was made 1.5 to 2 times more dilute than reported (17), was filtered before starting the reaction, and the reaction was carried out until the color of the solution had changed to a light yellow and the dark brown precipitate on the tube, used to bubble carbon monoxide through the solution, was starting to form at an appreciable rate.

Since the water content of the starting chloroiridic acid was unknown. percentage yields based on iridium or a comparison with the literature yields is not possible. A typical procedure starting with 1.2 g $H_2IrCl_6 \cdot XH_2O$ yielded 0.9 g of product.

Preparation of trans-Chlorocarbonylbis(dimethylphenylphosphine)iridium(I) {trans-[IrClCO-{$(CH_3)_2C_6H_5P$}$_2$]}

This complex was prepared by the dehydrohalogenation of hydridodichlorocarbonylbis(dimethylphenylphosphine)iridium(III) according to the method reported by Deeming and Shaw (17). Recrystallization of the crude product from methanol under a nitrogen atmosphere yielded fine yellow needles with a melting point 116–123 °C (decomposition) and molar extinction coefficient (ε) at 432 nm in benzene at 25.0 °C, of 610 $M^{-1}\ cm^{-1}$. The reported melting point and ε_{432} in benzene for this compound are 116–122 °C (decomposition) (17) and 598 $M^{-1}\ cm^{-1}$ (18), respectively.

Dichloro-3,5-dinitrobenzoylcarbonylbis(dimethylphenylphosphine)iridium(III) (Compound A)

3,5-Dinitrobenzoyl chloride (0.17 g, 7.5×10^{-4} mol) in benzene (1.0 ml) was added under nitrogen with continuous stirring to a solution of *trans*-[IrClCO{$(CH_3)_2C_6H_5P$}$_2$] (0.20 g, 3.76×10^{-4} mol) in benzene (1.0 ml).

Within a few minutes a yellow solid precipitated out of solution. The solid was stirred with the solution for about an hour then collected by filtration under nitrogen and washed with cold dry benzene. Yield of dry product: 0.12 g (67%). Recrystallization from a benzene–petroleum ether (90–120 °C) mixture yielded bright yellow needles, melting point 125–131 °C (decomposition).

Anal. Calcd. for $C_{27}H_{28}N_2O_6Cl_2P_2Ir$ (compound with 0.50 mol benzene of solution per mole of Ir complex); C, 40.45; H, 3.53; N, 3.50; Cl, 8.87. Found: C, 40.22; H, 3.59; N, 3.43; Cl, 9.21.

Recrystallization of the yellow solid from a chloroform–ethanol mixture also yielded bright yellow needles, melting point, 121–125 °C (decomposition).

Anal. Calcd. for compound with 0.50 mol chloroform of solution per mole of Ir complex: C, 35.80; H, 3.10; N, 3.31; Cl, 15.10. Found: C, 35.92; H, 3.16; N, 3.52; Cl, 15.64.

Dichloro-3,5-dinitrobenzoylcarbonylbis(dimethylphenylphosphine)iridium(III) (Compound B)

A solution of 3,5-dinitrobenzoyl chloride (0.11 g, 4.7×10^{-4} mol) in ether (5 ml) was added under nitrogen with stirring to a solution of *trans*-[IrClCO{$(CH_3)_2C_6H_5P$}$_2$] (0.25 g, 4.7×10^{-4} mol) in 25 ml of ether. A yellow solid precipitated almost immediately and was collected by filtration under nitrogen. Chromatography of the yellow solid on neutral activated alumina with chloroform as eluent, followed by precipitation of the solid by addition of ethanol to the chloroform solution, yielded the product as pale yellow plates, melting point 197–200 °C (decomposition with gas evolution).

Anal. Calcd. for $C_{24}H_{25}N_2O_6Cl_2P_2Ir$: C, 37.80; H, 3.31; N, 3.67; Cl, 9.30. Found: C, 37.46; H, 3.20; N, 3.59; Cl, 9.28.

Results and Discussion

On mixing benzene solutions of *trans*-[IrClCO{$(CH_3)_2C_6H_5P$}$_2$] and 3,5-dinitrobenzoyl chloride under nitrogen the absorbance at 432 nm, the absorption maximum of the Ir(I) complex, decreased with time and eventually a colorless solution resulted. Kinetic studies in benzene at 25.0 °C indicated that the reaction was first order in both reactants and had a specific rate constant in the forward direction of approximately 3 $M^{-1}\ s^{-1}$. Infrared (i.r.) spectra of benzene solutions at various stages of the re-

action showed that as the intensities of the Ir(I) carbonyl and 3,5-dinitrobenzoyl chloride acyl stretching frequencies (at 1960 and 1760 cm^{-1}, respectively) decreased, new bands which appeared at approximately 2060 and 1600 cm^{-1} simultaneously increased in intensity. Proton magnetic resonance (p.m.r.) spectra in the 8 τ region of reaction mixtures at different times showed, in addition to resonances attributable to the Ir(I) complex, eight well-separated lines of approximately equal intensity plus a pair of overlapping triplets. The integration ratio of the eight single lines to the pair of overlapping triplets was approximately 3:1 and was apparently constant throughout the course of the reaction. When reaction of the Ir(I) complex was complete, the number of resonance absorbances in the 0 to 10 τ region and the relative intensities of these absorbances remained constant. The results indicate therefore the fairly rapid formation in benzene of at least two Ir(III) complexes (A and B) in the approximate ratio 3:1 with negligible interconversion between the two complexes under the conditions used to study the i.r. and p.m.r. spectra.

Preparative reactions in either benzene or ether gave mixtures of A and B. For reactions carried out in benzene, conditions could be chosen such that A preferentially crystallized from the reaction mixture. The solution which remained contained both A and B. Both products were precipitated from solution by adding the reaction mixture to 40–50 ml of boiling *n*-hexane. Recovery of pure A could be achieved by recrystallizing this mixture from a benzene – petroleum ether (90–120 °C) mixture. Recovery of pure B resulted when the mixture of solids was recrystallized from a chloroform–ethanol mixture. Compound A in benzene underwent no changes but in chloroform was converted, over a period of several days at room temperature, to compound B. Both the bright yellow, needle-like crystals of compound A and the pale yellow, plate-like crystals of compound B were found to be light sensitive and to darken after several days of exposure to light. The nature of the decomposition products was not ascertained.

Pertinent infrared absorption data for the starting reactants and the two products A and B are listed in Table 1. The most dramatic change in the frequencies attributable to the 3,5-dinitrobenzoyl group occur in the acyl (C=O) stretching frequency. The shift from 1760 cm^{-1} to about 1600 cm^{-1} is similar to changes observed in the oxidative addition of other acyl halides (7, 19, 20). The shift of the C≡O stretching frequency from 1960 cm^{-1} in the Ir(I) complex to 2065 and 2055 cm^{-1} in the two Ir(III) complexes is a characteristic feature of oxidative addition reactions of this type (17, 20, 21). This increase in CO frequency is diagnostic of decreased backbonding to CO as a result of the oxidation.

The stereochemical arrangements of chlorine atoms about Ir(III) can be readily determined by far i.r. data since the Ir—Cl stretching frequency is quite dependent on the ligand *trans* to the chlorine and is insensitive to the *cis* ligands (22). For example, compounds with Cl *trans* to Cl absorb in the region 315–335 cm^{-1}; Cl *trans* to CO, in the region 297–315 cm^{-1}; Cl *trans* to a trialkyl- or triarylphosphine, in the 270–290 cm^{-1} region; and Cl *trans* to an acyl group, in the 215–247 cm^{-1} region.

On the basis of the far i.r. data compound A contains a Cl *trans* to a CO (307 cm^{-1}) and a Cl *trans* to a dimethylphenylphosphine (271 cm^{-1}) and no Cl *trans* to an acyl group. Compound B, on the other hand, contains a Cl *trans* to CO (304 cm^{-1}) and a Cl *trans* to an acyl group (224 cm^{-1}). The lack of any strong absorption

‖H_A and H_B refer to the two *ortho* protons and the one *para* proton respectively on the nitroaromatic ring. P_1 and P_2 refer to the two non-equivalent phosphorus nuclei at 32 and 43 p.p.m. respectively from 85% H_3PO_4.

for either compound in the region 315 to 335 cm^{-1} rules out a Cl *trans* to a Cl in either compound.

The relative positions of methyl-substituted phosphine ligands in octahedral iridium(III) complexes can be determined by p.m.r. spectroscopy using the method of Jenkins and Shaw (23). Complexes with mutually *trans* phosphines exhibit a triplet for the methyl proton resonances because of strong coupling between the *trans* phosphorus nuclei. With the phosphorus atoms in a mutually *cis* position the resonance of the methyl protons is split into a doublet since the two phosphorus atoms do not couple strongly in this case.

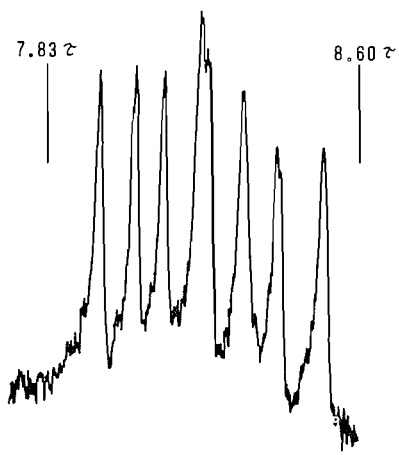

FIG. 1. Proton magnetic resonance spectrum of compound A in the methylphosphine resonance region.

The p.m.r. spectrum of compound A showed eight distinct sharp resonances in the methyl hydrogen region of the spectrum (Fig. 1, Table 2). By using INDOR techniques (24) it was shown that the eight lines were due to magnetically non-equivalent methyl groups coupled with two non-equivalent phosphorus nuclei at 32 and 43 p.p.m. upfield from 85% H_3PO_4. On irradiating at one phosphorus resonance four of the eight lines collapsed to a doublet leaving the position of the other four lines unaltered. Irradiation at the

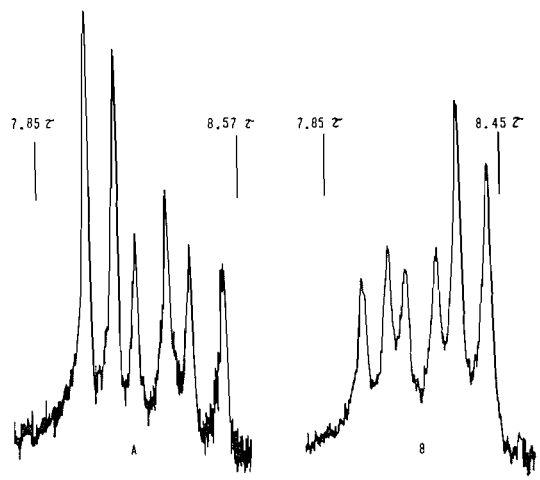

FIG. 2. Proton magnetic resonance spectrum of compound A in the methylphosphine resonance region when (*A*) the phosphorus nucleus 43 p.p.m. upfield from 85% H_3PO_4 is decoupled and (*B*) the phosphorus nucleus 32 p.p.m. upfield from 85% H_3PO_4 is decoupled.

For personal use only.

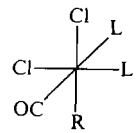
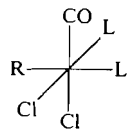
second phosphorus resonance had the opposite effect (Fig. 2). These observations can only be consistent with a molecule containing mutually *cis*, non-equivalent dimethylphenylphosphines with no plane of symmetry through the Ir—P bonds. Of the two structures **1** and **2** which satisfy these requirements, only structure **2** is also



1



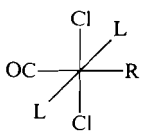
2

R = $(O_2N)_2C_6H_3C(=O)$—
L = $(CH_3)_2C_6H_5P$

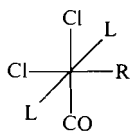
R = $(O_2N)_2C_6H_3C(=O)$—
L = $(CH_3)_2C_6H_5P$

consistent with the far i.r. data which shows that compound A contains a Cl *trans* to a CO and a Cl *trans* to a dimethylphenylphosphine. Compound A is therefore assigned Structure **2**. By virtue of the disposition of the dimethylphenylphosphine ligands in this compound it is hereafter referred to as the *cis* isomer.

The p.m.r. spectrum of compound B in the methyl hydrogen region showed a pair of overlapping triplets which collapsed to a sharp narrow doublet as a result of phosphorus-31 decoupling. Thus a *trans* arrangement of phosphines must exist in the molecule. Of the two possible structures **3** and **4** containing *trans* phosphines, **3** must be excluded since it has a plane of symmetry through the Ir—P bonds and would be expected to give rise to a single triplet in the methyl hydrogen region. The assignment of structure **4** to compound B is fully in accord with



3



4

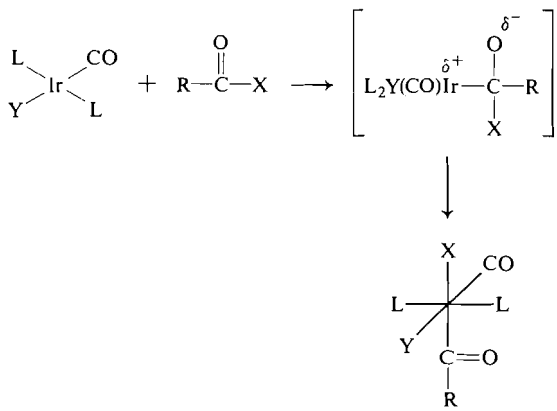
R = $(O_2N)_2C_6H_3C(=O)$—
L = $(CH_3)_2C_6H_5P$

R = $(O_2N)_2C_6H_3C(=O)$—
L = $(CH_3)_2C_6H_5P$

the far i.r. results which indicate that this compound contains a Cl *trans* to a CO and a Cl *trans* to an acyl group. Since the dimethylphosphine ligands are *trans* in structure **4**, compound B is referred to as the *trans* isomer.

