Anal. Calcd. for $C_{17}H_{23}NO_2 \cdot HCl$: C, 65.90; H, 7.81; N, 4.52. Found: C, 65.57; H, 7.85; N, 4.27.

Alternatively, **9d** was obtained in a 53% overall yield from **8b** via **9b**, after treatment of the latter with 1.5 *N* NaOH in methanol–water (3:1) at reflux temperature for 3 h, without isolation of **9b**.

17-Cyclobutylcarbonyl-14-hydroxy-3-methoxyisomorphinan (9e)

To a stirred and cooled (ice) solution of **9d** (2.1 g) and triethylamine (1.0 g) in dichloromethane (20 ml) was added dropwise a solution of cyclobutanecarboxylic acid chloride (1.07 g) in dichloromethane (10 ml). The mixture was then washed with water, dried, and concentrated. The residual oil crystallized from ether to give **9e** (2.0 g) as a white solid, m.p. 136–138°.

Anal. Calcd. for $C_{22}H_{20}NO_3$: C, 74.33; H, 8.22; N, 3.94. Found: C, 74.53; H, 8.37; N, 3.78.

14-Hydroxy-3-methoxy-17-methylisomorphinan (9f)

To a solution of lithium aluminum hydride (3.8 g) in anhydrous ether (100 ml) was added dropwise under nitrogen atmosphere a solution of urethane **9a** (34.5 g) in ether (200 ml). The mixture was heated under reflux for 1 h and then worked-up in the usual manner. The crude product, an oil, was converted to its hydrochloride salt in methanol to give **9f** (23.0 g, 65%) as a white solid, m.p. 252–254°; i.r. (free base in $CDCl_3$) 3550 cm^{-1}; n.m.r. (free base in $CDCl_3$) δ 6.6–7.1 (3H, m), 3.76 (3H, s), 0.9–2.1 (10H, m).

Anal. Calcd. for $C_{18}H_{25}NO_2 \cdot HCl$: C, 66.76; H, 8.09; N, 4.32. Found: C, 67.03; H, 8.27; N, 4.18.

17-Cyclopropylmethyl-14-hydroxy-3-methoxyisomorphinan (9g)

A solution of **9c** (1.6 g) in THF (20 ml) was added dropwise to a solution of lithium aluminum hydride (0.47 g) in THF (10 ml) and the mixture was heated under reflux for 1 h. Work-up in the usual manner yielded **9g** as an oil which was converted to its hydrochloride salt in ether. Recrystallization from methanol afforded pure product (1.24 g, 71%) as a white solid, containing ½ mol of water of crystallization, m.p. 229–230°.

Anal. Calcd. for $C_{21}H_{29}NO_3 \cdot HCl \cdot \frac{1}{2}H_2O$: C, 67.67; H, 8.37; N, 3.72. Found: C, 67.63; H, 8.34; N, 3.65.

17-Cyclobutylmethyl-14-hydroxy-3-methoxyisomorphinan (9h)

The hydroxyisomorphinan **9h** was obtained in 74% yield from **9e** by a procedure similar to that given for the preparation of **9g**; hydrochloride salt, m.p. 239–241°.

Anal. Calcd. for $C_{22}H_{31}NO_2 \cdot HCl$: C, 69.91; H, 8.53; N, 3.71. Found: C, 69.71; H, 8.67; N, 3.48.

3,14-Dihydroxy-17-methylisomorphinan (9i)

A solution of **9f** (1.0 g) in 48% hydrobromic acid (10 ml) was heated under reflux for 10 min under nitrogen. After cooling, the mixture was diluted with water, made basic with ammonium hydroxide, and extracted with chloroform. The extract was dried, evaporated, and the residual oil crystallized from ether to afford **9i** (650 mg) as a white solid. Recrystallization from methanol–ether gave an analytical sample, m.p. 191–193°; n.m.r. ($CDCl_3$) δ 6.4–7.0 (3H, m), 2.4–3.0 (5H, m), 2.3 (3H, s), 0.8–2.2 (10H, m).

Anal. Calcd. for $C_{17}H_{23}NO_2$: C, 74.71; H, 8.48; N, 5.13. Found: C, 74.63; H, 8.52; N, 5.01.

17-Cyclopropylmethyl-3,14-dihydroxyisomorphinan (9j)

To a cooled (ice–salt) and stirred solution of boron tribromide (1.85 g) in anhydrous dichloromethane (10 ml) under nitrogen was added a solution of methoxyisomorphinan **9g** (0.80 g) in dichloromethane (10 ml) and the mixture stirred for 2 h at room temperature. It was then slowly poured onto ice–water, basified with ammonium hydroxide, and the layers separated. The organic layer was dried (Na_2SO_4), evaporated *in vacuo*, and the residual amorphous solid treated with dry hydrochloric acid in ether to give 0.59 g of hydrochloride salt of the dihydroxyisomorphinan **9j**. A sample for analysis was recrystallized from methanol, m.p. 222–224°.

Anal. Calcd. for $C_{20}H_{23}NO_2 \cdot HCl \cdot \frac{1}{4}CH_3OH$: C, 67.29; H, 8.27; N, 3.83. Found: C, 66.91; H, 8.35; N, 3.86.

17-Cyclobutylmethyl-3,14-dihydroxyisomorphinan (9k)

The dihydroxyisomorphinan **9k** was obtained in 68% yield from the methoxyisomorphinan **9h** as a white solid (free base), m.p. 162–164°, by a procedure similar to that given for the preparation of **9j**. Recrystallization from methanol gave an analytical sample, m.p. 170–171°.

Anal. Calcd. for $C_{21}H_{29}NO_2$: C, 77.02; H, 8.93; N, 4.28. Found: C, 77.17; H, 9.09; N, 4.11.

3,14-Dimethoxy-17-methylisomorphinan (9l)

A solution of chloramine **3g** (5.0 g) in methanol (150 ml) was heated under reflux for 24 h. The methanol was evaporated *in vacuo* and the residue extracted with petroleum ether. The extract was evaporated to give an oil (4.5 g), which was chromatographed on an alumina column (activity III to IV; eluent, dichloromethane) to give the dimethoxyisomorphinan **9l** (1.45 g) as an oil; n.m.r. ($CDCl_3$) δ 6.5–7.3 (3H, m), 3.84 (3H, s), 3.11 (3H, s), 2.38 (3H, s), 2.2–3.4 (5H, m), 0.8–2.2 (10H, m). The hydrochloride salt was recrystallized from isopropyl alcohol, m.p. 248–250°.

Anal. Calcd. for $C_{19}H_{27}NO_2 \cdot HCl$: C, 67.54; H, 8.35; N, 4.14. Found: C, 67.41; H, 8.35; N, 3.90.

17-Allyl-14-hydroxy-3-methoxyisomorphinan (9m)

A solution of **9d** (1.09 g), triethylamine (2.02 g), and allylbromide (0.73 g) in dry ethanol was heated under reflux and under nitrogen for 18 h. After cooling, it was partitioned between chloroform and dilute ammonium hydroxide. The organic layer was separated, dried, and evaporated to yield 1.20 g of **9m** as an oil; i.r. (neat) 3460 and 3560 cm^{-1}; n.m.r. ($CDCl_3$) δ 6.6–7.2 (3H, m), 5.0–6.4 (3H, m), 3.68 (3H, s), 0.8–3.2 (17H).

A sample for analysis was purified as the hydrochloride salt which was recrystallized from methanol–ether, m.p. 243–245°.

Anal. Calcd. for $C_{20}H_{27}NO_2 \cdot HCl$: C, 68.65; H, 8.07; N, 4.00. Found: C, 68.46; H, 8.18; N, 3.93.

17-Allyl-3,14-dihydroxyisomorphinan (9n)

To a cooled (ice–salt) solution of boron tribromide (1.75 g) in dichloromethane (10 ml) was added under nitrogen a solution of **9m** (1.1 g) in dichloromethane (10 ml) and the mixture was stirred for 1 h at room temperature. It was then treated with ice and concentrated ammonium hydroxide and the layers separated. The organic layer was dried (Na_2SO_4) and concentrated *in vacuo* to afford 1.0 g of **9n** as an oil; i.r. (neat) 3200 cm^{-1}; n.m.r. ($CDCl_3$) δ 6.1–7.1 (3H, m), 3.9–6.1 (3H, m), 0.5–3.2 (17H). The hydrochloride salt was recrystallized from 2-propanol, m.p. 248–250° (dec.).

Anal. Calcd. for $C_{19}H_{25}NO_2 \cdot HCl$: C, 67.94; H, 7.80; N, 4.17. Found: C, 67.75; H, 7.88; N, 3.96.

9α-Hydroxy-3-methoxy-17-methylhasubanan (10) and the Corresponding 14-Hydroxyisomorphinan (9f)

To a solution of *N*-trifluoroacetyl epoxide **8d** (5.4 g) in methanol (160 ml) was added a 10% aqueous solution of potassium carbonate (150 ml) and the mixture was stirred at room temperature for 2 h. It was then concentrated to a small volume, diluted with water, and extracted with ether to yield after drying and evaporation of the ether extract an oil (3.50 g). This was dissolved in methanol (50 ml) and the solution heated under reflux for 18 h under nitrogen. The solvent was then evaporated, and the residue chromatographed on an alumina column (activity III to IV; eluent, $CHCl_3$) to give at first 14-hydroxyisomorphinan **9f** (1.49 g) followed by 9α-hydroxyhasubanan **10** (1.52 g) as an oil; i.r. (neat) 3400 cm^{-1}; n.m.r. δ 6.6–7.2 (3H, m), 4.2 (1H, dd, J_1 = 6 Hz, J_2 = 9 Hz, 9-H), 3.79 (3H, s), 2.7–3.3 (4H, m), 2.62 (3H, s), 0.8–2.2 (10H, m).

The oxalate salt of **10** crystallized from methanol–acetone with ½ mol of methanol of crystallization, m.p. 109–111°.

Anal. Calcd. for $C_{18}H_{25}NO_2 \cdot C_2H_2O_4 \cdot \frac{1}{2}CH_3OH$: C, 62.58; H, 7.43; N, 3.56. Found: C, 62.69; H, 7.73; N, 3.31.

17-Ethoxycarbonyl-3-methoxy-$\Delta^{8,14}$-morphinan (11a)

To a cooled (ice–water) solution of hydroxyisomorphinan **9a** (48.0 g) in pyridine (96 ml) was added dropwise under nitrogen phosphorous oxychloride (48 ml) and the mixture was left at room temperature for 7 days. It was then diluted with benzene (200 ml) and carefully poured onto ice–water. The layers were separated and the water layer extracted with benzene (100 ml). The combined benzene extracts were washed with water, dried, and concentrated *in vacuo*. The residual brown oil was dissolved in ether followed by addition of petroleum ether. The turbid mixture was filtered through Celite–charcoal cake and evaporated to dryness to yield $\Delta^{8,14}$-morphinan **11a** (36.0 g; 79%) as a colorless oil; i.r. (neat) 1680 cm^{-1}; n.m.r. δ 6.6–7.2 (3H, m), 5.78 (1H, t, J = 4 Hz, 8-H), 4.16 (2H, q, J = 7 Hz), 3.82 (3H, s), 2.5–3.2 (5H, m), 1.28 (3H, t, J = 7 Hz), 1.2–2.4 (8H, m).

Anal. Calcd. for $C_{20}H_{25}NO_3$: C, 73.37; H, 7.70; N, 4.28. Found: C, 73.22; H, 7.33; N, 4.12.

3-Methoxy-$\Delta^{8,14}$-morphinan (11b)

A mixture of *N*-carbethoxymorphinan **11a** (32.7 g) and potassium hydroxide pellets (28.0 g) in 1-octanol (160 ml) was heated under reflux and under nitrogen for 45 min. The mixture was then worked-up as described above for the preparation of **9d** to give 20 g of a crude oily product. The oil was dissolved in acetone and treated with an acetone solution of oxalic acid. Addition of ether caused precipitation of a solid which was recrystallized from methanol–acetone to afford pure **11b** (12.0 g, 34.8%) as white crystals, m.p. 187–189°; n.m.r. (free base in CCl_4) δ 6.45–7.05 (3H, m), 5.5 (1H, t, J = 4 Hz), 3.71 (3H, s), 2.5–3.5 (5H, m), 1.2–2.5 (8H, m).

Anal. Calcd. for $C_{17}H_{21}NO \cdot C_2H_2O_4$: C, 66.07; H, 6.71; N, 4.06. Found: C, 66.28; H, 6.72; N, 4.11.

Total Synthesis of Monosaccharides. Synthesis of Methyl DL-Pentopyranosides with α- and β-*lyxo*, β-*ribo*, α-*xylo*, and α-*arabino* Configurations from Furfuryl Alcohol[1]

OSMAN ACHMATOWICZ, JR.[2] AND PAWEL BUKOWSKI
Institute of Organic Chemistry, Polish Academy of Sciences, 00-961, Warsaw, Poland

Received March 17, 1975

OSMAN ACHMATOWICZ, JR. and PAWEL BUKOWSKI. Can. J. Chem. **53**, 2524 (1975).

Hydroxylation and epoxidation, followed by the oxirane ring opening, of methyl 2,3-dideoxy-α and β-DL-pent-2-enopyranosides, readily available by the transformation of furfuryl alcohol, afforded the title compounds. Steric course of hydroxylation and epoxidation reactions were examined. The p.m.r. data of methyl 4-*O*-acetyl-2,3-anhydro-DL-pentopyranosides are reported.

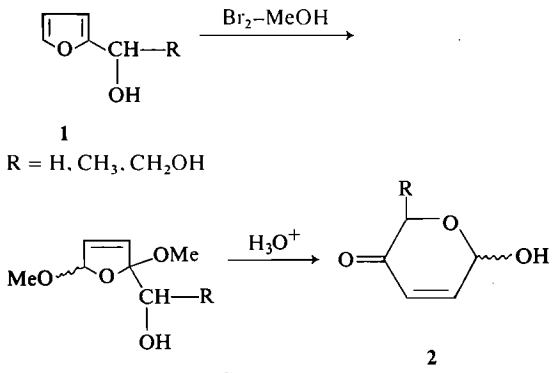
OSMAN ACHMATOWICZ, JR. et PAWEL BUKOWSKI. Can. J. Chem. **53**, 2524 (1975).

L'hydroxylation et l'époxydation, suivie d'une ouverture du cycle oxyrannique, du didéoxy-2,3 α- et β-DL-penténo-2 pyrannosides, facilement obtenu par transformation du furanne-2 méthanol, conduit aux composés du titre. On a étudié la stéréochimie de l'hydroxylation et de l'époxydation. Les données du spectre r.p.m. du méthyl *O*-acétyl-4 anhydro-2,3 DL-pentopyrannosides sont présentées. [Traduit par le journal]

In a recent paper (1) from this laboratory we have reported on the transformation (Scheme 1) of 2-furylcarbinols of general formula **1** into methyl 2,3-dideoxy-DL-alk-2-enopyranosid-4-uloses (**2**) which are potentially useful as substrates for versatile total syntheses of sugars. In the present paper we describe the application of the above mentioned transformation to the preparation of methyl DL-pentopyranosides.

Results and Discussion

Furfuryl alcohol (**3**) was transformed in three steps (1) into methyl 2,3-dideoxy-DL-pent-2-enopyranosid-4-ulose (**4**), which on reduction with sodium borohydride gave an excellent yield of methyl 2,3-dideoxy-α-DL-*glycero*-pent-2-enopyranoside (**5**) (Scheme 2). The isomer having β configuration (**6**) was obtained from **5** by inversion of the configuration at C-4 (2). Compounds **5** and **6** served as direct substrates for the synthesis of methyl DL-pentopyranosides and methyl 2,3-anhydro-DL-pentopyranosides.



SCHEME 1

Methyl α-DL-*Lyxopyranoside (7)*

Cis hydroxylation of the double bond in **5** by means of hydrogen peroxide in the presence of catalytic amounts of osmium tetroxide (Milas' reagent) gave 45% yield of a single (t.l.c.) crystalline product. Its elemental analysis and i.r. spectrum were those required by methyl pentoside. Assuming that the hydroxylating agent was attacking from the side of the smaller steric hindrance, we assigned to the obtained product the structure of methyl α-DL-lyxopyranoside (**7**). This structure was confirmed by comparison of t.l.c. R_f values and p.m.r. spectra of the tri-*O*-acetyl derivative **7***a* with those of an authentic sample of methyl 2,3,4-tri-*O*-acetyl-α-D-lyxopyranoside.

Methyl β-DL-*Ribo- (8) and Methyl* β-DL-*Lyxopyranoside (9)*

Cis hydroxylation of methyl 2,3-dideoxy-β-DL-pent-2-enopyranoside (**6**) with Milas' reagent gave 42% yield of a mixture of two compounds

in the ratio 6:4 (g.l.c.). Their R_f values in t.l.c. corresponded to those of methyl β-D-ribo- and methyl β-D-lyxopyranosides. Both compounds were isolated by chromatography on silica gel columns. The preponderant component of the mixture was converted into its tri-*O*-acetyl derivative (**8***a*), having R_f values in t.l.c. and p.m.r. spectrum identical with those of methyl 2,3,4-tri-*O*-acetyl-β-D-ribopyranoside, prepared from natural D-ribose. Comparison of g.l.c. chromatograms of trimethyl silyl ethers of the second component of the mixture and methyl glycosides of natural pentoses proved that it was methyl β-DL-lyxopyranoside (**9**).

The foregoing results show the predictable (3) sensitivity of the *cis* hydroxylation with Milas' reagent towards steric hindrance. In the case of compound **5**, having both substituents on the same side of the ring, the reaction is fully stereoselective, whereas hydroxylation of compound **6**, in which the steric hindrance due to substituents at C-1 and C-4 acts in opposite directions, results in a mixture of two products.

*Methyl 2,3-Anhydro-*DL*-pentopyranosides, α- and* β*-ribo and* α*- and* β*-lyxo*

Preparation of methyl DL-pentosides having *arabino* and *xylo* configurations required an introduction of hydroxyl groups to the double bond of compound **5** or **6** in relation *trans* to each other. This was achieved by epoxidation followed by opening of the oxirane ring.

The epoxidation of compounds **5** and **6** with *m*-chloroperbenzoic acid gave mixtures of two products in the ratio 9:1 and 10:1, respectively, which were separated on silica gel column. All compounds gave elemental analysis and i.r. spectra required by methyl 2,3-anhydropentopyranosides. Their configurations were determined on the basis of p.m.r. spectra of 4-*O*-acetyl derivatives. Stereoselectivity of the epoxidation reaction was in agreement with that previously found in similar systems (4), that is, prevailing formation of the oxirane ring *cis* to the hydroxyl group. In the p.m.r. spectrum of 4-*O*-acetyl derivative (**10***a*) of the main epoxidation product obtained from **5**, the coupling constant of protons H-1 and H-2 was 2.8 Hz. Hence we ascribed[4] to it α-*ribo* configuration (**10**); α-*lyxo* configuration (**11**) was assigned to the minor product, on the basis of H-1 and H-2 coupling constants, which in this case amounted to about 0 Hz.

In the 2,3-anhydro compound, the major product from **6**, the respective coupling constants indicated a *cis* relation for protons H-3 and H-4 (J_{34} = 4.8 Hz) and *trans* for H-1 and H-2 (J_{12} = 0 Hz), hence it was assigned β-*ribo* configuration (**12**). The minor product, from the *cis* relation of H-1 and H-2 protons (J_{12} = 2.4 Hz), had β-*lyxo* (**13**) configuration.

It should be also noted that stereoselectivity of epoxidation with *m*-chloroperbenzoic acid of **5** could be reversed by carrying out reaction on its 4-*O*-acetyl derivative **5***a* (*cf.* Table 1). The results of epoxidation reactions and p.m.r. data of methyl 4-*O*-acetyl-2,3-anhydro-DL-pentopyranosides are shown in Tables 1 and 2.

Methyl α*-*DL*-Xylopyranoside (14)*

Hydrolysis of the sugar epoxides with stabilized conformation of the pyranose ring proceeds according to the Fürst–Plattner rule, *i.e.* by diaxial opening of the oxirane ring (6). For conformationally mobile[5] methyl 2,3-anhydropentopyranosides it was found that due to the inductive effect of the acetal group, the attack of the reagent at C-3 is predominant (ref. 7, p. 31 and references cited therein). In fact alkaline[6] hydrolysis of the oxirane ring in methyl 2,3-anhydro-α-DL-ribopyranoside (**10**) gave in 73% yield a mixture of two products in the ratio 8:2, which in t.l.c. had R_f values corresponding to methyl α-L-xylo- and α-D-arabinopyranosides, respectively. The main component of the mixture was isolated by chromatography on silica gel column. This crystalline material, m.p. 124–126° afforded tri-*O*-acetyl derivative **14***a* with R_f values in t.l.c. and p.m.r. spectrum identical with those of methyl tri-*O*-acetyl-α-L-xylopyranoside. In this experiment methyl α-DL-arabinopyranoside, which was present in the reaction mixture, could not be isolated in the analytically pure state.

Methyl α*-*DL*-arabinopyranoside (15)*

The major product derived from cleavage of epoxide **11** (α-*lyxo* configuration) should be methyl-α-DL-arabinopyranoside **15**, by analogy

[4]It has been shown by numerous examples (5), that in methyl 2,3-anhydropyranosides the coupling constant value of *cis* H-1 and H-2 (or H-3 and H-4) protons is between 2.5 and 4.0 Hz, whereas that of the corresponding *trans* protons is close to zero.

[5]Different factors governing regio- and stereoselectivity of oxirane ring scission were recently discussed in an excellent review (7).

[6]Hydrolysis of **10** with 80% acetic acid gave unsatisfactory results.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

to the opening of epoxides possessing the α-*ribo* configuration. In the event, methyl 4-*O*-acetyl-2,3-anhydro-α-DL-lyxopyranoside **11***a*, on reaction with 80% acetic acid, afforded **15** as the only isolable product (60%) characterized by comparison to an authentic sample and its tri-*O*-acetyl derivative **15***b*. High regioselectivity of the oxirane ring opening in the anhydrosugar **11***a* is presumedly due to the neighboring acetoxy group participation. Also conformational equilibrium[7] of **11***a* favors this course of the reaction (7). In the case of the anhydro sugar **10** axial approach of the reagent to C-3 is possible for minor conformer, hence lower stereoselectivity of the oxirane ring opening.

Alkaline hydrolysis of epoxide **11***a* was accompanied by considerable 'migration' of the oxirane ring (8). As a result, the predominant product of the reaction (along with small amount of methyl α-DL-arabinopyranoside **15**) was methyl α-DL-lyxopyranoside (**7**), which was identified by direct comparison with a sample of this compound previously obtained by *cis* hydroxylation of **5**.

Conclusions

The foregoing reactions of hydroxylation and epoxidation (followed by oxirane ring opening) of racemic methyl 2,3-unsaturated glycosides **5** and **6** afforded all methyl DL-pentopyranosides. These results indicate also that the method can be used for the preparation of modified (*O*-substituted, amino-, deoxy-, *etc.*) pentoses, via 2,3-anhydro compounds **10**, **11**, and **13**, from furfuryl alcohol.

It is worth notice that furfural is the final product of the well known degradation of pentoses by acids (9). Since compounds **5** and **6** have been readily obtained from furfuryl alcohol (2) and consequently from furfural, the present report concludes the reverse process initiated in our previous paper (1), namely stereoselective transformation of furfural into methyl DL-pentopyranosides.

[7]From the coupling constants J_{45} and $J_{45'}$ (Table 2) it follows that **10***a* and **11***a* appear predominantly in the depicted conformations.

Experimental

Melting points were determined on a Koffler block and are uncorrected. Boiling points refer to the air bath temperature. The i.r. spectra were obtained on Unicam SP-200, using KBr discs for solids and films for liquids. The p.m.r. spectra were measured on Varian HA-60-IL or Jeol JNM-4H-100 spectrometers. Gas–liquid chromatographic analyses were made with a Willy Giede gas chromatograph 18/3. Elemental analyses were carried out on micro scale. For column chromatography silica gel Schuchardt, 100–200 mesh was used. All reactions and chromatographic separations were monitored by t.l.c., which was done using silica gel G (E. Merck). Solvents were removed by rotatory evaporator under vacuum.

Acetylations were carried out with acetic anhydride – pyridine 1:1 mixture at room temperature. Epoxidations were performed according to the following general procedure. A solution of methyl 2,3-dideoxy-DL-pent-2-enopyranoside and 10% molar excess of 80% *m*-chloroperbenzoic acid in methylene chloride was left at room temperature. When reaction was complete (as indicated by t.l.c.) precipitated *m*-chlorobenzoic acid was filtered off, the solution evaporated to dryness, and pure products were isolated by column chromatography using benzene – ethyl acetate (4:1) as eluant. Epoxidation data are given in Table 1.

Methyl pentopyranosides and their tri-*O*-acetyl derivatives, which were used for comparison, were prepared from natural pentoses and had reported m.p. values and optical rotations.

Methyl α-DL-*Lyxopyranoside (7)*

A solution of 4.4 mg (0.017 mmol) of osmium tetroxide in 1 ml of *tert*-butyl alcohol was added to a solution of 260 mg (2.00 mmol) of **5** in 5 ml of 6% hydrogen peroxide in *tert*-butyl alcohol. After 6 days the reaction was completed, solvents removed and the residue chromatographed on silica gel (6 g) column. Elution with ethyl acetate and ethyl acetate – propanol (95:5) afforded 146 mg (45%) of **7**, m.p. 119–120° (methanol–ether); i.r. (KBr): 3400, 3300 (OH), 1090 cm^{-1} (C—O).

Anal. Calcd. for $C_6H_{12}O_5$: C, 43.9; H, 7.4. Found: C, 43.7; H, 7.3.

Methyl 2,3,4-tri-*O*-acetyl-α-DL-lyxopyranoside (**7***a*), m.p. 88–89° (sublimed), i.r. (KBr): 1750, 1235 cm^{-1} (—OAc).

Anal. Calcd. for $C_{12}H_{18}O_8$: C, 49.7; H, 6.3. Found: C, 49.8; H, 6.4.

Methyl β-DL-*Ribopyranoside (8)*

A solution of 19 mg (0.075 mmol) of osmium tetroxide in 1 ml of *tert*-butyl alcohol was added to a solution of 177 mg (1.36 mmol) of **6** in 6 ml of 6% hydrogen peroxide in *tert*-butyl alcohol. After 7 days the reaction mixture was evaporated to dryness and the residue chromatographed on silica gel (6 g) column. Elution with ethyl acetate gave 57 mg (26%) of **8**, colorless oil; i.r.: 3420 (OH), 1060 cm^{-1} (C—O). Compound **8**, treated with acetic anhydride – pyridine mixture gave 2,3,4-tri-*O*-acetyl derivative **8***a*, b.p. 120°/10^{-3} Torr, i.r. (film): 1745, 1240 cm^{-1} (—OAc).

Anal. Calcd. for $C_{12}H_{18}O_8$: C, 49.7; H, 6.3. Found: C, 50.0; H, 6.4.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Methyl β-DL-Lyxopyranoside (9)

Elution of the chromatographic column from the previous experiment with ethyl acetate – propanol (95:5) gave 10 mg (5%) of **8** and **9** mixture and then 37 mg (17%) of **9**; i.r. (film): 3500, 3400 (OH), 1100–1040 cm^{-1} (C—O). Compound **9** was identified by comparison of retention times of its trimethyl silyl ether with that of methyl β-D-lyxopyranoside.

Methyl α-DL-Xylopyranoside (14)

A solution of 690 mg (4.7 mmol) of **10** in 2 ml of 1 *N* aqueous sodium hydroxide was heated at 95° for 8 h, chilled, filtered through 20 ml of Amberlite IRC-50 (H^+) column, and washed with water. Combined filtrates were taken to dryness to give 811 mg of dark gum, which was chromatographed on silica gel (18 g) column. Elution with ethyl acetate and than ethyl acetate – propanol (95:5) afforded 299 mg (39%) of homogeneous (t.l.c.) **14**, m.p. 124–126° (methanol–ether), i.r. (KBr): 3400 (OH), 1100, 1050 (C—O), 940 cm^{-1} (tetrahydropyran).

Anal. Calcd. for $C_6H_{12}O_5$: C, 43.9; H, 7.4. Found: C, 44.2; H, 7.5.

Further elution of the chromatographic column with the same solvent gave 266 mg (34%) of an oil which comprised (t.l.c.) **14** and **15**.

Methyl 2,3,4-tri-*O*-acetyl-α-DL-xylopyranoside (**14***a*), m.p. 156.5–158°; i.r. (KBr): 1750, 1230 (—OAc), 1050 (C—O), 940 cm^{-1} (tetrahydropyran).

Anal. Calcd. for $C_{12}H_{18}O_8$: C, 49.7; H, 6.3. Found: C, 49.9; H, 6.3.

Rearrangement of Methyl 4-O-Acetyl-2,3-anhydro-α-DL-lyxopyranoside (11a). Methyl α-DL-Lyxopyranoside (7)

A portion (217 mg, 1.15 mmol) of **11***a*, when treated with 2 ml of 1 *N* aqueous sodium hydroxide at 95° for 4 h and worked-up as described in the previous experiment, gave 142 mg (57%) of **7**, identical in every respect (t.l.c., i.r., p.m.r.) with the sample obtained by *cis* hydroxylation of **5**.

Methyl 4-O-Acetyl-α-DL-arabinopyranoside (15a)

A solution of 735 mg (3.9 mmol) of **11***a* in 6.5 ml of 80% acetic acid was heated under reflux for 20 min, the solvent evaporated and the residue recrystallized from ethyl acetate – ether mixture to give 474 mg (59%) of **15***a*, m.p. 110.5–111.5°; i.r. (KBr): 3450 (OH), 1745, 1240 cm^{-1} (—OAc); p.m.r. (D_2O): δ 5.12 (m, 1H, H-4), 4.33 (d, J_{12} = 7.2 Hz, 1H, H-1), 3.57 (s, 3H, OCH_3), 1.89 (s, 3H, OAc).

Anal. Calcd. for $C_8H_{14}O_6$: C, 46.6; H, 6.8. Found: C, 46.7; H, 7.1.

Methyl α-DL-Arabinopyranoside (15)

To a solution of 134 mg (0.65 mmol) of **15***a* in 10 ml of methanol, about 2 mg of sodium was added. After 45 min the reaction mixture was neutralized with acetic acid, evaporated to dryness, residue dissolved in 10 ml of water, filtered through 0.5 ml Amberlite IR-120 (H^+) column, and evaporated again to give 104 mg (97%) of product, which solidified. Recrystallization from ethyl acetate afforded 80 mg of **15**, m.p. 107.5–110°; i.r. (KBr): 3450 (OH), 1090, 1070 cm^{-1} (C—O).

Anal. Calcd. for $C_6H_{12}O_5$: C, 43.9; H, 7.4. Found: C, 44.2; H, 7.4.

Methyl 2,3,4-tri-*O*-acetyl-α-DL-arabinopyranoside (**15***b*), m.p. 124–125° (recrystallization from ether – petroleum ether and sublimation), i.r. (KBr): 1750, 1230 (—OAc), 1060 cm^{-1} (C—O).

Anal. Calcd. for $C_{12}H_{18}O_8$: C, 49.7; H, 6.3. Found: C, 50.0; H, 6.5.

Introduction

While developing a method for gas chromatographic (g.c.) analysis of organic acids in tobacco, three products were observed from oxalic acid when the total free acid extract was treated with an excess of ethereal diazomethane. On the basis of a comparison of infrared, nuclear magnetic resonance, and mass spectra, and gas chromatographic retention times with those of authentic samples, the products were identified as dimethyl oxalate, methylethyl oxalate, and diethyl oxalate.

The reaction of diazomethane with ketones is well known. However, there appears to be only one report (1) of this reagent attacking ester carbonyls. In that study, esters having an adjacent strong electron-withdrawing group such as $-CF_3$ or $-CCl_3$, reacted readily with diazomethane to form an ester and/or epoxide. Furthermore, diethyl oxalate was converted to methylethyl oxalate in 32% yield.

Transesterification of acetates (2, 3), benzoates (2), and lactones (3) has been observed in the presence of alcohol and diazomethane.

Results and Discussion

In the first part of this study, diazomethane was prepared from Diazald ® using the two methods given by the manufacturer. Preparation A involves use of ethanol, which partially codistills with the ether and diazomethane, and preparation B involves use of 2-(2-ethoxyethoxy)-ethanol, which does not. Aliquots of the resulting ethereal solutions containing the desired amount of diazomethane were added to ice-chilled ether solutions of oxalic acid or its esters. After standing at room temperature for about 24 h, the resulting solutions were analyzed by gas chromatography.

Normally the reaction between an acid and diazomethane is instantaneous. However, longer reaction times were required in the initial work on the tobacco acids and it was only under these conditions that the multiplicity of products was observed when diazomethane from preparation A was used.

The data in Table 1 show that when oxalic acid is treated with an alcohol-free solution of diazomethane, dimethyl oxalate is the only product. If small amounts of ethanol are present, some of the dimethyl ester is converted to the methylethyl and diethyl esters, the degree of conversion being dependent upon the amount of alcohol present. When an oxalate ester is treated with an alcohol-free solution of diazomethane there is no reaction; however, after an alcohol is added, products dependent upon the nature of the alcohol are formed. Treatment of dimethyloxalate with a blank prepared by procedure A without Diazald resulted in no change. Under these conditions no reaction was observed between diethyl oxalate and diazomethane in the absence of alcohol.

Figure 1 shows a time dependent analysis of the reaction between dimethyl oxalate and a solution containing 10 equiv. of diazomethane from preparation A and clearly indicates an equilibrium reaction.

The evidence suggests that oxalic acid esters

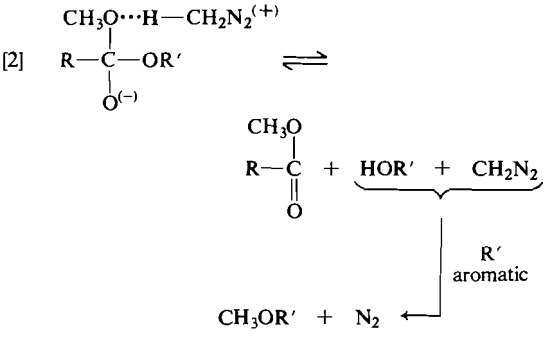
undergo diazomethane-catalyzed transesterification with alcohols. This transesterification appears to be restricted to oxalic acid esters; under identical conditions using preparation A, methyl esters of homologous dicarboxylic acids (malonic, succinic, and glutaric) and other polycarboxylic acids (malic and citric) were unaffected.

Methanol has been shown (4) to form a complex with diazomethane. Bredereck *et al.* (2)

[1] $$CH_3OH + CH_2N_2 \rightleftharpoons [CH_3O]^-[H{-}CH_2N_2]^+$$

postulated that the ester carbonyl undergoes nucleophilic attack by the methoxide moiety, and the resulting transition complex dissassociates to yield a new ester and an alcohol. When R′ is aromatic, the phenol reacts irreversibly to form an ether. The majority of the acetates and benzoates studied by Bredereck *et al.* (2) had R′ aromatic and were run in methanol as solvent, both factors favoring transesterification.

[2]



One can rationalize the apparent nonreactivity of polycarboxylic acids other than oxalic after examining the relative rates of nucleophilic alkaline hydrolysis of dicarboxylic acid esters, summarized in Table 2. It is readily apparent that nucleophilic attack by hydroxide ion proceeds at least four orders of magnitude more quickly on oxalate carbonyls than on other saturated homologs. This can be explained as due

[b]Data from ref. 1.

to the effect of one carboxyl group inductively increasing the electrophilicity of the other. The unsaturated diesters that can be influenced by this inductive effect also show some rate enhancement over their saturated analog. An investigation of the transesterification of these unsaturated diesters would have been instructive but this reaction could not be studied since these esters readily undergo 1,3-dipolar addition of diazomethane to form pyrazoline derivatives (11).

The conditions under which diazomethane reactions are conducted can influence the results. The data in Table 3 show that when alcohol-free diazomethane is bubbled into diethyl oxalate some reaction does occur, in agreement with Green's findings (1). In the presence of methanol, transesterification of diethyl oxalate is the predominant reaction, the degree of conversion being dependent upon the amount of alcohol rather than the amount of diazomethane. Transesterification of malonate esters, not observed under the milder conditions of preparation A, does occur slightly when larger amounts of alcohol are present.

Thus, it is prudent to exercise care when alkylating carboxylic acids with diazoalkanes. Others have observed the influence of conditions on side reactions. Pike *et al.* (12) recently reported that palmitic acid and ethereal diazoethane afforded the expected ethyl ester; however, a 7% yield of the methyl ester was also observed when aqueous 1,2-dimethoxyethane was the solvent. Mlejnek (13) reported that pyrazoline formation with unsaturated diacids could be suppressed at −60 °C and higher yields of dimethyl adipate were obtained when dioxane replaced ether as solvent.

Experimental

Spectral Determinations

Infrared spectra were determined in carbon tetrachloride on a Beckman IR-20A spectrometer. Nuclear magnetic resonance spectra were determined in carbon tetrachloride on a Varian T-60 spectrometer. Mass spectra were determined on a Finnigan 9500 gas chromatograph

(1.8 m × 6.5 mm od glass column containing 3% SE-30 ultraphase on high performance Chromosorb W, 80–100 mesh) coupled to a 3100D quadrapole mass spectrometer and a 6000 computer controlled data aquisition system.

Preparation and Analysis of Diazomethane

Diazomethane was prepared from Diazald (Aldrich Chemical Company, Inc.) using the two procedures given on the reagent bottle. Preparation A involves use of ethanol as solvent and affords an alcoholic ethereal solution. Preparation B involves use of 2-(2-ethoxyethoxy)-ethanol as solvent and affords an alcohol-free ethereal solution. Preparation C, based on the method of Green (1), involves redistilling the product from preparation B and then bubbling dry nitrogen through the distillate into an ester or its solution. The resulting solutions were analyzed by adding an aliquot to an excess of benzoic acid and back titrating with a standardized sodium hydroxide solution.

Preparation of Standards

Dimethyl, diethyl, and dipropyl oxalates were prepared by refluxing a solution of oxalic acid, sulfuric acid, and the appropriate alcohol in benzene, followed by normal work-up (14). Methylethyl oxalate was prepared by treating an ethereal solution of monoethyl oxalate with ethereal diazomethane and immediately working up the reaction mixture. Methylpropyl and ethylpropyl oxalates were prepared by the method of Ivashchenko and Moshchitskii (15) by distilling a mixture of propanol and cuprous chloride and dimethyl or diethyl oxalate, respectively. Methylethyl malonate was prepared by treating an ethereal solution of monoethyl malonate (16) with ethereal diazomethane and immediately working up the reaction mixture. Other acids and esters were obtained from commercial sources. All standards showed spectral properties consistent with their structures.

Product Ratio Analysis

Product ratios were determined on a Pye 104 gas chromatograph with a flame ionization detector and 1.5 m × 6.5 mm od glass column containing 4.5% DEGS on Gas Chrom G, 80–100 mesh, or 5% Carbowax 20M on high performance Chromosorb W, 80–100 mesh. Products were isolated by gc fractionation using an effluent splitter and thermal gradient collector (17) and then identified by comparison of gc retention times and i.r. n.m.r., and mass spectra with those of standards.

Reaction of Oxalic Acid and Oxalate Esters in Presence of Diazomethane from Preparations A and B

In a typical experiment, an ice-chilled solution of 10 mg oxalic acid or its ester in 10 ml of ether was treated with a chilled ethereal solution containing the desired amount of diazomethane. After standing at room temperature for 24 h, the resulting solution was analyzed by gc. See Table 1 for relative amounts of reagents, solvent conditions, and results. The product ratios represent actual yields.

Reaction of Diethyl Oxalate and Diethyl Malonate in Presence of Diazomethane from Preparation C

Green's procedure (1) was followed. A slow stream of dry nitrogen was bubbled through an ice-chilled alcohol-free ethereal solution of diazomethane into 0.5 mmol of ester and methanol, if any, contained in a flask equipped with a Dry Ice-acetone condenser. After addition was complete, the reaction mixture was allowed to stand overnight at room temperature and then analyzed by gc. See Table 3 for relative amounts of reagents and results. The product ratios represent actual yields.

Attempted Reaction of Polycarboxylic Acid Methyl Esters in Presence of Diazomethane from Preparation A

Ethereal solutions of methyl esters of malonic, succinic, glutaric, malic, and citric acids were treated with 10 equiv. of diazomethane from preparation A and allowed to stand for 24 h at room temperature. In all cases, starting material was recovered unchanged.

The author wishes to thank Mr. J. Lapointe for technical assistance and Mr. D. Dobson, Technical Services Unit, for obtaining mass spectra.

Cyclization of Some 2,3,5,6-Tetrafluorophenylhydrazine Derivatives. Use of Nuclear Overhauser Effect Measurements in Structural Assignment

ARTHUR J. ELLIOTT AND MARTIN S. GIBSON
Department of Chemistry, McMaster University, Hamilton, Ontario
Received March 18, 1975

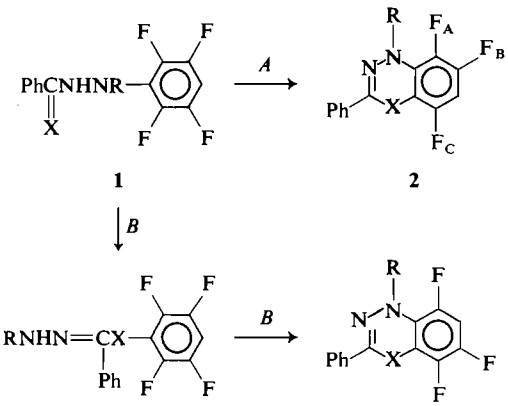
ARTHUR J. ELLIOTT and MARTIN S. GIBSON. Can. J. Chem. **53**, 2534 (1975).

Treatment of *N*-(2,3,5,6-tetrafluorophenyl)-*N'*-thiobenzoylhydrazine and of *N*-benzoyl-*N'*-(2,3,5,6-tetrafluorophenyl)hydrazine with acetic anhydride and triethylamine proceed without rearrangement to give 4-acetyl-2-phenyl-5,6,8-trifluoro-4*H*-1,3,4-benzthiadiazine and -benzoxadiazine, respectively. Structures follow from ^{19}F n.m.r. and n.O.e. data.

ARTHUR J. ELLIOTT et MARTIN S. GIBSON. Can. J. Chem. **53**, 2534 (1975).

Le traitement de la *N*-(tétrafluoro-2,3,5,6 phényl) *N'*-thiobenzoyl hydrazine et de la *N*-benzoyl *N'*-(tétrafluoro-2,3,5,6 phényl) hydrazine par l'anhydride acétique et la triéthylamine se fait sans réarrangement; on obtient respectivement les acétyl-4 phényl-2 trifluoro-5,6,8 4*H*-benzothiadiazine-1,3,4 et la benzoxadiazine-1,3,4. On détermine les structures à partir des données de r.m.n. de ^{19}F et des données de e.O.n. [Traduit par le journal]

While cyclization of *N*-acetyl-*N*-(2,3,5,6-tetrafluorophenyl)-*N'*-thiobenzoylhydrazine (**1***b*) under basic conditions would be expected to yield 4-acetyl-2-phenyl-5,6,8-trifluoro-4*H*-1,3,4-benzothiadiazine (**2***b*) by direct nucleophilic displacement of an *ortho*-fluorine atom by the sulfur atom (path *A*) (1), an alternative (path *B*) involving a Smiles-type rearrangement (2) should also be considered. This would involve nucleophilic displacement of the acetyl-bearing nitrogen atom by the sulfur atom via a spirocyclic transition state, followed by nucleophilic displacement of an *ortho*-fluorine atom by the acetyl-bearing nitrogen atom to give compound (**3***b*). Similar considerations apply to the oxygen analog (**1***d*). These possible routes have been distinguished by recourse to ^{19}F n.m.r. and intramolecular nuclear Overhauser effect (n.O.e.) studies (3, 4).



a X = S; R = H
b X = S; R = $COCH_3$
c X = O; R = H
d X = O; R = $COCH_3$

Compound **1***a* was smoothly converted by reaction with acetic anhydride (Ac_2O) and triethylamine (NEt_3) into a compound $C_{15}H_9F_3N_2OS$, subsequently identified as **2***b*; it was shown that acetylation of **1***a* preceded ring closure although the intermediate **1***b* was not isolated. Hydrolysis of **2***b* gave **2***a*. Under slightly different conditions, **1***c* was converted to **2***d*, acetylation again preceding ring closure; satisfactory conditions for hydrolysis of **2***d* to **2***c* were not realized.

The ^{19}F n.m.r. and n.O.e. data for these compounds are set out in Table 1 and are seen to substantiate formulations **2***a*, *b*, and *d* (5). The *ortho* F,F coupling constants lie in the range 20–22 Hz, distinctly larger than the corresponding *para* and (in turn) *meta* values. The *ortho* H,F coupling constants are also somewhat larger than the corresponding *meta* values. The long range couplings between the N–H and F_A and F_B in **2***a* are of special interest since a similar effect is observable for H_A in the p.m.r. spectrum of 7-bromo-2-*p*-methoxyphenyl-4*H*-1,3,4-benzothiadiazine.[1] The ^{19}F chemical shifts are consistent with these structural assignments. Notably deacetylation of **2***b* to **2***a* results in a shift upfield

[1]The p.m.r. spectrum of this compound at 100 MHz in $CDCl_3$ shows a high-field aromatic proton absorption for the C-5 proton H_A as a doublet at δ 6.56 (J_{AB} = 9.0 Hz) which is further split by coupling with the N—H proton; this collapses to a sharp doublet on exchange with D_2O.

Irradiate C-7 proton; obsvd.	F_A	0	0	0
	F_B	22	21	23
	F_C	33	32	33

*Upfield from CF_3CCl_3.

for F_A, whereas F_B and F_C are barely affected; analogous shifts upfield for H_A occur on deacetylation of benzothiadiazines with no 5 substituent. The higher field positions of F_B and F_C in the benzoxadiazine **2***d* than in **2***b* are consistent with increased electron density in the ring, the smaller oxygen atom being capable of a greater resonance effect.

A large n.O.e. is observed for F_A when the N—H peak of **2***a* is irradiated, whereas F_B and F_C are unaffected. Saturation of the methyl protons of **2***b* produces a similar though smaller n.O.e. for F_A, while F_B and F_C are again unchanged. Large n.O.e. values are observed for F_B and F_C on saturation of the ring proton (at C-7) of **2***a* and **2***b*, while F_A is unaffected. Similar results are obtained for **2***d*.

Only structures **2***a*, *b*, and *d* are consistent with the above data and hence overall the above cyclization reactions must follow path *A* and not path *B*. Such n.O.e. measurements should continue to find use in confirming the course of substitution and cyclization reactions of polyfluoroaromatic compounds.

Experimental

^{19}F n.m.r. spectra were recorded on a Varian Associates DP-60 IL spectrometer in $CDCl_3$ solution at 56.4 MHz; results are given as p.p.m. (δ) upfield from 1,1,1-trichlorotrifluoroethane (internal standard). Proton magnetic resonance spectra were recorded on Varian Associates A-60 and T-60 spectrometers in $CDCl_3$ at 60 MHz; results are given as p.p.m. downfield from tetramethylsilane (internal standard). The presence of exchangeable protons was confirmed by use of D_2O. The procedure for n.O.e. measurements was essentially that described in ref. 4.

2,3,5,6-Tetrafluorophenylhydrazine was prepared from pentafluorobenzene and 100% hydrazine hydrate with minor modification of the published procedure and had m.p. 89–91 °C (lit. (6), m.p. 90–91.5 °C).

N-(2,3,5,6-Tetrafluorophenyl)-N′-thiobenzoylhydrazine (1a)

2,3,5,6-Tetrafluorophenylhydrazine (18.0 g, 0.1 mol) was added in portions to a stirred solution of carboxymethyl dithiobenzoate (7) (21.2 g, 0.1 mol) in aqueous 1 *M* KOH solution (100 ml) during 10 min; 1 *M* KOH was added as required to keep the p*H* at 10. The solution was then heated to 70 °C and allowed to cool to room temperature over 1 h. Dilute acetic acid was added till the p*H* reached 6. The solid was collected, washed, and dried. Crystallization from hexane gave the *thiohydrazide* **1***a* (17.1 g, 57%) as yellow needles, m.p. 90–92 °C; p.m.r. δ 9.35 (s, br 1H, exchangeable), 7.92 (s, br, 1H, exchangeable), 7.81–7.61 (m, 2H), 7.50–7.18 (m, 3H), and 7.00–6.25 (m, 1H).

Anal. Calcd. for $C_{13}H_8F_4N_2S$: C, 52.00; H, 2.67; N, 9.33. Found: C, 51.97; H, 2.68; H, 9.28.

4-Acetyl-2-phenyl-5,6,8-trifluoro-4H-1,3,4-benzothiadiazine (2b)

A mixture of **1***a* (3.0 g, 0.01 mol), NEt_3 (20 ml), and Ac_2O (20 ml) was boiled under reflux for 2 h, cooled, and poured into water. The solid was collected, washed, and dried. Crystallization from ethanol or hexane gave the *thiadiazine* **2***b* (3.1 g, 91%) as buff needles, m.p. 127–128 °C; i.r. (KBr) 1710 cm^{-1} (C=O); p.m.r. δ 8.13–7.92 (m, 2H), 7.62–7.43 (m, 3H), 7.33–6.77 (m, 1H), and 2.50 (s, 3H).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Anal. Calcd. for $C_{15}H_9F_3N_2OS$: C, 55.90; H, 2.80; F, 17.70. Found: C, 56.05; H, 2.84; F, 17.68.

In a separate experiment, a mixture of **1***a* (2.0 g), NEt_3 (15 ml), and ethanol (15 ml) was refluxed for 5 h. Evaporation *in vacuo* and crystallization from benzene–hexane gave the *1:1 adduct* or salt of **1***a* and NEt_3 as buff needles, m.p. 106–108 °C; p.m.r. δ 9.64 (s, br, 2H, exchangeable), 8.24–8.00 (m, 2H), 7.41–7.17 (m, 3H), 6.75–6.10 (m, 1H), 2.72 (q, 6H), and 1.05 (t, 9H).

Anal. Calcd. for $C_{19}H_{23}F_4N_3S$: C, 56.86; H, 5.74; N, 10.47. Found: C, 56.77; H, 5.85; N, 10.47.

Decomposition of the 1:1 adduct with boiling ethanol – concentrated HCl regenerated **1***a*, m.p. and mixture m.p. 90–91 °C; identity was confirmed by i.r. spectral correlation.

*2-Phenyl-5,6,8-trifluoro-4H-1,3,4-benzothiadiazine (**2a**)*

A mixture of **2***b* (2.0 g), ethanol (30 ml), and concentrated HCl (20 ml) was refluxed for 1 h, cooled, and the solid was collected. Crystallization from ethanol gave the *4H-thiadiazine* **2***a* (1.4 g, 80%) as yellow needles, m.p. 107–108 °C.

Anal. Calcd. for $C_{13}H_7F_3N_2S$: C, 55.71; H, 2.50. Found: C, 55.77; H, 2.53.

