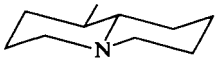
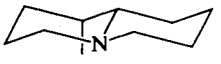
The structural difference between **2** and thiobinupharidine, **1**, resides in the configuration of the C-1 and C-1′ methyls. The methyl ^{1}H n.m.r. signals appear somewhat downfield in **2** relative to the spectrum of **1** which exhibits them at 0.93 p.p.m. This observation in conjunction with the known chemical shift dependence (6) on the axial–equatorial disposition of the methyl group attached to the quinolizidine ring was the first indication that the C-1 methyls were axial.

In our earlier Nuphar alkaloid work, we employed an aromatic solvent induced shift of the methyl ^{1}H resonances to determine the axial or equatorial orientation of the methyl groups. Equatorial 1- and 3-methyl quinolizidines undergo upfield shifts whereas the axial methyls meet with a downfield shift (7). No significant solvent shift of methyl groups in **2** was observed and consequently no confirmation of methyl conformation was afforded. However, the ^{13}C n.m.r. spectrum in comparison with that of **1** clearly indicated the methyls in **2** were axial. Figure 1 shows that the highest field resonance of **2**, attributed to the coincidental methyl groups, is considerably shielded relative to the methyls of **1**. This chemical shift increment and those for the α, β and γ carbons are given in Table 1 which also compares the increments for corresponding carbon centers in model quinolizidines **7** and **8**.



7



8

Table 1 illustrates that the shieldings of all of the various carbons, represented by the sign of the increments, is consistent with the known shift differences resulting from equatorial to axial changes of substituent groups in piperidine and quinolizidine rings (2, 8).

All of the spectral evidence important in determining that **2** belongs to the thiobinupharidine stereochemical family is given also (see Experimental) by the mixture of **3** and **4**, the components of which defied separation by conventional elution and thin layer chromatographic methods. Clearly the comparison of ^{13}C spectra given in Fig. 1 demonstrates that the mixture contains components with both axial and equatorial C-1 and C-1′ methyls. That the mixture consists of **3** and **4** and not **1** and **2** is apparent

Me	18.7	13.8	−4.9	19.2	13.4	−5.8

[a]δ in p.p.m. from TMS.
[b]Chemical shift assignments for **2** are tentative and are based on the best fit of increment values to those of the model pair as well as the line separations of pairs of primed and non-primed carbon numbers in **1** (*e.g.* 10 and 10′, 6 and 6′ etc.).
[c]$\Delta\delta = \delta^{13c}$ (axial Me) − δ^{13c} (equatorial Me).
[d]Chemical shifts are taken from ref. 2.
[e]Chemical shifts are taken from ref. 3.
[f]Chemical shifts are given for primed and non-primed carbon numbers when separate resonances are observed.

from comparing the ^{13}C n.m.r. of these mixtures, especially in the regions occupied by C-7, C-7′, C-12, and C-12′ resonances. Moreover, the thin layer chromatographic behavior of thiobinupharidine, **1**, and the mixture of **3** and **4** are clearly distinguishable, the spot representing **1** being less mobile and widely separated from the spot, or on occasion the two spots, representing **3** and **4**. Therefore the isolated sample containing both axial and equatorial C-1 and C-1′ methyl groups must consist of two epimeric thiobinupharidines, the one possessing C-1 axial, C-1′ equatorial methyls, **3**, and the other C-1 equatorial and C-1′ axial methyls, **4**.

Evidence, primarily from ^1H n.m.r., indicates that the three piperidine Nuphar alkaloids nuphenine (9), 3-epinuphamine (10), and 3-epinupharamine (11) possess axial C-1 methyl groups. The newly isolated **2**, **3**, and **4** are the first quinolizidine Nuphar alkaloids possessing axial C-1 methyl groups. Also noteworthy is the previously mentioned isolation of the deuterium labelled material possessing both the mass spectral and thin layer chromatographic properties of the 1-*epi*- and 1′-*epi*-thiobinupharidines. This finding means that the 1-*epi*-thiobinupharidines are also present in the plant extracts as hemiaminals.

Experimental

Measurements and Methods

Spectra were determined as follows: mass spectra (m.s.) on a Hitachi–Perkin-Elmer RMU6E using a direct inlet probe, 70 eV and 120 °C; high resolution mass spectra (h.r.m.s.) were determined at the High Resolution Mass Spectrometry Laboratory, Battelle's Columbus Laboratories, Columbus, Ohio, using an AEI MS-9 spectrometer employing a direct inlet probe, 70 eV and 200 °C; infrared spectra (i.r.) in CCl_4 solution on Perkin-Elmer 137 and 621 spectrometers; ^1H n.m.r. in $CDCl_3$ and C_6D_6 (1% TMS, δ 0.00) as indicated on Varian A 60 and XL-100-15, the latter controlled by a VFT-100L computer and operating in the FT mode (m, s, d, t, q, and br referring to multiplet, singlet, doublet, triplet, quartet, and broad); ^{13}C n.m.r. in 5 mm tubes in $CDCl_3$, used also as a secondary reference (77.2 p.p.m. from TMS at δ 0.00 p.p.m.), on a Varian XL-100-15 operating at 25.16 MHz in the FT absorption mode employing 8192 data points. Field frequency lock was established on the deuterium resonance of $CDCl_3$. Fully decoupled spectra of **2** and the mixture of **3** and **4** were obtained from 71.5 and 74.4 K transients respectively. Chemical shifts are accurate to 0.1 p.p.m. Thin layer chromatography (t.l.c.) was performed on microscope slides uniformly coated (0.25 mm) with Alumina GF_{254} and using the solvent systems indicated.

Detection of Monodeuterated epi-Thiobinupharidines in a Reduction Mixture

A 2.1 mg chromatography fraction originating from *Nuphar luteum* from Poland had been obtained in the course of purifying 6- and 6′-hydroxythiobinupharidine

(1). This fraction was dissolved in 5 drops of methanol and the resulting solution was treated with 10 mg of sodium borodeuteride at ambient temperature for 30 min at the end of which time the product mixture was processed by the usual procedure to obtain 2 mg of colorless oil: t.l.c. (Et_2O–hexane, 1:9) R_f 0.12 (neothiobinupharidine), 0.39 (thiobinupharidine), and 0.56 ('Deoxynupharidine' (*epi*-thiobinupharidine)).

Chromatography of the above described mixture was effected on a column of 6 g of neutral Alumina (5% H_2O) eluted first with 30 ml of Et_2O–hexane (5:95); thereafter several 5-drop fractions of the same solvent were taken. Combined fractions 1–10 yielded ~1 mg of *epi*-thiobinupharidines: t.l.c. (Et_2O–hexane, 1:9) R_f 0.56; m.s. *m/e* (relative intensity, %) 495(21), 494(18), 360(11), 359(8), 231(43), 230(53), 179(100), 178(82), 136(21), 107(56), 94(91).

Isolation of 1-epi-1′-epi-Thiobinupharidine, 2, and a Mixture of 1-epi- and 1′-epi-Thiobinupharidine, 3 and 4

Three chromatographic fractions (5) which had been eluted with hexane, and previously designated A1, A2, and A3, were combined (219 mg) and chromatographed on 5 g of neutral alumina (activity 2) that was first eluted with 75 ml of hexane, to obtain 140 mg of u.v. active but Dragendorf inactive material, and then with 30 ml of Et_2O–hexane (5:95) to obtain 75 mg of material. The latter was dissolved in 15 ml of Et_2O and the resulting solution was shaken with 15 ml of 0.01 *N* aqueous HCl and then with water. The aqueous acid and water layers were combined, made alkaline with powdered sodium hydroxide, saturated with salt, and finally extracted several times with small portions of methylene chloride. The combined extracts were dried (Na_2SO_4) and the solvent removed at the rotary evaporator to obtain 58 mg of a colorless oily residue which was chromatographed on a column (1 cm o.d. × 15.5 cm) containing 20 g of neutral alumina (5% water) by eluting with: 75 ml of hexane (fraction A′1, 0 mg); Et_2O–hexane in eight 20-drop portions (combined fraction A′2, 4.4 mg); Et_2O–hexane in eighteen 30-drop portions (combined fractions A′3, 25 mg); 150 ml of Et_2O–hexane (fraction A′4, 20 mg). This chromatography and the one below were monitored by t.l.c. (Alumina GF_{254}, 0.25 mm). Combined fractions A′2 and A′3 were admixed and chromatographed on a similar column by eluting with: 10 ml of hexane (fraction B′1, 0 mg); six 20-drop fractions of hexane (combined fraction B′2, 9.3 mg); three 20-drop fractions of hexane (combined fraction B′3, 3.7 mg); ten 20-drop fractions of hexane (combined fraction B′4, 8.3 mg); 20 ml of methylene chloride (fraction B′5, 0.2 mg). Fraction B′2 was pure 1-*epi*-1′-*epi*-thiobinupharidine, **2**: t.l.c. (eluted three times with Et_2O–hexane, 5:95) R_f 0.65 (R_f thiobinupharidine, 0.33); $[\alpha]_D^{25}$ 30.9 (*c* 9 mg/ml, 95% EtOH); i.r. 2810–2490 cm^{-1} (Bohlmann band) and 877 cm^{-1} (3-furyl); ^1H n.m.r. (100 MHz, $CDCl_3$) δ 2.7–3.1 (m, 4H, C-6 eq., C-6′ eq., C-4, and C-4′), 2.34 (AB q, J = 12.5 Hz, 2H, CH_2S) 1.90 (br s, 2H, C-7 CH_2), and 1.11 and 1.14 (2d, 6H, C-1 and C-1′ CH_3); ^1H n.m.r. (100 MHz, C_6D_6) δ 3.12 (2d, J = 12.5 Hz, 2H, C-6 eq., and C-6′ eq.), 2.70 (m, 2H, C-4, and C-4′), 2.29 (AB q, J = 13 Hz, 2H, CH_2S), 2.13 (AB q, J = 13 Hz, 2H, C-7 CH_2), 1.13 (2d, 6H, C-1, and C-1′); ^{13}C n.m.r. (7 mg in 0.3 ml $CDCl_3$) δ 29.6, 37.2, 39.7, 42.6, 44.4, 49.2, 56.9, 60.6, 60.8, 63.8, 66.5, 109.7 (C-15 or C-15′) (3), 109.7 (C-15′ or C-15), 129.7 (C-13 or C-13′), 129.9 (C-13′ or C-13), 139.7 (C-14 and C-14′), 143.0 (C-16 and C-16′) and assigned resonances given in Table 1; h.r.m.s. obsvd/calcd mass (formula) 494.2957/494.2967 ($C_{30}H_{42}N_2O_2S$), 447.3021/447.3011 ($C_{29}H_{39}N_2O_2$), 359.2140/359.2157 ($C_{21}H_{31}N_2OS$), 230.1523/230.1545 ($C_{15}H_{20}NO$), 136.0868/136.0888 ($C_9H_{12}O$), 107.0497/107.0497 (C_7H_7O), 94.0413/94.0419 (C_6H_6O), and 81.0337/81.0340 (C_5H_5O).

Fractions A′4 and B′4 were combined to give 27 mg of a mixture of 1-*epi*- and 1′-*epi*-thiobinupharidine: t.l.c. (eluted three times with Et_2O–hexane, 5:95) R_f 0.61 (R_f thiobinupharidine, 0.33; R_f 1-*epi*-1′-*epi*-thiobinupharidine, 0.65); $[\alpha]_D^{25}$ 23.9 (*c* 27 mg/ml, 95% EtOH); i.r. 2810–2490 (Bohlmann bands, intensities equivalent to those exhibited by thiobinupharidine), 877 cm^{-1} (3-furyl); ^1H n.m.r. (60 MHz, $CDCl_3$) δ 2.6–3.15 (m, 4H, C-6 eq., C-6′ eq., C-4, and C-4′), 2.31 (AB q, J = 12.5 Hz, 2H, —CH_2S—), 1.88 (br s, 2H, C-7 CH_2), 1.13 (2d, J = 6.5 Hz, 3H), and 0.94 (2d, 3H); ^1H n.m.r. (60 MHz, C_6D_6) δ 3.2 (m, C-6 eq. and C-6′ eq.), 2.75 (m, C-4 and C-4′), 2.33 (AB q, J = 12.5 Hz, 2H, CH_2S), 2.17 (AB q, J = 12.5 Hz, 2H, C-7 CH_2), 1.12 (2d, J = 6.5 Hz, 3H), 0.84 (2d, 3H); ^{13}C n.m.r. (27 mg in 0.3 ml $CDCl_3$) δ 13.6, 13.7, 19.2, 28.8, 29.3, 29.4, 29.6, 30.0, 30.1, 32.2, 32.5, 32.7, 33.7, 35.2, 36.1, 37.3, 37.5, 39.5, 42.6, 42.7, 44.8, 44.9, 49.0, 49.4, 56.8, 57.1, 59.9, 60.1, 60.5, 60.7, 63.6, 64.8, 65.9, 66.2, 66.4, 68.8, 69.7, 109.7, 109.8, 129.6, 129.9, 139.7, and 143.0; h.r.m.s. obsvd/calcd mass (formula) 494.2950/494.2967 ($C_{30}H_{42}N_2O_2S$), 447.2976/447.3011 ($C_{29}H_{39}N_2O_2$), 359.2094/359.2157 ($C_{21}H_{31}N_2OS$), 230.1520/230.1545 ($C_{15}H_{20}NO$), 136.0907/136.0888 ($C_9H_{12}O$), 107.0497/107.0497 (C_7H_7O), 94.0414/94.0419 (C_6H_6O), and 81.0339/81.0340 (C_5H_5O).

Mixture of Thiobinupharidine, 1, and 1-epi-1′-epi-Thiobinupharidine, 2

^{13}C n.m.r. (5 mg of **1** and 5 mg of **2** in 0.3 ml $CDCl_3$) δ 13.4, 13.5, 19.3, 28.8, 29.3, 29.5, 29.7, 30.1, 30.2, 32.1, 32.4, 32.6, 32.8, 33.9, 35.4, 36.3, 37.3, 37.5, 39.7, 39.8, 42.8, 44.5, 45.3, 49.3, 57.1, 60.0, 60.2, 60.8, 61.0, 63.4, 64.0, 64.8, 65.9, 66.1, 66.6, 68.9, 109.9, 129.7, 130.5, 140.0, and 143.2.

Support of this work by the National Institutes of Health, U.S. Public Health Service (Grant No. AI-10188) is gratefully acknowledged. We also acknowledge the assistance of L. McCandless for determining the 100 MHz ^1H n.m.r. and the ^{13}C n.m.r. spectra. The authors are grateful to the National Science Foundation for an equipment grant to the Department of Chemistry, State University of New York, College of Environmental Science and Forestry toward the purchase of the XL-100-15 spectrometer and the VFT100 computer used in this study.

Etudes conformationnelles de dérivés d'oligométhylène glycols et de composés apparentés. Partie II. Structure cristalline et moléculaire du di(parachlorobenzoate) d'éthylène glycol, $C_{16}H_{12}O_4Cl_2$

SERGE PÉREZ ET FRANÇOIS BRISSE

Département de Chimie, Université de Montréal, C.P. 6210, Succ. A, Montréal, Québec H3C 3V1

Reçu le 30 mai 1975

SERGE PÉREZ et FRANÇOIS BRISSE. Can. J. Chem. **53**, 3551 (1975).

Les cristaux de di(*para*-chlorobenzoate) d'éthylène glycol cristallisent dans le groupe spatial centrosymétrique $C2/c$ du système monoclinique. Les paramètres cristallins sont $a = 12.733(9)$, $b = 9.522(8)$, $c = 12.762(8)$ Å, $\beta = 79.63(10)°$ et $Z = 4$. Les intensités de 1206 réflexions indépendantes ont été mesurées sur un diffractomètre automatique Picker. La structure a été résolue par la méthode de multisolution. Un affinement anisotrope a conduit à un facteur de reliabilité final de 0.033.

La molécule est placée en position particulière: un axe cristallographique de rotation d'ordre 2 est perpendiculaire au milieu de la liaison CH_2—CH_2. Contrairement à la molécule de dibenzoate d'éthylène glycol qui se trouve dans la conformation *trans*, ce dérivé se présente dans la conformation *gauche*. Cette différence de conformation n'empêche néanmoins pas de retrouver le raccourcissement notable de la liaison CH_2—CH_2 dont la longueur est 1.493(2) Å. Les forces de van der Waals assurent la cohésion des molécules dans le cristal.

SERGE PÉREZ and FRANÇOIS BRISSE. Can. J. Chem. **53**, 3551 (1975).

Ethylene glycol di(*para*-chlorobenzoate) crystals are monoclinic, space group $C2/c$, with $a = 12.733(9)$, $b = 9.522(8)$, $c = 12.762(8)$ Å, $\beta = 79.63(10)°$, and $Z = 4$. The structure was solved by direct methods from 1206 independent reflections collected on a Picker diffractometer. An anisotropic refinement led to a final R factor of 0.033.

The molecule has a crystallographic twofold axis of rotation perpendicular to the middle of the CH_2—CH_2 bond. Unlike ethylene glycol dibenzoate which was shown to be in the *trans*-conformation, this derivative is nearly in the *gauche*-conformation. However the same significant shortening of the ethylene part of the molecule is observed: the CH_2—CH_2 distance is only 1.493(2) Å. The molecules are held in the crystal by van der Waals interactions only.

Introduction

Dans le cadre de notre étude systématique (1) sur les molécules modèles des polyesters, nous présentons ici la détermination de la structure cristalline du di(*para*-chlorobenzoate) d'éthylène glycol. Cette molécule, tout comme celle du dibenzoate d'éthylène glycol étudiée précédemment (2), sert de modèle partiel au polyéthylène téréphtalate.

Ce travail a aussi été entrepris pour obtenir des valeurs expérimentales en vue de confirmer les résultats de l'analyse conformationnelle menée sur le diacétate d'éthylène glycol (3).

Partie expérimentale

Le di(*para*-chlorobenzoate) d'éthylène glycol $C_{16}H_{12}O_4Cl_2$ a été préparé par réaction d'éthylène glycol et de chlorure de *para*-chlorobenzoyle en présence de pyridine (4). Le produit est ensuite recristallisé lentement dans le chloroforme à température ambiante. Les clichés obtenus sur chambres de Weissenberg et de précession ont permis de déterminer les conditions d'existences: hkl, $h + k = 2n$; $h0l$, $l = 2n$. Les deux groupes spatiaux Cc non-centrosymétrique et $C2/c$ centrosymétrique présentent les mêmes conditions d'extinctions systématiques. Il n'est pas possible de lever l'ambiguïté sur la détermination du groupe spatial. En effet, la détermination du nombre d'homologues $Z = 4$ est compatible avec les deux groupes spatiaux car l'existence d'une symétrie cristallographique de la molécule, composée de deux parties chimiquement équivalentes, ne peut être exclue.

L'affinement des dimensions de la maille a été effectué par la méthode des moindres-carrés appliquée à douze réflexions centrées sur le diffractomètre. Ces valeurs ainsi que les écarts-type correspondants sont groupés ci-dessous.

Données cristallographiques

$C_{16}H_{12}O_4Cl_2$ poids mol. = 339.27

p.f. = 140 °C, $F(000) = 694$, monoclinique, $C2/c$, $a = 12.733(9)$, $b = 9.522(8)$, $c = 12.762(8)$ Å, $\beta = 79.63(10)°$, $V = 1552$ Å^3, $Z = 4$, $d_{obs} = 1.48$, $d_{cal} = 1.452$ g cm^{-3}, $\mu(MoK\alpha) = 3.0$ cm^{-1}, $\lambda(MoK\bar{\alpha}) = 0.71069$ Å, $T = 20(1)$ °C.

Les intensités de 1472 réflexions indépendantes, à l'intérieur de la sphère limitée par $2\theta \leq 52°$, ont été mesurées sur le diffractomètre automatique Picker. La méthode de mesure θ–2θ a été utilisée avec une vitesse de

balayage de $1°(2\theta)\ mn^{-1}$ et une largeur de balayage de $1.75°(2\theta)$. Le temps de comptage du bruit de fond de part et d'autre de la réflexion (compteur fixe, cristal fixe) était de 20 s. La moyenne des intensités de trois réflexions témoins mesurées toutes les 30 réflexions a décru de 10% au cours de la durée de la collection des données. Toutes les intensités ont été corrigées du bruit de fond et ramenées à une même échelle. La réduction des données, par utilisation des programmes de Ahmed *et al.* (5), a été conduite de façon usuelle. Parmi les 1472 réflexions mesurées, 1206 d'entre elles telles que $I/\sigma(I) \geq 2.5$ ont été considérées comme observées (81%). $\sigma(I)$ a été calculé par la relation $\sigma(I) = [I_T + (t/40)^2B + (0.03I_N)^2]^{1/2}$, où I_T est le nombre total de coups, B est le bruit de fond total, I_N est le nombre net de coups et t la durée du balayage d'une réflexion.

Etant données les dimensions géométriques du cristal utilisé ($0.40 \times 0.35 \times 0.35$ mm), et la faible valeur du coefficient d'absorption pour la longueur d'onde utilisée, aucune correction d'absorption n'a été effectuée. Les valeurs des facteurs de diffusion des atomes C, O et Cl sont celles de Cromer et Waber (6) et celles de Stewart *et al.* (7) pour l'hydrogène. Les valeurs données par Cromer (8) ont été employées pour les parties réelle et imaginaire de la dispersion anomale du chlore.

Determination de la structure et affinement

Après correction de l'agitation thermique isotrope, les résultats de la moyenne statistique des facteurs de structure normalisés $|E|$ indiquaient une distribution centrosymétrique (tableau 1). Malgré ces indications, et pour les raisons expliquées précédemment, la recherche de la structure de départ a été effectuée dans le groupe spatial non-centrosymétrique *Cc*, par application du programme de multisolution MULTAN (9). Les différentes étapes de la recherche sont résumées ci-dessous.

On a utilisé 118 réflexions ayant $|E| \geq 1.90$, soit 5.3 réflexions par atome semi-lourd à déterminer, pour générer 680 relations $\Sigma 2$. La phase de la réflexion 060 a été déterminée par $\Sigma 1$ avec une probabilité de 1 tandis que l'origine a été fixée par les deux réflexions 12.4.5 et 773. Par ailleurs des symboles furent assignés aux phases des réflexions $66\bar{4}$, 2.6.12 et 2.10.3.

Les phases des 118 réflexions, correspondant au set possédant le meilleur ensemble de figures de mérite, ont permis de réaliser une carte de Fourier où tous les atomes semi-lourds de la molécule ont pu être localisés. A ce niveau, un affinement isotrope des 22 positions atomiques (groupe *Cc*) a conduit à un facteur de reliabilité $R = 0.113$. Comme cet affinement a été exécuté par la méthode de matrice entière, il a été possible de détecter de fortes corrélations existant entre les atomes correspondants des deux parties chimiquement équivalentes de la molécule. L'existence d'une symétrie moléculaire (groupe *C2/c*) a alors été de nouveau envisagée. A ce stade, les affinements par la méthode d'approximation par blocs diagonaux ont été menés parallèlement pour les groupes *C2/c* et *Cc*. Les principales étapes de ces affinements sont présentées dans le tableau 2. En fin d'affinement, les valeurs trouvées pour les facteurs de reliabilité et les grandeurs σ_F dans le cas des groupes *C2/c* ou *Cc* ne permettent pas de choisir sans ambiguïté le groupe spatial. L'application du test d'Hamilton (10, 11) aux facteurs de reliabilité pondérés donne pour vraisemblable l'hypothèse du groupe non-centrosymétrique *Cc* pour des niveaux d'acceptation α compris entre 0.50 et 0.005. Ce sont en fait des considérations d'ordre stéréochimique qui nous font pencher en faveur du groupe d'espace centrosymétrique.

En fin d'affinement dans le groupe *Cc*, le calcul des distances et des angles intramoléculaires conduisait à des résultats extrêmement incohérents. Les différences entre les longueurs de liens chimiquement équivalents étaient de l'ordre de 20 à 30 fois l'écart type. Par exemple, les distances Csp^2—Csp^2 à l'intérieur d'un même cycle aromatique variaient entre 1.250(3) et 1.450(3) Å. Comme de tels résultats sont chimiquement inacceptables et qu'il y avait des corrélations importantes entre les coordonnées d'atomes équivalents, l'hypothèse du groupe spatial *Cc* a été définitivement rejetée. Les poids $w = 1/\sigma^2(F)$ dérivés de $\sigma(I)$ ont été appliqués à chaque reflexion.

Un calcul de section différence effectué en fin d'affinement dans le groupe *C2/c* a montré que les maxima de densité électronique résiduelle variaient entre -0.19 et $+0.14\ e\ Å^{-3}$.

*Les coordonnées fractionnaires des atomes semi-lourds sont $\times 10^5$ et les facteurs thermiques anisotrope sont $\times 10^4$, les coordonnées des atomes d'hydrogène sont $\times 10^4$, les facteurs thermiques isotropes sont $\times 10^3$.

Résultats et discussion[1]

Les coordonnées atomiques, les facteurs d'agitation thermiques anisotropes et leurs écarts type sont présentés dans le tableau 3. Les facteurs thermiques sont les coefficients de l'expression $T = \exp[-2\pi^2(U_{11}a^{*2}h^2 + \ldots + 2U_{12}a^*b^*hk + \ldots)]$. La molécule de di(*para*-chlorobenzoate) d'éthylène glycol est représentée fig. 1.

[1]On peut obtenir la série complète des tableaux à un prix nominal, en s'adressant au Dépôt de données non publiées, ICIST, Conseil national de recherches du Canada, Ottawa, Canada K1A 0S2.

Distances et angles interatomiques

La fig. 2 rassemble schématiquement les distances et les angles d'une molécule de $C_{16}H_{12}O_4Cl_2$. Les erreurs estimées sont de 0.002 Å et de 0.15° pour les distances et angles entre atomes 'semi-lourds' respectivement; les erreurs correspondantes lorsque les atomes d'hydrogène sont impliqués sont de 0.015 Å et de 0.9° respectivement.

La molécule de di(*para*-chlorobenzoate) d'éthylène glycol est située sur l'axe cristallographique d'ordre 2, passant par le milieu de la liaison CH_2—CH_2. La géométrie du groupe chlorophenyle est en bon accord avec

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

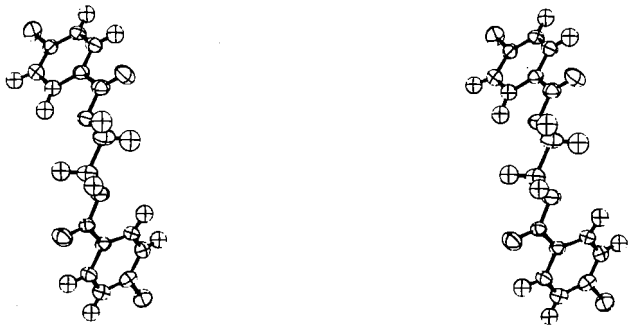

FIG. 1. Vue stéréoscopique d'une molécule de di(*para*-chlorobenzoate) d'éthylène glycol.

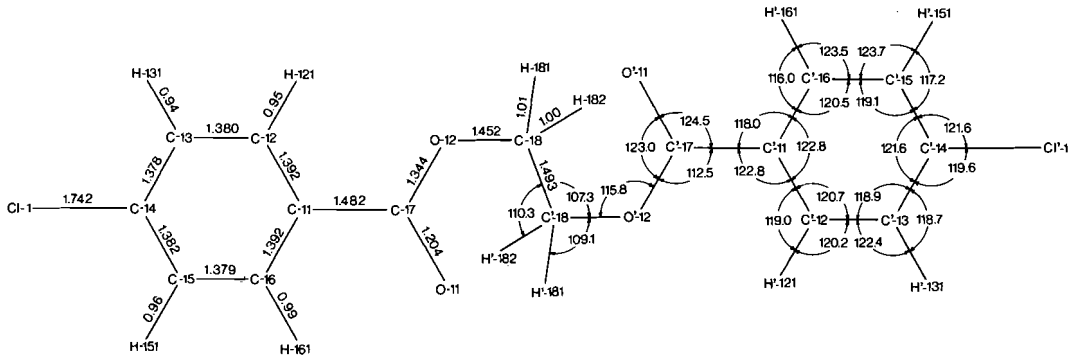

FIG. 2. Distances et angles dans la molécule de di(*para*-chlorobenzoate) d'éthylène glycol.

l'analyse faite récemment sur les groupes halogénophényles (13). La distance Csp^2—Cl de 1.742(2) Å est voisine de la moyenne de 1.736(2) Å calculée par Palenik *et al.* (14). La présence du chlore en *para* se manifeste par une légère augmentation de l'angle C(13)—C(14)—C(15) = 121.6° tandis que les deux angles C(11)—C(14)—C(13) et C(11)—C(14)—C(15) ont des valeurs proches de 119°. D'autre part on observe aussi que le chlore est légèrement en dehors du plan moyen du cycle. En ce qui concerne les distances C—H du cycle on observe une valeur moyenne de 0.96 Å tandis que les angles C—C—H sont tous voisins de 120°.

La géométrie du groupe carboxylate est comparable en tout points à celle trouvée pour le dibenzoate d'éthylène glycol (2).

La longueur de la liaison CH_2—CH_2 = 1.493(2) Å est significativement plus courte que la distance communément attendue de 1.537 Å pour une liaison Csp^3—Csp^3 (15). Afin de s'assurer que ce raccourcissement n'était pas dû aux mouvements de rotations moléculaires, nous avons entrepris l'analyse des mouvements thermiques par la méthode de Schomaker et Trueblood (16). La racine carrée de l'erreur quadratique moyenne des U_{ij}, $[\sum(\Delta U_{ij})^2/(r - s)]^{1/2}$, où r est le nombre de U_{ij} et s le nombre de paramètres du corps rigide, n'est que de 0.005 Å^2. Les corrections des longueurs de liaison sont au maximum de 0.002 Å, et la valeur corrigée du lien CH_2—CH_2, 1.494 Å, reste toujours significativement très courte. Une distance comparable de 1.499(2) Å avait été remarquée dans la structure du dibenzoate d'éthylène glycol (2). Afin d'élucider les raisons du raccourcissement de la liaison CH_2—CH_2 nous avons entrepris l'étude systématique de structures de composés de type (*a*) R—C_6H_4—CO—O—$(CH_2)_x$—O—CO—C_6H_4—R, où R = H, CH_3, NO_2, Cl et x = 2 à 6; (*b*) C_6H_5—R—$(CH_2)_2$—R—C_6H_5 où R = —O—CO, —CO—NH— et —CO—CH_2—.

L'angle[2] O(12)—C(18)—C′(18) a une valeur

[2]Les atomes primés (coordonnées $\bar{x}$, y, $\frac{1}{2} - z$) sont les équivalents, par rotation d'ordre 2, des atomes non primés (coordonnées x, y, z) portant le même numéro.

de 107.3(2)° alors que les angles correspondants du dibenzoate d'éthylène glycol sont encore plus refermés: 104.7(2) et 105.2(2)°.

Plans moyens et angles de torsion

Les équations des plans moyens du cycle aromatique (plan A) et du groupe carboxylique (plan B) sont données dans le tableau 4. Comme il a été indiqué précédemment, l'atome de chlore se trouve en dehors du plan moyen du cycle. Le groupement carboxylique est aussi situé légèrement en dehors du plan A et fait un angle de 7.5° avec ce dernier. Les angles de torsion[3] sont rassemblés dans le tableau 5. La conformation de la molécule est *trans–gauche*. Cette conformation diffère considérablement de la conformation *trans–trans* rapportée pour le dibenzoate d'éthylène glycol (2). Les projections de Newman le long du lien CH_2—CH_2 de ces deux molécules sont comparées à la fig. 3. Il est assez surprenant d'observer deux conformations radicalement différentes pour deux molécules qui somme toute ne diffèrent que par la présence d'un atome de chlore en para sur le groupe phényle.

Dans l'article suivant (3) Sundararajan *et al.* calculent l'énergie conformationnelle d'une

[3]L'angle de torsion pour la conformation *trans* est de 180° (17).

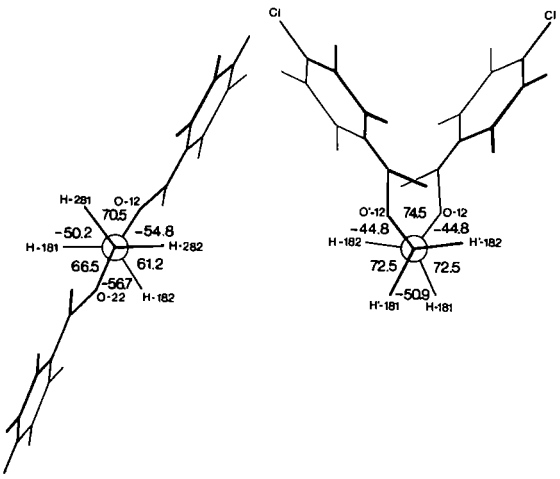

FIG. 3. Représentation de Newman du dibenzoate d'éthylène glycol (à gauche) et du di(*para*-chlorobenzoate) d'éthylène glycol (à droite). Projection le long du lien CH_2—CH_2.

molécule isolée de diacétate d'éthylène glycol en tenant compte de l'énergie électrostatique, de l'énergie d'interactions entre atomes non liés et de l'énergie de torsion.

Les deux conformations observées par diffraction des rayons-X se retrouvent parmi les conformations de basses énergies proposées par ces auteurs.

La conformation *trans–trans* du dibenzoate d'éthylène glycol correspond à la forme d'énergie minimum (1.10 kcal mol^{-1}) pour laquelle les angles de torsion calculés sont $\phi_1 = \phi_2 = 180°$. Les angles de torsion observés dans le di(*para*-chlorobenzoate) d'éthylène glycol (tableau 5) sont comparables aux angles calculés pour la forme *trans–gauche* ($\phi_1 = -179°$, $\phi_2 = 62°$). L'énergie calculée de la conformation *trans–gauche* ne diffère que de 300 cal mol^{-1} de celle de la forme *trans–trans*.

Les différences entre les valeurs observées et calculées des angles de torsion se manifestent surtout au niveau de l'angle ϕ_2, angle de torsion autour de la liaison CH_2—CH_2. Ces désaccords sont peut-être attribuables au fait que les valeurs standard des distances et des angles utilisées par Sundararajan *et al.* (3) sont assez différentes des distances et des angles observés ici, particulièrement en ce qui concerne le lien CH_2—CH_2 et l'angle O(12)—C(18)—C′(18).

Arrangement moléculaire

Une vue stéréoscopique (fig. 4) montre l'arrangement des molécules de di(*para*-chloro-

Conformational Studies on Oligomethylene Glycol Derivatives
III. Ethylene Glycol Diacetate

PUDUPADI R. SUNDARARAJAN, PIERRE LABRIE, AND ROBERT H. MARCHESSAULT

Department of Chemistry, Université de Montréal, Montreal, Quebec H3C 3V1

Received May 30, 1975

PUDUPADI R. SUNDARARAJAN, PIERRE LABRIE, and ROBERT H. MARCHESSAULT. Can. J. Chem. **53**, 3557 (1975).

Conformational energies were calculated for the molecule ethylene glycol diacetate, using semiempirical methods. Several conformations corresponding to the *trans* and *gauche* states of the C—O and C—C single bonds are preferred. The $g^{\pm}$ state of the C—O bond is shifted from $\pm 120°$ by 10 to 32°. The relative energies of the various preferred conformations are found to depend on the value of the valence angle C—O—C. Calculations with C—O—C ranging from 110 to 124° showed that a value of 115° would be preferred for this angle. The predicted values of the torsion angles and bond angles are found to be in agreement with the crystal structure data on the benzoate derivatives of ethylene glycol.

PUDUPADI R. SUNDARARAJAN, PIERRE LABRIE et ROBERT H. MARCHESSAULT. Can. J. Chem. **53**, 3557 (1975).

Des calculs d'énergies de conformation, basés sur des méthodes semiempiriques, sont décrits pour le diacétate d'éthylène glycol. Plusieurs conformations correspondant aux formes *trans* et *gauche* des liaisons simples C—O et C—C sont les plus probables. La forme $g^{\pm}$ de la liaison C—O est déplacée de 10 à 32° par rapport à $\pm 120°$. Les énergies relatives des nombreuses conformations probables dépendent de la valeur de l'angle de valence C—O—C. En faisant varier cet angle de 110 à 124°, les calculs nous indiquent que la valeur de 115° serait la plus probable. Les valeurs trouvées pour les angles de torsion et les angles de valence sont en accord avec les données cristallines de la structure des dérivés benzoate de l'éthylène glycol.

[Traduit par le journal]

Introduction

Structural studies of aliphatic polyesters of the type $\text{-[-CO—(CH}_2)_x\text{—CO—O—(CH}_2)_y\text{—O-]}_n$ derived from ethylene glycol ($y = 2$), trimethylene glycol ($y = 3$), and dekamethylene glycol ($y = 10$) were first made by Fuller *et al.* (1–4), using X-ray diffraction methods. Among the polyesters of the ethylene glycol series, these authors observed a shortening of the fiber repeat from the value expected for a fully extended chain. These are summarized in Table 1. A difference of 1.4 Å was observed for polyethylene succinate ($x = 2$, $y = 2$) and this was interpreted as due to a twist around the CH_2—CH_2 bond of the glycol portion of the chain, so as to bring the oxygen atoms towards each other, as in **1**. Later studies by Tadokoro and co-workers (5) showed that the dihedral angles around the two CH_2—CH_2 bonds in the repeat unit correspond to the g^+ and g^- *gauche* conformations. Turner-Jones and Bunn (6) studied the structures of polyethylene adipate ($x = 4$, $y = 2$) and polyethylene suberate ($x = 6$, $y = 2$), and attributed the shortening (of about 0.5 Å) of the fiber repeat to a rotation of 66° (see **2**) around the C—O bond, while the planar *trans* conformation is preserved around the CH_2—CH_2 bonds. As seen in **2**, a twist of 18° in the glycol portion, around the CO—O bond was also introduced, making the ester group nonplanar.

The vast amount of work on the conformational analysis of polypeptides, polysaccharides, and polynucleotides has shown that a knowledge

of the structural parameters (bond lengths, bond angles, and torsion angles) and the relative stability of several conformations of analogous small molecules is essential to derive reliable information on the conformations of a polymer (7–11). Hence, the conformational features of the molecule ethylene glycol diacetate (EGDA) were studied, since it can serve as a model compound for the class of polyesters mentioned above. This analysis predicts the probable rotational states of the various bonds in the molecule and the effect of varying the geometrical parameters, such as the bond angle, on the relative stability of these rotational states.

Geometrical Data

A schematic of EGDA is given in Fig. 1. The bond lengths and bond angles used in this study are given in Table 2, and were taken from previous studies on esters and acetates (12). The ester group is taken to be in the *trans* conformation. Any deviation from perfect planarity is measured by the angle ω. Several conformations of the molecule were generated by rotations ϕ_1, ϕ_2, and ϕ_3 around the single bonds, as shown in Fig. 1. Due to the chemical symmetry of the molecule, the dihedral angles ϕ_1 and ϕ_3 were taken to be equal. The all-*trans* planar conformation defines the starting position with $\phi_1 = \phi_2 = \phi_3 = 0°$. A positive increment in ϕ_1 and ϕ_3 is given by a clockwise rotation of the acetate groups on either side, viewing along the CH_2—O bonds. Looking along the CH_2—CH_2 bond from left to right, a clockwise rotation of the part of the molecule on the right hand side gives a positive increment in ϕ_2.

Parameters for Energy Calculations

Intrinsic torsional potentials with a threefold barrier of 2.8 kcal mol^{-1} and a twofold barrier of

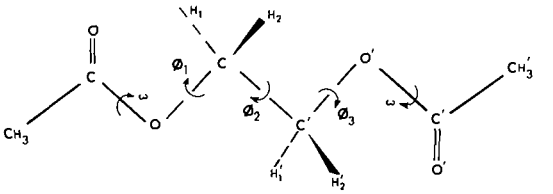

FIG. 1. Schematic of ethylene glycol diacetate (EGDA) molecule. The relevant torsion angles are marked.

8.75 kcal mol^{-1} were assigned to rotations about the CH_2—CH_2 bond (rotation ϕ_2) and the C═O bonds (rotation ω), respectively (12*a*). The torsional barrier for the C—O bond (rotations ϕ_1 and ϕ_3) was taken to be zero (12*a*).

Nonbonded interactions were computed using the Lennard-Jones function $E_{ij} = a_{ij}/r_{ij}^{12} - b_{ij}/r_{ij}^{6}$ for each pair of interacting atoms *i* and *j*, excluding the 1–3 interactions. The constants a_{ij} and b_{ij} were calculated according to the methods described previously (12, 13). The CH_3 group was treated as a spherical domain of van der Waals radius of 1.9 Å.

Coulombic interactions were evaluated (12*a*, 13) by assigning partial charges to the atoms, using bond moments of 0.82 D for C—O, 2.3 D for C═O, 0.74 D for C⋯O, and 0.38 D for C—H. An apparent dielectric constant of 2 was used (13).

The energy of deformation of the valence angles was estimated according to $V(\theta) = A(\Delta\theta)^2$ where $\Delta\theta$ is the distortion of an angle θ and *A* is half the force constant. A value of 80 kcal mol^{-1} was used for *A*, for the C—O—C and C—C—O valence angles whose standard value was taken to be 110°.

Results and Discussion

Iso-energy contours, plotted at intervals of 1 kcal mol^{-1} with respect to the minimum denoted by zero, are given in Fig. 2, as a function

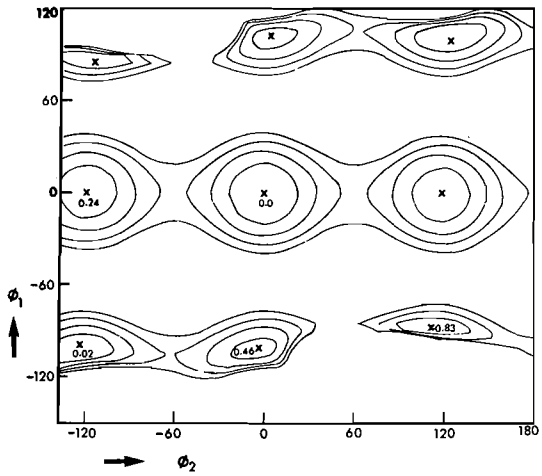

FIG. 2. Iso-energy contours for EGDA as a function of ϕ_1 and ϕ_2. Contours are drawn at intervals of 1 kcal mol^{-1} with respect to the minimum marked by 0.0. Values of $\omega = 0°$, $\angle COC = 112°$, and $\angle CCO = 110°$ are used here.

of $\phi_1 (= \phi_3)$ and ϕ_2. Energies were calculated at intervals of 1° in ϕ_1 and ϕ_2 in the neighborhood of the minima and at intervals of 10° elsewhere. Values of C—O—C = 112°, C—C—O = 110°, and $\omega = 0°$ were used here.

In addition to the *tt* conformation ($\phi_1 = \phi_2 = 0°$, *trans*), minima are recorded for the g^+ (*gauche*, +120°) and g^- (*gauche*, −120°) states of the bonds. The latter minima, in some conformations, are shifted significantly from the ideal ±120° position for perfect staggering. The values of ϕ_1 and ϕ_2 for all the minima are given in Table 3.

The relative energies of the minima show that the various possible conformations differ very little in energy from the *tt* state. The g^-g^- conformation is of equal energy to the *tt* state; the tg^- and g^-t states are only 0.24 and 0.45 kcal mol^{-1} higher in energy than the *tt* state. The g^-g^+ conformation, which is about 0.83 kcal mol^{-1} higher in energy, cannot be ruled out completely. The significant interactions which are relieved to some extent by a shift of the minima to nonstaggered conformations are given in Table 3. The higher energy of the perfectly staggered g^-g^+ conformation is due to the interactions involving carbonyl carbon and carbonyl oxygen. The severity of these interactions is reduced by a significant shift of ϕ_1 (to −88°) from perfect staggering. It is also to be noted that in all the conformations g^-g^+, g^-t, and g^-g^-, appreciable

shift from perfect staggering is recorded for ϕ_1 only, rather than for ϕ_2.

Though one would imagine that the *tt* conformation in which the C=O dipoles are antiparallel to each other would be most favored, examination of models would show that in all the conformations listed in Table 3, the dipoles are antiparallel. This is necessarily due to the fact that the parts of the molecule on either side of the CH_2—CH_2 bond are related by a twofold axis. This relationship is also borne out by the energy map shown in Fig. 2.

Effect of ω *Rotation*

As mentioned above, Turner-Jones and Bunn (6) proposed the torsional angle ω = 18° for the structures of polyethylene adipate and polyethylene suberate. A survey (14) of the crystallographic data on small molecules showed that the value of ω differs very little from 0°. In the present analysis, the value of ω was varied, from 0 to 10°, to examine its effect on the energy of the molecule.

Figure 3 shows the variation of energy as a function of ω, for the various preferred states of the molecule deduced from Fig. 2. The relative energy of the various conformations, compared to that of the *tt* state, remains almost the same through the range of ω presented here. These curves show that the energy of the molecule, in all the preferred conformations, does not decrease by choosing a value of ω other than 0°. The energy variation is negligible up to about ω = 2°, and thereafter an increase is noted. In all the conformations except g^-g^+, the increase in energy is mainly due to the torsional potential. The nonbonded distances show no significant variation. In the g^-g^+ conformation, the O...O′ (carbonyl) distance decreases from 2.8 to 2.7 Å as ω increases from 0 to 10°. The $CH_3\cdots C'$ (carbonyl) and $CH_3\cdots O'$ (carbonyl) distances are 3.56 and 3.20 Å respectively for ω = 10°. These two distances are greater than the sum of the van der Waals radii for ω = 0°. The increase in energy through the range of 0 to 10° is only of the order of 500 to 600 kcal mol^{-1}. However, a definite trend towards higher energy cannot be neglected. Hence, in the subsequent calculations, the value of ω was restricted to 0°.

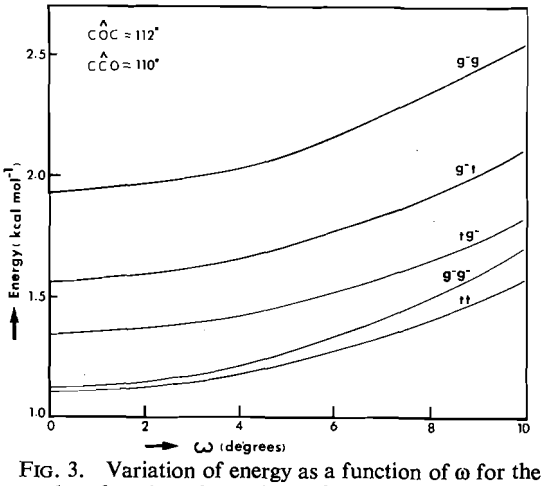

FIG. 3. Variation of energy as a function of ω for the several preferred conformations of EGDA.

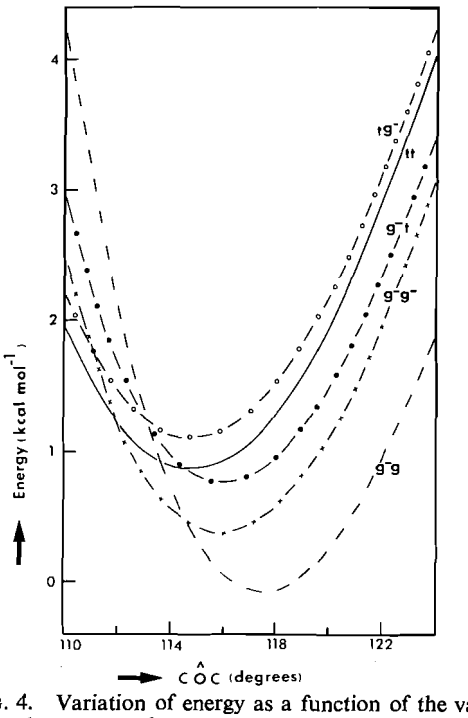

FIG. 4. Variation of energy as a function of the valence angle C—O—C for the following conformations: —, *tt*; ○, tg^-; ···, g^-t; ×, g^-g^-; and ---, g^-g^+.

Effect of Variation in the Angle C—O—C

The proper choice of the value for the valence angle C—O—C for conformational analysis of polymers is problematic. Studies on various types of small molecules have shown that the value of this angle varies from 110 to 122° depending upon the bulkiness of the group of atoms attached to the two carbons (7, 11).

The variation of energy of EGDA as a function of the angle C—O—C is shown in Fig. 4 for the five representative conformations. Consider-

For personal use only.

able decrease in energy is noted as the angle is increased from 110°. For the *tt* and tg^- conformations, a minimum in the curves is observed at about 115°, and a further increase in the angle results in a sharp increase in energy due to the increasing contribution from $V(\theta)$. For the conformations g^-t and g^-g^-, the minimum is found at C—O—C = 116°. The preferred value is shifted to 118° for the g^-g^+ conformation. It would seem that the interaction between the carbonyl oxygens is relieved considerably by an increase in the value of the valence angle C—O—C. This is substantiated by a rather sharp decrease in energy with an increase of C—O—C from 110 to 118° for the g^-g^+ conformation, compared to the other curves in Fig. 4. Thus, the calculations show that with the exception of the g^-g^+ conformation, the most probable value of C—O—C would be 115° in EGDA.

The value of about 114–116° for C—O—C seems to be the range in which the relative stabilities of the conformations undergo a change. Throughout the range of C—O—C = 110 to 124°, the energy difference between the *tt* and tg^- states remains the same. However, beyond 114°, the energies of g^-t and g^-g^- conformations are found to be lower than that of *tt*. The g^-g^+ state, which is of highest energy for C—O—C = 110°, becomes the conformation of lowest energy beyond 115°.

Effect of Variation of Angle C—C—O

The iso-energy contours, as a function of the angles C—O—C and C—C—O are shown in Fig. 5 for the *tt* conformation. The minimum energy is observed for the values C—O—C = 115° and C—C—O = 109°. With C—O—C = 115°, as the value of C—C—O is decreased from 109 to 105°, the increase in energy is about 0.6 kcal mol^{-1}. Keeping C—C—O = 109°, the same amount of increase in energy results from a change of 3° in C—O—C, from 115 to 118°. Apart from this difference, the variation of energy seems to be equally sensitive to changes in both bond angles.

Comparison with Experimental Results

As seen from Table 3, various conformations are energetically possible for the EGDA molecule. These predictions are expected to be valid even if the CH_3 group is replaced by another kind of atom or group of atoms, *e.g.*, the aromatic moiety of van der Waals radius of 1.8 Å or the

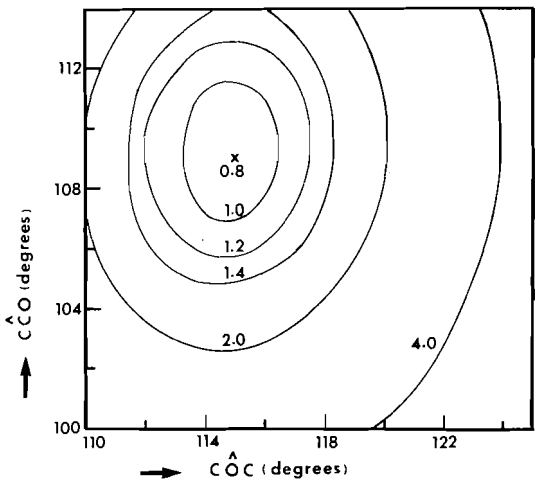

FIG. 5. Iso-energy contours as a function of the valence angles C—O—C and C—C—O for the *tt* state of EGDA. The minimum is marked by X. Energies are expressed in kcal mol^{-1}.

ethyl and propyl groups, should behave in the same way, the latter with a slightly larger van der Waals radius. In which of the predicted conformations these derivatives crystallize would depend upon the crystallization conditions and possibly packing requirements.

The crystal structure of ethylene glycol dibenzoate was reported previously (15). This molecule was found to be in the all-*trans* conformation, with $\phi_1 = 3.9°$ and $\phi_2 = 4.4°$. On the other hand, ethylene glycol di(*para*-chlorobenzoate) (16), crystallized under different conditions, was found to be in the tg^+ (or tg^-) conformation, with $\phi_1 = 5°$ and $\phi_2 = 105.5°$. The value of ω was found to be about 3° in these structures. In spite of the aromatic substitution (instead of CH_3), the values of the torsion angles ϕ_1, ϕ_2, and ω are in very good agreement with the values obtained for *tt* and $tg^{\pm}$ states theoretically. That remarkably similar values were obtained for the angle C—O—C, from the crystal structure analyses (115.5 to 115.9°) and the theoretical calculations (about 115°) is also very encouraging. The value of the angle C—C—O, in the crystal structure, is about 105°. This is rather small compared to the theoretical value of 108 to 110°. However, as seen from Fig. 5, the variation in energy as the angle C—C—O is reduced from 109 to 105° is only about 0.6 kcal mol^{-1}.

Table 4 shows a comparison of the atomic coordinates deduced from the crystal structure of the ethylene glycol di(*para*-chlorobenzoate)

TABLE 4. Comparison of the atomic coordinates (in Å) derived from calculations and the crystal structure

(which is in the tg^+ or tg^- conformation) and the atomic parameters derived from the present calculations for the tg^+ conformation of ethylene glycol diacetate. In spite of the minor differences in the angle C—C—O, there is a close agreement between the two sets of parameters. This demonstrates the potential of calculations of the type presented here to explain the occurrence of non-extended conformations for polyesters and model compounds based on ethylene glycol diesters.

Virtual Bond Method in Conformational Analysis of Polymers

PUDUPADI R. SUNDARARAJAN AND ROBERT H. MARCHESSAULT
Department of Chemistry, Université de Montréal, C.P. 6210, Succ. A, Montreal, Quebec H3C 3V1
Received May 13, 1975

PUDUPADI R. SUNDARARAJAN and ROBERT H. MARCHESSAULT. Can. J. Chem. **53**, 3563 (1975).

A detailed description of the virtual bond method is presented. Simple equations are set up to examine the various relative dispositions of the repeating units along the polymer helix, if the repeat distance and the screw symmetry are known from X-ray data. The method is demonstrated with the examples of β-D-1,4′-xylan helix and the α-helix. Due to the rapidity and simplicity of this procedure, the effect of using different geometries for the residues can be examined readily. Diagrams are presented, from which one can deduce the torsion angles ϕ, ψ for the various values of the valence angle at the bridge atom. This method does not involve a prior knowledge of ϕ, ψ and hence, derivation of atomic coordinates of the residue for Fourier transform or structure factor calculations is simple.

PUDUPADI R. SUNDARARAJAN et ROBERT H. MARCHESSAULT. Can. J. Chem. **53**, 3563 (1975).

La méthode d'analyse conformationnelle pour polymères employant le concept de la liaison virtuelle est décrite. Des équations simples permettent l'étude de conformations hélicoidales, si les symétries et les périodicités d'hélices sont déterminées auparavant par diffraction des rayons X. La méthode est appliquée à deux exemples: le polysaccharide β-D-1,4′ xylane et l'hélice α des polypeptides. La méthode permet facilement de faire varier la géométrie des unités de base. A partir de diagrammes, on peut déduire les angles de torsion: ϕ, ψ pour des valeurs données de l'angle de valence entre les unités de répétition. Cette méthode n'implique pas une connaissance préalable de ϕ, ψ, donc la détermination des coordonnées atomiques de l'unité de répétition pour le calcul de la transformée de Fourier, ou pour le calcul de facteurs de structure s'avère très simple.

[Traduit par le journal]

Conformational analysis of polymers in terms of rotations around single bonds connecting the repeat units is extensively used (1–3). Relative orientations of contiguous residues are described by the torsion angles ϕ and ψ which define the rotations around the bonds C(1)—O and O—C-(n') in a $1 \rightarrow n'$ linked polysaccharide, and around the bonds N_i—C_i^{α} and C_i^{α}—C_i' in the case of polypeptides. Energies for each relative orientation, computed as a sum of interactions between atoms of contiguous residues, are plotted as *iso*-energy contours in the (ϕ, ψ) plane and this defines the relative stability of the conformational regions accessible to the molecule. The *iso*-energy maps are employed for evaluation of the statistical mechanical average properties of macromolecules (3).

Methods are also available (2, 4) to evaluate the helical parameters n (the number of residues per turn of the helical chain) and h (the projected height of the residue along the helix axis), and again these parameters are plotted as *iso-n* and *iso-h* contours on a (ϕ, ψ) surface. Simultaneous use of the *iso* energy and the helical parameters maps aids in the selection of the most probable helical conformations of polymers in the solid state. In computing the *iso*-energy map and the helical parameters, the residue geometry as well as the angle τ at the bridge atom (τ = C(1)—O—C(n') for polysaccharides and N_i—C_i^{α}—C_i' for polypeptides) are fixed for any one particular map. Thus, for each polymer one should consider a family of maps, computed by varying τ over the range of acceptable values.

In order to generate the atomic coordinates of the atoms of the residues along a helix with a given set of n, h, and τ, one has to know the precise values of ϕ, ψ yielding the corresponding n, h and also the direction cosines of the helix axis in the defined coordinate system. This is usually achieved by interpolation of n, h values calculated at specific intervals of ϕ, ψ and while the interpolation may be graphical or computerized, in either case it is a tedious process. The task is multiplied if this has to be repeated for various values of τ. An alternate analytical method to deduce the

internal rotation angles was suggested by Nagai and Kobayashi (5), for structures with one, two, or three atom repeat units. The method presented here provides a simple way of deducing ϕ, ψ for a helical structure for various values of τ, in addition to serving as a tool to determine the best helical conformation.

A relatively simple method, that of rotation of the residue about the virtual bond was first applied to the analysis of cellulose conformation by Jones (6). Since then, the conformations of β-D-1,4′-xylan (7), acetyl amylose (8), and mycodextran (9) were treated by this procedure. Identical results have been reported in the case of β-D-1,4′-xylan (7, 10) and mycodextran (9), where the virtual bond method as well as the ϕ, ψ method were applied. A detailed description of the virtual bond method has not been presented so far. In this report, the details of the method will be set forth and the usefulness of this type of approach will be discussed.

The virtual bond method is applicable to a helix of given n, h, and chirality. It then examines the possible relative orientations of the contiguous residues, which obey the constraints imposed by the chosen n and h. Different conformations are generated by a rotation of the residue through angle θ around the virtual bond. The virtual bond itself is defined as the vector joining the contiguous bridge atoms (O(n') and O(1) atoms in polysaccharides, and C_{i-1}^{α} and C_i^{α} in polypeptides) with the residue geometry fixed.

The procedure will be illustrated with an example of the β-D-1,4′-xylan helix (7). Here $n = \pm 3$, and $h = 4.95$ Å. The negative sign of n applies for the left-handed helix. The angular twist about the helix axis relating two successive residues is then ± 120 ($360°/n$). The residue atoms are defined in the system (7) where the atom O(4) is at the origin and O(1) is along the positive Z axis. The starting position ($\theta = 0°$) is so chosen as to place the O(2) atom along the positive X-axis (Fig. 1*a*). In order to rotate the residue about the virtual bond, a counterclockwise rotation is applied to the residue, viewing towards the origin along the Z axis (*cf.* Fig. 1*a*). In order to transform the residue to the proper position along the helix, we have to do the following operations: (*i*) Viewing towards the origin along the X-axis rotate the residue clockwise through an angle μ (*cf.* Fig. 1*b*); this causes the residue to be at the proper tilt with respect to the helix axis (Z axis).

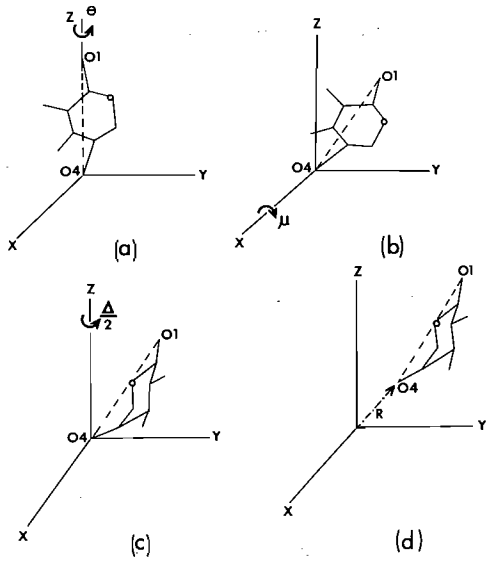

FIG. 1. Schematic representation of the virtual bond method, showing the (*a*) θ rotation, (*b*) μ tilt, (*c*) $\Delta/2$ rotation, and (*d*) translation through R. The virtual bond connecting O(4) and O(1) atoms is shown by dashed line.

(*ii*) Viewing towards the origin along Z axis, rotate the residue counterclockwise about the Z-axis through an angle $\pm\Delta/2$, the negative sign applying to left-handed helix (Fig. 1*c*). (*iii*) Translate the residue along the X-axis through $\pm R$, this being the radius of the atoms O(1) and O(4) with respect to the helix axis (Fig. 1*d*).

The parameters μ and R are calculated for the atoms O(1) and O(4) and the transformations involving these parameters are applied to all the atoms in the residue, since these are affine transformations. Thus, if $\boldsymbol{r}_1$ and $\boldsymbol{r}_2$ are the position vectors of an atom in the residue before and after transformation,

$$[1] \quad \boldsymbol{r}_2 = M_{0,0,1}^{\pm\Delta/2} M_{1,0,0}^{-\mu} \mathbf{M}_{0,0,1}^{\theta} [\boldsymbol{r}_1] \pm R$$

The matrices **M** have the general form described before (2). The subscripts denote the direction cosines of the axis of rotation: X or Z axis.

The parameter μ, which defines the tilt of the virtual bond with respect to the helix axis, and R are deduced from Fig. 2. In this figure, $\mu' = (90° - \mu)$. L represents the length of the virtual bond, h is the projected height of the residue, and Δ is the twist. From the diagram,

$$[2] \quad \mu = \cos^{-1}(h/L)$$

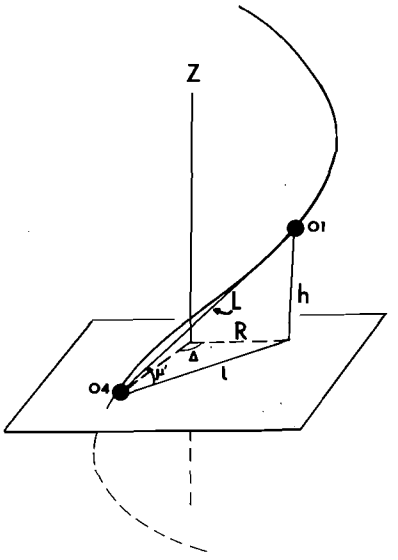

FIG. 2. Diagram showing the relationship between the virtual bond and the helix axis.

Since

$$[3] \qquad l = (L^2 - h^2)^{1/2}$$

and

$$[4] \qquad R = l/[2(1 - \cos \Delta)]^{1/2}$$

it follows that

$$[5] \qquad R = \frac{(L^2 - h^2)^{1/2}}{2 \sin\left(\frac{\Delta}{2}\right)}$$

After the rotation through μ described in step (*i*), the atom O(1) will have coordinates $x = 0$, $y = l$, $z = h$ (*cf.* Fig. 1*b*). It is essential that after translation through $\pm R$ along the X-axis (step *iii*), the radius of the atom O(1) with respect to the helix axis be R. Suppose that a clockwise rotation ε is applied to O(1) along Z axis, after step (*i*). Then, the coordinates of O(1) become

$$[6] \qquad x' = l \sin \varepsilon$$

$$y' = l \cos \varepsilon$$

After translation through R along the x-axis, the following condition should be satisfied

$$[7] \qquad (l \sin \varepsilon \pm R)^2 + l^2 \cos^2 \varepsilon = R^2$$

This equation simplifies to

$$[8] \qquad \sin \varepsilon = \pm \frac{l}{2R}$$

Since $l/2R = \sin(\Delta/2)$ (see eq. 5), it follows that a rotation $\varepsilon = \pm\Delta/2$ as described in step (*ii*) would transform O(1) to a position, which after step (*iii*), would place O(1) at a radius R with respect to the helix axis.

Once the residue is transformed to the correct helical orientation, the contiguous residue may be generated simply by the helix symmetry operation (rotation of the residue through $\pm\Delta$ about the helix axis and a translation h parallel to the helix axis). The angle C(1)—O—C(4′) at the bridge atom will vary as the value of θ is changed. From the coordinates of the atoms in a pair of residues generated as above, the value of τ can be readily obtained. The torsion angles ϕ and ψ are also easily deduced.

The variation of the angle τ as a function of the rotation θ is given in Fig. 3 for left-handed β-D-1,4′-xylan helix. The atomic coordinates given in ref. 7 were used. The angle τ varies from 113° to about 118° in the crystal structures of carbohydrates (11, 12). Figure 3 shows that, as we proceed along the solid curve (τ curve) the values of θ corresponding to the above range of τ are from 130 to 215°. Also given in Fig. 3 are the torsional angles ϕ = [H(1)—C(1)—O—C(4′)] and ψ = [C(1)—O—C(4′)—H(4′)]. It is seen that the values of ϕ and ψ for any given angle τ can be

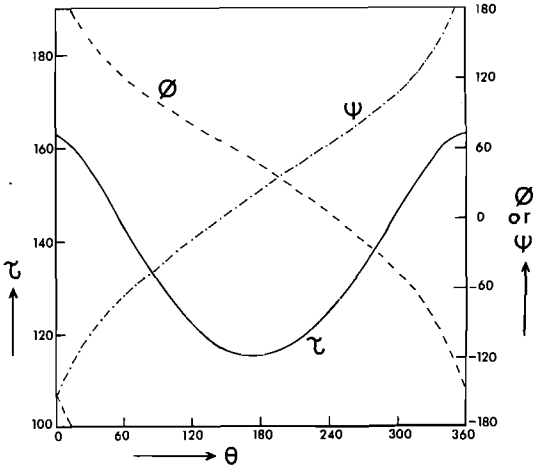

FIG. 3. Variation of τ (—, left ordinate), ϕ (---, right ordinate) and ψ (-·-·-, right ordinate) as a function of θ, the rotation about the virtual bond for left-handed β-D-1,4′-xylan helix.

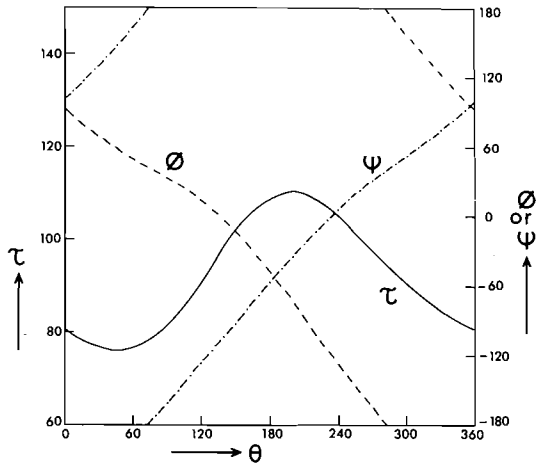

FIG. 4. Variation of τ (—, left ordinate), φ (---, right ordinate), and ψ (·····, right ordinate) as a function of θ, the rotation about the virtual bond for right-handed α-helix.

obtained from this figure in a straightforward manner. For example, with $\tau = 117.5$, the φ, ψ values which permit a 3_1 helix are: (66.1, −1.3) and (28.8, 40.5). From the φ, ψ energy map (10), it was shown that conformations similar to φ, ψ = 66.1, −1.3 are energetically favorable. The values of φ, ψ given here differ slightly from those in ref. 10 due to different residue geometries used in the two papers and due to differences in the definition of the starting position $\phi = \psi = 0$.

While two sets of values of φ, ψ are possible for values of τ such as 117.5°, only one set of φ, ψ is possible for the value of τ at the trough of the solid curve in Fig. 3. In this case, for $\tau = 115.4°$, the φ, ψ values are (48.7, 19.4). For $\tau < 115.4°$ it would be impossible to construct a xylan chain with the chosen residue geometry and the helical parameters. This value of τ which yields a unique φ, ψ for a helical conformation was termed (13) the 'critical τ' (τ_c).

One could evaluate the disaccharide energy (with due regard for the energy involved in changing τ) for each θ and plot a curve in Fig. 3. Such an energy curve would be of help in choosing the helix of minimum conformational energy.

A similar set of curves showing the variation of φ, ψ, and τ as a function of θ are given in Fig. 4 for the right-handed α-helix. The Pauling–Corey *trans* planar peptide geometry was used. It is seen that the critical τ_c in this case, at the apex of the solid curve, corresponds to a value of 110.4°, implying that an α-helix with $\tau > 110.4°$ cannot be generated with the planar peptide unit. For $\tau =$ 110° there are two sets of φ, ψ which satisfy the helix symmetry. These are (−58.4, −46.5) and (−86.3, −23.1). Only the former is the accepted α-helical conformation; the latter would fall in the disallowed area in the Ramachandran map, though dipeptide conformations with this value of φ, ψ are found in myoglobin and lysozyme (2).

The method and the results presented here show that for a given set of *n* and *h*, and the residue geometry, the values of φ and ψ can be evaluated rapidly for a series of values of τ. The critical τ is also made available immediately. In addition, comparison of the energy of the helices with varying τ is also possible. Due to its rapidity and simplicity, the effect of using different residue geometries can be examined easily. Since this procedure does not involve prior knowledge of φ, ψ or the direction cosines of the helix axis, derivation of atomic coordinates of the residue for calculations of Fourier transforms or structure factors is simplified.

Thus, while the φ, ψ approach looks at different possible helices with a given τ, the virtual bond method examines a chosen type of helix with varying τ, and in addition provides additional information which is of immediate use to the solid state conformational analyst.

On the Preparation of MoS_2 Catalysts from MoS_3

E. FURIMSKY AND C. H. AMBERG

Department of Chemistry, Carleton University, Ottawa, Canada K1S 5B6

Received May 29, 1975

E. FURIMSKY and C. H. AMBERG. Can. J. Chem. **53**, 3567 (1975).

We have examined the effect of reducing MoS_3 in hydrogen in the range 450–800 °C on the properties of the resulting MoS_2 catalyst. The appearance of rhombohedral MoS_2 at 800 °C is disputed. Instead, an 'overreduced' catalyst containing some Mo metal and hexagonal MoS_2 was formed. Catalytic activity in thiophene hydrodesulfurization was insensitive to pretreatment.

E. FURIMSKY et C. H. AMBERG. Can. J. Chem. **53**, 3567 (1975).

On a examiné l'effet de la réduction de MoS_3 par l'hydrogène à des températures de 450–800 °C sur les propriétés du catalyseur MoS_2 qui en résulte. On met en doute l'apparition de MoS_2 rhomboédrique à 800 °C. On suggère à la place de cette conclusion qu'il y a formation d'un catalyseur 'superréduit' contenant du Mo métallique et du MoS_2 hexagonal. L'activité catalytique vis-à-vis de l'hydrodésulfurisation du thiophène est insensible à un prétraitement.

Introduction

MoS_2 is frequently used as a model catalyst in hydrodesulfurization (HDS) studies, and as such is often prepared from MoS_3. The activity of this catalyst in general is thought to depend on the temperature of reduction or pretreatment. For instance, it was shown earlier (1) that reduction of MoS_3 at 400 °C gave rise to significantly higher surface area and HDS activity per unit area than was found for the same MoS_2 catalyst sintered at 650 °C. Treatment at the higher temperature was said to have been responsible for improved reduction and/or thermal destruction of unstable surface states in the MoS_2 crystallites. A temperature increase to 800 °C resulted in a further decrease in surface area, but left the catalytic activity per unit surface area approximately unchanged.

There is conflicting evidence in the literature regarding the fate of MoS_2 catalysts subjected to thermal or reductive treatments. Ratnasamy and Léonard (2) in studying the structural evolution of MoS_2 concluded that the decrease in activity with increasing reduction temperatures was caused by a gradual build-up of rhombohedral MoS_2; this phase was presumed to be less active than hexagonal MoS_2. On the other hand, Wildervanck and Jellinek (3), who prepared MoS_2 by thermal dissociation of MoS_3, observed only hexagonal MoS_2 throughout the whole region of 350 to 1100 °C, with improved crystallinity detectable at the higher temperatures. Prolonged heating of the rhombohedral polymorph at 1000 °C effected the transition back to the hexagonal form. Silverman (4) demonstrated that rhombohedral MoS_2 can be prepared from its elements at temperatures higher than 1100 °C under ultrahigh pressures. Moreover, he observed that the hexagonal/rhombohedral transition occurs only in the neighborhood of 2000 °C, again under ultrahigh pressure.

Recently Aoshima and Wise (5) have studied the effect of varying the degree of reduction of a single crystal of hexagonal MoS_2 on the conversion of butanethiol. Through measurement of changes in electrical conductivity they were able to infer that with increasing reduction the number of S^{2-} ion vacancies in the crystal increased. In terms of the desulfurization of the thiol, an optimum region existed. However, beyond this, the crystal would be overreduced, and this caused loss of both activity and stability, some of which was due to an accumulation of carbon and sulfur species on the catalyst surface.

In view of these various observations a reexamination of several of the pertinent factors was thought to be worthwhile.

Experimental

Catalyst

MoS_3 was prepared by saturating a 200 g l^{-1} aqueous solution of ammonium paramolybdate with H_2S. After neutralizing with HCl, filtering, and washing, the brown precipitate which had formed was dried at 110 °C for 20 h. The material was then reduced in a quartz tube using a hydrogen stream (90 cc min^{-1}) near atmospheric

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

pressure at the temperatures 450, 600, and 800 °C and for various time periods. Fresh samples of MoS_3 were used for each reduction and time period.

Apparatus and Procedure

The microreactor and flow system were essentially the same as described previously (1). X-Ray analysis was carried out on a Siemens X-ray diffractometer using Cu K(α) radiation. Surface areas were determined in a volumetric B.E.T. apparatus using N_2 at liquid nitrogen temperature. Samples were outgassed at 200 °C.

Catalyst activity was tested at 400 °C, reactants consisting of a stream of hydrogen (30 cc min^{-1} near atmospheric pressure) containing a nominal partial pressure of thiophene of 21.4 Torr. The exact partial pressures, obtained by means of a thiophene bubble saturator which was kept at 0 °C, were measured on a routine basis during each test run. Thiophene conversion was analyzed by g.l.c. using a 6-ft squalane column (25% w/w) at 85 °C. Percent conversion was always expressed in terms of thiophene converted.

Results and Discussion

In the following we shall refer to the reaction which leads to the formation of MoS_2 as a reduction in hydrogen. It should be pointed out, however, that significant evolution of sulfur was observed at 600 and 800 °C, presumably through thermal dissociation of MoS_3. Sulfur deposits accumulated to a much smaller extent at 450 °C.

The change in crystallinity of our samples was examined by X-ray analysis throughout the time of reduction between 30 min and 20 h at constant temperature. No significant changes were observed at 450 and 600 °C, except for sharpening and intensification of the 002 band, indicating enhanced orientation around the *c*-axis at both these temperatures. Also, this band, as well as the broad 103, 101, and 105 reflections of the hexagonal MoS_2 lattice were sharper and more intense at 600 °C than at 450 °C, in agreement with the observations of Wildervanck and Jellinek (3). A marked increase in crystallinity appeared with reduction at 800 °C, as indicated by all lines of the spectrum, and this improved further with the time of reduction. In addition to this a new set of sharp lines was found after 8 h of reduction at 800 °C (Fig. 1*a*). As shown in Fig. 1*b*, these lines correspond closely with those of metallic molybdenum, in contradiction of the conclusions of Ratnasamy and Léonard (2) who interpreted their data in terms of the appearance of rhombohedral MoS_2. The experiments of the latter authors were performed under the same conditions as ours, except for possible differences in hydrogen flow rates, which were not cited in their paper. On reduction of highly crystalline and stoichiometric MoS_2 (Anachemia), again at 800 °C for 20 h, we were unable to detect any lines other than those of hexagonal MoS_2 (Fig. 1*c*).

Stubbles and Richardson (6) showed that the complete reduction of MoS_2 to Mo is possible via the following steps

$$[1] \qquad 2MoS_2 + H_2 \rightarrow Mo_2S_3 + H_2S$$

$$[2] \qquad \tfrac{1}{3}Mo_2S_3 + H_2 \rightarrow \tfrac{2}{3}Mo + H_2S$$

These authors used very pure synthetic MoS_2, and studied the equilibria obtained at temperatures between 850 and 1200 °C by circulating hydrogen over the powdered materials until constant H_2S pressures had been established. Reaction [1] was found to be much slower than [2]. Although our temperature was 50 °C below the bottom limit of their range, other conditions in our case were bound to favor further reduction of MoS_2. Thus, our reactor ensured a continuous supply of fresh hydrogen and removal of H_2S. Furthermore, our slightly sulfur-deficient MoS_2 of comparatively high surface area (Table 1) could be expected to be considerably more reactive than the 200-mesh powders of Stubbles and Richardson, the opposite extreme being represented by our inert Anachemia sample (surface area ~ 3 m^2 g^{-1}).

We have re-examined the data published by Ratnasamy and Léonard (2) for their 800 °C-sample, and found the X-ray lines to be consistent with the presence of both MoS_2 and Mo_2S_3; in other words, with 'overreduction' according to step [1] above. The X-ray diffractogram of these authors did not go to sufficiently high angles to permit us to establish the presence of molybdenum metal, because the four unique Mo lines at high angles (Fig. 1*b*) could not be seen.

In Table 1 we have recorded the surface area and sulfur content of all catalysts, as well as percent conversion and reaction rate per unit surface area in the hydrodesulfurization reaction.

At all temperatures, the initial reduction of MoS_3 resulted in a first steep increase in surface area to a maximum. The first entry at each temperature (1.0, 0.5, 0.5 h, respectively) represents this maximum. Thereafter, surface area decreased, reaching a steady value after 2–3 h at 600 °C, and after about 1 h at 800 °C. There was no sign of levelling off at 450 °C even after 20 h of reduction.

It is difficult to compare the initial surface

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

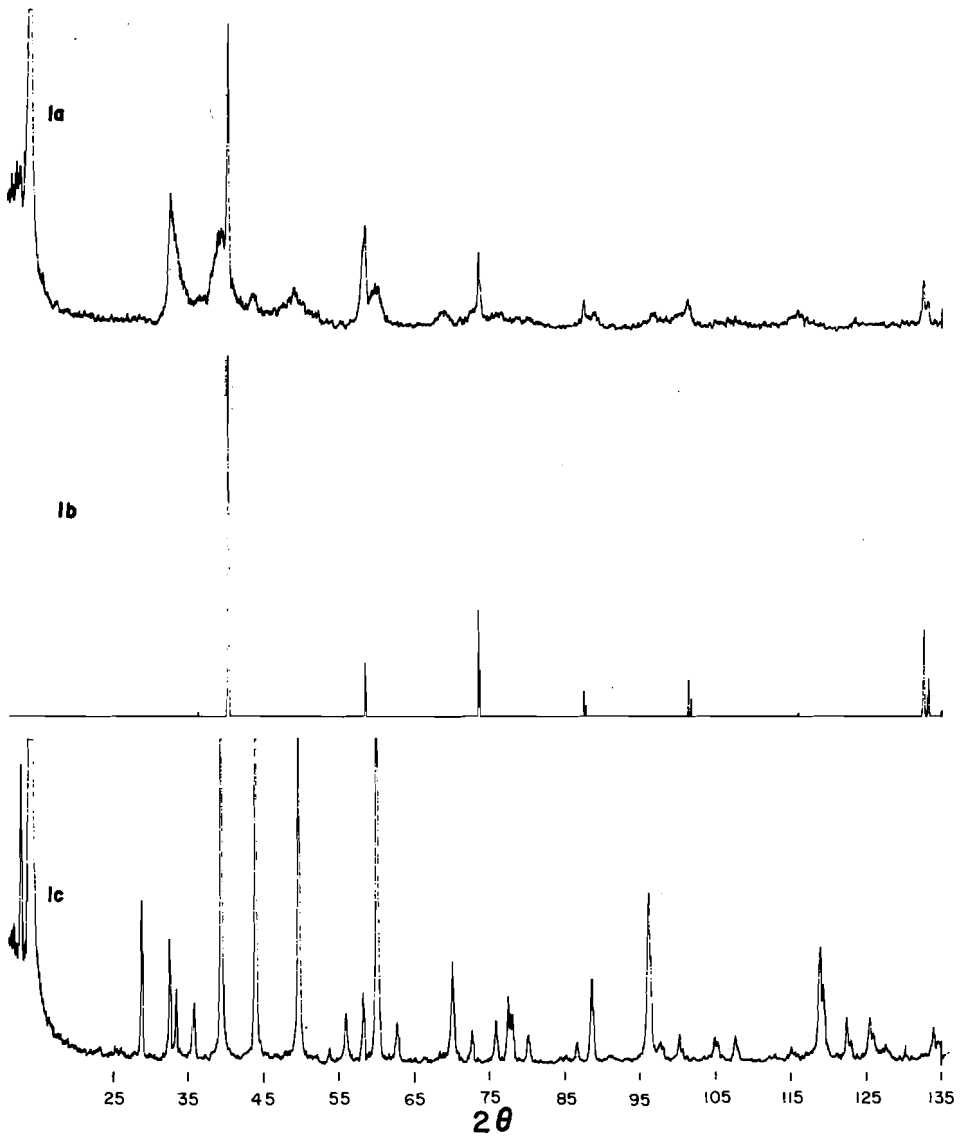

FIG. 1. X-Ray diffractograms of (*a*) catalyst prepared by the reduction of MoS_3 in hydrogen at 800 °C for 11 h, (*b*) Mo powder of better than 99.99% purity, (*c*) hexagonal MoS_2 (Anachemia).

areas (before reaction) with initial activities, because inevitably the first contact with the reaction stream leads to rapid sulfiding of what are presumed to be catalytically active S-vacancies. Nevertheless, by choosing an arbitrary 'initial' time of 10 min on stream one can see that percent conversion at this point parallels the decrease in surface area at 450 and 600 °C as expressed by the initial reaction rate. Thus the dominant feature in this temperature range would appear to be a decrease in area due to crystallization and sintering without significantly changing the number of catalytic sites per unit area. The initial reaction rate at 800 °C, however, is larger by a factor of 2 whereas surface area has decreased by 1/3 from the lowest value reached at 600 °C. This is consistent with 'overreduction' having created more vacancies, which have not yet been resulfided. Note, for instance, that initial S-content at 800 °C decreases with time of reduction at essentially constant surface area.

In earlier work (1) it had been demonstrated

TABLE 1. Surface area, catalytic activity, and sulfur contents of MoS_2 catalysts after various reductive pretreatments

that the steady-state activity of a number of stabilized MoS_2 surfaces was surprisingly insensitive to their method of preparation. The same conclusion can be reached from the present final reaction rate data, even for the still relatively unstable catalyst reduced at 450 °C. In all cases the reaction rate decreased from its initial value; this is generally observed during the sulfiding stage of catalyst preparation. The detailed mechanism of this decrease is a combination of further crystallization (especially at 450 °C), electronic lattice modifications (5), and surface re-organization, the latter including strong sorption of inhibiting species such as polymeric carbon compounds (coking) and inactive sulfur species (5). Surface area losses during the reaction are least pronounced in the case of the 800 °C-samples, whereas their reaction rates experience the largest decrease. That this is not entirely due to resulfiding is reflected in the fact that with increasing time of reduction it becomes more difficult to replace the sulfur originally lost. This is probably due to the blocking of S-vacancies by inhibiting surface species, such as were suggested above.

We thank Mr. Gary Harris for technical assistance, and Professor George Chao of the Carleton University Geology Department for the use of his X-ray diffractometer. We are grateful to the National Research Council of Canada for financial support.

Pulse Radiolysis of Alkali Metal Solutions in Methylamine[1]

JOHN WALLACE FLETCHER, WILLIAM ARTHUR SEDDON, JOHN JOSEPH JEVCAK, AND FRED CHARLES SOPCHYSHYN

Physical Chemistry Branch, Atomic Energy of Canada Limited, Chalk River Nuclear Laboratories, Chalk River, Ontario K0J 1J0

Received May 5, 1975

JOHN WALLACE FLETCHER, WILLIAM ARTHUR SEDDON, JOHN JOSEPH JEVCAK, and FRED CHARLES SOPCHYSHYN. Can. J. Chem. **53**, 3571 (1975).

Pulse radiolysis studies of solutions of alkali metal methylamides (CH_3NHM) in methylamine indicate the formation of solvated electrons, e_s^-, ion-pairs (M^+, e_s^-), and alkali metal anions M^-. This paper compares the spectra, extinction coefficients, and yields of e_s^-, Li, Na, K, and Cs species, with those observed previously in other solvents. The overall reaction kinetics are complex and, in CH_3NHNa/NaI solutions, suggest the formation of a higher aggregate or triple ion species (Na_2^{2+}, e_s^-). A reaction mechanism, quantitatively consistent with experiment, is presented and discussed in detail for solutions containing Na^+.

JOHN WALLACE FLETCHER, WILLIAM ARTHUR SEDDON, JOHN JOSEPH JEVCAK et FRED CHARLES SOPCHYSHYN. Can. J. Chem. **53**, 3571 (1975).

Des études de radiolyse pulsée de solutions de méthylamidures de métaux alcalins dans la methylamine indiquent qu'il y a formation d'électrons solvatés, e_s^-, de paires d'ions (M^+, e_s^-) et d'anions de métaux alcalins, M^- Cette publication compare les spectres, les coefficients d'extinction et les rendements en espèces e_s^-, Li, Na, K et Cs avec ceux obtenus antérieurement dans d'autres solvants. La cinétique globale de la réaction est complexe et, pour des solutions dans CH_3NHNa/NaI, elle suggère qu'il y a formation d'un aggrégat supérieur ou d'espèces ioniques triples (Na_2^{2+}, e_s^-). On présente un mécanisme réactionnel en accord quantitatif avec l'expérience et on le discute en détail pour des solutions contenant du Na^+.

[Traduit par le journal]

Introduction

Extensive investigations (refs. 1–3 and references therein) on the optical, magnetic, and conductance properties of alkali metal solutions in liquid amines have shown that solvated electrons, e_s^-, ion-pairs (M^+, e_s^-), and alkali metal anions, M^-, coexist in equilibrium according to the reactions

$$[1] \qquad e_s^- + M^+ \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} (M^+, e_s^-) \text{ or } M$$

$$[2] \qquad M + e_s^- \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} M^-$$

Such solutions are intensely colored and stable but can be catalytically decomposed to give the corresponding alkali metal alkylamides as represented by the overall reaction

$$[3] \qquad RCH_2NH_2 + M \rightarrow RCH_2NHM + \tfrac{1}{2}H_2$$

A pulse radiolysis study of alkali metal ethylamides in ethylamine (4) showed three distinct optical bands attributed to e_s^-, (M^+, e_s^-), and M^-. Furthermore it was demonstrated that the rate and equilibrium constants for the formation of the species (M^+, e_s^-) and M^- were markedly dependent on the nature of the alkali metal amide.

This paper describes the spectra and more detailed kinetics for the corresponding species generated by pulse radiolysis of alkali metal methylamides in methylamine.

Experimental

Details of our pulse radiolysis facilities have been described elsewhere (5). Methylamine was obtained from Matheson Co. Ltd. The earlier paper on ethylamine (4) should be consulted for purification procedures and additional experimental details. Appropriate quantities of sodium iodide (Fisher Chemicals) were 'purified' by standing in dilute metal–methylamine solutions followed by solvent distillation.

Results

Spectra

Figure 1 shows the absorption spectrum observed at room temperature immediately after a 0.5 μs pulse in pure methylamine and in dilute

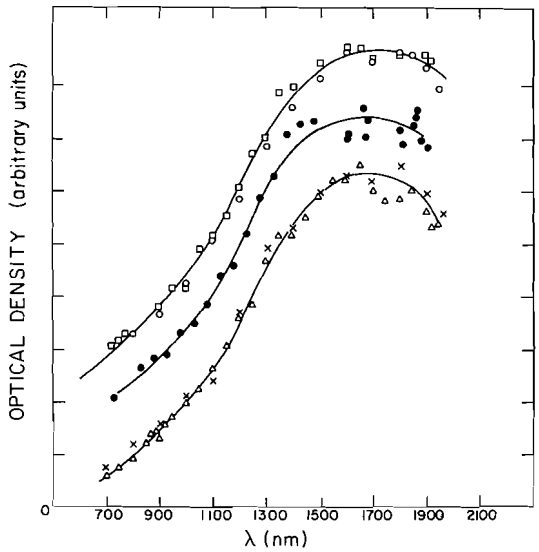

FIG. 1. Transient absorption spectra observed immediately after the pulse in pure methylamine and $\leq 10^{-5}$ *M* alkali metal methylamide solutions in methylamine; ●, pure CH_3NH_2; ○, Li; □, Na; △, K; ×, Cs. The curves are normalized to a common peak height of 6.9 divisions but arbitrarily displaced for clarity.

solutions ($\leq 10^{-5}$ *M*) containing Li, Na, K, or Cs methylamide. In all cases the absorption maximum occurs at ~1700 nm. In pure methylamine the absorption decays completely on a μs time scale whereas in methylamide solutions an additional growth in absorption is observed after the pulse.

Figure 2 shows the spectra observed 400 μs after the pulse for $\geq 10^{-3}$ *M* solutions of Li, Na, K, and Cs methylamide. Apart from the post pulse increase in intensity the infrared peak at ~1700 nm remains independent of the alkali metal for Li, Na, and K, and shows no distinct shift from that observed immediately after the pulse (Fig. 1). A blue shift to 1500 nm is observed with Cs. With the exception of Na solutions (see below) the infrared absorption is quite stable showing no decay over a period of ≤1 ms.

In K solutions the long time scale spectrum also exhibits a slight shoulder at ~900 nm. By repetitively flashing the analyzing light, after the electron pulse, it could be shown that the peak at ~1700 nm decayed with a $t_{1/2}$ ~ 60 s producing at the same time a relative increase in the peak at 900 nm.

In the Na solutions the infrared absorption band decays on a μs time scale forming a long-lived species with an absorption maximum at 690 nm.

Effect of Added "Crown Ether"

Earlier studies (2, 3) have shown that the addition of a cyclic polyether such as dicyclohexyl-18-crown-6 ("crown ether") complexes alkali metal cations and enhances their solubility in a variety of amines and ethers. Figure 3 shows the optical spectra and transient signals observed from solutions containing ~10^{-3} *M* potassium methylamide and ~10^{-3} *M* crown ether.

At low doses, $\leq 6 \times 10^{18}$ eV/l per pulse, the transient absorption shows no sign of a growth or decay over a period of ≥40 μs. At higher doses the absorption consists of an initial rapid decay followed by a long-lived residual component. Both the initial and long-lived species have identical spectra with an absorption maximum at ≥1800 nm.

Dose Dependence and Kinetics

The transient absorptions show a marked dose dependence in both the yield and in the decay kinetics. Plots of optical density as a function of dose per pulse are presented in Fig. 4 for Na methylamide solutions. In any given solution

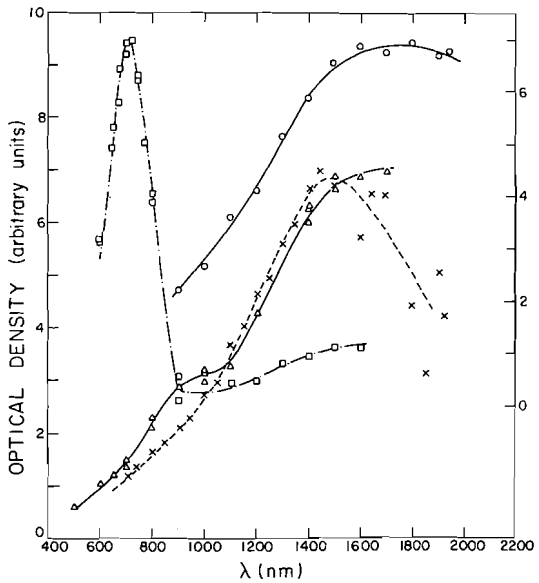

FIG. 2. Absorption spectra observed 400 μs after the pulse in $\geq 10^{-3}$ *M* alkali metal methylamide solutions in methylamine; ○, Li; □, Na; △, K; ×, Cs. The curves are normalized to a peak height of 6.9 units but with ○ and □ displaced 2.5 units for clarity (right hand scale).

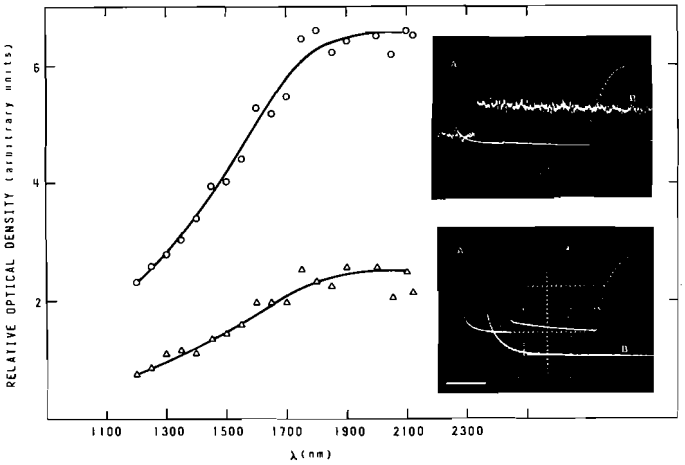

FIG. 3. Transient absorption spectrum observed in solutions containing $\sim 10^{-3}$ *M* CH_3NHK, and $\sim 10^{-3}$ *M* crown ether, ○, immediately after the pulse; △, 35 μs after the pulse. Upper curve *B*, dose 6.1×10^{18} eV/l; 1% absorption/division, 5 μs/division. Lower curve *B*, dose 1.52×10^{20} eV/l, 10% absorption/division, 5 μs/division. Wavelength 1650 nm and cell length 1.0 cm in both cases. Trace *A* shows the profile of the analyzing light at lower gain and a sweep speed of 500 μs/division.

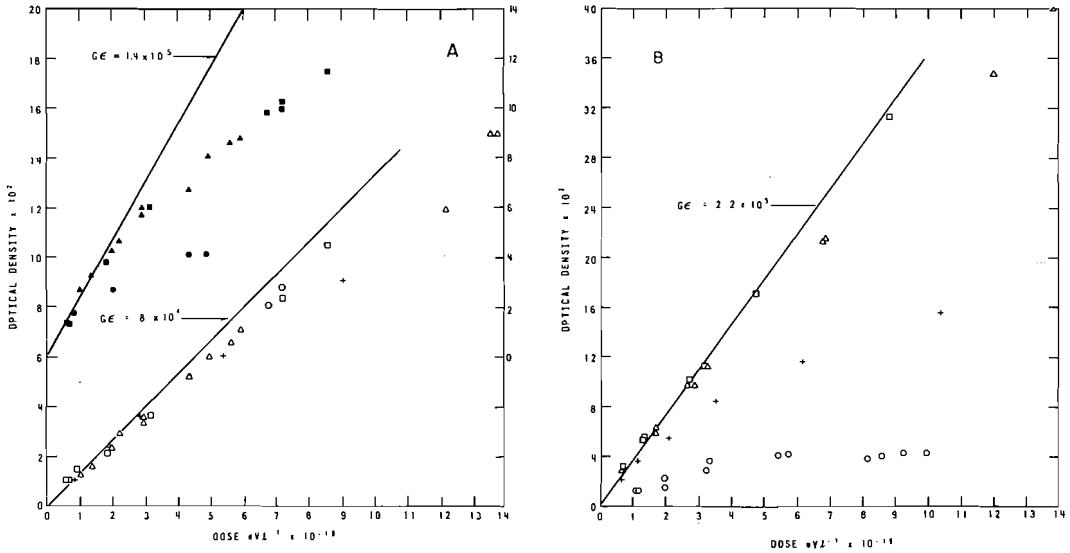

FIG. 4. (*A*) Effect of increasing dose per pulse on the transient absorptions observed at 1485 nm in sodium methylamide solutions: immediately after the pulse; +, 2×10^{-4} *M* (plus 10^{-3} *M* NaI); △, 1.1×10^{-3} *M*, □, 1.3×10^{-2} *M*: maximum absorption; ●, 1.0×10^{-4} *M* (100 μs); ▲, 1.1×10^{-3} *M* (50 μs); ■, 1.3×10^{-2} *M* (15 μs). Values in parentheses refer to the time required after the pulse to reach the maximum. (*B*) Effect of increasing dose per pulse on the absorption due to Na^- as observed at 700 nm ~ 400 μs after the pulse; +, 2×10^{-4} *M* (plus 10^{-3} *M* NaI); ○, 1.0×10^{-4} *M*; △, 1.1×10^{-3} *M*; □, 1.3×10^{-2} *M*. Cell length in both *A* and *B*, 1.0 cm.

the departure from linearity decreases with increasing methylamide concentration but increases again with the addition of NaI.

Similar plots were obtained for the other metals in the series. At corresponding concentrations Li solutions exhibit the most, and Cs solutions the least, dose effect of the series.

In the Na solutions the infrared absorption decays by a second order process with the concomitant formation of the 690 nm band. The latter is stable for times ≥ 10 s.

Potassium solutions appear to behave similarly but the rate is much too slow to deduce the kinetic order by our existing technique.

Discussion

Spectral Assignments

The spectra obtained in methylamine are similar to those observed in ethylamine and the reader is referred to the earlier paper (4) for background information and a general introduction. In pure methylamine, dilute methylamide solutions ($\leq 10^{-5}$ *M*), and solutions containing "crown ether", the spectrum observed immediately after the pulse (Figs. 1 and 3) is attributed to e_s^-. As a consequence of solvent absorption the maximum is difficult to resolve and therefore the observed peak may not be real. However, as in ethylamine, the maximum does occur at $\geq$1700–1800 nm.

On longer time scales the infrared band (Fig. 2) is more intense but very similar to the initial absorption. Its rate of formation is first order in methylamide concentration and dependent on the nature of the cation. In common with other recent work (4, 6, 7) we propose that this enhanced absorption is due to the formation of an ion-pair (M^+, e_s^-) or monomer species of stoichiometry M.

The lack of a significant change in the spectral shape of the infrared band with ion-pair formation is comparable to the situation observed in ethylenediamine (8, 9) and liquid ammonia (3, 10, 11). In ethylamine the ion-pair band for Na, K, and Cs is distinctly shifted but only about 400 nm below that of e_s^- (4).

In addition to the ion-pair peak at ~1700 nm it is evident that underlying absorptions are also present. This is most clear for sodium solutions where the predominant long-lived absorption occurs at 690 nm and is undoubtedly due to the species Na^- (1, 3, 12, 13).

In the case of potassium solutions the shoulder at 900 nm can likewise be assigned to K^- (1, 3, 12, 13). The relative predominance and stability of the infrared band is consistent with absorption spectra observed in potassium methylamine solutions (14) and contrasts sharply with ethylamine solutions (4, 14). For cesium solutions the slight blue shift to ~1500 nm may be due to the presence of some unresolved Cs^- which has a maximum at 1100 nm (2, 3, 12). Alternatively, since in methylamine only Cs and Rb show hyperfine splitting (15) the optical shift may be associated with the higher electron density for the Cs ion-pair (or monomer) as compared to the Li, Na, or K ion-pairs.[2]

[2]We acknowledge one of the referees for pointing out this possibility.

It is worth noting that the above results contrast sharply with ion-pair spectra observed in ethers (6, 7) where marked differences occur in the ion-pair and e_s^- absorption bands. For example, λ_{max} for e_s^- in tetrahydrofuran (THF) is given as 2120 nm (16, 17) whereas the corresponding maxima for (Na^+, e_s^-), (K^+, e_s^-), and (Cs^+, e_s^-) occur at 890, 1125, and 1400 nm, respectively (6, 7).

Formation of (M^+, e_s^-)

Studies of dilute solutions of Li, Na, K, and Cs methylamides ($\leq 6 \times 10^{-3}$ *M*) monitored at 1485 nm indicate that the rate of formation of (M^+, e_s^-) is first order and consistent with [1]. However very little information exists on the dissociation constants of alkali metal methylamides in methylamine. Data obtained for the potassium salt at -62.2 and -90 °C give values of 4×10^{-7} and 3×10^{-7} *M*, respectively, between 10^{-3} and 10^{-2} *M* (18). It is likely therefore that the methylamides are largely associated in methylamine at room temperature. Consequently, we have made no attempt to differentiate between [1] and those conceivably involving the undissociated salt CH_3NHM.

$$[4] \quad CH_3NHM + e_s^- \rightleftharpoons CH_3NH^- + (M^+, e_s^-)$$

The kinetic analysis suffers the same complications as noted previously (4). Quoted values for the rate constant k_1 in Table 1 are based on the total concentration of methylamide in solution and are not corrected for any back reaction.

As a general observation such rate constants are an order of magnitude slower than for the corresponding reactions in ethylamine (see Table 1). This may simply be due to the different degrees of dissociation of the various alkyl amides in the respective solvents. In either case the values are low in comparison with the diffusion controlled rates in THF, where for example, $k(e_s^- + Na^+) = 7.8 \times 10^{11}\ M^{-1}\ s^{-1}$ (6, 7). Until dissociation constants are established in the amines these details cannot be resolved.

Formation of M^-

The most notable feature of the results is that, with the exception of sodium solutions, the lifetime of the ion-pair is considerably longer than was observed in ethylamine (4). Consequently information relating to the formation of M^- can be obtained only for sodium solutions since in all other cases the reaction is too slow to be followed by our present technique. The kinetics were monitored either by observing the

TABLE 1. Rate constants for the formation of (M^+, e_s^-) in methylamine

Alkali metal	Methylamide concentration (M)	k_1 (M^{-1} s^{-1}) In methylamine	k_1 (M^{-1} s^{-1}) In ethylamine*
Li	$\sim 1 \times 10^{-3}$	5×10^6	4×10^6 ($\sim 1 \times 10^{-3}$)
Na	1×10^{-4}	2.1×10^8	1.2×10^9 (2.5×10^{-4})
	1×10^{-3}	7×10^7	
K	6×10^{-3}	1.2×10^7	1.6×10^8 (4.5×10^{-4})
Cs	7×10^{-5}	1×10^9	2×10^{10} ($\sim 3.5 \times 10^{-6}$)

*Values in parentheses give the appropriate ethylamide concentrations (M) obtained from ref. 4.

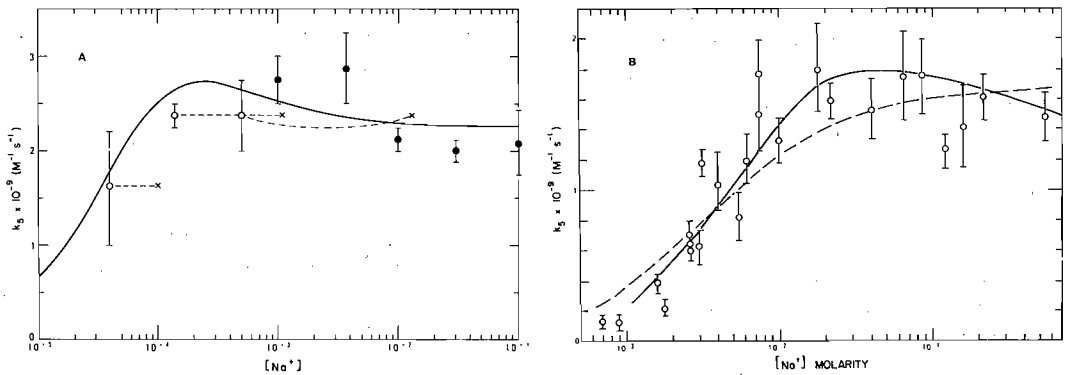

FIG. 5. Pseudo second order rate constants for the formation of Na^- in methylamine and ethylenediamine. (*A*) Methylamine; ○, Na^+ added as CH_3NHNa taking $K_{diss} = 2 \times 10^{-5} M$; ×, assumes CH_3NHNa is fully dissociated, dotted lines show relative displacement; ●, Na^+ added as $\sim 5 \times 10^{-4} M$ CH_3NHNa + NaI, assumes NaI fully dissociated. The solid line represents the calculated 'best fit' as described in the text. (*B*) Ethylenediamine (Na^+ added as NaBr plus sodium, potassium, or cesium ethylenediamide) see ref. 9 for specific details. The dotted line was calculated (9) on the basis of [7] and [8] and the solid line according to our mechanism (see text).

build up of Na^- at 690 nm or via the concomitant decay of (Na^+, e_s^-) at 1485 nm. As in the case of ethylamine (4) and ethylenediamine (9) the kinetics are pseudo second order and consistent with the overall stoichiometry represented by [5],

$$[5] \qquad e_s^- + e_s^- \overset{M^+}{\rightleftharpoons} M^-$$

Again it is important to note that the precise determination of the pseudo second order rate constant, represented by k_5, is difficult. Large errors in the kinetic analysis arise from the uncertainties in determining the optical densities corresponding to the complete formation of either (Na^+, e_s^-) or Na^-. Since the equilibria lie predominantly to the right the best values are deduced by monitoring the build up of absorption of Na^- at 690 nm. Assuming $\varepsilon_{M^-} = 1 \times 10^5 M^{-1}\,cm^{-1}$ (4) values increase, as a function of Na^+ concentration, from $4k_5 = 6.4 \times 10^9$ to 11.6×10^9 M^{-1} s^{-1} (Fig. 5*A*).

In ethylenediamine Dye *et al.* (9) considered a reaction scheme previously proposed from e.s.r. studies in dimethoxyethane (13)

$$[1] \qquad e_s^- + Na^+ \rightleftharpoons (Na^+, e_s^-)$$

$$[2] \qquad (Na^+, e_s^-) + e_s^- \rightarrow Na^-$$

with the modification that [2] be written as equivalent to [6]

$$[6] \qquad (Na^+, e_s^-) + (Na^+, e_s^-) \rightarrow Na^- + Na^+$$

Reactions 1 and 2 are, by themselves, inadequate to explain the results since the equilibrium for [1] lies to the right and, at high Na^+ concentrations, would result in a marked decrease in the rate of formation of Na^-.

This mechanism was then ruled out since the rate of Na^- formation was independent of other cations (K^+ or Cs^+) present in excess. Consequently they concluded that the formation of a species containing two electrons occurred prior to the formation of Na^-

$$[7] \qquad e_s^- + e_s^- \rightleftharpoons e_2^{2-}$$

$$[8] \qquad e_2^{2-} + Na^+ \rightarrow Na^-$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

It was also noted that [9] and [10] were considered equivalent to [7] and [8]

[9] $(M^+, e_s^-) + (M^+, e_s^-) \rightleftharpoons (M^+, e_s^-)_2$

[10] $(M^+, e_s^-)_2 + Na^+ \rightarrow Na^- + 2M^+$

However, from studies on mixed sodium–potassium solutions in ethylamine (19) we have deduced that the formation of Na^- can occur via [11]

[11] $$K^- \xrightarrow{Na^+} Na^- + K^+$$

at an overall rate not significantly different from pure sodium solutions. Furthermore, in sodium aluminum hydride solutions in tetrahydrofuran (7), [1], [2], and [6] are essential to explain the formation of Na^-. The analogous potassium reaction 6 is apparently much slower with K^- formation occurring via the corresponding reaction 2.

We therefore conclude that [1], [2], and [6] are also applicable to the amine–amide systems. It was pointed out that for this to be valid in ethylenediamine (9), the equilibrium constant for the formation of a species of stoichiometry Na must be much greater than the corresponding reaction to form Cs or K, and furthermore the spectrum of Na must be nearly the same as e_s^-. The latter is now thought to be the case whereas the former is still unknown. A comparison of the observed pseudo second order rate constants for methylamine (this work) with ethylenediamine (9) is given in Fig. 5. In the case of ethylenediamine the Na^+ concentration refers to the total concentration of added sodium (metal plus salt). In methylamine we have assumed that NaI is fully dissociated. A value of 2×10^{-5} M was chosen for the dissociation constant of CH_3NHNa since this gave the 'best fit' as judged by the initial slope in Fig. 5*A*. This compares well with that for $NaNH_2$ in liquid NH_3 (2.24×10^{-5} M at -33.5 °C (20)) but is greater than that for CH_3NHK in methylamine (4×10^{-7} M at -62.2 °C (18)).

The solid curves in Fig. 5 represent the calculated 'best fit' to the data where k_5 is given by

[12] $$k_{obs(Na^-)/4} \equiv k_5 = (k_2K' + k_6)/(1 + K')^2$$

and

$$K' = k_{-1}/k_1[Na^+]$$

Values for k_1 and k_{-1} for methylamine were estimated from the observed rate of formation of (Na^+, e_s^-) as a function of Na^+ concentration.

$$k_{obs(Na^+, e_s^-)} = k_{-1} + k_1[Na^+]$$

At high concentrations ($\geq 10^{-3}$ M) k_{-1} becomes unimportant and

$$k_{obs(Na^+, e_s^-)} \sim k_1[Na^+]$$

On this basis $k_1 = 1 \times 10^8$ M^{-1} s^{-1} and $k_{-1} = 8 \times 10^3$ s^{-1}. The equilibrium constant $K_{-1} = 1.2 \times 10^{-4}$ M as determined from the relative (Na^+, e_s^-) yield as a function of $[Na^+]$. This leads to a slightly higher, but comparable value for $k_{-1} = 1.2 \times 10^4$ s^{-1}.

At low concentrations ($\leq 10^{-4}$ M) k_6 becomes negligible and

$$k_{obs(Na^-)} \sim k_2K'/(1 + K')^2$$

Therefore k_6 was estimated via [12] from the decrease in $k_{obs(Na^-)}$ with increasing Na^+ concentration.

A similar iterative procedure was adopted for ethylenediamine using the original data from ref. 9. The appropriate constants deduced for both systems are summarized in Table 2. It can be seen that this mechanism composed of [1], [2], and [6] fits the ethylenediamine results equally as well as the mechanism (dotted line) composed of [7] and [8] (9).

These calculations also indicate that K_{-1} for methylamine is about two orders of magnitude less than that for ethylenediamine. Values for K_{-1} have been determined by conductance measurements for Li, K, Cs, and Rb in ethylenediamine (8), and Cs in methylamine (21), and are typically about 1×10^{-4} M. The conductance behavior of Na solutions differ markedly from the other alkali metals and therefore the corresponding values are not available for comparison.

Using the computer program WR 20 (7, 22, 23) we therefore sought to check the validity of this reaction sequence by comparing with experiment the calculated formation and decay of (Na^+, e_s^-) and Na^- (in methylamine) as a function of $[Na^+]$ and dose per pulse. Initial calculations demonstrated that the mechanism fails to predict observed effects of Na^+ concentration. While changes in rate constants could produce agreement in dilute solutions, such revised values would be inconsistent at higher concentrations, and vice versa.

Firstly, in dilute methylamide solutions ($\leq 10^{-4}$ M Na^+), the calculations did not predict

TABLE 2. Reactions and rate constants used to calculate the 'best fit' solid lines shown in Fig. 5

Reaction	Rate constant: Methylamine	Rate constant: Ethylenediamine
[1] $e_s^- + Na^+ \rightarrow (Na^+, e_s^-)$	$1 \times 10^8\ M^{-1}\ s^{-1}$	$3.3 \times 10^7\ M^{-1}\ s^{-1}$
[−1] $(Na^+, e_s^-) \rightarrow e_s^- + Na^+$	$1.2 \times 10^4\ s^{-1}$	$5 \times 10^5\ s^{-1}$
[2] $(Na^+, e_s^-) + e_s^- \rightarrow Na^-$	$6.7 \times 10^9\ M^{-1}\ s^{-1}$	$5 \times 10^9\ M^{-1}\ s^{-1}$
[6] $(Na^+, e_s^-) + (Na^+, e_s^-) \rightarrow Na^- + Na^+$	$2.0 \times 10^9\ M^{-1}\ s^{-1}$	$1.5 \times 10^9\ M^{-1}\ s^{-1}$

a sufficient build up of (Na^+, e_s^-). The appropriate increase in absorption could only be approximated by reducing k_{-1} effectively to zero, implying that (Na^+, e_s^-) is not dissociated. This in turn requires Na^- to be formed entirely by [6], the rate of which would then be independent of $[Na^+]$ and hence inconsistent with experiment.

Secondly, the equilibrium constant $K_{-6} = [Na^+, e_s^-]^2/[Na^-][Na^+]$ and, as a first approximation, $K_{-6}[Na^+] \propto \text{o.d.}^2_{1485}/\text{o.d.}_{690}$ (4), where o.d._{1485} and o.d._{690} are the optical densities observed ~400 μs after the pulse at 1485 nm and 690 nm, respectively. Experimentally it is found that this ratio decreases from 22×10^{-3} to 1.2×10^{-3} with increasing $[Na^+]$ from 1×10^{-4} to $1 \times 10^{-1}\ M$, respectively. With $k_{-1} = 0$, one would expect an increase in the ratio $\text{o.d.}^2_{1485}/\text{o.d.}_{690}$ with increasing $[Na^+]$. Alternatively, if Na^- dissociates exclusively via [−2], then the ratio would be independent of $[Na^-]$. Again, therefore, $k_{-1} \neq 0$.

Finally, at high $[Na^+]$ (sodium methylamide solutions containing $\geq 10^{-3}\ M$ NaI), the calculations predict an initial absorption due to (Na^+, e_s^-) about double that observed experimentally, but at the same time correctly predict the rate of formation and final yield of Na^-. In other words the observed lower initial absorption is not reflected by a stoichiometric reduction in the final product Na^-.

These discrepancies in detail can be resolved if we postulate at the higher concentrations a second order dependence on Na^+ involving the formation of a triple ion (24–26), such as (Na_2^{2+}, e_s^-). This can perhaps be regarded as analogous to the triple ions suggested in polymerization processes (27, 28) or in the reduction of semiquinones (29–32).

[13] $(Na^+, e_s^-) + Na^+ \rightleftharpoons (Na_2^{2+}, e_s^-)$

This additional species must also absorb in the infrared with an extinction coefficient about one-half that of (Na^+, e_s^-) at 1485 nm and be formed with $k_{13} \sim 5 \times 10^7\ M^{-1}\ s^{-1}$ and $K_{-13} \sim 2 \times 10^{-2}\ M$. Likewise it must also react at a rate and manner similar to (Na^+, e_s^-), reactions 14–16, to produce Na^-.

[14] $(Na_2^{2+}, e_s^-) + e_s^- \rightarrow Na^- + Na^+$

[15] $(Na_2^{2+}, e_s^-) + (Na^+, e_s^-) \rightarrow Na^- + 2Na^+$

[16] $(Na_2^{2+}, e_s^-) + (Na_2^{2+}, e_s^-) \rightarrow Na^- + 3Na^+$

Additional refinements are necessary, however, since at low methylamide concentrations and/or high doses per pulse an initial rapid decay is observed in the transient absorptions. As noted previously (4), and established in THF (7), we attribute this behavior to reaction with radiolytically produced radicals. For example, [17] to [19] in competition with [20].

[17] $e_s^- + R \rightarrow \text{product}$

[18] $(Na^+, e_s^-) + R \rightarrow \text{product}$

[19] $Na^- + R \rightarrow \text{product}$

[20] $R + R \rightarrow \text{product}$

For a given dose per pulse the effect decreases with increasing concentrations of methylamide suggesting, in a manner analogous to ethanol (33, 34), that the solvent base converts the radicals into a less reactive basic form, *e.g.*

[21] $\dot{C}H_2NH_2 + CH_3NH^- \rightarrow CH_2{=}NH^- + CH_3NH_2$

Estimates for k_{17} and k_{19} of ~6 and $1 \times 10^{10}\ M^{-1}\ s^{-1}$, respectively, were obtained from the initial rapid second order decays observed at high doses at 1485 and 720 nm, respectively.

At high [NaI] the situation is further complicated by ionic strength and common ion effects. The latter restricts the dissociation of CH_3NHNa and hence the significance of [21]. The observation of increased dose effects in solutions containing NaI is explicable on this basis.

Finally, the reactions by which $G_{e_s^-}$ increases from 2.2 in the pure solvent to 4.8 in basic

*Extrapolated by curve fitting.
†Extinction coefficients can be estimated by taking $G_{e_s^-} = 2.2$, $G_M = 4.8$, and $G_{M^-} = 2.4$.

solution are not clear (35). The build up of the ion-pair absorption may be associated with such processes since the alternative of an extinction coefficient for (Na^+, e_s^-) about twice that for e_s^- would, since the spectra are the same, be inconsistent with oscillator strengths of ~1 for each species (6, 9). However, since the final yields of Na^- are only compatible with $G_{e_s^-} = 4.8$ it is necessary to adopt this value in the computer calculations[3] and simulate the build up by using an extinction coefficient for $e_s^- \sim (Na^+, e_s^-)/2$ to be consistent with measured $G\varepsilon$ values (Table 3).

In summary more information is needed on solute and ion-pair dissociation constants and the effect of base before further detail is justified. However, we believe that an additional intermediate such as (Na_2^{2+}, e_s^-) best explains all the data and that radical reactions with e_s^- and metal–electron species are an additional complication in the radiolytic system.

Kinetics in the Presence of "Crown Ether"

The results obtained in this study are very similar to those obtained in ethylamine (4). This earlier paper should be consulted for a general discussion. Again there is no evidence for the formation of either (M^+, e_s^-) or M^-. The solvated electron or e_s^-–crown complex thus becomes the predominant reactive species and at low doses is stable for ≥50 μs.

Yields and Extinction Coefficients

Figure 4 shows examples of the formation of the various sodium species as a function of dose per pulse. Because of the dose dependence the initial yields, and hence the corresponding $G\varepsilon$ values, are estimated from the linear portion of such curves. Values for Li, Na, K, and Cs solutions are summarized in Table 3 and, again, these are very similar to those observed in ethylamine (4). However, in the case of e_s^- the $G\varepsilon$ values of 8×10^4 are about four times greater than in ethylamine. This difference is not understood but may imply that the true absorption maximum for e_s^- in methylamine is closer toward the visible than is the case for ethylamine.

The points on the dose curves are taken directly from the original photographs. If the buildups in absorption are curve fitted to infinite time then slightly higher values are obtained (Table 3). Such fitting takes into account the decay of (Na^+, e_s^-) and Na^- concurrent with their formation and hence requires a larger value of $G\varepsilon(Na^+, e_s^-)$ and $G\varepsilon(Na^-)$ to give the best fit with experiment.

To calculate the extinction coefficients we have taken the value $G_{e_s^-} = 2.2$ and 4.8 in neutral and basic solution, respectively (35). On this basis we estimate $\varepsilon_{e_s^-} = 3.6 \times 10^4$, $\varepsilon_{(M^+, e_s^-)} = 3.0 \times 10^4$, and $\varepsilon_{Na^-} = 9.2 \times 10^4\ M^{-1}\ cm^{-1}$. These values are comparable with values of $\varepsilon_{e_s^-} = 2 \times 10^4$ in ethylenediamine (9, 36), $\varepsilon_{(M^+, e_s^-)} = 2.4$–$2.9 \times$

[3]Additional details showing comparisons with oscilloscope traces over a range of dose and $[Na^+]$ are available, at a nominal charge, from the Depository of Unpublished data, CISTI, National Research Council of Canada, Ottawa, Canada K1A 0S2.

10^4 in THF (6, 7), and $\varepsilon_{Na^-} = 8.2–12.0 \times 10^4$ (4, 36).

Conclusions

As in the case of ethylamine the results of this study are consistent with the formation of three distinct species e_s^-, (M^+, e_s^-), and M^-. However, in sodium solutions the more detailed kinetic analysis indicates the formation of an additional metal–electron species suggested to be (Na_2^{2+}, e_s^-). In general the overall rates of reactions are much slower in methylamine and, with the exception of Na^-, the equilibria appear to lie more in favor of (M^+, e_s^-) than M^-.

Received July 11, 1975

C.-J. CHEN, M. H. BACK, and R. A. BACK. Can. J. Chem. **53**, 3580 (1975).

The pyrolysis of methane has been studied in a static system at temperatures of 995, 1038, 1068, and 1103 K and pressures from 25 to 700 Torr. It was concluded that the initial stages of the reaction can be described by a simple homogeneous, nonchain radical mechanism:

[1] $CH_4 \rightarrow CH_3 + H$

[2] $H + CH_4 \rightarrow CH_3 + H_2$

[3] $2CH_3 \rightarrow C_2H_6$

[4] $CH_3 + C_2H_6 \rightarrow CH_4 + C_2H_5$

[5] $C_2H_5 \rightarrow C_2H_4 + H$

Initial rates of reaction were measured, based on analysis of hydrogen, ethane, and ethylene, and k_1 was found to be pressure dependent and homogeneous. Quantitative agreement was obtained with values of k_1 calculated by R.R.K.M. theory. Values of $A^\infty = 2.8 \times 10^{16}$ s^{-1} and $E^\infty = 107.6$ kcal/mol were obtained, the latter appreciably greater than the value of $E_0 = 103$ kcal/mol used in the calculations. Comparison of previous shock-tube and flow-system data at temperatures up to 2200 K showed good agreement with values of k_1 obtained by extrapolation of the present R.R.K.M. calculations. It was concluded that in all previous studies, the initial dissociation was in its pressure-dependent region. Estimates were also made of the rate constant for the reverse of [1] and showed fair agreement with recent experimental measurements.

C.-J. CHEN, M. H. BACK et R. A. BACK. Can. J. Chem. **53**, 3580 (1975).

On a étudié la pyrolyse du méthane dans un système statique à des températures de 995, 1038, 1068 et 1103 K et à des pressions allant de 25 à 770 Torr. On en conclut que les étapes initiales de la réaction peuvent être décrites par un mécanisme simple, homogène et n'impliquant pas de chaîne radicalaire:

[1] $CH_4 \rightarrow CH_3 + H$

[2] $H + CH_4 \rightarrow CH_3 + H_2$

[3] $2CH_3 \rightarrow C_2H_6$

[4] $CH_3 + C_2H_6 \rightarrow CH_4 + C_2H_5$

[5] $C_2H_5 \rightarrow C_2H_4 + H$

On a mesuré les vitesses initiales en se basant sur l'analyse de l'hydrogène, de l'éthane et de l'éthylène et on a trouvé que k_1 dépend de la pression et est homogène. On a obtenu une corrélation quantitative avec les valeurs de k_1 calculées d'après la théorie R.R.K.M. On a obtenu des valeurs de $A^\infty = 2.8 \times 10^{16}$ s^{-1} et $E^\infty = 107.6$ kcal/mol; cette dernière est supérieure à la valeur de $E_0 = 103$ kcal/mol utilisée dans les calculs. Un bon accord existe entre des données obtenues antérieurement à des températures allant jusqu'à 2200 K, et les valeurs k_1 obtenues par extrapolation des calculs R.R.K.M. actuels. On en conclut que dans toutes les études antérieures, la dissociation initiale se faisait dans une région dépendante de la température. On a aussi fait des évaluations de la vitesse de la réaction inverse à [1] et on a montré qu'il y a un bon accord avec des mesures expérimentales récentes.

Introduction

Although the pyrolysis of methane has been studied many times before, important details of the reaction mechanism have remained obscure (1–5). It is well established that the initial products are C_2H_6 and H_2, and in some shock-tube experiments the pyrolysis has been effectively limited to this stage and initial rates measured. Even in these systems, however, the reaction mechanism is uncertain; it has not been shown clearly whether methane dissociates initially into $CH_3 + H$ or $CH_2 + H_2$, and the pressure dependence of the primary dissociation has not been established. In static and flow systems at lower temperatures the mechanism is even less well understood, because rapid secondary reactions set in at extremely low conversions, yielding successively ethylene, acetylene, and finally carbon. Induction periods and autocatalysis have been observed; activation energies generally lie between 75 and 90 kcal/mol, and because these are well below the bond dissociation energy of methane, radical chain reactions have been suggested; these have never been proven. Neither the primary dissociation process nor the secondary reactions leading to the formation of C_2 hydrocarbons and carbon has been established.

The present work was undertaken to resolve some of these uncertainties, particularly those of the low-temperature pyrolysis, by a careful study of the static pyrolysis in its very early stages. The present paper is concerned chiefly with the primary dissociation process and its pressure dependence, while subsequent papers deal with the secondary reactions.

Experimental

Apparatus

A conventional glass vacuum apparatus was used with Hoke metal valves in the portions having contact with methane and the reaction products. The apparatus could be evacuated to about 10^{-6} Torr measured with a McLeod gauge. The reaction vessel was a quartz cylinder of 478 cc, 20.4 cm long, and 6.0 cm o.d. Capillary tubing connected the vessel to a quartz spiral pressure gauge and through valves to the vacuum line. The reaction vessel was enclosed in a quartz tube of 7.0 cm o.d. and nitrogen gas was continuously passed through this annular space at a pressure of about 20 Torr above atmospheric and a flow rate of 3 cc per min. This eliminated the possibility of diffusion of oxygen through the wall of the reaction vessel at high temperatures. Some experiments were done with air replacing nitrogen in the jacket around the reaction vessel; this had no effect on the reaction rates. It appears therefore that diffusion of oxygen through the vessel wall is not a factor in the methane pyrolysis. Its greater effect in the thermal H_2–D_2 exchange reaction, where it doubled the rate at about 1000 K (6), must be due to the long chain character of the reaction. A quartz tube, 6 mm i.d., sealed through the center of the vessel, served as a thermocouple well and was also flushed with nitrogen. Before installation the vessel was treated with hot concentrated nitric acid and washed with distilled water. A vessel of the same dimensions packed with quartz tubes, which increased the S/V ratio by a factor of 10, was used to test for heterogeneous processes.

An Autoclave High Temperature cylindrical furnace with matching control unit gave a maximum variation in temperature of 1.5 deg. The heating element was tapped to allow adjustment of the temperature gradient along the reaction vessel which was less than 0.3 deg within 8 cm of the center and less than 1 °C in the last 2 cm. The thermocouple was calibrated at the melting point of sodium chloride.

Materials

Research grade methane was obtained from Matheson, Canada Ltd; the impurities were 6 p.p.m. oxygen, 20 p.p.m. ethane, and 100 p.p.m. nitrogen. Oxygen was removed by passing the methane through a column containing 3 kg of Ridox reagent (Fisher Scientific), activated with hydrogen at 230 °C. The ethane was removed by a 3 m column of activated charcoal maintained at −78 °C which was activated by heating under vacuum at 300 °C for 24 h. The purified methane contained less than 1 p.p.m. oxygen and 0.1 p.p.m. ethane, the limits detectable by the analytical system. Methane-d_4 was obtained from Merck, Sharp and Dohme, Canada Ltd., and oxygen was removed with Ridox reagent. Mass spectrometric analysis showed a D-atom purity of 99%. Research grade ethane, ethylene, and acetylene from Matheson, Canada Ltd., were used for calibrations.

Analysis

The products hydrogen, ethane, ethylene, acetylene, and the oxygen impurity were analyzed by gas chromatography. A separation of hydrogen, oxygen, argon, nitrogen, and methane was achieved with a 3 m × 6 mm column of molecular sieve 5A at room temperature, activated by heating at 370 °C for 12 h. Hydrogen was converted to water in a copper oxide furnace before entering the thermal conductivity detector. Larger amounts of hydrogen from longer experiments were collected through a solid nitrogen trap in series with a silica gel column at −196 °C, passed through a palladium thimble, and measured in a gas burette. A partial separation of the large quantities of methane from the small amounts of higher molecular weight products was achieved with a 30 cm × 3 mm silica gel column held at −78 °C. After most of the methane was removed the column was warmed to room temperature and the effluent injected into a second silica gel column composed of 30 cm × 3 mm plus 120 cm × 9 mm maintained at room temperature. H_2, HD, and D_2 were analyzed on a 2 m column of alumina treated with $MnCl_3$ and operated at the temperature of liquid nitrogen (7). Deuterated methanes were analyzed by mass spectrometer.

Experimental Procedure

Methane was admitted to the reaction vessel from a calibrated volume. The pressure and temperature were recorded during the experiment. At the end of the re-

action methane and products were condensed in solid nitrogen traps and analyzed as described. Prolonged pyrolysis (several hours) led to the deposition of carbon on the surface, which enhanced the rate of decomposition. This effect was negligible in the much shorter reaction times used in the kinetic studies. Nevertheless, to avoid accumulation of carbon from repeated experiments, air was admitted to the vessel after each experiment to burn off any carbon deposit. To ensure that no traces of oxygen remained after this procedure a small amount of methane was pyrolyzed for a few seconds before the experiment, then pumped away.