The experimental results indicate therefore that in benzene, ether and benzene–ether mixtures *trans*-$[IrClCO\{(CH_3)_2C_6H_5P\}_2]$ reacts with 3,5-dinitrobenzoyl chloride to yield an approximately 3:1 mixture of the *cis*- and *trans*-dichloro-3,5-dinitrobenzoylcarbonylbis(dimethylphenylphosphine)iridium(III) complexes.

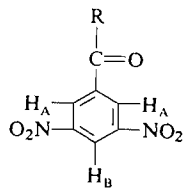
Oxidative addition of acyl halides to square planar iridium(I) complexes of the type *trans*-$IrClCOL_2$ (where L = *tertiary* phosphine or arsine) are well known (7, 20, 25) and have been reported (20, 26) to give *trans*-adducts via the following mechanism (14)



That the solvent can play an important role in determining the stereochemistry of the addition and possible isomerization of the initial product has been the subject of several reports (26–28). Our experimental results indicate that both **2** and **4** are being produced in the same ratio throughout the reaction and that conversion between the two forms is very slow. Whereas the *cis* isomer (**2**) can only arise from a *cis* addition of the acyl halide, the *trans* isomer (**4**) could be the result of either a *cis*- or a *trans*-addition. Our results cannot tell us whether these two addition reactions are proceeding simultaneously to yield the observed mixture of isomers or whether there is an initial formation of a third species which rapidly rearranges to give a mixture of the isomers. It is clear however, that oxidative addition of 3,5-dinitrobenzoyl chloride to *trans*-$[IrCOCl\{(CH_3)_2C_6H_5P\}_2]$ proceeds via a mechanism quite different to that proposed by Halpern (14). Steric factors may be very important in this system in determining both the mode of addition and the stereochemistry of the final products.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

The resonance absorbance patterns of the ring protons in 3,5-dinitrobenzoyl chloride and in the 3,5-dinitrobenzoyl groups in the *cis* and *trans* isomers are not identical. In both 3,5-dinitrobenzoyl chloride and the *trans* isomer, the magnetically non-equivalent H_A and H_B protons in **5** gave the expected doublet and triplet in the ratio



5

R = Cl, $IrCl_2CO\{(CH_3)_2C_6H_5P\}_2$

of 2:1. In the *cis* isomer a sharp singlet was found at 1.07 τ which integrated to three protons relative to the twelve protons associated with the methyl hydrogens of the two dimethylphenylphosphines. The two protons H_A and H_B seem therefore to be magnetically equivalent in the *cis* isomer. The p.m.r. spectra of aromatic compounds are known to be markedly affected by solvents (29),[1] and a highly specific solvent nitroaromatic ring interaction may be the source of the differences noted above. A study of the p.m.r. spectra of 3,5-dinitrobenzoyl chloride and the *cis* and *trans* isomers in a variety of solvents and over a range of temperatures is planned in an effort to ascertain the factors which give rise to these differences in resonance absorbance patterns.

The i.r. and p.m.r. spectra of the two isomers show some interesting differences (Tables 1 and 2). The N—O stretching modes in the *cis* isomer are only slightly lower (2 and 6 cm^{-1}) than the corresponding vibrations in 3,5-dinitrobenzoyl chloride. This suggests that in the *cis* isomer the electron density in the ring is not significantly altered compared to the electron density in 3,5-dinitrobenzoyl chloride. The observation that in the *cis* isomer the resonance absorbance of the nitroaromatic ring protons is only 20 Hz upfield from the mean position of the resonance absorbances of the protons in 3,5-dinitrobenzoyl chloride is consistent with this suggestion. In the *trans* isomer the resonance absorbances of the H_A and H_B protons are shifted further upfield (38 and 87 Hz, respectively) and there is a somewhat larger decrease (6 and 10 cm^{-1}) in the frequencies of the N—O stretching modes. Both observations imply that there is a more extensive delocalization of the electron density from the metal center into the ring in the case of the *trans* isomer (5).

An attempted decarbonylation of the *cis* isomer by refluxing in toluene for 24 h under nitrogen resulted in no decarbonylation but a complete conversion to the *trans* isomer. Refluxing a *p*-xylene solution of the *trans* isomer under nitrogen for 24 h did not result in decarbonylation and the starting material was recovered unchanged. The evolution of a gas on melting of the *trans* isomer at 197–200 °C may imply loss of CO from the compound but the nature of the resulting product has not yet been established. Kubota *et al.* (7–9) have noted that decarbonylation reactions of Ir(III) complexes containing

O
‖
RC—

are not as facile when R = *p*-$NO_2C_6H_4$— as when R = *p*-$CH_3OC_6H_4$— or $C_6H_5CH_2$—. Therefore it may prove to be very difficult to decarbonylate or decarboxylate iridium(III) complexes in which the R group contains two or more nitro groups on the ring. If this is indeed the case, oxidative additions of an appropriately substituted acyl halide or benzoic acid followed by decarbonylation or decarboxylation may not offer a simple general route to the preparation of complexes containing a metal center directly σ-bonded to an aromatic ring containing one or more nitro groups.

Both *cis* and *trans* isomers and 3,5-dinitrobenzoyl chloride react with tetraphenylarsonium cyanide in chloroform to give the characteristically deep red colored solutions associated with the formation of σ complexes (12, 13, 30). The results of equilibrium and kinetic studies of these interactions will be published separately.

[1]In hexadeuteroacetone the p.m.r. spectrum of 3,5-dinitrobenzoyl chloride shows a sharp singlet for the three nitroaromatic ring protons.

A portion of this work was carried out while one of the authors (A.R.N.) was on a sabbatical leave at Stanford University. Thanks are extended to Professor H. Taube for making research space and equipment available during that time. The authors are indebted to Drs. M. C. Baird and B. K. Hunter for numerous valuable discussions concerning the p.m.r. spectra. Financial support by the National Research Council of Canada is gratefully acknowledged.

Hydrogen Peroxide Oxidation of Coordinated Thiocyanate Ion in *cis*- and *trans*-$[Coen_2NH_3NCS]^{2+}$: The Preparation and Properties of *trans*-$[Coen_2NH_3CN]^{2+}$

ALBERT RICHARD NORRIS AND JAMES WILLIAM LENNOX WILSON

Department of Chemistry, Queen's University, Kingston, Ontario

Received July 19, 1973

The hydrogen peroxide oxidation of thiocyanate ion in *cis*- and *trans*-$[Coen_2NH_3NCS]^{2+}$ leads to the formation of the corresponding *cis*- and *trans*-cyanoammine- and diamminebis(ethylenediamine)cobalt-(III) complexes. The spectral properties of the previously unreported *trans*-$[Coen_2NH_3CN]^{2+}$ are reported and compared to the spectral properties of the *cis*-isomer.

Observations are made concerning the reaction conditions which favor a high percent conversion of *trans*-$[Coen_2NH_3NCS]^{2+}$ to *trans*-$[Coen_2NH_3CN]^{2+}$.

L'oxydation par le peroxyde d'hydrogène de l'ion thiocyanate dans le $[Coen_2NH_3NCS]^{2+}$-*cis* et -*trans* conduit à la formation des complexes *cis* et *trans* cyanoamine et diamine bis(éthylenediamine) cobalt (III). Les propriétés spectrales du composé, pas encore décrit, $[Coen_2NH_3CN]^{2+}$-*trans* sont rapportées et comparées à celles de l'isomère-*cis*.

On fait certaines observations concernant les conditions de réaction qui favorisent une conversion complète du $[Coen_2NH_3NCS]^{2+}$-*trans* en $[Coen_2NH_3CN]^{2+}$-*trans*. [Traduit par le journal]

Can. J. Chem., **51**, 4152 (1973)

Introduction

We have previously reported (1) that oxidation of coordinated thiocyanate ion in $[Co(NH_3)_5NCS]^{2+}$ by hydrogen peroxide in an acid medium leads to the formation of both $[Co(NH_3)_5CN]^{2+}$ and $[Co(NH_3)_6]^{3+}$. Other oxidizing agents such as IO_3^-, IO_4^-, MnO_4^-, $S_2O_8^{2-}$, ClO_2^-, BrO_3^-, and Ce^{4+} are also capable of oxidizing the coordinated thiocyanate ion but none appears to be as effective as hydrogen peroxide in producing the cyanide-substituted product (2–4).

As part of kinetic studies[1] of the hydrogen peroxide oxidation of thiocyanate ion in *cis*- and *trans*-$[Coen_2NH_3NCS]^{2+}$ we have established that the starting complexes give rise exclusively to the corresponding *cis* and *trans*-cyanoammine- and diamminebis(ethylenediamine)cobalt-(III) complexes. Infrared, ultraviolet–visible, and proton magnetic resonance spectra have been recorded for the previously unreported *trans*-$[Coen_2NH_3CN]Cl_2$. These are compared to the corresponding spectra of the *cis*-isomer. Observations are also presented concerning the dependence of the percent conversion of *trans*-$[Coen_2NH_3NCS]^{2+}$ to *trans*-$[Coen_2NH_3CN]^{2+}$ on various reaction parameters.

[1]A. R. Norris and J. W. L. Wilson. Results to be published.

Experimental

Reagents

trans-$[Coen_2Cl_2]Cl$, *trans*-$[Coen_2ClNCS]NCS$, *trans*-$[Coen_2NH_3NCS](NCS)_2$, *cis*-$[Coen_2NH_3NCS]S_2O_6$, *cis*-$[Coen_2NH_3CN]Cl_2$, *trans*-$[Coen_2(NH_3)_2]Br_3$, and *cis*-$[Coen_2(NH_3)_2]Cl_3$ were prepared and recrystallized following published procedures (5–7).

trans-$[Coen_2NH_3NCS]Cl_2$ was prepared as follows. A solution containing about 400 mg of the twice-recrystallized thiocyanate salt was dissolved in approximately 30 ml of dilute aqueous acetic acid and the solution passed through a column (1 × 12 cm) of Dowex 50W-X2 ion-exchange resin (200–400 mesh) in the acid form. When all the complex was absorbed the column was washed with 50 to 100 ml of 0.01 *M* HCl in order to completely remove any thiocyanate ion. On passage of 1.0 *M* HCl through the column a small amount of *trans*-$[Coen_2(NCS)_2]^+$ was eluted from the column. Elution with 2.0 *M* HCl brought down an orange-colored solution which was filtered and freeze-dried. The solid obtained in the freeze-drying procedure was recrystallized from an ethanol–water mixture containing added tetra-*n*-butylammonium chloride. The crystals which formed were collected by filtration and dried to constant weight in vacuo over phosphorus(V) pentoxide. In a typical procedure 400 mg of thiocyanate salt yielded approximately 300 mg of freeze-dried solid and 200 mg of recrystallized *trans*-$[Coen_2NH_3NCS]Cl_2$. In spite of repeated recrystallizations, *trans*-$[Coen_2NH_3NCS](NCS)_2$ always contained small amounts of *trans*-$[Coen_2(NCS)_2]NCS$ as an impurity. This impurity could only be removed by employing the chromatographic procedure described above.

Values of absorption maxima (λ_1 and λ_2) and molar extinction coefficients at the absorption maxima (ε_1 and ε_2) for each of the complexes prepared in this study are given in Table 1.

*Values were measured on a Cary 14 recording spectrophotometer employing solutions of approximately 10^{-3} *M* concentration and matched cells of path lengths 1.0, 2.0, and 5.0 cm. The cell compartment was thermostatted at 25.0 °C in all cases.

Stock solutions of hydrogen peroxide (~10 *M*) were prepared using Baker hydrogen peroxide (30 vol%) containing 0.05% $Na_4P_2O_7 \cdot 10H_2O$ as a preservative. The peroxide content was determined iodimetrically following Vogel's procedure (8). The stock solutions were stored in the refrigerator when not in use and were re-standardized periodically.

Stock solutions, 2.50 *M* in perchloric acid, were prepared by diluting 207 ml of G. F. Smith double-distilled, lead-free, 70% perchloric acid to 1000 ml total volume with distilled water. The stock solutions were standardized by titration of 1.0 ml aliquots with 0.100 *N* sodium hydroxide to the phenolphthalein end-point.

Stock solutions, 2.50 *M* in sodium perchlorate, were prepared by dissolving 153.055 g (1.250 mol) of sodium perchlorate (G. F. Smith reagent grade, anhydrous, dried at 100 °C for 24 h) in distilled water and diluting to 500 ml total volume. The concentration of sodium perchlorate was checked by pipetting 5.0 ml aliquots of stock solution into tared evaporating dishes, evaporating the solvent and drying the resulting solids to constant weight at 100 °C.

Stock solutions containing *cis*- and *trans*-$[Coen_2NH_3NCS]^{2+}$ were prepared by dissolving an accurately weighed amount of *cis*-$[Coen_2NH_3NCS]S_2O_6$ or *trans*-$[Coen_2NH_3NCS]Cl_2$ in a known volume of distilled water. To inhibit base hydrolysis solutions were acidified to p*H* 3.00 with dilute hydrochloric acid and stored in the refrigerator when not in use. No detectable changes in the ultraviolet–visible absorption spectrum of either stock solution were noticed after 10 days storage under these conditions.

All other reagents used were A.R. grade or better and were used without further purification.

Instruments

Ultraviolet–visible absorption spectra were recorded on a Cary 14 recording spectrophotometer using matched silica cells of 1.0 and 5.0 cm path lengths. The temperature in the cells was maintained constant to ±0.1 °C by circulating water from a constant temperature bath through a specially designed cell holder in the spectrophotometer.

Infrared spectra were recorded on Beckman IR-10 and Perkin–Elmer 180 recording spectrophotometers operating in the double-beam mode. Samples were prepared in potassium bromide or cesium iodide discs (1% w/w concentration) and spectra recorded versus air or an attenuator in the reference beam path. Spectra were calibrated using a polystyrene film and all frequencies are believed to be accurate to within ±5 cm^{-1}.