*N-Benzoyl-N'-(2,3,5,6-tetrafluorophenyl)hydrazine (**1c**)*

Benzoyl chloride (2.8 g, 0.02 mol) was added dropwise to a stirred solution of 2,3,5,6-tetrafluorophenylhydrazine (3.6 g, 0.02 mol) and NEt_3 (5 ml) in dry ether (50 ml) at −78 °C. Stirring was continued for 2 h at −78 °C and the mixture was then allowed to warm to room temperature. Solvent was removed *in vacuo* and the solid was washed well with ice-cold water. Crystallization from aqueous methanol gave the *hydrazide* **1***c* (4.2 g, 75%) as needles, m.p. 176 °C.

Anal. Calcd. for $C_{13}H_8F_4N_2O$: C, 54.93; H, 2.82; N, 9.86. Found: C, 54.80; H, 2.87; N, 9.83.

*4-Acetyl-2-phenyl-5,6,8-trifluoro-4H-1,3,4-benzoxadiazine (**2d**)*

A mixture of **1***c* (1.0 g), NEt_3 (5 ml), Ac_2O (5 ml), and dimethylformamide (15 ml) was boiled under reflux for 4 h, cooled, and poured into dilute acetic acid. The solid was filtered off, washed, and dried. Crystallization from hexane gave the *oxadiazine* **2***d* (0.6 g, 65%) as needles, m.p. 144–145 °C; i.r. 1700 cm^{-1} (C=O).

Anal. Calcd. for $C_{15}H_9F_3N_2O_2$: C, 58.82; H, 2.94. Found: C, 58.62; H, 2.85.

In a separate experiment, a mixture of **1***c* (1.0 g), NEt_3 (2 ml), NaOH (0.4 g), and dimethylformamide (20 ml) was refluxed for 4 h. Isolation as above gave a yellow gum which contained **1***c* and at least four other materials, none of which was fluorescent (t.l.c.).

Attempted hydrolysis of **2***d* gave dark gums.

We are indebted to Dr. J. K. Saunders for the n.O.e. measurements and the National Research Council of Canada for financial support.

π-Perfluoroallyltricarbonylcobalt: Synthesis and Reaction with Triphenylphosphine

KEITH STANLEY[1] AND D. W. MCBRIDE
Department of Chemistry, University of Manitoba, Winnipeg, Manitoba R3T 2N2

Received March 17, 1975

KEITH STANLEY and D. W. MCBRIDE. Can. J. Chem. **53**, 2537 (1975).

Perfluoroallyl iodide reacts with $Zn[Co(CO)_4]_2$ to give π-$C_3F_5Co(CO)_3$ and $CF_3CF{=}CFCo(CO)_4$. The reaction of π-$C_3F_5Co(CO)_3$ with PPh_3 gives two products; *trans*-$CF_3CF{=}CFCo(CO)_3PPh_3$ and a compound tentatively identified as *cis*-$CF_2{=}CFCF_2Co(CO)_3PPh_3$; (*cis* and *trans* refer to configuration about cobalt). Infrared and n.m.r. data for the compounds are reported.

KEITH STANLEY et D. W. MCBRIDE. Can. J. Chem. **53**, 2537 (1975).

L'idodure de perfluoroallyle réagit avec $Zn[(Co(CO)_4]_2$ pour conduire à π-$C_3F_5Co(CO)_3$ et $CF_3CF{=}CFCo(CO)_4$. La réaction du π-$C_3F_5Co(CO)_3$ avec PPh_3 donne deux produits; le $CF_3CF{=}CFCo(CO)_3PPh_3$ *trans* et un autre composé identifié comme étant le $CF_2{=}CFCF_2$-$Co(CO)_3$ PPh_3 *cis* (les géométries *cis* et *trans* sont définies à partir de la configuration autour du cobalt). On rapporte les caractéristiques i.r. et r.m.n. des composés.

[Traduit par le journal]

Introduction

In view of the extensive interest in both π-allyl complexes and perfluorocarbon ligands, it seemed surprising that a π-perfluoroallyl complex had not been prepared. Attempts which may have yielded such a complex gave only σ-perfluoropropenyl or σ-perfluoroallyl (1–3) complexes. Perfluororcyclic ligands have been reported to bond to iron (4) and cobalt (5) through a π-allyl linkage. We report here the synthesis of π-perfluoroallyltricarbonylcobalt π-$C_3F_5Co(CO)_3$, and examine its reaction with triphenylphosphine.

Results

The reaction of perfluoroallyl iodide[2] with $Zn[Co(CO)_4]_2$ in pentane followed by trap-to-trap distillation *in vacuo* of the product mixture gave two products. The less volatile compound was identified as π-$C_3F_5Co(CO)_3$. The compound is an air sensitive yellow liquid at room temperature which decomposes rapidly at 35° *in vacuo*. The ^{19}F n.m.r. spectrum is properly described as an AA'BB'X pattern (Fig. 1) but analysis as an A_2M_2X pattern does not affect the coupling constants significantly. The reason for the broadening of the absorption lines of F_s cannot be determined in a first-order analysis.

The i.r. spectrum of π-$C_3F_5Co(CO)_3$ shows two sharp terminal carbonyl bands at 2115.0(m) and 2064.0(s) cm^{-1} corresponding to the A_1 and E stretching vibrations for a molecule with local C_{3v} symmetry. A medium intensity absorption at 1425 cm^{-1} is assigned to a stretching vibration of the π-allyl moiety. By comparison, the hydrocarbon analog π-$C_3H_5Co(CO)_3$ (6) shows C—O stretching bands at 2065 (A_1) and 1998 cm^{-1} (E). The $(C—C—C)_{asym}$ mode was assigned the 1388 cm^{-1} frequency.

The more volatile component was identified as $CF_3CF{=}CFCo(CO)_4$. The ^{19}F n.m.r. spectrum (see Table 1) is similar to those of other σ-perfluoropropenyl complexes studied (1–3) having a *trans* configuration[3] about the C=C bond (7) ($J_{F_A-F_B}$ = 147 Hz).

The i.r. spectrum of $CF_3CF{=}CFCo(CO)_4$ shows four carbonyl bands which is consistent with C_{3v} symmetry ($2A_1 + E$) about the cobalt

[1]Present address: Department of Chemistry, Queen's University, Kingston, Ontario K7L 3N6.

[2]In a paper by Ramsey and Brey (21) the ^{19}F n.m.r. chemical shift of the perfluoromethylene CF_2 group in $CF_2{=}CFCF_2I$ was reported to be 63.6 p.p.m. (upfield from $CFCl_3$). In our work this value was measured to be 49.7 p.p.m. All coupling constants and other δ values were found to be the same as reported. This δ value of 49.7 p.p.m. fits the trend observed by Brey and Ramsey for perfluoroallyl chloride (δ_{CF_2} = 62.0 p.p.m.) and bromide (δ_{CF_2} = 55.1 p.p.m.) derivatives.

[3]The perfluoropropenyl group in all compounds here exists in a *trans* configuration and unless specifically relating to this group the terms *cis* and *trans* will relate to the configuration about the cobalt center.

atom where the *E* mode is split due to the non-axially symmetric R_f–metal group. This splitting is seen in other $R_fCo(CO)_4$ complexes (8). The C=C stretching frequency is at 1640 cm^{-1}. The compound is a liquid above $-15°$ and is extremely thermally unstable above 0°, precluding an elemental analysis.

A ^{19}F n.m.r. spectrum of the reaction mixture after carbon monoxide evolution had essentially ceased showed, in addition to peaks due to the two products already discussed, an octet at 41.6 p.p.m. The coupling constants were almost the same as those for perfluoroallyl iodide in which the CF_2 group is at 49.7 p.p.m. (see footnote 2). It has been shown for $R_fCo(CO)_4$ compounds (9, 10) that a downfield shift of about 7 to 8 p.p.m. results when the iodine in perfluoroalkyl iodides is replaced by a $Co(CO)_4$ group. The ^{19}F n.m.r. of π-$C_5H_5Ni(CO)CF_2CF{=}CF_2$ shows that J values do not change significantly upon coordination to a metal (3). This evidence suggests that $CF_2{=}CFCF_2Co(CO)_4$ is an intermediate in the reaction. The single fluorine resonances of this complex, however, could not be observed because of the low concentration of this species in solution.

While this compound could not be isolated, its presence in low concentration in the reaction mixture indicates the initial formation of a σ-perfluoroallyl complex from which both final products originate as proposed in Scheme 1. The pathway involving the loss of carbon

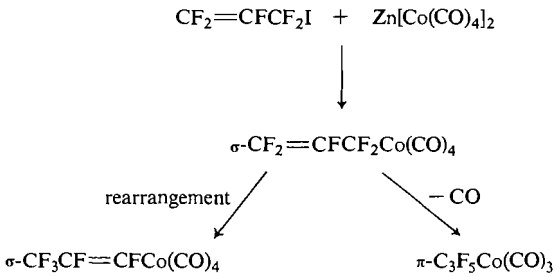
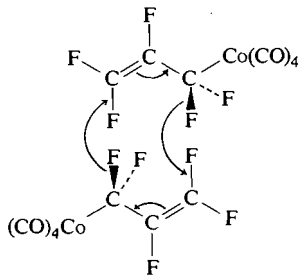


SCHEME 1

monoxide is analogous to the formation of π-$C_3H_5Co(CO)_3$ (11). The rearrangement of σ-perfluoroallyl compounds to perfluoropropenyl derivatives has been examined by Goldwhite *et al.* (12) who proposed a transition state such as **1**, in which intermolecular fluorine

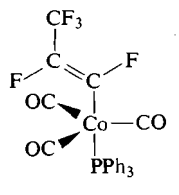


1

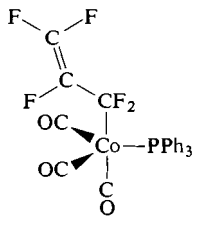
migration occurs to give the perfluoropropenyl group.

The reaction of π-$C_3F_5Co(CO)_3$ with triphenylphosphine proceeds without the evolution of carbon monoxide and two isomeric compounds were isolated by fractional recrystallization from methylcyclohexane. Neither complex contains the π-perfluoroallyl ligand. This result contrasts with the reaction of π-$C_3H_5Co(CO)_3$ with PPh_3 where carbon monoxide is vigorously evolved and π-$C_3H_5Co(CO)_2PPh_3$ is the only product (13).

From spectral evidence, the structures of the two isomers are concluded to be **2** and **3**.



2



3

The ^{19}F n.m.r. spectrum of **2** (see Table 1 for spectral data on **2**) shows a perfluoropropenyl group with a *trans*-configuration (J_{FF} = 146 Hz) about the C=C bond. The coupling constant J_{P,F_A} = 30 Hz indicates a *trans* configuration about the cobalt atom as in other $R_fCo(CO)_3PPh_3$ complexes reported (8). The i.r. spectrum has three CO stretching bands which is predicted by group theory for a *trans* configuration (C_{3v} symmetry, $A_1 + E$) where the E mode is split because of the nonaxially symmetric R_f–Co group (8, 14). The C=C stretching frequency is at 1640(w) cm^{-1}. The compound is identified as *trans*-$CF_3CF{=}CFCo(CO)_3PPh_3$.

The infrared spectra for **3** suggests the structure which is drawn. A weak intensity band at 1750 cm^{-1}, assigned to the C=C stretching vibration, indicates a σ-perfluoroallyl group. The C=C stretch in perfluoroallyl iodide is at 1750 cm^{-1}. For the *cis* configuration (C_s symmetry) about the cobalt, group theory predicts (8) three equal intensity C—O absorptions. This pattern is observed for **3** (see Fig. 2).

Unfortunately, the compound is thermally unstable in solution. This instability has little effect on the i.r. spectrum (*i.e.* the spectrum does not change over a 15 min period) but the ^{19}F n.m.r. spectrum could not be recorded because of broadening by paramagnetic materials. Decomposition of the compound to paramagnetic species was rapid above 10° in any solvents in which the compound is soluble ($CHCl_3$, CH_2Cl_2, THF, $C_6H_5CH_3$); below 10° the solubility was very low.

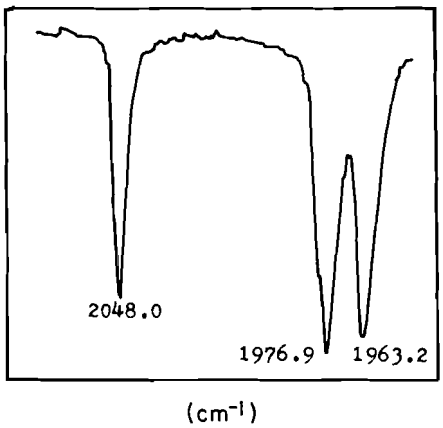


FIG. 2. Infrared carbonyl absorption bands of *cis*-σ-$CF_2{=}CFCF_2Co(CO)_3PPh_3$ in methylcyclohexane; (frequencies in cm^{-1}).

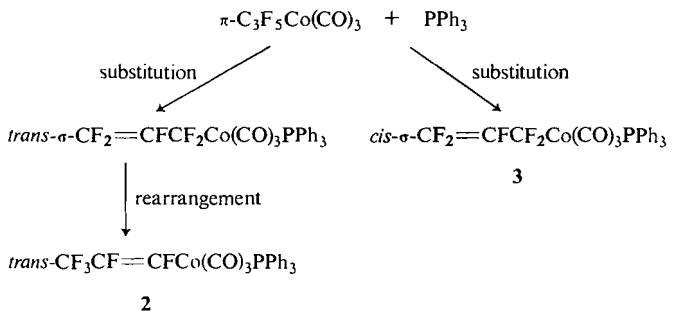

SCHEME 2

The reaction of π-$C_3F_5Co(CO)_3$ with PPh_3 can be written as shown in Scheme 2.

The reaction proceeds in two different pathways depending on whether the PPh_3 substitution results in a *cis* or *trans* configuration of the σ-perfluoroallyl and PPh_3 groups. In the *trans* route the substitution is followed by the rearrangement of the σ-perfluoroallyl ligand to the σ-perfluoropropenyl group by the mechanism of the bimolecular transition state proposed by Goldwhite *et al.* (12). This complex is similar to other *trans*-$R_fCo(CO)_3PPh_3$ complexes that have been prepared (8).

The *cis* pathway gives the complex **3** which does not undergo any further reactions for the following reasons. Cardaci *et al.* (15) in their examination of the reaction of (π-CH_2CClCH_2)-$Fe(CO)_2NO$ with PPh_3 isolated the σ-allyl intermediate *cis*-(σ-CH_2=$CClCH_2$)$Fe(CO)_2NO$-PPh_3 which decarbonylated to reform a π-allyl complex. The complex **3** does not decarbonylate but it has been shown by Cramer (16) that fluorinated olefins are poorer electron donors than hydrocarbon olefins and are therefore less likely to displace a CO group, especially in this case where the Co—CO bond has been strengthened by the presence of the coordinated PPh_3. The σ-perfluoroallyl ligand does not rearrange to a σ-perfluoropropenyl ligand as occurred in the *trans* pathway. A molecular model of complex **3** shows that because of the bulky PPh_3 in a *cis* position, a bimolecular rearrangement transition state could not be attained owing to extreme steric interactions.

Experimental

Nuclear magnetic resonance spectra were determined using a Varian A-56/60A instrument with a variable temperature unit. Infrared spectra were recorded on a Perkin-Elmer 337 instrument using double-beam techniques. Polystyrene was used to calibrate full spectra and indene used for expanded scale spectra of the carbonyl region. Melting points were taken on a Fischer-Johns melting point apparatus and are uncorrected. For compounds which were liquid at room temperature, the melting points were taken by sealing the sample inside a glass tube, cooling to −80° in Dry Ice – acetone, and allowing the bath to warm up slowly with stirring. When the frozen sample melted, the temperature of the bath was recorded as the melting point.

Perfluoroallyl chloride (17) was reacted with NaI in acetone to give perfluoroallyl iodide (18). The distilled C_3F_5I (b.p. 53–55° at 760 Torr) was stored at 0° to reduce decomposition. $Zn[Co(CO)_4]_2$ (19) was prepared from $Hg[Co(CO)_4]_2$ (20) and granulated zinc in toluene. The toluene was removed *in vacuo* and pentane added to the solid under nitrogen.

Preparation of CF_3CF=$CFCo(CO)_4$ and π-$C_3F_5Co(CO)_3$

Perfluoroallyl iodide (0.6 g, 2.4 mmol) and $Zn[Co(CO)_4]_2$ (5 g, 1.2 mmol) were reacted in pentane (40 ml) at 25° under N_2 until carbon monoxide evolution had ceased. The pentane was removed *in vacuo* (static) at −30° (bromobenzene slush bath). The products were distilled into a conventional vacuum trapping system at room temperature. The products were separated by trap-to-trap distillation techniques under dynamic vacuum (0.01 Torr). The product passing through a −30° trap was collected at −196°. It melted to a deep yellow liquid at −15° and decomposed rapidly when warmed above 0°. The compound was identified by i.r. and n.m.r. spectra as CF_3CF=$CFCo(CO)_4$ (yield 20%). An elemental analysis was not possible. The product which was trapped at −30° was stable *in vacuo* or under N_2 at room temperature. It was a yellow liquid above 5°. It was identified by i.r. and n.m.r. spectra as π-$C_3F_5Co(CO)_3$. Recrystallization from pentane (at −80°) gave the pure product, yield 25%.

Anal. Calcd. for $C_3F_5Co(CO)_3$: C, 26.3; F, 34.7. Found: C, 26.4; F, 34.7.

Nuclear magnetic resonance samples were prepared by condensing the compound, solvent, and $CFCl_3$ into the n.m.r. tube *in vacuo* and flame sealing the tube.

Infrared samples were prepared under nitrogen and transferred to a two port infrared cell (capped with 5 mm silicone rubber septa and flushed with nitrogen) by syringe.

Reaction of π-$C_3F_5Co(CO)_3$ with PPh_3

Triphenylphosphine (0.95 g, 3.6 mmol) was added to π-$C_3F_5Co(CO)_3$ (1 g, 3.6 mmol) in 50 ml pentane at 25° and stirred for 1 h *in vacuo*. No carbon monoxide was evolved as the solution went from yellow to orange. The pentane was removed under vacuum and the product mixture dissolved in a minimum amount of boiling methylcyclohexane. All purifications were carried out under N_2. The hot solution was centrifuged to remove any insoluble material and decanted. On slow cooling to 0° the product *cis*-σ-CF_2=$CFCF_2Co(CO)_3PPh_3$ **3** was obtained as a yellow powder (m.p. 110° dec.). The compound was difficult to obtain pure.

Anal. Calcd. for $C_{24}H_{15}CoF_5O_3P$: C, 53.8; H, 2.8; F, 17.7; P, 5.8. Found: C, 54.4; H, 2.9; F, 18.3; P, 5.8.

On further cooling to −80° yellow crystals of *trans*-CF_3CF=$CFCo(CO)_3PPh_3$ (**2**) were deposited (m.p. 123°.

Anal. Calcd. for $C_{24}H_{15}CoF_5O_3P$: C, 53.8; H, 2.8; F, 17.7; P, 5.8. Found: C, 53.9; H, 2.8; F, 17.8; P, 5.6.

Both products were recrystallized separately several times from methylcyclohexane.

The Role of Cobalt in Unsupported MoS_2 Hydrodesulfurization Catalysts[1]

E. FURIMSKY AND C. H. AMBERG
Department of Chemistry, Carleton University, Ottawa, Canada K1S 5B6

Received January 27, 1975

E. FURIMSKY and C. H. AMBERG. Can. J. Chem. **53**, 2542 (1975).

Crystalline MoS_2 catalysts were impregnated with cobalt over the total composition range, and their catalytic activity in the hydrodesulfurization of thiophene tested in a microreactor at 400° and near atmospheric pressure. Three principal composition regions could be distinguished in the sulfided catalysts: (*1*) Co/(Co + Mo) compositions 0–0.4. In this region intercalated Co enhances the intrinsic activity which reaches a maximum near a Co content of 0.25. The region is sulfur "deficient" with respect to $MoS_2 + Co_9S_8$ and there is no evidence for the presence of Co_9S_8. (*2*) Compositions 0.4–0.65. This region is characterized by the exact stoichiometry $MoS_2 + Co_9S_8$ and by the appearance of a Co_9S_8 phase. Surface area experiences a fivefold increase, as does percent conversion, but intrinsic activity changes very little. (*3*) Compositions > 0.65. A region of lesser interest, it is sulfur "deficient", possibly through the formation of Co_4S_3, and surface area decreases steeply with Co content.

E. FURIMSKY et C. H. AMBERG. Can. J. Chem. **53**, 2542 (1975).

On a imprégné de cobalt les catalyseurs cristallins MoS_2 dans toute l'étendue du domaine de composition. On en a vérifié l'activité catalytique par hydrodésulfurisation du thiophène dans un micro-réacteur à 400° et près de la pression atmosphérique. On peut distinguer trois régions principales de composition des catalyseurs sulfurés: (*1*) Les compositions Co/(Co + Mo) de 0 à 0.4. Dans cette région la présence de Co accroît l'activité intrinsèque qui atteint un maximum pour une teneur en Co voisine de 0.25. Cette région est "déficitaire" en soufre par rapport à $MoS_2 + Co_9S_8$ et il n'y a pas de preuve indiquant la présence de Co_9S_8. (*2*) Les compositions 0.4–0.65. Cette région est caractérisée par une stoechiométrie exacte $MoS_2 + Co_9S_8$ et par l'apparition d'une phase Co_9S_8. La surface augmente par un facteur de cinq, tout comme le pourcentage de conversion, mais l'activité intrinsèque varie très peu. (*3*) Les compositions > 0.65. C'est une région d'intérêt moindre, qui est "déficitaire" en soufre probablement à cause de la formation de Co_4S_3. La surface décroît rapidement avec la teneur en Co.

[Traduit par le journal]

Introduction

The sulfided oxides of molybdenum and cobalt, supported on alumina, are frequently used as catalysts in hydrodesulfurization. Their effective components are the metal sulfides formed during the initial conditioning (sulfiding) stage. Although a great deal of information is available regarding these "cobalt molybdate" catalysts (1–7), their structure and its impact on reaction mechanisms is so far not completely understood. For this reason the activation of unsupported MoS_2 by Co has been undertaken recently by several workers in the hope of narrowing down at least some of the complexities of the commercial catalysts. Hagenbach *et al.* (8) found that cobalt raised the activity towards both thiophene hydrodesulfurization and cyclohexene hydrogenation when added to unsupported MoS_2. A theoretical model was provided in a study by Farragher and Cossee (9), in which Ni was shown to intercalate in the edges of WS_2 crystals, thus creating a more highly faceted surface containing exposed W^{3+} ions. These latter ions were thought to be the active sites in benzene hydrogenation. The MoS_2/Co system was presumed to behave in an analogous fashion. Divalent Co ions can be accommodated in the octahedral holes between the MoS_2 layers adjacent to the exposed Mo ions, and reduce the latter to triply coordinated ions. Thus this situation can occur in the surface, even though crystal field considerations show it to be energetically unfavorable in the ideal trigonal prismatic environment of the Mo^{4+} ions in MoS_2. Catalyst particles would be particularly susceptible to intercalation, their small size leading to increased edge-to-bulk ratios, while

their method of preparation frequently introduces other crystal defects.

In the present study the promotion of MoS_2 by Co was followed by the measurement of catalytic activity in the hydrodesulfurization of thiophene. Apart from chemical analysis, catalysts were characterized by determinations of BET surface areas, X-ray spectra, and, in some instances, electron scanning micrographs.

Experimental

Materials

MoS_2, Anachemia, as received. This is the same material described previously (10); $Co(NO_3)_2$, Fisher, certified reagent; H_2, Union Carbide purified by passing through Pd catalyst, then dried over Drierite; thiophene, Eastman, purified in preparative gas chromatograph.

Catalysts

The commercial catalyst used was Girdler G35A (catalyst G), through 65 mesh, prepared from crushed pellets. This is a "cobalt molybdate" on aluminum catalyst, used in earlier work (10–12). All other catalysts investigated were made by impregnating the commercial MoS_2 with $Co(NO_3)_2$ in liquid ammonia (9). After evaporation of the ammonia the mixture was dried for 2 h at 110°. This was followed by reduction in hydrogen for 4 h at 450°. The catalyst was then placed in the microreactor and sulfided in a reaction stream under operating conditions.

The Mo and Co contents of the catalysts were determined by atomic absorption spectroscopy using a Techtron Model AA3 spectrometer. An N_2O/acetylene flame was employed for Mo and an air/acetylene flame for Co.

Sulfur content was determined gravimetrically as $BaSO_4$.

Apparatus

The microreactor and flow system were essentially the same as described in previous work by one of the authors (10). X-Ray analysis was carried out on a Siemens X-ray diffractometer using Cu(Kα) and, in some instances where higher sensitivity was desirable, Co(Kα) radiation. All BET areas were determined in a conventional volumetric apparatus, using N_2 at liquid nitrogen temperatures, after outgassing for 10 h at 200°. The low temperatures were measured by means of an oxygen vapor pressure thermometer.

Procedure

Catalysts were tested at 400°, using hydrogen flow of 30 cc min^{-1} near atmospheric pressure. The thiophene bubble saturator was kept at 0°, corresponding to a partial pressure of thiophene of 21.4 Torr. Exact pressures were, however, measured independently during each test run on a routine basis.

Thiophene conversion was analyzed by g.l.c. using a 6-ft squalane column (25% w/w) at 25°. Percent conversion was always expressed in terms of thiophene converted rather than C_4 hydrocarbons formed.

All determinations on catalysts were performed after steady-state conditions had been attained in the desulfurization reaction, except where noted otherwise.

Results and Discussion

The change in conversion during the initial stages of conditioning of the Co-promoted MoS_2 catalysts showed the customary pattern as seen in Fig. 1. The initial high value decreased and reached a steady level after about 1 h.

A typical C_4 product distribution over the promoted catalysts has been summarized in Table 1 and compared to that over the supported commercial catalyst G. Total hydrogenation as reflected by total butane yield is small over Co/MoS_2 in contrast to the significantly higher yield obtained with the supported catalyst. Apart from this the product distribution over the various catalysts showed great similarity. It should be pointed out that low yields (*e.g.* total conversion over unpromoted MoS_2) resulted in correspondingly lower accuracy of measurement with the thermal conductivity detector. The last column in Table 1 gives the ratio of thiophene converted to total C_4 yield as being close to unity. Even though there is considerable scatter owing to the combined integration errors of five chromatogram bands, the column does not indicate any loss of reactants or products through adsorption or coking.

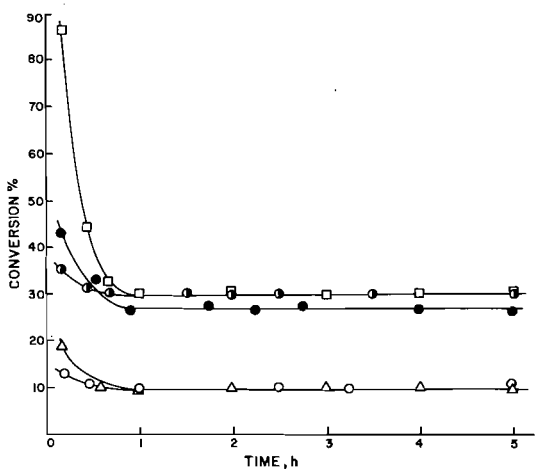

FIG. 1. Percent conversion of thiophene as a function of time in the reaction stream for catalysts of cobalt content Co/(Co + Mo), as noted. Fresh catalysts: △, 0.06; □, 0.55; ●, 0.74. Sulfided catalysts, after short exposure to atmosphere at room temperature: ○, 0.06; ◑, 0.55. Conditions: 400°; 30 ml min^{-1} H_2; partial pressure of thiophene 20 Torr; total pressure 760 Torr; 1 g catalyst.

TABLE 1. A typical products distribution, and percent conversion of thiophene, over Co-promoted MoS_2 catalysts and one commercial supported cobalt molybdate catalyst (G). Conditions: 400°; 30 ml min^{-1} H_2; partial pressure of thiophene 20 Torr; total pressure 760 Torr; 1 g catalyst

Our X-ray data revealed the MoS_2 to be well crystallized material of trigonal prismatic structure. An increase in cobalt content resulted in a decrease in the intensity of the MoS_2 reflections, without affecting line width. This decrease exceeded that expected from a straight comparison with the decreasing fraction of MoS_2 present, probably because of absorption by cobalt. At Co/(Co + Mo) ratios higher than 0.40, a second phase became detectable which had lattice parameters identical with those of Co_9S_8. Hydrogen reduction equilibria determined under hydrodesulfurization conditions also confirm that Co_9S_8 is the most likely phase to be present (1). In view of the fact that other authors have expressed the opinion that Co_9S_8 exists as a separate phase at lower concentrations of Co(8) we have attempted to establish a probable lower limit for its existence. Unfortunately the only sufficiently sensitive parameter exhibiting a consistent correlation with Co concentration was the intensity of the Co_9S_8 diffraction bands, when using Co(Kα) radiation. Considerable scatter was to be expected, because the method of preparing slides from powder samples is not geared to the precise reproduction of intensity values and it must be regarded as a highly empirical procedure. Accordingly, we performed a regression analysis on the 3,1,1 and 4,0,0 lines of eight samples ranging from Co/(Co + Mo) ratios of 0.40 to 0.85; this enabled us to estimate the Co content below which the separate Co_9S_8 phase could no longer exist. The values of these zero intercepts in terms of Co/(Co + Mo) were 0.31 and 0.34 for the 3,1,1 and 4,0,0 lines respectively, with uncertainties of ±26 and ±14% at the 75% confidence level. While we do not wish to claim greater certainty for the estimate than is implied by these statistics, it is nevertheless interesting to note that the cobalt concentration at which chemical analysis coincided with the composition $MoS_2 + Co_9S_8$, was at a Co/(Co + Mo) value of 0.40.

This can be readily seen in Fig. 2, where the dashed straight line has been computed by assuming that stoichiometric MoS_2 and Co_9S_8 were the only phases present over the whole range of Co concentrations, and where the solid line represents the experimentally determined values of samples fully sulfided after impregnation, as described in the Experimental section.

In the region of fractional Co content 0.40 to

0.65, the experimental values appear to conform well to those expected from the assumed nature of the two phases present. On the other hand, both below and above this range, there is a sulfur deficiency with respect to these phases. It was suggestive in the case of the higher range, that a sample of pure $Co(NO_3)_2$, which had been treated in a manner similar to that of the impregnated MoS_2 catalysts, yielded a sulfide of stoichiometry close to Co_4S_3. Unfortunately it was not of sufficient crystallinity to determine its structure. Co_9S_8 and Co_4S_3 have barely distinguishable diffraction patterns, so that the impregnated catalysts which showed that pattern may well have contained the latter form of sulfide.

The lower range of Co contents is of greater interest in terms of the catalytic reaction. As one possibility, the presumed sulfur deficiency could be associated with Co, leaving MoS_2 stoichiometrically intact. For example, at Co/(Co + Mo) = 0.25, 25% of the Co would be unsulfided, the remainder being in the form of Co_9S_8. The proportion of unsulfided Co would increase with lower overall Co content. Richardson (13) in his study of Co-promoted molybdate catalysts assumed that the true catalyst is MoS_2 promoted with "active cobalt", which must have been reduced and unsulfided. A comparison of the thermodynamic parameters of MoS_2 and Co_9S_8 shows both crystals to be stable in the temperature range under consideration, with a preference for MoS_2 under standard conditions (*e.g.*, for the reaction $4MoS_2 + 9Co \rightarrow Co_9S_8 + 4Mo$, $\Delta G_{700K}^0 \approx 43$ kcal mol^{-1}). It is unlikely, though, that these thermodynamic data could be used in support of the "active cobalt" model. Even if one could assume the exclusive existence of the compounds represented by the above equation, the initial activities at low Co concentrations are far from unity, and would certainly permit the existence of a stable Co_9S_8 phase.

However, there is now considerable evidence that such arguments do not take into account the complexity of these systems. Farragher and Cossee (9) have shown convincingly that there are several types of sulfur atoms in small MoS_2 crystals: the normal ones, which are triply bridging, each being bonded to three metal atoms; and the atypical ones, which are situated at the crystal edges and are either doubly bridging or nonbridging. The last of these are said to be most reactive in hydrogenation processes, in which they can be easily removed. Their stability can be improved by coordination to cobalt, and it is thought that at low Co concentrations all the Co can be accommodated by the available nonbridging sulfur at the crystal edges. Thus Co can be said to be dissolved in the surface regions of the MoS_2 crystal, where it contributes to its stability.

Our own results in the region of fractional Co content 0–0.4 show only a moderate increase in surface area (Fig. 3). There is no X-ray evidence for the existence of unsulfided Co in our catalysts and we regard its presence in our samples as highly unlikely. A comparison of percent thiophene conversion (Fig. 4) and reaction rate per unit surface area (Fig. 5), both as a function of fractional Co content, shows that a significant factor other than surface area increase must be operative in the initial region. In fact, the maximum rate coincides with the highest sulfur "deficiency" (Fig. 2). Under these conditions, we assume with Voorhoeve (14), and Farragher and Cossee (9) that surface anion vacancies adjacent to Mo^{3+} cations are favored, and that they are responsible for the catalytic activity. Van Sint Fiet (15) assumed that Mo^{3+} can be created from the fully reduced MoS_2 in hydrodesulfurization processes. Farragher and Cossee (9) argued that one of the necessary consequences of their model was the rounding of crystal edges of WS_2 upon impregnation with Ni. They were able to demonstrate this effect through electron microscopy. We were able to confirm a similar crystal reconstruction of MoS_2 crystals by Co with a scanning electron microscope; impregnation induced a similar rounding of edges which

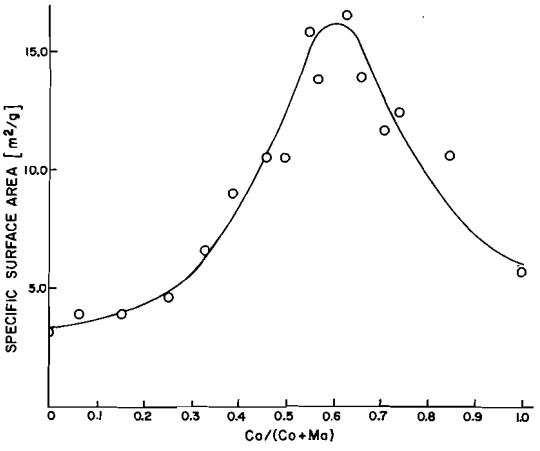

FIG. 3. Surface area as a function of catalyst composition.

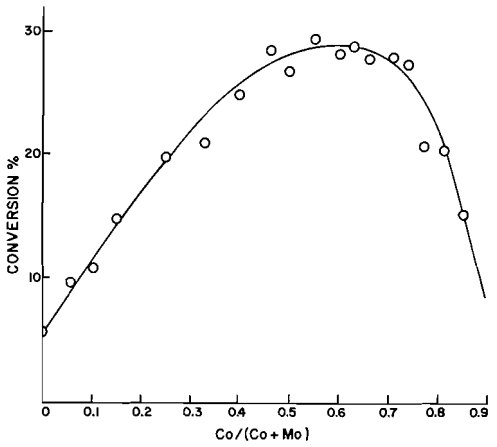

FIG. 4. Percent conversion of thiophene as a function of catalyst composition. Conditions as in Fig. 1.

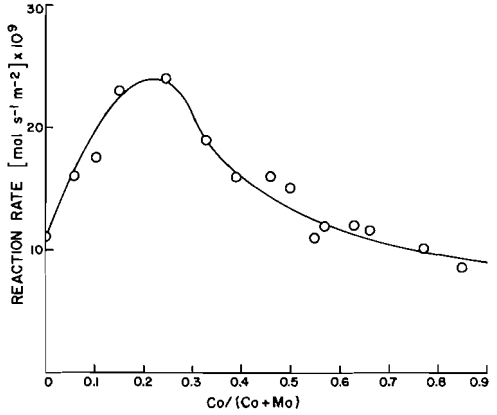

FIG. 5. Reaction rate as a function of catalyst composition. Conditions as in Fig. 1.

was identifiable even at the lower resolving power of the s.e.m.

The initial moderate rise in surface area (Fig. 3) has already been cited, but its cause is not entirely clear. It may well be connected with the increased stability in the surface region, and thus greater resistance to sintering during catalyst preparation. In the higher Co range, in which the stoichiometry coincides exactly with the composition $MoS_2 + Co_9S_8$, and in which both these crystals are clearly identifiable in the X-ray spectra, the area increases more steeply up to a maximum near a fractional Co value of 0.6. At this point it is five times that of the unpromoted MoS_2. Undoubtedly, the increased area is due to the appearance and growth of the Co_9S_8 phase. The latter could act very much like an inert catalyst support in its ability to stabilize crystal sizes. Initially it might have contributed to comminution of the MoS_2 crystallites through intercalation and subsequent growth between the weakly bonded layers of the hexagonal MoS_2 lattice, leading ultimately to cleavage. Regrettably, crystal sizes were not small enough to have enabled us to confirm the latter mechanism through X-ray line broadening; or else the appearance of such small MoS_2 crystals in the surface region was too small in extent to register in the presence of the larger sized bulk phase crystals.

The surface area increase is almost exactly mirrored by an increase in percent conversion (Fig. 4) by a similar factor, with a maximum also at Co/(Co + Mo) = 0.6. At the same time, the reaction rate (Fig. 5) experiences an only insignificant decrease in the middle region of composition. Taken together, these results can only be interpreted as meaning that the extent of the available active surface increases, but that there is little change in the intrinsic activity or surface concentration of active sites. In other words, the Co_9S_8 phase must be regarded as catalytically inactive.

The final collapse of the surface area and percent conversion sets in exactly at the composition at which the stoichiometry again begins to become sulfur "deficient", due to the possible appearance of Co_4S_3 (see above). Again, the reaction rate decreases only minimally, so that behavior in this region might be associated with sintering and crystal growth phenomena. The last point in Figs. 3 and 4 was obtained by treating a sample of pure $Co(NO_3)_2$ in the same manner as the Co-promoted MoS_2 catalysts; the surface area value was 5.6 $m^2\ g^{-1}$ as compared to 3.1 $m^2\ g^{-1}$ for unpromoted MoS_2.

Finally we wish to emphasize that the detailed structure of catalysts such as ours is very much dependent on method of preparation. Thus it is not surprising to find that Hagenbach *et al.* (8) report observations somewhat different from ours, in that their catalyst was prepared by coprecipitation rather than impregnation. This would account for the formation of a Co_9S_8 phase even at lower Co content during the initial catalyst preparation, even before the onset of a possible intercalation process. In our case Co_9S_8 appeared only after the impregnated catalyst had been subjected to sulfiding.

Study of Chemically Induced Dynamic Nuclear Polarization of Aliphatic Aldehydes in D_2O and other Solvents

HOLGER E. CHEN, MICHAEL COCIVERA, AND SHIV P. VAISH
Department of Chemistry, University of Guelph, Guelph, Ontario N1G 2W1

Received April 8, 1975

HOLGER E. CHEN, MICHAEL COCIVERA, and SHIV P. VAISH. Can. J. Chem. **53**, 2548 (1975).

The chemically induced dynamic nuclear polarization arising from irradiation of aliphatic aldehydes in D_2O and various other solvents is reported. The aldehydes included acetaldehyde, propionaldehyde, isobutyraldehyde, and pivalaldehyde, and the solvents were benzene, acetonitrile, cyclohexane, methylcyclohexane, perfluoromethylcyclohexane, D_2O, and D_2O/acetonitrile. For propionaldehyde, the variation of c.i.d.n.p. with solvent can be explained by a variation of the relative importance of α-cleavage *vs.* hydrogen abstraction which occur via an excited triplet state. In addition, when D_2O is the solvent, the c.i.d.n.p. provides information about secondary radical reactions not observed in the other solvents. For the other aldehydes, the nature of the solvent does not seem to affect the relative importance of α-cleavage *vs.* hydrogen abstraction. Acetaldehyde undergoes hydrogen abstraction whereas isobutyraldehyde and pivalaldehyde undgero α-cleavage via an excited triplet state.

HOLGER E. CHEN, MICHAEL COCIVERA et SHIV P. VAISH. Can. J. Chem. **53**, 2548 (1975).

On rapporte la polarisation nucléaire dynamique induite chimiquement dérivant de l'irradiation d'aldéhydes aliphatiques en solution dans D_2O et divers autres solvants. Les aldéhydes comprennent l'acétaldéhyde, la propionaldéhyde, l'isobutyraldéhyde et le pivalaldéhyde alors que les solvants utilisés sont le benzène, l'acétonitrile, le cyclohexane, le méthylcyclohexane, le perfluorométhylcyclohexane, D_2O et D_2O/acétonitrile. Pour le propionaldéhyde, on peut expliquer la variation de la p.n.d.i.c. avec le solvant par une variation de l'importance relative du clivage α *vs.* l'enlèvement de l'hydrogène qui se produisent par l'intermédiaire d'un état triplet excité. De plus dans l'eau lourde, la p.n.d.i.c. fournit des informations concernant des réactions radicalaires secondaires qui ne sont pas observées dans d'autres solvants. Pour les autres aldéhydes, il ne semble pas que la nature du solvant affecte l'importance relative du clivage α *vs.* l'enlèvement d'hydrogène. L'acétaldéhyde subit un enlèvement d'hydrogène alors que l'isobutyraldéhyde et le pivalaldéhyde subissent un clivage α pa l'intermédiaire d'un état triplet excité. [Traduit par le journal]

The photochemistry of various aliphatic aldehydes has been studied using chemically induced dynamic nuclear polarization (c.i.d.n.p.) (1–3).

An earlier preliminary report (2*b*) briefly described the effect of solvent on the c.i.d.n.p. of propionaldehyde. In the present paper, we present the details of a c.i.d.n.p. study of solvent effects on the photochemistry of propionaldehyde as well as acetaldehyde, isobutyraldehyde, and pivalaldehyde. The solvents include perfluoromethylcyclohexane, benzene, methylcyclohexane, acetonitrile, water, and water/acetonitrile mixtures. According to previous work (1, 2), these aliphatic aldehydes in excited triplet states can react via two paths in solution.

[1] $RCHO^T \rightarrow [\dot{R}\ \dot{C}HO]^T \rightarrow$ dissociation and products

[2] $RCHO^T + RCHO \rightarrow [R\dot{C}H(OH)\ R\dot{C}O]^T \rightarrow$ dissociation and products

In these reactions, R represents the methyl, ethyl, isopropyl, or *tert*-butyl group. Reaction 1 indicates α-cleavage, and reaction 2 involves hydrogen atom abstraction. The brackets indicate a radical pair, and T signifies a triplet precursor for the radical pair. Nuclear spin polarization occurs as a result of reaction via the radical pair. The importance of each route to nuclear spin polarization depends on the R group. For the methyl group, the observed polarization can be explained by [2] (1*a*). For *tert*-butyl, [1] accounts for the polarization (2*a*). For ethyl, both [1] and [2] are needed to account for the polarization (2*b* and *c*). Furthermore the contribution of the two paths appears to depend on the solvent employed (2*b*). The results of the present study indicate that the polarization observed for acetaldehyde, isobutyraldehyde, and pivalaldehyde shows little solvent effect on the contributions of the two paths. However an interesting offshoot of this study is that the use of water as a solvent results in the observation of additional secondary reactions not detected in the other solvents.

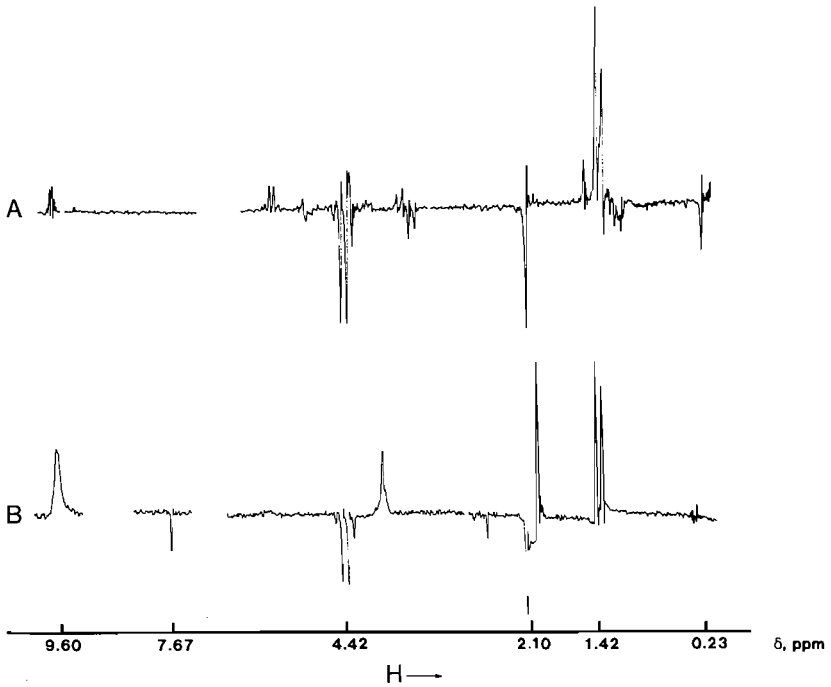

FIG. 1. Nuclear magnetic resonance spectra during irradiation of acetaldehyde in D_2O/CD_3CN (1:1 by volume). (*A*) Without CCl_4. The HDO signal position (at 4.42 p.p.m.) varies during irradiation because it is temperature sensitive. (*B*) With 0.1 *M* CCl_4.

Experimental

Chemicals

The solvents, which were usually reagent grade, were purified by fractional distillation when deemed necessary. The aldehydes were obtained from Baker or Aldrich and were purified by fractional distillation. Acetaldehyde-d_1 (Merck) was used without purification. Propionaldehyde-2,2-d_2 (Merck) was fraction distilled once at atmospheric pressure. Other compounds which were used for chemical shift determinations were not purified.

Nuclear Magnetic Resonance

The proton n.m.r. spectra at 100 MHz were obtained using a Varian HA-100-15 spectrometer which we have modified to operate on a time sharing mode. In this mode we are able to use a quartz probe which allowed direct irradiation of the sample while the n.m.r. spectrum was obtained. This probe was built in our laboratory and the details are given elsewhere (4). The probe temperature was maintained at 15 °C, although local heating due to irradiation raised the temperature of a portion of the sample. The n.m.r. spectra were obtained before, during and after irradiation. The radiation source was a 1000 W Hanovia mercury–xenon lamp. For some of the experiments, a Pyrex plate was used to filter out radiation having wavelength less than 310 nm. The detailed structure of the spectrum was the same with and without the filter. However, larger intensities were obtained without the filter.

Results

Rather than present spectra for each aldehyde in all the solvents, we present spectra for each aldehyde in acetonitrile/D_2O mixtures (50/50 by volume) without and with CCl_4 present since the largest number of products and additional reactions are observed in this solvent. The acetonitrile/D_2O mixture gives the same results as pure D_2O, although the signals are more intense in pure D_2O. This mixture was chosen to increase the solubility of CCl_4 for radical trapping experiments. Any differences between the results for this solvent and those for the other solvents are noted in the tables or in the text. Figures 1 to 4 illustrate the spectra for acetaldehyde, propionaldehyde, isobutyraldehyde, and pivalaldehyde, respectively. In each figure, spectrum *A* is obtained without CCl_4 and *B* is obtained with CCl_4 present. The dashed lines indicate signal heights after irradiation is stopped. As can be seen, a variety of enhanced absorption and emission signals are detected, indicating the occurrence of non-Boltzmann nuclear spin polariz-

tion. The assignment of the signals at the various chemical shifts in p.p.m. relative to the methyl resonance of tetramethylsilane are given in Tables 1 to 4 for acetaldehyde, propionaldehyde, isobutyraldehyde, and pivalaldehyde, respectively. In addition, these tables also list the assignments for signals detected when perfluoromethylcyclohexane is the solvent. For other solvents (acetonitrile, benzene, methylcyclohexane, and cyclohexane), the spectra look like either the one for perfluoromethylcyclohexane or the one for the acetonitrile/D_2O mixture (except for the hydrate compounds), depending on the aliphatic aldehyde. The nature of the signal is indicated as enhanced absorption A, emission E, and multiplet with low field absorption and high field emission A/E. Two aspects which should be pointed out for the CD_3CN/D_2O solvent are the occurrence of hydrates of aldehydes and in the case of propionaldehyde, isobutyraldehyde and pivalaldehyde, the effect on the HDO signal in the absence and in the presence of 0.1 *M* CCl_4. In the absence of CCl_4 the HDO signal is in emission whereas it appears as enhanced absorption when CCl_4 is present. The same results are obtained when the sample is degassed to less than 2 μ to remove molecular oxygen. The polarization effect on HDO appears to be smaller for pivalaldehyde than for the other two aldehydes.

Discussion

The polarization results described above can be accounted for by the radical pair model (5) and the occurrence of the reactions given by [1]

and [2] and a variety of secondary radical reactions. In addition the effect on the HDO signal can be used as evidence for another reaction of the excited aldehyde. Since all of these aldehydes have been studied previously in at least one solvent (1, 2), the polarizations have been calculated already for a number of the compounds. Therefore, rather than repeat the presentation of calculated spectra, the simple Kaptein rules (6) are used to indicate the sense of the polarization for particular compounds formed by reaction via a given radical pair.

The results for propionaldehyde in Table 2 are consistent with the occurrence of [1], [2], and [3]. The importance of these routes to the polarization depends on the solvent employed. Comparison of the two solvents in Table 2 illustrates this point. In perfluoromethylcyclohexane, the carbonyl hydrogen of propionaldehyde exhibits enhanced absorption and $CH_3CH_2CH(OH)$-$COCH_2CH_3$ is formed, and their nuclear polarizations can be accounted for by [2] and [3].

$$[3] \quad [R\dot{C}H(OH)\ \dot{C}OR]^{T,F} \rightarrow R\dot{C}H(OH)^* + R\dot{C}O$$
$$R\dot{C}H(OH)^* + RCHO \rightarrow RCHO^* + R\dot{C}H(OH)$$

The asterisk indicates nuclear spin polarization. According to this scheme, the aldehyde is formed with nuclear spin polarization by a radical trapping step which involves the transfer of a hydrogen atom. Using the Kaptein rules, the carbonyl hydrogen polarization for this route agrees with the observed polarization. Thus, [3] and/or disproportionation in $[R\dot{C}H(OH)\ \dot{C}OR]^T$ to give the aldehyde plus its enol can account for the enhanced absorption observed for the carbonyl hydrogen. The fact that enhanced absorption is observed for the carbonyl hydrogen when CH_3CDO is irradiated supports the second route (see Table 1). Furthermore, as discussed below, there is also evidence in support of [3]. Thus, it appears that both mechanisms are operating.