Results and Discussion

Initial Rate of Formation of Products

The products hydrogen, ethane, ethylene, propylene, and acetylene were analyzed as a function of time at the temperatures 995, 1038, 1068, and 1103 K over the pressure range 25–740 Torr. Typical yield–time plots are shown in Figs. 1 and 2. The results show clearly that in the initial stage of the reaction hydrogen and ethane are the only products. No pressure change was observed at this stage of the reaction and the rate of formation of ethane in the packed vessel was identical to that measured in the unpacked vessel. It may be concluded that the initial rate of formation of ethane is a measure of the initial homogeneous rate of decomposition of methane.

As the concentration of ethane builds up in the system, but while the conversion is still less

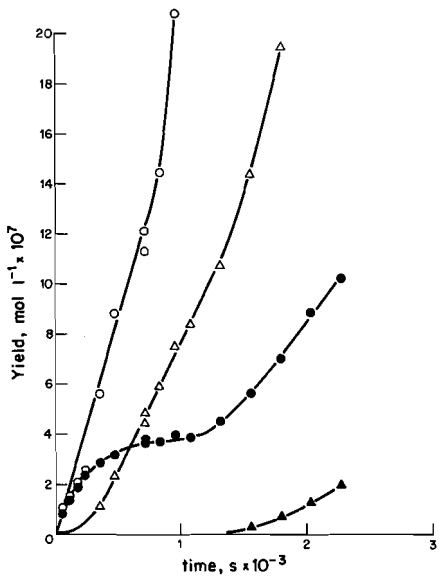

FIG. 1. Yield of the principal products as a function of time. ○, H_2; ●, C_2H_6; △, C_2H_4; ▲, C_2H_2; T = 1038 K.

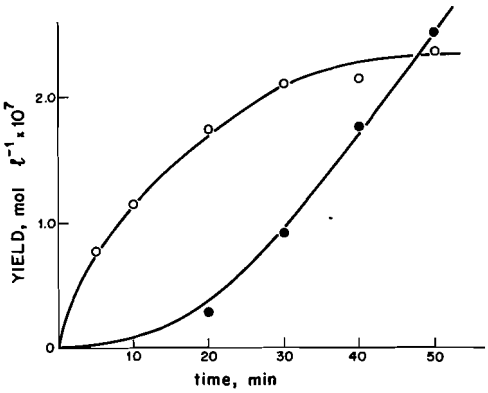

FIG. 2. Yield of ethane and ethylene in the initial stages of the reaction. ○, C_2H_6; ●, C_2H_4; T = 995 K.

than 0.01%, ethane begins to be consumed in secondary reactions and its concentration gradually approaches a steady value. Ethylene is clearly a secondary product and propylene and acetylene are tertiary, appearing only after the concentration of ethylene has surpassed that of ethane. As the reaction proceeds still further a marked increase in the rate of formation of ethane and the other products was observed. Mechanisms for this autocatalysis, which may involve, at least partially, the formation of carbon, will be discussed in a subsequent paper. In the present study, where any carbon deposit was burned off before each experiment, we have been able to measure the rates of product formation in the initial stages of the reaction well before the autocatalysis became significant. In almost all previous studies in static and flow systems rates were measured at conversions where the autocatalysis was important. This is particularly true of kinetic studies based on pressure measurements, since measurable pressure increase occurs only in the region of secondary acceleration.

The Mechanism of the Decomposition

The Initiation Step

Two initial dissociation reactions have been suggested in methane,

[1*a*] $$CH_4 \rightarrow CH_3 + H$$

and

[1*b*] $$CH_4 \rightarrow CH_2 + H_2$$

The endothermicity of [1*a*] has long been established as about 102–104 kcal/mol (3, 5, 8). The endothermicity of [1*b*] has been much more un-

TABLE 1. Comparison of measured rate constant and calculated value of k_{1b}[a]

Measured rate	16.4	106.7	−6.9

[a]All values are taken from ref. 14 except $\Delta H_f(CH_2)$ which is from ref. 12.

certain; at one time it was thought to be substantially (10 to 20 kcal) less than that of [1a], and in a number of studies of the methane pyrolysis where the activation energy was less than 103 kcal, it was concluded that [1b] must be predominant (1, 9, 10); conversely in other experiments, mostly in shock tubes, where the activation energy was about 103 kcal it was concluded that only [1a] was important (11). Subsequently it became evident that the endothermicity of [1b] was probably equal to or greater than that of [1a], so that all the earlier conclusions about the initial dissociation process based on activation energy had to be discounted (5). There now appears to be convincing evidence (12) for a value of $\Delta H_f^0(CH_2)$ of about 93 kcal/mol, which makes [1b] endothermic by about 109 kcal. The rate constant for reaction of CH_2 with H_2, the reverse of [1b], has been measured recently (13) and it thus becomes possible to calculate the rate constant for [1b]. Thermochemical data used in these and later calculations are given in Table 1 together with the rate constant for [1b] at 1000 K and the rate constant for the initial dissociation measured in the present study. It should be noted that both these values refer to the limiting high-pressure region. In the measurement by Braun *et al.* (13), singlet CH_2 was consumed in the reaction with hydrogen irrespective of whether the resulting CH_4* was stabilized, since the latter should have decomposed preferentially to $CH_3 + H$ rather than reforming $CH_2 + H_2$.

It is clear from Table 1 that [1b] should be of negligible importance in the pyrolysis of methane. This conclusion is further strengthened by the fact that in several respects the calculations in Table 1 probably overestimate the magnitude of k_{1b}, so that the values obtained should be regarded as upper limits. In particular, the rate constant measured by Braun *et al.* (13) for the reverse reaction was for CH_2 in its excited singlet state; the corresponding reaction of the ground-state triplet is undoubtedly much slower. On the other hand, the heat of formation of 93 kcal/mol is presumably for ground-state CH_2 and there appear to be convincing arguments (15) that the singlet state lies from 6 to 10 kcal higher in energy than the triplet ground state. It is not clear whether singlet or triplet CH_2 would be produced in [1b]; production of the former conserves spin, but if the energy barrier is much higher than for triplet formation, the latter may occur but with a reduced frequency factor associated with the spin violation. By using ΔH_f for the triplet in our calculation, and the reverse rate constant for the singlet, our estimate of k_{1b} is clearly an upper limit, and the true value may be much lower. It may also be noted that if there is an appreciable activation energy for the reaction of CH_2 with H_2 or if the CH_2 radicals in the experiments by Braun *et al.* were vibrationally excited, k_{1b} would be further overestimated in our calculation.

Experimentally it is not easy to distinguish between [1a] and [1b]. It will be seen later that the secondary reactions observed in the system point strongly to the presence of CH_3 radicals, but these could be generated from the reaction of CH_2 with CH_4 even if [1a] did not occur. Analysis of the isotopic composition of hydrogen produced in the initial stage of the pyrolysis of a

mixture of CH_4 and CD_4 should reveal the occurrence of [1*b*]. This has been done recently in the shock pyrolysis at 1560 K (16), in which it was found that the ratio $[HD]^2/[H_2][D_2]$ was close to the value expected for hydrogen formation by atomic reactions only. Similar experiments have been performed in the present study, with similar results, shown in Table 2. The ratio $[C_2H_6]/[C_2H_4]$ corresponds to the ratio of primary to secondary hydrogen, so that at the shortest times greater than 90% of the hydrogen should have come from the primary reactions. It can be shown by comparison with the CH_3–CD_3 radical exchange[3] that molecular hydrogen should not have been appreciably exchanged after its formation. The data in Table 2 are scattered because the amounts of hydrogen, and particularly deuterium, analyzed were necessarily small, but within this scatter there is no significant deviation from a value of about four expected for hydrogen formed by an atomic mechanism. Reaction 1*b* should of course yield a $[HD]^2/[H_2][D_2]$ ratio of zero. From these experiments and from the calculations in Table 1, it can be concluded that [1*a*] is the only initial dissociation of importance. It will be seen later that all our experimental observations are quantitatively in accord with this conclusion.

Secondary Reactions

The initial stages of the reaction before propylene and acetylene are formed may be explained by a very simple mechanism

[1] $$CH_4 \rightarrow CH_3 + H$$

[2] $$H + CH_4 \rightarrow H_2 + CH_3$$

[3] $$2CH_3 \rightarrow C_2H_6$$

[4] $$CH_3 + C_2H_6 \rightarrow CH_4 + C_2H_5$$

[5] $$C_2H_5 \rightarrow C_2H_4 + H$$

In the earliest stages where only [1], [2], and [3] are important the yield of hydrogen was equal to the yield of ethane and no pressure increase was observed. As [4] and [5] became important ethane was converted to ethylene and hydrogen. During this period the quantities $[C_2H_4] + [C_2H_6]$ and $([H_2] + [C_2H_6])/2$ were both linear functions of time, showing that these were the only products at this stage of the reaction. The yield of ethane as it approaches its steady-state value can in fact be quantitatively accounted for by [4] and [5].[3] These and other subsequent secondary reactions will not be discussed further in the present paper which is concerned chiefly with the rate of [1].

Measurement of k_1

From the proposed mechanism it follows that

[6] $$k_1[CH_4] = R^0_{C_2H_6} = R^0_{H_2}$$

where R^0 signifies an initial rate of formation. Values of R^0 for ethane and hydrogen can be obtained directly from yield–time plots, but because [4] and [5] set in at very low conversion, accurate initial rates could not always be measured. $R^0_{C_2H_6}$ may also be equated to $R_{(C_2H_6+C_2H_4)}$ or to $\frac{1}{2}R_{(H_2+C_2H_6)}$, which corrects for loss of ethane in [4], and k_1 can be obtained from linear plots of these functions. While these various measurements of initial rates were in substantial agreement, the most accurate and consistent measurements of $R^0_{C_2H_6}$ and hence of k_1 were obtained from the yield–time plot of ethane alone by fitting the experimental points to a theoretical curve based on the proposed simple mechanism for loss of ethane, using a computer to obtain

the best fit, and this was the method finally employed. Values of the rate constant, k_1, obtained in this way over a range of temperature and pressure are given in Table 3. Error limits based on the values obtained by the various methods are indicated in Fig. 3 by vertical bars.

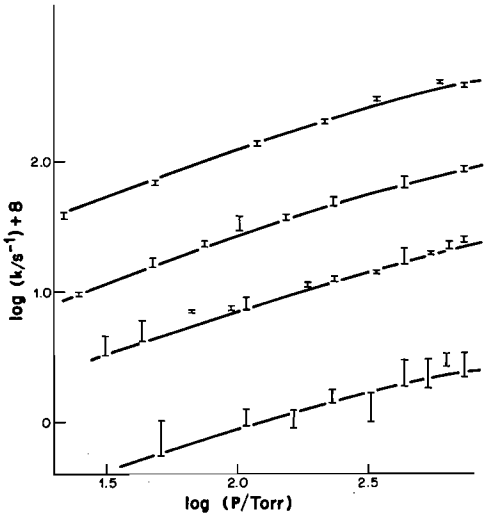

FIG. 3. The variation of k_1 with pressure. The experimental results are shown as vertical bars, indicating the error limits, while the solid lines are the calculated values. The temperatures are: 995, 1038, 1068, and 1103 K.

The Pressure Dependence of k_1

log k_1 is shown in Fig. 3 as a function of log (methane pressure). It is clear that k_1 depends markedly on the pressure of methane under the conditions of the present experiments. The obvious and simplest explanation of this behavior is that [1] is a unimolecular reaction in its pressure-dependent region. Such a pressure dependence is indeed expected for a molecule as small as methane (3), although it has not been clearly demonstrated before at these temperatures. Alternatively, it might be suggested that the dependence of k_1 on methane pressure could arise from a complex radical-chain mechanism. The only possible propagation step in pure methane appears to be

[7] $$CH_3 + CH_4 \rightarrow C_2H_6 + H$$

This has frequently been suggested in the past (1), and together with [2] constitutes a chain yielding C_2H_6 and H_2. There are several arguments against such a chain in the methane pyrolysis. First, [7], an inversion reaction at a simple saturated carbon atom, is without precedent in gas-phase radical reactions and would have a high activation energy (14). The chain mechanism in fact would require E_7 to be about 50 kcal to give the overall observed activation energy, and therefore [7] although unlikely, probably cannot be ruled out *a priori*. Second, if

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

[7] occurred, the rate of reaction would be given by the expression

$$[8]\quad R^0_{C_2H_6} = R^0_{H_2} = k_1[CH_4] + k_7[CH_4](k_1[CH_4]/k_3)^{1/2}$$

with the right hand side consisting of two terms, the first for the nonchain process, the second for the chain reaction. Recognizing that both k_1 and k_3 may be pressure dependent, it can be seen that their dependence on methane pressure will cancel at low pressure and disappear at high pressure, leaving a simple overall dependence of the chain process on $[CH_4]^{3/2}$ in the high and low pressure limits. At intermediate pressures when both k_1 and k_3 are pressure dependent, the order will rise above $\frac{3}{2}$ because k_4 would reach its high-pressure limit well before k_1. The result on a log–log plot of k_1 against CH_4 pressure would be two parallel lines at high and low pressure with slope $\frac{1}{2}$, displaced laterally and joined by a sigmoid curve at intermediate pressure. This prediction may be compared with Fig. 3, in which the slope in fact decreases monotonically from about 0.6 at the lowest pressure to 0.4 at the highest. Finally, and most convincingly, it will be seen that the measured values of k_1 over the whole range of pressure and temperature are quantitatively in accord with theoretical calculations for the simple unimolecular dissociation of methane in its pressure-dependent region. Thus while the occurrence of [7] cannot be ruled out completely, the present evidence weighs heavily against it, and it seems most unlikely that it is of any importance in the methane pyrolysis.

Theoretical Calculations of k_1 and its Pressure Dependence

Calculations of k_1 were based on the R.R.K.M. theory, well described by Robinson and Holbrook (17). The general expression for the unimolecular rate constant is

$$[9]\quad k_{uni} = \frac{L^{\ddagger}Q_1^{+}}{hQ_1Q_2}\exp(-E_0/RT) \times \int_0^{\infty} \frac{\sum_{E^+_{v=0}}^{E^+} P(E_v^{+})\exp(-E^{+}/RT)\,dE^{+}}{1 + k_a(E^* + \langle\Delta E_J\rangle)/k_2[M]}$$

where

$$[10]\quad k_a(E^* + \langle\Delta E_J\rangle) = \frac{L^{\ddagger}\sum_{E^+_{v=0}}^{E^+} P(E_v^{+})}{hFN^*(E^*)}$$

The sum of states, $\sum P(E_v^{+})$, was evaluated by the direct count method. The density of states, $N^*(E^*)$, was calculated using the approximation described by Tardy *et al.* (18). The centrifugal correction factor, F, was given by Marcus (19) and by Waage and Rabinovitch (20) as follows

$$[11]\quad N^*(E^* + \langle\Delta E_j\rangle) = FN^*(E^*)$$

where

$$[12]\quad F = \frac{\left[E^* + aE_z - \left(\frac{I^+}{I} - 1\right)RT\right]^{s-1}}{(E^* + aE_z)^{s-1}}$$

A constant energy increment of 0.5 kcal/mol was used in the computations. The symbols follow the nomenclature used by Robinson and Holbrook: $\sum P$ = sum of states of the transition state for energy = E^+; $N^*(E^*)$ = density of states of molecules of energy E^*; Q_1^{+} = partition function of inactive modes of activated complex; Q_1, Q_2 = partition functions of rotation and vibrational modes of the molecule; E^+ = total nonfixed energy in the active degrees of freedom of the activated complex; E_0 = critical energy; E^* = nonfixed energy in the energized molecule; E_z = total zero-point energy; $L^{\ddagger}$ = reaction path degeneracy. Values for k_1^{∞} were not obtained in the present study but are not necessary for the calculation since the bond dissociation energy, E_0, for methane is well established. A value of E_0 of 103 kcal/mol gave agreement with the magnitude of the measured value of k_1 while the dependence on pressure was matched by adjustment of the bending frequencies and of the moment of inertia of the activated complex. The methyl radical was assumed to be planar in the complex. All rotations were taken as adiabatic and centrifugal corrections were applied to the two external rotations. The complex is similar to the Model 4 described by Placzek *et al.* (21). The values used in the calculations are shown in Table 4. The vibrational frequencies of the molecule and of the methyl radical were taken from JANAF (22).

The results of the calculations are shown in Fig. 3 as the solid lines. The calculated values for k_1 are seen to represent both the pressure dependence and the absolute value for k_1 found experimentally. This provides strong confirmation of the interpretation of the present results in terms of the simple mechanism described by [1]–[5].

Values of k_1^{∞} obtained from [9] are listed in Table 3 together with the corresponding values

TABLE 4. Values used in calculations

	$I_b = I_c = 17.0 \times 10^{-40}$ g cm^2

[a]For purposes of calculation γ_1 and γ_3 were combined as 3122 cm^{-1}.

of A^∞ and E^∞ calculated at each temperature. The striking feature of these results is the large difference (4.6 kcal/mol) between E^∞ and E_0. For a dissociation reaction in the high-pressure region, the experimental activation energy is always larger than E_0, which is defined as the difference in zero-point energies of the reactants and the activated complex because the population of excited vibrational levels will always be larger in the activated complex than in the reactant. The difference between E^∞ and E_0 has commonly been found to be about 2 kcal/mol. For example for the isomerization of 1,1-dichlorocyclopropane, $E^\infty = 57.7$ and $E_0 = 55.5$ kcal/mol (17). Most of the unimolecular decompositions which have been studied have activation energies in this range. The critical energy for decomposition of methane is much larger and the temperature at which decomposition occurs is correspondingly higher. Taking into account as well the very low vibrational frequencies of three of the normal modes of the complex as compared to the reactant, a relatively large population of excited vibrational levels in the activated molecule will be expected. The result is a large difference between E^∞ and E_0, larger than has previously been reported.

Comparison of k_1 Measured in Static, Flow, and Shock Tube Pyrolysis

Using the parameters for the unimolecular dissociation of methane determined in the preceding section, the rate constant may be calculated for a wide range of temperature and pressure. These values are shown as solid lines in Fig. 4. The values of k_1 obtained at the highest temperature in the present work are shown together with recent values of k_1 obtained from shock tube pyrolysis and studies in a flow system. In most of these studies argon was used as diluent. To compute a total equivalent pressure of methane, Ar was assumed to be one-third as efficient as methane as a collision partner (17). The same efficiency was assumed for other inert diluents. For comparison purposes only representative data were chosen from the range of values reported by most authors.

The data of Palmer and Hirt (5) obtained in a flow system at 1200 and 1400 K are in good agreement with the calculated values. From shock tube studies, the results of Skinner and Ruehrwein (11) at 1200 and 1400 K, Kozlov and Knorre (23) at 1800 and 2000 K, and Glick (9) at 2000 K are in very close agreement; those of Kevorkian *et al.* (10) at 1670 K and Glick (9) at 2200 K are slightly higher, and those of Napier and Subrahmanyam (24) at 2000 K slightly lower, than the calculated values. In all of these studies the authors assumed that the rate constant was not pressure dependent. However, the scatter in the rate constants obtained by Glick at 2200 K and by Kozlov and Knorre at 1800 K would encompass the variation with pressure which we predict, and their data are therefore

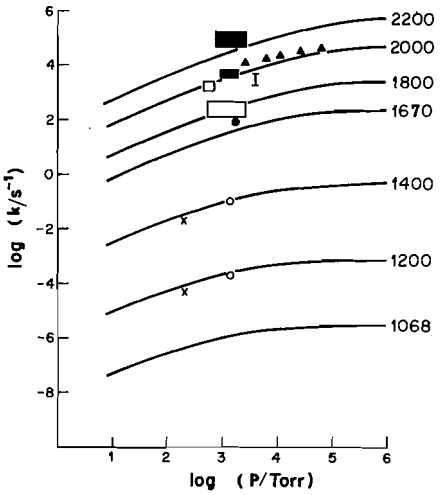

FIG. 4. The variation of k_1 with pressure for temperatures up to 2200 K. The solid lines are calculated from [9] and the experimental results were obtained in shock-tube studies or flow-system pyrolysis. ○, ref. 11; ×, ref. 5; ●, ref. 10; □, ref. 23; I, ref. 24; ■, ref. 9; ▲ ref. 25.

compatible with the present results. In only one shock-tube study, that of Hartig *et al.* (25), was the rate constant shown to be pressure dependent. This dependence is also close to that predicted by the present model but the measured value of k_1 is about six times lower than the calculated value; the reason for this discrepancy is not obvious. Agreement between observed and calculated rate constants is on the whole very good, especially as it is well known that the uncertainty in the measurement of temperature in a shock tube may easily be 50 deg. All the results except those of Hartig *et al.* fall within this range of the calculated values.

The most interesting aspect of these comparisons is the demonstration that all the measurements of the rate constant for dissociation of methane reported so far have been made in the pressure-dependent region. This fact was recognized in only one study, that of Hartig *et al.* An Arrhenius plot of rate constants in the pressure-dependent region is not very meaningful because the activation energy in this region is not simply related to the bond dissociation energy and because the ratio k/k^∞ is itself a function of temperature. Indeed a wide range of values for the activation energy of k_1 has been reported (85–103 kcal/mol) and the reason for the disagreement may be traced to the pressure dependence of k_1. Fortuitously, however, the measured activation energy from several studies of about 103 kcal/mol appeared close to the bond dissociation energy and the authors were led to believe that a high-pressure value for k_1 had been measured. The present calculations show that the activation energy of k_1 in the pressure-independent region, E^∞, of 107 kcal/mol, is in fact several kcal/mol higher than $D^0(CH_3—H)$, which was taken as 103 kcal/mol. The observed activation energy of k_1 in its pressure-dependent region is therefore lower than the value of E^∞ as predicted by unimolecular theory.

Calculations of k_{-1} and Comparison with Measured Values

Using the value of the equilibrium constant for [1] and the expression obtained for k_1, values of k_{-1}, the rate constant for the combination of a methyl radical and a hydrogen atom, were calculated over a range of pressures at 500, 700, and 1038 K. The results are shown in Fig. 5 and are listed in Table 5 together with the thermodynamic values used in the calculation. The results of three recent measurements of k_{-1} are also included. These measurements were made in an Ar or He carrier and the total pressure has therefore been reduced by a factor of three to correct for the efficiency of these gases as third bodies relative to methane (17). The measurements of Camilleri *et al.* (26) in the range 500–700 K are in good agreement with the present calculations. Comparison with the data of Dodonov *et al.* (27), Pratt and Veltman (28), and Halstead *et al.* (29) all at about 295–300 K is less certain because extension of [9] to this tempera-

ture presented some computational difficulties and was not pursued. If the trend at the three higher temperatures continues, the value of Dodonov *et al.* appears rather high; the other data are somewhat lower than predicted, but in reasonable agreement. The value of k_{-1}^{∞} obtained in these calculations is 2.5×10^{11} l mol^{-1} s^{-1}, which is about one-quarter of the collision number for these radicals.

The extension of [9], with the model of the activated complex for methane described herein, down to 500 K and up to 2200 K provides a stringent test for the theory. The agreement with other measurements at both ends of the temperature range is strong support for the validity of this method. There are several approximations in these calculations which might be expected to limit the range of applicability of any particular model. For example, in the calculation of the density of states the harmonic oscillator approximation has been used. The limitations of this assumption have been discussed by Forst (30) and Forst and Prášil (31) have investigated the dependence on energy of the density of states and of the unimolecular rate constant k_a, eq. 10, for a small molecule, hydrogen peroxide. Their results showed that the unimolecular rate constant calculated using Morse oscillators is lower by about a factor of two than the rate constant calculated using purely harmonic oscillators, in the 'low energy' region applicable to thermal systems. The ratio of the two rate constants, however, did not change appreciably with an increase in the excitation energy in the low energy region. The excitation energy of the activated complex for the thermal dissociation of methane lies well within this low energy region considered by Forst and Prášil (31) and it may be concluded that inclusion of anharmonic effects in the present calculations will not change the relative values of the rate constants over the temperature range considered here.

The model of the activated complex is itself an approximation and modifications to it could be explored for better agreement over the whole temperature range. For example, Forst and Prášil (31) have calculated the effect on k_a of a complex in which one oscillator is coupled with a two-dimensional rotor, taking hydrogen peroxide as the dissociating molecule. Some lowering of k_a was observed as the excitation energy and the rotational quantum number was increased. The effect, however, was not large in the low range of excitation energy encountered in thermal systems, and taking into account the large uncertainties in the values of k_1 in the region of 2000 K and of k_{-1} at the low temperature end it was not considered profitable to pursue such calculations. It may be concluded that the model chosen for the activated complex provides a reasonable agreement with other measurements in the temperature range 500–2000 K.

The present system demonstrates some of the advantages gained from pyrolysis studies in a static system. Precise control of temperature, reaction time, and reactant concentration are of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

prime importance in the measurement of rate constants. Sufficient precision for comparison of experimental and calculated unimolecular rate constants can probably be achieved only in a static system.

The authors thank the National Research Council of Canada for generous financial support.

Stereochemical Determination of Key Substrates of the Cope Rearrangement by ^{13}C Nuclear Magnetic Resonance Spectroscopy

DONALD C. WIGFIELD AND KEVSER TAYMAZ

Department of Chemistry, Carleton University, Ottawa, Canada K1S 5B6

Received July 15, 1975

DONALD C. WIGFIELD and KEVSER TAYMAZ. Can. J. Chem. **53**, 3591 (1975).

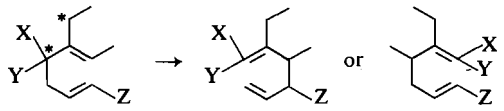
The ^{13}C n.m.r. spectra of two key substrates of the Cope rearrangement (compounds **3** and **5**) have been assigned and compared with those of their monosaturated analogs. The spectra are consistent with the substrates being stereochemically homogeneous and with the *E* configuration around the trisubstituted double bond.

DONALD C. WIGFIELD et KEVSER TAYMAZ. Can. J. Chem. **53**, 3591 (1975).

On a attribué les spectres r.m.n. du ^{13}C de deux (composés **3** et **5**) substrats-clé du réarrangement de Cope et on les a comparés avec ceux de leurs analogues monosaturés. Les spectres sont en accord avec le fait que les substrats sont stéréochimiquement homogènes et de configuration *E* autour de la liaison double trisubstituée.

[Traduit par le journal]

Since its discovery in 1940 (1), the Cope rearrangement has been the subject of exhaustive mechanistic study. Kinetic studies have figured prominently in these mechanistic determinations and, due to both synthetic and kinetic convenience, these studies, both originally (2, 3), and more recently (4–6), have frequently utilized the type of substrates indicated in Scheme 1 where X and Y are most frequently CN or COOEt (originating in the synthesis from malononitrile, ethyl cyanoacetate, or diethyl malonate) and Z is either H or an aromatic group.



SCHEME 1. Substrates for the Cope rearrangement.

We have previously pointed out (7) that, in this type of Cope rearrangement substrate, a major stereochemical ambiguity exists. While the geometrical configuration around the double bond to which the group Z is attached is easily assigned (7), the configuration around the other double bond has always remained obscure, being either *E* (as written) (8) or *Z*, or a mixture of both diastereomers. The absence of any evidence of heterogeneity in such samples does not aid the stereochemical assignment; indeed it hinders it, as almost all methods of such determination require the comparison of both stereoisomers (see refs. 19–26 of ref. 7). It is somewhat disquieting that much of the fundamental kinetic work on the Cope rearrangement thus rests on the kinetics of samples of unknown stereochemical homogeneity, and one cannot help but wonder whether it was entirely fortuitous that Cope and his co-workers reported their most satisfactory kinetic data on a different but related compound, one devoid of this particular ambiguity (see ref. 2, footnote 6).

One method for making this type of stereochemical distinction, not necessarily requiring the possession of both stereoisomers, and one that has not previously been applied to these substrates, is ^{13}C n.m.r. spectroscopy. It is now well established that the α-carbons in *trans*-isomers are generally deshielded (by 2–5 p.p.m.) whereas the α-carbons in *cis*-isomers are shielded (by 1–3 p.p.m.) relative to the saturated analogs (9). Examination of the shifts of the starred atoms (Scheme 1) upon insertion of the double bond, therefore, provides the desired analysis. Accordingly, we have conducted a program to assign the ^{13}C signals in two representative Cope rearrangement substrates, and thereby determine the double bond stereochemistry in these compounds.

Results and Discussion

The two substrates chosen for examination in this study were compounds **3** and **5**, **3** being representative of the kinetically studied substrates (2–6) and **5** being the compound whose rearrangement has provided evidence of the ionic Cope rearrangement (7). (In the literature these

1 2 3 4 5

SCHEME 2. Peak assignment sequence for compounds examined by ^{13}C n.m.r. spectroscopy, and carbon numbering scheme used.

compounds have always been drawn in the *E* configuration; we arbitrarily continue this practice here.)

In order to facilitate unambiguous peak assignment, the series of compounds indicated in Scheme 2 were examined, the peaks of the simplest compound, 2-(1-ethylpropyl)malononitrile **1** being easily assigned. Addition of the allyl group and application of the alkane additivity shielding effects (ref. 9, p. 58) yields the assignments for compound **2**, which differs from compound **3** only by insertion of the double bond. Compound **2** is also instrumental in peak assignment of compound **4**, the two differing only by the *p*-methoxyphenyl group at C-8; and insertion of the double bond gives the assignments to compound **5**. Comparison of the shifts of C-2 and of C-4 in both compounds **2** and **3**, and in compounds **4** and **5** is the desired stereochemical analysis. Although clearly the assignment of many peaks is irrelevant to the question at hand, the complete peak assignments for all compounds have been made. These assignments are shown in Table 1.

Synthesis of Substrates

The synthetic sequence to compounds **1**–**5**, is shown in Scheme 3. 2-(1-Ethyl-propylidene)malononitrile was prepared, as previously (5, 10), by condensation of malononitrile with 3-pentanone, and this was then condensed with the appropriate allyl chloride to yield hexadienes **3** and **5**

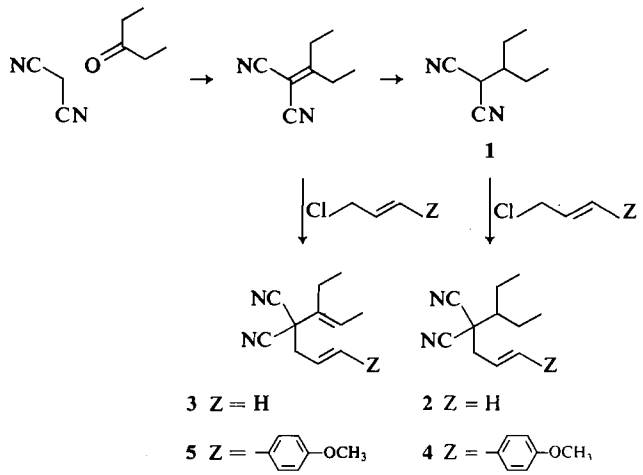

SCHEME 3. Synthetic procedure.

(7). Attempts to prepare 2-(3-pentyl)malononitrile **1** by condensation of malononitrile with 3-bromopentane were not successful, and compound **1** was therefore prepared by reduction of 2-(1-ethylpropylidene)malononitrile, this reduction being accomplished very conveniently by aluminum amalgam, a reagent of some antiquity (11). Condensation of compound **1** with the appropriate allyl chloride yielded the reference compounds **2** and **4**.

Peak assignments (see Table 1 and Scheme 2)

Compound 1

The ^{13}C spectrum of compound **1** consists of five peaks of which the peak at 112.9 p.p.m. is clearly due to the nitrile carbons. The other assignments made were confirmed by selective decoupling at δ 3.88 p.p.m. (C4-H), under which conditions the peak for C-1 became a quartet, that for C-2 a triplet, and that for C-3 a doublet, while C-4 remained a singlet.

Compound 2

Peak assignments for compound **2** were made with reference to the assignments for compound **1** utilizing the alkane α–ε additivity factors for the additional allyl group (ref. 9, p. 58). This gave the following calculated values for the peak positions of C-1–C-4 (observed position in parentheses): C-1, 11.3 (11.6); C-2, 22.0 (23.2);

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

For personal use only.

C-3, 50.3 (46.6); C-4, 42.9 (42.4). Possible confusion between the assignments for C-4 and C-6 was eliminated by selective decoupling at δ 2.68 p.p.m. (C6-H), under which conditions the peak at 39.8 p.p.m. remained a singlet.

Compound 3

Assignments for compound **3** were made in comparison with those for compound **2**, the introduction of the double bond having little effect on carbon nuclei separated by two or more σ bonds (9). It is noteworthy that C-1 and C-1′ have almost identical chemical shifts. Rigorous distinction of the assignments for C-1′ and C-2 was made by selective decoupling at δ 1.78 p.p.m. (C1′-H), under which conditions the possible ambiguity between assignments for C-4 and C-6 was also resolved, the peak at 42.0 p.p.m. (C-6) degenerating to a triplet.

Compound 4

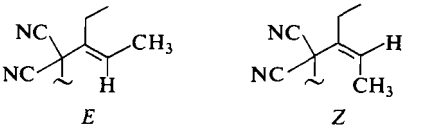
Assignments of the high-field peaks of compound **4** were made by comparison to those of compound **2**, the introduction of the *p*-methoxyphenyl group having little effect on these shifts. Confirmation of the assignments for C-1–C-4, C-6, and C-9 was also obtained by the appropriate multiplicity changes on selective decoupling at δ 2.77 p.p.m. (C6-H). The aromatic carbon peaks were identified by a combination of calculation (ref. 9, p. 197) and comparison with the known spectrum of *p*-methoxystyrene (12). Carbons 11 and 12 are easily identified as high intensity peaks that are split into doublets upon selective decoupling at other hydrogens. The shift for C-11 of 128.0 p.p.m. compares with the calculated (ref. 9, p. 197) value of 126.7 p.p.m. and the shift of the corresponding carbon in *p*-methoxystyrene of 126.8 p.p.m. (12). For C-12 (114.2 p.p.m.) the corresponding shifts are 113.4 and 113.6 p.p.m. respectively. Similar comparisons on the smaller peaks due to C-10 (calculated 129.3 p.p.m., comparison 130.4 p.p.m., observed 128.9 p.p.m.) and C-13 (calculated 158.4 p.p.m., comparison 159.0 p.p.m., observed 160.0 p.p.m.) allowed their assignment. These assignments leave, by difference, the peaks at 117.6 and 137.0 p.p.m. as C-7 and C-8 respectively; the assignments appear reasonable by comparison with the spectra of compounds **2** and **3**, bearing in mind that an α substituent is deshielding but an α′ substituent shielding (ref. 9, p. 72). Multiplicity changes on selective decoupling at δ 2.77 p.p.m. were consistent with all the above assignments.

Compound 5

With the assignments for compounds **3** and **4** in hand, the assignments of the 15 signals of compound **5** are straightforward. Inspection of Table 1 reveals that the low-field portion of the spectrum is virtually identical with that of compound **4**, with the addition of two signals due to C-2′ and C-3 which have the characteristic shifts exhibited by the corresponding carbons in compound **3**. As in compound **3**, there is barely any distinction between carbons 1 and 1′, and, as before, rigorous distinction between the shifts of C-4 and C-6 was made by selective decoupling at δ 1.73 p.p.m. (C1′-H) and at δ 2.82 p.p.m. (C6-H), all other multiplicity changes being consistent with assignment.

Stereochemical Analysis

Comparison of the chemical shifts of C-2 in compounds **2** and **3**, and in compounds **4** and **5** (Table 1) show that an upfield shift of 1.85 and 1.71 p.p.m. respectively occurs upon insertion of the double bond, this shift being indicative of C-2 being *cis* to the methyl group in both compounds **3** and **5**. Similarly the shift of the



E *Z*

quaternary carbon C-4 is downfield in both comparisons (compounds **2** and **3**, 0.12 p.p.m.; compounds **4** and **5**, 1.61 p.p.m.), consistent with C-4 being *trans* to the methyl group. These shifts appear to demand the *E* configuration for the trisubstituted double bond of both compounds **3** and **5**. One curious feature of the spectra is that the methyl group (C-1, C-1′) in both cases undergoes a downfield shift (2.04, 2.15 p.p.m.) upon insertion of the double bond despite the fact that the methyl clearly must be *cis* to one group or the other. This may be a case, however, of electronic factors being superimposed on steric factors, the methyl becoming conjugated in a homoallylic sense with the nitrile groups on insertion of the double bond.

Conclusions

The ^{13}C chemical shifts of C-2 and C-4 in compounds **2–5** are consistent with compounds **3** and **5** having the *E* configuration around the trisubstituted double bond which has been implicitly assumed for many years. No extra

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

spurious peaks suggestive of an *E–Z* mixture are evident. This result lends support to the validity of numerous kinetic studies on Cope rearrangements of this type of substrate, and thus to the various mechanistic deductions drawn therefrom.

Experimental

2-(1-Ethylpropylidene)malononitrile was prepared as previously described (5, 13).

2-(1-Ethylpropyl)malononitrile ***1***

Aluminum amalgam (prepared according to Fieser and Fieser (13)) (15 g) was added to a solution of 2-(1-ethylpropylidene)malononitrile (13.4 g, 0.1 mol) in ether (200 ml). Water (200 ml) was added and the mixture heated under reflux until reduction was complete, the reaction being monitored by measuring the n.m.r. spectrum of the ether layer. Fresh amalgam (10 g) was added after 3 days, and the reaction was complete after 1 week. The ether layer was removed, 100 ml of ice-cold hydrochloric acid added to the aqueous layer, and the aqueous layer extracted with ether (3 × 100 ml). The combined ether extracts were dried (Na_2SO_4), evaporated, and distilled (80 °C, 0.14 Torr) to give the title compound (9.2 g, 67%), n_D^{20} 1.4431; ν_{max}(film) 2986, 2950, 2251, 2214, and 1463 cm^{-1}; δ 0.99 (6H, t, J = 5 Hz, CH_3), 1.37–2.20 (5H, m, CH_2 and adjacent CH), and 3.9 p.p.m. (1H, d, J = 5 Hz, $CH(CN)_2$).

Anal. Calcd. for $C_8H_{12}N_2$: C, 70.56; H, 8.87; N, 20.57. Found: C, 70.61; H, 9.00; N, 20.64.

2-Allyl-2-(1-ethylpropyl)malononitrile ***2***

A solution of sodium isopropoxide was prepared by dissolving sodium (0.23 g, 0.01 mol) in 2-propanol (25 ml) at 50 °C. The solution was then cooled in an ice–water bath and 2-(1-ethylpropyl)malononitrile **1** (1.36 g, 0.01 mol) added dropwise to give a clear yellow solution. Allyl chloride (0.76 g, 0.01 mol) was added in one portion and the mixture stirred at room temperature for 1 h. Water (100 ml) was added and the solution extracted with benzene (3 × 30 ml). The combined extracts were washed with water (2 × 25 ml), dried (Na_2SO_4), and evaporated to give a yellow liquid (1.7 g). Preparative layer chromatography (silica gel; 25% ether in benzene) yielded the pure compound (0.8 g, 45%), n_D^{20} 1.4512; ν_{max}(film) 3000, 2970, 2255, 1470, 975, 910 cm^{-1}; δ 1.06 (6H, t, J = 5 Hz, CH_3), 1.64 (5H, m, —CH—$(CH_2—)_2$), 2.65 (2H, d, J = 6 Hz, allylic CH_2), and 5.06–6.32 p.p.m. (3H, m, olefinic H); high resolution mass spectrometry m/e 176.1313, calcd. for $C_{11}H_{16}N_2$, 176.1313.

Anal. Calcd. for $C_{11}H_{16}N_2$: C, 74.95; H, 9.16; N, 15.89. Found: C, 74.89; H, 9.20; N, 15.07.

2-Allyl-2-(1-ethyl-1-propenyl)malononitrile **3** was prepared as described previously (2, 5).

2-(3-p-Methoxyphenylallyl)-2-(1-ethylpropyl)malononitrile ***4***

2-(1-Ethylpropyl)malononitrile **1** (1.36 g, 0.01 mol) was added dropwise at 0 °C to a solution of sodium isopropoxide (0.01 mol) in isopropanol (25 ml). *p*-Methoxycinnamyl chloride (1.82, 0.01 mol) was added in one portion, and the mixture stirred at room temperature for 1 day, and then refluxed for 1 h. Water (100 ml) was added and the solution extracted with benzene (3 × 30 ml). The combined extracts were washed with water (2 × 25 ml), dried (Na_2SO_4), and evaporated giving a dark yellow viscous liquid (2.8 g). Preparative layer chromatography (silica gel; 10% ether in benzene, and then repurification using 50% ether in petroleum ether (b.p. 30–60 °C)) yielded the pure product (0.6 g, 21.3%), n_D^{20} 1.5982; ν_{max}(film) 3000, 2230, 1610, 1510, 1255, and 1040 cm^{-1}; δ 1.10 (6H, t, J = 5 Hz, CH_3), 1.66 (5H, m, —CH—$(CH_2—)_2$), 2.77 (2H, d, J = 7 Hz, allylic CH_2), 3.72 (3H, s, OCH_3), 5.88–6.50 (2H, m, olefinic H), and 6.68–7.46 p.p.m. (4H, m, aromatic H); high resolution mass spectrometry m/e 282.1734, calcd. for $C_{18}H_{22}N_2O$, 282.1732.

Anal. Calcd. for $C_{18}H_{22}N_2O$: C, 76.59; H, 7.85; N, 9.92. Found: C, 76.61; H, 7.86; N, 9.25.

2-(1-Ethyl-1-propenyl)-2-(3-*p*-methoxyphenylallyl)malononitrile **5** was prepared as described previously (7).

Spectral Measurements

Infrared spectra were obtained on a Perkin-Elmer 257 spectrophotometer, and p.m.r. spectra in $CDCl_3$, with TMS as internal standard on a Varian T-60 instrument. ^{13}C spectra (natural abundance) were obtained on a Varian XL-100-12 n.m.r. spectrometer equipped with a Nicolet Technology Corporation Fourier Transform data system. High resolution mass spectra were obtained through the courtesy of J. P. Kutney and G. Eigendorf, University of British Columbia.

It is a pleasure to acknowledge the helpful advice provided by Dr. G. W. Buchanan of this Department at various stages of the work. The financial support of the National Research Council of Canada is also gratefully acknowledged.

Reçu le 22 avril 1975

FRANÇOIS BRISSE, AVIVA BATTAT, JEAN-CLAUDE RICHER, PIERRE MAZEROLLES et ALFREDA FAUCHER. Can. J. Chem. **53**, 3596 (1975).

Les diméthyl-1,1 germa-1 (et sila-1) cycloundécanediols-6,7 ($C_{12}H_{26}O_2Ge$ et $C_{12}H_{26}O_2Si$) sont caractérisés par leurs diagrammes de poudres; ces composés sont isostructuraux. Les dimensions des mailles tricliniques sont $a = 10.53$, $b = 12.45$ et $c = 12.43$ Å, $\alpha = 81.5°$, $\beta = 67.0°$ et $\gamma = 76.3°$ pour le dérivé silicié et $a = 10.56$, $b = 12.50$ et $c = 12.58$ Å, $\alpha = 82.1°$, $\beta = 67.8°$ et $\gamma = 76.1°$ pour le dérivé germanié. Si le groupe spatial est $P\bar{1}$, il y aura deux molécules indépendantes par unité asymétrique.

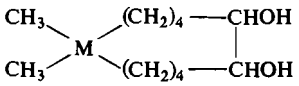
FRANÇOIS BRISSE, AVIVA BATTAT, JEAN-CLAUDE RICHER, PIERRE MAZEROLLES, and ALFREDA FAUCHER. Can. J. Chem. **53**, 3596 (1975).

1,1-Dimethyl-1-germa (and -1-sila) -6,7-cycloundecanediol ($C_{12}H_{26}O_2Ge$ and $C_{12}H_{26}O_2Si$) are isostructural as established by their X-ray powder patterns. The dimensions of the triclinic cells are as follows: for the silicon derivative, $a = 10.53$, $b = 12.45$, and $c = 12.43$ Å, $\alpha = 81.5°$, $\beta = 67.0°$, and $\gamma = 76.3°$; for the germanium derivative, $a = 10.56$, $b = 12.50$, and $c = 12.58$ Å, $\alpha = 82.1°$, $\beta = 67.8°$, and $\gamma = 76.1°$. If the space group is $P\bar{1}$, there will be two independent molecules in each asymmetric unit.

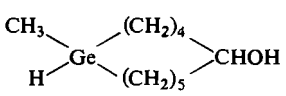
[Journal translation]

Introduction

Dans le cadre de nos travaux (1) sur la synthèse et les propriétés de cycles moyens contenant du germanium et du silicium, nous avons été amenés à examiner la structure cristalline du diméthyl-1,1 germacycloundécanediol-6,7 (**1***a*) et de son analogue silicié **1***b* dont la préparation a été décrite antérieurement (2). On a établi précédemment (1) que le méthyl-1 germacycloundécanol-6 (**2**) perd de l'hydrogène pour conduire,



1*a* M = Ge
1*b* M = Si



2

par une réaction de cyclisation intramoléculaire, à la formation du méthyl-1 oxa-12 germa-1 bicyclo[5.4.1]dodécane (**3**) qui résulte aussi de la cyclisation intramoléculaire, en présence de zinc, de la méthyl-1 germacycloundécanone-6 (**4***a*) formée transitoirement par réduction partielle de la chloro-1 méthyl-1 germacyclodécanone (**4***b*). Ces cyclisations intramoléculaires résulteraient d'un effet de proximité semblable à celui mis en évidence par Prelog et Schenler (3) et par Cope *et al.* (4) pour divers composés contenant des cycles moyens. Ces réactions laissent supposer que, dans les composés **2** et **4***a*,

4*a* X = H
4*b* X = Cl

les distances interatomiques entre le germanium et les atomes d'oxygène de l'alcool ou de la cétone sont courtes. C'est dans le but de vérifier si cette hypothèse est valable à l'état solide que les travaux actuels ont été entrepris.

Résultats et discussion

L'étude des cristaux uniques des deux composés **1***a* et **1***b* entreprise sur la caméra de précession a révélé que tous les cristaux observés étaient maclés et que les intensités diffractées s'atténuaient très rapidement en fonction de l'angle de diffraction. Les dimensions approchées des mailles tricliniques ont été obtenues à partir des films de précession. Ces mailles ont été réduites (5) et les nouvelles dimensions ont servi comme valeurs initiales pour l'indexation des films de poudres. Les paramètres des mailles élémentaires affinés par moindres carrés selon la méthode de Cohen (6) sont présentées (tableau 1). Les distances réticulaires et les intensités observées pour les deux composés sont présentées (tableau 2).

Le volume de la maille du composé germanié est légèrement supérieur à celui du dérivé silicié correspondant. Les densités déterminées expérimentalement par flottaison indiquent qu'il y a quatre molécules par maille triclinique. Si l'on suppose que le groupe spatial est centrosymétrique il y aurait donc deux molécules indépendantes par unité asymétrique. Le nombre de paramètres structuraux est au moins doublé rendant les chances de détermination de ces structures très peu probables compte tenu du maclage et du petit nombre de réflexions observables. Aucun travail ultérieur n'est donc prévu sur ces composés particuliers.

Partie expérimentale

Les cristaux uniques ont été étudiés sur la caméra de précession en se servant de la radiation du cuivre tandis que les diagrammes de poudres ont été pris à l'aide d'une caméra Debye-Scherrer de 114.5 mm de diamètre en utilisant la radiation du chrome (λ CrK$\bar{\alpha}$ 2.29092 Å) filtrée par le vanadium. Les échantillons ont été introduits dans des capillaires de Lindemann de 0.3 mm de diamètre. Les intensités ont été estimées visuellement.

Received May 27, 1975

H. BERNHARD SCHLEGEL, SAUL WOLFE, and FERNANDO BERNARDI. Can. J. Chem. **53**, 3599 (1975).

The dissociation energies of second and third period hydrides have been estimated by fitting a Morse potential to the harmonic and cubic stretching force constants computed from *ab initio* wavefunctions. The estimates thus obtained are superior to dissociation energies computed by direct differences of Hartree–Fock energies.

H. BERNHARD SCHLEGEL, SAUL WOLFE et FERNANDO BERNARDI. Can. J. Chem. **53**, 3599 (1975).

On a estimé les énergies de dissociation des hydrures de la deuxième et de la troisième période en ajustant un potentiel de Morse aux potentiels de vibration harmonique et cubique calculés à l'aide de fonction d'ondes *ab initio*. Ces estimés sont supérieurs aux énergies de dissociation calculés par les différences directes des énergies de Hartree et Fock.

[Traduit par le journal]

The calculation of bond dissociation energies *ab initio* has proved to be a virtually intractable theoretical problem. Reasonable agreement with experiment has been achieved only in a relatively small number of cases because large and complicated wavefunctions that take electron correlation specifically into account must be employed. The purpose of this paper is to outline a method for the estimation of the dissociation energies of hydride bonds which requires only SCF wavefunctions computed with a moderate size basis set.

The general shapes of interatomic potentials are well known from studies of the band spectra of diatomic molecules (1). In favorable cases the R.K.R. method (2) allows the exact shape of the potential curve to be deduced directly from the vibrational spectrum. When the vibrational spectrum is insufficiently well known for the computation of an R.K.R. potential, it is possible to fit the experimental data to one of a number of empirical curves. The best known of these is the Morse function (3),

$$[1] \qquad V(r) = D_e[1 - \exp(-\alpha(r - r_e))]^2$$

in which D_e is the dissociation energy and r_e is the equilibrium bond length. The parameter α is usually adjusted by fitting the potential V to the harmonic force constant k_2. A particular advantage of the Morse function is its ability to reproduce the cubic and quartic force constants, k_3 and k_4. Thus, when the dissociation energy D_e is unobtainable or unreliable, the potential can be fitted to the observed cubic force constant by the use of [2*a*] and [2*b*].

$$[2a] \qquad \left.\frac{\partial^2 V}{\partial r^2}\right|_{r_e} = k_2$$

$$[2b] \qquad \left.\frac{\partial^3 V}{\partial r^3}\right|_{r_e} = k_3$$

In a recent study of the force fields of second and third period hydrides (4), it was found that harmonic and cubic stretching force constants computed by the force method (5) are in excellent agreement with experiment. This suggested that, as has been done experimentally, it might be possible to estimate dissociation energies by fitting a three-parameter potential to the bond length and the calculated harmonic and cubic force constants. A number of possible functions have been evaluated (6, 7). Those due to Morse eq. 1, Rydberg (2*a*) eq. 3, Varshni (6) eq. 4, and

Lippincott and co-worker (8) eq. 5 were considered to be the most suitable (7).

$$[3]\quad V(r) = D_e[1 - (1 + \beta(r - r_e)) \times \exp(-\beta(r - r_e))]$$

$$[4]\quad V(r) = D_e\left[1 - \frac{r_e}{r}\exp(-\beta(r^2 - r_e^2))\right]^2$$

$$[5]\quad V(r) = D_e[(1 - \exp(-x)) \times (1 - ab\sqrt{x}\exp(-b\sqrt{xr/r_e}))]$$

$$b = 1.065$$

$$x = k_2 r_e(r - r_e)^2/2D_e r$$

For the Morse and Rydberg potentials the resulting expressions for dissociation energy have the simple form shown in [6] and [7].

$$[6]\quad D_e(\text{Morse}) = 9k_2^3/2k_3^2$$

$$[7]\quad D_e(\text{Rydberg}) = 4k_2^3/k_3^2$$

For the Varshni potential, the dissociation energy is given by [8*a*].

$$[8a]\quad D_e(\text{Varshni}) = 2C^3/(B^2 + 2BC - 3C^2 - (C + B)\sqrt{(C + B)^2 - 8C^2})$$

in which

$$[8b]\quad B = -k_3 r_e^3/6$$

$$[8c]\quad C = k_2 r_e^2/2$$

In the case of the Lippincott potential, the procedure of ref. 8 is adopted, *i.e.*,

$$[9a]\quad D_e(\text{Lippincott}) = (b^2/2)k_2 r_e^2(1 - 5a/4)$$

in which

$$[9b]\quad a = F/(1 + 5F/4)$$

$$[9c]\quad F = B/C - 1$$

(*i.e.* F is defined as in ref. 6)

Table 1 summarizes the results. The computed k_2 and k_3 were used in [6]–[9] to estimate the dissociation energy. The Varshni function was not suitable for H_2. The experimental D_e refer to the process $XY \rightarrow X + Y$ and $XH_n \rightarrow XH_{n-1} + H$. The calculated Hartree–Fock and SCF D_e were obtained from the difference between the energy of the molecule and the fragments computed either near the Hartree–Fock limit or at the same level as the force constant calculations. Since energies were in general not readily available for the dissociation fragments of the polyatomic hydride, D_e was estimated as $(1/n)(XH_n \rightarrow nH + X)$.

If the complete range of molecules is examined, it is evident that the estimated and calculated D_e's for F_2 are very much in error, and these will not be considered further. The dissociation energies of the remaining molecules seem to be represented best by the Varshni function, [8], but closer examination reveals that the reason for this is the lower error in the non-hydride molecules. If only the hydrides are considered, the Morse function is clearly superior and it is evident that D_e computed with the Morse potential, [6], are much better than either the Hartree–Fock D_e or the SCF D_e.

It has thus been found that the dissociation energies of hydride bonds can be computed satisfactorily with moderate size SCF wavefunctions. The method is superior to the direct computation of dissociation energies in terms of energy differences. Application of the procedure to the study of the dependence of bond dissociation energies on molecular conformations and the effects of substituents on bond dissociation energies is in progress.

We thank the National Research Council of Canada and the donors of the Petroleum Research Fund, administered by the American Chemical Society, for financial support of this research.

Received May 9, 1975

JOHN E. DRAKE, CHRIS RIDDLE, and L. COATSWORTH. Can. J. Chem. **53**, 3602 (1975).

Core-level binding energies of all atoms are reported for two series of compounds; Me_nMCl_{4-n} and Me_3MX ($n = 0 \rightarrow 4$, M = Si or Ge, X = F, Cl, Br, I and (for M = Ge) CN, N_3, and NCS). Binding energy shifts are discussed using a 'whole-molecule' approach and are correlated with estimated atomic charges derived from an electronegativity-equalization procedure. Carbon 1*s* binding energies are also correlated to ^{13}C n.m.r. chemical shifts.

JOHN E. DRAKE, CHRIS RIDDLE et L. COATSWORTH. Can. J. Chem. **53**, 3602 (1975).

On rapporte les énergies de liaison au niveau du noyau de tous les atomes pour deux séries de composés; Me_nMCl_{4-n} et Me_3MX ($n = 0 \rightarrow 4$, M = Si ou Ge, X = F, Cl, Br, I et (pour M = Ge) CN, N_3 et NCS). On discute des déplacements d'énergie de liaison en utilisant l'approche de la molécule complète et l'on fait une corrélation de ces déplacements avec les charges atomiques calculées à partir d'une méthode d'égalisation des électronégativités. On fait aussi une corrélation entre les énergies de liaison du carbone 1*s* avec les déplacements chimiques en r.m.n. du ^{13}C.

[Traduit par le journal]

Introduction

Two groups of workers (1–6) have previously presented ESCA data of silicon and germanium derivatives. Van Wazer and co-workers (1, 2) have reported core-level binding energies for a number of solid compounds, chosen to cover the expected range of binding energy shifts. These shifts were compared in analogous carbon, silicon, germanium, tin, and lead series. The observed decreases in chemical shift with increasing atomic size were similar to those predicted theoretically. Perry and Jolly (3–6) have examined gaseous samples, thus eliminating effects due to charging and uncertainties in Madelung potential. Binding energies have been related to various calculated atomic charges (6, 7) using the potential model equation of Siegbahn *et al.* (8). These calculations have met with considerable success although the correlations were least successful with the tetramethyl derivatives. Similar problems have been noted for organo-tin derivatives (9).

Our approach is to take closely related series of compounds and to observe the change in binding energies of *all* the atoms throughout the series. This initial study is designed to provide a basis for individual comparisons and an indication of which trends might be most general.

Experimental

Core-electron binding energies were determined on a McPherson ESCA-36 photoelectron spectrometer using magnesium Kα X-radiation (1253.6 eV) for photoelectron excitation. Samples were introduced in the vapor phase at pressures close to 5×10^{-5} Torr. Argon gas was bled in to form 20% of the total sample. All binding energies were referenced to the argon $2p_{3/2}$ level at 248.63 eV (10). (Those of the germanium 3*d* and silicon 2*p* levels are reported relative to the neon 2*s* level at 48.47 (10).) In a selected number of runs, the effect of varying the sample-pressure was found to be minimal as was running the samples in the absence of argon gas. Nonetheless, all of the values were obtained under similar conditions. The determinations were at least duplicated; for some compounds binding energies were determined on different samples at dates ranging over a six-month period. Reproducibility of the observed binding energies was generally excellent. Thus, the carbon 1*s* level of Me_3GeF was computed as 290.16, 290.17, 290.17, 290.21, and 290.25 eV. The separation of the neon 1*s* and argon $2p_{3/2}$ levels was determined to be 621.64 eV. This compares with a published separation of 621.76 eV (10). Typically, each spectrum was scanned five times over a 10 eV range using a 111 point array and a dwell time of one second per point. The scans were accumulated. The observed spectral lines were curve-fitted using a

computer program (ESCAPLOT) written by one of us (L. Coatsworth) and modified to run on the Windsor IBM S/360-50 series computer. (The program obtains a weighted least-squares fit to the data by means of stepwise Gauss–Newton iterations on the parameters. Within each iteration parameters are selected for modification in a stepwise manner. The parameter selected at a given step is the one which, differentially at least, makes the greatest reduction in the error sum of squares. If it is necessary to avoid matrix singularity problems, only a subset of the parameters may be modified in a given iteration. In addition, parameters with boundary values whose modification in a given iteration would lead to boundary violations are not modified.) Mixed Gauss–Lorentz band contours were fitted on a quadratic baseline. The reproducibility of data from separate runs was such that binding energies are quoted to ±0.05 eV (Tables 1 and 2). Data, which have been reported (3, 4, 6) for Me_4M and MCl_4 (M = Si, Ge), are included in Table 1 in parentheses and referred to argon at 248.63 eV. Values for C 1*s* and Cl $2p_{3/2}$ levels agreed to within the quoted error limits. For silicon 2*p* and germanium 3*d*, our values were *ca.* 0.1 eV higher on average than those of Jolly *et al.* and the separation of binding energies $MCl_4 \rightarrow MMe_4$ were in close agreement. The experimental binding energies of the Me_3MX series are given in Table 2.

The calculations of peak positions were performed

without the introduction of constraints. Gauss fractions between 0.3 and 0.6 were normal; values outside this range generally reflected poor quality spectra and an inability to obtain a good computer fit. The argon $2p_{3/2}$ level was consistently observed at 248.2 ± 0.2 eV with a full-width at half-maximum (f.w.h.m.) of 0.96 eV (average of 33 determinations). Average f.w.h.m. values for the simple singlet peaks of C 1*s*, F 1*s*, and N 1*s* were 1.24 eV (41 determinations), 1.25 eV (4 determinations), and 1.09 eV (4 determinations), respectively. For peaks where there was a good separation of levels, I $3d_{5/2}$ and Cl $2p_{3/2}$ f.w.h.m. values were 1.26 eV (4 determinations) and 1.18 eV (15 determinations), respectively. The separation between Cl $2p_{3/2}$ and $2p_{1/2}$ levels was 1.62 ± 0.03 eV and their areas averaged to 1:0.50 (±0.1) (14 determinations). Similarly for argon the $2p_{3/2}$ to $2p_{1/2}$ ratio was determined as 1:0.48 (±0.1). The Br $3d_{5/2}$ level was separated only 1.08 eV on average from the $3d_{3/2}$ level. With an average f.w.h.m. value of 1.30 eV (7 determinations) it was not always possible to get good peak deconvolution and values are only quoted to ±0.10 eV. Sulfur similarly was not always well resolved. Peak separation was 1.17 eV and f.w.h.m. values averaged to 1.15 eV (2 determinations).

^{13}C n.m.r. spectra were recorded on a Varian XL-100 spectrometer locked on the ^{2}H resonance of the $CDCl_3$ solvent and using TMS as internal reference. Chemical shifts are reported in p.p.m. (downfield (+)) from TMS (Table 3).

Materials

Tetramethylsilane, trimethylchlorosilane, dimethyldichlorosilane, methyltrichlorosilane, tetrachlorosilane, tetramethylgermane, dimethyldichlorogermane, methyltrichlorogermane, tetrachlorogermane, and trimethylbromogermane were obtained commercially (Ventron Corporation, Alfa Products) as was Me_3SiCH_2Cl (Laramie Chem. Co.). Samples of trimethylfluorosilane, hexamethyldisiloxane, trimethylfluorogermane, trimethylcyanogermane, trimethylazidogermane, and trimethylisothiocyanatogermane were generously donated by Dr. R. T. Hemmings. Trimethylchlorogermane was prepared by treating dimethyldichlorogermane with methyllithium (11). Reaction of trimethylsilane with bromine or iodine yielded trimethylbromosilane and trimethyliodosilane (based on details given in ref. 12). Trimethyliodogermane was synthesized in the exchange reaction of hydrogen iodide and trimethylbromogermane (based on details given in ref. 13).

All samples were distilled on the vacuum line and their purity checked by infrared and n.m.r. spectroscopy and, where appropriate, by vapor pressure determination.

Charge Calculations

The mode of calculation was basically that described in detail elsewhere (14). This gives partial charges based on the Hinze–Jaffé concept of orbital electronegativity (15–17). The calculations use the value of the valence shell ionization potentials, *I*, and electron affinities, *A* (15, 17). The relationship of the orbital electronegativity of the element, χ_M, to the charge, δ_M, on the element M is given by (14)

$$\chi_M = a + b\delta_M$$

where

$$a = (I + A)/2$$

and

$$b = I - A$$

The previously reported values of *a* and *b* (14, 15, 17) are listed in the footnote of Table 4.

Charge transfer was estimated by setting the electronegativity function of one atom equal to that of the other and solving the appropriate equations. The charge calculations for the two series, Me_nGeCl_{4-n} and Me_3GeX, where $n = 0 \rightarrow 4$ and X = F, Cl, Br, I, are shown in Table 4*a*, where the methyl group was treated as a moiety (*i.e.* $\chi_C = 7.37 + 3.29\delta_C$) and the halogen atoms were assumed to utilize only *p*-orbitals. Charge calculations were also carried out (Table 4*b*) with the carbon atom treated as an 'unbonded tetrahedral carbon atom' (*i.e.* $\chi_C = 7.98 + 13.27\delta_C$). (The correlations of these charge calculations with the experimental binding energies are displayed in Figs. 3 and 4*a*.)

Further calculations were carried out to allow for the incorporation of *s*-orbital participation on the part of the halogen atoms. For this purpose plots were made of $(I + A)$ for the change from 100% *s*- to 100% *p*-character for each halogen (15) (see Fig. 1 for an example using chlorine) and a linear correlation assumed for the corresponding changes in *I*. From these plots, $(I + A)$ and *I* values can be read for any % *s*-character and the *a* and *b* values calculated. The appropriate $(I + A)$ and *I* values, transcribed from Jaffe's papers (15, 17) are listed as a footnote in Table 5 while the *a* and *b* values for various degrees of *s*-character are listed in Table 5. The calculated charges appear in Tables 6 and 7.

Sample Calculations

(i) $GeCl_4$

$\chi_{Ge} = 8.07 + 6.82\delta_{Ge}$ for tetrahedral Ge

$\chi_{Cl} = 9.38 + 11.30\delta_{Cl}$ for the *p*-orbitals of Cl

In the molecule

$$\chi_{Ge} = \chi_{Cl}$$

[1] $\therefore\ 8.07 + 6.82\delta_{Ge} = 9.38 + 11.30\delta_{Cl}$

and

[2] $$\delta_{Ge} + 4\delta_{Cl} = 0$$

Solving [1] and [2] we obtain

$$\delta_{Ge} = +0.136$$

$$\delta_{Cl} = -0.034$$

TABLE 4. Calculated partial charges, δ*

	(a)			(b)

Me_3GeI	−0.085	+0.037	−0.027	−0.005	+0.002	−0.001
GeF_4	+0.368	—	−0.092	+0.368	—	−0.092
$GeBr_4$	+0.036	—	−0.009	+0.036	—	−0.009

*Charges calculated assuming that germanium is using sp^3 hybrid orbitals, $\chi_{Ge} = 8.07 + 6.82\delta_{Ge}$; that the halogens are using only *p*-orbitals, $\chi_F = 12.18 + 17.36\delta_F$; $\chi_{Cl} = 9.38 + 11.30\delta_{Cl}$; $\chi_{Br} = 8.40 + 9.40\delta_{Br}$; $\chi_I = 8.10 + 9.15\delta_I$; and that the carbon atom is treated as (*a*) a methyl group moiety using $\chi_C = 7.37 + 3.99\delta_C$ as suggested by Huheey (14), or (*b*) as an 'unbonded tetrahedral carbon atom' using $\chi_C = 7.98 + 13.27\delta_C$.

(ii) $MeGeCl_3$

Assuming 10% *s*-character in Cl orbital; *i.e.* EESOP, for Cl:

From Fig. 1

$$I + A = 20.6$$

$$I = 16.0$$

$$A = 4.6$$

$$\therefore\ a = 10.3$$

$$b = 11.4$$

$$10.3 + 11.4\delta_{Cl} = 8.07 + 6.82\delta_{Ge}$$

$$[3] \qquad \delta_{Cl} = -0.196 + 0.598\delta_{Ge}$$

Also

$$7.98 + 13.27\delta_C = 8.07 + 6.82\delta_{Ge}$$

$$[4] \qquad \delta_C = 0.007 + 0.514\delta_{Ge}$$

Since

$$\delta_C + \delta_{Ge} + 3\delta_{Cl} = 0$$

$$0.007 + 0.514\delta_{Ge} + \delta_{Ge} - 0.588 + 1.794\delta_{Ge} = 0$$

$$3.308\delta_{Ge} = 0.581$$

$$\therefore\ \delta_{Ge} = +0.176$$

From [3]

$$\delta_{Cl} = -0.196 + (0.598 \times 0.176) = -0.091$$

From [4]

$$\delta_C = 0.007 + (0.514 \times 0.176) = +0.097$$

Results and Discussion

The experimentally-determined computer-fitted binding energies for two series of silicon and germanium compounds, a 'methyl–halogen' replacement series, Me_nMCl_{4-n}, and a 'halogen–halogen' replacement series, Me_3MX, are presented in Tables 1 and 2. The trends in the core-level binding energies of the former series are illustrated in Fig. 2. Clearly, there is a step-wise *increase* in *all* of the binding energies as chlorine atoms successively 'replace' methyl groups in the series Me_4M through to MCl_4 (M = Si, Ge), which may be rationalized by consideration of the inductive effect. As the more electron-

*Calculated using the following values of I and $(I + A)$: fluorine, $I = 20.86(p)$, $38.24(s)$; $(I + A) = 24.36(p)$, $62.61(s)$; chlorine, $I = 15.03(p)$, $24.02(s)$; $(I + A) = 18.76(p)$, $38.47(s)$; bromine, $I = 13.10(p)$, $22.07(s)$; $(I + A) = 16.80(p)$, $36.57(s)$; iodine, $I = 12.67(p)$, $18.00(s)$; $(I + A) = 16.19(p)$, $31.38(s)$; see refs. 15, 17.

withdrawing chlorine atoms are introduced so one might expect the electron density to be redistributed from the carbon atoms toward the chlorine atoms.

The observed increase in C 1s binding energies (as $n = 4 \rightarrow 1$ in the series Me_nMCl_{4-n}) is thus as expected as the carbon atoms become increasingly $\delta+$. The slope of the two lines (M = Si and M = Ge) are similar, though slightly steeper for the germanium series, suggesting that the transmission of charge is marginally more favorable with germanium than with silicon. The increases in the binding energies (silicon 2p or germanium 3d) of the central atom (as $n = 4 \rightarrow 0$ in the series Me_nMCl_{4-n}) are also as expected for the increases in the $\delta+$ character of Si and Ge. The slopes of the two series are similar and indeed the differences in the binding energies, (Δb.e.) from Me_4M to MCl_4 are not large, being 4.15 eV for M = Si and 3.96 eV for M = Ge. (By extrapolation, the change in the corresponding tin series is *ca.* 3.4 eV.) The ionic radii of silicon and germanium are close enough that a similar change in binding energy is to be expected for similar charge changes. Thus, a similar bonding model is suggested for both series.

The slopes of the two chlorine $2p_{3/2}$ plots are similar for both series. The increase in the Cl $2p_{3/2}$ binding energies (as $n = 3 \rightarrow 0$ Me_nMCl_{4-n}) suggests that the chlorine atoms are becoming *less* $\delta-$ as the redistributed charge comes from fewer methyl groups and there is increasing 'competition' from other chlorine atoms. The values of the chlorine $2p_{3/2}$ binding energies are consistently lower for the germanium series (Cl more $\delta-$ for the germanium analogs). This suggests that the inductive effect is greater for individual germanium compounds than for the silicon analogs and is in agreement with known dipole-moments (*e.g.* Me_3SiCl 2.1 D, Me_3GeCl 2.8 D; remembering that the Si—Cl and Ge—Cl bond lengths in these compounds (2.03 and 2.17 Å, respectively) are similar).

In the case of Me_3SiCH_2Cl, we find the methyl C 1*s* binding energy and the silicon 2*p* binding energy intermediate between those of Me_4Si and Me_3SiCl. The methylene carbon adjacent to chlorine is shifted 1 eV to higher binding energy than the methyl carbons. However, the chlorine $2p_{3/2}$ level is not as negative as that for Me_3SiCl but nearer to that for Me_2SiCl_2. If the chlorine in Me_3SiCl were involved in π-bonding we might have expected it to have an unduly high binding energy; clearly this is not so.

In the 'halogen–halogen' replacement series, Me_3MX (Table 2), the central atom binding energies increase only slightly across the series $F \rightarrow I$, (0.38 eV for M = Si and 0.29 eV for M = Ge). The 1*s* binding energies of the methyl carbon atoms are equal within experimental error for all the silanes. The same is true for the germanium compounds where the C 1*s* binding energies are *ca.* 0.2 eV above those for the silanes. Thus, different halogens have similar effects on binding energies although their Pauling electronegativities vary considerably. We will return to this point later.

Charge Calculations

To complement the preceding qualitative analysis of the data we determined the relationship of the binding energies to calculated charges on the individual atoms. The correlations should be linear (1–7) since aberrations due to relaxation effects should not significantly alter the general linearity. However, such correlations have not been as successful with organoderivatives as they have with the binary halides (9) or the hydrogen halides (6) of group IV. Because the *absolute* value of the calculated charge is less significant than the *relative* values based on a particular model and because it seems desirable to avoid the introduction of many arbitrary constants (7) we base our calculations of charge on those of Huheey (14) which in turn were based on the Hinze–Jaffe method (15–17).

Initially, the charges (for the methylchlorogermane series) on Ge, C, and Cl were calculated on the assumption that germanium used sp^3 hybrids and chlorine used pure *p*-orbitals in bonding while C is part of a methyl group moiety (14). The resulting plots of binding energy (b.e.) *vs.* charge lead to nonlinear plots in *all* cases (for example, Fig. 3, b.e.(Ge 3*d*) *vs.* δ_{Ge}). These plots suggest that the calculations are over-emphasizing the electron-releasing nature of the methyl group. This apparently results because no distinction can be made in the simple equalization procedure between a hydrogen atom attached to carbon or directly to germanium. Nevertheless, the plots do show the general trends previously noted, namely, that the charges on *all* of the atoms become more positive (or less negative) as an increasing number of chlorine atoms replace methyl groups, and that the binding energies of all the trimethylhalogermanes are similar.

An alternative to overemphasizing the influence of the hydrogen atoms on the partial charges of nonadjacent groups is to ignore their presence. This is reasonable as chemical shift effects are not long range. Thus, charges were calculated treating the carbon atom as an 'unbonded tetrahedral carbon'. A remarkably linear plot of b.e.(Ge 3*d*) *vs.* δ_{Ge} for the methylchlorogermane series (Fig. 4, *A*) is now obtained. However, $GeBr_4$ and GeF_4 fall well off the line and plots of b.e.(Cl $2p_{3/2}$) *vs.* δ_{Cl} for the germanium series, while linear, do not coincide with those of the silicon series, nor do the b.e.(C 1*s*) *vs.* δ_C plots for the two series. Further, the calculated charges on germanium are very much lower than those obtained by Perry and Jolly by their CHELEQ method (6). A similarity might be expected since their calculations are based on the concept of charge equalization and the orbital electronegativity values of Jaffe *et al.* (14, 16). One 'mechanism' for allowing a greater charge-transfer to halides is to assume a degree of hybridization or *s*-

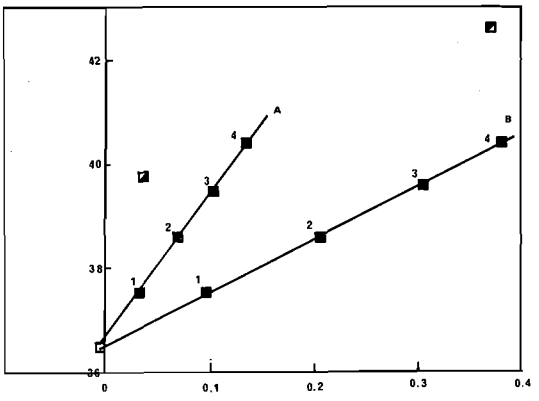

FIG. 4. Ge 3*d* core-level binding energies (eV) as a function of the calculated charge on germanium, δ_{Ge}. (Assuming an 'unbonded tetrahedral carbon' atom and that the halogen atoms are using (*A*) 'pure *p*-orbitals' and (*B*) 25% *s*-orbitals.) ■: $GeCl_4$, (*4*); $MeGeCl_3$, (*3*); Me_2GeCl_2, (*2*); Me_3GeCl, (*1*). ⊡, Me_4Ge. ◩, GeF_4 (using pure *p*). ◪, $GeBr_4$ (using pure *p*).

orbital participation. Siegbahn *et al.* suggest such an approximation in treating the data for fluoro- and bromo-methanes (ref. 8, p. 110). In Fig. 4, *B*, it can be seen that by assuming *ca.* 25% *s*-orbital participation (essentially half that possible on symmetry grounds) a linear plot is still maintained but the absolute values of the charges are significantly increased. Obviously, for all of the halides, the calculated charge can be altered merely by altering the allowance for *s*-orbital participation. It is not possible to know (*a*) how much *s*-orbital participation, if any, is most reasonable, and (*b*) how much such participation is likely to vary through the halide series. To obtain coincident plots along the series Me_4Ge, $GeBr_4$, $GeCl_4$, and GeF_4, a decreasing amount of *s*-orbital participation is required from Br through to F. Thus, it is possible to get relative values on this model, by 'fixing' fluorine as using 'pure-*p*' orbitals (not unreasonable in view of the large difference in the energy of its 2*s* and 2*p*-orbitals). The *s*-character for chlorine and bromine was then altered until a linear plot was obtained. Figure 5 displays a good correlation with 10% *s*-character on the chlorine atom. With 15% and 20% *s*-character for bromine and iodine, respectively, Me_3GeI, Me_3GeBr, and $GeBr_4$ fit the same linear plot. (We describe these calculations which assume *e*lectronegativity *e*qualization involving *s*-*o*rbital *p*articipation as EESOP calculations.)

Using these EESOP values, a plot of b.e.(C 1*s*) *vs.* δ_C is also remarkably linear and when the concept is extended to the silicon series a single linear plot can be obtained for b.e.(C 1*s*) *vs.* δ_C (Fig. 6) provided it is assumed that the *s*-character involved in the silicon series is slightly reduced (5% for Cl, 10% for Br, and 15% for I). Further, if a plot is made of b.e.(Cl $2p_{3/2}$) *vs.*

δ_{Cl} using the values for both the germanium and silicon series, another linear correlation is obtained (Fig. 7). Finally, the plot of b.e.(Si $2p$) *vs.* δ_{Si} for the various halides is linear (Fig. 8).

In summation, the features noted in the opening of the discussion can be rationalized by allowing for varying degrees of *s*-orbital participation by the halogen atoms (other than fluorine). In view of the assumptions, no claims are made of the importance of the absolute values. However, on this model the degree of *s*-orbital participation is, not unreasonably, Cl < Br < I and is marginally less for the silanes than the germanes. We can reproduce Perry and Jolly's charge calculations for the series GeF_4, $GeCl_4$, and $GeBr_4$, in which *d*-orbital participation was assumed (6) by allowing the *s*-orbital participation for fluorine to be *ca.* 12%, for chlorine *ca.* 17.5%, and for bromine *ca.* 20%. Our value of δ_{Ge} for Me_4Ge, based on the 'non-bonded tetrahedral atom' is essentially the same as that displayed in their correlation (6).

The EESOP approximation gives similar values to the 'electronegativities' of all of the halogens. Thus, the similarity in the influence of the various halogens in the series Me_3MX (X = F, Cl, Br, I) is consistent with this model. It is clear, however, that Me_3GeF and Me_3SiF do not 'fit' on the C 1*s*, the Ge 3*d*, or the Si $2p$ plots. Even with no *s*-character it is clear that the calculated charges on Ge, Si, and C need to be less positive. Obviously, one mechanism for reducing the positive charge would be (p–d) π back-donation from F to Ge or Si.

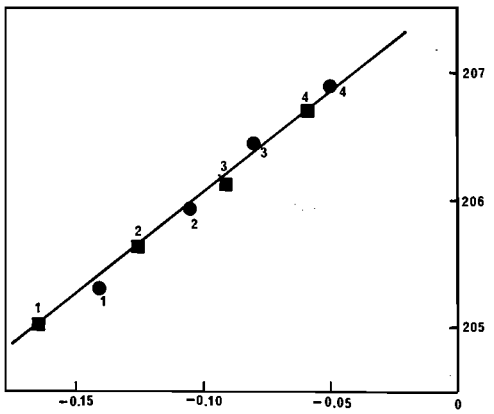

FIG. 7. Cl $2p_{3/2}$ core-level binding energies (eV) as a function of the calculated charge on chlorine δ_{Cl}. (Assuming an 'unbonded tetrahedral carbon' atom and that the chlorine atoms are using 5% *s*-character for the silicon series and 10% *s*-character for the germanium series.) ■: $GeCl_4$, (*4*); $MeGeCl_3$, (*3*); Me_2GeCl_2, (*2*); Me_3GeCl, (*1*). ●: $SiCl_4$, (*4*); $MeSiCl_3$, (*3*); Me_2SiCl_2, (*2*); Me_3SiCl, (*1*).

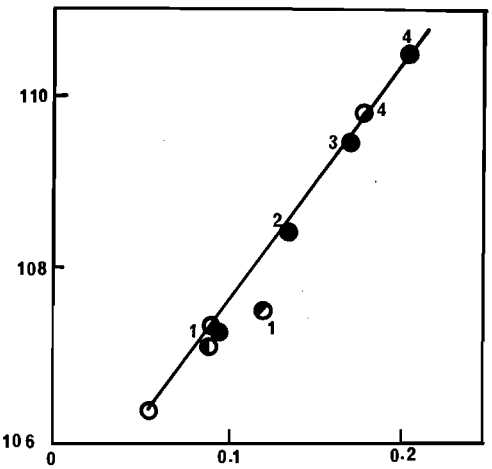

FIG. 8. Si $2p_{3/2}$ core-level binding energies (eV) as a function of calculated charge, δ_{Si}. (Assuming an 'unbonded tetrahedral carbon' atom and that the halogen atoms are using varying degrees of *s*-orbital participation (F = 0%, Cl = 5%, Br = 10%, I = 15%.) ●: $SiCl_4$, (*4*); $MeSiCl_3$, (*3*); Me_2SiCl_2, (*2*); Me_3SiCl, (*1*). ⊙, Me_4Si. ◐, Me_3SiF. ◑: $SiBr_4$, (*4*); Me_3SiBr, (*1*). ◐, Me_3SiI.

Data was collected on selected pseudohalides that contain a bond from germanium to a first row element. The binding energy of the methyl (C 1*s*) in Me_3GeN_3 is similar to the values for the halogens but in Me_3GeNCS and Me_3GeCN it increases. The germanium binding energy increases, again only slightly, as $N_3 \rightarrow CN \rightarrow NCS$, so that the azide lies between the bromide and iodide, the cyanide may be compared to the chloride and the isothiocyanate to the fluoride. Thus, charges on germanium that were associated with equal charging of the methyl groups for X = F, Cl, Br, and I now accompany varying methyl carbon charges.

Based on our EESOP calculations the binding energies (Ge 3*d* and C 1*s*) for the series $Me_3Ge—N_3$, —NCS, and —CN (Table 2) correspond to charges on germanium of 0.04, 0.055, and 0.05, respectively (Fig. 5), and on the carbon atom of the methyl-group of 0.025, 0.029, and 0.034, respectively (Fig. 6). This 'leaves' a charge of −0.115, −0.142, and −0.152 to be assigned to the $—N_3$, —NCS, and —CN groups, respectively. In $Me_3Ge—N_3$ the azido

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

group does not induce a large charge difference. This apparently low electronegativity is consistent with a degree of (π–d) π-bonding between Ge and the $-N_3$ group as has been suggested from the p.e. spectrum of silicon azides (18). The nitrogen 1s binding energies cannot be compared absolutely with those of the ionic azides (19) because of the phase change. However, ours are *ca.* 4.0 eV higher, which is consistent with the lower negative charge on the covalent azide. The separation of the N 1s levels is *ca.* 4.2 eV for both $Na^+N_3^-$ and $Me_3Ge—N_3$. Thus, delocalization of electron density within the N—N—N π-system apparently allows redistribution of any induced partial charge with similar results for both ionic and covalent azides. Alternatively, one can naively consider that the resonance structures $(Me_3Ge)N{=}\overset{+}{N}{=}\overset{-}{N}$ and $(Me_3Ge)\overset{-}{N}{-}\overset{+}{N}{\equiv}N$ allow the nitrogen atoms to maintain their relative charge differences. In $Me_3Ge—NCS$, the thiocyanato group apparently acts as a more electronegative group than the azide, or indeed any halogen group. The N 1s binding energy is slightly higher than that of the 'non-central' nitrogen atom in the azide. These two facts are consistent with its formulation as $(Me_3Ge)N{=}C{=}S$. There is N-bonding to germanium, the induced partial charge is spread over the whole moiety but there is no effective contribution from a resonance form that makes the nitrogen more negative. The nitrogen 1s binding energies in Me_3GeCN and Me_3GeNCS are separated by *ca.* 0.5 eV as has been observed in the potassium salts by Jolly *et al.* (19). In Me_3GeCN, the value is again slightly higher, but still much closer to, the 'non-central' nitrogen atom value. The C 1s binding energies of the Me— groups and the —CN group are so close that they form one, unresolvable peak. This is consistent with the expected C-bonded structure. Had the isocyanide form been important, then contributions from forms such as $Me_3Ge\overset{+}{N}{\equiv}\overset{-}{C}$ would surely result in the nitrogen atom having a binding energy approaching that of the 'central' nitrogen atom in an azide, while the binding energy of the carbon atom would be much lower than that of the methyl group carbon atom.

Finally, it is interesting to note that our correlations have been achieved despite the fact that no allowance has been made for relaxation energies nor has the potential term been included. The deficiencies in the assumptions may become apparent as more data are accumulated, but to date there is no reason to believe that consideration of the factors would improve the correlations.

Addendum

The N.M.R./ESCA Correlation

The idea that n.m.r. chemical shifts and ESCA core-level binding energies might be related parameters was held briefly (20). As Gelius has pointed out (21) there is some basis for such a correlation. In the n.m.r. effect the average screening constant, changes in which are called 'chemical shifts', contains paramagnetic and diamagnetic components. The paramagnetic term is the dominant one and does not depend on the molecular ground-state electron distribution. The diamagnetic term *only* is proportional to the ESCA shift. Although no general correlation can therefore be expected it has been postulated that in a closely related series the paramagnetic term might remain fairly constant. In the halomethanes CH_nX_{4-n} ($n = 0 \rightarrow 4$, X = F, Cl, Br, I) thirteen of the possible seventeen compounds have ^{13}C data reported. There is no general correlation of *all* these data, but for any one value of n all derivatives do exhibit linearity of δ_{13_C} *vs.* b.e.(C 1s) (21). Our δ_{13_C} values for a limited number of the germanium derivatives (Table 3) correspond to the analogs in the halomethane series (R_nMX_{4-n}, R = H or Me, M = C or Ge, respectively). That a plot of δ_{13_C} *vs.* b.e.(C 1s) for Me_4Ge, Me_3GeBr, Me_2GeCl_2, and $MeGeCl_3$ is linear we suggest is merely fortuitous for so was a similar plot for CH_4, CH_3Br, CH_2Cl_2, and $CHCl_3$. It is clear that neither b.e.(C 1s) *vs.* δ_{13_C} value in Me_3GeCN will fall on this same plot.

We are grateful to I. Adams, R. Lazier, and in particular to M. Bancroft, for their assistance in running the McPherson-36 and for helpful discussion. We also are indebted to M. Baillargeon for his work in modifying the computer program. We thank the National Research Council of Canada for financial support.

Synthèse de l'aza-1-twistane

PIERRE DESLONGCHAMPS, LUC RUEST ET SERGE DUBÉ[1]

Laboratoire de synthèse organique, Université de Sherbrooke, Sherbrooke, Québec J1K 2R1

Reçu le 27 mars 1975

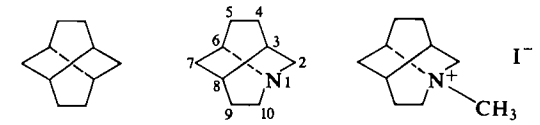
PIERRE DESLONGCHAMPS, LUC RUEST et SERGE DUBÉ. Can. J. Chem. **53**, 3613 (1975).

Nous avons réalisé une synthèse en cinq étapes de l'aza-1-twistane à partir de la benzoyl-2 octahydro-1,2,3,4,4a,7,8,8a isoquinolone-6(5) *cis* (**7**).

PIERRE DESLONGCHAMPS, LUC RUEST, and SERGE DUBÉ. Can. J. Chem. **53**, 3613 (1975).

A five-step synthesis of 1-azatwistane starting from the known *cis* 2-benzoyl-1,2,3,4,4a,7,8,8a-octahydro-6(5)-isoquinolone (**7**) is reported.

C'est à la suite de travaux réalisés dans notre laboratoire sur le twistane, **1**, (1–3) que nous avons entrepris la synthèse de l'analogue azoté, l'aza-1-twistane, **2**. D'autres groupes de recherche se sont intéressés en même temps que nous à la synthèse de l'aza-1-twistane. Perelman *et al.* (4) ont réussi à faire la synthèse de l'iodure de méthyl-1 aza-1-twistanium, **3**. Cependant il leur a été impossible d'effectuer la déméthylation du produit **3** de façon à obtenir l'aza-1-twistane. La méthode de fermeture de cycle utilisée par



1

6

Perelman *et al.* est semblable à celle que nous avons utilisée dans notre synthèse de l'aza-1-twistane. Nous avions déjà utilisé cette méthode dans la synthèse du twistane. Dans sa synthèse de l'aza-1-twistane, Heusler (5) utilise comme précurseur la chloroamine **4** qu'il transforme en un mélange de deux chloro-5 aza-1-twistanes épimériques, **5**, dont il obtient par réduction l'aza-1-twistane **2**. Notre synthèse de l'aza-1-twistane a déjà fait l'objet d'une publication préliminaire (6), qui a paru en même temps que les publications préliminaires de Perelman *et al.* (4) et de Heusler (5). Nous présentons maintenant notre travail d'une manière détaillée.

Au départ, la synthèse de l'aza-1-twistane ne semblait pas présenter plus de problèmes que la synthèse du twistane, Essentiellement, il s'agissait d'utiliser comme précurseur un produit du genre de la molécule modèle **6**. Cette molécule porte sur l'atome d'azote un groupement quelconque 'R' susceptible d'être enlevé en temps opportun et, en position 6, un bon groupe partant (*e.g.* atome de chlore, groupement mésylate, groupement tosylate, etc.). On trouve, au sein même de la molécule, une base (l'atome d'azote) susceptible d'effectuer facilement la cyclisation, du moins nous l'espérions, par déplacement du groupe placé en position 6 de l'isoquinoléine. Pour que soit possible la substitution nucléophilique interne impliquée dans la cyclisation, il fallait que les hydrogènes en positions 4a et 8a soient *cis* l'un par rapport à l'autre. Il fallait en outre que le groupe partant soit du même côté de la molécule que les hydrogènes de la jonction. C'est pour satisfaire à ces exigences que nous avons choisi comme produit de départ l'isoquinolone *cis* **7**.

Augustine (7) avait déjà effectué la préparation du produit **7**. Nous avons repris sa méthode. Nous avons d'abord préparé l'isoquinolone **8** par addition de méthylvinylcétone à l'énamine de la *N*-benzoylpipéridone. Par hydrogénation catalytique dans l'éthanol, en présence d'acide chlorhydrique, l'isoquinolone **8** a conduit à un mélange des deux cétones saturées **7** et **9**, que nous avons séparées par chromatographie préparative sur plaque de silice. Le mélange contenait 65% d'un isomère, présumément le *cis*, et 35% de l'autre isomère, présumément le *trans*. Augus-

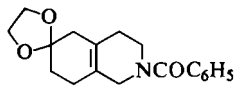
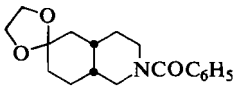
tine avait établi la stéréochimie des produits **7** et **9** par analogie avec la série des β-décalones et par application de la règle de von Auwers et de Skita. Nous avons utilisé une preuve chimique, plus sûre: nous avons fait une réduction de Birch sur la cétone insaturée **8**. Il est connu (8) qu'une telle réaction conduit exclusivement à l'isomère *trans*. Les résultats que nous avons obtenus confirment la stéréochimie établie par Augustine.

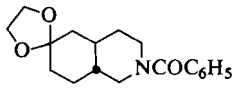
Dans le but de faciliter l'accès à notre produit de départ, l'isoquinolone **7**, nous avons tenté une autre synthèse de ce produit, par l'intermédiaire des cétals **10** et **11**. Par chauffage dans le benzène en présence d'éthylène glycol et d'acide *p*-toluènesulfonique, la cétone **8** a conduit au cétal **10**. L'hydrogénation du cétal **10** a conduit à un mélange des cétals **11** et **12**, comme on peut le voir par comparaison avec des échantillons authentiques préparés à partir des cétones **7** et **9**. L'analyse par chromatographie en phase



10



11

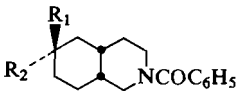


12

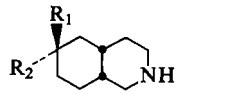
gazeuse du mélange des cétones **7** et **9** obtenu par hydrolyse du mélange des cétals **11** et **12** a démontré que le mélange contenant environ 55% du cétal *cis*. Nous espérions aussi par cette voie pouvoir séparer plus facilement les isomères *cis* et *trans* au niveau des cétals **11** et **12**. Cependant les cétals **11** et **12** avaient des valeurs de R_f très voisines et il nous a été impossible de les séparer. C'est pourquoi il nous a fallu revenir à notre méthode initiale, soit l'hydrogénation catalytique de la cétone **8**.

Il existait au départ plusieurs voies possibles pour passer de la cétone **7** à l'aza-1-twistane. Nous avions tout d'abord pensé travailler avec les amines secondaires **13**, **15** et **16**. Dans ce cas, il s'agissait de libérer d'abord l'amine par hydrolyse de la fonction amide du produit **7**, puis de transformer le groupement fonctionnel en position 6 en un bon nucléofuge.

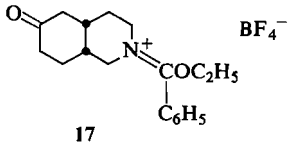
Le produit **7** fut d'abord transformé en sel d'imidate correspondant **17** à l'aide du tétrafluoroborure de triéthyloxonium. L'hydrolyse du sel **17** en milieu basique aqueux a fournit la cétone-amine **13** (9, 10). Par réduction avec de



18 R_1 = OH, R_2 = H
19 R_1 = H, R_2 = OH
20 R_1 = OSO_2CH_3, R_2 = H
21 R_1 = H, R_2 = OSO_2CH_3



14 R_1 = H, R_2 = OH
15 R_1 = OH, R_2 = H
16 R_1 = OSO_2CH_3, R_2 = H
22 R_1 = H, R_2 = OSO_2CH_3



17

l'hydrure de lithium et d'aluminium, la cétone-amine **13** a conduit présumément à un mélange des alcools **14** et **15**. Les deux alcools avaient la même valeur de R_f et il a été impossible de les séparer ou de déterminer la proportion de chacun dans le mélange. De plus, à cause de l'instabilité de ces amines et de leur grande polarité, l'utilisation des techniques de chromatographie était difficile. A ce stade, nous nous sommes rendus compte qu'il serait difficile de faire la synthèse de l'aza-1-twistane, **2**, par la voie des amines secondaires (**7** → **13** → **15** → **16** → **2**).

Nous avons alors décidé de tenter de faire plutôt la synthèse de l'aza-1-twistane par la voie des amides (**7** → **18** → **20** → **16** → **2**). Comme les amides sont des produits plus stables que les amines secondaires, nous avons choisi de conserver le plus longtemps possible la fonction amide et de travailler à placer d'abord en position 6 un bon nucléofuge. Nous espérions aussi pouvoir en cours de route séparer le mélange d'épimères que nous devions nous attendre à obtenir au niveau de la position 6.

Nous avons tout d'abord réduit la cétone **7** à l'aide de borohydrure de sodium. Le produit de la réaction était présumément un mélange des

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

For personal use only.

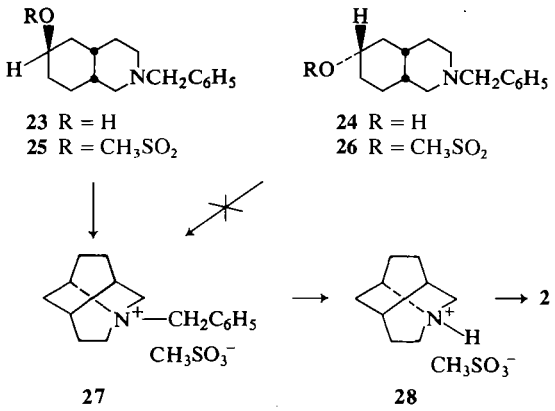
alcools **18** et **19**, mais les deux épimères avaient la même valeur de R_f et il a été impossible de les séparer. Par traitement avec du chlorure de méthanesulfonyle dans le dichlorométhane, en présence de pyridine, à $-15\,°C$, nous avons transformé le mélange des alcools **18** et **19** en un mélange des mésylates **20** et **21**. Les mésylates **20** et **21**, tout comme les alcools **18** et **19**, avaient la même valeur de R_f et il a été impossible de les séparer par chromatographie sur couche mince ou sur colonne. Nous avons fait l'hydrolyse de la fonction amide des mésylates **20** et **21** de la même façon que précédemment (**7** → **13**). Là encore les épimères, les mésylates **16** et **22**, avaient la même valeur de R_f et il a été impossible de les séparer. Rappelons que seulement l'un des deux épimères, c'est-à-dire le mésylate **16**, pouvait nous conduire à l'aza-1-twistane, **2**. Ce contretemps compromettait notre synthèse, mais nous avons quand même tenter d'effectuer la fermeture de cycle qui devait nous conduire à l'aza-1-twistane, **2**. Pour ce faire, nous avons chauffé le mélange des mésylates **16** et **22** dans le benzène pendant 30 h. Il semble sur la foi de comparaisons faites sur plaque mince avec un échantillon authentique[2] d'aza-1-twistane, **2** que nous ayons effectivement obtenu le produit désiré, en quantité si minime cependant qu'il nous a été impossible de le caractériser davantage. Le milieu réactionnel contenait en plus beaucoup d'autres produits, provenant peut-être de la décomposition de l'épimère de mauvaise configuration. Il se peut en outre que la cyclisation ait été incomplète ou bien qu'il y ait eu prépondérance du mauvais épimère **22** dans le mélange de départ.

Il était important à l'étape de la cyclisation d'avoir une réaction nette, parce que l'aza-1-twistane, **2**, une substance très polaire, est difficile à purifier par les méthodes habituelles. Nous avons alors décidé de procéder par la voie des amines tertiaires (**7** → **23** → **25** → **27** → **28** → **2**). La réduction de la cétone **7**, par traitement avec de l'hydrure de lithium et d'aluminium dans le tétrahydrofuranne, a conduit comme prévu à un mélange des alcools épimériques **23** et **24**. Même si les deux alcools avaient des valeurs de R_f très voisines, nous avons réussi à les séparer par chromatographie préparative. Le mélange



23 R = H
25 R = CH_3SO_2

24 R = H
26 R = CH_3SO_2

27 **28**

contenait environ 30% d'un épimère et environ 70% de l'autre épimère. Nous ignorions la stéréochimie de chacun des alcools au niveau de la position 6. La meilleure façon d'établir la stéréochimie des deux épimères, c'était en définitive de faire la synthèse de l'aza-1-twistane, **2**. C'est pourquoi nous avons décidé d'effectuer la même série de réactions sur les deux alcools **23** et **24**. Seul l'épimère α pouvait nous conduire à l'aza-1-twistane, **2**.

Nous avons préparé de la façon habituelle les mésylates **25** et **26** à partir des alcools **23** et **24**. L'un des deux mésylates devait nous conduire à l'aza-1-twistane, **2**. Nous avons tout d'abord chauffé à tour de rôle les deux mésylates dans le benzène pendant 48 h sans noter aucune réaction. Nous avons alors repris le mésylate de l'alcool majoritaire **27** et nous l'avons chauffé dans le toluène pendant 24 h. L'analyse sur plaque mince du produit obtenu a montré la présence de plusieurs produits de décomposition. Nous avons finalement chauffé à reflux dans le toluène pendant 20 h le mésylate de l'alcool minoritaire **25**. Nous avons obtenu de cette façon avec un rendement de 86% le sel quaternaire **27**. Ces résultats nous ont permis d'établir *a posteriori* la stéréochimie des alcools **23** et **24** et des mésylates **25** et **26**.

Il a été facile ensuite d'obtenir l'aza-1-twistane **2**. Nous avons fait sans difficulté l'hydrogénolyse du sel quaternaire **27** pour obtenir le méthanesulfonate de l'aza-1-twistane **28** quantitativement. Il suffisait ensuite de laver le sel **28** en milieu basique pour obtenir l'aza-1-twistane. Nous avons caractérisé le produit sous forme de chlorhydrate, car l'amine elle-même est instable. Les données physiques et spectrales concordent avec la nature du produit et sont identiques à celles

[2]Cet échantillon nous a été généreusement fourni par le docteur K. Heusler, de l'Institut de recherche Woodward (Bâle, Suisse) (*cf.* réf. 5).

d'un échantillon authentique. L'identité des deux produits a été confirmée par chromatographie sur plaque mince et par chromatographie en phase gazeuse. Le spectre infrarouge du chlorhydrate de l'azatwistane est reproduit à la Fig. 1.

Partie expérimentale

Nous avons pris les spectres infrarouges sur deux spectrophotomètres Perkin-Elmer, modèles 137 et 257. Pour les spectres de résonance magnétique nucléaire nous avons utilisé un appareil A-60 de la compagnie Varian, le tétraméthylsilane servant de référence interne. Les spectres de masse ont été pris sur un appareil Hitachi–Perkin-Elmer, modèle RMU-6D.

Les points de fusion, déterminés au moyen d'un appareil Büchi, ne sont pas corrigés. Pour nos analyses en phase gazeuse, nous nous sommes servis d'un chromatographe Varian, modèle 90-P, utilisant l'hélium comme gaz porteur. La colonne, d'une longueur de 5 pieds et d'un diamètre de $\frac{1}{4}$ po, contenait du SE-30 5% sur Chromosorb P.

Nous avons utilisé comme desséchant du sulfate de sodium anhydre. Les plaques minces utilisées pour les chromatographies sur couche mince étaient faites de gel de silice GF 254 de Merck ou G/UV 254 de Macherey, Nagel et cie ou d'alumine GF 254 ou G/UV 254 des mêmes fournisseurs. Nous avons aussi utilisé des chromagrammes de silice (no 6060) et d'alumine (no 6063) de la compagnie Eastman. Nous avons utilisé comme révélateur un réactif au chlorure de platine pour les amines et l'iode pour les autres produits. Les chromatographies sur colonne ont été faites sur du gel de silice de Baker (60–200 M) ou de Merck (75–325 M, p*H* 7). L'éther de pétrole utilisé est la fraction de pétrole distillant entre 30 et 60 °C.

Cétone insaturée ***8***

Nous avons essentiellement suivi la méthode expérimentale rapportée par Augustine (7) pour préparer la cétone insaturée **8**. On a préparé un échantillon analytique par recristallisation du produit dans un mélange de benzène et d'éther de pétrole; p.f. 142–143 °C (litt. (7) 144–145 °C); s.m. *m/e* 255 (M^+, ion moléculaire); i.r. ν_{max} ($CHCl_3$) 1685 et 1630 cm^{-1}; r.m.n. ($CDCl_3$) 6.00 δ (1H, CCHCO).

Anal. calc. pour $C_{16}H_{17}NO_2$: C, 75.27; H, 6.71; N, 5.48. Trouvé: C, 75.36; H, 6.74; N, 5.70.

Cétones saturées ***7*** *et* ***9***

La cétone **8** (2.1 g) a été réduite selon le mode opératoire décrit par Augustine (7). On recueille une substance cristalline blanche (2.2 g, 100%) fondant à 142–146°C. La substance est constituée de deux produits, qu'on sépare par chromatographie préparative sur silice, à raison de 75 mg par plaque de 20 cm × 40 cm (éluant, solution de méthanol dans l'éther à 5%). Le mélange contient 64% (1.4 g) de la cétone **7** et 32% (800 mg) de la cétone **9**.

On prépare un échantillon analytique de la cétone **7** par recristallisation du produit dans un mélange de benzène et d'éther de pétrole; p.f. 153 °C (litt. (7) 148–149 °C); s.m. *m/e* 257 (M^+, ion moléculaire); i.r. ν_{max} ($CHCl_3$) 1750 et 1630 cm^{-1}.

Anal. calc. pour $C_{16}H_{19}NO_2$: C, 74.67; H, 7.44; N, 5.44. Trouvé: C, 74.66; H, 7.52; N, 5.69.

On prépare un échantillon analytique de la cétone **9** par recristallisation du produit dans un mélange de benzène et d'éther de pétrole; p.f. 164.5–165.5 °C (litt. (7) 159–160 °C); s.m. *m/e* 257 (M^+, ion moléculaire); i.r. ν_{max} ($CHCl_3$) 1705 et 1630 cm^{-1}.

Anal. calc. pour $C_{16}H_{19}NO_2$: C, 74.67; H, 7.44; N, 5.44. Trouvé; C, 74.78; H, 7.59; N, 5.52.

Réduction de Birch sur la cétone ***8***

A de l'ammoniac liquide préalablement distillé (250 ml), on ajoute du lithium jusqu'à persistance de la coloration bleue, puis la cétone **8** (1.03 g) en solution dans du tétrahydrofuranne (10 ml). Après avoir laissé agiter pendant 60 s, on ajoute du chlorure d'ammonium pour détruire l'excès de lithium. On laisse évaporer l'ammoniac, on ajoute de l'eau et on extrait au dichlorométhane. Après séchage et évaporation du solvant, on obtient une huile jaunâtre (800 mg), dont on tire par chromatographie sur colonne (silice) la fraction correspondant aux cétones **7**, **8** et **9** (720 mg). Le mélange obtenu était constitué uniquement du produit de départ, la cétone **8** et de la cétone **9**. On sépare les deux produits par chromatographie préparative sur silice (éluant, solution de méthanol dans l'éther à 5%). Les propriétés physiques et spectrales du produit réduit sont identiques à celles du produit **9**. Il a été impossible de trouver trace du produit **7** dans le milieu réactionnel.

Cétal ***10***

A une solution de la cétone insaturée **8** (400 mg, 1.57 mmol) dans du benzène anhydre (200 ml), on ajoute de l'éthylène glycol (900 mg, 14.5 mol) et de l'acide *p*-toluènesulfonique (5 mg). On coiffe le ballon d'un séparateur d'eau et d'un réfrigérant et on chauffe à reflux pendant 40 h. Après réduction du volume de la solution, on ajoute une solution saturée (100 ml) de carbonate de sodium et on extrait au dichlorométhane. On lave la phase organique avec une solution saturée de chlorure de sodium. L'huile obtenue après séchage et évaporation du solvant est ensuite purifiée par chromatographie préparative sur silice (éluant, solution de méthanol dans l'éther à 5%). On obtient ainsi une huile incolore (190 mg, 41%). On prépare un échantillon analytique par microdistillation sous vide; s.m. *m/e* 299 (M^+, ion moléculaire); i.r. ν_{max} (CH_2Cl_2) 1640, 1455 et 1115 cm^{-1}; r.m.n. ($CDCl_3$) 3.97 δ (4H, singulet, OCH_2CH_2O).

Anal. calc. pour $C_{18}H_{21}NO_3$: C, 72.21; H, 7.07; N, 4.68. Trouvé: C, 72.30; H, 7.07; N, 4.92.

Cétal ***11***

A une solution de la cétone **7** (200 mg, 0.78 mmol) dans du benzène anhydre (150 ml), on ajoute de l'éthylène glycol (360 mg, 5.8 mmol) et de l'acide *p*-toluènesulfonique (5 mg). On coiffe le ballon d'un séparateur d'eau et d'un réfrigérant et on chauffe à reflux pendant 24 h. Après réduction du volume de la solution, on ajoute une solution saturée (100 ml) de carbonate de sodium et on extrait au dichlorométhane. On lave la phase organique avec une solution saturée de chlorure de sodium. L'huile obtenue après séchage et évaporation du solvant est ensuite purifiée par chromatographie préparative sur silice (éluant, solution de méthanol dans l'éther à 5%). On obtient ainsi une huile incolore qu'on cristallise par

For personal use only.

trituration dans du cyclohexane (222 mg, 100%). Un échantillon est recristallisé dans le cyclohexane pour envoi à l'analyse; p.f. 108 °C; s.m. *m/e* 301 (M^+, ion moléculaire); i.r. ν_{max} (CH_2Cl_2) 1625, 1440 et 1118 cm^{-1}; r.m.n. ($CDCl_3$) 3.92 δ (4H, singulet, OCH_2CH_2O).

Anal. calc. pour $C_{18}H_{23}NO_3$: C, 71.73; H, 7.64; N, 4.65. Trouvé: C, 71.91; H, 7.72; N, 4.72.

Cétal ***12***

A une solution de la cétone **9** (500 mg, 1.95 mmol) dans du benzène anhydre (175 ml) on ajoute de l'éthylène glycol (900 mg, 14.5 mmol) et de l'acide *p*-toluènesulfonique (25 mg). On coiffe le ballon d'un séparateur d'eau et d'un réfrigérant et on chauffe à reflux pendant 37 h. Après réduction du volume de la solution, on ajoute une solution saturée (100 ml) de carbonate de sodium et on extrait au chloroforme. On lave la phase organique avec une solution saturée de chlorure de sodium. L'huile obtenue après séchage et évaporation du solvant est cristallisée par trituration dans du cyclohexane chaud (468 mg, 80%). Un échantillon est recristallisé dans le cyclohexane pour envoi à l'analyse; p.f. 124–125 °C; s.m. *m/e* 301 (M^+, ion moléculaire); i.r. ν_{max} (CH_2Cl_2) 1628, 1442 et 1120 cm^{-1}; r.m.n. ($CDCl_3$) 3.95 δ (4H, singulet, OCH_2CH_2O).

Anal. calc. pour $C_{18}H_{23}NO_3$: C, 71.73; H, 7.85. Trouvé: C, 71.64; H, 7.85.

Hydrogénation du cétal ***10***

A une solution du cétal **10** (975 mg, 3.25 mmol) dans l'éthanol (150 ml), placée dans un ballon à hydrogénation, on ajoute de l'oxyde de platine (200 mg). Après avoir enlevé l'air, on place sous atmosphère d'hydrogène (3 atm) et on agite mécaniquement à la température de la pièce pendant 36 h. Après avoir filtré le catalyseur, on évapore l'éthanol, puis on reprend le résidu dans du dichlorométhane. Après séchage et évaporation du solvant, on recueille une huile incolore (975 mg, 100%) constituée de deux produits, les cétals **11** et **12**, qu'il a été impossible de séparer. Il a également été impossible de déterminer la proportion de chacun des produits dans le mélange; i.r. ν_{max} (CH_2Cl_2) 1632, 1450 et 1122 cm^{-1}; r.m.n. ($CDCl_3$) 3.92 δ (4H, singulet, OCH_2CH_2O).

Hydrolyse du mélange des cétals ***11*** *et* ***12***

A une solution du mélange des cétals **11** et **12** (238 mg) dans l'éther (20 ml) on ajoute de l'acide chlorhydrique 0.5 *N* (30 ml), puis on laisse agiter à la température de la pièce pendant 4 h. On sépare ensuite la phase éthérée qu'on lave avec une solution saturée de chlorure de sodium jusqu'à neutralité. Après séchage et évaporation du solvant, on recueille des cristaux blancs (185 mg, 85%). Des comparaisons faites avec des échantillons authentiques des cétones **7** et **9** par chromatographie en phase gazeuse ont permis d'établir que le mélange contient environ 45% de la cétone **9** et environ 55% de la cétone **7**.

Cétone ***13***

A une solution du réactif de Meerwein (3.0 g, 16 mmol) dans du dichlorométhane (20 ml) filtré sur alumine, on ajoute du carbonate de sodium (1.2 g, 11 mmol) et on agite vigoureusement pendant 15 min. Après addition de la cétone **7** (300 mg, 1.17 mmol) on agite pendant 75 min. Le milieu réactionnel est ensuite lavé soigneusement à deux reprises avec une solution saturée de carbonate de sodium (25 ml). Après séchage et évaporation du solvant, l'huile résiduelle est dissoute dans une solution d'acide chlorhydrique 0.1 *N* (25 ml). On lave la phase aqueuse avec du dichlorométhane pour enlever le benzoate d'éthyle formé au cours de la réaction. Après basification de la phase aqueuse, extraction au dichlorométhane, séchage et évaporation du solvant, on recueille une huile incolore (182 mg, 100%). Il a été impossible de cristalliser le chlorhydrate et le picrate de la cétone **13**. Le styphnate, recristallisé dans un mélange d'éthanol et d'éther de pétrole, fond à 174–176 °C (déc.); s.m. *m/e* 153 (M^+, ion moléculaire); i.r. ν_{max} (film liquide) 3500 et 1715 cm^{-1}; r.m.n. ($CDCl_3$) 0.7–3.1 δ (massif).

Anal. calc. pour le styphnate: C, 45.23; H, 4.55; N, 14.07. Trouvé: C, 45.21; H, 4.62; N, 13.95.

Alcools ***14*** *et* ***15***

A une suspension d'hydrure de lithium et d'aluminium (280 mg, 7.8 mmol) dans le tétrahydrofuranne anhydre (35 ml), on ajoute la cétone **13** (362 mg, 2.4 mmol) et on chauffe à reflux pendant 3 h. On laisse ensuite refroidir le milieu réactionnel, puis on ajoute de l'eau pour détruire l'excès d'hydrure. Après séchage et évaporation du solvant, on obtient une huile jaunâtre (195 mg, 54%); i.r ν_{max} (CH_2Cl_2) 3575 cm^{-1}.

Alcools ***18*** *et* ***19***

A une solution de la cétone **7** (258 mg, 1.0 mmol) dans le méthanol (10 ml), on ajoute du borohydrure de sodium (81 mg, 2.5 mmol) en solution dans l'eau (5 ml). Après avoir laissé agiter pendant 3 h, on ajoute de l'acétone (1 ml) pour détruire l'excès d'hydrure. On réduit le volume de la solution, on ajoute de l'eau et on extrait à l'éther. Après séchage et évaporation du solvant, on obtient une huile incolore très épaisse (249 mg, 96%); s.m. *m/e* 259 (M^+, ion moléculaire); i.r. ν_{max} ($CHCl_3$) 3570, 3450 et 1615 cm^{-1}.

Mésylates ***20*** *et* ***21***

A une solution des alcools **18** et **19** (258 mg, 1 mmol) dans du dichlorométhane (10 ml) distillé et filtré sur alumine on ajoute de la pyridine (2 ml) et on refroidit la solution à 0 °C. Après addition de chlorure de méthanesulfonyle (450 mg, 0.3 ml, 3.9 mmol), on conserve au congélateur pendant 48 h. On jette ensuite le milieu réactionnel dans une solution saturée de carbonate de sodium et on extrait au dichlorométhane. Le produit obtenu après séchage et évaporation du solvant est purifié par chromatographie préparative sur silice (éluant, solution de méthanol dans l'éther à 5%). On obtient une huile jaunâtre (280 mg, 83%); s.m. *m/e* 337 (M^+, ion moléculaire); i.r. ν_{max} ($CHCl_3$) 1358, 1170 et 935 cm^{-1}; r.m.n. ($CDCl_3$) 3.02 δ (3H, singulet, OSO_2CH_3).

Mésylates ***16*** *et* ***22***

A une solution du réactif de Meerwein (1.0 g, 5.3 mmol) dans du dichlorométhane (10 ml) filtré sur alumine, on ajoute du carbonate de sodium (282 mg, 2.6 mmol) et on agite vigoureusement pendant 15 min. On ajoute une solution des mésylates **20** et **21** (250 mg, 0.74 mmol) dans du dichlorométhane (3 ml), puis on laisse agiter à la température de la pièce pendant 2 h. Dilué par addition de dichlorométhane (10 ml), le milieu réactionnel est versé dans une solution saturée de carbonate de sodium (25 ml). On agite vigoureusement pendant 15 min. Après séparation de la phase organique, séchage et évaporation du solvant on obtient une huile jaunâtre

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

dont on tire par chromatographie préparative sur alumine (éluant, solution de méthanol dans le chloroforme à 50%) une huile incolore (170 mg, 100%); s.m. *m/e* 233 (M^+, ion moléculaire); i.r. ν_{max} ($CHCl_3$) 1340, 1165 et 925 cm^{-1}; r.m.n. ($CDCl_3$) 3.00 δ (3H, singulet, OSO_2CH_3).

Alcools 23 et 24

A une solution de la cétone **7** (258 mg, 1 mmol) dans du tétrahydrofuranne anhydre (30 ml) on ajoute de l'hydrure de lithium et d'aluminium (380 mg, 10 mmol) et on chauffe à reflux pendant 4 h. Après addition d'eau pour détruire l'excès d'hydrure, la solution est séchée et le solvant est évaporé. On recueille une huile incolore (233 mg, 91%), constituée de deux produits qu'on sépare par chromatographie préparative sur silice (éluant, solution de méthanol dans l'éther à 5%).

L'alcool **24** (R_f 0.4, 77%) est une huile incolore qui solidifie après un séjour de 6 mois au congélateur. Le picrate et le styphnate, recristallisés tous les deux dans l'éthanol absolu, fondent à 77–79 °C et 96–97 °C respectivement. Le flavianate, recristallisé dans le méthanol, a un point de fusion de 148–149 °C; s.m. *m/e* 245 (M^+, ion moléculaire); i.r. ν_{max} ($CHCl_3$) 3610 et 3450 cm^{-1}; r.m.n. ($CDCl_3$) 3.50 δ (2H, singulet NCH_2C), 3.4–3.9 δ (1H, massif, CHO) et 7.30 δ (5H, singulet, C_6H_5).

Anal. calc. pour le picrate: C, 55.69; H, 5.52. Trouvé: C, 55.59; H, 5.64.

L'alcool **23** (R_f 0.5, 23%) est une huile incolore dont le picrate, recristallisé dans l'éthanol absolu, fond à 163–164 °C; s.m. *m/e* 245 (M^+, ion moléculaire); i.r. ν_{max} ($CHCl_3$) 3600 et 3450 cm^{-1}; r.m.n. ($CDCl_3$) 3.49 δ (2H, singulet, NCH_2C), 3.5–4.1 δ (1H, massif, CHO) et 7.39 δ (5H, singulet, C_6H_5).

Anal. calc. pour le picrate: C, 55.69; H, 5.52; N, 11.81. Trouvé: C, 55.37; H, 5.48; N, 11.86.

Mésylate 26

A une solution de l'alcool **24** (224 mg, 0.91 mmol) dans du dichlorométhane anhydre (25 ml) on ajoute de la pyridine (1.8 ml) et on refroidit la solution à 0 °C. Après addition de chlorure de méthanesulfonyl (450 mg, 0.3 ml, 3.9 mmol) on place au congélateur pendant 15 h. On jette ensuite le milieu réactionnel dans une solution saturée de carbonate de sodium et on extrait au dichlorométhane. La phase organique est ensuite lavée à l'eau. Après séchage et évaporation du solvant, on obtient un solide brunâtre fondant à 75–80 °C (300 mg, 100%). Le chlorhydrate du produit **26**, recristallisé dans un mélange de chloroforme et d'éther de pétrole, fond à 128–129 °C, tandis que son picrate, recristallisé dans l'éthanol absolu, a un point de fusion de 155–156 °C; s.m. *m/e* 323 (M^+, ion moléculaire); i.r. ν_{max} (CH_2Cl_2) 1360, 1200 et 1050 cm^{-1}; r.m.n. ($CDCl_3$) 2.98 δ (3H, singulet, OSO_2CH_3).

Anal. calc. pour le picrate: C, 49.99; H, 5.10; N, 10.13. Trouvé: C, 50.30; H, 5.44; N, 9.84.

Mésylate 25

A une solution de l'alcool **23** (640 mg, 2.6 mmol) dans du dichlorométhane anhydre (30 ml) on ajoute de la pyridine (5 ml) et on refroidit la solution à 0 °C. Après addition du chlorure de méthanesulfonyle (1.36 g, 0.9 ml, 12 mmol) on place au congélateur pendant 15 h. On jette ensuite le milieu réactionnel dans une solution saturée de carbonate de sodium et on extrait au dichlorométhane. La phase organique est ensuite lavée à l'eau. Après séchage et évaporation du solvant, on recueille une huile jaunâtre, (844 mg, 100%). Le chlorhydrate du produit **25**, recristallisé dans l'acétone, fond à 166–167 °C; s.m. *m/e* 323 (M^+, ion moléculaire); i.r. ν_{max} (CH_2Cl_2) 1355, 1178 et 935 cm^{-1}; r.m.n. ($CDCl_3$) 2.98 δ (3H, singulet, OSO_2CH_3).

Anal. calc. pour le chlorhydrate: C, 55.77; H, 7.22. Trouvé: C, 55.96; H, 7.19.

Cyclisation du mésylate 25

On chauffe à reflux pendant 20 h une solution du mésylate **25** (700 mg) dans le toluène (100 ml). Par filtration on recueille un solide blanc fondant à 180–181 °C (600 mg, 86%). On prépare un échantillon analytique du sel quaternaire **27** par recristallisation dans l'acétone; p.f. 188 °C; i.r. ν_{max} (CH_2Cl_2) 1205 et 1045 cm^{-1}; r.m.n. (CDCl) 2.80 δ (3H, singulet, OSO_2CH_3), 4.72 δ (2H, singulet large, NCH_2C) et 7.2–7.7 δ (5H, massif, C_6H_5).

Anal. calc. pour $C_{17}H_2N_5O_3S$: C, 63.15; H, 7.74; N, 4.33. Trouvé: C, 63.02; H, 7.69; N, 4.58.

Aza-1-twistane, 2

A une solution du sel quaternaire **27** (321 mg, 1 mmol) dans de l'éthanol anhydre (70 ml) on ajoute du charbon palladié (400 mg, préparation commerciale à 10%). Après avoir enlevé l'air, on place sous atmosphère d'hydrogène (1 atm) et on agite mécaniquement à la température de la pièce pendant 40 h. On filtre le catalyseur. Après évaporation du solvant, on recueille une huile incolore (**28**, 237 mg, 100%); r.m.n. ($CDCl_3$) 2.37 δ (3H, singulet, CH_3). On dissout l'huile dans l'ammoniaque diluée et on extrait au dichlorométhane. Après séchage et évaporation du solvant, on obtient une huile jaunâtre (**2**, 135 mg, 100%). Le chlorhydrate, recristallisé dans un mélange de dichlorométhane et d'acétone pour envoi à l'analyse, fond à 320–323 °C (déc.); s.m. *m/e* 137 (M^+, ion moléculaire). La seule bande importante du spectre infrarouge du chlorhydrate est une bande large centrée à 2450 cm^{-1} (Fig. 1); r.m.n. ($CDCl_3$) 1.3–2.6 δ (10H), 2.8–3.6 δ (4H, $CH_2\overset{H}{\underset{|}{N}}\overset{+}{C}H_4$), 3.7–4.0 δ (1H, CH) et 9.0–10.0 δ (1H, $\overset{+}{N}H$).

Anal. calc. pour le chlorhydrate: C, 62.24; H, 9.30. Trouvé: C, 62.49; H, 9.45.

The Synthesis of Primary Alkyl Chlorides from Alcohols and Hydrogen Chloride in Hexamethylphosphoric Triamide[1]

RICHARD FUCHS

Department of Chemistry, University of Houston, Houston, Texas 77004

AND

LARRY L. COLE

Department of Chemistry, Prairie View A & M University, Prairie View, Texas 77445

Received July 11, 1975

RICHARD FUCHS and LARRY L. COLE. Can. J. Chem. **53**, 3620 (1975).

The reaction of hydrogen chloride with primary alcohols, which occurs slowly and in poor yields in water, has been found to give good yields of alkyl chlorides in 30–45 min at 70–85 °C in the solvent hexamethylphosphoric triamide. 2-Octanol and neopentyl alcohol required longer reaction periods. Neopentyl chloride was formed without contamination by rearrangement products.

RICHARD FUCHS et LARRY L. COLE. Can. J. Chem. **53**, 3620 (1975).

La réaction de l'acide chlorhydrique avec les alcools primaires, qui se produit lentement et avec de faibles rendements dans l'eau, conduit à des bons rendements en chlorure d'alkyle en 30–45 min, à 70–85 °C, dans le HMPT comme solvant. L'octanol-2 et l'alcool néopentylique demandent des périodes de réaction plus longues. Le chlorure de néopentyle se forme sans contamination par des produits de réarrangement.

[Traduit par le journal]

The much greater reactivity of aqueous hydriodic acid compared with hydrochloric acid toward primary alcohols is usually attributed to the greater nucleophilicity of iodide ion (*vs.* chloride). Both acids are sufficiently strong to protonate alcohols extensively, but the subsequent S_N2 displacement of water from the protonated alcohol occurs readily only with iodide. For this reason the conversion of primary alcohols to chlorides with hydrochloric acid usually requires quite high temperatures and the addition of large amounts of zinc chloride, or poor yields are the result (1).

It has occurred to us that the reaction rate could be increased by making use of the greater nucleophilicity of chloride ion in dipolar aprotic solvents compared with protonic solvents (2). We have chosen to examine hexamethylphosphoric triamide (HMPT), because it is moderately resistant to acid attack (3), and the products of such attack by hydrogen chloride are readily separated from alkyl chlorides.

The reaction is carried out at 50–85 °C using a 35–37% (by weight) solution of hydrogen chloride in HMPT. Within 30 min the alcohol is essentially undetectable by gas chromatography. Yields given in Table 1 are based on isolated products.

The reaction appears to be a convenient method giving very good yields, for the conversion of primary alcohols to the corresponding chloride. The mechanism may involve direct attack of chloride ion on a protonated alcohol:

$$RCH_2OH \overset{H^+}{\rightleftarrows} RCH_2\overset{+}{O}H_2 \overset{Cl^-}{\underset{S_N2}{\rightarrow}} RCH_2Cl + H_2O$$

but the intervention of a reagent containing a phosphorus–chloride bond (formed by the reaction of hydrogen chloride with HMPT) cannot at present be ruled out.

When optically active 2-octanol was used as substrate, the resulting 2-chlorooctane was racemized, probably by repeated displacement of chloride from the initially formed product by the chloride ion in the reaction mixture. No conclusions can therefore be drawn concerning the mechanism of hydroxyl replacement.

Experimental

The reagent is prepared by slowly passing hydrogen chloride gas from a commercial cylinder into HMPT. The mixture is allowed to warm somewhat to prevent crystal-

TABLE 1. Reaction of alcohols with hydrogen chloride in HMPT

Product	b.p. (°C)	i.r.(C–Cl, cm^{-1})	Reaction temperature (°C)	Yield (%)
1-Chlorohexane	130–133	650, 704	75–85	76
1-Chlorooctane	120–123 (137 Torr)	654, 790	75–85	87
2-Chlorooctane*	115 (140 Torr)	672	75–87	89
1-Chlorobutane	74–78	653, 709	70–80	74
Neopentyl chloride†	80–85	714, 900	71–80	65
m-Methoxybenzyl chloride	116 (10 Torr)‡	680	50–65	87

*When the temperature was raised to 100 °C the crude product of 2-chlorooctane showed (by g.c.) large amounts of 2-octene and unchanged 2-octanol.

†Although unchanged neopentyl alcohol was detected in the pentane extract, a g.c. analysis showed no traces of products of rearrangement. A number of other cases of neopentyl displacement in HMPT without rearrangement have recently been reported (6), although these reactions were not under acidic conditions. Neopentyl chloride has been prepared from the alcohol in two steps (53% overall yield) via neopentyl tosylate, and in unstated yield by the reaction of the alcohol with triphenylphosphine and carbon tetrachloride (6).

‡Reported (4, 5) 55 °C at 0.3 Torr, 124 °C at 13 Torr.

lization, but is maintained below 115 °C. Above this temperature an exothermic reaction occurs resulting in solvent decomposition. Gas flow is continued until the composition reaches 35–37% hydrogen chloride by weight. Smaller concentrations of hydrogen chloride lead to incomplete conversion, as do molar ratios (HCl:ROH) appreciably less than 10.

1-Chlorohexane was prepared by mixing 4.2 g (39 mmol) of 1-hexanol with 40 g of the HMPT·HCl reagent and heating on the steam bath for 45 min. The mixture was diluted with 50 ml of ice and water and was extracted twice with 40 ml of hexane. The organic layer was washed with sodium bicarbonate solution and with water, dried with magnesium sulfate, and filtered. Hexane was removed on a rotary evaporator and the residue of 1-chlorohexane was distilled at 130–133 °C (lit. (1) 131–134 °C) to give 3.59 g (76% yield). The identity of the product was confirmed by comparison of the g.c. retention time and i.r. spectrum with those of an authentic sample.

1- and 2-chlorooctanes, 1-chlorobutane, *m*-methoxybenzyl chloride, and neopentyl chloride were prepared by a procedure similar to that described for the preparation of 1-chlorohexane.

When hydrogen fluoride replaced hydrogen chloride in the reactions described above, no trace of alkyl fluoride was found.

Further studies are required before the stereochemical and mechanistic details of this reaction can be more fully understood.

Separation of the Enthalpic and Entropic Contributions to Substituent Effects for the Equilibrium Constants of Aromatic Acids

T. M. KRYGOWSKI[1] AND W. R. FAWCETT

Guelph-Waterloo Centre for Graduate Studies in Chemistry (Guelph Campus), University of Guelph, Guelph, Ontario N1G 2W1

Received February 19, 1975

T. M. KRYGOWSKI and W. R. FAWCETT. Can. J. Chem. **53**, 3622 (1975).

Separation of the substituent effect $\rho\sigma$ into entropic $\rho_S\sigma_S$ and enthalpic $\rho_H\sigma_H$ contributions is presented within the framework of the general Hammett equation. Analysis of the experimental data for aromatic acids shows that, in general, entropic effects are the major contribution to the total substituent effect, the entropic reaction constant being approximately equal to the normal Hammett ρ. A comparison of the present results with those based on a separation of inductive and resonance effects shows that the entropic and inductive effects are directly related. On the other hand, strongly resonance interacting substituents were found to be enthalpy controlled. The substituent effect on enthalpy and entropy changes is discussed from a molecular point of view and related to inductive and resonance effects. A list of 16 enthalpic (σ_H) and entropic (σ_S) substituent constants are presented.