Proton magnetic resonance spectra of the *cis*- and *trans*-series of complexes were recorded on Varian HA-100 and Bruker HX-60 spectrometers respectively. For spectra recorded on the HX-60, the sodium salt of 3-(trimethylsilyl)-propane sulfonic acid (DSS) was used as an internal standard with the proton signal of the methyl groups being used as the "lock" signal. For spectra recorded on the HA-100, external tetramethylsilane (TMS) was used as a reference and a "lock" signal. Chemical shift values (τ) are given relative to the standard (τ = 10.00 p.p.m.). Samples normally contained about 20 mg of complex dissolved in 0.50 ml 1.8 *M* D_2SO_4. Spectra were always recorded immediately after preparation of the solutions and again after intervals of 12 and 24 h to check for signs of possible decomposition of the complex.

Product Distribution Studies and Recovery of Reaction Products

One hundred ml of solution containing from 1.0×10^{-4} to 1.2×10^{-3} mol of complex and known amounts of H_2O_2, $HClO_4$, and $NaClO_4$ was allowed to stand in the dark at 25.0 °C until the reaction had gone to completion (> 10 half-lives). The ultraviolet–visible absorption spectrum of a portion of the solution was recorded, the solution diluted by a factor of about two and passed through an ion-exchange column (1 × 12 cm) containing Dowex 50W-X2 (200–400 mesh) in the H^+ form. When all the complex was absorbed the column was washed with 100 ml of distilled water to ensure the removal of all counter-anions. With 0.50 *M* HCl as eluent no colored species were removed from the column though there was some slight separation of the band at the top of the column into a lower yellow band and an upper orange band. The yellow band could be completely removed from the column by using 1 *M* HCl as eluent while 3 *M* HCl was

required to remove the material contained in the orange band. No evidence was ever obtained for other species, such as $[Co(H_2O)_6]^{2+}$, being present on the resin. The ultraviolet–visible spectra of the filtered 1 and the 3 *M* HCl fractions were recorded and the solids in these fractions recovered by freeze-drying of the solutions.

Two methods of determining product distribution were employed. For the reaction mixtures, absorbances at the known positions of maximum absorption of each complex were used in conjunction with the known molar extinction coefficients of each product at those wavelengths to calculate the amount of each complex present in solution. Alternatively, for each fraction from the ion-exchange column, the absorbances at the absorption maxima could be used together with the known molar extinction coefficients of the complex at the absorption maxima and the volume of eluent to calculate the amount of complex in that particular fraction. The two methods of determining the amount of each product usually agreed to better than ±5 %.

The following procedure was used to recrystallize the solid recovered from the freeze-drying of the 1 *M* HCl fractions. Fifty to one hundred mg of the yellow solid was dissolved in 0.50 ml of warm (~60 °C) distilled water containing 0.5 g tetra-*n*-butylammonium chloride. Enough warm absolute ethanol was added to the solution to cause a slight turbidity (~1 ml) and the solution then allowed to cool in an ice-salt bath. The yellow crystals which formed were collected by filtration, washed thoroughly with absolute ethanol, acetone, and ether and dried to constant weight *in vacuo* over phosphorus(V) pentoxide. A second crop of crystals could usually be obtained by adding further ethanol and tetra-*n*-butylammonium chloride to the filtrate obtained in the first filtration. The recrystallized yellow salts recovered from the 1 *M* HCl fractions obtained in the oxidations of *cis*- and *trans*-$[Coen_2NH_3NCS]^{2+}$ are hereafter referred to as compounds A and C, respectively.

In studies of the oxidation of *cis*-$[Coen_2NH_3NCS]^{2+}$ the orange solid recovered by freeze-drying of the 3 *M* HCl fractions was very hygroscopic and could not be precipitated from solution as a chloride or bromide salt. For this reason the freeze-dried solid was simply dried to constant weight *in vacuo* over phosphorus(V) pentoxide before its spectral properties were determined. This salt is referred to hereafter as compound B.

In studies of the oxidation of *trans*-$[Coen_2NH_3NCS]^{2+}$ the orange solid recovered by freeze-drying of the 3 *M* HCl fractions was recrystallized both as a chloride salt from ethanol–water (using the procedure described above) and as a bromide salt from an aqueous solution containing added sodium bromide. The recovered crystals were washed with ethanol, acetone, and ether and dried to constant weight *in vacuo* over phosphorus(V) pentoxide. Both the chloride and the bromide salt are hereafter referred to as compound D.

Elemental analyses were carried out by Galbraith Laboratories, Inc. (Knoxville, Tenn.) and by the Analytical Services Section, Department of Chemistry, Stanford University.

Results and Discussion

By analogy with the results obtained in the oxidation of $[Co(NH_3)_5NCS]^{2+}$ (1), the oxidation of *cis*- and *trans*-$[Coen_2NH_3NCS]^{2+}$ by hydrogen peroxide in an acid medium might be expected to lead to cyanoammine- and diamminebis(ethylenediamine)cobalt(III) species. The results of the chromatographic separation indicated that this was almost certainly the case: for both starting complexes the only products eluted from the column came off with 1 and 3 *M* HCl indicating charges of +1 and +3 respectively for the complexes formed (9).

The results of elemental analysis on three separate sample preparations of compound A and the calculated percentages of carbon, hydrogen, nitrogen, and chlorine in $[Coen_2NH_3CN]Cl_2$ are given in Table 2. The results of elemental analysis are completely consistent with the formulation of the +1-charged complex recovered from the 1 *M* HCl fraction as a cyanoamminebis(ethylenediamine)cobalt(III) chloride.

Values of λ_1, λ_2, ε_1, and ε_2 for compound A and for a sample of *cis*-$[Coen_2NH_3CN]Cl_2$, prepared according to the method of Ohkawa, Hidaka, and Shimura (7), are listed in Table 1. Both of the compounds have values of absorp-

tion maxima and molar extinction coefficients in reasonable agreement with those reported for *cis*-$[Coen_2NH_3CN]Cl_2$ (7). Compound A possessed absorption minima at 371 ($\varepsilon = 19.5\ M^{-1}\ cm^{-1}$) and 282 nm ($\varepsilon = 22.0\ M^{-1}\ cm^{-1}$) while the prepared sample of *cis*-$[Coen_2NH_3CN]Cl_2$ possessed absorption minima at 371 ($\varepsilon = 17.2\ M^{-1}\ cm^{-1}$) and 282 nm ($\varepsilon = 15.6\ M^{-1}\ cm^{-1}$). Ohkawa, Hidaka, and Shimura's resolution of the *cis*-compound into its enantiomers (7) leaves little doubt that the complex has a *cis*-geometry.

The infrared (i.r.) spectrum of compound A was identical in all respects to the i.r. spectrum of an authentic sample of *cis*-$[Coen_2NH_3CN]Cl_2$.

Pertinent details of the spectrum are given in Table 3.

The proton magnetic resonance (p.m.r.) spectra of compound A and an authentic sample of *cis*-$[Coen_2NH_3CN]Cl_2$ were also identical. Resonance absorbances were noted at 4.96, 5.42, 6.16, and 7.20 τ. The first two resonance absorbances were rather broad and were not of equal intensity. The third resonance absorbance was very broad and of low intensity but always present in the spectra of the samples. The last absorbance was broad, had a shoulder on the downfield side and, at the maximum, showed some indication of splitting (peak separation ~3 Hz). The ratio of the sum of the areas of the peaks at 4.96, 5.42, and 6.16 τ to the area of the peak at 7.20 τ was 1:1.35. If the resonances at 4.96, 5.42, and 6.16 τ are assigned to the NH_2 protons of ethylenediamine, and the resonances in the 7.20 τ region assigned to the NH_3 protons and the CH_2 protons of ethylenediamine, the expected ratio of areas is 1:1.37. When either compound A or authentic *cis*-$[Coen_2NH_3CN]Cl_2$ was dissolved in D_2O there was a rapid disappearance of the resonances at 4.96, 5.42, and 6.16 τ and the shoulder on the downfield side of 7.20 τ resonance, and a considerable narrowing of the band width of the 7.20 τ resonance absorbance. These observations are fully consistent with the proposed assignments.

The starting *cis*-$[Coen_2NH_3NCS]^{2+}$ complex ion in 1.8 *M* D_2SO_4 possessed resonance absorbances at 4.72, 5.54, 6.50, and 7.17 τ. Integration ratios were 2.50(4.72 + 5.54 τ):1(6.50 τ):2.70-(7.17 τ). Assignments of the resonance absorbances at 4.72 and 5.54 τ to NH_2 protons, the resonance at 6.50 τ to the NH_3 protons and the resonance at 7.17 τ to the CH_2 protons of ethylenediamine would require the integration ratios to be 2.66:1:2.66.

Compound B and an authentic sample of *cis*-$[Coen_2(NH_3)_2]Cl_2$ were found to have identical ultraviolet–visible, i.r., and p.m.r. spectra. Ultraviolet–visible absorption maxima occurred at 470 and 341 nm in good agreement with published values (10). Proton resonance absorbances occurred at 5.04, 5.42, 6.72, and 7.22 τ. The 5.04 τ resonance absorbance was very broad compared to the three remaining resonances. Integration ratios were 1.32(5.04 + 5.42 τ):1(6.72 τ):1.35-(7.22 τ). Assignment of the 5.04 and 5.42 τ resonances to the NH_2 protons, the 6.72 τ resonance to the NH_3 protons and the 7.22 τ resonances to the CH_2 protons of ethylenediamine would require the integration ratios to be 1.33:1:1.33. Buckingham, Durham, and Sargeson (11) have reported a similar p.m.r. spectrum for *cis*-$[Coen_2(NH_3)_2](ClO_4)_3$ in 1.8 *M* D_2SO_4 though with possibly more splitting of the band at 5.04 τ than we observed.

All the available evidence indicates therefore that oxidation of *cis*-$[Coen_2NH_3NCS]^{2+}$ by hydrogen peroxide in an acid medium leads to the formation of *cis*-$[Coen_2NH_3CN]^{2+}$ and *cis*-$[Coen_2(NH_3)_2]^{3+}$ as the only products.

The results of elemental analysis for two different sample preparations of compound C and the calculated percentages of carbon, hydrogen, nitrogen, and chlorine in $[Coen_2NH_3CN]Cl_2 \cdot H_2O$ are given in Table 2. The analytical results support the formulation of compound C as a cyanoamminebis(ethylenediamine)cobalt(III) complex.

Values of λ_1, λ_2, ε_1, and ε_2 for compound C are given in Table 1. Minima in the absorption curve occurred at 368 (ε = 14.0 M^{-1} cm^{-1}) and 287 nm (ε = 24.9 M^{-1} cm^{-1}). The positions of the absorption maxima and minima and the values of $\varepsilon_{(\lambda_{max})}$ and $\varepsilon_{(\lambda_{min})}$ which characterize compound C clearly distinguish it from *cis*-$[Coen_2NH_3CN]Cl_2$. The lower values of $\varepsilon_{(\lambda_{max})}$ for compound C, as compared to the $\varepsilon_{(\lambda_{max})}$ values for compound A, are completely compatible with the formulation of compound C as the *trans*-isomer of cyanoammine bis(ethylenediamine)-cobalt(III) chloride (12–14).

The i.r. spectrum of compound C possesses a strong, sharp C≡N stretch at 2030 cm^{-1} as does the i.r. spectrum of compound A. Otherwise the i.r. spectra of the two compounds are markedly different. A tabulation of the i.r. absorption bands of the two compounds together with tentative assignments of the various bands are given in Table 3. Given that both compounds A and C are cyanoamminebis(ethylenediamine)cobalt(III) salts, a comparison of the spectra of the two compounds in the 1580–1620, 870–900 and 610–500 cm^{-1} regions would lead to the prediction that compound A had the *cis*-configuration and compound C had the *trans*-configuration (15–17).

The proton magnetic resonance spectrum of compound C in 1.8 *M* D_2SO_4 showed resonance absorbances at 5.25, 5.65, 6.43, and 7.18 τ. The 5.25 and 5.65 τ resonances were broad and of equal intensity and the third and fourth resonances were fairly sharp. The resonances at

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

5.25 and 5.65 τ are assigned to the NH_3 protons,[2] the resonance at 6.43 is assigned to the protons on NH_3 and the resonance at 7.18 τ is assigned to the CH_2 protons of ethylenediamine. On this basis the expected ratios of peak areas are 2.67:1:2.67. The observed ratios were 2.91:1:2.71. *trans*-$[Coen_2NH_3NCS]Cl_2$ possessed a broad resonance absorbance centered at 4.89 τ and a sharp resonance centered at 7.10 τ. The ratio of the integrated areas was 1:1.41.

The analytical data for compound D (as the chloride salt) and the calculated percentages of carbon, hydrogen, nitrogen, and chlorine in $[Coen_2(NH_3)_2]Cl_3 \cdot H_2O$ are shown in Table 2.

The absorption maxima of the chloride and bromide salts of compound D were identical to those of an authentic sample of *trans*-$[Coen_2(NH_3)_2]Br_3$ and the molar extinction coefficients of all three species were nearly identical (Table 1).

The i.r. spectra of D, recrystallized as the bromide salt, and an authentic sample of *trans*-$[Coen_2(NH_3)_2]Br_3$ were essentially identical and agreed in all respects with the spectrum reported by Rigg and Sherwin (18).

Proton magnetic resonance spectra of D and an authentic sample of *trans*-$[Coen_2(NH_3)_2]Br_3$ were also identical. Resonance absorbances were noted at 4.97 τ and 7.11 τ with a shoulder on the 7.11 τ resonance at approximately 6.93 τ. The ratio of the integrated areas was 1:1.76. If the resonance at 4.97 τ is assigned to the NH_2 protons, that at 6.93 τ to the NH_3 protons and that at 7.11 τ to the CH_2 protons of ethylenediamine, the expected integration ratio is 1:1.75.

Thus, on the basis of the available evidence, oxidation of *trans*-$[Coen_2NH_3NCS]^{2+}$ by H_2O_2 in acid media leads to *trans*-$[Coen_2NH_3CN]^{2+}$ and *trans*-$[Coen_2(NH_3)_2]^{3+}$ as the only products.