Ethane is formed with emission which is not prevented by the presence of CCl_4. Since this polarization persists in the presence of CCl_4, it probably is not formed via F-type radical pairs. The emission of ethane is consistent with disproportionation via $[CH_3\dot{C}H_2\ \dot{C}HO]^T$ and can be taken as evidence for reaction according to [1]. However, since recombination of this radical pair would result in emission for the carbonyl hydrogen of propionaldehyde (which is not observed), reaction according to [2] and [3] is more important in perfluoromethylcyclohexane. The same conclusion appears to hold for methylcyclohexane. In contrast the mechanism given by [1] appears more important when acetonitrile/D_2O

is the solvent because emission is observed for the carbonyl hydrogen of propionaldehyde and the emission of ethane becomes more intense relative to the other signals. Furthermore the observation of CH_3CH_2Cl, CCl_3CHO, and $CH_3CH_2CCl_3$ when CCl_4 is present supports α-cleavage via an excited propionaldehyde. The polarization observed for $CH_3CH_2CCl_3$ is consistent with formation via the radical pair $[CH_3\dot{C}H_2\ \dot{C}Cl_3]^F$ since the *g*-factor for $\dot{C}Cl_3$ is larger than the one for $CH_3\dot{C}H_2$ (7, 8). The polarization for CH_3CH_2Cl is consistent with trapping of $CH_3\dot{C}H_2$ by CCl_4 after dissociation from this radical pair. The emission observed for CCl_3CHO is consistent with formation via the radical pair $[\dot{C}Cl_3\ \dot{C}HO]^F$. Chloroform formation can occur via both radical pairs. In addition, since the presence of CCl_4 does not prevent the emission observed for ethane and carbonyl hydrogen of propionaldehyde, these compounds must be formed in part from the initial radical pair $[CH_3\dot{C}H_2\ \dot{C}HO]^T$ because CCl_4 would pre-

vent the formation of the F-type radical pair by trapping the free radicals $CH_3\dot{C}H_2$ and $\dot{C}HO$, as mentioned above. In contrast with the acetonitrile/D_2O solvent, the use of perfluoromethyl cyclohexane does not seem to result in detectable amounts of $CH_3CH_2CCl_3$ and CH_3CH_2Cl, indicating that reaction via [1] is less important. On the other hand the fact that $CH_3CH_2CH(OH)$-$COCH_2CH_3$ is detected in acetonitrile/D_2O indicates the reaction according to [2] occurs in this solvent, also, but to a lesser extent than in the fluorocarbon. The other compounds are formed via F-type radical pairs as discussed previously for the fluorocarbon solvent (2*b* and *c*). The observation of $CCl_3CH(OH)_2$ supports the occurrence of [1] in acetonitrile/D_2O. CCl_3CH-$(OH)_2$ results from a combination of $\dot{C}Cl_3$ with $\dot{C}HO$ to form chloral which in turn hydrates in the mixed solvent. The formation of the other chloro compounds has been described previously. The polarization of the HDO signal will be discussed below.

The occurrence of [3] has been confirmed by the photolysis of propionaldehyde-2,2-d_2 in the fluorocarbon. Since disproportion of $[CH_3CD_2$-$\dot{C}H(OH)\ \dot{C}OCD_2CH_3]^T$ leads to the enol plus CH_3CD_2CDO which has no carbonyl hydrogen resonance, the detection of CH_3CD_2CHO with enhanced absorption for the carbonyl hydrogen resonance is consistent with the occurrence of [3]. A similar mechanism is used for benzaldehyde (9). To determine the sign of the polarization according to the Kaptein rules, the *g*-factors decrease in the order $CH_3CH_2\dot{C}HOH$, $CH_3\dot{C}H_2$, and $\dot{C}HO$, $\dot{C}OCH_2CH_3$ (10). Also, the value for the electron–proton hyperfine coupling constant for $\dot{C}HO$ is positive (10*a*). Thus, it appears that the reactions given by [1] and [2] occur in all of the solvents used for propionaldehyde. The relative importance of these two reactions depends on the solvent with [2] being more important when the solvent is perfluoromethylcyclohexane or methylcyclohexane and [1] more important in the other solvents. In addition in these solvents, there is evidence for the occurrence of the process given by [3].

The nature of the solvent appears to have no significant effect on the c.i.d.n.p. spectra observed during irradiation of acetaldehyde, isobutyraldehyde, or pivalaldehyde, as can be seen from the results in Tables 1, 3, and 4. The nature of the compounds and the polarization observed for isobutyraldehyde or pivalaldehyde are consistent with reaction according to [1] and subsequent reaction via F-type radical pairs. On the other hand, the nature of the compounds and polarization for irradiation of acetaldehyde are consistent with an initial reaction according to [2]. Since these mechanisms have been discussed previously for pivalaldehyde in perfluoromethylcyclohexane (2*a*), isobutyraldehyde in benzene (1*b*), and acetaldehyde in benzene (1*a*), the detailed steps will not be repeated in this paper, except for one aspect concerning acetaldehyde. The enhanced absorption observed for the carbonyl hydrogen of acetaldehyde has been explained (1*a*) by a mechanism involving disproportionation of the radical pair $[CH_3\ \dot{C}H(OH)$ $\dot{C}OCH_3]^T$ to give acetaldehyde and its enol. Since our results with propionaldehyde-d_2 indicate that the mechanism given by [3] makes an important contribution to the enhanced absorption observed for the carbonyl hydrogen of propionaldehyde, we have tested the importance of the mechanism for acetaldehyde by irradiating CH_3CDO. Under these conditions enhanced absorption is observed for the carbonyl hydrogen, as indicated in Table 1. Thus, both mechanisms may be operating for acetaldehyde and propionaldehyde.

It should be noted that polarization is observed for the hydrates of various aldehydes as well as for HDO. The polarization for each hydrate is consistent with the formation of the aldehyde according to mechanisms described above followed by hydration at a rate more rapid than the spin–lattice relaxation rate. This conclusion is consistent with the fact that no hydrate of pivalaldehyde (polarized or otherwise) is observed. An emission signal is observed for HDO during irradiation of all of the aldehydes (except acetaldehyde) in D_2O/acetonitrile mixtures. A possible mechanism might involve a reaction of radicals with molecular O_2. Degassing samples to less than 2 μ to remove molecular oxygen did not prevent the emission signal for HDO. This result does not preclude the occurrence of a path involving molecular oxygen. However, it does indicate that another reaction path is at least in part responsible for the polarization observed for HDO. A chemically reasonable route is polarization of the protons of one of the organic solutes which can exchange one of its polarized protons with D_2O. While OH protons are easily exchanged with water, it seems unlikely that any

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

of the OH containing compounds formed from the steps mentioned above can provide the polarization. This conclusion is based on the fact HDO is not polarized during irradiation of acetaldehyde which provides a number of OH containing compounds via the above mentioned steps. Furthermore, no OH containing compounds were detected during the irradiation of isobutyraldehyde, but HDO was polarized. Likewise the absence of HDO polarization during irradiation of acetaldehyde suggests that the formation of the formyl radical ĊHO is involved in the reaction step which provides the exchangeable proton, since α-cleavage was not detected for acetaldehyde. This conclusion is supported by the fact that HDO polarization is observed during the irradiation of propionaldehyde-2,2-d_2, thus indicating that the methylene protons do not eventually end up polarized on HDO molecules.

While the involvement of the formyl radical seems likely, a mechanism which is compatible for propionaldehyde, isobutyraldehyde, and pivalaldehyde simultaneously is difficult to conceive. The low *g*-factor of the formyl radical relative to the other radicals present and the positive hyperfine coupling constant for its proton rules out a radical trapping mechanism which would require enhanced absorption rather than the observed emission. A mechanism which could account for the HDO polarization for propionaldehyde and isobutyraldehyde but not pivalaldehyde involves the formation of the radical RR′Ċ CHO followed by disproportionation via the radical pair $[RR'\dot{C}—CHO\ \dot{C}HO]^F$ to give the enol RR′C=CH(OH) plus CO. In this case, the exchangeable OH-proton of the enol is negatively polarized. This mechanism is compatible with the HDO emission observed when propionaldehyde-2,2-d_2 is used, also.

The enhanced absorption observed for the HDO signal when CCl_4 is present is easier to explain. As indicated, the enhanced HDO signal is observed for all of the aldehydes except acetaldehyde. Since all of the aldehydes except acetaldehyde react according to [1], it seems likely that the formyl radical is involved. This conclusion is consistent with the absence of signals due to formaldehyde and its hydrate when CCl_4 is present. Thus, since the *g*-factor for each of the alkyl radicals derived from these aldehydes is larger than the one for the formyl radical, the enhanced absorption can be explained by the following mechanism.

$$[\dot{R}\ \dot{C}HO]^T \rightarrow \dot{R} + \dot{C}HO$$

$$\dot{C}HO + CCl_4 \rightarrow ClCHO + \dot{C}Cl_3$$

$$ClCHO + D_2O \rightarrow HD_2O^+ + Cl^- + CO$$

According to this mechanism, the formyl radical which results from dissociation of the radical pair $[\dot{R}\ \dot{C}HO]^T$ is trapped by CCl_4 to form ClCHO before the polarization of the proton is lost via spin–lattice relaxation. In turn, ClCHO decomposes to HCl + CO at a rate which is faster than the spin–lattice relaxation rate and provides the polarization for the HDO proton. This mechanism, which would result in enhanced absorption, is supported by the observation that ClCHO can be formed only at low temperatures and decomposes readily at room temperature (11).

In conclusion, only in the case of propionaldehyde can a solvent effect on the c.i.d.n.p. spectrum be detected conclusively. A solvent effect on the relative importance of the initial photochemical reactions given by [1] and [2] can explain the c.i.d.n.p. spectra. The nature of the solvent effect on these reactions is not clear. However, on the basis of the solvents employed it is possible to conclude that the effect cannot be based solely on solvent polarity. Furthermore, since the effect occurs with or without radiation having wavelength shorter than 310 nm, this effect is not evidence for a competition between a lower and a higher energy transition. For the other aldehydes, a solvent effect is not observed, and in all the solvents listed, the initial reaction for acetaldehyde appears to be [2] whereas [1] appears to be the initial photochemical reaction for isobutyraldehyde and pivalaldehyde. This increase in the relative importance of reaction via [1] as the branching of the alkyl group is increased is paralleled by the relative thermochemical energies of the alkyl free radicals which result from α-cleavage (12). In view of the relative energies of the alkyl free radicals and the absence of any solvent effect on the initial photochemical step for acetaldehyde and isobutyraldehyde, the solvent effect observed for propionaldehyde can involve no more than a few kilocalories. While D_2O does not take part in the photochemical or radical reactions, its reactivity with some of the

products provides information about some reactions not detected in the other solvents employed.

Solution Studies of the Dynamic Stereochemistry of Palladium(II) Carboxylate Complexes

THOMAS R. JACK AND JOHN POWELL

Lash Miller Chemical Laboratories, University of Toronto, Toronto, Ontario M5S 1A1

Received March 11, 1975

THOMAS R. JACK and JOHN POWELL. Can. J. Chem. **53**, 2558 (1975).

A series of dimeric tertiary phosphine carboxylate complexes of palladium(II) of the general types $[(PR_3)Pd(O_2CR)_2]_2$ and $[(PR_3)Pd(O_2CR)(O_2CR')]_2$ have been synthesized and structurally characterized. The dynamic stereochemistry of the complexes where $PR_3 = Me_2PhP$ has been investigated using variable temperature n.m.r. techniques. Exchange of the stereochemically nonequivalent methyl groups of the coordinated Me_2PhP ligand occurs via a solvent assisted process involving ring opening of the "$Pd_2(OCO)_2$" bridged structure. For the trifluoroacetate complexes solution equilibria between monomer and dimer are readily apparent at low temperatures in the ^{19}F n.m.r. The observed equilibrium constants are a function of the solvent and the size of the PR_3 ligand. The reaction of $[(PMe_2Ph)Pd(O_2CCF_3)_2]_2$ with excess AgO_2CCF_3 gives an unusual crystalline complex of stoichiometry $Ag[(PMe_2Ph)Pd(O_2CCF_3)_3]$. A quantitative measure of the ability of a coordinated carboxylate to stabilize intermediate species via chelation has been obtained from a variable temperature n.m.r. study of [(π-2-methylallyl)Pd(O_2CR)(Me_2PhP)] (R = CH_3, CH_2Cl, $CHCl_2$, CCl_3, CF_3, CMe_3, CPh_3, CH_2Ph).

THOMAS R. JACK et JOHN POWELL. Can. J. Chem. **53**, 2558 (1975).

On a synthétisé et caractérisé au point de vue structural une série de complexes à l'état dimère de palladium(II) de formule générale $[(PR_3)Pd(O_2CR)_2]_2$ et $[(PR_3)Pd(O_2CR)(O_2CR')]_2$. On a étudié par r.m.n. à différentes températures la stéréochimie dynamique des complexes avec $PR_3 = Me_2PhP$. L'échange de groupes méthyles de Me_2PhP non équivalents du point de vue stéréochimie se fait par un procédé aidé d'un solvant qui comprend l'ouverture du noyau "$Pd_2(OCO)_2$" de la structure pontée. Pour les complexes du trifluoroacétate, l'équilibre en solution entre le momomère et le dimère est nettement apparent en r.m.n. ^{19}F à basses températures. Les constantes observées pour l'équilibre sont fonction du solvant et de la grosseur du groupe PR_3. La réaction de $[(PMe_2Ph)Pd(O_2CCF_3)_2]_2$ avec un excès de AgO_2CCF_3 donne un complexe cristallin inusité $Ag[(PMe_2Ph)Pd(O_2CCF_3)_3]$. On obtient une mesure quantitative de l'effet du groupe carboxylate coordonné sur la stabilisation des espèces intermédiaires par voie de chélation par une étude r.m.n. à différentes températures de [(π-méthylallyl-2)Pd(O_2CR)(Me_2PhP)] où (R = CH_3,CH_2Cl, $CHCl_2$, CCl_3, CF_3, CMe_3, CPh_3, CH_2Ph).

[Traduit par le journal]

Introduction

Previous studies have shown that several palladium(II) carboxylate complexes possess a dynamic stereochemistry in solution (1–4). The asymmetric solution isomer **1** (Fig. 1) of π-allylpalladium acetate undergoes an (apparently) intramolecular process which exchanges the nonequivalent π-allyl sites. A mechanism involving the inversion of the boat conformation of the $Pd_2(OCO)_2$ ring (Fig. 1) was originally postulated (1–3). The structurally related di-μ-carboxylate dimers $[(Me_2PhP)XM(O_2CR)]_2$ **2** (M = Pd or Pt; X = halide) have since been shown (4) to undergo a process in $CHCl_3$ which leads to the n.m.r. equivalence of the diastereotopic methyl groups of the Me_2PhP ligands by a mechanism involving the *dissociation* of *one* palladium–oxygen bond to give a *ring opened mono-μ-carboxylate bridged intermediate* (Fig. 2) which may re-form **2** in such a way as to effectively invert the boat conformation of the $Pd_2(OCO)_2$ ring. On the basis of solvent effects (4) it is probable that this mechanism is also the major pathway for the (apparently) intramolecular π-allyl site exchange observed for complex **1**.

We here report a further extension of our studies of the dynamic stereochemistry of the carboxylate ligand. We have synthesized and investigated the solution structures of two series of compounds of the types $[(R_3'P)Pd(O_2CR)_2]_2$ and [(π-2-methylallyl)Pd(O_2CR)($R_3'P$)]. The former are of special interest for their resemblance to the solution species which catalyze

FIG. 1. The "acetate bridge inversion" mechanism originally proposed to account for the apparently intramolecular exchange of π-allyl sites (A and B) in the π-allyl palladium acetate isomer **1**.

the arylation of olefins (5, 6) and the polymerization of allenes (7, 8).

Results and Discussion

In 1967, Wilkinson and co-worker (9) prepared the complex $[(Ph_3P)Pd(OOCCH_3)_2]_2$ by the stoichiometric addition of triphenylphosphine to palladium(II) acetate. The infrared spectrum of this complex was assignable to the presence of both terminal and bridging bidentate carboxylates consistent with a structure **3**.

The complexes $[(R_3'P)Pd(OOCR)_2]_n$ described herein were prepared by the reaction of the appropriate halide bridged dimer with silver carboxylate[1]

$$[(R_3'P)PdCl_2]_2 + 4AgOOCR \rightarrow \frac{2}{n}[(R_3'P)Pd(OOCR)_2]_n + 4AgCl$$

where $n = 1$ or 2.

[1]Attempts to prepare $[(Me_2PhP)Pd(OOCCH_3)_2]_2$ in solution by the stoichiometric addition of Me_2PhP to palladium(II) acetate led to the formation of reaction mixtures which gave rise to complex ^1H n.m.r. spectra, possibly due to impurities in the reagent palladium acetate.

Attempts to prepare the analogous platinum complexes $[(R_3'P)Pt(OOCR)_2]_2$ by this route failed; only decomposition and $[(R_3'P)ClPt(OOCR)]_2$ complexes were obtained with extended reaction times.

Structural Characterization of the Compounds $[(R_3'P)Pd(O_2CR)_2]_n$

Molecular weights of the complexes $[(R_3'P)Pd(OOCR)_2]_n$ in chloroform at 37 °C depend on the nature of the phosphine and the carboxylate substituents (Table 2). The complexes $[(Me_2PhP)Pd(OOCR)_2]_n$ ($R = CH_3$, CH_2Cl, CF_3) are all dimeric (*i.e.* $n = 2$), but the triethylphosphine analogs $[(Et_3P)Pd(OOCR)_2]_n$ show evidence of partial dissociation of the dimer to monomer for the more electronegative carboxylate substituents ($R = CH_2Cl$, CF_3).

The infrared spectra are consistent with the

presence of both unidentate and bidentate carboxylate ligands in all cases as is apparent by the asymmetric C—O stretching absorptions in Table 1. Chloroform solution spectra were used to avoid solid state effects (10) which cause up to four asymmetric C—O stretching absorptions (Nujol mull).

In either solid state (Nujol mull) or chloroform solution, the trifluoroacetate complexes display at least four strong absorptions in the region 1120–1240 cm^{-1} due to C—F stretching vibrations. It has been recently pointed out (11) that a bidentate trifluoroacetate will have a minimum of two C—F stretching frequencies and a unidentate trifluoroacetate three C—F stretching frequencies in the infrared.[2] Hence the observed multiplicity is consistent with the presence of both unidentate and bidentate carboxylates as expected for structure **3**.

In the absence of exchange, the dimeric complexes $[(R_3'P)Pd(OOCR)_2]_2$ display distinct n.m.r. signals for unidentate and bidentate carboxylate ligands consistent with structure **3**. Further, where $R_3'P$ is Me_2PhP, two methyl doublet resonances are observed assignable to the nonequivalent methyl groups as expected for a dimer of structure **3**. The methyl groups are nonequivalent owing to the lack of a plane of symmetry containing the P—Pd axis. The methyl groups of the two Me_2PhP ligands are however related to each other by the twofold axis of molecular symmetry in structure **3**. For example the ^1H n.m.r. spectrum of $[(Me_2PhP)Pd(OOCH)_3)_2]_2$ in $CDCl_3$ at −30 °C (Fig. 3*A*) displays two Me_2PhP methyl doublets (J_{P-H} = 13.6 Hz) and two acetate methyl singlets, as expected for structure **3**. The low temperature n.m.r. spectra of the other dimeric complexes $[(R_3'P)Pd(OOCR)_2]_2$ are likewise consistent with structure **3**.

Variable Temperature Nuclear Magnetic Resonance Studies

On warming, a concentration independent process is observed for the dimers $[(R_3'P)Pd(OOCR)_2]_2$, which effectively exchanges the bridging and terminal carboxylate ligands. The exchange of the Me_2PhP methyl sites occurs simultaneously with the carboxylate site exchange. For $[(Me_2PhP)Pd(OOCCH_3)_2]_2$ the fast exchange ^1H n.m.r. spectrum at +35 °C is shown in Fig. 3*B*. Table 3 gives chemical shift data for all of the complexes in the region of fast carboxylate exchange.

[2]It has been observed by Orrell and co-workers (11) that for a variety of transition metal trifluoroacetate complexes, a degeneracy of two C—F stretching modes results in the appearance of two C—F stretching modes in the vibrational spectrum of a bidentate trifluoroacetate (compared to three C—F stretching modes for a monodentate trifluoroacetate). However, in light of the fact that the C_s group symmetry, to which the bidentate trifluoroacetate has been assigned, allows three nondegenerate C—F stretching modes, the observed degeneracy is accidental and may not be a generally reliable indication of the mode of trifluoroacetate coordination.

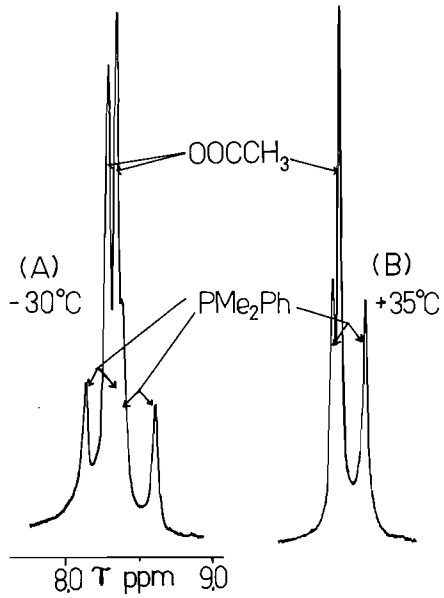

FIG. 3. The ^1H n.m.r. spectra (60 MHz) of the methyl protons in the complex $[(Me_2PhP)Pd(OOCCH_3)_2]_2$ in $CDCl_3$; (*A*) at −30 °C and (*B*) at +35 °C.

Of the two mechanisms previously postulated to account for the dynamic nature of this type of di-μ-carboxylate palladium(II) dimer (the "acetate bridge inversion" mechanism (Fig. 1) and the partially dissociative ring opening mechanism (Fig. 2)) only the latter accounts for the simultaneous exchange of both the Me_2PhP methyl sites and the terminal bridge carboxylate sites. In such a mechanism, the dissociation of one palladium–oxygen bond in $[(R_3'P)Pd(OOCR)_2]_2$ would lead to an intermediate **4** (Fig. 4) in which either of the unidentate carboxylates on the nonsolvated palladium can reform the bridge while simultaneously exchanging the Me_2PhP methyl environments. This mechanism for $[(R_3'P)Pd(OOCR)_2]_2$ complexes is identical to that found previously for the complexes $[(Me_2PhP)XPd(OOCR)]_2$ where X = halide (4).

Addition of Weak Bridge Splitting Ligands to $[(R_3'P)Pd(OOCR)_2]_2$

The addition of small aliquots of acetone or ether to a chloroform solution of $[(Me_2PhP)Pd(OOCCH_3)_2]_2$ had no effect on the ^1H n.m.r. spectra or the rate of exchange. Similar additions of methanol or acetic acid resulted in significant enhancement of the rate of exchange while, even in the fast exchange region, no exchange was observed between the added acetic acid and the acetate ligands. This behavior is identical to that observed previously for the $[(Me_2PhP)XPd(OOCR)]_2$ complexes (4) and supports the idea of a common exchange mechanism.

The addition of py, a weak bridge splitting ligand, to $[(Me_2PhP)Pd(OOCCF_3)_2]_2$ at −60 °C in a ratio of less than one py per palladium gave a new singlet resonance in the ^{19}F n.m.r. in addition to the spectrum of the reagent dimer $[(Me_2PhP)Pd(OOCCF_3)_2]_2$. The presence of

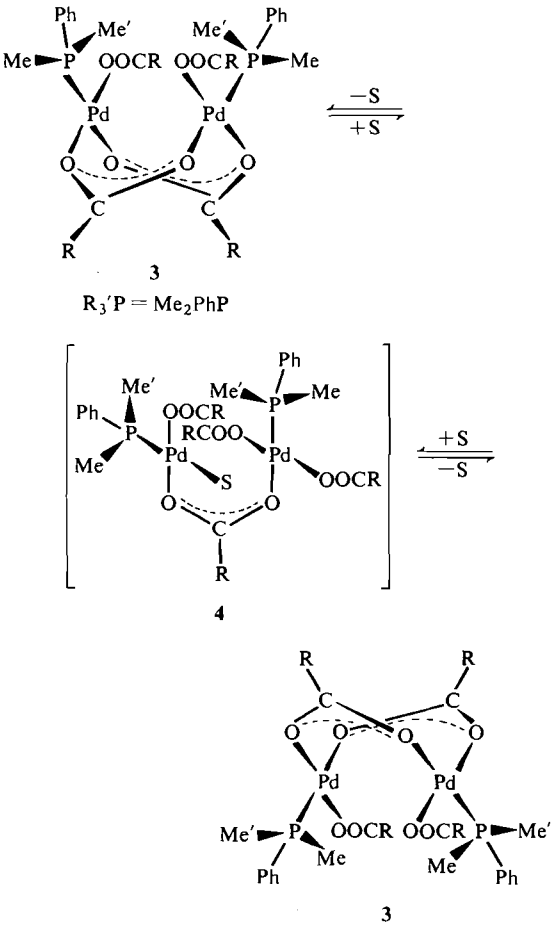

FIG. 4. The "partially dissociative" mechanism for the simultaneous exchange of the terminal and bridging acetate and Me_2PhP methyl sites in the complex $[(Me_2PhP)Pd(OOCCH_3)_2]_2$.

this species (probably *trans*-$[(Me_2PhP)Pd(OOCCF_3)_2py]$)[3] had no effect on the temperature dependent n.m.r. spectra of the residual dimer even in the region of fast exchange.

Free Energy of Activation for the Exchange Processes

The free energy of activation for both the methyl site exchange in the Me_2PhP ligand and the terminal–bridge exchange for the carboxylate ligands can be evaluated by variable temperature n.m.r. techniques.

The rate of exchange, k, at the coalescence temperature, T_c(K), is a function of the separation of the resonances in the absence of exchange, $\Delta\nu_0$ (Hz) as shown in the Gutowsky–Holm expression [1] (12).

$$[1] \qquad k = \frac{\pi}{\sqrt{2}}\Delta\nu_0$$

$$[2] \quad \Delta G_{T_c}^{\ddagger} = 4.576T_c[10.319 + \log(T_c/k)]$$

The rate of exchange k so obtained can then be substituted into the Eyring equation (eq. 2) to obtain the free energy of activation, $\Delta G_{T_c}^{\ddagger}$ (kcal/mol), for the exchange at T_c (13). The values in Table 4 for the dimers $[(R_3'P)Pd(OOCR)_2]_2$ are found to be in good agreement with those previously reported (4) for the complexes $[(Me_2PhP)XPd(OOCR)]_2$ (*e.g.* see Table 4 for data where X = I). Again this similarity in $\Delta G_{T_c}^{\ddagger}$ for the Me_2PhP methyl site exchange in the $[(Me_2PhP)XPd(OOCR)]_2$ and $[(R_3'P)Pd(OOCR)_2]_2$ systems substantiates the hypothesis of a common mechanism. $\Delta\nu_0$ increases (for either carboxylate or Me_2PhP methyl site exchange) in the order $R = CH_3 < CH_2Cl < CF_3$ and the coalescence temperatures vary in the inverse order $R = CF_3 < CH_2Cl < CH_3$. We conclude that the exchange process is facilitated by more electronegative substituents.

The Activation Energy for the Exchange Processes in $[(Me_2PhP)Pd(OOCCH_3)_2]_2$

The rates of exchange for Me_2PhP methyls and terminal–bridging acetates were determined over a range of temperatures by the method of peak separation (eq. 3) (12, 14)

$$[3] \qquad k = \frac{\pi}{\sqrt{2}}(\Delta\nu_0^2 - \Delta\nu^2)^{1/2}$$

An Arrhenius plot (Fig. 5) shows that the activation energies of the Me_2PhP methyl site exchange and the acetate terminal–bridging site exchange are approximately equal as expected if these exchanges arise from the same process. The low activation energies necessitate a large negative entropy $\Delta S^{\ddagger} \sim -30$ e.u., to account for $\Delta G_{T_c}^{\ddagger} \sim 14.5$ kcal/mol observed for the exchange processes in $[(Me_2PhP)Pd(OOCCH_3)_2]_2$.

Again the values of E_A and $\Delta S^{\ddagger}$ are essentially

[3]The singlet ^{19}F n.m.r. resonance due to the trifluoroacetates in the monomeric species is compatible with either a "*trans*" disposition of these ligands or a rapid process of site exchange which averages all the trifluoroacetate environments.

identical to those found for $[(Me_2PhP)XPd(OOCR)]_2$ (4).

The Importance of Chelation by Carboxylate in the Partially Dissociative Ring Opening Mechanism in the Complexes $[(Me_2PhP)Pd(OOCR)_2]_2$

We considered it possible that the ring opened intermediate might be stabilized by chelation, *i.e.* **5** in Fig. 6. To assess the relative importance of a carboxylate chelated intermediate **5** *vs.* intermediate **4** a new series of dimers $[(Me_2PhP)(OOCR')Pd(OOCR)]_2$ **6** was prepared by mixing the complexes $[(Me_2PhP)Pd(OOCR)_2]_2$ and $[(Me_2PhP)Pd(OOCR')_2]_2$ in a 1:1 ratio in $CDCl_3$ [4].

[4] $[(Me_2PhP)Pd(OOCCF_3)_2]_2 + [(Me_2PhP)Pd(OOCR)_2]_2 \rightleftharpoons 2[(Me_2PhP)(OOCCF_3)Pd(OOCR)]_2$

R = CH_3, CH_2Cl

methyl groups, typical of the dimeric structure, has been retained, but only one sharp singlet is present in the acetate protons. In the ^{19}F n.m.r. a sharp temperature invariant singlet is present for the trifluoroacetate. By the simplicity of this spectrum, it is apparent that there is only one major solution species present wherein there is one site for the acetate and one site for the trifluoroacetate in a dimeric structure. Such spectral features would be expected for the mixture in [4] if the equilibrium lay totally to the right *and* if the trifluoroacetate and acetate ligands occupied the terminal and bridging sites respectively as shown in **6** where R = CH_3. Similar spectra were obtained for R = CH_2Cl.

Since the ease of the ring opening process is related to the bidentate ability of the bridging carboxylate, the inference of the earlier variable temperature n.m.r. exchange study is that the bidentate ability of the carboxylate ligand diminishes with increasingly electronegative substitution of the carboxylate; CH_3 > CH_2Cl > CF_3. This trend has also been reported by Hammond *et al.* (15) as the controlling influence in determining the bidentate, unidentate coordination of the carboxylate in the structures of copper(I) carboxylates, $[(Ph_3P)_nCu(OOCR)]$, where $n = 2$ or 3. Consequently the preferred structure **6** having terminal trifluoroacetates and bridging acetates (or monochloroacetates) is reasonable.

Mixing the complexes $[(Me_2PhP)Pd(OOCCH_3)_2]_2$ and $[(Me_2PhP)Pd(OOCCH_2Cl)_2]_2$ in a 1:1 ratio (eq. 5) gave a system analogous to those described above in [4]. The major solution species in [5] is the mixed carboxylate species $[(Me_2PhP)Pd(OOCCH_3)(OOCCH_2Cl)]_2$ in which the *acetate functions as the bridging ligand and the monochloroacetate is a terminal ligand.*

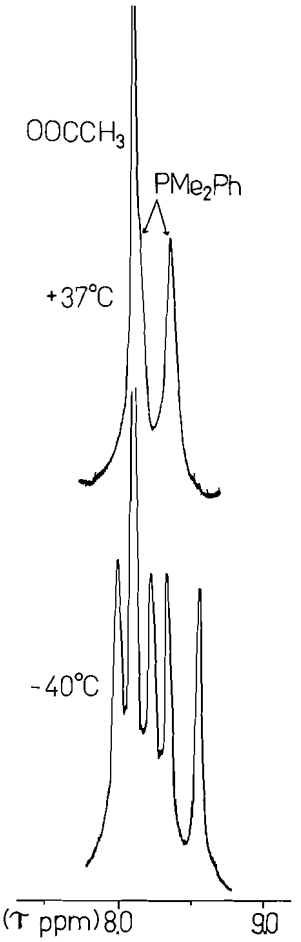

FIG. 7. The ^1H n.m.r. spectra (60 MHz) of the methyl protons in a 1:1 mixture of $[(Me_2PhP)Pd(OOCCF_3)_2]_2$ and $[(Me_2PhP)Pd(OOCCH_3)_2]_2$ in $CDCl_3$, at −40 °C and at +37 °C.

[5] $[(Me_2PhP)Pd(OOCCH_3)_2]_2 + [(Me_2PhP)Pd(OOCCH_2Cl)_2]_2 \rightleftarrows 2[(Me_2PhP)Pd(OOCCH_3)(OOCCH_2Cl)]_2$

6

In all cases warming solutions of **6** caused exchange of Me_2PhP methyl sites by the partially dissociative ring opening mechanism (Fig. 4). In each case $\Delta G_{T_c}^{\ddagger}$ for Me_2PhP methyl exchange (Table 4) is almost identical to that found for the parent complex of the least electronegatively substituted carboxylate. Thus, the exchange parameters for $[(Me_2PhP)Pd(OOCCH_3)(OOCCH_2Cl)]_2$ and $[(Me_2PhP)Pd(OOCCH_3)_2]_2$ are very similar. The implication is that the ease of exchange is a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

function of the bridging carboxylate substituents but is independent of the nature of the terminal carboxylate.

In a later section, it will be established that the chelating ability of a carboxylate ligand depends on the electronegativity of its substituents. Thus, if chelation were important in the intermediate for the Me_2PhP methyl site, bridging–terminal carboxylate site exchange (*i.e.* intermediate **5**, Fig. 6) then the exchange parameters would be dependent on the nature of the terminal carboxylate and this is not observed. Therefore the chelated intermediate **5** (Fig. 6) is not important in the exchange process.

Dissociation of the Dimers $[(R_3'P)Pd(OOCR)_2]_2$ in Solution

The complex, $[(Et_3P)Pd(OOCCF_3)_2]_n$, has been observed by osmometry to exist as a monomer, dimer equilibrium (eq. 6) in chloroform at 37 °C (Table 2).

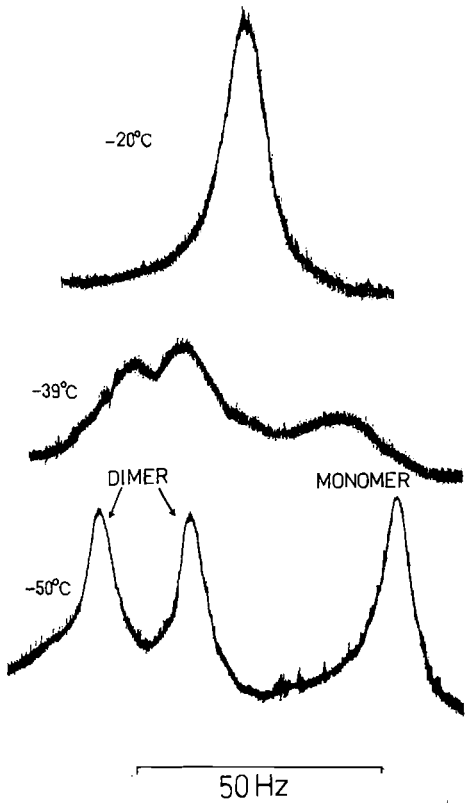

FIG. 8. The variable temperature ^{19}F n.m.r. spectra (56 MHz) of the complex $[(Et_3P)Pd(OOCCF_3)_2]_n$ in $CDCl_3$.

[6] $[(Et_3P)Pd(OOCCF_3)_2]_2 \underset{\text{monomer}}{\overset{K_6}{\rightleftharpoons}} 2[(Et_3P)Pd(OOCCF_3)_2.S]$

where S is solvent. The low temperature ^{19}F n.m.r. shown in Fig. 8 (−50 °C) exhibits two low field resonances assignable to the dimer $[(Et_3P)Pd(OOCCF_3)_2]_2$ and an upfield singlet assignable to the monomer $[(Et_3P)Pd(OOCCF_3)_2.S]$ where S is solvent.[3] Dilution of the ^{19}F n.m.r. sample increases the monomer to dimer ratio. On warming, all the ^{19}F resonances coalesce to give a singlet resonance in the fast exchange region (Fig. 8, −20 °C). From the dimer/monomer ratio obtained by integration of the ^{19}F n.m.r. spectra, the equilibrium constant, K_6 can be determined. The effect of solvent on K_6 is shown in Table 5. In toluene, dichloromethane, and chloroform containing 0.75% ethanol, the ^{19}F n.m.r. spectra are analogous to that obtained in $CDCl_3$ (Fig. 8). In ethanol and acetone only a sharp singlet is observed even at −75 °C. Since the addition of only 0.75% ethanol to a chloroform solution of $[(Et_3P)Pd(OOCCF_3)_2]_n$ at −63 °C results in substantial enhancement of the monomer concentration, we conclude that the complex exists totally as the monomer ($n = 1$) in ethanol. Similarly, only monomer ($n = 1$) is present in acetone.

The ability of acetone to promote monomer formation in the $[(Et_3P)Pd(OOCCF_3)_2]_2$ case is mimicked for the complex $[(Me_2PhP)Pd(OOCCF_3)_2]_n$, which, as noted in Table 4, is dimeric ($n = 2$) in chloroform-d_1 or toluene-d_8 but exists in a monomer ($n = 1$), dimer ($n = 2$) equilibrium in neat acetone-d_6 with a temperature dependent ^{19}F n.m.r. exactly analogous to that shown in Fig. 8. This ability of acetone to stabilize the monomer is probably related to its ability to coordinate to palladium(II) trifluoroacetate complexes, as evidenced by the isolation of complexes such as $[(acetone)Pd(OOCCF_3)_2]_2$ (9), in which the acetone functions as a ligand.

The occurrence of dimer dissociation in the complexes $[(R_3'P)Pd(OOCR)_2]_2$ (Table 4) may be rationalized in terms of electronic effects. Increasing the electronegativity of the carboxylate ligand promotes dissociation of the dimers $[(R_3'P)Pd(OOCR)_2]_2$ ($CH_3 < CH_2Cl < CF_3$), as does increasing the donor ability of the phos-

phine ($Et_3P > Me_2PhP$) (16). A similar destabilization of the binuclear configuration of cupric carboxylates, $Cu_2(OOCR)_4.2L$, has been ascribed to the repulsive interaction between the residual charges on the adjacent copper atoms ($R = CF_3 > CH_3$) (17, 18).

The Effect of Bulky Phosphines in $[(R_3'P)Pd(OOCCF_3)_2]_n$

The introduction of bulky phosphines Ph_2MeP or Ph_3P in the complexes $[(R_3'P)Pd(OOCCF_3)_2]_n$ results in the destabilization of the dimer **3** by steric crowding. The effect of these phosphine substituents on the dimer dissociation in chloroform is summarized in Table 6. $[(Ph_3P)Pd(OOCCF_3)_2]_n$ is insoluble in $CDCl_3$ or toluene-d_8 but very soluble in alcohols or acetone. In these solvents only one sharp singlet resonance is apparent in the ^{19}F n.m.r. spectrum at −80 °C, as expected for monomer. The corresponding acetate complex, $[(Ph_3P)Pd(OOCCH_3)_2]_2$, has been formulated as a dimer by Wilkinson and co-worker (9). Such behavior is reminiscent of Lewis's cupric benzoate complexes which are polymeric for highly electron withdrawing carboxylates and dimeric for less electronegative ones (19). Thus it is possible that the steric strain imposed by the bulky Ph_3P group in $[(Ph_3P)Pd(OOCCF_3)_2]_n$ causes the loss of the binuclear structure **3** in the solid state in favor of a bridged trifluoroacetate polymeric structure.

Preparation and Characterization of $Ag(Me_2PhP)Pd(OOCCF_3)_3$

Reaction of the bridged halide dimer $[(Me_2PhP)PdCl_2]_2$ with excess $AgOOCCF_3$ yielded yellow needles which analyzed as $[Ag(Me_2PhP)Pd(OOCCF_3)_3]$ (Table 1). Three asymmetric C—O stretching frequencies are observed in the solid state infrared spectrum at 1680vs, 1660vs, and 1635vs (Nujol mull). The ^1H n.m.r. spectrum consisted of one doublet in the Me_2PhP methyl region (Table 3) which remained invariant from −60 to +35 °C in $CDCl_3$. The low temperature ^{19}F n.m.r. spectrum showed two sharp singlets in a 2:1 ratio which collapsed on warming above −30 °C to give two broad overlapping peaks at +62 °C. Molecular weight data (Table 2) showed the compound to be aggregated in solution, the degree of aggregation being concentration dependent. Even dilute solutions in chloroform (8×10^{-4} *M*) were nonconducting.

The chemical reactivity of the silver species proved consistent with the formulation

$Ag(Me_2PhP)Pd(OOCCF_3)_3$. Reaction with the bridged halide $[(Me_2PhP)PdCl_2]_2$ in a ratio of 4:1 yielded AgCl (94% yield) and the previously prepared complex, $[(Me_2PhP)Pd(OOCCF_3)_2]_2$ (eq. 7).

[7] $4Ag(Me_2PhP)Pd(OOCCF_3)_3 + [(Me_2PhP)PdCl_2]_2 \rightarrow 4AgCl\downarrow + 3[(Me_2PhP)Pd(OOCCF_3)_2]_2$

The Ag^+ could be displaced by NH_4^+ or $AsPh_4^+$ as shown in [8].

[8] $Ag(Me_2PhP)Pd(OOCCF_3)_3 + \text{cation}^+ Cl^- \xrightarrow[MeOH]{} AgCl\downarrow + \text{cation}^+ [(Me_2PhP)Pd(OOCCF_3)_3]^-$

Evaporation of the solution after removal of the AgCl precipitate gave a yellow oil for either NH_4^+ or $AsPh_4^+$. In the case of NH_4^+, dissolving this oil in CH_2Cl_2 resulted in the quantitative precipitation of NH_4OOCCF_3, leaving $[(Me_2PhP)Pd(OOCCF_3)_2]_2$ in solution. Dissolution of the $AsPh_4^+$ oil in chloroform did not precipitate $AsPh_4OOCCF_3$, and the n.m.r. spectra of the solution were very similar to those of the original silver complex: a temperature invariant methyl doublet for the Me_2PhP ligand (−59 to +35 °C) in the ^1H n.m.r. spectrum and two singlets in a 2:1 ratio in the ^{19}F n.m.r. spectrum.

In acetonitrile, a solvent of good coordinating ability and high dielectric constant $Ag(Me_2PhP)Pd(OOCCF_3)_3$ ionizes to give a conductance with a nonlinear concentration dependence which does not correspond to a simple electrolyte type.

Attempts to prepare analogous complexes of the other carboxylates (*i.e.* $Ag(Me_2PhP)Pd(OOCR)_3$, where R = CH_3 or CH_2Cl) only resulted in the formation of $[(Me_2PhP)Pd(OOCR)_2]_2$ in varying states of impurity.

The Dependence of Carboxylate Chelation Ability on the Inductive Effect of the Carboxylate Substituents

In evaluating the importance of the carboxylate chelate intermediate **5** (Fig. 6) in the exchange processes we made the hypothesis that chelation of the carboxylate ligand is a function of the electronegativity of the carboxylate substituents. This can be substantiated by studying a model system which undergoes an observable exchange process wherein the intermediate or transition state is stabilized by chelation.

It has been established that the intramolecular 3,4-allylic proton site exchange observed in the

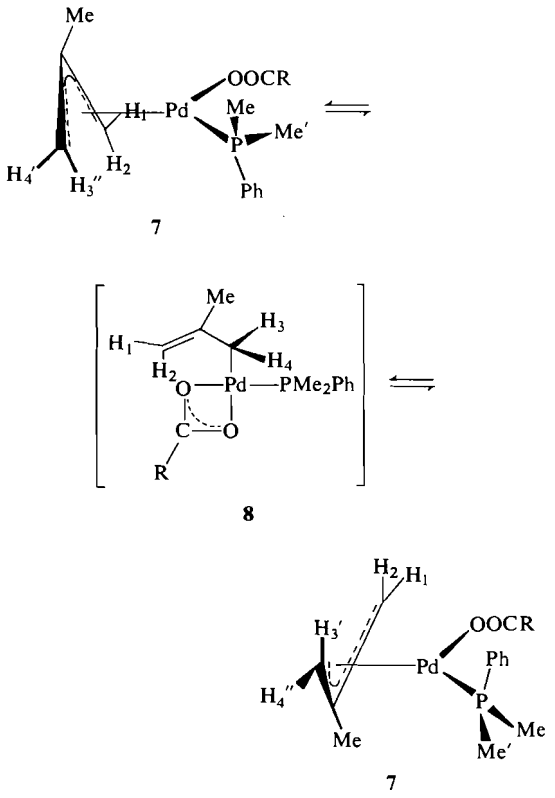

FIG. 9. The π–σ–π mechanism for the exchange of the 3,4 (syn,anti) allylic proton sites in the complex [(π-2-methylallyl) Pd(OOCR) (Me_2PhP)].

complexes, [(π-2-methylallyl)Pd(OOCR)($R_3'P$)] **7** takes place via a π–σ–π exchange mechanism (illustrated in Fig. 9) (2, 20–22). Where $R_3'P$ is Me_2PhP, a concurrent exchange of the nonequivalent Me_2PhP methyl environments is also apparent (as illustrated in Fig. 9). The ^{31}P—^1H coupling between the $R_3'P$ ligand and the 1,2-allylic protons is preserved even in the region of fast 3,4-allylic proton site exchange (2, 20–22).

To test the relative chelating ability of a series of carboxylate ligands, the complexes [(π-2-methylallyl)Pd(OOCR)($R_3'P$)] ($R_3'P$ = Me_2PhP or Ph_3P and R = CH_3, CMe_3, CPh_3, CH_2Ph, CH_2Cl, CCl_3, and CF_3) were prepared directly in an n.m.r. tube by the stoichiometric addition of $R_3'P$ to the appropriate carboxylate bridged dimer, $[(\pi\text{-2-methylallyl})Pd(OOCR)]_2$ (23) in $CDCl_3$ or C_6H_5Cl, under nitrogen, immediately prior to the n.m.r. observations.

$CDCl_3$ solution are listed in Table 7. The parameters for the intramolecular exchange of the 3,4-allylic protons by the π–σ–π mechanism (Fig. 9) are reported in Table 8, ($R_3'P = Ph_3P$) and Table 9, ($R_3'P = Me_2PhP$). $\Delta G_{T_c}^{\ddagger}$ was calculated as described above. For [(π-2-methylallyl)Pd($OOCCH_3$)(Ph_3P)] and [(π-2-methylallyl)Pd($OOCCH_2Cl$)(Ph_3P)] changing the solvent from $CDCl_3$ to CD_2Cl_2 does not appreciably alter the exchange parameters for 3,4-allylic proton exchange. However, in the trifluoroacetate complex, [(π-2-methylallyl)Pd($OOCCF_3$)(Ph_3P)], changing the solvent from $CDCl_3$ to C_6H_5Cl causes a complete change in the observed exchange process. The first process observed on warming in C_6H_5Cl is the syn,syn and anti,anti allylic proton site exchange typical of the corresponding arsine complexes [(π-allylic)Pd(OOCR)($R_3'As$)] (20). The loss of coupling between the Ph_3P (^{31}P) and the allylic protons indicates that the mechanism involves the intermolecular exchange of the Ph_3P ligand. For the series of complexes [(π-2-methylallyl)Pd(OOCR)Ph_3P] the order of increasing free energy of activation of $\Delta G_{T_c}^{\ddagger}$ ($R = CH_3 < CH_2Ph < CH_2Cl < CF_3$) for 3,4-allylic proton exchange is consistent with a decreasing ability of the carboxylate ligand to stabilize the intermediate **8** by chelation. (Although the $\Delta G_{T_c}^{\ddagger}$ values are not determined at the same temperature, the order of $\Delta G_{T_c}^{\ddagger}$ for a given series of complexes is valid where $\Delta\nu_0$ (Hz), the resonance separation in the absence of exchange, is constant or increasing in the opposite direction to $\Delta G_{T_c}^{\ddagger}$).

In the complexes [(π-2-methylallyl)Pd(OOCR)-Me_2PhP] in $CDCl_3$, the parameters for both the Me_2PhP methyl site and 3,4-allylic proton site exchange (as listed in Table 9) are consistent with the π–σ–π mechanism (Fig. 9). Again the ease of the exchange process depends on the inductive influence of the carboxylate substituents ($R = CH_3 < CH_2Ph < CH_2Cl$) and reflects the decreasing ability of the carboxylate to stabilize the σ-allylic intermediate **8** by bidentate chelation.

In the case of [(π-2-methylallyl)Pd(OOCR)-Me_2PhP] where R = CCl_3 or CF_3, the loss of ^{31}P coupling to the 1,2-allylic protons occurs before the coalescence of 3,4-allylic proton resonances (Table 9) and indicates that the Me_2PhP ligand is involved in intermolecular exchange as well as π–σ–π exchange (Fig. 9). On warming, total collapse of all the allylic proton resonances is observed as expected for simultaneous 3,4 and syn,syn and anti,anti allylic proton exchange. With two exchange processes active in the system, the values of $\Delta G_{T_c}^{\ddagger}$ obtained from Me_2PhP site exchange in the R = CF_3 and CCl_3 complexes are in effect lower limits since intermolecular exchange is already contributing to the collapse of the Me_2PhP methyl proton resonances. Thus in Fig. 10 the values of $\Delta G_{T_c}^{\ddagger}$ for R = CF_3 and CCl_3 (where $R_3'P$ is Me_2PhP) deviate markedly from the otherwise consistent trend in $\Delta G_{T_c}^{\ddagger}$

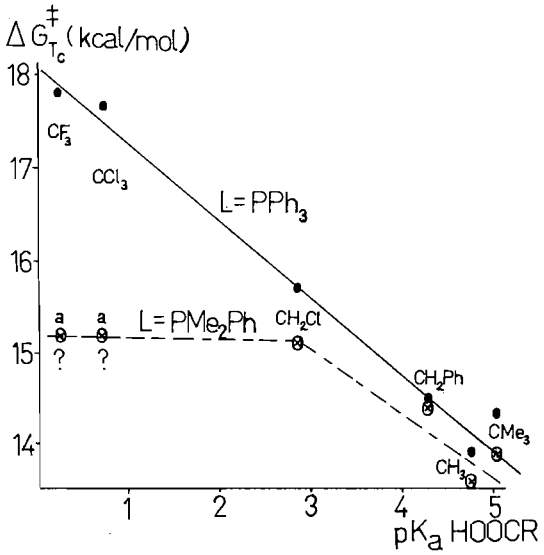

FIG. 10. The variation of the free energy of activation, $\Delta G_{T_c}^{\ddagger}$, for the 3,4-allylic proton site exchange in the complexes [(π-2-methylallyl)Pd(OOCR)(L)] with the inductive effect of the carboxylate substituents, R, expressed in terms of the pK_a of the corresponding carboxylic acid, HOOCR. a; two processes of exchange are operating (see text).

with the inductive effect of the carboxylate substituents.

From the data, summarized in Fig. 10, it may be concluded that the ability of the carboxylate ligand to stabilize a transition state by chelation diminishes with increasingly electronegative substitution.

The Influence of $AgOOCCF_3$ on 3,4-Allylic Proton Site Exchange in the Complexes [(π-2-methylallyl)Pd($OOCCF_3$)$R_3'P$]

In order to obtain reproducible results for the complexes, [(π-2-methylallyl)Pd($OOCCF_3$)$R_3'P$] where $R_3'P$ is Me_2PhP or Ph_3P, it proved necessary to completely remove all $AgOOCCF_3$ (lingering from the preparation of the reagent bridging carboxylate dimer) by passing the reagent dimer solution through activated alumina prior to the addition of $R_3'P$. The presence of even trace amounts of $AgOOCCF_3$ initiated a concentration dependent 3,4-allylic proton site exchange in $CDCl_3$ presumably due to a π–σ rearrangement (24) via a bimolecular interaction between $AgOOCCF_3$ and [(π-2-methylallyl)Pd(OOCR)$R_3'P$].