T. M. KRYGOWSKI et W. R. FAWCETT. Can. J. Chem. **53**, 3622 (1975).

On présente une séparation des effets de substituants $\rho\sigma$ en contributions entropique $\rho_S\sigma_S$ et enthalpique $\rho_H\sigma_H$ à l'intérieur de la généralisation de l'équation de Hammett. Une analyse des données expérimentales, pour des acides aromatiques, montre qu'en général les effets entropiques contribuent d'une façon majeure à l'effet total du substituant; la constante de réaction entropique est pratiquement égale à la valeur normale de ρ. Une comparaison des résultats actuels avec ceux calculés en faisant l'hypothèse qu'il existe une séparation des effets inductif et de résonance, montre que les effets entropiques et inductifs sont reliés directement. Par ailleurs, on a trouvé que les substituants interagissant d'une façon forte par résonance sont controlés par l'enthalpie. On discute de l'effet des substituants sur les changements dans l'enthalpie et dans l'entropie à partir d'un point de vue moléculaire relié aux effets inductif et de résonance. On présente une liste de 16 constantes de substituants enthalpiques (σ_H) et entropiques (σ_S).

[Traduit par le journal]

Introduction

Structure–reactivity relationships are usually discussed in physical organic chemistry within the context of linear free energy relationships (LFER) (1–4), the most popular examples being the Brønsted (5) and Hammett (6) equations. The LFER postulate states that changes in the free energy of activation $\Delta G^{\ddagger}$ within the reaction series $\{R_s\}$ in which the compounds undergo a regular variation in structure can be linearly related to the appropriate changes in standard free energy of reaction, ΔG^0 provided these changes are produced by the same kind of variation in structure. The postulate may be expressed quantitatively as follows:

$$[1] \qquad \Delta G^{\ddagger} = \alpha(\Delta G^0) + \beta$$

where α and β are constants.

In the case of the Hammett equation, ΔG^0 is replaced by the substituent constant σ which depends only on the nature of the substituent[2] and is independent of the nature of the reaction. According to Hammett (3, 6) and others (1, 8, 9) σ is defined for the so-called Hammett reaction, [2], in water in the following way:

$$[2] \quad \text{X—Ph—COOH} + \text{Ph—COO}^- \overset{K}{\rightleftharpoons} \text{X—Ph—COO}^- + \text{Ph—COOH}$$

$$[3] \qquad \log K = \rho\sigma$$

or

$$[4] \qquad \delta(\Delta G^0) = -2.303RT\,\rho\sigma$$

where ρ is the reaction constant and $\delta(\Delta G^0)$ is the variation in ΔG^0 due to changes in structure. The reaction constant is defined to be unity for

[1]Visiting professor on leave from the Department of Chemistry, University of Warsaw, Poland.

[2]This is true according to the generalized concept of substituent (7); otherwise, substituent constants also depend on their position in relation to the reaction site.

the Hammett reaction in water at 25 °C and 1 atm.

The LFER concept was developed further by Taft (10) who postulated that the separate contributions of resonance, inductive, and steric effects to the observed substituent effect could be estimated quantitatively using a modified form of [1]. Taft's postulate can be summarized as follows (11): (*i*) the effects being separated operate in the system independently, that is, by independent mechanisms; (*ii*) the LFER postulate, [1], holds separately for each of the effects. The postulate can be expressed quantitatively as follows:

$$[5] \qquad (\Delta G^{+})_j = \alpha_j(\Delta G^0)_j + \beta_j$$

where the subscript j refers to each of the independent effects, generally considered to be inductive (i), resonance (r), and steric (s). In general, the proportionality constants α_j are not equal for the various contributions ($\alpha_i \neq \alpha_r \neq \alpha_s$) and they depend on the nature of the reaction and on experimental conditions.

Application of Taft's equation has permitted the different effects of substituents at the reaction site to be analyzed. Although several other extensions of the Hammett equation, including those by Exner (12), van Bekkum *et al.* (13), and Yukawa and Tsuno (14), have been developed, they all represent extensions of the Taft postulate in different ways and on the basis of different model reactions. It should be pointed out that Hammett in his early discussion of the relation between structure and reactivity pointed out that the free energy change with substituent can be considered as a sum of three terms: an entropy change, and the changes in kinetic and potential energies. All three terms must be considered in any attempt to correlate structure with reactivity but little is usually known about the first two (4).

A recent analysis (15) of the Taft postulates has led to the following conclusions[3]: (*i*) a Hammett $\rho\sigma$ equation with constant σ values valid over a range of temperatures for a variety of reactions in different solvents holds only when either the field or the resonance interaction is negligible compared with the other; (*ii*) a simple relationship between ΔH^0 and ΔS^0 values for a given reaction series cannot be anticipated when a substantial range of substituents are considered.

[3]For a general discussion of this problem see also refs. 1, 3, 10, and 11.

The aim of the present paper is to introduce a different extension of the LFER, namely in terms of the independent enthalpic $\delta\Delta H^0$ and entropic $\delta\Delta S^0$ contributions to the structural effect normally considered, $\delta\Delta G^0$. The results of the new analysis are compared with those from the normal Hammett equation as well as those from its extension in which substituent effects are separated into inductive and resonance contributions (16). Finally, the separation of the substituent effect into enthalpic and entropic contributions is associated with the so-called compensation effect (17) and the related concepts of isokinetic (18) and isoequilibrium relationships (19).

Independence of the Enthalpic and Entropic Contributions in the LFER

It is implicitly assumed in the general LFER as well as in its extension by Taft that the enthalpic and entropic terms in ΔG are mutually colinear and vary in the same way with changes in structure, or that one or other of these terms is constant within the reaction series. Thus, the ratio $\Delta S/\Delta H$ or ΔS or ΔH should be constant, independent of the nature of the reaction which follows a LFER. It is clear from the literature that no one of these conditions is generally fulfilled (15). Thus, on the basis of a thorough statistical analysis of enthalpy–entropy relationships, Exner (18, 20) has concluded that much of the earlier evidence for linearity between ΔH and ΔS is doubtful since these quantities were normally obtained from Arrhenius or van't Hoff plots and could not be considered as statistically independent.

It is postulated here that for a series of compounds with some regular variation in structure, the effects of structure variation can be represented by a linear variation in two independent quantities, one enthalpic and the second entropic. Thus, the linear relationships used here are

$$[6] \qquad \Delta H = \alpha_H(\Delta H^0) + \beta_H$$

and

$$[7] \qquad \Delta S = \alpha_S(\Delta S^0) + \beta_S$$

ΔH and ΔS represent either standard enthalpy and entropy changes or the enthalpy and entropy of activation depending on whether equilibrium constant or rate constant data, respectively are being considered. These may be combined to

*f_H and f_S are fractional substituent constants and are defined by [19]; when multiplied by 100 they simply express the percentage of enthalpic and entropic contribution to the total substituent effect.

obtain the following expression for the variation in free energy change:

$$[8] \quad \Delta G = \alpha_H(\Delta H^0) - \alpha_S(T\Delta S^0) + \beta_H - \beta_S T$$

When this relationship is compared with the common LFER, [1], it is apparent that the essential difference in the present approach is that the proportionality constants α_H and α_S are not assumed to be necessarily equal as they are in the usual LFER.

When the above postulate is extended to the particular case of the Hammett equation, one may rewrite [3] in the form

$$[9] \quad \log K = \rho_H\sigma_H + \rho_S\sigma_S$$

where σ_H and σ_S are independent substituent constants accounting for the enthalpic and entropic contributions, respectively and ρ_H and ρ_S, the corresponding reaction constants analogous to α_H and α_S in the general linear relations [6] and [7]. In the present paper only equilibrium constant data will be considered but, as usual, [9] may be applied to either rate or equilibrium constant data. σ_H and σ_S are defined by the relations

$$[10a] \quad \sigma_H = \frac{-\delta(\Delta H^0)}{2.303RT}$$

and

$$[10b] \quad \sigma_S = \frac{\delta(\Delta S^0)}{2.303R}$$

where $\delta(\Delta H^0)$ and $\delta(\Delta S^0)$ are the changes in the standard enthalpy and entropy of [2] with changes in substituent. These quantities may be calculated from the recently published data of Hepler and co-workers (9). In agreement with Hammett's original concept ρ_H and ρ_S are defined to be unity for [2] in water at 25 °C and 1 atm. Available values of σ_H and σ_S together with original σ values from McDaniel and Brown (8) and Hepler (9) are summarized in Table 1.

Interpretation of σ_H and σ_S

The Hammett σ constants directly reflect a shift in the position of [2] with a change in substituent. Thus, when σ is positive, [2] is shifted to the right and the substituted anion $XPhCOO^-$ acts as a weaker base than the unsubstituted anion $PhCOO^-$. Thus, substituents with positive σ's are normally classified as electron withdrawing such that they decrease the total electron charge density on the reaction site for both the acid and its anion. When σ is negative, the reverse situation holds; the sub-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

stituent is assumed to be electron repelling and to increase the electron charge density at the reaction site.

The same kind of interpretation cannot be applied to σ_H and σ_S. From [2] it is apparent that changes in ΔS^0 with substituent chiefly reflect changes in the way the components of this equilibrium interact with the medium, the more important contributions being from the anions. However, although $\delta\Delta S^0$ reflects changes in solute–solvent interactions, its magnitude is governed by changes in the electron charge density distribution in the solute molecule. According to Hepler (21) changes in ΔH^0 with the substituent can be attributed to both intramolecular (internal) and intermolecular (external) changes, that is

$$[11] \qquad \delta\Delta H^0 = \delta\Delta H^0_{int} + \delta\Delta H^0_{ext}$$

The latter contribution is often assumed to be proportional to the corresponding entropy change (21):

$$[12] \qquad \delta\Delta H^0_{ext} = \beta_e \delta\Delta S^0$$

where β_e has the significance of a temperature and should be the same for all aqueous acids of the same charge type (21). From a molecular point of view the internal contribution to the change in enthalpy is composed of inductive (field) and resonance contributions:

$$[13] \qquad \delta\Delta H^0_{int} = \delta\Delta H^0_i + \delta\Delta H^0_r$$

Thus, combining [11]–[13], one obtains the following expression for $\delta\Delta G^0$:

$$[14] \quad \delta\Delta G^0 = \delta\Delta H^0_i + \delta\Delta H^0_r + (\beta_e - T)\,\delta\Delta S^0$$

Previous extensions of the original Hammett relationship have assumed that the inductive and resonance contributions to the total substituent effect are independent (16). The relationship of $\delta\Delta S^0$ to these contributions is more subtle and will be examined in more detail below. However, it is apparent that $\delta\Delta H^0$ and $\delta\Delta S^0$, and thus σ_H and σ_S are related to one another, albeit, in a complicated fashion.

On plotting σ_S against σ_H (Fig. 1), an approximate linear correlation is apparent if three of the 16 substituents listed in Table 1 (*p*-OH, *p*-OCH_3, and *p*-CH_3) are excluded. The best straight line for the remaining 13 points is

$$[15] \qquad \sigma_S = -3.6\,\sigma_H + 0.15$$

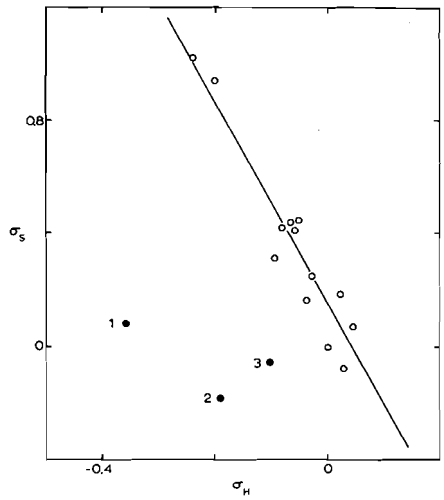

FIG. 1. Plot of the entropy substituent constant, σ_S against the enthalpy substituent constant, σ_H. The three points (●) lying outside the approximate linear relationship are (*1*) *p*-CH_3O, (*2*) *p*-OH, and (*3*) *p*-CH_3.

with a correlation coefficient $R = 0.953$. The large value of the slope is evidence for the predominant role of entropy in the substituent effect, a point which is well recognized in the literature (1).

The three substituents which deviate from the linear relationship in Fig. 1 are known to interact with the reaction site (—COOH or $—COO^-$) by resonance as electron donors. In considering the role of inductive and resonance contributions in substituent effects in more detail, two points must be emphasized: (*i*) $\delta\Delta H^0_i$ and $\delta\Delta H^0_r$ are not necessarily related to each other in any regular fashion; (*ii*) since these quantities are associated with variation in the electron charge distribution in the solute molecules, changes in ΔH^0_i and ΔH^0_r will cause changes in solvent organization around the solute and thus changes in ΔS^0. In other words, one may assume an empirical relationship between these quantities of the form

$$[16] \qquad \delta\Delta S^0 = \alpha_i \delta\Delta H^0_i + \alpha_r \delta\Delta H^0_r + \gamma$$

Inductive and resonance contributions to the substituent effect are normally estimated using the well known substituent constants σ_i and σ_r (16). If it is assumed that $\delta\Delta H^0_i$ and $\delta\Delta H^0_r$ can be related to these experimentally independent quantities by equations similar to [10], then the above relationship may be tested by planar regression. Application of standard regression

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

techniques to values of σ_S for *para*-substituents results in the equation

$$[17a] \quad \sigma_S(para) = (1.2 \pm 0.2)\sigma_i \pm (0.8 \pm 0.2)\sigma_r + (0 \pm 0.1)$$

for 8 points with $R = 0.946$. Keeping in mind the fact that there is no correlation between σ_i and σ_r ($R_{ir} = -0.081$), this result is good evidence that both inductive and resonance effects contribute to $\delta\Delta S^0$, the inductive contribution being predominant (67% of the explained variation in σ_S). When this analysis is applied to *meta*-substituent constants the resulting regression plane is

$$[17b] \quad \sigma_S(meta) = (1.2 \pm 0.1)\sigma_i + (0.4 \pm 0.1)\sigma_r + (0 \pm 0.1)$$

Thus, although ρ_i is independent of the position of the substituent, ρ_r increases significantly when *meta*-substituents are replaced by *para*-substituents. The first result agrees with the usual assumption that the inductive effect is approximately the same for *para*- and *meta*-substituents. In fact, a more rigorous treatment of this question has shown that the difference in inductive effects for these substituents should be the order of 10% (42) but this difference could not be detected within the precision of the present analysis. The increase in ρ_r when the substituent is moved from a *meta*-position to a *para*-position follows the generally accepted concept that resonance effects are considerably higher in the *para*-position.

As pointed out above, resonance interactions between the substituent and reaction site (COOH or COO^-) are only important for *para*-substituted electron-donating groups, the chief contribution to this interaction being generally inductive in character. This is probably the chief reason for the good correlation between σ and σ_S, namely

$$[18] \quad \sigma = 0.91\sigma_S - 0.07$$

with $R = 0.946$ for 16 points. Thus, the total substituent effect closely follows the entropic contribution. The enthalpic contribution, being relatively small and related through [14] and [16], is hidden in the statistical analysis because of the small non-inductive contribution of the reaction sites in the chosen reference reaction [2]. Thus, the generally observed validity of the original Hammett substituent constants breaks down when there is a significant increase or decrease in the enthalpic contribution for a process being compared with the reference reaction.

In order to assess more easily the relative contributions of enthalpy and entropy to the substituent effect of individual substituents, fractional substituent constants f_H and f_S defined by the following equations are included in Table 1:

$$[19a] \quad f_H = \frac{|\sigma_H|}{|\sigma_H| + |\sigma_S|}$$

$$[19b] \quad f_S = \frac{|\sigma_S|}{|\sigma_H| + |\sigma_S|}$$

where $|\sigma_H|$ and $|\sigma_S|$ are the absolute values of the enthalpic and entropic substituent constants for a given substituent. It is apparent that for most substituents considered the entropic contribution is more than 80% of the total substituent effect. Only in three cases (*p*-OH, *p*-CH_3, and *p*-OCH_3) is the enthalpic contribution greater than 50%. As argued above, this reflects the fact that resonance interactions are strong for these substituents. This point may be further clarified on the basis of the following analysis. In that interaction of *meta*-substituents is chiefly inductive in character, one may assume that $\Delta^{pm}(\Delta H^0)$ and $\Delta^{pm}(\Delta S^0)$ which are defined by the equations

$$[20a] \quad \Delta^{pm}(\Delta H^0) = \Delta H^0_{para} - \Delta H^0_{meta}$$

$$[20b] \quad \Delta^{pm}(\Delta S^0) = \Delta S^0_{para} - \Delta S^0_{meta}$$

chiefly reflect the excess in the given thermodynamic quantity due to resonance when a given substituent is *para*-substituted rather than *meta*-substituted. Then, following Hepler and coworkers (15, 19, 21), one may estimate the internal contribution to ΔH^0 due to resonance as

$$[21] \quad \Delta H_r = \Delta^{pm}(\Delta H^0) - \beta_e\Delta^{pm}(\Delta S^0)$$

where $\beta_e \simeq 300$ K (21, 22). When ΔH_r was plotted against the experimentally independent parameter σ_r, a good straight line was obtained. Although the analysis must be considered approximate because of the approximations made, and the small magnitude of ΔH_r with respect to experimental error, it clearly shows that the resonance contribution to the substituent effect for *p*-OH and *p*-OCH_3 is the largest for the substituents considered here.

Considerable insight into the relative importance of internal and environmental contributions to the substituent effect can be obtained

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

by examining thermodynamic data for the corresponding reaction in the gas phase. One would expect ΔH^0 for [2] in the gas phase to be negative for electron-withdrawing substituents because the energy required to break the O—H bond in the substituted acid should be less than that required for the unsubstituted acid. This trend is confirmed in experimental studies of the intrinsic acidities of organic acids in the gas phase (23). On the other hand, the environmental contribution to ΔH^0 should be positive for electron-withdrawing substituents since energy must be expended in breaking the hydrogen bonds in the structured solvent, water. If one accepts that the environmental contribution to ΔH^0 is proportional to ΔS^0, then the positive contribution should increase with increase in electron-withdrawing character. The fact that the majority of σ_H values are negative indicates that the environmental contribution to $\delta(\Delta H^0)$ is greater than the intrinsic contribution. A more extensive analysis of data for the gas phase acidities of substituted benzoic acids obtained recently by Kebarle and co-workers (41) is given in the following section.

Application to Equilibrium Data for the Ionization of Aromatic Acids

The proposal made above was tested with equilibrium constant data for reactions of substituted aromatic acids in various solvents including the ionization of anilinium cations and phenols. The latter two reaction series are known not to fit the original Hammett equation well because of resonance interaction of some substituents with the reaction site ($-NH_3^+$ or —OH). The results are compared with the parameters obtained by analyzing the same data on the basis of substituent constants for the separate inductive and resonance effects (16) and on the basis of the classical Hammett equation.

The constants ρ_H, ρ_S, ρ_i, ρ_r, and ρ in the equations

$$[22] \quad \log K_e = \log K_{eo} + \rho_H\sigma_H + \rho_S\sigma_S$$

$$[23] \quad \log K_e = \log K_{eo} + \rho_i\sigma_i + \rho_r\sigma_r$$

$$[24] \quad \log K_e = \log K_{eo} + \rho\sigma$$

were determined by standard regression techniques (24) for a plane and straight line. K_e is the equilibrium constant and K_{eo}, the value for the unsubstituted compound in the given series.[4] The results together with estimated errors and correlation coefficients are summarized in Table 2. It should be noted that the values of σ used were those obtained recently by Hepler and co-workers (9).

Since σ_H and σ_S do not vary by the same amounts for a given data set, it is not possible to determine the relative contributions of enthalpy and entropy to the explained variation in log K_e simply by examining the values of ρ_H and ρ_S obtained by the regression analysis. However, this may be achieved by calculating the partial regression coefficients (24) which are defined by the equations

$$[25a] \quad \rho_H' = |\rho_H| \left(\frac{\sum_{i=1}^{n} (\sigma_{H,i} - \bar{\sigma}_H)^2}{\sum_{i=1}^{n} (\log K_{e,i} - \overline{\log K_e})^2} \right)^{1/2}$$

and

$$[25b] \quad \rho_S' = |\rho_S| \left(\frac{\sum_{i=1}^{n} (\sigma_{S,i} - \bar{\sigma}_S)^2}{\sum_{i=1}^{n} (\log K_{e,i} - \overline{\log K_e})^2} \right)^{1/2}$$

where $\bar{\sigma}_H$, $\bar{\sigma}_S$, and $\overline{\log K_e}$ represent the average values of the quantities σ_H, σ_S, and log K_e for the given data set. For convenience ρ_H' and ρ_S' are normalized in the following way:

$$[26a] \quad \bar{\rho}_H = \frac{100\rho_H'}{\rho_H' + \rho_S'}$$

and

$$[26b] \quad \bar{\rho}_S = \frac{100\rho_S'}{\rho_H' + \rho_S'}$$

$\bar{\rho}_H$ and $\bar{\rho}_S$ may be regarded as the percentage of enthalpic and entropic contributions, respectively to the observed substituent effects. Values of $\bar{\rho}_H$ and $\bar{\rho}_S$ calculated for the data considered are also recorded in Table 2. The same kind of analysis was performed when the data for *para*-substituted compounds were analyzed on the basis of [23].

[4]Equations 3 and 9 imply that ρ, and ρ_H and ρ_S should be determined by one and two parameter fits, respectively, rather than by two and three parameter fits as indicated by [22] and [24]. Comparison of results obtained by the two methods showed no significant difference in ρ values. Thus, the results are reported for fits of [22] and [24] since [24] corresponds to the form of the Hammett equation normally used.

*$\bar{\rho}_H$ and $\bar{\rho}_S$ are normalized partial reaction constants (see [25] and [26]) which give the percent of the explained variation in log K_e which can be attributed to enthalpic and entropic effects, respectively. $\Delta\bar{\rho}_S$ is the difference between $\bar{\rho}_S$ for the given reaction and that for the reference reaction calculated on the basis of the same set of substituents. R_P and R_L are the correlation coefficients for planar and linear regressions, respectively and n, the number of data points.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

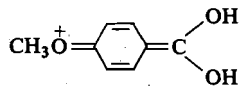
It is apparent from the data in Table 2 that ρ_S is approximately equal to the classical Hammett reaction constant ρ. This result is a direct consequence of the linear relationship between σ and σ_S pointed out above. On the other hand, ρ_H is usually less than ρ_S even though ρ_H is defined to be equal to ρ_S for the reference reaction. The data in Table 2 clearly show that the relative contributions of enthalpy and entropy to the changes in standard free energy of reaction vary with the nature of the reaction and with the medium.

Keeping in mind the analysis of the relationship between σ_H and σ_S presented above, one might expect ρ_H and ρ_S to depend somewhat on the nature of the specific substituents chosen in a given experimental study, that is, on whether enthalpy controlled substituents are included. In order to avoid misinterpretation of the data presented in Table 2, $\bar{\rho}^0{}_S$, the value of $\bar{\rho}_S$ for the reference reaction, [2], estimated for the same collection of substituents considered in a given data set was also calculated. The quantity $\Delta\bar{\rho}_S = \bar{\rho}_S - \bar{\rho}^0{}_S$ and its estimated error reported in Table 2 were used as a test of statistical reliability of $\bar{\rho}_S$. Thus, when $\Delta\bar{\rho}_S$ is non-zero and greater than its estimated error, the value of $\bar{\rho}_S$ for the given reaction was considered to be reliably different from the value obtained for the reference reaction. The same calculation was not carried out for $\bar{\rho}_H$ since this parameter is normally estimated with less precision.

From the data in Table 2, it is apparent that $\Delta\bar{\rho}_S$ is significant for 11 of the 31 cases considered; these systems will be emphasized in the following discussion. Although the entropic contribution usually accounts for approximately 80% of the explained variation in log K_e, $\bar{\rho}_S$ varies from a low of 63% for the protonation of benzoic acid in 60% sulfuric acid (29) to a high of 95% for the ionization of 5-methyl-2-hydroxyazobenzenes in dimethylsulfoxide (32).

The variation in $\bar{\rho}_S$ can be discussed both from the point of view of changes in internal interactions and changes in solute–solvent interactions, although it is clear that the two effects cannot be separated completely. Considering internal interactions first, it is useful to compare the protonation of benzoic acid, and ionization of phenol with the ionization of benzoic acid. The protonated form of benzoic acid can interact strongly by resonance with electron-donating substituents such as methoxy:



1

Since electron-donating substituents in the *para*-position are enthalpy controlled, one expects $\bar{\rho}_H$ to be significantly higher for the protonation of benzoic acid than it is for the reference reaction. In the case of ionization of phenols, the phenoxide anion can interact strongly by resonance with electron-withdrawing substituents. These substituents are entropy controlled, so that this reaction has a higher value of $\bar{\rho}_S$ than the reference reaction. Thus, in some cases, the change in $\bar{\rho}_S$ with nature of the reaction can be clearly attributed to changes in resonance interactions.

The effect of medium on reaction parameters for [2] can be seen by examining the first 13 sets of data presented in Table 2. Since internal contributions to the substituent effect will not change, the changes observed can be attributed to change in solute–solvent interactions and thus, are most conveniently discussed in terms of changes in ρ_S. Considering the fact that the charged components of [2] are anions, the most important property of the solvent is its acidity, that is its ability to solvate anions (38). If one chooses the Dimroth–Reichardt parameter E_T (39) as a measure of solvent acidity it is apparent that ρ_S decreases with an increase in solvent acidity. Thus ρ_S has its largest value in dimethylsulfoxide which in turn is the least acidic of the solvents considered (E_T = 45.0) and its lowest value in water the most acidic solvent (E_T = 63.1). This result is consistent with well known solvent effects on acid–base reactions. Thus, as solute–solvent interactions increase in strength, the differentiation in the acidity of benzoic acids due to change in substituent becomes less pronounced. The above type of analysis only considers solute–solvent interactions in terms of their acidity or basicity and ignores structure-breaking and structure-making effects which accompany solute–solvent interactions. Obviously, a complete analysis must consider all effects (38).

When the recent gas phase data for the acidity constants of benzoic acids measured by Kebarle

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

and co-workers (41) are analyzed according to [9], the following result is obtained.[5]

$$[27] \qquad \log K_a = 8.2\sigma_S + 2.8\sigma_H$$

with $R = 0.990$ for 12 points. The value of ρ_S is surprisingly high compared to ρ_H, the corresponding values of $\bar{\rho}_S$ and $\Delta\bar{\rho}_S$ being 90 and 15%, respectively. These results indicate that there is a very strong correlation between the standard enthalpy change for the gas phase reaction and σ_S, whereas that for σ_H is weak. No explanation can be offered for this result. However, the high values of ρ_S and ρ_H support the proposal made above that the reaction constants increase with a decrease in solute–solvent interactions, the highest value of ρ_S being that observed in the gas phase. Thus, when solute–solvent interactions are absent the differentiation n acidities of the benzoic acids increases significantly.

Values of ρ_i obtained by fitting [23] to data for *para*-substituted derivatives in the 32 reaction series listed in Table 2 have been compared with the corresponding values of ρ_S, a good linear relationship being obtained. This result is interpreted as evidence that the chief intramolecular interaction which controls solute–solvent interactions and which is quantitatively estimated for the substituent effect as ρ_S, is inductive in character. On the other hand, a purely electronic (intramolecular) interpretation of ρ_i must be considered naive because it does not account for changes in ρ_i with the nature of the solvent.

Discussion

In the same way that the LFER is an empirical relationship with no clear theoretical basis, there is no theoretical justification for a linear enthalpy–entropy relationship. However, the above analysis suggests that use of the method proposed here would result in a significant clarification of the relative importance of the inductive and resonance contributions to the observed changes in ΔG with substituent, and also of the relationship of internal interactions in the reactant molecule to external interactions with surrounding solvent molecules. The fact that there is a good correlation between the classical σ and σ_S means that addition of the parameter σ_H to the relationship describing substituent effects should result in an improved fit of the data; this is confirmed by the results summarized in Table 2. A comparison of the present analysis with that based on separation of inductive and resonance effects reveals the direct relationship between the inductive reaction constant ρ_i and the entropic one, ρ_S. However, the inductive–resonance analysis describes the total substituent effect much more poorly and thus, does not provide a clear indication of the relative importance of these two effects. As argued above, the relative contributions of entropy and enthalpy to the substituent effect, $\bar{\rho}_S$ and $\bar{\rho}_H$ provide a clear indication of the relative importance of resonance effects in comparison with the reference reaction.

Further support for the proposed analysis is obtained by analysis of the dependence of other substituent constants on σ_H and σ_S. As is well known (16, 40), several different series of substituent constants have been proposed for reaction types which do not follow the original Hammett equation and for *ortho*-substituents. Results of fitting the equation

$$[28] \qquad \sigma_j = \rho_H\sigma_H + \rho_S\sigma_S$$

where σ_j represents a particular series of substituent constants are summarized for five sets of constants in Table 3. It is immediately apparent that good fits are obtained in all cases so that all these analyses could be replaced by the analysis proposed here. Two results are of particular interest. The 'right' substituent constants (σ^0) are proposed for reactions with very low or negligible contribution from resonance interaction. On applying [28] one obtains $\bar{\rho}_S = 86\%$, that is, 10% higher than that for the reference reaction. Thus, a reaction with low resonance interactions may be described as entropy controlled. On the other hand, the parameter σ_p^+ is used when electron-donating substituents interact strongly with the reaction site by resonance (16). Then, $\bar{\rho}_S$ is decreased to 44% indicating that such reactions may be described as enthalpy controlled.

From the analysis of the data presented here it is evident that the theoretical background of the LFER must be more carefully investigated using advanced quantum mechanical calculations and

[5]The data of Kebarle and co-workers (41) are actually estimates of the standard enthalpy change for the gas phase ionization of benzoic acids and correspond to the difference between the bond dissociation energy for the O—H bond in the acid and the electron affinity of the corresponding radical, RCOO·. Assuming ΔS^0 for the reaction is negligible, $\log K_a$ is given by $-\Delta H^0/2.3RT$.

TABLE 3. Results of application of the enthalpy–entropy separated Hammett equation to various substituent constants*

Substituent constant σ_J	ρ_H	ρ_S	$\bar{\rho}_H$	$\bar{\rho}_S$	$\Delta\bar{\rho}_S$	R_P	n
1. σ^0 (or σ^n) (16)	0.45±0.16	0.87±0.05	14	86	10± 5	0.978	16
2. σ_p^+ (16)	2.3 ±0.3	1.4 ±0.3	56	44	−13± 8	0.982	7
3. σ_{ortho} (40)	1.25±0.08	1.08±0.03	30	70	− 3± 2	0.999	6
4. σ^0_{ortho} (40)	2.5 ±0.1	1.38±0.05	41	59	−13± 2	0.998	6
5. σ^-_{ortho} (40)	1.4 ±0.5	1.3 ±0.2	29	71	− 1±11	0.967	6

*For definitions of the various substituent constants see refs. 16 and 40. The various parameters tabulated are defined in Table 2. In the case of *ortho*-substituent constants (3–5), σ_S and σ_H for *para*-positions were chosen for the regression analysis.

gas phase measurements of the appropriate equilibrium constants. It should then be possible to separate intramolecular and intermolecular interactions which the above analysis has shown to contribute to both enthalpic and entropic changes in a complex way. The usefulness of the present analysis in elucidating these effects could be increased considerably if values of ΔH^0 and ΔS^0 were available for a larger variety of substituents, especially those which interact strongly by resonance. In this regard, it must be emphasized that these 'irregular' substituents should be included in any experimental study of substituent effects in order that statistically reliable results be obtained.

The data analyzed in this paper represent only a small fraction of those available. However, the data selected amply illustrate the usefulness of separately considering enthalpic and entropic contributions to the substituent effect. The present treatment could prove especially useful in the analysis of kinetic data obtained for a series of compounds at one temperature in that it provides a method of separating enthalpic and entropic effects. Thus, it could be used to obtain a better picture of the transition state and of its interactions with the environment.

Finally the approach presented in this paper is limited to the Hammett representation of the LFER. Undoubtedly, the same type of treatment could be extended to other equations based on LFER in the areas of both structure–property relationships and medium effects.

The authors would like to express their gratitude to M. Charton, L. G. Hepler, and J. Shorter for helpful comments and discussion of an original version of this paper.

Direct Specific Heat Measurements on Solutions of Volatile Solutes by Flow Microcalorimetry: Partial Molal Heat Capacity of Benzene in Water at 25 °C

CARMEL JOLICOEUR, PATRICK PICKER, AND GÉRALD PERRON

CACTUS (Centre d'Applications en Calorimétrie et Thermodynamique de l'Université de Sherbrooke), Université de Sherbrooke, Sherbrooke, Québec J1K 2R1

Received April 11, 1975

CARMEL JOLICOEUR, PATRICK PICKER, and GÉRALD PERRON. Can. J. Chem. **53**, 3634 (1975).

The direct specific heat measurement on aqueous benzene solutions by flow microcalorimetry have been repeated to elucidate discrepancies among earlier results. Through extensive variations of experimental conditions, the origin of difficulties encountered previously has been investigated and a simple procedure has been devised to circumvent problems inherent to this particular type of measurements.

CARMEL JOLICOEUR, PATRICK PICKER et GÉRALD PERRON. Can. J. Chem. **53**, 3634 (1975).

La chaleur spécifique des solutions aqueuses de benzène a été redéterminée par microcalorimétrie dynamique dans le but de résoudre le désaccord entre différentes valeurs publiées antérieurement. Les difficultés rencontrées dans ce type de mesures ont été étudiées par des variations systématiques des conditions expérimentales et une procédure fut mise au point pour éliminer certains effets parasites décelés récemment.

Introduction

In collaboration with other workers, we recently investigated the partial molal volumes and heat capacities of various organic solutes in water and in methanol (1). As part of the latter study, direct differential specific heat measurements had been carried out on dilute aqueous solutions of benzene, using the flow microcalorimeter described by Picker *et al.* (2). From these data, the limiting apparent molal heat capacity ϕ_c^0 of benzene in water was calculated as 552 J K^{-1} mol^{-1}, in reasonable agreement with previous results derived from solubility measurements (3). However, data reported recently by other investigators (4) indicated quite clearly that the earlier ϕ_c^0 values for benzene were erroneous. This problem, and other experimental difficulties encountered with solutions containing volatile organic solutes, has prompted us to reexamine the method of direct measurements of specific heat increments, which has been found precise and useful in a variety of other systems (5). A series of systematic tests were thus performed with aqueous solutions of benzene, to identify the potential sources of problem in specific heat measurements with such volatile solutes.

Experimental

The water used for these measurements was distilled and deionized (specific conductance: <1 μmho). Fisher Spectranalyzed benzene was used either as such, or after washing with dilute aqueous sulfuric acid and sodium hydroxide and drying over molecular sieve (Davidson Chemicals, 3 Å). Benzene solutions were prepared by weight, following vacuum degassing of the water. The solution was then separated into 25 ml aliquots which were sealed under Teflon in glass bottles, leaving minimal vapor space. The vials were kept at ~ 10 °C until and during the measurement, to minimize benzene evaporation. Under these conditions, no significant variation could be detected in three consecutive runs from the same aliquot.

The differential flow microcalorimeter used in this study (2) consists of twin capillary cells which are heated at equal and constant power ($\Delta T = 1$–2 K). When the liquid flow rates are identical, any difference in volumetric specific heat creates a temperature difference between the twin cells, which is nulled by feedback action on the Joules heating in the reference cell. The ratio of the volumetric specific heats of the flowing liquids is then equal to the ratio of heating powers under steady-state thermal equilibrium. The condition of identical flow rates is achieved by simply connecting the twin cells in series. (See Fig. 2, ref. 2). A coil of capillary tubing, inserted in series between the two cells, acts as a delay line allowing different solutions to flow in each cell, for a time determined by the length of the coil and the flow rate.

Results and Discussion

The main findings of this investigation are given in Fig. 1, which illustrates actual recorder tracings obtained while flowing alternately in the microcalorimeter a solution of benzene (0.01167 *m*) and water, under a flow rate of 1.0 cm^3/min and a heating power of 112.9 mW.

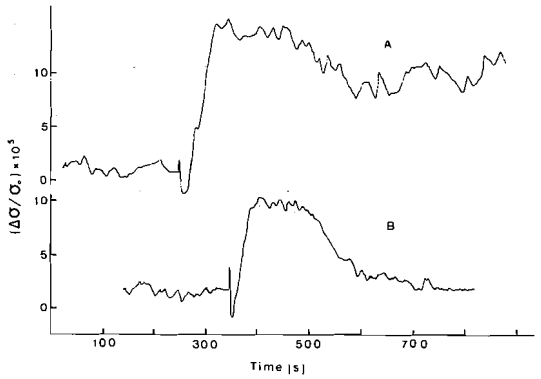

FIG. 1. Recorder tracing of differential specific heat measurement for an aqueous benzene solution (0.01167 *m*) against water; *A*: run under usual conditions; *B*: run carried out while cooling the liquids after passage in the first cell.

The initial base line corresponds to water flowing in both cells, and a steady-state increment is observed when the benzene solution flows in the working cell. As the benzene solution reaches the reference cell, symmetry is restored and the base line should again be observed, as in the case of recording B. In curve A, which was obtained under usual conditions, the last portion (benzene solution in both cells) exhibits a rather large noise, an effect previously attributed to the formation of benzene vapor bubbles as the solution flows past the heating elements. In earlier work (1), the specific heat increment was measured from the initial base line only, discarding the last part of the curve. It has been found in the present investigation that the magnitude of the base line shift (recording A) can be enhanced or reduced by respectively heating or cooling the delay coil between the two flow cells. Hence, the tracing B was recorded with the capillary tubing coil immersed in a water bath at 10 °C; under these conditions, the base line offset was suppressed, and the steady-state deviation was found significantly smaller than had been measured previously.

The above observations strongly suggest that the base line offset was related to evaporation of benzene in the flow cells, a phenomenon which could affect the measurement in two ways. The endothermic evaporation of benzene will cause a base line shift if the heat of evaporation is not symmetrically evolved in both cells. On the other hand, once benzene vapor bubbles are formed, they can remain trapped in the delay coil (this was noted to occur), thus changing the relative flow rates in the cells.

While the suggested corrective measure seems broadly valid (it has been used successfully with solutions of other volatile solutes, namely, tetrahydropyran), the explanation remains tentative. Other phenomena such as surface adsorption of benzene in the cells and delay coil, and microphase separation (demixing) in the cells could also contribute to the effects observed. We have, on the other hand, tested that the addition of ionic and non-ionic surfactants ($C < 0.01$ *M*) to both the water and the benzene solution had no significant consequence on the base line shift. Likewise, degassing of the water before preparing the solutions had no noticeable influence on the behavior of the latter. Also, changing the benzene concentration, flow rates or heating power did not affect the relative importance of the observed base line shift. We were thus left with the explanation that cooling of the solution after passage through the first cell presumably redissolves the benzene, thus restoring homogeneity and concentration symmetry.

From eight successive runs such as that shown in Fig. 1*B*, the fractional increment in volumetric specific heat (σ) of benzene solution (0.01167 *m*) relative to water was found as: $(\sigma - \sigma_0)/\sigma_0 = 0.76 \times 10^{-4}$ with a standard deviation of $\pm 0.06 \times 10^{-4}$ (σ_0 is the volumetric specific heat of water: $\sigma_0 = c_p^0 d_0$, with $d_0 = 0.997047$ g cm^{-3} (6) and $c_p^0 = 4.1793$ J K^{-1} g^{-1} (7)). The density difference between the benzene solution and water ($d - d_0$) was taken as -56 p.p.m. from measurements reported by Masterton (8) combined with our own data obtained at higher benzene concentrations. The apparent molal heat capacity of benzene was then calculated (5) as 374 ± 2 J K^{-1} mol^{-1}. Considering the difficulties involved in the measurements, this is in rather good agreement with the value of 356 ± 5 J K^{-1} mol^{-1} reported recently by Gill *et al.* (4). Though it is possible that there remains a small systematic error in our measurements, the procedure suggested here seems useful in that it enables direct measurements on volatile solutes with the same ease and precision as had been achieved with nonvolatile solutes (5).

Derivatives of 2-Pyrazolin-5-one. II. Catalyzed Sodium Borohydride Reduction of Some 4–(2-Nitrobenzylidene)-2-pyrazolin-5-ones. A Reappraisal[1]

RONALD T. COUTTS AND ABDEL-MONAEM EL-HAWARI

Faculty of Pharmacy and Pharmaceutical Sciences, University of Alberta, Edmonton, Alberta T6G 2H7

Received June 12, 1975

RONALD T. COUTTS and ABDEL-MONAEM EL-HAWARI. Can. J. Chem. **53**, 3637 (1975).

A reexamination of the sodium borohydride and palladium–charcoal reduction of 3-methyl-4-(*o*-nitrobenzylidene)-1-phenyl-2-pyrazolin-5-one (**3***a*) has revealed that the final product is 3-methyl-4-(*o*-aminobenzyl)-1-phenyl-2-pyrazolin-5-one (**5***a*), and not 9-hydroxy-3-methyl-3a,4,9,9a-tetrahydro-1*H*-pyrazolo[3,4-*b*]quinoline as claimed previously. Reduction of **3***a* to **5***a* proceeds via the 4-(*o*-nitrobenzyl) compound. Chemical and physical properties of **5***a* are described which support the assignment of this revised structure to the reduction product of **3***a*. Two analogs of **3***a* were also reduced in the same manner and yielded products analogous to **5***a* and not the previously claimed pyrazolo[3,4-*b*]quinolines.

RONALD T. COUTTS et ABDEL-MONAEM EL-HAWARI. Can. J. Chem. **53**, 3637 (1975).

Un réexamen de la réduction, par le borohydrure de sodium et le palladium sur charbon, de la méthyl-3 (*o*-nitrobenzylidène)-4 phényl-1 pyrazoline-2 one-5 (**3***a*) révèle que le produit final est la méthyl-3 (*o*-aminobenzyl)-4 phényl-1 pyrazoline-2 one-5 (**5***a*) et non pas l'hydroxy-9 méthyl-3 tétrahydro-3a,4,9,9a 1*H*-pyrazolo[3,4-*b*]quinoléine tel qu'il avait été prétendu antérieurement. La réduction de **3***a* en **5***a* se produit par l'intermédiaire du composé (*o*-nitrobenzyl)-4. Les propriétés chimiques et physiques de **5***a* sont en accord avec la structure revisée du produit de réduction de **3***a*. On a aussi réduit de la même manière deux analogues de **3***a*; ils conduisent aussi à des produits analogues à **5***a* et non pas aux pyrazolo[3,4-*b*]quinoléines proposées antérieurement.

[Traduit par le journal]

Narang *et al.* (1) first claimed that one product of the reduction of 3-methyl-4-(*o*-nitrobenzylidene)-1-phenyl-2-pyrazolin-5-one (**1***a*) by aluminum amalgam, zinc and acetic acid, or alcoholic hydrochloric acid, was a cyclic hydroxylamine, namely 9-hydroxy-3-methyl-3a,4,9,9a-tetrahydro-1*H*-pyrazolo[3,4-*b*]quinoline, **2***a*. The same product was the major one obtained by us (2) when **1***a* was reduced with sodium borohydride and palladium–charcoal or with cyclohexene and palladium–charcoal. We also concluded that other *N*-hydroxypyrazolo[3,4-*b*]quinolines (**2***b*–**2***e*), together with unidentified reduced products, were formed when the appropriate pyrazolones (**1***b*–**1***e*) were similarly reduced. We now report that some of our previous conclusions (2) were erroneous. A more detailed investigation of the reduction of three pyrazolones (**1***a*–**1***c*) is now described and the major products correctly identified. Structures of previously unidentified products have also been deduced. Chemical properties of the products of reduction of pyrazolones (**1***a*–**1***c*) are also described.

Initially the (*o*-nitrobenzylidene)pyrazolones (**1***a*–**1***c*) were reduced by the previously reported method (2) except that methanol was used as solvent instead of an ethanol–methanol mixture. The same products were isolated, *i.e.* the major amphoteric compounds which were claimed to be the 9-hydroxypyrazolo[3,4-*b*]quinolines (**2***a*–**2***c*), and the minor ones which had been left unidentified. However, due to some difficulties in obtaining pure analytical samples of some of these derivatives, a modification in the reduction procedure was sought. The *o*-nitrobenzylidene derivatives (**1***a*–**1***c*) were first reduced by means of sodium borohydride in dioxane solution in the absence of catalyst. This resulted in the reduction of only the benzylidene double bond and 4-(2-nitrobenzyl)-2-pyrazolin-5-ones, **3**, were isolated in excellent yields. These compounds were readily characterized by elemental analysis, i.r., and n.m.r. spectroscopy.

Once the benzylidene double bond is reduced, these pyrazolones (**3**) become soluble in dilute

[1]A previous study (2) is considered to be part I of the series.

e	Me	OMe	OMe

alkali due to their ability to enolize (**3** ⇋ **4**). In view of this, catalytic (10% Pd–C) sodium borohydride reductions of the pyrazolones, **3**, were carried out in dilute sodium hydroxide solution. Acidification of the filtrate from the reaction with dilute acetic acid caused precipitation of the reduced products. By using this modified procedure, only one product was isolated from each reaction. Although melting points were considerably higher than those of the amphoteric products obtained by reduction in methanol, they had the same solubility characteristics and the same i.r. spectra as those reported for the compounds prepared by Coutts and Edwards (2).

Narang *et al.* (1) concluded that the 9-hydroxypyrazolo[3,4-*b*]quinoline **2***a* was the reduction product of the pyrazolone **1***a* from a correct elemental analysis, and because the product was found to be soluble in both acids and alkalis. When Coutts and Edwards (2) reduced the same compound, **1***a*, and derivatives, **1***b*–**1***e*, they concluded that in addition to the correct elemental analyses and solubility characteristics, the i.r. spectra of the reduction products were also in agreement with structure **2**. The i.r. spectra (solid) showed broad absorption in the 2100–3500 cm^{-1} range with maxima between 2850 and 3090 cm^{-1} which was attributed to the N—OH function. Also a C=O absorption band was apparently absent from these spectra. Similar spectra were obtained when the pure samples obtained in the present investigation were examined as solids (KBr or Nujol), but two additional medium intensity absorption maxima were located at ~3200 and ~3350 cm^{-1}. This observation was considered initially to be due to the ability of such compounds as **2** to tautomerize and thus display an NH absorption band in addition to that of the N—OH function. However, the plausibility of *N*-hydroxy structures being formed at all, was seriously questioned when the p.m.r. and mass spectra of these reduction products were recorded and interpreted.

The p.m.r. spectrum of the amphoteric product obtained by reduction of the pyrazolone **3***a*, displayed two signals at δ 2.10 (CH_3) and at δ 3.43 (CH_2) and an aromatic multiplet (12 protons). When the sample was shaken with deuterium oxide, three protons within the aromatic area were found to be D-exchangeable. Three D-exchangeable protons, with almost the same chemical shifts were also found in the p.m.r.

SCHEME 1

spectrum of the reduction product of the analogs **3***b* and **3***c*. The presence of three D-exchangeable protons in each of these spectra does not agree with the proposed structure **2** or the NH tautomer, in which only one or two such protons would be expected.

The mass spectra of the reduction products of **3***a* and **3***b* were also inconsistent with structure **2**. The mode of fragmentation of these compounds under electron impact (Scheme 1) revealed that intact pyrazolone rings (ion **ii**) were present. This, together with additional evidence from the mass spectra (Scheme 1) and the p.m.r. data, indicated that the amine structure (**5** ⇋ **6** ⇋ **7**) was more acceptable for the amphoteric reduction products. This structure better explains the solubility of the reduced products in sodium hydroxide solution. It is now questioned whether cyclic hydroxylamines of structure **2** would have acidic properties; the literature describes some related cyclic hydroxylamines which are weakly acidic (3, 4), and others which have no acidic properties (3, 5).

An examination of the i.r. spectra of amines **5***a*–**5***c* as solids revealed the presence of strong absorption bands at 1628, 1625, and 1630 cm^{-1} respectively. These bands were not considered to be due to carbonyl stretching and were initially assigned to C=N absorption (2). An additional strong peak between 1600 and 1604 cm^{-1} in each of the spectra of **5***a*–**5***c* was not explained. This apparent lack of carbonyl absorption contributed to the earlier incorrect assignment of structure **2** to the amphoteric reduction products. It is now obvious that the bands at 1600–1604 cm^{-1} are due to C=N stretching. 3-Methyl-1-phenyl-2-pyrazolin-5-ones are known (6, 7) to exist only in the 'OH-forms' (*cf.* **6**) in the solid state; we have confirmed that their i.r. spectra lack C=O absorption and the C=N absorption bands are located at 1606 and 1601 cm^{-1} respectively. Accordingly, the other strong absorption band located between 1625 and 1630 cm^{-1} in the solid spectra of **5***a*–**5***c* must be due to a bonded C=O absorption and suggests that the amines exist in the 'NH-form' (7) in the solid state. Intra- and

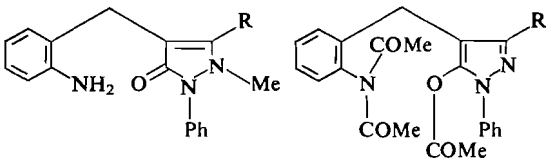
intermolecular hydrogen-bonding between the carbonyl group and the amine group would explain the carbonyl absorption frequencies, and the presence of the amine absorption maxima at relatively low wave numbers. Dilute solutions (2%) of the amines **5***a* and **5***b* in chloroform gave spectra with carbonyl absorption bands at 1712 and 1711 cm^{-1} respectively, indicative of the 'CH-form' (**5**) existing in solution.

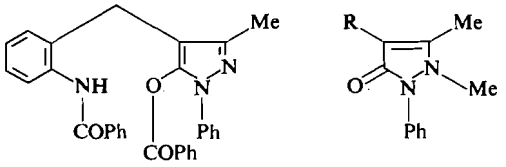
The assignment of the absorption bands near 1625 cm^{-1} in the solid spectra of **5***a*–**5***c* to a C=O absorption was substantiated by examining the spectra of some derivatives of amines **5***a* and **5***b* whose syntheses are described below. The i.r. spectra of the *N*-methyl derivatives **8***a* and **8***b*, which cannot tautomerize and therefore cannot display C=N absorption bands, show carbonyl absorption at 1624 and 1630 cm^{-1} respectively. On the other hand, the dibenzoyl compound **9** and the triacetyl derivatives **10***a* and **10***b* lack a pyrazolone C=O group but possess a ring C=N function. No absorption near 1625 cm^{-1} was observed in the i.r. spectra of these compounds; all showed strong bands in the 1595–1600 cm^{-1} region attributable to C=N.

Methyl derivatives of the amines **5***a* and **5***b* were prepared by reacting them with dimethyl sulfate. *N*-methyl derivatives, **8**, were the only products obtained although theoretically, the C_4-methyl and *O*-methyl isomers were possible products. The i.r., p.m.r., and mass spectra of the methylated products were consistent with the proposed structures. The methyl signals of **8***a* and **8***b* were located at δ 2.98 and 2.91 respectively; the *N*-methyl signals of antipyrene, **11***a*, and aminopyrene, **11***b*, were found to have similar chemical shifts (δ 2.95 and 2.90). The methyl derivative **8***a* displayed a strong fragment ion (97% relative abundance) at *m/e* 56 which was shown by accurate mass to be $C_3H_6N^+$ and corresponds to $MeC\overset{+}{\equiv}NMe \leftrightarrow MeC\overset{+}{=}NMe$. This peak is also the base peak in aminopyrene, **11***b*. Similarly, the base peak in the mass spectrum of the phenyl analog **8***b* was at *m/e* 118 ($PhC\overset{+}{\equiv}NMe \leftrightarrow PhC\overset{+}{=}NMe$). These results are in agreement with previous reports that the pyrazolone ring is preferentially methylated with dimethyl sulfate at N-2 (8, 9).

The action of benzoyl chloride on the amine **5***a* produced a dibenzoyl derivative identified as **9** from its elemental analysis ($C_{31}H_{25}N_3O_3$), i.r., p.m.r., and mass spectra. This compound was insoluble in sodium hydroxide solution which indicated that the labile proton in the pyrazolone ring was replaced during benzoylation. The i.r. spectrum (solid) displayed two C=O absorption bands at 1645 cm^{-1} (NHCOPh) and at 1760 cm^{-1} (OCOPh) and an NH absorption band at 3315 cm^{-1}. The p.m.r. spectrum showed a methyl signal, a methylene signal, an appropriate aromatic multiplet, and a D-exchangeable proton at δ 8.01 (NH). The mass spectrum of **5** displayed the molecular ion at *m/e* 487 which fragmented initially by the expulsion of benzoyl (PhCO·)



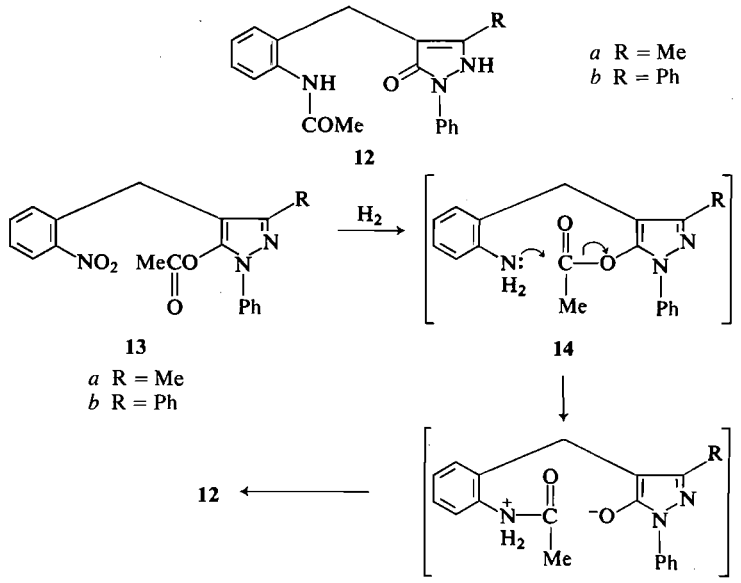
8 *a* R = Me, *b* R = Ph **10**



9 **11** *a* R = H, *b* R = NMe_2

and benzoyloxy (PhCOO·) radicals and a benzoic acid molecule. The presence of two strong metastable ions at *m/e* 275.1 and 273.6 suggested that the last two expulsions were direct fragmentations of the molecular ion.

Acetylation of the amine derivatives **5***a* and **5***b* by heating with acetic anhydride for 1 h gave monoacetyl derivatives. However, when heating was prolonged, triacetyl products were isolated. The monoacetylated derivatives were soluble in dilute alkali solutions and if these solutions were immediately acidified, the acetylated products reprecipitated. Due to this ability to enolize, the products were obviously *N*-acetates and not *O*-acetates. Elemental analysis, i.r. spectroscopy, and mass spectrometry all confirmed the structures of the monoacetates as being **12***a* and **12***b*. The mass spectrum of **12***a*, for example, showed a molecular ion at *m/e* 321 which fragmented initially by the expulsion of a water molecule, a ketene molecule, and a CH_3CONH radical. The triacetates are identified as 5-acetyloxy-4-(2-diacetylaminobenzyl)-1-phenyl-pyrazolones, **10***a*



SCHEME 2

and **10***b*. Both dissolved slowly in dilute alkalis. When the alkaline solutions were acidified, they yielded the monoacetyl derivatives **12**. The elemental analyses as well as the i.r., p.m.r., and mass spectra supported the proposed structures, **10***a* and **10***b*. Both p.m.r. spectra displayed a six-proton signal for the *N*-diacetyl function, a three-proton signal for the *O*-acetyl group, a methylene signal, and an aromatic multiplet. The i.r. spectra were devoid of any NH or OH absorption bands. The methyl derivative **10***a* displayed three strong C=O bands at 1790 cm^{-1} ($OCOCH_3$), and at 1685 and 1730 cm^{-1} due to the *N*,*N*-diacetyl doublet (10). In the i.r. spectrum of the phenyl analog **10***b*, the corresponding bands appeared at 1793, 1705, and 1718 cm^{-1}. The presence of the carbonyl absorptions of an *N*,*N*-diacetyl function at a higher frequency than the carbonyl absorption bands of monoacetyl compounds has already been commented upon (11).

Attempts were made to prepare the *O*-acetyl derivatives **14**, for comparison purposes, through the reduction of the 5-acetyloxy-4-(2-nitrobenzyl)-1-phenylpyrazoles, **13**. The latter compounds were prepared by treating the appropriate nitropyrazolone, **3**, with acetic anhydride. The presence of *O*-acetyl functions in the products was confirmed by i.r. spectroscopy (ν_{max} 1781 cm^{-1} in **13***a* and 1790 cm^{-1} in **13***b*), by p.m.r. ($OCOCH_3$ protons came to resonance at δ 2.03 in **13***a* and δ 2.02 in **13***b*) and by mass spectral fragmentation (direct loss of $CH_3COO^{\bullet}$ radical from the molecular ion). When the *O*-acetyl compounds were reduced either by catalytic hydrogenation over platinum or by sodium borohydride – palladium–charcoal in dioxane, oily products were obtained. The only crystallizable compounds isolated were the *N*-acetyl derivatives, **12**, rather than the desired *O*-acetates, **14**. The isolation of such products indicated that the acetyl group, originally attached to the oxygen atom of the pyrazole ring, migrated to the amine function once the latter was formed. Migration of acyl residues from one heteroatom to another in the same molecule is well documented (12–16) but no examples comparable to the one shown in this present study between the *O*-acetyl lactam and the amine function appear to have been reported. In this instance, the amine and acetyl group seem suitably orientated to allow this migration to occur intramolecularly (Scheme 2).

Experimental

Melting points (capillary tube) are uncorrected. Infrared spectra were recorded as Nujol mulls, unless stated otherwise, on a Beckman IR-10 spectrophotometer; p.m.r. spectra were taken on a Varian A-60D spectrometer with tetramethylsilane as internal standard. Mass spectra were determined by Dr. A. M. Hogg and his associates, Department of Chemistry, University of Alberta, on an AEI MS-9 or MS-12 mass spectrometer at an ionizing potential of 70 eV using the direct probe technique. Elemental

analyses were determined in the microanalytical laboratories of the Faculty of Pharmacy and Pharmaceutical Sciences and the Department of Chemistry, University of Alberta.

3-Methyl-4-(2-nitrobenzyl)-1-phenyl-2-pyrazolin-5-one, 3a

A solution of 3-methyl-4-(2-nitrobenzylidene)-1-phenyl-2-pyrazolin-5-one (2) (**1***a*, 4.0 g) in dioxane (80 ml) was added dropwise to a stirred solution of sodium borohydride (2.0 g) in 50% aqueous dioxane (20.0 ml). After addition was completed, stirring was continued for 1 h. The reaction mixture was cooled and acidified with dilute hydrochloric acid then diluted with water. The precipitate was collected and crystallized from ethanol to give the title compound as yellow crystals (3.4 g); m.p. 168–169 °C; i.r. ν_{max} 2300–3200 (OH), 1605 (C=N), and 1530 and 1335 (NO_2) cm^{-1}; p.m.r. (DMSO-d_6) δ 2.05 (3H, s, CH_3), 3.95 (2H, s, CH_2), 7.41 (1H, br, exchanged with D_2O, OH), and 7.10–8.10 (9H, m, aromatic protons).

Anal. Calcd. for $C_{17}H_{15}N_3O_3$: C, 66.01; H, 4.88; N, 13.58. Found: C, 65.91; H, 5.00; N, 13.39.

1,3-Diphenyl-4-(2-nitrobenzyl)-2-pyrazolin-5-one, 3b

This compound (2.7 g, m.p. 185–186 °C) was obtained as yellow crystals when 1,3-diphenyl-4-(2-nitrobenzylidene)-2-pyrazolin-5-one (2) (**1***b*, 3.0 g) was reduced as described in the preparation of **3***a*; i.r. ν_{max} 2400–3200 (OH), 1604 (C=N), and 1527 and 1340 (NO_2) cm^{-1}; p.m.r. (DMSO-d_6) δ 4.20 (2H, br s, CH_2), 7.81 (1H, br s, exchanged with D_2O, OH), and 7.10–8.10 (14H, m, aromatic protons).

Anal. Calcd. for $C_{22}H_{17}N_3O_3$: C, 71.15; H, 4.61; N, 11.31. Found: C, 17.30; H, 4.41; N, 11.24.

4-(5-Chloro-2-nitrobenzyl)-3-methyl-1-phenyl-2-pyrazolin-5-one, 3c

This pale yellow solid (2.65 g, m.p. 145–146 °C) was obtained when 4-(5-chloro-2-nitrobenzylidene)-3-methyl-1-phenyl-2-pyrazolin-5-one (2) (**1***c*, 3.0 g) was reduced as described in the preparation of **3***a*; i.r. ν_{max} 2100–3300 (OH), 1606 (C=N), and 1526 and 1342 (NO_2) cm^{-1}; p.m.r. (DMSO-d_6) δ 2.12 (3H, s, CH_3), 4.03 (2H, s, CH_2), 7.10–8.31 (8H, m, aromatic protons), and 11.00–12.70 (1H, br s, exchanged with D_2O, OH).

Anal. Calcd. for $C_{17}H_{14}ClN_3O_3$: C, 59.39; H, 4.10; N, 12.22. Found: C, 59.53; H, 4.21; N, 12.47.

General Procedure for Sodium Borohydride and Palladium–Charcoal Reductions

A solution of sodium borohydride (1.0 g) in water (20 ml) was carefully added to a suspension of palladium–charcoal (0.10 g) in water (10 ml). To the resulting suspension, a solution of the nitro compound (2.0 g), dissolved in 10% aqueous sodium hydroxide (40 ml) was added dropwise over a period of 30 min. Nitrogen was bubbled through the reaction mixture during the addition of the nitro compound and for a further 15 min. The mixture was then filtered and the filtrate acidified with dilute acetic acid and diluted with ice-cold water. The precipitated product was crystallized from methanol or ethanol.

4-(2-Aminobenzyl)-3-methyl-1-phenyl-2-pyrazolin-5-one, 5a

This colorless compound (1.70 g), m.p. 153–154 °C (from ethanol) was obtained when the pyrazolone **3***a* was reduced according to the *general procedure* outlined above (lit. (1, 2) m.p. 142 °C). Infrared (Nujol) ν_{max} 1628 (bonded C=O), 1604 (C=N), and broad absorption between 2100 and 3500 with maxima at 3200 and 3345 (OH and NH_2) cm^{-1}; (chloroform, 2% solution) ν_{max} 1712 (C=O) cm^{-1}; (DMSO-d_6, 2% solution) ν_{max} 1660 (C=O) and 1603 (C=N) cm^{-1}; p.m.r. (DMSO-d_6) δ 2.10 (3H, s, CH_3), 3.43 (2H, s, CH_2), and 6.30–7.90 (12H, m, aromatic protons and 3 additional protons which exchanged with D_2O, *i.e.* NH_2 and pyrazolone proton); ($CDCl_3$) δ 6.50–8.20 (9H, m, aromatic protons) and 6.00–6.50 (3H, br, exchanged with D_2O, NH_2 and pyrazolone proton); mass spectrum (see Scheme 1) ion **ii** measured 186.0790, $C_{11}H_{10}N_2O$ requires 186.0793; ion **i** measured 106.0655, C_7H_8N requires 106.0657.

Anal. Calcd. for $C_{17}H_{17}N_3O$: C, 73.09; H, 6.13; N, 15.04. Found: C, 73.08; H, 6.08; N, 14.91.

The hydrochloride of **5***a* was obtained by bubbling dry hydrogen chloride through a solution of the title compound in tetrahydrofuran. Compound **5***a*·HCl was colorless with m.p. 254–256 °C (lit. (2) m.p. 252–254 °C).

Anal. Calcd. for $C_{17}H_{18}ClN_3O$: C, 64.65; H, 5.74; N, 13.31. Found: C, 64.71; H, 5.72; N, 13.19.

4-(2-Aminobenzyl)-1,3-diphenyl-2-pyrazolin-5-one, 5b

When pyrazolone **3***b* was reduced using the *general procedure*, the title compound (1.79 g), m.p. 151–153 °C (from ethanol) was obtained as colorless needles. Infrared (Nujol) ν_{max} 1625 (bonded C=O), 1600 (C=N), and 2200–3400 with maxima at 3170 and 3350 (OH and NH_2) cm^{-1}; (chloroform, 2% solution) ν_{max} 1711 (C=O) cm^{-1}; (DMSO-d_6, 2% solution) ν_{max} 1654 (C=O) cm^{-1}; p.m.r. (DMSO-d_6) δ 3.68 (2H, s, CH_2) and 6.30–8.00 (17H, m, aromatic protons and 3 additional protons which exchanged with D_2O, *i.e.* NH_2 and pyrazolone proton); ($CDCl_3$) δ 3.63 (2H, s, CH_2), 6.40–8.20 (14H, m, aromatic protons), and 5.00–5.60 (3H, br, exchanged with D_2O, NH_2 and pyrazolone proton). Mass spectrum (see Scheme 1) ion **i** measured 106.0661, C_7H_8N requires 106.0657; ion **ii** measured 248.0945, $C_{16}H_{12}N_2O$ requires 248.0950; ion **iii** measured 93.0584, C_6H_7N requires 93.0579.

The hydrochloride of **5***b* was a colorless solid, m.p. 211–213 °C (from methanol) (lit. (2) m.p. 182–183 °C).

Anal. Calcd. for $C_{22}H_{20}ClN_3O$: C, 69.93; H, 5.34; N, 11.12. Found: C, 69.99; H, 5.20; N, 11.08.

4-(2-Amino-5-chlorobenzyl)-3-methyl-1-phenyl-2-pyrazolin-5-one, 5c

When pyrazolone **3***c* was reduced by the *general procedure*, the title compound was obtained as a colorless solid (1.22 g), m.p. 119–121 °C (from ethanol). Infrared ν_{max} 1630 (bonded C=O), 1602 (C=N), and 2100–3420 with maxima at 3230 and 3390 (OH and NH_2) cm^{-1}; p.m.r. (DMSO-d_6) δ 2.08 (3H, s, CH_3), 3.48 (2H, s, CH_2), and 6.40–8.00 (11H, m, aromatic protons and 3 D_2O-exchangeable protons, *i.e.* NH_2 and pyrazolone proton).

Anal Calcd. for $C_{17}H_{16}ClN_3O$: C, 65.06; H, 5.14; N, 13.39. Found: C, 65.12; H, 5.21; N, 13.45.

When this compound was dissolved in aqueous sodium hydroxide, and the alkaline solution acidified with dilute hydrochloric acid, the hydrochloride of **5***c* precipitated as a pale yellow solid, m.p. 229–230 °C (from methanol) (lit. (2) m.p. 224–225 °C).

Anal. Calcd. for $C_{17}H_{17}Cl_2N_3O$: C, 58.29; H, 4.89; N, 11.99. Found: C, 58.53; H, 5.03; N, 12.21.

4-(2-Aminobenzyl)-2,3-dimethyl-1-phenyl-3-pyrazolin-5-one, 8a

To an ice-cold solution of 4-(2-aminobenzyl)-3-methyl-1-phenyl-2-pyrazolin-5-one (0.5 g) in 10% sodium hydroxide (15 ml), dimethyl sulfate (0.25 g) was added dropwise with stirring. The mixture was heated under reflux for 1 h. After cooling, the gummy precipitate formed was collected and washed with 10% sodium hydroxide, then with water. Crystallization from methanol gave the title compound as colorless needles (0.18 g); m.p. 191–192 °C. Infrared ν_{max} 1624 (bonded C=O) and 3230 and 3375 (NH_2) cm^{-1}; p.m.r. (DMSO-d_6) δ 2.20 (3H, s, C—CH_3), 2.98 (3H, s, N—CH_3), 3.35 (2H, s, CH_2), 5.16 (2H, br s, exchanged with D_2O, NH_2), and 6.30–7.60 (9H, m, aromatic protons); mass spectrum *m/e* (% relative abundance) 293 (M^+, 100), 263 (61), 56 (97).

Anal. Calcd. for $C_{18}H_{19}N_3O$: C, 73.69; H, 6.53; N, 14.32. Found: C, 73.78; H, 6.43; N, 14.12.

4-(2-Aminobenzyl)-1,3-diphenyl-3-methyl-3-pyrazolin-5-one, 8b

This compound (0.26 g) ,m.p. 195–196 °C was obtained as colorless needles when 4-(2-aminobenzyl)-1,3-diphenyl-2-pyrazolin-5-one (**5b**, 0.5 g) was treated with dimethyl sulfate in the manner described immediately above. Infrared ν_{max} 1630 (C=O) and 3235 and 3405 (NH_2) cm^{-1}; p.m.r. (DMSO-d_6) δ 2.91 (3H, s, N—CH_3), 3.44 (2H, s, CH_2), 5.17 (2H, br s, exchanged with D_2O, NH_2), and 6.30–7.90 (14H, m, aromatic protons); mass spectrum *m/e* (% relative abundance) 355 (M^+, 72), 325 (40), 118 (100); accurate mass measurements 325.1337 ($C_{22}H_{17}N_2O$ requires 325.1341), 118.0658 (C_8H_8N requires 118.0657).

Anal. Calcd. for $C_{23}H_{21}N_3O$: C, 77.72; H, 5.96; N, 11.82. Found: C, 77.40; H, 5.97; N, 12.11.

4-(2-Benzoylamino)benzyl-5-benzoyloxy-3-methyl-1-phenylpyrazole, 9

To an ice-cold solution of 4-(2-aminobenzyl)-3-methyl-1-phenyl-2-pyrazolin-5-one (0.5 g) in dilute sodium hydroxide (10 ml) was added benzoyl chloride (0.75 ml) with vigorous stirring. After 1 h, more benzoyl chloride (0.5 ml) was added and stirring continued at room temperature for a further 30 min. The reaction mixture was extracted with ether then the ethereal extract was washed successively with 10% hydrochloric acid, 10% sodium carbonate, and water. Concentration of the dried ethereal solution gave the colorless title compound (0.51 g), m.p. 137–138 °C (from chloroform); i.r. ν_{max} 1760 (OCOPh), 1645 (NHCOPh), 1600 (C=N), and 3315 (NH) cm^{-1}; p.m.r. ($CDCl_3$) δ 2.12 (3H, s, CH_3), 3.80 (2H, s, CH_2), 8.02 (1H, br s, exchanges with D_2O, NH), and 6.80–7.90 (19H, m, aromatic protons); mass spectrum *m/e* (% relative abundance) 487 (M^+, 4), 382 (3), 366 (9), 365 (30), 105 (100).

Anal. Calcd. for $C_{31}H_{25}N_3O_3$: C, 76.37; H, 5.17; N, 8.61. Found: C, 76.43; H, 5.33; N, 8.60.

Acetylation of 4-(2-Aminobenzyl)-3-methyl-1-phenyl-2-pyrazolin-5-one, 5a, and the Phenyl Analog, 5b

(*a*) A solution of the title compound (**5a**, 0.5 g) in acetic anhydride (5.0 ml) was heated under reflux for 1 h. The cooled solution was poured into 5% aqueous sodium hydroxide and stirred until homogeneous; the alkaline solution was then extracted with ether. This was dried (Na_2SO_4) and evaporated to give a yellow solid residue which crystallized from ethanol into white crystals (0.4 g), m.p. 208–209 °C, identified as *4-(2-acetylaminobenzyl)-3-methyl-1-phenyl-2-pyrazolin-5-one* (**12a**). Infrared ν_{max} 1660 (C=O) and 2500–3300 with maximum at 3180 (OH and NH) cm^{-1}; p.m.r. (DMSO-d_6) δ 2.14 (3H, s, CH_3), 2.20 (3H, s, CH_3), 3.57 (2H, s, CH_2), 7.00–7.90 (9H, m, aromatic protons), and 9.21 (1H, br s, exchanged with D_2O, NH); mass spectrum *m/e* (% relative abundance) 321 (M^+, 62), 303 (23), 278 (14), 263 (22), 186 (29).

Anal. Calcd. for $C_{19}H_{19}N_3O_2$: C, 71.01; H, 5.96; N, 13.08. Found: C, 70.87; H, 5.81; N, 13.12.

(*b*) When the above reaction was repeated and the mixture heated under reflux for 3 h, a colorless crystalline product (0.43 g), m.p. 113–114 °C, was obtained after crystallization from ethanol. This was *5-acetyloxy-4-(2-diacetylaminobenzyl)-3-methyl-1-phenylpyrazole* (**10a**). Infrared ν_{max} 1790 (ester C=O), 1730 and 1685 (diacetyl C=O), and 1600 (C=N) cm^{-1}; p.m.r. (DMSO-d_6) δ 2.02 (3H, s, CH_3,) 2.18 (3H, s, CH_3), 2.11 (6H, s, diacetyl protons), 3.48 (2H, s, CH_2), and 7.20–7.50 (9H, m, aromatic protons); mass spectrum *m/e* (% relative abundance) 405 (M^+, 2), 363 (85), 345 (6), 321 (100), 303 (41).

Anal. Calcd. for $C_{23}H_{23}N_3O_4$: C, 68.15; H, 5.68; N, 10.37. Found: C, 68.03; H, 5.71; N, 10.51.

This compound was insoluble in aqueous sodium hydroxide, but on stirring for several hours in 5% sodium hydroxide solution it dissolved. The solution was filtered and acidified with acetic acid to give a white precipitate which crystallized from ethanol, m.p. 208–210 °C. The i.r. spectrum of this product was identical with that of the monoacetyl derivative **12a**.

(*c*) Similarly, heating 4-(2-aminobenzyl)-1,3-diphenyl-2-pyrazolin-5-one (**5b**, 0.5 g) in acetic anhydride (5.0 ml) for 1 h yielded *4-(2-acetylaminobenzyl)-1,3-diphenyl-2-pyrazolin-5-one* (**12b**) as colorless crystals (0.41 g) m.p. 219–221 °C (from ethanol); i.r. ν_{max} 1662 (C=O) and 2100–3260 (NH and OH) cm^{-1}; p.m.r. (DMSO-d_6) δ 2.10 (3H, s, CH_3), 3.84 (2H, s, CH_2), 6.80–8.00 (15H, m, aromatic protons), and 9.33 (1H, br s, exchanged with D_2O, NH).

Anal. Calcd. for $C_{24}H_{21}N_3O_2$: C, 75.21; H, 5.52; N, 10.96. Found: C, 75.22; H, 5.53; N, 10.75.

(*d*) A triacetyl derivative, *5-acetyloxy-4-(2-diacetylaminobenzyl)-1,3-diphenylpyrazole* (**10b**) was isolated as colorless crystals (0.42 g), m.p. 110–111 °C (from ethanol) when the above reaction, *c*, was repeated and heating with acetic anhydride was prolonged for 4 h. Infrared ν_{max} 1793 (ester C=O), 1718 and 1705 (diacetyl C=O), and 1595 (C=N) cm^{-1}; p.m.r. (DMSO-d_6) δ 2.02 (6H, s, diacetyl protons), 2.20 (3H, s, $OCOCH_3$), 3.75 (2H, s, CH_2), and 7.05–7.70 (14H, m, aromatic protons).

Anal. Calcd. for $C_{28}H_{25}N_3O_4$: C, 71.93; H, 5.39; N, 8.98. Found: C, 72.13; H, 5.18; N, 8.85.

Hydrolysis of this compound with 5% aqueous sodium hydroxide readily gave the monoacetyl derivative **12b**.

5-Acetyloxy-3-methyl-4-(2-nitrobenzyl)-1-phenylpyrazole, 13a, and the 3-Phenyl Analog, 13b; Preparation and Reduction

(*a*) A solution of 3-methyl-4-(2-nitrobenzyl)-1-phenyl-2-pyrazolin-5-one (1.0 g) in acetic anhydride (10 ml) was heated under reflux for 1 h. After cooling, the reaction mixture was poured into ice-cold 5% sodium hydroxide solution (100 ml). Stirring precipitated a pale yellow solid (1.05 g) which crystallized from ethanol as colorless

crystals, m.p. 85–86 °C. This was the title compound, **13***a*; i.r. ν_{max} 1781 (C=O) and 1600 (C=N) cm^{-1}; p.m.r. ($CDCl_3$) δ 2.17 (3H, s, C—CH_3), 2.03 (3H, s, CO—CH_3), 4.05 (2H, s, CH_2), and 7.20–8.10 (9H, m, aromatic protons).

Anal. Calcd. for $C_{19}H_{17}N_3O_4$: C, 64.94; H, 4.88; N, 11.95. Found: C, 64.77; H, 5.15; N, 11.79.

(*b*) Acetylation of 1,3-diphenyl-4-(2-nitrobenzyl)-2-pyrazolin-5-one (1.0 g) using the above method yielded *5-acetyloxy-1,3-diphenyl-4-(2-nitrobenzyl)pyrazole* (**13***b*) (1.01 g) as a pale yellow crystalline powder, m.p. 118–119 °C (from ethanol); i.r. ν_{max} 1790 (C=O) and 1597 (C=N) cm^{-1}; p.m.r. ($CDCl_3$) δ 2.02 (3H, s, $COCH_3$), 4.28 (2H, s, CH_2), and 7.20–8.10 (14H, m, aromatic protons); mass spectrum *m/e* (% relative abundance) 413 (M^+, 12) 371 (51), 354 (14), 353 (18).

Anal. Calcd. for $C_{24}H_{19}N_3O_4$: C, 69.70; H, 4.64; N, 10.16. Found: C, 69.90; H, 5.06; N, 10.41.

(*c*) A solution of 5-acetyloxy-2-methyl-4-(2-nitrobenzyl)-1-phenylpyrazole (0.5 g) in ethanol (20 ml) was hydrogenated over platinum oxide at room temperature and atmospheric pressure. When the calculated amount of hydrogen was taken up, the solution was filtered and the filtrate evaporated to yield a yellow oil. Trituration of this oil with methanol gave a pale yellow solid (0.15 g). This was crystallized as pale yellow crystals, m.p. 205–207 °C, from the same solvent and was found (i.r. mixture m.p.) to be identical to the previously identified 4-(2-acetylaminobenzyl)-3-methyl-1-phenyl-2-pyrazolin-5-one, **12***a*.

(*d*) A solution of 5-acetyloxy-2-methyl-4-(2-nitrobenzyl)-1-phenylpyrazole (0.5 g) in dioxane (20 ml) was reduced with sodium borohydride and palladium–charcoal using the general procedure outlined earlier, except for the solvent change. After acidification of the filtered reaction mixture with acetic acid, it was extracted with ether. The ethereal extract was washed with 10% sodium carbonate, dried (Na_2SO_4), and then evaporated. Crystallization of the resulting semisolid from ethanol yielded a pale yellow solid (0.12 g), m.p. 206–207 °C identified (i.r., mixture m.p.) as 4-(2-acetylaminobenzyl)-3-methyl-1-phenyl-2-pyrazolin-5-one, **12***a*.

(*e*) Hydrogenation of 5-acetyloxy-1,3-diphenyl-4-(2-nitrobenzyl)pyrazole (0.5 g) over platinum oxide as described in *c* above gave a white crystalline compound (0.21 g), m.p. 218–219 °C (from ethanol). Comparison of its i.r. and p.m.r. spectra with those of an authentic sample indicated that it was 4-(2-acetylaminobenzyl)-1,3-diphenyl-2-pyrazolin-5-one, **12***b*.

The authors wish to thank the Medical Research Council of Canada for operating grant MA-2993 which financed this project and Mr. W. Dylke for technical assistance.

Derivatives of 2-Pyrazolin-5-one. III. The Preparation and Properties of Some 1′-Phenylspiro[indoline-2,4′-[2]pyrazoline]-5′-ones[1]

RONALD T. COUTTS, ABDEL-MONAEM EL-HAWARI, AND DAVID F. BIGGS

Faculty of Pharmacy and Pharmaceutical Sciences, University of Alberta, Edmonton, Alberta T6G 2H7

Received June 12, 1975

RONALD T. COUTTS, ABDEL-MONAEM EL-HAWARI, and DAVID F. BIGGS. Can. J. Chem. **53**, 3645 (1975).

The choice of solvent has a great influence on the nature of the products obtained when suitably substituted aromatic nitro-compounds are reduced by means of sodium borohydride in the presence of palladium–charcoal. When derivatives of 4-(2-nitrobenzylidene)-1-phenyl-2-pyrazolin-5-one are reduced by this reagent in dioxane, three products are obtained. They are identified as derivatives of 1′-phenylspiro[indoline-2,4′-[2]pyrazoline]-5′-one, of 1-hydroxy-1′-phenylspiro[indoline-2,4′-[2]pyrazoline]-5′-one, and of 4-(2-aminobenzyl)-1-phenyl-2-pyrazolin-5-one. The 1-hydroxyspiro[indolinepyrazolones] are very reactive compounds. The products of their oxidation, reductions with various reagents, and reactions with chemical nucleophiles have been isolated and identified. Some preliminary pharmacological properties of four of the synthesized compounds are reported.

RONALD T. COUTTS, ABDEL-MONAEM EL-HAWARI et DAVID F. BIGGS. Can. J. Chem. **53**, 3645 (1975).

Le choix du solvant a une grande influence sur la nature des produits obtenus lors de la réduction, par $NaBH_4$ en présence de Pd–C, de composés nitro-aromatiques substitués de façon appropriée. Quand on réduit la (nitro-2 benzylidène)-4 phényl-1 pyrazoline-2 one-5 par ce réactif dans le dioxanne, on obtient trois produits: la phényl-1′ spiro[indoline-2,4′-[2]-pyrazoline]-one-5′, l'hydroxy-1 phényl-1′ spiro[indoline-2,4′-[2]-pyrazoline]-one-5′ et la (amino-2 benzyl)-4 phényl-1 pyrazoline-2 one-5. Les hydroxy-1 spiro[indolinepyrazolones] sont des composés très réactifs. On a isolé et identifié les produits de leur oxydation, de leur réduction avec divers réactifs et de leurs réactions avec des nucléophiles chimiques. On rapporte quelques propriétés pharmacologiques préliminaires pour quatre des composés synthétisés.

[Traduit par le journal]

When 3-methyl-4-(2-nitrobenzylidene)-1-phenyl-2-pyrazolin-5-one, **1***a*, and the 3-phenyl analog **1***b* were reduced by sodium borohydride in the presence of 10% palladium–charcoal and using an ethanol–methanol mixture as solvent, two products were obtained in each instance (1). The major products were concluded initially to be cyclic hydroxylamines, **2**, but are now known (2) to be the aminobenzyl compounds, **3**; the minor products were left unidentified because of difficulties in purification.

It is well known that metal hydride reductions are often influenced by the nature of the solvent used (3, 4). This fact led to a repeat of the sodium borohydride – palladium–charcoal reductions just described, in another solvent, to determine whether this might facilitate cyclization to the desired *N*-hydroxy compounds, **2**, and whether previously unidentified products could be obtained in pure form. We have found dioxane to be a suitable solvent for catalytic sodium borohydride reductions (1, 5, 6) so this solvent was selected for the present investigation.

3-Methyl-4-(2-nitrobenzylidene)-1-phenyl-2-pyrazolin-5-one, **1***a*, therefore, was reduced with sodium borohydride and palladium–charcoal in dioxane. When hydrochloric acid was used to decompose the surplus hydride and precipitate the acidic products, a yellow impure

For personal use only.

solid was obtained. Replacing hydrochloric acid with acetic acid produced a white solid which was easily separated by fractional crystallization into three compounds. The major product is identified as the cyclic *N*-hydroxy compound, 1-hydroxy-3′-methyl-1′-phenylspiro[indoline-2,4′-[2]pyrazoline]-5′-one, **4***a*. The other two products are shown to be 3′-methyl-1′-phenylspiro[indoline-2,4′-[2]pyrazoline]-5′-one, **4***b*, and the previously described amphoteric amine **3***a*.

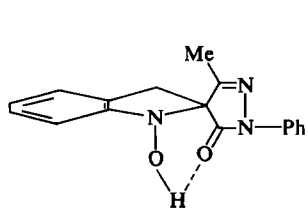
e	OH	Me	Cl
f	H	Me	Cl
g	H	Me	OMe
h	H	Me	OH
i	H	Me	OAc

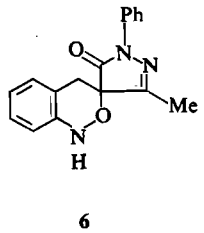
The identity of the *N*-hydroxy compound **4***a* was first suspected from its analysis ($C_{17}H_{15}N_3O_2$; M^+ *m/e* 293) and from the observations that it reduced Tollen's reagent, and gave a purple-red color with triphenyltetrazolium chloride, a reaction which is claimed to be specific for hydroxylamine derivatives (7, 8). That the pyrazolone ring still remained intact was suspected from the i.r. spectrum which showed a C=O absorption band at 1690 cm^{-1}. This C=O is present at a lower frequency than that usually demonstrated in 5,5-disubstituted pyrazolone derivatives. However, an intramolecular hydrogen bonding with the N—OH group is possible in such a structure **5** in which the donor and the acceptor groups are in *peri* positions. Katritzky and Lagowski (9) described a similar effect in 8-hydroxyquinoline 1-oxide and its azo derivative. Support for hydrogen bonding in **4***a* is the position of the i.r. O—H stretching band which was broad and centered at 3275 cm^{-1}.

All pyrazolones which have a hydrogen atom at C-4 are soluble in dilute sodium hydroxide solution. The product, $C_{17}H_{15}N_3O_2$, obtained by reduction of **1***a*, was not soluble in aqueous alkali, which was indicative of the absence of a hydrogen atom at C-4, and consistent with the cyclic hydroxylamine structure **4***a*.

The p.m.r. spectrum of the compound suspected to be **4***a* was consistent with that structure. When recorded in DMSO-d_6, the spectrum displayed, in addition to the aromatic and methyl



5



6

signals, a broad methylene signal at δ 3.28, and a one-proton signal at δ 9.67 which exchanged with deuterium. Assignment of this D-exchangeable signal to the N—OH function is consistent with the conclusions reached by other investigators of hydroxylamines (10–12). The appearance of the two methylene protons as a broad singlet was not expected since these two protons are non-equivalent. However, this appears to be only a solvent effect since the p.m.r. spectrum repeated in pyridine displayed, for these methylene protons, a doublet of doublets with a geminal coupling constant of 16 Hz. Also, in pyridine, the N—OH signal appeared further downfield as a broad peak centered at δ 12.1. Most of the data so far presented are also compatible with the reduction product, $C_{17}H_{15}N_3O_2$, being the isomeric structure **6**. This was considered, but the fact that the product isolated was neutral suggested that such a structure was not appropriate. Compound **6** would be expected to be basic since it is known that the related isoxazolidines (cyclic 5-membered-NH—O-compounds) are strong bases (13). Interpretation of the mass spectrum of the reduced product and its chemical reactivity confirmed that structure **6** was not tenable and that structure **4***a* was indeed the appropriate one. The mass spectrum contained an abundant molecular ion and diagnostic $(M-1)^+$, $(M-16)^+$ and $(M-17)^+$ ions. The last two fragments correspond to the loss of an oxygen atom and a hydroxyl radical from the molecular ion. A strong metastable ion of appropriate *m/e* value in the spectrum indicated that the transition $M^+ \rightarrow (M-17)^+$ was direct. No literature studies have been reported on the mass spectra of cyclic hydroxylamines, but these findings are consistent with our previous study (14) on aromatic hydroxylamines which were found to fragment by expelling an oxygen atom and a hydroxyl radical.

Some speculation on a possible mechanism to explain this unexpected formation of spiro-compound **4***a* by reduction of **1***a*, is warranted.

If the initial stage in the reduction of **1***a* is the hydrogenation of the benzylidene double bond to produce 3-methyl-4-(2-nitrobenzyl)-1-phenyl-2-pyrazolin-5-one, **7***a*, (*cf* 2), this intermediate might be expected to undergo base-catalyzed cyclization to the indoline **8**, which, on subsequent reduction and dehydration, would be converted to the 1-hydroxyspiro[indolinepyrazolone], **4***a*. Such a mechanism is in keeping with the one suggested to explain the formation of 1-hydroxyindoles by base-catalyzed cyclization of a variety of *o*-nitrobenzyl derivatives. A similar intermediate (**9**, in which R^1 and R^2 are electron-withdrawing groups) was proposed for that reaction (15, 16).

9

When the *N*-hydroxy compound **4***a* was reduced catalytically it gave an almost quantitative yield of a product, $C_{17}H_{15}N_3O$, which is identified as the previously mentioned spiroamine **4***b*. The same product was also isolated when the reduction was carried out using iron and ferrous ammonium sulfate or zinc and ammonium chloride. The base peak in the mass spectrum of this compound was the molecular ion (*m/e* 277) which fragmented initially by the expulsion of a CO molecule to a fragment ion of *m/e* 249. In the mass spectrum of the deuterated reduced compound, these two ions appeared at *m/e* 278 and 250 respectively, consistent with a compound with one D-exchangeable hydrogen atom (**4***b*, NH → ND). The i.r. and p.m.r. spectra were also consistent with structure **4***b*.

4-(2-Nitrobenzylidene)-1,3-diphenyl-2-pyrazolin-5-one, **1***b*, was then reduced with sodium borohydride and palladium–charcoal in a manner similar to that described for the methyl analog **1***a*. In this case, only two products were obtained. For reasons similar to those presented to identify the products obtained in the reduction of the methyl analog **1***a*, the major product obtained from the reduction of **1***b* is identified as 1′,3′-diphenyl-1-hydroxyspiro[indoline-2,4′-[2]pyrazoline]-5′-one, **4***c*, while the minor product was found to be the amphoteric amine **3***b* (2).

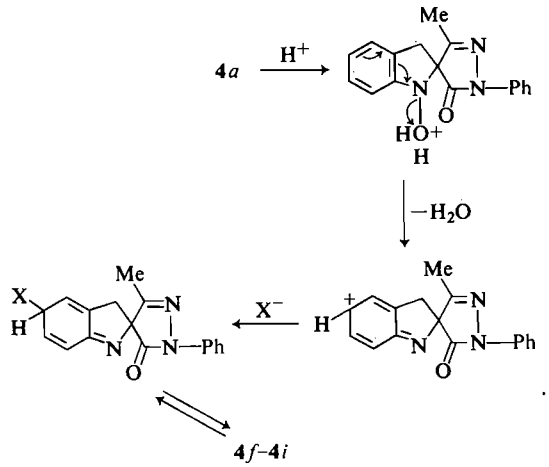
Reduction of this hydroxylamine **4***c* either catalytically or using iron and ferrous ammonium sulfate as just described for the methyl analog **4***a*, yielded a compound $C_{22}H_{17}N_3O$, which gave i.r., p.m.r., and mass spectra consistent with this compound being the phenyl analog of **4***b*, *i.e.* 1′,3′-diphenylspiro[indoline-2,4′-[2]pyrazoline]-5′-one, **4***d*. Zinc and ammonium chloride reduction of 1,3-diphenyl-4-(2-nitrobenzyl)-2-pyrazolin-5-one, **7***b*, was an alternative way of preparing the spiro(indoline)pyrazolone **4***d*. The precursor **7***b* is readily obtained by sodium borohydride reduction of the nitrobenzylidene compound **1***b* (2).

Relatively mild oxidation will convert some cyclic *N*-hydroxy compounds to the corresponding nitrones. Frequently, this is done in the absence of any catalyst by simply bubbling air through solutions of the *N*-hydroxy compound. Often, however, a catalyst is required before oxidation occurs, and copper sulfate – ammonia has been used extensively for this purpose (17, 18). It was also used in the present study to oxidize **4***a*. Crystallization of the crude product gave a dark brown solid which, despite difficulty in getting a pure sample for elemental analysis, is believed to consist mainly of the cyclic *N*-oxide **10**. The mass spectrum of this compound displayed a molecular ion at *m/e* 291 ($C_{17}H_{13}N_3O_2$). It liberated iodine from potassium iodide solution, a property common to *N*-oxides (19). Its i.r. spectrum was devoid of any amine or hydroxy absorption, and it displayed a carbonyl band at 1728 cm^{-1} which was located at a higher frequency than that of the *N*-hydroxy compound **4***a* due to the lack of any hydrogen bonding. The p.m.r. spectrum showed no D-exchangeable protons; it displayed only two signals, a methyl singlet and an aromatic 10-proton multiplet.

Various nucleophilic reagents are known to react with aromatic hydroxylamines and hydroxamic acids. Reactions in which the nucleophile is a halogen (20, 21), oxygen (22), sulfur (23, 24), nitrogen (25), or carbon (26) species have been

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

reported. Few of these reactions involved cyclic hydroxylamines. Therefore, in the present study, different nucleophilic species, *i.e.* chloride ion, water, methanol, and acetic acid, were reacted, in acidic media, with the *N*-hydroxy compound **4***a*. In each case, it was deduced that a 5-substituted indoline derivative (**4***f*–**4***i*) was obtained, possible by an S_NI' mechanism (Scheme 1) such as that proposed by Heller *et al.* (27) for nucleophilic attack on phenylhydroxylamine. Thus, when hydrogen chloride was bubbled through a cold solution of the *N*-hydroxy compound **4***a* in tetrahydrofuran, a black semisolid product was obtained. Chromatography of this product on a silica gel column yielded 5-chloro-3′-methyl-5′-phenylspiro[indoline-2,4′-[2]pyrazoline]-5′-one, **4***f*, as a crystalline solid. This compound was identified by its elemental analysis ($C_{17}H_{14}ClN_3O$) as well as its spectral (i.r., n.m.r.) properties. The location of the chlorine atom in the position *para* to the nitrogen atom (**4***f*) was suggested from the ample literature evidence which has revealed that when hydrochloric acid and other nucleophilic reagents react with aromatic hydroxylamines, *p*-substituted amines are the major products isolated (20, 28, 29). Confirmation of this assignment could not be obtained from the p.m.r. spectrum of the product since the aromatic signal was complex and could not be easily interpreted. Proof of the location of the chlorine atom became necessary when another isomeric chlorinated compound was obtained by the action of acetyl chloride on the hydroxylamine **4***a*. Both chloro compounds displayed very similar mass spectra but their melting points, i.r. and p.m.r. spectra were different. Therefore, it was found necessary to prepare an authentic sample of **4***f* for comparison purposes.



SCHEME 1

3-Chloro-6-nitrobenzaldehyde was condensed with 3-methyl-1-phenyl-2-pyrazolin-5-one and the product **1***c* (1) was reduced with sodium borohydride and palladium–charcoal in dioxane. 5-Chloro-1-hydroxy-3′-methyl-1′-phenylspiro[indoline-2,4′-[2]pyrazoline]-5′-one **4***e*, $C_{17}H_{14}ClN_3O_2$, was the main product isolated, as well as a small amount of 4-(2-amino-5-chlorobenzyl)-3-methyl-1-phenyl-2-pyrazolin-5-one, **3***c*. The major product, **4***e*, was identified from its physical and chemical properties which were similar to those of the other *N*-hydroxyindolines, **4***a* and **4***c*. Catalytic hydrogenation of **4***e* over platinum yielded the 5-chloroindoline **4***f*. Comparison of the spectral data and melting points of this compound with those of the product obtained by treating **4***a* with hydrogen chloride proved that both were identical. The 5-chloroindoline **4***f* and the *N*-hydroxy derivative **4***e* were also both obtained when 4-(5-chloro-2-nitrobenzyl)-3-methyl-1-phenyl-2-pyrazolin-5-one **7***c* (2) was reduced by means of zinc and ammonium chloride in ethanol.

Heating the *N*-hydroxy compound **4***a* with methanol in the presence of a catalytic amount of sulfuric acid, resulted in decomposition. When this reaction was repeated at 0 °C, a dark green solution was obtained from which was isolated a colorless compound which was identified as 5-methoxy-3′-methyl-1′-phenylspiro[indoline-2,4′-[2]pyrazoline]-5′-one, **4***g*, since it analyzed correctly for $C_{18}H_{17}N_3O_2$ and its mass spectrum displayed a molecular ion at *m/e* 307, and showed, with minor differences, fragmentation patterns similar to those of the 5-chloroindoline **4***f*. The i.r. and p.m.r. spectra were consistent with structure **4***g*. The complexity of the n.m.r. aromatic signal did not allow deduction of the exact location of the OCH_3 group but the pattern displayed for this signal was very similar to that in the spectrum of the 5-chloroindoline **4***f*.

A better yield of this compound was obtained when methanolic sulfuric acid was replaced with a solution of boron trifluoride in methanol. This observation was the result of an attempt to methylate the *N*-hydroxy function by the use of diazomethane in methanol, with boron trifluoride as a catalyst. Acid catalyzed nucleophilic attack

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

by methanol occurred rather than methylation of the *N*-hydroxy function, and the only product isolated was the 5-methoxy compound **4***g*.

When the *N*-hydroxy compound **4***a* was reacted with a mixture of dioxane and water in the presence of catalytic amounts of sulfuric acid, an alkali-soluble product, $C_{17}H_{15}N_3O_2$, was isolated. A comparison of its i.r., p.m.r., and mass spectra with those of **4***f* and **4***g* indicated that this phenolic product was 5-hydroxy-3′-methyl-1′-phenylspiro[indoline-2,4′-[2]pyrazoline]-5′-one, **4***h*.

The related 5-acetoxy derivative **4***i* was obtained by heating **4***a* with glacial acetic acid for 1 h. This compound was identified by its elemental analysis ($C_{19}H_{17}N_3O_3$), mass spectrum (M^+ at *m/e* 335), i.r., and p.m.r. spectra.

Previous studies have shown that the cyclic *N*-acetoxy carbonyl function gives rise to an i.r. absorption band in the region of 1800 cm^{-1} and the presence of this absorption band is very diagnostic (30, 31). It was desirable, therefore, to acetylate the cyclic *N*-hydroxy compounds (**4***a* and **4***c*) as a means of confirming their structures and to study the chemical behavior of these *N*-acetyloxy products. A number of conventional procedures were attempted but most of them led to the formation of rearrangement and decomposition products. The only successful method was to react the *N*-hydroxy compound in pyridine at -10 °C with excess acetic anhydride. The *N*-acetyloxy products thus obtained were stable for several weeks at 0 °C but decomposed rapidly on standing at room temperature.

The acetylated product, ($C_{19}H_{17}N_3O_3$; M^+, *m/e* 335), obtained from the *N*-hydroxy compound **4***a* was identified as 1-acetyloxy-3′-methyl-1′-phenylspiro[indoline-2,4′-[2]pyrazoline]-5′-one, **11***a*. That *O*-acetylation had occurred was confirmed by the presence of an *N*-acetyloxy C=O absorption band at 1790 cm^{-1}. In addition a lactam C=O band was located at 1723 cm^{-1} and the spectrum was devoid of any O—H or N—H bands. The p.m.r. spectrum showed two methyl signals (C—CH_3 and $OCOCH_3$), an aromatic multiplet (9 protons) and the methylene group signal as a doublet of doublets (J = 16.5 Hz). This spectrum had to be measured directly after dissolving in cold solvent because, in both solvents used, the compound decomposed and/or rearranged very rapidly; the *N*-acetyloxy signal disappeared with the appearance of some new signals and the spectrum became very complicated.

Heating the *N*-acetyloxy compound **11***a* in methanol or ethanol yielded two different crystalline products. One was identical to the 5-acetyloxy derivative **4***i* obtained earlier by the nucleophilic attack of acetic acid at C-5. The other product remains unidentified, although it is known from its elemental analysis ($C_{17}H_{13}N_3O$) and its mass spectrum (M^+, *m/e* 275) that it is a result of the loss of an acetic acid molecule from the parent *N*-acetoxy compound **11***a*. The same compound was also isolated, as described later, during attempts to methylate the *N*-hydroxy compound **4***a*.

Acetylation of the cyclic *N*-hydroxyindoline **4***c* with acetic anhydride and pyridine at -10 °C also yielded an *N*-acetoxy derivative identified as 1-acetyloxy-1′,3′-diphenylspiro[indoline-2,4′-[2]pyrazoline]-5′-one **11***b* by its elemental analysis ($C_{24}H_{19}N_3O_3$) and by similarities of its spectral data with those of the methyl analog **11***a*. It was noted that the acetyloxy derivative **11***b* was relatively stable at room temperature

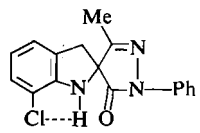
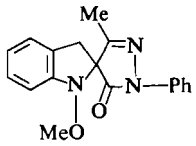
4*f*



13



14

and in cold solvents. Rearrangement still occurred in solution but at a much slower rate than that demonstrated by the methyl analog **11***a*. Heating **11***b* in ethanol produced only one re-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

arrangement product of formula $C_{24}H_{19}N_3O_3$. Infrared evidence supported the presence of an NH and two C=O groups (lactam and ester) in the molecule. The p.m.r. spectrum had signals which could be ascribed to $COCH_3$, CH_2, NH, and thirteen aromatic protons. Based on these data this compound was identified as *x*-acetyloxy-1′,3′-diphenylspiro[indoline-2,4′-[2]pyrazoline]-5′-one **12**. Although it is most likely that **12** is substituted at the 5-position as was the case with the methyl analog **4***i*, the exact position of the substituent was not determined due to the complex nature of the aromatic signal in the p.m.r. spectrum and due to the lack of an authentic sample.

When 1-hydroxy-3′-methyl-1′-phenylspiro[indoline-2,4′-[2]pyrazoline]-5′-one, **4***a*, was treated with acetyl chloride at room temperature it failed to react. When this mixture was heated in dry benzene for several hours, a reddish solution was formed which on evaporation and crystallization yielded two compounds, neither of which was the *N*-acetyloxy derivative **11***a*. The minor product $C_{19}H_{15}N_3O_3$, was dark red in color and was shown by mass spectrometry to be a monoacetate (M^+, *m/e* 333; $M-CH_2=C=O$, *m/e* 291). It readily hydrolyzed to give a phenol, $C_{17}H_{13}N_3O_2$ (M^+, *m/e* 291) which was yellow in color. Insufficient quantities of this acetate were isolated to permit identification. Its dark color, however, is indicative of a highly conjugated system.

The elemental analysis ($C_{17}H_{14}ClN_3O$) as well as the mass spectrum (M^+, *m/e* 311) of the major product confirmed the presence of a chlorine atom in its molecular formula. The possibility of this compound being the same 5-chloroindoline, **4***f*, obtained earlier was ruled out by comparing i.r. and p.m.r. spectra and by the depression of a mixture melting point. However, the similarities of the spectral data of this product and that of **4***f* suggested that they were isomeric. The p.m.r. spectrum was essentially similar to that of the 5-chloroindoline derivative **4***f* except in the aromatic area where the substitution pattern differed. Again, this pattern was complex and could not be resolved. Since the chlorine atom in isomer **4***f* was known to be located at the 5-position, it was considered likely that the other isomer was a 7-chloro derivative, **13**. These two positions are more susceptible than any other position to attack by nucleophilic reagents. Accordingly, this product is tentatively identified as 7-chloro-3′-methyl-1′-phenylspiro[indoline-2,4′-[2]pyrazoline]-5′-one, **13**. Support for this conclusion was found in its i.r. spectrum which had an NH absorption band at 3295 cm^{-1} and a C=O band at 1728 cm^{-1}. Compared to the corresponding absorption bands (3365 and 1710 cm^{-1}) in the related 5-chloroindoline, **4***f*, the N—H absorption showed a bathochromic shift of 70 cm^{-1} and the C=O a hypsochromic shift of 18 cm^{-1}. Intramolecular hydrogen bonding between the chlorine atom at C-7 and the amine hydrogen may be responsible for these shifts. In addition to the effect on the NH absorption, this also could affect the C=O absorption which is now located near the normal value ($\sim$1725 cm^{-1}) for compounds which do not display intramolecular hydrogen bonding. Hydrogen bonding between chlorine and hydrogen is now accepted (32) and the large frequency shift demonstrated here for the NH absorption may indicate that chlorine is a stronger electron donor than oxygen in this molecule.

The formation of a chlorinated product as a result of treating the *N*-hydroxy compound **4***a* with acetyl chloride was not unexpected due to the availability, in the reaction mixture, of chloride ions for nucleophilic attack. An explanation as to why a C-7 (**13**) and not a C-5 (**4***f*) chlorinated product, was obtained in the reaction with acetyl chloride is not possible although it may be due in part to the different solvents used (tetrahydrofuran for C-5 substitution and benzene for C-7 attack).

An attempt to react the 1-hydroxyindoline **4***a* with diazomethane, in the absence of any catalyst, failed to yield a methoxy derivative. When this reaction was carried out in methanol using boron trifluoride as catalyst, it produced the 5-methoxyindole **4***g*. The reaction was repeated in dioxane, and alcohol-free diazomethane and boron trifluoride-ether complex were used. This produced initially a dark-green product which was converted to a high melting pale yellow solid when treated with cold ethanol. This latter compound analyzed for $C_{17}H_{13}N_3O$ (M^+, *m/e* 275) and gave i.r. and mass spectra which were identical to the dehydrated product obtained when the *N*-acetyloxy compound **11***a* was treated with ethanol, as described earlier. A mixture melting point of both compounds showed no depression. The desired *N*-methoxyindoline, **14**, was obtained by methylating **4***a* with methyl iodide in the presence of sodium methoxide.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Identification of this compound was based on its elemental analysis ($C_{18}H_{17}N_3O_2$) as well as its i.r. (ν C=O at 1719 cm^{-1}) and p.m.r. (N—OH signal absent; N—OCH_3 at δ 3.80) spectra. The mass spectrum of this compound was also informative; it displayed a molecular ion at *m/e* 307 and strong $(M - 30)^+$ and $(M - 31)^+$ ions resulting from the expulsion of a CH_2O molecule and a CH_3O radical respectively from the molecular ion. The expulsion of a methoxy radical is not normally observed in the mass spectra of methyl ethers other than aromatic ethers where an *ortho*-effect operates (33, 34).

Pharmacology

A preliminary pharmacological screening of four of the compounds described above was undertaken. An observational technique similar to that described by Irwin (35, 36) was employed in an attempt to detect any behavioral neurological or autonomic changes after administering each compound to mice. Since the synthesized compounds possess a [2]pyrazolin-5-one nucleus and thus bear some chemical similarity to the known analgesics, antipyrine, aminopyrine, and nifenazone, selected compounds were also evaluated for their analgesic activity by means of the phenylquinone writhing test (37).

The two 1-hydroxyspiro[indolinepyrazolones] (**4***a* and **4***c*) were virtually devoid of pharmacological activity showing only a small decrease in motor activity and orientating movements when a 200 mg/kg oral dose of each was given to mice. On the other hand the spiro[indolinepyrazolones] (**4***b* and **4***d*) possessed some pharmacological activity. At an oral dose of 100 mg/kg or an intraperitoneal dose of 50 mg/kg, compound **4***b* caused a marked decrease in motor activity and orientating movements, and some muscle relaxation. Similar signs were observed with chlordiazepoxide (50 mg/kg intraperitoneally) in mice except that with this latter compound, ptosis and more marked muscle relaxation were evident.

The two spiro[indolinepyrazolones] (**4***b* and **4***d*) showed weak analgesic activity in mice. At oral doses of 200 mg/kg, these two compounds caused 45–48% protection as compared with 94% protection when the same dose of aminopyrine was administered.

Experimental

Melting points (capillary tube) are uncorrected. Infrared spectra were recorded as Nujol mulls, unless stated otherwise, using a Beckman IR-10 spectrophotometer, and p.m.r. spectra were obtained using a Varian A-60D spectrometer with DMSO-d_6 as solvent and TMS as internal standard. Mass spectra were measured on an A.E.I. MS-9 or MS-12 mass spectrometer at an ionization potential of 70 eV by Dr. A. M. Hogg and his associates, Department of Chemistry, University of Alberta, using the direct probe technique. Elemental analyses were performed by Mr. W. Dylke of our faculty. Deuterated **4***b* was prepared by repeatedly crystallizing **4***b* from dioxane–D_2O.

Reduction of 3-Methyl-4-(2-nitrobenzylidene)-1-phenyl-2-pyrazolin-5-one, 1a

(*a*) A solution of sodium borohydride (1.5 g) in water (20 ml) was added to a suspension of palladium–charcoal (10%, 0.15 g) in water (10 ml), followed by dioxane (20 ml). A solution of 3-methyl-4-(2-nitrobenzylidene)-1-phenyl-2-pyrazolin-5-one (1) (3.0 g) in dioxane (50 ml) was added dropwise to this mixture over a period of 30 min. Nitrogen was bubbled through the reaction mixture during the addition of the nitro-compound and for a further 15 min. The mixture was filtered and acidified with dilute hydrochloric acid then flooded with water (300 ml). It yielded a dark yellow precipitate (2.8 g). Attempts to purify the crude product by crystallization proved difficult. Chromatography on a silica gel column using chloroform–ether (9:1) followed by evaporation of eluate gave a yellowish crystalline compound (1.2 g), m.p. 187–188 °C dec. (ethanol) which was identified as 1-hydroxy-3′-methyl-1′-phenylspiro[indoline-2,4′-[2]pyrazoline]-5′-one, **4***a*. This compound reduced Tollen's reagent and gave, in the presence of alkali, a purple-red color with triphenyltetrazolium chloride. Infrared ν_{max} 1690 (C=O) and 3275 br (N—OH) cm^{-1}; p.m.r. δ 1.97 (3H, s, CH_3), 3.28 (2H, br, CH_2), 9.67 (1H, br, exchanged with D_2O, N—OH), and 6.70–8.10 (9H, m, aromatic protons); p.m.r. (pyridine) δ 2.10 (3H, s, CH_3), 3.44 (2H, doublet of doublets, J = 16 Hz, CH_2), 12.11 (1H, br s, D-exchangeable, N—OH), and 7.10—7.80 (9H, m, aromatic protons); mass spectrum *m/e* (% relative abundance) 293 (M^+, 70), 292 (18), 277 (55), 276 (32), 249 (35).

Anal. Calcd. for $C_{17}H_{15}N_3O_2$: C, 69.61; H, 5.16; N, 14.33. Found: C, 69.62; H, 5.07; N, 14.29.

Further elution of the column with a more polar solvent yielded only small amounts of dark brown oils which were not investigated.

(*b*) The above reaction was repeated but this time the filtrate was diluted with ice-cold water until a precipitate formed. The white solid (1.6 g) had m.p. 192–193 °C dec. (from ethanol). Infrared and p.m.r. spectra were identical to those of the *N*-hydroxyindoline **4***a* described in preparation *a*.

The filtrate remaining was acidified with glacial acetic acid to give a white precipitate (0.5 g) which was crystallized from ethanol to a small amount (0.08 g) of colorless crystals identified as 3′-methyl-1′-phenylspiro[indoline-2,4′-[2]pyrazoline]-5′-one, **4***b*, m.p. 126–127 °C. Infrared ν_{max} 1725 (C=O) and 3305 (NH) cm^{-1}; p.m.r. ($CDCl_3$) δ 2.09 (3H, s, CH_3), 3.33 (2H, d of d, J = 16.5 Hz, CH_2), 5.57 (1H, br s, D-exchangeable, NH), and 6.56–8.10 (9H, m, aromatic protons); mass spectrum *m/e* (% relative abundance) 277 (100), 276 (18), 260 (7), 249 (33).

Anal. Calcd. for $C_{17}H_{15}N_3O$: C, 73.63; H, 5.45; N, 15.15. Found: C, 73.93; H, 5.49; N, 14.94.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

The mother liquor remaining after the removal of the above product was concentrated to yield a third product (0.33 g), m.p. 153–154 °C. This was 4-(2-aminobenzyl)-3-methyl-1-phenyl-2-pyrazolin-5-one, **3***a*, (lit. (2) m.p. 153–154 °C); i.r., p.m.r., and mass spectrum were identical to literature spectra (2).

Anal. Calcd. for $C_{17}H_{17}N_3O$: C, 73.09; H, 6.13; N, 15.04. Found: C, 73.18; H, 6.18; N, 14.98.

Reduction of 1,3-Diphenyl-4-(2-nitrobenzylidene)-2-pyrazolin-5-one, 1b

The title compound (1) (3.0 g) was reduced in the same manner as the analog **1***a*, using method *a*. The reaction mixture was filtered free of palladium–charcoal and acidified with dilute acetic acid (300 ml).

The precipitate formed was crystallized from ethanol to an off-white solid (1.2 g), m.p. 178–179 °C dec. which was identified as 1′,3′-diphenyl-1-hydroxyspiro[indoline-2,4′-[2]pyrazoline]-5′-one, **4***c*. This compound reduced Tollen's reagent and gave a positive test with triphenyltetrazolium chloride (7, 8) for an *N*-hydroxy compound. Infrared ν_{max} 1696 (C=O) and 3347 (N—OH) cm^{-1}; p.m.r. δ 3.47 (2H, br s, CH_2), 9.80 (1H, br s, D-exchangeable, N—OH), and 6.70–8.32 (14H, m, aromatic protons). Mass spectrum *m/e* (% relative abundance) 355 (42), 354 (4), 339 (100), 338 (24), 323 (9), 311 (50).

Anal. Calcd. for $C_{22}H_{17}N_3O_2$: C, 74.35; H, 4.79; N, 11.82. Found: C, 74.23; H, 4.87; N, 11.89.

Concentration of the mother liquors after the removal of the above product gave 0.35 g of a second compound, 4-(2-aminobenzyl)-1,3-diphenyl-2-pyrazolin-5-one, **3***b*, m.p. 151–153 °C (lit. (2) m.p. 151–153 °C). Infrared, p.m.r., and mass spectrum were identical to literature spectra (2).

Anal. Calcd. for $C_{22}H_{19}N_3O$: C, 77.40; H, 5.61; N, 12.31. Found: C, 77.46; H, 5.76; N, 12.26.

Reduction of 4-(5-Chloro-2-nitrobenzylidene)-3-methyl-1-phenyl-2-pyrazolin-5-one, 1c

The title compound (1) (2.0 g) was reduced in the same manner as the analog **1***a*, using method *a* except that the filtrate was acidified with dilute acetic acid, followed by water. This yielded a white solid (1.3 g), m.p. 143–145 °C (from ethanol) which reduced Tollen's reagent and gave a purple-red color with triphenyltetrazolium chloride, and is identified as 5-chloro-1-hydroxy-3′-methyl-1′-phenylspiro[indoline-2,4′-[2]pyrazoline]-5′-one, **4***e*. Infrared ν_{max} 1685 (C=O), 3280 br (N—OH), and 1605 (C=N) cm^{-1}; p.m.r. δ 2.20 (3H, s, CH_3), 3.46 (2H, s, CH_2), 6.90–8.10 (8H, m, aromatic protons), and 8.60 (1H, br s, D-exchangeable, N—OH); mass spectrum *m/e* (% relative abundance) 329 (12), 327 (32), 313 (44), 312 (23), 311 (76), 310 (33), 285 (14), 283 (35).

Concentration of the mother liquors after removal of the above product gave 4-(2-amino-5-chlorobenzyl)-3-methyl-1-phenyl-2-pyrazolin-5-one, **3***c*, (0.18 g), m.p. 118–120 °C (lit. (2) m.p. 119–121 °C). Infrared, p.m.r., and mass spectra were identical to those reported (2).

Anal. Calcd. for $C_{17}H_{16}ClN_3O$: C, 65.06; H, 5.14. Found: C, 65.08; H, 5.12.

3′-Methyl-1′-phenylspiro[indoline-2,4′-[2]pyrazoline]-5′-one, 4b

(*a*) This compound was a minor product of the reduction of **1***a*, method *b*, as described above.

(*b*) A solution of 1-hydroxy-3′-methyl-1′-phenylspiro[indoline-2,4′-[2]pyrazoline]-5′-one (**4***a*, 0.5 g) in ethanol (70 ml) was hydrogenated over platinum oxide (0.05 g) at atmospheric pressure and room temperature. After the theoretical amount of hydrogen was absorbed, the catalyst was removed by filtration and the filtrate was concentrated *in vacuo*, then cooled, and a white crystalline product (0.43 g) separated. This was recrystallized from ethanol giving 3′-methyl-1′-phenylspiro[indoline-2,4′-[2]pyrazoline]-5′-one, **4***b*, as white crystals, m.p. 129–130 °C, identical to the product obtained by method *a*.

(*c*) To a heated solution of the 1-hydroxyspiro[indoline-pyrazolone] (**4***a*, 0.5 g) in ethanol (30 ml) was added reduced iron (1.0 g) followed by a solution of ferrous ammonium sulfate (0.3 g) in water (25 ml) and the mixture was heated, under reflux, for 10 h then filtered. The filtrate was evaporated to dryness and the residue was dissolved in hot ethanol and refiltered. Cooling of this filtrate yielded the spiro(indoline)pyrazolone **4***b* as white crystals (0.44 g), m.p. 128–129 °C, identical to the product obtained by method *a*.

(*d*) Ammonium chloride (0.1 g) in water (5 ml) was added to a stirred solution of the *N*-hydroxy compound (**4***a*, 0.5 g) in 60% ethanol (25 ml). Zinc powder (0.5 g) was added in small portions and the mixture was refluxed for 1 h. After removal of the excess zinc and zinc oxide, the solution was concentrated *in vacuo* and extracted with chloroform (50 ml). Evaporation of the dried ($CaCl_2$) chloroform gave a white solid (0.41 g) which crystallized from ethanol as colorless crystals of **4***b*, m.p. 127–129 °C, identical to the product obtained by method *a*.

1,3′-Diphenylspiro[indoline-2,4′-[2]pyrazoline]-5′-one, 4d

(*a*) 1-Hydroxy-1′,3′-diphenylspiro[indoline-2,4′-[2]pyrazoline]-5′-one (**4***c*, 0.5 g) was hydrogenated in a manner similar to that described for the preparation of **4***b*, method *b*. This gave the pale yellow title compound (**4***d*, 0.38 g), m.p. 193–194 °C. Infrared ν_{max} 1728 (C=O) and 3390 (NH) cm^{-1}; p.m.r. δ 3.51 (2H, br s, CH_2), 4.60 (1H, br s, D-exchangeable, NH), and 6.60–8.30 (14H, m, aromatic protons); mass spectrum *m/e* (% relative abundance) 339 (100), 338 (22), 322 (9), 311 (49).

Anal. Calcd. for $C_{22}H_{17}N_3O$: C, 77.85; H, 5.05; N, 12.38. Found: C, 77.69; H, 5.14; N, 12.41.

(*b*) Reduction of the 1-hydroxyspiro[indolinepyrazolone] (**4***c*, 0.4 g) with iron and ferrous ammonium sulfate in the manner described for the preparation of compound **4***b*, method *c*, gave the title compound (**4***d*, 0.29 g) as pale yellow crystals, m.p. 192–194 °C.

(*c*) 1,3-Diphenyl-4-(2-nitrobenzyl)-2-pyrazolin-5-one (2) (**7***b*, 1.0 g), dissolved in 50% ethanol (40 ml), was added to a solution of ammonium chloride (0.2 g) in water (10 ml). Zinc dust (0.5 g) was added and the mixture was heated under reflux for 2 h under nitrogen, then filtered. The filtrate was evaporated and the residue was recrystallized from ethanol to give the title compound (**4***d*, 0.78 g), m.p. 193–194 °C, as pale yellow crystals identical to the product obtained by method *a*.

5-Chloro-3′-methyl-1′-phenylspiro[indoline-2,4′-[2]pyrazoline]-5′-one, 4f

(*a*) A stream of hydrogen chloride was passed through a solution of 1-hydroxy-3′-methyl-1′-phenylspiro[indoline-2,4′-[2]pyrazoline]-5′-one (**4***a*, 0.5 g) in tetrahydrofuran (10 ml) for 30 s at 0 °C. The solution was left

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

standing at 0 °C for 12 h then evaporated *in vacuo* to dryness. The resulting black semisolid was chromatographed on a silica gel column using petroleum ether (30–60 °C, 100 ml) then benzene (100 ml) as solvent. Evaporation of the benzene eluate gave a dark yellow solid which crystallized from ethanol yielding the title compound **4***f* as white crystals (0.26 g), m.p. 153–154 °C. Infrared ν_{max} 1710 (C=O) and 3365 (N—H) cm^{-1}; p.m.r. ($CDCl_3$) δ 2.04 (3H, s, CH_3), 3.33 (2H, d of d, J = 16 Hz, CH_2), 4.00 (1H, br s, D-exchangeable, N—H), and 6.40–8.10 (8H, m, aromatic protons); mass spectrum *m/e* (% relative abundance) 313 (34), 312 (23), 311 (100), 310 (13), 294 (6), 285 (20), 283 (57).

Anal. Calcd. for $C_{17}H_{14}ClN_3O$: C, 65.49; H, 4.53; N, 13.48. Found: C, 65.06; H, 4.67; N, 13.21.

(*b*) Catalytic hydrogenation of 5-chloro-1-hydroxy-3′-methyl-1′-phenylspiro[indoline-2,4′-[2]pyrazoline]-5′-one (**4***e*, 0.35 g) in the way described for the preparation of **4***b*, method *b*, gave the title compound **4***f* (0.21 g) as colorless crystals, m.p. 152–153 °C, identical to the product obtained by method *a* immediately above.

(*c*) 4-(5-Chloro-2-nitrobenzyl)-3-methyl-1-phenyl-2-pyrazolin-5-one (2) (1.0 g) was reduced with zinc and ammonium chloride in the manner described for the preparation of the analog **4***d*, method *c*. This gave the title compound **4***f* (0.41 g) m.p. 153–154 °C with identical properties to the product obtained by method *a* immediately above.

Concentration of the mother liquors remaining after the removal of the above product yielded a second product (0.15 g), m.p. 144–145 °C which was identical (i.r., mass spectrum) to 5-chloro-1-hydroxy-3′-methyl-1′-phenylspiro[indoline-2,4′-[2]pyrazoline]-5′-one, **4***e*.

Oxidation of 1-Hydroxy-3′-methyl-1′-phenylspiro[indoline-2,4′-[2]pyrazoline]-5′-one, 4a

Air was bubbled for 3 h through a solution of the 1-hydroxyspiro[indolinepyrazolone] (**4***a*, 0.3 g) in aqueous (60%) ethanol (25 ml) containing ammonia (1 ml) and copper sulfate (5 mg). Water (50 ml) was added and the dark brown precipitate which formed was extracted into chloroform (20 ml). The dried ($CaCl_2$) chloroform solution was concentrated *in vacuo* and the residue was crystallized from aqueous ethanol as a dark brown solid (0.18 g), m.p. 121–124 °C. This compound was tentatively identified as 3′-methyl-1′-phenylspiro[[2*H*]indole-2,4′-[2]pyrazoline]-5′-one-1-oxide (**10**); i.r. ν_{max} 1728 (C=O) cm^{-1}, NH and OH absorption absent; p.m.r. ($CDCl_3$) δ 2.07 (3H, s, CH_3) and 6.70–8.20 (10H, m, aromatic protons; mass spectrum M^+ *m/e* 291 ($C_{17}H_{13}N_3O_2$).

Anal. Calcd. for $C_{17}H_{13}N_3O_2$: N, 14.42. Found: N, 14.22. (Satisfactory C, H analyses could not be obtained.)

5-Methoxy-3′-methyl-1′-phenylspiro[indoline-2,4′-[2]pyrazoline]-5′-one, 4g

(*a*) Concentrated sulfuric acid (0.5 ml) was added dropwise to a suspension of 1-hydroxy-3′-methyl-1′-phenylspiro[indoline-2,4′-[2]pyrazoline]-5′-one (**4***a*, 0.5 g) in methanol (15 ml) at 0 °C, and the mixture was left overnight at 0 °C. The solution was made alkaline with dilute sodium hydroxide then reacidified with glacial acetic acid and extracted with chloroform. The dried ($MgSO_4$) chloroform solution was evaporated to dryness to give a dark green oil which solidified when triturated with methanol. This was crystallized from ethanol as white crystals (0.37 g), m.p. 135–137 °C and is identified as the title compound **4***g*. Infrared ν_{max} 1710 (C=O) and 3310 (NH) cm^{-1}; p.m.r. ($CDCl_3$) δ 2.03 (3H, s, C—CH_3), 3.77 (3H, s, O—CH_3), 3.33 (2H, d of d, J = 16.5 Hz, CH_2), 4.28 (1H, br s, D-exchangeable, NH), and 6.50–8.40 (8H, m, aromatic protons); mass spectrum *m/e* (% relative abundance) 307 (100), 306 (34), 290 (9), 279 (26).

Anal. Calcd. for $C_{18}H_{17}N_3O_2$: C, 70.34; H, 5.58; N, 13.67. Found: C, 70.21; H, 5.49; N, 13.70.

(*b*) Excess diazomethane in ether was added to a stirred solution of 1-hydroxy-3′-methyl-1′-phenylspiro[indoline-2,4′-[2]pyrazoline]-5′-one (**4***a*, 0.8 g) in methanol (80 ml) containing a catalytic amount (2 ml) of boron trifluoride (14% solution in methanol). The resulting green solution was allowed to stand for 24 h at room temperature then evaporated under reduced pressure leaving a green solid. Crystallization of this crude product from ethanol yielded a white crystalline solid (0.68 g), m.p. 137–138 °C, which was identical (i.r., p.m.r.) to the product **4***g* obtained by method *a* immediately above.

5-Hydroxy-3′-methyl-1′-phenylspiro[indoline-2,4′-[2]pyrazoline]-5′-one, 4h

1-Hydroxy-3′-methyl-1′-phenylspiro[indoline-2,4′-[2*H*]pyrazoline]-5′-one (**4***a*, 0.5 g) was dissolved in an ice-cold mixture of dioxane (8 ml) and water (7 ml). Concentrated sulfuric acid (0.5 ml) was added dropwise and the reaction mixture was allowed to stand at room temperature for 12 h. Dilute sodium hydroxide (10 ml) was added, and the solution was reacidified with glacial acetic acid and extracted with chloroform. Evaporation of the dried ($MgSO_4$) chloroform extract yielded the title compound **4***h* as a pale brown solid which crystallized from aqueous ethanol to an off-white alkali-soluble solid (0.19 g), m.p. 114–116 °C. Infrared ν_{max} 1709 (C=O) and 3100–3500 (NH, OH) cm^{-1}; p.m.r. δ 2.10 (3H, s, CH_3), 3.29 (2H, br s, CH_2), 4.70 (1H, br s, D-exchangeable, NH) 11.10 (1H, br s, D-exchangeable, OH), and 6.70–8.35 (8H, m, aromatic protons); mass spectrum *m/e* (% relative abundance) 293 (M^+, 19), 265 (26).

Anal. Calcd. for $C_{17}H_{15}N_3O_2$: C, 69.61; H, 5.16. Found: C, 70.09; H, 4.73.

5-Acetyloxy-3′-methyl-1′-phenylspiro[indoline-2,4′-[2]pyrazoline]-5′-one, 4i

A solution of the 1-hydroxyspiro[indolinepyrazolone] (**4***a*, 0.5 g) in glacial acetic acid (10 ml) was heated under reflux for 1 h. The resulting red solution was added to cold water (100 ml) and the pale brown precipitate formed was extracted with ether. The ethereal extract was washed with a saturated solution of sodium bicarbonate then with water and dried (Na_2SO_4). Evaporation of this extract yielded a pale yellow solid (0.38 g) which crystallized from ethanol to off-white crystals of the title compound **4***i*, m.p. 120–121 °C. Infrared ν_{max} 1712 (lactam C=O), 1744 (ester C=O), and 3380 (NH) cm^{-1}; p.m.r. ($CDCl_3$) δ 2.06 (3H, s, C—CH_3), 2.23 (3H, s, $COCH_3$), 3.36 (2H, d of d, J = 15 Hz, CH_2), 4.52 (1H, br s, D-exchangeable, NH), and 6.50–8.50 (8H, m, aromatic protons); mass spectrum *m/e* (% relative abundance) 335 (59), 293 (80), 292 (25), 277 (37), 265 (33), 249 (36), 91 (100).

Anal. Calcd. for $C_{19}H_{17}N_3O_3$: C, 68.05; H, 5.11; N, 12.53. Found: C, 67.95; H, 5.17; N, 12.31.