As no cleavage of a cobalt–nitrogen bond is required in the conversion of a coordinated thiocyanate ion to a coordinated ammonia, ammine-containing products of the same geometry as the starting complex are not unexpected. Garbett and Gillard have shown that periodate oxidation of a number of optically active thiocyanate-containing cobalt(III) complexes yielded the corresponding ammine-containing product in which the optical activity was preserved (19). The oxidation of a coordinated thiocyanate ion to yield a coordinated cyanide ion must at some point, however, involve a linkage isomerization in order to yield the resulting C-bonded cyanide-containing complex. It is of interest that for both our *cis*- and *trans*- starting complexes and for (−) *cis*-$[Coen_2(NCS)_2]^+$ (20) this presumably intramolecular isomerization leads to no geometrical isomerization. To determine how general this behavior is we plan to investigate the reactions of other suitable *cis*–*trans* pairs.

Since other methods of preparing *trans*-$[Coen_2NH_3CN]^{2+}$ have not been reported an effort was made to determine reaction conditions which would lead to the highest percent conversion of *trans*-$[Coen_2NH_3NCS]^{2+}$ to *trans*-$[Coen_2NH_3CN]^{2+}$. Experimentally the hydrogen peroxide concentration range covered was from 0.5 to 7.0 *M*, the $[H^+]$ was varied from 0.05 to 0.50 *M* and the initial concentration of complex was varied from 1.0×10^{-4} to 1.0×10^{-3} *M*. All studies were carried out at 25.0 °C.

At fixed concentrations of hydrogen peroxide, hydrogen ion, and initial complex, variations in the ionic strength of the medium over the range 0.1 to 0.50 *M* had no apparent effect on the percent conversion of the starting complex to *trans*-cyanoamminebis(ethylenediamine)cobalt(III).

At a fixed ionic strength and fixed concentrations of hydrogen peroxide and hydrogen ion, the percent conversion depended markedly on the initial concentration of complex. As indicated in Fig. 1, highest percent conversions were obtained at the lowest initial concentrations of *trans*-$[Coen_2NH_3NCS]^{2+}$. Perhaps Werner's failure to isolate a cyanide ion-containing product in any of his studies (6, 21) lies with this result as he used solutions containing very high concentrations of the starting complex and, under these conditions, we would expect an almost 100% conversion of the starting complex to the ammine-containing product.

The addition of *trans*-$[Coen_2NH_3CN]^{2+}$ to the reaction mixtures had no apparent effect on the percent conversion of starting complex to *trans*-$[Coen_2NH_3CN]^{2+}$. In solutions to which *trans*-$[Coen_2(NH_3)_2]^{3+}$ was added, the percent conversion of starting complex to *trans*-$[Coen_2NH_3CN]^{2+}$ decreased slightly as the initial concentra-

[2]For a series of *trans*-$[Coen_2NH_3X]^{n+}$ complexes (X = Cl^-, Br^-, NCS^-, NH_3, H_2O, and CN^-), only for X = CN^- did the NH_2 protons show a distinct splitting into two resonances. However, it has been observed that the higher X is in the spectrochemical series the greater is the half-width at half-height of the band associated with the NH_2 resonances. This phenomenon is under further investigation.

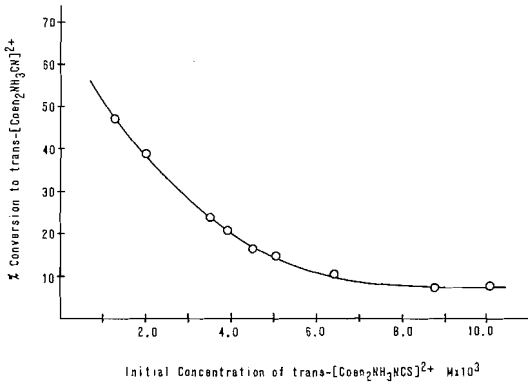

FIG. 1. % conversion of *trans*-$[Coen_2NH_3NCS]^{2+}$ to *trans*-$[Coen_2NH_3CN]^{2+}$ as a function of the initial concentration of *trans*-$[Coen_2NH_3NCS]^{2+}$; $[H_2O_2] = 2.00$ M; $[H^+] = 0.50$ M; $\mu = 0.50$ M; $T = 25.0$ °C.

tion of *trans*-$[Coen_2(NH_3)_2]^{3+}$ was increased. Separate studies showed that neither of the reaction products undergoes further reaction under the conditions employed in these studies. It is somewhat surprising therefore to find that the addition of *trans*-$[Coen_2(NH_3)_2]^{3+}$ should affect the percent conversion.

At a fixed ionic strength and fixed concentration of starting complex and hydrogen ion the percent conversion showed a maximum as the concentration of hydrogen peroxide was increased from 0.50 to 7.0 M. This point of maximum conversion moved to lower concentration of hydrogen peroxide as the concentration of hydrogen ion was increased. Over the range 0.10 to 0.50 M in hydrogen ion, the maximum occurred in the 3.5 to 1.5 M range of hydrogen peroxide concentrations. As the concentration of hydrogen ion was increased from 0.10 to 0.50 M, there was only a slight increase in the percent conversion at all concentrations of hydrogen peroxide.

In summary, the highest percent conversions of *trans*-$[Coen_2NH_3NCS]^{2+}$ to *trans*-$[Coen_2NH_3CN]^{2+}$ at 25.0 °C were found for solutions whose initial concentration of complex was $< 1 \times 10^{-4}$ M, whose concentration of hydrogen ion was about 0.50 M and whose concentration of hydrogen peroxide was in the range 1.5 to 2.5 M. The implications of these observations regarding the mechanism of conversion of *trans*-$[Coen_2NH_3NCS]^{2+}$ to *trans*-$[Coen_2NH_3CN]^{2+}$ are under investigation.

A portion of the work described was carried out while one of the authors (A.R.N.) was on a sabbatical leave at Stanford University. Thanks are extended to Professor H. Taube for several valuable discussions concerning the results of this work and for making research space and equipment available during that time. Financial support by the National Research Council of Canada is acknowledged.

An Ionization Chamber Study of Electron and Ion Decay in Irradiated Ammonia

D. R. McCracken and D. A. Armstrong

Department of Chemistry, University of Calgary, Calgary, Alberta T2N 1N4

Received July 9, 1973

Ionization chambers with plane parallel and coaxial electrodes have been used to study the ion and electron concentrations in ammonia subjected to 120 kvp X-ray pulses of 17 and 30 ms duration. Differences in the numbers of positive and negative ions collected on the application of pulses of high voltage imply that free diffusion of electrons to the cell walls occurs in the early part of the X-ray pulse until it is inhibited by the positive ion space charge. Thereafter, positive and negative ions decay at equal rates.

The rate constant for the neutralization reaction

$$e + NH_4^+.nNH_3 \rightarrow \text{Neutral products}$$

at 1200 Torr of ammonia and 297 °K was calculated to be $4.2 \pm 1.0 \times 10^{-5}$ cm^3 ion^{-1} s^{-1}. However, unless extensive precautions are taken to remove electron-attaching impurities reactions between $NH_4^+.nNH_3$ ions and impurity negative ions are dominant. The results are discussed and compared to other work on electron–ion neutralization reactions.

On a utilisé des chambres d'ionisation possédant des électrodes planes parallèles et coaxiales afin d'étudier les concentrations d'ions et d'électrons dans de l'ammoniaque soumis à des expositions de rayons-X (120 kvp) d'une durée de 17 et de 30 ms. Les différences dans le nombre des ions positifs et négatifs recueilli lors d'application d'impulsions de haut voltage impliquent qu'une diffusion libre des électrons vers les parois de la cellule se produit au début de l'exposition de rayons-X jusqu'à ce qu'elle soit arrêtée par la charge des ions positifs dans l'espace.

La constante de vitesse pour la réaction de neutralisation

$$e + NH_4^+.nNH_3 \rightarrow \text{produits neutres}$$

à 1200 Torr en ammoniaque et à 297 °K est égale à $4.2 \pm 1.0 \times 10^{-5}$ cm^3 ion^{-1} s^{-1}. Cependant, à moins de prendre de sérieuses précautions afin d'enlever les impuretés susceptibles de fixer des électrons, les réactions dominantes sont celles entre les ions $NH_4^+.nNH_3$ et les impuretés ioniques négatives. On discute les résultats et on les compare aux autres travaux sur les réactions de neutralisation ion-électron.

[Traduit par le journal]

Can. J. Chem., 51, 4159 (1973)

Introduction

Ion neutralization reactions are an essential component of the mechanism of any gas phase radiolysis and a knowledge of their nature is therefore necessary for a complete understanding of such systems. For example, it is important to know whether ion neutralization is predominantly homogeneous or whether it occurs at the walls of the radiation cell (1). Also, when homogeneous processes *are* involved it is desirable to determine whether these are two- or three-body in nature, since the energetics and dynamics are different.

Rate coefficients for the neutralization reactions of various pairs of negative and positive ions have already been reported (2). Also, measurements of ion decay in ionization chambers have been used to determine the three-body neutralization coefficient α for the ions formed by pulse-radiolysis in several electron-attaching gases such as air (3), oxygen (4), the hydrogen halides, and nitrous oxide (5). However, apart from studies in high temperature flames (6) and recent work on the neutralization of positive ions of aromatic hydrocarbons in nitrogen (7), there is a lack of information on electron–ion neutralization processes in systems where electrons may remain free at the temperatures and pressures typically employed in radiation chemistry. The purpose of this investigation was to study ion recombination in ammonia utilizing the pulsed-X-ray ion decay technique. Drift tube experiments (8) have shown electrons to remain free up to at least 170 Torr in this gas and from high

pressure mass spectrometric studies (9) the positive ions formed by radiation are known to be $NH_4^+.nNH_3$.

Experimental

Materials

Research grade ammonia from the Matheson Company was purified and stored in a mercury-free high vacuum system fitted with an oil diffusion pump and a Wallace–Tiernan pressure gauge. It was thoroughly degassed by pumping on it during sublimation from one trap to a second which was held at liquid nitrogen temperature. After this, except in a few initial experiments (see below), it was sublimed into a tube containing metallic sodium and liquified until the characteristic blue color of sodium solutions in ammonia had appeared. This procedure served to remove water and electron-attaching impurities. Any gases evolved were pumped off, and if deemed necessary the ammonia was subjected to a second set of sublimations. Finally, it was stored at liquid nitrogen temperature in a tube containing sodium.

Irradiation Cells

Some experiments were carried out in a cyclindrical Pyrex cell with plain parallel ends serving as electrodes. This cell, with length 2 cm and diameter 10 cm, had a continuous aluminized electrode at one end and a 4 cm diameter collecting electrode circumscribed by an insulating space of 2 mm and a 10 cm diameter guard ring at the other end. However, most experiments were conducted in coaxial cells of the type shown in Fig. 1. The electrodes were constructed by coating the Pyrex surface with graphite. Prior to use all cells were baked under vacuum at a temperature of 400 °C for a period of at least 10 h. In most experiments a small side arm containing a sodium mirror was attached to the ionization chamber.

Lifetime Apparatus

The X-ray unit and rotating sector have already been described (5). The pulse widths used here were 17.6 or 30 ms, each being followed by an identical decay period.

Apart from a few minor modifications the design of the electronic system and bridge circuit were essentially the same as those used by McGowan (3). At a set delay time after each ionizing pulse a high voltage was applied to an electrode within the cell for a period of about 4 ms and the charge due to ions remaining in the calibrated volume of the cell was collected on a second electrode connected through the bridge to the input of a dynamic capacitor electrometer (Victoreen 475A). The time constant of the electrometer was long relative to the time of revolution of the sector, so that a steady electrometer current was recorded. The number of ions collected per revolution is equal to the magnitude of this current divided by the frequency of rotation of the sector and the electron charge (3).

Procedures

The ionization chambers were attached to the vacuum line and after evacuation and baking were filled with freshly degassed ammonia to the desired pressure. The ammonia was then condensed in the side-arm of the cell and the cell sealed off under vacuum. Subsequently, the ammonia was liquified, allowing any remaining electron-attaching impurities to react with electrons produced by dissolution of the sodium mirror in those cases where one was present. Following this treatment the ammonia was slowly evaporated into the cell leaving any solid reaction products in the sidearm. The cell was then placed in position in the ion lifetime apparatus. All experiments reported here were performed at 297 ± 2 °K.

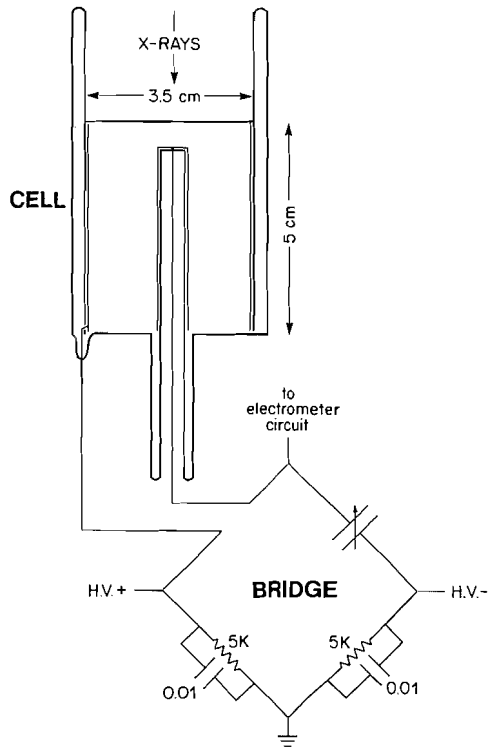

FIG. 1. Diagram of cylindrical cell with graphite coated coaxial electrodes. Cell is shown connected to bridge for (+,i) collection (see text).