Summary and Conclusions

The facility of the intramolecular partially dissociative $Pd_2(OCO)_2$ ring opening process (Figs. 2 and 4) observed for the complexes $[(Me_2PhP)XPd(OOCR)]_2$ and $[(R_3'P)Pd(OOCR)_2]_2$ increases with the electronegativity of the carboxylate substituents, CH_3 < CH_2Cl < CF_3. Similarly, the ability of the carboxylate ligand to stabilize a transition state by chelation decreases in the same order, as noted for 3,4-allylic proton exchange in [(π-2-methylallyl)Pd(OOCR)$R_3'P$] complexes. It would appear in general then that the stability of the bidentate coordination of the carboxylate ligand (relative to unidentate coordination)

diminishes as the carboxylate substituents withdraw electron density from the oxygens of the carboxyl group.

The present work establishes the order and relative magnitude of the influence of the carboxylate substituents on various solution processes involving the chelation and bidentate bridging coordination of the carboxylate ligand. The results obtained have been used elsewhere (25) to rationalize the observed dependence of catalytic systems on the nature of carboxylate substituents such as that observed for the polymerization of butadiene by $[(\pi\text{-allylic})\text{-Ni(OOCR)}]_2$ (26, 27).

Experimental

Preparation of Compounds

The bridging halide dimers $[(R_3P)PdCl_2]_2$ were prepared by the method of Jenkins and Shaw (28). In all cases, the presence of excess silver carboxylates was avoided and special care was taken to remove extraneous silver compounds from the reaction mixtures by columning the reaction mixtures through activated alumina or Fisher Scientific Florisil.

Di-μ-acetatodiacetatobis(dimethylphenylphosphine)dipalladium(II)

A solution of di-μ-chlorodichlorobis(dimethylphenylphosphine)dipalladium(II) (0.507 g) in chloroform (15 ml) was shaken with silver acetate (0.536 g) for 3 h. The solution was columned through Florisil to remove precipitated silver chloride and unreacted silver acetate. The product was isolated by evaporation as an orange oil. Recrystallization from benzene and hexanes yielded yellow plates (0.268 g, 47%).

Di-μ-monochloroacetatodimonochloroacetatobis(dimethylphenylphosphine)dipalladium(II)

A solution of di-μ-chlorodichlorobis(dimethylphenylphosphine)dipalladium(II) (0.676 g) in dichloromethane (30 ml) was shaken with silver monochloroacetate (0.866 g) for 5 h. The solution was columned through alumina to remove silver compounds and then evaporated down to give an orange oil. Recrystallization from benzene/hexanes gave yellow solid (0.621 g, 67%).

Di-μ-trifluoroacetatoditrifluoroacetatobis(dimethylphenylphosphine)dipalladium(II)

A solution of di-μ-chlorodichlorobis(dimethylphenylphosphine)dipalladium(II) (0.509 g) in dichloromethane (20 ml) was shaken for 90 min with silver trifluoroacetate (0.711 g). The reaction mixture was columned through alumina and evaporated to yield a yellow bubbly glass. Recrystallization from benzene/hexane gave yellow needles (0.395 g, 52%).

Di-μ-acetatodiacetatobis(triethylphosphine)dipalladium(II)

A solution of di-μ-chlorodichlorobis(triethylphosphine)dipalladium(II) (0.378 g) in dichloromethane (15 ml) was shaken 3 h with silver acetate (0.430 g). The solution was columned through Florisil and evaporated to give a yellow solid. Recrystallization from dichloromethane/hexanes gave orange prisms (0.308 g, 70%).

Di-μ-monochloroacetatodimonochloroacetatobis(triethylphosphine)dipalladium(II)

A solution of di-μ-chlorodichlorobis(triethylphosphine)dipalladium(II) (0.214 g) in dichloromethane (20 ml) was shaken for 2 h with silver monochloroacetate (0.293 g). The solution was columned through Florisil and evaporated to a yellow oil. Recrystallization from dichloromethane/hexane gave yellow–orange prisms, (0.272 g, 91%).

Di-μ-trifluoroacetatoditrifluoroacetatobis(triethylphosphine)dipalladium(II)

A solution of di-μ-chlorodichlorobis(triethylphosphine)dipalladium(II) (0.138 g) in dichloromethane (10 ml) was shaken for 1 h with silver trifluoroacetate (0.207 g). The solution was columned through Florisil and evaporated to a yellow solid. Recrystallization from dichloromethane/hexanes gave yellow prisms (0.135 g, 67%).

Di-μ-trifluoroacetatoditrifluoroacetatobis(triphenylphosphine)dipalladium(II)

A solution of di-μ-chlorodichlorobis(triphenylphosphine)dipalladium(II) (0.413 g) in dichloromethane (30 ml) was shaken for 90 min with silver trifluoroacetate (0.415 g). The solution was columned through Florisil and evaporated to yellow solid. Recrystallization from dichloromethane/ether/hexanes gave yellow solid (0.436 g, 78%).

Di-μ-trifluoroacetatoditrifluoroacetatobis(methyldiphenylphosphine)dipalladium(II)

A solution of di-μ-chlorodichlorobis(methyldiphenylphosphine)dipalladium(II) (0.570 g) in dichloromethane (20 ml) was shaken for 90 min with silver trifluoroacetate (0.669 g). The solution was columned through Florisil and evaporated to orange oil. Recrystallization from chloroform/hexanes gave orange prisms (0.607 g, 76%).

Silver Tri(trifluoroacetato)dimethylphenylphosphinepalladium(II)

A solution of di-μ-chlorodichlorobis(dimethylphenylphosphine)dipalladium(II) (0.223 g) in dichloromethane (20 ml) was shaken for 2 h with silver trifluoroacetate (0.468 g). The bright yellow solution was filtered and evaporated down with continual addition of hexanes until crystallization gave bright yellow needles (0.375 g, 84%). Redissolution always left a trace of silver trifluoroacetate residue.

Physical Measurements

The variable temperature ^1H and ^{19}F n.m.r. spectra were recorded on a Varian Associates A56/60D spectrometer with temperature calibration by measurement of a methanol spectrum using the equations of Van Geet (29). The molecular weight studies were carried out osmometrically in ethanol free chloroform at 37 °C using a Mechrolab 301A Vapour Phase Osmometer. The infrared spectra were recorded using a Beckman IR-20 spectrometer; conductivity measurements were determined using a Barnstead PM70CB Conductivity Bridge; and melting points are from a Kofler hot stage apparatus and are corrected.

The Kinetics of Quinoline Hydrodenitrogenation through Reaction Intermediate Products

AHMED KADRY ABOUL-GHEIT

Petroleum Department, National Research Centre, Dokki, Cairo, Egypt

Received September 17, 1974[1]

AHMED KADRY ABOUL-GHEIT. Can. J. Chem. **53**, 2575 (1975).

Under petroleum hydrotreating conditions and in the presence of a Co–Mo–alumina catalyst, quinoline is hydrodenitrogenated through a consecutive first order reaction involving a hydrogenation step followed by two hydrocracking steps. The first step is too fast to measure whereas the second step is the slowest. The ratio of the rate constants of the second to the third step ranges between 0.33 and 0.62 at reaction temperatures between 350 and 400 °C. The second step can be considered responsible for the relatively high activation energy and enthalpy values obtained for the overall reaction. The activation entropy obtained for the overall reaction is -38.2 e.u. mol^{-1}, while the second and the third steps have values of -43.9 and -58.0 e.u. mol^{-1}, respectively. These values indicate the progressive complexity of the steps involved in the reaction sequence as it proceeds towards ammonia production.

AHMED KADRY ABOUL-GHEIT. Can. J. Chem. **53**, 2575 (1975).

Dans les conditions de traitement du pétrole et en présence d'un catalyseur Co–Mo–alumine, la quinoléine est hydrodénitrogénée en passant par une réaction du premier ordre impliquant une étape d'hydrogénation suivie de deux étapes d'hydrocraquage. La première étape est trop rapide pour être mesurée alors que la deuxième est la plus lente. Le rapport des constantes de vitesse de la deuxième à la troisième étape se situe entre 0.33 et 0.62 pour des températures de réaction de 350 à 400 °C. La seconde étape peut être considérée comme étant responsable des valeurs relativement élevées de l'énergie d'activation et de l'enthalpie obtenues pour la réaction totale. L'entropie d'activation obtenue pour la réaction globale est -38.2 u.e. mol^{-1}, alors que les deuxième et troisième étapes ont respectivement les valeurs de -43.9 et -58.0 u.e. mol^{-1}. Ces valeurs indiquent la complexité progressive des étapes impliquées dans la séquence des réactions qui conduisent à la production d'ammoniac. [Traduit par le journal]

Introduction

Hydrodenitrogenation (HDN) is a petroleum hydrotreating reaction of prime importance since nitrogen compounds cause serious problems in the processing and storage of petroleum products. Under hydrotreating conditions, HDN is much more difficult than hydrodesulfurization (1, 2). For high HDN levels, high hydrogen pressures are employed (3, 4). Temperatures above 400 °C are undesirable in hydrotreating since they enhance hydrocracking reactions that result in lower liquid yields, higher hydrogen consumption, and lower viscosity of lubricating oil stocks.

Hydrodenitrogenation is a stepwise process involving hydrogenation and hydrocracking reactions (4–9). The catalysts employed in this process possess both hydrogenation–dehydrogenation and cracking functions (dual functional catalysts). Over such catalysts, the petroleum nitrogen compounds are converted through intermediate products to ammonia. Each of these intermediates possesses different adsorptivity on the catalyst surface (9).

The subject of this paper is to study the kinetic and thermodynamic parameters for quinoline HDN involving the formation and conversion of intermediate products in order to clarify the reaction mechanism.

Experimental

Catalyst

A catalyst containing 3% cobalt oxide and 10% molybdenum oxide was prepared by impregnating $\frac{1}{8}$ in. extrudates of γ-alumina with cobalt nitrate solution, drying at 110 °C overnight, and calcinating at 550 °C for 4 h. Another impregnation with ammonium molybdate solution was then carried out followed by drying and calcination as above. The catalyst was then ground into 60–80 mesh particles because this has been shown to be the optimum size (5). The surface areas (measured by the BET method) of the alumina support and the prepared Co–Mo–alumina catalyst were 228 and 196 m^2/g, respectively.

Feedstock

Extra-pure grade Merck quinoline was redistilled under

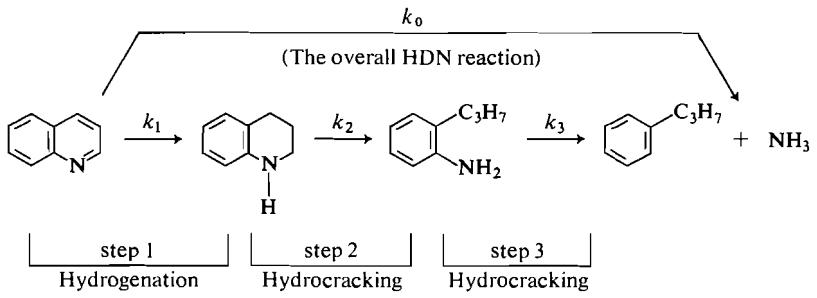

SCHEME 1

reduced pressure, then dissolved in a high purity paraffin oil. The oil exhibited no absorbance in the ultraviolet spectral region. The ebullioscopically determined average molecular weight of the oil was 185. The concentration of quinoline in the oil was 4.6 wt.%. *i.e.*, equivalent to 0.5 wt.% nitrogen. The quinoline solution was preserved in a dark container under nitrogen atmosphere and used as the feedstock.

Hydrogenation Procedure

The HDN experiments were carried out in a 2-l batch autoclave. After closing and purging twice with nitrogen and twice with hydrogen, the autoclave was filled with high purity hydrogen to a predetermined initial hydrogen pressure such that the operating pressure at the working temperature was 200 atm. The pressure dropped by only 3 atm after a reaction period of 8 h at 400 °C. The pressure drop was even less at lower temperatures and shorter reaction periods. The autoclave was heated to the reaction temperature, then a mixture of 250 g of the feedstock and 25 g of the catalyst was introduced into the reactor via a high pressure injector. At this moment, the autoclave's magnetic stirrer was switched on at a velocity of 1500 r.p.m. and the time was considered as zero. This stirring velocity has been shown to be optimum (5). Liquid samples of 2 ml volume were withdrawn from the system every hour, except for the first sample that was taken after a reaction period of $\frac{1}{2}$ h. The catalyst was removed from the sample by filtration while the dissolved ammonia was removed by bubbling a gentle current of nitrogen gas.

Analysis

The product samples were analyzed to determine the nitrogen content using a micro-Dumas technique via a Coleman Nitrogen Analyzer model 29. The individual nitrogen components were isolated from the product samples with 5% aqueous HCl solution then freed with 10% NaOH solution and extracted by ether. The ether was evaporated and the concentrate of nitrogenous components was analyzed by gas–liquid chromatography using an SE-30 column. The apparatus and conditions were described elsewhere (6, 7). Lower anilines (aniline, *o*-toluidine, and *o*-ethylaniline) in the products were always less than 2.0% and were calculated as *o*-propylaniline, whereas alkylquinolines were always less than 3.5% and were calculated as unreacted quinoline. A spectrophotometric search for pyrrolic nitrogen compounds in the product samples (10) showed the presence of negligible quantities only.

Results and Discussion

The hydrotreating process is carried out at relatively mild temperatures and high pressures, using supported or unsupported metal oxide or sulfide catalysts. Under such conditions, the hydrocarbon composition of the oil to be hydrotreated is only slightly affected, whereas the hetero compounds, including sulfur, nitrogen, and oxygen compounds, are greatly transformed. In this investigation, the paraffin-oil diluent was slightly hydrocracked, whereas the quinoline molecule was hydrodenitrogenated through a series of hydrogenation and hydrocracking reactions to yield ultimately ammonia and the "clean" hydrocarbon *n*-propylbenzene as envisaged in Scheme 1, where the subscripts 0, 1, 2, and 3 designate the overall HDN reaction, the first, second, and third step in the HDN sequence, respectively.

The overall process rate constant, k_0, has been shown (5) to be first order with respect to quinoline via both integral and differential approaches, hence, k_0 is herein graphically calculated from a plot of log $(1 - M_D)$ *vs.* t, as given in Fig. 1.

From Fig. 2, it is evident that virtually all of the quinoline reacted is converted to 1,2,3,4-

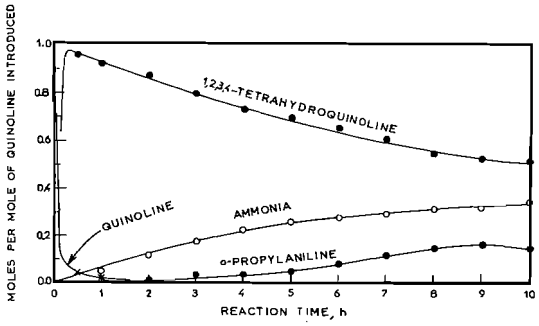

FIG. 2. Kinetic curve for quinoline hydrodenitrogenation at 350 °C.

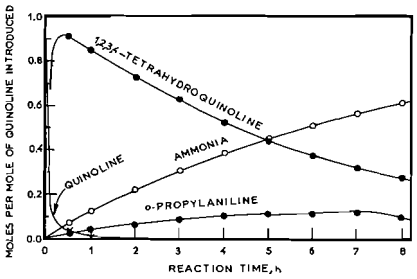

FIG. 3. Kinetic curve for quinoline hydrodenitrogenation at 375 °C.

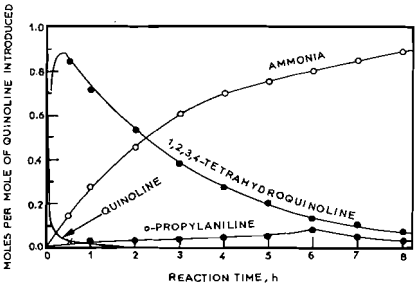

FIG. 4. Kinetic curve for quinoline hydrodenitrogenation at 400 °C.

tetrahydroquinoline at an early stage in the HDN process. The conversion is so fast that the molar concentration of the tetrahydroquinoline reaches 96% after ½ h of reaction. In this case, it appears reasonable to calculate k_2 from a plot of log $(1 - M_B)$ *vs.* t, as given in Fig. 5. The straight line relationship obtained confirms that step 2 in Scheme 1 follows first order kinetics and substantiates the feasibility of the approach used to calculate k_2.

The instantaneous rates of component concentration changes, considering first order reaction of the consecutive type are given by the following series of equations:

$$[1] \qquad dM_A/dt = -k_1 M_A$$

$$[2] \qquad dM_B/dt = k_1 M_A - k_2 M_B$$

$$[3] \qquad dM_C/dt = k_2 M_B - k_3 M_C$$

$$[4] \qquad dM_D/dt = k_3 M_D$$

where M is the component concentration, mole fraction, and the subscripts A, B, C, and D designate quinoline, 1,2,3,4-tetrahydroquinoline, *o*-propylaniline, and ammonia, respectively. The approach of quasi-stationary concentrations (steady state) is used to calculate k_3, whereby the term dM_C/dt in [3] is set equal to zero at a definite reaction time, t_{max}, where t_{max} is the reaction period at which *o*-propylaniline is of maximum concentration. From Figs. 2–4, it is evident that t_{max} is 9, 7, and 6 h at reaction temperatures of 350, 375, and 400 °C, respectively. The constants obtained for steps 2 and 3, as well as the overall HDN rate constant, at hydrotreating temperatures, are given in Table 1.

The ratio of k_2/k_3 is 0.33 at 350 °C, 0.51 at 375 °C, and 0.62 at 400 °C. The fact that step 2 is the slowest step in the HDN of quinoline is also supported by Larson (9) who has found the k_2/k_3 ratio to be 0.80. However, Larson does not indicate his method for calculating these rate constants.

TABLE 1. Reaction rate constants at hydrotreating temperatures[a]

Rate constant $\times 10^4$ (s^{-1})	Temperature (°C)		
	350	375	400
k_1[b]	Fast	Fast	Fast
k_2	0.204	0.454	0.908
k_3	0.623	0.884	1.475
k_0	0.137	0.332	0.767

[a]Rate constants refer to the use of 25 g of catalyst.
[b]k_1 is too large to be measured by the methods used in this study.

The temperature dependence of the rate constants gives linear Arrhenius plots as shown in Fig. 6. Accordingly, the rate constants can be represented by [5–7].

$$[5] \qquad k_2 = 4.416 \times 10^3 \, e^{-24700/RT} \, s^{-1}$$

$$[6] \qquad k_3 = 5.728 \, e^{-14180/RT} \, s^{-1}$$

$$[7] \qquad k_0 = 1.478 \times 10^5 \, e^{-28590/RT} \, s^{-1}$$

Since the HDN reaction is carried out in the liquid phase (11), [8] will relate the energy of

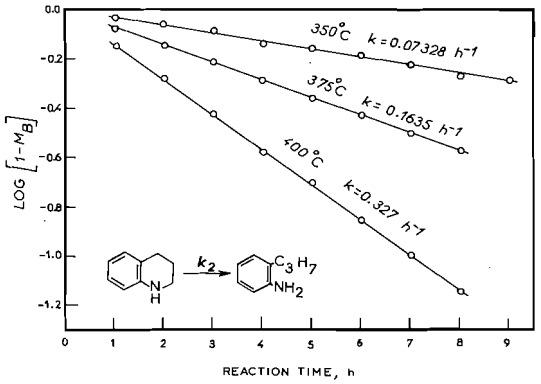

FIG. 5. First order plot for the second step in quinoline hydrodenitrogenation.

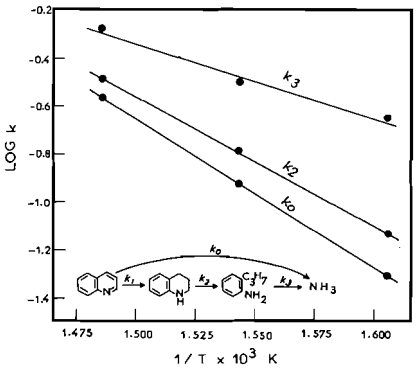

FIG. 6. Arrhenius plot for the overall reaction, the second, and third step.

activation to an enthalpy of activation

$$[8] \qquad E_a = RT + \Delta H^{\ddagger}$$

and accordingly the calculated average $\Delta H^{\ddagger}$ values, in the temperature range of 350–400 °C, are as follows: $\Delta H_2{}^{\ddagger} = 23.400$ kcal mol^{-1}; $\Delta H_3{}^{\ddagger} = 12.880$ kcal mol^{-1}; $\Delta H_0{}^{\ddagger} = 27.290$ kcal mol^{-1}.

According to the theory of absolute reaction rates (12), the rate constant is related to the entropy and enthalpy of activation by [9].

$$[9] \qquad k = \frac{k_b T}{h} \exp\left(\frac{\Delta S^{\ddagger}}{R} - \frac{\Delta H^{\ddagger}}{RT}\right)$$

where k_b = Boltzmann's constant, 1.380×10^{-16} erg/K. The following values of enthalpy and entropy of activation are calculated from plots of log k/T *vs.* $1/T$ (Fig. 7) by applying [9]:

Parameter	Value (kcal mol^{-1})	Parameter	Value (e.u. mol^{-1})
$\Delta H_2{}^{\ddagger}$	23.330	$\Delta S_2{}^{\ddagger}$	−43.9
$\Delta H_3{}^{\ddagger}$	13.265	$\Delta S_3{}^{\ddagger}$	−58.0
$\Delta H_0{}^{\ddagger}$	27.445	$\Delta S_0{}^{\ddagger}$	−38.2

The values of E_a and $\Delta H^{\ddagger}$ obtained for step 2 (the slowest step) do not significantly differ from those obtained for the overall HDN reaction; thus step 2 can be considered responsible for the relatively higher values of E_a and $\Delta H^{\ddagger}$ obtained for the overall reaction (5).

The magnitude of the entropy values obtained in this study shows that the activated complex is an immobile molecule attached to the catalyst surface and the product molecule is much like the activated complex. Since the entropy of activation for desorption is expected to be small and positive, or nil, the entropy values obtained cannot be associated with desorption as the rate controlling process. The high hydrogen pressure employed in this study should greatly influence the product desorption. The magnitude of the activation energies and enthalpies obtained also suggests that diffusion is not the rate controlling process.

Since step 1 in Scheme 1 is too fast to measure, it is not possible to calculate $\Delta S_1{}^{\ddagger}$ from the experimental data. Nevertheless, a $\Delta S_0{}^{\ddagger}$ value of −38.2 e.u. mol^{-1} compared with a value of −43.9 e.u. mol^{-1} for $\Delta S_2{}^{\ddagger}$ and −58.0 e.u. mol^{-1} for $\Delta S_3{}^{\ddagger}$, is indicative of a much smaller negative value (or even positive) for $\Delta S_1{}^{\ddagger}$.

When the quinoline molecule is first hydrogenated to the tetrahydroquinoline (which is expected to be more strongly basic than quinoline) (9), this product competes for the catalyst's

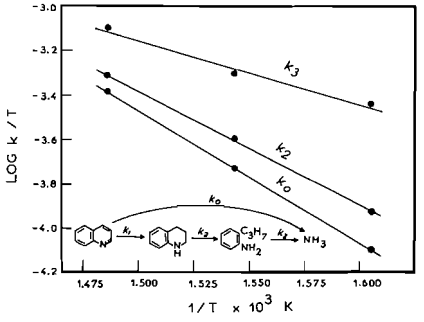

FIG. 7. Eyring plot for the overall reaction, the second step, and third step.

For personal use only.

active sites. The complexity encountered in orienting and adsorbing on the surface of the catalyst gives rise to a loss of several degrees of freedom whereby an entropy change of -43.9 e.u. mol^{-1} is obtained.

As the tetrahydroderivative is hydrocracked to *o*-propylaniline, the latter competes to attach to the catalyst and the reaction becomes more complex due to the loss of additional degrees of freedom. Hence, a much larger negative entropy change results ($\Delta S_3^{\ddagger} = -58.0$ e.u. mol^{-1}).

The effect of basicity of the intermediates produced during the HDN reactions cannot be ignored. However, its influence is not yet clarified. For instance, Larson (9) assumes that the most adsorbed phase on the catalyst is the aniline-type compound. McIlvried (4), on the other hand, assumes that all of the intermediate basic compounds produced during the HDN of pyridine appear to be equally strongly adsorbed on the denitrogenation sites.[2] The basicity of the nitrogen compounds at the reaction temperatures should be greatly different from that measured at normal temperatures, and no decisive explanation for the behavior of the quinoline intermediates, based on their basicities, could be achieved. However, the results of this study seem to agree with Larson's assumption.

The hydrogenation function of the catalyst employed in this investigation appears high enough to achieve fast hydrogenation of the quinoline-type compounds (Figs. 2–4). On the other hand, the cracking function of the catalyst is relatively less active (step 2 is the slowest step). Therefore, if the cracking function of this catalyst is activated through some treatment, a more active HDN catalyst is obtained. For instance, when the catalyst under investigation has been treated with HCl gas, the quinoline solution employed becomes completely hydrodenitrogenated after a reaction period of 3.5 h at 400 °C.[3]

The author wishes to thank Dr. Sami A. Shama of the Lowell Technological Institute, Lowell, U.S.A., for his interest and valuable discussions.

Recherches sur les composés éthyléniques.[1] V. Liens entre la structure des alcènes et leur fréquence de vibration $\nu_{C=C}$, influence des effets structuraux et établissement d'une relation de topo-information

J. H. Basso, S. Delattre, R. Lanteri et R. Luft[2]

Laboratoire de chimie organique, Institut Polytechique Méditerranéen, Université de Nice, 28, av. de Valrose, F 06034, Nice Cedex, France

Reçu le 1 octobre 1974[3]

J. H. Basso, S. Delattre, R. Lanteri et R. Luft. Can. J. Chem. **53**, 2580 (1975).

L'examen des données spectroscopiques de 43 alcènes montre l'influence d'un encombrement croissant au niveau du carbone positionné en α ou en β de la liaison éthylénique. Une contrainte stérique particulièrement élevée provoque l'apparition d'une seule conformation privilégiée et s'accompagne d'une forte diminution (10 cm^{-1}) de la fréquence du vibrateur $\nu_{C=C}$.

Une analyse quantitative peut être réalisée grâce à la "méthode topochimique D.A.R.C.". Des relations de topo-information ont pu être mises en évidence pour la famille des 2-alkyléthylènes et celle des 2,2-dialkyléthylènes. Elles permettent de chiffrer la contribution de chacun des sites topologiques à la valeur de la fréquence $\nu_{C=C}$. Pour la première famille, l'empreinte établie grâce à 9 composés, permet une proférence sur 30 composés; en ce qui concerne la seconde famille, la proférence est réalisée sur 159 composés, l'empreinte étant établie à partir de 13 autres alcènes.

J. H. Basso, S. Delattre, R. Lanteri, and R. Luft. Can. J. Chem. **53**, 2580 (1975).

An examination of spectroscopic data for 43 alkenes reveals the influence of increasing substitution at the carbon atoms α or β to the ethylenic bond. The presence of a particularly large steric constraint requires that there be a single preferred molecular conformation: in such a case the frequency of the $\nu_{C=C}$ vibrator is strongly decreased (10 cm^{-1}).

A quantitative analysis of the phenomenon can be achieved using the "topological-chemical method D.A.R.C.". Topologic-information relationships could be developed for the two series 2-alkylethylenes and 2,2-dialkylethylenes. These permit the calculation of the contribution of each topological site to the frequency $\nu_{C=C}$. For the first series, the relationship, based on 9 compounds, permits predictions about 30 others. For the second series, deductions are made concerning 159 compounds from a relationship established on a base of 13 compounds.

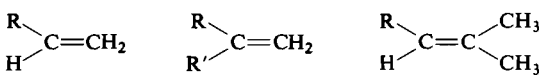
[Journal translation]

La position des bandes d'absorption infrarouge et leur intensité sont des paramètres liés aux influences des facteurs structuraux. Chaque vibrateur peut varier autour d'une fréquence moyenne et à l'intérieur des plages délimitées on peut définir des bandes plus étroites, caractérisant la taille et la nature des substituants de ces vibrateurs (2, 3). Par ailleurs, on a pu observer des relations linéaires entre différents vibrateurs d'une molécule (4).

Parallèlement aux études expérimentales il a été possible de calculer les fréquences des vibrateurs à partir des données moléculaires (5–7) et de prévoir l'intensité absolue des bandes $\nu_{C=C}$ d'alcènes-1 par la méthode CNDO (8).

Dans ce contexte, il nous a paru intéressant de mieux préciser, dans le cas des alcènes, la contribution des divers substituants aux fréquences de vibration (9).

A cet effet, nous avons examiné (tableau 1) une population d'alcènes appartenant aux trois types suivants:



Discussion des résultats spectroscopiques

Le tableau 1 montre que la fréquence évolue avec la structure des substituants de la fonction éthylénique, selon des lois propres à chaque vibrateur.

Cette variation est très peu sensible dans le cas du vibrateur ν_{C-H}; en ce qui concerne le vibrateur $\nu_{C=C}$ on observe un effet hypsochrome, lorsqu'on passe d'un terme de la série des

NOTE: Les valeurs relatives au propène et au butène-1 ont été relevées dans la littérature (7). Pour la fréquence $\nu_{C=C}$ du méthyl-2 propène nous avons opéré en solution dans le CCl_4. Les bandes $\nu_{C=C}$ et δ_{C-H} ont été déterminées avec un spectrophotomètre PE457, les bandes ν_{C-H} avec un Beckman DK 2A. L'étalonnage des appareils et le contrôle des spectres ont été réalisés en se servant des bandes de calibration de l'eau, de l'iodure de méthyle et du styrène (10, 11). Pour l'ensemble des mesures les écarts types sont de ± 1 cm^{-1} en ce qui concerne les bandes $\nu_{C=C}$ et δ_{C-H} et de ± 2 cm^{-1} en ce qui concerne les bandes ν_{C-H}. Toutes les bandes enveloppes examinées dans le présent travail sont de forme lorentzienne. Pour le pentaméthyl-2,3,3,4,4 pentène-1 Monsieur LOMAS (laboratoire du J. E. Dubois, Université de Paris VII) a mesuré $\nu_{C=C} = 1627$ cm^{-1}. Nous utiliserons cette valeur pour l'établissement des relations de topologie-information.

alkyl-2 éthylènes[4] aux termes correspondants des méthyl-2 alkyl-2 éthylènes et des diméthyl-1,1 alkyl-2 éthylènes.

Enfin, le vibrateur δ_{C-H} présente des valeurs à peu près constantes dans les séries des alkyl-2 éthylènes et des méthyl-2 alkyl-2 éthylènes. De même, les composés de cette dernière sous-population accusent, par rapport à leurs homologues déméthylés sur le carbone 2, un effet bathochrome constant.

Etude qualitative de la variation de la fréquence $\nu_{C=C}$

Examen des fréquences

Ces variations peuvent être mieux mises en évidence dans le cas du vibrateur $\nu_{C=C}$, lorsqu'on regroupe les composés du tableau 1, en tenant-compte pour chacune des trois sous-populations de la localisation des ramifications et de leur nombre.

Pour chacune des 3 sous-population nous avons retenu deux composés de base qui se différencient entre-eux par la longueur de leur chaîne alkyle (méthyle ou éthyle). Nous leur avons adjoint dans les trois cas les substances qui en dérivent grâce à la substitution progressive par des groupements méthyles du carbone terminal de leur chaîne alkyle (méthyle ou éthyle), de façon à observer l'influence d'un encombrement croissant au niveau du carbone positionné en α ou en β de la liaison éthylénique ("site α ou site β"). L'évolution de la fréquence $\nu_{C=C}$ des familles d'alcènes retenues est représentée dans la fig. 1 dont l'examen détaillé met an évidence des divergences de comportement du vibrateur $\nu_{C=C}$:

Alkyl-2 éthylènes

Chaque groupe méthyle fixé sur un site α ou un site β entraîne un abaissement de fréquence régulier.

Méthyl-2 alkyl-2 éthylènes

Au cours de la méthylation progressive du site α, chaque substitution provoque une même variation moyenne $\Delta\nu$; on observe un phénomène analogue au niveau du site β, sauf en ce qui concerne le remplacement du dernier atome d'hydrogène où la variation de fréquence est très importants (passage du groupe isobutyle au groupe néopentyle avec $\Delta\nu = -9\ cm^{-1}$).

Diméthyl-1,1 alkyl-2 éthylènes

Cette fois-ci, la méthylation du site β entraîne une variation régulière $\Delta\nu$ et on observe par contre une diminution brutale de la fréquence lors du remplacement du dernier atome d'hydrogène du site α (passage du groupe isopropyle au groupe tertiobutyle $\Delta\nu = -10\ cm^{-1}$).

S'il est évident que les variations de fréquence $\nu_{C=C}$, et en particulier les divergences que nous venons de signaler sont liées à la structure des substituants de la fonction alcène, il n'existe cependant pas, à notre connaissance, de relation simple entre la fréquence $\nu_{C=C}$ et la taille ou la position des groupements R, en dehors de celle (12) dégagée d'une étude relative à la réhybridation des atomes de la fonction alcène, sous l'action du facteur stérique.

Examen des modèles moléculaires

Seule une étude des dispositions spatiales relatives des atomes entourant la fonction alcène devrait pouvoir nous renseigner sur l'existence de contraintes éventuelles et permettre l'interprétation des divergences de comportement observées entre le méthyl-2 néopentyl-2 éthylène et le diméthyl-1,1 néopentyl-2

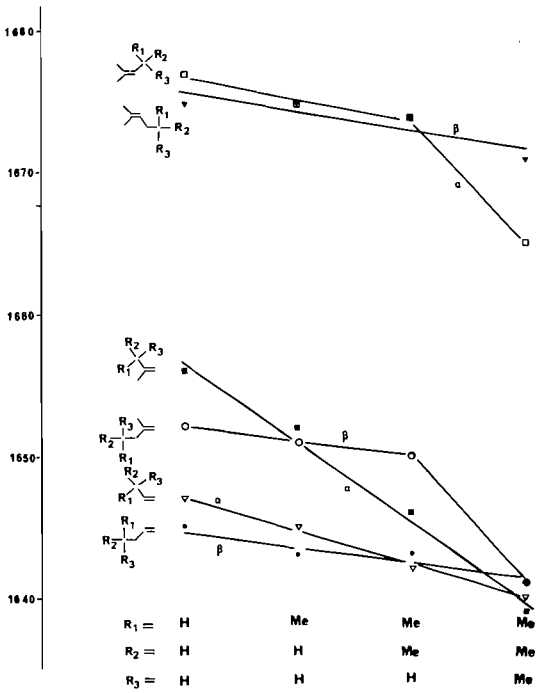

FIG. 1. Examen de l'influence, sur la fréquence $\nu_{C=C}$, de la méthylation progressive d'un atome de carbone en α ou en β du groupe fonctionnel, pour trois familles.

[4]Pour des raisons d'homogénéïté, nous avons préféré utiliser cette nomenclature de travail pour la désignation des sous-populations.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

éthylène d'une part, le méthyl-2 tertiobutyl-2 éthylène et le diméthyl-1,1 tertiobutyl-2 éthylène d'autre part.

Pour cette analyse conformationnelle, nous avons utilisé les modèles moléculaires compacts Stuart–Briegleb des Ets Leybold, particulièrement adaptés à l'étude des domaines de van der Waals.

Signalons d'autre part que pour cette étude qualitative nous n'avons pas cherché à évaluer les interactions éventuelles avec les orbitales π.

Alkyl-2 éthylènes

La libre rotation n'est pas entravée, même pour les termes les plus substitués.

Méthyl-2 alkyl-2 éthylènes

Méthylation du site α — On constate une légère interaction entre les hydrogènes du substituant méthyle et ceux portés par le second atome de carbone du groupe alkyle.

Ces mêmes hydrogènes se trouvent simultanément en disposition d'interaction légère avec l'un des deux hydrogènes du carbone 1 de la fonction éthylénique; la libre rotation n'en semble pas empêchée néanmoins.

Globalement, les interactions sont plus nombreuses que dans le cas des alkyl-2 éthylènes, les écarts successifs observés, $\Delta\nu_{C=C}$, sont plus importants.

Méthylation du site β — Dans ce cas, on relève la possibilité de deux zones d'interactions qui peuvent freiner, voire empêcher, la libre rotation du groupe alkyle. On les observe à partir de deux conformations planes dans lesquelles le groupe méthyle fixé sur le site β est en interaction soit avec un hydrogène vinylique, soit avec le méthyle porté par la double liaison.

Diméthyl-1,1 alkyl-2 éthylènes

Méthylation du site α — Dans cette série l'un des deux méthyles de la fonction alcène entre en interaction avec le groupe alkyle R en disposition Z, dès que le carbone C_α de ce groupe R porte un premier substituant méthyle; il empêche ainsi la libre rotation du groupe R. Lorsque le site α porte trois groupes méthyles (R = tertioBu), la molécule atteint un contenu énergétique minimal pour une seule conformation; celle-ci correspond à la répartition symétrique des méthyles par rapport au plan moléculaire, même une faible oscillation du groupe tertiobutyle requiert une quantité d'énergie élevée.

Méthylation du site β — Lorsque les carbones C_α et C_β du groupe alkyle sont dans le plan moléculaire et dans une conformation telle que le carbone C_β soit le plus éloigné possible du méthyle Z, la libre rotation autour de la liaison C_α—C_β ne semble affectée que par un atome d'hydrogène, quel que soit le nombre de méthyles fixés sur le site β.

La libre rotation autour de l'axe C_2—C_α ne peut avoir lieu, mais dans tous les cas une oscillation de grande amplitude autour de cet axe reste possible.

Examen général des données qualitatives

En définitive, pour chacune des familles examinées il apparaît que la création d'une contrainte stérique particulièrement élevée, provoquant l'apparition d'une seule conformation privilégiée, s'accompagne d'une forte diminution de la fréquence du vibrateur $\nu_{C=C}$.

L'existence d'un lien entre cette diminution et la rigidité d'une conformation n'est pas en contradiction avec l'idée de l'intervention d'une compression stérique, que l'on envisage cette dernière sous l'aspect d'une rehybridation (12), sous celle d'une déformation des angles de liaison (7, 13) ou d'un gauchissement du plan moléculaire tel que l'envisage Rea (14) pour certains types de molécules. Seule l'étude détaillée de la géométrie rigoureuse des molécules pourrait permettre de trancher de cas à cas en faveur de l'une ou l'autre hypothèse.

Une telle étude ne nous était pas accessible, mais il nous a semblé possible d'arriver cependant à une analyse fine, quoique empirique, à l'aide de méthodes de traitement mathématique des données physicochimiques (15, 16).

Etude quantitative de l'influence des substituants sur la fréquence $\nu_{C=C}$

Pour atteindre des résultats quantitatifs, en particulier en ce qui concerne l'interaction des substituants alkyles entre eux, nous avons fait appel à l'informatique chimique et plus particulièrement au système D.A.R.C. (15). Ce dernier permet d'établir des relations quantitatives entre le comportement chimique ou physicochimique d'une population de composés et leur topologie (16–18).

Avec l'école du Dubois, nous distinguerons deux notions: le foyer "FO" qui caractérise le site privilégié commun à tous les individus de la population examinée, et les parties extérieures à ce site qui constituent l'environnement *6*

et se développent le long de "directions de développement" à partir d'origines dont le nombre est lié au choix de la structure du foyer. Pour atteindre une description correcte, il faut que cet environnement soit ordonné, pour aboutir à une "empreinte". "L'empreinte d'une population est un environnement ordonné qui rassemble les sites occupés au moins une fois dans les environnements des différents individus constitutifs de la population" (15).

L'environnement $\mathscr{E}$ est représenté par un vecteur topologie $T(\mathscr{E}) = (t_1, t_2, \ldots, t_n)$.

Si, pour un individu donné de la population, un site i est occupé, la composante t_i sera prise égale à 1, si par contre ce site n'est pas occupé, nous noterons $t_i = 0$.

De leur côté, les propriétés physicochimiques ou chimiques sont représentées par un vecteur information $I(m)$ dont les composantes, déterminées à partir des m composés qui constituent la population clef, permettent de chiffrer la contribution de chacun des sites topologiques. A partir des notions $T(\mathscr{E})$ et $I(m)$ on aboutit à une "relation de topo-information"

$$[1] \qquad I(\mathscr{E}) = \langle T(\mathscr{E}) | I(m) \rangle$$

dans laquelle l'information $I(\mathscr{E})$ est reliée à la contribution de l'environnement $\mathscr{E}$.

Cet environnement peut se caractériser par une ou plusieurs directions de développement. Dans ce dernier cas, deux situations peuvent se présenter:

il n'y a pas d'interaction, ou interaction constante entre les sites des directions de développement. L'interaction ne peut être chiffrée, la relation 1 est satisfaisante (critères statistiques basés sur le coefficient de corrélation (19) et le test d'Exner (20)).

il y a interaction, variable avec la structure, entre les arborescences issues des différentes directions de développement. Cette interaction ne se manifeste de façon sensible que sur un petit nombre de sites de l'empreinte. Pour en tenir compte, il faut introduire dans l'expression 1 un terme d'interaction; ce qui conduit à la relation

$$[2] \quad I(\mathscr{E}) = \langle T(\mathscr{E}) | I(m) \rangle + \langle T(\mathscr{E}) | M | T(\mathscr{E}) \rangle$$

où M est la matrice d'interaction.

Tentative de corrélation de la population des alkyl-2 et dialkyl-2,2 éthylènes

Nous n'avons pas réussi pour l'instant à obtenir une relation de topo-information satisfaisante pour la population globale. Cependant, le coefficient de corrélation multiple élevé ($r = 0.986$) nous a incité à étudier des populations plus restreintes, en particulier celles des alkyl-2 éthylènes et des dialkyl-2,2 éthylènes.

Cas des alkyl-2 éthylènes

La relation linéaire de topologie-information est la suivante

$$\nu_{C=C} = 1647.1 - 2.4(A_1 + A_2 + A_3) - 1.7B_{11} - 1.0(B_{12} + B_{13}) - 0.5(C_{111} + C_{112}) + 1.4C_{113}$$

$r = 0.994$, $\psi = 0.19$, écart type $= 0.15\ cm^{-1}$, structure du foyer FO: $(H_2C{=}CH{-}C)\lessgtr$. Elle a été établie à partir de 9 alkyl-2 éthylènes et nous avons contrôlé sa validité pour les trois composés suivants:

	Valeur (cm^{-1})	
	Mesurée	Estimée
Méthyl-3 pentène-1	1641	1640.5
Méthyl-4 pentène-1	1643	1642
Méthyl-3 hexène-1	1641	1640

Cas des dialkyl-2,2 éthylènes

Afin de nous limiter à un nombre minimal de paramètres, nous avons établi la relation de topo-information en nous basant sur l'hypothèse de l'apport de contributions identiques dans les deux directions de développement, complétée par celle de la possibilité d'une interaction dans les cas suivants: $A_3{}^1$ et $A_3{}^2$; $B_{13}{}^1$ et $B_{13}{}^2$; $A_3{}^1$ et $B_{13}{}^1$. Nous obtenons ainsi le graphe suivant: $r = 0.9998$, $\psi = 0.05$, écart type: $0.6\ cm^{-1}$.

Ce graphe et la relation linéaire de topo-information qui lui est associée ont été établis à partir de 13 dialkyl-2,2 éthylènes et nous avons controlé sa validité pour les composés suivants:

	Valeur (cm^{-1})	
	Mesurée	Estimée
Diméthyl-2,3 pentène-1	1646	1646
Tertiobutyl-2 butène-1	1636	1635
Triméthyl-2,4,4 pentène-1	1641	1641
Diméthyl-2,4 hexène-1	1649	1648
Diméthyl-2,3 hexène-1	1645	1645
Méthyl-2 hexène-1	1650	1650

Conclusion

Pour chacune des sous-populations étudiées la relation linéaire de topo-information est très satisfaisante en fonction des critères statistiques retenus (19, 20).

La concordance entre les valeurs mesurées et estimées à l'aide des relations de topo-information justifient la proférence de ces relations sur l'ensemble des substances réunies dans les deux empreintes des sous-populations examinées. Dans le cas des alkyl-2 éthylènes cette proférence est de 30, dans le cas des dialkyl-2,2 éthylènes elle est de 159. Dans ce dernier cas notons cependant que la proférence n'est pas stricte chaque fois qu'un groupement triptyle intervient dans la molécule.

Ces résultats nous encouragent à poursuivre notre recherche en vue de l'obtention d'une relation linéaire de topo-information suffisamment générale pour englober l'ensemble de la population des alcènes examinés dans le présent travail.

Certains alcènes ont été mis à notre disposition par le laboratoire de chimie organique physique (Professeur J. E. Dubois) de l'Université de Paris VII et nous tenons à le remercier ici.

Synthesis and Ion-exchange Properties of Tantalum Arsenate

J. P. RAWAT AND S. QASIM MUJTABA
Department of Chemistry, Aligarh Muslim University, Aligarh, (U.P.), India

Received November 5, 1974

J. P. RAWAT and S. QASIM MUJTABA. Can. J. Chem. 53, 2586 (1975).

A new inorganic ion-exchanger, tantalum arsenate, has been prepared under varying conditions. The exchanger prepared by mixing 0.1 *M* tantalum pentoxide and 0.1 *M* sodium arsenate in the ratio of 1:4 at p*H* 0 has been studied in detail for its ion-exchange capacity, p*H* titrations, and K_d values. The material can be prepared reproducibly. Its analytical importance has been established by the following quantitative separations: Zr^{4+} from Tm^{3+}, Zr^{4+} from Eu^{3+}, Pr^{3+} from Eu^{3+}, and Pr^{3+} from Tm^{3+}.

J. P. RAWAT et S. QASIM MUJTABA. Can. J. Chem. 53, 2586 (1975).

On a préparé, utilisant diverses conditions expérimentales, un nouvel échangeur d'ions de nature inorganique. On a étudié particulièrement l'échangeur préparé en mélangeant du pentoxyde de tantale 0.1 *M* et de l'arséniate de sodium 0.1 *M* dans un rapport de 1:4 à un p*H* de 0 afin de déterminer sa capacité pour échanger des ions, pour des titrations de p*H* et pour ses valeurs K_d. On peut reproduire la préparation de ce composé. On a établi son importance analytique en suivant la séparation quantitative du Zr^{4+} de Tm^{3+}, du Zr^{4+} de Eu^{3+}, du Pr^{3+} de Eu^{3+} et du Pr^{3+} de Tm^{3+}. [Traduit par le journal]

Introduction

In recent years, there has been a revived interest in the study of synthetic inorganic ion-exchangers, since they are unaffected by ionizing radiations, are less sensitive to higher temperatures, and are selective to certain ions and hence can be used for the separation of ions in varied conditions. A wide variety of inorganic ion-exchangers has been reviewed by Amphlett (1). The emphasis has been mainly on zirconium phosphate and zirconium oxide types. Vesely and Pekarek (2, 3) have given an exhaustive literature survey on the preparation, properties, and uses of the hydrous oxides, acidic salts of multivalent metals, insoluble ferrocyanides, and various other materials as inorganic ion-exchangers. The analytical applications of inorganic ion-exchangers have been reviewed by Inczedy (4) and Walton (5). A search of the literature shows that no such studies have been reported on tantalum arsenate. The present work was, therefore, undertaken to synthesize and to investigate the ion-exchange properties of this material. Some important separations have been achieved practically.

Experimental

Reagents

Tantalum pentoxide (BARC, India) and sodium arsenate (Riedel, Germany) were used. The rest of the reagents were of AnalaR grade.

Apparatus

p*H* measurements were made with an ELICO model LI-10 p*H* meter. An electric temperature controlled SICO shaker and Stanton thermobalance type H_4 were used for equilibrium and thermogravimetric studies respectively.

Synthesis

A number of samples were prepared under a range of conditions as given in Table 1. Sodium arsenate solutions were added to tantalum pentoxide solutions slowly with constant shaking. Sodium hydroxide solution was then added dropwise with constant shaking until the p*H* was zero. The precipitate was allowed to settle for 24 h at room temperature, and was then washed several times by decantation with distilled water, filtered, and dried at 40 °C. The dried material broke down into small particles when immersed in water. The exchanger was then converted to the hydrogen form by treatment with 2 *M* HNO_3. Finally it was washed several times with demineralized water and dried at room temperature.

Ion-exchange Capacity

Ion-exchange capacities of inorganic ion-exchangers depend upon the concentration and volume of the eluent, because they are weak cation exchangers. To determine the optimum concentration and volume for the measurement of ion-exchange capacity, 0.1, 0.5, 1.0, 2.0, 3.0, and 4.0 *M* solutions of potassium nitrate were used as eluent and the capacity (per gram exchanger) was determined by the volume of NaOH consumed for 250 ml effluent collected in 5 ml fractions. It was found that the optimum results are obtained with 1 *M* KNO_3, and almost all H^+ ions are eluted in the first 100 ml solution. Ion-exchange capacity of tantalum arsenate was also determined by eluting some uni- and bivalent cations. One molar solutions of NaCl, KCl, $Mg(NO_3)_2$, $Sr(NO_3)_2$ and $BaCl_2$ were taken as eluent for this purpose. The results are given in Table 2.

TABLE 1. Synthesis and properties of tantalum arsenates

Sample number	Tantalum pentoxide		Sodium arsenate		Mixing ratio V/V Ta:As	pH of the mixture	Ion-exchange capacity in mequiv./g	Chemical composition Ta:As
	Concentration (*M*)	pH	Concentration (*M*)	pH				
T(A)	0.1	Negative	0.1	0	1:4	0	1.09	2.80:1
T(B)	0.1	Negative	0.1	0	3:7	0	1.04	3.21:1
T(C)	0.1	Negative	0.1	0	7:3	0	0.54	20:1
T(D)	0.1	Negative	0.1	0	1:1	0	0.90	6.27:1
T(E)	0.1	Negative	0.1	0	1:4	1.0	1.00	2.50:1

TABLE 2. Ion-exchange capacity of tantalum arsenate sample T(A) using some uni- and bivalent cations

Metal ion	Capacity (mequiv./g)
Na^+	0.99
K^+	1.09
Mg^{2+}	1.09
Sr^{2+}	1.00
Ba^{2+}	1.18

The change of hydrogen liberation capacity in the course of absorption was studied up to 6 cycles with 2 *M* nitric acid as regenerant and 1 *M* potassium nitrate solution as eluent. The ion-exchange capacity changes from 1.09 to 1.02 mequiv./g after six cycles.

Chemical Composition

The well powdered exchanger (TaAs, 200 mg) was dissolved in 10 ml of hot concentrated sulfuric acid. Arsenate was estimated volumetrically (6) and tantalum was determined gravimetrically as the cupferron precipitate (7) from the exchanger solution containing 5% tartaric acid and 10% H_2SO_4 (8). The results are given in Table 1.

Stability

All the samples were apparently stable in water and mineral acids. They were, however, attacked by hot concentrated sulfuric acid. All the samples were completely dissolved in concentrated sulfuric acid when heated with ammonium sulfate.

pH Titrations

pH titrations were performed on sample T(A) for LiCl–LiOH, NaCl–NaOH, KCl–KOH, and NH_4Cl–NH_4OH as described earlier (9). The curves are shown in Fig. 1.