1-Acetyloxy-3′-methyl-1′-phenylspiro[indoline-2,4′-[2]pyrazoline]-5′-one, 11a

Cold acetic anhydride (3.0 ml) was added to a solution

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

of the 1-hydroxyspiro[indolinepyrazolone] (**4***a*, 0.3 g) in cold pyridine (3.0 ml) and the mixture was kept for 24 h at −10 °C. The title compound **11***a* separated as a colorless crystalline solid (0.26 g), m.p. 92–93 °C. Infrared ν_{max} 1790 (*N*-acetyloxy C=O) and 1723 (lactam C=O) cm^{-1} (NH and OH absorption bands absent); p.m.r. (measured directly after dissolving in cold $CDCl_3$ or DMSO-d_6) δ 2.05 (3H, s, CH_3), 2.14 (3H, s, CH_3), 3.38 (2H, d of d, J = 16.5 Hz, CH_2), and 6.50–8.20 (9H, m, aromatic protons); mass spectrum *m/e* (% relative abundance) 335 (55), 307 (7), 293 (56), 275 (66), 265 (60).

Anal. Calcd. for $C_{19}H_{17}N_3O_3$: C, 68.05; H, 5.11; N, 12.53. Found: C, 68.31; H, 5.23; N, 12.81.

Attempts to crystallize **11***a* (0.25 g) from ethanol or methanol resulted in the formation of an off-white crystalline solid (0.09 g), m.p. 306–308 °C; i.r. ν_{max} 1640 br (C=O) and 3410 (NH) cm^{-1}; p.m.r. δ 2.63 (3H, s, CH_3), 4.00–5.10 (1H, br s, D-exchangeable), and 7.20–8.30 (9H, m, aromatic protons); mass spectrum *m/e* (% relative abundance) 275 (100), 274 (81), 260 (5), 115 (16), 77 (15).

Anal. Calcd. for $C_{17}H_{13}N_3O$: C, 74.19; H, 4.76; N, 15.27. Found: C, 74.49; H, 4.57; N, 14.98.

When the mother liquor remaining after removal of the above compound was concentrated and allowed to stand, a pale yellow solid (0.13 g), m.p. 117–118 °C deposited and was identified (i.r., p.m.r.) as 5-acetyloxy-3′-methyl-1′-phenylspiro[indoline-2,4′-[2]pyrazoline]-5′-one, **4***i*.

1-Acetyloxy-1′,3′-diphenylspiro[indoline-2,4′-[2]pyrazoline]-5′-one, 11b

When 1′,3′-diphenyl-1-hydroxyspiro[indoline-2,4′-[2]-pyrazoline]-5′-one (**4***c*, 0.3 g) was acetylated in the same manner as described above in the preparation of compound **11***a*, no product separated from the cooled solution. It was then diluted with ethanol (3 ml) and poured into ice-cold water with stirring. The title compound (**11***b*, 0.32 g) precipitated, m.p. 90–91 °C. Infrared ν_{max} 1792 (*N*-acetyloxy C=O), 1725 (lactam C=O) cm^{-1} (NH and OH absorption bands absent); p.m.r. (measured rapidly) δ 2.00 (3H, s, $OCOCH_3$), 3.61 (2H, d of d, J = 16.0 Hz, CH_2), and 6.90–9.30 (14H, m, aromatic protons); mass spectrum *m/e* (% relative abundance) 397 (24), 369 (9), 355 (22), 354 (14), 339 (13), 337 (10), 327 (38), 311 (15).

Anal. Calcd. for $C_{24}H_{19}N_3O_3$: C, 72.53; H, 4.81; N, 10.57. Found: C, 72.19; H, 4.83; N, 10.26.

Heating the above compound (**11***b*, 0.3 g) in ethanol produced a reddish solution. This was added, with stirring, to ice-cold water (100 ml) and the brown precipitate formed was collected and dried. Crystallization twice from benzene–petroleum ether (40–60 °C) gave a yellow solid (0.12 g), m.p. 115–117 °C, which is partially identified as *x*-acetyloxy-1′,3′-diphenylspiro[indoline-2,4′-[2]pyrazoline]-5′-one, **12**. Infrared ν_{max} 1723 (lactam C=O), 1750 (ester C=O), and 3340 (NH) cm^{-1}; p.m.r. ($CDCl_3$) δ 2.23 (3H, s, $COCH_3$), 3.58 (2H, d of d, J = 15.5 Hz, CH_2), 5.70 (1H, br s, D-exchangeable, NH), and 6.70–8.30 (13H, m, aromatic protons).

Anal. Calcd. for $C_{24}H_{19}N_3O_3$: C, 72.53; H, 4.81; N, 10.57. Found: C, 72.11; H, 4.99; N, 10.29.

Action of Acetyl Chloride on 1-Hydroxy-3′-methyl-1′-phenylspiro[indoline-2,4′-[2]pyrazoline]-5′-one, 4a

To a solution of the title compound (**4***a*, 0.5 g) in hot dry benzene (10 ml), acetyl chloride (1.0 ml) was added and the mixture heated under reflux for 10 h. The resulting red solution was evaporated to dryness, leaving a dark oil which was dissolved in hot ethanol. Cooling gave a small quantity (0.07 g) of a product as red needles, m.p. 209–210 °C. This compound remains unidentified (its hydrolysis is described below). Infrared ν_{max} 1688 and 1712 (C=O) cm^{-1}; p.m.r. ($CDCl_3$) δ 2.44 (3H, s, CH_3), 2.48 (3H, s, CH_3), 7.00–8.20 (8H, m, aromatic protons), and 9.80 (1H, d, J = 8 Hz, unassigned); mass spectrum *m/e* (% relative abundance) 333 (47), 291 (70), 186 (7), 158 (24), 77 (100).

Anal. Calcd. for $C_{19}H_{15}N_3O_3$: C, 68.46; H, 4.54; N, 12.61. Found: C, 68.74; H, 4.95; N, 12.75.

After the above product was collected, the filtrate was concentrated and from it pale orange crystals (0.30 g), m.p. 188–189 °C separated. This was 7-chloro-3′-methyl-1′-phenylspiro[indoline-2,4′-[2]pyrazoline]-5′-one, **13**; i.r. ν_{max} 1728 (C=O) and 3295 (NH) cm^{-1}; p.m.r. ($CDCl_3$) δ 2.10 (3H, s, CH_3), 3.46 (2H, d of d, J = 16 Hz, CH_2), 4.58 (1H, br s, D-exchangeable, NH), and 6.55–8.10 (8H, m, aromatic protons); mass spectrum *m/e* (% relative abundance) 311 (M^+, 100), 294 (9), 283 (60).

Anal. Calcd. for $C_{17}H_{14}ClN_3O$: C, 65.49; H, 4.53; N, 13.48. Found: C, 65.31; H, 4.66; N, 13.11.

A sample (60 mg) of the unidentified acetate, m.p. 209–210 °C described above was suspended in 10% aqueous sodium hydroxide (5.0 ml) and stirred for 2 h. The resulting yellow solution was filtered, acidified with dilute hydrochloric acid and extracted with ether. Evaporation of the dried (Na_2SO_4) ethereal extract yielded a yellow solid (40 mg), m.p. 179–180 °C (ethanol). Infrared ν_{max} 1637 (C=O) and 2000–3300 (OH) cm^{-1}; p.m.r. δ 2.58 (3H, s, CH_3), 4.00–5.20 (1H, br s, D-exchangeable, OH), 8.62 (1H, d, J = 8 Hz, unassigned), and 6.70–8.10 (8H, m, aromatic protons); mass spectrum *m/e* (% relative abundance) 291 (M^+, 72), 205 (8), 200 (8), 186 (10), 178 (10), 158 (59), 130 (24), 120 (100).

Anal. Calcd. for $C_{17}H_{13}N_3O_2$: C, 70.09; H, 4.50; N, 14.42. Found: C, 69.73; H, 4.51; N, 14.02.

Methylation of 1-Hydroxy-3′-methyl-1′-phenylspiro[indoline-2,4′-[2]pyrazoline]-5′-one, 4a

(*a*) See preparation of 5-methoxy-3′-methyl-1′-phenylspiro[indoline-2,4′-[2]pyrazoline]-5′-one, **4***g*, method *b*.

(*b*) Reaction *a* was repeated in dioxane (80.0 ml) using alcohol-free ethereal solution of diazomethane and boron trifluoride – ether complex (1 ml). Solvents were removed under reduced pressure leaving a green residue which was extracted with chloroform. Evaporation of the chloroform solution yielded a green solid, i.r. ν_{max} 1720 (C=O) cm^{-1}, NH and OH absorption absent, which recrystallized from ethanol as a yellow solid (0.21 g), m.p. 306–308 °C, identical to the unidentified product obtained by crystallizing **9***a* from ethanol.

(*c*) Methyl iodide (1.0 g) in methanol (5.0 ml) was added to a solution of the 1-hydroxyspiro[indolinepyrazolone] (**4***a*, 0.5 g) in methanol (15.0 ml) containing 0.2 g of sodium. The mixture was heated under reflux for 3 h during which time a yellow color developed. The solvent was evaporated and the residue extracted with ether. Evaporation of the dried (Na_2SO_4) ethereal extract gave a yellow solid which was crystallized from methanol to give 1-methoxy-3′-methyl-1′-phenylspiro[indoline-2,4′-[2]pyrazoline]-5′-one, **14**, as pale yellow crystals (0.39 g), m.p. 112–114 °C. Infrared ν_{max} 1719 (C=O) cm^{-1} (NH,

OH absorption absent); p.m.r. ($CDCl_3$) δ 1.96 (3H, s, C—CH_3), 3.80 (3H, s, O—CH_3), 3.27 (2H, d of d, J = 17 Hz, CH_2), and 6.80–8.30 (9H, m, aromatic protons); mass spectrum *m/e* (% relative abundance) 307 (80), 276 (61), 248 (28), 233 (7), 207 (7).

Anal. Calcd. for $C_{18}H_{17}N_3O_2$: C, 70.34; H, 5.58; N, 13.67. Found: C, 70.41; H, 5.38; N, 13.29.

Organic Sulfur Mechanisms. 17. A Brief Study of the Photolysis of an Unsaturated Cyclic Sulfone

J. F. KING, E. G. LEWARS, D. R. K. HARDING, AND R. M. ENANOZA
Department of Chemistry, University of Western Ontario, London, Ontario N6A 5B7

Received July 14, 1975

J. F. KING, E. G. LEWARS, D. R. K. HARDING, and R. M. ENANOZA. Can. J. Chem. **53**, 3656 (1975).

Photolysis of 3-phenyl-2*H*-thiopyran 1,1-dioxide (**3**) in methanol gives a mixture of 3-phenyl-5-methoxy-5,6-dihydro-2*H*-thiopyran 1,1-dioxide (**4**) and methyl 4-phenyl-2,4-pentadiene-1-sulfonate (**5**). Formation of **5** shows that the photochemical ring opening of cyclohexadienic sulfonyl compounds (**1**) does not require an atom bearing a free electron pair in the heterocyclic ring, and therefore argues in favor of a mechanism involving cycloreversion to the sulfene (**1** → **2**).

J. F. KING, E. G. LEWARS, D. R. K. HARDING et R. M. ENANOZA. Can. J. Chem. **53**, 3656 (1975).

La photolyse du phényl-3 2*H*-thiopyrannedioxyde-1,1 (**3**) dans le méthanol conduit à un mélange de phényl-3 méthoxy-5 dihydro-5,6 2*H*-thiopyrannedioxyde-1,1 (**4**) et de phényl-4 pentadiène-2,4 sulfonate-1 de méthyle (**5**). La formation de **5** démontre que l'ouverture photochimique du cycle des composés cyclohexadiénique sulfonyle (**1**) ne requière pas un atome portant une paire d'électrons libre dans le noyau hétérocyclique et suggère ainsi un mécanisme impliquant une cycloréversion vers le sulfène (**1** → **2**).

[Traduit par le journal]

Photolysis of unsaturated sultones (1–3), and sultams (4) derived from **1***a* and **1***b*, respectively, is known to give products formulated as arising from the sulfene **2** formed by photochemical ring opening. Doubt about the actual intermediacy of

1 *a* X = O *b* X = N—R *c* X = CH_2 **2**

the sulfene in these reactions, however, has been expressed by Charlton and de Mayo (5) as a result of flash photolysis experiments, which required any sulfene formed in these reactions to have a lifetime of less than 20 μs. In the examples which had been studied, X is an oxygen atom or an N—R group, and in **2** the oxygen or nitrogen is particularly favorably arranged for an intramolecular reaction with the sulfene portion, *e.g.* to reform the starting material. This consideration when taken with the high reactivity of sulfenes (for a review see ref. 6), led us to conclude that such a short lifetime was not inconsistent with structures **2***a* and **2***b*. Because of the smaller nucleophilicity of an olefinic carbon as compared with a carbonyl oxygen or an imine nitrogen, we hoped that **2***c*, if formed from **1***c*, might have a longer lifetime and be observable on flash photolysis. The experience of Chapman and coworkers (7, 8) with ketene analogs of these systems lends support to such a notion. Accordingly, we have looked at the photolysis of 3-phenyl-2*H*-thiopyran 1,1-dioxide, **3**, and although the original aim has not been achieved, we have made a relevant observation which we wish to record in this brief note.

Photolysis of a methanolic solution of **3** (9) gave two principal products, which were separable on thin layer chromatography (t.l.c.). Structures **4** and **5** for the respective major (43%) and minor (30%) products were deduced from their i.r. and n.m.r. spectra and were confirmed by synthesis, respectively, of (*a*) **4** by methylation of **6** (the precursor of **3**), and (*b*) **7**, the tetrahydro derivative of **5**, via a sulfo-Cope rearrangement (10) of **8** followed by hydrogenation and esterification, as shown in Scheme 1. Nuclear magnetic resonance spectra of different samples of **5** indicated the presence of varying amounts of another product consistent with the presence of a small amount of the geometric isomer (presumably *trans*) of **5**.

Compound **4** presumably arises from a photochemical Markovnikov addition of the solvent (11, 12); compare, for example, the addition of

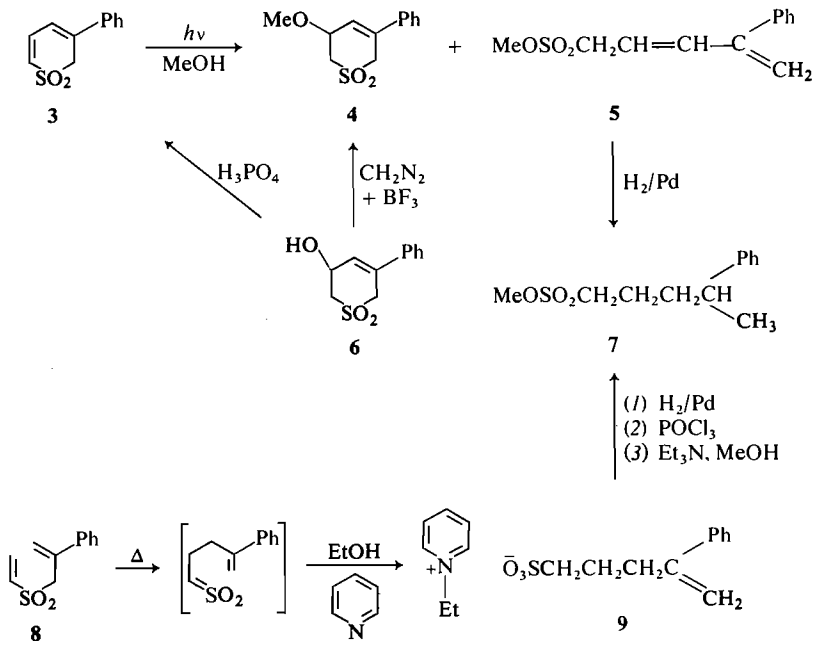
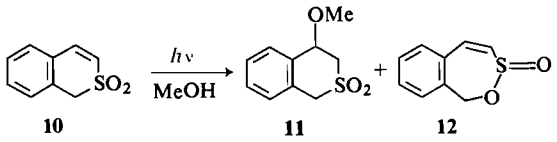


SCHEME 1

methanol to 1-phenylcyclohexene (11, 13). Of greater interest to us, however, is the formation of **5**, which is obviously consistent with the intermediacy of the 4-phenyl derivative of sulfene **2***c*. Some of the more plausible alternative mechanisms to sulfene formation in the photolyses of **1***a* or **1***b* derivatives, involve excitation of the non-bonded electrons on the ring oxygen or nitrogen atoms. No such process can be invoked in the present case (**3** → **5**), and further, since the ring opening can take place in the absence of these non-bonded electron pairs, they are clearly not required for this reaction to occur. To the extent that the proof of a reaction mechanism involves the accumulation of evidence discrediting all possible alternative routes, the observation of the reaction **3** → **5** lends further credibility to the proposal of the general sulfene-forming cycloreversion **1** → **2** originally proposed by de Mayo (1).

Hall and Smith in an independent study (14) appearing after completion of our work, have made closely related observations (Scheme 2). They suggest that the sultine (**12**) arises from the sulfene formed by ring-opening of **10**; sultine formation from cyclization of unsaturated sulfenes has been proposed previously (see ref. 6).

Photolysis of **3** in an aprotic solvent led to a mixture which included a crystalline product which appeared from its spectra to possess both formyl and sulfinyl groups, suggesting perhaps the further transformation of a cyclic sultine (akin to **12**). The nature of this reaction indicated that this system would need considerable work before it might be appropriate to attempt the



SCHEME 2

flash photolysis experiments which initially prompted this study, and work on this has been suspended for now.

Experimental

Solutions were irradiated in 1.7 × 20 cm Pyrex tubes suspended *ca.* 2 cm from the cooling jacket of a 450 W medium-pressure Hanovia mercury lamp and immersed in a water bath at *ca.* 10 °C. The progress of the photolyses was followed by observing the disappearance of the peak due to starting diene **3**, using a Varian Series 1400 gas chromatograph with a flame ionization detector, fitted with a 3% SE-30 on Varaport 30 (100–120 mesh) 5 ft × $\frac{1}{8}$ in. copper column at 180 °C, with nitrogen as the carrier gas. Control experiments showed that no reaction of **3** with methanol takes place without irradiation (even in the presence of added H_2SO_4).

Preparative t.l.c. was performed using 20 × 20 cm glass

plates bearing 20 g of silica gel, and analytical t.l.c. using microscope slides coated with thin layers of silica gel. The bands on the preparative plates were visualized by means of the ultraviolet phosphor in the silica gel, and extracted with CH_2Cl_2–MeOH (100:15 v/v). Infrared spectra were measured with a Beckman IR 20-A spectrometer, 60 MHz n.m.r. spectra were taken with a Varian T-60, and 100 MHz n.m.r. spectra with a Varian HA-100 spectrometer.

Formation of Photoadducts 4 and 5

A solution of the diene **3** (342 mg) in methanol (Fisher Spectrograde, 35 ml) was purged with nitrogen for 10 min, then irradiated for 2 h, when v.p.c. showed that little if any **3** remained. Two identical irradiations were conducted, so a total of 684 mg of **3** was irradiated. The combined solutions (clear and colorless with no sign of polymer) were evaporated at *ca.* 35 °C to give a pale brown oil (816 mg). This was subjected to preparative t.l.c. (CH_2Cl_2), giving two bands. The less mobile band (338 mg, 43%) was shown to be 3-phenyl-5-methoxyl-5,6-dihydro-2*H*-thiopyran 1,1-dioxide, **4**, by comparison of its n.m.r. and i.r. spectra with those obtained from a specimen synthesized by an independent route, whereas the more mobile band (226 mg, 30%) was identified as the sulfonate **5** by synthesis of its tetrahydro derivative (for details see below). The ester **5**, as obtained from t.l.c. appeared from its spectra to be substantially pure, but like the sulfone **4** was not obtained in a form which gave fully satisfactory analyses; molecular distillation (oil diffusion pump, 110 °C) led to decomposition.

The 100 MHz n.m.r. spectrum of **5** showed bands assigned (and confirmed by decoupling experiments) as follows: δ 3.72 (s, 3H, CH_3O), 3.84 (dd, 2H, C-1 H's, $J_{1,2}$ = 8 Hz, $J_{1,3}$ = 1.5 Hz), 5.28 (apparent t, 1H, C-5, H, $J_{gem} \sim$ 1.5 Hz, $J_{3,5} \sim$ 1.5 Hz), 5.58 (apparent d, 1H, C-5 H), 5.79 (dt, 1H, C-2 H, $J_{2,3}$ = 11 Hz), 6.50 (d of m, 1H, C-3 H), and 7.27 p.p.m. (m, 5H, Ph). In addition a peak at 3.56 p.p.m. perhaps due to the methoxyl peak of (about 5% of) the geometric isomer of **5** (*i.e.* probably *trans*) was observed. The i.r. spectrum of **5** showed strong bands at 1355, 1175, and 990 cm^{-1}.

Hydrogenation of sulfonate **5** to the hydrogenated sulfonate **7** was readily effected: sulfonate **5** (distilled; 18.8 mg) and 5% Pd/C *ca.* 20 mg) in ethyl acetate (3 ml) were hydrogenated at 25 °C and *ca.* 1 atm; hydrogen uptake was complete in 15 min, and 97% of the theoretical amount of hydrogen needed to saturate the two double bonds of **5** was absorbed. The reaction mixture was filtered through Celite and evaporated to give the hydrogenated sulfonate **7** as a colorless oil, 17 mg (90%). The i.r. and n.m.r. spectra of this material were identical to those of an authentic specimen synthesized as described below.

Synthesis of Methyl 4-Phenylpentane-1-sulfonate, 7, from 8

The *N*-ethylpyridinium salt **9** (4.5 g. 13.5 mmol), obtained by heating 2-phenyl-2-propenyl vinyl sulfone, **8**, for 2 h at 170 °C in a mixture of equal volumes of ethanol and pyridine in a sealed tube (*cf.* ref. 10), was dissolved in ethanol (70 ml) and hydrogenated for 15 h at 4 atm over platinum oxide (500 mg) on a Parr apparatus. The hydrogenation was then stopped. A further portion of catalyst (250 mg) was added and then the hydrogenation was continued for another 3 h. Removal of the catalyst and the solvent yielded, after drying *in vacuo*, 4.15 g (90%) of sticky crystalline material. The n.m.r. (HA 100) showed ($CDCl_3$) δ 0.60–2.30 (m, *ca.* 15 H), 2.35–4.10 (m, 10 H), and 6.80–7.50 p.p.m. (m, 5 H) (*i.e.* apparently the pyridine ring was reduced).

The reduced salt (4 g, 11.8 mmol) was heated with phosphorus oxychloride (20 ml) for 1 h on a steam bath. The solution was cooled and then poured onto ice. The resulting mixture was stirred for 0.25 h and then extracted with ether. The ether layer was washed several times with water until the aqueous wash remained neutral. The ether layer was dried over magnesium sulfate. Removal of the ether and subsequent drying *in vacuo* afforded 2.2 g (76%) of the sulfonyl chloride; this corresponds to a 56% yield from the starting sulfone. A small amount of this oil was distilled twice on a cold finger apparatus. The n.m.r. (HA 100) showed ($CDCl_3$) δ 1.26 (d, 3H), 1.55–2.15 (m, 4 H), 2.50–2.90 (m, 1 H), 3.40–3.65 (m, 2 H), and 7.00–7.45 p.p.m. (m, 5 H). The i.r. showed ν_{max} (film) 1365 and 1158 cm^{-1}.

Anal. Calcd. for $C_{11}H_{15}ClO_2S$: C, 53.54; H, 6.13; Cl, 14.37; S, 13.00. Found: C, 53.49; H, 6.12; Cl, 14.21; S, 12.80.

4-Phenylpentane-1-sulfonyl chloride (0.5 g, 2.04 mmol) was dissolved in dry methanol (10 ml) and treated with triethylamine (0.5 ml). The mixture was stirred for 0.5 h before the methanol was removed. The residue was partitioned between water and ether. The ether layer was washed successively with 3 *N* hydrochloric acid and saturated sodium bicarbonate solution and then dried over magnesium sulfate. Removal of the ether and drying *in vacuo* gave 0.35 g (71%) of oil. This material was distilled on a cold finger apparatus. The n.m.r. (HA 100) showed ($CDCl_3$) δ 1.24 (d, 3 H), 1.44–2.02 (m, 4 H), 2.50–2.85 (m, 1 H), 2.85–3.21 (m, 2 H), 3.77 (s, 3 H), and 7.00–7.50 p.p.m. (m, 5 H). The i.r. showed ν_{max} (CCl_4) 1365, 1345, and 1162 (SO_2) cm^{-1}.

Anal. Calcd. for $C_{12}H_{18}O_3S$: C, 59.47; H, 7.49; S, 13.23. Found: C, 59.52; H, 7.35; S, 13.02.

Synthesis of 3-Phenyl-5-methoxy-5,6-dihydro-2H-thiopyran 1,1-dioxide, 4

To a solution of 3-phenyl-5-keto-5,6-dihydro-2*H*-thiopyran-1,1-dioxide (9) (0.20 g, 0.90 mmol) in ethanol (10 ml) was added with stirring at room temperature a solution of sodium borohydride (0.042 g, 1.08 mmol) in water (2 ml). After stirring for 3 h, hydrochloric acid solution (1 *N*, 5 ml) was added and the mixture was then concentrated *in vacuo* at 50 °C to a gummy residue. Traces of water were removed by an azeotropic distillation *in vacuo* at 50 °C of a methanolic solution of the residue. The final residue was then taken up in methylene chloride (20 ml), filtered, dried over anhydrous magnesium sulfate, and evaporated to dryness to give crude 3-phenyl-5-hydroxy-5,6-dihydro-2*H*-thiopyran-1,1-dioxide (**6**). To this hydroxysulfone in methylene chloride (25 ml) over an ice-water bath was added boron trifluoride etherate (2 drops) and an ethereal solution (50 ml) of diazomethane (generated from 1 g of *N*-nitrosomethylurea). Nitrogen was immediately evolved. Boron trifluoride was destroyed by anhydrous sodium carbonate and the mixture was then filtered and evaporated to dryness leaving a mobile residue which was distilled (100–120 °C at 1 Torr) to give the desired product (0.115 g or 54%). The n.m.r. spectrum

($CDCl_3$) showed bands assigned (by first order analysis with the aid of decoupling experiments) as follows: δ 7.31 (5H, Ph), 6.25 (m, $W_{1/2}$ = 7 Hz, C-4H), 4.50 (m, $W_{1/2}$ = 23 Hz, C-5H), 4.10 (d of t, C-2eq H), 3.90 (d of m, C-2ax H), 3.60 (m, C-6eq H), 3.45 (s, OCH_3), and 3.10 p.p.m. (dd, C-6ax H). The major couplings were $J_{2a,2e}$ = 17.0 Hz, $J_{6a,6e}$ = 13.5 Hz, $J_{5,6e}$ = 5.5 Hz, $J_{5,6a}$ = 10.0 Hz; in addition small couplings (1 to 3 Hz) were observed as follows: the C-4H with 2ax, 2eq, 5, and 6eq, the C-5H also with 2ax and 2eq, and the C-2eq H with 6eq (this last being the basis for assigning the 4.10 p.p.m. signal to the equatorial hydrogen on C-2). The i.r. spectrum showed strong bands at 1328, 1129, and 1086 cm^{-1}.

We thank the National Research Council of Canada for support of this work.

Aryne Formation from 2-Bromolaudanosine. Fate of the 5,6,12,12a-Tetrahydrodibenzo[*b*,*g*]indolizinium Ion and an Alternative Synthesis of Glaucine

IJAZ AHMAD AND MARTIN S. GIBSON

Department of Chemistry, Brock University, St. Catharines, Ontario L2S 3A1

Received May 30, 1975

IJAZ AHMAD and MARTIN S. GIBSON. Can. J. Chem. **53**, 3660 (1975).

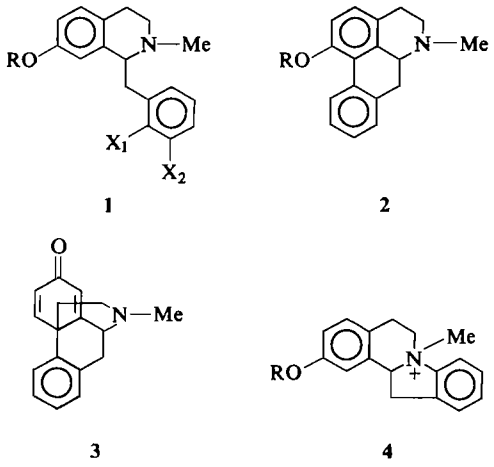
A synthesis of 2-bromolaudanosine (**10**) is described. The aryne formed from **10** and amide ion in ammonia yields the corresponding 5,6,12,12a-tetrahydrodibenzo[*b*,*g*]indolizinium ion (**13**) by intramolecular capture, and 2-aminolaudanosine (**11**) by external addition of amide ion. Compound **13** is converted *in situ* to 5,6-dimethoxy-2-(4,5-dimethoxy-2-vinylphenyl)-1-methylindoline (**14**) and 5,6-dimethoxy-2-(4,5-dimethoxy-2-ethylphenyl)-1-methylindole (**15**). Compound **11** provides an alternative source of glaucine (**12**).

IJAZ AHMAD et MARTIN S. GIBSON. Can. J. Chem. **53**, 3660 (1975).

On décrit une synthèse de la bromo-2 laudanosine (**10**). L'aryne, qui se forme par réaction de **10** avec l'ion amidure dans l'ammoniac, conduit à l'ion correspondant tétrahydro-5,6,12,12a dibenzo[*b*,*g*] indolizinium (**13**) par capture intramoléculaire et à l'amino-2 laudanosine (**11**) par addition externe de l'ion amidure. On transforme *in situ* le composé **13** en diméthoxy-5,6 (diméthoxy-4,5 vinyl-2 phényl)-2 méthyl-1 indoline (**14**) et en diméthoxy-5,6 (diméthoxy-4,5 éthyl-2 phényl)-2 méthyl-1 indole (**15**). Le composé **11** s'avère une source de rechange pour la glaucine (**12**).

[Traduit par le journal]

The use of appropriately substituted 1-(2- or 3-halogenobenzyl)-1,2,3,4-tetrahydroisoquinolines (**1**) as sources of arynes for synthesis of modified 1-benzyl-1,2,3,4-tetrahydroisoquinoline alkaloids such as aporphines (**2**), morphinandienones (**3**), and 5,6,12,12a-tetrahydrodibenzo-[*b*,*g*]indolizinium salts (**4**)(Scheme 1) has attracted considerable attention in recent years.[1] Thus, cine-substitution via an aryne (X_1 = H, X_2 = Br → X_1 = NH_2, X_2 = H), coupled with Pschorr cyclization, has been used in synthesis of the aporphine alkaloid laureline (1), whilst direct aporphine formation from a phenolic precursor (R = H) has been achieved in a synthesis of domesticine (2). The possibility of aporphine and morphinandienone formation occurring from such a phenolic precursor (R = H) has also been explored, without success under the conditions initially employed (1*b*), but successfully at higher mole ratios (between 8 and 10 to 1) of sodamide or potassamide to halogenocompound (3, 4). Parallel routes have been used to synthesize 5,6,12,12a-tetrahydrodibenzo[*b*,*g*]-indolizinium salts, both via the corresponding tetrahydroindolizines (5, 6) and directly (4, 7).



SCHEME I

An aryne route has also been used for indoline synthesis associated with *Erythrina* alkaloid studies (8).

The formation and demise of 5,6,12,12a-tetrahydrodibenzo[*b*,*g*]indolizinium ions in potassamide-ammonia is important in leading to by-products in such aporphine syntheses (1). Direct evidence for formation of such ions under these conditions was provided in due course by Kametani *et al.* (7) using a 7-hydroxyisoquinoline

[1]Other substituents are omitted for simplicity in formulae **1–4**.

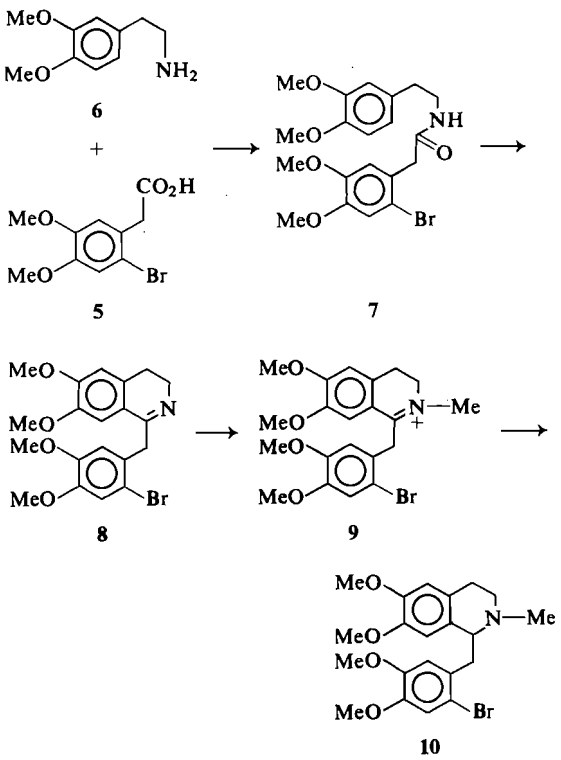
precursor, the cation produced being presumably stabilized by deprotonation of the phenolic group and regenerated during work-up; no Hofmann elimination was observed. Similar results have been reported by Kessar *et al.* (4). These workers also obtained indications of Hofmann elimination (1) when using a 6-hydroxyisoquinoline precursor although this case was complicated by accompanying dehydrogenation. The original problem of the behavior of non-phenolic 5,6,12,-12a-tetrahydrodibenzo[*b*,*g*]indolizinium ions in potassamide–ammonia is considered in the present communication.

The tetramethoxy series shown (Scheme 2) was chosen for examination. Bromination of 3,4-dimethoxyphenylacetic acid gave the bromo-acid **5** which was treated with thionyl (or oxalyl) chloride, followed by the amine **6**, to give the amide **7**. After cyclization of **7** with phosphoryl chloride in benzene, isolation of the product **8** as the iminium chloride **8***a* was most conveniently effected by treatment of the reaction mixture with anhydrous methanol. Treatment of **8** with methyl iodide gave **9** which was reduced with sodium borohydride to 2-bromolaudanosine (**10**), identical with material prepared by brominating a sample of (±)-laudanosine.



SCHEME 2

Aryne reactions of **10** were carried out both with potassamide and with sodamide in liquid ammonia and the products were isolated chromatographically. In order of elution, these were **A** ($C_{21}H_{25}NO_4$), **B** ($C_{21}H_{25}NO_4$), and **C** ($C_{21}H_{28}N_2O_4$).

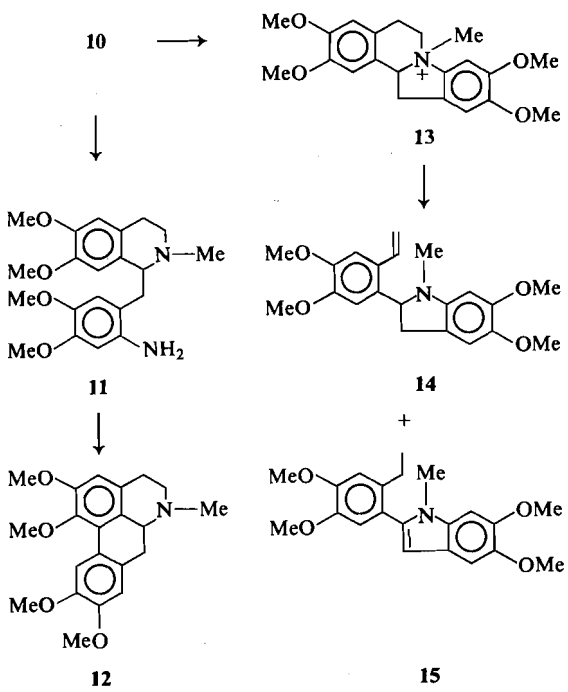
Compound **C** was recognized as the diamine **11** by melting point and i.r. spectral correlations and by known conversion to (±)-glaucine, **12**, (Scheme 3) which was characterized as the methiodide (9). External addition of amide ion to the aryne had thus occurred preferentially at the carbon atom remote from the methoxy-groups as expected (1); interestingly, 4-amino-veratrole had been previously identified as the main product from reaction of 4-bromoveratrole with potassamide in ammonia.[2]

Compound **B** proved to be the indoline **14**, identity being confirmed by comparison with an authentic sample prepared from **13** by conventional Hofmann elimination (10). The mass spectrum of **14** shows the $M - 2$ fragment characteristically associated with indolines (dihydroindoles) which can undergo loss of hydrogen to give the corresponding indoles (6, 8). Contrary to earlier report, **14** forms a methiodide (10).

Compound **A**, the most interesting product, was identified as the indole **15**. This formulation is supported by the n.m.r. spectrum, which established *inter alia* the presence of an ethyl group, mass spectrum, and instantaneous positive Ehrlich reaction. Formation of **15** from **13** under analogous conditions was confirmed in a separate experiment.

It is clear that intramolecular addition of the tertiary nitrogen atom to the aryne will compete with other possible internal or external nucleophilic additions in these reactions. The likely fate of the resulting tetrahydrodibenzoindolizinium ion (unless otherwise stabilized) is Hofmann elimination to give the corresponding indoline.[3] The isomeric indole presumably arises from isomerization of the indoline, or of its conjugate base followed by reprotonation, under the reaction conditions though these mechanisms have yet to be distinguished experimentally. There is

[2]M. S. Gibson and G. W. Prenton. Unpublished results.
[3]Available data on the (impure) laureline by-product are consistent with this view.



SCHEME 3

no direct evidence for alternative Hofmann elimination to give a nine-membered ring, but we subscribe to the view that any such process might pass unnoticed owing to protonation and recyclization to the indolizinium ion, *e.g.* during workup (4). Some phenolic indolizinium ions survive potassamide–ammonia treatment (*i.e.* do not undergo Hofmann elimination), as noted above (4, 7).

The indolizinium salt **13** was required during this work, necessitating a reexamination of the reaction of 2-bromotetrahydropapaverine with sodamide in ammonia. This has been reported to yield the desired 5,6,12,12a-tetrahydrodibenzo[*b*,*g*]indolizine together with its product of oxidation, the 5,6-dihydrodibenzo[*b*,*g*]indolizine (6). We were not able to isolate the former compound satisfactorily using the published procedure and have found it expedient to collect the two products together, concentrate the former, and quaternize with methyl iodide to give the indolizinium salt **13**. The relative ease of oxidation of the tetrahydro- to the dihydroindolizines (cf. oxidation of indolines to indoles) is presumably a cause of difficultly reproducible yields in these reactions and *ipso facto* of discrepancies in yields reported in syntheses of 5,6,12,12a - tetrahydrodibenzo[*b*,*g*]indolizinium alkaloids (5, 6).

Experimental

Proton magnetic resonance spectra were recorded on a Varian A-60 spectrometer using tetramethylsilane as internal standard. Mass spectra were determined with an AEI-MS30 double-beam double-focusing mass spectrometer.

Liquid ammonia was distilled from potassium chips prior to use.

2-Bromo-4,5-dimethoxyphenylacetic Acid, 5

The published method (11) was modified as follows. A solution of bromine (4.2 g) in glacial acetic acid (25 ml) was added dropwise to a stirred solution of 3,4-dimethoxyphenylacetic acid (5.0 g) in acetic acid (20 ml) with external cooling in ice water. The resulting slurry was heated at 60 °C for 20 min and then poured into ice water with stirring. The precipitate was filtered off and washed with aqueous sodium bisulfite solution and water. Crystallization from aqueous ethanol (50%) gave the bromo-acid **5** as needles (5.0 g, 71%), m.p. 117–118 °C (lit. (11) m.p. 113–114 °C).

N-(3,4-Dimethoxyphenethyl)-2-bromo-4,5-dimethoxyphenylacetamide, 7

2-Bromo-4,5-dimethoxyphenylacetic acid **5** (5.0 g) was converted to the acid chloride by reaction with $SOCl_2$ (6.5 ml) in dry benzene (20 ml). After removal of excess $SOCl_2$ and benzene *in vacuo*, the acid chloride was dissolved in ether (25 ml) and added during 15 min to a stirred solution of 3,4-dimethoxyphenethylamine **6** (4.3 ml) in ether (70 ml) and 40% (w/v) aqueous NaOH solution (4 ml). The resulting mixture was poured into water (250 ml) with stirring and the p*H* was adjusted to 8–9. The precipitate was filtered off, washed with water, and dried. Crystallization from benzene–ethanol gave the *amide* **7** as needles (6.7 g, 84%), m.p. 161–162 °C.

Anal. Calcd. for $C_{20}H_{24}BrNO_5$: C, 54.80; H, 5.52; N, 3.20 Found: C, 54.86; H, 5.43; N, 3.14.

1-(2-Bromo-4,5-dimethoxybenzyl)-3,4-dihydro-6,7-dimethoxyisoquinolinium Chloride, 8a

A solution of **7** (5.0 g) in dry benzene (11 ml) and freshly distilled $POCl_3$ (7.5 ml) was heated under reflux (steam bath) for 3.5 h under dry nitrogen. Excess $POCl_3$ was destroyed by dropwise addition of anhydrous methanol (35 ml) to the cooled solution until the vigorous reaction subsided, when more methanol (15 ml) was added to ensure completion. After 1 h, the mixture was poured into ether (400 ml) and, after chilling, the precipitate was filtered off, washed with ether, and dried. Crystallization from ether–methanol gave the *iminium chloride* **8a** (4.8 g, 92%) as a hemi-solvate, m.p. 232–234 °C; i.r. (KBr) 1655 cm^{-1} ($\diagdown C{=}\overset{+}{N}-$). Alternative attempts at crystallization resulted in yellowing of the sample.

Anal. Calcd. for $C_{20}H_{23}BrClNO_4 \cdot \frac{1}{2}CH_3OH$: C, 52.07; H, 5.32; N, 2.96. Found: C, 51.76; H, 5.10; N, 3.07.

1-(2-Bromo-4,5-dimethoxybenzyl)-3,4-dihydro-2-methyl-6,7-dimethoxyisoquinolinium Iodide, 9

The iminium chloride **8a** (2.5 g) was shaken with ammonium hydroxide (25 ml, *d* 0.88), water (10 ml), and benzene (100 ml) until the solid disappeared. The benzene layer was separated, washed with water, dried (K_2CO_3), and evaporated. The residual base was dissolved in

methanol (5 ml) and methyl iodide (7 ml) was added. After 48 h, the crystalline *iminium iodide* **9** (3.0 g, 97%) was filtered off. Crystallization from acetonitrile gave pale yellow orthorhombic crystals, m.p. 246–247 °C (dec.); i.r. (KBr) 1630 cm^{-1} ($\diagdown C{=}\overset{+}{N}{-}\diagup$).

Anal. Calcd. for $C_{21}H_{25}BrINO_4$: C, 44.86; H, 4.48; N, 2.49. Found: C, 44.67; H, 4.41; N, 2.45.

1-(2-Bromo-4,5-dimethoxybenzyl)-1,2,3,4-tetrahydro-2-methyl-6,7-dimethoxyisoquinoline [(±)-2-Bromolaudanosine], 10

To a stirred suspension of the iminium iodide **9** (2.5 g) in methanol (125 ml) and water (15 ml) was added $NaBH_4$ (2 g) in very small portions. The yellow color slowly faded. The solution was then stirred for 6 h at room temperature followed by 30 min at reflux. Solvents were evaporated and the residue was treated with water, made basic (NaOH), and extracted with ether. The ether extract was washed, dried (K_2CO_3), and evaporated to give (±)-2-bromolaudanosine **10** (1.5 g, 77%), which crystallized from ethanol as needles, m.p. 122–124 °C identical with a sample (m.p. 123–124 °C) prepared by Dr. G. W. Prenton by brominating (±)-laudanosine.

Anal. Calcd. for $C_{21}H_{26}BrNO_4$: C, 57.80; H, 5.96; Br, 18.18; N, 3.18. Found: C, 57.8; H, 6.1; Br, 18.2; N, 3.3.

Aryne Reaction of 2-Bromolaudanosine, (a), with Potassamide, (b), with Sodamide in Ammonia

(*a*) A solution of (±)-2-bromolaudanosine **10** (4.5 g) in anhydrous tetrahydrofuran (35 ml) was added slowly to a stirred solution of potassamide, prepared from potassium (14 g), in liquid ammonia (300 ml). The resulting reddish-brown mixture was stirred in refluxing ammonia for 6 h and ammonium chloride (35 g) was then added in portions. Ammonia was allowed to evaporate overnight under a stream of nitrogen and the residue was then treated with water (80 ml) and extracted with benzene (total; 800 ml). The benzene extract was washed with water, dried (K_2CO_3), and evaporated to give a dark brown oil which contained at least five components (t.l.c.).

The oil was chromatographed on neutral alumina using benzene as eluant. One component concentrated in the first eluates (totalling 900 ml). Evaporation *in vacuo* gave a pale yellow oil which was dissolved in ethanol (5 ml) and kept overnight to give colorless crystals (0.4 g, 11%) of *5,6-dimethoxy-2-(4,5-dimethoxy-2-ethylphenyl)-1-methylindole*, **15**, m.p. 132–133 °C; n.m.r. ($CDCl_3$) δ 7.11 (s, 1H, aromatic proton), 6.86 (s, 2H, aromatic protons), 6.79 (s, 1H, aromatic proton), 6.32 (s, 1H, aromatic proton), 3.96 (s, 3H, OMe), 3.91 (s, 6H, OMe), 3.82 (s, 3H, OMe), 3.46 (s, 3H, NMe), 2.49 (q, J = 8.0 Hz, 2H, CH_2CH_3), and 1.09 (t, J = 8.0 Hz, 3H, CH_2CH_3); mass spectrum *m/e* 355 (M^+), 340 ($M - CH_3$), 190 ($C_{11}H_{12}NO_2$), 177.5 (M^{2+}), and 165 ($C_{10}H_{13}O_2$); u.v. λ_{max} (methanol) 304 (log ε 4.03) and 220 nm (4.36). Compound **15** gave an immediate violet coloration when treated with a cold solution of *p*-dimethylaminobenzaldehyde in ethanol and HCl (Ehrlich's reagent), and did not form a methiodide when treated with methyl iodide.

Anal. Calcd. for $C_{21}H_{25}NO_4$: C, 70.96; H, 7.09; N, 3.94. Found: C, 71.24; H, 7.37; N, 3.74.

Further elution with benzene–ether (9:1) gave eluates (totalling 700 ml) which were evaporated *in vacuo* to yield a pale yellow oil which crystallized slowly after addition of a few drops of methanol. Recrystallization from methanol gave colorless aggregates (0.1 g, 2.7%) of 5,6-dimethoxy-2-(4,5-dimethoxy-2-vinylphenyl)-1-methylindoline, **14**, m.p. 125–127 °C, identical with a sample prepared as described below; mass spectrum *m/e* 355 (M^+), 353 ($M - 2$), 340 ($M - CH_3$), 338, 324, 312, 310, 201, 192 ($C_{11}H_{14}NO_2$), 180, 177.5 (M^{2+}), 177, 165, 162, 161, 146 and 136; u.v. λ_{max} (methanol) 306 (log ε 3.85) and 258 nm (4.20).

Elution was continued, increasing the proportion of ether in the eluting mixture to benzene–ether (2:1). Evaporation of these eluates *in vacuo* gave a yellow oil which crystallized slowly from methanol (20 ml) to give colorless needles (1.35 g, 35%), m.p. 142–144 °C, of 1-(2-amino-4,5-dimethoxybenzyl)-1,2,3,4-tetrahydro-2-methyl-6,7-dimethoxyisoquinoline, **11**, identical (mixture m.p., t.l.c., i.r. spectrum) with a sample from a previous experiment.

From a previous similar experiment using 2-bromolaudanosine (2.0 g), compound **11** was isolated according to an earlier procedure (9). The product was decolorized (charcoal) and crystallized three times from methanol to give colorless needles (0.3 g, 18%) of **11**, m.p. 144 °C (lit. (9) m.p. 144–145 °C); the i.r. spectrum corresponded with published data.

(*b*) A solution of 2-bromolaudanosine (4.0 g) in anhydrous tetrahydrofuran (35 ml) was added slowly to a stirred solution of sodamide, prepared from sodium (15 g), in liquid ammonia (375 ml). The brown mixture was stirred for 5 h and ammonium chloride (50 g) was then added in portions. The mixture was then worked up as in the foregoing experiment to give a brown oil which contained, as above, at least five components (t.l.c.).

Chromatography (Florisil–benzene) gave, from the first eluates, a pale yellow oil which crystallized slowly after addition of a few drops of ethanol to give the indole **15** (0.08 g, 2.5%), m.p. 132–133 °C, identical with the foregoing sample (mixture m.p., i.r. and u.v. spectra, t.l.c., and Ehrlich reaction).

Further elution (benzene–ether) gave a pale yellow oil which crystallized, as above, from methanol to give the indoline **14** (0.8 g, 25%), m.p. 125–127 °C, identical with a sample prepared as described below.

Next eluted was a small amount of unidentified reddish material, followed (ether as eluant) by **11** (0.3 g, 8%), m.p. 143–145 °C, identical with the foregoing sample (mixture m.p., t.l.c., i.r. spectrum).

1,2,9,10-Tetramethoxyaporphine [(±)-Glaucine], 12

Compound **11** was converted to glaucine **12** as described by Kametani and Noguchi (9) and was characterized as the methiodide (2–3% overall), m.p. 216 °C (lit. (9) m.p. 218–220 °C); mass spectrum *m/e* 370 (M^+), 369 ($M - 1$), 355 ($M - CH_3$), 354, 340, 324, 312, 165, 152, 142 (CH_3I), 128 (HI), and 127 (I). The u.v. spectrum was identical with that reported.

1-(2-Bromo-4,5-dimethoxybenzyl)-1,2,3,4-tetrahydro-6,7-dimethoxyisoquinoline [(±)-2-Bromotetrahydropapaverine]

Sodium borohydride (1.6 g) was added in small portions to a stirred solution of the iminium chloride **8***a* (2.0 g) in methanol (50 ml) and water (7 ml). After 8 h at room temperature followed by 1 h at reflux, solvents were evaporated *in vacuo* and the solid residue was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

treated with water, made basic (NaOH), and the mixture was extracted with ether. The ether solution was washed, dried (K_2CO_3), and evaporated to give 2-bromotetrahydropapaverine as plates (1.7 g, 89%), m.p. 112 °C (lit. (12) m.p. 111 °C). Infrared and n.m.r. data corresponded with those reported.

Aryne Reaction of 2-Bromotetrahydropapaverine: 5,6-Dihydro-2,3,9,10-tetramethoxydibenzo[b,g]indolizine and 5,6,12,12a-Tetrahydro-2,3,9,10-tetramethoxy-7-methyldibenzo[b,g]indolizinium Iodide

(*a*) The published procedure (6) was first followed, but from the complex mixture only the dihydroindolizine (2–5%), m.p. 200–202 °C, could be isolated; none of the desired iodide was obtained when the mixture was treated with methyl iodide.

From a similar experiment with 2-bromotetrahydropapaverine (5.0 g), the crude product was chromatographed on Florisil using benzene and benzene–ether as eluants to give an oil; this was treated with methyl iodide (15 ml) in benzene (5 ml) to give the desired iodide which crystallized from acetonitrile as colorless needles (0.6 g, 10.5%), m.p. 243–245 °C (dec.), identical with the product from the following procedure.

(*b*) A solution of 2-bromotetrahydropapaverine (5.0 g) in dry tetrahydrofuran (45 ml) was added slowly to a stirred solution of potassamide, prepared from potassium (14 g) in liquid ammonia (500 ml). After 5 h, ammonium chloride (35 g) was added and the reaction products were isolated using benzene as in the cases described above. The brown oil thus obtained was chromatographed on Florisil using benzene and benzene–ether (6:1) as eluants and the 5,6-dihydro- and 5,6,12,12a-tetrahydroindolizines were collected together (volume eluted, 900 ml). Evaporation *in vacuo* and crystallization of the pale yellow residue from ethanol gave the 5,6-dihydroindolizine as colorless scales (0.92 g, 23%), m.p. 201–202 °C (lit. (6) m.p. 202–204 °C); the mass spectrum corresponded with that reported. The ethanolic mother liquor was evaporated *in vacuo* and the residue was treated with methyl iodide (15 ml) in benzene (7 ml). The 5,6,12,12*a*-tetrahydroindolizinium iodide, **13**, crystallized from acetonitrile as needles (1.4 g, 25%), m.p. 243–245 °C (dec.) (lit. (6) m.p. 243–245 °C (dec.)); identity was confirmed by mass spectral correlation.

*Formation of 5,6-Dimethoxy-2-(4,5-dimethoxy-2-ethylphenyl)-1-methylindole, **15** from the 5,6,12,12a-Tetrahydroindolizinium Iodide, **13***

Compound **13** (0.5 g) was added to a stirred solution of potassamide, prepared from potassium (2 g), in liquid ammonia (100 ml) and dry tetrahydrofuran (5 ml). After 5.5 h, ammonium chloride (10 g) was added and the mixture was worked up in the normal way to give a brown oil. Thin layer chromatography showed the presence of at least four components, resembling those obtained (with the exception of **11**) from reaction of 2-bromolaudanosine and potassamide under similar conditions. The oil was chromatographed on Florisil using benzene and benzene–ether as eluants. Fractions containing **15** (t.l.c.) were collected and evaporated. Addition of a few drops of ethanol to the pale yellow oil led to the slow crystallization of the indole **15** (20 mg, 5.5%), m.p. 132–133 °C, identical (mixture m.p., t.l.c., and mass spectrum) with the foregoing sample.

5,6-Dimethoxy-2-(4,5-dimethoxy-2-vinylphenyl)-1-methylindoline and -1,1-dimethylindolinium Iodide

The published procedure (10) was modified as follows. Potassium hydroxide (6.0 g) was added to a boiling solution of **13** (0.25 g) in water (21 ml) and the mixture was refluxed for 6 h, cooled, and extracted with ether. The ether solution was washed, dried (K_2CO_3), and evaporated *in vacuo* to give a pale yellow oil which crystallized slowly after addition of a few drops of methanol. Recrystallization from methanol gave the indoline **14** (0.16 g, 87%), m.p. 126–127.5 °C (lit. (10) m.p. 125–126 °C). The indoline produced a violet coloration slowly when heated with Ehrlich's reagent, presumably as a result of conversion to an indole derivative. Identity of the various samples of **14** was established by mixture m.p., t.l.c., and spectral correlations.

Methyl iodide (2.5 ml) was added to a solution of **14** (0.1 g) in benzene (0.75 ml). After 28h at *ca.* 40 °C, the crystalline deposit was collected and crystallized from acetonitrile to give *5,6-dimethoxy-2-(4,5-dimethoxy-2-vinylphenyl)-1,1-dimethylindolinium iodide* as colorless needles (0.13 g, 93%), m.p. 214–215 °C; the mass spectrum showed *m/e* 369 ($M^+ - 1$), 355 ($M^+ - CH_3$), 354, 353, 340, 338, and 326.

Anal. Calcd. for $C_{22}H_{28}INO_4$: C, 53.13; H, 5.67; N, 2.82. Found: C, 53.48; H, 5.57; N, 3.01.

Crystal Structure of $Zn_3V_{0.5}P_{1.5}O_8$

K. Loralee Idler and Crispin Calvo

Department of Chemistry, McMaster University, Hamilton, Ontario L8S 4M1

Received May 26, 1975

K. Loralee Idler and Crispin Calvo. Can. J. Chem. **53**, 3665 (1975).

The stable phase in the $Zn_3(PO_4)_2$–$Zn_3(VO_4)_2$ system near 25 mol% $Zn_3(VO_4)_2$ is monoclinic with space group $C2/c$ and unit cell parameters $a = 15.941(6)$, $b = 5.314(2)$, $c = 8.265(2)$ Å, $\beta = 106.96(3)°$ and $Z = 4$. The structure was refined by full-matrix least-squares methods using 910 reflections, $R = 0.073$. The composition, $Zn_3P_{1.50}V_{0.50(4)}O_8$, was determined by site population analysis with the V and P randomly distributed. One-third of the zinc ions lie on twofold axes and these show an average Zn—O bond length of 1.955 Å while the remaining ZnO_4 group has a mean Zn—O bond length of 1.948 Å. The structure consists of sheets parallel to (100) formed of chains containing rings of corner shared $Zn(1)O_4$ and $(V,P)O_4$ tetrahedra. The $Zn(2)O_4$ groups, in turn, form chains parallel to the b axis through corner sharing.

K. Loralee Idler et Crispin Calvo. Can. J. Chem. **53**, 3665 (1975).

La phase stable dans le système $Zn_3(PO_4)_2$–$Zn_3(VO_4)_2$ près de 25 mol% en $Zn_3(VO_4)_2$ est monoclinique avec un groupe d'espace $C2/c$ et des paramètres de maille de $a = 15.941(6)$, $b = 5.314(2)$, $c = 8.265(2)$ Å, $\beta = 106.96(3)°$ et $Z = 4$. On a affiné la structure par la méthode des moindres carrés (matrice complète) utilisant 910 réflexions. $R = 0.073$. On a déterminé la composition $Zn_3P_{1.50}V_{0.50(4)}O_8$ par une analyse des populations de site avec le V et le P distribués au hazard. Un tiers des ions Zn se trouve sur un axe binaire et pour ceux-ci on trouve une longueur moyenne du lien Zn—O de 1.955 Å alors que le reste des groupes ZnO_4 a une longueur moyenne du lien Zn—O de 1.948 Å. La structure consiste de feuillets parallèles à l'axe 100 formés de chaînes contenant des cycles de tétraèdre $Zn(1)O_4$ et $(V,P)O_4$ dont les sommets sont mis en commun. Les groupes $Zn(2)O_4$ toutefois forment des chaînes parallèles à l'axe b par la mise en commun de sommets.

[Traduit par le journal]

Introduction

In their study of the $Zn_3(PO_4)_2$–$Zn_3(VO_4)_2$ join, Brown and Hummel (1) found a new phase stable between 18 and 28 mol% $Zn_3(VO_4)_2$ and below 835 °C. Below 800 °C only 2 or 3% $Zn_3(VO_4)_2$ dissolves in α-$Zn_3(PO_4)_2$, whereas above this temperature the solubility of the vanadate in the phosphate increases sharply. Previous phase studies involving $Zn_3(PO_4)_2$ and $M_3(PO_4)_2$ (2–4) have shown the intolerance of the α-$Zn_3(PO_4)_2$ structure to the substitution of divalent cations. Since all the cations are tetrahedrally coordinated in this phase (5) this instability could be a result of the octahedral site preference of the added cations. Alternately, Baur and Tillmanns (6) have indicated that the edge shared between ZnO_4 tetrahedra, in violation of Pauling's third rule, might be the source of the instability.

The substitution for the pentavalent ion has not been much investigated. A large number of unique structures, showing $M_3X_2O_8$ stoichiometry with X a tetrahedrally coordinated pentavalent ion and M a divalent ion with an ionic radius less than 1 Å, have been determined. Although isomorphism between the arsenates and vanadates is common, only one structure type, graftonite, has been found among the phosphates and either the vanadates and/or the arsenates. Thus new structure types, at least compared to the end members, would be expected in systems with mixed anions. Uniform coordination numbers for either the M ion or the anion are rare with the $M_3X_2O_8$ stoichiometry. Previous to the present investigation only α-$Zn_3(PO_4)_2$ has shown fourfold coordination for all of the M type ions.

Experiments

Small crystals of $Zn_3P_{1.5}V_{0.5}O_8$ were grown from a melt composed of 44 mol% of $Zn_3P_2O_8$ in $Zn_3V_2O_8$. The melt was slowly cooled from 900 to 750 °C as suggested by the phase diagram (1). A small, very irregularly shaped crystal with dimensions 0.04 × 0.08 × 0.10 mm was used to determine both the unit cell parameters and the diffraction intensities. Fifteen reflections with 2θ values lying between 25 and 30° were accurately centered on a Syntex $P\bar{1}$ automatic diffractometer. Graphite monochromatized MoKα radiation (0.71069 Å) was used. The crystal data at 21 °C are as follows:

*The expression for the temperature factor is $\exp[-2\pi^2 10^{-4}(U_{11}h^2b_1^2 + \ldots + 2U_{12}hk\,b_1b_2 + \ldots)]$ and the b_i's are reciprocal lattice parameters.
†X = 0.25(2)V + 0.75P.

$Zn_3P_{1.5}V_{0.5}O_8$ f.w. = 396.04

Monoclinic, $a = 15.941(6)$, $b = 5.314(2)$, $c = 8.265(2)$ Å, $\beta = 106.96(3)°$, $V = 669.59$ Å^3, $Z = 4$, $D_x = 3.92$ g cm^{-3}. Space group $C2/c$. Systematic absences: $h + k$ odd in general, $h0l$ with l odd.

The density was not measured because the sample was not uniform and a sufficient number of crystals could not be extracted. Intensity data, using a $\theta/2\theta$ scan, were collected with a sphere defined by $2\theta \leq 60°$. The background was measured at either side of the peak and used to determine the intensity measure. Those data with $I > 0$, 910 in number, were used in this refinement. All the data were corrected for Lorentz and polarization effects. Absorption corrections were applied assuming an idealized crystal shape.

A trial structure with Zn(1) on the twofold axes, was derived from the Patterson function. This model was refined by full-matrix least-squares methods. Atomic scattering factors for Zn^{2+}, V^{5+}, P, and O were obtained from Cromer and Waber (7). Anomalous-scattering corrections were applied (8).

The ratio of V-to-P was determined using the program RFINE (9) assuming the site to be fully occupied. Extinction corrections were applied as suggested by Larson (10). Weights were set equal to $(10.7 + 0.073F_o + 0.0005F_o^2 + 3500(\sigma(F_o)/F_o)^2$ with the coefficients for the observed structure factors, F_o, chosen so that the difference between the observed and calculated structure factors would be independent of the structure factor. The refinement was terminated when the calculated shifts were less than $1/4\sigma$. The R value was 0.073 and

$$R_w = \{\Sigma\omega|F_o - F_c|^2/\Sigma\omega|F_o|^2\}^{1/2} = 0.056$$

The final atomic and thermal parameters are in Table 1.[1]

Description of the Structure

All the cations are coordinated to four oxygen atoms which lie at the corners of a distorted tetrahedron. The Zn(I)O_4 and XO_4 groups are linked, each at two corners, into four-membered rings about the centers of symmetry (Fig. 1). These rings form chains generated by translational symmetry along a and the twofold axis through Zn(1). Adjacent chains are linked by Zn(2) which shares O(4) and O(4)′. The Zn(2)O_4 groups form chains with adjacent tetrahedra and are generated by the twofold screw axes. Each oxygen of this group is shared with a separate XO_4 group.

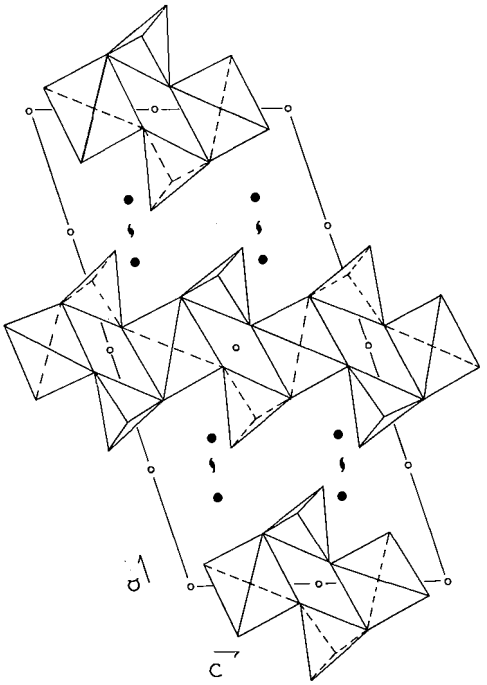

FIG. 1. The structure of $Zn_3V_{1/2}P_{3/2}O_8$ viewed down the b axis. The Zn(1)O_4 and PO_4 tetrahedra are outlined. The Zn(2) ions are indicated as filled circles.

The average X—O bond length is 1.575 Å (Table 2). If Vegard's law is assumed valid the composition weighted mean of the ⟨P—O⟩ (1.537 Å) and ⟨V—O⟩ (1.721 Å) (11) for tetrahedral coordination predicts a value of 1.583 Å for ⟨X—O⟩. The individual X—O bonds faithfully reflect the environments of the oxygen atoms. O(2) and O(3) are both shared between X and only one Zn ion and their X—O bond lengths are shorter than those involving O(1) and O(4) in which each is shared with two

Zn(2)—O(1)	1.960(7)	O(1)—Zn(2)—O(2)	114.7(3)	O(2)—Zn(2)—O(4)	102.2(2)
—O(2)	1.911(6)	—O(4)	111.3(3)	—O(4)′	113.6(2)
—O(4)	1.976(5)	—O(4)′	103.7(3)	O(4)—Zn(2)—O(4)′	111.6(2)
—O(4)′	1.948(6)				
X—O(1)	1.593(8)	O(1)—X—O(2)	109.6(5)	O(2)—X—O(3)	115.7(5)
—O(2)	1.541(8)	—O(3)	108.1(4)	—O(4)	107.8(4)
—O(3)	1.539(9)	—O(4)	106.2(4)	O(3)—X—O(4)	108.9(5)
—O(4)	1.626(5)				

Zn ions. Further, the average Zn—O(1) bond is longer than the average Zn—O(4) bond leading to X—O(4) > X—O(1). A parallel situation exists for O(1) and O(3) but the bond lengths involved are not significantly different. The major angular distortion of the XO_4 group involves a large O(1)—X—O(3) bond angle reflecting an enhanced repulsion between the oxygen atoms arising from the short X—O bond lengths.

Both ZnO_4 groups show a large range of O—Zn—O angles showing that the $Zn(1)O_4$ tetrahedron is distorted by a displacement of Zn ions towards the O(1)—O(1)′ edge. The O(*n*)—Zn(1)—O(*n*)′ angle is 116.6° for $n = 3$ and 104.6° for $n = 1$. The O(3)—O(3)′ and O(1)—O(1)′ edges are twisted about the twofold axis so as to subtend an angle deviating by 10° from the orthogonality required for a regular tetrahedron. The distortion of the $Zn(2)O_4$ group is smaller since the range of bond angles and the bond lengths is smaller than for the $Zn(1)O_4$ group. The mean Zn(*N*)—O bond lengths, at 1.955 and 1.948 Å for $N = 1$ and 2, respectively, are hardly significantly different, although the former cation has six neighboring cations and the latter has only five.

Discussion

The present structure has all the cations tetrahedrally coordinated as in the case in α-$Zn_3(PO_4)_2$. The unit cell parameters of the latter are $a = 8.196, b = 5.634, c = 15.007$ Å, $\beta = 105.0°$, $Z = 4$ and space group $C2/c$ (5). Its structure consists of interconnected $Zn(1)O_4$ and PO_4 groups forming sheets generated by the twofold screw axes at the 1/4,1/4 and 1/4,3/4 (Fig. 2). These $Zn(1)O_4$ groups lie on twofold axes and the $Zn(2)O_4$ groups lie in general positions but share an edge across centers of symmetry. The glide planes related adjacent sheets in α-$Zn_3(PO_4)_2$ and, in contrast, groups within a sheet in the present structure. The ⟨Zn—O⟩ distance is 1.956 Å in α-$Zn_3(PO_4)_2$ and 1.950 Å in the present case.

The role of the added cations in destabilizing the α-$Zn_3P_2O_8$ structure may lie in finding an alternative to the shared edges between the divalent cations of type 2, as has been previously suggested (6). This would be expected particularly if cation substitution increasingly generates cation pairs of different types in the sites that share this edge. The alternative structure possibilities, β-$Zn_3P_2O_8$ and γ-$Zn_3P_2O_8$, both have all the anions shared with three cations provided all bonds less than 2.55 Å are counted as being in the primary coordination sphere of the divalent cations. In α-$Zn_3P_2O_8$ and the present struc-

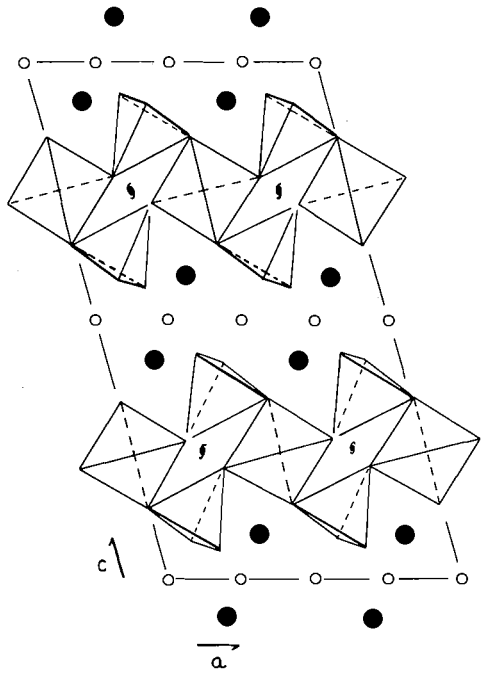

FIG. 2. The structure of α-$Zn_3P_2O_8$ viewed down the *b* axis. The $Zn(1)O_4$ and PO_4 tetrahedra are outlined. The Zn(2) ions are indicated as filled circles.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

ture the average coordination number of the anion is 2.5. Thus there seems to be some preference for tetrahedral Zn at low temperatures for these compositions.

The role of the added vanadium is even less apparent and very little further can be said. The XO_4 tetrahedra in α-$Zn_3(PO_4)_2$ and the present structure show similar angular distortions from ideality. This follows if the Zn on the twofold axes and further the oxygen atoms shared by the same number of cations are considered equivalent. Thus, the angle subtended at the phosphorus atom by those oxygen atoms bonded to only one Zn and one P atom is 115.4(3)° in α-$Zn_3(PO_4)_2$ (5*b*) compared with 115.7(5)° in the present structure. However, the distortion of the zinc ion site at the twofold axis is entirely different. In α-$Zn_3P_2O_8$ the edge O(1)—O(1)′, where the oxygen atoms are threefold coordinated, subtends an O(1)—Zn(1)—O(1) angle of 102° whereas the O(4)—O(4)′ edge involving twofold coordinated oxygen atoms shows an angle of 130° at the zinc ion. The distortions are opposite in the present structure. The substitution of vanadium for phosphorus in α-$Zn_3(PO_4)_2$, assuming just a radial distortion of the XO_4, would cause the two O(*n*)—Zn—O(*n*)′, $n = 1$ and 3, to become more nearly identical, thus pushing the structure in the correct direction. However, this assumes that all the other features are maintained constant.

Reactions of Sodium Tetrahydroborate and Cyanotrihydroborate with Rhodium(I), (II), and (III) Systems in the Presence of Tertiary Phosphines

DAVID G. HOLAH, ALAN N. HUGHES, AND BENJAMIN C. HUI
Department of Chemistry, Lakehead University, Thunder Bay, Ontario P7B 5E1
Received June 6, 1975

DAVID G. HOLAH, ALAN N. HUGHES, and BENJAMIN C. HUI. Can. J. Chem. **53**, 3669 (1975).

The nitrogen atmosphere reactions of phosphine – Rh(I), Rh(II), and Rh(III) chloride systems with $NaBH_4$ and $NaBH_3CN$ and also similar reactions of $[RhCl(CO)_2]_2$ in the presence of phosphines are reported. Among the interesting products formed in the various reactions are hydrido, tetrahydroborato, hydrido–tetrahydroborato and hydrido–cyanotrihydroborato complexes such as the highly unstable Rh(I) species $Rh(BH_4)(PPh_3)_2$, the much more stable Rh(II) complex $RhH(BH_4)(o\text{-tolyl}_3P)$, the Rh(III)–5-phenyl-5*H*-dibenzophosphole (DBP) complex $RhH_2Cl(DBP)_3$, and the Rh(III) complex $RhH_2(BH_3CN)(PPh_3)_3$. Complexes of Rh(I) with BH_3CN and additional CO and N_2 ligands are also reported. These results are briefly discussed in the context of the previously proposed mechanism for the reaction of tetrahydroborate ion with Co, Ni, and Cu halides in the presence of phosphine ligands.

DAVID G. HOLAH, ALAN N. HUGHES et BENJAMIN C. HUI. Can. J. Chem. **53**, 3669 (1975).

On rapporte les réactions, sous atmosphère d'azote, des systèmes phosphine/chlorure de Rh(I), Rh(II) et Rh(III) avec $NaBH_4$ et $NaBH_3CN$ et d'autres réactions similaires du $[RhCl(CO)_2]_2$ en présence de phosphine. Parmi les produits intéressants formés dans les diverses réactions on retrouve des complexes hydrido, tétrahydroborato, hydrido tétrahydroborato et hydrido cyanotrihydroborato telle que l'espèce très instable du Rh(I), $Rh(BH_4)(PPh_3)_2$, le complexe beaucoup plus stable du Rh(II), $RhH(BH_4)(o\text{-tolyl}_3P)$, le complexe Rh(III) phényl-5 (5H) dibenzophosphole (DBP), $RhH_2Cl(DBP)_3$, et le complexe du Rh(III), $RhH_2(BH_3CN)(PPh_3)_3$. On rapporte aussi les complexes de Rh(I) avec BH_3CN et des ligands CO et N_2 additionnels. On discute de ces résultats dans le contexte du mécanisme proposé antérieurement pour la réaction de l'ion tétrahydroborate avec les halogénures de Co, Ni et Cu en présence de ligands de phosphine.

[Traduit par le journal]

Introduction

Recently we have reported (1–3) that solutions of divalent metal compounds, in the presence of stabilizing ligands, can be reduced in a stepwise manner by $NaBH_4$ to give a variety of thermodynamically stable complexes, including some with coordinated tetrahydroborate groupings. In particular, a series of univalent metal complexes such as $MClL_3$ (where M = Co or Ni, L = PPh_3), $M(BH_4)L_3$ (M = Co or Ni), $Cu(BH_4)L_2$, the related $M(BH_3CN)L_2$ (M = Ni or Cu), and $M(BH_3CN)L_4$ (M = Co; L = DBP or ½(diphos)) can be synthesized by carefully controlling reaction conditions.

In this paper we report an extension of this work to similar reactions involving rhodium(I), (II), and (III) systems. Relatively few tetrahydroborato complexes of rhodium are known. For example, the active homogeneous hydrogenation catalyst $RhCl_2(BH_4)(py)_2(dmf)$ (4) (py = pyridine, dmf = dimethylformamide), which may be prepared by the reaction of $NaBH_4$ on $RhCl_3(py)_3$ in dmf (4, 5), is interesting in that it contains neither carbonyl nor phosphine ligands, unlike all other reported rhodium (or iridium) tetrahydroborato and cyanotrihydroborato complexes. Thus, the complexes $M(BH_4)(CO)L_2$ and $M(BH_3CN)(CO)L_2$ have been prepared (6, 7) by the reaction of $NaBH_4$ or $NaBH_3CN$ on the compounds $MX(CO)L_2$ (M = Rh or Ir, X = Cl or ClO_4, and L = PPh_3, $P(C_6H_{11})_3$, $P[(CH_3)_3SiCH_2]_3$). Infrared spectra (6, 7) strongly indicate a bidentate BH_4 structure for the $M(BH_4)(CO)L_2$ complexes, while the BH_3CN in $M(BH_3CN)(CO)L_2$ is *N*-bonded to the metal, as in the case of similar Cu and Co complexes (3). The same workers (6) have also found that the nature of the product depends largely upon the metal and the phosphine ligand. For example, sometimes only hydrido complexes are obtained.

Results and Discussion

Sodium tetrahydroborate and cyanotrihydroborate react with $RhCl_3$ in the presence of phosphine ligands, with various Rh(I), (II), and (III)

phosphine complexes and with Rh(I) carbonyl complexes in the presence of phosphine ligands under an N_2 atmosphere to yield hydrido, tetrahydroborato, or cyanotrihydroborato complexes. These results are presented and discussed below.

Reactions of $RhCl_3.3H_2O$ with $NaBH_4$ and $NaBH_3CN$ in the Presence of a Ligand

The reaction of $RhCl_3.3H_2O$ in ethanol with a sixfold excess of PPh_3 and $NaBH_4$ at room temperature does not produce any tetrahydroborato complex, and only $RhH(PPh_3)_4$ (8) can be isolated. $NaBH_3CN$ also reacts readily with a mixture of $RhCl_3$ and PPh_3 to give a yellow solution, but we have been unable to isolate any characterizable product from this reaction. Other ligands such as DBP[1] and $AsPh_3$ (in 6 molar ratio) also fail to form tetrahydroborato complexes. Thus, with DBP, the known (9) homogeneous hydrogenation catalyst $RhH(DBP)_4$ forms while with $AsPh_3$, only $RhH_2Cl(AsPh_3)_2$ (10) can be isolated. Presumably the great differences in the nature of the products obtained from the DBP and $AsPh_3$ reactions are due to the fact that DBP complexes with $RhCl_3$ only slowly and it is the free $RhCl_3$ which is reacting with $NaBH_4$ whereas in the case of $AsPh_3$, complex formation is rapid and it is an Rh(III)–arsine complex which is reacting with $NaBH_4$.

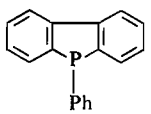
Reactions of Rh(I), Rh(II), and Rh(III) Phosphine Complexes

Treatment of $RhCl(PPh_3)_3$ (11) in the presence of some free phosphine (3–6 mol) with $NaBH_4$ in EtOH again yields only the hydrido–tetrakisphosphine complex as in the reaction with $RhCl_3$ in the presence of PPh_3. However, it has been observed (7) that an excess of phosphine in the reactions involving $NaBH_4$ and phosphine–metal complexes tends to lead to the formation of hydrido complexes. Several (mainly unsuccessful) attempts have therefore been made to prepare tetrahydroborato complexes of Rh(I) (*e.g.* $Rh(BH_4)(PPh_3)_3$, the Rh(I) analog of the known Co(I) complex $Co(BH_4)(PPh_3)_3$ (3)) by using $RhCl(PPh_3)_3$ alone as starting material. For example, with no added PPh_3, in EtOH, THF/EtOH or C_6H_6/EtOH, $RhCl(PPh_3)_3$ reacts with $NaBH_4$ (1 mol or a large excess) to produce only the known (8) orange $RhH(PPh_3)_3$. However, that this reaction goes through an intermediate complex which contains a BH_4 ligand is clear since such a complex can be isolated by decreasing the reaction time although the conditions required for this appear to be critical. Thus, if after adding $NaBH_4$ to $RhCl(PPh_3)_3$ in C_6H_6/EtOH and stirring for 5 min the solution is concentrated, addition of EtOH immediately precipitates a yellow complex which analyzes very well for $Rh(BH_4)(PPh_3)_2$ (Table 1). The infrared spectrum of this compound is compatible with the proposed structure since it has bands at 2410 and 2382 cm^{-1} assignable to the stretching frequencies of the terminal B—H bonds (see ref. 3 for a discussion of the i.r. spectra of BH_4 complexes) and a band at 1890 cm^{-1} probably due to the ring breathing mode of Rh—H_2—B. However, this tetrahydroborato complex is extremely air sensitive (ignites in air) and must also be very unstable in solution since as already mentioned, prolonging the reaction time leads only to the formation of $RhH(PPh_3)_3$ even when only 1 mol of $NaBH_4$ is used. It has therefore been impossible to characterize this adduct more fully, and, indeed, it is extremely difficult to duplicate the reaction.

Turning to cyanotrihydroborate reactions with $RhCl(PPh_3)_3$, $NaBH_3CN$ reacts readily with this Rh(I) complex in 1:1 C_6H_6/EtOH solution to produce the pale yellow Rh(III) *N*-bonded complex $RhH_2(BH_3CN)(PPh_3)_3$ which presumably is formed by the oxidative addition of hydrogen to an intermediate Rh(I)–BH_3CN species. Such additions of H_2 or N_2 to Rh(I) complexes are relatively common and they occur spontaneously in solution. In this connection, we have also noted previously (3) that similar complexes of Co(I) readily form dinitrogen complexes. It is possible that these additions are dictated by steric requirements of the various ligands.

The infrared spectrum of this compound (see Table 1) shows the expected bands at 2048 and 2060 cm^{-1} corresponding to the Rh—H stretching frequencies for the *cis* dihydride structure which would be anticipated from oxidative H_2 addition. Furthermore, the cyanotrihydroborate grouping shows bands at 2260 and 2328 cm^{-1}

[1]DBP is the cyclic phosphine, 5-phenyl-5*H*-dibenzophosphole which is a somewhat more rigid, flattened version of PPh_3.



DBP

(ν_{B-H}) and at 2207 cm^{-1} ($\nu_{C\equiv N}$) indicative of an *N*-bonded BH_3CN grouping (3, 6). For comparison with this and other compounds reported in this paper, i.r. data for some of the related known Rh complexes are also listed in Table 1. Unfortunately, it was not possible to identify the Rh—H protons in the high-field n.m.r. spectrum since $RhH_2(BH_3CN)(PPh_3)_3$ decomposes immediately by eliminating a gas (presumably molecular hydrogen) on dissolving in suitable n.m.r. solvents such as benzene or chloroform. Such decompositions of Rh(III) hydrides are well known (12).

Regarding reactions of Rh(II) complexes, the paramagnetic, bluish-green, square planar Rh(II) complex of tri-*o*-tolylphosphine, $RhCl_2(o\text{-tolyl}_3P)_2$ (13), reacts with $NaBH_4$ in benzene/ethanol solution to yield a dark pyrophoric solid. The infrared spectrum of this compound shows the presence of phosphine ligands and a broad band at ~1970 cm^{-1}, indicative of a hydrido species. Reproducible chemical analyses have not so far been obtained because of the extreme oxygen sensitivity of the compound and this species is presently under further investigation. However, a stable Rh(II)–tetrahydroborato complex with tri-*o*-tolylphosphine can be obtained if the $NaBH_4$ reaction with $RhCl_2(o\text{-tolyl}_3P)_2$ described above is carried out in ethanol solution in the presence of an excess of the free ligand. Thus, addition of an excess of $NaBH_4$ to a suspension of $RhCl_2(o\text{-tolyl}_3P)_2$ and 1 mol of $o\text{-tolyl}_3P$ in ethanol precipitates a greenish-brown solid. The compound analyzed well for $RhH(BH_4)(o\text{-tolyl}_3P)$ and appears to have some degree of stability in air over short periods. If no free ligand is present in the reaction mixture only impure adduct can be obtained.

Again, the i.r. spectrum is consistent with the proposed formula as it shows bands at 2425, 2380, and 1148 cm^{-1} corresponding to the stretching and bending modes of the terminal B—H bonds. Bands at 1966 and 1850 cm^{-1} probably correspond to bonding of the type Rh—H—B, while the weak absorption at 2135 cm^{-1} is associated with the Rh—H stretch.

Although the analytical results, the method of preparation and the infrared spectrum strongly indicate that the complex is $RhH(BH_4)(o\text{-tolyl}_3P)$, they do not by themselves exclude the possibility that $RhCl_2(o\text{-tolyl}_3P)_2$ is reduced to an Rh(I) tetrahydroborato species to which oxidative addition of H_2 occurs to give the Rh(III) complex $RhH_2(BH_4)(o\text{-tolyl}_3P)$. Neither do they exclude the possibility that, in an intermediate Rh(I)–BH_4–$o\text{-tolyl}_3P$ complex, internal metalation by insertion of an Rh atom into a CH_3 group occurs to give $RhH(BH_4)[CH_2C_6H_4P(o\text{-tolyl})_2]$ in which the resulting Rh(III) atom is coordinated by phosphorus, hydride, tetrahydroborate and a methylene group and in which the hydride group is derived from one of the methyl groups.[2] If the former (H_2 addition to Rh(I)) were to occur, analytical data would remain essentially unchanged and the metal hydride peak at 2135 cm^{-1} in the i.r. spectrum of the adduct is sufficiently broad to be an unresolved doublet similar to the doublet observed for $RhH_2(BH_3CN)(PPh_3)_3$ (Table 1). If the latter (internal metalation) were to occur, again the analytical data would remain unchanged and only one metal hydride i.r. absorption would be expected. However, such reactions would be unlikely in that they would almost certainly proceed via an Rh(I) chloro species in the presence of an excess of the phosphine and, as we have seen in the preceding section, the Rh(I) chloro compound $RhCl(PPh_3)_3$ yields with $NaBH_4$ only the Rh(I) complexes $Rh(BH_4)(PPh_3)_2$, $RhH(PPh_3)_3$, or $RhH(PPh_3)_4$ depending upon the reaction conditions.

That the adduct obtained by treatment of $RhCl_2(o\text{-tolyl}_3P)_2$ is indeed the Rh(II) complex $RhH(BH_4)(o\text{-tolyl}_3P)$ is clearly confirmed by n.m.r. spectroscopic studies. For example, the spectrum in dichloromethane solution shows a single Rh—H signal as a doublet centered on 30.0 τ with a coupling constant of 27 Hz indicative of a *cis* J_{P-H} arrangement. The peaks of the doublet are slightly broadened and this is presumably due to a small unresolved coupling with the BH_4 protons and/or the Rh atom. The methyl groups appear initially in the n.m.r. spectrum as three broadened peaks of unequal area at 7.61 τ (low intensity), 7.73 τ (medium intensity), and 7.82 τ (slightly higher intensity). This suggests possibly nonequivalence of the methyl groups and perhaps some coupling with the phosphorus atom. Nonequivalence could conceivably arise from π back-donation from the rhodium atom to the phosphorus atom thereby inhibiting rotation about the Rh—P bond. Al-

[2]We are indebted to a referee for this suggestion.

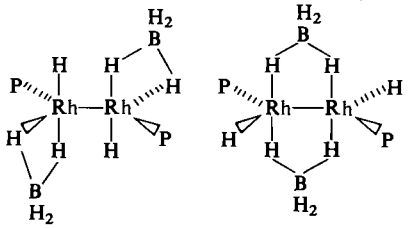
For personal use only.

ternatively, it could be simply a steric inhibition of rotation or a weak interaction of one methyl group with the rhodium atom. On the other hand, the signal multiplicity could arise from superimposed methyl and nonequivalent methylene signals of $RhH(BH_4)[CH_2C_6H_4P(o\text{-tolyl})_2]$.

No other signals occur in the range 7.80–40.00 τ. This shows that only one metal hydride grouping is present and therefore excludes the structure $RhH_2(BH_4)(o\text{-tolyl}_3P)$. If the spectrum is recorded in deuterated dichloromethane, careful integration over several samples of the aromatic and methyl regions of the spectrum shows a ratio of 12 aromatic protons to 8.9 methyl protons. This eliminates the possibility that internal metalation has occurred to give $RhH(BH_4)[CH_2C_6H_4P(o\text{-tolyl})_2]$, since this would require a ratio of 12 aromatic to 8 methyl and methylene protons.

The n.m.r. measurements must be carried out immediately on very freshly prepared solutions under a nitrogen atmosphere since fairly rapid decomposition of the adduct occurs in solution. This decomposition is reflected in the spectrum in which the Rh—H doublet broadens and becomes more complex before finally disappearing altogether after about 3 h. Also, during the decomposition, the methyl signal modifies to become a strong doublet (J = 8 Hz) at 7.61 τ and 7.75 τ with a weak doublet (J = 13 Hz) at 7.67 τ and 7.89 τ superimposed. This suggests the formation of at least two products during decomposition. The peak at 7.61 τ of this strong doublet in the decomposed solution coincides in location with the weak peak at 7.61 τ in freshly prepared solutions and indicates that even in the very fresh solutions, a small amount of decomposition had already occurred.

Magnetic measurements show that in contrast to the paramagnetic starting material, the adduct $RhH(BH_4)(o\text{-tolyl}_3P)$ is diamagnetic. It is therefore probable that $RhH(BH_4)(o\text{-tolyl}_3P)$ is dimeric with a strong Rh–Rh interaction although the solution instability precluded molecular weight measurements. This is not unexpected since although $RhCl_2(o\text{-tolyl}_3P)_2$ (13) and $RhCl_2(PBu^t{}_2R)_2$ (R = Me, Et, or Pr^n) (14) are monomeric and paramagnetic, the binuclear carboxylates $[Rh(OOCR)_2L]_2$ (L = H_2O, MeOH, or PPh_3) (15) and the Rh_2^{4+} ion (16) are dimeric and diamagnetic. This suggests that the complex $RhH(BH_4)(o\text{-tolyl}_3P)$ may have one of the following possible structures:



In either case, the metal hydride protons are equivalent and *cis* to the phosphine ligand as suggested by the n.m.r. spectrum although it should be noted that tetrahydroborato bridged complexes of the second type above appear not to have been previously reported.

This Rh(II) complex is interesting in that virtually all other known tetrahydroborato complexes of rhodium contain carbonyl and tertiary phosphine ligands (6, 7), except for the previously mentioned Rh(III) complex (4) which is stabilized by pyridine and the highly unstable and not fully characterized Rh(I) complex $Rh(BH_4)(PPh_3)_2$ reported in this paper. No identifiable product could be obtained from reactions of the Rh(II) complex with $NaBH_3CN$.

In reactions of Rh(III) phosphine complexes with tetrahydroborate and cyanotrihydroborate no Rh(III)–BH_4 or Rh(III)–BH_3CN complexes could be obtained. For example, the reaction of $RhCl_3(DBP)_3$ (17) with $NaBH_4$ proceeds readily in C_6H_6/ethanol and, when an excess of reducing agent is used, only $RhH_2Cl(DBP)_3$ can be obtained as a brown solid. Again the n.m.r. spectrum at high field does not show the presence of the metal hydrogen bonds since the complex shows the typical solution instability of Rh(III) hydrides and elimination of molecular hydrogen occurs on dissolution. The infrared spectrum of this compound, however, has broad bands at $\sim$1970 cm^{-1} possibly due to poor resolution of two metal–hydride stretching frequencies.

There are apparently two possible mechanisms for this reaction. Thus, a two-step replacement of two chlorine atoms on an Rh(III) atom may occur or it is possible that in this reaction, Rh(III) is reduced to Rh(I) which undergoes oxidative-addition of H_2 of the type observed in the case of the reaction of $RhCl(PPh_3)_3$ with $NaBH_3CN$. For reasons to be given later in this paper, we prefer the first of these mechanisms. On the other hand, the Rh(III) dibenzophos-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

phole complex is reduced by cyanotrihydroborate in C_6H_6/EtOH, to give a compound analyzing quite well for the Rh(I) species $Rh(BH_3CN)(N_2)(CO)(DBP)_3$. The infrared spectrum of this complex is virtually identical with that of $Rh(BH_3CN)(CO)(DBP)_3$ which may be prepared from $[RhCl(CO)_2]_2$ solution (see next section), except for the intense N_2 stretching frequency which occurs at 2108 cm^{-1} in the i.r. spectrum of the complex tentatively formulated as $Rh(BH_3CN)(N_2)(CO)(DBP)_3$ and also a small ($\sim$10 cm^{-1}) shift of the CO frequency to higher wave number compatible with competition in π back-donation from the Rh atom between coordinated N_2 and CO. Again, it is probably due to the steric and electronic requirements of both DBP and BH_3CN that both abstraction of CO from ethanol and coordination of dinitrogen occur. Repetition of this reaction under argon gave a crude product which formed an oil on treatment with dry solvents and which could not be characterized.

Reactions of $[RhCl(CO)_2]_2$ with $NaBH_4$ and $NaBH_3CN$ in the Presence of DBP

Addition of DBP in a 3:1 ratio to $[RhCl(CO)_2]_2$ (18) in ethanolic solution followed by an excess of $NaBH_4$ produces the hydrido complex $RhH(CO)(DBP)_3$, which cannot be made by the general method of adding $NaBH_4$ to $RhCl(CO)_2(DBP)$ in the presence of an excess of DBP in boiling ethanol (9). The n.m.r. spectrum of this complex in benzene shows the hydrogen bound to rhodium as a sharp quartet (1:3:3:1) of doublets with J_{P-H} = 14 Hz and J_{Rh-H} = 2.5 Hz centered at 19.05 τ. This pattern can be ascribed to a trigonal bipyramidal structure with the hydride and CO in the apical positions, *i.e.* an arrangement in which the three phosphorous atoms are magnetically equivalent and which would produce coupling constants of the magnitude observed. The sharpness of the peaks in the spectrum suggests that very little dissociation of the phosphine ligands occurs and, in this respect, the complex behaves quite differently from the analogous PPh_3 compound $RhH(CO)(PPh_3)_3$. This PPh_3 complex has been reported (19) to dissociate extensively at room temperature and the n.m.r. spectrum shows a broad metal hydride band at 19.27 τ. However, on cooling a solution of $RhH(CO)(PPh_3)_3$ to -30 °C, a similar quartet of doublets can be observed at 19.69 τ (19).

A similar reaction with $NaBH_3CN$ gives the five-coordinated $Rh(BH_3CN)(CO)(DBP)_3$ which shows bands in the i.r. spectrum assignable to ν_{B-H} (2340 cm^{-1}), ν_{CN} (2188 and 2202 cm^{-1}), and ν_{CO} (1984 cm^{-1}). Undoubtedly the compound can readily pick up dinitrogen to form $Rh(BH_3CN)(N_2)(CO)(DBP)_3$ (see previous discussion) as the i.r. spectrum also shows a weak band at 2108 cm^{-1} probably due to $\nu_{N\equiv N}$. The analogous four-coordinate species $Rh(BH_3CN)(CO)(PPh_3)_2$ has been synthesized (6) and the infrared spectrum is similar to that of the five-coordinate DBP complex (Table 1).

In summary, clearly the reactions of phosphine – Rh(I) chloride complexes with $NaBH_4$ follow in broad outline the mechanism proposed earlier (3) for the later stages of the similar reduction of divalent 3*d* metal halides with $NaBH_4$ in the presence of phosphines. The resulting unstable and highly air sensitive Rh(I)–BH_4 complex is considerably less stable than the corresponding Co(I) and Ni(I) complexes. This mechanism also appears to be the case in reactions of phosphine – Rh(I) chloride complexes with $NaBH_3CN$.

Rh(II) and Rh(III) appear generally to be stabilized by a complexing phosphine ligand and this supposition is supported by similar studies on ruthenium systems to be reported in a later paper. However, there are two possible mechanisms (discussed earlier) whereby some of the Rh(III) dihydrides may be formed from Rh(III) chloride complexes although, on the basis of the results discussed in this paper and results obtained with related ruthenium systems, we feel that these dihydrides arise from direct replacement of chloro groups by hydrido groups.

If this is the case, there is one anomaly in that reduction of $RhCl_3(DBP)_3$ with the milder reducing agent $NaBH_3CN$ leads to the Rh(I) complex $Rh(BH_3CN)(N_2)(CO)(DBP)_3$. This may, however, be explained by postulating an intermediate Rh(III) dihydro species such as $RhH_2(BH_3CN)(DBP)_2$ which, because of the known instability of Rh(III) hydrides (particularly in solution) mentioned earlier and possibly also steric requirements of the ligands, undergoes exchange of dihydrogen for molecular nitrogen.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Some support for this comes from the fact that although the i.r. spectrum of $Rh(BH_3CN)(N_2)(CO)(DBP)_3$ is virtually identical (apart from the N_2 peak) with that of the nitrogen free adduct $Rh(BH_3CN)(CO)(DBP)_3$ prepared by a different method, there is an additional very small but very sharp peak at 2132 cm^{-1} indicative of the presence of small amounts of an Rh(III) hydride and this indicates (as does the N analysis) that the H_2–N_2 exchange is not quite complete.

It is therefore clear that the question of platinum group metal halide reactions in the presence of phosphines and $NaBH_4$ or $NaBH_3CN$ requires further extensive study. In particular, it would seem desirable to extend the investigation to ruthenium systems and our studies in this area will form the subject of a later paper.

Experimental

Materials

DBP (20), $RhCl(PPh_3)_3$ (11), $[RhCl(CO)_2]_2$ (18), $RhCl_3(DBP)_3$ (17), and $RhCl_2(o\text{-tolyl}_3P)_2$ (13) were prepared as described in the literature. Rhodium trichloride hydrate was obtained from Engelhard Industries and $NaBH_4$, $NaBD_4$, and $NaBH_3CN$ were obtained from the Ventron Corporation. Triphenylphosphine was recrystallized from ethanol prior to use while other compounds were of reagent grade and were used without further purification. All solvents were purified in the usual manner, degassed, and stored over molecular sieves (type 4A).

Physical Measurements

All physical measurements were carried out as previously described (21). Nuclear magnetic resonance measurements were carried out on a Varian A60-A spectrometer using benzene or dichloromethane as solvent at room temperature. Chemical shifts were determined using the solvent itself as internal reference, calibration being made using the known complex $RhH(CO)(PPh_3)_3$ (19) as standard.

Syntheses

The general procedure was as previously described (3) with all reactions being carried out under strict nitrogen atmosphere conditions. Analytical and spectral data are given in Table 1. Yields were normally in the range 50–70%.

$Rh(BH_4)(PPh_3)_2$

$RhCl(PPh_3)_3$ (~0.2 g) was suspended in 2:1 benzene/ethanol mixture (~15 ml), and an excess of $NaBH_4$ (~0.1 g) suspended in ethanol (~5 ml) was added dropwise. The solution became clear reddish-brown. After 5 min, the solvent volume was greatly decreased under reduced pressure and ethanol (~10 ml) was added. The residual yellow solid was separated by filtration. The product was then washed successively with ethanol, water, ethanol, and *n*-hexane.

$RhH_2(BH_3CN)(PPh_3)_3$

An excess of $NaBH_3CN$ (~0.1 g) in ethanol (~5 ml) was added to $RhCl(PPh_3)_3$ (~0.2 g) dissolved in the minimum amount of benzene. The solution was stirred for ~20 h and then concentrated under reduced pressure to small volume. The product was precipitated by the addition of ethanol.

$RhH(BH_4)(o\text{-tolyl}_3P)$

An excess of $NaBH_4$ suspended in ethanol was added dropwise to a mixture of $RhCl_2(o\text{-tolyl}_3P)_2$ (0.34 g) and $o\text{-tolyl}_3P$ (0.15 g) also in ethanol (~5 ml). The mixture was stirred for at least 6 h before the brown product was separated by filtration.

$RhH_2Cl(DBP)_3$ and $Rh(BH_3CN)(N_2)(CO)(DBP)_3$

$RhCl_3(DBP)_3$ (0.3 g) was dissolved in the minimum amount of benzene to which an excess of $NaBH_4$ (or $NaBH_3CN$) suspended in ethanol was then added. The mixture was left stirring for ~20 h when a clear reddish-brown solution (orange-red for the Rh(I) complex) resulted. The solution was then concentrated to small volume and the product was precipitated by addition of ethanol.

$RhH(CO)(DBP)_3$ and $Rh(BH_3CN)(CO)(DBP)_3$

$[RhCl(CO)_2]_2$ (~0.2 g) and DBP (~0.46 g) were mixed together in the minimum amount of ethanol and this was followed by the addition of either $NaBH_4$ or $NaBH_3CN$ suspended in ethanol. The mixture was stirred for about 5 h before the product was separated by filtration.

We thank the National Research Council of Canada for generous financial support of this work. We also thank the Ventron Corporation, Beverly, Massachusetts, in particular Mr. Robert Wade, for a gift of chemicals.

Reçu le 9 avril 1975

JEAN-CLAUDE RICHER, PHILIPPE LAPOINTE, MARTINE BELJEAN et MICHEL PAYS. Can. J. Chem. **53**, 3677 (1975).

On rapporte les spectres de masse, sous impact électronique, des hydrazones de la méthyl-3 benzothiazolinone-2 (**1**), des chloro-4, 5, 6 et 7 méthyl-3 benzothiazolinones-2 (**2**, **3**, **4** et **5**) et de la méthyl-3 naphto[2,1-*d*]thiazolinone-2 (**6**) de même que ceux de l'hydrazino-2 benzothiazole (**7**), des chloro-4, 5, 6 et 7 hydrazino-2 benzothiazoles (**8**, **9**, **10** et **11**) et de l'hydrazino-2 naphto-[2,1-*d*]thiazole (**12**). On compare les résultats obtenus dans les deux séries. L'hydrazone-2 de la méthyl-3 benzothiazolinone-2 et ses dérivés présentent tous un pic de base équivalent à l'ion moléculaire; la fragmentation conduit principalement à des pertes successives de $H_2N\cdot$, HCN, HCN puis CS. Des chemins mineurs impliquent des pertes initiales de N_2H_2, $NH\cdot$ et NH_3. Dans le cas de l'hydrazino-2 benzothiazole et de ses dérivés, le pic de base est toujours équivalent à l'ion moléculaire; on note toutefois que les proportions relatives des divers ions de fragmentation varient suivant la position de la sonde à l'intérieur de l'appareil et l'on peut en conclure que l'on observe un spectre de masse correspondant au mélange des tautomères possibles hydrazone–hydrazine. Les principaux chemins de fragmentation impliquent la perte initiale de NH_3 (conduisant à un ion stabilisé), de $NH_2\cdot$ (probablement due à la forme hydrazone) et de N_2H_2.

JEAN-CLAUDE RICHER, PHILIPPE LAPOINTE, MARTINE BELJEAN, and MICHEL PAYS. Can. J. Chem. **53**, 3677 (1975).

Electron impact mass spectra are reported for the hydrazones of 3-methyl-2-benzothiazolinone (**1**), of 4-, 5-, 6-, and 7-chloro-3-methylbenzo-2-thiazolinones (**2**, **3**, **4**, and **5**) and of 3-methylnaphtho[2,1-*d*]-2-thiazolinone (**6**), as well as for 2-hydrazinobenzothiazole (**7**), for 4-, 5-, 6-, and 7-chloro-2-hydrazinobenzothiazoles (**8**, **9**, **10**, and **11**) and for 2-hydrazinonaphtho[2,1-*d*]thiazole (**12**). The results obtained in the two series are compared. The 2-hydrazone and 3-methylbenzo-2-thiazolinone and its derivatives all form a base peak corresponding to the molecular ion; fragmentation proceeds mainly by successive losses of $\cdot NH_2$, HCN, HCN, and then CS. Initial losses of N_2H_2, $NH\cdot$, and NH_3 are minor fragmentation routes.

In the case of 2-hydrazinobenzothiazole and its derivatives, the base peak is still that of the molecular ion; however, the relative proportions of the various fragment ions vary with the position of sampling probe inside the apparatus. Thus it is concluded that the observed mass spectrum is that of a mixture of the possible hydrazone–hydrazine tautomers. The principal fragmentations involve the initial loss of NH_3 (leading to a stabilized ion), of $NH_2\cdot$ (probably from the hydrazone form), and of N_2H_2.

Introduction

Dans le cadre de nos travaux (1) sur la synthèse et la caractérisation d'hydrazino-2 benzo- et naphtothiazoles et d'hydrazones de méthyl-3 benzo- et naphtothiazolones-2, nous avons été amenés (*a*) à examiner les modes de fragmentation de ces composés en spectrométrie de masse sous impact électronique et (*b*) à comparer nos résultats à ceux obtenus antérieurement (2) pour divers benzothiazoles. Ce sont les résultats obtenus au cours de ces études qui font l'objet de la présente communication.

Partie expérimentale

La synthèse des dérivés examinés a été rapportée antérieurement (1). On a obtenu les données relatives aux masses exactes à l'aide d'un spectromètre AEI MS-902 relié à un ordinateur PDP-8; toutes les valeurs expérimentales correspondent à ± 0.0015 unité de masse aux valeurs calculées. On a déterminé les spectres de masse à basse résolution à l'aide d'un spectromètre Hitachi RMU-

1 et **7** $R_1 = R_2 = R_3 = R_4 = H$
2 et **8** $R_1 = Cl, R_2 = R_3 = R_4 = H$
3 et **9** $R_2 = Cl, R_1 = R_3 = R_4 = H$
4 et **10** $R_3 = Cl, R_1 = R_2 = R_4 = H$
5 et **11** $R_4 = Cl, R_1 = R_2 = R_3 = H$
6 et **12** $R_1 = R_2 = H$, R_3 et $R_4 = —CH=CH—CH=CH—$

6D; l'énergie du faisceau ionisant était évaluée par une lecture directe du voltmètre puisque des mesures plus précises n'étaient pas nécessaires. On a observé des pics métastables dans ces spectres à basse résolution; quelques fois on les a obtenus en balayant la tension d'accélération avec le champ magnétique et le champ électrostatique à des valeurs constantes.

Résultats et discussion

Hydrazones des méthyl-3 benzo- et naphto[2,1-d]thiazolinones-2 (1 à 6)

Les spectres à 70 eV et à 15 eV des composés **1** à **6** présentent plusieurs caractéristiques communes. Le schéma 1 résume les divers modes de fragmentation des composés **2** à **5** qui sont à toutes fins pratiques identiques. L'ion moléculaire est le pic parent à 15 eV et à 70 eV pour tous ces composés. A 15 eV les seuls autres pics importants que l'on observe correspondent aux fragmentations $(M - H_2N\cdot)$, $(M - H_2N\cdot - HCN)$, $(M - H_2N\cdot - HCN - HCN)$ et $(M - H_2N\cdot - HCN - HCN - CS)$. On présente dans le schéma 2 une rationalisation de ce chemin principal de fragmentation. Aucune étude spéciale n'a toutefois été effectuée pour confirmer ces hypothèses; la perte de CS conduisant aux ions du type **b** est toutefois fréquente (3) pour des dérivés aromatiques.

En plus de ce chemin principal de fragmentation, on observe, à 70 eV, des chemins mineurs impliquant des pertes initiales de N_2H_2, de NH_3 et de NH. Les spectres à haute résolution ont confirmé que l'ion $(M - 15)$ correspond bien à une perte de NH et non pas à une perte de $CH_3\cdot$. Le fait que les dérivés **1** à **6** ne perdent pas de $\cdot CH_3$ est a rapproché du résultat obtenu antérieurement (2*b*) avec l'imino-2 méthyl-3 dihydro-2,3 benzothiazole (**13***c*) alors que de la même manière l'intensité de l'ion correspondant à la

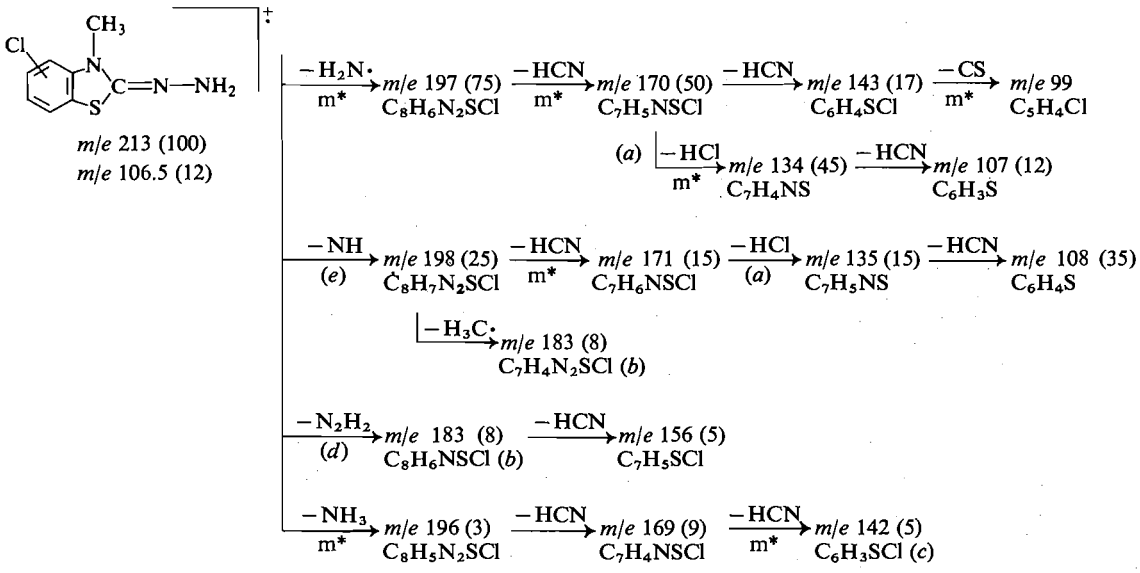

SCHÉMA 1. Fragmentations principales des composés **2** à **5**. Les compositions élémentaires résultent de mesures exactes des masses. Les valeurs entre parenthèse sont les intensités relatives à 70 eV. m* indique qu'un ion métastable a pu être observé sur le spectre à basse resolution alors que (*d*) indique qu'un ion métastable a été observé en balayant la tension d'accélération. (*a*) Ces fragmentations ne sont pas présentes dans les spectres des composés **1** et **6**. (*b*) On a pu montré que le pic à $(M - 30)$ est en fait un doublet pour lequel les ions correspondent respectivement à des pertes de N_2H_2 et CH_4N. (*c*) Dans le cas du dérivé naphtalénique **6**, on peut mettre en évidence que l'ion correspondant perd CS. (*e*) Aucun ion métastable n'a pu être observé pour cette fragmentation même en balayant la tension d'accélération.

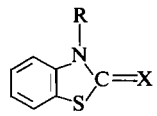
SCHÉMA 2. Rationalisation des principales fragmentations des hydrazones des méthyl-3 benzothiazolinones-2. Aucune étude spéciale n'a été effectuée pour confirmer ces hypothèses.



13

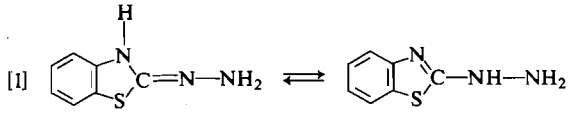
(*a*) R = —CH_2—$CH(CH_3)_2$, X = N—NH_2
(*b*) R = —$(CH_2)_9$—CH_3, X = N—NH_2
(*c*) R = CH_3, X = NH

perte d'un groupe méthyle est trop faible pour être mesurée. Aucun ion métastable n'a pu être observé pour la fragmentation impliquant la perte de NH; on ne peut donc pas éliminer la possibilité que la formation de l'ion (M − 15) provienne d'une autre voie comme, par exemple, une décomposition thermique dans la chambre à ionisation. Dans tous ces spectres, on n'observe pas de perte abondante de H·.

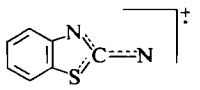
Les spectres des dérivés chlorés **2** à **5** présentent des particularités dues à la présence d'atomes de chlore qui sont expulsés sous forme de HCl. D'une façon générale, le schéma 1 peut toutefois aussi s'appliquer pour décrire les modes de fragmentation des dérivés **1** et **6**; originalement c'est d'ailleurs en se basant sur les résultats obtenus à l'aide du produit **6** qu'il a pu être mis en évidence que le pic à (M − 30) correspond à un doublet dû à la présence d'ions provenant de la perte de N_2H_2 et de CH_4N.

Hydrazino-2 benzo- et naphto[2,1-d]thiazoles (7 à 12)

Les spectres de masse, sous impact électronique, de ces dérivés présentent tous la caractéristique que les proportions relatives des divers ions de fragmentation varient suivant la position de la sonde à l'intérieur du spectromètre. Ces observations sont en accord avec le fait (4) que ces hydrazino-2 benzothiazoles existent sous forme de tautomères dont un couple est représenté par [1]; les divers spectres correspondent donc à des mélanges variables des divers tautomères. Certains composés examinés par Millard et Temple (2*a*) pouvaient présenter une telle isomérie; il ne semble pas qu'elle ait pu être détectée par spectrométrie de masse.



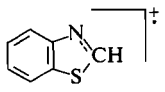
Dans les spectres de chacun de ces composés, la fragmentation principale correspond à la perte de NH_3 et à la formation d'entités du type **c** qui sont hautement stabilisées par résonance



Ion radical du type **c**

et qui, à l'exception des dérivés chlorés **8** à **11** qui perdent ·Cl, ne semblent pas subir de fragmentation ultérieure à 15 eV.

On observe aussi (*a*) une perte importante de N_2H_2 conduisant à un ion radical du type **d**



Ion radical du type **d**

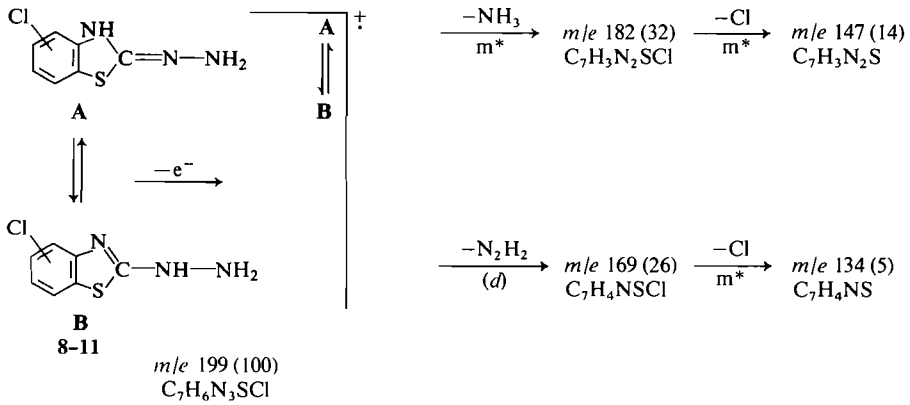


SCHÉMA 3. Fragmentations principales des composés **8** à **11**. La position de l'équilibre **A** ⇄ **B** est influencée par la position de la sonde à l'intérieur du spectromètre. Les intensités relatives des pics qui sont indiquées entre parenthèse ont été déterminées à 15 eV. Le (*d*) indique qu'un ion métastable a été observé en balayant la tension d'accélération.

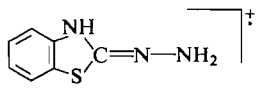
dont la formation a aussi été invoqué par DeJongh et Thomson (5) lors de la fragmentation de la benzothiazolethione-2 et (*b*) une perte de $H_2N\cdot$ telle qu'observée plus haut lors de la décomposition des méthyl-3 hydrazones correspondantes; toutefois ce processus de fragmentation est maintenant mineur par rapport aux précédents. A 15 eV, les principaux pics observés peuvent être résumés par le schéma 3.

On a effectué des essais supplémentaires avec les chlorhydrates des hydrazones des (méthyl-2 propyl)-3 et décyl-3 benzothiazolinones-2 (**13***a* et **13***b*). Dans ces cas, on observe encore un ion moléculaire correspondant à l'amine libre; ce pic n'est toutefois plus le pic de base. En effet la rupture de la chaîne latérale, avec transfert d'hydrogène, semble le processus le plus efficace et dans les deux cas l'ion le plus important est l'ion radical **e**. Il est donc peu probable que des



Ion radical du type **e**

hydrazones des benzothiazolinones-2 substituées par de longues chaînes en position 3 puissent s'avérer de quelque utilité que ce soit pour la caractérisation, par spectrométrie de masse sous forme d'azines, de divers composés carbonylés. Les résultats rapportés dans le présent travail suggèrent toutefois que les hydrazones de méthyl-3 benzo- ou naphtothiazolinones-2 pourraient être utiles à ces fins.

Les auteurs remercient vivement le Conseil National de Recherches du Canada et les autorités chargées d'administrer les accords culturels franco-québécois pour l'aide financière apportée sous forme d'octrois de recherches (CNR A-1295) et de frais de mission. Leur reconnaissance va aussi à Dr. A. S. Blair (Université de Montréal) pour l'aide technique fournie et au Dr. D. C. DeJongh pour des discussions utiles concernant cette publication.

Syntheses of Pentacyclic Morphinan Analogs

JAMES L. DOUGLAS AND JACQUES MEUNIER
Bristol Laboratories of Canada, Candiac, Quebec J5R 1J1

Received June 10, 1975

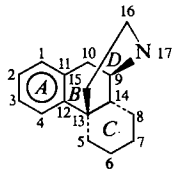
JAMES L. DOUGLAS and JACQUES MEUNIER. Can. J. Chem. **53**, 3681 (1975).

The synthesis of a series of morphinans with an additional aromatic or alicyclic ring fused to the 5,6 positions or an alicyclic ring fused to the 16,17 positions is described. The synthetic sequence involved elaboration of a 1,2,3,4,5,6-hexahydrobenz[*f*]isoquinoline or a quinolizidine, Grewe cyclization to a morphinan, and modification of the functional groups of the morphinan. These morphinans showed poor to moderate analgesic and narcotic antagonist activity.

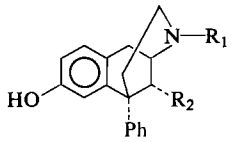
JAMES L. DOUGLAS et JACQUES MEUNIER. Can. J. Chem. **53**, 3681 (1975).

La synthèse d'une série de morphinanes ayant un cycle aromatique ou alicyclique additionnel se rattachant aux positions 5,6 ou ayant un cycle alicyclique en position 16,17 est décrite. L'élaboration de cette synthèse implique la préparation de l'hexahydro 1,2,3,4,5,6-benz[*f*]isoquinoline ou d'une quinolizidine suivi d'une cyclisation de Grewe et enfin la modification des divers groupements fonctionnels du morphinane. Ces derniers démontrèrent une activité analgésique et antagonistique des stupéfiants allant de faible à moyenne.

As part of a research program directed towards the synthesis of new analgesics with a minimum of side effects, it was decided to study elaborations of the morphinan[1] system **1**. Because of the good balance of analgesic activity to side effects claimed for phenyl substituted benzomorphans such as **2** (1) and **3** (2, 3), morphinans with a ring fused at the 5,6 positions (*e.g.* compounds such as **37**, for which we have coined the term 5,6-benzomorphinans) were one of the major objectives. Furthermore, since some



1

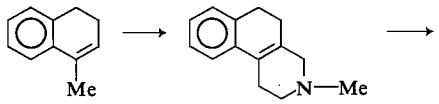


2 $R_1 = CONH_2$, $R_2 = H$
3 $R_1 = R_2 = Me$

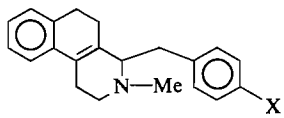
narcotic antagonists have been found to produce analgesia with low addiction liability (for recent reviews on narcotic analgesics and antagonists see ref. 4), another objective was to synthesize morphinans with nitrogen substituents such as cyclopropylmethyl that are known to produce antagonist activity. This effect of the nitrogen substituent also inspired the synthesis of the 16,17 fused ring compound **39**.

As the basis for our synthetic scheme, we used the Grewe cyclization to form the morphinan nucleus, a reaction that has long been used for the synthesis of morphinans and benzomorphans (1, 2, 5, 6). The precursors for the Grewe cyclizations were produced by several synthetic routes.

For the first route, the dihydronaphthalene **4** (7) was condensed with formaldehyde and methylamine to give the tricyclic amine **5**.[2] Reaction of **5** with benzyl or anisyl chloride gave a quaternary salt which on treatment with phenyllithium underwent a Steven's rearrangement to the benzisoquinoline derivative **6** or **7**. The Steven's rearrangement has been used in a



4 **5**



6 X = H **7** X = OMe

[1]Although the absolute configuration depicted in **1** (and following structures) is that of the natural opiates, the synthetic compounds are actually enantiomeric mixtures.

[2]Amine **5** was first synthesized by P. Rivest and M. Menard (8) of these laboratories.

similar manner for the preparation of benzomorphan precursors (1, 2, 9).

As an alternative synthesis of compounds with the skeleton of **6**, the following sequence was carried out. (It had the advantage that it was more amenable to the production of substituted derivatives of **6**.) The tetralones **8**, **9**, and **10** were treated with lithioacetonitrile (10) to give the cyano alcohols **11**, **12**, and **13**. These could be reduced, either *in situ* or as the isolated products, with lithium aluminum hydride, to the amino alcohols **14**, **15**, and **16**. The amino alcohols were readily dehydrated to the amino olefins **17**, **18**, and **19** by heating their hydro-

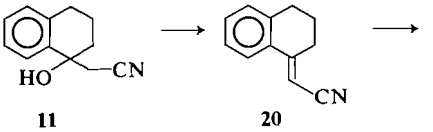
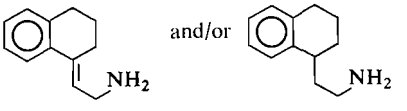
chloride salts. In fact, amino alcohol **15** dehydrated on attempted formation of its oxalate salt. The cyano alcohol **11** could be dehydrated to the exocyclic olefin **20**, but in our hands,



11 **20**



21 **22**

could only be reduced to the exocyclic olefin **21** or the fully reduced **22**, contrary to the report of Lockhart and co-workers (11), who produced endocyclic olefin **17** from **20**.

The condensation of an amine with an aldehyde (generated *in situ* from a glycidic ester) followed by acid catalyzed cyclization of the imine to an olefin to give morphinan and benzomorphan precursors has been used extensively (12). Thus the glycidic ester **23** hydrolyzed and underwent a decarboxylative rearrangement to *p*-methoxyphenylacetaldehyde under the acidic reaction conditions. The aldehyde condensed with the amine **17**, **18**, or **19** and the resulting imine cyclized to give the benzisoquinoline derivatives **24**, **25**, and **26**. The glycidic ester **23** was prepared by essentially the method of Knorr *et al.* (13).

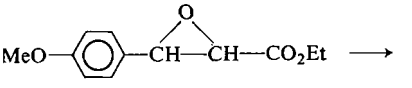
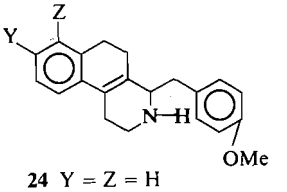
19 Y = H, Z = OMe

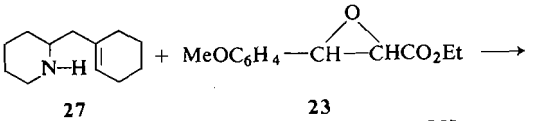


23

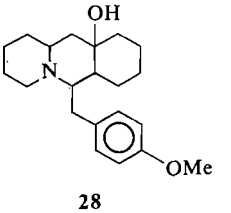


24 Y = Z = H
25 Y = OMe, Z = H
26 Y = H, Z = OMe

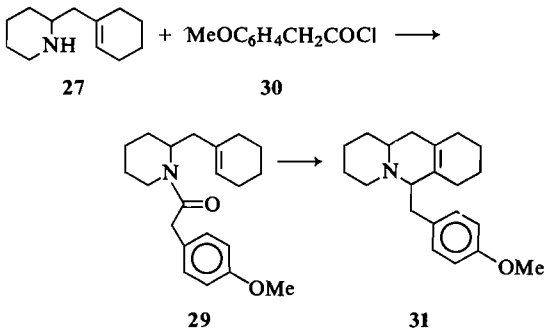
Because of the important effect of nitrogen substituents on the narcotic agonist–antagonist activity of morphinans, a morphinan with a ring fused to the 16,17 position was a synthetic objective. Such a compound would also be amenable to synthesis via Grewe cyclization. The pre-



27 **23**

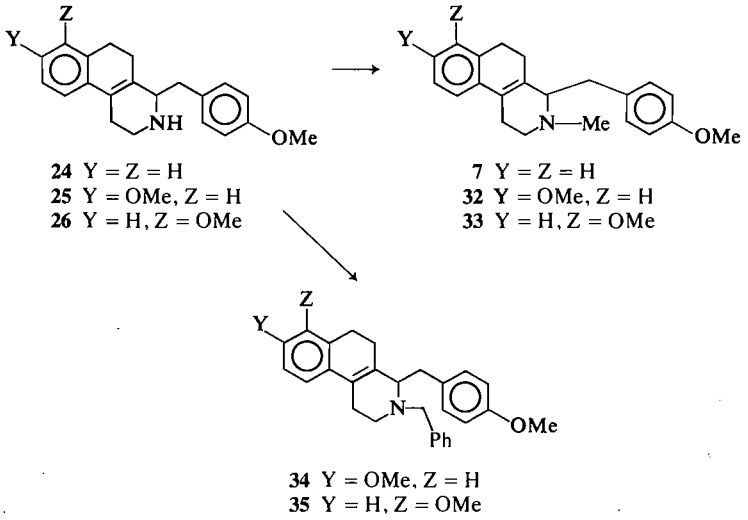


28



cursors were formed as follows. The piperidine **27** was prepared by the method of Prelog *et al.* (14). Picolyllithium was condensed with cyclohexanone to give a pyridine-cyclohexanol which on catalytic reduction and dehydration gave the piperidine **27**. The piperidine **27** could be converted to a suitable precursor for the Grewe cyclization by two methods. The amine–aldehyde condensation using glycidic ester **23** as the aldehyde precursor, gave the quinolizidine **28**. The yield was rather poor but this was likely due to the crystallization process used to purify **28** in which only one of its isomers was isolated. The other method used for generating a suitable quinolizidine involved a Bischler–Napieralski cyclization of an amide to an olefin. The amide **29** was prepared by acylation of amine **27** with acid chloride **30**. Treatment of amide **29** with phosphorus oxychloride (Bischler–Napieralski conditions) followed by reduction of the iminium salt with sodium borohydride gave the quinolizidine **31**.

It was found that the Grewe cyclization would not occur in the presence of a secondary amino group, so the benzisoquinolines **24**, **25**, and **26** were alkylated. Treatment of **24**, **25**, and **26** with



24 Y = Z = H

34 Y = OMe, Z = H
35 Y = H, Z = OMe

formic acid – formaldehyde (Clarke–Eschweiler conditions) gave the *N*-methyl derivatives **7**, **32**, and **33** while alkylation of **25** and **26** with benzyl bromide gave the *N*-benzyl derivatives **34** and **35**. Although *N*-cyclopropylmethyl substituted morphinans were desired, the intermediates **24**, **25**, and **26** were not alkylated with this group because of their likely instability to the strongly acidic Grewe cyclization conditions.

Several different reagents were used to carry out the Grewe cyclization. The unsubstituted morphinan **36** was synthesized by cyclization of benzisoquinoline **6** in 85% phosphoric acid (15). Strongly heating the morphinan precursors **7**, **35**, **28**, and **31** with 48% hydrobromic acid (2, 16) for 7–10 days gave the morphinans **37**, **38**, and **39**, rapid *O*-demethylation preceding the slow cyclization step. Hydrobromic acid induced *O*-demethylation was used to prepare derivatives **40** and **41** of **7** and **33**. Polyphosphoric acid cyclized the benzisoquinolines **32**, **33**, and **34** to the benzomorphinans **42**, **43**, and **44**. Attempted cyclization of **32** and **34** using hydrobromic acid failed, apparently due to instability of the inter-

39

mediate uncyclized diphenol. Hydrobromic acid was also used to demethylate the morphinans **42** and **43** to the diphenols **45** and **46**.

In order to convert morphinan **37** into other *N*-alkyl derivatives, *N*-demethylation with cyanogen bromide (**37–49**) was carried out in the manner described by Blocke and Clarke (1) for their benzomorphan series. Secondary amine **49** was acylated with cyclopropyl or cyclobutylcarbonyl chloride to give an ester amide (*i.e.*, **50**) which was reduced with lithium aluminum hydride to the cyclopropylmethyl or cyclobutylmethyl derivatives **51** or **52**.

Rather surprisingly, we were unable to remove the *N*-benzyl groups of **44** and **38** by hydrogenolysis, despite the use of various catalysts and varying conditions of solvent and acidity. However, by analogy with *N*-dealkylations using ethyl or phenyl chloroformate (17), it was found that cyclopropylcarbonyl chloride displaced the benzyl groups to give amides **53** and **54**. The reaction was very slow and required a large excess of the acid chloride. Reduction of the amides with lithium aluminum hydride gave the cyclopropylmethyl derivatives **55** and **56**. Since hydrobromic acid would undoubtedly have cleaved the cyclopropane ring, *O*-demethylation of **55** to diphenol **57** was accomplished with boron tribromide (18).

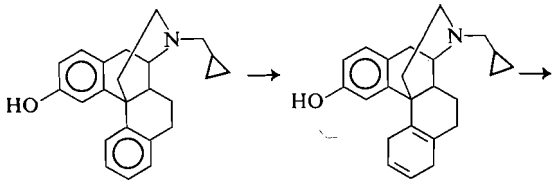
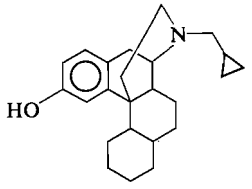
57 X = Y = OH, Z = H

A modification of the benzomorphinan skeleton was accomplished by reduction of the second aromatic ring. A selective Birch reduction (19) of benzomorphinan **51** gave the diene **58**. Conditions were fairly critical: if insufficient lithium was used, (an excess being required), the reduction was incomplete, while if too large an excess was used, reduction of the phenolic ring also occurred. Catalytic hydrogenation converted **58** to **59**. It was necessary to use a pre-reduced catalyst for this step because of the tendency of the catalyst to promote disproportionation of **58** to **59** and **51**.