Results and Interpretation

Effect of Oxygen and Electron-attaching Impurities

Typical behavior for an ammonia sample which was thoroughly degassed but had not been treated with sodium is illustrated in Fig. 2*a*. Assuming that the negative and positive ions have equal concentrations the value of α for homogeneous recombination is given by the slope of second-order plots of $1/n$ *vs.* decay time, where n is the ion concentration. Figure 2*a* gives such plots for n equal to the negative ion concentration for a 500 Torr sample of ammonia in the cylindrical cell with aluminum electrodes and guard ring. The line with closed circles was obtained

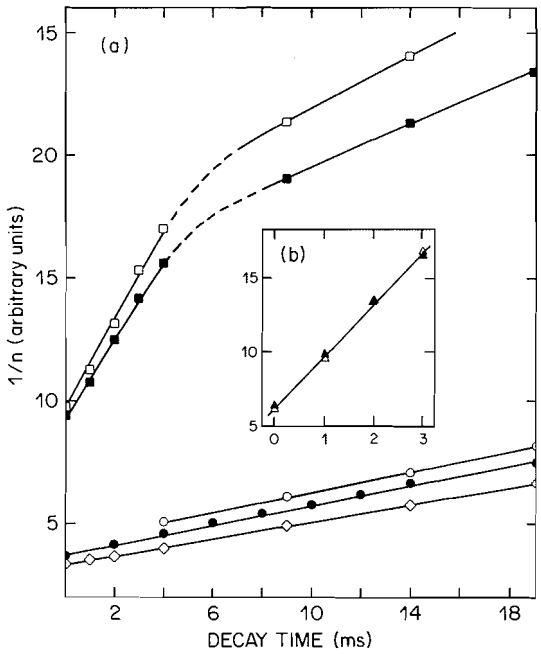

FIG. 2. Plots of $1/n$ *vs.* time: (*a*) Showing the effects of "radiation cleanup" and addition of oxygen for 500 Torr of NH_3 at 297 ± 2 °K in a cell with plane parallel aluminum electrodes. Accumulated doses in eV g^{-1} × 10^{-16} are: ●, ≃3; ○, ≃10; ■, ≃54; □, ≃100; and ◇, ≃100 after addition of ≃0.02 Torr of oxygen. (*b*) For 1200 Torr of "cleaned up" NH_3 at 297 ± 2 °K in a cell with coaxial graphite electrodes. △, after preirradiation to 10^{18} eV g^{-1}; ▲, same sample after treatment with sodium mirror.

immediately after preparation of the sample and gives $\alpha = 2.0 \times 10^{-6}$ cm^3 ion^{-1} s^{-1}. The other lines were observed after the doses stated in the figure caption had been absorbed by the sample. The increase in initial slope of the plots shows that α increases markedly with dose. The same type of behavior was observed in the cylindrical cells with graphite coated coaxial electrodes and in either cell at other pressures.

Using the G values for nitrogen and hydrogen production taken from the recent literature (10–12) it can be shown that the decomposition of 500 Torr of ammonia at a dose of 100×10^{16} eV per g would have been approximately 1.5×10^{-4}%. Since the products of irradiation, nitrogen and hydrogen, are non-polar and inert to electrons, at such small concentrations they should not influence the electron or positive ion reactions in the system. Furthermore, as has been previously reported (13) and further illustrated in Fig. 2*a*, the addition of minute traces of oxygen reduces the magnitude of α to 1.72×10^{-6} cm^3 ion^{-1} s^{-1}, which is typical of three-body ion neutralization coefficients in gases where the electrons are attached (5). We therefore attribute the change in α with initial irradiation in Fig. 2*a* to radiation removal of electron-attaching impurities. These are most likely to be oxygen and/or oxides of nitrogen, and they are probably converted to water and nitrogen in the reducing atmosphere of irradiated ammonia. The fact that the $1/n$ *vs.* time plots for irradiated ammonia in Fig. 2*a* bend over at decay times above 6 ms suggests that some long-lived ions are still present and that complete clean-up of electron-attaching impurities was not achieved at the doses given in Fig. 2*a*. However, as we shall see below the simple second order rate expression is not strictlyvalid under the present conditions and the curvature is due in part to this feature.

When the ammonia was liquified over sodium and thoroughly degassed prior to admission to the irradiation cell, values of α greater than 10^{-5} cm^3 s^{-1} were obtained without any previous irradiation treatment. When sodium was also present in the small side-arm attached to the ionization chamber and the ammonia was condensed on it after sealing off the cell, then very little pre-irradiation was required before the α value became independent of dose. At that point further treatment with sodium in the side-arm of the cell was also without effect. Figure 2*b* illustrates this for an ammonia sample at a pressure of 1150 Torr in a cell of the design shown in Fig. 1 with negative ions collected. The sample was irradiated to a total absorbed dose of about 10^{18} eV g^{-1} before the measurements plotted as open triangles were taken. It was then condensed on the sodium mirror and liquified. As shown in Fig. 2*b* this produced no change in the ion concentrations or the value of α.

The remainder of the experiments with ammonia were performed with samples which had been treated with sodium both prior to and after admission to the ionization chamber. They were also irradiated until no further change was observed in the ion concentrations before determinations of α were made.

Positive and Negative Ion Concentrations

For cells with coaxial geometry having a small axial electrode and a larger outer electrode four different collection arrangements are possible. First, the inner electrode can be attached

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

For personal use only.

to the point on the bridge at which the electrometer is connected (see Fig. 1) and the outer electrode to the same bridge terminal as the positive lead from the high voltage pulser. This causes positive ions to be collected on the inner electrode and is henceforth signified by (+,i). Reversal of the polarity of the voltage pulser causes negative ions to be collected on the inner electrode and is referred to as (−,i). The electrometer can also be made to receive current from the outer electrode by simply reversing the leads to the cell. The collection modes (+,o) and (−,o) can then be achieved by appropriate choice of polarity of the voltage pulser.

Because of the novel character of the results with ammonia some preliminary observations with air are presented first. As well as providing a useful check on the apparatus, they permit direct comparison between the behavior in ammonia and a typical electron-attaching gas in the same cell. Figures 3*a* and *b* show plots of $1/n$ and n *vs.* time for 660 Torr of air in the cell with coaxial electrodes. The points at negative times in Fig. 3*b* are for runs in which the collection of ions was pushed back into the period of irradiation. In these cases the number of ions collected per sector revolution exceeds the number present at the instant the voltage was applied by an amount equal to the product of the period of overlap of the high voltage with the radiation and the rate of ion production. The latter quantity can be determined by measuring the rate of ionization with the sector stopped. The ion concentrations at negative times in Fig. 3*b* were all corrected in this way. The concentrations of negative ions observed for (−,i) collection are seen to be identical for collection times of 1.5 and 4 ms and to be the same within experimental error as the positive ion concentrations for (+,i) collection.

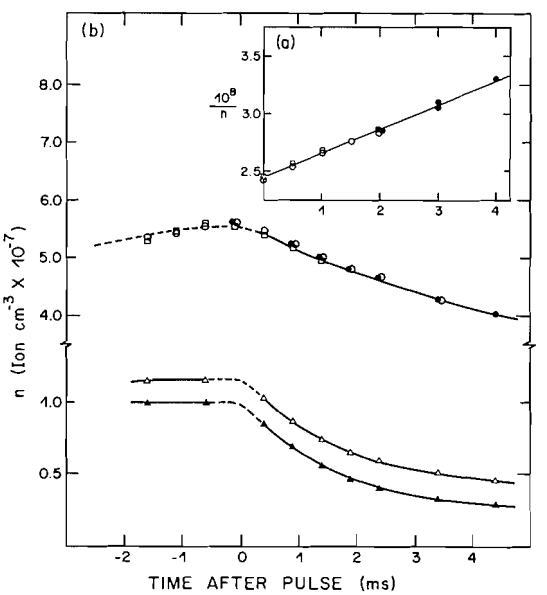

FIG. 3. Plots of $1/n$ and n *vs.* time after radiation pulse for air and ammonia in the cell with coaxial electrodes. Points on the line in Fig. 3*a* and upper curves in 3*b* are for 660 Torr of air with: ●, 1.4 ms (−,i) collection; ○, 4 ms (−,i) collection; and □, 4 ms (+,i) collection. Points on the two lower curves in Fig. 3*b* are for 1200 Torr of ammonia with: ▲, 4 ms (−,i) collection; and △, 4 ms (+,i) collection, respectively.

The slope of the single line through the second order plots in Fig. 3*a* gives $\alpha = 1.57 \times 10^{-6}$ cm^3 ion^{-1} s^{-1}, in good agreement with 1.63×10^{-6} observed by McGowan (3) for untreated laboratory air at a similar ion density and ion age. The line drawn through the data in Fig. 3*b* was calculated from this value of α and the steady ionization rate (6.12×10^9 ion pairs cm^{-3} s^{-1}).

The two lower lines in Fig. 3*b* are respectively the electron and positive ion concentrations calculated from the (−,i) and (+,i) ion currents for 1200 Torr of ammonia with a 4 ms collection period. The end of pulse concentrations are close to a steady state situation and when taken in conjunction with the rate of ionization during the radiation pulse (3.44×10^9 ion pairs cm^{-3} s^{-1}) they require $\alpha > 3 \times 10^{-5}$ cm^3 ion^{-1} s^{-1}, which is to be compared with similar high values from plots such as Fig. 2*b* and with $2.5 \pm 0.5 \times 10^{-5}$ cm^3 ion^{-1} s^{-1} previously reported (13) for ammonia at 500 Torr.

Of special interest is the significant difference between the positive ion and electron concentrations, which clearly exists before the end of the radiation pulse and continues through the decay period. Its occurrence is in complete contrast to the straightforward behavior discussed above for air and previously observed in other electron-attaching gases studied in this laboratory. Furthermore, there was no difference between the positive and negative ion concentrations for ammonia to which traces of oxygen had been added or from which the electron-attaching impurities had not been removed. For these reasons and because electrons have much higher diffusion coefficients and mobilities than molecular ions the present behavior in purified am-

For personal use only.

monia is attributed to losses of electrons which occur prior to the application of the collecting field. Mechanisms for this are considered below.

From experiments on the drift velocity of electrons in gaseous ammonia (8, 14) it can be shown that the diffusion coefficient of electrons at 297 °K and 1200 Torr should be 3 ± 1 cm^2 s^{-1}. By contrast the ammonium positive ions which would be clustered at our pressure by 5 or more ammonia molecules (9) will have a diffusion coefficient of about 0.015 cm^2 per s. (This has been calculated from expression (9–3–14) of ref. 15.[1]) Theoretical (17) and experimental studies (15) on plasmas have shown that when such a disparity in diffusion coefficients exists a significant fraction of the electrons produced during the ionization period may diffuse to the walls of the cell before their movement becomes controlled by the space charge resulting from the excess of positive ions which builds up in the body of the cell and the growing wall potential. At this point the effective diffusion coefficient of the electrons, D_s, falls appreciably below the free diffusion coefficient, D_e, while that of the positive ions rises above D_+, causing the wall currents of electrons and positive ions to become equal (17, 18). Assuming no stray potentials or imbalance of the bridge, the number of electrons diffusing to the inner and outer electrode in the cells with coaxial geometry should be in the first approximation proportional to their areas.[2] Since the inner one has one quarter of the area of the outer, 80% of the electrons which diffuse to the two electrodes during the period of free diffusion will be lost for (−,i) collection, whereas only 20% will be lost for (−,o) collection. Thus, the difference between the apparent electron concentrations derived from (−,o) and (−,i) collection should correspond to approximately 60% of the wall loss of electrons during the period of free diffusion.

Wall diffusion of electrons will also effect the apparent concentration of positive ions. When positive charge is collected the net current recorded by the electrometer is the difference between the number of positive ions arriving at the electrode during the period of collection and the number of electrons which reached it during the period of free diffusion. There should therefore be correspondence between the apparent ion concentrations derived from (+,i) and (−,o) ion currents and between those from (−,i) and (+,o). This correspondence is established in Fig. 4*a* in which plots of apparent ion concentration *vs.* time for all four methods of collection are presented. The 1200 Torr sample of ammonia was irradiated with the same X-ray intensity for each collection mode and the pulse widths were 17.0 ms.

The high mobility of electrons in ammonia (~ 150 cm^2 s^{-1} V^{-1} calculated from data in ref.

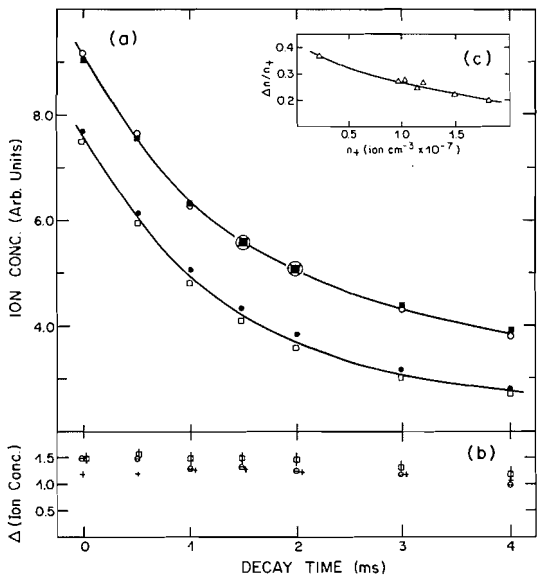

FIG. 4. Apparent ion concentrations *vs.* time for a 1200 Torr sample of ammonia in the cell with coaxial electrodes. (*a*) Apparent ion concentrations for □, (+,o); ●, (−,i); ■, (+,i); and ○, (−,o) plotted as a function of decay time. (*b*) For the same sample as in (*a*) above: ⊞, difference between n_+ from (+,i) and (+,o) collection; ⊖, difference between n_- from (−,o) and (−,i) collection; For a duplicate sample: +, difference between n_+ from (+,i) and (+,o). (*c*) $\Delta n/n_+$ (see text) plotted as a function of n_+.

[1]This expression actually gives the ion mobility K_+. However for our conditions the identity $D = KkT/e$ should hold (15). It should also be noted that the calculated value of K_+ (and hence D_+) for $NH_4^+.nNH_3$ does not change drastically with n, 0.82 and 0.60 cm^2 V^{-1} s^{-1} for $n = 4$ and 8, respectively (*cf.* 0.74 and 0.67 for positive ion clusters of $n = 2$ and 4 in H_2O (16)).

[2]The above analysis is approximate since the ends which constitute some 20% of the total area of the cell walls are neglected. However, electron loss to these insulating surfaces should be much less than to the electrodes, for while the former will build up a wall potential negative charge arriving at the electrodes will leak away through the electrometer or bridge circuit. Thus the positive ion space charge will be the single important factor controlling electron diffusion to the electrode surfaces. By the same token one may expect somewhat larger electron deficits in our cells than in systems without only insulating walls.