Reproducibility Test

To check the reproducibility of the exchanger, four samples of T(A) were prepared under similar conditions and their ion-exchange capacity and chemical composition were determined. All four samples gave the same exchange capacities and the same Ta:As ratios to within 1%.

Thermal Treatment

Thermogravimetric analysis of sample T(A) in H^+ and K^+ form was performed at a heating rate of 4°/min (Fig. 2). To examine the effect of drying temperature on the ion-exchange capacity, the sample T(A) was also dried at various temperatures in a muffle furnace for 2 h. The results are given in Table 3.

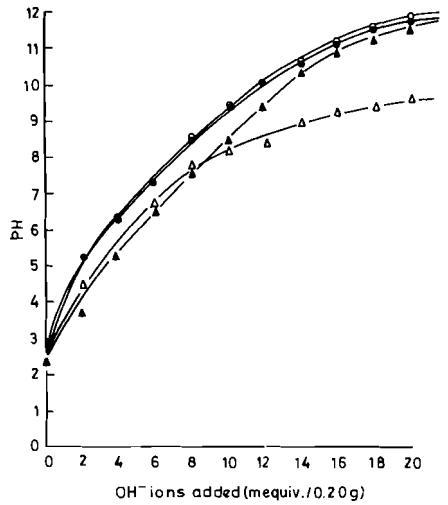

FIG. 1. pH titration curve of tantalum arsenate: ●, LiOH; ▲, NaOH; ○, KOH; △, NH_4OH.

Distribution Coefficients

In order to examine the affinity of tantalum arsenate towards various metal ions, distribution coefficients for 32 cations were determined at pH 1, pH 2, and in 1%

*T.A. = total absorption.

NH_4NO_3 solution. The concentration of cation solutions was taken as ~3% of the total ion-exchange capacity of the exchanger. In all the cases 0.5 g of the exchanger in H^+ form was taken and the equilibrating temperatures and time were 18 ± 2 °C and 6 h respectively. The results are summarized in Table 4.

Quantitative Separations of Metal Ions on Tantalum Arsenate Sample T(A) Column

For separation studies, a glass column was filled with TaAs in the H^+ form on a glass wool support. The flow rate was 8–10 drops/min. The metal ions in 10 ml fractions of the effluent were estimated by titration with 0.002 *M* EDTA. On the basis of a large difference in K_d values (separation factor > 10), some separations were tried. Those practically achieved quantitatively are listed in Table 5.

Discussion

The results given in Table 1 show that the ion-exchange capacity of sample T(A) is highest, therefore, all the studies were made on this sample. The results given in Table 2 show that

	Zr^{4+} 0.5 *N* HNO_3 + 0.5 *N* NH_4NO_3	110	365	383

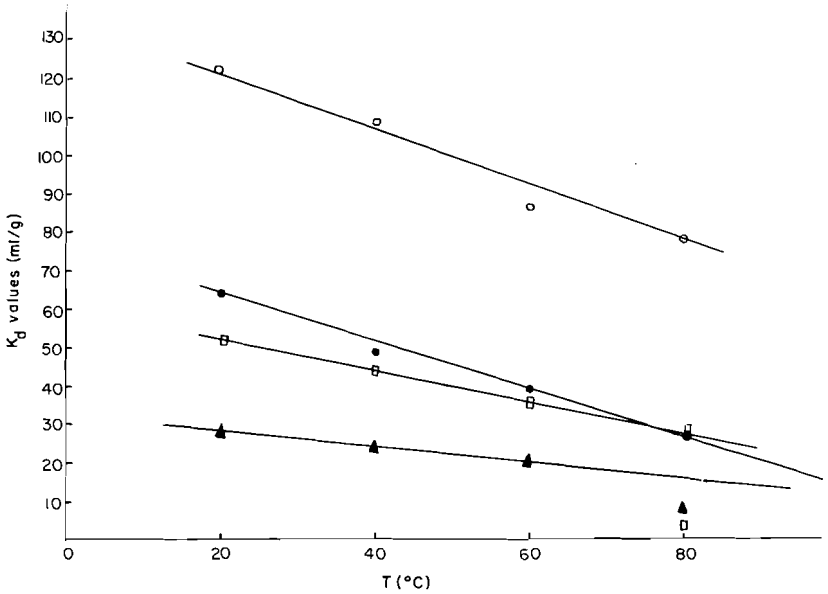

FIG. 3. Distribution coefficients as a function of temperature: ○, Ba^{2+}; ●; Sr^{2+}; □, Ca^{2+}; ▲, Mg^{2+}.

tantalum arsenate can be used as a good ion-exchanger for quantitative purposes. The ion-exchange capacity does not vary with the nature of the cation if concentration is ≥ 1 *M*. The lower value of ion-exchange capacity when the eluent taken is less than 1 *M* is observed because tantalum arsenate works as a monofunctional weak acid in H^+ form (Fig. 1), and is weakly ionized. Hence the removal of H^+ ions by salt is not complete if its concentrations are not high enough. The ion-exchange reaction is

$$RH^+ + NaNO_3 \rightleftharpoons RNa^+ + HNO_3$$

where RH^+ represents the ion-exchanger in hydrogen form and RNa^+ in sodium form. By increasing the $NaNO_3$ concentration the reaction will be favored in the forward direction and a saturation stage nearly at complete exchange of H^+ is reached at 1 *M* concentration of the salt. Tantalum arsenate shows a quantitative reversible ion-exchange behavior. The ion-exchange capacity remains nearly constant if it is measured in the regeneration cycles. A change of only 0.07 mequiv./g was observed after sixth regeneration. The exchanger can be prepared reproducibly. The chemical composition and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

the ion-exchange capacity of four different samples prepared under the same conditions were nearly the same.

Heat treatment of tantalum arsenate in air on a thermobalance (Fig. 2) shows that up to 100 °C there is not much loss in weight. From 100 to 250 °C a continuous loss in weight is recorded which is due to the removal of water present in the layers of the material. At 250 °C a 5% weight loss is recorded. From 250 to 600 °C there is no appreciable weight loss and the ion-exchange capacity within this range is hardly diminished. Further heating of the material from 600 to 700 °C shows a slight weight loss (2%) in K^+ form and much more weight loss (7%) in H^+ form. This may be due to the removal of structural water after condensation which is possible in H^+ form only and not in K^+ form. The studies on composition determination show that different samples are prepared with different tantalum and arsenic ratios. The sample T(A) which has been used for most of the studies has Ta:As ratio of 2.8:1. A study of distribution coefficients of numerous metal ions in three solvent systems *viz.*, HNO_3 system (p*H* 1, p*H* 2) and 1% NH_4NO_3 solution reveals that tantalum arsenate is very selective towards certain metal ions. The relatively large K_d values for Zr^{4+}, Hf^{4+}, Pr^{3+}, Vo^{2+}, and Ce^{3+} are very useful as these metal ions can be separated from numerous other metal ions. Separations of Tm^{3+} from Zr^{4+}, Tm^{3+} from Pr^{3+}, Eu^{3+} from Pr^{3+}, and Eu^{3+} from Zr^{4+} were quantitatively achieved (Table 5). Various other separations can be tried on the basis of the difference in K_d values. This shows the application of this exchanger in separation science for particular problems. An interesting point is noted when K_d values of alkaline earth metal ions at different equilibrating temperatures are plotted as a function of temperature (Fig. 3). The K_d value decreases linearly with rise in temperature. This behavior may be applied to thermodynamic studies.

Volumes and Heat Capacities of Cyclic Ethers and Amines in Water and of some Electrolytes in these Mixed Aqueous Solvents

OSAMU KIYOHARA, GÉRALD PERRON, AND JACQUES E. DESNOYERS[1]

Department of Chemistry, Université de Sherbrooke, Sherbrooke, Québec, J1K 2R1

Received April 3, 1975

OSAMU KIYOHARA, GÉRALD PERRON, and JACQUES E. DESNOYERS. Can. J. Chem. **53**, 2591 (1975).

The densities and volumetric specific heats of *p*-dioxane, tetrahydropyran, morpholine, piperidine, and piperazine were measured in water at 25 °C with a flow densimeter and a flow microcalorimeter. The same properties were also determined for LiCl, NaCl, Me_4NBr, and Bu_4NBr at 0.1 *m* in dioxane–water, morpholine–water, and piperidine–water mixtures. The derived apparent molal volumes and heat capacities of the nonelectrolytes in water and the transfer functions of the electrolytes from water to the mixed solvent suggest that all the present cyclic amines and ethers are hydrophobic; the overall structural influence is very small with dioxane and large with piperidine.

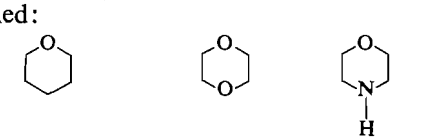
OSAMU KIYOHARA, GÉRALD PERRON et JACQUES E. DESNOYERS. Can. J. Chem. **53**, 2591 (1975).

Les masses volumiques et capacités calorifiques du *p*-dioxanne, du tétrahydropyranne, de la morpholine, de la pipéridine et de la pipérazine ont été mesurées dans l'eau à 25 °C avec un densimètre et un microcalorimètre à écoulement continu. Les mêmes propriétés ont aussi été obtenues pour LiCl, NaCl, Me_4NBr et Bu_4NBr à 0.1 *m* dans les mélanges eau–dioxanne, eau–morpholine et eau–pipéridine. Les capacités calorifiques et volumes apparents molaires des nonélectrolytes dans l'eau et les fonctions de transfert des électrolytes de l'eau aux solvants mixtes suggèrent que tous les amines et éthers cycliques présentement étudiés sont hydrophobes; l'effet structural global est très faible dans le cas du dioxanne et très marqué pour la pipéridine.

Introduction

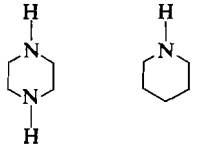
Dioxane–water mixtures have been extensively used as a mixed solvent for the study of electrolyte solutions, primarily because of the large range of dielectric constants that can be achieved with these mixtures. Even with its low dielectric constant and dipole moment, dioxane interacts strongly with water and with ions as a result of its high quadrupole moment. Despite the numerous studies on binary and ternary systems involving *p*-dioxane and similar nonelectrolytes, much controversy still exists in the literature on the nature of the interactions between *p*-dioxane and water (1–6).

We felt that probably some progress could be made through a systematic study of the thermodynamic properties of mixed aqueous solvents, where the cosolvents would have similar geometries and molecular weights. For this purpose, the cyclic ethers and amines were examined:



Tetrahydropyran (THP) | *p*-Dioxane (D) | Morpholine (M)

[1]To whom correspondence should be addressed.



Piperazine (PZ) | Piperidine (PD)

The largest difference in molecular weight is 3. We can therefore expect that the intrinsic thermodynamic values (volume, heat capacity) of these solutes in water would be, at least as a first approximation, constant. The observed difference in properties from one solute to another should therefore reflect mostly the differences in interactions. For completeness, it would have been useful to add cyclohexane to this study, but its low solubility made this impossible.

In addition to the properties of these solutes in water, the properties of typical electrolytes in these mixed solvents were also measured whenever the solubility of the cosolvent was sufficiently large. The electrolytes chosen were LiCl, NaCl, Me_4NBr, and Bu_4NBr: NaCl is the most studied alkali halide in ternary systems, Li^+ is probably the only alkali ion with a fairly stable hydration shell, Me_4N^+ is a weak structure breaker, and Bu_4N^+ is an hydrophobic ion.

The properties we have chosen to initiate this investigation are the apparent molal volumes ϕ_V and heat capacities ϕ_C. These properties are now readily available experimentally and have been shown to be sensitive to changes in solute–solvent and solute–solute interactions. Some ϕ_V (2, 7, 8) and ϕ_C (2, 3, 9) data exist in the literature for the present binary and ternary systems, but often the concentration ranges studied were too limited or the precision too low to allow us to use the data. Also, it is not advisable to calculate transfer functions from water to a mixed solvent using properties of the mixed solvents or properties of the electrolytes which have been obtained with a different technique.

Similar studies in urea–water (10), *tert*-butyl alcohol – water (11), dimethylsulfoxide–water, and acetone–water (12) mixtures, and a comparative study of these various mixed aqueous solvents (13) are given elsewhere.

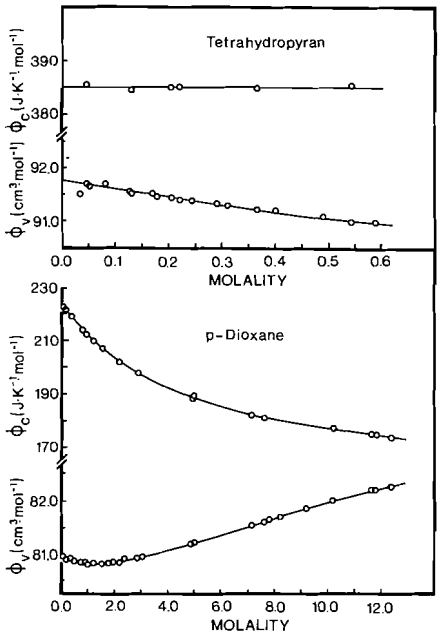

FIG. 1. Apparent molal volumes and heat capacities of *p*-dioxane and tetrahydropyran in water at 25 °C.

Experimental

The nonelectrolytes were purified as follows: PD and D (Fisher Certified Reagent) were dried with a molecular sieve (Davidson Chemical, grade 564, 3 Å), M (Practical grade, Baker Chem. Co.) was distilled (b.p. 129.5 °C) and dried with a molecular sieve, THP (98%, Aldrich Chem. Co.) was passed through M.N. Silica gel G (Macherey, Nagel and Co, D-516 Düssen, Germany), distilled (b.p. 89.0 °C) and dried with a molecular sieve, PZ (Practical grade, Eastman Kodak Co.) was recrystallized three times from benzene and dried under vacuum. Considerable care was taken to protect D and PZ from exposure to light and THP to air prior to use.

The origin and purification of the salts (LiCl, NaCl, Me_4NBr, and Bu_4NBr) were given elsewhere (14). All solutions were prepared by weight with deionized (Continental Deionized Water System) distilled water. All measurements were made at 25.00 ± 0.01 °C.

The densities d and volumetric specific heats σ were measured with a flow digital densimeter (15) and a flow microcalorimeter (16). The precision and method of calculating ϕ_V and ϕ_C of the ternary systems were discussed in the case of *tert*-butyl alcohol mixed solvents (11).

The densities and volumetric specific heats of the binary systems were measured over a wide-range of concentration[2] and the dependence on molality m of ϕ_V and ϕ_C of the nonelectrolytes are shown in Figs. 1 to 4. Significant hydrolysis occurs with the cyclic amines, and consequently the ϕ_V and ϕ_C were also measured in 0.1 N

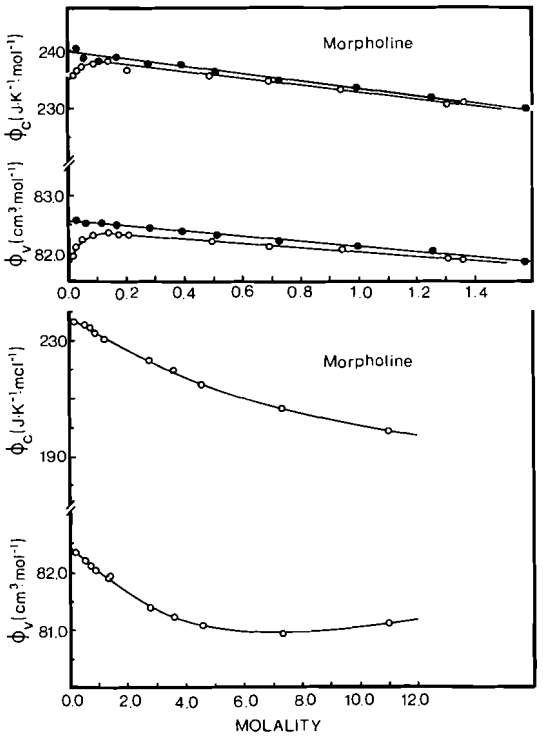

FIG. 2. Apparent molal volumes and heat capacities of morpholine in water and 0.1 N NaOH solvents at 25 °C: ○, water; ●, 0.1 N NaOH.

[2]Complete set of the actual experimental data is available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Canada K1A 0S2.

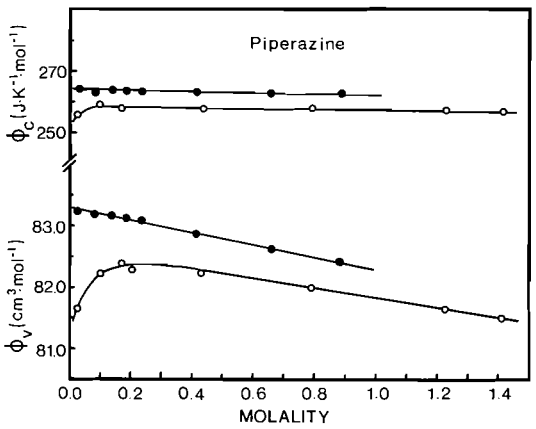

FIG. 3. Apparent molal volumes and heat capacities of piperazine in water and 0.1 *N* NaOH solvent at 25 °C: ○, water; ●, 0.1 *N* NaOH.

NaOH solution. The presence of NaOH essentially removes the sharp increase in ϕ_C and ϕ_V at low concentrations and shifts the overall ϕ_V and ϕ_C curves to higher values. As a further check, an hydrolysis correction was calculated for the PD–water system using the data and the equations given by Cabani *et al.* (7). The ϕ_V calculated for the unhydrolyzed PD are compared with those in 0.1 *N* NaOH solvent in Fig. 4. The agreement is satisfactory considering that the hydrolysis correction depends significantly on the choice of the hydrolysis constant (7). We are therefore justified in considering the data in 0.1 *N* NaOH to be close to those we would obtain for unhydrolyzed amines, and that the linear region of the ϕ_V and ϕ_C curves can be extrapolated to infinite dilution to obtain the standard $\bar{V}^0$ (= ϕ_V^0) and $\bar{C}_p^0$ (= ϕ_C^0). The ϕ_V and ϕ_C data were fitted with a parametric equation in molality

$$[1] \qquad \phi_Y = \phi_Y^0 + A_Y m + B_Y m^2 + \ldots,$$

where the symbol Y stands for V and C_p. The parameters of [1] are given in Table 1, and the standard literature values are also included for comparison. In general, the agreement between the present ϕ_V^0 data and those from the literature is excellent, but the deviations are larger with ϕ_C^0. As it will be shown in the Discussion, the group additivity gives us confidence in the reliability of the present ϕ_C data.

The standard transfer functions of the electrolyte E from water W to a water–nonelectrolyte mixture W + N are defined by

$$[2] \quad \Delta Y_E^0(W \rightarrow W + N) = \phi_Y^0(W + N) - \phi_Y^0(W)$$

It was established previously (11) that the transfer functions of an 0.1 *m* electrolyte are very close to the infinite dilution value. Therefore, ϕ_Y were measured at 0.1 *m* only.[2] The corresponding ϕ_Y data in pure water were taken from the literature: ϕ_C of LiCl and NaCl (18), of Me_4NBr and Bu_4NBr (19), ϕ_V of LiCl and NaCl (14), and of Me_4NBr and Bu_4NBr (20).

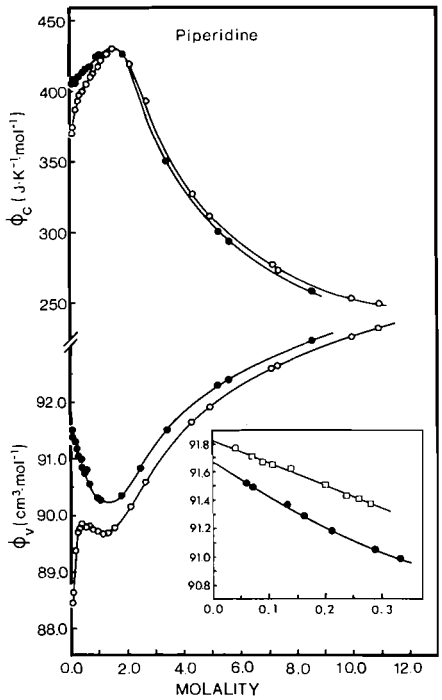

FIG. 4. Apparent molal volumes and heat capacities of piperidine in water and 0.1 *N* NaOH solvent at 25 °C: ○, water; ●, 0.1 *N* NaOH; □, corrected ϕ_V (K_a = 1.39×10^{-3}) for the hydrolysis effect at low concentration (*cf.* ref. 7).

The transfer functions of the various electrolytes from W to W–D, W–M, and W–PD are shown in Figs. 5 to 7. The solubilities in water of THP and PZ were too low to warrant measurements on the ternary systems. The effect of hydrolysis on the transfer functions was investigated in the case of NaCl and Bu_4NBr in W–PD mixtures by repeating the measurements in 0.1 *N* NaOH. These are shown in Fig. 7. As with the binary systems, a general shift in the curves is observed, but the general trends are essentially the same. Therefore, as long as only trends are examined, the effect of hydrolysis on the transfer functions can be ignored.

Discussion

Group Additivity

One of the aims of systematic studies of organic solutes is to devise methods of predicting the thermodynamic properties of large molecules from additivity rules. The present family of nonelectrolytes leads itself readily to study the additivity of various groups to the $\bar{V}^0$ and $\bar{C}_p^0$ of cyclic molecules in water. From the five compounds investigated there are various ways of calculating the group contributions. For

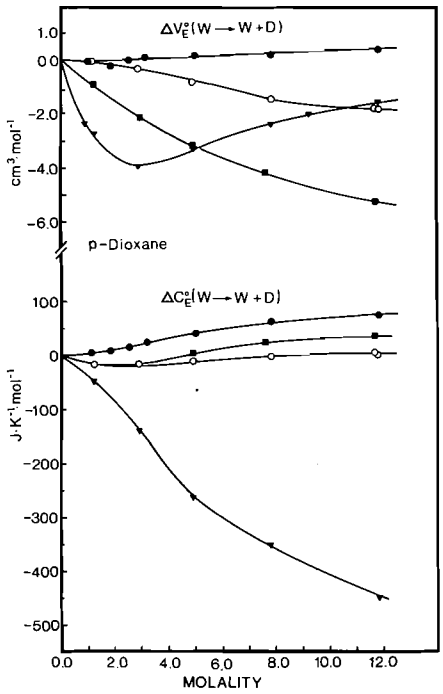

FIG. 5. Volumes and heat capacities of transfer of electrolytes at 0.100 *m* from water to water–*p*-dioxane mixtures at 25 °C: ○, LiCl; ●, NaCl; ■, Me_4NBr; ▼, Bu_4NBr.

example

$$\bar{V}^0(\text{—}CH_2\text{—}) = \tfrac{1}{6}\{2\bar{V}^0(\text{THP}) - \bar{V}^0(\text{D})\}$$
$$= \tfrac{1}{6}\{2\bar{V}^0(\text{PD}) - \bar{V}^0(\text{PZ})\}$$
$$\bar{V}^0(\text{—O—}) = \bar{V}^0(\text{D}) - \bar{V}^0(\text{THP}) + \bar{V}^0(\text{—}CH_2\text{—})$$
$$= \bar{V}^0(\text{M}) - \bar{V}^0(\text{PD}) + \bar{V}^0(\text{—}CH_2\text{—})$$

The values for each group obtained by a least-squares method are

	$\bar{V}^0$ (cm³ mol⁻¹)	$\bar{C}_p^0$ (J K⁻¹ mol⁻¹)
—CH_2—	16.9	91
—NH—	7.9	−51
—O—	7.0	−72

with a mean deviation for $\bar{V}^0$ of 0.4 cm³ mol⁻¹ and for $\bar{C}_p^0$ of 1 J K⁻¹ mol⁻¹.

The $\bar{C}_p^0$ of the five nonelectrolytes can be predicted to 1 J K⁻¹ mol⁻¹ with these values which is inside the experimental error. This test for additivity is therefore a good indication of the reliability of the present measurements. It is interesting to note that the methylene contribution is very similar to that of linear chains (*cf.* 21) which implies that cyclization has little effect on $\bar{C}_p^0$ with six-membered rings. On the other hand increasing or decreasing the ring size from six causes a significant decrease in $\bar{C}_p^0$(—CH_2—) (22). This suggests that six-membered ring molecules or ions have a geometry which is as compatible with the structure of water as a linear chain.

The additivity is not quite as good with $\bar{V}^0$ since experimentally $\bar{V}^0$ should be reliable to better than 0.1 cm³ mol⁻¹. Also $\bar{V}^0$(—CH_2—) is about 1 cm³ mol⁻¹ larger than that for linear chains (23). It could be that the addition of 0.1 *N* NaOH has a larger effect on $\bar{V}^0$ than on $\bar{C}_p^0$. Here again a change in the ring size causes a large decrease in the average $\bar{V}^0$(—CH_2—) (22). It therefore seems that $\bar{V}^0$ is more sensitive than $\bar{C}_p^0$ to geometrical and position factors. For example, the $\bar{V}^0$ of an α CH_2 group of homologous aliphatic ions is often different from those

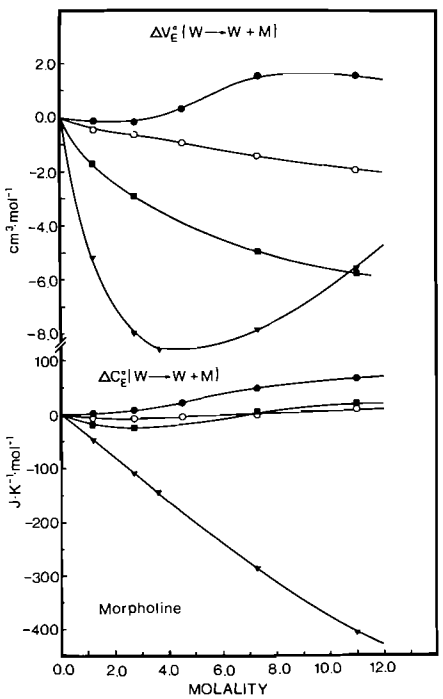

FIG. 6. Volumes and heat capacities of transfer of electrolytes at 0.100 *m* from water to water–morpholine mixtures at 25 °C: ○, LiCl; ●, NaCl, ■, Me_4NBr; ▼, Bu_4NBr.

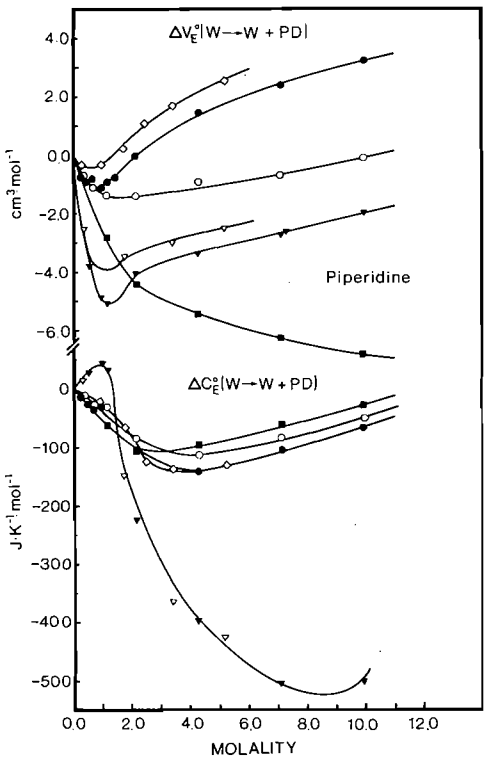

FIG. 7. Volumes and heat capacities of transfer of electrolytes at 0.100 *m* from water to water–piperidine mixtures and of NaCl and Bu_4NBr at 0.100 *m* from 0.1 *N* NaOH to 0.1 *N* NaOH–piperidine mixtures at 25 °C: ○, LiCl; ●, NaCl; ◇, NaCl (0.1 *N* NaOH); ■, Me_4NBr; ▼, Bu_4NBr; ▽, Bu_4NBr (0.1 *N* NaOH).

further away from the charge (23, 24), which is not the case with $\bar{C}_p^0$ (21).

Binary Systems

An examination of the standard functions $\bar{V}^0$ and initial slopes A_Y of the cyclic nonelectrolytes in Table 1 shows definite trends in the direction D → M → PZ → THP → PD; $\bar{V}^0$, $\bar{C}_p^0$, and A_C generally increase in value while A_V decreases. Similarly, the group contribution to $\bar{V}^0$ and $\bar{C}_p^0$ increased in the order —O—, —NH—, and $—CH_2—$.

It is not easy to interpret small changes in $\bar{V}^0$, especially when polar groups are involved (2). However, the other trends suggest that there is a large decrease in hydrophobic (or increase in hydrophilic) character when a $—CH_2—$ group is replaced by —NH— and a further small change when —NH— is replaced by an ether group. This tendency is not unexpected since, although —NH— and —O— are both polar groups, the ether group should interact more strongly with water, in view of the larger electronegativity of the oxygen atom.

The magnitude of $\bar{C}_p^0$ and concentration dependence of ϕ_V and ϕ_C of PD (Fig. 4) are typical of strong hydrophobic solutes (11); there seems to be some association similar to micellization starting at about 1.5 *m* and a characteristic maximum in ϕ_C and minimum in ϕ_V. At the other extreme, D shows a much smaller effect on water; ϕ_C^0 is still larger than the molar heat capacity of pure D (25) by about 40% suggesting that D is hydrophobic in agreement with the excess enthalpy data (26). On the other hand, little can be said about the excess functions. At high concentrations, ϕ_V and ϕ_C are tending in a very gradual way to their intrinsic values. There are some solute–solute interactions making a negative contribution to both excess functions but the effects are too small to allow an unambiguous interpretation. Therefore D is probably an hydrophobic solute but the overall structural interactions are certainly quite small. Similar conclusions can be drawn with M.

Ternary Systems

It has been shown recently (11) that the standard transfer functions $Y_E^0(W \rightarrow W + N)$ can be interpreted in terms of solute–solute interactions between E and N. At low cosolvent concentration, where only pair interactions are important, the dependence of $Y_E^0(W \rightarrow W + N)$ on the N concentration is numerically equal to the dependence of the converse standard transfer function $Y_N^0(W \rightarrow W + E)$ on E concentration (13, 27, 28).

The concentration dependence of the transfer functions $\Delta Y_E^0(W \rightarrow W + PD)$ are qualitatively the same as $\Delta Y_E^0(W \rightarrow W +$ *tert*-butyl alcohol). Again we find the maximum in heat capacities and minimum in volumes characteristic of strong hydrophobic interactions with Bu_4NBr; Bu_4N^+ probably associates with PD at high cosolvent concentrations. The trends with hydrophilic electrolytes also indicate strong hydrophilic–hydrophobic interactions at low concentration (11) and enhanced hydrophobic bonding of PD near an hydrophilic electrolyte through salting-out of the monomers.

At the other extreme, $\Delta Y_E^0(W \rightarrow W + D)$ shows very little specific interaction if we consider that at high D concentration $\Delta Y_E^0(W \rightarrow W + D)$ is tending to $\Delta Y_E^0(W \rightarrow D)$. In pure D,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

For personal use only.

$\bar{C}_p^0$ of hydrophilic solutes should be more positive (loss of structure-breaking effect) and those of hydrophobic solutes more negative. If data for $\bar{Y}^0$ were available in pure D we would be able to calculate the nonideal contribution to $\Delta Y_E^0(W, D \rightarrow W + D)$ from ref. 29

$$\bar{Y}_E^0(W + D) - X_D\bar{Y}_E^0(D) - (1 - X_D)\bar{Y}_E^0(W)$$

where X_D is the mole fraction of D. The sign of this nonideal contribution can still be seen if we assume that at high cosolvent concentration $\Delta Y_E^0(W \rightarrow W + D)$ is tending to the ideal behavior. If this is done, then the deviations in Fig. 5 are in the direction of weak hydrophobic–hydrophobic interactions with Bu_4NBr and weak hydrophobic–hydrophilic ones with the other electrolytes. The only anomaly is $\Delta V^0_{Bu_4NBr}(W \rightarrow W + D)$ which seems to suggest rather important hydrophobic–hydrophobic interactions. The $\Delta Y_E^0(W \rightarrow W + M)$ are qualitatively the same as $\Delta Y_E^0(W \rightarrow W + D)$ but as expected from the slightly more hydrophobic character of M, the trends are somewhat more pronounced.

The deductions based on the data for binary and ternary systems are consistent and suggest that probably all the presently studied cyclic ethers and amines are hydrophobic, although the net effect is very small with D. It therefore seems that the charge–dipole interactions between a simple hydrophilic ion and water are not too different from the ones between an ion and the oxygen of one-half of the D molecule (30). Even Li^+ which is usually considered highly hydrated shows little preference between the two solvents. It is only in the long-range ordering of the solvent that some differences are observed. This therefore confirms that, with properties that are not too sensitive to structural changes, the D + W system is ideal to study the effect of dielectric constant on long-range solute–solute interactions.

We are grateful to Environment Canada and to the Defence Research Board of Canada for financial assistance.

Thiophene Isosters of Phenylethanolamines

JEHAN F. BAGLI AND E. FERDINANDI[1]

Ayerst Research Laboratories, Montreal, Quebec H3C 3J1

Received February 21, 1975

JEHAN F. BAGLI and E. FERDINANDI. Can. J. Chem. **53**, 2598 (1975).

The reaction of a variety of substituted thiophenes, under Friedel–Craft conditions, leading to acetylthiophenes is described. Some of the by-products obtained are isolated and their mode of formation rationalized. The bromination, the reduction of the bromoketones, and their transformation to thienylethanolamines is reported. The degradation products of bromohydrin as well as isomeric amines obtained in the final substitution reaction are characterized and a possible mechanism for the formation of these compounds is proposed.

JEHAN F. BAGLI et E. FERDINANDI. Can. J. Chem. **53**, 2598 (1975).

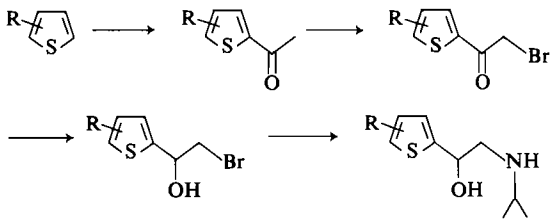
On décrit la réaction d'une série de thiophènes substitués dans les conditions de Friedel–Craft. Cette réaction conduit aux acétyl thiophènes. Les produits secondaires de la réaction sont isolés et leurs modes de formation sont rationalisés. On décrit la bromation, la réduction des bromocétones ainsi que leur transformation en thiényléthanolamines. Les produits de dégradation de la bromhydrine ainsi que les amines isomères obtenues par la réaction de substitution finale, sont caractérisés; un mécanisme est proposé pour expliquer la formation de ces composés.

[Traduit par le journal]

Introduction

Epinephrine and norepinephrine, the two adrenergic neurotransmitters are well known for their broad biological profile. This has led to a variety of potential therapeutic utilities for them such as nasal decongestant, for pressor effects, as local anesthetics, bronchodilators, and cardiac stimulant. However, the natural sympathetic amines have a major disadvantage of having a very short half-life. Consequently, considerable effort has been spent to synthesize sympathomimetic phenylethylamines to achieve selectivity of biological activity and sustained therapeutic effect. While the isosteric nature of the thiophene ring with the phenyl nucleus is well known, only very few thiophene isosters of catacholamine analogs have been reported in the literature.

Although a number of routes to arylethanolamines (1, 2) including β-(2-thienyl)ethanolamines (3, 4) and chloro substituted thiophenethanolamines (5) have been published, the synthesis of alkoxy substituted thiophenethanolamines has not been reported. In this paper we describe the synthesis of some novel methoxy and halogen substituted thiophenethanolamines. The general sequence to the thiophenethanolamines described in this paper is shown below.



We also report some products of the side reactions encountered in the synthesis and conditions under which they can be eliminated. The formation of the by-products was rationalized as resulting from the pseudoaromatic character of the thiophene nucleus. The ethanolamines described in this paper were evaluated for their biological activity in the cardiovascular field (6).

Acetylthiophenes

Various substituted thiophenes (Table 1) required for the purpose of acylation were synthesized using known procedures or modifications thereof (7–9 and see Experimental).

The acetylthiophenes were generally prepared by the reaction of the substituted thiophene with acetyl chloride using stannic chloride as the catalyst (10). Relative to the halothiophenes, the Friedel–Crafts reaction of the methoxy- and acetoxythiophenes was much more rapid. For example, acylation of 2-acetoxy-3-bromothiophene (**1***k*) required only 30 min whereas the acylation

*A, bromine; B, pyridinium bromide perbromide; C, copper(II) bromide; D, *n*BuLi, bromoacetyl bromide.

of 2-chlorothiophene (**1***d*) required 15 h to complete. This difference in reactivity of substituted thiophenes to the Friedel–Crafts reaction is similar to that found for substituted benzenes under analogous conditions (11).

Acylation of the *t*-butoxythiophene **1***j* with acetyl chloride – stannic chloride at 0° gave none of the desired acetylthiophene. Instead, the only isolable compound was the thiolactone **4**. When boron trifluoride etherate was used, instead of stannic chloride, the thiolactone **4** was obtained in 80% yield. Such an efficient cleavage of the *t*-butyl ethers with Lewis acids was unexpected since a similar cleavage using *p*-toluenesulfonic acid catalyst required elevated temperatures (9). The acylation of 5-methoxythiophene **1***g*, on the other hand, did give the desired acetyl derivative **2***g*, together with the compound **5** as a by-product. This by-product was eliminated by replacing the benzene by carbon disulfide in the acylation and conducting the reaction at −78° (8). In the case of 3,4-dimethoxythiophene **1***h* (12), acylation at −78° for 2 h led to acyl derivative **2***h* as the sole product.

The fact that no acylation product was obtained in the case of *t*-butoxythiophene **1***j* as against methoxythiophene **1***g* appears clearly a reflection of the difference in the rates of cleavage of the two ethers by Lewis acid catalyst. Since reaction of 3,4-dimethoxythiophene **1***h* using stannic chloride – acetyl chloride yielded exclusively the desired acetyl derivative **2***h*, the cleavage of alkyl ethers at position 2 must be regiospecific and involve a participation of unshared sulfur electrons.

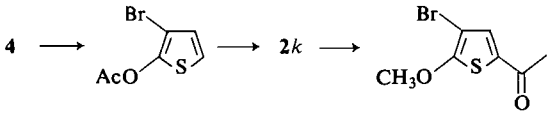
The mode of formation **5** may be rationalized by considering an attack by nucleophile **2***g* in a Michael manner on the thiolactone generated from **1***g*. The formation of **5** may be catalyzed by the Lewis acid present in the reaction mixture.

The thiolactone **4** was acetylated with acetic anhydride in pyridine to yield acetoxy thiophene (**1***k*).

The acylation of **1***k* yielded along with the desired acetylthiophene **2***k*, the thiolactone **4**. The formation of **4** in this case may be because of acid catalyzed hydrolysis of the acetate group of **1***k*. Treatment of **2***k* with base, followed by diazomethane yielded methoxy derivative **2***i*.

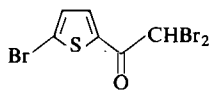


1*k* **2***i*

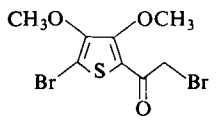
α-Bromoacetylthiophenes

The next step in the synthesis of the ethanolamines involved the bromination of the methyl group of the acetylthiophenes. In general, this was achieved by treating the 5-substituted 2-acetyl-thiophenes *e.g.* 5-bromo-2-acetylthiophene (**2***a*) with bromine or pyridinium bromide perbromide (PBP). The bromoacetylthiophene **3***a* was obtained in moderate yields together with the dibromoacetyl derivative **6**. The formation of the dibromoacetylthiophene was minimized when PBP was used as the brominating agent.

However, when the 5 position was unsubstituted, a significant amount of bromination oc-

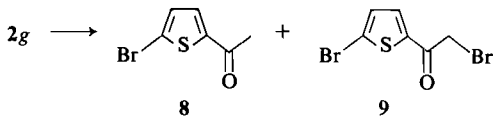


6

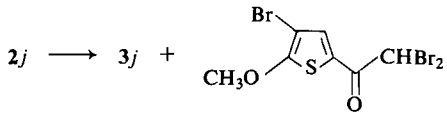


7

curred at C-5 as well as on the acetyl methyl group. For example, the reaction of 2-acetyl-3,4-dimethoxythiophene **2***h* with PBP gave the bromoacetyl derivative **3***h* and the dibromide **7** in 31 and 25% yield, respectively. This side reaction (formation of **7**) was eliminated by using copper(II) bromide as the brominating agent (14). A summary of all the bromination reactions is shown in Table 1.



8 **9**



10

The bromination of 5-methoxy-2-acetylthiophene (**2***g*) took an unexpected course. The reaction with PBP gave a complicated mixture of products from which the compounds **8** and **9** were isolated. In contrast, the 2-acetyl-4-bromo-5-methoxythiophene (**2***i*) was successfully brominated either with bromine or PBP to the bromo ketone **3***j* together with small amounts of dibromide **10**. The displacement of methoxyl in **2***g* must involve a nucleophilic 1,6-addition of bromide ion at C-5 followed by elimination of the methoxide. That such a displacement does not occur in the case of **2***i* may be attributed to steric factors.

The 5-methoxyl-α-bromoacetylthiophene (**3***g*) was synthesized by two methods although the yield was low in both cases. Reacting the acetylthiophene **2***g* with copper(II) bromide or treating 2-methoxythiophene (**1***g*) with *n*-butyllithium followed by bromoacetylbromide, led to the formation of **3***g*.

Reduction of the α-Bromoketone and Reaction with Isopropylamine

The synthesis of the ethanolamine from the bromoketone required first, the reduction of the ketone, followed by reaction of the resulting bromohydrin with isopropylamine. The reduction of the ketone with sodium borohydride in methanol at 0°, gave the bromohydrin in good yield. It was found that on standing at room temperature the bromohydrins decomposed at different rates depending on the substituents on the thiophene ring. For example, the bromohydrin **11***b* was stable enough to be chromatographed and distilled while the bromohydrin **11***i* could not be isolated.

While a detailed study of the decomposition products of the various bromohydrins was not carried out, the major decomposition products

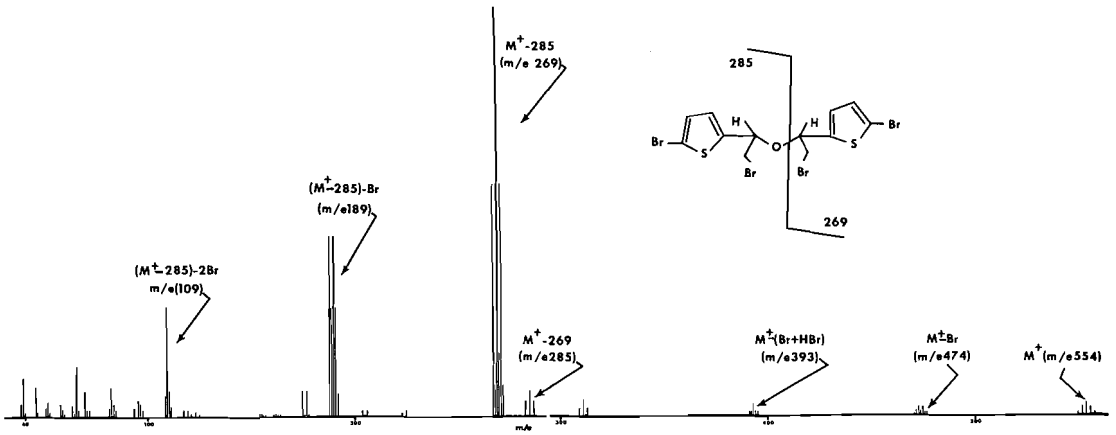


FIG. 1. Mass spectrum of tetrabromoether **12**.

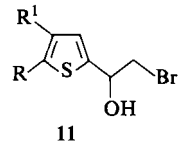

11

a R = Br; R^1 = H
b R = R^1 = Br
i R = OCH_3; R^1 = Br

of the bromohydrin **11***a* were isolated and identified. On standing (neat) at room temperature for 7 days, the bromohydrin **11***a* had decomposed to a mixture of products from which four compounds were isolated by column chromatography on silica gel and identified from their spectroscopic and analytical data. The major decomposition products were the diastereomeric tetrabromoethers **12** and **13**. The two compounds had almost identical i.r. and n.m.r. spectra. The mass spectra, which were identical for both isomers, showed a characteristic Br_4 pattern M^+ (*m/e* 554) and a fragmentation pattern consistent with the proposed structure (Fig. 1).

Not enough data were available to distinguish the two isomers. A minor component of the mixture was the vinyl bromide **14**. The n.m.r. spectrum of the olefinic protons showed two doublets, δ 6.21, 7.21, having a coupling constant of 8.0 Hz consistent for the coupling of two *cis* vinylic protons (15). The acetylthiophene **2***a*, also a minor component of the mixture, was identified by comparison of spectral data and mixture melting point with the authentic sample.

The bromohydrin **11***a* can decompose by participation of electrons of the thiophene ring (*a*, *b*) or by mesomeric effect due to C-5 bromine (*c*) to yield the intermediates **15** and **16**, respectively (Scheme 1). These intermediates upon a proton abstraction can lead to ketone **2***a*. The hydrobromic acid generated in this process can catalyze the ejection of OH^- from **11***a* leading to **17**. This intermediate can generate the olefin **14** by isomerization or can lead to the generation of **12** and **13** by nucleophilic attack of another molecule of **11***a*. This mechanism does not preclude the formation of the *trans* isomer of **14**. However, under the working conditions employed none was isolated.

The reaction of isopropylamine with the bromohydrins **11** was carried out in a pressure bottle at 90° and, in most cases, two regioisomeric ethanolamines **18** and **19** were isolated. The structural assignment of the isomers was based on the difference in the chemical shift of the α-hydroxy and α-amino protons in their n.m.r. spectra. Formation of these two isomers can conceivably involve an epoxide of the type **20** as an intermediate. Opening of the epoxide is then governed by the substituents present on the thiophene nucleus. A summary of this substitution reaction is shown in Table 1.

The nucleophilic attack occurred predominantly at the β-position. However, when the 3 or 5 position was substituted with a methoxyl group as in **11***i* and **11***h*, the α position became the predominant point of attack.

The relative stability of the halothienylbromohydrin compared with those of the methoxythienylbromohydrins and the differences in the

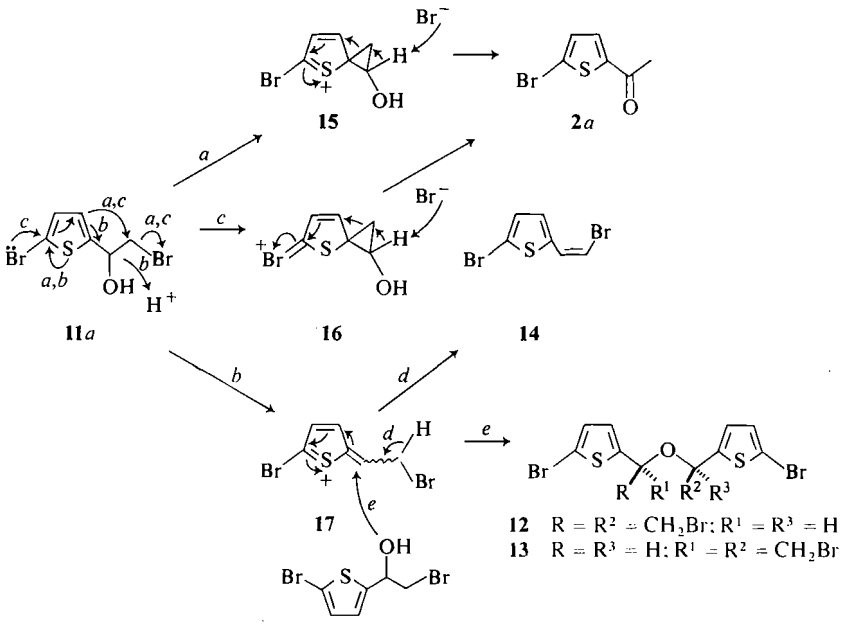

SCHEME I

regiospecificity of isopropylamine addition on to these two types of compounds appear to be a reflection of the mesomeric effect of the two substituent groups. For substituted benzene, halides have a positive while the methoxyl group has a negative value in the Hammett equation (16). The greater electron donating ability of the methoxyl group favors a resonance structure such as **21** (for the 3,4-dimethoxy analog) and the α-ethanolamine **19** is the predominant product.

To establish the intermediacy of the epoxide in the isopropylamine reaction and also to eliminate the formation of the isomer **19** in the case of **11***i* and **11***h*, the hydroxyl group of **11***i* was protected as tetrahydropyranyl ether and that of **11***h* as silyl ether. When the reaction of **11***m* and **11***n* was carried out with isopropylamine no trace of isomer **19** was detectable in either of the products. However, the yields in the case of **11***m* were very low (~10%).

Since the 5-methoxythienylbromohydrin **11***g*

22
a R = OC_2H_5
b R = OH
c R = $NHCH(CH_3)_2$

was very unstable, no 5-methoxythiophenethanolamine was obtained by this synthetic route. An alternative approach was developed starting from 2-methoxythiophene. Treatment of the methoxythiophene **1***g* with butyllithium followed by diethyloxalate gave the α-keto ester **22***a* in good yield. Hydrolysis of the ester **22***a* gave the keto acid **22***b* which was converted to the amide **22***c* via a mixed anhydride. The overall yield in this sequence was 38%. The reduction of the keto amide **22***c* using triethyloxonium fluoroborate and sodium borohydride (17) gave the ethanolamine **18***g* in 23% yield.

The ethanolamines were converted to their hydrochloride salt for biological testing. A complete list of the compounds and their physical properties is tabulated (Table 2) in the Experimental.

Experimental

The i.r. spectra were done on a Perkin-Elmer diffraction grating instrument and u.v. spectra were recorded on a Unicam spectrophotometer. The melting points were taken on a Thomas-Hoover apparatus and are uncorrected. The n.m.r. spectra were recorded on a Varian A60A apparatus and mass spectra were performed on a Hitachi RMU-60 spectrometer. Organic extracts were dried over anhydrous magnesium sulfate and solvents were always removed under vacuum. Merck silica gel 60 (70–230 mesh) was used for column chromatography.

phene (**1***m*) were purchased commercially. The following compounds were prepared according to previously published procedures: 2,3-dibromothiophene (**1***b*, (19)), 3,4-dibromothiophene (**1***c*, (20)), 2-methoxythiophene (**1***g*, (8)), 3,4-dimethoxythiophene (**1***h*, (12)), and 2-*t*-butoxy-3-bromothiophene (**1***j*, (9)). 3,4-Dichlorothiophene (**1***f*, (7, 21)) was prepared (n.m.r. ($CDCl_3$) δ 7.20) from 3,4,5-trichloro-2-thiophenecarboxylic acid (**22**) using the dehalogenation and decarboxylation procedure described by Steinkopf and Köhler (7).

Acetyl Thiophenes

In general the acylation of the substituted thiophenes was carried out using acetyl chloride in benzene with stannic chloride as the catalyst (10). For example, 2-bromothiophene (**1***a*, 60 g) and acetyl chloride (28.9 g) were dissolved in 250 ml benzene and cooled to 0°. The stannic chloride (104 g) dissolved in 50 ml benzene was added dropwise. After stirring the reaction mixture for 20 h at room temperature, it was poured into ice water and extracted with ether. The ethereal extract was washed with water and saturated saline solution, dried, and concentrated. The resulting acetylthiophene **2***a* was recrystallized from hexane – ethyl acetate, m.p. 94–95° (lit. (23) m.p. 94–95°); λ_{max} ($CHCl_3$) 1675 cm^{-1}; n.m.r. ($CDCl_3$) δ 2.49 (s, 3H, CH_3).