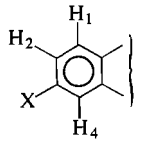


51 **58**



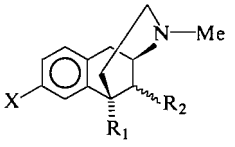
59

Structural assignments for the various new compounds follow in a straightforward manner from their mode of synthesis with confirmation provided by analyses and n.m.r. and i.r. spectra. Some trouble was had in obtaining satisfactory analyses for the phenolic morphinans. This was probably caused by difficulties in purification due to their insolubility in common solvents. The n.m.r. spectra readily indicated the success or lack of it in the Grewe cyclization by the appearance of high field methylene protons at δ 1.3–2.0 p.p.m. and the characteristic pattern due to aromatic portion **60** (see Experimental).



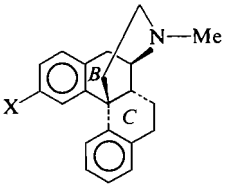
60

Although the Grewe cyclization normally gives morphinans with a *B*/*C cis* ring fusion (5, 20) it was desirable to have further proof of this for the benzomorphinans described here. Fullerton *et al.* (20) have described a method for determining the relative stereochemistry of alkyl group R_2 in a series of benzomorphans of type **61**. The quaternization of **61** with methyl iodide

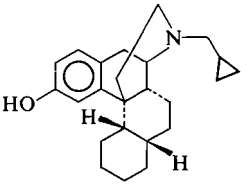


61

under carefully specified conditions was found to proceed to 85–95% of completion after 16 h for compounds with R_1/R_2 *cis* and only 5–30% for compounds with R_1/R_2 *trans*. As Table 1 shows, benzomorphinans **36** and **37** showed



36 X = H
37 X = OH



59

TABLE 1. Rate of quaternization of benzomorphinans (as % reaction)

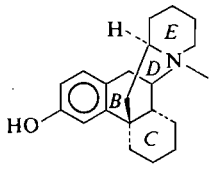
Compound	Percentage reaction at reaction times				
	2 h	6 h	8 h	16 h	72 h
36	—	67.4	—	95.0	—
37	30.4	67.7	—	98.0	—
61*	32.5	—	75.0	91.9	—
61†	—	—	3.9	7.8	26.8

*X = OH, R_1 = *n*-propyl, R_2 = α-*n*-propyl (20).
†X = OH, R_1 = *n*-propyl, R_2 = β-*n*-propyl (20).

reaction rates comparable to R_1/R_2 *cis* of the benzomorphans when the conditions of Fullerton *et al.* (20) were followed closely, probably indicating a *B/C cis* ring junction. (Two typical examples from the work of Fullerton *et al.* (20) are included in the table.)

That the Birch reduction of **51** gave the unconjugated diene **58** is indicated by its u.v. spectrum; the spectrum (λ_{max} 282 nm, ε 1970) shows only the phenolic chromophore and no conjugated diene. The n.m.r. spectrum of **58** indicates that it is not one of the other possible unconjugated isomers. Catalytic hydrogenation of **58** probably gives the isomer shown for **59** on steric grounds but there is no proof of this.

The existence of Bohlmann bands (at 2760 cm^{-1}) in the i.r. spectra of quinolizidines **28** and **31** is evidence that they have a *trans* ring fusion (21). Although the broad phenolic absorption in the spectrum of **39** obscures the region of the Bohlmann bands, it is possible that the *trans* fusion is carried into this structure, giving the relative stereochemistry shown; rings *C*, *D*, *E* all *trans* chair conformations.



39

Table 2 shows the pharmacological activities found for the various morphinans tested. Those compounds that are active range from moderate to poor, the most interesting being **51**, which shows a balance of analgesic and antagonist activity similar to pentazocine.[3]

[3]Pentazocine is an analgesic which shows low addiction liability and which has been introduced into clinical practice in recent years.

Experimental

Melting points were determined in a Gallenkamp melting point apparatus and are not corrected. Melting points above 250 °C were determined on samples sealed in evacuated capillaries. The n.m.r. spectra were recorded with a Varian A-60A spectrometer in deuteriochloroform, or when necessary to effect solution, mixed deuteriochloroform and deuteriodimethylsulfoxide, with tetramethylsilane as internal standard. The i.r. spectra were recorded on a Unicam SP-200G spectrometer with solids as Nujol mulls. The u.v. spectra were recorded with a Unicam SP-800 spectrometer as methanol solutions. The phrase 'extracted in the usual manner' is used to indicate the following. The aqueous mixture was extracted by shaking with an equal volume of the specified solvent followed by a further extraction with half the volume of solvent. The combined organic extracts were washed with half their volume of water (and the water further extracted with a small volume of organic solvent) and in the case of ethyl acetate or ether, further washed with saturated NaCl solution. The combined organic extracts were dried over Na_2SO_4, treated with charcoal if highly colored, filtered, and the solvent evaporated under reduced pressure.

4-Benzyl- and 4-(4-Methoxybenzyl)-3-methyl-1,2,3,4,5,6-hexahydrobenz[f]isoquinoline, 6 and 7

The preparation is described for **7**; essentially the same method was used for **6**.

A solution of anisyl chloride (24) (26.7 g, 170 mmol) and amine **5** (8) (34.0 g, 170 mmol) in 100 ml of acetone was maintained at 0 °C for 1 h then at 24 °C for ½ h. The solvent was evaporated to give a foam. The powdered foam was suspended in ether (300 ml) and a solution of 220 ml of 2.2 *M* phenyllithium in 40 ml of ether and 40 ml of benzene was added with stirring at such a rate that reflux was maintained. The reaction mixture was allowed to cool to 24 °C over ½ h then cooled to 0 °C and added to ice water (550 ml). The resulting mixture was extracted with ether in the usual manner to give the crude product as an oil. The oil was mixed wih *n*-hexane (260 ml) and 3 *N* HCl (260 ml) and enough methanol added to bring the oily hydrochloride salt into solution. After separation, the aqueous layer was made basic with 25% NaOH and extracted in the usual manner with methylene chloride to give the product as an oil (57.9 g).

Amine **6** was distilled at 150–166 °C/0.05 Torr to give the product in 70% yield as a yellow oil, n.m.r. δ 1.8–3.1 (m, 11 H, methylene and methine), 2.33 (s, 3H, N—CH_3), and 6.8–7.2 (m, 9H, aromatic).

crystallized from ethanol–acetonitrile, m.p. 264–265 °C (dec.), 74% yield.

Anal. Calcd. for $C_{21}H_{23}NO{\cdot}HBr$: C, 65.29; H, 6.26; N, 3.63; Br, 20.68. Found: C, 65.38; H, 6.40; N, 3.62; Br, 20.83.

*7- and 8-Methoxy-4-(2-aminoethyl)-1,2-dihydronaphthalene, **17**, **18**, and **19***

A 1.67 *M* solution of *n*-butyllithium in hexane (288 ml, 0.48 mol) was cooled to −78 °C and 240 ml of tetrahydrofuran (THF) was added. A solution of acetonitrile (24 ml, 0.46 mol) in 360 ml of THF was added over 20 min. The mixture was stirred for 1 h at −78 °C and a solution of methoxytetralone **9** or **10** (70.4 g, 0.40 mol) or tetralone **8** (58.5 g, 0.40 mol) in 400 ml of THF was added over 15 min. The cold bath was removed and stirring was continued for another 15 min. Lithium aluminum hydride (18 g, 0.48 mol) was added and the mixture was stirred at 24 °C for 3 h, then cooled to 0 °C. Water (18 ml) was added cautiously followed by 13.5 ml of 20% NaOH and 63 ml of water. The mixture was stirred at 24 °C for 15 min and the inorganic salts were filtered off. The ether solution was extracted with 10% HCl (2 × 500 + 200 ml) and the aqueous layers were made basic with 25% NaOH and extracted in the usual manner with ether (3 × 500 ml) to give a yellow oil. A benzene solution of the oil was saturated with HCl (gas) and refluxed under a water separator until water ceased to pass over. The mixture was cooled to 10 °C and the crystalline hydrochloride salt was collected in approximately 70% overall yield.

The free base **17** had n.m.r. δ 0.98 (s, 2H, NH_2), 2.0–3.0 (m, 8H, methylene), 5.85 (t, 1H, J = 4 Hz, olefin), and 7.1 (m, 4H, aromatic).

The free base **18** had n.m.r. δ 0.93 (s, 2H, NH_2), 2.0–3.0 (m, 8H, methylene), 3.79 (s, 3H, OCH_3), 5.78 (t, 1H, J = 4.5 Hz, olefin), 6.7 (m, 2H, aromatic), and 7.20 (d, 1H, J = 9.5 Hz, aromatic). The oxalate salt had m.p. 272–275 °C (dec.).

Anal. Calcd. for $C_{13}H_{13}NO{\cdot}\frac{1}{2}C_2H_2O_4$: C, 67.72; H, 7.31; N, 5.64. Found: C, 67.87; H, 7.33; N, 5.55.

The free base **19** had n.m.r. δ 1.08 (s, 2H, NH_2), 2.0–3.0 (m, 8H, methylene), 3.73 (s, 3H, OCH_3), 5.80 (t, 1H, J = 4 Hz, olefin), and 6.5–7.1 (m, 3H, aromatic). Its hydrochloride salt had m.p. 218–220 °C (dec.).

Anal. Calcd. for $C_{13}H_{17}NO{\cdot}HCl$: C, 65.14; H, 7.57; N, 5.84; Cl, 14.78. Found: C, 65.13; H, 7.44; N, 5.69; Cl, 14.61.

*Ethyl-3-(4-methoxyphenyl)-2,3-epoxypropionate, **23***

Ethanol free sodium ethoxide (prepared from 10.0 g (0.432 g atom) of sodium) was mixed with 200 ml of toluene and cooled to 0 °C. A solution of *p*-methoxybenzaldehyde (56.0 g, 0.412 mol) and ethyl chloroacetate (50.5 g, 0.412 mol) in 200 ml of toluene was added at such a rate that the temperature remained below 10 °C. The mixture was stirred at 24 °C for 16 h, washed with water (2 × 400 ml), dried (Na_2SO_4), and the solvent evaporated to give a yellow liquid of about 80% purity (81.2 g). The liquid solidified on standing at 5 °C and could be partially purified by washing with a small volume of cold ethanol to give pale yellow crystals of **23**; m.p. 40–43 °C; i.r. ν_{max} 1750 (ester) cm^{-1}; n.m.r. δ 1.28 (t, 3H, J = 7 Hz, $CO_2CH_2CH_3$), 3.33 and 3.93 (d, 1H each, J = 1.5 Hz, methines of epoxide), 3.73 (s, 3H, OCH_3), 4.20 (q, 2H, J = 7 Hz, $CO_2CH_2CH_3$), and 6.80 and 7.13 (d, 2H each, J = 8.5 Hz, aromatic).

*7- and 8-Methoxy-4-(4-methoxybenzyl)-1,2,3,4,5,6-hexahydrobenz[f]isoquinoline, **24**, **25**, and **26***

A mixture of the hydrochloride salt of **17**, **18**, or **19** (0.138 mol) in water (800 ml) was acidified to p*H* 3 by the addition of HCl (aqueous). The resulting mixture was heated under reflux (under nitrogen) and with vigorous stirring a solution of glycidic ester **23** (38.0 g, 0.172 mol) in 200 ml of ethanol was added dropwise over a period of 8 h. Reflux was maintained for 16 h, 300 ml of concentrated HCl was added and reflux was continued for a further 4 h. The mixture was allowed to cool, seeded to induce crystallization, then cooled to 0 °C. The hydrochloride salt was collected and recrystallized from methanol to give the product **25** or **26** (37.2 g, 71% yield). In the case of **24**, after the final period of reflux benzene, hexane, and methanol were added, the mixture shaken and the aqueous layer separated. The aqueous layer was made basic and extracted with methylene chloride in the usual way to give **24** (56% yield) which had n.m.r. δ 1.97 (s, 1H, NH), 2.1–3.3 (m, 11H, methylene and methine), 3.80 (s, 3H, OCH_3), and 6.8–7.4 (m, 8H, aromatic).

The free base **25** had n.m.r. δ 1.90 (s, 1H, NH), 2.2–3.3 (m, 11H, methylene and methine), 3.83 (s, 6H, OCH_3), and 6.7–7.4 (m, 7H, aromatic). The hydrochloride salt of **25** had m.p. 241–243 °C (dec.).

Anal. Calcd. for $C_{22}H_{25}NO_2{\cdot}HCl$: C, 71.05; H, 7.05; N, 3.77; Cl, 9.53. Found: C, 71.13; H, 7.14; N, 3.75; Cl, 9.75.

The free base **26** had n.m.r. δ 1.56 (s, 1H, NH), 2.1–3.3 (m, 11H, methylene and methine), 3.68 and 3.73 (s, 3H each, OCH_3), and 6.5–7.1 (m, 7H, aromatic). The hydrochloride salt of **26** had m.p. 254–256 °C (dec.).

Anal. Calcd. for $C_{22}H_{25}NO_2{\cdot}HCl$: C, 71.05; H, 7.05; N, 3.77; Cl, 9.53. Found: C, 71.06; H, 7.17; N, 3.79; Cl, 9.77.

*7- and 8-Methoxy-4-(4-methoxybenzyl)-3-methyl-1,2,3,4,5,6-hexahydrobenz[f]isoquinoline, **7**, **32**, and **33***

A solution of 85% formic acid (1.30 g) and 37% formaldehyde (2.16 g) was added slowly with cooling to 10 mmol of the secondary amine **24**, **25**, or **26** (as their free bases). The mixture was heated gently until CO_2 evolution ceased and was then heated under reflux for 5 h. The mixture was allowed to cool, 10% NaOH (20 ml) was added and the mixture was extracted in the usual way with methylene chloride to give the *N*-methyl amine **7**, **32**, or **33** as a yellow oil (90–95% yield).

Amine **32** had n.m.r. δ 1.9–3.2 (m, 11H, methylene and methine), 2.33 (s, 3H, NCH_3), 3.60 and 3.62 (s, 3H each, OCH_3), and 6.5–7.2 (m, 7H, aromatic).

Amine **33** had n.m.r. δ 1.9–3.3 (m, 11H, methylene and methine), 2.43 (s, 3H, NCH_3), 3.77 and 3.82 (s, 3H each, OCH_3), and 6.7–7.4 (m, 7H, aromatic).

Heating **33** under reflux for 3 h with 48% HBr followed by base treatment (concentrated NH_4OH) and extraction in the usual manner with ethyl acetate gave the diphenol **41**, recrystallized from acetone, m.p. 110 °C (dec.).

Anal. Calcd. for $C_{21}H_{23}NO_2{\cdot}C_3H_6O$: C, 75.96; H, 7.70; N, 3.69. Found: C, 75.99; H, 7.84; N, 3.64.

7- and 8-Methoxy-4-(4-methoxybenzyl)-3-benzyl-1,2,3,4,5,6-hexahydrobenz[f]isoquinoline, 34 and 35

A solution of benzyl bromide (1.3 ml, 11 mmol) in 10 ml of benzene was added over 1.75 h to a refluxing solution of **25** or **26** (3.35 g, 10 mmol) and triethylamine (2.0 ml, 14.6 mmol) in 33 ml of benzene. The solution was heated under reflux for another 4 h, then left at 24 °C for 16 h. The resulting mixture was washed with water (3 × 20 ml), dried, and the solvent evaporated to give the product **34** or **35** as a yellow oil (3.7 g, 85% yield). Amine **34** had n.m.r. δ 1.9–3.2 (m, 11H, methylene and methine), 3.63 (s, 2H, benzyl CH_2), 3.73 (s, 6H, OCH_3), and 6.6–7.1 (m, 12H, aromatic). Amine **35** had n.m.r. δ 1.9–3.2 (m, 11H, methylene and methine), 3.63 (s, 2H, benzyl CH_2), 3.72 and 3.75 (s, 3H each, OCH_3), and 6.5–7.1 (m, 12H, aromatic). The hydrochloride salt of **35** (recrystallized from acetone) had m.p. 201–202 °C.

Anal. Calcd. for $C_{29}H_{31}NO_2 \cdot HCl$: C, 75.39; H, 6.98; N, 3.03; Cl, 7.67. Found: C, 75.63; H, 7.03; N, 3.08; Cl, 7.78.

17-Methyl-5,6-benzomorphinan, 36

Amine **6** (10 g) was stirred with 100 ml of 85% phosphoric acid under nitrogen at 150 °C for 43 h. The cooled mixture was poured into ice water (600 ml), made basic with 50% NaOH and extracted with methylene chloride in the usual manner to give a brown oil (9.8 g). The oil was chromatographed on grade II alumina (750 g); elution with benzene–chloroform 9:1 gave the product as a pale brown solid (4.75 g, 47.5% yield). Recrystallization from hexane–cyclohexane gave **36** as cubic crystals, m.p. 95.5–97 °C; n.m.r. δ 1.5–3.1 (m, 12H, methylene and methine), 2.39 (s, 3H, N—CH_3), and 6.8–7.7 (m, 8H, aromatic).

Anal. Calcd. for $C_{21}H_{23}N$: C, 87.15; H, 8.01; N, 4.84. Found: C, 87.34; H, 8.06; N, 4.78.

3-Hydroxy-17-methyl-5,6-benzomorphinan, 37 and 3,18-dihydroxy-17-benzyl-5,6-benzomorphinan, 38

A mixture of amine **7** or **35** (10 g) was heated under nitrogen at 135–140 °C for 10 days with 48% HBr (100 ml). The cooled mixture was poured into ice water (200 ml), made basic with concentrated NH_4OH and extracted with chloroform or ethyl acetate in the usual manner to give the crude product, **37** or **38**.

Benzomorphinan **37** was recrystallized from benzene–ethanol to give crystals (4.66 g, 49%) with m.p. 243–245 °C (dec.); i.r. ν_{max} 2500–3100 (H-bonded OH) cm^{-1}; n.m.r. δ 1.5–3.0 (m, 12H, methylene and methine), 2.27 (s, 3H, NCH_3), 6.30 (d, 1H, J = 2 Hz, H_4) 6.53 (d of d, 1H, J = 8.5 and 2 Hz, H_2), 6.94 (d, 1H, J = 8.5 Hz, H_1), 7.1–7.6 (m, 4H, aromatic), and 8.96 (s, 1H, OH).

Anal. Calcd. for $C_{21}H_{23}NO$: C, 82.58; H, 7.59; N, 4.59. Found: C, 82.78; H, 7.54; N, 4.57.

Benzomorphinan **38** (10 g) was chromatographed on 2 kg of silicic acid (elution with chloroform–methanol 9:1) to give 6.0 g (64%) of colorless solid with n.m.r. δ 1.5–3.1 (m, 12H, methylene and methine), 3.73 (s, 2H, NCH_2Ph), and 6.4–7.4 (m, 13H, aromatic + OH).

18- and 19-Methoxy-17-methyl-3,6-benzomorphinan, 42 and 43 and 19-Methoxy-17-benzyl-5,6-benzomorphinan, 44

A mixture of the amine **32**, **33**, or **34** (8.0 g) and polyphosphoric acid (40 g) was heated at 100 °C with stirring for 6 h. To the cooled mixture, 50 ml of water followed by 250 ml of 25% NaOH were added cautiously. The resulting mixture was extracted in the usual manner with ethyl acetate to give an orange oil (4 to 5 g).

The benzomorphinans **42** and **43** were purified by chromatography on silica gel (1 kg, elution with chloroform–methanol 9:1) to give 2.7 to 2.9 g (34 to 36% yield) of colorless solid.

Benzomorphinan **42** had n.m.r. δ 1.5–3.1 (m, 12H, methylene and methine), 2.43 (s, 3H, NCH_3), 3.57 and 3.73 (s, 3H each, OCH_3), and 6.5–7.5 (m, 6H, aromatic).

Benzomorphinan **43** was recrystallized from ethyl acetate to give crystals with m.p. 143–145 °C, n.m.r. δ 1.5–3.1 (m, 12H, methylene and methine), 2.43 (s, 3H, NCH_3), 3.59 and 3.77 (s, 3H each, OCH_3), and 6.4–7.3 (m, 6H, aromatic).

Anal. Calcd. for $C_{23}H_{27}NO_2$: C, 79.05; H, 7.79; N, 4.01. Found: C, 79.12; H, 7.96; N, 3.81.

The crude *N*-benzylbenzomorphinan **44** was converted to its hydrochloride salt and recrystallized from acetone to give a 21% yield of moderately pure product. The free base of **44** had n.m.r. δ 1.5–3.1 (m, 12H, methylene and methine), 2.14 (s, 3H, NCH_3), 3.62 and 3.79 (s, 3H each, OCH_3), 3.73 (s, 2H, NCH_2Ph), and 6.5–7.6 (m, 11H, aromatic).

3,18- and 3,19-Dihydroxy-17-methyl-5,6-benzomorphinans, 45 and 46

A mixture of the dimethoxybenzomorphinan **42** or **43** (1.72 g) and 17 ml of 48% HBr was heated under reflux for 3 h. The solution was cooled to 0 °C and 150 ml of water followed by 150 ml of concentrated NH_4OH were added. The resulting mixture was extracted in the usual manner with ethyl acetate to give the diphenol **45** or **46** (1.5 g, 95% yield) as a brown solid. The products were recrystallized from ethyl acetate.

Diphenol **45** had m.p. 287–289 °C; n.m.r. δ 1.4–3.2 (m, 12H, methylene and methine), 2.32 (s, 3H, NCH_3), 6.3–7.4 (m, 6H, aromatic), and 8.3 (br, 2H, OH).

Anal. Calcd. for $C_{21}H_{23}NO_2$: C, 78.47; H, 7.21; N, 4.36. Found: C, 78.20; H, 7.26; N, 4.27.

Diphenol **46** had m.p. 307–309 °C; n.m.r. δ 1.4–3.2 (m, 12H, methylene and methine), 2.33 (s, 3H, NCH_3), 6.3–7.1 (m, 6H, aromatic), and 8.3 (br, 2H, OH).

Anal. Calcd. for $C_{21}H_{23}NO_2 \cdot \frac{1}{4}H_2O$: C, 77.39; H, 7.27; N, 4.30. Found: C, 77.54; H, 7.26; N, 4.20.

3-Acetoxy-17-methyl-5,6-benzomorphinan, 47

The benzomorphinan **37** was converted to its acetate **47** in virtually quantitative yield by the method of Block and Clarke (1). The product had i.r. ν_{max} 1770 (acetate) cm^{-1}; n.m.r. δ 1.5–3.1 (m, 12H, methylene and methine), 2.17 (s, 3H, CH_3CO_2), 2.47 (s, 3H, NCH_3), and 6.6–7.7 (m, 7H, aromatic).

3-Acetoxy-17-cyano-5,6-benzomorphinan, 48

The acetoxy benzomorphinan **47** was *N*-demethylated with cyanogen bromide by the method of Block and Clarke (1) to give the cyano compound **48** in quantitative yield, which had i.r. ν_{max} 2220 (N—CN), and 1770 (acetate) cm^{-1}; n.m.r. δ 1.5–3.9 (m, 12H, methylene and methine), 2.20 (s, 3H, CH_3CO_2), and 6.7–7.6 (m, 7H, aromatic).

For personal use only.

3-Hydroxy-5,6-benzomorphinan, 49

The acetoxy-cyano compound **48** was reduced with lithium aluminum hydride by the method of Block and Clarke (1) to give the benzomorphinan **49** in high yield. The product was recrystallized from methanol to give crystals with m.p. 301–304 °C (dec.); i.r. ν_{max} 3280 (NH), and 2400–3300 (hydrogen bonded OH) cm^{-1}; n.m.r. δ 1.4–3.2 (m, 12H, methylene and methine) 4.6 (br, 1H, NH), 6.08 (d, 1H, J = 2.5 Hz, H_4), 6.25 (d of d, 1H, J = 8.5 and 2.5 Hz, H_2), 6.70 (d, 1H, J = 8.5 Hz, H_1), and 7.0–7.6 (m, 5H, aromatic and OH).

3-Hydroxy-17-cyclopropylmethyl and Cyclobutylmethyl-5,6-benzomorphinans, 51 and 52

The procedure is described for **51** but essentially the same method was used for **52**.

A solution of cyclopropylcarbonyl chloride (4.2 g, 40 mmol) in 20 ml of methylene chloride was added over 10 min to a slurry of benzomorphinan **49** (5.4 g, 18.5 mmol) and pyridine (7.0 ml, 40 mmol) in 30 ml of methylene chloride. The solution was stirred at 24 °C for 30 min and washed with water, 10% aqueous $NaHCO_3$, 10% HCl, and water. The solvent was evaporated to give the crude ester amide **50** (6.4 g) as a yellow foam. The product had i.r. ν_{max} 1760 (ester), and 1645 (amide) cm^{-1}.

A solution of the amide **50** (6.4 g, 15 mmol) in 100 ml of THF was added over 10 min to a slurry of lithium aluminum hydride (3.5 g, 92 mmol) in 30 ml of THF. The mixture was heated under reflux for 1 h, allowed to cool, and saturated NaCl (18.5 ml) was added dropwise. THF (30 ml) was added and the mixture was heated under reflux for 30 min. Inorganic salts were filtered from the cooled mixture and the solvent was evaporated to give the crude product. The product was purified by trituration with benzene–ethanol to give benzomorphinan **51** as an almost colorless powder (2.51 g, 49% yield) which had m.p. 263–265 °C; i.r. ν_{max} 2400–3100 (hydrogen bonded OH) cm^{-1}; n.m.r. δ 0–1.3 (m, 5H, cyclopropyl), 1.5–3.5 (m, 14H, methylene and methine), 6.43 (d, 1H, J = 2.5 Hz, H_4), 6.58 (d of d, 1H, J = 8 and 2.5 Hz, H_2), 6.97 (d, 1H, J = 8 Hz, H_1), and 7.1–7.7 (m, 5H, aromatic + OH).

The cyclobutylbenzomorphinan **52** was recrystallized from dioxane–water and had m.p. 224–225 °C; n.m.r. δ 1.5–3.0 (m, 21H, methylene and methine), 6.32 (d, 1H, J = 2 Hz, H_4), 6.47 (d of d, 1H, J = 8 and 2 Hz, H_2), 6.83 (d, 1H, J = 8 Hz, H_1), and 7.0–7.6 (m, 4H, aromatic).

Anal. Calcd. for $C_{25}H_{29}NO \cdot \frac{1}{2}H_2O$: C, 81.48; H, 8.21; N, 3.80. Found: C, 81.63; H, 8.27; N, 3.80.

3,19-Dimethoxy-17-cyclopropylcarbonyl-5,6-benzomorphinan, 53

A solution of the benzylamine **44** (4.0 g, 9.4 mmol) in 40 ml toluene was heated under reflux and 3 portions of cyclopropylcarbonyl chloride (1 ml each) were added at 5 h intervals. The mixture was cooled, washed with dilute NaOH, dried, then reacted further by addition of 5 portions of acid chloride (1 ml each) at 5 h intervals (except for two overnight reflux periods). The cooled mixture was washed with dilute NaOH and two times with 3 *N* HCl (aqueous) – methanol. The solvent was evaporated to give the crude amide **53** as a brown foam (2.64 g, 69% yield). The product had i.r. ν_{max} 1640 (amide) cm^{-1}; n.m.r. δ 0.5–1.1 (m, 4H, cyclopropyl), 1.5–3.2 (m, 13H, methylene and methine), 3.63 and 3.80 (s, 3H each, OCH_3), and 6.5–7.6 (m, 6H, aromatic).

3,19-Dimethoxy-17-cyclopropylmethyl-5,6-benzomorphinan, 55

Lithium aluminum hydride (600 mg, 16 mmol) was added to a solution of amide **53** (3.1 g, 7.7 mmol) in 45 ml of THF and the stirred mixture was heated under reflux for 2.25 h. The mixture was cooled to 0 °C and 0.6 ml of water followed by 0.6 ml of 25% NaOH and 2.4 ml of water was added cautiously. The mixture was stirred for 15 min, the inorganic salts were filtered off, and the solvent was evaporated. The crude product (as its hydrochloride salt) was recrystallized from methanol–chloroform to give pure amine (HCl salt) **55** (2.24 g, 68% yield) with m.p. 307–309 °C; n.m.r. (on free base) δ −0.1–1.3 (m, 5H, cyclopropyl), 1.4–3.3 (m, 14H, methylene and methine), 3.62 and 3.78 (s, 3H each, OCH_3), and 6.5–7.6 (m, 6H, aromatic).

Anal. Calcd. for $C_{26}H_{31}NO \cdot HCl$: C, 73.31; H, 7.57; N, 3.29; Cl, 8.32. Found: C, 73.19; H, 7.63; N, 3.29; Cl, 8.22.

3,19-Dihydroxy-17-cyclopropylmethyl-5,6-benzomorphinan, 57

A solution of the methoxy compound **55** (1.3 g, 3.3 mmol) in 25 ml of methylene chloride was added over 30 min to a solution of boron tribromide (0.95 ml, 2.48 g, 9.9 mmol) in 12 ml of methylene chloride under nitrogen at −78 °C. The resulting mixture was stirred at 24 °C for 3 h, then poured into ice and concentrated NH_4OH. The methylene chloride was separated and the aqueous layer was extracted with ethyl acetate – methanol in the usual manner (the methylene chloride solution was combined with the other organic extracts) to give the crude product. The product was recrystallized from methanol–acetone to give diphenol **57** (490 mg, 41% yield) with m.p. 285–287 °C (dec.); n.m.r. δ −0.2–1.1 (m, 5H, cyclopropyl), 1.4–4.0 (m, 14H, methylene and methine) 6.3–7.5 (m, 6H, aromatic), and 8.9 (br, 2H, OH).

Anal. Calcd. for $C_{24}H_{27}NO_2 \cdot \frac{1}{2}CH_4O$: C, 77.95; H, 7.74; N, 3.71. Found: C, 78.25; H, 7.66; N, 3.64.

3,18-Dihydroxy-17-cyclopropylmethyl-5,6-benzomorphinan, 56

A solution of cyclopropylcarbonyl chloride (1.84 g, 17.7 mmol) in 10 ml of chloroform was added over 15 min to a mixture of diphenol **38** (3.1 g, 7.7 mmol) and pyridine (1.44 g, 18.2 mmol) in 30 ml of chloroform. The mixture was stirred at 24 °C for 1 h, washed with water, dilute $NaHCO_3$, and water, then dried. The solvent was evaporated to give the crude diester (4.1 g) as an orange oil.

The oil was treated with repeated quantities of the acid chloride in the same manner as **53** was prepared. The resulting diester amide **54** had i.r. ν_{max} 1750 (ester), and 1630 (amide) cm^{-1}; n.m.r. δ 0.4–1.4 (m, 12H, cyclopropyl), 1.4–3.8 (m, 15H, methylene and methine), and 6.7–7.5 (m, 6H, aromatic).

The diester amide **54** was reduced with lithium aluminum hydride in the same manner as **55** to give the diphenol **56** as a brown powder which had m.p. 257–260 °C; n.m.r. δ −0.1–1.0 (m, 5H, cyclopropyl), 1.5–3.5 (m, 14H, methylene and methine), and 6.5–7.5 (m, 6H, aromatic).

3-Hydroxy-17-cyclopropylmethyl-18,21-dihydro-5,6-benzomorphinan, 58

Lithium (500 mg, 72 mmol) was added in small portions to a slurry of phenol **51** (2.51 g, 7.3 mmol) in 25 ml of dimethoxyethane and 50 ml of liquid ammonia at −78 °C. The mixture was stirred at the ammonia reflux temperature for 1 h. A solution of *tert*-butyl alcohol (7.4 g, 100 mmol) in 15 ml of dimethoxyethane was added over 15 min and the resulting mixture was stirred for 2 h while the ammonia evaporated. Ethanol (5 ml) was added and after a further 30 min stirring, dilute HCl was added until the mixture was acidic. The mixture was made basic with concentrated NH_4OH and extracted in the usual manner with chloroform to give the crude diene **58** as a brown solid (2.34 g, 93%). The product was recrystallized from ethanol–chloroform to give material with m.p. 240–243 °C (dec.); i.r. ν_{max} 2400–3200 (hydrogen bonded OH) cm^{-1}; u.v. λ_{max}^{MeOH} 282 nm (ε 1970); n.m.r. δ −0.1–1.1 (m, 5H, cyclopropyl), 1.2–3.3 (m, 18H, methylene and methine), 5.84 (m, 2H, olefin), and 6.5–7.1 (m, 3H, aromatic).

Anal. Calcd. for $C_{24}H_{29}NO \cdot \frac{1}{2}C_2H_6O$: C, 81.05; H, 8.71; N, 3.78. Found: C, 80.93; H, 8.61; N, 3.78.

3-Hydroxy-17-cyclopropylmethyl-5,6-butanomorphinan, 59

A mixture of crude diene **58** (1.14 g) and pre-hydrogenated 10% palladium-on-charcoal (1.0 g) in 100 ml of methanol was hydrogenated in a Parr shaker at 24 °C and 4 atm pressure. After the rapid uptake of hydrogen had ceased, the catalyst was filtered off and the solution concentrated. Crystalline morphinan **59** (530 mg, 46%) was collected and recrystallized from methanol to give material with m.p. 222–224 °C (dec.); n.m.r. δ −0.1–1.0 (m, 5H, cyclopropyl), 1.1–3.2 (m, 24H, methylene and methine), 6.58 (d of d, 1H, J = 8 and 2 Hz, H_2), 6.77 (d, 1H, J = 2 Hz, H_4), and 6.88 (d, 1H, J = 8 Hz, H_1).

1-(2-Piperidylmethyl)-cyclohexene, 27

The piperidine **27** was prepared in 63% overall yield from α-picoline by the method of Prelog *et al.* (14) and had i.r. ν_{max} 3200–3100 (NH) cm^{-1}; n.m.r. δ 0.9–3.2 (m, 19H, methylene and methine), 1.33 (s, 1H, NH), and 5.50 (br, 1H, olefin).

4-(4-Methoxybenzyl)-2-hydroxy-2,3-butanoquinolizidine, 28

A mixture of amine **27** (18 g, 0.10 mol) and 550 ml water was acidified to p*H* 3 by the addition of concentrated HCl. To the stirred, refluxing mixture was added a solution of the glycidic ester **23** (41 g, containing *ca.* 0.15 mol) in 180 ml ethanol over a period of 4 days. Methanol and HCl were added to the mixture and it was washed twice with benzene–hexane. The aqueous layer was made basic with 25% NaOH and extracted in the usual manner with methylene chloride to give the crude product (22 g). Since this material contained more than 50% starting material (by n.m.r.), it was dissolved in methylene chloride and treated for 30 min at 24 °C with trifluoroacetic anhydride. The resulting solution was extracted with dilute HCl containing methanol. The aqueous layers were washed with benzene–hexane, made basic with NaOH and extracted in the usual way with methylene chloride to give the amine **28** (9.5 g) as a brown oil. The amine was purified via its hydrochloride salt, crystallized from toluene (4.4 g, 12% yield) and recrystallized from ethyl acetate – methanol to give crystals with m.p. 241–243 °C (dec.). The free base **28** had i.r. ν_{max} 3350 (OH), 2800, 2760, and 2680 (w) (Bohlmann bands) cm^{-1}; n.m.r. δ 0.9–3.5 (m, 24H, aliphatic + OH), 3.74 (s, 3H, OCH_3), and 6.79 and 7.18 (d, 2H each, J = 9 Hz, aromatic).

Anal. Calcd. for $C_{21}H_{31}NO_2 \cdot HCl$: C, 68.93; H, 8.82; N, 3.83; Cl, 9.69. Found: C, 68.79; H, 8.95; N, 3.75; Cl, 9.58.

1-(1-(4-Methoxyphenylacetyl)-2-piperidylmethyl)-cyclohexene, 29

para-Methoxyphenylacetyl chloride **30** was prepared from *p*-methoxyphenylacetic acid and thionyl chloride and obtained as an unstable yellow liquid, b.p. 88–90 °C/0.2 Torr.

A solution of the acid chloride **30** (26.6 g, 0.145 mol) in 54 ml of benzene was added over 15 min to a solution of piperidine **27** (22.2 g, 0.124 mol) and triethylamine (37 ml, 0.27 mol) in 67 ml of benzene at 5 °C. The mixture was stirred at 24 °C for 30 min and then heated under reflux for 30 min. The cooled mixture was washed with 2 *N* HCl (400 + 200 ml), 10% NaOH (5 × 100 ml) and water (100 ml). The solvent was evaporated to give the amide **29** as a yellow oil (35.0 g, 74%) which had i.r. ν_{max} 1630 (amide) cm^{-1}; n.m.r. δ 1.2–3.0 (m, 19H, methylene and methine), 3.70 (s, 2H, $COCH_2Ar$), 3.84 (s, 3H, OCH_3), 5.52 (br, 1H, olefin), and 6.97 and 7.30 (d, 2H each, J = 9 Hz, aromatic).

4-(4-Methoxybenzyl)-2,3-butano-2,3-dehydroquinolizidine, 31

A solution of amide **29** (28.5 g, 87.5 mmol) and phosphorus oxychloride (28.5 ml, 47.6 g, 311 mmol) in 285 ml of toluene was heated under reflux for 5 h. The cooled solution was washed with 25% NaOH (until the washings remained basic) and with water. Evaporation of the solvent gave a brown oil. A solution of the oil in 230 ml of ethanol was acidified to p*H* 2 with concentrated HCl, cooled to 0 °C and sodium borohydride (5.7 g, 150 mmol) was added in small portions over 1 h. The mixture was stirred for 16 h at 24 °C, then concentrated to an oily residue. The residue was mixed with 2% NaOH and extracted in the usual manner with methylene chloride to give a brown oil. The oil was dissolved in benzene–hexane and extracted with 3 *N* HCl containing methanol. The aqueous layer was washed with benzene–hexane, made basic with 50% NaOH and extracted with benzene in the usual way to give the crude product as a brown oil. The product was purified by forming its picrate salt, which was recrystallized from acetone (m.p. 163–166 °C (dec.)). The free base **31** was obtained as a pale yellow oil (6.0 g, 19% overall yield from piperidine **27**) which had i.r. ν_{max} 2920, 2860, 2840, 2810, 2780, 2760, and 2680 cm^{-1}; n.m.r. δ 1.0–3.4 (m, 22H, methylene and methine), 3.83 (s, 3H, OCH_3), and 6.87 and 7.83 (d, 2H each, J = 9 Hz, aromatic).

3-Hydroxy-16,17-butanomorphinan, 39

The procedure is described for amine **31**; the same method was used to convert the hydrochloride salt of **28** to morphinan **39**.

A mixture of the amine **31** (6.0 g, 19.3 mmol), in 60 ml of 48% HBr was heated under reflux for 7 days. The cooled mixture was made basic with concentrated NH_4OH and

extracted in the usual manner with chloroform to give the crude product as a brown tar. The tar was crystallized from ethyl acetate to give the morphinan **39** (1.2 g, 21% yield) which had m.p. 195–197 °C (dec.); i.r. ν_{max} 2500–3300 (hydrogen bonded OH) cm^{-1}; n.m.r. δ 0.5–3.0 (m, 23H, aliphatic), 6.40 (d of d, 1H, J = 8 and 2 Hz, H_2), 6.58 (d, 1H, J = 2 Hz, H_4), 6.68 (d, 1H, J = 8 Hz, H_1), and 8.4 (br, 1H, OH).

Anal. Calcd. for $C_{20}H_{27}NO$: C, 80.76; H, 9.15; N, 4.71. Found: C, 80.50; H, 9.19; N, 4.45.

We thank Mr. L. Morris for the synthesis of compound **52** and Dr. A. W. Pircio of Bristol Laboratories, Syracuse, N.Y., for the pharmacological data. Thanks are also given to Dr. Y. G. Perron and Dr. M. Menard of these laboratories and Dr. B. Belleau of McGill University, Montreal, Quebec for their comments and suggestions during the course of this work.

A General, Selective Synthesis of Thiol Esters

SATORU MASAMUNE, SUSUMU KAMATA, JAMES DIAKUR, YOSHIKAZU SUGIHARA, AND GORDON S. BATES

Department of Chemistry, University of Alberta, Edmonton, Alberta T6G 2G2

Received August 14, 1975

SATORU MASAMUNE, SUSUMU KAMATA, JAMES DIAKUR, YOSHIKAZU SUGIHARA, and GORDON S. BATES. Can. J. Chem. **53**, 3693 (1975).

Use of diethyl phosphorochloridate and Tl(I) thiolates constitutes a general, selective synthesis of thiol esters. Primary, secondary, and tertiary alkane- and arenethiols of various carboxylic acids, including those containing hydroxy groups have been prepared under mild conditions.

SATORU MASAMUNE, SUSUMU KAMATA, JAMES DIAKUR, YOSHIKAZU SUGIHARA et GORDON S. BATES. Can. J. Chem. **53**, 3693 (1975).

L'utilisation de phosphodichloridate de diéthyle et de thiolates de Tl(I) s'avère être une méthode générale et sélective pour la synthèse de thiol esters. On a préparé, sous des conditions douces, des arène- et alkane thiols primaires, secondaires et tertiaires de divers acides carboxyliques y compris ceux contenant des groupes hydroxyles.

[Traduit par le journal]

In view of ever-increasing interest in the enzymatic synthesis of acyl-CoA (1*a*) and its involvement in fatty acid biosynthesis (acyl transfer reaction) (1*b*), it is rather surprising that there has not been developed a general, *selective* method to prepare thiol esters, applicable to sensitive, complex organic substrates (for a recent review see ref. 2). Two procedures recently reported are useful in a certain case, but both seem to be limited in scope. One employing disulfides and triphenylphosphine (3) is applicable to the preparation of pyridine-2-thiol and benzenethiol esters, but not to that of alkanethiol esters, while the other involving diphenoxy or diethyloxyphosphinyl alkanecarboxylate intermediates (4) proceeds well only with less substituted (mainly primary) alkanethiols.[1] A mechanistic examination of the latter reaction has led to the development of a versatile and effective synthesis of thiol esters as summarized below. This method also solves one of the general problems in the synthesis of macrolide antibiotics in which the 2-methylpropane-2-thiol ester has already been shown to be a superb protective group and to be readily activated for further reactions (5).

The reaction sequence that we have found to be most satisfactory is formulated below.

$$RCO_2H \xrightarrow[(C_2H_5)_3N \text{ in THF}]{(C_2H_5O)_2P(O)Cl} \underset{\mathbf{1}}{RCO_2P(OC_2H_5)_2} \xrightarrow{Tl(I)SR'} RCOSR'$$

The selection of diethyl phosphorochloridate (6) is due to the high selectivity of the chloridate towards the carboxy group with respect to hydroxy, a requirement that must be met in many cases. This selectivity,[2] as is clearly demonstrated by entries 3 and 4 in Table 1, can be favorably compared with that occurring with the methods involving triphenylphosphine and carbon tetrachloride (or conventional halogenating reagents) which react with both the carboxy (7) and hydroxy groups (8).

Near quantitative precipitation of triethyl-

[1]We have eliminated the possibility (although obviously remote) that $(C_2H_5O)_2P(O)SC_2H_5$ (I) is an intermediate in the reaction of Yamada *et al.* (4), since the reaction of (I) and cyclohexanecarboxylic acid in dimethyl formamide did not proceed even in the presence of triethylamine.

[2]Both cyclohexanol and *tert*-butyl alcohol were recovered virtually quantitatively under the present conditions using diethyl phosphorochloridate.

TABLE 1. Selected examples of the thiol ester synthesis

Entry	Product*		Yield (%)

*Elemental analyses and spectral data of all products are consistent with those formulated in Table 1.

amine hydrochloride that is removed by filtration in the first step ensures the formation of the intermediate anhydride (**1**) and also avoids some complications that may arise with the use of other phosphorating reagents (4, 9).

Because of the thermal instability of the intermediate (**1**),[3] the ensuing last step requires an appropriate thiolate counter-ion that brings the reaction to completion with high efficiency. Among several common cations tested, such as Na^+ and K^+, Tl(I) proved to be the most satisfactory, because of the case of preparation and reasonable solubility in aprotic solvents of its crystalline thiolate salts. Thus, the yellow Tl(I) salts of primary, secondary, and tertiary (*5b*) alkanethiols have been prepared in excellent yields with the use of Tl(I) ethoxide and the thiols. In this way a high-yield synthesis of thiol esters, regardless of the nature of substitution in the alkane- and arenethiols, has now been achieved under mild conditions. This method is applicable to even a reactive thiol ester such as pyridine-2-thiol (entry 2 in Table 1) and appears in some cases to supersede those methods employed previously,[4] because of its simplicity of work-up procedure. Needless to say, in the case of a hydroxy acid, the selectivity of the present method allows one to operate on the hydroxy group of the resulting alkanethiol ester, and then to effect further conversion of the carboxy group.[5] The following experimental description illustrates the procedure summarized in Table 1.

The 2-Methylpropane-2-thiol Ester of Cholic Acid

To a solution of 817 mg (2 mmol) of cholic acid and 222 mg (2.2 mmol) of triethylamine in 10 ml of anhydrous tetrahydrofuran was added a solution of 363 mg (2.1 mmol) of diethyl phosphorochloridate in 5 ml of tetrahydrofuran dropwise at room temperature under a nitrogen

[3]The intermediate is rather labile to heat and base and prone to disproportionate (10) according to the equation: $2RCO_2P(O)(OR')_2 = (RCO)_2O + ((R'O)_2PO)_2O$.

[4]Pyridine-2-thiol esters were prepared previously either through the acid chloride or by means of dicyclohexylcarbodiimide (11) and later by Mukaiyama *et al.* (3) and by other groups, using triphenylphosphine and the corresponding disulfide. The latter procedure very often involves a tedious work-up to isolate the pure product from triphenylphosphine oxide that forms concomitantly.

[5]In cases where the acid chlorides are available, and thus the selective activation of the carboxy group is not demanded, the method previously reported (*5b*) is to be preferred. Conventional methods of preparing thiol esters often require more vigorous conditions and lead to lower yields, in particular with highly substituted thiols.

atmosphere. The mixture was stirred at room temperature for 3 h, and the precipitated triethylamine hydrochloride was removed by filtration and washed with 10 ml of tetrahydrofuran. To the combined filtrate and washings was added 650 mg (2.2 mmol) of Tl(I) 2-methyl-2-propanethiolate, and the mixture was stirred at room temperature overnight. The tetrahydrofuran was evaporated under reduced pressure, and then ethyl acetate was added to the residue. The work-up involving washings with aqueous solutions in the usual manner gave 840 mg (86%) of the crystalline thiol ester, m.p. 164–165 °C (from ether – Skelly B).

Mechanistic Information from the Effect of Pressure on the Kinetics of Hydrolysis of Iodopentaaquochromium(III) Ion

MILTON CORNELIUS WEEKES AND THOMAS WILSON SWADDLE[1]

Department of Chemistry, The University of Calgary, Calgary, Alberta T2N 1N4

Received July 9, 1975

MILTON CORNELIUS WEEKES and THOMAS WILSON SWADDLE. Can. J. Chem. **53**, 3697 (1975).

The rate of hydrolysis of iodopentaaquochromium(III) ion has been measured as a function of pressure (0.1 to 250 MPa) and hydrogen ion concentration (0.1 to 1.0 mol kg^{-1}) at 298.2 K and ionic strength 1.0 mol kg^{-1} (aqueous $HClO_4$–$LiClO_4$). The volumes of activation for the acid independent and inversely acid dependent hydrolysis pathways are -5.4 ± 0.5 and -1.6 ± 0.3 cm^3 mol^{-1} respectively, and are not detectably pressure-dependent. Consideration of these values, together with the molar volume change of -3.3 ± 0.3 cm^3 mol^{-1} determined dilatometrically for the completed hydrolysis reaction, indicates that the mechanisms of the two pathways are associative interchange (I_a) and dissociative conjugate base (D_{cb}) respectively.

MILTON CORNELIUS WEEKES et THOMAS WILSON SWADDLE. Can. J. Chem. **53**, 3697 (1975).

On a mesuré la vitesse d'hydrolyse de l'ion iodopentaaquochrome(III) en fonction de la pression (0.1 à 250 MPa) et de la concentration des ions hydrogènes (0.1 à 1.0 mol kg^{-1}) à 298.2 K et à une force ionique de 1.0 mol kg^{-1} ($HClO_4/LiClO_4$ aqueux). Les volumes d'activation pour les hydrolyses indépendante de l'acide et dépendante inversement sur l'acide sont respectivement de -5.4 ± 0.5 et -1.6 ± 0.3 cm^3 mol^{-1} et ne sont pas dépendantes de la pression dans les limites de détection. Un examen de ces valeurs, en comparaison avec les changements volumiques molaires de -3.3 ± 0.3 cm^3 mol^{-1} déterminés d'une façon dilatométrique pour la réaction d'hydrolyse complète, indique que les mecanismes des deux voies sont respectivement un interchange associatif (I_a) et une base conjuguée dissociative (D_{cb}).

[Traduit par le journal]

Introduction

In recent articles (1, 2), we summarized evidence which we take to indicate that simple chromium(III) substitution reactions of the type

[1] $Cr(solvent)_5X^{(3-n)+} + solvent \rightleftharpoons Cr(solvent)_6^{3+} + X^{n-}$

proceed via an associative interchange (I_a) mechanism (3), except perhaps where 'induced solvolysis' (*e.g.*, of $Cr(solvent)_5N_3^{2+}$ by NO^+), *trans*-activation, or conjugate base solvolysis are involved, in which cases the mechanism is probably of the dissociative type (D or D_{cb}). For the aquation of the iodopentaaquochromium(III) ion, however, the distinction between I_a and alternative D or I_d mechanisms is less clear, since I^- is an excellent 'leaving group'.

[2] $Cr(H_2O)_5I^{2+} + H_2O \rightarrow Cr(H_2O)_5^{3+} + I^-$

King and co-workers (4, 5) have presented observations relating to the solvolysis of $Cr(H_2O)_5I^{2+}$ in acidic aqueous methanol and aqueous dimethylsulfoxide which are most readily interpreted in terms of a D mechanism, but which do not rule out an I_a process (1). We have therefore sought mechanistic information

from the effects of pressure on the rates of the acid independent (aquation) and inversely acid dependent (conjugate base hydrolysis) pathways of reaction 2, which operate concurrently in aqueous solutions in which the hydrogen ion concentration is about 0.1 to 1.0 mol kg^{-1}.

Experimental

Solutions were prepared at 294 K on the basis of the molar (mol dm^{-3}) concentration scale, but the molar concentrations of solutes in the solutions used in the kinetic studies (1.000 mol dm^{-3} $HClO_4$–$LiClO_4$) were converted to the pressure-independent molal (mol kg^{-1}) scale by multiplying by 1.048.

Solutions of $Cr(H_2O)_5I^{2+}$ perchlorate in aqueous perchloric acid were prepared and characterized as previously described (6). Solid $[Cr(H_2O)_5I]SO_4 \cdot H_2O$ was made by the method of Moore and Basolo (7), and analyzed gravimetrically for I^- and SO_4^{2-} and spectrophotometrically for Cr as CrO_4^{2-} after oxidation with alkaline hydrogen peroxide solution. The spectrum of the freshly-aquated sulfate salt in aqueous $HClO_4$ showed that no significant amount of $Cr(H_2O)_5SO_4^+$ was present in the solid salt.

Anal. Calcd. for $[Cr(H_2O)_5I]SO_4 \cdot H_2O$: Cr, 13.6; I, 33.1; SO_4, 25.1. Found: Cr, 13.2; I, 32.8; SO_4, 26.0.

Kinetic Measurements

The rate of disappearance of $(H_2O)_5CrI^{2+}$ in aqueous $HClO_4$–$LiClO_4$ solutions was followed spectrophotometrically at 260 nm using a Cary 17H spectrophotometer, the solution sample being contained in the Hastelloy-C-lined pressurizable assembly described previously (8). The pressurizable optical cell was thermostated (298.2 ± 0.1 K) with a close-fitting aluminum jacket through which water circulated rapidly from an external thermostat bath.

Measurement of Volume of Reaction

Typically, a weighted sample ($\sim 2 \times 10^{-4}$ mol) of $[Cr(H_2O)_5I]SO_4 \cdot H_2O$ was dissolved rapidly in 50 cm^3 $HClO_4$ (1.00 mol dm^{-3}) which was maintained at 298.15 K, with a variation of less than 0.01 K, in an oilbath shielded from drafts. A Carlsberg-type dilatometer, also at 298.15 K, was quickly filled with the solution and replaced promptly in the bath, and the progress of reaction 2 was then followed by observing the meniscus height h_t as a function of time t (9). It was shown, using plain water, that the initial temperature perturbations associated with this procedure subsided within 20 min at most.

Results

The rate of aquation of $(H_2O)_5CrI^{2+}$ was accurately first order in $[(H_2O)_5CrI^{2+}]$ at a given $[H^+]$; the corresponding rate coefficients k_{obs} (Table 1), obtained by least-squares reduction of the spectrophotometric data, reproducible within 1%, were the same at atmospheric pressure and a given $[H^+]$ whether the reaction was carried out in the pressurizable assembly or in ordinary glass vessels, and agreed well with those reported previously (6). Graphical analysis of the data of Table 1 (supplemented with data from ref. 6, for atmospheric pressure) showed that, at any one pressure, k_{obs} was accurately a linear function of $[H^+]^{-1}$, the intercept k_a and slope k_b representing the rate coefficients of the aquation and conjugate base hydrolysis pathways respectively.

$$[3] \qquad k_{obs} = k_a + k_b[H^+]^{-1}$$

Plots of $\ln k_a$ and $\ln k_b$ against pressure P were also linear, within the experimental uncertainty, with no systematic deviations of the data points from the representative straight line. Thus, the volumes of activation ΔV_a^* and ΔV_b^* (−5.6 and −1.4 cm^3 mol^{-1} respectively, from the slopes of these plots) were independent of pressure ($0 < P \leq 250$ MPa) within the experimental error, and were therefore recalculated directly using an IBM 371/145 computer by a least-squares fit of

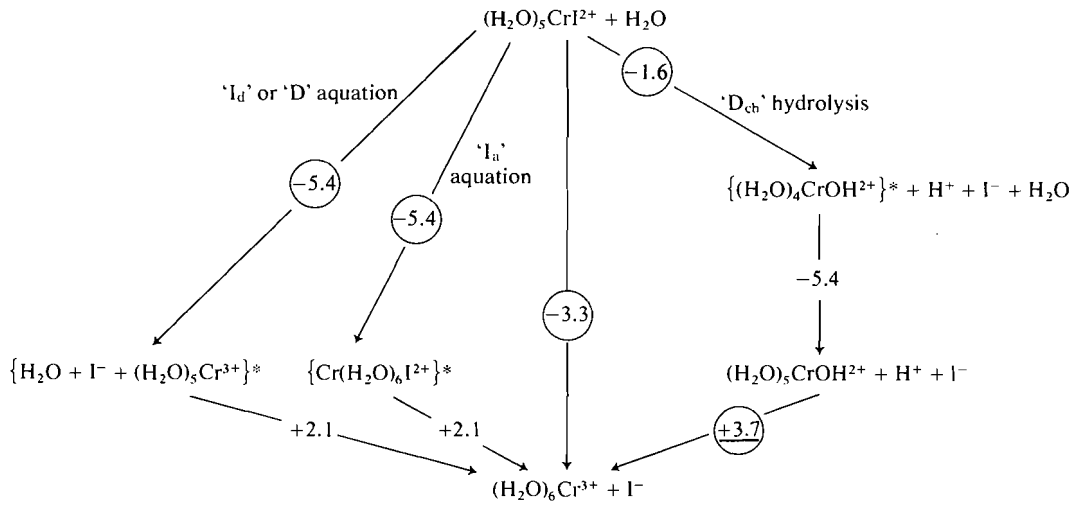

FIG. 1. Volume changes ($cm^3\ mol^{-1}$) associated with the various steps in the aquation (left hand side) and conjugate base hydrolysis (right hand side) of the iodopentaaquochromium(III) ion in aqueous perchlorate media at 298.2 K and ionic strength 1.0 mol kg^{-1}. Asterisks denote transition states. Circled data are from this study, that underlined is from ref. 8, and the remainder are obtained by difference.

k_{obs} values to the equation

$$[4]\quad k_{obs} = k_a^0 \exp(-P\Delta V_a^*/RT) + k_b^0[H^+]^{-1} \exp(-P\Delta V_b^*/RT)$$

where k_a^0 and k_b^0 represent the values of k_a and k_b at zero pressure. The values and standard errors of the parameters so calculated were

$$\Delta V_a^* = -5.4 \pm 0.5\ cm^3\ mol^{-1}$$

$$\Delta V_b^* = -1.6 \pm 0.3\ cm^3\ mol^{-1}$$

$$k_a^0 = (7.84 \pm 0.28) \times 10^{-5}\ s^{-1}$$

and

$$k_b^0 = (3.72 \pm 0.06) \times 10^{-5}\ mol\ kg^{-1}\ s^{-1}$$

for $T = 298.2$ K and ionic strength $I = 1.048$ mol kg^{-1} ($HClO_4$–$LiClO_4$).

From the dilatometric measurements, plots of $\ln(h_t - h_\infty)$ *vs.* time t were found to be linear, with slopes corresponding to k_{obs} values in satisfactory agreement with those obtained spectrophotometrically, and, by extrapolation of h_t back to the time of dissolution of the $[Cr(H_2O)_5I]SO_4 \cdot H_2O$, the molar volume change ΔV^0 for the completed reaction 2 was calculated. The mean of five such determinations gave $\Delta V^0 = -3.3 \pm 0.3\ cm^3\ mol^{-1}$ for $I = 1.05$ mol kg^{-1} at 298.15 K and 0.1 MPa.

Discussion

The volume changes associated with the various steps in the hydrolysis of $Cr(H_2O)_5I^{2+}$ are summarized in Fig. 1, in which no distinction is made between D and I_d mechanisms for aquation, the transition states for both being represented by $\{I^- + (H_2O)_5Cr^{3+}\}^*$. This simplification seems justified in the present context. There is no reason to suppose that the hypothetical D *intermediate* $(H_2O)_5Cr^{3+}$ would differ much in free energy from the *transition state* for its formation, and hence, on the basis of the Hammond principle (10), the D transition state itself may be represented approximately as $\{I^- + (H_2O)_5Cr^{3+}\}$. In an I_d process, as typified by substitution reactions of cobalt(III) ammines (1, 3, 11), the bond between the central metal atom and the departing ligand is broken and the departing ligand fully solvated, in the transition state, so that the distinction between I_d and D transition states need not be made in the present context.

The volume change $\Delta V_a^* = -5.4\ cm^3\ mol^{-1}$ on going from the initial state to the transition state of the aquation reaction is certainly consistent with an I_a mechanism, in which H_2O—Cr bond formation must involve contraction (12), but does not *in itself* rule out the possibility of a dissociative type of mechanism in which the positive contribution of Cr—I bond breaking to ΔV_a^* is more than compensated for by a large, negative contribution from solvation of the newly-created tripositive chromium(III) ion and mononegative iodide. However, when ΔV_a^* is com-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

pared to the molar volume change $\Delta V^0 = -3.3$ cm^3 mol^{-1} for the completed reaction, it becomes very difficult to reconcile it with a D or I_d aquation mechanism, since these would then require that the difference in solvation between the initial and transition states be greater than between the initial and final states. This point is brought into sharper focus by consideration of the *positive* volume change that occurs on going from the transition state to the final state; it is very hard to accept that this could arise from the formation of a bond between the incoming water molecule and the $Cr(H_2O)_5^{3+}$ moiety, so that the possibility that the acid-independent aquation reaction proceeds via a D or I_d mechanism may be discounted. This observation is, however, consistent with an overall I_a aquation process whereby the iodide ligand is expelled from the transition state $\{Cr(H_2O)_6I^{2+}\}^*$ in which the modest degree of additional solvation required (see below) has been partly achieved (9), so that the bond-breaking contribution to the further volume change outweighs the solvational part. The same argument can be applied in support of an I_a mechanism for the aquations of $Cr(NH_3)_5X^{2+}$ (X = Cl, Br, I), for which ΔV_a^* is again some 2 to 3 cm^3 mol^{-1} more negative than ΔV^0 (9). By contrast, for the aquations of $Co(NH_3)_5X^{(3-n)+}$, to which an I_d mechanism is assigned, ΔV_a^* is always more *positive* than ΔV^0 by an amount which corresponds to the addition of H_2O to a transient $Co(NH_3)_5^{3+}$ species (11).

In the conjugate base hydrolysis pathway (right hand side of Fig. 1), the presumed intermediate $(H_2O)_4CrOH^{2+}$ of a D_{cb} process is identified with the transition state of the reaction. This transition state will be reached in two steps

$$[5] \quad (H_2O)_5CrI^{2+} \overset{\text{fast}}{\rightleftharpoons} (H_2O)_4Cr(OH)I^+ + H^+$$

$$[6] \quad (H_2O)_4Cr(OH)I^+ \xrightarrow{\text{rate determining}} (H_2O)_4CrOH^{2+} + I^-$$

The volume change associated with [5] is not known, but ΔV values for the analogous reactions of $Cr(H_2O)_6^{3+}$ (8), $Fe(H_2O)_6^{3+}$ (13), $Tl(H_2O)_6^{3+}$ (13), and $Co(NH_3)_5OH_2^{3+}$ (8) all lie in the range -1 to -4 cm^3 mol^{-1}, so that ΔV is likely to be about -2 cm^3 mol^{-1} for [5]. The volume change for [6] can therefore be estimated to be very close to zero, which is reasonable if the mechanism is D_{cb} and the bond-breaking and solvational changes effectively cancel each other, but not if the mechanism were of an associative type, since both the H_2O—Cr bond-making and the solvational changes would then be expected to make negative contributions to the volume change. This inferred near-cancellation of Cr—I bond-breaking and solvational contributions indicates that the solvational changes must be fairly small in the reaction under consideration, since the bond-breaking contribution is small in metal complexes, and this is confirmed by the lack of any significant pressure-dependence of ΔV_a^* or ΔV_b^* (11).

This same inferred compensation of volume changes arising from Cr—I bond stretching by the contraction due to concomitant solvation of the developing additional charges lends further support to the assignment of an I_a mechanism to the aquation reaction, as ΔV_a^* may then be largely accounted for in terms of the contraction caused by removal of the attacking water molecule from the second coordination sphere of the dipositive complex ion and its implantation in the first (12). This interpretation is, in turn, supported by the inference from Fig. 1 that ΔV_a^* is the same as the volume change (-5.4 cm^3 mol^{-1}) for the similar addition of a water molecule to $\{(H_2O)_4CrOH^{2+}\}^*$, which, despite the difference in coordination number, resembles $(H_2O)_5CrI^{2+}$ closely in that it is an aquochromium(III) complex containing a simple mononegative anion in its first coordination sphere.

ΔV_a^* for $(H_2O)_5CrI^{2+}$ is about 60% as large numerically as the corresponding quantity for aquo-exchange in $Cr(H_2O)_6^{3+}$ (12), which again seems reasonable when ΔV_a^* is ascribed in large part to the H_2O—CrI^{2+} bond-making contribution, since the second coordination sphere from which the attacking water molecule is removed is presumably more extensive and structured in the tripositive than in the dipositive complex ion.

In summary, we can say that if, as in this discussion, the mechanisms of hydrolysis of $Cr(H_2O)_5I^{2+}$ are to be represented in terms of the Langford–Gray models (3), then the mechanism of simple aquation is best described as I_a and that of conjugate base hydrolysis as D_{cb}, on the basis of the respective volumes of activation relative to the overall volume of reaction. Whatever detailed mechanistic model is proposed, it does at least seem necessary to recognize that the aquation pathway (left hand side of Fig. 1) involves a rate determining step which is mechanistically different from, and more com-

pact than, that of the conjugate base hydrolysis pathway (reaction 6). Full confirmation of this would, however, require direct measurement of the volume change associated with [5].

Chromic Acid Esters as Corrosion Inhibitors

EDWARD L. GHALI AND BERTRAND GIRARD

Department of Applied Science, University of Quebec at Chicoutimi, Chicoutimi, Quebec G7H 2B1

AND

JEAN-MARIE HACHEY

Department of Pure Science, University of Quebec at Chicoutimi, Chicoutimi, Quebec G7H 2B1

Received February 17, 1975[1]

EDWARD L. GHALI, BERTRAND GIRARD, and JEAN-MARIE HACHEY. Can. J. Chem. **53**, 3702 (1975).

The hydrolysis of the chromate ester, derived from 1-methylcyclohexanol, was studied by electrochemical methods. Progressive and complete hydrolysis in an open or closed system yields chromic acid and 1-methylcyclohexanol. No evidence of the presence of monoester was detected. In a closed system, where most of the hydrolyzed alcohol is retained in solution, a side reaction between chromic acid and the alcohol has been detected and followed by conductivity measurements.

Electrochemical characteristics of pure iron immersed in aqueous solutions containing hydrolyzed ester were found to be identical to those in aqueous solutions containing equivalent quantities of Cr^{VI} as CrO_3. Sulfuric acid additions to the above solutions still give comparable electrochemical characteristics; however, the anodic current in the passive region was found to be less for solutions containing hydrolyzed ester than for solutions containing equivalent quantities of Cr^{VI} as CrO_3.

EDWARD L. GHALI, BERTRAND GIRARD et JEAN-MARIE HACHEY. Can. J. Chem. **53**, 3702 (1975).

L'hydrolyse de l'ester chromique dérivé du méthyl-1 cyclohexanol fut étudiée par des méthodes électrochimiques. L'hydrolyse progressive et complète dans un système ouvert ou fermé donne l'acide chromique et le méthyl-1 cyclohexanol. Nous n'avons pas pu détecter la présence de monoester. Dans un système fermé, où presque tout l'alcool est retenu en solution, une réaction secondaire entre l'acide chromique et l'alcool a été décelée par des mesures de la conductivité.

Les caractéristiques électrochimiques du fer pur dans l'eau contenant les produits d'hydrolyse de l'ester sont identiques à celles déterminées dans des solutions aqueuses contenant des quantités équivalentes de Cr^{VI} sous forme de CrO_3. Des additions d'acide sulfurique dans ces solutions donnent toujours des caractéristiques électrochimiques comparables. Cependant, dans le cas des solutions contenant les produits d'hydrolyse de l'ester, le courant anodique dans la région de passivation était inférieur à celui mesuré pour des solutions renfermant des quantités équivalentes de Cr^{VI} sous forme de CrO_3.

Chromates and dichromates of alkaline metals, and even chromium trioxide, have long been utilized as corrosion inhibitors in aqueous media in many industrial applications; different mechanisms to explain the kinetics of inhibition have been suggested (1–3).

Chromic acid esters derived from tertiary alcohols have been synthesized and briefly described in the literature by many authors; several papers published in this field have been summarized in a review article (4). In particular, the synthesis of the chromate ester derived from 1-methylcyclohexanol has already been accomplished by Cerveny (5); however, the spectroscopic characteristics of this compound were not described. He principally carried out some studies concerning the inhibiting effect of different chromic acid esters and especially those of tertiary alcohols (5–7).

The mechanism of the action of chromic acid esters can be summarized as follows: (*a*) the ester, soluble in a nonpolar phase, diffuses to the interface of the nonpolar and polar solutions, (*b*) hydrolysis occurs, and (*c*) the liberated chromate ions may act as corrosion inhibitors. Cerveny found that the diffusion of the ester, the liberation of chromate ions by hydrolysis, and concomitant passivation occur so fast that in a real system electrochemical corrosion of metal can be stopped in the presence of an oil film containing the ester. The physico-chemical properties of mineral oils are affected slightly or not at all by the chromic acid esters. Cerveny also reported that the minimum concentration of the

chromate in aqueous solutions necessary for inhibition is 10^{-5} to 10^{-4} *M* (5, 7).

Chromate esters have the advantage of being soluble in nonpolar media; many interesting applications can then be found if they have the same inhibiting effect as inorganic inhibitors in aqueous solutions. For the system 'atmosphere – oil containing chromic acid ester – aqueous layer – metal' or other comparable systems, the process of hydrolysis is considered as one of the important stages in the inhibition by chromic acid esters since it liberates the chromates which contribute to the protection of the metal. It is also interesting to determine whether the inhibiting action of hydrolyzed esters is different or equivalent to that of the chromates. The object of this work was then to study the process of hydrolysis of chromic acid esters and to examine the products of hydrolysis as corrosion inhibitors, compared to the chromates, in distilled water and in acidic medium.

Experimental

Synthesis of Di(1-methylcyclohexyl) Chromate

This product was synthesized according to the general procedure described by Wienhaus (8) for chromate esters derived from tertiary alcohols. The infrared spectra, the proton magnetic resonance spectra and gas chromatographic analysis were taken to identify the ester and its products of hydrolysis. The infrared spectra were measured on a Unicam Spectrophotometer, Model SP-1000 as films of pure liquid and in solution in CCl_4 between NaCl plates. Proton magnetic resonance spectra were taken on a Hitachi–Perkin–Elmer spectrometer, Model R-24 at 60 MHz. Tetramethylsilane was used as the internal standard and chemical shifts on the δ scale are given. The ultraviolet spectra were recorded on a Perkin–Elmer spectrophotometer, Model Coleman 124. Gas chromatographic analyses were done on a Hewlett–Packard instrument, Model 5754B (column: Cu 3/16 in. i.d. × 6 ft, Carbowax 20 M 10% (w/w) on Chromosorb P, 60–80 mesh, oven temperature 140 °C).

Analytically pure chemicals were used for the preparation of the ester and for the electrochemical investigations. The pure iron (Ferrovac) used was prepared by Colt Industries (Canada) Ltd. and was delivered in the form of hot rolled rods of 1 in. diameter. It had the following percentage composition: C: 0.004; Mn: 0.001; P: 0.002; S: 0.005; Si: 0.008; Ni: 0.027; Cr: 0.01; Mo: 0.001; V: 0.004; W: 0.01; Co: 0.003.

The potentiostat for polarization studies was PRT 30-01 Type, Tacussel Electronique, ultra-fast. Conductivity measurements were made using CDM 2e Type Radiometer (Copenhagen). p*H* measurements were conducted employing Fisher Accumet Model 220 p*H* meter.

Preliminary experiments showed that the water/ester ratio may have an influence on the product of hydrolysis. Hydrolysis in both closed and open systems was achieved by mixing an excess of water (1 l) with a small quantity of ester (0.095 to 9.5 g). (A closed system is one in an air-tight beaker insulated from the atmosphere by a watch-glass cover sealed with paraffin. An open system is one where the solution was in direct contact with the atmosphere.)

Electrochemical characteristics of iron including polarization curves were determined in aqueous solutions with the addition of hydrolyzed chromate ester or equivalent quantities of Cr^{VI} as CrO_3. The same study was also done in acidic solutions (sulfuric acid) containing hydrolyzed esters and chromates, respectively. The rectangular surface examined had a geometrical area of 1 cm^2. The surface was mechanically polished with abrasive papers and finally with aluminum oxide suspensions of 1 μ followed by 0.05 μ. The sample was washed with distilled water, alcohol, then distilled water, and finally immersed immediately in the electrolyte. The solution used for polarization studies was deaerated by bubbling nitrogen for 12 h. Cathodic polarization was carried out for 30 min at 1200 mV/S.C.E. before plotting the potentiokinetic curve. The potential was varied in the noble direction at a uniform rate of 16.7 mV/min. The 1 l solution used was circulated (50 ml/min) and maintained at a constant temperature of 26 ± 0.5 °C. Concentration of chloride ions in solution was found to be less than 1 p.p.m.

Results and Discussion

Identification of Di(1-methylcyclohexyl) Chromate

The infrared spectra of the chromate ester show the following characteristics: (1) disappearance of all —OH bands; (2) presence of Cr—O bands at 968 and 990 cm^{-1}. These results agree well with those of Zeiss and Matthews (9) who observed Cr—O bands at 971 and 990 cm^{-1} for di(2,4-dimethyl-4-hexyl) chromate.

Characteristics of the p.m.r. spectrum in CCl_4 of the synthesized chromic acid ester are given in Table 1. A comparison is made with those of 1-methylcyclohexanol. It can be observed that the methyl group of the chromate ester appears at a lower field (~1.5 p.p.m.) in comparison to the methyl group of the alcohol (~1.2 p.p.m.). The protons of the ring are also deshielded but to a less degree (6 Hz). Similar observations have previously been noted (10) in the case of other tertiary alicyclic alcohols methylated in the α position.

The ultraviolet spectrum in hexane (reagent grade) shows a maximum absorbance at 375 nm ($\log \varepsilon = 1.7$) and at 285 nm ($\log \varepsilon = 3.9$). Zeiss and Zwanzig (11) noted two absorption bands for the chromate ester derived from 2-methylfenchol: one at 287 and the other at 393 nm. However, these authors gave no values for the extinction coefficient.

The quantity of chromium determined by

TABLE 1. Proton magnetic resonance spectra determined in CCl_4

Compound	Chemical shift	Multiplicity	Type of protons
1-Methylcyclohexanol	1.18±0.02	Singlet	CH_3
	1.48±0.02	Broad singlet	$(CH_2)_5$
	3.10±0.02	Singlet	OH
Di(1-methylcyclohexyl) chromate	1.50±0.02	Singlet	CH_3
	1.57±0.02	Broad singlet	$(CH_2)_5$

chemical analysis (12) was in good agreement with stoichiometric composition of di(1-methylcyclohexyl) chromate.

Hydrolysis of Di(1-methylcyclohexyl) Chromate

The p*H* values were measured at different times during the hydrolysis of di(1-methylcyclohexyl) chromate in a closed system (~9.5 g of ester in 1 l water).

In the first 10 min, the p*H* value decreased rapidly (Fig. 1). Further decrease was much slower, and the p*H* value remained practically constant (within the limits of the sensitivity of the p*H* meter and other experimental errors) even after one week. The first rapid decrease obviously corresponded to the progressive hydrolysis of the chromate ester into chromic acid and 1-methylcyclohexanol. This period was followed by a very slight gradual increase in p*H*, but this could not be characterized clearly because of the limit of sensitivity of the method employed.

Assuming that one of the products of hydrolysis is a good electrolyte (chromic acid) as compared to the ester, measurement of conductivity should indicate the rate of hydrolysis of the ester. Preliminary measurements showed a variation of conductivity of an 'ester + water' solution as a function of time, and also the variation depended on whether the system was open or closed. Results are given in Fig. 2.

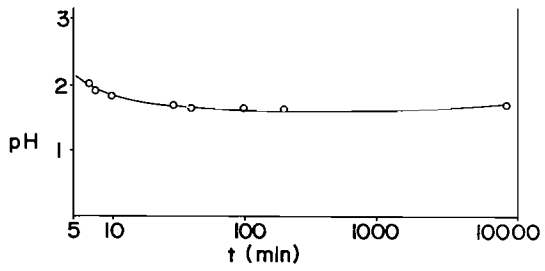

FIG. 1. Hydrolysis of chromic acid ester; p*H* as a function of time.

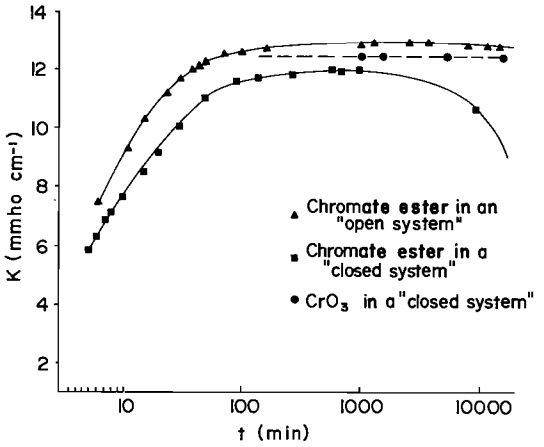

FIG. 2. Hydrolysis of chromic acid ester; specific conductivity as a function of time.

Hydrolysis of a closed system led to three distinct regions of conductivity as a function of time. (*1*) A region where conductivity increased rapidly and continuously for the first 2 h. (*2*) A region where conductivity was a maximum and could be considered constant for a period of 20 h. (*3*) A region where conductivity first decreased rapidly, then slowly; and the slow drift was observed even after 25 days.

In an open system conductivity first increased as in (*1*) until the maximum was reached. It then remained constant even after 25 days.

Conductivity of an inorganic chromate in a closed system is also given in Fig. 2. The final conductivity of the hydrolyzed ester in an open system is equal to the conductivity of a chromate solution containing the same amount of Cr^{VI}. Hydrolysis of the ester was completed after 1000 min.

Electrochemical Characteristics of Pure Iron in Solutions Containing Hydrolyzed Chromic Acid Ester

Aqueous Solutions

The dissolution or corrosion potential of iron immersed in a solution with hydrolysis products

of chromate ester of 1-methylcyclohexanol is the same as that of iron immersed in a solution containing CrO_3 with the equivalent quantity of Cr^{VI} and with the same pH. This result has been confirmed for different concentrations and different values of pH (Fig. 3). The linear relation between potential and the logarithm of the concentration is found to be the same for CrO_3 and for hydrolyzed ester. Figure 4 gives the polarization curves for iron immersed in a solution with hydrolysis products of chromate ester and with CrO_3 containing the equivalent quantity of Cr^{VI}. The cathodic curves of iron in the two solutions were found to be almost the same. This is also valid for anodic curves. However, it can be noted that the anodic current in the passivation region is somewhat more important in the case of CrO_3 than in the presence of hydrolysis products of chromate ester.

The electrochemical characteristics (corrosion current, cathodic exchange current, and hydrogen overvoltage) are determined for iron in different concentrations of CrO_3 and hydrolyzed chromate ester. The results are given in Figs. 5 and 6, which show that for the concentrations and pH used, the electrochemical parameters are almost the same as those determined previously.

Aqueous Solutions Containing Sulfuric Acid

Figure 7 shows polarization curves of iron in the two solutions containing sulfuric acid (5×10^{-4} M): one with CrO_3 and the other with hydrolyzed chromic acid ester with the equivalent quantity for Cr^{VI}. The curves are almost identical, indicating that the electrochemical

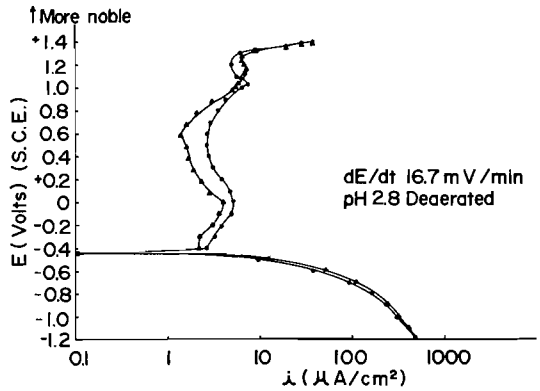

FIG. 4. Polarization curves of CrO_3 in water (●) and hydrolyzed chromate ester (▲). $[Cr^{VI}] = 3 \times 10^{-3}$ M; pH = 2.8.

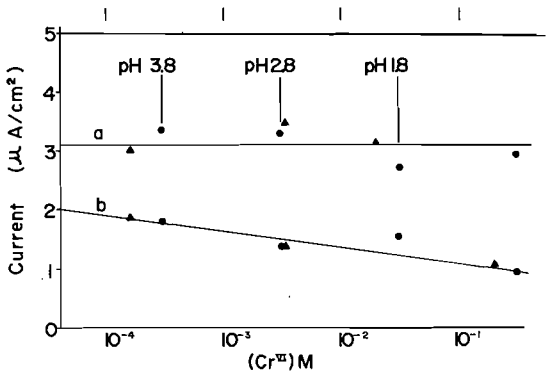

FIG. 5. Corrosion currents (*a*) and cathodic exchange currents (*b*) as a function of pH and Cr^{VI} content of hydrolyzed chromate ester (▲) and CrO_3 in water (●).

parameters are not different. It can also be observed that the anodic current during passivation is more important in the case of CrO_3 than that of hydrolyzed ester.

We can also mention that for a low concentration of hydrolyzed ester, below that required to produce an effective inhibition, we found that there is no important variation of electrochemical characteristics of iron if compared with that of iron in the same solution but with equivalent quantity of Cr^{VI} in a CrO_3 solution.

Interpretations

The results of hydrolysis (Fig. 2) suggest the following explanations in the case of large excess of water and small quantities of ester. In the closed system, the first step where the conduct-

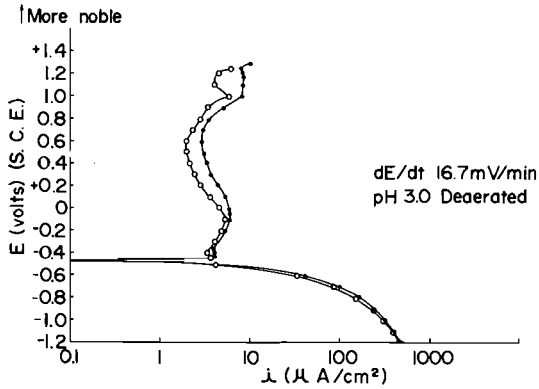

FIG. 7. Polarization curves of iron in $5 \times 10^{-4}\ M$ H_2SO_4 solutions containing CrO_3 (●) or hydrolyzed chromate ester (○). $[Cr^{VI}] = 1 \times 10^{-2}\ M$; p$H$ = 3.0.

ivity is continuously increasing agrees with the progressive hydrolysis of the chromic acid ester.

The region of maximum conductivity would correspond to complete hydrolysis, *i.e.*, the reaction mixture then contains 1-methylcyclohexanol and chromic acid

$$ROCrO_2OR \xrightarrow{\text{excess } H_2O} 2ROH + H_2CrO_4$$

Finally, the region showing a drift in conductivity after the maximum would correspond to the reaction of a strong acid (chromic acid) with a weak base (1-methylcyclohexanol). Indeed, the behavior of 1-methylcyclohexanol in the presence of chromic acid is a consequence of the basic character of the alcohols (13, 14) which act as Lewis bases, capable of accepting a proton dissociated from the chromic acid. This reaction is obviously impossible if one permits evaporation of the alcohol in an open system (Fig. 2). This hypothesis has been verified by preparing a solution with a mixture of 1-methylcyclohexanol and chromic acid similar to that expected from complete hydrolysis of the chromic ester; a similar curve for the region showing a drift in the conductivity was obtained.

This explanation is also supported by the following results: the extraction of the hydrolysis products derived from di(1-methylcyclohexyl) chromate gives more than 80% of the expected amount of 1-methylcyclohexanol; it is the single organic product obtained from the mixture. In view of these results, one must conclude that there is no oxidation–reduction reaction during the hydrolysis. Moreover, during the extraction, the organic layer remains colorless, indicating the absence of chromate ester, which is soluble in the organic solvents used (ether, hexane). In order to extract all traces of organic compounds possibly present, extractions have also been performed after saturation of the aqueous layer with NaCl; these extractions gave the same results as those obtained in the untreated aqueous layer. Similar results were observed after the extraction of the aqueous layer previously neutralized with a solution of 10% NaOH.

Furthermore, we mixed 1-methylcyclohexanol and an aqueous solution of chromic acid under the same conditions as the hydrolysis of di(1-methylcyclohexyl) chromate. We extracted the mixture with hexane and observed that the hexane fraction always remained colorless. The absence of chromic ester was verified by p.m.r. analysis; the hydrolyzed chromate ester gave (Table 2) the same characteristics as those observed for the mixture '1-methylcyclohexanol + CrO_3 + H_2O'. These results also show the disappearance of the —OH signal, which is fused with the H_2O signal.

In order to evaluate the stability of CrO_3 in water, we studied the behavior of an aqueous solution of CrO_3 under the same conditions as those existing during the hydrolysis (*i.e.* closed system, continuous agitation, constant temperature). Conductivity of such a solution remained constant (Fig. 2), thus indicating the stability of the chromates.

The maximum conductivity of completely hydrolyzed chromate ester in either an open or closed system corresponds to the conductivity of an equivalent quantity of Cr^{VI} present as H_2CrO_4. Figure 8 shows a linear relation between the concentration of Cr^{VI} (in p.p.m.) contained in H_2CrO_4 and log K (in $\mu mho\ cm^{-1}$). The calculated quantities of Cr^{VI} as H_2CrO_4,

assuming complete hydrolysis of ester in chromate, show the same linear relation with respect to log K. This observation is confirmed for four different concentrations of hydrolyzed esters. We can therefore conclude that complete dissociation gives chromic acid as a final product along with the alcohol.

It is interesting to consider the stable ions formed during hydrolysis. We consider that maximum conductivity in an open or closed system corresponds to complete dissociation. The progressively increasing conductivities from the beginning of dissociation until the maximum permits an estimate of the rate of dissociation. The fraction of ester hydrolyzed at any time of the hydrolysis can thus be determined. By using a calibration curve of conductivity *vs.* $[CrO_3]$ (Fig. 8), and by assuming that the chromate ester hydrolysis products are completely dissociated, it is possible to construct calculated curves of conductivity *vs.* time during the hydrolysis of chromic acid ester. Close agreement between the calculated and experimental curves (Fig. 9) support the assumption that the chromic acid ions are the ones responsible for the conductivity values obtained. There may be some formation of monoester but this intermediate cannot be detected.

The presence of alcohol as a product of hydrolysis of chromate ester does not affect the inhibiting power of chromates in an aqueous solution, with or without the presence of sulfuric acid. This is the case at least when water is present in large excess, certainly corresponds to most of the practical conditions. This assumption may not hold when the amount of alcohol is comparable to the amount of water present. It may be noted from Figs. 4 and 7 that the current density during passivation is slightly lower for iron in solutions containing hydrolyzed chromate ester than for solutions containing CrO_3 and this may contribute to a slightly higher protective power of chromate ester employed as inhibitors.

In a closed system, a side reaction occurs between the protons of the chromic acid and the alcohol. This may shift the pH towards higher values. If this shift is very significant, it will affect the electrochemical characteristics of iron and consequently improve the inhibiting power of hydrolyzed esters.

Conclusions

The hydrolyzed chromate ester of 1-methylcyclohexanol is as effective as chromium trioxide for protecting metallic surfaces in a polar medium. The complete and progressive hydrolysis of chromate ester gives chromic acid and the alcohol. The monoester, if present, is assumed to be very unstable. If the hydrolysis is done in a closed system, a side reaction of the chromic acid with alcohol may occur. It has been shown that conductivity measurement is suitable to study the rate of hydrolysis of organometallic compounds.

Kinetics and Mechanism of the Oxidation of Benzyl Alcohol and Benzaldehyde by Aqueous Sodium Dichromate

DONALD G. LEE AND UDO A. SPITZER

The Department of Chemistry, University of Regina, Regina, Saskatchewan S4S 0A2

Received May 6, 1975

DONALD G. LEE and UDO A. SPITZER. Can. J. Chem. **53**, 3709 (1975).

A kinetic study of the oxidation of a series of substituted benzyl alcohols and benzaldehydes by neutral aqueous sodium dichromate has been completed. The aldehydes are more resistant to oxidation because the reaction mechanism presumably involves hydration prior to oxidation, and under the conditions employed the extent of this hydration is suppressed. These conclusions are consistent with the activation parameters which indicate that the difference in oxidation rate is due to a more negative entropy of activation for the aldehydes.

DONALD G. LEE et UDO A. SPITZER. Can. J. Chem. **53**, 3709 (1975).

On a complété une étude cinétique de l'oxydation d'une série d'alcools benzyliques substitués et de benzaldéhydes par du dichromate de sodium aqueux en milieu neutre. Les aldéhydes sont plus résistants à l'oxydation dû au fait que le mécanisme de réaction implique probablement une hydratation avant l'oxydation et dans les conditions utilisées l'hydratation est supprimée. Ces conclusions sont en accord avec les paramètres d'activation qui indiquent que les différences entre les vitesses de réaction sont dûes à une entropie qui est plus négative pour l'activation des aldéhydes.

[Traduit par le journal]

Introduction

The oxidation of aromatic alcohols to the corresponding aldehydes by aqueous sodium dichromate at elevated temperatures (~100 °C) is a reaction that may be used for synthetic preparations that are difficult to accomplish using other oxidants (1). For example, Wakselman *et al.* have recently described the preparation of 7-coumarincarbaldehyde in 84% yield by treatment of the corresponding alcohol with aqueous sodium dichromate at reflux temperature (2). The reaction is of particular interest because it is known that under acidic conditions (which are usually employed for chromic acid oxidations) primary alcohols are oxidized by chromium(VI) to give substantial amounts of carboxylic acids or esters (3, 4) unless the aldehyde can be distilled from the reaction mixture as it forms (5, 6). However, neutral chromium(VI) solutions do not oxidize aromatic aldehydes at an appreciable rate until considerably higher temperatures (150–200 °C) are attained (1).

In the present work we have attempted to increase our quantitative understanding of these reactions by studying the kinetics of the oxidation of several substituted benzyl alcohols and benzaldehydes by aqueous sodium dichromate.

Experimental

The kinetic analyses were performed using a pseudo first-order approach where the substrate concentrations were in excess and the chromium(VI) concentration was monitored spectrophotometrically. In all cases good pseudo first-order kinetics were maintained for more than two half-lives of the reaction (Fig. 1).

The rate data were obtained in the following manner. The required amount of alcohol was weighed into a flask, 20 ml of phosphate buffer was added, and the flask was stoppered and placed in a thermostated bath. Then 1.00 ml of 0.1 *M* chromium(VI) solution was added and the timer started after the solution had been thoroughly mixed. One ml aliquots were withdrawn at intervals, quenched by dilution with cold water to 10.0 ml, centrifuged, and analyzed spectrophotometrically for chromium(VI).

Since the oxidation of the aldehydes could only be studied at temperatures above 150 °C it was necessary to use a sealed reactor for these experiments. The reaction vessel, which has previously been described (7), was charged with the reactants at room temperature, sealed, purged with nitrogen, and brought to a pressure of 320 p.s.i. of N_2. The reactor was then heated to and stabilized at the desired temperature. This required about 1 h of heating; however, since the reactions were always pseudo first-order the rates could be followed by withdrawing samples when the temperature had stabilized and taking the time of the first sample as zero.

The pseudo first-order rate constants were obtained from the slopes of plots of the logarithm of the concentration of $HCrO_4^-$ against time, and then converted to second-order rate constants through division by the concentration of the substrate.

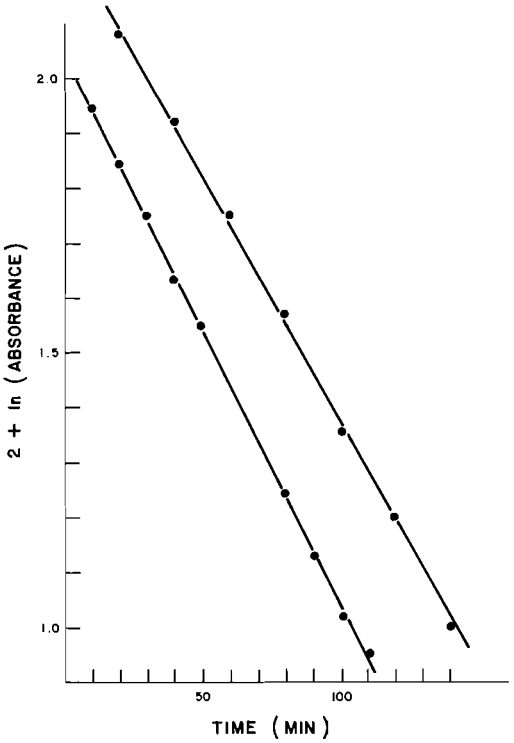

FIG. 1. Pseudo first-order rate plots for the oxidation of benzyl alcohol at 95.9 °C (upper) and the oxidation of benzaldehyde at 170 °C (lower).

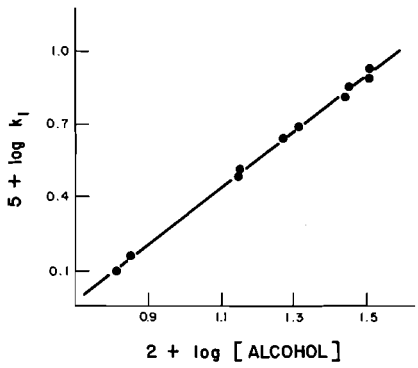

FIG. 2. Dependence of rate constants upon benzyl alcohol concentration. Slope = 1.09, r = 0.997.

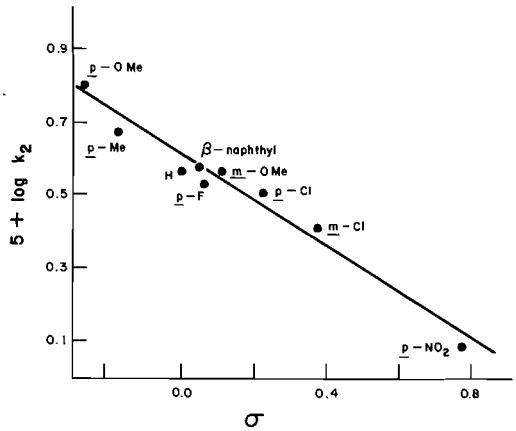

FIG. 3. Hammett plot for the aqueous dichromate oxidation of benzyl alcohols. Slope = −0.61, r = 0.972.

The substituted benzyl alcohols and benzaldehydes were all obtained commercially and purified prior to use. Benzyl alcohol α,α-d_2 was prepared by the lithium aluminum deuteride reduction of benzoic acid (8).

Results and Discussions

Oxidation of Benzyl Alcohol

The aqueous dichromate oxidation of benzyl alcohol appears to be similar in several respects to chromic acid oxidations (9). Some of the common features are: the reaction is first-order in oxidant (Fig. 1) and in benzyl alcohol (Fig. 2); a primary isotope effect is observed when the α-hydrogens are replaced by deuterium (Table 1); a negative Hammett ρ value is obtained (Fig. 3); and similar activation parameters ($\Delta H^{\ddagger}$ = 17.9 ± 0.4 kcal/mole and $\Delta S^{\ddagger}$ = 25 ± 2 e.u.) are obtained (10). Furthermore, chromic acid oxidations of alcohols are known to exhibit rate increases when non-polar organic co-solvents are used (11). These increases, caused by the decrease in solvent polarity, have been attributed to an equilibrium shift favoring the formation of chromate esters. A similar effect was noted in the aqueous sodium dichromate oxidations when various mixtures of dioxane and water were used.

Because of these several similarities it is not unlikely that parallel mechanisms prevail for the two reactions. Consequently we have assumed, in analogy with chromic acid oxidations, that chromium(VI) esters are also involved as intermediates in the oxidation of alcohols by aqueous sodium dichromate. (See Scheme 1).

[2] $\phi CH_2OCrO_3^- \rightarrow \phi CHO + HCrO_3^-$

SCHEME 1

The unfavorable entropy of activation may, at least partially, be due to formation of a cyclic transition state such as **1**.

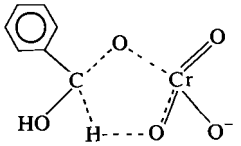
1

The negative Hammett ρ value (−0.6) is probably a consequence of the fact that the slow step involves development of a carbonyl which would be destabilized by electron-withdrawing substituents. The magnitude of the ρ value is less than that observed for the corresponding chromic acid oxidations, thus suggesting that the carbonyl is less fully developed under neutral conditions.

The slight increase in rate that is observed as the pH is decreased (Table 2) is difficult to account for quantitatively and may, in fact, be due to experimental uncertainties since the pH was measured at 25 °C while the reactions were actually carried out at 96 °C (7).



2

The Oxidation of Benzaldehyde

The rate of the oxidation of benzaldehyde shows a first-order dependence upon both the oxidant (Fig. 1) and the substrate (Fig. 4), but requires a much higher temperature than the oxidation of benzyl alcohol (Table 3).

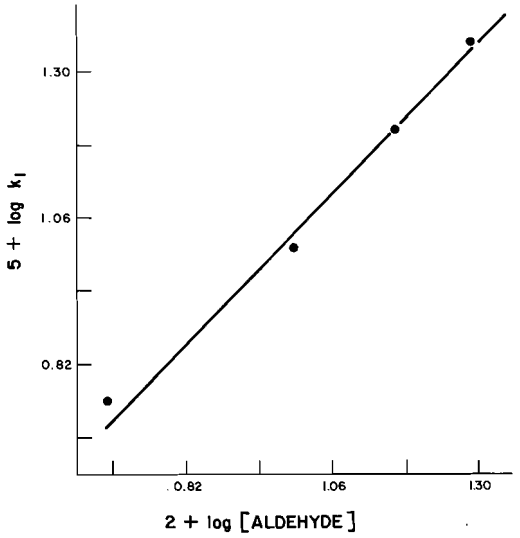


FIG. 4. Dependence of rate upon benzaldehyde concentration. Slope = 0.9 ± 0.1, r = 0.989.

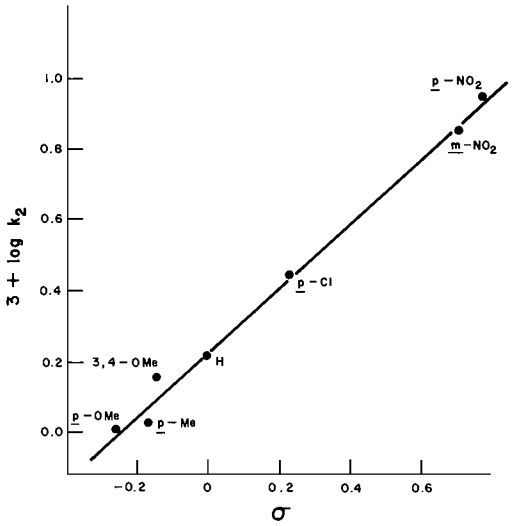

FIG. 5. Hammett plot for the aqueous dichromate oxidation of benzaldehyde. Slope = 1.1, r = 0.983.

The Hammett ρ value is positive for the oxidation of substituted benzaldehydes (Fig. 5) in contrast to the negative ρ value observed for the oxidation of the corresponding benzyl alcohols. A similar observation for the oxidation of aldehydes by chromic acid (12) has been shown to be due to a pre-oxidative hydration step [3]. The suppression of such a hydration step at high temperatures (13) offers an explanation as to why aldehydes are more resistant to oxidation under the conditions required for oxidation by aqueous

$$[3] \qquad RCHO + H_2O \overset{K}{\rightleftharpoons} RCH(OH)_2$$

sodium dichromate. Because $HCrO_4^-$ is not a vigorous oxidant, high temperatures must be used to obtain a reasonable reaction rate; however, independent studies have shown that the extent of carbonyl hydration decreases as temperature increases (13, 14). Consequently the expected increase in the rate of [6] (Scheme 2)

$$[4] \qquad \phi CHO + H_2O \overset{K_4}{\rightleftharpoons} \phi CH(OH)_2$$

$$[5] \qquad \phi CH(OH)_2 + HCrO_4^- \rightleftharpoons \phi \overset{OH}{\overset{|}{C}}HOCrO_3^- + H_2O$$

$$[6] \qquad \phi \overset{OH}{\overset{|}{C}}HOCrO_3^- \rightarrow \phi CO_2H + HCrO_3^-$$

SCHEME 2

with temperature would be partly nulified by a concurrent decrease in K_4, and it is thus necessary to use higher temperatures for aldehyde oxidations than for alcohol oxidations. It is for this reason that aqueous sodium dichromate is particularly useful for the oxidation of alcohols to aldehydes (1).

When the response of the rate of reaction to temperature changes was studied the activation parameters were found to be $\Delta H^{\ddagger} = 13.2 \pm 0.4$ kcal/mole and $\Delta S^{\ddagger} = -30 \pm 4$ e.u. This highly unfavorable entropy of activation is probably due to a combination of three factors: (*i*) the transition state is likely cyclic as in **2**, (*ii*) the formation of an aldehyde hydrate which precedes the rate determining step would have a negative entropy (14), and (*iii*) it is likely that the esterification step would also exhibit a negative entropy (15).

A further interesting fact that emerges from a consideration of the activation parameters is that the difference in the rates of oxidation of benzyl alcohol and benzaldehyde is due mainly to a difference in the entropy of activation, which is in turn likely related to the additional hydration step that occurs only in the aldehyde oxidation mechanism.

The authors are grateful to the National Research Council of Canada and the Saskatchewan Research Council for financial assistance.

4-Methylene-1,2,3-benzotriazines

HANDRICK FONG AND KEITH VAUGHAN

Department of Chemistry, Saint Mary's University, Halifax, Nova Scotia B3H 3C3

Received June 3, 1975

HANDRICK FONG and KEITH VAUGHAN. Can. J. Chem. **53,** 3714 (1975).

Diazotization of 2′-aminoacetophenone, followed by coupling with primary aliphatic amines, affords unstable triazenes which readily undergo cyclodehydration over neutral alumina to give 3-alkyl-4-methylene-1,2,3-benzotriazines (**5***a–d*). 3-Aryl-4-methylene-1,2,3-benzotriazines (**8***a–c*) are likewise obtained by cyclodehydration of the stable 1-(*ortho*-acetylphenyl)-3-aryltriazenes (**7***a–c*). Attempted synthesis of the unsubstituted 4-methylene-1,2,3-benzotriazine (**5***e*), by the same method, did not succeed. 4-Hydroxy-1,2,3-benzotriazines (**4**) are postulated as intermediates in the cyclodehydration; this hypothesis is supported by the isolation of the stable 4-hydroxy-1,2,3-benzotriazine (**12**) from the coupling reaction of methylamine with the diazonium salt derived from *ortho*-aminobenzophenone. An account of a preliminary study of the thermolysis of 3-methyl-4-methylene-1,2,3-benzotriazine (**5***a*) is included.

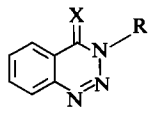
HANDRICK FONG et KEITH VAUGHAN. Can. J. Chem. **53,** 3714 (1975).

La diazotation de l'amino-2′ acétophénone suivie par un couplage avec des amines aliphatiques primaires conduit aux triazènes instables qui subissent facilement une cyclodéshydratation en présence d'alumine neutre pour donner les alkyl-3 méthylène-4 benzotriazines-1,2,3 (**5***a–d*). De la même manière on peut obtenir les aryl-3 méthylène-4 benzotriazines-1,2,3,(**8***a–c*) par cyclodéshydratation des(*ortho*-acétylphényl-1) aryl-3 triazènes (**7***a–c*) stables. On n'a pas réussi à synthétiser par cette méthode le méthylène-4 benzotriazine-1,2,3 (**5***e*) non-substitué. On fait l'hypothèse que les hydroxy-4 benzotriazines-1,2,3 (**4**) sont des intermédiaires dans la cyclodéshydratation; cette hypothèse se base sur le fait que l'on peut isoler l'hydroxy-4 benzotriazine-1,2,3 (**12**) stable à partir de la réaction de couplage de la méthylamine avec le sel de diazonium dérivé de l'*ortho*-aminobenzophénone. On inclut un rapport préliminaire sur l'étude de la thermolyse du méthyl-3 méthylène-4 benzotriazine-1,2,3 (**5***a*).

[Traduit par le journal]

Introduction

In the series of 1,2,3-benzotriazines represented by **1**, the 4-oxo (**1***a*), 4-thio (**1***b*), and 4-imino (**1***c*) derivatives are well known and have been extensively studied (1).



1 *a* X = O; *b* X = S; *c* X = NR′; *d* X = CH_2

Several methods are available for the synthesis of the 4-oxo derivatives; for example, the diazotization of substituted anthranilamides has long been known to give 1,2,3-benzotriazinones (2). In a similar manner, diazotization of *ortho*-aminothiobenzamide gives rise to 4-mercapto-1,2,3-benzotriazine, the tautomer of **1***b* (R = H) (3). Early work (4) on the diazotization of *ortho*-aminobenzamidines, which affords the 4-imino-1,2,3-benzotriazines (**1***c*), has been extended by Stevens and co-workers (5) to cover a wide variety of *N*-alkyl and *N*-aryl substituents. In contrast to the extent of knowledge of the derivatives **1***a*, **1***b*, and **1***c*, no example of a 4-methylene derivative (**1***d*) has previously been reported.[1]

In a previous report (6), the formation of triazenes, **2**, in the coupling reaction of aryl diazonium salts with primary aliphatic amines was shown to be strongly influenced by the nature of the substituent X [1].

[1] 
2

Maximum yields of triazene are obtained when X is a strongly electron-withdrawing group (*i.e.* —NO_2, —COMe, —CO_2Me, —CN), preferably in the *para*-position. However, reaction of *ortho*-substituted diazonium salts with alkylamines frequently afforded unstable triazenes, sometimes giving rise to anomalous products. For example, 1-(*ortho*-carbalkoxyphenyl)-3-alkyltriazenes, **9**,

[1]4-Methyl-1,2,3-benzotriazine, which has been reported recently (ref. 12), could be regarded as the 'tautomer' of the unsubstituted 4-methylene-1,2,3-benzotriazine (**1***d*, R = H).

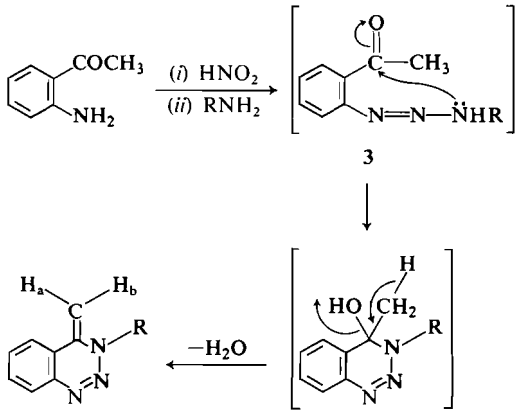
have previously been shown (7) to undergo facile cyclization to 4-oxo-1,2,3-benzotriazines, **1***a*, and the *ortho*-nitrophenyltriazene (**2**, X = *ortho*-NO_2, R = Me) decomposes in the solid state or in solution (6). In the present work, we describe a study of the coupling reaction of the diazonium salts derived from *ortho*-aminophenyl ketones with primary amines; the triazenes obtained therefrom are the precursors of 4-methylene-1,2,3-benzotriazines (**1***d*), reported here for the first time.

Discussion

Treatment of an aqueous solution of the diazonium salt derived from *ortho*-aminoacetophenone with an excess of methylamine afforded an unstable orange-red solid **A**. Stirring the solid **A** in chloroform solution over neutral alumina gave a high yield of 3-methyl-4-methylene-1,2,3-benzotriazine (**5***a*, R = Me), the expected product of cyclodehydration of the *ortho*-acetylphenyltriazene, **3** (Scheme 1); no other product



5 *a* R = Me
b R = Et
c R = *n*-Pr
d R = $PhCH_2$
e R = H

SCHEME 1

was obtained from the alumina catalyzed reaction. The n.m.r. spectrum of the orange-red solid **A** suggests the presence of the open-chain triazene **3**, as well as the 4-methylenetriazine **5***a*, and at least one other component, which may be the hydroxytriazine intermediate, **4**. The presence of the open-chain triazene **3** is inferred from comparison with the n.m.r. spectrum of the previously reported isomer, 1-(*para*-acetylphenyl)-3-methyltriazene (6). Attempted purification of the orange-red solid **A** by column chromatography on alumina, with CCl_4 as eluent, resulted only in formation of the 4-methylenetriazine **5***a*. Apparently the cyclodehydration of the triazene **3** occurs incompletely during the coupling reaction and is catalyzed by adsorption on alumina during chromatography or in the slurry. Attempted recrystallization of the orange-red solid **A** was unsuccessful, being accompanied by considerable decomposition.

3-Methyl-4-methylene-1,2,3-benzotriazine, **5***a*, is a yellow crystalline solid, which displays the expected spectral characteristics. Carbonyl absorption is absent in the infrared spectrum; the only prominent absorption in the i.r. is at 1620 cm^{-1}, assigned to the exocyclic C=C ethylenic group (8). The most characteristic features of the n.m.r. spectrum of **5***a* are the doublets at 4.40 and 3.83 p.p.m., arising from geminal coupling of the non-equivalent vinylic protons of the 4-methylene-group, H_A and H_B; the observed coupling constant (2.4 Hz) is typical of geminal, vinylic systems (ref. 8, p. 128). The assignment of the resonances at 4.40 and 3.83 p.p.m. to the vinylic protons H_A and H_B respectively is based on consideration of the deshielding effect of the benzene ring; proton H_A is in closer proximity to the π-electron system of the benzene ring and should therefore resonate at lower field. The AB pattern exhibited by **5***a* is typical of all 4-methylene-triazines described here.

The mass spectrum of **5***a*, surprisingly, does not exhibit a fragment corresponding to direct loss of N_2, which is characteristic of 1,2,3-benzotriazines (9). The initial fragmentation, as indicated by the base peak at *m/e* 130, involves the loss of CH_3N from the molecular ion. The most likely explanation for this unusual mode of fragmentation is that the molecular ion rearranges to give the more stable methylaminocinnoline ion (Scheme 2), which would then readily lose the methylamino group as CH_3N to give the parent cinnoline ion at *m/e* 130. The strong peak at *m/e* 103 in the mass spectrum of **5***a* is invariably observed in the mass spectra of benzodiazines (10), arising in this case by loss of HCN from the cinnoline fragment. An alternative mode of fragmentation of the molecular ion, indicated by a less abundant fragment at *m/e* 116, probably involves loss of the CH_3N_2 grouping from the unrearranged molecular ion.

The formation of 3-alkyl-4-methylene-1,2,3-benzotriazines by the method described above

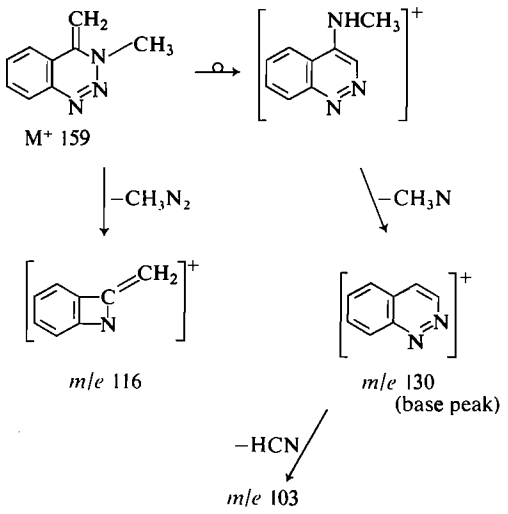
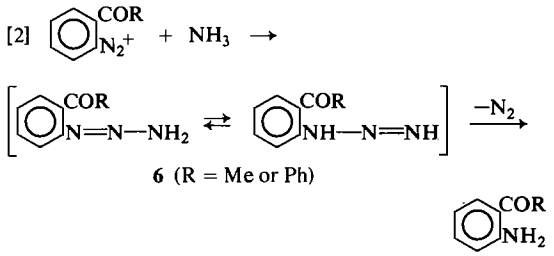


SCHEME 2

has been extended to the 3-ethyl- (**5***b*), 3-*n*-propyl- (**5***c*), and 3-benzyl- (**5***d*) 4-methylene-1,2,3-benzotriazines, which exhibit spectral characteristics analogous to those of 3-methyl-4-methylene-1,2,3-benzotriazine (Table 1). The 3-ethyl- and 3-*n*-propyl derivatives are both oils, with a strong orange color, whereas the 3-benzyl-derivative is, like the 3-methyl analog, a yellow solid. Attempted synthesis of the unsubstituted 4-methylene-1,2,3-benzotriazine, **5***e*, by the same method did not succeed; treatment of the diazonium salt from *ortho*-aminoacetophenone with aqueous ammonia afforded only *ortho*-aminoacetophenone, presumably by formation and fragmentation of the 1-aryltriazene (**6**, R = Me) [2]. Similar treatment of *ortho*-aminobenzophenone likewise resulted in regeneration of starting material.



3-Aryl-4-methylene-1,2,3-benzotriazines, **8**, should, by analogy, be available from the cyclization of 1,3-diaryltriazenes, Ar—N=N—NH-Ar′, with an *ortho*-acetyl substituent in one aryl group. A search of the literature determined that no such diaryltriazene had previously been reported. Accordingly, *ortho*-aminoacetophenone was diazotized and coupled, in turn, with aniline, *para*-anisidine, *para*-aminoacetophenone, and methyl *para*-aminobenzoate, affording the 3-aryl-1-(*ortho*-acetylphenyl)-triazenes **7***a* (X = H), **7***b* (X = —OMe), **7***c* (X = —COMe), and **7***d* (X = —CO_2Me) respectively. Unlike the 3-alkyl-1-(*ortho*-acetylphenyl)-triazenes, these diaryltriazenes are stable crystalline solids, which exhibit the expected spectral characteristics (Table 2).

Some difficulty was encountered when cyclization of 3-phenyl-1-(*ortho*-acetylphenyl)-triazene, **7***a*, was attempted over alumina. Experiments carried out with acidic, basic, and neutral alumina, in turn, led to the conclusion that, as in the case of the 3-alkyl analogs, the best catalyst for the cyclization is neutral alumina. Various times for the reaction over neutral alumina were employed; surprisingly, a reaction time of only 2.5 h was necessary to effect complete cyclization. Longer reaction times resulted in a change in the nature of the product, but the exact course

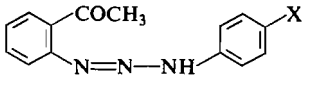
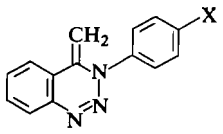
TABLE 2. Spectral data for 1-(*ortho*-acetylphenyl)-3-aryltriazenes (7)

	X	$\nu_{max}(cm^{-1})$	δ (p.p.m.) Aromatic	*ortho*-CH_3CO—	X
7*a*	H	3200 (NH) 1645 (C=O)	6.7–8.0 (m)	2.55 (s)	—
7*b*	CH_3O—	3200 (NH) 1645 (C=O)	6.7–8.0 (m)	2.60 (s)	3.80 (s, O—CH_3)
7*c*	CH_3CO—	3200 (NH) 1680 (C=O, *para*) 1645 (C=O, *ortho*)	7.0–8.2 (m)	2.60 (s)	2.67 (s, *para*-CH_3CO—)
7*d*	CH_3OCO—	3200 (NH) 1730 (C=O, ester) 1645 (C=O, ketone)	7.0–8.2 (m)	2.65 (s)	3.95 (s, CH_3OCO—)

of this apparent decomposition has not been determined. The product of the 2.5 h treatment of 7*a* over neutral alumina is a red oil, which resisted attempts at crystallization and appeared



7 *a* X = H
b X = OMe
c X = COMe
d X = CO_2Me

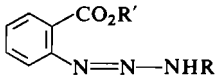


8 *a* X = H
b X = OMe
c X = COMe

to decompose during column chromatography. In spite of these difficulties, the spectral characteristics of the red oil demonstrate unequivocally that it is 3-phenyl-4-methylene-1,2,3-benzotriazine, 8*a*. The carbonyl absorption at 1645 cm^{-1} in the i.r. spectrum of 7*a* is completely absent in the i.r. spectrum of 8*a*. The conversion 7*a* → 8*a* is also accompanied by a characteristic change in the n.m.r. spectrum; the methyl singlet at 2.55 p.p.m. in the n.m.r. spectrum of 7*a* is absent in the n.m.r. spectrum of 8*a*, being replaced by the twin doublets of the vinylic protons, H_A and H_B, at 4.40 and 3.85 p.p.m. respectively.

Likewise, 3-(*para*-methoxyphenyl)-4-methylene-1,2,3-benzotriazine, 8*b*, was obtained as an oil from the corresponding triazene, 7*b*; on the other hand, 3-(*para*-acetylphenyl)-4-methylene-1,2,3-benzotriazine, 8*c*, was obtained as a crystalline solid. Both compounds display spectral characteristics analogous to those of the 3-phenyl derivative (Table 3). However, attempts to cyclize the ester 7*d* by this method did not succeed.

The facile cyclization of the *ortho*-acetylphenyltriazenes, 3, is somewhat different from the previously reported behavior of the unstable 1-(*ortho*-carbalkoxyphenyl)-3-alkyltriazenes, 9,



9

which readily undergo cyclization to the benzotriazinones (1*a*, R = alkyl) (7). The cyclization of the esters is a straight forward example of nucleophilic substitution at the carbonyl group, but analogous cyclization of the ketone 3 (Scheme 1) would afford the 4-hydroxytriazine intermediate 4 which is precluded from formation of an oxo derivative by the nature of the leaving group (*i.e.* CH_3—). Instead elimination of water from the 4-hydroxytriazine, involving the α-hydrogen of the original keto group, can take place, affording the 4-methylenetriazine 5.

Thus, the formation of the 4-methylenetriazines 5 necessitates the presence of α-hydrogen in the acyl group of the *ortho*-aminophenyl ketone used as starting material; absence of an α-hydrogen might well be the condition required for the formation of a stable 4-hydroxytriazine analogous to 4. Accordingly, *ortho*-aminobenzophenone, 10, was diazotized and the resulting diazonium salt solution was treated with an excess of methylamine, whereupon a white solid precipitated immediately. The white solid is quite stable, but does not exhibit the spectral characteristics of the expected triazene 11. Although

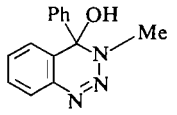
10 **11**



12

the molecular weight of 239, determined by mass spectrometry, correlated with formula **11**, the i.r. spectrum of the white solid does not display a band in the carbonyl region. There is, however, a strong, broad band at 2600–3300 cm^{-1}, indicating the presence of a hydroxyl group. The mass and i.r. spectral evidence clearly show that the white solid is the 4-hydroxy-1,2,3-benzotriazine, **12**; the n.m.r. spectrum of the white solid is also consistent with structure **12**. The 4-hydroxytriazine, **12**, represents the first reported example of a triazine derivative of this type.

Due to the interest in the thermolysis of 1,2,3-benzotriazines reflected in the recent literature (11), the thermal properties of the 4-methylenetriazines **5**, seem to be of potential significance. However, the results obtained so far from thermolysis experiments with the 3-methyl derivative **5***a* are disappointing. Little or no change was observed after refluxing **5***a* in ethanol, benzene, or *para*-xylene. Decomposition did take place when **5***a* was refluxed in diglyme, but this reaction afforded only intractable tar. The 3-methyl derivative **5***a* does decompose in the cold when stored for long periods; the yellow crystalline solid darkens in color and becomes gummy in texture. The exact nature of this decomposition is under further investigation.

Experimental

Melting points were obtained on a hot-stage apparatus and are uncorrected. Infrared spectra were recorded with liquid paraffin mulls on a Perkin-Elmer Model 467 grating spectrophotometer, and u.v. spectra on a Perkin-Elmer Model 402 ultraviolet and visible spectrophotometer. Nuclear magnetic resonance spectra were recorded in deuteriochloroform as solvent, using tetramethylsilane as internal standard, with a Varian EM360 60 MHz spectrometer. Mass spectral data were obtained with a Dupont–C.E.C. Model 21-491 spectrometer.

3-Methyl-4-methylene-1,2,3-benzotriazine, 5a

ortho-Aminoacetophenone (0.85 g, 0.0063 mol) was dissolved in 15 ml of 2 *M* hydrochloric acid and diluted with 15 ml of water. The resulting solution was cooled to 0–5 °C, diazotized by the dropwise addition of an aqueous solution of sodium nitrite (0.45 g, 0.0065 mol), and left stirring for 15 min. Aqueous methylamine (2.8 ml of 40%, 0.036 mol) was then added to the cold diazonium salt solution in one portion. After stirring for a further 10 min, filtration of the resulting mixture afforded a bright orange-red solid (yield 0.91 g, m.p. 59–62 °C).

After drying under suction, the orange-red solid (0.91 g) was dissolved in chloroform (50 ml) and neutral alumina (28 g) was added. The resulting slurry was stirred at room temperature for 4.5 h, after which the alumina was removed by filtration and washed several times with small portions of chloroform. The combined chloroform extract and washings were evaporated to dryness affording 3-methyl-4-methylene-1,2,3-benzotriazine, **5***a*, (0.785 g, 0.0049 mol, 78.5%) m.p. 64–66 °C, as yellow needles; ν_{max} 1620 cm^{-1} (exocyclic C=C); λ_{max} (cyclohexane) 210 (ε 36 500), 268 (ε 14 300), 277 (ε 14 100), 333 (ε 4300), 348 (ε 3500), 375 (ε 1800), and 394 (ε 1800) nm; M^+ 159 ($C_9H_9N_3$), *m/e* 130 ($M - NCH_3$, base), 116 ($M - N_2CH_3$), 103, 89.[2]

The above procedure was repeated with ethylamine, *n*-propylamine, or benzylamine in place of methylamine to afford the 3-alkyl-4-methylene-1,2,3-benzotriazines: **5***b*, R = Et, b.p. 103 °C (2.0 Torr), 60% yield; **5***c*, R = *n*-Pr, b.p. 97 °C (dec.) (1.5 Torr), 90% yield; **5***d*, R = $PhCH_2$, m.p. 80 °C (dec.), 67% yield. Spectral data of these compounds are given in Table 1.

1-(ortho-Acetylphenyl)-3-aryltriazenes, 7

ortho-Aminoacetophenone (0.02 mol) was dissolved in 2 *M* hydrochloric acid (30 ml), and diluted with water (20 ml). The solution was cooled to 0–5 °C, diazotized with sodium nitrite (0.02 mol) in water and stirred for 20 min. A solution of the aromatic amine (0.025 mol) in 2 *M*

[2]Elemental analysis was not attempted, due to the unstable nature of the compound which could only be stored under refrigeration.

hydrochloric acid (30 ml) was added slowly to the diazonium salt solution, and, after stirring for a further 15 min, the resulting mixture was neutralized with an excess of sodium acetate trihydrate (~50 g). The resulting yellow precipitate was filtered and recrystallized from ethanol affording the 1-(*ortho*-acetylphenyl)-3-aryltriazene as follows (aromatic amine, X, % yield, m.p.): **7***a*, aniline, X = H, 63% yield, m.p. 102–104 °C; **7***b*, *p*-anisidine, X = OCH_3, 81% yield, m.p. 136–138 °C; **7***c*, *p*-aminoacetophenone, X = $COCH_3$, 94% yield, m.p. 175–177 °C; **7***d*, methyl *p*-aminobenzoate, X = CO_2CH_3, 51% yield, m.p. 126–128 °C. Spectral data of these compounds are given in Table 2.

3-Aryl-4-methylene-1,2,3-benzotriazines, 8

The 1-(*ortho*-acetylphenyl)-3-aryltriazene **7** (0.003 mol) was dissolved in chloroform (50 ml) and stirred over neutral alumina (25 g) for 2.5–5.0 h. Filtration of the slurry, followed by washing of the alumina with chloroform, and evaporation of the combined chloroform washings afforded the 3-aryl-4-methylene-1,2,3-benzotriazines as follows: **8***a*, X = H, red oil, 70% yield (reaction time 2.5 h); **8***b*, X = OCH_3, red oil, 57% yield (reaction time 4.5 h); **8***c*, X = $COCH_3$, m.p. 121–123 °C ($CHCl_3$), 48% yield (reaction time 5.0 h). Spectral data of these compounds are given in Table 3.

4-Hydroxy-3-methyl-4-phenyl-1,2,3-benzotriazine, 12

ortho-Aminobenzophenone (5.08 g) was suspended in 2 *M* hydrochloric acid (60 ml) and the mixture heated to boiling. Concentrated hydrochloric acid (4.0 ml) was added to bring the amine into solution, which was then diluted with water (80 ml) and cooled to 0–5 °C. At this point, the hydrochloride salt precipitated. The cold slurry was diazotized with sodium nitrite (1.8 g) in a minimum volume of water over a period of 1 h, after which time a clear solution was obtained. Aqueous methylamine (40%, 11.2 ml) was added in one portion, and the resulting white precipitate was filtered, suction dried, and recrystallized from ethanol, affording 4-hydroxy-3-methyl-4-phenyl-1,2,3-benzotriazine, **12** (4.6 g, 76%), m.p. 142–144 °C (EtOH), ν_{max} 2600–3300 cm^{-1} (broad, OH); δ 6.9–7.8 (9H, m, aromatic), 3.6 (1H, s, broad, OH), and 3.3 (3H, s, N—CH_3) p.p.m.; M^+ 239.

Anal. Calcd. for $C_{14}H_{13}N_3O$: C, 70.28; H, 5.48; N, 17.56. Found: C, 70.08; H, 5.37; N, 17.33.

Attempted Synthesis of 1-ortho-Acetylphenyltriazene, 3 (R = H)

ortho-Aminoacetophenone (1.71 g) was dissolved in 2 *M* hydrochloric acid (20 ml), diluted with water (40 ml) and diazotized at 0 °C with sodium nitrite (0.90 g). Concentrated ammonia was added dropwise to the diazonium salt solution until slightly basic and the resulting mixture extracted with chloroform. Evaporation of the dried chloroform extracts afforded *ortho*-aminoacetophenone (quantitative recovery), identical in all respects with the starting material.

Likewise, diazotization of *ortho*-aminobenzophenone followed by neutralization of the diazonium salt solution with ammonia, afforded the starting material, recovery 82%.

Thermolysis of 3-Methyl-4-methylene-1,2,3-benzotriazine, 5a

(*a*) The 4-methylenetriazine (0.67 g) was heated dry over a steam bath for 1.0 h. The residue, although considerably darkened in color, crystallized on cooling and was found to be identical with the starting material.

(*b*) The 4-methylenetriazine (0.53 g) was recovered unchanged after refluxing in absolute ethanol (50 ml) for 3 h.

(*c*) The 4-methylenetriazine (0.94 g) was refluxed in benzene (50 ml) for 24 h and, after evaporation of the solvent, was recovered unchanged (87% recovery).

(*d*) The 4-methylenetriazine (0.74 g) was refluxed in *p*-xylene (25 ml) for 2 h; evaporation afforded unchanged starting material (93%).

(*e*) The 4-methylenetriazine (0.785 g) was refluxed in anhydrous diglyme for 6.5 h; evaporation under vacuum at 100 °C afforded a black oil, which was purified by column chromatography on neutral alumina with chloroform eluent affording unchanged starting material (83% recovery).

(*f*) The 4-methylenetriazine (0.9 g) was refluxed in diglyme for 18 h; the residue, after evaporation, was a black tar, which remained intractable to purification. This residue did not appear to contain starting material.

The financial assistance of the National Research Council of Canada is gratefully acknowledged as is that of the Saint Mary's University Senate Research Committee which supported the completion of this project.

Preparation and Properties of Carboxylic, Monothiocarboxylic, Dithiocarboxylic, and Sulfinic Acid Derivatives of Trithiane, Tetrathiocane, and Pentathiecane

MICHAEL E. PEACH,[1] MAX SCHMIDT, AND ECKHARD WEISSFLOG

Institut für Anorganische Chemie der Universität Würzburg, 87 Würzburg, Am Hubland, West Germany

Received July 14, 1975

MICHAEL E. PEACH, MAX SCHMIDT, and ECKHARD WEISSFLOG. Can. J. Chem. **53**, 3720 (1975).

The monoacids derived from trithiane, tetrathiocane, and pentathiecane, $C_3H_5S_3X$ (X = CO_2H, COSH, CS_2H), $C_4H_7S_4X$ (X = CO_2H, CS_2H), and $C_5H_9S_5X$ (X = CO_2H, CS_2H) and the lithium salts $C_3H_5S_3SO_2Li$, $C_4H_7S_4SO_2Li$, and $C_5H_9S_5SO_2Li$ have been prepared and their reactions studied. The corresponding esters $C_3H_5S_3CO_2R$ (R = CH_3, C_2H_5, *n*-C_3H_7, *i*-C_3H_7, *n*-C_4H_9, *n*-C_5H_{11}), $C_3H_5S_3COSCH_3$, $C_4H_7S_4CO_2R$ (R = CH_3, C_2H_5) and the ammonium salts, $C_3H_5S_3CO_2NH_4$, $C_3H_5S_3CS_2NH_4$, $C_3H_5S_3CS_2N(n\text{-}Bu)_4$, $C_4H_7S_4CO_2NH_4$, $(C_4H_7S_4CO_2)_2(Me_2NHCH_2)_2$, and $C_5H_9S_5CO_2NH_4$ have been isolated. The reactions of the acid anion with various metal ions have been investigated. Nuclear magnetic resonance, mass, and infrared spectroscopic data of some of the products are reported.

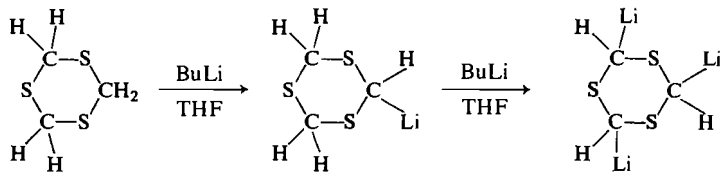
MICHAEL E. PEACH, MAX SCHMIDT et ECKHARD WEISSFLOG. Can. J. Chem. **53**, 3720 (1975).