14 as opposed to 0.5 to 3 for molecular ions, *cf.* ~2.2 for O_2^- in oxygen from ref. 19) means that stray potentials arising from minor imbalances in the bridge circuit or contact potentials in the cell electrodes could also cause a preferential electron current to the outer electrode. The complete reversibility of the system as exemplified in Fig. 4*a* eliminates any possibility of a large contribution from circuit imbalance. The effect of contact potentials is harder to assess. However, when subjected to continuous irradiation and connected to the electrometer with no applied potential, the cells used here usually gave only small ionization currents,[3] and in some instances, as for example the cell with the ammonia used for the experiments in Fig. 4*a*, the ionization current corresponded to electron transport to *the inner* electrode, not the outer. Also the electron deficit was reproducible from one coaxial cell to another and was observed in the 10 cm diameter cell with plane parallel aluminum electrodes. These observations lead to the conclusion that it is primarily caused by free diffusion of the electrons and not by fortuitous contact potentials.

To determine whether the electrons continued to diffuse independently of the positive ions during the period of decay, the differences between the (−,o) and (−,i) concentrations and between the (+,i) and (+,o) concentrations were plotted as a function of time after the irradiation pulse in Fig. 4*b*. A similar plot of the difference between (+,i) and (+,o) for a different run under similar conditions is given for comparison. In all three instances the magnitude of the difference is seen to remain reasonably constant and perhaps to decrease slightly at longer times. This confirms that free diffusion of electrons has ceased at the end of the pulse, if not before. The magnitude of the fractional electron deficit $\Delta n/n_+$ $(=(n_+ - n_-)/n_+)$ calculated from the ion concentrations is shown as a function of the positive ion concentration n_+ in Fig. 4*c*.

Kinetics of the Ion and Electron Decay

The electron deficiencies noted above have quite far-reaching kinetic consequences. First, although the initial slopes of $1/n_+$ or $1/n_e$ *vs.* time plots are linear and provide an estimate of α and a useful measure of the purity of the ammonia samples, the simple rate expression.

$$[1] \qquad \alpha t = \frac{1}{n} - \frac{1}{n_0}$$

does not apply. Secondly, the spatial distributions of the electrons and positive ions at the end of the pulse differ. Thirdly, as the ion concentrations decrease during the decay period the rate of diffusion of both electrons and positive ions to the wall will increase. This is shown both by the theoretical analysis of Allis and Rose (17) and recent experiments (18). In the light of these facts we chose to avoid the use of integrated rate expressions, and calculated the neutralization coefficient from the slopes of ion decay plots and the concentrations of electrons and positive ions at 1 ms after the irradiation pulse. These values are referred to as α_{app}, since they require correction for spatial inhomogeneity and the wall diffusion contribution to decay.

Both the present experimental data in Fig. 4*c* and theoretical work (17, 18) show that $(n_+ - n_-)/n_+$ becomes smaller as n_+ increases. Furthermore, it is well known that the contribution of wall diffusion to α_{app} decreases with ion density (20). Therefore to minimize the uncertainty from these two sources values of α_{app} were plotted against $1/n_+$ in Fig. 5 and extrapolated to $1/n_+ = 0$. The intercept gave $\alpha = 4.2 \times 10^{-5}$ cm^3 ion^{-1} s^{-1} for ammonia at 298 °K and 1200 Torr. The remaining uncertainty should not exceed ±25%, which is the magnitude of $(n_+ - n_-)/n_+$ at $n_+ = 1.5 \times 10^7$ (see Fig. 3*c*).

Discussion

The effects illustrated in Fig. 2*a* demonstrate the need for extreme care in ensuring the removal of electron-attaching impurities from gases which

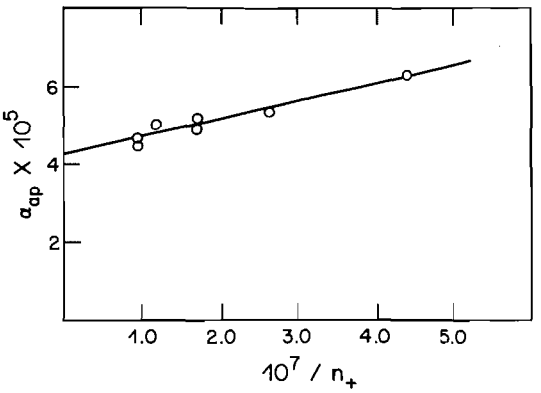

FIG. 5. Plot of α_{app} *vs.* $1/n_+$.

[3]Approximately 0.1% of the saturation ionization current with applied voltage.

are themselves unreactive toward electrons.[4] This is particularly serious in low dose-rate studies with Co^{60} sources which produce steady state ion concentrations of $n_+ \lesssim 10^8$ ion cm^{-3}. Here as little as $4 \times 10^{-4}\%$ of an impurity with a three-body attachment coefficient of $\sim 4 \times 10^{-30}$ cm^6 $molecule^{-2}$ s^{-1} (*cf.* oxygen, Table 6.7 of ref. 14) in a non-attaching gas at normal pressure will scavenge all electrons, altering the nature of the ion neutralization reactions until cleanup has been achieved. For other impurities with two-body electron capture reactions even lower levels of impurity may be required. The present experience with ammonia shows that pumping during sublimation does not remove all attaching components. Thus, impurities other than oxygen may be present.

Electron deficits do not appear to have been recognized previously in gases under conditions relevant to radiation chemistry. However, as indicated above the present observations are qualitatively in accord with theoretical and experimental studies of low pressure plasmas. Furthermore the mathematical analysis of Kregel (21) for Frieberg and Weaver's data (22) on isothermal helium plasmas leads to electron deficits of $1–2 \times 10^6$ cm^3. These are in the same range as the deficiencies that can be calculated from our data (*cf.* Figs. 3*b* and 4*c*), and they give comparable electrical fields of 0.5–1.5 V at the cell perimeters (21).

Ion–ion neutralization reactions in gases at normal pressure typically have neutralization coefficients of 3×10^{-6} ion cm^{-3} s^{-1} or less (5, 15) and the present value of α is some ten to twenty times larger. In a preliminary note (13) this was attributed to the approximately hundred-fold larger relative velocity for electron–ion collisions, and it should be noted that the three other neutralization reactions reported to have $\alpha \gtrsim 10^{-5}$ cm^3 ion^{-1} s^{-1} involve collisions of this type. Thus, the room temperature rate constant for hydronium neutralization

[2] $e + H_3O^+ \rightarrow$ Neutral products

calculated from the flame ionization data of Kelly and Padley (6) is 8×10^{-6} cm^3 ion^{-1} s^{-1}, and Lawrence and Firestone (23) have reported $k_3 = 7.6 \times 10^{-4}$ cm^3 ion^{-1}

[3] $e + CH_5^+ \rightarrow$ Neutral products

from a competition kinetic study. More recently Sauer and Mulac (7) have observed a value in excess of 10^{-5} cm^3 ion^{-1} s^{-1} for k_4

[4] $e +$ naphthalene$^+ \rightarrow$ Neutral products

in a pulse radiolysis study.

In addition to the high relative velocity of approach large neutralization coefficients require an efficient mechanism for stabilization of the electron–ion pair. In this connection it should be noted that the positive NH_4^+ ions would have been heavily clustered in ammonia at the temperatures and pressures used here. Indeed from the results of high pressure mass spectrometry (9) we conclude that the proportion of ions with n less than 5 taking part in reaction 5

[5] $e + NH_4^+.nNH_3 \rightarrow$ Neutral products

would have been negligible. Furthermore, n may be as large as twenty, and ionic radii of 8 Å and higher may be expected. Since the electron may approach to within 13 Å or less of the positive ion,[5] the chances of its exciting vibrations in the cluster are relatively high and clustering may greatly enhance the cross section for stabilization in two body encounters. Further work will be required before the relative importance of this and other possible mechanisms of stabilization, such as radiation emission and collision with a neutral molecule, can be established. Continued investigations of the present kind should yield information concerning the temperature and pressure dependence of α in ammonia. It is also expected that the work will be extended to hydrocarbons and other gases of common interest to radiation chemists.

The authors are indebted to Dr. D. E. Wilson for many helpful discussions and for contributing to experimental data during the early part of this work. They also

[4]It is worth noting that a 60% increase in the electron drift velocity in ammonia was observed under conditions which caused a 20% decomposition (8). Since no special precautions to remove electron-attaching impurities were reported it would seem that these effects could have been due to the slowing of the electron drift by attachment–detachment reactions with impurities, which were cleaned up on long exposure to electrons as in the present instance. The value of D_e in NH_3 at 1200 Torr may therefore be larger than 3 cm^2 s^{-1} calculated above.

[5]From collision theory it can be shown (*cf.* ref. 2) that the cross section derived from $\alpha = 4.2 \times 10^{-5}$ cm^3 ion^{-1} s^{-1} effectively corresponds to approach of the electron to a distance of 13 Å or less from the positive charge. Strong interactions with the clustered molecules should therefore occur.

Ring C Functionalized Diterpenoids. Part II.[1] Cleavage of the Cyclopropane Ring in Methyl *ent*-Trachyloban-19-oate with Thallic Acetate

HELEN MARGARET CAMPBELL, PATRICK ALISTAIR GUNN, ALAN JAMES MCALEES, AND ROBERT MCCRINDLE[2]

Chemistry Department, University of Guelph, Guelph, Ontario N1G 2W1

Received July 26, 1973

Reaction of methyl *ent*-trachyloban-19-oate (**1***a*) with thallic acetate gave four major products including the *ent*-atisane derivatives, **2–4**. Since the substrate is readily obtainable from the common sunflower, this reaction provides a valuable route to these and related compounds. The fourth compound, **5**, may derive from an *ent*-atisane intermediate by contraction of ring D.

La réaction de l'*ent*-trachylobanoate-19 de méthyle avec l'acétate thallique a conduit à quatre produits majeurs dont les dérivés **2–4** de l'*ent*-atisane. Puisque le substrat est facile à isoler du tournesol commun, cette réaction permet donc d'obtenir aisément ces différents produits. Le quatrième composé, **5**, peut provenir d'un intermédiaire *ent*-atisane par contraction du cycle D. [Traduit par le journal]

Can. J. Chem., **51**, 4167 (1973)

As indicated in the preceding paper, we have been interested in synthesizing ring C oxygenated diterpenoids, among them 13-substituted *ent*-atisanes. Consideration of short yet potentially efficient routes to the latter led us to investigate the reaction of methyl *ent*-trachyloban-19-oate (**1***a*) with thallic acetate in acetic acid. It was anticipated that this oxidative cleavage would lead to functionalized derivatives of the type required since **1***b* is known to give predominantly isoatisirene (**6**) when exposed to electrophilic reagents such as protonic (2, 3) or Lewis (4) acids. The present paper deals with the four major products obtained by oxidative cleavage of **1***a* with thallic acetate and indicates that this reaction does indeed provide a useful route to 13-substituted *ent*-atisanes.

Extraction (1) of sunflower (*Helianthus annuus*) heads, depleted of seeds, afforded *ent*-trachylobanic acid, the methyl ester (**1***a*) of which was then treated with thallic acetate in acetic acid at 75° for 4 days. The fractions obtained by chromatography of the product over alumina fell, on t.l.c. analysis, into four main groups. The first of these consisted of substrate (20%). The second group (38%, based on substrate consumed) obviously contained several compounds and indeed subsequent investigations of these fractions have revealed the presence of at least 12 components, olefinic monoacetates and ketones. The next group (26%) comprised three diacetates while the ultimate fractions (*ca.* 7%) contained more polar compounds which have not yet been examined further. Four of the reaction products were present in major amount, two olefinic monoacetates and two diacetates. The former pair were contained in several of the more polar fractions in the second group. Since these could not be resolved readily by preparative t.l.c. they were combined and subjected to mild hydrolysis with sodium hydroxide in aqueous methanol, conditions which did not affect the carbomethoxy group. The two major components of the resulting mixture were separated and purified by preparative t.l.c., first on silica gel and then silica gel – silver nitrate (12%). The less polar of the two was an allylic alcohol (**7***a*; 8%),[3] m.p. 163–164°. Multiplets at τ 4.11 (d, 1 H-14), 4.48 (q), and 6.57 (d) and singlets at τ 9.54 (3 H-20), 8.89 (3 H-17), and 8.83 (3 H-18) show the presence of an isolated allylic system (*cf.* ref. 5) and of three quaternary methyl groups respectively. The high-field position of the C-20 methyl resonance results from shielding by the Δ^{13} olefinic bond (5, 6). The hydroxyl group is placed at C-12 rather than at C-14 since a very large downfield shift of the C-17 methyl group resonance is observed upon addition of tris(dipivaloylmethanato)europium ($Eu(dpm)_3$), the normalized (7) ratio of the shifts induced in the methyl resonances being 10:2.7:1.4 for C-17,

C-20, and C-18, respectively. Use of the shift reagent also resolves the two doublets ($J = 11$ Hz) expected for the isolated C-15 methylene group. The observation that the magnitude of the lanthanide induced shift of the resonance of one of these protons (the α proton) is even greater than that of the C-17 methyl resonance (normalized ratio 10:7.7, respectively) allows assignment of the β configuration to the hydroxyl function. Conversion of the allylic alcohol (**7***a*) into the corresponding acetate (**5**) and ketone (**7***b*) and a study of their spectroscopic properties reinforced our conclusions concerning the structure of **7***a*. Further support for this structural assignment comes from the plausible nature of the mechanism one may write (see below) to explain the formation of **5** from **1***a*. It was shown by analytical t.l.c. on silica gel and silver nitrate – silica gel that the acetate (**5**) prepared from **7***a* was indeed a major product in the original monoacetate fraction.