The following acetylthiophenes, prepared in the same manner, have been previously synthesized by other acylation methods: 2-acetyl-4,5-dibromothiophene (**2***b*), m.p. 84–85° (lit. (22) m.p. 86–88°); 2-acetyl-3,4-dibromothiophene (**2***c*), m.p. 80–81° (lit. (22) m.p. 83–85°); 2-acetyl-5-chlorothiophene (**2***d*), m.p. 46° (lit. (23) m.p. 46.5–47°); 2-acetyl-3,4-dichlorothiophene (**2***f*), m.p. 51–52° (lit. (7), m.p. 56°).

2-Acetyl-4,5-dichlorothiophene (2e)

Methyl lithium (2.1 equiv.) was added to 4,5-dichloro-2-thiophenecarboxylic acid (7) (17.4 g) dissolved in 250 ml anhydrous ether and cooled to −50° under nitrogen atmosphere. The reaction mixture was slowly brought to 0° (*ca.* 1 h) and then quenched with an ice cold solution of saturated ammonium chloride. The aqueous portion was separated and extracted with ether. The combined ether phase was washed with water and saturated saline, then dried and concentrated. The title compound (10.3 g) was recrystallized from hexane, m.p. 66–67° (lit. (24) m.p. 66°).

3-Bromo-2(5H)-thiophenone (4)

Boron trifluoride etherate (42.0 g) was added dropwise over a period of 15 min to a solution of 3-bromo-2-*t*-butoxythiophene (**1***j*, 55 g) in 200 ml benzene at 0°. The solution was stirred until the reaction was complete by t.l.c. (*ca.* 1 h), then poured into ice water and extracted with ether. The ether extract was washed with water and saturated saline solution, then dried and concentrated. The crude product was chromatographed on a column of silica gel (2.2 kg) in benzene. Recrystallization from a benzene–hexane mixture gave the title compound in 80% yield, m.p. 81–82°; ν_{max} (CCl_4) 1720, 1620 cm^{-1}; n.m.r. ($CDCl_3$) δ 4.05 (d, J = 3.0 Hz, 2H, CH_2S), 7.22 (t, J = 3.0 Hz, 1H, C=C*H*); λ_{max} (95% C_2H_5OH) 239 (ε 7900), 263 nm (ε 2900).

Anal. Calcd. for C_4H_3BrOS: Br, 44.69; S, 17.87. Found: Br, 44.02; S, 17.56.

5-Methoxy-2-acetylthiophene (2g)

(*A*) The title compound was obtained in 57% yield when the acylation on 2-methoxythiophene (**1***g*) was carried out in carbon disulfide at −78° (8); ν_{max} ($CHCl_3$): 1640, 1535, 1225 cm^{-1}; n.m.r. ($CDCl_3$): δ 2.43 (s, 3H, CH_3CO), 3.96 (s, 3H, CH_3O), 6.25 (d, J = 4.5 Hz, 1H, C=C*H*).

(*B*) 5-Methoxythiophene (**1***g*, 35 g) and acetyl chloride (24 g) were dissolved in 100 ml benzene and cooled to 0°. Stannic chloride (81 g) dissolved in 100 ml benzene was then added dropwise in over a period of 30 min. The reaction mixture was then poured into water and extracted with ether. The ether fraction was washed with water, saturated saline solution, dried and concentrated. The crude product was chromatographed on a column of silica gel (benzene – ethyl acetate 8:2) and two compounds were isolated: the title compound **2***g* (29%) and the thiolactone (10%); m.p. 117–118° (benzene–hexane); λ_{max} ($CHCl_3$) 1700, 1650, 1560, 1510, 1390, 1265 cm^{-1}; n.m.r. ($CDCl_3$) δ 2.45 (s, 3H, CH_3CO), 2.80 (m, 2H, CH_2O), 3.60 (m, 3H, CH_2S, —C=C*H*), 4.07 (s, 3H, —OCH_3), 7.11 (s, 1H, =C*H*); λ_{max} (95% C_2H_5OH) 230 (ε 12 400), 290 nm (ε 3700); mass spectrum M^+ (*m/e* 256).

2-Acetyl-3,4-dimethoxythiophene (2h)

Stannic chloride (36 g) dissolved in 20 ml benzene, was added dropwise to a solution of 3,4-dimethoxythiophene (**1***h*, 19.7 g) and acetyl chloride (10.7 g) in 100 ml benzene at 0°. After stirring the reaction mixture at 0° for 1.5 h, it was poured onto crushed ice and extracted with ether. The ethereal extract was washed with water and saturated saline solution, dried, and concentrated. The crude product (24 g) was purified by chromatography on a column of silica gel in benzene. An analytical sample was obtained by distillation, b.p. 102°/0.5 Torr; ν_{max} (film) 1650 cm^{-1}; λ_{max} (95% C_2H_5OH) 275 (ε 12 800), 304 nm (ε 5300); n.m.r. ($CDCl_3$) δ 2.53 (s, 3H, CH_3CO), 3.83, 4.02 (two s, 3H each, CH_3O), 6.52 (s, 1H, C=C*H*).

toxythiophene **1***k* (24.6 g) dissolved in 50 ml benzene was added dropwise over a period of 25 min. After stirring an additional 5 min, the solution was poured into ice water and extracted with ether. The ethereal extract was washed with water and saturated saline solution, dried, and concentrated. The resulting oil was chromatographed on a column of silica gel (1 kg, benzene elution) and two compounds were isolated: (*i*) the bromothiolactone **4** (15%) and (*ii*) the acetylthiophene **2***k*, 17.5 g (60%) was recrystallized from hexane–benzene, m.p. 66°; ν_{max} ($CHCl_3$) 1760, 1665 cm^{-1}; λ_{max} (95% C_2H_5OH) 261 (ε 6100), 310 nm (ε 7000); n.m.r. ($CDCl_3$) δ 2.41 (s, 3H, CH_3CO_2), 2.51 (s, 3H, $COCH_3$), 7.53 (s, 1H, C=C*H*).

Anal. Calcd. for $C_8H_7BrO_3S$: Br, 30.42; S, 12.17. Found: Br, 30.23; S, 12.12.

*2-Acetyl-4-bromo-5-methoxythiophene (**2***i*)*

The acetylthiophene **2***k*, (10 g), dissolved in 50 ml methanol, was rapidly added to a 1% potassium carbonate solution in aqueous methanol (200 ml) at 0°. After stirring for 5 min, the reaction mixture was poured into ice water, acidified with 10% HCl, and extracted several times with ether. The ethereal extract was washed with water and saturated saline solution and dried. An ethereal solution containing excess diazomethane was then added to the ether extract. The solution stood at room temperature for 10 min and then was concentrated. The resulting solid (9.0 g, 100%) was recrystallized from hexane–benzene, m.p. 111–112°; ν_{max} ($CHCl_3$) 1650; λ_{max} (95% C_2H_5OH) 255 (ε 4600), 324 nm (ε 9700); n.m.r. ($CDCl_3$) δ 2.47 (s, 3H, CH_3CO), 4.10 (s, 3H, CH_3O), 7.56 (s, 1H, C=C*H*).

Anal. Calcd. for $C_7H_7BrO_2S$: Br, 34.04; S, 13.62. Found: Br, 34.12; S, 13.48.

Bromination of Acetylthiophenes

An example of the bromination reactions using different reagents is described below.

(*A*) *Bromine*

Bromine (23.4 g) dissolved in 50 ml chloroform was added dropwise to a stirred solution of 2-acetyl-5-bromothiophene (**2***a*, 30 g). The reaction mixture was stirred until all the ketone had reacted (*ca.* 2 h), then diluted with ether, washed with water, 5% sodium bicarbonate, and saturated saline solution. The ethereal phase was finally dried, concentrated, and the resulting bromoketone **3***a* (33 g, 80%) was purified by crystallization from hexane – ethyl acetate, m.p. 90–91°; ν_{max} ($CHCl_3$) 1660 cm^{-1}; n.m.r. ($CDCl_3$) δ 4.30 (s, 2H, CH_2Br).

Anal. Calcd. for $C_6H_4Br_2OS$: Br, 56.34; S, 11.27. Found: Br, 57.01; S, 11.19.

A second product, the dibromomethyl ketone **6**, was isolated by column chromatography on silica gel (benzene–hexane 8:2) in 10% yield: ν_{max} ($CHCl_3$) 1680, 1655 cm^{-1}; n.m.r. ($CDCl_3$) δ 6.43 (s, 1H, $CHBr_2$), 7.20, 7.78 (two d, J = 4 Hz, 2H, C=C*H*).

(*B*) *Pyridinium Bromide Perbromide (PBP)*

2-Acetyl-5-chlorothiophene (**2***d*, 42.5 g) was dissolved in 250 ml chloroform and cooled to 0°. Pyridinium bromide perbromide (106 g) was added in four portions to the stirred solution over a period of 40 min. Upon completion of the reaction (as indicated by t.l.c.) the solution was poured into ice water and extracted with ether.The combined ether fractions were finally washed with water and saturated saline solution, dried, and concentrated. The resulting bromoketone **3***d* was recrystallized from hexane–benzene giving 46 g (75%) of the pure compound, m.p. 72–73°; ν_{max} ($CHCl_3$) 1662 cm^{-1}; n.m.r. ($CDCl_3$) δ 4.30 (s, 2H, CH_2Br).

(*C*) *Copper(II) Bromide (14)*

2-Acetyl-3,4-dimethoxythiophene (**2***h*, 16.5 g) dissolved in 125 ml chloroform was added to a suspension of copper(II) bromide (41.4 g) in refluxing ethyl acetate (12.5 ml). After 2 h refluxing the dark cupric bromide had been converted to the white cuprous bromide. The reaction mixture was then cooled, filtered, concentrated, and chromatographed on a column of silica gel (1 kg,benzene elution). The bromomethyl thienyl ketone **3***h* was isolated as an oil (14 g, 60%); ν_{max} ($CHCl_3$) 1650 cm^{-1}; n.m.r. ($CDCl_3$) δ 4.41 (s, 2H, CH_2Br).

When the bromination was carried out with PBP (procedure B), the bromomethyl ketone **3***h* was isolated in only 31% yield and α-bromomethyl 5-bromo-3,4-dimethoxy-2-thienyl ketone **7** was obtained in 25% yield; crystallized from hexane–benzene m.p. 94°; ν_{max} ($CHCl_3$) 1650 cm^{-1}; n.m.r. ($CDCl_3$) δ 3.92, 4.15 (two s, 3H each, OCH_3), 4.36 (s, 2H, CH_2Br).

Anal. Calcd. for $C_8H_8Br_2O_3S$: Br, 46.51; S, 9.30. Found: Br, 46.73; S, 9.31.

(*D*) *Bromoacetyl Bromide*

Butyllithium (1.1 equiv.) was added to an ethereal solution of 5-methoxythiophene (**1***g*). The reaction mixture was refluxed for 2 h, cooled, and transferred to a suspension of freshly prepared magnesium bromide in ether at 0°. After 30 min at room temperature, the Grignard reagent thus obtained was transferred to a dropping funnel and added dropwise to ethereal solution of bromoacetyl bromide (26.3 g) cooled to −78°. The reaction mixture was stirred for 1 h at −78° then quenched with a saturated ammonium chloride solution and extracted with ether. The ethereal extract was washed with water and saturated saline solution, dried, concentrated, and chromatographed on a column of silica gel (1 kg, benzene elution). The bromomethyl thienyl ketone **3***g* was isolated as an oil (4.4 g, 15%); ν_{max} ($CHCl_3$) 1640 cm^{-1}; n.m.r. ($CDCl_3$) δ 4.00 (s, 3H, OCH_3), 4.26 (s, 2H, CH_2Br), 6.31, 7.60 (two d, J = 4.5 Hz, 1H each C=C*H*).

Reduction of the Bromomethyl Thienyl Ketone with $NaBH_4$

Bromomethyl 5-bromothienyl ketone (**3***a*, 35 g) was suspended in 250 ml methanol and cooled to 0°. Sodium borohydride (4.68 g) in 40 ml methanol was added. The reaction was stirred at room temperature for 30 min then diluted with water and extracted with ether. The ethereal extract was washed with water and saturated saline solution, dried, and concentrated. The bromohydrin was reacted directly without further purification with isopropylamine. All the bromomethyl thienyl ketones were reacted in the same manner.

*Isolation of the Decomposition Products of α-Bromomethyl-2-(5-bromothiophene)methanol (**11***a*)*

α-Bromomethyl-2-(5-bromothiophene)methanol (**11***a*, 2 g) was left (neat) at room temperature for 1 week. The resulting mixture of compounds was chromatographed on silica gel (100 g, benzene–hexane 8:2) and four constituents of this mixture were isolated and identified.

($CDCl_3$) δ 3.52 (m, 4H, CH_2Br), 4.79 (m, 2H, C*H*O), 6.43 (d, J = 4.0 Hz, 2H, C=C*H*), 7.01 (d, J = 4.0 Hz, 2H, C=C*H*); mass spectrum M^+ (*m/e* 554), $M^+ - 80$ (*m/e* 474), $M^+ - 161$ (*m/e* 393), $M^+ - 269$ (*m/e* 285), $M^+ - 285$ (*m/e* 269), $M^+ - 365$ (189), $M^+ - 445$ (*m/e* 109) (see Fig. 1 for details).

Anal. Calcd. for $C_{12}H_{10}OBr_4S_2$: Br, 57.76; S, 11.55. Found: Br, 57.94; S, 11.74.

(*iii*) Di-1-[2-bromo-1-(5-bromothiophene)]ethyl ether (**13**), (450 mg (23%)), was isolated as an oil; ν_{max} (CCl_4) 1080 cm^{-1}; n.m.r. ($CDCl_3$) δ 3.62 (m, 4H, CH_2Br), 4.95 (m, 2H, C*H*O), 6.72 (d, J = 4.0 Hz, 2H, =C*H*), 6.91 (d, J = 4.0 Hz, 2H, =C*H*); mass spectrum was identical with that described above for its isomer.

Anal. Calcd. for $C_{12}H_{10}OBr_4S_2$: Br, 57.76; S, 11.55. Found: Br, 57.33; S, 11.31.

(*iv*) 2-Acetyl-5-bromothiophene (**2***a*) was obtained as a mixture with unreacted bromohydrin **11***a*. The compound, (160 mg (11%)) was isolated by crystallization from hexane – ethyl acetate; m.p. 92–94°, mixture m.p. with authentic **2***a* 93–95°. The i.r. and n.m.r. spectra were identical with those of the authentic acetyl ketone **2***a*.

*α-Bromomethyl-2-(4-bromo-5-methoxythiophene)methyl Tetrahydropyranyl Ether (**11***m*)*

The bromohydrin **11***i* (0.65 g) was dissolved in 10 ml ether. Dihydropyran (0.21 g, 1.2 equiv.) was added followed by *p*-toluenesulfonic acid (6 mg). The reaction was followed by t.l.c. and was found to be complete after 30 min. The mixture was diluted with ether (100 ml) and washed with 5% $NaHCO_3$, water, and saturated saline solution. The ether was then dried, concentrated, and the title compound was obtained in 87% yield; ν_{max} ($CHCl_3$) 1225, 1125, 1075, 1030, 1023, 970 cm^{-1}; n.m.r. ($CDCl_3$) δ 1.70 (m, 6H, C—CH_2—C), 3.60 (m, 2H, CH_2Br), 3.70 (m, 2H, CH_2O), 3.96 (s, 3H, CH_3O), 4.98 (m, 2H, C=C—C*H*O), 6.72 (s, 1H, C=C*H*).

*α-Bromomethyl-2-(3,4-dimethoxythiophene)methyl Trimethylsilyl Ether (**11***n*)*

The bromohydrin **11***h* (1.0 g), trimethylchlorosilane (0.54 g), and hexamethyldisilazane (0.80 g) were dissolved in anhydrous tetrahydrofuran and refluxed 70 min under a nitrogen atmosphere. After cooling, the reaction mixture was poured into ether and crushed ice. This was separated and the aqueous fraction was extracted with ether. The combined ether fractions were washed with water and saturated saline solution, dried, and concentrated. The trimethylsilyl ether **11***n* was obtained in 60% yield; ν_{max} ($CHCl_3$) 3130, 845 cm^{-1}; n.m.r. ($CDCl_3$) δ 0.1 (s, 9H, Si(CH_3)$_3$), 3.46 (m, 2H, CH_2Br), 3.77, 3.84 (two s, 6H, OCH_3), 5.12 (m, 1H, C*H*O), 6.09 (s, 1H, C=C*H*).

*Reaction of the Bromohydrin **11** with Isopropylamine*

All reactions were carried out in the same manner. A typical example is described below. α-Bromomethyl-2-(5-bromothiophene)methanol (**11***a*, 30 g) was dissolved in 70 ml isopropylamine in a pressure bottle. The bottle was flushed with nitrogen, sealed, and after an initial exothermic reaction had taken place, the flask was heated to 90° for 4 h. Upon cooling, the flask was opened and the rereaction mixture was taken up in ether and water. This was separated and the ether was further extracted with cold 10% hydrochloric acid. The combined aqueous fractions were cooled with crushed ice, basified with 10% sodium hydroxide, and extracted with ether. The ethereal extract was washed with water and saturated saline solution, dried, and concentrated. The resulting mixture (26 g) of regioisomers **18***a* and **19***a* was chromatographed on a column of silica gel (chloroform–methanol 8:2). The ethanolamine **18***a*, obtained as a crystalline solid (13 g, 60%), was eluted first: crystallized from hexane, m.p. 82°; ν_{max} ($CHCl_3$) 3590, 3300 cm^{-1}; n.m.r. ($CDCl_3$) δ 1.04 (d, J = 6.5 Hz, 6H, C(CH_3)$_2$), 2.80 (m, 3H, CH_2N, C*H*N), 3.58 (m, 2H, exchangeable, O*H*, N*H*), 4.67 (m, 1H, C*H*O).

Anal. Calcd. for $C_9H_{14}BrNOS$: Br, 30.30; N, 5.30; S, 12.12. Found: Br, 30.35; N, 5.33; S, 12.13.

The regioisomer **19***a* was obtained as an amorphous solid (4 g, 20%) after further elution: m.p. 62–64°; ν_{max} ($CHCl_3$) 3605, 3430; n.m.r. ($CDCl_3$) δ 1.10 (d, J = 6.5 Hz, 6H, C(CH_3)$_2$), 2.31 (broad, 2H, exchangeable, O*H*, N*H*), 2.90 (m, 1H, C*H*N), 3.95 (m, 2H, CH_2O), 4.11 (m, 1H, C=CC*H*N), 6.74 (two d, J = 3.5 Hz, 2H, C=C*H*).

Anal. Calcd. for $C_9H_{14}BrNOS$: S, 12.12. Found: S, 12.05.

*2-(5-Methoxythiophene)-2-oxoacetic Acid (**22***b*)*

n-Butyllithium (0.135 mol) was added dropwise at room temperature to a 100 ml THF solution of 2-methoxythiophene (**1***g*, 15.4 g). The solution was stirred for 15 h at room temperature then refluxed for 1 h. The thienyllithium reagent was then transferred by means of a siphon to a dropping funnel and added to diethyl oxalate dissolved in tetrahydrofuran (150 ml) cooled to −78°. The reaction mixture was stirred at −78° for 3 h then slowly brought to −10° and quenched by the addition of a cold saturated ammonium chloride solution. The separated aqueous phase was extracted with ether and the combined ether phase was washed with water and saturated saline solution, dried, and concentrated. The resulting crude product was not purified at this point but subjected directly to basic hydrolysis.

The crude reaction mixture was stirred at room temperature for 15 h in 5% aqueous methanolic potassium hydroxide. It was then diluted with water and extracted with ether. The aqueous fraction was cooled with crushed ice, acidified with concentrated HCl, and extracted with ether. The ethereal extract was washed with water, saturated saline solution, dried and concentrated. The keto acid **22***b* was obtained as a crystalline solid in 56% yield from **1***g*; ν_{max} ($CHCl_3$) 3000, 1705 cm^{-1}.

*N-Isopropyl-2-(5-methoxythiophene)-2-oxoacetic Acid Amide (**22***c*)*

The keto acid **22***b* (14 g) and triethylamine (9 g), dissolved in THF at 0°, were treated with methyl chloro-

formate. After stirring the reaction mixture for 2 h at 0°, isopropylamine (30 ml) was added dropwise and stirring was continued for an additional 2 h at 0°. The reaction mixture was then poured into ice water and extracted with ether. The ethereal extracts were washed with water and saturated saline solution, dried, and concentrated. The crude product was chromatographed on a column of silica gel (750 g) in benzene – ethyl acetate 95:5 and the amide **22***c* was isolated in 67% yield; m.p. 72–73° (hexane–benzene); ν_{max} ($CHCl_3$) 3440, 3380, 1715, 1677, 1630 cm^{-1}.

Anal. Calcd. for $C_{10}H_{13}NO_3S$: C, 52.86; H, 5.72; N, 6.16; S, 14.09. Found: C, 52.73; H, 5.77; N, 603; S, 14.20.

*α-(Isopropylaminomethyl)-5-methoxy-2-thiophenemethanol (**18g**)*

The triethyloxonium fluoroborate was prepared according to the method described by Meerwein (18). Epichlorohydrin (3.5 ml) was added to freshly distilled boron trifluoride etherate (7.69 ml) in ether so that the solution was refluxing. After refluxing the resulting solution an additional 1.5 h with vigorous stirring, the ether was distilled off and replaced with methylene chloride (50 ml). The amide **22***c* (8 g) was then added and the solution was stirred for 56 h at room temperature. After replacing the methylene chloride with 50 ml anhydrous methanol, the solution was cooled to 0°, and sodium borohydride (4 g) was carefully added over a period of 4 h. The reaction mixture was stirred at room temperature for 24 h, then diluted with ice water and extracted with ether. The ethereal extract was washed with water and saturated saline solution, dried, and concentrated. The crude product was chromatographed on a column of silica gel (400 g) in chloroform–methanol 8:2 and the title compound was isolated in 23% yield as a crystalline solid; m.p. 81° (hexane); ν_{max} ($CHCl_3$) 3600, 3300 cm^{-1}; n.m.r. ($CDCl_3$) δ 1.04 (d, J = 6.5 Hz, 6H, —C—(CH_3)$_2$), 2.82 (m, 3H, CH_2N), 3.32 (broad, exchangeable, 2H, O*H*, N*H*), 3.84 (s, 3H, OCH_3), 4.78 (m, 1H, *CH*O), 6.02, 6.57 (two d, J = 4 Hz, 2H, C=C*H*).

Anal. Calcd. for $C_{10}H_{17}NO_2S$: C, 55.81; H, 7.91; N, 6.51; S, 14.88. Found: C, 55.75; H, 7.86; N, 6.47; S, 14.79.

Preparation of the Hydrochloride Salt

The ethanolamines **18** and **19** were converted to their hydrochloride salt by the addition of a saturated ethereal HCl solution to an ether solution of the amine. The resulting salt was filtered and recrystallized from isopropanol–methanol. The physical constants and analysis of the hydrochloride salts are listed in Table 2.

The authors wish to express their appreciation to Dr. G. Schilling and his associates for microanalytical and spectral data. Thanks are due to the National Research Council of Canada for a Fellowship (to E.F.) during the tenure of which this work was carried out.

The Calculation of Effective Pair Potentials in Solution from Activity Coefficient Data: Nitrobenzene in Benzene

SAUL GOLDMAN

Department of Chemistry, University of Guelph, Guelph, Ontario N1G 2W1

Received February 18, 1975

SAUL GOLDMAN. Can. J. Chem. **53**, 2608 (1975).

The stoichiometric activity coefficients of nitrobenzene in benzene at low concentrations over the range 5.5–25 °C were represented by a temperature-dependent dimerization constant. Constant Pressure Solution Theory was used to derive a relationship between this dimerization constant and the sum of two cluster integrals. One of these integrals involves an effective nitrobenzene–nitrobenzene pair potential in benzene, and the other, an effective nitrobenzene–benzene pair potential in benzene. Two approximate mathematical models, each involving dipole–dipole and square-well potentials were used to evaluate the cluster integrals. The resultant expressions were fitted to the data. It was found that unique expressions for the pair potentials could not be obtained, and therefore ranges of solutions were reported. These solutions indicated (*i*) that the effective pair potentials in solution were of the same order of magnitude as those determined for comparable systems from gas-phase second virial coefficient data and (*ii*) that there existed a relatively short-range stabilizing effect in the nitrobenzene–benzene pair potential that was absent in the nonelectrostatic part of the nitrobenzene–nitrobenzene pair potential. This was explained in terms of a charge-transfer interaction between nitrobenzene and benzene, an explanation that is consistent with n.m.r. shift data.

SAUL GOLDMAN. Can. J. Chem. **53**, 2608 (1975).

A basses concentrations et à des températures allant de 5.5 à 25 °C, les coefficients d'activité stoichiométriques du nitrobenzène dans le benzène peuvent être représentés par une constante de dimérisation dépendante sur la température. On a utilisé la théorie de solutions à pression constante pour établir une relation entre cette constante de dimérisation et la somme des deux intégrales d'agglomérations. Un de ces intégrales implique une paire potentielle effective nitro-benzène–nitrobenzène dans le benzène, et l'autre une paire potentielle effective nitrobenzène–benzène dans le benzène. On a utilisé deux modèles mathématiques approchés pour évaluer les intégrales d'agglomération; chacun implique des potentiels dipole–dipole et point-carré. On a trouvé que l'on ne peut obtenir des expressions uniques pour les paires de potentiels; on rapporte donc des limites pour les solutions. Ces solutions indiquent (*i*) que les potentiels des paires effectives en solution sont du même ordre de grandeur que ceux déterminés en phase gazeuse pour des systèmes comparables à partir de coefficients seconds virials; (*ii*) qu'il existe un effet stabilisant agissant à courte portée dans le potentiel de la paire nitrobenzène–benzène mais qui est absent de la partie nonélectrostatique du potentiel de la paire nitrobenzène–nitrobenzène. On explique ceci en termes d'une interaction de transfert de charge entre le nitrobenzène et le benzène; cette explication est en accord avec les données des déplacements chimiques en r.m.n.

[Traduit par le journal]

Introduction

It has long been known that many dipolar nonelectrolytes behave nonideally in low dielectric constant nondissociating media (1, 2). In the past this nonideality was explained in terms of solute self-association. However, because an appropriate theoretical framework did not exist, it was not possible to interpret the association constants obtained in terms of the molecular properties of the solution under consideration. Subsequent statistical-mechanical developments have made it possible, at least for dilute solutions, to begin to interpret the thermodynamic properties of solutions in terms of the molecular properties of their constituents. A considerable amount of work has been done along these lines for aqueous electrolyte solutions (see for example refs. 3–8), and some molecular-based interpretive work has been done in the study of aqueous nonelectrolyte solutions (9–12). The object of the present work is to apply a statistical-mechanical approach to a dilute solution of a dipolar solute in a nonaqueous solvent with a view to gaining molecular-based insight into the solute–solute and solute–solvent interactions which occur in such a solution.

An important example of a nonideal system consisting of a dipolar solute dissolved in a nonaqueous solvent is the system nitrobenzene in benzene. This system has been extensively studied by a variety of methods including freezing point depression (1, 13–17), vapor pressure lowering (18), polarization measurements (1, 19), and calorimetry (20). In a previous article (20) freezing point depression and calorimetric data were combined to obtain values for the dimerization constant (or equivalently the stoichiometric activity coefficient) of nitrobenzene in benzene over the range 5.5 (freezing point of benzene) to 25 °C. In the present work, Hill's Constant Pressure Solution Theory (21–23), and the connection between this theory and McMillan–Mayer theory (23), are used to derive a relationship between the dimerization constant of nitrobenzene in benzene and the sum of two cluster integrals. One of these integrals involves the nitrobenzene–nitrobenzene pair potential in benzene, and the other, the nitrobenzene–benzene pair potential in benzene. Approximate mathematical models for this system are developed, and are used together with the experimental data to obtain a number of solutions for the pair potentials relative to the two above-mentioned interactions. The solutions are discussed in relation to both gas-phase second virial coefficient data and solution magnetic resonance data.

Derivation

Starting from the semigrand partition function for a binary system that is open with respect to the solute (component 2), closed with respect to the solvent (component 1), and maintained at fixed temperature (T) and fixed total pressure (p), Hill derived expressions for the chemical potentials of the solute and solvent as power series in the molality of the solute (21). The result that is relevant to the present purpose can be expressed in the form

$$[1]\quad \ln \gamma_2(p,T,m_2) = \sum_{k\geq 1} \left(\frac{k+1}{k}\right) C_{k+1}(p,T) \left(\frac{M_1 m_2}{1000}\right)^k$$

where $\gamma_2 \equiv$ the molal activity coefficient of the solute, $M_1 \equiv$ the molecular weight of the solvent, $m_2 \equiv$ the conventional molality of the solute, $C_n \equiv$ constant pressure coefficients. From its definition (21), γ_2 is seen to be identical with the conventional stoichiometric molal activity coefficient of a solute.

In a previous study the following relationship between the dimerization constant K, and the stoichiometric activity coefficient of nitrobenzene in benzene was derived (ref. 20, eq. 9):

$$[2]\quad \frac{1-\gamma_2(p,T,m_2)}{\gamma_2{}^2(p,T,m_2)} = 2m_2K(p,T)$$

For dilute solutions (*i.e.* $8m_2K < 1$) [2] can be written as the power series:

$$[3]\quad \ln \gamma_2(p,T,m_2) = -2K(p,T)m_2 + 6K^2(p,T)m_2{}^2 - \ldots$$

Comparing the coefficients of m_2 in [1] and [3]

$$[4]\quad K(p,T) = \frac{-C_2(p,T)M_1}{1000}$$

Next, we use Hill's result (ref. 23, eqs. 40 and 45):

$$[5]\quad 2C_2v_1 = 2B_2{}' - \bar{v}_2{}^0 + b_{11}{}'$$

where $v_1 \equiv$ the molecular volume of the pure solvent, $\bar{v}_2{}^0 \equiv$ the partial molecular volume of the solute in the solvent at infinite dilution of the solute,

$$B_2{}' \equiv -\frac{1}{2V}\int_V \int_V (e^{-W_{22}/kT} - 1)\, d\boldsymbol{r}_1 d\boldsymbol{r}_2$$

$$b_{11}{}' \equiv \frac{1}{V}\int_V \int_V (e^{-W_{12}/kT} - 1)\, d\boldsymbol{r}_1 d\boldsymbol{r}_2$$

$V \equiv$ volume of the system, $W_{22} \equiv$ the potential of mean force (see below) between two solute molecules at positions $\boldsymbol{r}_1$ and $\boldsymbol{r}_2$ in the infinitely dilute solution, $W_{12} \equiv$ the potential of mean force between one solute molecule and one solvent molecule at positions $\boldsymbol{r}_1$ and $\boldsymbol{r}_2$ in the infinitely dilute solution. It is taken as understood in [5] that all the terms are functions of pressure and temperature. The potential of mean force (introduced above) may be pictured as the effective potential energy of interaction between a selected pair of molecules in the infinitely dilute solution at fixed relative positions and orientations, statistically averaged over all possible configurations of the other (solvent) molecules in the system. For convenience these potentials of mean force will be referred to as effective pair potentials.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The final result is obtained after multiplying both sides of [5] by Avogadro's number N, and combining the result with [4]:

$$[6] \qquad 2B_2 + b_{11} = \bar{V}_2^0 - \frac{2000K}{d_1}$$

where d_1 = the density of the pure solvent; $\bar{V}_2^0 \equiv N\bar{v}_2^0$, $B_2 \equiv NB_2'$, $b_{11} \equiv Nb_{11}'$. Equation 6 provides the sought relationship between the experimental data and the sum of the two cluster integrals B_2 and b_{11}. In the subsequent sections, approximate mathematical models are developed and are fitted to the experimental data via [6] so as to obtain solutions for the functions W_{22} and W_{12}.

The electrostatic part of the interaction between two nitrobenzene molecules will be approximated by a point-dipole–point-dipole potential, and the dispersion and repulsion contributions (for both the nitrobenzene–nitrobenzene and nitrobenzene–benzene interactions) will be represented by square wells. While it is acknowledged that these potentials greatly simplify the real system, it is also pointed out that a realistic potential for this system (involving higher order multipole moments together with shape factors for both the repulsion and dispersion interactions) would introduce prohibitive complexity.

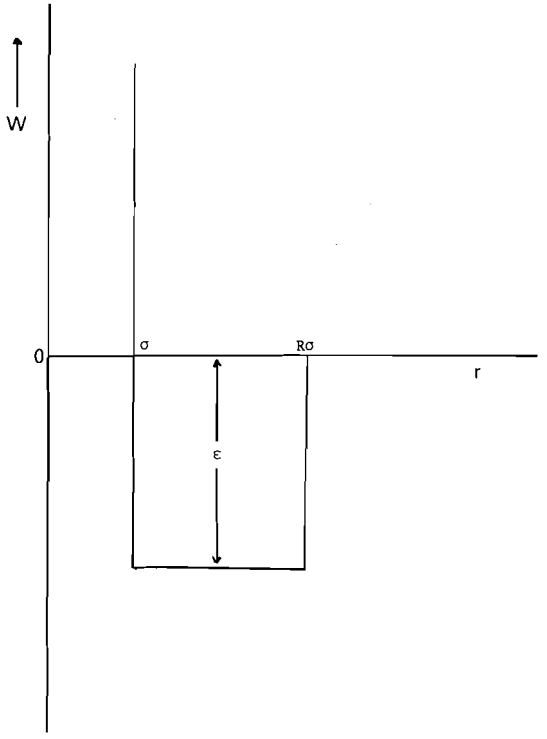

FIG. 1. A plot of potential energy *vs.* center-to-center distance for a square-well potential.

Centered Dipole Model (Model 1)

It is assumed that W_{22} can be represented by the sum:

$$[7] \qquad W_{22} = W_{22}^{ne} + W_{22}^{e}$$

where W_{22}^{ne} and W_{22}^{e} represent respectively the nonelectrostatic and electrostatic contributions to W_{22}. W_{22}^{ne} is assumed to be given by a square well (see Fig. 1), and W_{22}^{e} in model 1 is the interaction energy between two point dipoles each situated at the center of a hard sphere of diameter σ_{22}. The dipole–dipole potential is assumed to be mitigated by a factor of $1/D$ (where D is the dielectric constant of the solvent) and the dipole moment of nitrobenzene in benzene (u_2) is approximated by the equation (24):

$$[8] \qquad u_2 = u_g\left[\frac{2D+1}{2D+n_D^2}\cdot\frac{n_D^2+2}{3}\right]$$

where u_g is the gas-phase dipole moment of nitrobenzene and n_D is the refractive index of nitrobenzene for sodium light. From these considerations:

$$[9] \qquad W_{22} = \begin{cases} \infty & 0 \leqslant r < \sigma_{22} \\ -\varepsilon_{22} + \dfrac{u_2^2 g(\theta_1,\theta_2,\phi)}{Dr^3} & \sigma_{22} < r < R_{22}\sigma_{22} \\ \dfrac{u_2^2 g(\theta_1,\theta_2,\phi)}{Dr^3} & r > R_{22}\sigma_{22} \end{cases}$$

where $g \equiv 2\cos\theta_1\cos\theta_2 + \sin\theta_1\sin\theta_2\cos\phi$. In [9] r is the distance between the molecular centers, and the angles θ_1, θ_2, and ϕ are illustrated in Fig. 2, which should be read for this illustration with the quantity "a" in that figure set equal to zero. For use with angle-dependent potentials the expression for B_2 (given with [5] and [6]) is first transformed (ref. 25, p. 153)

[10] $$B_2 = -\frac{N}{4}\int_0^\infty \int_\Omega (e^{-W_{22}/kT} - 1)r^2\, dr\, d\Omega$$

where

$$\int_\Omega d\Omega = \int_0^{2\pi}\int_0^{\pi}\int_0^{\pi} \sin\theta_1 d\theta_1 \sin\theta_2 d\theta_2 d\phi = 8\pi$$

Next, [9] is inserted into [10] to give

[11] $$2B_2 = \frac{4\pi N\sigma_{22}^3}{3}\{1 - [R_{22}^3 - 1][e^{\varepsilon_{22}/kT} - 1] - e^{\varepsilon_{22}/kT}S_1 - S_2\}$$

where

$$S_1 \equiv \sum_{n=1}^{\infty} \frac{G_n}{(2n)!(2n-1)}\left(\frac{u_2^2}{DkT\sigma_{22}^3}\right)^{2n}(1 - R_{22}^{3-6n})$$

$$S_2 \equiv \sum_{n=1}^{\infty} \frac{G_n R_{22}^{3-6n}}{(2n)!(2n-1)}\left(\frac{u_2^2}{DkT\sigma_{22}^3}\right)^{2n}$$

$$G_n \equiv \frac{1}{8\pi}\int_\Omega g(\theta_1,\theta_2,\phi)^{2n}\, d\Omega = \frac{1}{2n+1}\sum_{m=0}^{n}\binom{n}{m}\frac{3^m}{2m+1}$$

$$\binom{n}{m} \equiv \text{binomial coefficients}$$

The summation given above for G_n was first given by Stockmayer (26).

The nitrobenzene–benzene pair potential is represented by the square well:

[12] $$W_{12}(r) = \begin{cases} \infty & 0 \leqslant r < \sigma_{12} \\ -\varepsilon_{12} & \sigma_{12} < r < R_{12}\sigma_{12} \\ 0 & r > R_{12}\sigma_{12} \end{cases}$$

where

$$\sigma_{12} \equiv \left(\frac{\sigma_{11} + \sigma_{22}}{2}\right)$$

ε_{12} and R_{12} are analogous to ε_{22} and R_{22} (Fig. 1). The expression for b_{11} given with [5] and [6] is first transformed (ref. 25, p. 153):

[13] $$b_{11} = 4\pi N\int_0^\infty [e^{-W_{12}/kT} - 1]r^2\, dr$$

Equation 12 is inserted into [13] to give

[14] $$b_{11} = \frac{-4\pi N\sigma_{12}^3}{3}\{1 - [R_{12}^3 - 1][e^{\varepsilon_{12}/kT} - 1]\}$$

The sought relationship for model 1 is obtained by combining [6], [11], and [14]

[15] $$\frac{4\pi N\sigma_{22}^3}{3}\{1 - [R_{22}^3 - 1][e^{\varepsilon_{22}/kT} - 1] - e^{\varepsilon_{22}/kT}S_1 - S_2\} - \frac{4\pi N\sigma_{12}^3}{3}\{1 - [R_{12}^3 - 1][e^{\varepsilon_{12}/kT} - 1]\} = \bar{V}_2^0 - \frac{2000K}{d_1}$$

Equation 15 connects the experimental stoichiometric activity coefficient data (via K) with molecular parameters that characterize the effective nitrobenzene–nitrobenzene and nitrobenzene–benzene pair potentials in benzene. This equation is now fitted to the experimental data.

Fitting Procedure

The experimental values of K, $\bar{V}_2^0$, and d_1

that were used are given in columns 2, 3, and 5 respectively of Table 1. The values of the experimental function $(\bar{V}_2^0 - 2000K/d_1)$ calculated from these data are given in column 7 of Table 1, and are illustrated by the solid curve in Fig. 3.

There are six unknown temperature-invariant parameters (σ_{12}, σ_{22}, R_{12}, R_{22}, ε_{12}, ε_{22}) on the left-hand side of [15]. The values sought for these parameters are those, which when substituted into the left-hand side of [15], reproduce the experimental data, *i.e.* the curve in Fig. 3. Obviously, if each of these parameters were allowed to assume any possible value, there would exist a very great number of mathematical solutions which would satisfy [15] over the experimental temperature range. It is possible, however, to greatly reduce the number of solutions by restricting the parameters to physically reasonable values. Specifically the results from scaled-particle theory will be used to obtain values for σ_{12} and σ_{22}, and gas-phase virial coefficient data will be used as a guide for establishing physically reasonable ranges for R_{12}, R_{22}, ε_{12}, and ε_{22}. In the actual fitting procedure only ε_{12} and ε_{22} will be taken as adjustable parameters.

Scaled-particle theory (27–29) has been applied to explain the surface tensions, compressibilities, and gas solubility data for a number of pure liquids including benzene and nitrobenzene (30, 31). From refs. 30 and 31 the values of σ_{22} and σ_{12} were estimated to be: $\sigma_{22} = 5.64$ Å and $\sigma_{12} = (\sigma_{11} + \sigma_{22})/2 = 5.37$ Å. These values were used for σ_{12} and σ_{22} in all the calculations described below.

Gas-phase second virial coefficient data are used as a guide in establishing possible ranges for values of R_{12}, R_{22}, ε_{12}, and ε_{22}. An examination of tabulated values of R and ε (ref. 25, p. 160), obtained by fitting a square-well potential to second virial coefficient data, reveals that for most complex polyatomic molecules R lies between ~1.2 and ~1.5, and ε is always positive but is never greater than $10kT$ ($T = 298$ K). Therefore in the present work R_{12} and R_{22} were each allowed values between 1.2 and 1.5, and ε_{12} and ε_{22} were each allowed values between 0 and $10kT$.

Equation 15 was solved for ε_{12} and ε_{22} (the adjustable parameters) as follows. With $\sigma_{12} = 5.37$ Å and $\sigma_{22} = 5.64$ Å, R_{12} and R_{22} were each allowed to vary between 1.2 and 1.5 in steps of 0.1. For every possible pair of values of R_{12} and R_{22}, a corresponding pair of values

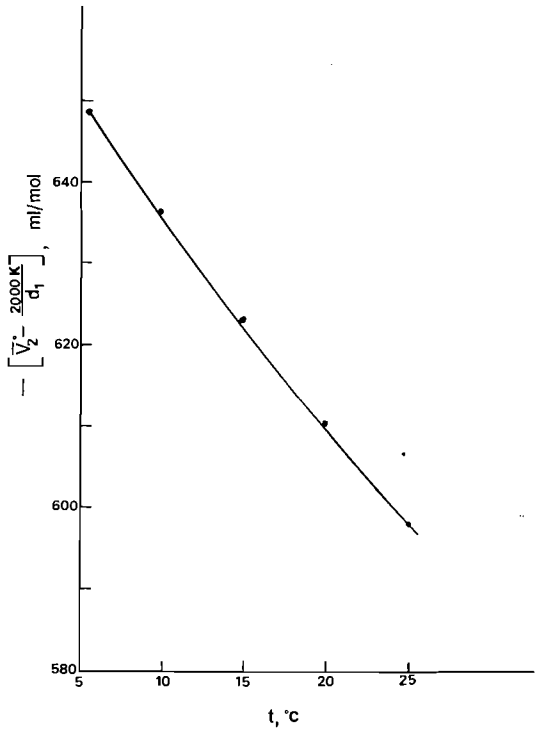

FIG. 3. Solid curve calculated from experimental data (Table 1). Points are calculated theoretically from solutions in Tables 3 and 4 used with [15] and [17] respectively.

for ε_{12} and ε_{22} that would reproduce the curve in Fig. 3 was sought by trial calculation. In seeking these solutions ε_{12} and ε_{22} were each restricted to values between 0 and $10kT$ (T = 298 K). The quantities S_1 and S_2 were obtained from the respective summations given with [11], using the values of D and u_2 entered in Table 1. These sums converged rapidly, and in practice their values were taken as the sum of the first 10 terms. The values of S_1 and S_2 used in these calculations are entered in columns 3 and 4 of Table 2.

In this way it was found that a fit to the data could only be obtained when $R_{22} > R_{12}$. That is for $R_{12} \geq R_{22}$ values of ε_{12} and ε_{22} in the range 0–$10kT$ did not satisfy [15] over the range 5.5–25 °C. However in all cases for which $R_{22} > R_{12}$ a very good fit was obtained, and each fit involved reasonable values of ε_{12} and ε_{22}. These solutions are given, each as a separate row, in Table 3. It is also seen from Table 3 that for each solution $\varepsilon_{12} > \varepsilon_{22}$. The adequacy of these solutions is illustrated by the points shown in Fig. 3. That is, the set of values entered in any single row of Table 3, when used in the left-hand side of [15] (with the appropriate values of S_1 and S_2) gives rise to the points shown in Fig. 3. Whereas the calculated value of the left-hand side of [15] at each temperature is slightly different for the different solutions, these differences are too small to be distinguished using the scale in Fig. 3.

The potential functions represented by one of these solutions (row 2, Table 3) are illustrated in Fig. 4. For comparison, the contribution of the dipole–dipole potential to W_{22} for two dipole orientations is included in Fig. 4. It is

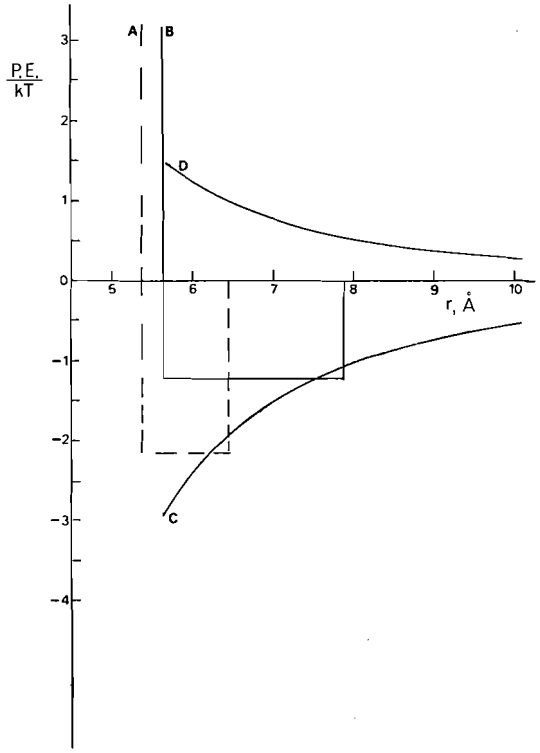

FIG. 4. The square wells A and B represent the solution given in Table 3 row 2. A is the benzene–nitrobenzene pair potential. B is the nonelectrostatic part of the nitrobenzene–nitrobenzene pair potential. C and D are the electrostatic contributions (reckoned by Model 1) for two selected dipole orientations: C, $\theta_1 = 0°$, $\theta_2 = 180°$; D, $\theta_1 = \theta_2 = 90°$, $\phi = 0°$ (value of kT is for $T = 298$ K).

seen from this figure that the contribution to W_{22} made by the dipole–dipole potential is very significant, a result which is not surprising in view of the large dipole moment of nitrobenzene (Table 1).

Off-centered Dipole Model (Model 2)

Model 1 resulted in a fit to the data only when $R_{22} > R_{12}$. This result, which may seem odd at first sight, has an interesting implication which will be discussed later (see Discussion). However Model 1 is very simple, and it is conceivable that the above result is merely an artifact of the model. Therefore it is important to determine whether or not the result $R_{22} > R_{12}$ is sustained for a model that corresponds somewhat more closely to the real system. In their studies on the second virial coefficients of polar gases Lawley and Smith (32), and Dymond and Smith (33)

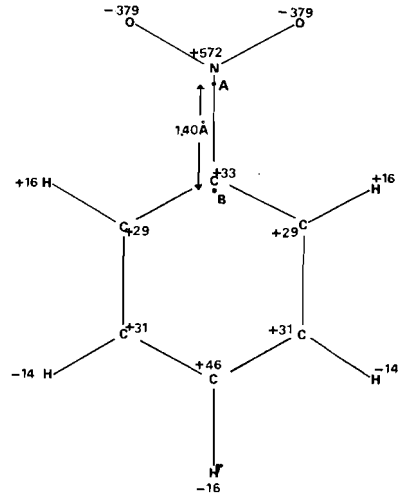

FIG. 5. The charge distribution in nitrobenzene. The charges on the atoms are given in units of 10^{-3} electrons. B is the center of mass of the molecule. A is the dipole center (electrical center of gravity).

have shown that displacement of the electrical center of a molecule from its geometric center can have a significant influence on the calculated values of the molecular parameters. Because the dipole in nitrobenzene is expected to be eccentric rather than centered, and because such a refinement is relatively simple to make, it was considered worthwhile to repeat the calculations for R_{12}, R_{22}, ε_{12}, and ε_{22} using an off-centered dipole model for the nitrobenzene molecule.

It is first necessary to obtain an estimate for the degree of eccentricity of the dipole in nitrobenzene. This was done by calculating the charge distribution in the nitrobenzene molecule, using the known geometry of the molecule (34) together with an INDO/2 molecular orbital calculation.[1] The charge distribution that resulted from this calculation is given in Fig. 5. The center of the molecule (the effective center of the dispersion and repulsion forces) is here identified with the center of mass of the molecule. Using this definition as the center, and the charge distribution given in Fig. 5, it is readily shown from simple electrostatic considerations that the center of the dipole is displaced from the center of mass by 1.40 Å (see Fig. 5).

The derivation for Model 2 parallels that

[1]The program used for the INDO/2 calculation was written by M. Zerner and J. Ridley and is similar to one described elsewhere (35).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

given for Model 1, and the equations for the second virial coefficient of eccentric dipolar molecules have previously been derived (32, 33). Therefore the development given below is brief.

As with Model 1 it is assumed that the effective pair potential between two nitrobenzene molecules can be written as the sum of a square-well potential and a dipole–dipole potential

[7] $$W_{22} = W_{22}^{ne} + W_{22}^{e}$$

where

$$W_{22}^{ne} = \begin{cases} \infty & 0 \leqslant r < \sigma_{22} \\ -\varepsilon_{22} & \sigma_{22} < r < R_{22}\sigma_{22} \\ 0 & r > R_{22}\sigma_{22} \end{cases}$$

$$W_{22}^{e} = \frac{u_2^2}{DR^3}\left[3\left(\frac{R_0}{R}\right)^2 n_1 n_2 + 3\left[\left(\frac{a}{R}\right)(1 + n_1 n_2 - l_1 l_2)\right]^2 - \frac{3aR_0}{R^2}\left[(1 + n_1 n_2 - l_1 l_2)(n_1 + n_2) - n_1 n_2 + l_1 l_2\right]\right]$$

$$R \equiv (R_0^2 + 2a^2[1 + n_1 n_2 - l_1 l_2] - 2aR_0(n_1 + n_2))^{1/2}$$

$$n_i \equiv \cos\theta_i$$

$$l_1 l_2 \equiv \sin\theta_1 \sin\theta_2 \cos\phi$$

$$a \equiv \text{distance by which dipole is off-centered}$$

$$R_0 \equiv \text{hard-sphere center-to-center distance}$$

The above quantities are illustrated in Fig. 2. The equation for W_{22}^{e} gives the potential energy of interaction of two off-centered point-dipoles interacting through a medium of dielectric constant D. It was derived by combining Coulomb's law with straightforward (but lengthy) algebraic manipulations and it may be shown (apart from the factor $1/D$) to be equivalent to eq. 6 in ref. 32.[2]

Next [7] is inserted into [10]. After carrying out the simple integrations and rearranging terms, the result is

[16] $$2B_2 = \frac{4\pi N\sigma_{22}^3}{3}\{1 - [R_{22}^3 - 1][e^{\varepsilon_{22}/kT} - 1] - e^{\varepsilon_{22}/kT}S_1' - S_2'\}$$

where

$$S_1' \equiv 1 - R_{22}^3 + 3\delta^3 \int_{\sigma_{22}/a}^{R_{22}\sigma_{22}/a} \langle x\rangle r_0^2\, dr_0$$

$$S_2' \equiv -3\delta^3 \int_{R_{22}\sigma_{22}/a}^{\infty} (1 - \langle x\rangle) r_0^2\, dr_0$$

$$\delta \equiv \left(\frac{a}{\sigma_{22}}\right)$$

$$r_0 \equiv \left(\frac{R_0}{a}\right)$$

$$\langle x\rangle \equiv \frac{1}{8\pi}\int_{\Omega} e^{-W_{22}^{e}/kT}\, d\Omega$$

It is seen by comparing [11] and [16] that the quantities S_1' and S_2' of Model 2 are functionally equivalent to S_1 and S_2 respectively of Model 1.