On a préparé et étudié les réactions des monoacides dérivés du trithiane, tétrathiocane et pentathiécane, $C_3H_5S_3X$ (X = CO_2H, COSH, CS_2H), $C_4H_7S_4X$ (X = CO_2H, CS_2H) et $C_5H_9S_5X$ (X = CO_2H, CS_2H) et les sels de lithium $C_3H_5S_3SO_2Li$, $C_4H_7S_4SO_2Li$ et $C_5H_9S_5SO_2Li$. Les esters correspondants $C_3H_5S_3CO_2R$ (R = CH_3, C_2H_5, *n*-C_3H_7, *i*-C_3H_7, *n*-C_4H_9, *n*-C_5H_{11}), $C_3H_5S_3COSCH_3$, $C_4H_7S_4CO_2R$ (R = CH_3, C_2H_5) et les sels d'ammonium $C_3H_5S_3CO_2NH_4$, $C_3H_5S_3CS_2NH_4$, $C_3H_5S_3CS_2N(n\text{-}Bu)_4$, $C_4H_7S_4CO_2NH_4$, $(C_4H_7S_4CO_2)_2$-$(Me_2NHCH_2)_2$ et $C_5H_9S_5CO_2NH_4$ ont été isolés. On a examiné les réactions de l'anion acide avec divers ions métalliques. On rapporte les spectres r.m.n., de masse et les propriétés spectroscopiques infrarouges de quelques-uns des composés.

[Traduit par le journal]

Introduction

The methylene protons in *s*-trithiane (1,3,5-trithiocyclohexane abbreviated as TrH) and 2-monosubstituted as well as 2,4,6-trisubstituted trithianes are slightly acidic and monolithium and trilithium derivatives respectively were obtained on treatment with *n*-butyllithium in THF. The lithium derivatives reacted with various electrophiles to form more highly substituted trithianes (1, 2). Analogous lithium derivatives of tetrathiocane (TtH 1,3,5,7-tetrathiocyclooctane) have been prepared and their substitution reactions studied (3). This paper describes the addition of carbon dioxide, carbonyl sulfide, carbon disulfide, and sulfur dioxide to various lithium derivatives of *s*-trithiane, tetrathiocane, and pentathiecane (PeH 1,3,5,7,9-pentathiocyclodecane) and the properties and reactions of the products isolated.



(TrH) (TrLi)

Results and Discussion

Acids

Carbon dioxide, carbonyl sulfide, and carbon disulfide can be added to organolithium compounds to give the lithium salts of the corresponding carboxylic, monothiocarboxylic and

For personal use only.

dithiocarboxylic acids respectively (4). The monolithium derivatives of *s*-trithiane reacted similarly:

$$\mathrm{TrLi} + \mathrm{CO_2} \rightarrow \mathrm{TrCO_2Li} \xrightarrow{\mathrm{H^+}} \mathrm{TrCO_2H}$$

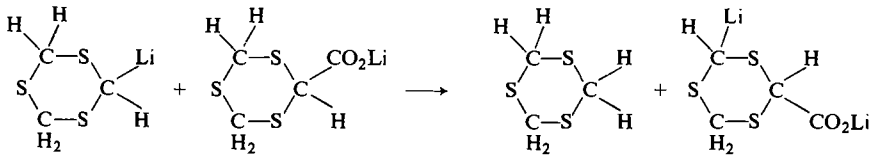
$$\mathrm{TrLi} + \mathrm{COS} \rightarrow \mathrm{TrCOSLi} \xrightarrow{\mathrm{H^+}} \mathrm{TrCOSH}$$

$$\mathrm{TrLi} + \mathrm{CS_2} \rightarrow \mathrm{TrCS_2Li} \xrightarrow{\mathrm{H^+}} \mathrm{TrCS_2H}$$

The free acids precipitated upon acidification of an aqueous solution of the lithium salt. The crystalline acids $\mathrm{TtCO_2H}$ and $\mathrm{PeCO_2H}$ were prepared analogously from carbon dioxide addition to TtLi and PeLi respectively. The acids $\mathrm{TtCS_2H}$ and $\mathrm{PeCS_2H}$ were non-crystalline. Attempts to purify TtCOSH always resulted in partial hydrolysis to $\mathrm{TtCO_2H}$. The carboxylic acid $\mathrm{TtCO_2H}$ was isolated when the impure TtCOSH was dissolved in aqueous ammonia (from which $\mathrm{TtCO_2NH_4}$ could be isolated) and the mixture acidified with hydrochloric acid.

It should be possible to prepare the sulfinic acids ($\mathrm{RSO_2H}$) by addition of sulfur dioxide to a lithium derivative (RLi) followed by acidification (4). The free sulfinic acids of monosubstituted *s*-trithiane, tetrathiocane, and pentathiecane could not be isolated from aqueous solution, but decomposed with liberation of sulfur dioxide. Slightly impure lithium sulfinates precipitated from the THF solutions at room temperature. If an aqueous solution of $\mathrm{TrSO_2H}$ was allowed to stand at room temperature for 2–3 days, the yellow sulfone $\mathrm{Tr_2SO_2}$ precipitated.

Attempts to prepare the trifunctional acids from trithiane, $(\mathrm{CH(CO_2H)S})_3$ and $(\mathrm{CH(CS_2H)S})_3$, gave unidentified oily products which could not be purified by distillation, extraction etc. and appeared to decompose at room temperature. Similar products were obtained when gaseous carbon dioxide was blown through a THF solution of TrLi at −20 °C. This may be due to preferential formation of a lithium derivative with the carboxylate.



The possibility of partial formation of a ketone cannot be excluded (4):

$$\mathrm{TrLi} + \mathrm{TrCO_2Li} \xrightarrow{\mathrm{H_2O}} \mathrm{Tr_2CO} + 2\mathrm{LiOH}$$

The monoacids were obtained by effectively reacting all the lithium derivative TrLi immediately. This was achieved by pouring the THF solution of TrLi onto an excess of solid $\mathrm{CO_2}$ or by adding an excess of liquid $\mathrm{CS_2}$, $\mathrm{SO_2}$, or a THF solution of COS to the TrLi solution at or below −10 °C.

Esters

The methyl ester of $\mathrm{TrCO_2Me}$ was prepared by the reaction of a methanol solution of the free acid with diazomethane at 0 °C:

$$\mathrm{TrCO_2H} + \mathrm{CH_2N_2} \rightarrow \mathrm{TrCO_2CH_3} + \mathrm{N_2}\uparrow$$

Impure TrCOSMe and $\mathrm{TrCS_2Me}$ could be prepared analogously using a methanol suspension of the free acids TrCOSH or $\mathrm{TrCS_2H}$. Attempts to prepare the methyl esters by reaction of the lithium salt $\mathrm{TrCS_2Li}$, as prepared in THF solution, or a suspension of $\mathrm{Pb(S_2CTr)_2}$ or $\mathrm{AgS_2CTr}$ in carbon tetrachloride with methyl iodide failed. The carboxylic esters were obtained by various other methods, either acid catalyzed reaction of the free acid with an alcohol;

$$\mathrm{TrCO_2H} + \mathrm{ROH} \xrightarrow{\mathrm{H^+}} \mathrm{TrCO_2R} + \mathrm{H_2O} \qquad \mathrm{R} = \mathrm{Me, Et, }n\text{-Pr, }i\text{-Pr, }n\text{-Bu}$$

$$\mathrm{TtCO_2H} + \mathrm{ROH} \xrightarrow{\mathrm{H^+}} \mathrm{TtCO_2R} + \mathrm{H_2O} \qquad \mathrm{R} = \mathrm{Me, Et}$$

or via the intermediate formation of an acid chloride (not isolated), which also reacted with methanethiol;

$$\mathrm{TrCO_2H} + \mathrm{SOCl_2} \rightarrow \mathrm{TrCOCl} \begin{cases} \xrightarrow{\mathrm{EtOH}} \mathrm{TrCO_2Et} + \mathrm{HCl} \\ \xrightarrow{\mathrm{MeSH}} \mathrm{TrCOSMe} + \mathrm{HCl} \end{cases}$$

or by alcoholysis; *e.g.*

$$\mathrm{TrCO_2Me} + \mathrm{ROH} \rightarrow \mathrm{TrCO_2R} + \mathrm{MeOH} \qquad \mathrm{R} = n\text{-Bu, amyl}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

The ethyl ester, $TrCO_2Et$, has previously been prepared from the lithium derivative TrLi and ethyl chloroformate, $ClCO_2Et$ (1).

Salts

The ammonium salts of the carboxylic, monothiocarboxylic and dithiocarboxylic acids, $TrCO_2NH_4$, $TrCOSNH_4$, $TrCS_2NH_4$, $TtCO_2NH_4$, and $PeCO_2NH_4$ were readily obtained by dissolving the acid in a slight excess of aqueous ammonia and subsequent removal of the solvent. The tetra-*n*-butylammonium salt $(n\text{-}Bu)_4NS_2CTr$ precipitated on adding an aqueous solution of tetra-*n*-butylammonium iodide to a solution of the lithium salt, $TrCS_2Li$. The tetra-*n*-butylammonium salts $(n\text{-}Bu)_4NSOCTr$ and $(n\text{-}Bu)_4NO_2CTr$ did not precipitate from aqueous solution. The lithium salts $TrCO_2Li$ and $TrCS_2Li$ could not be isolated. The salts of $TrCS_2H$ decomposed to a tar on storage for over a week at room temperature. A tar was formed immediately in the reaction of a benzene solution of $TrCS_2H$ with piperidine and an impure pyridinium salt precipitated with pyridine. Piperidine salts of dithiocarboxylic acids are stable and have been used to prepare the compounds CH_3CS_2X ($X = CH_3$, Me_3Si, Me_3Ge, Me_3Sn, and Et_3Pb) (5). The analogous derivatives $TrCS_2SiMe_3$ and $TrCS_2SnMe_3$ could not be obtained by the reaction of a THF solution of $TrCS_2Li$ with Me_3SiCl or Me_3SnI. The salt $(TtCO_2)_2(Me_2NHCH_2)_2$ precipitated from an aqueous solution of $TtCO_2Li$ on addition of tetramethylethylenediamine, followed by acidification.

Metal Derivatives

Trithiane has a chair structure and can act as a mono-, di-, or tridentate ligand. Complexes have been formed with some metal ions Ag(I) (6), Hg(II) (6), Cu(I) (7), and various metal carbonyls (8). Pentathiecane can be purified via its silver complex (9). Carboxylic acids (10), monothiocarboxylic acids (11), and dithiocarboxylic acids (12) can also form derivatives with various metal ions. The acids $TrCO_2H$, TrCOSH, and $TrCS_2H$ have two functional groups, the trithiane ring and the acidic group, either or both of which could react with metal ions.

Precipitates formed on mixing solutions of the lithium or ammonium salts with solutions of various metal ions. Qualitative tests showed that the anions $TrCO_2^-$, $TrCOS^-$, $TrCS_2^-$, $TrSO_2^-$, $TtCO_2^-$, $TtCS_2^-$, $TtSO_2^-$, $PeCO_2^-$, $PeCS_2^-$, and $PeSO_2^-$ formed white-brown, green-brown, and brown precipitates with Ag^+, Cu^{2+}, and Fe^{3+} ions respectively. Precipitates were also formed on mixing aqueous solutions of $TrCS_2^-$ or $TrCOS^-$ anions with Pb^{2+}, Ni^{2+}, Co^{2+}, or Zn^{2+} cations. Most of these products were not analytically pure, and probably hydrated (see Table 1). The infrared spectra showed water to be present in most cases.

Attempts to prepare the derivatives of $TrCS_2H$ with the cations Tl^+, Pd^{2+}, and Hg^{2+} by shaking an aqueous acidic solution of the cation with a benzene solution of the acid only gave a pure product with Pd^{2+}.

The derivatives were insoluble in most common solvents. It is not clear what their structures are, but the extreme insolubility may be caused by complexing with the sulfur in the ring and the acidic group of the molecule. Most of the metal derivatives were relatively thermally unstable and could not be purified by Soxhlet extraction.

Oxidation

Dithiocarboxylic acids can readily be oxidized even in air to the corresponding disulfide RC(S)SSC(S)R (11). Trithiane forms adducts with iodine (13) and bromine causes fracture of the C—S bond.[2] An unidentified product, the mass spectrum of which showed it to contain iodine, was obtained by the addition of a DMSO–I_2 – KI solution to a solution of $TrCS_2H$ in DMSO, or a similar reaction in aqueous solution using $TrCS_2Li$. Only traces of a product were obtained when oxygen was blown through a solution of $TrCS_2H$ in aqueous ammonia. It is also noteworthy that metal derivatives of the oxidizing anions Cu(II) and Fe(III) could be isolated; these cations usually oxidize thiols to disulfides, being reduced to Cu(I) and Fe(II) respectively (14).

Infrared

The structures of the products were deduced from their i.r., n.m.r. and mass spectra. The i.r. spectra were characteristic of the functional groups present. The monothio acid, TrCOSH, could contain a —C(=O)SH or a —C(=S)OH group. A recent microwave study of monothioformic acid, HCOSH, has confirmed earlier observations that the structure is HC(=O)SH,

and shown that this can exist in *cis* and *trans* forms (15). The i.r. spectra showed that the structure was TrC(=O)SH, with S—H and C=O bands observed at 2498 and 2542, and 1675 cm^{-1} respectively.

Nuclear Magnetic Resonance Spectra

The n.m.r. spectra of monosubstituted *s*-trithiane derivatives should be an AB system for the methylene groups at positions C-4 and C-6. A single line should be observed for the proton remaining at position C-2, unless it can couple with the other substituent on C-2. Such spectra have been observed previously for a number of monosubstituted *s*-trithiane derivatives (1, 2). The acids $TrCO_2H$, TrCOSH, and $TrCS_2H$ are insufficiently soluble in normal organic solvents to allow their ^1H n.m.r. spectra to be measured. The spectra can be obtained using DMSO-d_6 as solvent or for $TrCO_2H$, D_2O. The acidic protons cannot be observed due to exchange with the deuterated solvent. The acid $TrCS_2H$ decom-

posed relatively rapidly in DMSO and the spectrum of a freshly prepared solution was not consistent with that of a monosubstituted derivative of *s*-trithiane. Details of some of the spectra are shown in Table 2.

The chemical shift of the methyl group in $TrCO_2Me$, 3.87 p.p.m., is similar to that observed in methyl formate, 3.77 p.p.m. (16), while that in TrCOSMe, 2.42 p.p.m., is considerably different. The presence of a —SMe group in TrCOSMe was indicated. The chemical shift was somewhat similar to that observed for the —SMe group in MeSEt, namely 2.10 p.p.m. (16).

Mass Spectra

The 70 eV mass spectra of the various acids and, where possible, the methyl esters have been examined. In all cases the molecular ion was observed, confirming the molecular structure. In the various trithiane derivatives a relatively intense peak was observed at *m/e* 137, corresponding to reactions such as

$$C_3H_5S_3COSH^{\ddagger} \rightarrow C_3H_5S_3^{+} + COSH\cdot$$

The spectra below *m/e* 137 were somewhat similar to that of *s*-trithiane, except that the ions CHS^{+} (*m/e* 45) and $C_2H_3S_2^{+}$ (*m/e* 91) were more intense than the ions $CH_2S^{\ddagger}$ (*m/e* 46) and $C_2H_4S_2^{\ddagger}$ (*m/e* 92) whereas the reverse was observed in the mass spectrum of *s*-trithiane (17). Only one metastable peak was observed, and this corresponded to the reaction

$$C_3H_5S_3CO_2CH_3^{\ddagger} \xrightarrow{*} C_2H_5SCO_2CH_3^{\ddagger} + CS_2$$

An analogous reaction involving loss of CS_2 from the molecular ion is observed in the spectrum of trithiane (17).

Thermal Stability

Trithiane and pentathiecane are stable up to at least 250 °C, and trithiane sublimes before reaching its melting point, 215–218 °C (18). Tetrathiacane is not as thermally stable and decomposed above its melting point, 51–52 °C (19). The acids prepared were not very thermally stable and decomposition occurred above their melting points, see Table 3. The metal derivatives of $TrCO_2H$, TrCOSH, $TrCS_2H$ were considerably less thermally stable, making their purification by Soxhlet extraction virtually impossible.

Experimental

The starting materials trithiane, tetrathiocane, and pentathiecane were prepared by literature methods (18, 19). The physical properties and analyses of the new compounds are shown in Table 3.

Microanalyses (C, H, and N) were performed by combustion (Frau Ullrich, Universität Würzburg). The sulfur was estimated by microcombustion, according to Schöninger. Infrared spectra were recorded as KBr discs or mulls with Nujol on a Perkin-Elmer 457. The proton n.m.r. spectra were recorded on a Varian T60. Mass spectra were obtained using a Varian MAT-CH7 and DTA on a DuPont Thermal Analyser 990.

Preparation of Acids

Solutions of approximately 10 mmol of the monolithium derivatives TrLi, TtLi, or PeLi were prepared by literature methods (2, 3). Trithiane (1.38 g, 10 mmol) in 100 ml dry THF was refluxed in a nitrogen atmosphere until it had dissolved. The solution was cooled rapidly to −10 °C and the trithiane precipitated as fine crystals. The suspension was well stirred and kept at −10 – −20 °C during the drop by drop addition of 10 mmol of *n*-BuLi in hexane. The precipitate dissolved, forming a colorless solution. After 0.5 h at −10 – −20 °C the solution at −20 °C was poured onto an excess of Dry Ice under nitrogen and allowed to warm to room temperature. Water (100 ml) was added and the organic solvent removed under vacuum. The unreacted trithiane was filtered off. The free acid precipitated from the aqueous solution at 0 °C on acidification with HCl to p*H* 1. Further product was obtained by reducing the volume of the solution. The product was purified by dissolving in alkali and reprecipitation with acid or recrystallization from water. It was dried in a vacuum desiccator.

The same procedure was used to prepare the monothio- and dithiocarboxylic acids and sulfinic acids except that a THF solution of COS (prepared by bubbling a brisk stream of COS through 50 ml of THF at −50 to −60 °C) or 10 ml of CS_2 or liquid SO_2 (10 ml) was added to the solution of the lithium derivative, instead of pouring onto solid CO_2. The free sulfinic acids could not be isolated, probably due to decomposition *in vacuo* of RSO_2H with loss of SO_2.

Preparation of Ammonium Salts

The free acid was dissolved in the minimum quantity of aqueous ammonia. The solvent and excess ammonia were removed under vacuum. The salt $(Me_2HNCH_2CH_2NHMe_2)^{2+}$ $(TtCO_2^{-})_2$ precipitated on adding excess tetramethylethylenediamine to the $TtCO_2^{-}Li^{+}$ solution, followed by acidification. Addition of a saturated aqueous solution of Bu_4NI to $TrCS_2Li$ precipitated the salt Bu_4NS_2CTr. No precipitate formed with Bu_4NI and $TrCO_2Li$ or TrCOSLi. The impure pyridinium salt, $PyHS_2CTr$, precipitated on adding pyridine to a benzene solution of $TrCS_2H$. A tar formed using piperidine instead of pyridine.

Preparation of Esters

The ester $TrCO_2Me$ precipitated when approximately 10 mmol of CH_2N_2 in ether was added to 1 mmol of $TrCO_2H$ in 20 ml MeOH (0 °C). The esters $TrCO_2R$

(R = Me, Et, *n*-Pr, *i*-Pr, *n*-Bu) and $TtCO_2R$ (R = Me, Et) were prepared by the acid catalyzed reaction of $TrCO_2H$ or $TtCO_2H$ (5 mmol) with 20 ml of ROH and 0.5 ml concentrated H_2SO_4 catalyst. This mixture was refluxed for 1 h and the ester precipitated on cooling. The product was purified by refluxing in ROH, and further washing. $TrCO_2$(*n*-Bu) was prepared by alcoholysis of $TrCO_2Me$ (5 mmol) with 20 ml *n*-BuOH and 1 ml concentrated H_2SO_4. The mixture was refluxed for 15 h and the product precipitated on cooling. The *n*-amylester was prepared similarly from $TrCO_2Me$ and amyl alcohol. $TrCO_2Et$ and TrCOSMe were prepared from the acid chloride, TrCOCl, which was not isolated, and EtOH or MeSH. $TrCO_2H$ (5 mmol) was dissolved in 20 ml $SOCl_2$ (40 °C); after completion of the reaction the excess $SOCl_2$ was removed under vacuum, leaving an oily liquid. Absolute EtOH (5 ml) or 25 ml of a benzene solution of MeSH were added and the product precipitated.

Metal Derivatives

Approximately 2 mmol of either the freshly prepared solution of the lithium salt, or of the corresponding ammonium salt was added to a slight excess of an aqueous solution of the metal ion. The precipitate was filtered off and dried *in vacuo*. The compound $(TrCS_2)_2Pd$ was prepared by shaking an aqueous acidic solution of $PdCl_2$ with a benzene solution of $TrCS_2H$. Similar attempts to prepare $TrCS_2Tl$ and $(TrCS_2)_2Hg$ gave impure products.

This work was supported by Fonds der Chemischen Industrie. One of the authors (M.E.P.) wishes to thank the Alexander von Humboldt Foundation for the award of a fellowship while on leave from Acadia University, Wolfville, Nova Scotia. Mr. Alfred Kreiner is thanked for help with some of the experimental work.

Preparation and Properties of some Trimethylgermyl and Trimethylplumbyl Esters of Dimethylcarbamic and Dimethylthiocarbamic Acids

A. E. LEMIRE AND J. C. THOMPSON

University of Toronto, Department of Chemistry, Toronto, Ontario M5S 1A1

Received March 21, 1975

A. E. LEMIRE and J. C. THOMPSON. Can. J. Chem. **53**, 3727 (1975).

The preparation of the trimethylgermyl esters of *N,N*-dimethylcarbamic, *N,N*-dimethylmonothiocarbamic, and *N,N*-dimethyldithiocarbamic acids and the trimethylplumbyl ester of *N,N*-dimethylmonothiocarbamic acid is reported. Some of these esters exhibit temperature dependent n.m.r. spectra. Infrared and u.v. spectra for these and related compounds are also described.

A. E. LEMIRE et J. C. THOMPSON. Can. J. Chem. **53**, 3727 (1975).

On rapporte la préparation des esters triméthylgermylés des acides *N,N* diméthylcarbamique, *N,N*-diméthylmonothiocarbamique et *N,N*-diméthyldithiocarbamique et la préparation de l'ester triméthylplumbyle de l'acide *N,N*-diméthylmonothiocarbamique. Dans quelques uns de ces esters, le spectre r.m.n. varie en fonction de la température. On décrit aussi les spectres i.r. et u.v. de ces composés et d'autres qui leur sont reliés.

[Traduit par le journal]

For personal use only.

While many reports of the stannyl esters of dialkyldithiocarbamic acid may be found in the literature (1, 2), there is comparatively little information on germyl and plumbyl esters. Satgé *et al.* (3) have reported the preparation of a few esters of diethyldithiocarbamic acid and diethylcarbamic acid. The trimethylplumbyl ester of dimethyldithiocarbamic has also been prepared (4).

As part of a systematic n.m.r. study (5–7) of hindered rotation in such esters we had occasion to synthesize the trimethylgermyl and trimethylplumbyl esters of dimethylcarbamic and dimethylthiocarbamic acids and in this paper report upon their synthesis and properties.

Generally the synthesis of such compounds has been carried out by reacting aminosilanes, germanes, or stannanes with CO_2, CS_2, or COS (1, 3), although the dithiocarbamates have sometimes been prepared by reacting the trialkyl group IV halide with sodium dialkyldithiocarbamate. We have found that the monothiocarbamates and carbamates may also be conveniently prepared by the reaction between the group IV halide and an acid salt; this procedure obviates the necessity of working directly with the aminosilanes etc., which are often quite moisture sensitive.

Experimental

Synthesis

The following general procedure was followed for all of the compounds except $Me_2NC(S)SPbMe_3$ (4).

A solution of the trimethylgermyl halide or trimethylplumbyl acetate in hexane was added to a slurry of the stoichiometric amount of $Me_2NC(X)YH{\cdot}HNMe_2$ (8, 9) (X = O, S; Y = O, S) in hexane under a nitrogen atmosphere. The reaction mixture was stirred for 2 h, then filtered under nitrogen and the solvent was evaporated under vacuum to yield an oil. The oil was distilled under vacuum with warming and condensed in a Dry Ice trap. Results of analyses are listed in Table 1.

The compound $Me_2NC(O)SGeMe_3$ appears to be somewhat air sensitive; it also decomposes after standing several months in a sealed tube (under vacuum). It may also be prepared by the direct reaction of Me_3GeNMe_2 and COS.

An attempt to prepare $Me_2NC(S)OGeMe_3$ by the reaction of $Me_2NC(S)Cl$ and Me_3GeOLi was made but only starting materials were recovered.

Solutions of $Me_2NC(S)SPbMe_3$ are unstable; a white precipitate forms if the solution is allowed to stand for a few hours.

$Me_2NC(O)SPbMe_3$ decomposes (turns grey) on standing several weeks in a sealed tube.

Spectra

Nuclear magnetic resonance spectra were obtained on a Varian A56-60D n.m.r. spectrometer. Details of sample preparation have been described previously (5–7).

Infrared spectra were run on a Perkin-Elmer 180 i.r. spectrometer. Demountable cells with NaCl windows and a 1 mm path length were used. Solutions of ~10 mol% concentration in CCl_4 and $CHCl_3$ were used. The spectrometer was calibrated using the standard polystyrene film.

Ultraviolet spectra were run on a Unicam SP 800 spectrometer over the range 210–450 nm. Solutions were made up to cover the concentration range 0.05–0.00005 mol l^{-1}.

Results and Discussion

Nuclear Magnetic Resonance

The ^1H chemical shifts for the compounds described herein are listed in Table 2. As would

*In 10 mol% solution in CCl_4 at the ambient temperature of the probe.

be expected, the chemical shifts of the protons of the ester group —Y—MMe_3 follow the same pattern as that observed in the tetramethyl compounds Me_4M (10).

The carbamate and dithiocarbamate esters exhibit a single resonance for the *N*-methyl protons at room temperature.

When the temperature is lowered the *N*-methyl resonance of trimethylgermyl *N,N*-dimethyldithiocarbamate (in $CHCl_3$ solution) splits into a doublet of separation ~1.3 Hz below 250 K. However, no splitting of the resonance was observed in hexane solutions at temperatures as low as 214 K. The trimethylplumbyl ester of *N,N*-dimethyldithiocarbamic acid showed no splitting of the *N*-methyl resonance at 211 K in either chloroform or *n*-hexane solutions.

Similarly trimethylgermyl dimethylcarbamate showed no splitting of the *N*-methyl peak at 214 K in *n*-hexane and chloroform solution. In chloroform solution, however, the *N*-methyl peak was broad at room temperatures and sharpened at lower temperatures.

The *N*-methyl resonance of the trimethylgermyl monothiocarbamate splits into a doublet just below room temperature in both chloroform and *n*-hexane solution.

In chloroform solution the two *N*-methyl peaks were asymmetric at low temperatures with the low field peak being broader than the high field one. At temperatures just below the coalescence temperature, however, they appeared to have the same widths. In *n*-hexane solution the two peaks had the same widths at low temperatures.

The trimethylplumbyl monothiocarbamate showed a splitting of the *N*-methyl resonance in both *n*-hexane and chloroform solutions at room temperature. In both solutions at low temperatures the low field *N*-methyl peak was slightly broader.

The splitting of the *N*-methyl resonance in these compounds is due to hindered rotation about the C—N bond which causes the two *N*-methyl groups to reside in slightly different magnetic environments; the situation is exactly analogous to that in amides. Activation parameters for the hindered rotation in these and similar compounds have been determined (27).

The unequal line widths of the two *N*-methyl resonances in the monothiocarbamates are somewhat unusual. We have also observed unequal *N*-methyl line widths in solutions of trimethylstannyl dimethylmonothiocarbamate (7). A similar broadening was reported in the compound $(CH_3)_2CClSn(SSeCNC(CH_3)_2)_2$ and attributed to unequal coupling with the ^{77}Se isotope (11). In light of the results of our work, it appears that the effect is more general and is not due to selenium coupling.[1] We have previously suggested that the broadening may be due to the formation of dimeric or higher polymeric species at low temperatures (7).

Infrared Spectra

Normal coordinate analysis of the dimethyldithiocarbamate anion (12) and dimethylamides and thioamides (13) suggest that a high degree of coupling of i.r. modes takes place and hence few of the bands can be described as 'pure'. Thus a detailed analysis of the i.r. spectra would prove quite difficult.

However, a few major bands may be identified.

The dithiocarbamates have a strong band at ~1489 cm^{-1} which may be identified as the 'thioureide' band which Chatt *et al.* (14) have

[1]A referee has suggested that the unequal broadening may be due to unequal quadrupole broadening as part of unresolved $J(^1H–^{14}N)$ coupling. If this were indeed the case, however, it is rather strange that analogous broadening is not observed in the spectra of all the compounds studied.

suggested arises from a polar $\overset{+}{N}$—C—$\bar{S}$ vibration.

Trimethylgermyl dimethylcarbamate has a strong band at 1662 cm^{-1} in (10% CCl_4 solutions) which may be identified as the carbonyl stretch. The band position shifts 20 cm^{-1} to lower wave numbers in chloroform solution. This is consistent with an H-bonding interaction between the carbamate and the chloroform which tends to weaken the carbon–oxygen bond.

The monothiocarbamates also have a strong band in the carbonyl stretching region (1630 cm^{-1}, $Me_2NC(O)SGeMe_3$; 1609 cm^{-1} $Me_2NC(O)SPbMe_3$) and the monothiocarbamates may thus be established as being the *S*-esters rather than the *O*-esters.

Ultraviolet Spectra

The u.v. spectra of these and related compounds are listed in Table 3.

The u.v. spectra of dithiocarbamates have been fairly extensively studied (15–23) and four types of bands may be distinguished which have been assigned as follows: (*a*) Type I, $n \rightarrow \pi^*$ (280–360 nm); (*b*) Type II, $\pi \rightarrow \pi$ (280 nm); (*c*) Type III, $\pi \rightarrow \pi^*$ (240–250 nm); (*d*) Type IV, unassigned (220 nm).

In the trimethylsilyl and trimethylgermyl dithiocarbamates, bands I and II shift to longer wavelengths relative to the analogous *tert*-butyl ester while band III shifts to shorter wavelengths. The shift of the $n \rightarrow \pi^*$ (band I) transition in these esters suggests that the extent of conjugation at the ester sulfur with the thiocarbonyl group is being reduced (15, 16, 24). This might arise if the trimethylsilyl and trimethylgermyl groups were acting as π acceptors (Si > Ge). The trimethylplumbyl dithiocarbamate has a u.v. spectrum very similar to the methyl and *tert*-butyl esters and thus shows little evidence of conjugation. The u.v. spectra of the trimethylstannyl dithiocarbamate is considerably different from the silyl and germyl derivatives. This may reflect some internal coordination in the tin structure in solution; some internal coordination in the solid state has been demonstrated in its crystal structure (25).

The trimethylgermyl and plumbyl monothiocarbamates have only an $n \rightarrow \pi^*$ transition in the region above 220 nm; the $\pi \rightarrow \pi^*$ transitions are presumably shifted to lower wavelengths. Once again the shift of the $n \rightarrow \pi^*$ transition in the germyl ester suggests that the —$GeMe_3$ group is acting as a π acceptor. The position of the $n \rightarrow \pi^*$ transition in the trimethylplumbyl monothiocarbamate is obscured by strong end absorption which has a broad tail and presumably arises from the expected $\pi \rightarrow \pi^*$ transition below 220 nm.

The carbamates showed no u.v. absorption above 220 nm.

It must be noted that for all the compounds studied the shifts of the u.v. bands were slight and hence interpretation of the reason for these shifts is somewhat speculative. Nonetheless the trend of the shifts appear to be real in that in a recent paper (26) quite similar shifts were reported for group IV esters of several dithioacids.

Studies of Hindered Rotation in Some Group IV Esters of Dimethylcarbamic and Dimethylthiocarbamic Acids

A. E. LEMIRE AND J. C. THOMPSON

Department of Chemistry, University of Toronto, Toronto, Ontario M5S 1A1

Received March 24, 1975

A. E. LEMIRE and J. C. THOMPSON. Can. J. Chem. **53,** 3732 (1975).

Activation parameters for hindered rotation about the C—N bond have been obtained for some trimethylgermyl, trimethylplumbyl, and *tert*-butyl esters of *N,N*-dimethylcarbamic, *N,N*-dimethylmonothiocarbamic, and *N,N*-dimethyldithiocarbamic acids. These are compared with previous results for some group IV esters and general considerations as to factors influencing barriers to rotation are discussed. It was found that the degeneracy of the *N*-methyl resonances observed in the room or low temperature ^1H spectra appeared also to extend to the room temperature ^{13}C spectra. A 'steric' effect was noted on the carbonyl and thiocarbonyl resonances.

A. E. LEMIRE et J. C. THOMPSON. Can. J. Chem. **53,** 3732 (1975).

On a obtenu les paramètres d'activation pour la rotation empêchée autour du lien C—N des quelques esters *N,N*-diméthylcarbamates, *N,N*-diméthylmonothiocarbamates et *N,N*-diméthyldithiocarbamates de triméthylgermyle, de triméthylplumbyle et de *tert*-butyle. On compare ces données avec des résultats antérieurs pour quelques esters du groupe IV; on discute aussi, sous forme de considérations générales, des facteurs influençant les barrières à la rotation. On a trouvé que la dégénérescence des résonances de *N*-méthyles, qui est observée dans les spectres du proton à température de la pièce ou a basse température, semble s'étendre aussi aux spectres du ^{13}C à température de la pièce. On note un effet 'stérique' sur les résonances du carbonyle et du thiocarbonyle.

[Traduit par le journal]

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

As part of a systematic study of factors influencing the barrier to rotation about the C—N bond in amide-like systems, we have previously reported activation parameters for hindered rotation for methyl (1), trimethylsilyl (2), and trimethylstannyl (3) esters of *N,N*-dimethylthiocarbamic acids. In this paper we complete the study by reporting on the results obtained for the trimethylgermyl, trimethylplumbyl, and *tert*-butyl esters.

Although, after the advent of total line shape methods, many compounds were studied by variable temperature n.m.r., systematic studies are still rare. However, for some systems, primarily amides and thioamides, some correlations have been made between structural features and activation parameters (4, 5). One of the most comprehensive studies is a recent series of papers by Reeves and co-workers (6–8) in which they discussed factors influencing rates of rotation in amides and thioamides with halide and pseudo-halide substituents.

Some difficulties arose in interpreting the results obtained when the *N*-methyl resonances exhibited no splitting at low temperatures, as in such cases it is impossible to decide whether the barrier to rotation is so low that exchange cannot be frozen out or whether the two *N*-methyl resonances are instead degenerate. As the *N*-methyl ^{13}C splitting in dimethylamides is at least an order of magnitude greater than the ^1H splitting (9), we felt ^{13}C studies of the esters might resolve this difficulty and we thus present the results of some preliminary investigations.

Experimental

Preparation of Compounds

The synthesis of most of the compounds used in this study have been described previously (1–3, 10–12). However, the preparation of $Me_2NC(S)SCMe_3$ does not appear to have been reported in the literature and is therefore described herein.

$Me_2NC(S)SCMe_3$

Me_3CSH (4.5 g, 0.05 mol) dissolved in 10 ml of pentane was added dropwise with stirring to 40 ml of a 1.26 *M* solution of $(CH_3)_3CLi$ in a 3-necked flask equipped with an N_2 inlet, a dropping funnel, and a condenser. The reaction was very vigorous and it was necessary to cool the reaction flask in a Dry Ice bath throughout the period of addition. A white precipitate formed halfway through the addition.

$Me_2NC(S)Cl$ (6.1 g, 0.05 mol) dissolved in 25 ml of dry ether was then added while cooling the reaction flask in a Dry Ice bath. When the addition was complete, the reaction mixture was allowed to warm gradually to room

[a]The error limits quoted are those obtained from the statistical treatment of the least squares line but, as has been pointed out by several workers, may not be indicative of the true error situation (30, 31).
[b]At coalescence temperature.

temperature. At this time the reaction mixture consisted of a colorless solution with a white precipitate. The reaction mixture was then stirred for 2 h at room temperature during which time the solution turned yellow. The solution was filtered and the solvent evaporated off using a water pump to yield a yellow oil.

The oil was fractionally distilled and a 10% yield of a yellow viscous liquid boiling at 40 °C at 5 Torr was obtained.

Anal. Calcd. for $Me_2NC(S)SCMe_3$: C, 47.41; H, 8.53; N, 7.90; S, 36.17. Found: C, 47.40; H, 8.54; N, 7.96; S, 36.16.

Methods

The techniques for obtaining and analyzing n.m.r. spectra have been described previously (1–3). ^1H spectra were obtained on a Varian A56-60D n.m.r. spectrometer. ^{13}C spectra were run on a Varian XL-100 n.m.r. spectrometer.

Results

A summary of activation parameters obtained from the ^1H spectra for hindered rotation in the compounds $Me_2NC(X)YMMe_3$ (X = O, S; Y = O, S; M = C → Pb) is found in Table 1. We have previously reported values for the methyl (1), trimethylsilyl (2), and trimethylstannyl (3) esters and these are included here to facilitate comparisons.

The trimethylgermyl, trimethylplumbyl, and *tert*-butyl (except $Me_2NC(O)OCMe_3$) have not

For personal use only.

been studied previously and hence are discussed in some detail here.

$Me_2NC(O)OCMe_3$

A 10 mol% solution of the ester in *n*-hexane showed no splitting of the *N*-methyl resonance at 210 K. A very small splitting (*ca.* 0.5 Hz) was observed in a 10 mol% solution in chloroform at 210 K. The nonexchanging chemical shift exhibited a marked temperature dependence. Previously Lustig *et al.* (10) had observed a broadening of the *N*-methyl peak at 233 K but no splitting.

Activation parameters were not calculated because, with such a small *N*-methyl splitting, the exchange region covers only 2–3 K. Moreover, when the peak separation and the line widths are of the same order of magnitude the line shape equation becomes very insensitive. However, the free energy of activation $\Delta G^{\ddagger}$ may be estimated as 12 ± 2 kcal/mol from an analysis of the coalescence temperature spectrum.

$Me_2NC(O)SCMe_3$

A 10 mol% solution of the ester in hexane showed no splitting of the *N*-methyl resonance at 205.9 K. A splitting was observed in a 10 mol% solution in chloroform at low temperatures. The nonexchanging chemical shift was small (*ca.* 1.1 Hz) and exhibited a marked temperature dependence.

$Me_2NC(S)SCMe_3$

A 10 mol% solution in hexane exhibited no splitting of the *N*-methyl resonance at room temperature but a splitting of 6.03 Hz was observed at low temperatures. The limited solubility of the compound precluded an extensive study of the temperature dependence of the nonexchanging chemical shifts.

In a 10 mol% solution in chloroform, a splitting of 8.10 Hz was observed at low temperatures. The nonexchanging chemical shift showed a negligible temperature dependence outside the exchange region.

$Me_2NC(O)OGeMe_3$

No splitting of the *N*-methyl peak was observed in an *n*-hexane solution (10 mol%) at 213.9 K nor in a chloroform solution (10 mol%) at 213.0 K.

$Me_2NC(O)SGeMe_3$

Splitting of the *N*-methyl resonance just below room temperature was observed in both chloroform (10 mol%) and *n*-hexane (10 mol%). In chloroform solution, at low temperatures below the exchange region, the low field *N*-methyl peak was slightly broader than the high field one.

$Me_2NC(O)SPbMe_3$

A splitting of the *N*-methyl resonance was observed at room temperature in *n*-hexane ($\delta\nu_\infty$ = 14.5 Hz) and in chloroform ($\delta\nu_\infty$ = 14.0 Hz) solution. At low temperatures, the two *N*-methyl peaks had slightly different widths.

$Me_2NC(S)SPbMe_3$

No splitting of the *N*-methyl resonance was observed at 211.2 K in dilute solutions in chloroform and *n*-hexane.

Discussion

Proton Chemical Shifts

The proton chemical shifts are listed in Table 2. The chemical shifts of the protons of the ester grouping, $—MMe_3$, follow the same

TABLE 2. ^1H chemical shifts

Compound	Chemical shifts, δ[a]	
	NMe_2	Ester grouping
$Me_2NC(O)OMe$	2.87	3.60
$Me_2NC(O)SMe$	2.97	2.26

[a]In $CDCl_3$ solution.

pattern that was observed in the tetramethyl compounds by Allred and Rochow (13).

In dithiocarbamate systems, Nikolov (14) has suggested that the position of the *N*-methyl resonance might be taken as a measure of the C—N bond order, but we have found little correlation between the *N*-methyl chemical shift and barriers to rotation (1–8).

It has also been suggested that *N*-methyl resonances at 3.4 δ are indicative of chelated dithiocarbamate ligands (15), but our results for the methyl ester, $Me_2NC(S)SMe$, suggest that this correlation is unlikely.

It appears, however, that correlations of ^{15}N chemical shifts with bond order may well exist (16).[1]

^{13}C Chemical Shifts

The ^{13}C chemical shifts obtained in this study are listed in Table 3. While spectra were run in both $CDCl_3$ and C_6D_{12} solutions, only the $CDCl_3$ results are listed for the sake of simplicity, as there were no significant differences observed. While solvent effects on the position of the carbonyl resonance have previously been noted (17), Maciel and Natterstad (18) have found that substituents (capable of conjugation) in a position adjacent to the carbonyl group tended to reduce the sensitivity of its shielding to solvent changes; this also appeared to be the case in the systems we have studied. Downfield shifts of carbonyl carbons relative to olefin carbons have been explained as being due to the polarization, $\overset{+}{C}—\overset{-}{O}$, of the carbonyl bond (ref. 19, p. 102). Adjacent heteroatoms with unshared electrons offset this effect as conjugation between the heteroatom and carbon can result in higher electron density at the carbonyl carbon than in an isolated carbonyl bond (ref. 19, p. 280, 20).

Such an effect is demonstrated by the compounds studied in this work. The carbonyl resonance in the carbamate and thiocarbamate

esters was shifted upfield relative to the carbonyl resonance in ketones.

Such an effect also makes correlation of the ^{13}C chemical shift of the carbonyl carbon with barriers to rotation seem unlikely as conjugation involving either the nitrogen or the ester lone pair would put extra charge density upon the carbon but would affect the barriers to rotation about the C—N bond in opposite directions.

This expectation was borne out in our studies. For example, there is little change in the ^{13}C chemical shift of $Me_2NC(O)SCMe_3$ and $Me_2NC(O)SGeMe_3$ while there is a considerable difference in the barriers to rotation.

As was expected, in those cases where the *N*-methyl resonance is split, the splitting is generally greater than that observed in the proton spectra. The larger splitting is probably due to a steric shift to lower field of the *N*-methyl carbon *cis* to the C=X chromophore (21).

In spite of the expected larger splittings, however, a splitting of the *N*-methyl ^{13}C resonance was observed only for those compounds for which a splitting was also observed at room temperature or lower in the proton spectra.

Those compounds which showed no splitting (*i.e.*, $Me_2NC(O)OMMe_3$, M = Ge → Sn; $Me_2NC(S)SMMe_3$, M = Sn, Pb) or a small splitting of the order of 1 Hz (*i.e.*, $Me_2NC(O)OMMe_3$, M = C, Si; $Me_2NC(S)SMMe_3$, M = Si, Ge; $Me_2NC(O)OMe$; $Me_2NC(O)SMe$; $Me_2NC(O)SCMe_3$) also showed no splitting in the room temperature ^{13}C spectra.

The ^{13}C spectra also show some unusual effects arising from the presence of the group IV atoms.

For a given series of esters, the resonances of the trimethyl grouping follow the order C > Pb > Ge > Si > Sn. This may be contrasted with the order C > Si > Ge > Pb > Sn obtained for the tetramethyl compounds (22).

Even in the alkyl compounds the shifts are rather unusual for they do not parallel those observed for the ^1H chemical shifts and hence electronegativities derived from ^{13}C and ^1H chemical shifts are not consistent with each other (13). However, in the case of the tetramethyl derivatives, it has been suggested that the ^{13}C chemical shifts are considerably dependent upon diamagnetic contributions, σ_d, as well as paramagnetic contributions, σ_p (23). Both σ_d and σ_p vary with atomic number; however they do not vary at the same rate and for heavier elements, σ_d takes on an increasing importance. This interplay has been used to rationalize the shifts observed in the tetramethyl derivatives (23).

That the order in the carbamate and thiocarbamate esters is different from that in the tetraalkyl derivatives is not wholly unexpected as the bonding between the ester sulfur or oxygen and the central metal is expected to be different from that between carbon and the metal and hence may lead to different magnetic anisotropy contributions. What is unusual, is that the trends are the same whether M is bonded to oxygen or sulfur; whereas in the case of silicon, for example, it is generally felt that the bonding between silicon and oxygen involves a greater *d–p* π overlap than does the bond between silicon and sulfur (24).

Another interesting feature of the spectra of both the thiocarbamates and carbamates is the shift of the carbonyl or thiocarbonyl resonance to lower fields in the heavier members of the series. This may be contrasted with the upfield shifts observed by Grishin *et al.* (25) in the ^{13}C spectra of organometallic ketones.

A similar downfield shift was noted in the C_2 phenyl chemical shift of some phenyl organometallics by Doddrell *et al.* (26) and attributed by them to a decrease in the γ-effects of the methyls due to less steric compression about C_2 as the C—M bond length increases.

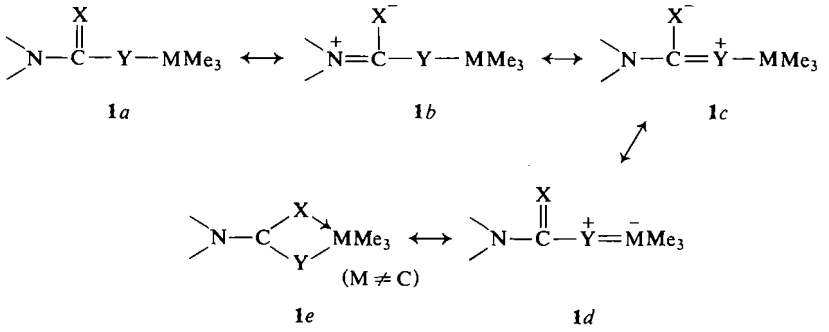
It appears likely that the shift observed in the carbamate and thiocarbamate esters is due to a similar steric effect rather than being indicative of any variation in bonding of the group IV element and the ester sulfur or oxygen.

Barriers to Rotation

As has been noted previously, a general lowering of barriers is seen on going from amides or thioamides to carbamates or thiocarbamates due to the possibility of competitive delocalization occurring in the latter two cases (Scheme 1, **1c**) (1–3, 27).

With group IV esters of carbamic and thiocarbamic acids, two further interactions (**1***d* and **1***e*) are possible and would be expected to modify barriers to rotation.

In **1***d* the —MMe_3 group acts as an electron-withdrawing group and tends to raise barriers to rotation by decreasing the importance of resonance form **1***c*. In **1***e*, the group IV element



SCHEME 1

achieves five-coordination and a raising of the barrier would be expected because donation of the lone pair on nitrogen into the N—C—X system would be facilitated.

In the cases of the monothiocarbamates studied in this work, there appears to be a general raising of barriers to rotation relative to the analogous methyl esters. There also appears to be a raising of barriers relative to the *tert*-butyl ester $Me_2NC(O)SCMe_3$, but because of the small $\delta\nu_\infty$ observed in this system, the measured barrier is probably not sufficiently accurate to justify any conclusions.

We believe the raising of barriers in the monothiocarbamates to be largely due to the presence of contributions such as **1***d*. The i.r. evidence is more consistent with a unidentate mode of bonding of the monothiocarbamate group (**1***d*) than with a bidentate mode (**1***e*) (12).

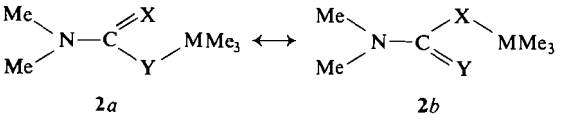
However if the $—MMe_3$ group is acting as an electron-withdrawing group as in **1***d*, then one would expect the order to be Ge > Sn > Pb, C as germanium is generally believed to be much more likely to take part in (*p–d*) π interactions than is tin (28). The actual ordering however is Sn > Ge, Pb > C. This suggests that the actual situation may involve contributions from both **1***d* and **1***e* with the contribution of **1***e* becoming more important in the tin ester because of the greater tendency of tin to higher coordination.

It must also be noted that the raising of the barriers relative to the *tert*-butyl esters is small (*ca.* 2 kcal). This is not entirely unexpected as contributing structures such as **1***d* and **1***e* would only have a second order effect and also the increasing size of the substituent $—MMe_3$ (M = C → Pb) would be expected to act to counteract any raising of the barriers.

The reason for the small *N*-methyl splittings or lack of any splitting observed in the dithiocarbamates and the carbamates is somewhat more ambiguous.

In the case of no splitting at all, three possible explanations come to mind: (*a*) formation of a cyclic structure **1***e*, (*b*) intramolecular exchange (Scheme 2), or (*c*) the —MMe group acting as an electron-releasing group and hence lowering barriers to rotation (but this would be an opposite role to that observed in monothiocarbamates).

Intramolecular exchange may be ruled out in the case of the monothiocarbamates as one would expect to see separate resonances for both species **2***a* and **2***b*, but only one set of signals is observed.



SCHEME 2

Such a process cannot be ruled out *a priori* in the case of the dithiocarbamates or the carbamates. However the process does not explain why the magnitude of the *N*-methyl splitting should be so much smaller in the trimethylsilyl and trimethylgermyl dithiocarbamates relative to the methyl and *tert*-butyl esters.

Nonetheless small *N*-methyl splittings have been observed for some cases where symmetric structures are highly unlikely (6–8) and the question of what factors determine the anisotropy that gives rise to two nonequivalent *N*-methyl positions is an interesting but not completely resolved one. Reeves and co-workers (29) have suggested that competitive delocalization (**1***c*) may cause the charge distributions in both the C—X and C—Y bonds to become similar.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

However as even the maximum $\delta\nu_\infty$ observed are relatively small (maximum $\sim$14 Hz) and exhibit marked solvent effects, any explanation for lack of splitting being observed can only be speculative.

In our studies we have also noted a dependence of activation parameters on solvent. In general there appears to be a slight raising of barriers in going from hexane to chloroform solutions.

Finally in all studies of hindered rotation the question of the actual meaning of the activation entropies obtained is a problem. Theoretical considerations suggest $\Delta S^\ddagger$ should lie within the limits $0 \rightarrow 1.4$ e.u. (29) and Reeves has recently suggested that experimentally determined values assuming realistic error limits would probably fall in the range -4 to $+4$ e.u.[1]

In a few cases the entropies we obtained lay outside these limits. While solvation effects would be expected to alter $\Delta S^\ddagger$ and might cause it to lie outside these limits, it seems a highly dubious procedure to ascribe large ΔS values to solvation effects. It is much more likely that the ΔS values arise from systematic errors occurring because of difficulties in determining what the true $\delta\nu_\infty$ is when $\delta\nu_\infty$ exhibits a temperature dependence outside the exchange region. The extreme sensitivity of E_a and $\Delta S^\ddagger$ to errors in input parameters has been pointed out by several workers (30, 31). Thus $\Delta G^\ddagger$ seems still to be the safest parameter to use in making comparisons.

A Relationship between the Sizes and Energies of Atomic Orbitals

R. DAUDEL AND P. G. MEZEY
Centre de Mécanique Ondulatoire Appliquée, C.N.R.S., Paris, France
AND
J. D. GODDARD AND I. G. CSIZMADIA
Department of Chemistry, University of Toronto, Toronto, Ontario M5S 1A1

Received May 9, 1975

R. DAUDEL, P. G. MEZEY, J. D. GODDARD, and I. G. CSIZMADIA. Can. J. Chem. **53**, 3739 (1975).

An approximate relationship of the form

$$\bar{E}^{1.5}V = \text{constant}$$

where $\bar{E}$ is the mean potential acting upon and V the mean volume of an electron in a closed shell of an atom has previously been proposed. This concept of a simple relationship between the sizes and energies of atomic orbitals which is predicted by simple quantum mechanical arguments has been further examined in this present work. The potential energy for a series of two electron atoms and ions has been replaced by the total electronic energy as these two quantities are simply connected by the virial theorem. For polyelectronic atoms, a quantity per electron pair which sums to the total electronic energy has been used. The volume of the ith atomic orbital

$$V_i = \frac{4\pi}{3}\langle r_i^2\rangle^{3/2}$$

has been calculated from its size as previously defined in terms of the spherical quadratic operator evaluated at the orbital centroid of charge. A relationship of the above form between the sizes and energies of atomic orbitals holds well for core orbitals but gradually deteriorates on going from the innermost (core) to outermost (valence) shell.

R. DAUDEL, P. G. MEZEY, J. D. GODDARD et I. G. CSIZMADIA. Can. J. Chem. **53**, 3739 (1975).

On a proposé antérieurement une relation approchée de la forme

$$\bar{E}^{1.5}V = \text{constante}$$

où $\bar{E}$ est le potentiel moyen agissant sur et V le volume moyen d'un électron dans la sphère fermée d'un atome. Ce concept d'une relation simple entre les grosseurs et les énergies des orbitales atomiques, qui est prédit par des arguments simples de mécanique quantique, est examiné à nouveau dans le présent travail. On a remplacé l'énergie potentielle pour une série d'atomes et d'ions à deux électrons par une énergie électronique totale puisque ces deux quantités sont reliées d'une façon simple par le théorème viriel. Pour des atomes polyélectroniques, on a utilisé une quantité par paire d'électrons qui correspond à la somme de l'énergie électronique totale. Le volume de la $i$eme orbitale atomique

$$V_i = \frac{4\pi}{3}\langle r_i^2\rangle^{3/2}$$

est calculé à partir de sa grosseur telle que définie antérieurement en termes de l'opérateur quadratique sphérique évalué au centroïde de charge de l'orbitale. Une relation de la forme mentionnée plus haut entre les grosseurs et les énergies des orbitales atomiques est valable pour les orbitales du noyau mais se détériore graduellement lorsque l'on passe des couches de l'intérieur (noyau) vers celles de l'extérieur (valance).

[Traduit par le journal]

Introduction

An earlier investigation (1) of atomic electronic distributions revealed that

$$[1] \qquad \bar{E}_i^{1.5}\, V_i = \text{constant}$$

where $\bar{E}_i$ is the mean Hartree potential experienced by and V_i the mean volume associated with an electron when it visits the ith loge. The deviations from [1] were small, *i.e.* never greater than a factor of two while $\bar{E}_i$ and V_i varied by 10^4 and 10^5, respectively. The results of ref. 1 were later analyzed (2) in terms of the Thomas–Fermi statistical model for atomic electronic structure and it was shown that the Thomas–Fermi model predicts a relationship of the form of [1]. In addition, the analysis showed that such a relationship should hold better when $\bar{E}$ is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

greatest, *i.e.* better for inner orbitals as compared to outer orbitals.

An even simpler quantum mechanical model, namely, the particle-in-a-box also predicts that a relationship like [1] should hold (3). For a particle in a one-dimensional box or in a sphere the energy is given by

$$[2] \qquad E_0 = -n^2 \frac{\pi^2 \hbar^2}{2ml^2}$$

where n is a quantum number and l is the linear dimension of a volume $1/N$ times the confining volume, where N is the number of identical particles including consideration of the electron spin, *i.e.*

$$[3] \qquad l = \left(\frac{V}{N}\right)^{1/3}$$

Substituting [3] into [2] and rearranging gives

$$[4a] \qquad E_0 V^{2/3} = -n^2 \frac{\pi^2 \hbar^2}{2m} \left(\frac{1}{N}\right)^{-2/3}$$

or

$$[4b] \qquad {E_0}^{3/2} V = \text{constant}$$

which is equivalent to the empirically observed relation [1]. Rearrangement and conversion from c.g.s. to atomic units of [4*a*] yields

$$[4c] \qquad \frac{1}{E_0} = -\frac{2}{n^2\pi^2} \left(\frac{1}{N}\right)^{2/3} V^{2/3}$$

The volume may be rewritten in terms of $\langle r^2 \rangle$ as

$$[5a] \qquad V = \frac{4\pi}{3} \langle r^2 \rangle^{3/2}$$

and substituted into [4*c*] to give

$$[4d] \qquad \frac{1}{E_0} = -\frac{2}{\pi^2} \frac{1}{n^2} \left(\frac{4\pi}{3}\right)^{2/3} \left(\frac{1}{N}\right)^{2/3} \langle r^2 \rangle$$

which with evaluation of the numerical constant yields

$$[4e] \qquad \frac{1}{E_0} \approx -0.53 \frac{1}{n^2} \left(\frac{1}{N}\right)^{2/3} \langle r^2 \rangle$$

as the predicted energy–size relationship on the basis of a particle-in-a-box model. Therefore it is plausible that a relationship between the size or volume of an atomic orbital and its energy may indeed exist. In the present work, the basic concepts of refs. 1 and 4 have been retained. The energies were obtained from Hartree–Fock–Roothaan SCF calculations on four sets of systems corresponding to four different electronic configurations (helium, beryllium, neon, and magnesium) of closed shell atoms and ions. The volumes of the atomic orbitals were calculated in terms of their sizes (5) as given by the expectation value of r^2 evaluated at the centroid of charge of the atomic orbital, *i.e.* at the nucleus. The volume of the ith atomic orbital may be written as

$$[5b] \qquad V_i = \frac{4\pi}{3} \langle r_i^2 \rangle^{3/2}$$

and rewriting [1] with a redefinition of the constant term yields [6] where e_i is an energy quantity for the ith atomic orbital

$$[6] \qquad e_i \langle r_i^2 \rangle = \text{constant}$$

However, it should be noted that there exists a degree of arbitrariness in the definitions of both the energy and the size or volume terms. A more flexible functional form

$$[7] \qquad e_i \langle r_i^2 \rangle^{\gamma} = C$$

where γ is a positive parameter and C a constant was also considered.

Method of Calculation

Hartree–Fock–Roothaan SCF calculations were performed on the closed shell atomic species given in Table 1. The SCF atomic orbitals were expanded in terms of an extensive set of uncontracted gaussian type functions with the exponents from the work of Huzinaga *et al.* (6, 7). For Al^+, Al^{3+}, Si^{2+}, and P^{3+} the final sets of four p-type gaussians specified by Huzinaga were not included in the basis set since such functions are primarily introduced to describe the 3p orbitals which is unnecessary for the cations considered in which the outermost filled orbital is 3s. The calculated total atomic energies for all the species studied are compared to the Hartree–Fock values (8, 9) in Table 2. The total atomic energies are all close to the Hartree–Fock limit. Previous studies (10) have indicated that $\langle r^2 \rangle$ and hence size is not strongly basis set dependent. It may be concluded that both the values for the energies and for the sizes are of near Hartree–Fock quality. All calculations were performed on the IBM 370/165 of the Centre Interregionale des Calculs Electroniques (CIRCE) Orsay, France, employing the the IBMOL-IV program system (11).

For the two-electron species the total electronic energy was employed as E in [6] or [7]. It was a

matter of choice to use the total energy as either component could equally well have been employed since the virial theorem relates all three quantities.

[8] total $E = -\text{kinetic } E = \frac{1}{2}$ potential E

For atomic SCF calculations employing large gaussian basis sets, any deviations from [8] are small. For many electron atoms an analogous quantity was used

[9] $$e_i = 2h_i + \sum_j^{\text{all pairs}} g_{ij}$$

where h_i is the one-electron and g_{ij} the two-electron parts of the atomic hamiltonian. The quantity e_i includes on the average all interactions experienced by a given atomic orbital. The choice of e_i is consistent with the two electron case since these terms sum to the total atomic energy.

[10] $$E = \sum_i^{\text{all pairs}} e_i$$

The volume term was obtained from the size as discussed previously (*cf.* [5]). The $\langle r_i^2 \rangle$ was computed using the one-electron properties package available as part of the POLYATOM system (12). Calculation of the size then involves a simple coordinate transformation (5). The integrals from the SCF calculations were trans-

formed to integrals over the final self-consistent atomic orbitals to compute the energetic quantities.

The data for the various systems were used to determine the optimal parameters for the linear equation

$$[11a] \qquad \left(\frac{1}{e_i}\right) = m\langle r_i^2\rangle + \left(\frac{1}{e_i}\right)_0$$

which is a simple rearrangement of [6] with allowance made for the possibility of an intercept. Parameter optimization involved a standard linear least squares analysis. Rearrangement of [7] yields, allowing for an intercept,

$$[12] \qquad \left(\frac{1}{e_i}\right) = m\langle r_i^2\rangle^\gamma + \left(\frac{1}{e_i}\right)_0$$

where the parameters were obtained from a conjugate gradient minimization procedure.

Results and Discussion

The results for the energies and sizes for the helium-, beryllium-, neon-, and magnesium-like systems are collected according to atomic orbital type in Tables 3 to 6. Although the results for the energies and sizes for the mononegative ions are presented the data for the negatively charged species were not used in obtaining the parameters in the case of the outermost orbital (*e.g.* for the 1s orbital H^- was excluded, for the 2s orbital Li^-, etc). Attempted fittings verified that the sizes and energies for the outermost orbital of negative ions were not given properly by the SCF calculations.

The two electron helium-like systems (He, Li^+, Be^{2+}, B^{3+}) are unique in that the K shell is the valence shell. A linear relationship is adequate to fit the four data points as evidenced by the optimum exponent for the nonlinear fit (see Fig. 6) being close to unity. Figure 1 illustrates the linear fit for the neutral and cationic species of this series.

The K shells of the other atomic species studied may be considered to be core orbitals. In agreement with the predictions of (2) as judged by the deviations of the fits the series of heavier atoms or ions where E or e_i is greater are better described by a relationship of the form of [1] than is the beryllium-like system. A simple linear form is again adequate as evidenced by the optimal γ values (Fig. 6) close to unity. All 1s data can be fit to a single linear equation but there appears a distinction between inner and outer 1s orbitals as the systems are best described if treated separately.

Similar results were obtained for the 2s orbitals. It is clear from considering the parameters for both the linear and nonlinear equations that the outer 2s orbital (beryllium system) is best

treated separately from the 2s inner systems (neon and magnesium systems). The optimized nonlinear m values decrease from the m value of the linear case and smaller deviations suggest that a nonlinear equation is preferable for describing the energy–size relationship. The data for the heavier atoms and inner shells are more consistent with the existence of an energy–size relationship than are the data for the light atoms and outer orbitals. Since the m values for 1s and 2s orbital series are quite different no relationship as general as [6] or [7] holds, since the parameters show a marked dependence on the principal quantum number.

For the 3s orbital the m value has changed from the 1s and 2s results and the optimized exponent value has also further decreased. Since the 3s orbitals are valence in character previous results for the 1s and 2s valence series suggest that any fit should not be as good. Relative to

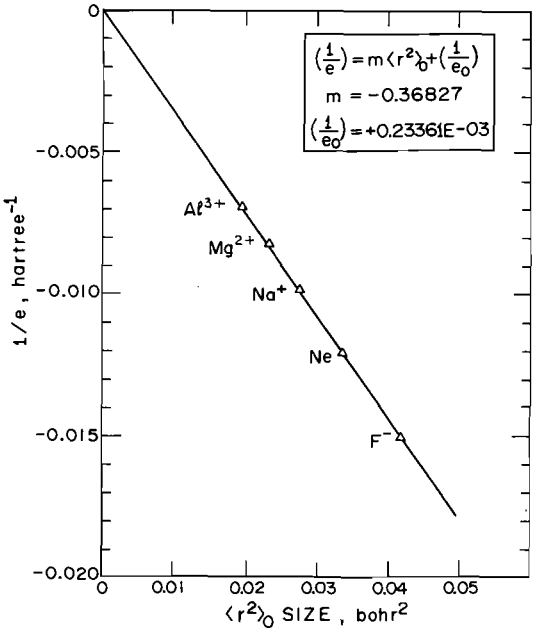

FIG. 3. Linear fit for the neon-like system: $1s^2$.

the inner shell 2s results the quality of the fit for the 3s orbitals has decreased by several powers of ten (standard deviations).

The same general comments may be made concerning the 2p orbitals, *i.e.* the valence and inner 2p orbitals are best treated separately and a nonlinear equation provides a better description. The m and γ values are different from the 2s results indicating dependence on the angular quantum number.

Linear fits for the various sets of 1s core orbitals are illustrated in Figs. 1 to 5. Judging from these plots the linear form is quite adequate to represent an energy–size relationship for core orbitals. The simultaneous linear fit for all 1s core orbitals is also adequate. For other orbitals the linear fits were not sufficient. The nonlinear plots for all orbitals are presented in Figs. 6 and 7. A dependence on the value of the principal quantum number is evident as is a distinction between core and valence orbitals. It is interesting that the most satisfactory energy–size relationship is obtained for the core orbitals which are essentially localized and close to the correct loge representation of electron pairs.

It might be anticipated that if individual electron pairs obey an energy–size relationship then so also should the total energies and total sizes.

$$[11b] \qquad \frac{1}{E} = m\langle r^2\rangle + \frac{1}{E_0}$$

For the energy quantity, such an extension is of particular interest since for the electron pairs the energy per pair (eq. 9) is somewhat arbitrarily defined as compared to the total energy. A linear plot for the total energy – total size relationship

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

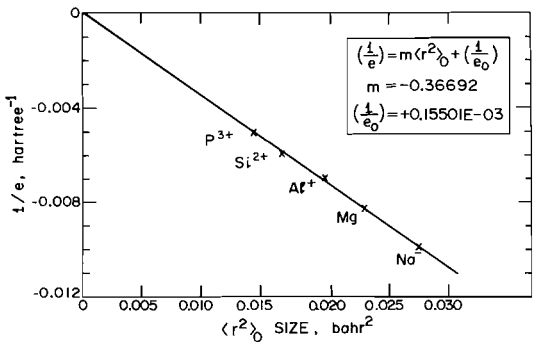

FIG. 4. Linear fit for the magnesium-like system: $1s^2$.

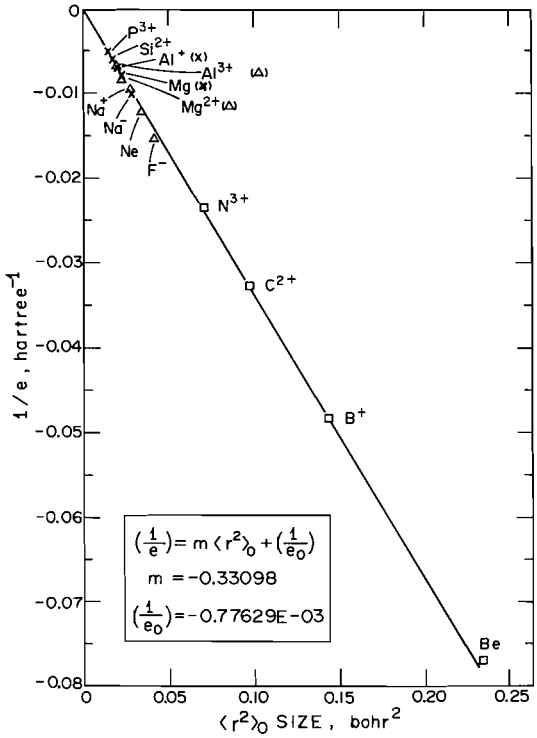

FIG. 5. Linear fit for all $1s^2$ core electrons.

is shown in Fig. 8. The fits are not in general as good as those for the individual orbitals and in particular not as good as the fits for the core orbitals. However, it appears that the relationship for the size and energy for individual orbitals is at least as valid for total atomic systems.

The association of a simple model with the nonlinear parameter (γ) in [7] requires noting the pattern in the variation of γ. The closer an orbital is to the nucleus the closer γ is to unity.

$$[13] \qquad \gamma_{3s} < \gamma_{2p} < \gamma_{2s} < \gamma_{1s} \approx 1$$

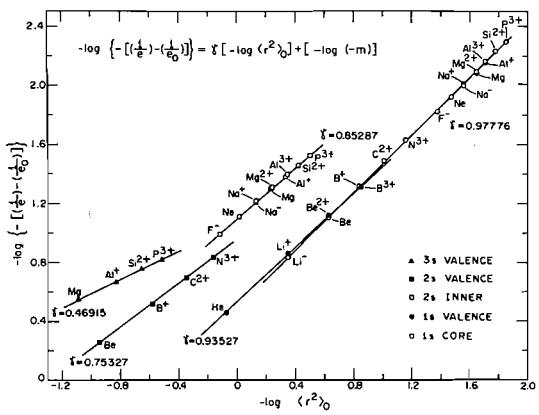

FIG. 6. Nonlinear fits for s electron pairs.

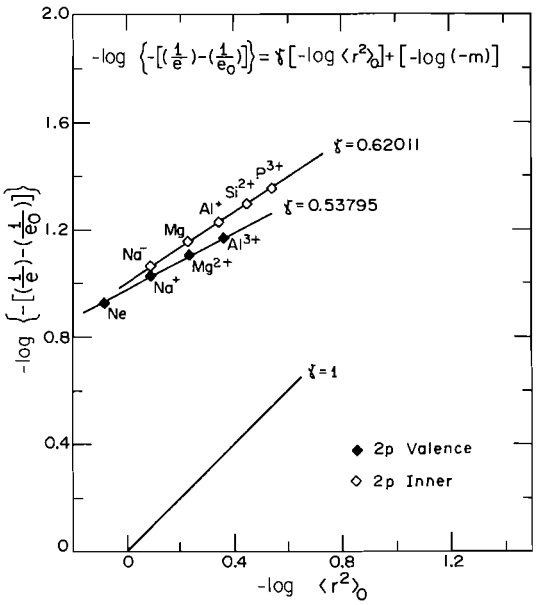

FIG. 7. Nonlinear fits for p electron pairs.

γ also varies with the saturation of a shell

$$[14] \qquad \gamma_{2s}^{Be} < \gamma_{2s}^{Ne} < 1$$

and

$$[15] \qquad \gamma_{2p}^{Ne} < \gamma_{2p}^{Mg} < 1$$

It appears that the presence of an outer orbital leads to an increase in the γ values of the inner orbitals towards unity.

A comparison of the calculated slopes for the linear energy–size relationship (eq. 11*a*) with the predicted quantities from the simple particle-in-a-box model proves of interest. Table 7 collects

TABLE 7. Comparison of particle-in-a-box predictions and calculated values (linear fits) for the slope (m) of the energy–size relationship

	Predicted m	Calculated m				
n	Particle-in-a-box	Electron	He	Be	Ne	Mg
1	−0.53	1s	−0.29	−0.32	−0.37	−0.37
2	−0.13	2s		−0.058	−0.072	−0.079
3	−0.059	3s				−0.014

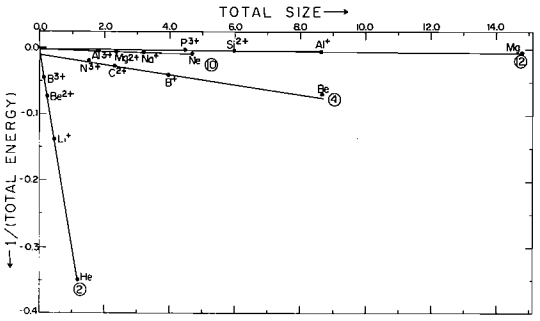

FIG. 8. Linear fits for total energy–total size.

the relevant data. In all cases the particle-in-a-box predicts a larger absolute value for the slope. Thus, the particle-in-a-box model for a certain energy value predicts a smaller size than calculated results for the same energy. Such a result is due to the uniform potential assumed by the particle in a box while the potential calculated for atomic systems is not uniform.

Conclusions

In agreement with the predictions of the particle-in-a-box and Thomas–Fermi models a simple relationship between the energies and sizes of core atomic SCF orbitals was found, namely

$$[16] \qquad \left\{\left(\frac{1}{e_i}\right) - \left(\frac{1}{e_{i0}}\right)\right\} = m\langle r_i^2\rangle_0$$

It was possible to successfully fit a more flexible nonlinear equation

$$[17] \qquad \left\{\left(\frac{1}{e_i}\right) - \left(\frac{1}{e_{i0}}\right)\right\} = m\langle r_i^2\rangle_0^{\gamma}$$

for all computed sets of atomic orbitals. Also of interest is the possibility of the existence of different energy–size relationships holding for different atomic and molecular states. Excited atomic states should, according to the particle-in-a-box model, show a dependence on the quantum number n. Calculations on atomic excited states are also planned. Extensions of similar energy–size relations to the core and valence localized molecular orbitals of simple molecules may prove of interest and work in this area is in progress.

IMRE G. CSIZMADIA

Department of Chemistry, University of Toronto, Toronto, Ontario M5S 1A1

Received June 3, 1975

ROY E. KARI and IMRE G. CSIZMADIA. Can. J. Chem. **53**, 3747 (1975).

Equilibrium geometries and energies are obtained for SH_n (n = 0, 1, 2, 3) neutral and charged species by the Roothaan LCAO–MO–SCF method. A large gaussian basis set including d and p polarization functions was employed. The calculated ionization potentials, electron, proton, hydrogen, and hydride affinities are discussed as well as compared with similar previously calculated properties for OH_n (n = 0, 1, 2, 3) species.

ROY E. KARI et IMRE G. CSIZMADIA. Can. J. Chem. **53**, 3747 (1975).

Utilisant la méthode LCAO–MO–SCF de Roothaan, on obtient les géométries et les énergies d'équilibre des espèces neutres et chargées SH_n (n = 0, 1, 2, 3). On a utilisé une base gaussiène large incluant des fonctions de polarisation d et p. On discute des potentiels d'ionisation calculés, des affinités des électrons, des protons, de l'hydrogène et de l'hydrure et on les compare avec les propriétés semblables calculées antérieurement pour les espèces OH_n (n = 0, 1, 2, 3).

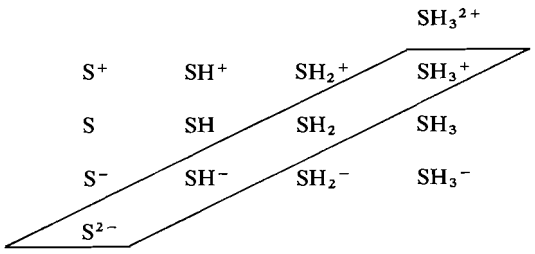
Introduction

The application of LCAO–MO–SCF single determinantal theory to determine molecular properties dependant on energy differences has not been altogether successful. The reason for this lack of success is evident when the total electronic energy (E_{el}) is written as

$$E_{el} = E_{SCF} + (E_{HF} - E_{SCF}) + E_C + E_R$$

where E_{HF} is the Hartree–Fock or lower limit of the single-determinantal (E_{SCF}) energy, E_C is the correlation energy, and E_R is the relativistic energy. In this scheme, the determination of energy differences (ΔE_{el}) is thus limited by the magnitude of the differences in the last three terms of the above equation. Neglecting the term E_R does not lead to large errors since the largest contributions to the relativistic energy are made by core electrons which are least disturbed in chemical reactions. Neglecting either of the other two remaining terms will often result in both appreciable and systematic errors.

Although numerous *ab initio* LCAO–MO–SCF calculations have been previously performed (1–11) to predict energetic properties of sulfur hydrides, the different basis sets used cause large variations in the $(E_{HF} - E_{SCF})$ term and hence are not suitable for making comparisons either within the set of sulfur hydrides or between sulfur and other atom hydrides. To alleviate this difficulty, the present study employed a uniform basis set, including d and p gaussian polarization functions, on a comprehensive selection of both charged and neutral sulfur atom and monosulfur hydride species as listed below.[1]



Since the same gaussian basis set was used to describe both charged and neutral species, some variation of the term $(E_{HF} - E_{SCF})$ still occurs. However, due to the systematic nature of this variation, it is possible to estimate both the magnitude and sign of this term. Then, in conjunction with known experimental values for

[1]Eighteen electron closed-shell species are enclosed in the box.

properties such as ionization potentials, electron and proton affinities, it is possible to estimate the changes in correlation energy. When sufficiently accurate experimental measurements are not available, an attempt is made to extrapolate these known correlation energy changes to obtain an estimate of the corresponding experimental values.

Method

For all singlet states, the normal Roothaan (12) closed-shell molecular orbital method was used. For states of higher multiplicity, the restricted single determinant open-shell molecular orbital method (13) was used. Although the open-shell method sometimes leads to energy convergence difficulties, no such difficulties were encountered here or in a previous study (14) of oxygen hydrides.

In a preliminary study (15) of the effects of polarization functions on calculated energy differences, it was found that unless these functions were used on both the sulfur and hydrogen atoms, less confidence could be placed on the relative as well as the absolute magnitudes of the calculated energy differences. This is caused by the varying effect that a given polarization function will have on the $(E_{HF} - E_{SCF})$ energy term of each molecular species. In addition, since the neutral species basis sets were not here modified for ionic species, polarization functions appear to have an added importance in describing the diffuse additional electron in the negatively charged hydrides.

The actual gaussian basis sets used in these calculations included a $(12^s, 9^p, 2^d)$ basis set on sulfur contracted to a $[6^s, 4^p, 2^d]$ basis set. The hydrogen atom was described by a $(4^s, 1^p)$ basis set contracted to a $[2^s, 1^p]$ basis set. The sulfur s and p exponents and contraction coefficients were those given by Veillard (16) and the hydrogen s exponents and contraction coefficients were those suggested by Basch *et al.* (17). The sulfur d exponents (0.25 and 1.3225) were estimated as being the most suitable for descriptions of the electron densities both near the nucleus and in the bonding regions. The hydrogen p exponent (0.9) was obtained from previous CI results given by Csizmadia *et al.* (18).

For the species investigated, the above basis sets represented the following basis set sizes: S, (51)–[30]; SH, (58)–[35]; SH_2, (65)–[40]; SH_3, (72)–[45]. No distinction was made in the basis sets for ionic or neutral species.

The potential surfaces $E(r,\phi)$, generated by variation of the S—H bond length (r) and the H—S—H bond angle (ϕ), were calculated for all of the hydrides listed in the introduction. For economic reasons, these variations were restricted to the following symmetries: SH, $C_{\infty v}$; SH_2, $D_{\infty h}$ and C_{2v}; SH_3, D_{3h} and C_{3v}. No equilibrium symmetries other than those presently investigated have been previously proposed. It is conceivable that SH_3, neutral or ionic, might exist in a pentagonal bipyramid form with the lone pairs forming two corners of a triangle. However, this geometry was not investigated.

Results and Discussion

Total Energies

The calculated total energies for all of the points on the potential surface considered are listed in Table 1 for atoms, Table 2 for diatomic hydrides, Table 3 for triatomic hydrides, and Table 4 for quaternatomic hydrides. In order to economize on the amount of computer time required to compute an energy surface for each species, the increments in both bond-angle and bond-length variations were deliberately chosen quite large.

The equilibrium energies and geometries listed in Tables 5 to 7 were obtained by a least-squares fitting of the energy surface points to a polynomial of the form

$$E(r,\phi) = \sum_{i,j=0} a_{ij} r^i \phi^j$$

Generally, the coefficient a_{ij} was found to be significant only for i equal to 0, 2, and 4 with j varying from 0 to 4. By comparing the results of this fitting with an alternative third order spline function fit, it was found that although the equilibrium bond angles could not be reproduced by both methods to more than 1 or 2°, both the equilibrium bond lengths and energies were reproduced to the significance quoted in Tables 5 to 7.

The Hartree–Fock energies listed in Tables 1 and 5 are either abstracted from previous estimates or based on best MO or present calculations. Those based on the present calculations were estimated by calculating $(E_{HF} - E_{SCF})$ as a percentage of E_{SCF} for species where E_{HF} was previously estimated and then decreasing the present calculated SCF energies by the same percentage. Generally, different percentages were

calculated for cations, anions, and neutral species.

Ionization Potentials and Electron Affinities

For all ionization potentials (IP) and electron affinities (EA) listed in Table 8, it was assumed that in the course of electron capture, the incoming electron occupied the lowest available empty orbital and the ionized electron was removed from the highest occupied orbital. As a consequence of these definitions, the EA of a species (M) is the negative, in the arithmetic sense, of the IP of the corresponding species having a charge smaller by +1 (*i.e.* M^-). For example, the EA of S is calculated to be −0.03 eV while the IP of S^- is calculated to be +0.03 eV.

As in the previous publication dealing with OH_n oxygen hydrides (14), the thermodynamic convention (endothermic processes show positive energy differences and exothermic processes show negative energy differences) will be used to specify energy differences. Thus, in any chemical reaction, the energy differences between products and reactants may be written as

$$\Delta E_T^M = \Delta E_{HF}^M(Re) + \Delta E_C^M(Re) + \Delta E_R^M(Re) + \Delta E_{ZP}^M(Re)$$

where $\Delta E_{HF}^M(Re)$ is the difference in Hartree–Fock energies between the products and the reactants in their respective equilibrium geometries and the other terms refer to similar correlation, relativistic, and zero-point energy differences. Hence, $IP(M) = \Delta E_T^M$ for the reaction $M \rightleftharpoons M^+ + e^-$ and $EA(M) = \Delta E_T^M$ for the reaction $M + e^- \rightleftharpoons M^-$.

Since one of the purposes of this work was to show that there are no fundamental differences between corresponding oxygen and sulfur hydrides, it is necessary to determine whether or

not the proof of this statement lies within the current SCF approximation and does not rely too heavily on correlation energy differences.

In previously dealing with oxygen hydrides (14), an estimate of $\Delta E_C{}^M(\mathrm{Re})$ was attempted for all energy difference properties. This was made possible by the wealth of previously published experimental and theoretical data describing oxygen hydrides. Due to the lack of similar data for sulfur hydrides, an estimate of $\Delta E_C{}^M(\mathrm{Re})$ here is not possible for any but the atomic and diatomic species. $\Delta E_C{}^M$ for the ionization potentials of O and S are estimated to be 1.8 (19) and 1.3 (20) eV respectively and illustrates a general trend (19–21) that $\Delta E_C{}^M$ is smaller in magnitude for second row atoms. However, the difference $(\Delta E_C{}^O - \Delta E_C{}^S)$ is only 0.5 eV whereas the corresponding calculated, estimated Hartree–Fock, and experimental energy differences are 2.5, 2.7, and 3.2 eV indicating that the calculated IP are entirely adequate to show qualitative differences between sulfur and oxygen hydrides.

Unfortunately, without the use of separately optimized exponents, the LCAO–MO–SCF method is not able to describe anions with the same consistency that it describes neutral and cationic species. For example, the IP of neutral (or EA of cations) and cationic sulfur or sulfur hydrides uniformly deviates from the experimental value by approximately 1.0 eV. This difference is well within the correlation energy correction. However, the EA of neutral (IP of anions) sulfur and sulfur hydrides differs from the experimental value by approximately 2.0 eV which can only be explained by assuming that the quantity $(E_{HF} - E_{SCF})$ is different for the anion and neutral species. Previously calculated EA of neutral oxygen and oxygen hydrides (14) differed from the experimental values by approximately 2.8 eV. Since the change in correlation energy contributes −1.03 and −1.93 eV to EA's of S and O (see Table 9 for details) respectively, the difference in the term $(E_{HF} - E_{SCF})$ must account for 0.97 and 0.87 eV of the discrepancy between calculated and experimental EA's of sulfur and oxygen atoms and hydrides. Although the calculated EA's of neutral sulfur and oxygen hydrides will differ considerably from those calculated with Hartree–Fock wavefunctions, they do so equally in the term $(E_{HF} - E_{SCF})$. Thus, the comparisons shown in Fig. 1 are relatively and qualitatively correct.

Proton, Hydrogen, and Hydride Affinities

The proton (A_{H^+}), hydrogen (A_H), and hydride (A_{H^-}) affinities for the reactions

$$M + H^+ \xrightarrow{A_{H^+}} MH^+$$

$$M + H \xrightarrow{A_H} MH$$

$$M + H^- \xrightarrow{A_{H^-}} MH^-$$

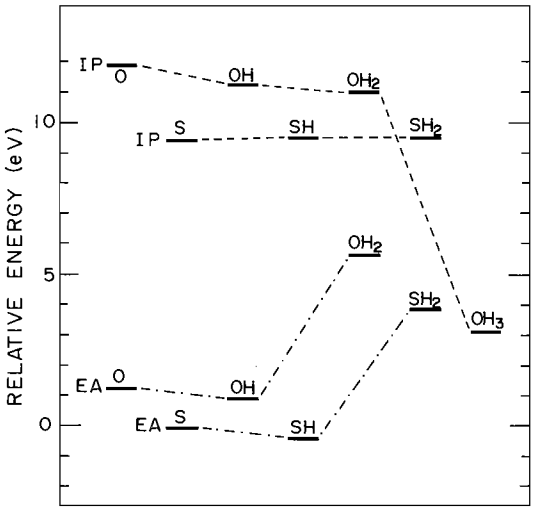

FIG. 1. Electron affinities and ionization potentials of some neutral oxygen and sulfur hydrides. The oxygen values are from ref. 14.

may be defined in theoretical terms as the sum of Hartree–Fock, correlation, relativistic, and zero-point energy component differences. To obtain an estimate of the accuracy of the presently calculated affinities, it is necessary to estimate the magnitudes of the energy components which are not accounted for in a single-determinantal SCF calculation of affinities. Because the majority of relativistic energy is accounted for by electrons near the core of the heavy atom nucleus and because the core is generally least disturbed in the formation of a chemical bond, it has become customary to ignore relativistic energy differences and to assume that these differences are negligible for all affinities. A similar assumption cannot be made for the differences between the remaining energy components.

Since the electronic energy of a bare proton is zero by definition, the proton affinity is equal to the difference in energy between the protonated species and the parent molecule and is thus the simplest affinity to examine in detail. Although a reasonably accurate estimate can be made for the Hartree–Fock energy from SCF calculations, the estimation of correlation energy components requires an experimental knowledge of both the proton affinity and the zero-point energies of the species involved. Unfortunately, only the proton affinity of SH_2 (22, 23) has been determined to any reasonable accuracy but, in this case, the zero-point energy of SH_3^+ is not available. Thus, the only recourse is to estimate experimental proton affinities from strictly theoretical considerations which in turn limits these considerations to the simplest system possible.

Theoretical estimates of the proton affinity components of O^- and S^- in the reactions

$$O^- + H^+ \rightarrow OH$$

$$S^- + H^+ \rightarrow SH$$

are summarized in Table 9. From this table, three methods may be used to estimate the experimental proton affinity. First, independently estimated experimental energies may be used; second, independently estimated Hartree–Fock energies may be coupled with united atom (u.a.) correlation energies and finally with separated atom (s.a.) correlation energies. Generally (1*a*), it has been noted that there is more correlation energy in a diatomic hydride (A—H) than in the s.a. estimate and less than that in the u.a. estimate. Thus, the correlation energy component in the u.a. approximation will form a lower bound while the s.a. approximation will form an upper bound. If it is assumed that the true proton affinities of O^- and S^- are -0.608 and -0.552 and the respective H—F A_{H^+} are -0.632 and -0.564, then zero-point energy corrections will tend to increase these latter values by approximately 0.008 and 0.006 hartree. The correlation energy component will also increase the H—F A_{H^+} value by 0.016 and 0.006 for O^- and S^- respectively. The positive correlation component implies that the magnitude of the correlation energy decreases in an isoelectronic series of the form

$$|E_C^{AH_2^+}| < |E_C^{AH}| < |E_C^{A^-}|$$

or

$$|E_C^{AH_3^+}| < |E_C^{AH}| < |E_C^{AH^-}|$$

Looking next at the term $(E_{HF} - E_{SCF})$ for the calculated proton affinities of O^- and S^-, it may be noted from Table 10 that the calculated values are both more negative than the Hartree–Fock values. This again is caused by the less adequate representation by the gaussian basis set of the negatively charged atom and results from the fact that gaussian exponents are generally optimized for neutral atoms and as such produce better representations of neutral rather than charged species. An unfortunate specific example of this behavior can be illustrated by the presently used hydrogen and hydride ion exponents. Uncontracted, these exponents yield an energy of

	A_H	−78.8	−77.2	—
SH_2	A_{H^+}	−172	−179	−169 ± 2[b]

[a]For all estimates, it is assumed that the zero-point energy of $SH^+ = SH = SH^- = 3.77$ kcal/mol.
[b]Reference 23.

−0.499 a.u. for the hydrogen atom and −0.4122075 for the hydride ion. With a partial reoptimization (exponents 18.9496, 2.9687, 0.46834, 0.074865) this energy is reduced to −0.4794386 a.u. for the hydride ion. Further examination of all of the proton affinities in Table 10 will show that, in general, the calculated affinity of a negative species will be more negative whereas the calculated affinity of a neutral species will be less negative than the corresponding Hartree–Fock affinities.

In summary, because the calculated A_{H^+} for neutral species represents an upper bound to the H—F A_{H^+} which in turn represents a lower bound to the experimental A_{H^+}, it is possible, for neutral species, to calculate A_{H^+} values which through fortuitous cancellations are very accurate. For negative ions, both correlation energy and the term $(E_{HF} - E_{SCF})$ reinforce each other resulting in a larger discrepancy between the experimental and calculated A_{H^+}. Thus, the calculated A_{H^+} represents only a lower bound to the true A_{H^+} and may differ from the true value by as much as 30 kcal/mol. In a previous study (15) of the effect of polarization functions on calculated proton affinities, it was noted that the difference between the calculated and H—F proton affinities decreased as the size of the species increased. This can be seen as well from Table 10 where the calculated A_{H^+} for S differs from the H—F value by 9 kcal/mol whereas the same difference for SH_2 is only −1 kcal/mol. Thus, the larger the species, then the greater the confidence that may be attached to the calculated A_{H^+}.

An analysis similar to the above could be done for both hydrogen and hydride affinities. Considering the sizeable error introduced by the poor representation of the hydride ion in the present calculations, such an exercise would not be productive for hydride affinities. For hydrogen affinities, since the bare hydrogen atom possesses no correlation energy, the only additional error not accounted for in the discussion of proton affinities is the term $(E_{HF} - E_{SCF})$ for the hydrogen atom. This term then accounts for 1.5 kcal/mol in the discrepancy between calculated and Hartree–Fock hydrogen affinities. Also, because the addition of a hydrogen atom does not change the charge on the species, the previous discussion concerning the basis set artifacts introduced in calculating energy differences between charged and neutral species is no longer relevant. Thus, provided that the calculated SCF energies of the parent and hydrogenated species are equally accurate relative to their respective

Hartree–Fock energies, the discrepancy between calculated and Hartree–Fock hydrogen affinities should be in the neighborhood of 1.5 kcal/mol. As can be seen from Table 10, this is indeed true for all species.

Conclusions

The ionization potentials of neutral sulfur hydrides are shown in Fig. 1 to be smaller in magnitude than the corresponding ionization potentials of neutral oxygen hydrides. But, the electron affinities of the same oxygen hydrides are considerably larger than the corresponding sulfur hydrides. Since the valence electrons of sulfur compounds are more readily available, the neutral sulfur compounds can be considered to be more basic, whereas for negatively charged species, the oxygen analogs are more basic. Also from Fig. 1, it may be noted that all of the sulfur values have a smaller spread. This indicates that the hydrogen adjacent to the heteroatom creates a smaller perturbation on the electronic structure of the S atom than on that of the O atom.

A previous study (1) on first and second row monohydrides showed that the IP's in this case did not correlate well with corresponding united atom ionization potentials. This same trend is shown in Fig. 1 for A, AH, and AH_2 where the IP's show a decrease whereas the united atom IP's show increases from O to Ne or S to Ar.

However, the IP of OH_3 does show a marked decrease which is consistent in the decrease in IP when comparing Ne and Na. Although no equilibrium structure was found for SH_3 in a C_{3v} symmetry, it is expected that should some other equilibrium structure for SH_3 exist, its IP would also show a marked decrease from that of SH_2.

The differences in affinities between similar oxygen and sulfur species are illustrated in Fig. 2 and listed in Table 11. The general trends which may be noted from this figure and table are as follows: (*a*) Proton affinities of the sulfur atom and neutral hydrides are less than analogous oxygen hydrides and this difference decreases as the number of attached hydrogen atoms increases. (*b*) Proton affinities of the sulfur anion and negatively charged hydrides are greater than analogous oxygen hydrides and this difference tends to increase as the number of attached hydrogen atoms increases. (*c*) Hydrogen affinities for all sulfur hydrides are greater than analogous oxygen hydrides and this difference tends to increase as the number of attached hydrogen atoms increases.

It was previously noted that the calculated proton affinities of neutral species tended to be more accurate in an absolute sense. This statement will no longer apply to the differences listed in Table 11 since basis set artifacts operate in a similar manner for both oxygen and sulfur hydrides. As can be seen from the small deviation of the calculated from Hartree–Fock affinities, the basis sets used to describe oxygen hydrides and sulfur hydrides are relatively equally good. In addition to the cancellation of these errors, the neglect of correlation energy is also cancelled insofar as the correlation energy changes are similar for both oxygen and sulfur hydrides. Thus, the calculated differences listed in Table 11 represent good estimates in both an absolute and relative sense.

The Redox Behavior of 9,10-Anthraquinone-2-sulfonate in Acidic Aqueous Solution

ARTHUR D. BROADBENT AND RONALD J. MELANSON

Department of Chemistry, Mount Allison University, Sackville, New Brunswick E0A 3C0

Received August 1, 1975

ARTHUR D. BROADBENT and RONALD J. MELANSON. Can. J. Chem. **53**, 3757 (1975).

A green intermediate, observed during reduction of 9,10-anthraquinone-2-sulfonate (A) to the corresponding anthrahydroquinone (AH_2) in acidic aqueous solution, has been identified as a quinhydrone-like charge-transfer complex of A and AH_2. Spectrophotometric and potentiometric measurements have shown that changes in the slope of the potentiometric titration curves with varying initial [A] are caused only by this complex ($A\cdot\cdot\cdot AH_2$) and not by any semiquinone radical ($AH\cdot$) or radical anion ($A\cdot^-$) intermediate. The very low semiquinone formation constant in acidic solution indicates that the pK_a of $AH\cdot < 7.0$. Electrochemically determined pK_a values for similar radicals in the range 8.5–10.5 are invalid because of interference by charge-transfer complexes of this type.

ARTHUR D. BROADBENT et RONALD J. MELANSON. Can. J. Chem. **53**, 3757 (1975).

On identifie l'intermédiaire vert, observé durant la réduction de l'anthraquinone-9,10 sulfonate-2 (A) en anthrahydroquinone (AH_2) correspondante en solution acide aqueuse, comme étant un complexe de transfert de charge de type quinhydrone dérivé de A et AH_2. Des mesures spectrophotométriques et potentiométriques ont permis de montrer que les changements dans la pente des courbes de titrations potentiométriques, lorsque l'on fait varier les [A] initiales, sont uniquement causés par ce complexe ($A\cdot\cdot\cdot AH_2$) et non pas par le radical semiquinone ($AH\cdot$) ou le radical anion ($A\cdot^-$) intermédiaire. La très basse constante de formation de la semiquinone en solution acide indique que le pK_a de $AH\cdot < 7.0$. Les valeurs de pK_a de 8.5 à 10.5 déterminées électrochimiquement pour des radicaux similaires sont invalides à cause de l'interférence des complexes de transfert de charge de ce type.

Introduction

Flash photolysis of 9,10-anthraquinone-2-sulfonate (A) in aqueous solution causes reduction to the corresponding anthrasemiquinone radical ($AH\cdot$) or radical anion ($A\cdot^-$). Variations in the yields of these radicals with changing pH indicate that the pK_a of $AH\cdot$ is 3.25 (1), in agreement with values for related radicals generated by pulse radiolysis or flash photolysis (2, 3). However, Gill and Stonehill (4) have reported a polarographically determined pK_a of 9.02 for $AH\cdot$, and a full evaluation of the data of Burstein and Davidson (5) gives a value of 8.4 (see Fig. 1). This discrepancy in the reported pK_a values for $AH\cdot$ prompted a reexamination of the redox behavior of A in acidic solution.

The redox potential (E) in the reversible reduction of a quinone to a hydroquinone, involving a semiquinone radical intermediate, is given by the Nernst equations

$$[1] \qquad E = E_m + \frac{RT}{2F}\ln\frac{a_A}{a_{A^{2-}}} = E_2 + \frac{RT}{F}\ln\frac{a_A}{a_{A\cdot^-}} = E_1 + \frac{RT}{F}\ln\frac{a_{A\cdot^-}}{a_{A^{2-}}}$$

where E_m, E_1, and E_2 are the respective midpoint potentials for the two-electron ($A^{2-} \rightleftarrows A + 2e^-$) and single electron ($A^{2-} \rightleftarrows A\cdot^- + e^-$, $A\cdot^- \rightleftarrows A + e^-$) redox systems, and a is the activity of the species indicated. Equations 1 give

$$[2] \qquad E_m = \tfrac{1}{2}(E_1 + E_2)$$

$$[3] \qquad E_2 - E_1 = \frac{RT}{F}\ln K_s$$

where K_s, the semiquinone formation constant, is the equilibrium constant for

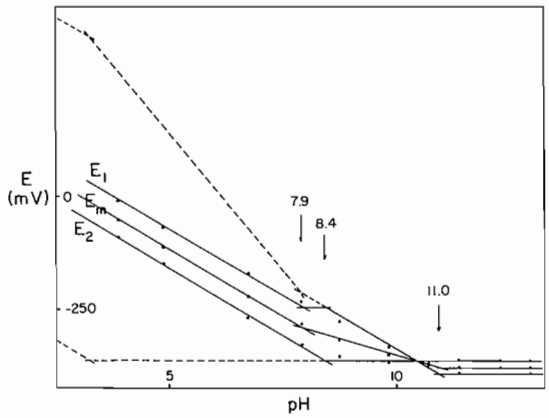

FIG. 1. Redox potentials E_m, E_1, and E_2 as a function of pH for A (E *vs.* n.h.e.).

$$[4] \qquad A + A^{2-} \rightleftarrows 2\,A\cdot^{-}$$

and can be determined from the slope of potentiometric titration curves using the Michaelis index potential, E_i (6). This is given by

$$[5] \quad E_i = E_{0.50} - E_{0.25} = E_{0.75} - E_{0.50} \qquad E_{0.50} = E_m$$

where the subscripts represent the fractional degree of oxidation of A^{2-} to A (α). E_m, E_1, and E_2, and therefore K_s, are pH-dependent because of acid–base equilibria of A^{2-} (conjugate acids AH^- and AH_2) and $A\cdot^-$ (conjugate acid AH·). Variations in these mid-point potentials with changing pH allows evaluation of pK_a values of species in the reversible redox system (7).

Figure 1 gives the fully evaluated data from the paper by Burstein and Davidson (5), clearly showing pK_a values of 7.9 and 11.0 for AH_2 and AH^-, respectively, and of 8.4 for AH·. The dependence of E_m on pH agrees with that of Conant *et al.* (8). The dotted lines represent the variations of E_1 and E_2 expected for a pK_a of 3.25 for AH·. A distinction between the pK_a values of 8.4 and 3.25 for AH· is thus possible, because of the large difference in the expected values of $E_2 - E_1$ and K_s in acidic solution.

Results

Changes in the visible spectrum of solutions of AH_2 with variation in pH allowed spectrophotometric titration as a means of pK_a measurement, and gave values of 7.97 and 11.08 for AH_2 and AH^-, respectively, in agreement with the potentiometrically determined values (5, 8).

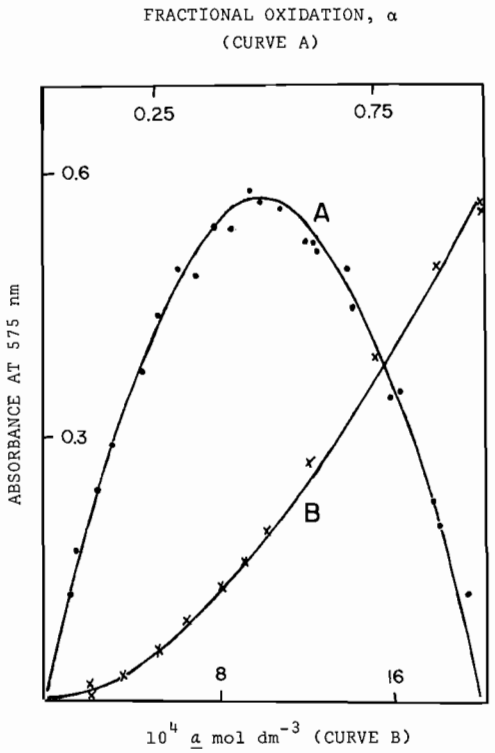

FIG. 2. Curve A: absorbance at 575 nm as a function of α ($a = 2 \times 10^{-3}$ mol dm^{-3}). Curve B: maximum absorbance at 575 nm (at $\alpha = 0.50$) as a function of a.

Reduction of A to AH_2 in acidic solution changes the almost colorless solution to greenish-yellow, but, at [A] $> 1 \times 10^{-3}$ mol dm^{-3}, an intense green intermediate (λ_{max} 575 nm) is clearly recognisable during the reduction. Figure 2 illustrates the variation of absorbance at 575 nm with change in the fractional oxidation of AH_2 (α), and also the variation of the maximum absorbance at 575 nm (at $\alpha = 0.50$) with change in the initial [A].

Oxidative potentiometric titrations of AH_2 in acetate buffer solution gave redox potential-titration curves which were perfectly symmetrical about the constant mid-point potential (E_m = −330 mV *vs.* s.c.e.), but for which E_i depended upon the initial [A] (Table 1).

Discussion

The experimental results indicate that the green intermediate, observed on reduction of A to AH_2 in acidic solution, is of the type described by Michaelis and Fetcher (9) for partially reduced phenanthraquinone-3-sulfonate in acidic solution, which they established (10) is a diamagnetic, quinhydrone-like complex which is now considered to be a charge-transfer complex of the quinone and hydroquinone, rather than a dimer of the semiquinone radical.

The variation of E_i with initial [A] demonstrates that the green intermediate is not AH· or $A^{\cdot -}$, neither of which exhibit pronounced absorption at 575 nm (1). The potentiometric E_i values decrease with decreasing initial [A] to values lower than reported by Burstein and Davidson (5). In fact, the results indicate that the observed E_i values can be accounted for solely by the formation of a quinhydrone-like complex ($A\cdots AH_2$), and that E_i would decrease to close to the limiting value of 14.1 mV at 25 °C, corresponding to a two-electron redox system with no intermediate, if the [A] were decreased below 2×10^{-4} mol dm^{-3}. Thus, in acidic solution, K_s is very small indeed, in agreement with a pK_a of 3.25 for AH·, which requires that $E_2 - E_1 \approx -550$ mV at pH 4.6, corresponding to $K_s \approx 10^{-9}$. Actually, because $K_s < 10^{-4}$ cannot be determined experimentally, the results only show that the pK_a of AH· < 7. The stability of $A^{\cdot -}$ in aqueous solutions is therefore determined exclusively by the acid–base behavior of the anthrahydroquinone.

It is probable that electrochemically determined pK_a values for other anthrasemiquinone radicals are also in error (4, 11) because of interference by quinhydrone complexes of the type described, which exist in acidic, neutral, and, to a lesser extent, in alkaline solutions of partially reduced quinones (9–12). Their presence leads to exaggerated E_i values, which are not indicative of semiquinone formation alone. In fact, the formation of soluble quinhydrones in organic redox systems has largely been ignored.

The symmetry of curve A in Fig. 2, and the symmetry of the potentiometric titration curves, indicate that charge-transfer complexes of A with AH· or $A^{\cdot -}$ are negligible at equilibrium, in accord with the low value of K_s, although there is evidence that $A\cdots AH_2$ and $A\cdots AH\cdot$ are kinetically significant (13). Ehrenberg (14) has demonstrated that solutions of partially reduced isoalloxazines contain a variety of bimolecular complexes of this type.

Assuming that for A, $K_s = 0$, the only complication in the reversible redox sequence is the reaction

$$[6] \qquad A + AH_2 \rightleftarrows A\cdots AH_2$$

Elimination of [A] and [AH_2] from equations

$$[7] \quad K_c = [A\cdots AH_2]/[A]\cdot[AH_2]$$

$$[8] \quad a = 2\,[A\cdots AH_2] + [A] + [AH_2]$$

$$[9] \quad \alpha = ([A\cdots AH_2] + [A])/a$$

yields the equation

$$[10] \quad [A\cdots AH_2] = \frac{(K_c a + 1) \pm [(2K_c a + 1) - K_c{}^2 a^2 (1 - 2\alpha)^2]^{1/2}}{2K_c}$$

which has the appropriate form since $[A\cdots AH_2] = 0$ when $\alpha = 0$ or 1, and $[A\cdots AH_2] = [A\cdots AH_2]_{max}$ when $\alpha = 0.50$.

Rearrangement of the Nernst equation gives

$$[11] \quad [A] = [AH_2]10^{\gamma} \text{ where } \gamma = \frac{(E - E_m)2F}{2.303RT}$$

Substitutions from [8], [9], and [11] into [7] and rearrangement gives

$$[12] \quad K_c = \frac{\alpha(10^{-\gamma} - 10^{\gamma}) + (10^{\gamma} - 1)}{a(1 - 2\alpha)^2}$$

Equation 12 is similar to but simpler than equations for the calculation of K_c developed by Michaelis (6, 9). It allows calculation of K_c from any point on the potentiometric titration curve. A large number of calculations based on various values of a and α resulted in a mean value of $K_c = 350 \pm 50$. Some typical results are shown in Table 2. The mean deviation is unavoidably large because the value of K_c from [12] is extremely sensitive to very small changes in the values of $E - E_m$ (*e.g.* ±0.1 mV) and α (*e.g.* ±0.005). The curves A and B in Fig. 2 and E_i values in Table 1 were all calculated from the

above equations assuming $K_c = 350$ and ε (575 nm) = 540 dm^3 mol^{-1} cm^{-1} for A$\cdots$AH$_2$.

Experimental

The spectrophotometric and potentiometric studies were performed on solutions of A containing 0.100 mol dm^{-3} acetic acid and sodium acetate at 24–25 °C (p*H* 4.65).

Absorbance measurements, using a Shimadzu QV500 spectrophotometer, were obtained at 575 nm using a 5.00 cm optical cell attached to a polarographic unit. After partial reduction of A with a small volume of weakly alkaline $Na_2S_2O_4$ solution, α was determined polarographically (Sargent Model XVI Recording Polarograph) from the limiting diffusion currents of A and AH$_2$, assuming equal diffusion coefficients, before the solution was admitted to the optical cell. All operations were conducted in a N_2 atmosphere.

For potentiometric titrations, A was reduced with a weakly alkaline solution of $Na_2S_2O_4$, or with hydrogen and colloidal palladium, and the resulting AH$_2$ was then titrated in a N_2 atmosphere with buffered $K_3Fe(CN)_6$ solution, the potentials established at two bright Pt electrodes being measured with respect to a saturated calomel electrode using a Leeds and Northrup Students' Potentiometer, calibrated with a Weston Standard Cell. No problems were encountered when using $Na_2S_2O_4$ to reduce A in the acidic buffer, provided that excess $Na_2S_2O_4$ was avoided.

The 1,3,5-Trinitrobenzene–Phenoxide σ-Complex. Ambident Phenoxide Ion in SNAr Systems[1]

ERWIN BUNCEL, ANDRZEJ JOŃCZYK,[2] AND JOHN G. K. WEBB
Department of Chemistry, Queen's University, Kingston, Ontario K7L 3N6
Received July 14, 1975

ERWIN BUNCEL, ANDRZEJ JOŃCZYK, and JOHN G. K. WEBB. Can. J. Chem. **53**, 3761 (1975).

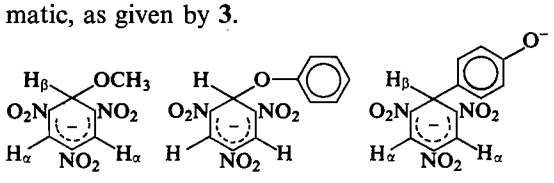
1,3,5-Trinitrobenzene reacts with potassium phenoxide in dimethyl sulfoxide solution to yield a σ-complex in which bonding has occurred between the *para* carbon of the phenoxy moiety and an unsubstituted carbon of the nitroaromatic substrate. A minor proportion of *ortho* adduct is also obtained. When the reaction is performed in DMSO–MeOH (80:20, v/v) one obtains initially the methoxide adduct of TNB which is then smoothly transformed into the phenoxide adduct. The latter is stable to dilute mineral acid, unlike the former; formation of a σ-complex involving bonding between the phenoxy oxygen and a carbon of TNB is thereby excluded. The reaction represents the first instance of phenoxide ion acting as an ambident nucleophile towards aromatic carbon. The implication of this finding on the course of related SNAr reactions is discussed on the basis of kinetic and thermodynamic control of product formation.

ERWIN BUNCEL, ANDRZEJ JOŃCZYK et JOHN G. K. WEBB. Can. J. Chem. **53**, 3761 (1975).

Le trinitro-1,3,5 benzène (TNB) réagit avec le phénolate de potassium dans le DMSO pour conduire à un complexe-σ dans lequel un lien s'établit entre la position-*para* d'un phénolate et un carbone non substitué du substrat nitroaromatique. On obtient aussi des quantités plus faibles d'adduit *ortho*. Quand on effectue la réaction dans le DMSO–MeOH (80:20 v/v) on obtient au début le produit d'addition du méthylate sur le TNB qui se transforme par la suite en adduit du phénolate. Ce dernier est stable en milieu acide dilué ce qui n'est pas le cas du premier; la formation d'un complexe-σ impliquant un lien entre l'oxygène du phénolate et un carbone du TNB est exclue sur cette base. La réaction correspond au premier cas où l'ion phénolate agit comme nucléophile ambident vis-à-vis un carbone aromatique. On discute de l'implication de ce résultat sur l'orientation des réactions SNAr; cette discussion est faite en se basant sur le contrôle cinétique et thermodynamique de la formation du produit.

[Traduit par le journal]

Whereas alkoxide ion σ-complexes of nitroaromatic compounds have been extensively investigated (1–4) and their structures fully established (*e.g.* **1**) (5, 6), corresponding aryloxide ion complexes have so far received only scant attention (7–10). Moreover, little agreement exists at present concerning the structures of such aryloxide complexes. Bond formation between the phenoxy oxygen and the nitrogen center of a nitro group was proposed by Tronov and co-workers (7, 8), on the basis of colorimetric studies, for the reaction of phenoxide ion with dinitrobenzene. A more conventional structure, **2**, involving bonding between phenoxy oxygen and an unsubstituted carbon of the nitroaromatic was advanced by Shein and Byval'kevich (9), on the basis of n.m.r. and u.v.–visible spectroscopy, for the phenoxide ion reaction with 1,3,5-trinitrobenzene (TNB). In contrast, we have reported evidence in a preliminary communication (10) for a structure involving bond formation between the *para* carbon of phenoxide and an unsubstituted carbon of the nitroaromatic, as given by **3**.



1 **2** **3**

Since **3** represents apparently the first case illustrating the ability of phenoxide ion to act as an ambident nucleophile towards aromatic carbon, we wish to present further evidence in order to reinforce our interpretation and also to discuss the implications of this unusual finding.

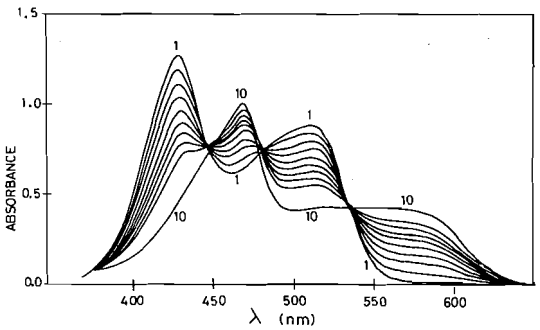

FIG. 1. Visible absorption spectra as a function of time demonstrating transformation of the trinitrobenzene–methoxide σ-complex to the trinitrobenzene phenoxide σ-complex.

Results and Discussion

Interaction Between TNB and Potassium Phenoxide in DMSO–Methanol

An instantaneous deep red color appears on mixing solutions of TNB (0.4 *M*) and PhOK (0.8 *M*) in DMSO–methanol (80:20, v/v). This color, however, is due to the TNB–methoxide adduct **1**, not a phenoxide adduct. Thus the u.v.–visible spectrum (following 100 fold dilution of the reaction solution and recording the spectrum in a 0.1 mm cell) taken 1 min after mixing is fully characteristic of complex **1** (spectrum 1 in Fig. 1). Periodic monitoring of the reaction solution in this way reveals certain spectral changes occurring with time, namely a decrease in the absorption maxima at 428 and 510 nm due to **1** and the appearance of new absorptions at 468 and 570 (broad) nm. The spectral changes are complete in about 6 h at 45 °C. An experiment performed using the authentic, separately prepared, TNB–methoxide complex (**1**) as the starting material showed identical spectral changes.

Evidence that the new complex is not the result of C—O bonding was obtained by acidification of the reaction solution. In Fig. 2*a* are shown selected spectra in a typical run, taken as described above, while in Fig. 2*b* are shown the spectra of the corresponding acidified reaction solutions. It is evident from these spectra that whereas the initially formed species is destroyed by acid the species responsible for the final spectrum is stable under acidic conditions. Alkoxide complexes of nitroaromatics are known to be decomposed by acid, regenerating the starting nitro compound (11). However aryl complexes

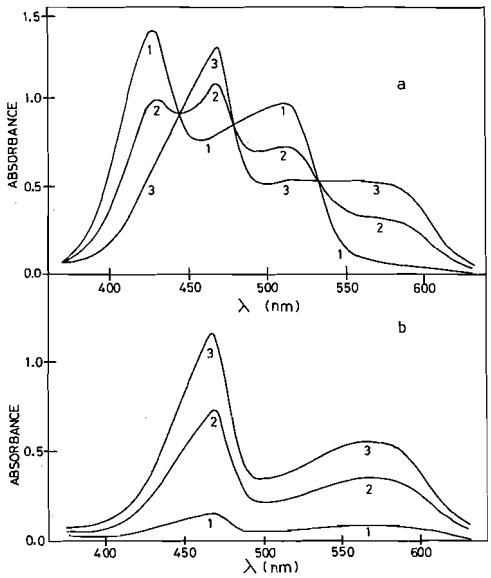

FIG. 2. (*a*) Selected spectra in the conversion of the TNB–methoxide complex to the TNB–phenoxide complex. (*b*) Spectra of the acidified reaction solutions.

are expected to be stable, in line with the much poorer leaving group ability of a phenyl moiety compared with methoxy (12, 13).

Confirmation of the postulated bonding type in the complex was afforded by n.m.r. spectroscopy. It was readily established that the initially formed spectrum in the interaction of TNB (0.4 *M*) and PhOK (0.8 *M*) in DMSO–MeOH (80:20, v/v) is due to the methoxide complex. On mixing the reactants the absorption at 9.25 p.p.m. due to TNB disappears while new absorptions characteristic of **1** arise. The H_α absorption occurs at 8.69 p.p.m. (doublet, $J = 1.2$ Hz) while H_β occurs at 6.37 p.p.m. (poorly resolved triplet). In time, as the reaction proceeds, these absorptions gradually disappear and new signals appear at 8.54 and 5.72 p.p.m. In the reaction mixture containing excess potassium phenoxide, or phenol, the phenoxy protons of the complex are difficult to resolve. The overall n.m.r. spectral characteristics are nevertheless suggestive of structure **3**.[3] In particular it can be noted that H_β in **3** is further upfield than the corresponding proton in **1**. The chemical shift dif-

[3]More precise characterization of the complex was obtained in further work using a Bruker 60 MHz instrument and is given in the section entitled 'Interaction between TNB and phenoxide in DMSO'. Evidence for formation of an *ortho* adduct will also be presented in that section.

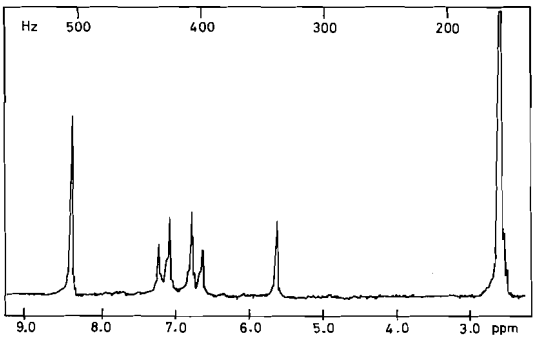

FIG. 3. Nuclear magnetic resonance spectrum of the isolated trinitrobenzene-phenoxide σ-complex in DMSO-d_6.

ference between H_α and H_β is 2.32 p.p.m. in the initial complex **1**, but 2.82 p.p.m. in the product. This is in accord with bonding at C_1 by an atom of lesser electronegativity than oxygen. Isolation of the reaction product on acidification (see Experimental) yielded a compound which showed, in addition to the above mentioned signals at 8.54 and 5.72 p.p.m. (integral height ratios 2.1 : 1.0), characteristic absorptions for the phenoxy moiety (integral 4.2). A quartet centered at 6.9 p.p.m. is characteristic of an A_2B_2 spin system for *para* disubstituted benzene derivatives. These features of the n.m.r. spectrum are completely in accord with structure **3**. The spectrum is reproduced in Fig. 3.[3]

Reaction Schemes

Several possible pathways may be proposed for formation of **3** in this system, as shown in Scheme 1. In this scheme, complex **1** is first generated via the solvolytic equilibrium $PhO^- + MeOH \rightleftarrows PhOH + MeO^-$ as a result of the highly favorable kinetic and thermodynamic factors in formation of **1** from TNB and MeO^- (14, 15). Proceeding from **1** as the effective starting material, paths *a*, *b*, and *c* represent displacement mechanisms by phenoxide ion. These displacements could occur directly by S_N2 type processes at the sp^3 center of the Meisenheimer complex or indirectly by S_N2' type displacement. Alternatively, prior dissociation of **1** to yield a small equilibrium concentration of free TNB would occur via *e*. Reaction of TNB with PhO^- could then proceed via *d* to give **2** and via *f* and *g* to give **3**. Since there seem to be no definitive cases known of S_N2 or S_N2' displacement processes on Meisenheimer complexes, we give preference to the dissociative mechanism, namely that **3** is formed from **1** via the route *e*, *f*, and *g*.

Interaction Between TNB and Phenoxide in DMSO; State of Ionization of the TNB–Phenoxide Adduct

In order to obtain an independent confirmation of our conclusions, experiments were carried out with trinitrobenzene and potassium phenoxide using pure DMSO as the medium, rather than DMSO–MeOH as described above. In summary, the work showed that the complex **3** can be obtained directly without the intervention of **1**. The evidence was obtained by u.v.–visible and n.m.r. spectroscopy on the complex formed *in situ* as well as on the isolated reaction product (see Experimental). The fact that one could obtain **3** directly in this manner supports the dissociative mechanism given at the end of the last

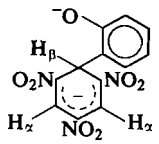
For personal use only.

section as the most probable pathway for formation of **3** in that system.

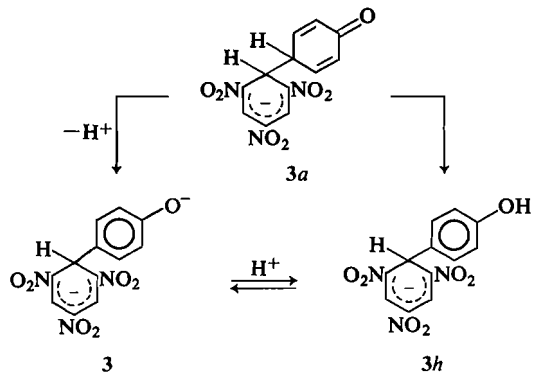
A noteworthy aspect revealed as a result of further investigation was evidence for the *ortho* phenoxy adduct, **4**, formed by bonding between



4

an *ortho* carbon of phenoxide ion and an unsubstituted carbon of TNB. Formation of another complex, apart from **3**, was indicated by the presence in a number of the n.m.r. spectra of a signal at 5.88 p.p.m., downfield of the 5.54 p.p.m. signal due to H_β of the *para* phenoxide adduct of TNB. That this new complex did not result from bonding via the oxygen of phenoxide was indicated by the fact that the 5.88 p.p.m. signal was observed both *in situ* in the reaction solutions and also in the product isolated on acidification. Generally the 5.88 p.p.m. signal was small relative to the 5.54 p.p.m. signal, though on one occasion it reached about a third of that magnitude. In that case a signal due to H_α of **4** was also seen at 8.35 p.p.m. (J = 0.3 Hz), slightly downfield of the H_α signal at 8.34 p.p.m. (J = 0.5 Hz) due to the *para* adduct. The H_β signal, however, appeared as a broadened singlet for both adducts. Moreover, the phenoxy protons of **4** could not be clearly distinguished but due to extensive overlap resulted in a diffuse pattern in the quartet arising from the phenoxy protons of the *para* adduct.

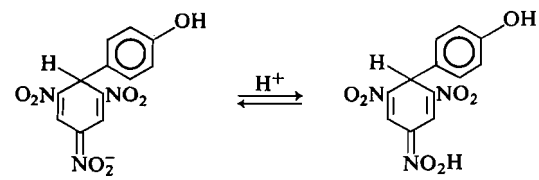
Information has also been obtained on the state(s) of ionization of the TNB–phenoxide adduct. In the first place the question arises whether aromatization of **3***a* leads to the dianionic complex **3** or a monoanionic species **3***h*. One would expect that if reaction of TNB with phenoxide is performed with at least a 2:1 molar ratio of PhOK–TNB, then **3** should be formed directly from **3***a* on proton abstraction by the base. On the other hand, if one uses a 1:1 molar ratio PhOK–TNB, then **3***h* should be obtained. In this case the tautomerization **3***a* → **3***h* would be effected by way of a solvent molecule, in an inter- or intramolecular fashion (12). In practice this series of experiments was generally performed using a PhOK–TNB ratio of 1.4:1 so



3*a* **3** **3***h*

that formation of a mixture of **3** and **3***h* would be expected. However when the conditions of a 1:1 and 2:1 ratio of PhOK–TNB were employed, some minor differences in the signal positions due to **3***h* and **3** could be observed. Thus the H_α and H_β signals of **3***h* (PhOK:TNB 1:1) are found at 8.34 and 5.54 p.p.m. respectively, while those of **3** (PhOK:TNB 2:1) occur at 8.30 and 5.40 p.p.m. The shift in signals corresponding to the change **3***h* → **3** was also seen on addition of KOMe–MeOH to a reaction mixture obtained from a 1:1 ratio PhOK–TNB. In that case one could also observe a shift of the center of the quartet due to the phenoxy ring hydrogens in the complex from 6.84 p.p.m. to 6.43 p.p.m. In solutions containing mixtures of **3***h* and **3** there is presumably rapid proton exchange between these species, accounting for the observation of a single peak. During isolation of the adduct the work-up procedure used involved acidification with a slight excess of sulfuric acid or with acetic acid (see Experimental). Under these conditions one expects to obtain the monoanion **3***h* and indeed the n.m.r. spectral characteristics as well as the elemental analysis of the isolated material corresponded to this species.

The possibility of observing a second protonation equilibrium arises in these systems, namely protonation of a nitro group of the adduct. The protonation of anion **3***h* to yield the nitronic acid derivative **3***h*$_2$ was in fact observed in the



3*h* **3***h*$_2$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

presence of moderately concentrated acid by u.v.-visible spectroscopy. Thus on treatment of a solution of **3***h* in DMSO–MeOH with concentrated sulfuric acid in increasing amounts the absorption maxima at 468 and 570 nm due to **3***h* diminished and eventually disappeared, while a new absorption at 372 nm increased in intensity. The spectrum in acid solution can be ascribed to species $\mathbf{3}h_2$, by analogy with literature data on nitronic acids derived from trinitrobenzene derivatives (16). Thus all three ionization states (3, **3***h*, $\mathbf{3}h_2$) have been realized in this work.

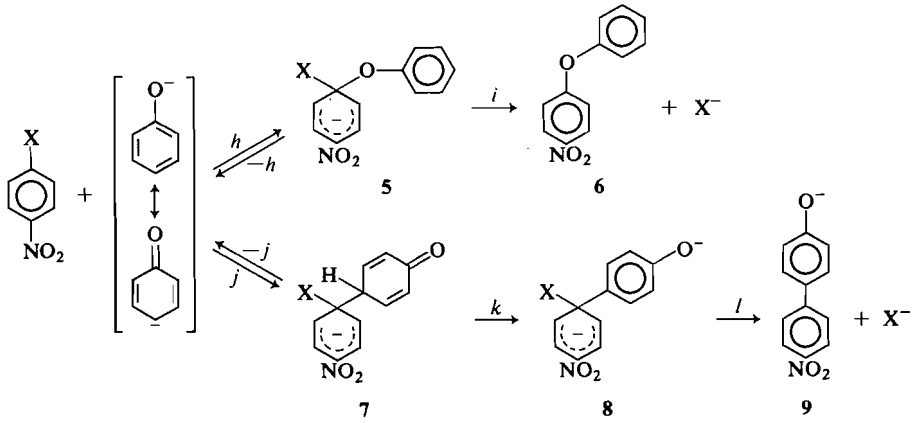
The Ambident Nature of Phenoxide Ion in SNAr Systems. Kinetic and Thermodynamic Control

Formation of complex **3** from TNB and phenoxide ion, rather than of complex **2** (Scheme 1), is accounted for on the basis of the ability of the phenoxide ion to act as an ambident nucleophile (17), coupled with considerations of kinetic and thermodynamic control. Thus whereas **2** would be expected to be the kinetically preferred product, literature data (15) indicate that the equilibrium constant for its formation should be small, several orders of magnitude less than for formation of **1**. This is in line with the much smaller basicity of PhO^- compared with MeO^-. Formation of **3***a* from TNB via path *f* is probably less facile kinetically than formation of **2** via *d*. However, whereas both *d* and *f* are reversible processes, *g*, proton loss from the *para* carbon of the quinoid intermediate **3***a* with concomitant rearomatization, is effectively irreversible. Therefore the overall process in which phenoxide ion acts as a carbon nucleophile leads to the product of thermodynamic control. It should be pointed out, however, that this discussion is not consistent with the findings of Shein and Byval'kevich (9) who report that TNB and phenoxide ion react in DMSO to give adduct **2**.

The ability of phenoxide ion to act as an ambident nucleophile in aliphatic systems is well established (17). This is in contrast with nucleophilic substitution at aromatic carbon (SNAr) where phenoxide appears to act only as an oxygen nucleophile. For example, picryl chloride reacts with phenoxide ion to yield picryl phenyl ether (18), which appears to be a general reaction of nitro-activated aryl halides (19, 20).

The interaction of phenoxide ion with nitro-activated aryl halides and other derivatives can be discussed according to Scheme 2. In this scheme σ-complexes are shown as reaction intermediates in accord with current views of the mechanism of nucleophilic aromatic substitution (19–25). Normally attack by oxygen of PhO^- (route *h*) is kinetically preferred and expulsion of X^- from intermediate **5** leads to the observed product **6**. In juxtaposition, route *j* is apparently disfavored in the typical reaction systems. Nevertheless, this route could in principle compete under certain conditions. This could occur, for example, if X were a poor leaving group so that step *i* would be relatively unfavorable, allowing competition from route *j*. Under such circumstances complex **8** might be observable as well as the final substitution product **9**.

Thus the possibility of phenoxide ion acting as a carbon nucleophile might be realized in certain activated aromatic derivatives. If one could observe such a process in suitably designed sys-



SCHEME 2

tems this would establish the validity of our discussion as well as provide a ready synthesis of diphenyl derivatives by a novel reaction. Investigation of reaction systems of these types is under active consideration.