The second component isolated from the hydrolysis mixture was the hydroxy ester **8***a* (10%), m.p. 124°, acetylation of which yielded **2**, m.p. 130–132°, the major constituent of the entire monoacetate fractions (t.l.c. evidence). Easily identified in the n.m.r. spectra of **2** and **8***a* are resonances attributable to two tertiary methyl groups, a carbinyl like proton, and a proton and a methyl group attached to an olefinic bond. The presence of these structural features and of —OH···π hydrogen bonding in the i.r. spectrum of **8***a* led us to consider two structures **2** and **9***a*, obtainable from **1***a* by scission of the C_{13}—C_{16} or C_{12}—C_{16} bonds, respectively, for the acetate. The former alternative was soon judged as more acceptable for three reasons. First, on mechanistic grounds, it was anticipated by analogy with the reaction of trachylobane (**1***b*) with acids (see above) that the C_{13}—C_{16} bond would be more susceptible to electrophilic attack. Second, the values of the chemical shift of the olefinic proton for the alcohol (τ 4.35) and the acetate (τ 4.27) accord more closely with those expected (8, 9) for isoatisirene (*ca.* τ 4.2–4.5) rather than isokaurene (*ca.* τ 5) derivatives. Third, in the n.m.r. spectrum of the derived ketone, m.p. 176–179°, if the structure were **8***b*, 2 H-14 should give rise to an AB quartet while in **9***b* the equivalent geminal pair of protons α to the ketonic carbonyl should show additional coupling to H-9. In fact the ketone shows a clean doublet (τ 7.39) with a spin–spin coupling (J_{AB} = 19 Hz) of the magnitude predicted (10) for a methylene group α to a carbonyl. This resonance is ascribed to the α-oriented hydrogen[4] at C-14. Unfortunately, the resonance due to the β-hydrogen, which is shielded by the double bond, is obscured by other resonances at higher field, even when the spectrum is recorded in benzene or in the presence of $Eu(dpm)_3$.

Since none of these arguments is compelling, more convincing proof of the structure of these compounds was sought. An obvious possibility would be to remove the oxygen function from ring C, thus forming **8***c* or **9***c*, both known (9) compounds, and two attempts were made to accomplish this. In the first, the possibility of forming the *p*-toluenesulfonate **8***d* or **9***d* and then removing this group reductively with lithium aluminum hydride was explored. However, as feared (*cf.* ref. 11), although the ester formed, it decomposed on work-up and gave[5] the alcohol **10**. It should be noted that the production of **10** does not serve to distinguish be-

[4]In this paper substituents designated α or β on the α-bridge of rings C–D refer to orientations *syn* and *anti* to C-20, respectively.

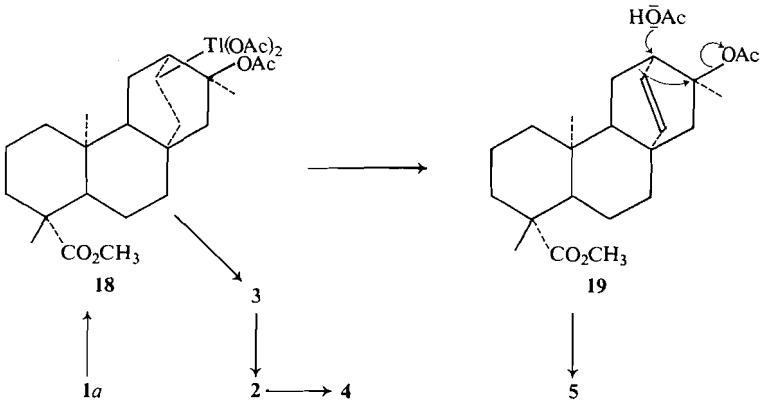
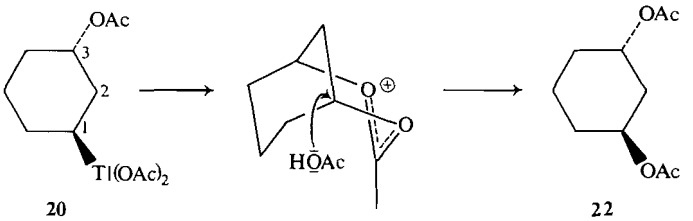
tween the possible structures of the tosylate, **8***d* or **9***d*, since *both* could readily rearrange to this alcohol. In the second attempt, the thioketal of the ketone (**8***b* or **9***b*) was prepared and treated with freshly prepared Raney nickel in acetone. The only pure product isolated by preparative t.l.c., in small yield, was an unstable diene, m.p. 132–136°, *m/e* 314, of probable structure **11**. It has n.m.r. resonances attributable to three olefinic protons at about τ 4, a methyl attached to a double bond, and two tertiary methyls, one of which (C-20) is strongly shielded by the new double bond and resonates at τ 9.58. A minute fraction, which appeared to be the expected isoatisirene **8***c* from its t.l.c. and g.l.c. behavior, was also isolated. There was no detectable amount of the isokaurene derivative **9***c* in the product. It seems likely that two major effects combine to reduce very severely the yield of the desired product, namely, the steric hindrance experienced by C-13 from the C-20 methyl group and the ease with which the system rearranges. Thus intermediate radicals at C-13 rather than attaching hydrogen atoms might form **11** or rearrangement products. In any event the reaction did not provide unambiguous proof of the structure of the substrate and therefore one further attempt was made to achieve this.

Catalytic hydrogenation of **8***a* afforded two alcohols the structures of which were readily assigned. The major, m.p. 134–135°, is the less polar on t.l.c. as would be expected if the hydroxyl and the C-17 methyl group interact sterically as in **12***a*. This conclusion gained strong support from the observation that $Eu(dpm)_3$ induces a much larger chemical shift change for the C-17 methyl in **12***a* (normalized ratio, C-17: C-20:C-18, 10:2.8:1.3) than in the minor alcohol **12***b*, m.p. 121–123° (corresponding ratio, 10:7.3:3.1). The tosylate (**12***c*) of the major alcohol when exposed to sodium *t*-amylate in *t*-amyl alcohol at 85° for 15 h formed three products (*cf.* ref. 12) which were separated by preparative t.l.c. on silver nitrate–silica gel. Structures were assigned to the two less polar, minor, products on chromatographic and spectral evidence only. The least polar of the three has *m/e* 316 (M) and an identical t.l.c. mobility to that of **1***a* on silver nitrate – silica gel but a slightly longer g.l.c. retention time on SE-30. Since its n.m.r. spectrum is devoid of resonances attributable to an olefinic proton but does indicate the presence of one secondary and two tertiary methyl groups in the molecule it may be formulated as **13**. The compound of intermediate polarity was readily recognized as a *t*-amyl ether from the complexity of the methyl region in its n.m.r. spectrum and the molecular ion peak at *m/e* 404 and the expected fragmentation pattern in its mass spectrum. Bearing in mind its genesis it may be assigned the tentative structure **14**. The most polar, major product, m.p. 89–93°, had n.m.r. signals from two olefinic protons (τ 4.05, d, J_{obs} = 4 Hz) and one secondary and two tertiary methyl groups. Two distinct pieces of evidence allowed a firm assignment of structure (**15**) to the compound. First, one of the tertiary methyl groups resonates at τ 9.61. This reveals that the double bond is exerting a marked shielding effect on the C-20 methyl group as is found in isoneoatisirene derivatives (6) but not in Δ^{11}-kaurenes (1, 13). Second, one of the most intense peaks in its mass spectrum appears at *m/e* 274(M − 42) and results from a retro-Diels–Alder reaction, a mode of cleavage which is unavailable to Δ^{11}-kaurenes. Thus the major component in the monoacetate fraction from the oxidative cleavage could be formulated as **2** rather than **9***a*.

The diacetate fraction, which contained three components, was subjected to preparative t.l.c. This yielded very major portions of both the most and the least polar of these in an essentially pure state. The remaining, minor, component has not been obtained free of the former. The n.m.r. spectrum of the least polar diacetate **3**, m.p. 162–163°, has a broad multiplet at τ 5.14 arising from a proton of the type C*H*OAc but no other low-field signals. Also present are singlets attributable to three methyl groups at τ 9.24 (C-20), 8.87 (C-18), and 8.42 (C-17), the chemical shift of the last reflecting its attachment to a carbon atom which in addition bears an acetate group. The similarity of several aspects of this n.m.r. spectrum to that of **2**, bearing in mind the expected (14) *trans* addition involved in the opening of the cyclopropane ring, led to a tentative assignment of structure **3** to this compound. The following transformations fully endorsed this conclusion. Pyrolysis of the diacetate at 200°/15 mm gave **2** while hydrolysis afforded the diol **16***a*, m.p. 220–221°. Significantly, i.r. spectra of dilute solutions of the derived diol monoacetate **16***b*, ν_{OH} 3612 cm^{-1}, show no evidence of intramolecular hydrogen bonding and thus the configuration at C-16 must



SCHEME 1



SCHEME 2

be as shown in **16** and **3**. A plausible structure (**4**) for the most polar diacetate was readily deduced by comparing its n.m.r. spectrum with that of **2**, the only outstanding difference being that the resonance at τ 8.24 (3 H-17) in the latter is replaced by one at τ 5.52 (2 H-17) in the former. Evincive evidence for this structure was obtained by subjecting the diacetate to hydrogenation in ethanol–triethylamine over palladized charcoal. One of the two products was simply the oily dihydro derivative **17**; however the other product was **2**, formed by hydrogenolysis of the allylic acetate group. It is noteworthy that **12***d* was not detected in the product.

The production, in reasonable yield, of **2** (10%), **3** (18%), and **4** (6%) by oxidative cleavage of methyl *ent*-trachyloban-19-oate represents an effective route to synthetically versatile *ent*-atisane intermediates. Especially attractive are the following aspects. The substrate is readily obtained from the common sunflower. The yield of monoacetate **2** can be bolstered, if desired, by its formation from **3** (*ca.* 90%) and **4** (*ca.* 55%). Finally, the axial substituent at C-4 provides a handle for the introduction of substituents into rings A and B.

Work is progressing on the minor products from the oxidative cleavage of **1***a* and the results will be presented later along with a detailed discussion of the mechanistic pathways to the various products. However, a provisional scheme which satisfactorily explains the production of compounds **2–5** is outlined (see Scheme 1, **18** and **19**). The formation of **18** involves a *trans* opening of the cyclopropane ring on reaction with thallic acetate as postulated (14). In the simple systems (*e.g.* **20**) upon which mechanistic conclusions have been based, solvolysis of the thallic substituent has been suggested to involve participation of the C-3 acetate group. Attack of acetate anion on this bridged acetoxonium ion (**21**) then leads to the observed product, the *trans* diacetate (**22**) (Scheme 2). In the present case (**18**), bridging of this nature is sterically impossible and retention of configuration at C-13 would appear to be most reasonably explained by internal nucleophilic substitution.

Experimental

Melting points are uncorrected and were determined on a Kofler hot-stage apparatus. For normal analytical and preparative t.l.c., chromatoplates were spread with

Kieselgel G. (Merck), while silver nitrate – silica gel chromatoplates in addition contained 12% of the former. Gas liquid chromatography was carried out with a Varian Aerograph 1200 gas chromatograph using a stainless steel column ($\frac{1}{8}$ in. × 10 ft packed with 5% SE-30) and nitrogen as carrier gas with a flow rate of 25 ml/min. Light petroleum was of b.p. 60–80°. Microanalyses were by Mr. H. S. McKinnon, Guelph. Infrared solution spectra were recorded in carbon tetrachloride on a Beckmann I.R. 12 spectrophotometer and u.v. spectra in ethanol on a Unicam S.P. 800 spectrophotometer. Proton magnetic resonance spectra were run on a Varian Associates A-60A or HA 100 spectrometer in carbon tetrachloride, unless otherwise stated, using approximately 0.3 *M* solutions and tetramethylsilane as internal standard. Mass spectra were run on a Varian Associates CH 7 instrument.

The Oxidative Cleavage

The ester **1***a* (3.40 g) was treated with thallic oxide (1.5 g) in glacial acetic acid (65 ml) for 2 days at 75° with stirring. More thallic oxide (1 g) was then added and the reaction allowed to proceed for a further 2 days. The solvent was removed *in vacuo* and the residue extracted with ether. This extract was washed carefully with saturated aqueous sodium bicarbonate (twice) and brine. The resulting solution was dried and the solvent evaporated to afford an oil (3.60 g). This oil was chromatographed over alumina (Fisher; 80–200 mesh; 120 g) in light petroleum. Elution with light petroleum – ethyl acetate (49:1) afforded starting material (690 mg) and with light petroleum – ethyl acetate (24:1) seven fractions (1.227 g total) containing several compounds of very similar mobility on t.l.c. The last three of these were combined (556 mg) and hydrolyzed with excess sodium hydroxide in refluxing methanol for 1 h (see below). Fractions (966 mg total) eluted with light petroleum – ethyl acetate (23:2) contained compounds giving three poorly resolved spots on t.l.c. (ethyl acetate – light petroleum, 1:4). These fractions were combined and subjected to preparative t.l.c. (ethyl acetate – light petroleum, 1:9, run thrice) (see below). Further elution of the column with light petroleum – ethyl acetate (9:1, 1:1, and 1:9) gave complex mixtures (289 mg) of more polar materials (t.l.c. evidence).

The hydrolysis products (see above) were separated by preparative t.l.c. (ethyl acetate – light petroleum, 1:9, run twice) and afforded the two major components. The least polar was the hydroxy ester *7a* (212 mg) which was further purified by preparative t.l.c. on silver nitrate – silica gel (ethyl acetate – light petroleum, 3:7) and then crystallization from a mixture of these two solvents. It had m.p. 163–164°; ν_{max} 3620 and 1730 cm^{-1}; τ 4.11 (d, 1 H-14, J = 9.5 Hz), 4.48 (q, 1 H-13, J = 3.5 and 9.5 Hz), 6.57 (d, 1 H-12, J = 3.5 Hz; s on irradiation at 4.48), 8.83 (s, 3 H-18), 8.89 (s, 3 H-17), and 9.54 (s, 3 H-20); in presence of 0.4*M* Eu(dpm)$_3$ τ 2.25 (d, 1 H-14, J = 9.5 Hz), 3.62 (d, 1 H-15, J = 11 Hz), 5.02 (s, 3 H-17), 6.46 (d, 1 H-15, J = 11 Hz), 8.27 (s, 3 H-18), and 8.48 (s, 3 H-20); *m/e* 332 (M).