[2]The reader should note that eq. 6 in ref. 32 gives a sign for the off-centered dipole–dipole potential that is inconsistent with Fig. 1 in that reference.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The nitrobenzene–benzene pair potential in Model 2 is assumed to be given by a square-well (*i.e.* by [12]). Hence b_{11} in Model 2 is given by [14]. Combining [6], [14], and [16], the result for Model 2 is

$$[17]\quad \frac{4\pi N\sigma_{22}^3}{3}\{1-[R_{22}^3-1][e^{\varepsilon_{22}/kT}-1]-e^{\varepsilon_{22}/kT}S_1'-S_2'\} - \frac{4\pi N\sigma_{12}^3}{3}\{1-[R_{12}^3-1][e^{\varepsilon_{12}/kT}-1]\} = \bar{V}_2^0-\frac{2000K}{d_1}$$

The integrals required for the calculation of S_1' and S_2' were obtained as follows. The integral

$$\int_{\sigma_{22}/a}^{R_{22}\sigma_{22}/a}\langle x\rangle r_0^2\,dr_0$$

was evaluated by multiple numerical integration using a 4-dimensional 16-point Gauss rule. That is, a 16-point Gauss rule was used for each of the successive integrations: $0\leqslant\theta_1\leqslant\pi$; $0\leqslant\theta_2\leqslant\pi$; $0\leqslant\phi\leqslant2\pi$; $(\sigma_{22}/a)\leqslant r_0\leqslant(R_{22}\sigma_{22}/a)$. The integral

$$\int_{R_{22}\sigma_{22}/a}^{\infty}(1-\langle x\rangle)r_0^2\,dr_0$$

was obtained analytically using the expansion for $\langle x\rangle$ given in ref. 33. By repeating one of the numerical integrations with a 4-dimensional 20-point Gauss rule it was found that the values of S_1' were known to within 0.5%. The accuracy of the programs used for these calculations was further confirmed in two other ways. They were applied, *mutatis mutandis*, to previously published work (33), and they were applied in the limit $a\rightarrow0$ whereupon it found (as expected) that $S_1'\rightarrow S_1$ and $S_2'\rightarrow S_2$. The calculated values of S_1' and S_2' are entered in columns 5 and 6 of Table 2.

Equation 17 was solved for ε_{12} and ε_{22} (the adjustable parameters) utilizing exactly the same procedure as was described for the solution of [15]. The results obtained are given in Table 4, from which it is seen that the solutions for Model 2 are qualitatively similar to those found for Model 1. That is, the experimental function $(\bar{V}_2^0-2000K/d_1)$ over the temperature range 5.5–25 °C could only be fitted when $R_{22}>R_{12}$ (when the values of R_{12} and R_{22} are restricted to the range 1.2–1.5 and the values of ε_{12} and ε_{22} are restricted to values between 0 and $10kT$). All combinations of R_{12} and R_{22} represented by $R_{12}\geq R_{22}$ did not result in a fit. For each solution it was found that $\varepsilon_{12}>\varepsilon_{22}$ (as with Model 1).

The adequacy of these solutions is demonstrated by the points in Fig. 3. Whereas each row in Table 4 (*i.e.* each solution) results, at a particular temperature, in a slightly different value for the left-hand side of [17], these values are indistinguishable from each other using the scale in Fig. 3. Likewise, using the scale in Fig. 3, these values are (at a particular temperature) indistinguishable from the corresponding values obtained with Model 1. For this reason the twelve solutions reported in this work (six in Table 3 for Model 1 and six in Table 4 for Model 2) are represented by only one set of points in Fig. 3.

Discussion

It was found with both the centered and off-centered dipole models that unique solutions for the effective pair potentials W_{12} and W_{22} could not be obtained. Therefore a range of solutions, for each model, was reported. The reason that unique solutions were unobtainable was that the experimental function $(\bar{V}_2^0-2000K/d_1)$ was equal to the sum of two cluster integrals which were similar in form but opposite in sign. However, when restrictions were placed on the possible values of the square-well parameters, and these restricted sets of values were used to seek a fit to the data, a qualitatively unique result was found. Namely, with both models: $R_{12}<R_{22}$ and $\varepsilon_{12}>\varepsilon_{22}$.

It is of interest to compare the values obtained for R_{12}, R_{22}, ε_{12}, and ε_{22} (Tables 3 and 4) with values for R and ε taken from gas-phase virial coefficient data. The second virial coefficients of

either pure nitrobenzene or benzene–nitrobenzene mixtures are unknown, so that a direct comparison is not possible. However, second virial coefficient data do exist for pure benzene and pure toluene. Since benzene was one of the constituents of the present system, and since toluene resembles nitrobenzene in size and shape (but not polarity) it is worthwhile to compare the gas-phase pair potentials for these molecules with the nonelectrostatic part of the potentials (*i.e.* the square wells) determined here. Therefore second virial coefficient data for benzene and toluene, (available for each over a range of temperatures (36)), were fitted to a square-well potential by least squares. To be consistent with the present work, the values of σ for benzene and toluene were taken from scaled-particle theory. The adjustable parameters in these fits were R and ε. The least-squares estimates for R and ε are given in Table 5. These estimates reproduce the second virial coefficient data for both benzene and toluene over the reported temperature ranges with an accuracy of about 2%. It is seen from a comparison of the values of R and ε in Table 5 with those given in Tables 3 and 4, that R and ε for both benzene and toluene fall within the range of solutions reported here. Therefore as far as it can be determined, the effective pair potentials that account for our activity coefficient data are consistent with gas-phase pair potentials for comparable molecules.

Perhaps the most significant result found in this work was the fact that for both the centered and off-centered dipole models, the square-well parameters obeyed the inequalities: $R_{12} < R_{22}$ and $\varepsilon_{12} > \varepsilon_{22}$. In other words, the data could only be fitted if the square-well that characterized the nitrobenzene–benzene pair potential was both narrower and deeper than the square-well that characterized the nonelectrostatic part of the nitrobenzene–nitrobenzene pair potential. An explanation for this is put forward below.

A narrower and deeper square-well for the benzene–nitrobenzene pair potential means that this potential, whatever its true form, has in it a relatively short-range stabilizing component that is absent in the nonelectrostatic part of the nitrobenzene–nitrobenzene pair potential. This in turn suggests that the nitrobenzene–benzene pair potential contains a stabilizing direction-dependent potential (in addition to the expected dispersion term) that is absent in the nonelectrostatic part of the nitrobenzene–nitrobenzene pair potential. The correspondence between stabilizing direction-dependent potentials, and their manifestation as narrow deep square-wells is illustrated by a simple example. When the second virial coefficients of the (isotropic) rare gases Ne, Kr, Xe are fitted to a square-well potential, R is found to be between 1.85–1.87 and (ε/k) ranges between 20–100 K (ref. 25, p. 160). However when the second virial coefficient of steam is fitted to a square-well potential, it is found that $R = 1.199$ and $(\varepsilon/k) = 1260$ K (ref. 25, p. 160). Clearly, the existence of hydrogen-bonding between two water molecules (a stabilizing direction-dependent potential that exists in addition to the dispersion potential) has the effect of making the square well of steam relatively narrow and deep. The point is that direction-dependent potentials become angle-averaged when represented by an isotropic square well and the effect of angle-averaging is to make the overall potential appear relatively short-range.

It has been found in solution n.m.r. shift measurements that benzene (an electron donor) forms a charge-transfer complex with both 1,3,5-trinitrobenzene and *para*-dinitrobenzene (electron acceptors) (37). Whereas a charge-transfer complex between benzene and nitrobenzene would be too weak to detect by n.m.r. shift measurements[3] the results with 1,3,5-trinitrobenzene and *para*-dinitrobenzene make it likely that the benzene–nitrobenzene pair potential does contain (in addition to the expected dispersion terms) some charge-transfer character. Because a charge-transfer complex between benzene and nitrobenzene would involve a stabilizing direction-dependent potential, one would expect, from the above discussion, that the use of a square well to describe such a potential would result in a relatively narrow deep square well. One would not expect the nitrobenzene–nitrobenzene pair potential to have any

TABLE 5. Square-well parameters for benzene and toluene from gas-phase second virial coefficient data

	σ^* (Å)	R	ε/k (K)

significant charge-transfer character. Thus the existence of a charge-transfer interaction between a benzene and a nitrobenzene molecule, but not between two nitrobenzene molecules, is consistent with the results found in this work.

The author is grateful to the National Research Council of Canada for financial assistance. He would also like to thank Professor M. C. Zerner for his help in calculating the charge distribution in nitrobenzene, and Professor C. A. Fyfe for pointing out the relevant charge-transfer data.

Chemistry of Transition Metals. V. Further Studies on the Mechanism of Reaction of *n*-Alkyl Chlorides with Metals of the First Transition Period

ROBERT W. EGAN[1] AND JOHN F. HARROD

Department of Chemistry, McGill University, P.O. Box 6070, Station A, Montreal, Quebec H3C 3G1

Received March 4, 1975

ROBERT W. EGAN and JOHN F. HARROD. Can. J. Chem. **53**, 2619 (1975).

The rate of reaction of *n*-propyl chloride on polycrystalline evaporated titanium films has been shown to follow a strictly half-order rate law in the pressure range 0.1–0.01 Torr at 220 °C. The reaction rate was not influenced by the product propene. Experiments using a mixture of 1-bromopropane and 1-chloropropane-1-d_1 gave no indication of halogen interchange on either titanium or chromium, thus excluding rapid, reversible dissociative adsorption of the carbon–halogen bond as an explanation of the half-order rate law.

ROBERT W. EGAN et JOHN F. HARROD. Can. J. Chem. **53**, 2619 (1975).

On démontre que la vitesse de réaction du chlorure de *n*-propyle sur des films polycristallins de titane évaporé suit strictement un équation de vitesse d'ordre une demie à des pressions allant de 0.1 à 0.01 Torr à 220 °C. L'équation de vitesse n'est pas modifiée par la présence du produit, le propène. Des expériences impliquant un mélange de bromo-1 propane et de chloro-1 propane d_1-1 ont été réalisées; on n'a pu détecter d'échange d'halogène soit sur le titane ou sur le chrome et on peut donc éliminer, comme explication de l'ordre une demie, la possibilité d'une adsorbtion dissociative reversible et rapide du lien carbone–halogène.

[Traduit par le journal)

Introduction

Previous investigations have shown that *n*-alkyl halides undergo dehydrohalogenation at the surfaces of metals of the first transition period (1, 2). With *n*-alkyl halides all of the halogen is deposited at the metal surface and, in most cases, leads to a rapid decrease in the rate of reaction. The main exceptions to this pattern of behavior were the metals titanium and manganese, neither of which was effectively poisoned by the surface deposited halide (1*a*, 2). In the latter two cases, the kinetic features of the reactions were investigated and were shown to have a time-order reaction of one-half over a wide range of experimental conditions. Indirect measurements of the reaction order on vanadium and chromium, both of which are poisoned by deposited halide, strongly suggested that in these cases also the order in reactant was one-half (2).

It is, to our knowledge, not possible to reconcile strict half-order kinetics over a wide range of experimental conditions with anything but a mechanism involving a dissociative pre-equilibrium. A mechanism was therefore proposed for the half-order reaction of *n*-alkyl halides on transition metals, the first step of which was a rapid, reversible, dissociative adsorption of the carbon–halogen bond at the metal surface (1*a*). Although the proposed mechanism fitted most of the observed experimental facts, it was disturbing to have to ignore an earlier conclusion of Anderson and McConkney that halogen exchange did not occur when suitably labelled methyl chlorides reacted with titanium (3). The latter observation is irreconcilable with a rapid, reversible predissociation step.

In the present paper we report some further experiments designed to test whether halogen interchange does occur with the reactants and under the conditions used by us and whether the reactions are truly half-order. A small measure of doubt remained concerning the latter point since, although a single experiment showed no influence of product on reaction rate, the concentration-order of the reactions had not in fact been rigorously tested (1*a*).

Experimental

The methods used for studying the stoichiometries and rates of reactions have been described previously (1, 2).

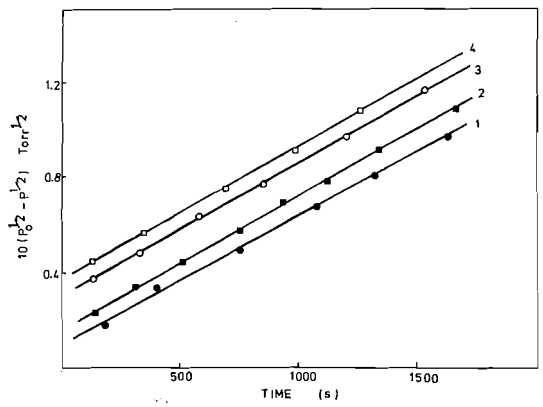

FIG. 1. Effect of added propene on the rate of dehydrochlorination of 1-chloropropane. (T = 222 °C; P_0(chloropropane) = 0.014 Torr.) Initial pressure of propene (Torr): ●, 0.0; ■, 0.013; ○, 0.045; □, 0.0. The ordinate scale refers to curve *1*; curves *2*, *3*, and *4* have been raised by 0.1, 0.2, and 0.3 units respectively to avoid congestion. Reactions carried out on a single film and reaction vessel pumped to 10^{-6} Torr between runs.

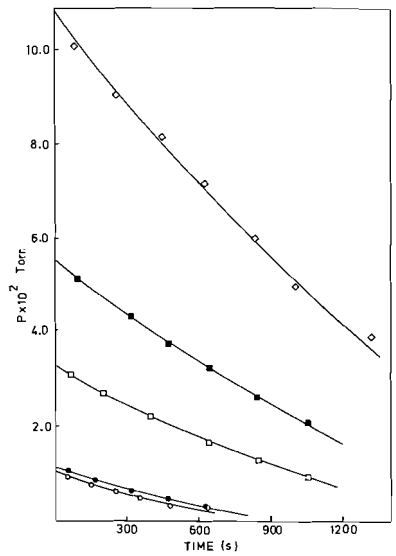

FIG. 2. Reaction of 1-chloropropane on titanium at different initial reactant pressures. Initial reactant pressures (Torr): ○, 0.012; ●, 0.013; □, 0.037; ■, 0.060; ◇, 0.110. Reaction temperature 220 °C. Reactions carried out as in Fig. 1.

The deuterated *n*-propyl halides were both prepared from 1-propanol-1-d_1 which was prepared by reaction of propanal with a 50% molar excess of lithium aluminum deuteride in ether. The bromide was prepared by reaction of the alcohol with excess phosphorus tribromide generated *in situ* by reaction of yellow phosphorus with bromine (4). The product of these reactions, after purification by preparative scale g.l.c., was found to be 1-bromopropane-1-d_1 contaminated with *ca.* 2 mol% of 2-bromopropane-1-d_1.

1-Chloropropane-1-d_1 was prepared by the zinc chloride catalyzed reaction of the alcohol with HCl (4). After distillation and purification by preparative scale g.l.c., the product was shown, by n.m.r. and analytical g.l.c., to be 1-chloropropane-1-d_1 contaminated with *ca.* 1% 2-chloropropane-1-d_1.

Results

The Effect of Added Propene on the Reaction of 1-Chloropropane with Titanium

The results of a series of reactions performed on the same metal film, in the presence and absence of added propene, are shown in Fig. 1. From these curves it is quite evident that the rate of reaction, as measured by the slope of the half-order plots, remains quite constant and that the presence of propene in the reaction mixture has no influence on the rate. The best fit slopes of the lines in Fig. 1 span the range 1.11 to 1.14×10^{-4} Torr$^{1/2}$ s^{-1}.

Determination of the Concentration Order of the Reaction of 1-Chloropropane with Titanium

The concentration order of the reaction was determined by following the decrease in reactant concentration with time for a series of reactions on the same metal film, but with differing initial reactant concentrations. The results of such a series are shown in Fig. 2. Using a standard curve-fitting program, an equation for the best line for each set of points was generated and from these equations the slope at zero time (V_0) for each curve was evaluated. A standard plot of log V_0 *vs.* log P_0, shown in Fig. 3, yielded a concentration order of 0.49 ± 0.02 and a half-order rate constant of $1.6 \pm 0.1 \times 10^{-4}$ Torr$^{1/2}$ s^{-1}. By plotting the data from each reaction separately as a half-order reaction, the rate constant for each reaction was determined. These rate constants had a median and range of $1.69 \pm 0.03 \times 10^{-4}$ Torr$^{1/2}$ s^{-1}, in excellent agreement with that determined from the effect of P_0 on V_0. There thus remains no question that this reaction proceeds by a strict half-order rate law. The differences in apparent rate constants derived from Figs. 1 and 2 arise from the nonidentical nature of different film preparations such as different geometric areas, roughness factors, and degrees of contamination.

Halogen Exchange Reactions

Design of the Experiments

It was pointed out above that a surface reaction proceeding by a strict half-order rate

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

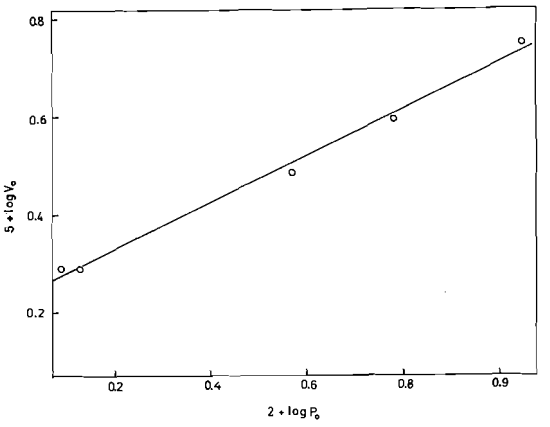

FIG. 3. Log–log plot of initial reaction rate (V_0) *vs.* initial reactant pressure (P_0) derived from curves in Fig. 2.

law is very difficult to explain by any mechanism other than one involving rapid, reversible dissociative adsorption of reactant. Further, in order that such a predissociation result in an overall half-order reaction, it must involve an equilibrium 1 which lies to the left, *i.e.* one in which $k_{-1} > k_1$.

$$[1] \qquad AB + 2^* \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} A^* + B^*$$

where * = a univalent surface site. Thus, if an appropriately labelled mixture of reactants AB and A′B′ were reacted simultaneously, interchange of the kind shown in [2] should proceed more rapidly than any subsequent reactions.

$$[2] \qquad AB + A'B' \rightleftharpoons AB' + A'B$$

The successful experimental study of equilibrium 2, when A (or A′) = alkyl and B (or B′) = halide, for the case of dehydrohalogenation of a primary alkyl halide on titanium, required satisfaction of the following criteria. (*1*) Halogen exchange must be detectable and distinguishable from dehydrohalogenation by mass spectrometry. (*2*) Both exchanging halides must compete favorably with each other for surface sites and must undergo reaction at comparable rates. (*3*) The free energy of [2] should be close to zero. (*4*) Both reactants should react by the same mechanism.

The simplest kinds of reaction which satisfy all of the criteria outlined above are the exchanges between $R_d{}^{35}Cl$ and $R_h{}^{37}Cl$, or $R(^{12}C)^{35}Cl$ and $R(^{13}C)^{37}Cl$. The latter reaction was previously used by Anderson and McConkney (3). The limited performance of the partial pressure analyzer used in our system was insufficient to discriminate reliably between $R^{35}Cl$ and $R^{37}Cl$ under reaction conditions.

The pair of reactants 1-bromopropane and 1-chloropropane had previously been observed to react at a similar rate and according to the same rate law (1*a*). This behavior was also shown, in the course of the present study, to be true of mixtures of these reactants. The further demonstration that 1-chloropropane and 1-chloropropane-1-d_1 reacted at the same rate established the pair of reactants 1-bromopropane and 1-chloropropane-1-d_1 as apparently fulfilling all of the criteria listed above. An investigation of the possibility of halogen exchange between these reactants over titanium and chromium was therefore undertaken.

The reaction mixture used in all of the exchange experiments consisted of a mixture of 1-bromopropane (40 mol%) and 1-chloropropane-1-d_1 (60 mol%). The equilibrium product from halogen exchange in such a mixture would contain 1-bromopropane (20%), 1-bromopropane-1-d_1 (20%), 1-chloropropane (20%) and 1-chloropropane-1-d_1 (40%). By calibrating the partial pressure analyzer with each of these components, it was possible to generate a continuous series of spectra from reactants to products, assuming halogen exchange to be the only reaction. Examination of these spectra showed that two peak ratios (42/43 and 44/43) were particularly sensitive to the exchange reaction. The 42/43 peak ratio changed from 0.30 to 0.7 and the 44/43 ratio from 0.15 to 0.36 on passing from the starting mixture to exchange equilibrium.

In the absence of the full fragmentation patterns for the deuterated propenes and propanes, it was not possible to follow the detailed course of the dehydrohalogenation reaction but the overall mass spectrum was easily measured. Such measurements showed that whilst the 44/43 peak ratio only changed from 0.15 to 0.18 on proceeding to complete dehydrohalogenation, the 42/43 peak ratio changed dramatically from 0.3 in starting mixture to 2.2 at complete reaction.

Results of Exchange Experiments

Reactions were run on titanium at both 195° and 165° and at an initial reactant pressure of 0.01 Torr. At the higher temperature the dehydrohalogenation reaction proceeded to completion within the time of the experiment, but at

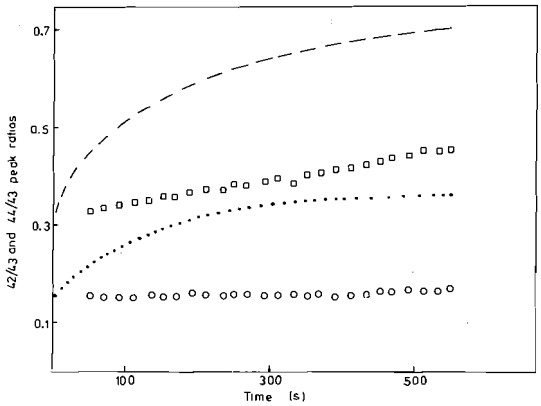

FIG. 4. Variation of 42/43 and 44/43 mass spectral peak intensity ratios for reaction of a mixture of 1-bromopropane and 1-chloropropane-1-d_1 on titanium at 165 °C. Initial pressure 0.014 Torr. Experimental points: ○, 44/43; □, 42/43. Theoretical curves, assuming equilibrium exchange after 10% dehydrohalogenation: ···, 44/43; ---, 42/43.

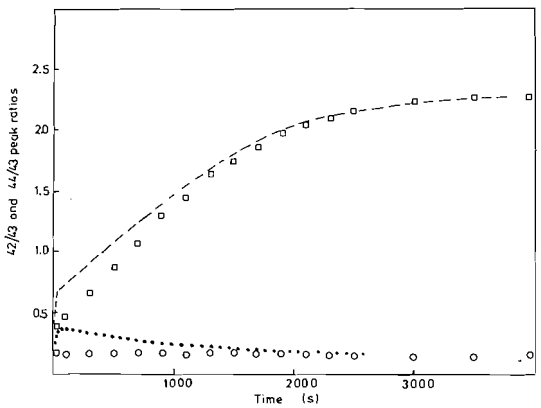

FIG. 5. Same as Fig. 4 but at 195 °C.

165° dehydrohalogenation is very slow and only proceeded to about 10% during the experiment. The results of these two experiments are shown in Figs. 4 and 5, together with curves illustrating the behavior expected for a reaction in which exchange proceeded to equilibrium by the time dehydrohalogenation was one-tenth complete. Although such a comparison is quite arbitrary, it does highlight the fact that the results give no indication of exchange occurring either before, or during, dehydrohalogenation. The rises in the 42/43 peak ratios in Figs. 4 and 5 can be entirely accounted for on the basis of the dehydrohalogenation reaction, but the failure of the 44/43 peak ratio to rise above 0.18 in either experiment cannot be reconciled with an exchange rate that is faster than dehydrohalogenation. These observations were confirmed by several repetitions of each experiment.

Although chromium metal undergoes poisoning by halide in the dehydrohalogenation of normal alkyl halides, it is possible to follow the reaction for several small doses (2). Experiments analogous to those described above gave essentially the same results on chromium, again indicating no appreciable halogen exchange.

Discussion

In the present work it has been established beyond any reasonable doubt that the high temperature dehydrochlorination of propyl chloride on titanium is a simple half-order reaction. Other studies have also shown that the reactions of ethyl and *n*-propyl chloride, bromide, and iodide (1*a*), and of 1,2-dichloroethane and 1,3-dichloropropane on titanium (1*c*) and of *n*-propyl chloride on V and Mn (2) are characterized by a reaction time-order of one-half.[2] It is now necessary to reconcile this apparently common simple kinetic pattern with the fact that halogen exchange between alkyl halides is not catalyzed by either of the metals so far studied.

The first and simplest possibility that presents itself is that the dissociative adsorption step involves not a C—Cl bond but a C—H bond. Such a dissociative adsorption at the 2-carbon atom, followed by chloride elimination would give the same overall rate behavior as the previously suggested mechanism (1*a*), in which dissociative C—Cl adsorption was followed by hydrogen elimination. The possibility that rapid reversible dissociative adsorption is occurring in these reactions has not yet been tested by, for example, looking for deuterium–hydrogen exchange between suitably labelled reactants, but the fact that 1,2-dihaloethanes and 1,3-dihalopropanes undergo clean dehalogenation without any detectable loss of hydrogen makes dissociative C—H adsorption an unlikely explanation of the half-order behavior in that case. Also, displacement of an alkyl residue from hydrogen rather than halogen as the initial step in an elimination reaction of an *n*-alkyl halide is

[2]Although the other metals of the first transition period may react similarly, the problem of surface poisoning by deposited halide precluded measurement of the kinetic rate law except for the metals cited above.

without precedent and can be argued to be unlikely on theoretical grounds (5).

A possible source of ambiguity in the present experiments is that the two alkyl halides may react selectively at different places on the reactive surface. Assuming such selective segregation of reactivity, it is possible to construct a model which accounts for lack of exchange yet still allows for the establishment of a dissociative preequilibrium between each reactant and its dissociation products at the surface. Although such a model resolves the present enigma, there is nothing in the experimental evidence to specifically support such a possibility.

The Infrared Spectrum Between 4000 and 200 cm^{-1} and the X-Ray Powder Diffraction Pattern of Hexamethylenetetramine Hexahydrate in Four Isotopic Forms at 100 K

JOHN E. BERTIE AND MARCO SOLINAS[1]

Department of Chemistry, University of Alberta, Edmonton, Alberta T6G 2G2

Received March 17, 1975

JOHN E. BERTIE and MARCO SOLINAS. Can. J. Chem. **53**, 2624 (1975).

The X-ray diffraction pattern of powdered hexamethylenetetramine hexahydrate (HMT-h_{12}·$6H_2O$) at 120 K has been recorded and analyzed. The thermal contraction occurs primarily along the trigonal axis. The infrared spectra of polycrystalline HMT-h_{12}·$6H_2O$, HMT-h_{12}·$6D_2O$, HMT-d_{12}·$6H_2O$, and HMT-d_{12}·$6D_2O$ at 95 K have been recorded. The most sensitive test for ice impurity is obtained from the OD stretching bands of HDO molecules in dilute solution in the hydrate, ν_{OD}(HDO), but ice impurity also affects the OH and OD stretching bands of H_2O and D_2O, $\nu_{OH}(H_2O)$ and $\nu_{OD}(D_2O)$. The absorption by HMT can be assigned to the single HMT molecule per diffraction unit cell. The symmetries of the vibrations under the C_{3v} diffraction site symmetry cannot be determined from this data, so the absorption is assigned to the parent vibration of pure HMT.

Three peaks arise from ν_{OH}(HDO) and ν_{OD}(HDO), at 2464 2369, and 2295 cm^{-1} for ν_{OD}(HDO). They can, with considerable uncertainty, be assigned to the three nonequivalent hydrogen bond lengths in the structure. An alternative assignment uses the hypothesis that the frequency of an O—D. . .O bond of given length is abnormally low when a three-coordinated oxygen atom is the base. A partial interpretation of the $\nu_{OH}(H_2O)$ and $\nu_{OD}(D_2O)$ bands is presented. It is quite clear that a large part of their breadth is due to Fermi resonance with the continuum of overtone and combination levels that lie close to the fundamental levels. Several fairly sharp features due to rotational vibrations of H_2O and D_2O, $\nu_R(H_2O)$ and $\nu_R(D_2O)$, provide the only evidence of the partial order in the positions of the hydrogen atoms. Three ν_R(HDO) frequencies have been detected, 860, 570, and 490 cm^{-1}. Their ratios agree well with the ratios of the square roots of the reciprocal moments of inertia, but not with the ratios of frequencies calculated following Blue's arguments.

JOHN E. BERTIE et MARCO SOLINAS. Can. J. Chem. **53**, 2624 (1975).

Le diagramme de poudre de l'hexaméthylènetétramine hexahydraté (HMT-h_{12}·$6H_2O$) a été pris à 120 K et a été interprété. La contraction thermique prend place principalement le long de l'axe d'ordre trois. On enregistre à 95 K les spectres infrarouges de HMT-h_{12}·$6H_2O$, HMT-h_{12}·$6D_2O$, HMT-d_{12}·$6H_2O$ et HMT-d_{12}·$6D_2O$ polycristallin. Le test le plus sensible des impuretés de glace est obtenu à partir des vibrations de valence de OD, ν_{OD}(HDO), des molécules HDO en solution diluée dans l'hydrate; mais les impuretés de glace modifient aussi les bandes de vibration de valence $\nu_{OH}(H_2O)$ et $\nu_{OD}(D_20)$ de OH et OD de H_2O et D_2O. L'absorption par HMT est attribuée à la seule molécule de HMT présente dans la maille cristalline. Il n'est pas possible de déterminer les symétries des vibrations en considérant la symétrie cristallographique ponctuelle C_{3v}; par conséquent l'absorption est attribuée à une vibration correspondante de HMT pur.

Trois pics à 2464, 2369 et 2295 cm^{-1} proviennent de ν_{OH}(HDO) et ν_{OD}(HDO) pour ν_{OD}-(HDO). On les attribue sans trop de certitude aux trois liens hydrogènes non équivalents de la structure. Une autre possibilité fait intervenir l'hypothèse que la fréquence d'une liaison O—D . . . O d'une longueur donnée est anormalement basse quand un atome d'oxygène de coordination trois en est la base. On interprète partiellement les bandes $\nu_{OH}(H_2O)$ et $\nu_{OD}(D_2O)$. Il est bien évident que la résonance de Fermi explique en grande partie la largeur des bandes avec le continuum des niveaux d'harmonique et de combinaison proche des niveaux fondamentaux. Plusieurs caractéristiques assez précises dues à des vibrations rotationnelles de H_2O et D_2O, $\nu_R(H_2O)$ et $\nu_R(D_2O)$ fournissent la seule preuve de l'ordre partiel des positions des atomes d'hydrogènes. Trois fréquences ν_R(HDO) à 860, 570 et 490 cm^{-1} ont été détectées. Leurs rapports coincident bien avec ceux des racines carrées des inverses des moments d'inertie, mais ne s'accordent pas avec les rapports des fréquences calculées d'après les arguments de Blue.

Introduction

Hexamethylenetetramine hexahydrate, $C_6H_{12}N_4 \cdot 6H_2O$, (hereafter called HMT·6H$_2$O) crystallizes from saturated aqueous solutions of HMT as colorless hexagonal needles which melt at 13.05 °C (1–5). The diffraction space group at −20 °C is $R3m$ (C_{3v}^5) with one formula unit per primitive unit cell, so that the diffraction site symmetry of the HMT molecule is C_{3v} (5). Two nonequivalent types of water molecules alternate in the structure, hydrogen bonded to form slightly-puckered hexagonal rings each of which is linked to six other hexagonal rings, thus forming cavities in which the HMT molecules are located (5). The compound can, thus, be termed a clathrate hydrate (4, 5). It differs markedly from the clathrate hydrates with the common structures I and II (6) because each HMT guest molecule is hydrogen-bonded to the water lattice through three hydrogen bonds. This requires that half of the water molecules are four coordinated and half are only three coordinated. We will designate the oxygen atoms of these two types of water molecules O(IV) and O(III), respectively, to emphasize their coordination, although they are elsewhere designated O(2) and O(1), respectively (5–7).

The diffraction site symmetry of each type of water molecule is C_s, but the water molecules are partially orientationally disordered (5, 7). The X-ray results indicated that the hydrogen atoms in the three O(III)—H. . .O(IV) bonds per unit cell which join the hexagonal rings, and those in the three O(IV)—H. . .N bonds, are ordered, and the remaining six hydrogen atoms show the limited disorder which is possible within a hexagonal ring (5). However the high value of the static dielectric constant between −10 and −110 °C requires that only the hydrogen atoms in the O(IV)—H. . .N bonds are ordered and the rest are disordered (7). This means, however, that each water molecule occupies one of three possible configurations, rather than the one of six configurations possible in the disordered ices, neglecting short-range correlations in both cases. Further, each hydrogen bond between oxygen atoms is of the type O(IV). . .O(III), and the probability that the hydrogen atom is near to O(III) is 0.67, compared to 0.5 in the ices, neglecting local correlation effects in both cases. Thus the degree of order in the orientations of the water molecules in HMT·6H$_2$O is considerable. The temperature dependence of the breadth of the dielectric absorption has led to the further suggestion that long-range ordering of the hydrogen atoms may occur at low temperatures (7).

The present study forms part of an examination of the vibrational spectra of the clathrate hydrates in this laboratory, to study the absorption by water molecules in different intermolecular configurations and the spectra of the clathrated guest molecules (8–10). Of particular interest in the present study are the presence of the three-coordinated water molecules, the partial orientational order of the water molecules and the possibility of long-range order at low temperature, and the loss of degeneracy and possible activation of vibrations in HMT by the reduction in site symmetry from the T_d of pure HMT (ref. 11 and references cited therein, 12) to C_{3v} in the hydrate.

Experimental

The source and purity of the normal and perdeuterated hexamethylenetetramine (HMT-h_{12} and HMT-d_{12}) have been described (12). Laboratory distilled water and D$_2$O obtained from Atomic Energy of Canada Limited or Columbia Organic Chemicals Co. Inc. were used. The nuclear magnetic resonance spectrum of the D$_2$O, containing dimethyl sulfoxide as an internal standard, showed that it contained 0.5 ± 0.1% of hydrogen.

HMT·6H$_2$O was prepared from aqueous solutions saturated with HMT at 2 to 5 °C. The crystallization was initiated by cooling, with liquid nitrogen, the tip of the test tube which contained the solution. The tube was then warmed until only a few small crystals remained and was left for several days in a refrigerator or cold room at +3 or +5 °C, both constant to ±1 °C. When half of the solution had crystallized, the mother liquor was decanted, the crystals were dried on paper tissue, put into a glass vial, and cooled in liquid nitrogen. In most cases (see section 'Infrared Spectra') the dried crystals were further dried at 0 °C under vacuum until a white powder (HMT) was observed on their surface. HMT·6D$_2$O was prepared in the same way, after exposing the glassware to D$_2$O for at least 12 h.

The infrared samples were mulls in propane, propylene, or trifluorochloromethane (Freon-13) at 95 ± 5 K, and the spectra were recorded on a Beckman I.R. 12 spectrophotometer which was purged with dry nitrogen and calibrated to 0.5 cm^{-1} below, and 1.0 cm^{-1} above, 2000 cm^{-1}. The X-ray samples consisted of the powdered hydrate in capillary tubes at 120 ± 20 K, and a Jarrell-Ash precession camera was used as a flat-plate powder camera. Full details of the sample handling methods and the instrumentation and its calibration have been published (8–10, 13).[2]

X-Ray Powder Diffraction Pattern

The interplanar spacings deduced from photographs of three different samples of HMT-h_{12}·6-H_2O at 120 ± 20 K are given in Table 1, with the indices, approximate intensities, and 2θ values of the reflections (CuK_α radiation, $\lambda = 1.5418$ Å). The indices are based on the triply primitive hexagonal cell of Mak (5). Except for the value 31.38° which arises from two sets of planes, the 2θ values were used to refine the lattice parameters through the Fortran IV program DREFINE (14).[2] The d-spacings calculated from the refined lattice parameters are included in Table 1 and the parameters are compared in Table 2 with those determined by Mak for HMT-h_{12}·$6H_2O$ at 253 K. Also in Table 2, the hydrogen-bond lengths determined by Mak are compared with those determined from the lattice parameters at 120 K under the assumption that the fractional coordinates of the atoms are the same at the two temperatures. It is clear that HMT·$6H_2O$ undergoes no phase change between 253 and 120 K and that the thermal contraction occurs predominantly along the threefold axis of the crystal. The mean plane of each hexagonal ring of water molecules is nearly perpendicular to c, so the O(III)...O(IV) hydrogen bonds in the ring contract very little on cooling. The O(III)...O-(IV) hydrogen bonds between the rings and the O(IV)...N bonds form angles 27 and 61°, respectively, with the c-axis, and contract by 0.025 and 0.01 Å, respectively, on cooling.

Infrared Spectra

The original spectra were of mulls in propane, propylene, and Freon 13, and contained the

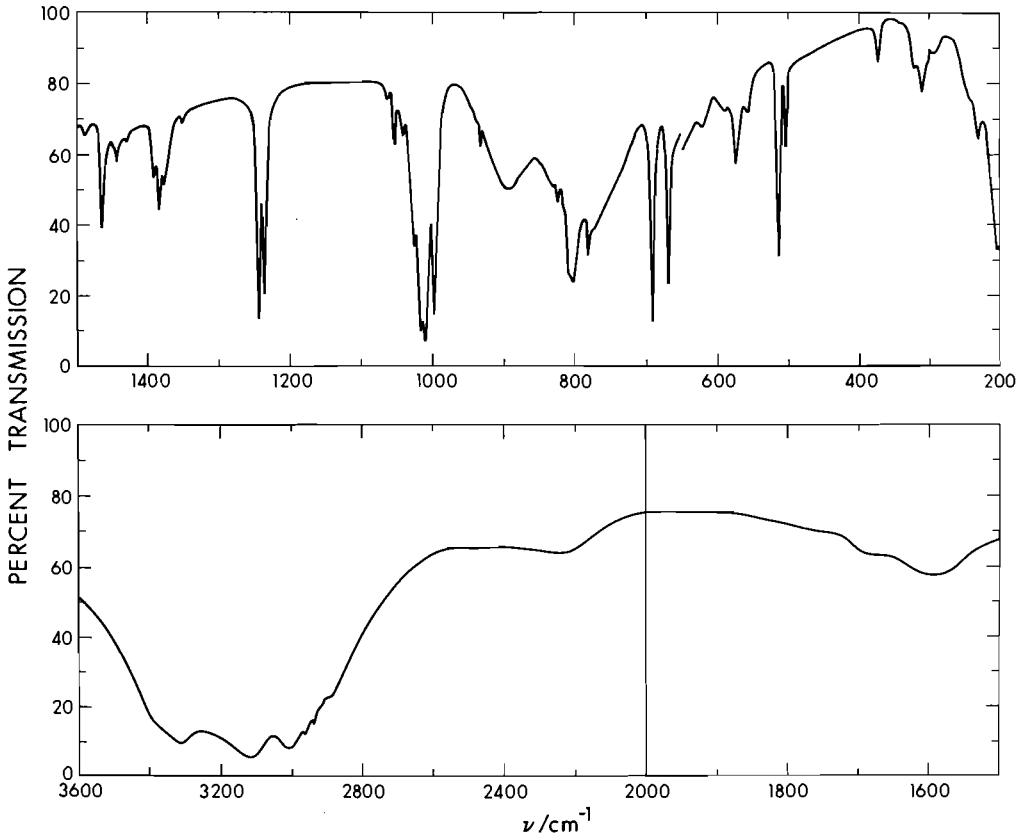

FIG. 1. The infrared spectrum of hexamethylenetetramine-h_{12} hexahydrate at 95 ± 5 K.

absorption by the mulling agents shown in Figs. 1 and 2 of ref. 9. From numerous spectra of each compound in the three mulling agents, the infrared spectra of HMT-h_{12}·6H$_2$O, HMT-d_{12}·6H$_2$O, HMT-h_{12}·6D$_2$O, and HMT-d_{12}·6D$_2$O at 95 K were deduced; these spectra are presented in Figs. 1 to 4. The resolution was better than 5 cm^{-1} below 650 cm^{-1} and better than 2 cm^{-1} above 650 cm^{-1}. The relative intensities of features taken from spectra in different mulling agents were scaled to give as accurate a description in Figs. 1 to 4 as possible. The region between 1300 and 2000 cm^{-1} has been omitted from Figs. 2 and 4 because the only observed features were the very broad features, which are due to the water, that can be seen in Figs. 1 and 3. No features were seen above 3600 cm^{-1} for HMT-h_{12}·6H$_2$O (Fig. 1) or above 3400 cm^{-1} for HMT-h_{12}·6D$_2$O (Fig. 3). The apparent drift in the absorption above 3600 cm^{-1} shown in Fig. 2 is undoubtedly due to reflection effects. The frequencies of the spectral features are listed in Table 3, with estimates of their accuracy. The only uncertainties in the spectra are: the exact shape of the high-frequency side of the strong absorption at 915 cm^{-1} by HMT-d_{12}·6H$_2$O (Fig. 2); the exact shape of the broad absorption near 1600 cm^{-1} by the deuterates (Fig. 3); the existence of the features at 1435 ± 1 cm^{-1} in the spectra of HMT-h_{12}·6H$_2$O and HMT-h_{12}·6D$_2$O (Figs. 1 and 3). All of these uncertainties are due to absorption by the mulling agents partly overlapping the features in question.

The assignment of the absorption peaks to vibrations of the water and HMT molecules follows from the isotope shifts. It is given in Table 3, where the letter subscripts to the symbol ν indicate vibrations of the water molecules and the number subscripts indicate vibrations of HMT molecules. The general assignment of the water absorption is obtained by comparison with the spectrum of ice (15).

The presence of ice impurity in the hydrate samples was carefully investigated. Initially the samples were dried on paper tissue but not under vacuum, and they all showed the very strong 00.2

*vw = very weak, w = weak, m = medium, s = strong, vs = very strong, sh = shoulder, br = broad. The letter subscripts to ν indicate vibrations of water; ν_B is usually called ν_2(H$_2$O) or ν_2(D$_2$O), and includes the possibility of $2\nu_R$. The numbered subscripts to ν indicate vibrations of HMT, where the vibrations are numbered as for pure HMT.

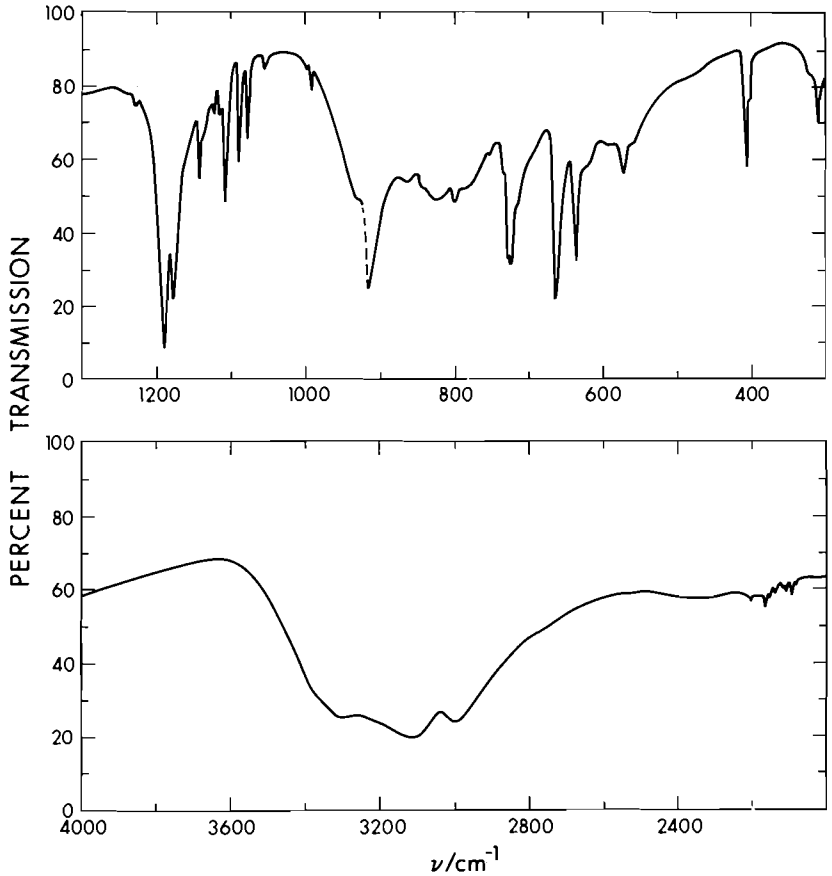

FIG. 2. The infrared spectrum of hexamethylenetetramine-d_{12} hexahydrate at 95 ± 5 K. The dashed line near 920 cm^{-1} indicates a region of slight uncertainty, due to absorption by the mulling agents. The spectrum between 1300 and 2000 cm^{-1} has been omitted for reasons given in the text.

line of ice Ih (16) as a very weak line at $2\theta \sim 24°$ in their X-ray powder pattern. The absorption by these samples is shown as curve *b* of Fig. 5. Samples that were dried under vacuum (Experimental section) showed no X-ray line at $2\theta \sim 24°$, and their absorption is shown as curve *a* of Fig. 5. Thus even a very small, as judged from the X-ray photograph, amount of ice impurity has a profound effect on the $\nu_{OH}(H_2O)$ band. The effect of ice impurity on the $\nu_{OD}(D_2O)$ band is much smaller, as shown by curves *a* (deuterate dried under vacuum) and *b* (deuterate not dried under vacuum) of Fig. 6. There was no detectable effect of ice impurity on the rest of the spectrum of either the hydrate or the deuterate.

The absorption by HDO in dilute solution in the hydrate or the deuterate provides the most sensitive test for ice impurity. The absorption by ν_{OH} and ν_{OD} of HDO in about 10 mol% solution in the deuterate and hydrate, respectively, is shown in Fig. 7. The short-dashed lines at ~3280 and 2420 cm^{-1} show where the absorption by $\nu_{OH}(HDO)$ or $\nu_{OD}(HDO)$ of ice appeared. This absorption was clearly visible even in samples whose $\nu_{OH}(H_2O)$ or $\nu_{OD}(D_2O)$ absorption was that shown as curves *a* in Figs. 5 and 6, and whose X-ray pattern gave no indication of ice impurity. The weak shoulders shown by the short-dashed lines are believed to be due to residual ice impurity. The pure HMT which was formed in small amounts when the samples were dried under vacuum did not influence the spectrum detectably, although its very strong 110 reflection (17) did contribute weakly to the X-ray powder pattern at $2\theta \sim 17°$.

The absorption by HDO molecules in the hydrate and deuterate was studied at HDO concentrations ranging from 2 to 10 mol%. The

frequencies, half-widths, approximate relative intensities, and isotope frequency ratios of the bands due to ν_{OH}(HDO) and ν_{OD}(HDO) are given in Table 4. Samples of hydrate and deuterate containing 10 mol% of HDO also showed HDO absorption at ~490 and 860 cm^{-1}, respectively, undoubtedly due to the rotational vibrations of HDO, ν_R(HDO). This absorption is shown in Fig. 8, which compares the absorption near the ν_R band of the host water molecules by pure hydrate and deuterate (actually 99.5% D_2O) with that by hydrate and deuterate containing 10% of HDO. These spectra show a third effect of HDO impurity, a significant broadening of the rather sharp bands due to $\nu_R(H_2O)$ at ~558, 571, and 590 cm^{-1}. These bands are expected near 420 cm^{-1} in the deuterate and probably correspond to the doublet 415.5/425 in HMT-h_{12}·6D_2O or 417.0/435 in HMT-d_{12}·6D_2O. These features in the deuterate show no effect of HDO impurity,

which does, however, cause an effect on the spectrum of the deuterate near 490 cm^{-1} and, as in the hydrate, near 570 cm^{-1}.

Discussion of the Absorption by the Hexamethylenetetramine Molecules

The absorption by HMT is sharp and well resolved (Figs. 1–4, 8), while that due to the water molecules is much broader. This suggests that the absorption by HMT can be interpreted by a diffraction factor group analysis of the single HMT molecule in the primitive diffraction unit cell, in spite of the known disorder of the water molecules. This may arise from the fact that neighboring HMT molecules are quite far apart (5), so that coupling of the vibrations of neighboring HMT molecules is small with the result that sharp absorption occurs even if vibrations of

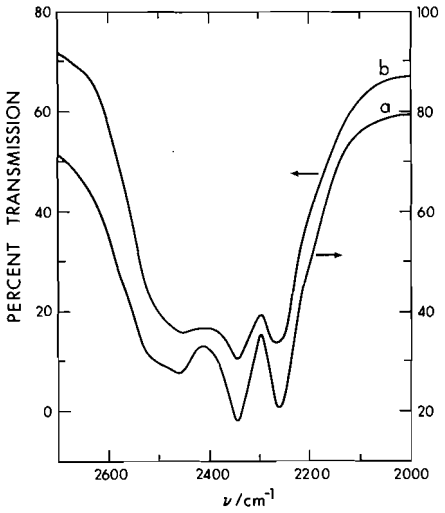

FIG. 6. The absorption by $\nu_{OD}(D_2O)$ in hexamethylenetetramine-h_{12} hexadeuterate at 95 ± 5 K. The deuterate sample was dried under vacuum for curve *a* but not for curve *b*. The arrows indicate the appropriate transmission scale.

nonzero wave vector (defined by the diffraction lattice) are active.