Experimental

Materials and Methods

Dimethyl sulfoxide was distilled either from barium oxide or from calcium hydride under nitrogen. Methanol was distilled from magnesium metal. Acetonitrile was dried over molecular sieves and distilled under nitrogen. The deuterated solvents were dried over molecular sieves. 1,3,5-Trinitrobenzene (TNB) was recrystallized from ethanol, m.p. 123 °C. Anhydrous potassium phenoxide was prepared by the method of Kornblum and Lurie (26). Methanolic potassium phenoxide was obtained by neutralizing phenol with MeOK–MeOH. Solutions of potassium phenoxide in DMSO were obtained by using the anhydrous PhOK, or from the methanolic solution by addition of DMSO and distilling off the methanol under reduced pressure. Potassium 1-methoxy-2,4,6-trinitrocyclohexadienate, **1**, was prepared as described previously (27). Manipulation of air/moisture sensitive materials was carried out in a dry box under nitrogen.

Nuclear magnetic resonance measurements were carried out on a Varian T60 instrument or on a Bruker 60 MHz HFX-60, the preliminary work (10) being done largely on the former instrument. Visible spectra were recorded on a Unicam SP800 spectrophotometer.

Reaction of TNB with Potassium Phenoxide in DMSO–MeOH (80:20, v/v)

Reaction solutions were prepared by mixing solutions of TNB in DMSO and PhOK in MeOH, such that the final solvent composition was 80:20 v/v DMSO:MeOH and reagent concentrations of the order TNB 0.4 *M*, PhOK 0.4–0.9 *M*. In some experiments excess phenol (up to 0.5 *M*) was present; the signal due to the H_β proton in **3** tended to be partly obscured by the solvent OH absorption and addition of phenol caused a low-field shift of the combined phenol–methanol OH signal, lessening the interference with the H_β signal. Most of the reactions were carried out at 45 °C by immersing the reaction vessel (usually a 10 ml volumetric flask) in a constant temperature bath. Samples for n.m.r. observation were removed at appropriate times and kept cold until analyzed. For visible spectral analysis 0.1 ml aliquots were removed, diluted to 10 ml with 80:20 DMSO–MeOH, and spectra recorded in a 0.1 mm cell. When testing for acid reversibility of complex formation, 0.1 ml of 1 *N* H_2SO_4 was added to the flasks containing the diluted solutions whose visible spectra had previously been recorded, and the spectra taken once more.

For isolation of the TNB–phenoxide complex, reaction was performed as described above but on a larger scale, using 0.042 mol of TNB, 0.085 mol PhOK, and 0.080 mol PhOH in 100 ml of 80:20 DMSO–MeOH (v/v). On completion of reaction, as shown by n.m.r. and u.v.–visible spectroscopy, the reaction mixture was cooled to 10 °C in a 250 ml round bottom flask and 4.25 ml 10 *N* H_2SO_4 slowly added while stirring. The dark red solution was added to 1.5 l chloroform which caused a tarry red material as well as a granular precipitate of K_2SO_4 to separate. The flask was shaken for 2 days during which time the chloroform was decanted several times and replaced with fresh solvent. Three successive extractions resulted in the tarry material becoming crystalline. After the final decantation of chloroform, acetonitrile was added to dissolve the red solid, and the inorganic material was filtered off. The acetonitrile solution was dried ($MgSO_4$), the solvent removed on a rotary evaporator, and the dark crystalline solid dried *in vacuo* (11.7 g). Attempts to crystallize the product were unsuccessful. Experimental analysis results (Schwartzkopf Laboratories): C, 40.55; H, 2.68; N, 11.04; S, 5.02; K, 8.85. The sulfur content is due to solvated DMSO, which is also shown by the n.m.r. spectrum, and corresponds to 0.60 mol of DMSO of solvation. Analysis calculated for $(C_{12}H_8N_3O_7K)\cdot 0.60(C_2H_6SO)$: C, 40.38; H, 3.02; N, 10.67; S, 5.02; K, 9.94. Thus the product is identified as the potassium salt of **3***h*.

Reaction of TNB with Potassium Phenoxide in DMSO

In this portion of the work anhydrous PhOK was usually used as the reagent. In a typical reaction, solutions of TNB and PhOK in DMSO were mixed so as to yield final concentrations of reagents 0.5 *M* and 0.7 *M* respectively. For n.m.r. observation the reaction solution was prepared in a sample tube and followed at the ambient temperature of the spectrophotometer. Monitoring by u.v.–visible absorption was performed by 100 fold dilution and use of 0.1 mm cells as previously.

Isolation of complex in this phase of the work was performed by a modified method. Following completion of the reaction, the DMSO solution was added to a stirred solution of chloroform containing acetic acid in slight excess. The treatment yielded at this stage the σ-complex as a solid material, rather than as the tarry oil obtained in the previous method. After several more extractions with chloroform the solid was dissolved in acetonitrile. Removal of solvent yielded a material in which DMSO of solvation was largely replaced by CH_3CN of solvation. The latter could be replaced by benzene after several treatments with this solvent, and drying *in vacuo* yielded the complex practically free of solvent of crystallization. The isolated TNB–phenoxide complex has absorptions at 468 nm (ε 31 800) and at 572 nm (ε 14 800).

Formation of Side Products

In a number of experiments formation of side products was indicated by the appearance of additional signals in the n.m.r. spectra as the reaction proceeded. Absorptions occurring at 8.10 p.p.m. (d, J = 2 Hz) and at 8.56 p.p.m. (t, J = 2 Hz) may be due to substitution of a nitro group by phenoxy. These absorptions increased in proportion when TNB was present in excess of PhOK (a condition which was avoided in the routine experiments).

Continuing financial support of this research by the National Research Council of Canada is gratefully acknowledged, as is a helpful discussion with Professor N. Kornblum.

Stereodynamic Investigation of Dibenzo-1,5-cyclooctadiene and 5,6,11,12-tetrahydrodibenzo[*b*,*f*][1,4]diazocine Derivatives

FRANÇOISE SAURIOL-LORD AND MAURICE ST-JACQUES

Département de chimie, Université de Montréal, Montréal, Québec H3C 3V1

Received July 14, 1975

FRANÇOISE SAURIOL-LORD and MAURICE ST-JACQUES. Can. J. Chem. **53**, 3768 (1975).

A dynamic n.m.r. study of a deuterated derivative of dibenzo-1,5-cyclooctadiene (**2**-d_4), *N*,*N*′-dimethyl-1,4-diazocine **3**, and *N*,*N*′-diacetyl-1,4-diazocine (**4**) is reported. Two spectral changes of different origin are observed for **2**-d_4, one for **3** and three for **4**. The results reveal the presence of a mixture of chair and twist-boat conformations for **2**-d_4 and **4**, while the single spectral change observed for **3** is interpreted in terms of a single twist-boat form. Interconversion pathways are suggested to explain the characteristic behavior of each compound investigated.

FRANÇOISE SAURIOL-LORD et MAURICE ST-JACQUES. Can. J. Chem. **53**, 3768 (1975).

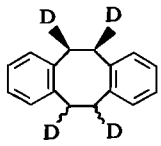
L'étude par r.m.n. dynamique d'un dérivé deutérié du dibenzo cyclooctadiène-1,5 (**2**-d_4), ainsi que de la *N*,*N*′-diméthyl diazocine-1,4 (**3**) et de la *N*,*N*′-diacétyl-1,4 diazocine (**4**) est présentée dans cet article. Deux modifications spectrales d'origine différente ont été observées pour **2**-d_4, un pour **3** et trois pour **4**. Les résultats ont révèlé la présence d'un mélange de conformations chaise et bateau-croisé pour **2**-d_4 et **4**, alors que le seul changement d'allure spectral observé pour le composé **3** est interprété uniquement en terme d'un bateau-croisé. Des chemins d'interconversion conformationnelle sont proposés pour expliquer le comportement dynamique de chaque composé examiné.

[Traduit par le journal]

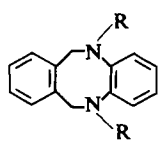
Important aspects of conformational analysis involve the assessment of the nature of the most stable conformation and of the rates of various types of stereomutations characterizing different classes of molecules.

Recently, dynamic nuclear magnetic resonance (d.n.m.r.) spectroscopy (1) has been used to study 1,5-cyclooctadiene (2), dibenzo-1,5-cyclooctadiene (3), *syn*-3,7-dibromo-*cis*,*cis*-1,5-cyclooctadiene (4), as well as derivatives of 5,6,11,12-tetrahydrodibenzo[*b*,*f*][1,4]diazocine (5–8) and has revealed the complexity of the stereodynamic properties of this fundamental ring system.

Specifically, the conformational properties of 1,5-cyclooctadiene (**1**) are significantly different from that of dibenzo-1,5-cyclooctadiene (**2**). The stable conformation of **1** has been reported to be a twist boat which can undergo two dynamic processes (2) while **2** exists as a mixture of chair and boat conformations of varying proportion depending on the nature of the solvent (3). For this latter molecule, owing to spectral complexities and solubility problems, only one of the possible dynamic processes has been identified for the boat form. In order to define more precisely the stereodynamic properties of **2**, the deuterated derivative **2**-d_4 was prepared and studied by the d.n.m.r. method.



2-d_4



3 R = CH_3

4 R = $COCH_3$

Several investigations (5–8) have shown that heteroatoms in the ring modify significantly its conformational properties and an examination of the literature has led us to anticipate a markedly different behavior for *N*,*N*′-dimethyldiazocine (**3**) and *N*,*N*′-diacetyldiazocine (**4**) because no spectral change was reported for compounds analogous to **3** (*e.g.* R = $CH_2C_6H_5$) whereas two spectral changes were observed for **4** but none was attributed to hindered amide bond rotation. Because of the basic importance of **3** and the apparently incomplete study of **4** it appeared that a detailed comparative study of **3** and **4** was necessary.

We now wish to report the results of our study of **2**-d_4, our observation of a spectral change for **3** and another spectral change for **4** which apparently has escaped earlier detection. These observations and their interpretation contribute significantly to our understanding of the conformational properties of such cyclic systems.

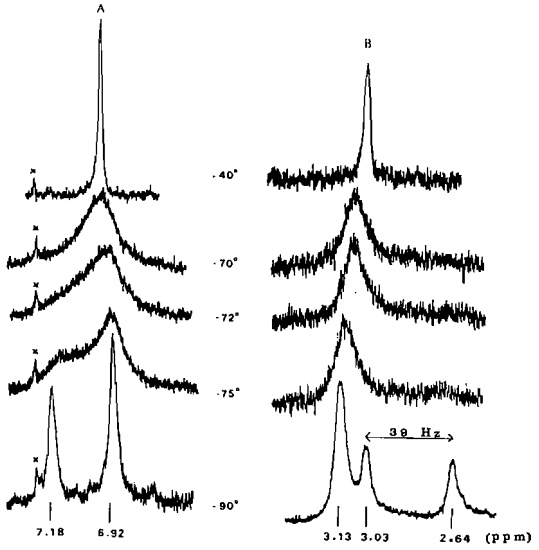

FIG. 1. Proton magnetic resonance spectra (100 MHz) of **2**-d_4 in $CDCl_3$–CS_2 (2:3) at several temperatures. (A) Aromatic region (* = $CHCl_3$ trace in the solvent). (B) Aliphatic (CHD) region.

Results

The 100 MHz deuterium decoupled p.m.r. spectrum of **2**-d_4 was recorded at several temperatures in two representative solvent systems: a mixture of $CDCl_3$–CS_2 (2:3 by volume) and a mixture of CD_2Cl_2–C_3H_6 (2:1). Firstly, Fig. 1 shows several spectra of **2**-d_4 in $CDCl_3$–CS_2. At temperatures above −40 °C both the aromatic (A) and the aliphatic (B) signals appear as singlets (δ 6.98 and δ 3.01 respectively) which broaden and change below −70 °C such that at −90 °C the aromatic region contains two peaks (δ 6.92 and δ 7.18) in the proportion 60:40, while the CHD region contains three peaks (δ 2.64, δ 3.03, and δ 3.13). Integration is less accurate in this region because of the overlap of the signals at δ 3.03 and δ 3.13.

Assuming an exchange between two equally populated sites and using a coalescence temperature (T_c) of −72 °C, a free energy of activation $\Delta G^{\ddagger} = 10.0 \pm 0.5$ kcal/mol is calculated from the change in the aromatic signal. The data are summarized with other information in Table 1 where the more intense lines are assigned to a conformation labelled B and the lesser intense lines are assigned to a conformation C.

Figure 2 shows the behavior of the CHD signal of **2**-d_4 dissolved in CD_2Cl_2–C_3H_6 (2:1) at several temperatures. The spectrum at −110 °C is similar to that observed in Fig. 1B with the exception that the signals of C are less intense. Below this temperature the tall signal broadens and splits up such that four lines are observed at −136 °C (δ 2.64 and 3.07; δ 2.90 and 3.40). Limited solubility made it difficult to obtain good spectra at lower temperatures. The value of $\Delta G^{\ddagger} = 7.8 \pm 0.3$ kcal/mol at −115 °C (T_c) is calculated from the splitting of the tall line. The aromatic region is the same as that published in a preliminary communication for **2** and the results are reported in Table 1.

Figure 3 illustrates the spectral change observed for the methylene protons of **3** in $CHFCl_2$ at low temperatures. The high temperature singlet (δ 4.23) broadens and below −95 °C (T_c) splits up into an AB quartet characterized by $\Delta\nu = 1.27$ p.p.m. and $J = -16.2$ Hz. The *N*-methyl signal (δ 2.85) remained unchanged down to −150 °C, the lowest temperature reached.

Figure 4 shows the spectral change observed for the methyl signal of the *N*-acetyl groups of **4** dissolved in pyridine. At +13 °C three signals are clearly visible, the most intense (δ 1.84) accounting for about 75% of the total intensity and the two others (δ 2.03 and δ 2.20) accounting equally for the rest. At higher temperatures these three signals merge together to give a

narrow singlet at 100 °C whereas at lower temperatures the high and low field lines split into doublets with components of unequal intensity as shown for the spectrum at −43 °C. These two spectral changes are characterized by $\Delta G^{\ddagger}$ values of 16.6 ± 0.5 and 13.0 ± 0.5 kcal/mol.

The temperature effect on the methylene proton signal of **4** was observed to be similar to that published (5, 6). The spectrum consists of a singlet at +110 °C, appears as an AB quartet at +25 °C, and consists of two AB quartets of unequal intensity at −50 °C. The $\Delta G^{\ddagger}$ values characterizing these two spectral changes are 16.9 and 12.9 kcal/mol (6). Careful recording of

the spectrum at +25 °C has however revealed the presence of additional very small peaks in this region which could be ascribed to a minor conformation.

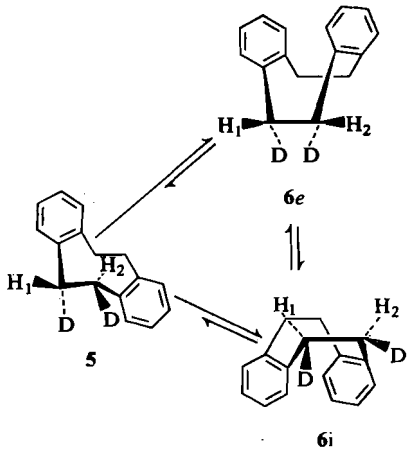
Discussion

Dibenzo-1,5-cyclooctadiene

Compound **2**-d_4 actually exists as a mixture of *syn* and *anti* isomers and for all practical purposes both sides of the molecule can be considered independent (9) as far as n.m.r. is concerned. The p.m.r. spectrum of the CHD region (Fig. 1B) can easily be interpreted in terms of a mixture of chair (C) and a member of the boat family whereby the doublet is assigned to the axial and equatorial protons of C and the intense line is assigned to the boat form whose proton environments are still averaged out by rapid inversion. Since 1,5-cyclooctadiene exists in a twist-boat (TB) form (2), it is very likely that **2**-d_4 should also exist as a TB (10). The spectrum of **2**-d_4 at −136 °C (Fig. 2) contains two intense lines characteristic of this TB form in addition to two less intense signals belonging to C. It is clear that the inversion process has been slowed down on the n.m.r. time scale but the observation of only two intense signals is compatible with either a symmetrical boat (B) or two rapidly equilibrating TB forms with average symmetry equivalent to B. In fact the spectrum of **2**-d_4 in a TB conformation should exhibit two AB patterns (eight lines) or four lines if the coupling constants were not resolved, unless the chemical shift differences for protons on the nonidentical carbons of TB are too small to be resolved. The spectrum of **2**-d_4 is therefore compatible with the existence of a major TB conformation and a minor C conformation in agreement with earlier suggestions for **2** (3, 6).

Consequently the spectral changes observed for **2**-d_4 identify and characterize the following processes: (*1*) chair-to-boat interconversion with $\Delta G^{\ddagger}$ = 10.0 kcal/mol and (*2*) boat inversion with $\Delta G^{\ddagger}$ = 7.8 kcal/mol as illustrated with structures **5**, **6***e*, and **6***i*.

The chair form **5** possesses two nonequivalent protons (namely the equatorial H_1 and the axial H_2 where the numbers are labels) and theoretically its low temperature spectrum should consist of an AB quartet. Instead a doublet is observed, suggesting that the coupling constant between H_1 and H_2 is not resolved at −90 °C (Fig. 1B) or −136 °C (Fig. 2) owing to line broadening through long range coupling with the aromatic



protons and a dihedral angle in the range 110 ± 10° as suggested from Dreiding models.

The averaged TB conformations represented by **6***e* and **6***i* then each account for a tall line in the spectrum of **2**-d_4 at −136 °C (Fig. 2) because H_1 and H_2 are both at equivalent exterior positions in **6***e* and both at equivalent interior positions in **6***i*.

An increase in temperature from −136 °C increases the rate of boat inversion (**6***e* ⇌ **6***i*) which exchanges exterior and interior proton environments and consequently produces a singlet above −115 °C. At still higher temperatures the chair-to-boat interconversion (**5** ⇌ **6***e* and **5** ⇌ **6***i*) becomes rapid on the p.m.r. time scale and all the aliphatic signals coalesce. Only this last process produces a change in the aromatic signal as shown in Fig. 1A.

Figure 5 illustrates possible pathways for the chair-to-boat interconversion whereby the E-conformations which contain six coplanar carbon atoms are of high energy (10). They can be reached from either B or C by a 'wagging' of a benzo group. Such a conformational modification interestingly requires an energy similar to that required for the inversion of benzocycloheptene (11) which has been shown to proceed via a benzo wag involving a $\Delta G^{\ddagger}$ = 10.7 kcal/mol. Furthermore the difference between $\Delta G^{\ddagger}$ for **1** and **2** ($\Delta\Delta G^{\ddagger}$ = 5.1 kcal/mol) is very similar to the $\Delta\Delta G^{\ddagger}$ = 5.7 kcal/mol observed for benzocycloheptene and cycloheptene (11).

Figure 6 illustrates the possible pathways for boat inversion which is shown to occur when the molecule passes through skew (S) forms. A possible transition state for this process could consist of a conformation intermediate between

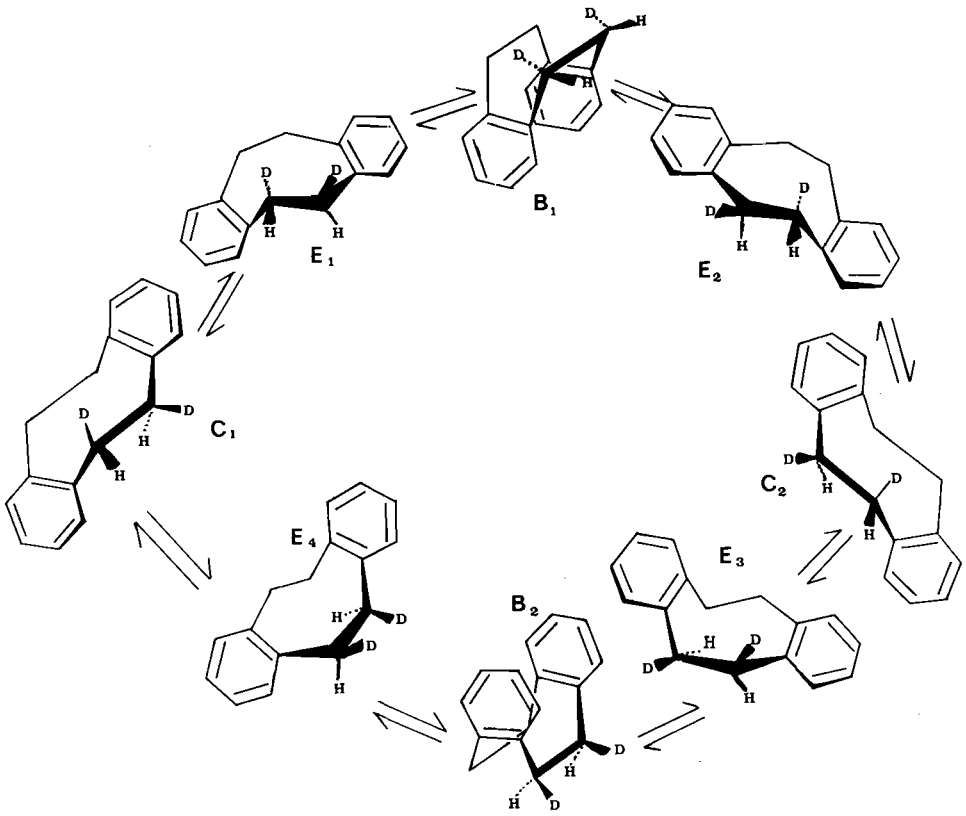


FIG. 5. Pathways for the boat-to-chair interconversion of **2**-d_4.

TB and S possessing two groups of five coplanar carbon atoms and called a folded boat (FB) by other workers (6), but recent calculations (10) suggest that S is of higher energy than FB. Consequently boat inversion through S has a lower $\Delta G^{\ddagger}$ (7.8 kcal/mol) than that characterizing a 'wagging' to E ($\Delta G^{\ddagger}$ = 10.0 kcal/mol). Furthermore it is clear that the partial averaging of two twist-boat forms (*e.g.* $TB_1 \rightleftharpoons B_1 \rightleftharpoons TB_4$) results in the average symmetry of B_1 and does not lead to an exchange of interior and exterior aliphatic protons in the boat family. Such an exchange of environment can only occur when the molecule goes through the S forms.

Finally, it is interesting to contrast the above conclusion that **2** exists as a mixture of chair and boat forms (the latter predominating) with the observation that this compound in the crystalline state exists in a centro-symmetrical form, presumably the chair (12).

N,N'-Dimethyldiazocine, **3**

The $\Delta G^{\ddagger}$ value of 8.2 kcal/mol calculated from the only spectral change observed for **3** provides a clue as to the nature of its stable conformation in solution and its inversion pathway. Results from studies of derivatives of cyclohexane (Ref. 1, p. 584) suggest that the replacement in **2**-d_4 of two CHD groups in a 1,4-relationship by two N—CH_3 groups might increase only slightly the activation energies for boat inversion and chair-to-boat interconversion. Since the value of 8.2 kcal/mol is rather close to that of 7.8 kcal/mol determined for boat inversion in **2**-d_4, it seems highly probable that the spectral change observed for **3** is due to a boat inversion and that its stable conformation is undoubtedly also a TB form. A mixture of B and C is ruled out because it is incompatible with the spectrum at −150 °C. A stable chair conformation with chair inversion responsible for the spectral change appears very unlikely since it would involve a $C \rightleftharpoons B$ step which is expected to have a $\Delta G^{\ddagger}$ near or slightly above 10.0 kcal/mol.

Thus only the TB form has been detected by n.m.r. for **3** and its inversion pathway is analo-

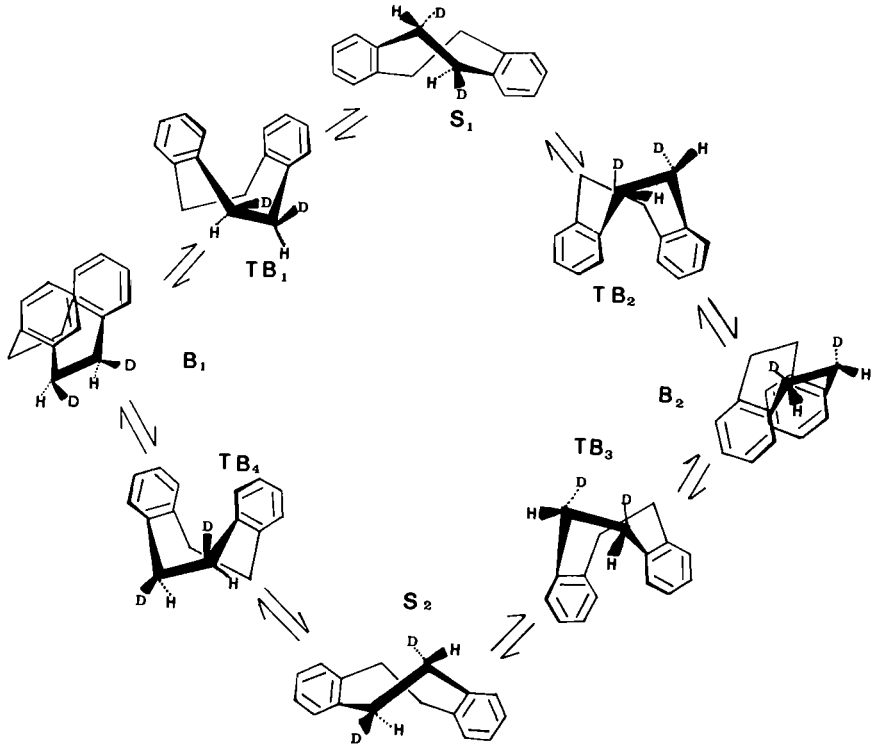

FIG. 6 Pathways for the boat inversion of **2**-d_4.

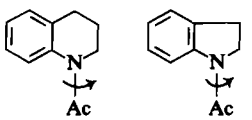
gous to that described in Fig. 6 keeping in mind that two 1,4-CHD are replaced by two N—CH_3 groups. As for **2**-d_4 the partial averaging TB ⇌ B ⇌ TB is still rapid at −150 °C for **3**. Furthermore it is logical to suggest that the failure to observe a spectral change for compounds analogous to **3** (*e.g.* R = alkyl) (6) can be interpreted in terms of a rapid boat inversion at the relatively high temperatures investigated.

N,N'-Diacetyldiazocine, 4

Our study of the acetyl methyl region of the spectrum of **4** has revealed two spectral changes: one near +50 °C ($\Delta G^{\ddagger}$ = 16.6 kcal/mol) which was apparently not detected by other workers (5, 6) and another near −11 °C ($\Delta G^{\ddagger}$ = 13.0 kcal/mol) which has previously been reported (5, 6). These activation energies are equal within experimental error to the values of 16.9 and 12.9 kcal/mol previously determined (6) from the two spectral changes observed for the methylene proton signal although the origin of the spectral changes with similar $\Delta G^{\ddagger}$ need not necessarily be the same.

Interpretation of the spectral behavior of the methylene protons has shown that at +13 °C the ring conformation is an average of chair and boat forms (6). The spectrum at +13 °C in Fig. 4 which consists of three lines of unequal intensity is also compatible with an averaged ring conformation for which the methyl lines reveal the existence of more than one rotational conformer for which methyl groups in different environments show characteristic chemical shifts which average out at higher temperature when rotation of the amide bond becomes rapid on the p.m.r. time scale.

Amide rotation barriers for the typical molecules **7** and **8** are 16.7 and 16.6 kcal/mol respectively (13). These values illustrate clearly that the value of 16.6 kcal/mol determined for **4** is of the correct magnitude.



7 **8**

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

A study (14) of the p.m.r. spectrum of *N*-methylacetanilide has shown that the *exo* conformer **9** is more stable than the *endo* conformer **10** and furthermore that the acetyl methyl absorbs at higher field in the *exo* form. Consequently a singlet, a doublet, and a singlet are expected for the methyl groups in structures **11**, **12**, and **13** respectively. Since both methyl groups are *exo* in **11**, the methyl signal is expected to appear at higher field than that of the *endo* methyls of **13**.

Accordingly the intense methyl line (δ 1.83) in the spectrum of **4** at +13 °C belongs to **11** while the less intense doublet (δ 2.03 and δ 2.20) must be associated with **12** for which methyl *a* is expected to be at higher field than *b*. Conformation **13** is apparently present in a negligible amount. Table 2 shows the relative proportions of *exo* and *endo* conformers for model amides. It is seen that structural factors have a very pronounced effect on the observed populations and the result obtained for **4** is indeed not abnormal.

It is important to explain at this point that only the methylene signals of the *exo–exo* chair and boat forms are sufficiently intense to be detected clearly for d.n.m.r. analysis (6).

Thus three dynamic processes have been identified for 4: (*1*) boat-to-chair interconversion with $\Delta G^{\ddagger}$ = 12.9 kcal/mol (6), (*2*) boat inversion with $\Delta G^{\ddagger}$ = 16.9 kcal/mol (6), and (*3*) hindered amide rotation with $\Delta G^{\ddagger}$ = 16.6 kcal/mol. The equality within experimental errors of the two last barriers suggests that boat inversion and amide rotation proceed through a common transition state. Accordingly detailed conformational transformation pathways are analyzed next for each process.

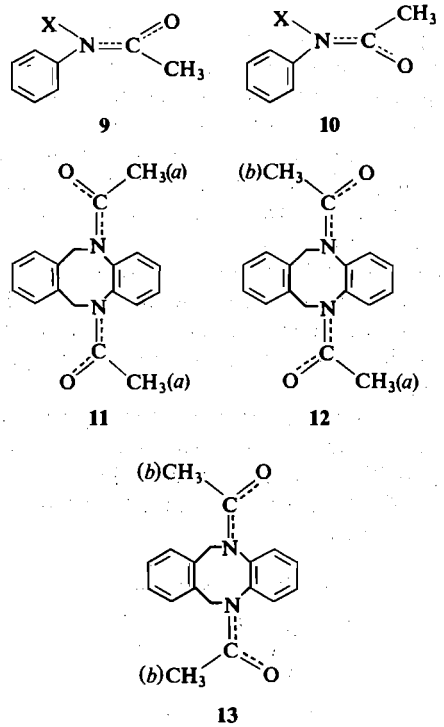


TABLE 2. Relative population of *exo* and *endo* conformers of a few amides

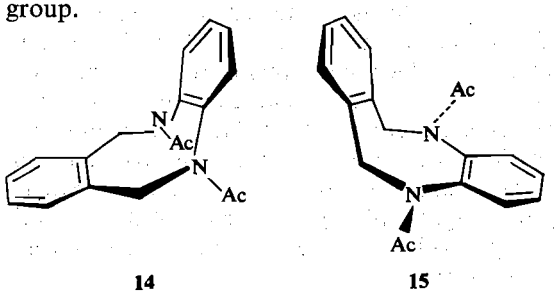
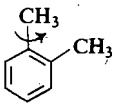
Compound	Conformation		Reference
	Exo (%)	*Endo* (%)	
	99.5	0.5	15
	11	89	15
	96	4	15
	**11**, 75% (2 *exo*) **12**, 25% (1 *endo* and 1 *exo*) **13**, 0% (2 *endo*)		This work

Firstly, let us consider the B ⇌ C transformation which effectively averages the two unequal methylene AB systems at low temperatures into an average AB near 25 °C. This process can be depicted in terms of Fig. 5 where two 1,4-CHD are replaced by two N—Ac groups. Accordingly one of the E forms becomes **14** which can be reached from B or C by 'wagging' of the carbon substituted benzo group while **15** requires the 'wagging' of the nitrogen substituted benzo group.

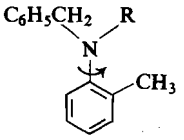


Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

A comparison of the barrier to Ar–C rotation in *o*-xylene (**16**) (1.5–2.0 kcal/mol) (16) and the Ar–N rotation in **17** (19.3 kcal/mol) (17) suggests that **14** should be of lower energy than **15** and hence the B $\rightleftharpoons$ C transformation should involve preferentially a wagging of the carbon end of the molecule (called *C*-wag compared to *N*-wag for the other end of the molecule). When *C*-wag is rapid on the n.m.r. time scale, the methylene protons are not completely averaged out in accord with the AB observed at +25 °C. Only when B inversion (or *N*-wag) becomes rapid will the methylene proton signal average to a singlet.



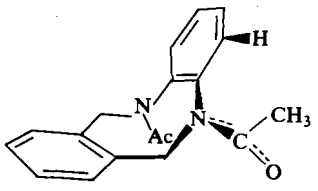
16



17; R = CH_3CO—
18; R = C_6H_5CO—
19; R = *p*-CH_3—C_6H_4—SO_2—
20; R = CH_3—

Comparison of the $\Delta G^{\ddagger}$ barrier of 12.9 kcal/mol of **4** with that of 10.0 kcal/mol for **2** suggests that structural factors other than Ar–C rotation are also responsible for the difference.

Boat inversion can easily be visualized with the aid of Fig. 6 after replacement of two CHD groups by N—Ac groups. The transition state for this process is either an FB form (6) which contains two sets of five coplanar ring atoms such as in **21** or the S form as calculated (10) for **2**. The N—Ac groups are in different positions for both conformations.



21

Since S and FB are close on the pseudorotation cycle of the boat family (10), it is not obvious which one will be more energetic for **4**. It is however significant that both forms must be overcome during boat inversion. The steric interaction between the methyl group and the *ortho* proton present in FB and shown in **21** may indeed make the energy of FB very close to that of S. This steric interaction may be the determining factor inducing amide rotation and consequently explain why amide rotation and boat inversion have essentially identical energy barriers.

Torsional interactions were found (10) to be important in determining the boat inversion barrier of **2**, and consequently the appreciable rotation about the Ar—N bonds required to go through conformations FB and S suggests that boat inversion should also be influenced by factors which determine the activation energy for this type of rotation. For example, the free energies of activation for boat inversion of **4** (16.9 kcal/mol), *N*,*N*′-dibenzoyl-1,4-diazocine (10.1 kcal/mol) (6), *N*,*N*′-di-*p*-tolylsulfonyl-1,4-diazocine (10.1 kcal/mol) (6), and **3** (8.2 kcal/mol) follow a trend parallel to the rotation barriers of analogous *o*-toluidine derivatives (17, 18): **17** (19.3 kcal/mol), **18** (18.1 kcal/mol), **19** (15.3 kcal/mol), and **20** (6.2 kcal/mol). Thus it is reasonable to conclude that Ar–N rotation accounts for a large part of $\Delta G^{\ddagger}$ observed for the boat inversion of **4**.

Our observations for **2**-d_4, **3**, and **4** thus prove to be essential to a complete understanding of the complex stereodynamic problem on hand. In fact, the comparable $\Delta G^{\ddagger}$ values for boat inversion in **2**-d_4 and **3** suggest that the transannular interactions invoked earlier (6) should not dominate the explanation of the trend reported earlier for derivatives of 1,4-diazocine (6) and that arguments involving Ar–N rotation presented above are more satisfying. Consequently the observation for **4** that boat inversion has a higher $\Delta G^{\ddagger}$ than the B $\rightleftharpoons$ C process (contrary to the order found for the parent compound **2**-d_4) can be explained by invoking a greater energy demand for the appreciable Ar–N rotation required to reach the transition state of boat inversion than for the *C*-wag involved in the B $\rightleftharpoons$ C process which requires little Ar–N rotation.

Experimental

The v.p.c. analyses and separations were carried out on a Varian-aerograph A90-P3 instrument using ¼ in. SE-30 columns and helium as carrier gas. Mass spectral analyses were performed on an Hitachi–Perkin–Elmer model RMU-6D instrument operating at 70 and 10 eV.

Routine analytical p.m.r. spectra were recorded on a JEOL C-60H spectrometer operating at 60 MHz in the external lock mode. The low temperature p.m.r. spectra were obtained at 100 MHz using a JEOL JNM-4H-100 spectrometer. Solutions containing a small quantity of

TMS were degassed and sealed. Deuterium decoupling, when required, was effected by means of the JEOL Hetero Spin Decoupler model JNM-SD-HC.

Temperatures were monitored by means of a JEOL temperature control unit model JES-VT-3 and determined accurately with a calibrated thermocouple placed inside a solvent-containing dummy n.m.r. tube.

Dibenzo-1,5-cyclooctadiene-d_4, 2-d_4

This compound was prepared by catalytic reduction of dibenzocyclooctatetraene (0.051 g) with deuterium gas and 0.14 g of palladium-on-carbon (5%) in 10 ml of ethyl acetate using an apparatus previously described (9). The crude product which showed no olefinic proton signal in the p.m.r. spectrum was purified by v.p.c. and identified by its p.m.r. spectrum in $CDCl_3$ (singlet at δ 7.0 (8H) and singlet at 3.0 p.p.m. (4H)) and had a retention time in analytical v.p.c. identical to the hydrogenated product.

The isotopic composition obtained from a mass spectrum at 10 eV is: $d_5 = 9.5\%$, $d_4 = 74.8\%$, $d_3 = 13.8\%$ and $d_2 = 1.9\%$.

The low temperature spectra were recorded for concentrations of 16–20 mg ml^{-1} of solution.

N,N'-Dimethyldiazocine, 3, and N,N'-Diacetyldiazocine, 4

These known compounds were prepared according to published procedures (19–21) and characterized by their melting points and p.m.r. spectra which agreed with those published.

The low temperature spectra were taken for an 8% solution of **3** in $CHFCl_2$ and a 10% solution of **4** in pyridine.

We wish to acknowledge the assistance of Mr. Robert Mayer with the recording of the p.m.r. spectra at low temperature and we express our gratitude to the National Research Council of Canada for financial assistance.

SCF MO Study of Benzo[*d*]aceheptylene

ARCHANA DASGUPTA AND NANDA K. DASGUPTA[1]

Department of Chemistry, The University of Alberta, Edmonton, Alberta T6G 2E1

Received March 24, 1975

ARCHANA DASGUPTA and NANDA K. DASGUPTA. Can. J. Chem. **53**, 3777 (1975).

The molecule benzo[*d*]aceheptylene has been studied using the method of Dewar and Harget, and Yamaguchi *et al.* Heats of atomization, bond energies, reactivity, bond length, and $\pi^* \leftarrow \pi$ transitions are reported and aromaticity of the molecule is discussed.

ARCHANA DASGUPTA et NANDA K. DASGUPTA. Can. J. Chem. **53**, 3777 (1975).

On a étudié la molécule benzo[*d*]aceheptylène à l'aide de la méthode de Dewar et d'Harget et de Yamaguchi *et al.* On rapporte les chaleurs d'atomisation, les énergies de liaison, la réactivité, les longueurs de liaison et les transitions $\pi^* \leftarrow \pi$ et on discute de l'aromaticité de la molécule.

[Traduit par le journal]

Introduction

Recently 8,5,10-trimethyl benzo[*d*]aceheptylene was isolated along with the synthesis of its isomer 2,4,11-trimethyl azuleno[8,8*a*,1,2-*def*]heptalene (1). The properties of the former compound have not been reported (2) but its structure (3) has been determined by X-ray analysis and found to have small but significant deviation from planar structure. Since the parent hydrocarbon, benzo[*d*]aceheptylene contains five-, six-, and seven-membered rings fused together, it would be interesting to predict the properties of the molecule (Fig. 1) using π-electron approximation in the context of the 'β-variable' method. Both the molecules, benzo[*d*]aceheptylene (molecule **1**) and azuleno[*def*]heptalene (molecule **2**), are iso-π-electronic containing 18π electrons. Since they obey Hückel's $4n + 2$ rule they might be aromatic. But it was observed that the molecule azuleno[*def*]heptalene (4) is not aromatic. Hence it would also be interesting to see whether the molecule benzo[*d*]aceheptylene behaves similarly as molecule **2** so far as aromaticity is concerned. Moreover the Pariser–Parr–Pople (PPP) theory was developed for the study of planar conjugated systems. But the molecule **1** has small deviation from planarity. Hence, how far it is justified to apply the PPP theory on such a molecule is questionable. However, we studied molecule **1** using a planar model with 1.4 Å as bond lengths to see how the predicted results are in agreement with the experimental ones. The difficulty is that only a few of the experimental results are available in the literature.

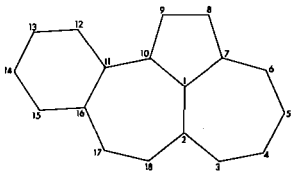

FIG. 1. Structure of benzo[*d*]aceheptylene.

Method and Parameters

The simple Hückel calculations were done. The SCF method used here is well known and has been described by Dewar and Harget (5) and Yamaguchi *et al.* (6). In a recent paper (7) we have applied this 'β-variable' technique proposed by Dewar and Harget (5) (designated as SCF(*a*)) and Yamaguchi *et al.* (6) (designated as SCF(*b*)) successfully on some nonbenzenoid hydrocarbons in predicting their properties. Spectral transitions have also been predicted using configuration interactions. The final vectors and integrals obtained from the SCF(*b*) method were used in the calculation of CI.

The pertinent integrals are calculated as follows:

(*i*) The one center, two electron repulsion integrals γ_{ss} (11.134 eV) were estimated from the relation

$$\gamma_{ss} = I_s - A_s$$

where I_s and A_s are the sp^2 valence state ionization energy (11.16 eV) (8) and electron affinity, respectively, of the carbon atom.

(*ii*) For the Dewar and Harget method, two center, two electron repulsion integrals were estimated using Ohno's formula (9) and for the other method we used Mataga–Nishimoto formula (10). In both SCF(*a*) and SCF(*b*) methods,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

the γ_{st} for non-neighboring centers were calculated from the initial geometry of the molecule and they are not varied during interaction. For bonded atoms, γ_{st} and the resonance integrals β_{st} were calculated after each iteration on the basis of bond length – bond order relations. For SCF(*a*) method the relations are

$$[1] \qquad r_{st}\,(\text{Å}) = 1.512 - 0.174\,p_{st}$$

and

$$[2] \qquad \beta_{st} = -6.927\,S_{st}$$

where p_{st} is the π-bond order and S_{st} is the overlap integral between two π_{2p} orbitals with orbital exponent 1.59.

For the SCF(*b*) method the relations are

$$[3] \qquad r_{st}\,(\text{Å}) = 1.520 - 0.186\,p_{st}$$

and

$$[4] \qquad \beta_{st} = \beta_0 \exp\,[a(r_0 - r_{st})]$$

where r_0 is equal to 1.397 (Å), a is equal to 1.7 Å^{-1}, and β_0 has been taken to be equal to −2.15 eV (7). In both SCF methods β_{st} for non-bonded atoms were taken to be equal to zero.

In the HMO method bond length has been calculated using [3].

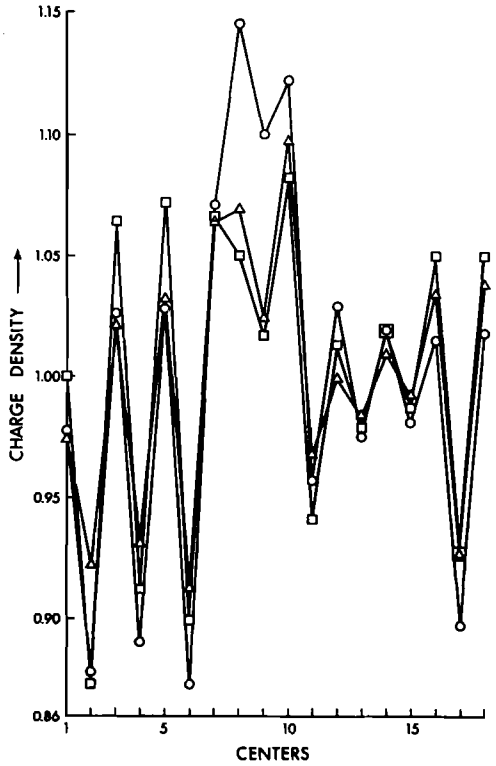

FIG. 2. Variation of charge density; Hückel, ○; SCF(*a*), □; SCF(*b*), △.

Results and Discussion

(a) Reactivity

Figure 2 represents the variation of charge densities. It is clear from the figure that the SCF(*b*) method has evened out the charge densities in the different centers. The wide variation in the π-dipole moment in the HMO (5.39 D), SCF (*a*) (1.65 D), and SCF (*b*) (2.31 D) methods can be expected from the calculated charge densities. In this type of compound HMO method predicts π-dipole moment too high compared to the SCF methods. This is also seen in this case. The large π-dipole moment predicts that there might be charge separation in the molecule rendering it reactive. The π-electron density of the five-membered ring is increased at the cost of seven-membered rings only as in azulene with a tendency to form a local sextet in all the five- and seven-membered rings and it is clear from Fig. 2 that the benzene ring retains its sextet.

According to HMO method the highest charge density is at C_8 suggesting that the electrophilic attack will be at this position. This is also in agreement with SCF(*b*) method though C_8 center has the second highest charge density. The highest charge density calculated by the SCF(*b*) method is at C_{10} but the position is not suitable for electrophilic attack. But SCF(*a*) method suggests that the center C_5 is the most favorable position for electrophilic attack as the calculated charge density is the second highest at this center, the highest being at C_{10}. The lowest charge density calculated by the HMO and SCF(*b*) method is at C_6 indicating that the nucleophilic attack takes place at this center. Although the lowest charge density calculated by the SCF(*a*) method is at C_2, the center is unfavorable for this reaction and the next favorable position is C_6. Thus it is seen that so far as prediction of position of nucleophilic attack the three methods agree whereas the SCF(*a*) method disagrees with the other two methods as regards the position of electrophilic attack.

All the three methods agree that the 17–18 bond of this molecule is the most suitable for dienophilic activity because it has the highest

*Private communication with Professor K. Hafner.

bond order (Hückel 0.777, SCF(*a*) 0.891, and SCF(*b*) 0.861).

(b) Bond Lengths

Bond lengths have been calculated according to the bond order – bond length relations shown earlier. Figure 3 shows the comparison between the bond lengths calculated by the three methods and experimental value. As expected with similar compounds the agreement of any set of theoretical bond lengths with the experimental is somewhat erratic. As in azulene, the bond common to the five- and seven-membered rings has a single bond character.

An interesting feature is that all bonds in the six-membered ring except C_{11}–C_{16} predicted by the three methods are equal and have a value lying between 1.39 and 1.41 Å which is the bond length of an aromatic hydrocarbon. Even the bond C_{11}–C_{16} has the value 1.404, 1.410, and 1.420 Å calculated by the SCF(*a*), SCF(*b*), and HMO methods, respectively. It seems that the π electrons are delocalized in this region. A similar situation is also observed in the periphery of the five-membered ring. In the other part of the molecule π-electrons are localized. Thus in the peripheries of the molecule it is seen that there are two regions, one aromatic and the other polyolefinic in nature.

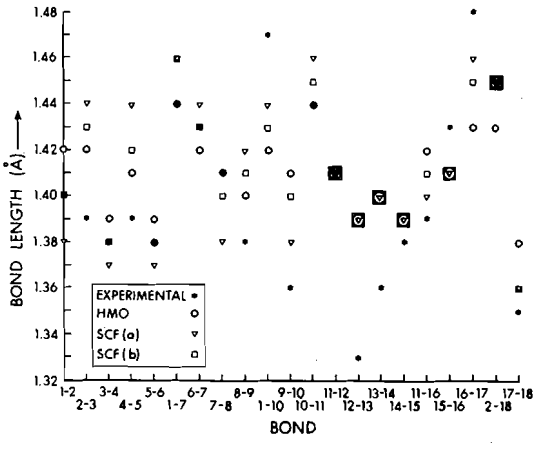

FIG. 3. Comparison of bond lengths.

(c) Spectra, Ionization Energy and Electron Affinity

The highest occupied orbital energy and lowest unoccupied orbital energy are respectively −8.12 and −3.15 eV. The ionization potential calculated by the formula of Kunii and Kuroda (11) is 7.06 eV. Table 1 contains the calculated $\pi^* \leftarrow \pi$ singlet–singlet transitions along with the oscillator strengths and experimental values. We attempted point-to-point correlation between the observed spectra and theoretical transitions. It is seen from Table 1 and Fig. 4 that the agreement between the theoretical results and the experimental value is good, specially very good with CI results.

(d) Aromaticity

It is well known that for the same number of π-electrons and the same number of rings delocalization energy per π-electron (DE/e) decreases as the number of benzene rings are replaced by five- and seven-membered rings. Thus the DE/e decreases in the order of chrysene (0.400) > benzo[*d*]aceheptylene (0.374) > azuleno[*def*]heptalene (0.356). However, DE/e is not useful in the prediction of aromaticity because many molecules which are not aromatic such as pentalene or heptalene have reasonably

high DE/e. Hence in order to predict aromaticity of the molecule we have calculated the resonance energy and resonance energy per C—C bond (E_R/C—C) using the method of Dewar and Harget (5) and resonance energy per π-electron (E_R/e) by the method of Hess and Schaad (12). Table 2 contains these results along with the resonance energy per C—C bond and resonance energy per π electron for some similar molecules. The heat of atomization, π- and σ-bond energies calculated by the method of Dewar and Harget (5) are respectively 156.479, 25.229, and 78.000 eV. Dewar and Harget have shown that calculated heat of atomization by this method is in good agreement with the experimental value for many conjugated systems. Semibenzenoid (4) nature of the molecule is exhibited by its E_R/C—C value which falls in between the benzenoid (0.111 to 0.163) and nonbenzenoid (0.032 to 0.048) (13) systems. If the E_R/C—C of the molecule is compared with that of other semibenzenoid compounds (13) it would be clear that E_R/C—C of the molecule is less than acenaphthylene (0.105), pleiadiene (0.091), acepleiadylene (0.080), cyclohept[*be*]acenaphthylene (0.081), and naphth[*cde*]azulene (0.082) which are aromatic. However, the E_R/C—C for this molecule is comparable to that of benzopleiadiene (0.075) and dipleiadadiene (0.069), both of which have not yet been synthesized. The same conclusion can be drawn by comparing the value of E_R/e calculated by Hess and Schaad's method for this molecule with that of other similar molecules (Table 2). Hence we can conclude that the molecule is not aromatic like its isomer azuleno[*def*]heptalene.

The authors take the opportunity to express their gratitude to Professor F. W. Birss for many stimulating discussions, helpful comments, and financial support. They are also thankful to the Computing Services, University of Alberta, for computational facilities. They are also thankful to Professor K. Hafner for supplying the spectral data.

Further Synthetic Applications of Functionalized 1,3-Dipoles

J. WILLIAM LOWN AND B. ERIK LANDBERG
Department of Chemistry, University of Alberta, Edmonton, Alberta T6G 2G2

Received July 8, 1975

J. WILLIAM LOWN and B. ERIK LANDBERG. Can. J. Chem. **53**, 3782 (1975).

Reactions of nitrile imines, azomethine imines, and ethyl diazoacetate (as representatives of functionalized 1,3-dipoles) with reactive olefins lead to a series of novel fused heterocycles after suitable ring closure. The influence of the nature of the heterocyclic leaving group and the substituents in the phenacyl residue in a group of phenacylimidazolium salts on the course of their reaction to produce 1,2-dihydrofurans and perhydropyrazolopyrroles is investigated.

J. WILLIAM LOWN et B. ERIK LANDBERG. Can. J. Chem. **53**, 3782 (1975).

Les réactions de nitrile-imines, azométhine-imines et diazoacétate d'éthyle (représentant des dipoles-1,3 fonctionnalisés) avec des alcènes réactifs conduisent, après une cyclisation appropriée, à une série de nouveaux hétérocycles fusionnés. On a étudié l'influence de la nature de l'hétérocycle nucléofuge et des substituants du résidu phénacyle dans le groupe des sels de phénacylimidazolium sur l'évolution de leur réaction pour conduire à des dihydro-1,2 furannes et des perhydropyrazolopyrroles.

[Traduit par le journal]

In preceding papers we have described a synthetic approach to a wide variety of fused heterocyclic systems employing cycloadditions with 1,3-dipoles bearing an additional functionality (*i.e.* besides their basic 4π electron reactive system) with subsequent ring closures (1–4) (see Eq. 1).

[1] 
Azomethine ylides were found to be especially suited for the study of stereo and regiochemistry which are important if subsequent elaboration of cycloadducts to fused systems was to be successful. This general scheme allowed the synthesis of 5–5, 5–6, 5–5–5, 6–5–6, 6–6–5, 6–6–5–5, 6–6–6–5, and 6–6–5–6 fused systems. This synthetic scheme is now extended into other 1,3-dipolar systems; nitrile and azomethine imines and ethyl diazoacetate to provide fused pyrazoles. Also in order to investigate the competition between Michael addition to form dihydrofurans (2) and 1,3-dipolar additions to activated alkenes, some reactions of azomethine ylides derived from phenacylimidazolium salts are described.

Nitrile imines can be generated by the thermal decomposition of pyridinium betaines (5). Phenylazophenacylpyridinium betaine **1***a* prepared by the method of Krollpfeiffer and Braun (6*a*) liberates the nitrile imine and pyridine in refluxing benzene [2]. The benzoylnitrile imine under-

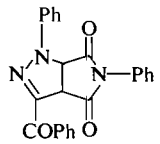
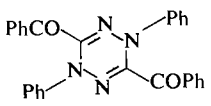
4

rection of condensation across the available carbonyl positions the chlorine labelled betaine **1***b* was employed in a similar experiment. The pyrazoline **2***b* and the pyrazole **3***b* were obtained in 38 and 57% yields respectively. The pyrazole **3***b* afforded upon reaction with hydrazine, 7-benzoyl-1,6-diphenyl-3-(4-chlorophenyl)-pyrazolo-[3,4-*d*]pyridazine, **4***b* in 68% yield. A peak in the mass spectrum at *m/e* 111 (C_6H_4Cl) but not at *m/e* 139 (ClC_6H_4CO) (both prominent peaks in the starting material), indicated that the condensation had proceeded as shown. The nitrile imine generated from **1***a* was found to be reactive toward *N*-phenylmaleimide. In this case (as well as the preceding reactions) the reaction conditions were found to be important in controlling yields. For example when 10 mmol amounts of **1***a* and *N*-phenylmaleimide were present in 50 ml of refluxing benzene, the yield of adduct **5** was 21% while the dipole dimer **6** was obtained in 54%



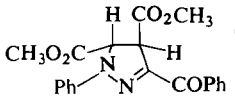
5



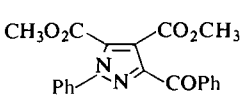
6

yield. Although originally described by Krollpfeiffer and Braun (6*a*) the correct structure of **6** was assigned by Huisgen and co-workers (6*b*). When a benzene solution of the betaine was slowly added to a refluxing solution of the dipolarophile, the yield of cycloadduct increased to 53% and the yield of dimer decreased to 12%. Huisgen has also shown that nitrile imine undergoes (3 + 3) self addition which is rare for 1,3-dipoles (6*c*). Reaction of betaine **1***a* under similar conditions with dimethyl fumarate afforded pyrazoline **7** and the pyrazole **8** in 19 and 39% yields respectively, the latter also being available from **7** by dehydrogenation with chloranil. Two equivalents of hydrazine reacted with **8** to give the pyrazolo[3,4-*d*]pyridazine derivative **9** in 35% yield.

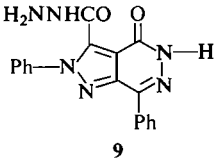
Reaction of the nitrile imine from betaine **1**



7



8

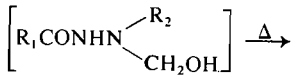


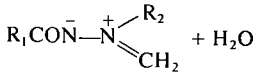
9

with phenylbenzoylacetylene occurred regiospecifically to give **3***c* directly in 28% yield. The direction of addition was proven by the quantitative conversion of the latter to give 1,4,6,7-tetraphenylpyrazolo[3,4-*d*]pyridazine, **4***c*. In general the nitrile imines were unreactive towards chalcones and only slightly reactive towards *cis*-dibenzoylethylene. A small amount of pyrazole **3***a* was isolated from the latter reaction.

Pyrazolines have also been generated employing azomethine imine cycloadditions to alkynes. Oppolzer's method of preparation allows the introduction of a functional group on the nitrogen end of the dipolar species, whereas nitrile imines are necessarily available only with the functional group on the carbon end (12). Two azomethine imines, derived from hydrazides and formaldehyde were investigated, [3]. The dipolar species

[3] $R_1CONHNHR_2 + H_2CO \longrightarrow$





10*a* R_1 = CH_3, R_2 = Ph
10*b* R_1 = Ph, R_2 = CH_3

10*a* was found to be unreactive toward dibenzoylethylene or dibenzoylacetylene but did react with *N*-phenylmaleimide to give cycloadduct **11**. However the functionalized azomethine imine **10***b* did react with dibenzoylethylene to afford pyrazolidine **12** in 63% yield. The latter compound was resistant to chloranil dehydrogenation in refluxing toluene. Reaction of dibenzoylacetylene with **10***b* gave the desired pyrazoline **13** in 63% yield. Condensation of the latter with hydrazine proceeded smoothly across

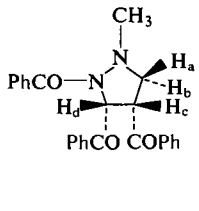
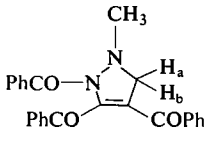
11

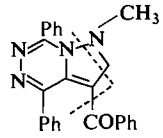


12

the *N*-benzoyl and 5-benzoyl moieties (rather than the 4,5 benzoyl groups) to give 3-benzoyl-4,7-diphenyl-1-methylpyrazolo[1,5-*d*]-as-triazine **14**. Two peaks in the mass spectrum of **14** at



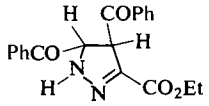
13



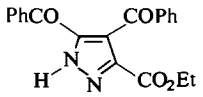
14

m/e 287 (*M* − COPh) and 244 (*M* − COPh − CH_3—N—CH_2) support the proposed structure and rule out the isomer corresponding to condensation across the 4,5-benzoyl groups of **13**.

Pyrazolines have long been available by the cycloadditions of ethyl diazoacetate to olefins (5, 7, 8). The ester function now allows development of the fused ring. Upon reaction of ethyl diazoacetate with *trans*-dibenzoylethylene the pyrazoline **15** and the pyrazole **16** were formed in 23 and 8% yields respectively. The tautomeric



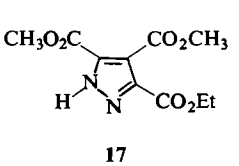
15



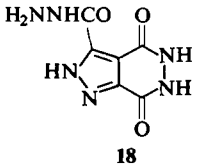
16

form **15** predominates for the pyrazoline as shown by i.r. and n.m.r. The i.r. spectrum of the pyrazole **16** shows N—H absorption and there is no evidence for methine in the n.m.r. Reaction of ethyl diazoacetate with benzoylacetylene afforded **16** in 64% yield. Similarly **17** formed by reaction with dimethyl acetylenedicarboxylate **14**, reacted with hydrazine to give the pyrazolopyridazine **18** in 99% yield.

Pyridinium, and isoquinolinium phenacylides undergo cycloadditions to reactive dipolarophiles to give, for example, indolizines and 1,3-diazapentalenes (2, 9–11). We have shown that although isoquinolinium phenacylide reacts as expected with *cis*- or *trans*-dibenzoylethylene to form cycloadducts (2) pyridinium phenacylides in contrast give 1,2-dihydrofurans **19** presumably



17



18

[4] 
19

via Michael addition followed by ring closure and elimination of pyridine [4]. Since the 1,2-dihydrofurans were valuable as a source of pyridazino[4,5-*c*]pyridazines via a novel ring transformation and the cycloadducts could be further developed synthetically, the distribution of these two types of product was examined as a function of the nature of the group leaving to form **19**.

3-Methylimidazolium phenacylide, generated from the chloride or bromide salt with triethylamine in pyridine at 50 °C afforded both the dihydrofuran **19** and a cycloadduct **20***a* in 23 and 12% yields respectively. The experiment was repeated with different substituents in the *para*-position of the phenacyl group.

It is apparent that as the substituent X becomes more electronegative the reaction favors

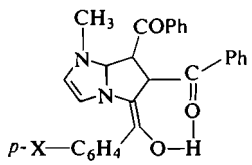
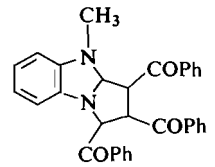
ring closure rather than cycloaddition. The i.r. and n.m.r. spectra of **20***a* and **20***b* indicated the presence of a concentration independent enolic OH. It is likely that it is the 5-aroyl group which is enolised since it then conjugates with the bridgehead nitrogen. Comparison of the n.m.r. spectra of **20***a* and **20***b* shows they are virtually identical except for the OH proton which appears at 5.90 δ in **20***a* and 6.14 δ in **20***b* as expected if this proton is adjacent to the aryl residue bearing the different substituents. A model shows that the OH group could be conveniently chelated to the 6-benzoyl group. 3-Methylbenzimidazolium phenacylide reacted with *trans*-dibenzoylethylene under these conditions to give the tricyclic structure **21** in 18% yield and no dihydrofuran while 3-methylbenzimidazolium 4′-nitrophenacylide yielded only dihydrofuran **19***d* in 45% yield.

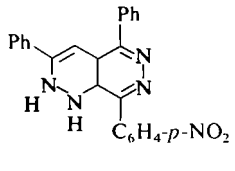


20*a* X = H
20*b* X = CH_3

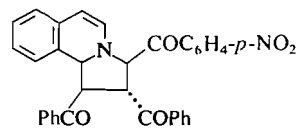


21

Compound **19***d* like **19***a* and **19***c* reported in a previous paper (2) underwent a ring transformation when treated with hydrazine to afford 3,5-diphenyl-8-(4′-nitrophenyl)-3,5,7-dihydropyridazino[4,5-*c*]pyridazine **22** in 30% yield. An attempt to force the isoquinolinium system to behave in a similar fashion (*i.e.* to eliminate isoquinoline) and form a dihydrofuran as in [5] failed in that only cycloadduct **23** was obtained in 55% yield analogous to products previously reported (2). The explanation for the sensitivity of the reaction's course to substituent effects in the case of the imidazole system seems to be twofold. First, as the X substituent becomes more electronegative, the enolate intermediate can more readily undergo ring closure owing to the increased partial positive charge adjacent to the heterocycle. Second, the degree of resonance energy in the imidazole system that must be overcome if cycloaddition is to occur is not as great as in the more aromatic pyridine but greater than in the isoquinoline system. The two effects, resonance energy and ease of elimination, are more nearly balanced in the imidazole system.

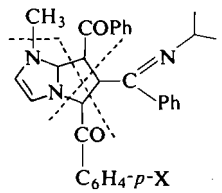


22



23

Although ring closure of functionalized 1,3-dipole adducts with hydrazine has proven to be a useful route to many fused heterocycles, attempts at the analogous Paal–Knorr condensations have in general met with only limited success (1–3). For example condensation of the carbonyl groups in **20***a* and **20***b* with isopropylamine was deemed plausible due to the ready formation of the enol and facile loss of water in the mass spectrum of the substrate. In the event, the amine reacted with only one carbonyl group (with loss of one molecule of H_2O) to give imines the structure of which (**24***a*, **24***b*) were determined by analysis of the mass spectrum. Detection of the fragments (*m/e* 199, $C_{12}H_{11}N_2O$), (*m/e* 185, $C_{11}H_9N_2O$), (*m/e* 290, $C_{20}H_{20}NO$), (*m/e* 272 $C_{17}H_{18}NO$), and (*m/e* 119, COC_6H_4-*p*-CH_3) rule out the two other possible isomers of **24**. In contrast to **20***a* and **20***b* the i.r. and n.m.r. spectra showed no trace of enolic OH. A space-filling model indicates that an enolic OH on the 5-aroyl group could not chelate to the imine nitrogen due to the steric hindrance of the isopropylmethine group. Compounds **24***a* and **24***b* are stable in refluxing toluene and show no tendency to complete the condensation.



24*a* X = H
24*b* X = CH_3

Experimental

Melting points were determined on a Fisher-Johns apparatus and are uncorrected. The i.r. spectra were recorded on a Perkin-Elmer 421 spectrophotometer. The n.m.r. spectra were recorded on Varian A-60, and A-100 spectrometers employing 10–15% solutions in $CDCl_3$ with tetramethylsilane as an internal standard. DMSO-d_6 was used for less soluble samples. Mass spectra were determined on Associated Electrical Industries MS-2 and MS-9 spectrometers. Peak measurements were made by comparison with perfluorotributylamine at a resolving power of 15 000. Microanalyses were carried out by Mrs. D. Mahlow of this department.

Materials

Phenylazophenacylpyridinium Betaine, 1a

This and the analogous *p*-chlorophenyl compound **1***b* were prepared by reacting the phenacylpyridinium bromides with benzenediazonium chloride according to the method of Krollpfeiffer and Braun (6*a*) in 35% yield, m.p. 120–121 °C (lit. (6) m.p. 122–123 °C).

3-Methyl-1-phenacylimidazolium Chloride

This and analogous salts were prepared by mixing equivalent amounts of the phenacyl chloride or bromide and 1-methylimidazole in tetrahydrofuran with continuous stirring for 12 h, followed by precipitation of the salt by addition of ether.

N-Benzoyl-N′-methylhydrazine

This compound was prepared in 6% yield from methylhydrazine and methyl benzoate, with the reflux period being 18 h, instead of 2 h as described by Hinman and Fulton (13). *N*-Acetyl-*N*′-phenylhydrazine was commercially available (Aldrich).

Cycloaddition Reactions with Azomethine Imines

Oppolzer's general procedure 'A' was employed in the synthesis of compounds **11**, **12**, and **13** (12). The preparation of **12** is described. To a solution of 3 g (12.7 mmol) of *trans*-dibenzoylethylene in 100 ml of toluene was added 1.5 g (10 mmol) of *N*-benzoyl-*N*′-methylhydrazine (13) and 0.4 g (13 mmol) of paraformaldehyde. The solution was refluxed 3 h through a Soxhlet thimble with molecular sieve, concentrated and the residue chromatographed on 100 g of Florisil with benzene to give 2.5 g (63% yield) of 1,4,5-tribenzoyl-2-methylpyrazolidine **12** as a yellow oil. Pyrazoline **13** was isolated in a similar manner and **11** precipitated from solution. The analytical and spectral data are summarized in Tables 1 and 2. Additional supportive data for the structures is provided by double irradiation experiments on pyrazolidines **11** and **12**.

Reaction of 1,4,5-Tribenzoyl-2-methyl-Δ^4-pyrazoline with Hydrazine

The pyrazoline **13** (1.8 g, 4.5 mmol) was dissolved in 20 ml of methanol, hydrazine (2 ml) was added, and the solution refluxed for 2 h. Removal of the solvent and excess hydrazine *in vacuo* and trituration with benzene – petroleum ether gave 1.6 g (90% yield) of 3-benzoyl-4,7-diphenyl-1-methylpyrazolo[1,5-*d*]-as-triazine **14** as a yellow oil. The mass spectrum contained major peaks at *m/e* 392 (molecular ion), 287 ($M - COC_6H_5$), 244 ($M - COC_6H_5 - CH_3 - N - CH_2$), 105 ($COC_6H_5$), and 77 ($C_6H_5$).

Cycloaddition Reactions with Nitrile Imines

This general procedure was developed for the synthesis of compounds **2***a*–**2***c*, **3***a*–**3***c*, **5**, **7**, and **8**. The representative preparation of **2***a* is described. To a solution of 2.36 g (10 mmol) of *trans*-dibenzoylethylene in 100 ml of benzene at reflux with stirring was added dropwise during 15 min a solution of 2.9 g (9.6 mmol) of phenylazophenacylpyridinium betaine in 60 ml of benzene. After a further 30 min at reflux the excess solvent was removed *in vacuo* and the residue subjected to column chromatography on 100 g of Florisil with 1:1 benzene – light petroleum as eluant. The first band to be eluted contained some dipole dimer (0.15 g), the second, eluted with 500 ml of benzene afforded 1.7 g (37% yield) of 1-phenyl-3,4,5-tribenzoyl-Δ^2-pyrazoline **2***a* as yellow powdery crystals m.p. 157–160 °C. The third dark band eluted with chloroform and 5% ethanol gave 2.2 g (48% yield) of 1-phenyl-3,4,5-tribenzoylpyrazole **3***a* as a red oil. Analytical and spectral data are summarized in Tables 1 and 2. The corresponding pyrazoles could be obtained from the pyrazolines by refluxing with one equivalent of *p*-chloranil in benzene as previously described (1).

Reactions of 1,4-Dicarbonyl Compounds with Hydrazine

Pyridazines **4***a*–**4***c*, **9**, and **18** were prepared in the following manner. 1-Phenyl-3,4,5-tribenzoylpyrrole (2 g, 4.4 mmol) was dissolved in 20 ml of 90% ethanol. Hydrazine (2 ml, 94%, 60 mmol) was added and the solution heated under reflux for 18 h. The pyridazine **4***a* was obtained upon trituration of the ethanolic solution with water in 69% yield (1.35 g). Spectral and analytical data are tabulated.

Cycloaddition Reactions of Ethyl Diazoacetate

Reaction with trans-Dibenzoylethylene

Ethyl diazoacetate (2.28 g, 20 mmol) and 4.72 g (20 mmol) of *trans*-dibenzoylethylene were heated in 50 ml of benzene at 50 °C for 18 h. Chromatography on 100 g of Florisil with benzene afforded in successive fractions, 1 g of *trans*-dibenzoylethylene, 1.35 g of the pyrazoline **15** (23% yield) as an orange oil and 0.5 g of the pyrazole **16** (8% yield), m.p. 180–181 °C in the third fraction eluted with chloroform and 5% ethanol.

Reaction with Dibenzoylacetylene and Dimethyl Acetylenedicarboxylate

Ethyl diazoacetate and dibenzoylacetylene (10 mmol each) were warmed in 50 ml of benzene at 40 °C for 2 h. After 1 h the product began to precipitate out. The precipitation was completed by adding an equal volume of hexane to give **16** in 64% yield. Reaction with dimethyl acetylenedicarboxylate afforded in the same manner a 60% yield of **17** as an orange oil after purification by chromatography (Florisil–benzene).

Reaction of Imidazolium Phenacylides with trans-Dibenzoylethylene

1-Phenacyl-3-methylimidazolium chloride (2.36 g, 10 mmol) and 2.36 g (10 mmol) of *trans*-dibenzoylethylene were stirred in 100 ml of pyridine at 40 °C when 3 ml (25 mmol) of triethylamine was added. The solution darkened and was stirred for 2 h at 50 °C. The solvent was removed *in vacuo* and the solution filtered to remove triethylamine hydrochloride. The remaining pyridine was evaporated, 10 ml of benzene was added to the residue and this solution subjected to chromatography on 100 g of Florisil with benzene as eluant. The first band gave 0.55 g of 4,5-dihydro-2-phenyl-4,5-dibenzoylfuran, **19***a* (16% yield), m.p. 119–121 °C (lit. (2) m.p. 116–119 °C). The second band, eluted with chloroform and 2% ethanol gave 4,5,6,6a-tetrahydro-1-methyl-4,5,6-tribenzoyl-1,3a-diazapentalene **20***a* as tan crystals from benzene (0.5 g, 12% yield) m.p. 180–181 °C. Compounds **19***b* and **20***b* were prepared and isolated in the same fashion in 12 and 19% yields respectively. The mass spectrum of **20***b* contained major peaks at *m/e* 450 (molecular ion), 432 ($M - H_2O$), 415, 399 ($M - 51$), 373 ($M - C_6H_5$), 345 ($M - COC_6H_5$), 331 ($M - COC_6H_4 - CH_3$), 313, 296, 264 ($M - 186$), 199 ($C_{12}H_{11}N_2O$), 185 ($C_{11}H_9N_2O$), 157, 199 ($COC_6H_4CH_3$), 105 (COC_6H_5), 91 ($C_6H_4CH_3$), 77 (C_6H_5).

Mass measurements. Calcd. for $C_{29}H_{26}N_2O_3$: 450.1943; found: 450.1930. Calcd. for $C_{12}H_{11}N_2O$: 199.0870; found: 199.0855. Calcd. for $C_{11}H_9N_2O$: 185.0714; found: 185.0715.

Reaction of Isoquinolinium p-Nitrophenacylide with trans-Dibenzoylethylene

p-Nitrophenacylisoquinolinium bromide (3.73 g, 10 mmol) and 2.36 g (10 mmol) of dibenzoylethylene in 100 ml of pyridine were heated to 50 °C and 3 ml (25 mmol) of triethylamine was added. The mixture turned dark and was stirred for 2 h at 50 °C, cooled and concentrated to half volume, filtered and then further concentrated. The residue was crystallized from benzene–hexane to give **23**, 2.8 g (52% yield), m.p. 182–183 °C. A further 0.15 g (3%) could be obtained by chromatography of the mother liquor on 100 g of Florisil with benzene as eluant. Spectral and analytical data of **23** are in Tables 1 and 2. The compound was insufficiently soluble in DMSO-d_6 to afford an n.m.r. spectrum.

Attempted Paal–Knorr Condensations

(*a*) Compound **20***b* (1 g, 2.2 mmol) in 20 ml of methanol was stirred 3 days at 40 °C with 5 ml (65 mmol) of isopropylamine in a stoppered flask. The solvent was removed *in vacuo* and the residue subjected to Florisil chromatography employing as the eluant a solution of chloroform and 2% ethanol affording **24***b*, 0.6 g of an orange oil (55% yield). The mass spectrum contained the following major peaks *m/e* 491 (M), 448 ($M - C_3H_7$), 434 ($M - N - C_3H_7$), 361, 330 ($435 - C_6H_5CO$), 303, 290 ($C_{20}H_{20}NO$), 276 ($C_{19}H_{18}NO$), 199 ($C_{12}H_{11}N_2O$), 157, 119 ($COC_6H_4CH_3$), 105 (COC_6H_5), 91 ($C_6H_4CH_3$), 77 (C_6H_5), 51, 43 (C_3H_7).

Mass measurements. Calcd. for $C_{32}H_{33}N_3O_2$: 491.2573; found: 491.2250. Calcd. for $C_{20}H_{20}NO$: 290.1545; found: 290.1532. Calcd. for $C_{19}H_{18}NO$: 276.1388; found: 276.1356. Calcd. for $C_{11}H_9N_2O$: 185.0714; found: 185.0722. Calcd. for $C_{12}H_{11}N_2O$: 199.0870; found: 199.0860.

(*b*) Compound **20***a* (1 g, 20 mmol) was subjected to similar reaction conditions to afford the imine **24***a*, 0.2 g (18% yield). Both imines are subject to hydrolysis on the column to afford some starting material. Neither imine reacted further in refluxing toluene.

Single Crystal Electron Spin Resonance of Low Spin Co(II) and of Cu(II) Schiff Base Complexes

V. MALATESTA AND B. R. MCGARVEY

Department of Chemistry, University of Windsor, Windsor, Ontario N9B 3P4

Received June 9, 1975

V. MALATESTA and B. R. MCGARVEY. Can. J. Chem. **53**, 3791 (1975).

Single crystal e.s.r. studies have been done on *N,N'*-ethylenebis(*o*-aminobenzylideniminato)-nickel(II) and *N,N'*-ethylenebis(benzoylacetoniminato)nickel(II) doped with the corresponding Co(II) and Cu(II) complexes. It is shown for the cobalt(II) complexes that the unpaired electron is in a d_{yz} orbital and that the d orbitals are arranged (d_{xz}), ($d_{x^2-y^2}$), (d_{z^2}), (d_{yz}), (d_{xy}) in order of increasing energy with the $d_{x^2-y^2}$, d_{z^2}, and d_{yz} orbitals being close together. The large energy separation between the d_{xz} and d_{yz} orbitals which is found in the cobalt(II) complexes is not observed in the corresponding copper(II) complexes. ^{14}N hyperfine constants were measured for both copper(II) complexes.

V. MALATESTA et B. R. MCGARVEY. Can. J. Chem. **53**, 3791 (1975).

On a fait des études r.p.e. de cristaux uniques du *N,N'*-éthylène bis(*o*-aminobenzylidèniminato) nickel(II) et du *N,N'*-éthylène bis(benzoylacétoniminato) nickel(II) dopés avec les complexes correspondants du Co(II) et du Cu(II). On a montré, dans le cas des complexes du Co(II), que l'électron non pairé occupé l'orbitale d_{yz} et que les orbitales d sont arrangées par ordre croissant d'énergie (d_{xz}) < ($d_{x^2-y^2}$) < (d_{z^2}) < (d_{yz}) < (d_{xy}) et que les trois orbitales centrales sont près les unes des autres. La grande séparation d'énergie qui est trouvée entre les orbitales d_{xz} et d_{yz} des complexes du cobalt(II) ne se retrouve pas dans les complexes correspondants du cuivre(II). On a mesuré les constantes hyperfines du ^{14}N pour les deux complexes du cuivre.

[Traduit par le journal]

Introduction

Many e.s.r. studies of four and five coordinate Schiff base complexes of low spin Co(II) have been reported in the past few years (1–10). The aim of many of these studies was to determine the ground state by comparing the spin Hamiltonian parameters predicted by theory for different ground states to the experimental parameters. Two difficulties associated with most of these studies have prevented a definitive determination of the ground states. First, with one exception (1), all of the work has been done on frozen solutions and powders in which it is not possible to assign the three g and A values in the spin Hamiltonian to specific molecular axes. Two studies (2, 5) have used frozen nematic solutions in an attempt to identify the axes but they disagreed as to which molecular axis will be the aligning axis in the liquid crystal. Second, the theory used to predict spin Hamiltonian parameters did not properly account for the large distortions from axial symmetry found in these complexes and the contribution of low lying excited quartet states to the g and A values.

Recently, the theory for the spin Hamiltonian of low spin d^7 complexes was reinvestigated (11) and the contribution of low lying quartet states was examined. Also, the effect of possible configuration interaction between d_{z^2} and $d_{x^2-y^2}$ orbitals in the $^2A_1$ state was considered for low symmetry complexes. For the low spin symmetry complexes studied here, it was found that an unambiguous assignment of ground states on the basis of g and ^{59}Co hyperfine splitting values alone is difficult in most cases due to the large number of variable parameters and is certainly impossible if the correct assignment to molecular axes is not known. The complexes considered here are four coordinate square planar complexes and the z direction is taken to be normal to the plane of the complex. In all cases the symmetry of the complex requires that the x and y axes bisect two cobalt ligand bonds. For this type of complex only two ground states need be considered, both of which have the d_{xy} orbitals unoccupied. One state is the $^2B_2$ state in which the unpaired electron occupies a d_{yz} orbital. The $^2B_1$ state in which the unpaired electron occupies a d_{xz} orbital is identical to the $^2B_2$ if one interchanges the x and y labels for the axes. The second state is the $^2A_1$ state in which the unpaired electron is in the ($ad_{z^2} + bd_{x^2-y^2}$) orbital

and b can vary from zero to unity in the low symmetry complexes and is a parameter to be fitted against experimental results. It was shown (11) that the relative values of g_y and g_z seem to provide a good indicator of which state is the correct one with $g_z > g_y$ for the $^2B_2$ state and $g_y > g_z$ for the $^2A_1$ state. Thus, it has become clear that only single crystal e.s.r. studies, in which the orientation of at least the z molecular axis is known, are essential if one hopes to determine the ground state.

Five single crystal studies of low spin Co(II) complexes are known to the authors (1, 12–15) and only two (1, 15) are of complexes having oxygen and nitrogen bonding to the cobalt ion. Zelewsky and Fierz (1) in their study of *N,N'*-ethylenebis(salicylideneiminato)cobalt(II), [Co(salen)], claimed that only a $^2B_2$ ground state would explain their results but they provided no details. Chacko and Manoharan (15) also claimed a $^2B_2$ ground state for bis[1-methyl-3-(2-chloro-6-methyl)phenyltriazine-1-oxide]cobalt(II), [Co(BPT)], but the crystal structure of their host lattice Ni(BPT) is unknown so that they could not be certain about their assignment of molecular axes.

We have succeeded in growing crystals of *N,N'*-ethylenebis(*o*-aminobenzylideniminato)nickel(II), [Ni(amben)], and *N,N'*-ethylenebis(benzoylacetoniminato)nickel(II), Ni[(benacacen)], into which the corresponding complexes of Co(II) and Cu(II) have been doped. The e.s.r. study of the copper complexes was undertaken primarily to determine the orientation of the complexes in the crystal since the crystal structure of both systems has not yet been done. The copper resonances for these complexes are always nearly axial with the axis perpendicular to the molecular plane. As will be seen, the results on ^{14}N hyperfine interactions in the copper complexes will be useful in interpreting the results for the cobalt complexes. In Fig. 1 is given the molecular structure for both complexes and the location of the x and y axes.

FIG. 1. (*a*) Structure of M(amben); (*b*) Structure of M(benacacen). M = Co, Cu.

Experimental

Preparation of Complexes

All solvents were carefully dried and stored under nitrogen. Particular care was taken with *N,N'*-dimethylformamide which was distilled *in vacuo* and stored over molecular sieves (4-A) in a nitrogen atmosphere. The reagents, 1-benzoylacetone, ethylenediamine, cobalt(II), nickel(II), copper(II) acetates were obtained commercially and used without further purification. *Ortho*-aminobenzaldehyde was prepared by the method described by Smith and Opie (16). Preparation and manipulation of cobalt complexes were carried out under an atmosphere of prepurified nitrogen to prevent formation of cobalt(II)-O_2-peroxycobalt(II) species.

Ni(amben), Co(amben), and Cu(amben) were prepared by the method of Green and Tasker (17). The complexes of Ni(benacacen), Co(benacacen), and Cu(benacacen) were prepared according to Everett and Holm (18).

Growth of Crystals

Ni(amben) crystals doped with approximately 2% Co(II) or 1% Cu(II) were prepared by slow evaporation of degassed dimethylformamide solutions. Dark red flat hexagonal crystals (Fig. 2) were obtained after several days. Dark red crystals of Ni(benacacen) doped with Co(II) and Cu(II) were grown from dichloromethane solutions. Dichloromethane was deaerated with a stream of nitrogen gas at room temperature for 1 h before solutes were added. Growth of crystals took place under an atmosphere of prepurified nitrogen. Hexagonal crystals in the shape depicted in Fig. 2 were obtained.

Electron Spin Resonance

Electron spin resonance spectra were taken with a Varian E-12 spectrometer having a rotating cylindrical cavity and a rotating magnet. Single crystals were mounted on a quartz rod along the axes labelled 1, 2, and 3 in Fig. 2 and spectra taken every 15° for a rotation of the magnetic field in the plane perpendicular to the mounting axis. A speck of DPPH was used to calibrate the klystron frequency. The magnetic field was calibrated by a proton n.m.r. spectrometer. All spectra were taken at room temperature with the exception of that for (Ni, Co)(benacacen) which were taken at liquid nitrogen temperature because

spin–lattice relaxation times for this Co(II) complex were too short at room temperature to give narrow lines in the spectra.

Results

The e.s.r. results have been fitted to the spin Hamiltonian

$$[1]\quad \mathcal{H} = \beta[g_xH_xS_x + g_yH_yS_y + g_zH_zS_z] + A_xS_xI_x + A_yS_yI_y + A_zS_zI_z + \sum_i [{}^{N}A_iS_zI_{zi} + {}^{N}B_i(S_xI_{xi} + S_yI_{yi})]$$

where A_x, A_y, and A_z are the hyperfine terms for the central metal nucleus and ${}^{N}A$ and ${}^{N}B$ are the nitrogen nuclear hyperfine terms which were resolved in the case of the copper complexes. In this study, the principal axes for the g and A tensors were found to be the same within experimental error for all complexes. For the nitrogen hyperfine terms the z direction for each nucleus is along the copper nitrogen bond.

M(amben)

For this system a pair of resonances from magnetically inequivalent complexes was observed only in the 23 planes, the two resonances becoming equivalent in the 12 and 13 planes. Further, one principal axis was along the 1 axis for both pairs. From the work of Weil *et al.* (19) we learn that this behavior indicates that the crystal is orthorhombic. Both the copper and cobalt crystals were studied at room temperature as it was found that the e.s.r. spectra for the Co(II) crystal did not display any appreciable line narrowing at liquid nitrogen temperatures. Representative spectra for Co(II) and Cu(II) doped crystals are given in Figs. 3 and 4. The copper resonance consisted of four sets of nine lines due to the hyperfine interaction of one copper nucleus ($I = \frac{3}{2}$) and four nearly equivalent nitrogen nuclei ($I = 1$). The hyperfine interaction of ^{65}Cu was not resolved from that of ^{63}Cu.

The spin Hamiltonian parameters for both Co(II) and Cu(II) complexes are given in Table 1. The orientation of the principal axes for g and A tensors is given by the two polar angles θ and ϕ where θ is the angle between the axis and crystal axis 1 and ϕ is the angle which the projection in the 23 plane makes with axis 2 of the crystal. The axis normal to the molecular plane or z axis is taken to be that axis with the large g value and A value in the copper system and is found to be in the 23 plane of the crystal. The x axis has been assigned by an analogy with similar Co(II) complexes (1, 13, 14) in which the large g value is always associated with the x axis. The growth habits of this crystal also support this assignment, since growth of the crystal along the long axis or y axis of molecule would be poor, which is the case for the 1 axis of the crystal.

The Co(II) results agree as well as can be expected with the powder results of Engelhardt *et al.* (10) but their assignment of g_z is in error. The assignment of xyz axes does agree with that of Urbach *et al.* (5), who studied related Co(II) complexes in frozen nematic solutions.

M(benacacen)

For this system a pair of resonances from magnetically inequivalent complexes was observed in both the 12 and 13 planes with both resonances becoming equivalent in the 23 plane. Since all three tensor components are different and have different orientations for the inequivalent pairs we deduce from Weil *et al.* (19) that the host crystal is monoclinic. The copper crystal was studied at room temperature, but it was necessary to study the Co(II) crystal at liquid nitrogen temperatures to obtain narrow lines in the spectrum. Representative spectra are given in Figs. 5 and 6. The copper resonance has four sets of five lines due to hyperfine interaction of one copper nucleus and two equivalent nitrogen nuclei. In Fig. 6 the outside copper

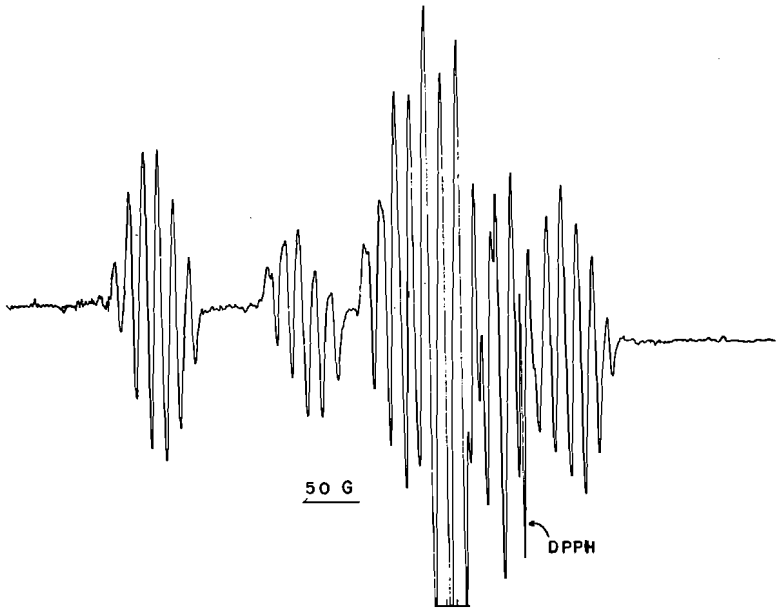

FIG. 6. Electron spin resonance spectrum of (Ni, Cu)(benacacen).

hyperfine lines are seen to consist of six lines due to partial resolution of ^{65}Cu hyperfine lines from those due to ^{63}Cu. We analyzed only the ^{63}Cu lines.

The spin Hamiltonian parameters for both Co(II) and Cu(II) complexes are given in Table 1. The x, y, and z axes have been assigned in a similar fashion to that used for M(amben). In this case, only the direction of the x axis in Co(II)(benacacen) and the z axis in Cu(II)(benacacen) are determined with any accuracy due to the near axial character of both resonances. These two axes are 92° from each other, so it appears reasonable to assume both complexes are oriented similarly in the host crystal. Due to the better resolution in this copper complex, it was possible to find the principal axes of the ^{14}N hyperfine. It was found that the z axis is perpendicular to the Cu z axis and 38 $\pm$ 10° from the Co x axis. Thus, as expected, we have confirmation that the x and y axes of the g and A tensors bisect the metal ligand bonds in the plane of the complex.

The Co(II) results agree rather poorly with the values found by Hoffman *et al.* (2) for a frozen nematic solution. They reported values of: $g_x = 3.084$, $g_y = 1.937$, $g_z = 2.01$, $A_x = 149.9 \times 10^{-4}$ cm^{-1}, $A_y = 28.9 \times 10^{-4}$ cm^{-1}, and $A_z = 30.8 \times 10^{-4}$ cm^{-1}. The considerable differences between these values and ours are very likely due to solvent interactions.

Discussion

The spin Hamiltonian parameters for other similar Co(II) complexes are compared to those determined in this study in Table 2. Co(amben), Co(benacacen), and Co(salen) all have $g_z > g_y$ which suggests that the $^2B_2$ state would be the better choice for all three complexes. In the case of Co(amben) there is additional evidence from ^{14}N hyperfine data which argues strongly against the ground state being $^2A_1$ with a small value for the b parameter.

If the unpaired electron were in an a_1 orbital, symmetry would allow direct admixture of 2s and $2p_\sigma$ orbitals from the nitrogen atom which would lead to a ^{14}N hyperfine splitting. We can estimate the extent of such a splitting for the case of a d_{z^2} orbital. The d_{z^2} orbital can be written as

$$[2] \qquad d_{z^2} = \frac{1}{\sqrt{3}}(d_{z^2-y^2} + d_{z^2-x^2})$$

where for our discussion the x and y axes are directed at the ligand atoms. The $d_{z^2-y^2}$ and $d_{z^2-x^2}$ orbitals are similar to the $d_{x^2-y^2}$ orbital occupied by the unpaired electron in copper complexes in that one of the lobes points towards a nitrogen atom. Thus, if we assume a similar

[a]Values $\times 10^{-4}$ cm^{-1}.

covalency in Co(II) and Cu(II) complexes we can estimate the hyperfine constant for a ^{14}N atom in the plane of a cobalt complex to be one-third that observed in the corresponding copper complex. In Co(amben) where the ^{14}N hyperfine splitting is not resolved we might expect a contribution of $\sim 5^{N}A$ to the line width. For Co(amben) the line width of resonance lines is 10×10^{-4} cm^{-1} when the magnetic field is along the z principal axis while the expected line width for a d_{z^2} electron due to ^{14}N hyperfine is 25×10^{-4} cm^{-1}. When the magnetic field is along the y principal axis the experimental line width is 17×10^{-4} cm^{-1} and the expected ^{14}N width would be 29×10^{-4} cm^{-1}. This would suggest the electron is either in a d_{yz} or d_{xz} orbital or an a_1 orbital in which the b parameter is large so that it is basically a $d_{x^2-y^2}$ or $d_{3y^2-r^2}$ orbital. A similar analysis of the Co(benacacen) spectra does not lead to any definite conclusions because the expected contribution to the line width in this case is only $\sim 2^{N}A$ and this predicts line widths comparable to those observed.

We have attempted to fit the spin Hamiltonian parameters to the theoretical equations for the $^2A_1$ state (11) when the b parameter is large and have found that it is possible, but the values of the various parameters are not very satisfactory. For the $^2B_2$ state theory gives for the spin Hamiltonian parameter the following equations (11):

$$[3]\quad g_z = 2.0023 + \frac{2}{3}\eta_5^2 - 3\eta_3^2 - \frac{2}{3}\eta_2\eta_5 - 3\eta_2\eta_3 + 2\eta_2$$

$$[4]\quad g_x = 2.0023 - 2\eta_2^2 - 3\eta_2\eta_3 + 6\eta_3 + 2\eta_4$$

$$[5]\quad g_y = 2.0023 + \frac{2}{3}\eta_5^2 - 3\eta_3^2 - 2\eta_1$$

$$[6]\quad A_z = K + P\left\{\frac{2}{7}(1 - \eta_5 + \eta_5') + \frac{3}{7}(\eta_3 - \eta_4 + \eta_1) + 2\eta_2 - \frac{2}{21}\eta_5^2 - \frac{9}{14}\eta_3^2 - \frac{8}{21}\eta_5\eta_2 - \frac{45}{14}\eta_3\eta_2\right\}$$

$$[7]\quad A_x = K + P\left\{-\frac{4}{7} + 6\eta_3 + 2\eta_4 + \frac{3}{7}(\eta_2 - \eta_1) + \frac{4}{21}\eta_5^2 + \frac{3}{14}\eta_3^2 - \frac{2}{21}\eta_5\eta_6 + \frac{4}{7}\eta_3\eta_6 - \frac{6}{7}\eta_2\eta_3 - \frac{2}{7}\eta_2\eta_5\right\}$$

$$[8]\quad A_y = K + P\left\{\frac{2}{7}(1 + \eta_5 - \eta_5') - \frac{3}{7}(\eta_2 + \eta_3 - \eta_4) - 2\eta_1 - \frac{2}{21}\eta_5^2 - \frac{8}{21}\eta_5\eta_6 + \frac{2}{7}\eta_3\eta_6 + \frac{1}{7}\eta_2\eta_5 + \frac{3}{14}\eta_2\eta_3\right\}$$

$$[9]\quad \begin{aligned} \eta_1 &= \xi/\Delta[^2A_2(yz \rightarrow xy)] \\ \eta_2 &= \xi/\Delta[^2B_1(xz \rightarrow yz)] \\ \eta_3 &= \xi/\Delta[^2A_1(z^2 \rightarrow yz)] \\ \eta_4 &= \xi/\Delta[^2A_1(x^2 - y^2 \rightarrow yz)] \\ \eta_5 &= \xi/\Delta[^4A_1(xz \rightarrow xy)] \\ \eta_6 &= \xi/\Delta[^4B_1(z^2 \rightarrow xy)] \\ \eta_5' &= \xi/\Delta[^2A_1(xz \rightarrow xy)] \end{aligned}$$

where K is the Fermi contact interaction, $P = 2.0023 g_N \beta_e \beta_N \langle r^{-3} \rangle$, ξ is the spin orbit interaction parameter for a single d electron, and $\Delta[^2A_2(yz \rightarrow xy)]$ is the energy difference between the excited $^2A_2$ state, produced by promoting an electron from the d_{yz} orbital to the d_{xy} orbital, and the ground state. The preceding equations were derived from the full determinental wave

functions and therefore all η_i parameters must have positive values.

There are nine adjustable parameters in eqs. 3–8 and only six equations. We must therefore make reasonable assumptions concerning the values of three parameters to obtain values for the other six. It can be shown that $\Delta[^2A_1(xz \rightarrow xy)]$ is $\sim 15\,000\ cm^{-1}$ larger than $\Delta[^4A_1(xz \rightarrow xy)]$ so that if we assume $\xi \sim 400\ cm^{-1}$ we can estimate η_5' from η_5 using the equation:

$$\eta_5' = \frac{2\eta_5}{2 + 75\eta_5}$$

$\Delta[^4B_1(z^2 \rightarrow xy)]$ should be smaller than $\Delta[^4A_1(xz \rightarrow xy)]$ so that $\eta_6 \geq \eta_5$. We have assumed $\eta_6 = \eta_5$ for convenience because the value chosen for η_6 has little influence on the values of the other parameters since it only appears in the small terms $\eta_5\eta_6$ and $\eta_3\eta_6$ and these two terms partially cancel each other out. We have shown that assuming $\eta_6 = 0$ changes none of the other parameters by more than a few percent. This assumption about η_6 might not be justified if both η_6 and η_3 or η_5 were very large but eqs. 3–8 are not valid when this occurs.

Unfortunately, there are no other approximations that appear intuitively reasonable. We have therefore solved eqs. 3–8 for different assumed values of η_1 to determine the possible range of values for the other η_i parameters plus P and K. A plot of the η_i's obtained is given in Figs. 7 and 8. For Co(amben) these were obtained assuming A_x is negative and A_y, A_z were positive because this choice of sign gave the most reasonable value for P. Similarly, the best choice for Co(benacacen) is to take A_x, A_y, and A_z as positive.

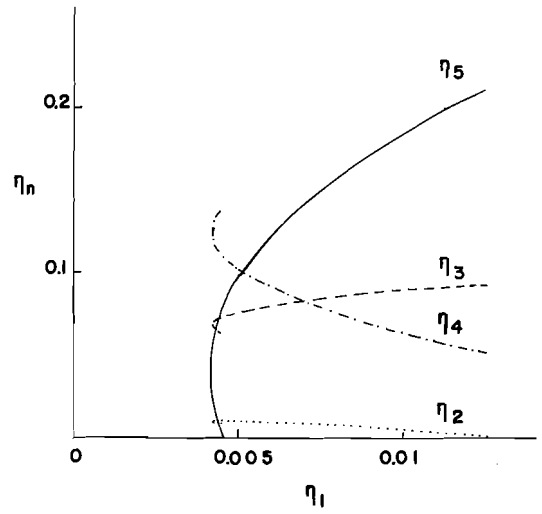

FIG. 7. Plot of η_i (as defined in text) for assumed values of η_1 for Co(amben).

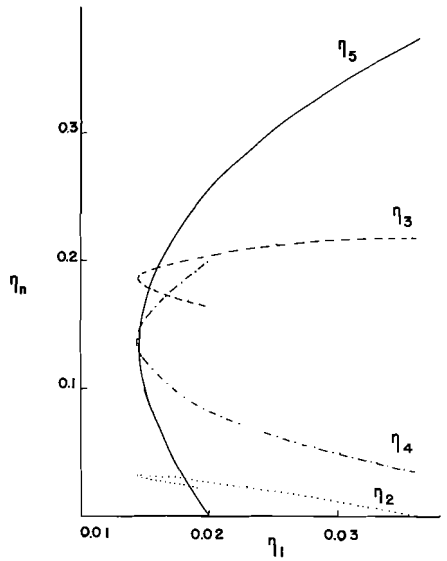

FIG. 8. Plot of η_i (as defined in text) for assumed values of η_1 for Co(benacacen).

For Co(amben) no solutions exist for $\eta_1 < 0.0042$, from 0.0042 to 0.0045 two solutions are found and from 0.0045 to 0.0125 one solution is found. Above 0.0125, η_2 becomes negative and therefore no physically meaningful solution is possible for $\eta_1 > 0.0125$. We note from Fig. 7 that η_2 and η_3 change slowly over the allowed range of η_1 and therefore approximate values for these parameters are obtained. The same is true for P and K with P ranging from 148 to 154 $\times 10^{-4}\ cm^{-1}$ and K from -16 to $-15 \times 10^{-4}\ cm^{-1}$.

For Co(benacacen) the results are similar except for scale. Allowed solutions occur only in the range of 0.0144 to 0.036 for η_1. Both η_3 and η_2 are larger than for Co(amben). It is this larger value of η_3 that makes both g_x and A_x much larger in magnitude for Co(benacacen) than for Co(amben). The value of $6\eta_3$ for Co(benacacen) in [7] is much larger in magnitude than the Fermi contact term K and the normal dipolar term of $\frac{4}{7}P$ and makes A_x large and positive. In Co(amben) η_3 is small enough that it just cancels out the negative Fermi and dipolar terms giving rise to an

For personal use only.

A_x of very small magnitude. P for Co(benacacen) varies from 250 to 238 $\times 10^{-4}$ cm^{-1}.

The P value for Co(benacacen) is normal for a Co(II) complex (11) but that for Co(amben) is appreciably smaller, indicating considerable delocalization of the unpaired electron into the π system of the ligand if our ground state assignment is correct. The K values are smaller in magnitude than normal (20) but this might be due to some small direct admixture of the 4s orbital with the d_{yz} orbital which is allowed in these complexes since the true site symmetry can be no better than C_2, with the symmetry axis aligned with the molecular x axis.

A simple crystal field analysis would indicate that $\Delta[^2B_1(xz \rightarrow yz)] + \Delta[^2A_2(yz \rightarrow xy)] \cong \Delta[^4A_1(xz \rightarrow xy)] + 15\,000$ cm^{-1}. Using reasonable values of ξ plus η_1 and η_2 shows that values of $\eta_5 > 0.05$ for Co(benacacen) and 0.01 for Co(amben) would be inconsistent with our model. For this range of values of η_5, $\eta_3 \sim \eta_4$, and $\eta_2 \sim \eta_1$ with (η_3, η_4) being approximately an order of magnitude larger than (η_2, η_1) for both cobalt(II) complexes. It is therefore clear that $\Delta[^2A_1(z^2 \rightarrow yz)]$ and $\Delta[^2A_1(x^2 - y^2 \rightarrow yz)]$ are smaller than $\Delta[^2A_2(yz \rightarrow xy)]$ and $\Delta[^2B_1(xz \rightarrow yz)]$ and this should be useful in assigning bands in the optical spectra of these complexes.

Optical studies on Co(benacacen), Co(amben), and related complexes have been carried out by several workers (5, 7, 17, 21–23). In general for CoN_2O_2 complexes two d–d bands are found, one between 4000 and 5000 cm^{-1} and a second between 8000 and 9000 cm^{-1}. Both bands appear to have structure but it is not clear whether this is due to vibronic couplings or to the presence of two or more separate transitions. In CoN_4 complexes the two bands are found in the regions of 5000–7000 cm^{-1} and 11 000–12 000 cm^{-1}. Circular dichroism studies (5, 7, 22) have revealed the possible presence of several more d–d bands between 16 000 and 21 000 cm^{-1} for CoN_2O_2 complexes and between 13 000 and 20 000 cm^{-1} for CoN_4 complexes.

No agreement concerning assignments of these transitions exists in the literature. Hipp and Baker (22) assumed in their assignments that the ground state had the unpaired electron in a $d_{x^2-y^2}$ orbital while most other workers assumed the unpaired electron to be in the d_{z^2} orbital. Busetto *et al.* (7, 21) and Urbach *et al.* (5) both tried to assign bands using e.s.r. results and crystal field theory but arrived at very different assignments assuming the same ground state. The assignment of Urbach *et al.* (5) is internally inconsistent because the crystal field parameters they used would predict the $(xy)(z^2)(yz)$ quartet state to be 5200 cm^{-1} below the doublet state they assumed as the ground state.

It is dangerous to base too much of an optical assignment on ΔE's estimated from e.s.r. parameters η_i, as has been done for these complexes (5, 7), because this requires a good estimate of ξ. It is well known (24) that the effective value of ξ can be less than 50% of the free ion value when there is strong covalency in both the ground state and the excited state coupled by the spin–orbit operator. In the Co(II) complexes studied here we can expect this might be the case for parameters η_1 and η_2 but not for the parameters η_3 and η_4 because these last two parameters involve excited states that have d orbitals that are not expected to have strong covalent interactions with ligand orbitals. Thus, although η_1 and η_2 are 10-fold smaller than η_3 and η_4 we cannot expect the respective values of ΔE's for η_1 and η_2 to be 10-fold larger than those for η_3 and η_4. It does seem reasonable, though, to assume that the lower frequency d–d band will be associated with $\Delta E[^2A_1(z^2 \rightarrow yz)]$ and $\Delta E[^2A_1(x^2 - y^2 \rightarrow yz)]$ while the second band is associated with $\Delta[^2A_2(yz \rightarrow xy)]$ or $\Delta[^2B_1(xz \rightarrow yz)]$ or perhaps with both.

These assignments are, of course, correct only if we are correct in our assumption as to the ground state. It does seem clear, however, from the behavior of the spectral bands and the e.s.r. parameters, that both complexes have the same ground state and that amben generates a stronger crystal field than benacacen. The smaller values of η_i in Co(amben) go along with the shift to higher frequencies of the optical bands.

A more comprehensive crystal field analysis of the e.s.r. and optical studies seems unwarranted at this time, but our results do indicate that orbital energies in increasing order are d_{xz}, ($d_{x^2-y^2}$, d_{z^2}, d_{yz}), d_{xy} with $d_{x^2-y^2}$, d_{z^2}, and d_{yz} being clustered closely together in undetermined order. This ordering suggests large configurational mixing of $d_{x^2-y^2}$ and d_{z^2}.

If we use standard methods (25) for estimating repulsion energies we find that $\Delta[^2B_1(xz \rightarrow yz)]$ is a direct measure of the difference in orbital energies of d_{xz} and d_{yz}. The small value of η_2 in both complexes studied indicates that this difference is large ($\geq$8000 cm^{-1} for Co(benaca-

For personal use only.

cen) and $\geq 11\,000\ cm^{-1}$ for Co(amben)). The near axial g values for the copper complexes indicates that d_{xz} and d_{yz} are nearly degenerate in these complexes. This apparent large splitting of d_{xz} and d_{yz} is not an artifact of our choice of ground state since any attempt to analyze the e.s.r. results in terms of a $^2A_1$ ground state also requires this same large splitting. Analysis of e.s.r. results on Co(sacsac) and $Co(mnt)_2^{2-}$ (11) in terms of a $^2A_1$ ground state also required the d_{yz} orbital to be much higher in energy than the d_{xz} orbital. It appears to be generally true that Co(II) complexes involving two chelate ligands have a large splitting of the d_{xz} and d_{yz} orbitals while the corresponding Cu(II) complexes have nearly degenerate d_{xz} and d_{yz} orbitals. We have no explanation for this but feel it is somehow connected to the fact that symmetry requires the d_{xz} and d_{yz} orbitals to interact with different π orbitals in the ligands.

It has been suggested that the large value of $\Delta[^2B_1(xz \rightarrow yz)]$ is not due to a difference in orbital energies but due to a difference in the repulsive coulombic and exchange integrals for d_{xz} and d_{yz}. Although this may be true, it does not really answer the question because if we accept the proposition that the coulombic and exchange integrals for d_{xz} and d_{yz} with the other d orbitals are very different; then the 'hole formalism' method of treating d^7 and d^9 configurations breaks down and we must conclude that all d–d transitions in both Co(II) and Cu(II) complexes involve nonzero repulsive energy differences. Following this reasoning further, we find we must now ask why the coulombic and exchange integrals for d_{xz} and d_{yz} are the same for Cu(II) complexes and very different for Co(II) complexes and therefore have not really solved the problem at all.

Analysis of the copper results yields little that is new or different from that found for other copper nitrogen complexes. The copper hyperfine terms in axial symmetry can be expressed (20) as

$$[10]\quad A_{\parallel} = K + P\left[-\frac{4}{7} + (g_{\parallel} - 2.0023) + \frac{3}{7}(g_{\perp} - 2.0023)\right]$$

$$[11]\quad A_{\perp} = K + P\left[\frac{2}{7} + \frac{11}{14}(g_{\perp} - 2.0023)\right]$$

These equations give $P = 217.5 \times 10^{-4}\ cm^{-1}$ and $K = -116.3 \times 10^{-4}\ cm^{-1}$ for Cu(amben) and $P = 237.6 \times 10^{-4}\ cm^{-1}$ and $K = -111.4 \times 10^{-4}\ cm^{-1}$ for Cu(benacacen). The values of K and P are consistent with the values found for other copper complexes (20). The smaller value of P for Cu(amben) would indicate slightly more σ bonding in this system consistent with a higher ligand field interaction for this ligand (5, 9).

Since very few reliable values of ^NA and ^NB are found in the literature, it is of interest to compare our values with those found for other complexes. Theory gives for ^NA and ^NB the approximate equations (24).

$$[12]\quad {}^NA = C_s^2A_{2s} + 2C_p^2A_{2p} + g_{\perp}P_M(1 - 4C_p^2)$$

$$[13]\quad {}^NB = C_s^2A_{2s} - C_p^2A_{2p} - \frac{1}{2}g_{\parallel}P_M(1 - 4C_p^2)$$

$$[14]\quad A_{2s} = \frac{4}{3}g_e g_N \beta_e \beta_N |\phi_{2s}(0)|^2$$

$$[15]\quad A_{2p} = \frac{2}{5}g_e g_N \beta_e \beta_N \langle r^{-3}\rangle_{2p}$$

$$[16]\quad P_M = g_e g_N \beta_e \beta_N / R^3$$

where g_e and g_N are electronic and nuclear g factors, β_e and β_N are electronic and nuclear magnetons, $|\phi_{2s}(0)|^2$ is the probability of a nitrogen 2s orbital at the nitrogen nucleus, $\langle r^{-3}\rangle_{2p}$ is average value of r^{-3} for a nitrogen 2p orbital, and R is the distance between a copper and nitrogen atom. From Morton (26) we obtain the values of $A_{2s} = 513 \times 10^{-4}\ cm^{-1}$ and $A_{2p} = 15.9 \times 10^{-4}\ cm^{-1}$. Assuming $R = 1.95$ Å gives $P_M = 0.26 \times 10^{-4}\ cm^{-1}$. C_p and C_s are MO mixing coefficients for a nitrogen atom 2p and 2s orbital in the MO containing the unpaired electron. The p orbital is σ in character. Values of C_s^2 and C_p^2 obtained from eqs. 12–16 are given in Table 3 for a series of copper complexes, including those studied here. In the case of Cu(amben) and Cu(benacacen) the errors in C_s^2 are $\sim \pm 0.001$ while those in C_p^2 are $\sim \pm 0.02$. Presumably similar errors apply to values from the literature.

It is seen from the data in Table 3 that in general C_p^2 is two to three times that of C_s^2 indicating that σ bonding to nitrogen occurs through an sp^2 to sp^3 hybrid. The main variation appears to be in C_s^2 which becomes larger for those ligands giving rise to the larger ligand

The Distribution of Oxidation States of Iodine Isotopes in the Fission by Protons of Natural Uranium[1,2]

M. DIKŠIĆ AND L. YAFFE

Department of Chemistry, McGill University, Montreal, Quebec H3C 3G1

Received June 27, 1975

M. DIKŠIĆ and L. YAFFE. Can. J. Chem. **53**, 3801 (1975).

Oxidation states of iodine, produced in the fission of uranium by protons of energies 30 and 80 MeV in solid matrices of $UO_2(NO_3)_2.6H_2O$ and $UO_2SO_4.3H_2O$, have been studied. No proton energy dependence was found. The percentage distribution of I^{7+} as $(IO_4)^-$ is independent of the matrix. However I^{5+} (as IO_3^-) is enriched at the expense of the reduced state ($I_2^0 + I^-$) due to oxidation by the $(NO_3)^-$ formed by the radiation decomposition of $UO_2(NO_3)_2.6H_2O$. Formation of the nuclide by isomeric decay does not perturb the distribution. The result of β^- decay is to increase the I^{7+} component. Iodine isotopes formed independently in fission have the same distribution of oxidation states, but not unique enough to serve as a measure of this mode of formation.

M. DIKŠIĆ et L. YAFFE. Can. J. Chem. **53**, 3801 (1975).

On a étudié les états d'oxydation de l'iode produit par la fission de l'uranium par des protons d'énergies 30 et 80 MeV dans des matrices solides du $UO_2(NO_3)_2 \cdot 6H_2O$ et $UO_2SO_4 \cdot 3H_2O$. On n'a pas trouvé de dépendance sur l'énergie des protons. La distribution des pourcentages de I^{7+} sous forme de $(IO_4)^-$ est indépendante de la matrice. Toutefois I^{5+} sous forme de (IO_3^-) est enrichi au dépens de l'état réduit ($I_2^0 + I^-$) dû à l'oxydation par $(NO_3)^-$ formé par la décomposition sous radiation de $UO_2(NO_3)_2 \cdot 6H_2O$. La formation de nuclides par décomposition isomérique ne perturbe pas la distribution. Le résultat d'une décomposition β^- est d'augmenter le composant I^{7+}. Les isotopes de l'iode formés indépendament dans la fission ont la même distribution d'état d'oxydation; cette distribution n'est toutefois pas suffisamment spécifique pour servir de mesure pour ce mode de formation.

[Traduit par le journal]

Introduction

Theoretical calculations (1–13) have shown that fission fragments should initially have a large positive charge. The linear velocity of the fragment following fission is very large compared to the slower-moving electrons, which will be left behind, and Perfilov (4), *e.g.*, has suggested an average initial charge of the fragments of ~20. These fragments will be very unstable chemically, and thus would abstract electrons from the matrix, leading to a dependence of the distribution of chemically stable oxidation states on the matrix (5, 6). The final distribution will also depend on the mode of disintegration, *e.g.* isomeric transition, short-lived isobaric precursor, etc. Changes in chemical states as a result of isomeric transitions have been studied for a variety of radionuclides (7–12).

The chemically stable oxidation states of iodine in solution are -1, 0, $1+$, $5+$, and $7+$. The chemical behavior of these oxidation states in solution is quite complex and not yet completely understood. The behavior of iodine in tracer quantities often differs from that of the element in macro concentrations (13, 14). Exchange between different chemical states is not likely in a solid matrix (15) on the tracer level, but might readily occur in solution. Burgus and Davies (14) have studied exchange reactions between different oxidation states of iodine as a function of concentration, time, and p*H*. The exchange between I^-–(IO_3^-) has been reported to be slow (16–19) at room temperature.

Brown and Wahl (20) suggested that the dependence of oxidation state on mode of formation of the fragment might be put to practical advantage. If the oxidation states were all the same for species formed independently in fission, these might be distinguished from those formed by isobaric decay of a precursor. Erdal *et al.* (21) determined the dependence of oxidation states of tin isotopes as a function of the β-decay process.

Differences in the oxidation states of iodine isotopes formed in fission have been reported by several groups (6, 22–27) and qualitative relationships have been proposed to explain the distribution of oxidation states as a function of the mode of formation of the isotopes. However, many of these appear as a combination of an isomeric transition and the result of a β-decay. Moreover, some of these isomeric transitions have only recently (28) been found, *e.g.* ^{134m}I, and thus were not taken into account. In addition, in previous work, separation of the fission-produced iodine commenced only after a time long enough to allow tellurium precursors to decay to iodine, thus introducing a product resulting from the combination of isomeric transition, direct formation, and β-decay.

No data are available for oxidation states of iodine produced by the proton-induced fission of uranium. This is the basis of the work presented in this paper. Separations were made as quickly as possible after irradiation. The nuclide ^{128}I is shielded from β-decay and was used at 80 MeV as an internal standard, presumably indicative of the distribution of oxidation states for a primary fragment. Cross sections at 30 MeV were too small to enable this to be used. No metastable state of ^{128}I has yet been reported, even though other odd–odd iodine isotopes in this mass region have such known states, *e.g.* ^{130}I, ^{132}I, ^{134}I, ^{136}I.

Experimental

(a) Exchange Experiments

Experiments were initially made to check the exchange of oxidation states under identical conditions used in the present investigations. Tracer ^{131}I was used in the form of I^- and IO_3^- to perform those experiments.

A mixture of ^{131}I in KI was oxidized to I_2^0 with NO_2^- in acid solution and I_2^0 was extracted with CCl_4. A stock solution of IO_3^- was prepared by oxidizing the I_2^0 with HNO_3. The $*I^-$ solutions (* refers to the tracer label) were prepared by reducing the I_2^0 with aqueous bisulfite solutions, and 6 *M* HNO_3 was added to the solution to destroy the bisulfite ion. The solution of labelled I^- was used the same day for the exchange experiments.

Experiments to determine whether exchange occurred between $*IO_3^-$ and IO_4^-, I_2^0 and $*IO_3^-$, $*I_2^0$ and IO_4^-, $*I^-$ and IO_3^-, $*I^-$ and IO_4^-, and $*IO_3^-$ and IO_4^-, both in 0.1 *M* HNO_3 and in the presence of uranyl nitrate and uranyl sulfate. Procedures used were similar to those of Willard and Thompson (22) and Burgus and Davies (14).

The fractions were separated approximately at the same time as in the post-irradiation studies. The I^- activity in the IO_4^- fraction was found to be just under 2%. No other exchange was observed in any of the other systems.

(b) Oxidation Distribution Studies

Samples of either uranyl nitrate or uranyl sulfate were placed in thin-walled aluminum tubes and irradiated in the internal circulating beam of the McGill proton synchrocyclotron. The targets after irradiation were dissolved in distilled H_2O (about 15 min after the end of the irradiation), made 0.1 *M* in HNO_3 and (typically 2 min after dissolution) $\sim 7 \times 10^{-4}$ mol IO_4^-, $\sim 7 \times 10^{-4}$ mol IO_3^-, and 7×10^{-5} mol I^- were added. The addition of the I^- resulted in its oxidation to I_2^0 by the IO_4^-. The *I_2^0 fraction* (representing the initial I^- and I_2^0 fractions), was extracted into CCl_4. The *IO_3^- fraction* was precipitated at *pH* = 3 by a 25-fold excess of Ba^{2+} ion. After separation, this fraction was reduced with hydroxylamine and the I_2^0 extracted into CCl_4. The *IO_4^- fraction* was precipitated with Bi^{3+} from 1 *M* HNO_3, reduced with $NH_2OH.HCl$ solution and I_2 extracted into CCl_4.

In each case for further purification, the iodine was re-extracted into HSO_3^- solution, oxidized with NO_2^-, and again reduced with HSO_3^-. The samples were finally precipitated as AgI, dried at 110 °C, and chemical yields determined by weighing.

The timing of the separation of each fraction was typically as follows. ($I^- + I_2^0$): about 2 min after the oxidation of I^- to I_2^0, IO_3^- and IO_4^- about 10 and 20 min respectively after the above oxidation. The I_2^0 was in contact with other oxidation states for a maximum period of 2 min.

The γ-radiation was measured by a 30-cc Ge(Li) detector, with a resolution at full-width at half-maximum of ~2.8 keV at 1.33 MeV, connected to a 4096-channel pulse-height analyzer. Full-peak areas were computed by subtracting a straight-line background using a computer code. The activities were determined and extrapolated to the end of irradiation by the CLSQ least-squares computer code (29).

Results and Discussion

The distribution of iodine isotopes found in different oxidation states is given in Tables 1–3. The first two tables contain results obtained from the fission of naturally-occurring uranium induced by protons of energies 30 and 80 MeV re-

TABLE 1. Distribution of oxidation states (%) of iodine isotopes in the fission of uranium (as $UO_2SO_4.3H_2O$) by protons of energy 80 MeV

Isotope	Relative amount		
	$I^- + I^0$	IO_3^-	IO_4^-
^{128}I	56±8	30±8	14±5
^{130}I	59±3	24±2	17±1
^{131}I	42±3	29±3	29±3
^{132m}I	59±5	24±2	17±2
$^{132m+g}$I	55±1	23±1	22±1
^{133}I	45±2	29±1	26±1
^{134}I	48±3	26±1	26±1
^{135}I	58±2	25±1	17±1

^{135}I	36±4	47±4	17±2

spectively in a matrix of $UO_2SO_4.3H_2O$. Table 3 shows the distribution obtained in a matrix of $UO_2(NO_3)_2.6H_2O$ with protons of 80-MeV energy. A comparison of Tables 1 and 2 shows no apparent energy dependence for the same matrix. The kinetic energy of the fragments does not differ significantly for fission induced by 30- and 80-MeV protons (30), so from this point of view an energy difference would have been surprising. Dehmer and Wahl (31), at any rate, showed that a recoil energy of ~100 eV was all that was needed for the reduction of higher oxidation states of tin to Sn^{2+} (an amount infinitesimally small compared to the recoil energies occurring in fission).

However, as the bombarding energy increases, Z_p, the most probable nuclear charge in fission will shift (32) towards Z_A, the most stable charge for mass A. Thus the ratios of nuclei formed directly in fission to those formed by the β-decay of a precursor or from an isomeric state will be quite different for 30 and 80 MeV bombarding energies. This would be expected to have a large influence on the distribution of oxidation states (see later discussion).

The percentage distribution of IO_4^- shows very little influence of the matrix on the oxidation states (*cf.* Tables 1 and 3). However, in the case of the other two oxidation states, I^{5+} (as IO_3^-) is enriched in the nitrate matrix directly at the expense of the reduced states ($I^- + I^0$) as shown in Table 4. This can readily be accounted for by the irradiation decomposition of uranyl nitrate. The standard oxidation–reduction potential for reducing NO_3^- to its reduced form is 1.3 V, sufficient to oxidize I_2 to IO_3^- (1.2 V), but not sufficient to oxidize IO_3^- to IO_4^- (1.7 V) (33). Thus the 'primeval' distribution should be that found in the sulfate matrix. One would expect, if this were the only mechanism occurring, to find the same percentage change for all the iodine isotopes. This within the limits of experimental error is true, with the exception of ^{130}I, ^{131}I, and ^{134}I. Some other mechanism, as yet unexplained, contributes to this difference.

The difference in distributions among the iodine isotopes themselves can be better understood if one understands their genetic origin. These are shown in Table 5 which lists the mode of production and calculates the percentage formed independently, taking into account cross sections for independent formation of the iodine isotopes and their precursors (34–36), and the contribution from the precursor during the irradiation (2 min) and from the end of irradiation till chemical separation (20 min) using known half-lives (37) and standard growth and decay equations.

The data in Table 1 show that ^{128}I (which has large error bars because of its low formation

TABLE 4. Differences in distributions of oxidation states of iodine isotopes formed in the fission of uranium by protons of energy 80 MeV as a function of matrix
[N = $UO_2(NO_3)_2.6H_2O$, S = $UO_2SO_4.3H_2O$]

Isotope	$\Delta_{IO_3^-}$ (N − S)	$\Delta_{I^-+I^0}$ (N − S)
^{128}I	16±12	−24±10
^{130}I	37±4	−36±3
^{131}I	16±6	−16±5
^{132m}I	27±5	−28±6
$^{132m+g}I$	31±2	−28±2
^{133}I	21±3	−23±3
^{134}I	18±2	−17±4
^{135}I	22±4	−22±4

TABLE 5. Production of iodine isotopes studied

Isotope	Mode of production	% Independent formation
^{128}I	Independent	100
^{130}I	Independent + isomer	97
^{131}I	Independent + ^{131}Te decay	58
^{132m}I	Independent	100
$^{132m+g}I$	Independent + isomer	70
^{133}I	Independent + ^{133}Te decay	69
^{134}I	Independent + isomer + ^{134}Te decay	34
^{135}I	Independent + ^{135}Te decay	91

cross sections at these energies), and ^{132m}I, each formed 100% independently have virtually similar distributions. However, the distribution is not unique enough to enable this to be a measure of independent formation (20). Distributions similar to these are also found in ^{130}I and $^{132m+g}I$, indicating that formation by isomeric decay does not perturb the distribution. The same conclusion has been reached by Jones (39), who studied the chemical effects of internal conversions (IT) of ^{80}Br in $NaBrO_3$ crystals, and Jones and Warren (41) who investigated the chemical effects of IT in ^{131}Te and the results of the β^- decay of ^{132}Te in telluric acid crystals. The study most closely related to the present one is the work of Hall and Walton (26) who studied the distribution of oxidation states of iodine isotopes produced in the thermal-neutron fission of uranium in $UO_2(IO_3)_2.H_2O$ crystals as a function of neutron dose and decay time. In their studies ^{135}I, which is mainly formed directly in the fission process at low excitation energies, behaved differently from the other iodine isotopes. Fragments formed directly in the fission process are stripped of approximately 20 electrons and thus one would expect those isobars closest in atomic number to the original fragments to be found in the highest oxidized state. The data reported in this paper, however, show that those products which are formed mainly independently, *e.g.* ^{132m}I, ^{128}I, and ^{130}I are the least oxidized. This is evidence for the fact that the initial electronic charge has no major effect on the final distribution in solid matrices. Similar conclusions were indeed reached by Hall and Walton (26) for their fissioning system.

It is very difficult to compare these conclusions with the data from other previous work. For example, Gordon (38) studied the distribution resulting from the decay of ^{132}Te and suggested a major role for Auger electrons in the break-up of the tellurate molecule. However, the study, unlike the present, was done in aqueous solution. Hillman and Weiss (7) studied the effect of the isomeric transition in ^{127}Te and ^{129}Te. Contrary to Gordon, they found no difference in yields of products resulting from decay of the monomeric and polymeric forms of tellurium, but found higher yields of Te(IV) resulting from the IT decay of a Te(IV) parent. However, again in aqueous solution vacancies could very quickly be occupied by electrons from the solvent and thus molecular disruption may not occur.

Bulbulian and Maddock (40) in the thermal annealing of telluric acid crystals studied the influence of isomeric transitions from ^{121}Te, ^{127}Te, and ^{129}Te. From their results one can derive the conclusion that the greater the percentage of isomeric transition in the decay (*cf.* ^{121}Te and ^{129}Te), the greater the retention of Te(VI). However, one should remember that the environment in their solid matrix has undergone less radiation damage than that in the present case.

In the case of the solid matrix used in this study the fission fragment will be thermalized and brought to rest in a region which has received very great radiation damage: a very 'hot' spot. Here one would have very little influence by the Auger electrons released during the isomeric transition, since the area would contain large numbers of free electrons.

Our results, *cf.* ^{131}I, ^{133}I, and ^{134}I, would indicate that in the solid matrix, the influence of β^--decay is to increase the I^{7+} component. Similar increases of the oxidized forms of iodine formed in β^- decay were reported by Hall and Walton (26). ^{135}I, which is produced mainly independently in this study, conforms to the independent distribution with a slight β-decay contribution.

If one examines Table 3, bearing in mind the oxidation effect due to matrix decomposition discussed earlier, the same trends are apparent.

The authors wish to record their appreciation once more to Professor S. K. T. Mark, Director, Foster Radiation Laboratory, for his cooperation.

The authors are also pleased to acknowledge with thanks valuable discussions with Dr. A. G. Maddock.

The Temperature Dependence of Raman Band Parameters for Aquated Mg(II) and Zn(II)

J. TIMOTHY BULMER, DONALD E. IRISH,[1] AND LARS ÖDBERG[2]

Guelph-Waterloo Centre for Graduate Work in Chemistry, Waterloo, Ontario N2L 3G1

Received July 3, 1975

J. TIMOTHY BULMER, DONALD E. IRISH, and LARS ÖDBERG. Can. J. Chem. **53**, 3806 (1975).

The weak polarized Raman bands, previously assigned to the ν_1 mode of the octahedral species $Mg(H_2O)_6^{2+}$ and $Zn(H_2O)_6^{2+}$, have been studied over the temperature ranges -32 to 99 °C and -29 to 80 °C respectively. The signal-to-noise ratio has been enhanced by multiscan averaging with a spectrometer interfaced to a PDP/11 computer. The digitized band profiles have been examined analytically to extract these parameters: position of maximum, position of centroid, full width at half height (f.w.h.h.), and intensity. The dependence on concentration and acidity has also been measured. Whereas the 390 cm^{-1} line of aquated zinc(II) shifts only 3 cm^{-1} to lower frequencies and broadens by about 16 cm^{-1} for a 110 °C temperature increase, the 362 cm^{-1} band of aquated magnesium(II) shifts down by 15 cm^{-1} but broadens to the same extent for a 130 °C temperature increase. The results are interpreted in terms of the difference in the magnitude of forces between these cations and hydrated water molecules.

J. TIMOTHY BULMER, DONALD E. IRISH et LARS ÖDBERG. Can. J. Chem. **53**, 3806 (1975).

On a étudié les bandes Raman faibles polarisées assignées antérieurement au mode ν_1, des espèces octaédriques $Mg(H_2O)_6^{2+}$ et $Zn(H_2O)_6^{2+}$, à des températures respectives allant de -32 à 99 °C et -29 à 80 °C. Le rapport signal à bruit a été augmenté en moyennant, à l'aide d'un balayage répétitif, avec un spectromètre relié avec un ordinateur PDP/11. Les profils des bandes digitalées ont été examinés d'une façon analytique pour en extraire ces paramètres: position du maximum, position du centroide, largeur complète à demi hauteur et intensité. On a aussi mesuré la dépendance sur la concentration et sur l'acidité. Alors que la ligne à 390 cm^{-1} du zinc(II) aqueux se déplace de 3 cm^{-1} vers les fréquences les plus basses et s'élargit par environ 16 cm^{-1} lorsque la température est augmenté de 110 °C, la bande à 362 cm^{-1} du magnésium(II) aqueux se déplace vers les bas champ par 15 cm^{-1} mais s'élargit par la même quantité pour une augmentation de température de 130 °C. On interprète les résultats en termes d'une différence dans l'amplitude des forces entre ces cations et les molécules d'eau hydratées.

[Traduit par le journal]

Introduction

Many physicochemical properties of electrolyte solutions have been rationalized by considering ions to bind water molecules to themselves sufficiently strongly that discrete species are formed. Especially for polyvalent cations, the species have been described as aquated cations or aquocomplex ions. In accordance with the model of Frank and Wen (1) a specific number of water molecules, the hydration number, occupy the peripheral solvation sphere and assume a reasonably well-defined spatial arrangement. For some cations, possibly Be^{2+}, a secondary layer of water molecules may be bound relatively strongly to the first but more often the secondary solvation sheath is conceived as consisting of a region occupied by disordered molecules interposed between the hydrogen-bonded structure of bulk water and the ion-imposed structure of the aquated cation (1). Hydration numbers have been estimated by a large number of methods, often yielding discordant results, but for many ions there is a growing confidence that reasonable values have been obtained (2, 3).