Anal. Calcd. for $C_{21}H_{32}O_3$: C, 75.86; H, 9.70. Found: C, 75.76; H, 10.00.

The derived (acetic anhydride – pyridine) acetate (**5**) had a mobility on t.l.c. on silica gel (ethyl acetate – light petroleum, 1:9) and silver nitrate – silica gel (ethyl acetate – light petroleum, 3:7) identical with that of one component of the fractions which had been hydrolyzed (see above). After crystallization from methanol it had m.p. 130–132°; τ ($CDCl_3$) 3.94 (d, 1 H-14, J = 9.5 Hz), 4.46 (q, 1 H-13, J = 3.5, 9.5 Hz), 5.14 (d, 1 H-12, J = 3.5 Hz), 7.96 (s, 3H, —OCO*CH*$_3$), 8.81 (s, 3H, —*CH*$_3$), 8.92 (*s*, 3H, —*CH*$_3$), and 9.49 (s, 3 H-20).

Anal. Calcd. for $C_{23}H_{34}O_4$: C, 73.76; H, 9.15. Found: C, 73.97; H, 9.16.

The more polar, major, component obtained by preparative t.l.c. of the hydrolysis products was the hydroxy ester **8***a* (287 mg). It also was further purified by preparative t.l.c. on silver nitrate – silica gel (ethyl acetate – light petroleum, 3:7) and then crystallization from a mixture of these two solvents. It had m.p. 124°; ν_{max} 3620 (free OH), 3603 (bonded OH), and 1728 cm^{-1}; τ 4.35 (br s, 1 H-15), 6.23 (m, 1 H-13), 8.24 (d, 3 H-17, J = 1.5 Hz), 8.86 (s, 3 H-18), and 9.32 (s, 3 H-20); *m/e* 332 (M).

Anal. Calcd. for $C_{21}H_{32}O_3$: C, 75.86; H, 9.70. Found: C, 76.10; H, 9.72.

The derived acetate (**2**) was identical (same criteria as for **5** above) with the major component of the fractions which had been hydrolyzed and had m.p. 130–132° (from methanol); τ ($CDCl_3$) 4.27 (broad s, 1 H-15), 5.16 (m, 1 H-13), 8.03 (s, 3H, —OCO*CH*$_3$), 8.24 (d, 3 H-17, J = 1.5 Hz), 8.82 (s, 3 H-18), and 9.23 (s, 3 H-20).

Anal. Calcd. for $C_{23}H_{34}O_4$: C, 73.76; H, 9.15. Found: C, 73.89; H, 9.02.

The fractions from the alumina column which were submitted directly to preparative t.l.c. (see above) yielded three components, the one (109 mg) of intermediate polarity being contaminated with a small amount of the most polar. The least polar, major, constituent was the diacetate **3** (652 mg) which crystallized readily from hexane and had m.p. 162–163°; τ 5.14 (m, 1 H-13), 8.05 (s, 3H, —OCO*CH*$_3$), 8.11 (s, 3H, —OCO*CH*$_3$), 8.42 (s, 3 H-17), 8.87 (s, 3 H-18), and 9.24 (s, 3 H-20).

Anal. Calcd. for $C_{25}H_{38}O_6$: C, 69.10; H, 8.81. Found: C, 69.38; H, 8.70.

This diacetate **3** (48 mg) on distillation (twice) at 200°/15 mm afforded essentially pure monoacetate **2** (37 mg), identified by m.p., m.m.p., n.m.r., and t.l.c.

The most polar component from preparative t.l.c. of the diacetate fractions was **4** (215 mg). This was obtained as an oil which failed to crystallize. It was purified by distillation at 165°/0.2 mm and had τ 4.05 (broad s, 1 H-15), 5.24 (m, 1 H-13), 5.52 (broad s, 2 H-17), 8.00 (s, 3H, —OCO*CH*$_3$), 8.11 (s, 3H, —OCO*CH*$_3$), 8.85 (s, 3 H-18), and 9.23 (s, 3 H-20), *m/e* 430 (M).

Anal. Calcd. for $C_{25}H_{36}O_6$: C, 69.42; H, 8.39. Found: C, 69.54; H, 8.53.

Enone 7b

Alcohol *7a* (52 mg) in methylene chloride (5 ml) was treated with a solution of chromium trioxide (150 mg) and pyridine (0.25 ml) in the same solvent (5 ml) at 20° for 30 min. Ethyl acetate (50 ml) was then added and the resulting mixture washed with water (twice). The recovered product, an oil (55 mg), by preparative t.l.c. (ethyl acetate – light petroleum, 1:4, run twice) afforded the enone *7b* (39 mg), which crystallized from light petroleum and had m.p. 152–155°; ν_{max} 1735 and 1695 cm^{-1}; λ_{max} 236 nm (ε 8700); τ ($CDCl_3$) 2.98 (q, 1 H-14, J = 2, 9.5 Hz, former long range to 1 H-15, see ref. 5), 4.14 (d, 1 H-13, J = 9.5 Hz), 8.81 (s, 3 H-17 and 3 H-18), and 9.53 (s, 3 H-20).

Ketone 8b

Oxidation of alcohol **8***a* (55 mg) as above afforded the ketone **8***b* (44 mg) which had m.p. 176–179° (from light petroleum); ν_{max} 1738 and 1705(sh) cm^{-1}; τ ($CDCl_3$) 4.17 (broad s, 1 H-15), 7.39 (d, 1 H-14, J = 19 Hz), 8.32 (d, 3 H-17, J = 1.5 Hz), 8.80 (s, 3 H-18), and 9.27 (s, 3 H-20).

Anal. Calcd. for $C_{21}H_{30}O_3$: C, 76.33; H, 9.15. Found: C, 76.28; H, 9.06.

Formation of the Thioketal 8e and its Treatment with Raney Nickel

A solution of the ketone **8***b* (42 mg) in dry ether was treated with freshly distilled boron trifluoride etherate (0.5 ml) and ethane dithiol (0.3 ml) at 20° for 6 days. Ether (20 ml) was then added and the resulting solution washed with aqueous potassium hydroxide (4 *N*, 10 ml, twice) and water, dried, and the solvent evaporated. Preparative t.l.c. of the product (55 mg) afforded as the least polar, major constituent, the oily thioketal **8***e* (48 mg); τ ($CDCl_3$) 4.36 (broad s, 1 H-15), 6.75 (m, 4H, thioketal), 8.15 (d, 3 H-17, J = 1.5 Hz), 8.82 (s, 3 H-18), and 9.10 (s, 3 H-20).

Freshly prepared Raney nickel (1 g) was deactivated by stirring in refluxing acetone for 3 h. The thioketal **8***e* (48 mg) was then added in acetone and the heating continued for a further 15 h. Removal of the Raney nickel and acetone left a residue, shown to be a complex mixture by t.l.c. A fraction (12 mg) of similar polarity to **8***c* was recovered by preparative t.l.c. (ethyl acetate – light petroleum, 1:19). This ran as seven spots, none of which had an R_f corresponding to that of **9***c* on silver nitrate – silica gel (ethyl acetate – light petroleum, 3:97). Separation of these by preparative t.l.c., using these conditions furnished a very small amount of an oil (< 1 mg) having identical t.l.c. ($AgNO_3$–SiO_2), g.l.c. (retention time at 200°, 265 s) and mass spectral behavior with that of an authentic sample of **8***c*.[6] The major, much more polar component (**11**) of the mixture was also recovered as an oil (6 mg) which slowly decomposed at 20° (t.l.c. evidence). Crystallization from moist methanol gave plates, m.p. 132–136°; τ ($CDCl_3$) 3.80 (m, 1 H-13 and 1 H-14), 4.43 (broad s, 1 H-15), 8.25 (d, 3 H-17, J = 1.5 Hz), 8.80 (s, 3 H-18), and 9.58 (s, 3 H-20); *m/e* 314 (M).

Catalytic Hydrogenation of the Hydroxy Ester 8a

Hydrogenation of **8***a* (175 mg) in ethyl acetate over palladized charcoal (180 mg) for 0.5 h yielded two products which were separated by preparative t.l.c. (ethyl acetate – light petroleum, 1:9, run twice). The less polar was the alcohol **12***a* (118 mg) which crystallized from ethyl acetate – light petroleum and had m.p. 134–135°; τ 6.10 (broad s, 1H-13), 8.83 (d, 3 H-17, J = 7 Hz), 8.88 (s, 3 H-18), and 9.32 (s, 3 H-20); with 0.4 *M* Eu(dpm)$_3$ τ 2.47 (d, 3 H-17, J = 7 Hz), 7.53 (s, 3 H-20) and 8.02 (s, 3 H-18).

Anal. Calcd. for $C_{21}H_{34}O_3$: C, 75.41; H, 10.25. Found: C, 75.58; H, 10.05.

The more polar was the isomeric alcohol **12***b* (50 mg) which, when crystallized from ethyl acetate – light petroleum had m.p. 121–123°; τ 6.12 (broad s, 1 H-13), 8.83 (s, 3 H-18), 9.02 (d, 3 H-17, J = 6.5 Hz), and 9.30 (s, 3 H-20); with 0.4 *M* Eu(dpm)$_3$ τ 6.58 (d, 3 H-17, J = 6.5 Hz), 7.52 (s, 3 H-20), and 8.08 (s, 3 H-18).

Anal. Calcd. for $C_{21}H_{34}O_3$: C, 75.41; H, 10.25. Found: C, 75.55; H, 10.49.

Formation of the Olefin 15

Alcohol **12***a* (88 mg) was treated with excess *p*-toluenesulfonyl chloride in pyridine (3 ml) for 14 h. Ether (50 ml) was added and the resulting mixture extracted with aqueous sodium hydroxide (20 ml, 2 *N*, twice) and water. The ether layer was then dried and the solvent evaporated *in vacuo*, residual pyridine being removed by azeotropic distillation with benzene. Thin layer chromatography of the oily residue showed one clean spot, the tosylate **8***d*, less polar than substrate. This tosylate was heated with a large excess of sodium *t*-amylate in *t*-amyl alcohol at 85° for 18 h. Work-up with ether–water furnished an oil (73 mg) which gave three major fractions, of very similar polarity, by preparative t.l.c. over silver nitrate – silica gel (ethyl acetate – light petroleum, 1:199, run five times). The least polar was the pentacyclic ester **13** (11 mg) which solidified and had m.p. 71–74°; τ 8.84 (s, 3 H-18), 8.98 (d, 3 H-17, J = 6.5 Hz), and 9.28 (s, 3 H-20); *m/e* 316 (M). It had an identical R_f with that of **1***a* on silver nitrate – silica gel (ethyl acetate – light petroleum, 3:97) but a slightly longer retention time (555 s) on g.l.c. at 182° than that (516 s) of **1***a*. The component of intermediate polarity (**14**) was also obtained as an oil (8 mg). It had a very complex n.m.r. spectrum at about τ 9 and *m/e* 404 (M), 375, 334, 333, 317, and 316. The most polar component was the olefin **15** (31 mg) which after crystallization from methanol had m.p. 89–93°; τ 4.05 (d, 1 H-13 and 1 H-14, J_{obs} = 4 Hz), 8.85 (s, 3 H-18), 9.26 (d, 3 H-17, J = 6 Hz), and 9.61 (s, 3 H-20); *m/e* 316 (M) and 274 (M – C_3H_6).

Anal. Calcd. for $C_{21}H_{32}O_2$: C, 79.70; H, 10.19. Found: C, 79.83; H, 10.27.

The Diol 16a and Monoacetate 16b

Diacetate **3** (34 mg) was hydrolyzed by treatment with potassium hydroxide in refluxing methanol for 3 h. Work-up with ether–water gave an oil, consisting essentially (t.l.c.) of one polar compound (**16***a*). This was purified by preparative t.l.c. (ethyl acetate – light petroleum, 3:7, run twice) and crystallization from a mixture of these two solvents. It (22 mg) had m.p. 220–221°; τ ($CDCl_3$) 6.00 (octet, 1 H-13), 8.55 (s, 3 H-17), 8.83 (s, 3 H-18), and 9.28 (s, 3 H-20).

Anal. Calcd. for $C_{21}H_{34}O_4$: C, 71.96; H, 9.78. Found: C, 72.03; H, 9.80.

Acetylation with acetic anhydride – pyridine furnished the monoacetate **16***b* which was purified by preparative t.l.c. (ethyl acetate – light petroleum, 1:5). The resulting oil had ν_{max} 3612 and 1735 cm^{-1}; τ 5.20 (m, 1 H-13), 8.10 (s, 3H, —OCOCH_3), 8.72 (s, 3 H-17), 8.88 (s, 3 H-18), and 9.27 (s, 1 H-20).

Catalytic Hydrogenation of the Diacetate 4

Hydrogenation of diacetate **4** (137 mg) in ethanol (60 ml) and triethylamine (10 ml) over 5% palladized charcoal (100 mg) yielded an oil giving only two spots on t.l.c. on both silica gel (ethyl acetate – light petroleum, 1:9) and silver nitrate – silica gel (ethyl acetate – light petroleum, 3:7). The two components were separated by preparative t.l.c. The less polar (68 mg) was the acetate **2**, m.p. 130–

[6]Professor R. M. Coates kindly supplied this sample.

132°, identified by m.m.p., t.l.c., and n.m.r. The more polar component, the oily diacetate **17** (54 mg), was purified by distillation at 165°/0.2 mm and had τ 5.15 (m, 1 H-13), 8.04 (s, 6H, 2 —OCOCH_3), 8.45 (s, 3 H-17), 8.83 (s, 3 H-18), and 9.23 (s, 3 H-20).

Anal. Calcd. for $C_{25}H_{38}O_6$: C, 69.10; H, 8.81. Found: C, 69.32, H, 8.88.

We thank the National Research Council of Canada for an operating grant.