One of the more direct manifestations of aquated cations is the observation of low-frequency vibrational bands. These bands have been observed for both crystalline hydrates (4–8) and aqueous solutions (4, 9–12). For the latter, the Raman bands are weak and diffuse, and there is some disagreement in the literature as to the existence of certain bands (8, 11). The observation of Raman intensity implies some covalence in the interaction and it is thus not surprising

that signals are strongest from those cations which are most electronegative (12); indeed lines have not yet been detected for ions of family 1A, or the heavier atoms of families 1B and 2A. The only characteristics reported have been frequencies and some estimated depolarization ratios.

In this study the potential of a laser Raman spectrometer interfaced to a PDP 11/20 computer has been exploited to obtain quality spectra of the ν_1 totally symmetric stretch of hexaquomagnesium(II) and hexaquozinc(II) ions. Frequencies, line widths (f.w.h.h.), intensities, and asymmetries have been studied over the temperature range −32 to 99 °C. Dependence on p*H* and concentration have also been examined. Accuracy and sensitivity was enhanced by multiple-scan averaging and spectral analyses were performed by digital computer methods.

Experimental

Fisher reagent grade magnesium nitrate and zinc nitrate were used without further purification. Solutions were prepared by weight and filtered before use through 0.6 μm Millipore filters. Raman spectra were excited by the 514.5 nm line of a Spectra-Physics 165 argon ion laser operating at 1.4 W and were recorded on a Jarrell-Ash 25-100 spectrophotometer equipped with SSR model 1105/1120 photon counting equipment, interfaced to a PDP 11/20 computer. Details are published elsewhere (13). Typical accumulation times were 8 h for Mg^{2+} and 4 h for Zn^{2+}. A spectral slit width of 6 cm^{-1} was used throughout the experiments. Depolarization ratios were obtained using a Polaroid analyzer and a Karl Lambrecht polarization scrambler mounted in the Jarrell-Ash accessory. Single spectra of the perpendicular and parallel components were recorded for this purpose.

Samples contained in sealed melting point tubes were placed in a specially constructed, variable temperature housing (Fig. 1). An evacuated chamber provided insulation from the surroundings and insured frost-free windows. The inner wall (H) of this jacket was a cylindrical Pyrex glass finger (17 mm i.d.) terminating in a graded glass-to-metal seal (N). The outer metal wall (B), contained an inlet window (A) and an outlet window (D) for the laser beam, a 25 mm window (C) for detection of the 90° scattered Raman signal, and a viewing window (G). The melting point tube was positioned in a recess (J) in a central copper block (I); a copper–constantan thermocouple (O) was mounted into this block. Temperature was controlled by the passage of nitrogen gas through the inner compartment; the gas came from liquid nitrogen boil off for low temperatures or from an electrical heater for high temperatures. The assembly was positioned on the Jarrell-Ash tripod, equipped with a translation stage for alignment. The laser beam passed down through the entrance window, glass wall, sample tube, glass wall, and exit window to focus on an alignment spot. Temperature was monitored with a Hewlett Packard 3420A differential voltmeter. The temperature stability was within ±1 °C.

The computer data analysis commenced with the summation of the individual scans. The curved background arising from the Rayleigh wing was then removed by the subtraction of an exponential–quadratic baseline. The advantages of this baseline function have recently been described in detail (13). The FORTRAN program for background removal also applies a trapezoidal area calculation to evaluate the intensity of the baseline-corrected spectrum and permits smoothing. Band statistics such as half-band width, peak maximum, and centroid of the baseline-corrected spectra were determined using a modified version of the program PC 134 developed by Jones *et al.* (14). Estimated errors in the band parameters are: $\bar{\nu}_{max}$, ±1 cm^{-1}; f.w.h.h., ±2 cm^{-1}; centroid, ±2 cm^{-1}; relative intensities, ±5%. A linear baseline correction and trapezoidal area calculation were applied to the 1050 cm^{-1} band of nitrate ion, recorded as an internal intensity reference. Band fitting was performed with an adaptation of the Murphy and Bernstein modification (15) of the program developed by Pitha and Jones (16).

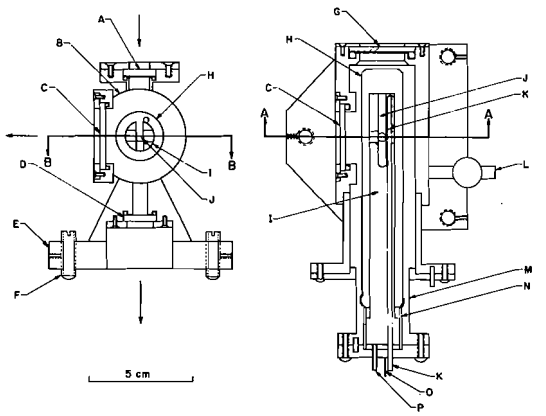

FIG. 1. Cross sections of sample thermostat. AA (end view): A, entrance window; B, outer metal jacket; C, window for collection of scattered light; D, exit window; E, base plate; F, levelling screw. Results

Zinc Nitrate

The Raman spectrum of 3.36 *m* zinc nitrate solution at 80 °C is shown in Fig. 2. The baseline obtained as described in the experimental section is also shown. The band parameters are given in Table 1. The intensity is expressed as a percentage of one-half the integrated intensity of the 1050 cm^{-1} line from the nitrate ion present; it is thus based on equal populations of the two species. In Fig. 3 the baseline-corrected spectra of samples held at the different temperatures are presented.

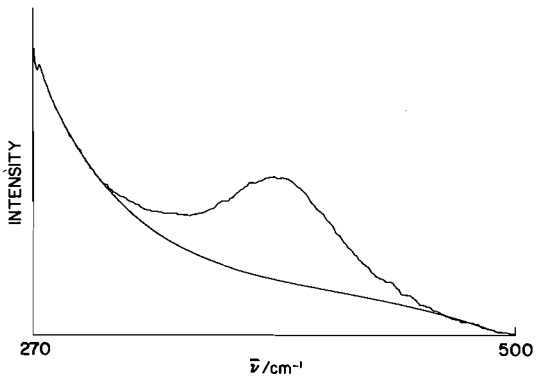

FIG. 2. Raman spectra of a 3.36 mol kg^{-1} $Zn(NO_3)_2$ solution at 80 °C. Accumulation time, 4.2 h. The exponential-quadratic baseline is also shown.

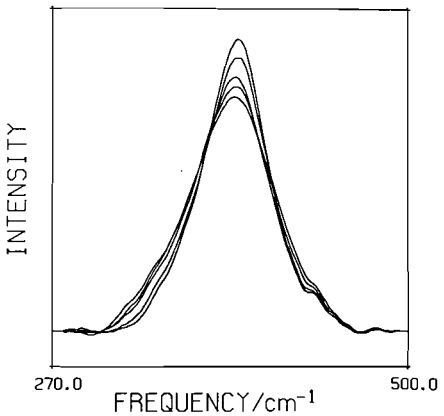

FIG. 3. Baseline-corrected, smoothed spectra of the 3.36 mol kg^{-1} $Zn(NO_3)_2$ solution at temperatures −29, −2, 24, 51, and 80 °C, in order of decreasing amplitudes.

The observed band is highly polarized. The depolarization ratio at −30 °C is 0.05 ± 0.02, and it decreases with increasing temperature. At temperatures above 25 °C we could no longer detect a perpendicular component, which implies $\rho < 0.02$.

Magnesium Nitrate

In Fig. 4, baseline-corrected Raman spectra for a 3.06 *m* magnesium nitrate solution recorded at different temperatures are plotted. The band parameters are given in Table 2. We have also investigated the dependence of the magnesium band parameters on concentration at 25 °C. The results are given in Table 3. To some samples concentrated HNO_3 was added. No changes in the spectra could be detected. Polarization studies revealed no perpendicular component of the band which implies $\rho < 0.05$; the band possesses only an isotropic component.

Discussion

If one accepts the view that the magnesium and zinc cations exist in solution as octahedral hexaquocations (2, 3) the representation of the normal modes and their activities are $A_{1g}(R) + E_g(R) + 2F_{1u}(i.r.) + F_{2g}(R) + F_{2u}(i.a.)$, neglecting the hydrogen atoms of water. From vibrational spectra of crystals (5, 6) and normal coordinate calculations (7) the Raman frequencies are 370, 205, 253 cm^{-1} for $Mg(H_2O)_6^{2+}$ and 393, 200, 296 cm^{-1} for $Zn(H_2O)_6^{2+}$. In aqueous solutions, vibrations at 357–365 and 240 cm^{-1}, and 385–400 and 230 cm^{-1}, have been reported for magnesium and zinc respectively (9–12). Da Silveira *et al.* (9) report a vibration at 315 cm^{-1} for concentrated magnesium solutions and at 335 cm^{-1} for concentrated zinc solutions. These two vibrations are within the spectral regions investigated by us. We found no evidence of these bands and doubt that they arise from the hexaquocations (8). Ananthanarayanan (6, 7) also reports no such lines. The vibrations at 360 and 390 cm^{-1} are the only ones with sufficient intensity for a quantitative study. The high polarization of these two bands strongly supports

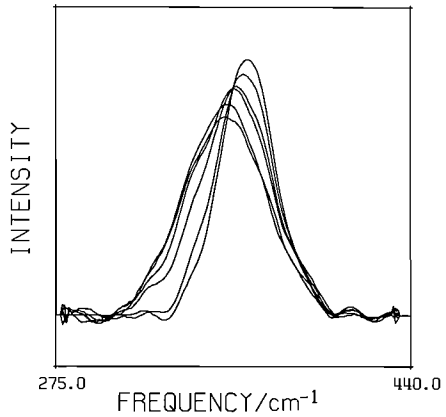

FIG. 4. Baseline-corrected, smoothed spectra of the 3.06 mol kg^{-1} $Mg(NO_3)_2$ solution at temperatures −32, −4, 26, 52, 80, and 99 °C, in order of decreasing amplitudes.

the assignment to the A_{1g} symmetric vibration.

From the results in Table 1 and Fig. 3 it can be seen that the band parameters for zinc, except the line width, stay virtually constant. This suggests that the hydrated zinc ion is a well-defined stable complex in the temperature interval investigated. The relatively high intensity of the vibration implies a substantial degree of covalent character of the metal–oxygen bond (17), and supports the assumption of a well-defined aquozinc complex.

For low frequency vibrations the excitation of 'hot bands' must be considered. At the lowest temperatures investigated 10% of the molecules occupy the $v = 1$ level and this fraction increases to about 20% over the temperature range. Thus transitions $2 \leftarrow 1$ must contribute to the observed contour. The small 3 cm^{-1} shift to low frequencies of both the band maximum and the centroid may arise from these transitions, but if so the anharmonicity of the potential surface cannot be large.

The broadening of the band with temperature increase is probably attributable to increased collisional frequency and vibrational energy transfer. The processes

$$2M(v = 1) \rightarrow M(v = 0) + M(v = 2)$$

and

$$M'(v = 1) + M(v = 0) \rightarrow M'(v = 0) + M(v = 1)$$

would decrease the lifetime in the excited state, τ, and increase the linewidth, $\bar{\nu}_{1/2}$; these are related by $\bar{\nu}_{1/2} = (\pi c \tau)^{-1}$ (18). The isotropic part of the scattered light is independent of reorientational changes and thus for the strongly polarized bands studied in this work contributions to the line shape from such motions can be

neglected. Such processes may make a small contribution to the line shape of the band from $Zn(H_2O)_6^{2+}$ at the lowest temperatures, where a slightly larger value of ρ was observed, but vibrational motions must be the greatest contributor to the line shape.

Another process which may contribute to line broadening is the exchange of water between the hydration sphere and the bulk solvent. From n.m.r. (19, 20) and ultrasonic studies (21) a rate of the order of 10^6 s^{-1} at room temperature and an activation energy of 12–14 kcal mol^{-1} have been inferred. Although presence of acid or nitrate ion may enhance this rate (22), this process is about five orders of magnitude too slow to broaden a Raman line (23). The observed line was also unaltered by addition of acid. For these reasons we believe this process need not be considered.

For the magnesium ion there is a significant decrease in the vibration frequency and the line shape changes as temperature increases. The potential surface for aquated magnesium is not likely to differ significantly from that of aquated zinc and thus 'hot bands' are not considered to be responsible for these differences. We will explore the plausibility of explanations which involve changes in the solvation number or the solvation geometry.

From examination of Fig. 4 one might infer that increase in temperature causes a lower frequency band to increase in intensity at the expense of the 362 cm^{-1} band. In order to evaluate appropriateness of a two-line model the contours were resolved into two Cauchy–Gauss product functions (15, 16). The effect of constraining the shape function, the positions and/or f.w.h.h.'s for the series was explored. Two bands at 362 and 343 cm^{-1} do fit the contours reasonably well. Two lines could imply a two species equilibrium

$$Mg(H_2O)_6^{2+} + (x - 6)H_2O \rightleftharpoons Mg(H_2O)_x^{2+}$$

In general when an additional halide ion binds to a metal ion the symmetric stretch of the resulting complex occurs at lower frequency (12). The series of complexes $TlCl_x^{(3-x)}$ provides one example of this trend: ν_1 shifts from 327 to 305 in about 7 cm^{-1} steps as x increases from 1 to 4 (24). A new line at 343 cm^{-1} could thus result from the addition of water to the solvation sphere of magnesium for temperatures ≥ -4 °C. From compressibilities and ionic vibration potentials Bockris and Saluja (25) obtained a solvation number of ten for Mg^{2+} which decreased to about five with increasing concentration. The Raman band profile exhibited no significant change in shape for a concentration increase from 1.02 to 4.36 *m*. The dilute solution value of Bockris and Saluja is not consistent with the value six obtained by n.m.r. experiments at low temperatures (22, 26, 27). Although the temperature increase would weaken the water–cation binding and thus permit entry of more water molecules, an increase of four seems unlikely; a closest-packed structure would be implied.

An alternative model which could require two lines but does not require equilibria between variously hydrated forms is heat-induced distortion of the octahedral symmetry. Weakening (and thus lengthening) of two water–cation bonds would lower the symmetry to D_{4h}. The E_g degeneracy would be lifted giving A_{1g} and B_{1g} modes. Two symmetric stretching modes would then occur; one arises from the stretch of the axial bonds and the other from the stretch of the equatorial bonds. Assignment of the two polarized bands at 362 and 343 cm^{-1} to these modes is analogous to a suggestion by Lundeen and Tobias (28) to explain two bands from $Ag(NH_3)_6^{+}$ for the $AgNO_3/NH_3$ system.

Yet another consideration is the possibility that the hydration sphere is perturbed by the introduction of the nitrate ion at higher temperatures. This is unlikely. No diagnostic splitting or asymmetry of the ν_4 band of nitrate ion was observed at any temperature (*cf.* ref. 11). The position of the maximum of the band from $Mg(H_2O)_6^{2+}$ occurs at 355 cm^{-1} and above whereas when nitrate is contacting Mg^{2+}, due to reduced water content, the line occurs at 345 cm^{-1} and lower (11).

Although it is impossible to exclude the above explanations completely, and some contribution to the line shape may come from these sources, the two-line model is not convincing on other grounds. The correlation coefficients from the band fitting program suggest a lack of uniqueness in the results. This is further indicated by failure to converge on the same fit for two spectra at 79 and 80 °C, and by some inconsistency in trends of f.w.h.h. and the ratio of the two band areas. It should also be noted that the spectra fail to display an isosbestic point (Fig. 4).

An alternative model which requires only a

single band, slightly skewed by the hot band, is attractive. As the temperature rises the entire array of ions and water molecules will move apart. The water–cation bonds would be uniformly weakened and the vibration would monotonically shift to lower frequencies. The fact that this effect is observed for Mg^{2+} and not for Zn^{2+} is consistent with the notion that water molecules are more strongly and symmetrically bound to the latter because of the intrinsic covalence endowed by the 'softer' zinc cation (29). The interpretation appears consistent with X-ray studies of aqueous $Mg(NO_3)_2$ solutions (30).

Magnetic and Spectral Studies on Cobalt(II) and Copper(II) Salts of Methylsulfuric, Trifluoromethylsulfuric, and Paratolylsulfuric Acids

ANITA L. ARDUINI, MAUREEN GARNETT, ROBERT C. THOMPSON, AND TONY C. T. WONG

Department of Chemistry, The University of British Columbia, Vancouver, British Columbia V6T 1W5

Received July 4, 1975

ANITA L. ARDUINI, MAUREEN GARNETT, ROBERT C. THOMPSON, and TONY C. T. WONG. Can. J. Chem. **53**, 3812 (1975).

The compounds $Co(CF_3SO_3)_2$, $Cu(CF_3SO_3)_2$, $Co(CH_3SO_3)_2$, $Cu(CH_3SO_3)_2$, $Co(p\text{-}CH_3C_6H_4SO_3)_2$, and $Cu(p\text{-}CH_3C_6H_4SO_3)_2$ have been prepared and infrared spectra, electronic spectra, and magnetic susceptibility studies are reported. Electronic spectral and magnetic studies have also been made on $Cu(FSO_3)_2$ and previously published data on $Co(FSO_3)_2$ are reexamined here. The studies indicate that in all salts the metal ions are hexacoordinated by oxygen atoms provided by anions acting as tridentate bridging ligands. The MO_6 skeleton is significantly distorted from regular octahedral geometry for all salts with the possible exceptions of $Co(FSO_3)_2$, $Co(p\text{-}CH_3C_6H_4SO_3)_2$, and $Co(CH_3SO_3)_2$. Values of the spin–orbit coupling constants for the salts, as estimated from the magnetic studies, decrease with increasing anion basicity, suggesting a correlation between basicity and the degree of covalent character in the metal–anion bonds. In the case of the cobalt salts the interelectron repulsion parameter B also seems to decrease with increasing anion basicity.

ANITA L. ARDUINI, MAUREEN GARNETT, ROBERT C. THOMPSON et TONY C. T. WONG. Can. J. Chem. **53**, 3812 (1975).

On a préparé les composés $Co(CF_3SO_3)_2$, $Cu(CF_3SO_3)_2$, $Co(CH_3SO_3)_2$, $Cu(CH_3SO_3)_2$, $Co(p\text{-}CH_3C_6H_4SO_3)_2$ et $Cu(p\text{-}CH_3C_6H_4SO_3)_2$ et on rapporte les spectres infrarouges, les spectres électroniques et les études de susceptibilité magnétique. On a aussi déterminé les spectres électroniques et effectué des études magnétiques sur le $Cu(FSO_3)_2$ et on réexamine ici les données publiées antérieurement sur le $Co(FSO_3)_2$. Ces études indiquent que dans tous ces sels les ions métalliques sont hexacoordonnés par des atomes d'oxygène qui leur sont fournis par les anions qui agissent comme ligands tridentates pontés. Le squelette MO_6 est assez déformé de la géométrie octaédrique régulière pour tous les sels à l'exception possiblement de $Co(FSO_3)_2$, $Co(p\text{-}CH_3C_6H_4SO_3)_2$ et $Co(CH_3SO_3)_2$. Les valeurs des constantes de couplage spin–orbite pour les sels, telles que déterminées par les études magnétiques, diminuent avec une augmentation de la basicité de l'anion suggérant une corrélation entre la basicité et le degré du caractère covalent des liens métal–anion. Dans le cas des sels de cobalt, le paramètre B de répulsion interélectronique semble aussi diminuer à mesure que la basicité de l'anion augmente.
[Traduit par le journal]

Introduction

Earlier studies on cobalt(II) and copper(II) salts of fluorosulfuric acid indicated polymeric structures for these compounds with FSO_3^- anions acting as tridentate ligands and metal ions in an environment of six oxygen atoms (1, 2). A structural model was proposed involving a layer type of structure in which each fluorosulfate group acts, via its three oxygen atoms, as a bridge between three different metal ions (2). On the basis of vibrational and electronic spectral studies and magnetic susceptibility measurements $Co(FSO_3)_2$ was shown to have octahedral coordination of cobalt ions with a CoO_6 skeleton not significantly distorted from O_h symmetry. In addition, a relatively high degree of ionic character in the metal–anion bonds was suggested for this salt, consistent with the fact that the fluorosulfate ion is the anion of a very strong acid (3, 4).

The work described here has involved the preparation of a related series of salts: cobalt(II) and copper(II) methylsulfate, trifluoromethylsulfate, and paratolylsulfate. Infrared spectra, electronic spectra, and magnetic susceptibility studies are recorded for these compounds along with the electronic spectrum and magnetic properties of the previously studied salt, $Cu(FSO_3)_2$.

The anions involved here are structurally similar, XSO_3^-, all having the potential to act as tridentate bridging ligands through the three oxygen atoms bonded to sulfur. Indeed, the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

studies to be presented here indicate that the salts all have similar basic structures and that the general structural model proposed previously for transition metal fluorosulfates (2) is equally plausible for all of the salts under consideration. While the anions are structurally similar their electronic properties are different. From studies on the relative acidities of the parent acids (5, 6) the base strengths of the anions may be considered to increase in the order

$$FSO_3^- \approx CF_3SO_3^- < CH_3SO_3^- \approx p\text{-}CH_3C_6H_4SO_3^-$$

The present work examines, in particular, the effect of such anion differences on details of the molecular and electronic structures of the salts.

Experimental

All solvents and starting materials were reagent grade and used without further purification unless otherwise stated. All of the anhydrous salts were found to be very hygroscopic and required handling in a nitrogen atmosphere dry box. The preparation of $Cu(FSO_3)_2$ has been described previously (7). Analyses were obtained in the A. Bernhardt microanalytical laboratories.

Preparations

Copper(II) Methylsulfate, $Cu(CH_3SO_3)_2$

This salt was prepared by the reaction of copper(II) benzoate with methylsulfuric acid in a procedure analogous to that used previously to prepare copper(II) fluorosulfate (7). Methylsulfuric acid was freshly distilled at approximately 120 °C and 1 Torr into a reaction flask containing copper(II) benzoate. Rapid reaction occurred and the insoluble, white, copper(II) methylsulfate was vacuum filtered, washed several times with diethyl ether, and dried under vacuum at room temperature.

Anal. Calcd. for $CuC_2H_6S_2O_6$: Cu, 25.0; S, 25.3; C, 9.46; H 2.38. Found: Cu, 25.2; S, 25.4; C, 9.63; H, 2.56.

Copper(II) Trifluoromethylsulfate, $Cu(CF_3SO_3)_2$

Trifluoromethylsulfuric acid was freshly distilled at about 70 °C and 20 Torr into a reaction flask containing copper(II) benzoate. The white, insoluble, salt was filtered, washed with freshly distilled trifluoromethylsulfuric acid, and dried under vacuum at 60 °C.

Anal. Calcd. for $CuC_2F_6S_2O_6$: Cu, 17.6; C, 6.64; F, 31.5; S, 17.7. Found: Cu, 17.7; C, 6.71; F, 31.5; S, 17.4.

Copper(II) Paratolysulfate, $Cu(p\text{-}CH_3C_6H_4SO_3)_2$

This compound was prepared by the reaction of aqueous solutions of silver(I) paratolysulfate and copper(II) chloride dihydrate in stoichiometric proportions. After removal of precipitated silver(I) chloride from the solution, the filtrate was evaporated to dryness yielding a pale blue solid. Dehydration of this solid by heating to 70 °C under vacuum gave the pale green anhydrous salt.

Anal. Calcd. for $CuC_{14}H_{14}S_2O_6$: Cu, 15.7; C, 41.4; H, 3.48; S, 15.8. Found: Cu, 16.0; C, 41.2; H, 3.72; S, 16.0.

Cobalt(II) Methylsulfate, $Co(CH_3SO_3)_2$

Barium methylsulfate, prepared as described previously (8) and cobalt(II) sulfate heptahydrate were reacted in stoichiometric proportions in aqueous solution. After removal of precipitated barium sulfate, the solution was evaporated to dryness and heating the product at 100 °C under vacuum gave the pale purple anhydrous salt.

Anal. Calcd. for $CoC_2H_6S_2O_6$: C, 9.63; H, 2.43; S, 25.7; Co, 23.7. Found: C, 9.51; H, 2.55; S, 25.5; Co, 23.8.

Cobalt(II) Trifluoromethylsulfate, $Co(CF_3SO_3)_2$

Using a procedure analogous to that described previously for the preparation of cobalt(II) fluorosulfate (2), excess trifluoromethylsulfuric acid was freshly distilled at 8 Torr and 56 °C into a reaction flask containing finely powdered anhydrous cobalt(II) metabromobenzoate. A pink precipitate of cobalt(II) trifluoromethylsulfate formed immediately in the exothermic reaction; the reaction mixture was left stirring for 48 h to ensure completion of the reaction. The solid product was filtered and dried under vacuum at 65 °C.

Anal. Calcd. for $CoC_2F_6S_2O_6$: C, 6.73; F, 31.9; S, 18.0; Co, 16.5. Found: C, 6.91; F, 31.7; S, 17.7; Co, 16.5.

Cobalt(II) Paratolysulfate, $Co(p\text{-}CH_3C_6H_4SO_3)_2$

This salt was prepared by the reaction of aqueous solutions of silver(I) paratolylsulfate and cobalt(II) chloride hexahydrate in stoichiometric proportions. After removal of precipitated silver chloride by filtration, the solution was evaporated to dryness. Heating the product at 120 °C under vacuum gave the pale blue anhydrous salt.

Physical Methods

Infrared spectra were obtained on samples mulled in Nujol and contained between KRS-5 (Harshaw Chemical Co.) plates on a Perkin–Elmer model 457 spectrophotometer. Spectra were calibrated using polystyrene film and frequencies are considered accurate to ± 4 cm^{-1}.

Electronic spectra were obtained on powdered samples (diffuse reflectance) over the range 13.5–28.5 kK using a Bausch and Lomb Spectronic 600 spectrophotometer and on samples mulled in hexachlorobutadiene and Nujol over the range 5–33 kK using a Cary model 14 spectrophotometer. The mull spectra were corrected for background due to light scattering from the sample (2).

Magnetic susceptibilities were determined at field strengths of approximately 4500 and 7000 G using the Guoy equipment and calibration procedure described previously (2). None of the samples gave evidence for dependence of magnetic susceptibilities on field strength. The diamagnetic susceptibilities used to correct molar magnetic susceptibility values for the diamagnetic contributions of ligands and metal ions are: 11×10^{-6} for copper, 13×10^{-6} for cobalt, 40×10^{-6} for FSO_3^-, 46×10^{-6} for $CF_3SO_3^-$, 35×10^{-6} for $CH_3SO_3^-$, and 89×10^{-6} for $CH_3C_6H_4SO_3^-$ (all values in units of cm^3 mol^{-1}).

Results and Discussion

Infrared Spectra

The infrared spectra (over the frequency range 250 to 1400 cm^{-1}) are given in Table 1 together with data previously reported (7) on $Cu(FSO_3)_2$ and $Co(FSO_3)_2$. Previous studies on the vibra-

tional spectra of fluorosulfates (1, 7, 9) methylsulfates (10, 11) and trifluoromethylsulfates (11–14) have provided a considerable amount of information in regard to the fundamental modes of vibration of these anions and, in the present work, have made possible the identification of those bands arising primarily from SO_3 stretching, SC stretching, and SO_3 deformation vibrations of the CSO_3 parts of the anions. This is done in Table 1 where C_{3v} nomenclature is used in band assignment. The $\nu_6(E)$ mode which occurs at 422 cm^{-1} in the spectrum of $Co(FSO_3)_2$ and appears as a split band at 428 and 416 cm^{-1} in $Cu(FSO_3)_2$ is not identified in the spectra of the other salts.

In addition, we were not able to identify with certainty the $\nu_2(A_1)$ mode described as an SC stretch in the spectra of $Cu(CF_3SO_3)_2$ and $Co(CF_3SO_3)_2$. A very weak peak is observed at 775 cm^{-1} in the spectra of both salts and this may be the ν_2 vibration. No attempt is made here at a detailed assignment of the internal vibrations of the CF_3, CH_3, and $CH_3C_6H_4$ parts of the anions. We do note, however, that bands at 1183 and 592 cm^{-1} in $Cu(CF_3SO_3)_2$ and at 1197 and 595 cm^{-1} in $Co(CF_3SO_3)_2$ may be assigned to CF_3 stretching and bending modes respectively. Other bands due to CF_3 vibrations in these salts are obscured by the relatively more intense SO_3 vibrations.

The vibrational spectra of $Co(CF_3SO)_2$ and $Co(p\text{-}CH_3C_6H_4SO_3)_2$ indicate C_{3v} symmetry for the CSO_3 groups in these salts. Within the limitation of resolution of the instrument used ($\sim$3 cm^{-1}) there is no evidence for splitting of either the $\nu_4(E)$ or $\nu_5(E)$ modes which would result from a lowering of symmetry below C_{3v}. We interpret this result as indicating that the anions are acting as tridentate bridging ligands in which the three oxygens are involved in coordination in an equivalent manner to cobalt ions. This form of anion coordination was proposed earlier for a number of metal bisfluorosulfates including $Co(FSO_3)_2$ (2, 7). The CSO_3 groups in $Co(CH_3SO_3)_2$ and $Cu(CF_3SO_3)_2$ have symmetries reduced below C_{3v} as evidenced by a splitting of ν_4 in the case of the copper salt and a splitting of both ν_4 and ν_5 in the case of the cobalt salt. This reduction in symmetry may result from a form of coordination in which two oxygen atoms of each anion are more strongly bonded to the metal ion than the third as described previously for $Cu(FSO_3)_2$ (1, 2).

The infrared spectra of $Cu(CH_3SO_3)_2$ and $Cu(p\text{-}CH_3C_6H_4SO_3)_2$ are relatively more complex than those described above. Whereas a maximum of three bands are expected in each of the SO_3 stretching and deformation regions, four to six bands are observed in these salts indicating the presence of more than one type of anion in the lattice. The postulate of non-equivalent fluorosulfate ions in $Sr(FSO_3)_2$, $Sn(FSO_3)_2$, $Pb(FSO_3)_2$, and $Sn(FSO_3)_4$ was made previously to account for similar complexities in their vibrational spectra (7, 15).

Electronic Spectra and Magnetism of Copper Salts

The electronic spectra of all four copper salts (including $Cu(FSO_3)_2$, the spectrum of which has not been reported previously) consist of absorption in the near-infrared region over the range of about 8.0 to 14.0 kK. $Cu(FSO_3)_2$, $Cu(CF_3SO_3)_2$, and $Cu(p\text{-}CH_3C_6H_4SO_3)_2$ exhibit single, broad, asymmetrical bands with band maxima at 10.4, 10.4, and 11.2 kK respectively. The absorption spectrum of $Cu(CH_3SO_3)_2$ is centered at about 10.8 kK and consists of a principal band with a maximum at 11.6 kK and a strong shoulder at about 9.5 kK. These ligand field bands are at 1 to 2 kK lower in energy than oberved for aqueous copper(II) consistent with hexacoordination of copper by ligands slightly lower than H_2O in the spectrochemical series.

Assuming an elongated tetragonal CuO_6 octahedron (D_{4h} symmetry), as was suggested previously for $Cu(FSO_3)_2$ (1, 2) three electronic transitions are expected, corresponding to transitions from a ground $^2B_{1g}$ state to excited $^2A_{1g}$, $^2B_{2g}$, and ^2E_g states. The absorption bands observed here likely contain all three transitions (or four if the symmetry is lower), only partly resolved in the case of $Cu(CH_3SO_3)_2$ and unresolved for the other three salts. Band energies in the electronic spectra of copper(II) species are determined, not only by the ligand field strengths of the ligands involved, but also by the degree of distortion from O_h symmetry. It has been shown, for example, that in ethylenediamine complexes of copper(II), band energies increase with increasing degree of tetragonal distortion (16) a consequence, largely, of a shift in the $^2B_{1g} \rightarrow {}^2E_g$ component to higher energies (17). The relatively low band energies observed for $Cu(FSO_3)_2$ and $Cu(CF_3SO_3)_2$ compared to the

[a]t.i.p. = $4N\beta^2/\Delta$ (18). The Δ values, obtained from the electronic spectra, were 10.4, 10.4, 11.6, and 11.2 kK for $Cu(FSO_3)_2$, $Cu(CF_3SO_3)_2$, $Cu(CH_3SO_3)_2$, and $Cu(p\text{-}CH_3C_6H_4SO_3)_2$ respectively. t.i.p. values are in units of $cm^3\ mol^{-1}$.
[b]$\mu_{eff} = 2.828\ [(\chi_M - \text{t.i.p.})T]^{1/2}$ B.M., where χ_M is the molar magnetic susceptibility corrected for the diamagnetism of all atoms and t.i.p. is the temperature independent paramagnetism.

other two salts may reflect both a smaller degree of tetragonal distortion in the salts and a weaker ligand field strength associated with the FSO_3^- and $CF_3SO_3^-$ anions.

Magnetic susceptibility data, obtained over the temperature range 312–95 K for the copper salts, are given in Table 2. Magnetic moment data for $Cu(FSO_3)_2$ were reported previously by Goubeau and Milne (1) and our results are in good agreement with the earlier study. The magnetic moments observed for all four salts are essentially temperature independent and of a magnitude normally observed for hexacoordinated copper(II) (18).

For a copper(II) ion a tetragonally elongated octahedral environment the magnetic susceptibility is anisotropic (19) and the average magnetic moment is given by the expression

$$\bar{\mu} = \left[\left(1 - \frac{4k_{\parallel}\lambda}{\Delta_2}\right)^2 + 2\left(1 - \frac{k_{\perp}\lambda}{\Delta_3}\right)^2\right]^{1/2}$$

where $k_{\parallel}$ and $k_{\perp}$ are orbital reduction factors, λ is the spin–orbit coupling constant, and Δ_2 and Δ_3 are the energy separations between the ground $^2B_{1g}$ state and the excited $^2B_{2g}$ and ^2E_g states respectively. Setting Δ_2 and Δ_3 at values ranging from 10.4 kK to 11.6 kK, as appropriate for the salts under consideration here, and $k_{\parallel}\lambda$ and $k_{\perp}\lambda$ at $-830\ cm^{-1}$ (free-ion value), the calculated values of $\bar{\mu}$ range from 1.99 to 2.02 B.M. The magnetic moments observed for three of the salts under investigation are significantly lower than these calculated values consistent with, as is commonly observed, a reduction in $k\lambda$ values below the free ion value. The relatively high magnetic moment observed for $Cu(FSO_3)_2$ indicates higher $k\lambda$ values for this salt compared to the other three. This, in turn, may reflect a relatively high degree of ionic character in the metal–anion bonds implying that, compared to the other three anions, FSO_3^- is a significantly weaker base towards copper ion.

Electronic Spectra and Magnetism of Cobalt Salts

The electronic spectra of $Co(CF_3SO_3)_2$, $Co(CH_3SO_3)_2$, and $Co(p\text{-}CH_3C_6H_4SO_3)_2$, with band assignments assuming a ligand environment of O_h symmetry about cobalt(II), are given in Table 3. The shoulder at 20.6 kK appears also in the spectrum of $Co(FSO_3)_2$ and has been assigned to an enhanced spin-forbidden transition (2). It is not possible to say for certain whether the additional structure which appears on the visible bands of $Co(CH_3SO_3)_2$ and $Co(p\text{-}CH_3C_6H_4SO_3)_2$ is due to spin–orbit coupling, low-symmetry splitting of the $^4T_{1g}(P)$ level or enhanced spin-forbidden transitions to doublet states. It has been pointed out (20) that in such cases the last possibility is likely in view of the presence of a number of doublet states near the $^4T_{1g}(P)$ state (21).

The ligand field parameters Dq and B were calculated as before (2) using the $^4T_{1g}(F) \rightarrow {}^4T_{2g}(F)$ transition energies given in Table 3 and the values 18.4, 17.9, and 17.6 kK (the latter value estimated from the center of the visible band) for the $^4T_{1g}(F) \rightarrow {}^4T_{1g}(P)$ transitions observed in the diffuse reflectance spectra of

[a]Data taken from ref. 2.

$Co(CF_3SO_3)_2$, $Co(CH_3SO_3)_2$, and $Co(p\text{-}CH_3C_6H_4SO_3)_2$ respectively. Values of Dq and B are given in Table 4 and, because of uncertainties in transition energies due to the broad nature of the ligand field bands, the parameters are considered accurate only to about $\pm 20\ cm^{-1}$. Thus, within experimental uncertainties, there is no difference in Dq values for the different salts and the variation in B is just significant. The B parameter is significantly lower than the free-ion value of 971 cm^{-1} in all salts.

The magnetic susceptibilities of $Co(CF_3SO_3)_2$, $Co(CH_3SO_3)_2$, and $Co(p\text{-}CH_3C_6H_4SO_3)_2$ were measured over the temperature range 310–85 K and the data are given in Table 5. All three salts exhibit magnetic moments which are in excess of the spin-only value and which are temperature dependent as expected for hexacoordinated cobalt(II).

The effects of electron delocalization and low symmetry ligand fields on the magnetic properties of complexes with $^4T_{1g}$ ground terms have been examined by Figgis *et al.* (22). These authors have calculated theoretical magnetic moments from expressions involving four parameters: λ, spin–orbit coupling constant; k, the orbital reduction factor which allows for a reduction in the orbital contribution to the magnetic moment due to electron delocalization; v, the distortion parameter which is equal to Δ/λ where Δ is the magnitude of splitting of the $^4T_{1g}(F)$ term by fields of axial symmetry, and A, which allows for the admixture of the higher lying $^4T_{1g}(P)$ term into the ground $^4T_{1g}(F)$ term by the primary cubic field. The experimental magnetic moment values for salts studied here were compared to the theoretical data tabulated by Figgis *et al.* and reasonable fits were obtained with $A = 1.43$ for all three salts and with the values of λ, k, and v listed in Table 4. The magnetic moment values given by the theory for each set of parameter values are given in Table 5 to enable a direct comparison between experiment and theory. The accuracy to which the parameters are determined is considered to be about $\pm 5\%$ in the case of k and λ and, because of the relative intensitivity of the calculated magnetic moments to small distortions, ± 2 in the case of v.

The analysis of the magnetic data for $Co(CF_3SO_3)_2$ gives $v = -3$, implying a splitting of the ground $^4T_{1g}(F)$ term by about 500 cm^{-1}. We note that the effect of this low symmetry field is not sufficiently large to give an observable splitting of the bands in the electronic spectrum

[a]$\mu_{eff} = 2.828\,(\chi_M T)^{1/2}$ where χ_M is the experimentally determined molar magnetic susceptibility corrected for the diamagnetism of all atoms.
[b]Data obtained from ref. 22 for $A = 1.43$ and λ, v, and k values given in Table 4.

of this salt. In addition, the observation of an infrared spectrum which shows C_{3v} symmetry for the CSO_3 part of the anion suggests the distortion of the CoO_6 skeleton is of a trigonal nature in which all of the metal–oxygen interactions remain equivalent and in which the C_{3v} symmetry of the anion is retained. The fact that $v = 0$ for the other salts implies less distortion of the CoO_6 skeleton in these salts; although, because of the relative insensitivity of the calculated magnetic moments to small distortions it is possible that distortions giving rise to splitting of ground terms by as much as 300 cm^{-1} could go undetected by the magnetic moment results.

The variation in λ values for the four cobalt salts under discussion correlates quite well with the variation in anion basicities given in the introduction. As the base strength of the anion increases the value of λ for the salt decreases; if λ reflects the degree of covalent bonding, there is a correlation between basicity and the degree of covalent character in the metal–anion bonds. The interelectron repulsion parameter, B, also provides a measure of covalent character in metal–ligand bonds and a similar reduction in B on going from $Co(FSO_3)_2$ and $Co(CF_3SO_3)_2$ to $Co(p\text{-}CH_3C_6H_4SO_3)_2$ is indicated by the analysis of the spectral data as discussed above. The values of k obtained for the four cobalt salts are all relatively high and the lack of correlation with λ is, according to Figgis *et al.* (22), not unexpected. These authors point out that the k values do not, in fact, provide a good measure of the degree of covalent bonding.

Studies on the Syntheses of Heterocyclic Compounds. Part DCXXXVI.[1] An Alternative Synthesis of Pentazocine

TETSUJI KAMETANI, TOSHIO HONDA, SHYH-PYNG HUANG, AND KEIICHIRO FUKUMOTO

Pharmaceutical Institute, Tohoku University, Aobayama, Sendai, Japan

Received June 10, 1975

TETSUJI KAMETANI, TOSHIO HONDA, SHYH-PYNG HUANG, and KEIICHIRO FUKUMOTO. Can. J. Chem. **53**, 3820–3823 (1975).

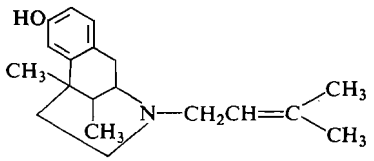
The important starting material in a synthesis of pentazocine (**1**) was easily prepared by treating gaseous formaldehyde with 2-lithio-2-butene. Both *E*- and *Z*-2-bromo-2-butenes (**2**, **3**) gave the same *Z*-type of alcohol (**4**) which was converted into pentazocine.

TETSUJI KAMETANI, TOSHIO HONDA, SHYH-PYNG HUANG et KEIICHIRO FUKUMOTO. Can. J. Chem. **53**, 3820–3823 (1975).

On a préparé, par réaction de la formaldehyde à l'état gazeux avec le lithio-2 butène-2, le composé important pour la synthèse de la pentazocine (**1**). Les deux bromo-2 butènes-3 *E* et *Z* (**2**, **3**) conduisent au même alcool de type *Z* (**4**) qui peut être transformé en pentazocine.

[Traduit par le journal]

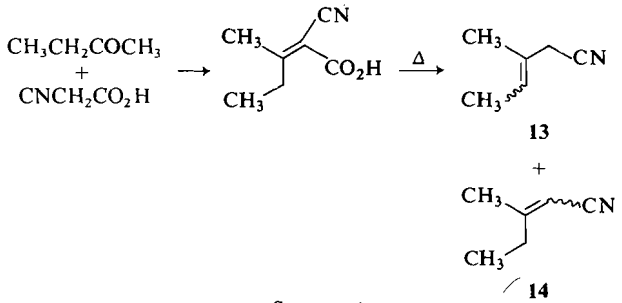
Previously, we reported two simple syntheses of pentazocine (**1**) (1, 2), an analgesic agent having no addiction liability (3–7), by Pictet–Spengler type reaction and Bischler–Napieralski type reaction. In both cases, the starting material is a mixture of two isomers, 1-cyano-2-methyl-1-



1

butene (**14**) and 1-cyano-2-methyl-2-butene (**13**), obtained by condensation of ethyl methyl ketone with cyanoacetic acid, and the stereochemistry of both compounds (**13** and **14**) is unknown. In order to clarify these points we have investigated the selective synthesis of 1-cyano-2-methyl-2-butene (**6**) whose stereochemistry was also determined easily, and here we wish to report a novel synthesis of *Z*-type 1-cyano-2-methyl-2-butene and the conversion of **6** into pentazocine (**1**).

The lithium derivatives (8) of *E*- and *Z*-2-bromo-2-butenes were prepared at −10 to −20 °C by reaction with lithium metal, and these were treated with formaldehyde gas separately to give the same *Z*-type alcohol (**4**) in 63% yield. The structure was easily determined by n.m.r. spectral analysis which showed a methylene proton at δ 3.96 as a singlet, indicating a *Z*-type olefin, while the corresponding signal in the *E*-isomer (11) should appear at higher field (δ 3.75–3.80). It has been reported by Lenox and Katzenellenbogen (11) that both the *E*- and *Z*-isomer were separable by gas chroma-



SCHEME 1

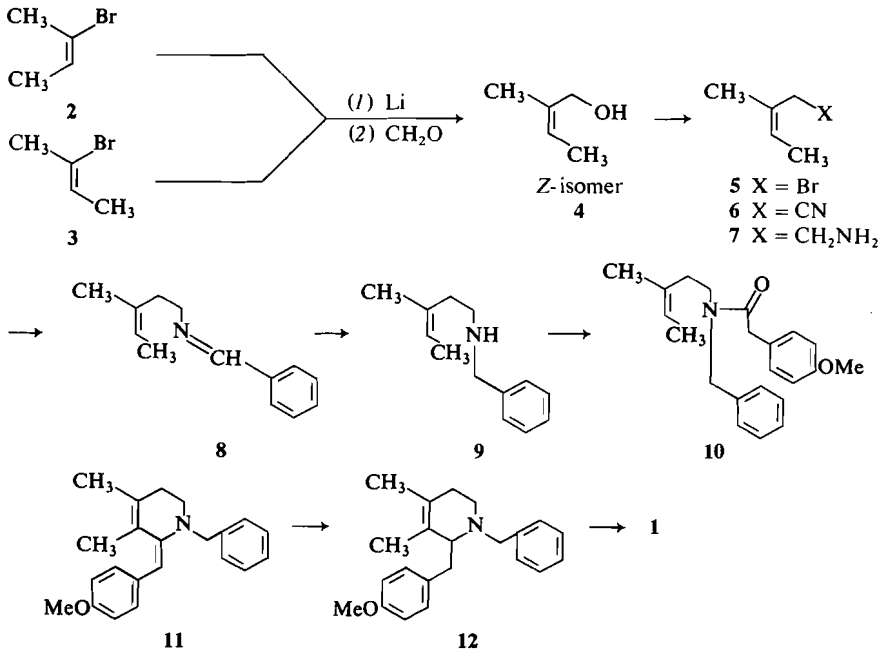

SCHEME 2

tography. However, our product (**4**) showed only one peak in the gas chromatogram in a condition described in the experimental part, indicating that it was not a mixture of the *E*- and *Z*-isomer. Although it has been reported (8, 9) that the reaction products of 2-lithio-2-butene with various electrophiles retained the configuration of the starting material, we obtained only the *Z*-type of alcohol from both the *Z*- and *E*-2-lithio-2-butenes, but the mechanism was not clear in this reaction. On the other hand, the *E*- and *Z*-type of alcohols have previously been prepared by two groups (10, 11). A convenient method using easily available starting materials has just been developed in our laboratory.

Treatment of the alcohol (**4**) with phosphorus tribromide gave the allylic bromide (**5**) which was converted into the corresponding cyanide (**6**) in 55% yield without the migration of the double bond by cuprous cyanide. Hydrogenation of the nitrile (**6**) in the presence of Raney cobalt in methanol, followed by condensation with benzaldehyde, afforded the Schiff base (**8**) which was treated with sodium borohydride to give in 56% yield the secondary amine (**9**). Schotten–Baumann reaction of the amine (**9**) with 4-methoxyphenylacetic acid chloride gave the tertiary amide (**10**) in 94% yield. Bischler–Napieralski reaction of the amide (**10**), followed by reduction with sodium borohydride, gave in 43% yield the 1-benzyl-1,2,5,6-tetrahydro-2-(4-methoxybenzyl)-3,4-dimethylpyridine (**12**), which was identical with the authentic sample.[2] The tetrahydropyridine derivative (**12**) was already converted into pentazocine. Thus, we were able to carry out satisfactorily the synthesis of pentazocine by using a facile method.

Experimental

Melting points are uncorrected. The i.r. spectra were taken in $CHCl_3$ solution with a Hitachi EPI-S2 spectrometer. Nuclear magnetic resonance spectra were measured on a JEOL JNM-PMX 60 in CCl_4 solution using TMS as an internal standard. The apparatus used for gas chromatography was a Shimazu GC 6A equipped with a hydrogen flame ionization detector and a 'silanized' spiral glass column (1 m × 3 mm i.d.). The column was packed with 10% Carbowax 6000 or 10% DEGS. Column temperature was 130 °C. Both the detector and flash heater were maintained at 150 °C. Nitrogen was used as a carrier gas at a flow-rate of 21 ml/min.

2-Methyl-2-butene-1-ol (4)

Lithium (2.3 g) was cut into small pieces and placed in a three-necked flask containing ether (200 ml), to which *E*-2-bromo-2-butene (20 g) was added with stirring at −10 to −20 °C. The addition requires about 1 h, and the

[2]The authentic sample was given by Dr. K. Kigasawa, Grelan Pharmaceutical Company.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

mixture was then stirred for a further 30 min at −10 °C. Formaldehyde gas, prepared by heating paraformaldehyde, was then distilled into the stirred reaction mixture at −10 °C. The reaction mixture was stirred at room temperature for 3 h and then treated with a saturated aqueous ammonium chloride solution. The ethereal layer was separated and the aqueous phase was extracted with ether. The combined extracts were washed with water and dried over Na_2SO_4. Evaporation of the solvent gave an oil which was distilled to afford the alcohol (**4**) (8 g) (63%) as a colorless oil; b.p. 58–60 °C/11 Torr; ν_{max} 3600 and 3450 (OH); n.m.r. δ 1.58 ($CH_3CH{=}C$<, 3H, d, J = 8 Hz), 1.68 (CH_3C=<, 3H, s), 3.96 (CH_2OH, 2H, s), and 5.22 (olefinic proton, 1H, q, J = 8 Hz).

Anal. Calcd. for $C_5H_{10}O$: C, 69.72; H, 11.70. Found: C, 69.24; H, 11.30.

The reaction of the *Z*-2-bromo-2-butene with lithium metal was carried out in the same manner as in the case of the *E*-isomer to give the lithium derivative, which was then treated with formaldehyde gas to afford the allylic alcohol (**4**). The alcohol was identical with that obtained from the *E*-2-bromo-2-butene by n.m.r. spectral and gas chromatographic comparisons.

*1-Cyano-2-methyl-2-butene (**6**)*

To a solution of the alcohol (**4**) (10 g) in methylene chloride (50 ml) was added dropwise phosphorus tribromide (10 g) at 0 °C with stirring. After stirring for an additional 1 h at the same temperature, the solution was washed with water and dried over Na_2SO_4. Evaporation of the solvent gave the allylic bromide (**5**) which was used in the next reaction without purification. A mixture of the bromide (**5**), cuprous cyanide (10 g), and dimethylformamide (50 ml) was stirred at room temperature for 5 h. The reaction mixture was poured into an excess of water and extracted with ether. The ethereal solution was washed with water, dried over Na_2SO_4, and evaporated. Vacuum distillation of the residue gave the nitrile (**6**) (6 g) as a colorless oil; b.p. 52–54 °C/14 Torr; ν_{max} 2250 (C≡N); n.m.r. 1.62 ($CH_3CH{=}C$<, 3H, d, J = 8 Hz), 1.68 (CH_3C=<, 3H, s), 2.92 (CH_2CN, 2H, s), and 5.50 (olefinic proton, 1H, q, J = 8 Hz).

Anal. Calcd. for C_6H_9N: C, 75.73; H, 9.54. Found: C, 75.78; H, 9.42.

*1-Amino-3-methyl-2-pentene (**7**)*

A solution of 1-cyano-2-methyl-2-butene (**6**) (3 g) in methanol (50 ml) was hydrogenated in the presence of Raney cobalt (1.5 g) at 80 °C under 100 atm of hydrogen until hydrogen uptake ceased (*ca.* 4 h). The mixture was filtered and the filtrate was used in the following reaction without isolation.

*5-Benzylamino-3-methyl-2-pentene (**9**)*

A mixture of the above amine (**7**) and benzaldehyde (2.2 g) in methanol (100 ml) was refluxed for 2 h. After the reaction mixture had been cooled at room temperature, sodium borohydride (1.5 g) was added in small portions to this solution with stirring. The stirring was continued for an additional 1 h. Evaporation of the solvent gave a pale yellowish oil, which was distilled *in vacuo* to give the benzylamine derivative (**9**) as a colorless oil (3.2 g); b.p. 114–116 °C/3 Torr; n.m.r. δ 1.58 (CH_3-CH=C<, 3H, d, J = 7 Hz), 1.63 (CH_3C=<, 3H, s), 2.22 (CH_2CH_2NH, 2H, t, J = 7 Hz), 2.60 (CH_2CH_2-NH, 2H, t, J = 7 Hz), 3.68 ($NHCH_2Ph$, 2H, s), 5.30 (olefinic proton, 1H, distorted q, J = 7 Hz), and 7.18 (C_6H_5, 5H, s). The oxalate of **9** was recrystallized from ethanol to afford colorless needles; m.p. 196–197 °C.

Anal. Calcd. for $C_{15}H_{21}O_4N$: C, 64.49; H, 7.58; N, 5.01. Found: C, 64.99; H, 7.66; N, 5.12.

*N-Benzyl-N-(3-methyl-2-pentenyl)-4-methoxyphenylacetamide (**10**)*

To a cooled and stirred solution of **9** (1 g) in ether (10 ml) was added dropwise a solution of the acid chloride, which was prepared by the usual method from 4-methoxyphenylacetic acid (1.2 g) in ether (20 ml). The reaction mixture was kept alkaline by simultaneous addition of saturated aqueous $NaHCO_3$ solution within 30 min. After the stirring had been continued at room temperature for 1 h, the reaction mixture was extracted with ether. The extract was washed successively with water, 5% HCl solution, and water, dried over Na_2SO_4, and evaporated to give the amide (1.6 g) as a colorless viscous syrup; ν_{max} 1650 (C=O); n.m.r. δ 1.42–1.68 (2 × CH_3, 6H), 2.33–2.66 (CH_2CH_2N, 4H, m), 3.43 ($COCH_2Ph$, 2H, s), 3.75 (OCH_3, 3H, s), 4.33 (NCH_2Ph, 2H, s), 5.16 (olefinic proton, 1H, broad s), 6.70 (aromatic protons, 2H, d, J = 8 Hz), 7.00 (aromatic protons, 2H, d, J = 8 Hz), and 7.15 (aromatic protons, 5H, s).

*1-Benzyl-1,2,5,6-tetrahydro-2-(4-methoxybenzyl)-3,4-dimethylpyridine (**12**)*

A solution of the amide (**10**) (1 g) and $POCl_3$ (1 ml) in dry benzene (20 ml) was heated at 70 °C for 2 h. After cooling, the reaction mixture was poured into an excess of *n*-hexane. The precipitated hydrochloride was separated by decantation and then dissolved in methanol. To this solution was added in small portions sodium borohydride (0.4 g) with stirring. After removal of the solvent, the residue was decomposed with water and then extracted with chloroform. The organic layer was washed with water and dried over Na_2SO_4. Evaporation of the solvent gave a pale yellowish oil (0.4 g), which was characterized as oxalate; m.p. 158–160 °C (lit. (*4a*) m.p. 158–160 °C, mixture m.p. 158–160 °C). The i.r. and n.m.r. spectra were identical with those of an authentic sample, which was given by Dr. K. Kigasawa, Grelan Pharmaceutical Co. Ltd.

Studies on the Syntheses of Heterocyclic Compounds. Part DCXXXVIII.[1] Simple Synthesis of Benz[*d*]indeno[1,2-*b*]azepine from 1-Benzoyl-3,4-dihydroisoquinoline

TETSUJI KAMETANI, MANAKKAL SIVARAMAN PREMILA, SHOJI HIRATA, HIDEHARU SETO, HIDEO NEMOTO, AND KEIICHIRO FUKUMOTO

Pharmaceutical Institute, Tohoku University, Aobayama, Sendai, Japan

Received June 10, 1975

TETSUJI KAMETANI, MANAKKAL SIVARAMAN PREMILA, SHOJI HIRATA, HIDEHARU SETO, HIDEO NEMOTO, and KEIICHIRO FUKUMOTO. Can. J. Chem. **53**, 3824 (1975).

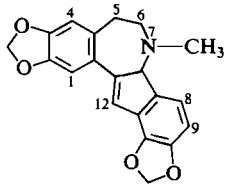
1-Benzoyl-3,4-dihydroisoquinoline methiodides (**13**, **14**, **15**) were converted into 5-benzoyl-2,3-dihydro-1*H*-3-benzazepines (**18**, **19**, **20**), respectively, cyclization and reduction of which gave benz[*d*]indeno[1,2-*b*]azepines (**27**, **28**, **29**).

TETSUJI KAMETANI, MANAKKAL SIVARAMAN PREMILA, SHOJI HIRATA, HIDEHARU SETO, HIDEO NEMOTO et KEIICHIRO FUKUMOTO. Can. J. Chem. **53**, 3824 (1975).

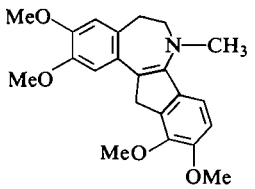
On a transformé respectivement les méthiodures (**13**, **14**, **15**) de benzoyl-1 dihydro-3,4 isoquinoléines en benzoyl-5 dihydro-2,3 1*H*-benzazépines-3 (**18**, **19**, **20**); la cyclisation et la réduction de ces derniers composés conduit aux benz[*d*] indéno[1,2-*b*]azépines (**27**, **28**, **29**).

[Traduit par le journal]

The 3-benzazepine skeleton is found in the rhoeadine, isopavine, and cephalotaxine type alkaloids (1, 2). The rhoeadine alkaloids have been synthesized by Irie *et al.* (3) through the benzindenoazepine (**1**), and by Brossi and co-workers (4) from the phthalide alkaloid, bicuculline. Recently, Manske and co-workers (5) reported the second conversion of the benzindenoazepine (**2**) into the rhoeadine ring system.



1



2

We have been investigating the synthesis of benzazepine and benzindenoazepine type compounds from 1-benzylisoquinolines and have reported the conversion of β-hydroxylaudanosine (**3**) into 2,3-dihydro-5-phenyl-1*H*-3-benzazepine (**4**) by rearrangement (6). We have also reported the conversion of the spiro-isoquinoline (**5**) into the benzindanoazepines (**6**, **7**) (7) and the total synthesis of reframidine (**9**), an isopavine alkaloid, by ring expansion of the 3,4-dihydroisoquinoline (**8**) with diazomethane (8). We are interested in this type of reaction and examined whether this ring expansion could provide the key step for the construction of the rhoeadine framework (9). We wish to report the synthesis of various substituted 5-benzoyl-2,3-dihydro-3-methyl-1*H*-3-benzazepines from the corresponding 1-benzoyl-3,4-dihydroisoquinoline methiodides by ring expansion and their conversion into 5,6,7,12-tetrahydro-7-methylbenz[*d*]indeno[1,2-*b*]azepines, which have the same framework as the key precursor (**2**) for the *cis*-alpigenine synthesis of Manske (5).

A methanol solution of 3,4-dihydro-6,7-dimethoxy-1-(3,4-methylenedioxybenzoyl)isoquinoline methiodide (**13**), prepared from 1-benzoyl-3,4-dihydroisoquinoline (**10**) (10) by reaction with methyl iodide in warm benzene, was treated with an excess of ethereal diazomethane at 0 °C to give in good yield a mixture of 5-benzoyl-2,3-dihydro-3-methyl-1*H*-3-benzazepine (**18**), m.p. 179–181 °C, and the isomeric 4-benzoylazepine (**21**), m.p. 125.5–126.5 °C, in the ratio of 5.5:1. The structure of **18** was assigned on the basis of spectral data. The molecular formula, $C_{21}H_{21}NO_5$, obtained by microanalysis and mass spectrum measurements (M^+, *m/e* 367) showed the introduction of one carbon atom, and the i.r.

For personal use only.

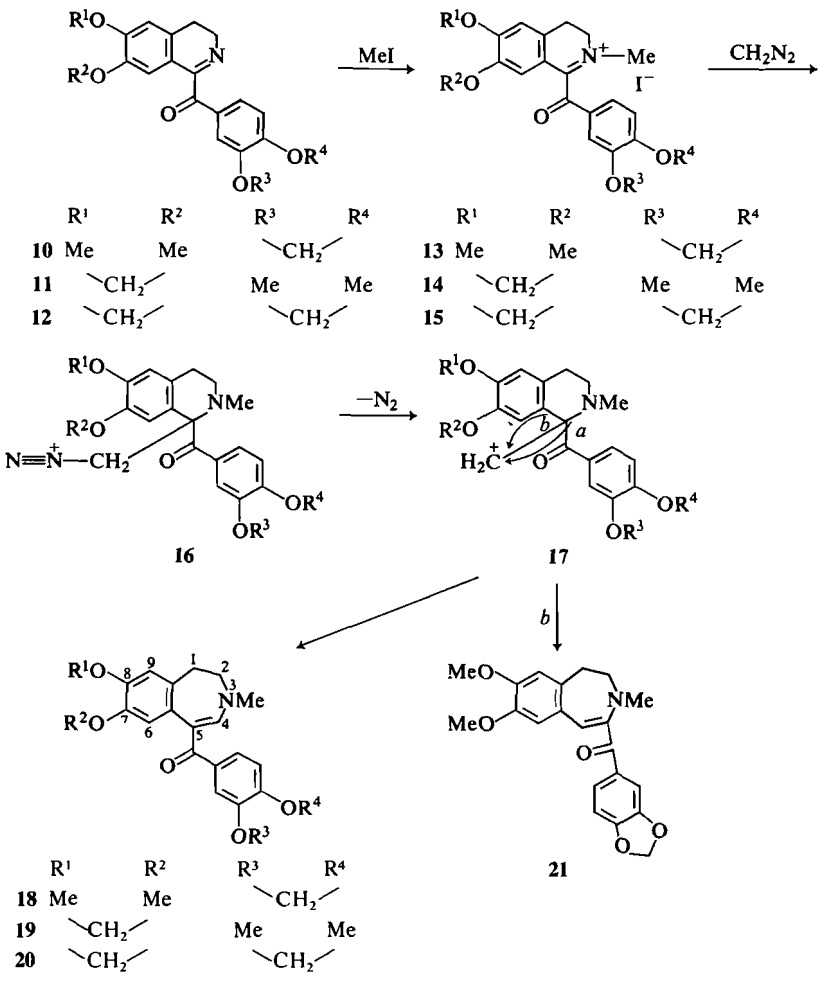
spectrum (ν_{max} ($CHCl_3$) 1637 cm^{-1}) indicated the presence of a conjugated carbonyl group. The u.v. spectrum revealed that λ_{max} (MeOH) 297 nm shifted to 287 nm on addition of concentrated hydrochloric acid. This shift indicated the presence of a conjugated enamine system (6), which was also supported by the n.m.r. spectrum which showed the *N*-methyl at δ 3.06. Moreover, the n.m.r. spectrum suggested the presence of a benzoyl group at the β-position of the enamine system as the chemical shifts of an aromatic proton (δ 6.55 or 6.61) and that of a methoxyl group (δ 3.6) resonated at unusually high field. The structure of the second benzazepine (**21**) was also determined by microanalysis, mass (M^+ *m/e* 307, $C_{21}H_{21}NO_5$), i.r. (ν_{max} ($CHCl_3$) 1640 cm^{-1}), u.v., and n.m.r. spectra. The n.m.r. spectrum showed the *N*-methyl group at δ 2.63 and the olefinic proton at δ 5.93 in addition to the normal chemical shift positions of the two methoxyls, the methylenedioxy, and five aromatic protons, indicating the presence of the benzoyl group at the α-position in the enamine system.

It is interesting that when chloroform is used as solvent instead of methanol, reaction of (**13**) with ethereal diazomethane afforded the 5-benzoylazepine (**18**) and a trace of the 4-isomer (**21**). This shows that in a more polar solvent such as methanol there is enhanced formation of carbonium ion (**17**) which has two paths, shown by arrows *a* and *b* in Scheme 2, for rearrangement whereas in a nonpolar solvent, chloroform, there is more likelihood for direct displacement of nitrogen by anchimeric assistance by path *a* (11) through intermediate formation of an aziridinium salt.

The attempted conversion of the 5-benzoylazepine (**18**) into the benz[*d*]indeno[1,2-*b*]azepine system by several methods, including treatment with a mineral acid, photolytic and thermolytic methods (12) along an electrocyclic reaction mechanism (13), gave only negative results. However, cyclization with phosphorus oxychloride in boiling toluene was successful and 12-chloro-5,6,7,7a-tetrahydro-7-methylbenz-[*d*]indeno[1,2-*b*]azepine (**22**) was formed in moderate yield. Its structure was supported by its mass (M^+, *m/e* 385 and 387 (isotope ion), 350 (M^+ − Cl)), i.r., and n.m.r. spectra. Thus, the absence of a carbonyl group in the i.r. spectrum, and the presence of four aromatic protons in the n.m.r. spectrum showed that cyclization had taken place. The chemical shifts of the methine protons (δ 4.90) and the *N*-methyl group (δ 2.15) were found at abnormally high field, and hence the olefinic linkage must be located between C-12 and C-12a.

Hydrogenolysis of the chlorine atom could be achieved by treatment of (**22**) with sodium



SCHEME 2

borohydride in methanol followed by addition of sodium hydroxide to give 5,6,7,12-tetrahydro-7-methylbenz[*d*]indeno[1,2-*b*]azepine (**27**), in moderate yield, which could also be obtained in poor yield by reduction of (**22**) using zinc and sodium hydroxide. The structure (**27**) of this product was easily determined by its mass (M^+; *m/e* 351) and n.m.r. spectrum which showed a methylene group (situated between the phenyl and olefinic carbon atoms) at δ 3.70 as a singlet, but lacked an olefinic proton. Moreover, the chemical shift of the *N*-methyl group at δ 2.93 indicated that this group formed part of an enamine system. Enamine formation by sodium borohydride reduction of König's salts is reported by Grewe and von Bonin (14).

Treatment of **22** with sodium borohydride in the absence of sodium hydroxide resulted in the recovery of the starting material, and the reaction of **22** with methanolic sodium hydroxide gave the unstable 5,6,7,7a-tetrahydro-12-methoxy-7-methylbenz[*d*]indeno[1,2-*b*]azepine (**30**) (δ ($CDCl_3$) 3.00 (>CH—OCH_3) and 5.47 (>C*H*—OCH_3)). Therefore, reduction must proceed through the enamine (**25**) and the α,β-unsaturated imminium salt (**26**) as shown in Scheme 3. The presence of sodium borohydride afforded compound **27** by attack of the hydride, but in the absence of a reducing agent gave **30** by attack of the solvent.

Similarly, the two other benz[*d*]indeno[1,2-*b*]azepines (**28, 29**) were synthesized from 3,4-

dihydro-1-(3,4-dimethoxybenzoyl)-(**11**) (15) and 3,4-dihydro-6,7-methylenedioxy-1-(3,4-methylenedioxybenzoyl)isoquinoline (**12**) (16), respectively. Thus, the 1-benzoyl-3,4-dihydroisoquinolines (**11**, **12**) were treated with methyl iodide to give the corresponding methiodides (**14**, **15**) which were subjected to ring expansion with an excess of ethereal diazomethane at 0 °C in chloroform to afford the 3-benzazepines (**19**, **20**). Heating the 3-benzazepines with phosphorus oxychloride in dry toluene furnished the 12-chloro - 5,6,7,7a - tetrahydrobenz[*d*]indeno[1,2 - *b*]azepines (**23**, **24**), which were reduced with sodium borohydride in methanol in the presence of sodium hydroxide to give the expected 5,6,7,12-tetrahydrobenz[*d*]indeno[1,2-*b*]azepines (**28**, **29**).

Thus, we have accomplished a convenient synthesis of 5,6,7,12-tetrahydrobenz[*d*]indeno-[1,2-*b*]azepines, which have the same framework as the key intermediate (**2**) for the total synthesis of *cis*-alpigenine by Manske, from 1-benzoyl-3,4-dihydroisoquinoline methiodides in three steps by an application of the ring expansion reaction with diazomethane.

Experimental

Melting points are not corrected and were measured with a Yanagimoto micro melting point apparatus (MP-S2). Infrared and u.v. spectra were measured with a Hitachi 215 grating spectrophotometer and with a Hitachi 124 spectrophotometer, respectively, n.m.r. spectra with a JEOL JNM-PMX 60 spectrometer with tetramethylsilane as internal standard, and mass spectra with a Hitachi RMU-7 spectrometer.

3,4-Dihydro-6,7-dimethoxy-2-methyl-1-(3,4-methylenedioxybenzoyl)isoquinolinium Iodide (13)

A mixture of 3,4-dihydro-6,7-dimethoxy-1-(3,4-methylenedioxybenzoyl)isoquinoline (**10**) (5.2 g), benzene (30 ml), and methyl iodide (11 ml) was gently refluxed for 2 h. The methiodide separated out after a short while. After allowing the mixture to cool, the methiodide was filtered off and washed with ether to obtain a yellow solid (7.2 g) which was recrystallized from MeOH to give yellow crystals (4.6 g), m.p. 190–192 °C.

Anal. Calcd. for $C_{20}H_{20}NO_5I \cdot \frac{1}{2}H_2O$: C, 48.99; H, 4.32; N, 2.86. Found: C, 49.20; H, 4.27; N, 2.91.

3,4-Dihydro-2-methyl-6,7-methylenedioxy-1-(3,4-methylenedioxybenzoyl)isoquinolinium Iodide (15)

A mixture of 3,4-dihydro-6,7-methylenedioxy-1-(3,4-methylenedioxybenzoyl)isoquinoline (**12**) (5.0 g), methyl iodide (28.0 ml), MeOH (150 ml), and acetone (150 ml) was refluxed for 3 h and then worked up as before to give the methiodide as orange needles (6.5 g) from MeOH; m.p. 221–222 °C; i.r. ($CHCl_3$) 1640 cm^{-1} (CO).

Anal. Calcd. for $C_{19}H_{16}NO_5I$: C, 49.05; H, 3.47; N, 3.01. Found: C, 48.88; H, 3.77; N, 2.99.

2,3-Dihydro-7,8-dimethoxy-3-methyl-5-(3,4-methylenedioxybenzoyl)-1H-3-benzazepine (18)

An excess of ethereal diazomethane was added to a solution of the methiodide (**13**) (4.3 g) in MeOH (500 ml) at 0 °C. After leaving it overnight in the refrigerator, the solvent was evaporated to leave a syrup which was dissolved in chloroform. The solution was then washed with 10% NH_4OH and water, dried (Na_2SO_4), and distilled to leave a syrup (4.2 g) which was chromatographed on silica gel (150 g). Elution with chloroform gave 2,3-dihydro-7,8-dimethoxy-3-methyl-4-(3,4-methylenedioxybenzoyl)-1*H*-3-benzazepine (**21**) (350 mg) which was crystallized from MeOH to give yellow crystals; m.p. 125.5–126.5 °C; i.r. ($CHCl_3$) 1640 cm^{-1} (CO); n.m.r. ($CDCl_3$) δ 2.63 (3H, s, NCH_3), 2.8–3.1 (2H, m, $ArCH_2CH_2N$), 3.15–3.4 (2H, m, $ArCH_2CH_2N$), 3.83 (3H, s, OCH_3), 3.88 (3H, s, OCH_3), 5.93 (1H, s, 5-H), 6.05 (2H, s, OCH_2O), 6.70 (2H, s, 6-H and 9-H), 6.83 (1H, d, J = 8 Hz, 5′-H), 7.46 (1H, d, J = 2 Hz. 2′-H), and 7.65 (1H, dd, J = 2 and 8 Hz, 6′-H); m.s. *m/e* 367 (M^+); u.v. (MeOH) 287 nm and u.v. (MeOH–HCl) 257, 317, and 363 nm.

Anal. Calcd. for $C_{21}H_{21}NO_5$: C, 68.65; H, 5.76; N, 3.81. Found: C, 68,58; H, 5.72; N, 3.85.

Further elution with chloroform gave the required 2,3-dihydro-7,8-dimethoxy-3-methyl-5-(3,4-methylenedioxybenzoyl)-1*H*-3-benzazepine (**18**) (2.3 g) which was recrystallized from MeOH to give yellow crystals (1.9 g); m.p. 179–181 °C; i.r. ($CHCl_3$) 1637 cm^{-1} (CO); n.m.r. ($CDCl_3$) δ 3.06 (3H, s, NCH_3), 2.9–3.2 (2H, m, $ArCH_2CH_2N$), 3.4–3.7 (2H, m, $ArCH_2CH_2N$), 3.6 (3H, s, 7-OCH_3), 3.85 (3H, s, 8-OCH_3), 5.96 (2H, s, OCH_2O), 6.56, 6.61, 6.80 (3H, each s, =CH and ArH), 7.06 (2H, s, ArH), and 7.13 (1H, dd, J = 2 and 7 Hz, 6′-H); m.s. *m/e* 367 (M^+); u.v. (MeOH) 297 and 350 nm and u.v. (MeOH–HCl) 266, 287, and 363 nm.

Anal. Calcd. for $C_{21}H_{21}NO_5$: C, 68,65; H, 5.76; N, 3.81. Found: C, 68.25; H, 5.92; N, 3.60.

2,3-Dihydro-5-(3,4-dimethoxybenzoyl)-3-methyl-7,8-methylenedioxy-1H-3-benzazepine (19)

An excess of ethereal diazomethane was added to a stirred solution of the methiodide (**14**) (15) (4 g) in chloroform (700 ml) at 0 °C. Stirring was continued for 1–1.5 h. The solvent was then removed *in vacuo* and the residue dissolved in chloroform. The chloroform extract was washed with 10% ammonia and water, dried (Na_2SO_4) and evaporated to leave a gum (4.1 g) which was purified by crystallization from benzene. Further recrystallization from MeOH gave yellow crystals; m.p. 204–205 °C; i.r. ($CHCl_3$) 1640 cm^{-1} (CO); n.m.r. ($CDCl_3$) δ 3.01 (3H, s, NCH_3), 2.85–3.15 (2H, m, $ArCH_2CH_2N$), 3.35–3.7 (2H, m, $ArCH_2CH_2N$), 3.81 (3H, s, OCH_3), 3.87 (3H, s, OCH_3), 5.81 (2H, s, OCH_2O), and 6.53–7.33 (5H, m, =CH— and ArH); m.s. *m/e* 367 (M^+); u.v. (MeOH) 303 and 347 nm and u.v. (MeOH–HCl) 265, 297, and 360 nm.

Anal. Calcd. for $C_{21}H_{21}NO_5$: C, 68.65; H, 5.75; N, 3.81. Found: C, 68.54; H, 5.93; N, 3.59.

2,3-Dihydro-3-methyl-7,8-methylenedioxy-5-(3,4-methylenedioxybenzoyl)-1H-3-benzazepine (20)

The methiodide (**15**) (5 g) in chloroform (400 ml) was treated with an excess of ethereal diazomethane at 0 °C for 5 h. After evaporation of chloroform, the residue was dissolved in chloroform and to this solution was added triethylamine (1.1 g), and the solvent was removed by distillation to leave a gum, which was subjected to alumina chromatography using benzene as a solvent to give the benzazepine (**20**) as yellow needles (3.5 g) from benzene; m.p. 165 °C; i.r. ($CHCl_3$) 1638 (CO) and 1570 cm^{-1} (C=C); n.m.r. ($CDCl_3$) 2.99 (3H, s, NCH_3), 2.8–3.1 (2H, m, $ArCH_2CH_2N$), 3.3–3.6 (2H, m, $ArCH_2CH_2N$), 5.78 (2H, s, OCH_2O), 5.91 (2H, s, OCH_2O), 6.46 (1H, s, 4-H), 6.58 (1H, s, 1-H), 6.73 (1H, s, 8-H), and 6.98–7.50 (3H, m, ArH); u.v. (MeOH) 300 and 233 nm and u.v. (MeOH–HCl) 330, 289, and 238.

Anal. Calcd. for $C_{20}H_{17}NO_5$: C, 68.37; H, 4.88; N, 3.99. Found: C, 68.10; H, 4.88; N, 3.91.

12-Chloro-5,6,7,7a-tetrahydro-2,3-dimethoxy-7-methyl-9,10-methylenedioxybenz[d]indeno[1,2-b]azepine (22)

A mixture of the dihydrobenzazepine (**18**) (200 mg), phosphorus oxychloride (0.4 ml), and toluene (50 ml) was refluxed for 1 h. The excess solvent and reagent were removed *in vacuo*, the residual syrup cooled and treated with MeOH when yellow crystals of the hydrochloride separated out. Collection by filtration gave the hydrochloride, whose suspension in chloroform was washed with 10% ammonia and water. The organic layer was dried (Na_2SO_4) and distilled to leave a syrup which on trituration with MeOH readily crystallized to give the indenobenzazepine (**22**) (100 mg); m.p. 156 °C (dec.) (sublime and darken); n.m.r. ($CDCl_3$) δ 2.15 (3H, s, NCH_3), 3.90 (6H, s, 2 × OCH_3), 4.90 (1H, s, 7a-H), 6.01 (2H, s, OCH_2O), 6.65, 6.93, 7.10, and 7.31 (4H, each s, ArH); m.s. *m/e* 385 and 387 (M^+), 350 (M^+ − Cl).

Anal. Calcd. for $C_{21}H_{20}NO_4Cl$: C, 65.36; H, 5.23; N, 3.63. Found: C, 65.19; H, 5.36; N, 3.78.

12-Chloro-5,6,7,7a-tetrahydro-9,10-dimethoxy-7-methyl-2,3-methylenedioxybenz[d]indeno[1,2-b]azepine (23)

A mixture of the dihydrobenzazepine (**19**) (0.2 g),

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

toluene (70 ml), and phosphorus oxychloride (0.4 ml) was refluxed for 0.5 h. It was worked up as before to give a residue which on crystallization from MeOH gave pale yellow crystals (105 mg); m.p. 158 °C (dec.); n.m.r. ($CDCl_3$) δ 2.08 (3H, s, NCH_3), 3.88 (3H, s, OCH_3), 3.93 (3H, s, OCH_3), 4.53 (1H, s, 7a-H), 5.92 (2H, s, OCH_2O), 6.59, 6.92, 7.05, and 7.15 (4H, each s, ArH); m.s. *m/e* 385 and 387 (M^+); u.v. (MeOH) 285 nm.

Anal. Calcd. for $C_{20}H_{20}NO_4Cl$: C, 65.36; H, 5.23; N, 3.63. Found: C, 64.92; H, 5.20; N, 3.51.

12-Chloro-5,6,7,7a-tetrahydro-7-methyl-2,3;9,10-bismethylenedioxybenz[d]indeno[1,2-b]azepine (24)

A mixture of the dihydrobenzazepine (**20**) (0.2 g), phosphorus oxychloride (0.2 g), and dry toluene (70 ml) was refluxed for 0.5 h. The reaction mixture was washed with 10% ammonia and water, dried (Na_2SO_4), and evaporated to afford a colorless syrup, which was purified with silica gel (5 g) chromatography by elution with chloroform to afford the indenoazepine (**24**) (200 mg); n.m.r. ($CDCl_3$) 2.07 (3H, s, NCH_3), 4.45 (1H, s, 7a-H), 5.90 (2H, s, OCH_2O), 5.95 (2H, s, OCH_2O), 6.53, 6.93, and 7.15 (each 1H, s, ArH). The hydrochloride of **4** gave colorless prisms from MeOH, m.p. 217–219 °C.

Anal. Calcd. for $C_{20}H_{16}NO_4Cl \cdot HCl \cdot \frac{1}{4}H_2O$: C, 58.47; H, 4.29. Found: C, 58.45; H, 4.28.

5,6,7,12-Tetrahydro-2,3-dimethoxy-7-methyl-9,10-methylenedioxybenz[d]indeno[1,2-b]azepine (27)

Sodium borohydride (100 mg) was added in portions to a stirred solution of the above chloroindenobenzazepine (**22**) (100 mg) in MeOH (70 ml). After addition, the mixture was stirred for 1–2 min and NaOH (1 pellet) was added and the stirring continued for 5 h. The solvent was removed, the residue was treated with water and extracted with chloroform. The chloroform extract was washed with water, dried (Na_2SO_4) and evaporated to leave a solid, which was crystallized from EtOH to give pale pink crystals (55 mg); m.p. 175–177 °C; n.m.r. ($CDCl_3$,) δ 2.93 (3H, s, NCH_3), 2.8–3.1 (2H, m, $ArCH_2CH_2N$), 3.1–3.4 (2H, m, $ArCH_2CH_2N$), 3.70 (2H, s, CH_2), 3.87, 3.90 (6H, each s, 2 × OCH_3), 5.93 (2H, s, OCH_2O), 6.65 (1H, s, ArH), 6.87 (1H, s, ArH), and 6.97 (2H, s, ArH); m.s. *m/e* 351 (M^+); u.v. (MeOH) 258 and 347 nm and u.v. (MeOH–HCl) 243, 293, and 355 nm.

Anal. Calcd. for $C_{21}H_{21}NO_4$: C, 71.78: H, 6.02; N, 3.95. Found: C, 71.55; H, 6.14; N, 4.04.

5,6,7,7a-Tetrahydro-2,3,12-trimethoxy-7-methyl-9,10-methylenedioxybenz[d]indeno[1,2-b]azepine (30)

Sodium hydroxide (1 pellet) was added to the chloroindenobenzazepine (**22**) (50 mg) in MeOH (30 ml) and the mixture left overnight at room temperature. The solvent was then removed *in vacuo* and the residue worked up as usual to give a brown syrup (53 mg) which on trituration with MeOH gave yellow crystals (20 mg); m.p. 145–147 °C; n.m.r. ($CDCl_3$) δ 2.83 (3H, s, NCH_3), 3.00 (3H, s, 12-OCH_3), 3.87, 3.93 (6H, each s, 2 × OCH_3), 5.47 (1H, s, 12-H), 5.97 (2H, s, OCH_2O), 6.63, 6.90, 6.95, and 7.62 (4H, each s, ArH); m.s. *m/e* 381 (M^+), which was so unstable that it darkened during purification.

5,6,7,12-Tetrahydro-9-10-dimethoxy-7-methyl-2,3-methylenedioxybenz[d]indeno[1,2-b]azepine (28)

Sodium borohydride (100 mg) was added in portions to a stirred solution of the above chloroindenobenzazepine (**23**) (100 mg) in MeOH (30.0 ml). After addition, the mixture was stirred for 3–4 min and sodium hydroxide (1 pellet) was added and the stirring continued for 5.5 h. It was worked up as before and crystallization from EtOH gave yellow crystals (56 mg); m.p. 189–191 °C; n.m.r. ($CDCl_3$) δ 2.97 (3H, s, NCH_3), 2.8–3.07 (2H, m, $ArCH_2CH_2N$), 3.1–3.37 (2H, m, $ArCH_2CH_2N$), 3.67 (2H, s, CH_2Ar), 3.88 (6H, s, 2 × OCH_3), 5.88 (2H, s, OCH_2O), 6.62 (1H, s, ArH), and 6.95 and 7.00 (3H, 2 × s, ArH); m.s. *m/e* 351 (M^+); u.v. (MeOH) 253 (sh), 273 (sh) and 347 nm and u.v. (MeOH–HCl) 243, 297, and 350 nm.

Anal. Calcd. for $C_{21}H_{21}NO_4$: C, 71.78; H, 6.02; N, 3.99. Found: C, 71.54; H, 5.98; N, 4.03.

5,6,7,12-Tetrahydro-7-methyl-2,3;9,10-bismethylenedioxybenz[d]indeno[1,2-b]azepine (29)

To a mixture of the chloroindenobenzazepine (**24**) (90 mg) and sodium borohydride (70 mg) in MeOH (30 ml) was added sodium hydroxide (70 mg), and this solution was stirred at room temperature for 2 h. The usual work up gave **8** (70 mg) as orange prisms from MeOH; m.p. 166–167 °C; n.m.r. ($CDCl_3$) δ 2.92 (3H, s, NCH_3), 2.7–3.05 (2H, m, $ArCH_2CH_2N$), 3.05–3.35 (2H, m, $ArCH_2CH_2N$), 3.62 (2H, s, $ArCH_2$), 5.87 (2H, s, OCH_2O), 5.92 (2H, s, OCH_2O), 6.60 (1H, s, ArH), 6.84 (1H, s, ArH), and 6.93 (2H, s, ArH).

Anal. Calcd. for $C_{20}H_{17}NO_4$: C, 71.63; H, 5.11; N, 4.18. Found: C, 71.90; H, 4.94; N, 4.50.

Molecular Rearrangements. Part VI. Aryl(alkyl)amines (II) Thermal Rearrangement of *N*-Benzylaniline

M. Z. A. BADR[1] AND H. A. H. EL-SHERIEF

Chemistry Department, Faculty of Science, Assiut University, Assiut, Egypt, E.A.R.

Received February 19, 1974[2]

M. Z. A. BADR and H. A. H. EL-SHERIEF. Can. J. Chem. **53**, 3831 (1975).

Heating *N*-benzylaniline resulted in migration of the benzyl group to the *ortho*- and *para*-positions of the aniline nucleus. Ammonia, toluene, biphenyl, diphenylmethane, dibenzyl, *trans*-stilbene, aniline, together with 9-phenylacridine, and 2,3-diphenylindole, were also formed.

When phenol, quinoline, or isoquinoline were used as solvents, the normal rearrangement products were accompanied by 2- and 4-benzylphenols, 3-benzylquinoline, 2- and 4-(aminophenyl)quinoline, 4-benzylisoquinoline, and 1-(aminophenyl)isoquinolines.

It is concluded that the pyrolysis of the secondary amine depends on its homolytic fission to benzyl and phenylamine free radicals. Homolysis of some initially separated products was also observed.

M. Z. A. BADR et H. A. H. EL-SHERIEF. Can. J. Chem. **53**, 3831 (1975).

Par chauffage, le groupe benzyle de la *N*-benzylaniline se transpose aux positions *ortho* et *para* du noyau aniline. On obtient aussi de l'ammoniac, du toluène, du biphényle, du diphénylméthane, du dibenzyle, du *trans*-stilbène, de l'aniline ainsi que du phényle-9 acridine et du diphényl-2,3 indole.

Quand on utilise le phénol, la quinoléine ou l'isoquinoléine comme solvants, on obtient les produits de réarrangement normaux ainsi que les benzyl-2 et -4 phénols, du benzyl-3 quinoléine, les (aminophényl)-2 et -4 quinoléine, le benzyl-4 isoquinoléine et l'(aminophényl)-1 isoquinoléine.

La pyrolyse de l'amine secondaire dépend de sa rupture homolytique en radicaux libres benzyle et phénylamine. On observe aussi l'homolyse de quelques produits préalablement isolés.

[Traduit par le journal]

The present paper describes a novel rearrangement of *N*-monoalkylaniline involving an alkyl–N bond fission to ring alkylated anilines, when heated at elevated temperature in absence of any promoter, either alone or in the presence of aromatic solvents where their ring alkylation was also observed. Thus *N*-benzylaniline reacted on heating in a sealed tube in nitrogen atmosphere at about 315 °C. Ammonia was produced together with aniline, toluene, biphenyl, diphenylmethane, dibenzyl, *trans*-stilbene, *o*- and *p*-aminodiphenylmethanes, 9-phenylacridine,and 2,3-diphenylindole in relatively high yield, together with high boiling products not yet resolved. When heated at its boiling point under reflux for 100 h, the amine gave about the same products but in lower yields, with the difference that some benzaldehyde was isolated, with stilbene, diphenyl, and 9-phenylacridine not easily identified.

The products of this thermal rearrangement are quite different from those of the proton catalyzed rearrangement.

The presence of toluene, aniline, biphenyl, diphenylmethane, and dibenzyl in the products strongly suggests that the change depends on a free radical mechanism. This suggestion was further confirmed through the study of the rearrangement in high boiling solvents and scavengers under nitrogen atmosphere. In phenol, the normal products of rearrangement were obtained together with 2- and 4-benzylphenols. However, in anisole, the solvent molecules underwent molecular rearrangement to the expected products of the alkyl–aryl ether reaction, namely, *o*- and *p*-cresol together with phenol and its benzylated products. The products of anisole rearrangement were also isolated when it was heated alone under the conditions of the amine rearrangement.

The thermal rearrangement of *N*-benzylaniline in quinoline gave the normal rearrangement

products together with 3-benzylquinoline, 2-(4-aminophenyl)quinoline, 4-(4-aminophenyl)-quinoline and an isomeric product which was identified as 4-(2-aminophenyl)quinoline.

With isoquinoline, the normal rearrangement products were accompanied by 4-benzylisoquinoline, 1-(4-aminophenyl)isoquinoline and the isomeric 1-(2-aminophenyl)isoquinoline as summarized in Table 1.

The rearrangement mechanism may take place according to Scheme 1.

Diphenylmethane may be produced through deamination of both isomeric *o*- and *p*-aminodiphenylmethane (route *a*) according to Scheme 2, however, heating the two isomers alone in a sealed tube under the conditions of the amine rearrangement produced neither ammonia nor diphenylmethane. On the other hand, heating aniline alone in a sealed tube at about 315 °C for 10 days resulted in the formation of ammonia (route *b*), which was collected in a concentrated HCl trap and identified as the hydrochloride and other derivatives. Consequently, diphenylmethane was most favorably produced through coupling of one phenyl free radical, which resulted from homolysis of the aniline byproduct, with the benzyl free radical (route *c*).

Combination of two phenyl radicals produced biphenyl (route *d*). The formation of biphenyl or diphenylmethane and ammonia may take place according to Scheme 2. The production of ammonia was assumed to partially proceed through intermediate formation of the amino free radical (route *b*). Such amino free radicals have been shown to exist (1).

9-Phenylacridine can reasonably be assumed to be formed from 2-aminodiphenylmethane as is shown in Scheme 3.

The formation of 2,3-diphenylindole can be explained according to Scheme 4.

Trans-stilbene could result from abstraction of the methylene hydrogens (β-scission) from dibenzyl under the influence of the free radicals present in the reaction medium in a procedure described previously (2).

Substitution by the benzyl radical on phenol gave the expected products. Production of *o*- and *p*-benzylphenols instead of isomeric benzylanisoles during the amine rearrangement insures that anisole rearrangement under such condi-

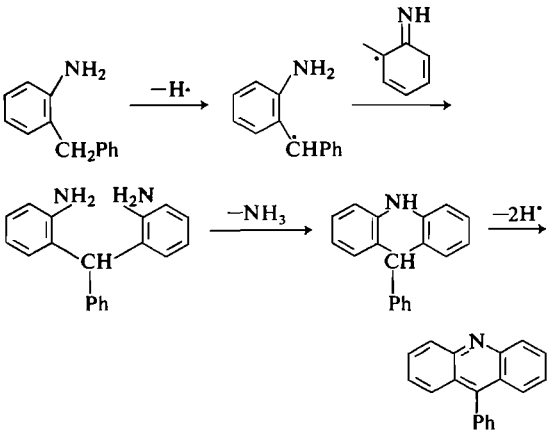

SCHEME 3

tions precedes the substitution step by benzyl radical, itself a product of the amine pyrolysis. However, absence of any other methyl derivatives among the products in an anisole solvent and the higher yield of *o*-cresol, strongly favor the assumption that the methyl group of anisole did not migrate as a separate free radical but possibly through an intramolecular route. However, the formation of *p*-cresol partially through an intermolecular migration of the methyl group within a solvent cage (3) was not excluded.

Thermal rearrangement of the amine in quinoline gave the expected products together with 3-benzylquinoline and three isomeric 2- and 4-(aminophenyl)quinolines. Free radical substitution at the 3-position of the quinoline nucleus was also observed by other workers (4, 5). Substitution by the benzyl radical at the 3-position of quinoline during the amine pyrolysis instead of at the 2- or 4-positions as observed in benzyl naphthyl ether pyrolysis in a quinoline solvent (6), could not be attributed to the difference in thermodynamic instability (7) of different isomeric benzylquinolines under such high thermal conditions. When both 2- and 4-benzylquinolines were heated under the conditions of the amine rearrangement, neither of the isomers were isomerized to their respective 3-benzylquinolines. On the other hand, the benzyl radical has less basic character (lower electron density) when compared with the aniline free radical (which has higher electron density). Since the increase of the nucleophilic character of a radical reflects an increase in its selectivity (8), consequently, in such radical competition the benzyl radical with its lower nucleophilic character will substitute selectively at the 3-position of quinoline which has a higher electron density than the 2- and 4-positions which will be attacked selectively and at a faster rate (9) by the anilino free radical with its higher nucleophilic character, producing the three isomeric 2- and 4-(aminophenyl)quinolines isolated.

Similarly, pyrolysis of the amine in isoquinoline gave the normal products together with 4-benzylisoquinoline and two isomeric 1-(2- and 4-aminophenyl)isoquinolines. On the same basis as above, during such radical competition, the less nucleophilic benzyl radical substitutes at the 4-position of isoquinoline with its higher electron density, while the anilino radical substitutes selectively and at a faster rate at the 1-position with its lower electron density.

The absence of biquinolyl or bi-isoquinolyl during such types of rearrangement strongly suggests that reactions with either quinoline or isoquinoline are based mainly on homolytic substitution steps rather than homolytic dehydrogenation processes yielding quinolyl or isoquinolyl radicals followed by coupling processes such as observed before (6).

Experimental

Analysis

Infrared spectroscopic analysis was carried out on a Pye-Unicam i.r. spectrophotometer, model SP 200G. The u.v. absorptions were carried out on a Pye-Unicam u.v. spectrophotometer, model SP8000. Gas-liquid chromatography analysis was carried out on a Pye-Unicam gas chromatograph, series 104, with a dual flame ionization detector, temperature programed, model 24. The column used was 20% SE30 on Chromosorb W (35–80) mesh. Thin layer chromatographic analysis was carried out on silica gel (25–40 mesh) using the solvents benzene–cyclo-

hexane (3:1 by volume) and *n*-hexane – ethyl acetate (7:3 by volume); the spots were visualized by iodine vapor. Paper chromatographic analysis was carried out using C. Schleicher and Schull paper No. 2316. In phenol analysis, the paper was sprayed before use to the point of saturation with 4% aqueous Na_2CO_3 solution and dried in air at room temperature. Molecular ion determinations were recorded on a UNC-CH Hitachi mass spectrometer at 70 eV.

Pyrolysis of N-Benzylaniline

N-Benzylaniline was heated alone or with phenol, anisole, quinoline, or isoquinoline in a nitrogen atmosphere and the reaction products were distilled first under atmospheric pressure where ammonia was evolved and trapped as its hydrochloride, and toluene collected. The higher boiling products were separated into neutral and amine ones by treatment with concentrated HCl and extraction with ether.

Phenolic products are separated by means of Claisen's solution. The results are summarized in Table 1.

Thermal Rearrangement of Anisole

Redistilled anisole (6 g) was heated in a sealed tube at about 315 °C for 12 days. Fractionation of the products gave together with recovered anisole, rearranged phenolic products (0.4 g; 6.7%) which were found by g.l.c. to consist of phenol (67.8%) and cresols (32.2%), a mixture of *o*-cresol (70.2%) and *p*-cresol (29.8%).

Preparation of Reference Compounds

N-Benzylaniline (10): b.p. 148–149 °C/3 Torr; m.p. 36 °C; picrate m.p. 48 °C.

Diphenylmethane (11): b.p. 261–262 °C/760 Torr; m.p. 26 °C; n_D^{27} 1.5788.

o-Aminodiphenylmethane (12): crystallized from petroleum ether (40–60 °C), m.p. 52 °C; *N*-acetyl derivative, m.p. 135 °C; *N*-benzoyl derivative, m.p. 116 °C.

p-Aminodiphenylmethane (13): b.p. 165–167 °C/2 Torr; crystallized from petroleum ether (40–60 °C), m.p. 34–36 °C; picrate, m.p. 179 °C.

9-Phenylacridine (14): Yellow prisms, m.p. 182–183 °C.

o-Benzylphenol (15): b.p. 172–180 °C/15 Torr; phenyl urethane derivative, m.p. 117 °C.

p-Benzylphenol (16): b.p. 170–190 °C/14 Torr; crystallized from petroleum ether (60–80 °C) as hairy white needles, m.p. 84 °C; benzoate m.p. 87 °C.

o-Benzylanisole (17): Crystallized from ethanol as white crystals, m.p. 27–28 °C.

p-Benzylanisole (18): b.p. 152–155 °C/7 Torr; n_D^{20} 1.5781.

2-Benzylquinoline (19): crystallized from methanol as yellow orange needles, m.p. 156–157 °C.

3-Benzylquinoline (20): b.p. 170–190 °C; crystallized from petroleum ether (60–80 °C), m.p. 67–68 °C; picrate m.p. 180–182 °C.

4-Benzylquinoline (21): b.p. 230 °C/14 Torr; picrate m.p. 179 °C.

4-Benzylisoquinoline (22): crystallized from petroleum ether (60–80 °C) as colorless crystals, m.p. 119–120 °C; picrate m.p. 195–196 °C, methiodide m.p. 196–197 °C.

2-(4-Aminophenyl)quinoline (23): yellow crystals m.p. 134 °C; picrate, m.p. 194 °C.

1-(4-Aminophenyl)isoquinoline (24): b.p. 200–215 °C/0.1 Torr, crystallized from benzene, m.p. 190–191 °C.

2,3-Diphenylindole (25): crystallized from petroleum ether (60–80 °C), m.p. 123–124 °C.

We thank Dr. M. M. Bursey for his assistance with the mass spectral measurements.

Fermi-Resonance Minima in the Vibrational Spectrum of Water in Crystalline Hydrates[1]

Received July 21, 1975

DAVID A. OTHEN, OSVALD KNOP, and MICHAEL FALK. Can. J. Chem. **53**, 3837 (1975).

The infrared absorption and Raman spectra of polycrystalline tetrachlorocuprate(II) dihydrates $M_2CuCl_4.2H_2O$ (M = K, Rb, Cs, NH_4) contain minima in the OH stretching region which sharpen at low temperature. These minima are shown to be 'Evans holes', or negative absorption features, caused by Fermi resonance between the broad and intense H_2O stretching fundamental ν_1 and a relatively narrow band due to the overtone of the H_2O bending vibration $2\nu_2$. Our findings confirm that Fermi resonance can lead to unusual spectral features, which must be taken into account in the analysis of the stretching region of the spectra of H_2O and D_2O in condensed phases, as has been done by Scherer *et al.* for the spectrum of liquid water.

DAVID A. OTHEN, OSVALD KNOP et MICHAEL FALK. Can. J. Chem. **53**, 3837 (1975).

La région des vibrations de valence OH dans les absorptions infrarouge et les spectres Raman des dihydrates de tétrachlorocuprate(II) cristallins, $M_2CuCl_4.2H_2O$ (M = K, Rb, Cs, NH_4), contient des minima qui se sont révélés "trous de Evans", c'est-à-dire caractéristiques d'absorption négative. Ces minima, qui deviennent plus étroits à basse température, sont causés par une résonance de Fermi entre la vibration fondamental ν_1 large et intense de l'eau et une bande relativement étroite due à la vibration harmonique $2\nu_2(H_2O)$ de déformation. Nos résultats confirment que la résonance de Fermi peut conduire, dans la région de vibration de valance, à des caractéristiques spectrales peu communes dont on doit tenir compte en analysant les spectres de H_2O et de D_2O dans des phases condensées, tel qu'il a été fait par Scherer *et al.* pour le spectre de l'eau liquide.

In the course of our recent study (1, 2) of the tetrachlorocuprates(II) $M_2CuCl_4.2H_2O$ (M = K, Rb, Cs, NH_4) unusual features were observed in the i.r. spectra of these compounds. They were recognized as 'Evans holes', or 'negative absorptions', arising from Fermi-resonance interactions. Their appearance was so striking as to merit a detailed discussion, especially in view of the importance of Evans holes to the interpretation of the OH stretching profiles in the spectrum of liquid water and hence to the problem of its structure (3, 4).

Evans (5) has shown that whenever a sharp vibrational transition of low inherent intensity, *e.g.* an overtone, falls within the energy range of a much broader and more intense transition of the same symmetry species, Fermi-resonance interaction may occur resulting in the spectral phenomena schematically illustrated in Fig. 1. When the sharp feature is located sufficiently close to the center of the broad absorption band, a transmittance window may form at the frequency of the sharp band. The 'missing' band intensity is redistributed by resonance repulsion into the absorption region on both sides of the transmittance window. Such transmittance windows, which have been detected in a wide variety of hydrogen-bonded systems exhibiting broad bands (6–10), are the Evans holes.

Recently Scherer *et al.* (11) have analyzed the stretching regions of their Raman spectra of liquid water and of water–$(CH_3)_2SO$ mixtures assuming the presence of an Evans hole, but the spectral feature corresponding to the transmittance window is not evident in the spectra. A clear demonstration that Evans holes do occur in the spectra of H_2O is therefore desirable. Spectra of crystalline hydrates afford a good opportunity for this, for many of them contain broad OH stretching bands but relatively narrow ν_2 and $2\nu_2$ bands.

Maximum effect, corresponding to case *c* in

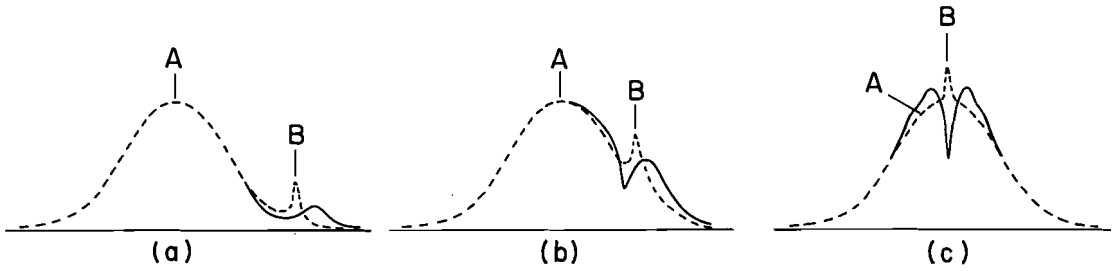

FIG. 1. Spectral phenomena resulting from Fermi resonance between an intense and broad vibrational transition *A* and a weak and relatively sharp vibrational transition *B* (schematic). Cases *a*, *b*, and *c* correspond to decreasing distances between band centers. Dashed line, resonance absent; full line, resonance taking place. After Evans (5) and Claydon and Sheppard (8).

Fig. 1, should arise in hydrates which are sufficiently strongly hydrogen-bonded for the values of OH stretching frequencies to be lowered into the 3200 cm^{-1} region where $2\nu_2$ normally occurs. This is the situation in the tetrachlorocuprates dihydrates, and so their spectra are particularly suited for a study of the phenomenon.

Experimental

The preparation and authentication of the samples and the preparation of specimens have been described elsewhere (1, 2). Sample powders were dispersed in KCl, RbCl, or CsCl pellets, or they were studied as Fluorolube mulls supported on KBr windows. A Perkin–Elmer model 521, and later a model 180, spectrophotometer was used in this work. A Cryo-Tip (Air Products and Chemicals, Inc.) low-temperature sample holder was used to cool samples below liquid-nitrogen temperature; it was capable of reaching about 23 K.

Results

Figure 2 shows the i.r. spectra of $K_2CuCl_4.2H_2O$ and $Rb_2CuCl_4.2H_2O$ in the region of the H_2O bending fundamental and in the OH stretching region.[2] The feature of interest (vertical arrow) is the absorbance minimum near 3200 cm^{-1}, which sharpens and intensifies on cooling. The minimum is present, with minor frequency shifts, in the spectra of all four dihydrates studied.

The following analysis shows that the minimum is not merely an accidentally narrow region of high transmittance between absorption bands but an Evans hole resulting from Fermi resonance between the broad, intense fundamental

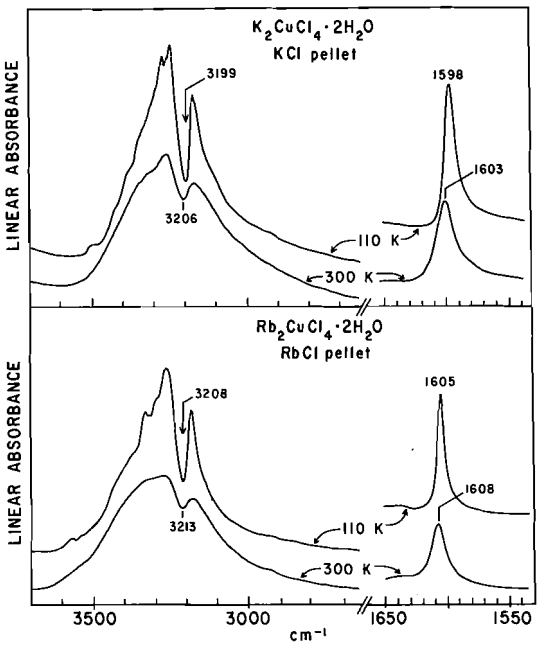

FIG. 2. Infrared spectra of $K_2CuCl_4.2H_2O$ and $Rb_2CuCl_4.2H_2O$ at 300 K and 110 K in the regions of the stretching and bending fundamentals of H_2O. Cooling to 23 K produced very little further change.

ν_1 and a relatively narrow combination band $\nu_2(i) + \nu_2(j)$ produced by different factor-group components i and j of ν_2.

(i) Frequency of the Minimum in the I.R. Spectrum

Analysis of the OH stretching frequencies of HDO and H_2O (1, 2) shows that the center of the ν_1 band of the tetrachlorocuprates dihydrates should occur near 3200 cm^{-1} and thus in the region of the minimum. The H_2O bending fundamental ν_2 in $M_2CuCl_4.2H_2O$ gives rise to four factor-group components, A_{1g}, B_{1g}, A_{2u}, and

[2]Spectral data for the corresponding Cs compound are listed in Table 2, but they are not as accurate as those for K and Rb. The i.r. spectrum of the ammonium compound has been studied in considerable detail but is not suitable for inclusion in this paper because of complications due to NH_4^+ bands; it will be described elsewhere (2).

[c]Inactive component. Frequency calculated on the assumption that the mean frequency of the four factor-group components equals the isotopically isolated frequency.
[d]Reference 12.
[e]The anharmonicity $2x_{22} = -29\ cm^{-1}$ has been assumed throughout (*cf.* ref. 2).
[f]Frequency estimated from Fig. 4 of ref. 12.

B_{2u}. For the K and Rb compounds all four frequencies are known (1, 2). From them one may calculate the expected frequencies of the two binary combinations of symmetry species A_{2u} that may enter into Fermi resonance with the i.r.-active A_{2u} component of ν_1. The calculation (Table 1) assumes an anharmonicity of $-2x_{22} = 29\ cm^{-1}$ (*cf.* ref. 2). The calculated frequencies of the two combination bands lie within a few cm^{-1} of each other and would not be expected to be resolved. The *mean* frequencies of these calculated doublets are in good agreement with the observed frequencies of the minimum in the i.r. spectra of the K and Rb compounds if allowance is made for the uncertainties in the frequencies of the i.r. and Raman components of ν_2 and for a small uncertainty in the anharmonicity.

(ii) Effect of Temperature

The shift of the frequency of the minimum with temperature is in the same direction for the K, Rb, and Cs compounds. Within experimental error it is twice the magnitude of the corresponding shifts of the i.r. active A_{2u} component of ν_2 (Table 2).

(iii) Effect of the Cation

In the series K, Rb, Cs the effect of the cation on the frequency of the minimum is in the same direction and, within experimental error, of twice the magnitude of the effect of the cation on the ν_2 band (Table 2).

(iv) Effect of Deuteration

A corresponding minimum is observed in the OD stretching region of the i.r. spectrum of each of the deuterated compounds. The frequency dependence on temperature and the cation (Table 2) is similar to that in the undeuterated compounds.

(v) Line Width

The half-width of the minimum in the spectra

*At 280 K.

of both the undeuterated and the deuterated compounds decreases on cooling (Fig. 2). An accidental region of low absorptivity between two absorption bands would be expected to widen at lower temperatures as the bands on both sides tend to become narrower.

(vi) Frequency of the Minimum in the Raman Spectrum

The four possible first overtones of the factor-group components of ν_2, *i.e.* the binary combinations $2\nu_2(i)$ where $i = A_{1g}$, B_{1g}, A_{2u}, or B_{2u}, have the symmetry species A_{1g} and can enter into Fermi resonance with the intense Raman-active A_{1g} component of ν_1. The calculated frequencies of these four components (Table 1) fall into two sets of closely-spaced doublets. As in the i.r. spectrum, each of these doublets may be expected to remain unresolved. The Raman spectra of the K and Rb compounds have been recorded by Mathieu and Couture-Mathieu (12); their Fig. 4 shows clearly two sharp minima in the OH stretching region. The separation of the two observed Raman minima is 53 cm^{-1} for the K and 49 cm^{-1} for the Rb compound; the separations of the mean frequencies of the calculated doublets are 52 and 50 cm^{-1} respectively, in very good agreement. The actual frequencies of the observed minima lie somewhat above the calculated frequencies of the unresolved doublets (Table 1). This is expected, as in the Raman spectrum the frequencies of the overtones occur *on the side* of the ν_1 band. The situation thus corresponds to case *b* in Fig. 1, while the situation in the i.r. spectrum appears to correspond to case *c*, with the frequency of the overtone very near to the center of the ν_1 band.

Conclusion

The occurrence of Fermi resonance between the vibrational levels ν_1 and $2\nu_2$ in $M_2CuCl_4.2H_2O$ and in other crystalline hydrates has been recognized before (1, 12). The present observations demonstrate that, in addition, an Evans hole is present, characterized by the close similarity of the spectral *minimum* in the i.r. spectrum and the frequency corresponding to $2\nu_2$.

Our findings confirm that Fermi resonance can lead to unusual spectral features, which must be taken into account in the analysis of the stretching region of the spectra of H_2O and D_2O in condensed phases, as has been done by Scherer *et al.* (11) for the spectrum of liquid water.

We wish to thank Mr. P. F. Seto and M. Denis Bégin for their assistance in obtaining some of the spectra. A grant-in-aid of research from the National Research Council of Canada to one of us (O.K.) is acknowledged.

Zinc Hydroxide: Solubility Product and Hydroxy-complex Stability Constants from 12.5–75 °C

RANDY A. REICHLE, KEITH G. MCCURDY, AND LOREN G. HEPLER
Department of Chemistry, University of Lethbridge, Lethbridge, Alberta T1K 3M4

Received June 30, 1975

RANDY A. REICHLE, KEITH G. MCCURDY, and LOREN G. HEPLER. Can. J. Chem. **53**, 3841 (1975).

We have made atomic absorption measurements leading to the solubility of zinc hydroxide at 12.5, 25.0, 50.0, and 75.0 °C from pH = 6.7 to pH = 13.8. Results have been used for evaluation of the solubility product and stepwise constants for association of Zn^{2+}(aq) with OH^-(aq) to form solute species of type $Zn(OH)_i^{2-i}$(aq) with i = 1–4. Evidence is presented to support the reliability of the various equilibrium constants. Uncertainties in derived enthalpies are assessed.

RANDY A. REICHLE, KEITH G. MCCURDY et LOREN G. HEPLER. Can. J. Chem. **53**, 3841 (1975).

On a fait des mesures d'absorption atomique conduisant à la solubilité de l'hydroxyde de zinc à 12.5, 25.0, 50.0 et 75.0 °C, à des pH = 6.7 à 13.8. On a utilisé les résultats pour évaluer le produit de solubilité et les constantes successives pour l'association de Zn^{2+}(aq) avec OH^-(aq) pour former des espèces solutées du type $Zn(OH)_i^{2-i}$(aq) avec i = 1–4. On présente des données pour supporter la fiabilité de diverses constantes d'équilibre. On établit les incertitudes dans les enthalpies qui en dérivent.

[Traduit par le journal]

Introduction

It is well established that zinc hydroxide is slightly soluble in water, becoming more soluble as the pH is either lowered or raised. There are, however, substantial differences between solubilities at 25 °C reported by various investigators and we know of no solubility measurements that have covered a substantial range of temperature. As a result of these limitations on the available solubility data there are related uncertainties in the equilibrium constants for association of Zn^{2+}(aq) with OH^-(aq) and in the solubility product of zinc hydroxide. We have therefore measured (by atomic absorption spectrophotometry) the solubility of zinc hydroxide at 12.5, 25.0, 50.0, and 75.0 °C from pH = 6.7 to pH = 13.8. Results have been used for evaluation of the solubility product and stepwise equilibrium constants for association of Zn^{2+}(aq) with OH^-(aq).

Experimental

Zinc hydroxide was first precipitated from aqueous zinc sulfate solution by NH_3(aq), washed thoroughly to remove all sulfate, and then dissolved in a small excess of NH_3(aq) as described by Dietrich and Johnston (1). The resulting solution was then transferred to a polyethylene container (to avoid contamination of the product with silica) and placed in a vacuum oven maintained at 60 °C; crystals of zinc hydroxide were soon formed. This procedure leads to the orthorhombic form of $Zn(OH)_2$(c), sometimes called the ε phase.

Solubility determinations began by adding zinc hydroxide and either HCl(aq) or NaOH(aq) to polyethylene test tubes with care taken to exclude CO_2. The stoppered test tubes (containing N_2) were then shaken gently in constant temperature baths controlled to within ±0.1° at 12.5 and 75 °C and to within ±0.05° at 25 and 50 °C. Additional HCl(aq) or NaOH(aq) was added to many of the tubes after they had been in the baths for a few days. Samples of solution in contact with solid zinc hydroxide were removed periodically for analysis. It was found that the concentration of zinc in these solutions usually approached constancy in about 10 days. Solutions were then allowed to stand (without agitation) in the baths for 3 days, which permitted zinc hydroxide to settle, thus facilitating removal of supernatant liquid for analysis.

Zinc analyses were done with a Model 500 Jarrell Ash Atomic Absorption Spectrophotometer. Six standard solutions for calibration were prepared by weight, ranging from 0.01533 to 7.05×10^{-5} m zinc sulfate. Further solutions for calibration were prepared by dilution of some of the original standard solutions, with final concentrations down to 1.41×10^{-6} m.

The pH of each solution (at the temperature of solubility measurement) was measured immediately after the supernatant liquid was removed for analysis for zinc. A Radiometer (Model 26) pH Meter with Corning multipurpose glass electrode and saturated KCl calomel reference electrode was used for these measurements. The system was calibrated with standard buffers described by Bower and Bates (2).

The first solubility measurements were made at 50 °C. The same solid samples were then successively equilibrated at 25 and 12.5 °C. A new set of samples was made up and equilibrated at 75 °C. Subsequent measurements were made by equilibrating separately prepared samples at each temperature. Uncertainties in our experimental solubilities (Table 1) are ~5%.

*S represents the solubility expressed in mol of zinc per kg of water.

Results and Calculations

Results of our solubility determinations are summarized in Table 1, where S represents the total molality of dissolved zinc. Earlier investigations have been cited by Sillén and Martell (3, 4) and Schindler (5). Our results at 25 °C generally agree with those of earlier investigators, although there are significant differences, particularly near the high and low ends of the pH range. There are no earlier solubility data available for higher temperatures to compare with our results.

We begin by interpreting our solubility results in terms of $Zn(OH)_2(c)$ in equilibrium with saturated solution that can contain species that we represent by $Zn^{2+}(aq)$, $Zn(OH)^+(aq)$, $Zn(OH)_2(aq)$, $Zn(OH)_3^-(aq)$, and $Zn(OH)_4^{2-}(aq)$. It is convenient to relate these species to one another and to our solubility data by way of the following equilibria and corresponding equilibrium constants:

$$[1a] \quad Zn(OH)_2(c) \rightleftharpoons Zn(OH)^+(aq) + OH^-(aq)$$

$$[1b] \quad K_1 = [Zn(OH)^+][OH^-]$$

$$[2a] \quad Zn(OH)_2(c) \rightleftharpoons Zn(OH)_2(aq)$$

$$[2b] \quad K_2 = [Zn(OH)_2]$$

$$[3a] \quad Zn(OH)_2(c) + OH^-(aq) \rightleftharpoons Zn(OH)_3^-(aq)$$

$$[3b] \quad K_3 = [Zn(OH)_3^-]/[OH^-]$$

$$[4a] \quad Zn(OH)_2(c) + 2OH^-(aq) \rightleftharpoons Zn(OH)_4^{2-}(aq)$$

$$[4b] \quad K_4 = [Zn(OH)_4^{2-}]/[OH^-]^2$$

$$[5a] \quad Zn(OH)_2(c) \rightleftharpoons Zn^{2+}(aq) + 2OH^-(aq)$$

$$[5b] \quad K_{sp} = [Zn^{2+}][OH^-]^2$$

The square brackets above 'should' indicate thermodynamic activities of the enclosed species, but we have used molalities instead, which means that the equilibrium constants we have evaluated might better be called equilibrium quotients. Consequences of the approximation $a \cong m$ are discussed later in this paper.

The total solubility S can be represented as the sum of molalities of all zinc-containing solute species

$$[6] \quad S = [Zn^{2+}] + [Zn(OH)^+] + [Zn(OH)_2] + [Zn(OH)_3^-] + [Zn(OH)_4^{2-}]$$

Substitution of [1b], [2b], [3b], [4b], and [5b] in [6] leads to

$$[7] \quad S = \frac{K_{sp}}{[OH^-]^2} + \frac{K_1}{[OH^-]} + K_2 + K_3[OH^-] + K_4[OH^-]^2$$

TABLE 2. Equilibrium constants derived from solubilities

t(°C)	K_{sp}(× 10^{17})	K_1(× 10^{11})	K_2(× 10^6)	K_3(× 10^3)	K_4(× 10^2)
12.5	1.42	1.13	1.66	1.12	5.70
25.0	1.74	2.54	2.62	1.32	6.47
50.0	2.34	7.70	7.02	2.56	7.92
75.0	3.16	20.2	15.0	2.74	8.99

Now there are several ways to proceed with evaluation of the various equilibrium constants in [7]. One way is to begin with consideration of our solubilities at relatively low pH where Zn^{2+}(aq) and $Zn(OH)^+$(aq) are likely to be the only important solute species so that we need use only the first two terms on the right hand side of [7]. We thus obtain

$$[8] \qquad S[OH^-] = (K_{sp}/[OH^-]) + K_1$$

that is suitable for graphical evaluation of K_{sp} and K_1. Using pK_w = 14.44, 14.00, 13.28, and 12.71 from Olofsson and Hepler (6) for t = 12.5, 25.0, 50.0, and 75.0 °C to obtain $[OH^-]$ values from our pH values (Table 1), we have constructed graphs of $S[OH^-]$ *vs.* $1/[OH^-]$ and derived the values of K_{sp} and K_1 that are listed in Table 2.

Next we have limited our attention to solubilities at high pH where only $Zn(OH)^-$(aq) and $Zn(OH)_4^{2-}$(aq) are likely to be important solute species. Taking only the last two terms on the right hand side of [7], we obtain

$$[9] \qquad S/[OH^-] = K_3 + K_4[OH^-]$$

and from graphs of $S/[OH^-]$ *vs.* $[OH^-]$ we find the values of K_3 and K_4 that are listed in Table 2.

Now we solve [7] for K_2 in terms of S, $[OH^-]$, and various K values already obtained by way of [8] and [9]. Because $Zn(OH)_2$(aq) is relatively most important at the minimum in solubility, we use the minimum solubility at each temperature with the corresponding pH and other equilibrium constants (Table 2) to obtain the K_2 values that are listed in Table 2.

It should be recognized that the evaluation procedure we have used effectively concentrates most of the uncertainties in all of our work in the reported values of K_2 rather than the other K values.

We have used K values in Table 2 to calculate the fraction f of Zn(II) that exists as Zn^{2+}(aq), $Zn(OH)^+$(aq), $Zn(OH)_2$(aq), $Zn(OH)_3^-$(aq), and $Zn(OH)_4^{2-}$(aq) as pH is varied. Results for 25 °C

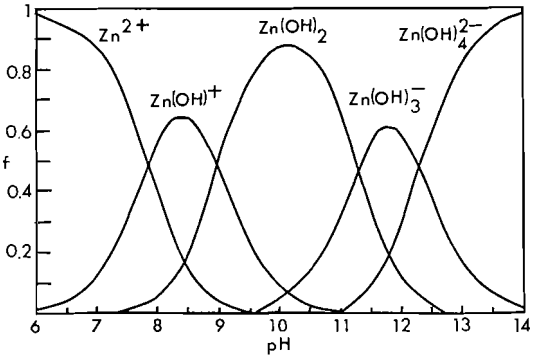

FIG. 1. Graph of fraction f of Zn(II) existing as Zn^{2+}(aq), $Zn(OH)^-$(aq), $Zn(OH)_2$(aq), $Zn(OH)_3^-$, and $Zn(OH)_4^{2-}$(aq) over a range of pH at 25 °C.

are displayed in Fig. 1. Ranges of satisfactory validity of [8] and [9] can be deduced from Fig. 1, or by using data in Table 1 for making appropriate graphs of $S/[OH^-]$ *vs.* $1/[OH^-]$ and $[OH^-]$.

Another approach has been to use all of our solubility–pH data at each temperature for computer calculations leading to overall 'best' fits of [7] and hence the desired K values. Different weighting procedures lead to slightly different K values, but all of the K values obtained in this way are in good agreement with those already listed in Table 2. For some further calculations and comparisons with results of earlier investigators, we will take the values listed in Table 2 to be the best ones that can be derived from our solubilities in combination with our neglect of activity coefficients.

Whether our K values do or do not have the significance we ascribe to them, use of these K values in [7] does lead to calculated solubilities that agree well with the experimental values in Table 1 over the whole range of temperature and pH. In this sense, our K values have uncertainties of a few percent.

Our measurements and calculations have led to $K_{sp} = 1.74 \times 10^{-17}$ at 25 °C. Because this K_{sp} was evaluated from our solubilities in solu-

tions of relatively low pH, all of which were quite dilute, it is appropriate to take this value to be nearly equal to the thermodynamic solubility product in spite of our neglect of activity coefficients. This value can be compared with results of previous investigators as follows.

Reported solubility products at or near 25 °C range from 10^{-13} to 10^{-21}. Here we consider only a few of what appear to be the best of these earlier investigations. Fulton and Swinehart (7) have found $K_{sp} = 0.7 \times 10^{-17}$. Schindler *et al.* (8) have reported $K_{sp} = 3.39 \times 10^{-17}$. Davies and Staveley (9) have reported $K_{sp} = 3.80 \times 10^{-17}$. Each of these thermodynamic (activity coefficients have been considered) solubility products applies to the orthorhombic (ε) modification of zinc hydroxide and can therefore be compared with our value. Our assessment of all of these investigations leads us to suggest that $K_{sp} = 3.5 \times 10^{-17}$ is the 'best' value. The discrepancy between this 'best' value and our result corresponds to a difference of 0.4 kcal mol^{-1} in ΔG^0 for [5*a*].

Application of $d \ln K_{sp}/dT = \Delta H^0/RT^2$ to our results leads to $\Delta H^0 = 2.5$ kcal mol^{-1} for the reaction represented by [5*a*]. We know of no published K_{sp} values at several temperatures that permit calculation of a ΔH^0 value to compare with our result above, but calorimetric measurements have led to ΔH_f^0 values listed in ref. 10 that correspond to $\Delta H^0 = 7.02$ kcal mol^{-1} for [5*a*]. More recently, Davies and Stavely (9) have made new calorimetric measurements that lead to $\Delta H^0 = 7.92$ kcal mol^{-1} for this same reaction. It is nearly certain that this last ΔH^0 is the best one available for this reaction.

The difference between our ΔH^0 and the calorimetric value (10) is much larger than can be accounted for on the basis of statistical analysis of 'reasonable' uncertainties in the various experimental results. It seems to us most likely that the source of the discrepancy lies in the interpretation of our solubilities in terms of [1*a*], [2*a*], [3*a*], [4*a*], and [5*a*] and/or the assumption that the solid phase remains pure $Zn(OH)_2$(c,ε) at temperatures above 25 °C.

Sillén and Martell (3, 4) have reviewed some evidence for dinuclear species in the Zn^{2+}–OH^- system and much evidence for a variety of di- and polynuclear species in other M^{2+}–OH^- systems. Experience with other systems (3, 4) suggests that neglect of small concentrations of these species would lead to only small errors in our K_{sp} values, but to substantially greater errors in the ΔH^0 obtained by differentiation and thence magnification of all experimental and interpretive errors.

The work of Schindler *et al.* (8) has shown that $Zn(OH)_2$(c,ε) is unstable with respect to ZnO(c) and H_2O(liq) and also with respect to $Zn(OH)_2$(amorph), with further evidence that conversion between the various forms of $Zn(OH)_2$ and ZnO is often slow. Since these conversions might be expected to proceed faster at higher temperatures, it is possible that the solid phase in apparent equilibrium with our saturated solutions above 25 °C was some phase other than $Zn(OH)_2$ (c,ε) or was a mixture of phases, which might also account for the error in our calculated ΔH^0 for [5*a*].

We have represented formation of $Zn(OH)^+$(aq) by [1*a*] and have obtained $K_1 = 2.54 \times 10^{-11}$ at 25 °C for this reaction. By combining our K_1 with our K_{sp} we also obtain the equilibrium constant for the reaction

$$[10] \quad Zn^{2+}(aq) + OH^-(aq) \rightleftharpoons Zn(OH)^+(aq)$$

that we report as $\beta_1 = 1.46 \times 10^6$. Further combination of this β_1 with K_w leads to the equilibrium constant for the 'hydrolysis' or 'acid ionization' reaction that we represent by

$$[11] \quad Zn^{2+}(aq) + H_2O(liq) \rightleftharpoons Zn(OH)^+(aq) + H^+(aq)$$

and $K_h = 1.46 \times 10^{-8}$. Because all of these values are based on solubilities in very dilute solutions, all are close to the thermodynamic constants in spite of our neglect of activity coefficients.

Sillén and Martell (3, 4) have reviewed many earlier investigations that have led to a wide range (10^{-3} to 10^3 times our values) of values for K_1, β_1, or K_h. We call particular attention to the $K_h = 1.10 \times 10^{-9}$ reported by Perrin (11) and the $\beta_1 = 2.04 \times 10^6$ reported by Gubeli and Ste-Marie (12) for 1.0 *M* $NaClO_4$ solution as the 'best' previous values for comparison with our results. It is seen that our K_h value is about 10 times that of Perrin (11) while our β_1 value is nearly the same as that of Gubeli and Ste-Marie (12).

Perrin's (11) K_h values at several temperatures from 15 to 42 °C have led him to $\Delta H^0 = 13.4$ kcal mol^{-1} (quoted as probably correct to within about 1 kcal mol^{-1}) for [11]. Combination of our $\Delta H^0 = 2.5$ kcal mol^{-1} for [5*a*] with our $\Delta H^0 = 8.9$ kcal mol^{-1} for [1*a*] (obtained from

d ln K_1/dT) and $\Delta H^0 = 13.3$ kcal mol^{-1} for ionization of water (6) leads to $\Delta H^0 = 19.7$ kcal mol^{-1} for [11]. Or we can combine our ΔH^0 for [1*a*] with ΔH^0 from Davies and Staveley (9) and ΔH^0 of ionization of water (6) to obtain $\Delta H^0 = 14.3$ kcal mol^{-1} for [11]. The former value is in poor agreement with Perrin (11), while the latter value is in good agreement with his results.

Formation constants for $Zn(OH)_i^{2-i}(aq)$ species as in

[12] $Zn^{2+}(aq) + iOH^-(aq) \rightleftharpoons Zn(OH)_i^{2-i}(aq)$

calculated from $\beta_1 = K_i/K_{sp}$ are as follows for 25 °C: $\beta_2 = 1.51 \times 10^{11}$, $\beta_3 = 7.59 \times 10^{13}$, and $\beta_4 = 3.72 \times 10^{15}$.

It is possible to calculate ΔH^0 values for reactions represented by [2*b*], [3*b*], and [4*b*] and thence for reactions of type [12] (i = 2–4) by way of d ln K/dT, but we decline to list the values so obtained. We have already discussed reasons for lack of confidence in related ΔH^0 values for [1*a*], [5*a*], [10], and [11]. Similar uncertainties apply to reactions of type [12] (i = 2–4). For these latter reactions and [2*a*], [3*a*], and [4*a*] there is also the increasingly significant error introduced by our neglect of activity coefficients.

Conclusions

The experimental work and subsequent calculations described here show that it is possible to use atomic absorption spectrophotometry to obtain reliable solubilities of sparingly soluble substances and then to derive reliable equilibrium constants (solubility products and stability constants) from these solubilities. Unfortunately, it also appears that the combination of experimental and interpretive uncertainties is sufficiently great that it is not possible to obtain entirely reliable enthalpies and entropies of reaction by way of d ln K/dT in this way.

We are grateful to the Alberta Department of the Environment for support of this research, and to the STEP program for support of some preliminary investigations that partly led to the work described here.