This interpretation also implies that no coupling occurs between the vibrations of HMT molecules and those of water molecules. This is probably not quite true, although it is a useful approximation, because there is some host dependence of the absorption by HMT. For HMT-h_{12}, the absorption at 812.9(s), 820.2(m), and 825 (sh) cm^{-1} by the deuterate (Figs. 3, 8) is sharper than, and different from, the corresponding absorption by the hydrate at 805.2(s), 810.2(sh), 820(sh), and 825.6(w) cm^{-1} (Fig. 1), even though the medium peak at 783.9 cm^{-1} is the same for both hosts. The doublet at 503.3/510.0 cm^{-1} in the spectrum of HMT-h_{12}·6D$_2$O is much weaker than the corresponding doublet at 502.6/512.6 cm^{-1} in that of HMT-h_{12}·6H$_2$O. The absorption at 999.3(vs), 1012.3(vs), 1018.0(vs), and 1027.3(vs) cm^{-1} by HMT-h_{12}·6H$_2$O changes to 998.6(vs), 1012.6(vs), and 1022(sh) cm^{-1} by HMT-h_{12}·6D$_2$O, and the doublet at 1237.0/1245.3 cm^{-1} in the spectrum of HMT-h_{12}·6H$_2$O is very well resolved while the corresponding doublet at 1238.3/1245.5 cm^{-1} in that of HMT-h_{12}·6D$_2$O is not. Similar differences can be seen in the absorption by HMT-d_{12} in the two hosts. The absorption at 728.5(s) and 734(sh) cm^{-1} by HMT-d_{12}·6D$_2$O (Fig. 4) corresponds to that at 717.3(sh), 722.4(s), 727.2(s), and 734(sh) cm^{-1} by HMT-d_{12}·6H$_2$O (Figs. 2 and 8). A shoulder and a peak appear at 403 and 405.7 cm^{-1}, respectively, in the spectrum of HMT-d_{12}·6H$_2$O, while two peaks at 400.5 and 417.0 cm^{-1} are seen in that of HMT-d_{12}·6D$_2$O, in which the 417.0 cm^{-1} peak is almost certainly due to $\nu_R(D_2O)$. Two strong, partly resolved peaks at 903.3 and 911.3 cm^{-1} in the spectrum of HMT-d_{12}·6D$_2$O correspond to a shoulder and a peak at 905 and 915 cm^{-1} in that of HMT-d_{12}·6H$_2$O, while other weaker absorptions by the deuterate at 932.6, 936, and 939.1 cm^{-1} are undetectable for the hydrate, even though they are undoubtedly due to HMT-d_{12}. Other smaller frequency and resolution differences between the spectra of the hydrate and deuterate are visible between 1100 and 1200 cm^{-1}. In particular, the very strong doublet absorption at 1177.7/1190.8 cm^{-1} by the hydrate is better resolved than that at 1174.2/1191.2 cm^{-1} by the deuterate.

Quite strong static forces exist between the water and HMT molecules, because they are joined by hydrogen bonds and because the HMT molecules are significantly distorted from the T_d symmetry of pure HMT (ref. 11 and references cited therein, 12) to the C_{3v} site symmetry in the hydrate and deuterate (5). Dynamic forces of similar origin could clearly cause the vibrations of the HMT and water molecules to interact, harmonically or anharmonically. Where the sharp HMT absorption is underlain by much broader, strong absorption by the water, such interaction is expected to broaden the sharp absorption. Transition dipole – transition dipole forces can have the same effect, and either of these forces can be used to rationalize the majority of the differences cited above, where the bands become less sharp and well-defined when they are very close to strong absorption by the water. However, it is not clear from these interpretations why the absorptions at 637.0 and 663.2 cm^{-1} by HMT-d_{12}·6H$_2$O, and those at 783.9, 670.9, and 692.0 cm^{-1} by HMT-h_{12}·6H$_2$O, are not more affected by replacement of H$_2$O by D$_2$O. Nor is it clear why the bands of HMT-h_{12} near 1000 cm^{-1} do differ so much in the spectra of the hydrates and deuterates, because neither host lattice has very strong absorption in this region, although they both probably absorb quite

For personal use only.

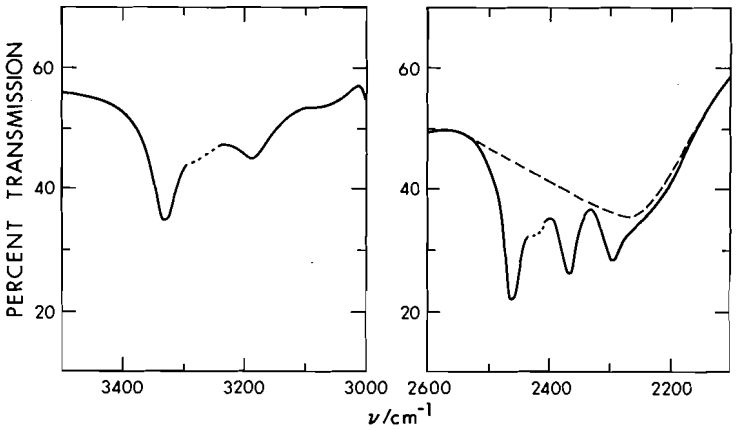

FIG. 7. The absorption by ν_{OH}(HDO) (left box) and ν_{OD}(HDO) (right box) in samples of hexamethylenetetramine hexahydrate (right box) and hexadeuterate (left box) at 95 ± 5 K which contain about 10 mol% of HDO. The long-dashed line indicates underlying H_2O absorption and the short-dashed line indicates absorption by ice impurity.

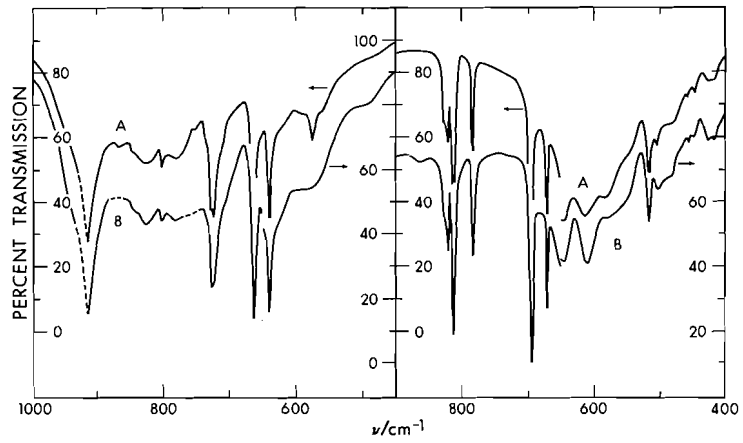

FIG. 8. Infrared absorption by HMT-d_{12}·6H_2O (left) and HMT-h_{12}·6D_2O (right) at 95 K. Curves *A* pure hydrate and deuterate (99.5% D_2O). Curves *B* samples containing 10 mol% of HDO. The breaks in the curves at 650 cm^{-1} are instrumental effects and the dashed lines indicate where the exact shape of the curve is uncertain. The arrows indicate the appropriate transmission scale.

strongly through overtone and combination transitions as is the case in ice Ih (18). Symmetry arguments cannot be used to explain these differences in behavior, because of the orientational disorder of the water molecules, and from the present evidence no further understanding seems possible. For those bands of HMT which differ in the spectra of the hydrate and the deuterate, we tentatively assume that the absorption that is sharper and better defined is characteristic of a single HMT molecule under the C_{3v} diffraction site symmetry in the hydrate or deuterate.

The correlation table between the point groups T_d and C_{3v} is given in Table 5. Lower case letters are used for the representations under C_{3v} to avoid confusion. Thus under the C_{3v} symmetry, the $9F_2$ modes of pure HMT (12) yield $9a_1 + 9e$ modes, the $6F_1$ modes become active through their *e* components, the $4A_1$ and $5E$ modes become infrared active, and only the single A_2 mode remains inactive by symmetry. The present data provide no evidence of the symmetry of the vibrations under C_{3v} that cause the various absorptions. Therefore we have assigned the HMT absorption by assuming that the frequency of a vibration in the hydrate or deuterate is very close to that of its parent vibration of pure HMT. Further, we have identified the vibrations by the number of the parent vibration (12). The

assignment of the fundamentals and a plausible, but not necessarily unique, assignment of the overtone and combination transitions is given in Table 3.

The effect of the C_{3v} site symmetry upon the vibrations of HMT is clearly seen. Nearly all of the modes derived from the A_1, E, and F_2 modes of pure HMT (12) can be readily assigned in the infrared spectra of the hydrate and deuterate, and the F_2 modes yield clear doublets ($a_1 + e$) in most cases. The only such vibrations that are not observed are those based on $\nu_{10}(E)$ of pure HMT-h_{12} and -d_{12} (~460 and ~432 cm^{-1}, respectively (12)) and the asymmetric CD_2 stretching modes, above 2200 cm^{-1} (12). However, only limited information is obtained about the F_1 modes of pure HMT. The absorptions by HMT-h_{12} and -d_{12} at 372 and 309 cm^{-1}, respectively, are undoubtedly derived from $\nu_{16}(F_1)$. The absorption by HMT-h_{12} at about 934, 1050, 1326, and 1389 cm^{-1} may be derived from $\nu_{15}(F_1)$ to $\nu_{12}(F_1)$, but may alternatively be derived from $2\nu_{10}$ or $\nu_{10} + \nu_{25}$, $\nu_{16} + \nu_{24}$, $\nu_{23} + \nu_{25}$ or $2\nu_{24}$, and $\nu_9 + \nu_{16}$ or $\nu_{10} + \nu_{15}$, respectively. Similarly, the absorption by HMT-d_{12} near 800 and 1000 cm^{-1} may be derived from $\nu_{15}(F_1)$ and $\nu_{13}(F_1)$ or from $2\nu_{25}$ and $\nu_{16} + \nu_{23}$.

Further discussion of the vibrations of HMT in its clathrate hydrate is best left until the symmetries, under C_{3v}, of the transitions causing the peaks are known from the Raman spectra of single crystals. These spectra are currently being obtained in this laboratory.

Discussion of the Absorption by the Water Molecules

OH and OD Stretching Vibrations

The frequencies, half-widths, and relative intensities of the absorption bands due to the OH and OD stretching modes of HDO (Fig. 7, Table 4) are the same for HDO concentrations between 2 and 10%. Therefore they reflect the properties of dynamically uncoupled OH or OD bonds. The half-widths are approximately the same as those for ice Ih (15, 19) and far exceed those for the ordered forms of ice, II and IX (20). Thus, they reflect the disorder in the positions of the hydrogen atoms, and give no evidence of the partial order. There are clearly three vibrationally nonequivalent types of OD (or OH) bonds in the structure, and if they were all O—D. . .O bonds, their multiplicities would be in the ratio of the absorption intensities, approximately 4, 2, and 1 in order of decreasing vibrational frequency (Table 4). One of these types of bonds must be, however, the O—D. . .N bond, whose intrinsic absorption intensity is expected to differ from that of O—D. . .O bonds.

Vibrationally nonequivalent O—D. . .O (or O—H. . .O) bonds are usually associated with different O—D. . .O lengths (9, 21). Bertie and Othen (9) have correlated the ν_{OD}(HDO) frequencies in the ice phases and ethylene oxide hydrate with the corresponding O---O distances. According to their correlations, the present frequencies correspond to the following O---O distances: 2464 cm^{-1}, 2.78 to 2.81 Å; 2369 cm^{-1}, 2.60 to 2.68 Å; 2295 cm^{-1}, 2.45 to 2.60 Å. These clearly do not agree well with the distances presented in Table 2, although the 2.78 Å may be as close to 2.76 Å as can be expected.

Falk and Knop (21) have presented two relations which correlate the frequencies reasonably well with the hydrogen bond lengths for various O—D. . .O and O—D. . .Cl bonds. To combine the two sets of data they converted the O---Cl lengths to equivalent O---O lengths, by subtracting 0.4 Å, the difference between the van der Waals radii of chlorine and oxygen (22). Their relations are: (*1*) $R = a - b(\Delta\nu)$ and (*2*) $R = C$ ($\ln d - \ln \Delta\nu$), where $a = 2.997$ Å, $b = (8.40 \pm 1.31) \times 10^{-4}$ Å cm, $\Delta\nu = (2727 - \nu)$ cm^{-1}, $C = 0.1391$ Å, and $\ln d = 25.56$.[3] These correlations gave the bond lengths associated with the frequencies 2464, 2369, and 2295 cm^{-1} as: correlation (*1*) 2.78, 2.70, 2.63 Å; correlation (*2*) 2.78, 2.74, 2.71 Å. The predicted O—D. . .N bond length can be calculated from these by the method of Falk and Knop by adding 0.1 Å, the

[3]These relations are incorrect in ref. 21. We thank M. Falk for providing the correct expressions.

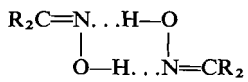
difference between the van der Waals radii of nitrogen and oxygen (22). From correlation (*2*) one can, then, assign the vibrations at 2464 cm^{-1} to the six O—D. . .O bonds within the hexagonal ring (5) of the unit cell, of length 2.76 Å (Table 2) rather than the 2.78 Å calculated, the vibrations at 2369 cm^{-1} to the three O—D. . .O bonds per unit cell, of length 2.74 Å, which link the hexagonal rings, and the vibrations at 2295 cm^{-1} to the three O—D. . .N bonds per unit cell, of length 2.81 Å. Falk and Knop (21) give the standard deviation of the bond length calculated from an observed frequency using their correlations as 0.03 Å, so the difference between 2.78 and 2.76 Å is not significant. Thus both the relative intensities and the frequencies are explained in this way, if one assumes that the O—D. . .N bond absorbs less strongly than the O—D. . .O bonds by a factor of about 2.

In spite of this agreement, the reliability of this assignment is very unclear. Only one of the four possible correlations fits the frequencies and bond lengths at all well. Further, all of the correlations are based on frequencies above 2420 cm^{-1}, so large extrapolations are involved for the two lower frequencies. Finally, the separation of the frequencies associated with O—D. . .O bonds of lengths 2.76 and 2.74 Å is predicted by the correlations to be 10 or 18 cm^{-1} (9), 24 cm^{-1} ((21), correlation (*1*)) and 45 cm^{-1} ((21), correlation (*2*)), compared with the observed difference, according to this assignment, of 95 cm^{-1}. To support this point, we are aware of no crystal which is formed primarily from hydrogen-bonded water molecules in which O—D. . .O bonds which differ in length by 0.02 Å have O—D stretching frequencies which differ by more than 25 cm^{-1}; it must be admitted, however, that only a small amount of data is available on this point. In summary, it appears that, if the above assignment is correct, hexamethylenetetramine hydrate shows most unusual behavior. Two sources of such unusual behavior are evident, the hydrogen-bonded nitrogen atoms and the three-coordinated water molecules. However, the probability that these cause unusual behavior leads immediately to an alternative assignment of the bands due to ν_{OD}(HDO).

This alternative assignment is based on the hypothesis that an O(IV)—D. . .O(III) hydrogen bond, in which a three-coordinated oxygen atom acts as the base, has a much lower frequency for a given O---O distance than does a normal O(IV)—D. . .O(IV) bond or an O(III)—D. . .O-(IV) bond. There are six O(III)—D. . .O(IV) bonds, three O(IV)—D. . .O(III) bonds, and three O(IV)—D. . .N bonds per unit cell of this hydrate (5). From the intensity ratio of the bands at 2464, 2369, and 2295 cm^{-1}, the six O(III)—D. . .O(IV) bonds can be assigned to the vibrations at 2464 cm^{-1}, the three O(IV)—D. . .O(III) bonds to the vibrations at 2369 cm^{-1}, and the O(IV)—D. . .N bonds to the vibrations at 2295 cm^{-1}. In fact, since the frequencies of O(IV)—D. . .O(III) bonds are postulated to be abnormal, the intensities could also be abnormal so other permutations of the assignment are possible, but this assignment minimizes the abnormality.

There is little evidence in the literature concerning the probable frequency of an O—D. . .N bond of length 2.81 Å. Nakamoto *et al.* (23) have correlated O—H. . .N bond lengths *vs.* ν_{OH} for cyclic systems of the type



but such correlations are of little relevance to the present case, particularly as they did not result from isotopic dilution studies to eliminate the effects of intermolecular vibrational coupling. Falk (24) has studied ν_{OD}(HDO) in trimethylamine hydrate and found a single peak at 2420 cm^{-1}. This hydrate must also contain three-coordinated water molecules, since one hydrogen atom is occupied by a hydrogen bond to the nitrogen (25). However in trimethylamine hydrate the multiplicity of normal O—D. . .O hydrogen bonds with four-coordinated water molecules acting as the base is 74, while those of the O—D. . .N and the O—D. . .O bonds with a three-coordinated water molecule as the base are both 4. Thus the bands due to ν_{OD}(HDO) for the latter two types of bond may well have been too weak to observe. It must be concluded that there is no evidence to support or to refute this second assignment, and it is as likely to be correct as the assignment which is based on the bond lengths. It should be noted that the second assignment, based on the coordination of the base, implies that the frequencies due to bonds 2.74 and 2.76 Å long are close enough to be unresolved in the two higher frequency bands, which have halfwidths of 30 and 35 cm^{-1}. The correlations clearly allow

TABLE 6. The assignment of the ν_{OH}(HDO) and ν_{OD}(HDO) bands in hexamethylenetetramine hexahydrate at 95 K

this requirement as they predict the separation to be as small as 10 cm^{-1}. The two assignments of the ν_{OH}(HDO) and ν_{OD}(HDO) bands are summarized in Table 6.

The bands due to $\nu_{OH}(H_2O)$ and $\nu_{OD}(D_2O)$ in solids formed by hydrogen-bonded water molecules are not well understood (9, 15, 18, 20, 26–28). There are, however, features of these bands in the present case, and of the structure of hexamethylenetetramine hydrate, which indicate a partial interpretation. The $\nu_{OD}(D_2O)$ band has maxima at 2256, 2341, and 2475 cm^{-1} and a shoulder at 2525 cm^{-1} (Fig. 6). These frequencies are close to 2295, 2369, and 2464 cm^{-1}, those of ν_{OD}(HDO). This similarity between the frequencies of ν_{OD}(HDO) and $\nu_{OD}(D_2O)$, and the quite large differences between the three ν_{OD}(HDO) frequencies, suggest that coupling between the vibrations of different O—D bonds is much smaller in this compound than in the deuterated ices and ethylene oxide deuterate, where no similarity between the frequencies of ν_{OD}(HDO) and $\nu_{OD}(D_2O)$ exists (9, 15, 20, 26).

One can be more specific about the vibrational coupling. According to either of the assignments of the ν_{OD}(HDO) bands, intramolecular coupling between the vibrations of the two O—D bonds on the four-coordinated oxygen atoms can only shift the vibration frequencies of these bonds by $\lesssim$20 cm^{-1} ($\lesssim$10 cm^{-1} for H_2O), because their isolated frequencies are 2295 and 2369 cm^{-1}, or 2295 and 2464 cm^{-1}, too different to allow strong coupling. If the second assignment of the ν_{OD}(HDO) bands is correct, the two O—D bonds attached to the three-coordinated oxygen atoms have the isolated vibration frequency 2464 cm^{-1}, so intramolecular coupling is expected to lead to symmetric and asymmetric vibrations of D_2O, separated by about 70 cm^{-1} (40 cm^{-1} for H_2O). Further, according to this assignment, strong intermolecular coupling between O—D vibrations is only possible between the O(III)—D . . .O(IV) bonds, because the other two types of bonds are surrounded by bonds of a different type. Thus the only strong coupling expected is intramolecular coupling between the two O(III)—D. . .O(IV) bonds which are attached to the same O(III) and intermolecular coupling between the two O(III)—D. . .O(IV) bonds about the same O(IV). We thus expect the bands due to $\nu_{OD}(D_2O)$ near to 2256 and 2341 cm^{-1} to be due to essentially uncoupled vibrations of O(IV)—D. . .N and O(IV)—D. . .O(III), respectively, and the features at 2475 and 2525 cm^{-1} to be due to the vibrations of O(III)—D. . .O(IV) which are subject to intramolecular and intermolecular coupling. The intermolecular coupling is expected to be less extensive than in ice I.

Arguments based on the first assignment of ν_{OD}(HDO) lead to a similar interpretation. There can be no strong intramolecular coupling of the vibrations of the O—D bonds attached to O(IV) (see above). Further, these vibrations cannot undergo strong intermolecular coupling because the nearest neighbor bonds are all of a different type. Thus the two low frequency peaks in the $\nu_{OD}(D_2O)$ band are due to essentially uncoupled vibrations of the O—D. . .N bonds and the O—D. . .O bonds between the rings. The ν_{OD} vibrations of the O—D. . .O bonds within the hexagonal rings are subject to intramolecular or intermolecular coupling. Intramolecular coupling occurs if both of the deuterium atoms attached to a three-coordinated oxygen atom are bonded within a hexagonal ring, and there is a 33% probability that this occurs. The remaining

67% probability is that a three-coordinated oxygen atom will act as the acid in one deuterium bond in the ring and as the base in a second deuterium bond in the ring, and in this case intermolecular coupling will occur.

Thus both of these assignments of the O—D stretching vibrations of HDO lead to the same conclusion. The bands due to $\nu_{OD}(D_2O)$ at 2475 and 2525 cm^{-1} are due to the coupled vibrations of O—D bonds whose isolated frequency is 2464 cm^{-1}. The bands at 2256 and 2341 cm^{-1} are due to the essentially uncoupled vibrations whose isolated frequencies are 2295 and 2369 cm^{-1}. These latter two bands are clearly shifted by 34 ± 6 cm^{-1} to low frequency in the pure deuterate, while the two higher frequency features are centered 36 cm^{-1} to high frequency of 2464 cm^{-1}. These shifts are probably due to Fermi resonance with $2\nu_2(D_2O)$ which is expected near 2400 cm^{-1}.

The OH stretching bands can be interpreted in the same way. The $\nu_{OH}(H_2O)$ bands are broader and less well-defined than the $\nu_{OD}(D_2O)$ bands (Figs. 5 and 6), as is usually the case (9, 15, 20, 26, 28) and must be due to anharmonic effects. The extraordinary breadth and diffuseness of the $\nu_{OH}(H_2O)$ and $\nu_{OD}(D_2O)$ bands may arise from anharmonic effects, or from the combined effect of strong vibrational coupling plus the absence of selection rules in orientationally disordered crystals (15, 20, 27, 28). It has been argued above that intermolecular coupling effects must be far smaller in HMT hydrate than in the ices, yet the $\nu_{OH}(H_2O)$ and $\nu_{OD}(D_2O)$ bands of the hydrate (deuterate) are just as broad as those of the ices and the component peaks are very broad for a system with little vibrational coupling. This provides strong evidence that the breadth of these bands is largely due to anharmonic interaction (Fermi resonance) between the fundamental stretching modes and the continuum of overtone and combination levels which underlies the fundamentals. These overtone and combination levels arise from the HOH or DOD angle bending modes, the water rotational modes, and the water translational modes. An objection to this interpretation is that the $\nu_{OH}(HDO)$ and $\nu_{OD}(HDO)$ bands are superimposed on the same continuum but are much sharper than the $\nu_{OH}(H_2O)$ and $\nu_{OD}(D_2O)$ bands. An answer to this objection which is worth placing in the literature, although it needs further theoretical investigation, is that there is not a continuum of overtone and combination levels due to HDO vibrations underlying the $\nu_{OH}(HDO)$ and $\nu_{OD}(HDO)$ fundamentals. It is probable that, with the possible exception of the translational vibrations of HDO, the vibrations of HDO do not couple extensively with the continuum of vibrations due to the host H_2O or D_2O molecules. Thus they do not form a continuum of overtone and combination levels which involve HDO motion with which $\nu_{OD}(HDO)$ and $\nu_{OH}(HDO)$ can Fermi resonate strongly. This interpretation is, clearly, somewhat speculative at present, but the experimental evidence suggests strongly that an interpretation along these lines is correct.

Rotational Vibrations

The bands due to the rotational vibrations of the water molecules $\nu_R(H_2O)$ and $\nu_R(D_2O)$ contain the sharpest features that have been seen on such bands in solids which are primarily formed from hydrogen-bonded water molecules (9, 15, 20, 26), except for the very sharp features seen for the ordered forms of ice, II and IX (20). For the deuterate these features are the two main peaks of the band at 645 and 612 cm^{-1} and the subpeak at 578 cm^{-1} (Figs. 3, 4, 8). For the hydrate these features are the peak at 891 cm^{-1} (Fig. 1) and sharper features near 800 cm^{-1} (Figs. 2, 8) and, particularly, at about 590, 571, and 558 cm^{-1} (Figs. 1, 2, 8). A detailed explanation of these features cannot be given because the ν_R bands are poorly understood (27, 28), even for the ordered forms of ice for which both sharp and very broad features are seen (20). It is probable, however, that they arise from the quite different hydrogen-bond strengths which exist in HMT hydrate at 100 K, judging from the isolated OH and OD stretching frequencies and the bond lengths, and the partial order in the positions of the hydrogen atoms.

Of particular interest is the broadening effect of the presence of a few percent of HDO molecules on the sharp features near 570 cm^{-1} in the $\nu_R(H_2O)$ band (Fig. 8). The sharp $\nu_R(H_2O)$ and $\nu_R(D_2O)$ features in the spectra of the ordered forms of ice broaden in the same way, and were consequently assigned to zero-wave-vector fundamental vibrations (20). The same is probably the case here even though HMT hydrate is only partially ordered.

The presence of a few percent of HDO also affects the spectrum of the deuterate near 570 cm^{-1} (Fig. 8), so it is clear that the third $\nu_R(HDO)$

mode also absorbs in this region. This then yields the frequencies 860, 570, and 490 cm^{-1} for the three rotational vibrations of HDO. The squares of these frequencies are in the ratio 3.1:1.35:1 which agrees well with the ratio of the reciprocal moments of inertia of HDO (29), 3.6:1.4:1. Blue (30) has argued that the three rotational vibrations of an isolated H_2O or D_2O molecule in an ice-like lattice have essentially the same frequency which, from specific heat data, he places at about 700 cm^{-1} for H_2O. His argument is that the restoring force on each atom depends linearly, and only, on its displacement, and is independent of the direction of the displacement and of whether it is a hydrogen or an oxygen atom. Using this argument, the squares of the ν_R(HDO) frequencies are calculated to be in the ratio 1.5:1.1:1, and to all be lower than the isolated $\nu_R(H_2O)$ frequencies. Clearly, neither of these results agrees with the experimental ν_R(HDO) frequencies. The experimental ν_R(HDO) frequencies are comparable to those observed in the ices (15, 20), so the structure of HMT hydrate is not responsible for the disagreement. It has been suggested that the ν_R(HDO) frequencies are coupled with the ν_R vibrations of the host lattice and are pushed apart by this coupling (15). An objection to this suggestion is that they still appear as rather sharp bands, which would not be expected if they do couple extensively with the host lattice. It is probable, therefore, that the ν_R(HDO) vibrations do not couple extensively with those of the host, and that Blue's model does not describe the rotational vibrations well.

The Far Infrared Spectra of Partially Orientationally Ordered Water Molecules: Hexamethylenetetramine Hexahydrate at 95 K

JOHN E. BERTIE AND MARCO SOLINAS[1]

Department of Chemistry, University of Alberta, Edmonton, Alberta T6G 2G2

Received March 17, 1975

JOHN E. BERTIE and MARCO SOLINAS. Can. J. Chem. **53**, 2642 (1975).

The far infrared spectra of four isotopic modifications of the partially orientationally ordered clathrate hydrate hexamethylenetetramine hexahydrate at 95 K are reported. The spectra are assigned to absorption allowed under the diffraction factor group, and to disorder-allowed absorption, following the theory for absorption by translational vibrations in orientationally disordered solids. Three phases formed primarily by hydrogen-bonded water molecules are known to be significantly, but only partially, orientationally ordered, hexamethylenetetramine hexahydrate, ice V, and ice VI. Of these phases, only ice VI fails to show sharp absorption in its far infrared spectrum in addition to the broad, disorder-allowed absorption.

JOHN E. BERTIE et MARCO SOLINAS. Can. J. Chem. **53**, 2642 (1975).

On décrit les spectres infrarouge lointain à 95 K des quatre modifications isotopiques de l'hydrate-clathrate d'orientation partiellement ordonnée de l'hexaméthylènetétramine hexahydraté. On attribue les spectres à des absorptions permises dans le groupe de facteur de diffraction et à des absorptions permises de désordre, suivant la théorie d'absorption par vibrations translationnelles dans des solides d'orientation désordonnée. Trois phases, l'hexaméthylènetétramine hexahydraté et les glaces V et VI, formées principalement par des molécules d'eau liées par des hydrogènes sont essentiellement d'orientation partiellement ordonnée. Parmi ces phases, seule celle de la glace VI ne montre pas dans le spectre infrarouge lointain une bande fine d'absorption en plus de la bande large d'absorption permise de désordre. [Traduit par le journal]

Introduction

The theory for absorption by translational vibrations in orientationally disordered molecular crystals (1) has been applied to several solids which are formed primarily by orientationally disordered, hydrogen-bonded water molecules (2–6). In such solids, the dipole moment derivative with respect to the displacement, in a given crystal direction, of one of a set of diffraction-equivalent molecules depends upon which molecule of the set is displaced (1). In a fully ordered crystal there would be no such dependence. For orientationally disordered crystals, therefore, the dipole moment derivative can be considered to contain two components: the average part is invariant from molecule to molecule within the set, and the irregular part depends totally upon which molecule of the set is displaced. Two types of absorption are predicted (1) to arise from these two components of the dipole moment derivative. The average part is predicted to yield sharp absorption, which arises from those vibrations which are allowed under the diffraction factor group of the crystal. The irregular part yields broad absorption, which is subject to no selection rules and corresponds to the density of vibrational states weighted by an intensity function. This intensity function is proportional to the square of the frequency in first approximation (1).

In all of the cases, except one, that have been studied to date (2–6), only broad absorption has been seen. This was, therefore, assigned to the density of vibrational states weighted by an intensity function. The one exception is ice V (3) which showed three rather sharp features between 150 and 90 cm^{-1}. These were tentatively assigned to 3 of the 18 vibrations which are allowed under the diffraction factor group (3). The absence of diffraction factor group allowed absorption by nearly all of the disordered phases studied to date can be rationalized in the following way. The dipole moment derivative with respect to O---O distance of an O—H...O bond must oppose that of an O...H—O bond. Therefore the direction of the dipole moment derivative with respect to the displacement of a hydrogen-bonded water molecule in a crystal should be closely related to the orientation of

that water molecule. In all of the disordered systems studied so far (2–6) the water molecules are all four-coordinated and, except in ices V and VI which are discussed later, each molecule of the sets of diffraction equivalent water molecules takes any one of the six orientations available to it with equal probability, neglecting the short-range correlation in the positions of the hydrogen atoms. Thus, the first approximation to the average part of the dipole moment derivative is zero. If the hydrogen atoms, and therefore the orientations of the water molecules, are partially ordered, the first approximation to the average part of the dipole moment derivative is not zero, and the diffraction factor-group-allowed vibrations may appear in the spectrum.

The literature concerning hexamethylenetetramine (HMT) hexahydrate has been recently reviewed (7). The diffraction factor group is isomorphous with C_{3v}. The diffraction site symmetries are C_{3v} for the one HMT molecule, and C_s for the six water molecules, per unit cell. The HMT molecules, and the three hydrogen bonds per unit cell which link them to the water molecules, are fully ordered (8). There are three four-coordinated and three three-coordinated water molecules per unit cell, and they are partially ordered to the point that they can adopt only three of the usual six orientations. The average part of the dipole moment derivative with respect to displacement of a water molecule is, therefore, expected to be quite large in the structure. Thus, sharp absorption which is allowed under the diffraction factor group is expected to be rather intense relative to the disorder-allowed absorption. In this paper we present the far infrared spectra of four isotopic modifications of HMT hexahydrate, and interpret the spectra according to the principles outlined above.

Experimental

The preparation and purification of HMT-h_{12}·6H$_2$O, HMT-h_{12}·6D$_2$O, HMT-d_{12}·6H$_2$O, and HMT-d_{12}·6D$_2$O have been reported (7). The samples were prepared as mulls in propane and held at 90 to 100 K by methods described elsewhere (5). Far infrared interferograms were recorded on a modified Beckman-R.I.I.C. model F.S. 720 interferometer, whose frequency accuracy is at least ± 0.2 cm^{-1} (5). The interferograms were recorded between $+0.65$ and -0.65 cm path differences and were Fourier transformed using triangular apodization. The intensities were obtained as the square roots of the sums of the squares of the sine and cosine transforms, and were ratioed against background spectra. The resulting spectra were then averaged in groups of four to enhance the signal-to-noise ratio. The theoretical resolution after apodization is 2.2 cm^{-1}, and spectra of gases have indicated a close similarity between the theoretical and actual resolutions.

Results and Discussion

The far infrared spectra of the four isotopic modifications of HMT hexahydrate at 95 K are shown in Fig. 1, and the frequencies of the features are listed in Table 1. The spectra clearly contain far more sharp features than those of any of the disordered phases studied previously (2–6), although a broad absorption is also present. The bands in the spectra of the HMT-d_{12} hydrate and deuterate appear rather broader than those for the HMT-h_{12} compounds. The low-temperature mulling technique is believed to be the source of this effect, because these spectra were studied

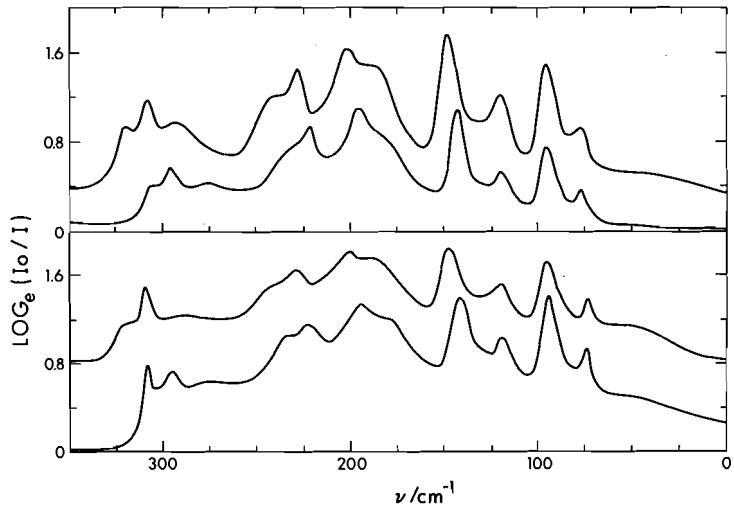

FIG. 1. Far infrared spectra of four isotopic forms of hexamethylenetetramine hexahydrate at 95 K. Upper box: upper curve is HMT-h_{12}·6H$_2$O, lower curve is HMT-h_{12}·6D$_2$O. Lower box: upper curve is HMT-d_{12}·6H$_2$O, lower curve is HMT-d_{12}·6D$_2$O.

primarily to obtain the frequencies of the features and, consequently, were not studied as extensively as those of the HMT-h_{12} compounds.

The feature at 309 cm^{-1} in the spectra of HMT-d_{12} hydrate and deuterate is due to the vibration which arises from $\nu_{16}(F_1)$ of pure HMT-d_{12} and is doubly degenerate under the C_{3v} diffraction unit cell group (7). The isotope shifts of the remaining features show that they arise from translational vibrations of water or HMT, or from rotational vibrations of HMT. The translational and rotational vibrations of HMT should be lower in HMT-d_{12} by about 4 and 9%, respectively, than in HMT-h_{12} if the HMT molecule vibrates against a body of infinite mass. In the present case, where the HMT vibrates against three water molecules, an isotope shift of about 1% is probably a closer approximation than 4% for the translational vibrations, and something less than 9% is expected for the rotational vibrations. The isotope shift on substitution of D$_2$O for H$_2$O should be 5% for relative displacements of one water molecule against another, and about 4.5% for water molecules vibrating against HMT. The exact shifts, of course, depend on the normal coordinates. The only assignments that can be made with any certainty from the observed isotope shifts are: (*1*) The rotational vibrations of HMT absorb at 78.2 cm^{-1}, shifting 5.3% on deuteration of the HMT and not significantly on deuteration of the water; (*2*) The vibration at 148.8 cm^{-1}, primarily involves translational vibrations of water molecules, with some translational motion of HMT; (*3*) The vibrations above 150 cm^{-1} are translational vibrations of water. The vibrations at 96 and 121 cm^{-1} definitely shift upon isotopic substitution, but the shifts are all very small. Apart from saying that they undoubtedly involve translational vibrations of water and HMT, no further assignment is possible until a normal coordinate calculation has rationalized these uniformly small isotope shifts.

The translational displacements of the water molecules form the representation $4A_1 + 2A_2 + 6E$ under the C_{3v} diffraction unit cell group, while the translational displacements of HMT form $A_1 + E$ and the rotational displacements form $A_2 + E$. The pure translations of the crystal form $A_1 + E$, which leaves $4A_1 + 3A_2 + 7E$ genuine vibrations with zero-wave-vector, of which $4A_1 + 7E$ are infrared active.

Eleven fairly sharp features are evident in the spectra of HMT-h_{12} hydrate and deuterate, so it is probable that these correspond to the 11 active vibrations under the diffraction factor group. Many of these features are rather broad compared with bands due to active vibrations in ordered crystals, such as ices II and IX (3), but this does not necessarily argue against this assignment. There is clearly broad, disorder-allowed absorption underlying the sharp absorption, and it is certain that diffraction factor-group-allowed vibrations can interact with the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

disorder-allowed vibrations, which gain intensity through the interaction and broaden the factor-group-allowed absorption. That this is definitely the correct interpretation of these spectra cannot be fully certain until the density of states of HMT hydrate has been calculated. However, further evidence may be supplied by the Raman spectra of single crystals, in which the factor-group-allowed transitions should show clear polarization properties and should be more intense relative to the disorder-allowed transitions than in the infrared (1). These Raman spectra are being obtained in this laboratory.

It was noted earlier that the only previous evidence of factor-group-allowed transitions in the spectra of the disordered forms of ice came from the spectrum of ice V. This can be rationalized by the fact that ice V is now known to be quite significantly ordered at about 100 K (9), the temperature at which the spectra were recorded (3). Only one phase spoils the pattern that some sharp features are observed in the far infrared spectrum if the phase is significantly orientationally ordered, and none are observed if no significant ordering is present. Ice VI is now known to be significantly ordered at 110 K (10), but no sharp features were observed in its far infrared spectrum (4). No reason for different behavior by ice VI is evident, but it should be pointed out that for the partially ordered, orthorhombic ice VI at 110 K (space group *Pmmn*, D_{2h}^{13}, $Z = 10$, 2 oxygens on sites *a* of symmetry C_{2v}, 8 oxygens on sites *g* of symmetry C_1 (10, 11)) nine translational vibrations of water molecules are allowed under the diffraction unit cell group, compared with 18 allowed vibrations for ice V (3, 9). There is, thus, a greater statistical probability that some will be seen for ice V than for ice VI.

We thank the National Research Council of Canada for financial support to J.E.B. and for the award of a scholarship to M.S.

Infrared Spectroscopic Study of Ammonia – Sulfur Dioxide – Water Solid State System[1]

I. C. HISATSUNE AND JULIAN HEICKLEN

Department of Chemistry and Center for Air Environment Studies, The Pennsylvania State University, University Park, Pennsylvania 16802

Received March 21, 1975

I. C. HISATSUNE and JULIAN HEICKLEN. Can. J. Chem. **53**, 2646 (1975).

Products formed during the solid state reactions between ammonia and sulfur dioxide in the presence or absence of water have been investigated by infrared spectroscopy. Warming of a low-temperature matrix of SO_2 with excess NH_3 produces $(NH_3)_2 \cdot SO_2$ at -90 °C. This adduct decomposes near -50 °C into $NH_3 \cdot SO_2$ which has a yellow color. With excess SO_2 only $NH_3 \cdot SO_2$ appears at -150 °C. The 1:1 complex disappears from the low-temperature infrared window at about -20 °C. With H_2O present in the matrix, $(NH_3)_2 \cdot SO_2$ is converted at -80 °C into ammonium sulfite which is stable to room temperature where it can be pumped off readily from the infrared window. With less than the stoichiometric amount of water, the final product of the warming sequence is ammonium pyrosulfite whose infrared spectrum varies considerably with experimental conditions. The pyrosulfite reacts further with water to give ammonium bisulfite. The infrared spectra of solid ammonium bisulfite and perdeuteroammonium bisulfite show that the hydrogen in the bisulfite ion is bonded to the sulfur atom. Vibrational assignments have been made for all the compounds.

I. C. HISATSUNE et JULIAN HEICKLEN. Can. J. Chem. **53**, 2646 (1975).

On a étudié, par spectroscopie infrarouge, la nature des produits formés par réactions, à l'état solide, de l'ammoniac avec le dioxyde de soufre en présence ou en l'absence d'eau. A -90 °C, lorsqu'on réchauffe une matrice de SO_2 dans un excès de NH_3, il y a production de $(NH_3)_2 \cdot SO_2$. Cet adduit se décompose près de -50 °C pour conduire au $NH_3 \cdot SO_2$ qui a une couleur jaune. A -150 °C, lorsque le SO_2 est en excès, il n'y a production que de $NH_3 \cdot SO_2$. Le complexe 1:1 disparait des fenêtres infrarouges à basse température lorsque la température est ramenée vers -20 °C. Lorsqu'il y a de l'eau présente dans la matrice, le $(NH_3)_2 \cdot SO_2$ se transforme vers -80 °C en sulfite d'ammonium qui est stable jusqu'à la température de la pièce alors qu'il peut être facilement enlevé de fenêtres infrarouges. Lorsque les quantités d'eau utilisées sont plus faibles que les proportions stoichiométriques, le produit final résultant du réchauffement est une pyrosulfite dont le spectre infrarouge varie d'une façon considérable suivant les conditions expérimentales. Le pyrosulfite réagit avec l'eau pour donner le bisulfite d'ammonium. Les spectres infrarouges du bisulfite d'ammonium solide et du perdeutéro bisulfite d'ammonium indiquent que l'hydrogène de l'ion bisulfite est lié à l'atome de soufre. On a fait des attributions pour toutes les vibrations de tous les composés.

[Traduit par le journal]

Introduction

The formation of the solid adducts $NH_3 \cdot SO_2$ and $(NH_3)_2 \cdot SO_2$ in the gas phase reaction of NH_3 with SO_2 appears to be well established (1, 2; references to earlier studies are given in ref. 2), but the infrared spectra of these complexes have not been reported. Hata (3) had examined the infrared spectrum of the solid products formed by the reaction between anhydrous NH_3 and SO_2 but had detected only ammonium pyrosulfite containing traces of sulfite and bisulfite ions. He carried out the reaction directly in the infrared cell using reactant pressures of about 150 Torr, but he recorded the spectrum after the cell had been evacuated thoroughly. When the reaction was carried out in a 4-litre vessel with 30 to 70 Torr of reactant gases, Hata found the products of this highly exothermic reaction to be the unstable thionyl imide and a solid which was light yellow or dark yellow depending, respectively, on whether the reaction vessel was cooled or not cooled. He concluded, therefore, that the overall reaction is

$$[1] \quad 3NH_3(g) + 3SO_2(g) \rightarrow HNSO(g) + (NH_4)_2S_2O_5(s)$$

In a related study carried out subsequently, Hata reported the infrared and Raman spectra of the stable 1:1 adducts of dimethyl and

trimethyl amines with SO_2 (4). Moderately strong, polarized Raman lines observed, respectively, at 206 and 174 cm^{-1} from the melts of these complexes were assigned to the N—S bond stretching mode.

Scargill also investigated the gas phase reaction between NH_3 and SO_2 in a flow system (5). He observed no reaction on mixing the anhydrous reactant gases which were diluted with dry air by 200-fold. However with the addition of a small amount of water, he observed the formation of a white solid which was analyzed to be ammonium pyrosulfite when SO_2 was in excess. When ammonia was in excess the white solid was found to be ammonium sulfite. Scargill reported the infrared spectra of the pyrosulfite and sulfite salts but not the peak frequencies. However, more detailed spectroscopic studies of the pyrosulfite ion (6–8) and the sulfite ion (9) have been reported by other investigators. The structure of the pyrosulfite ion is also known (10).

In the present investigation, a low-temperature infrared spectroscopic technique was used to examine the reaction between NH_3 and SO_2. Solid films consisting of layers of SO_2 and NH_3 films or of mixtures of NH_3 and SO_2 with one or the other in excess were prepared. These films were allowed to warm and the progress of the resulting reactions was examined by infrared spectroscopy. By this method the infrared spectra of $NH_3 \cdot SO_2$ and $(NH_3)_2 \cdot SO_2$ have been obtained for the first time. In addition, the complete spectrum of the bisulfite ion has been identified, and it has necessitated a revision of the previous assignment of the infrared spectrum of the pyrosulfite ion.

Experimental

Ammonia and sulfur dioxide were from the Matheson Co. These gases were liquefied in a high vacuum line and distilled, the central fraction being collected in storage bulbs. The source of ND_3 was Merck, Sharp, and Dohme of Canada, Ltd., and it was used directly. Distilled water and D_2O (99.8%) from Volk Radiochemical Co. were degassed in the vacuum line before use. The infrared spectra of the reagents showed no superfluous absorption bands.

The low-temperature infrared cell made of Pyrex glass was the same cell used in an earlier study of the olefin–ozone reactions (11). The operation of the cell had been described in detail in that study. The same Perkin-Elmer Model 225 grating infrared spectrophotometer was also used in the present study.

Solid samples for spectroscopic observations were prepared in two ways. In one method a film of one reactant was condensed first on the low-temperature infrared window and then the second reactant was deposited on top. In the second method, SO_2 and NH_3 were condensed in a storage vessel, the solid allowed to warm to room temperature, and then the gas from this storage vessel was condensed on the low-temperature infrared window. Solid samples with excess NH_3, excess SO_2, or equivalent amounts of the two reactants were prepared by these methods. After the initial spectrum of the sample was recorded, the solid was allowed to warm to a given temperature and then recooled to liquid nitrogen temperature to record its spectrum again. Such warming and recooling cycles were repeated to follow the progress of the reactions taking place in the solid phase. For the study of hydrolysis reactions, a film of water was deposited on top of the $[NH_3]/[SO_2]$ matrix after it was prepared or after it was carried through one or more warming cycles.

Results

When NH_3 and SO_2 were condensed as separate layers at liquid nitrogen temperature either on the infrared window or in the storage vessel, no reaction took place. The solid had a white color and its infrared spectrum consisted of absorption bands of NH_3 solid (12) and SO_2 solid (13). The lower curve in Fig. 1 illustrates a typical spectrum from a layer sample at liquid nitrogen temperature. Here, $[NH_3]/[SO_2] = 0.86$ and SO_2 was condensed first. The prominent peaks in this spectrum are readily assigned as the degenerate N—H stretch band at 3380 (2500) cm^{-1}, the degenerate NH_3 deformation band at 1650 (1200) cm^{-1}, the antisymmetric S—O stretch band at 1320 cm^{-1}, the symmetric S—O stretch band at 1150 cm^{-1}, the symmetric NH_3 deformation band at 1060 (820) cm^{-1}, the SO_2 deformation band at 530 cm^{-1}, and the NH_3 lattice band at 360 (320) cm^{-1}. Frequencies in parentheses are for the ND_3 species at liquid nitrogen temperature.

On warming the solid sample, changes in color and spectrum occurred. In the storage vessel where color changes were more readily observable, an excess NH_3 solid sample developed a deep yellow color about 1 min after the liquid nitrogen bath was removed. The yellow coloration was lighter when the sample contained excess SO_2. Further warming of the solid containing excess NH_3 or excess SO_2 to room temperature gave a yellow residue which generally turned white on evacuation of the storage vessel. The infrared spectra of the gases from these reactions showed only bands due to NH_3 and SO_2. The middle curve in Fig. 1 is a typical infrared spectrum of a room temperature residue obtained from a layer sample with

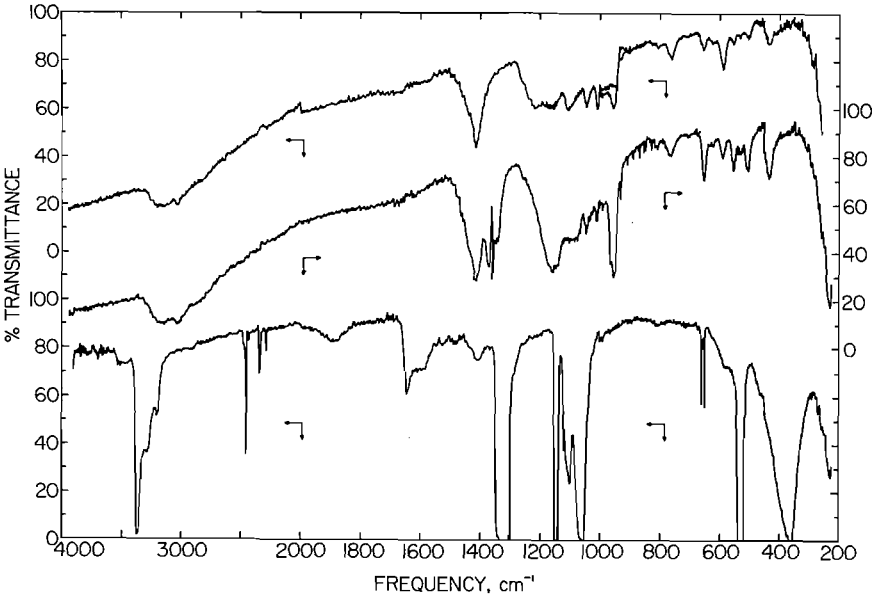

FIG. 1. Infrared spectra of residues from a solid state reaction between NH_3 and SO_2 with $[NH_3]/[SO_2] = 0.86$. Lower curve, initial solid sample at liquid nitrogen temperature; middle curve, sample after warming to room temperature; upper curve, residues after 20 min evacuation of the absorption cell.

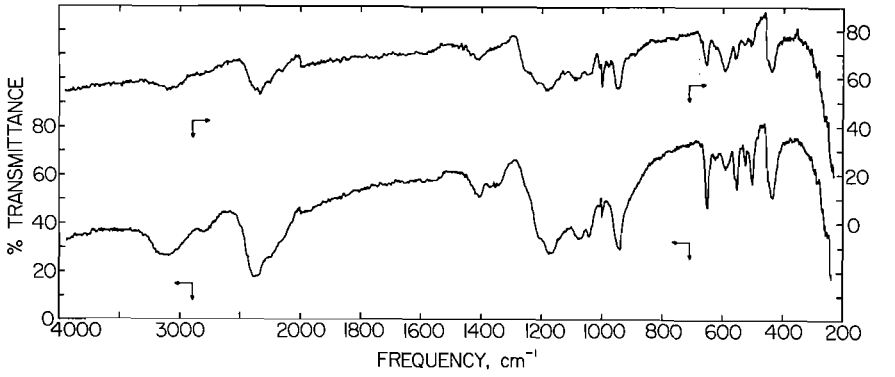

FIG. 2. Infrared spectra of residues from a solid state reaction between ND_3 and SO_2 with $[ND_3]/[SO_2] = 1.19$. Lower curve, reactant solid sample warmed to room temperature; upper curve, sample after recooling of the absorption cell to liquid nitrogen temperature.

$[NH_3]/[SO_2] = 0.86$, and the upper spectrum is from the same sample after it had been evacuated for 20 min. The room temperature residue from a layer sample with $[ND_3]/[SO_2] = 1.19$ gave the spectrum shown by the lower curve in Fig. 2. The upper curve in this figure is from the same sample after it had been recooled to liquid nitrogen temperature.

The changes in the spectra of these room temperature residues with evacuation or cooling, particularly in the S—O bond stretch mode region of 900 to 1300 cm^{-1}, indicated that these residues were somewhat volatile. However, their volatility and spectra appeared to depend on the relative concentrations of the reactants and particularly on the amount of water, added deliberately or present as an impurity, in the sample. Although the low-temperature cell and the gas transfer vacuum line were evacuated at least overnight with a three-stage oil diffusion pump, it was not possible to remove completely traces of water. Also, as our sample in the closed cell system was repeatedly warmed and recooled during an experiment which usually extended

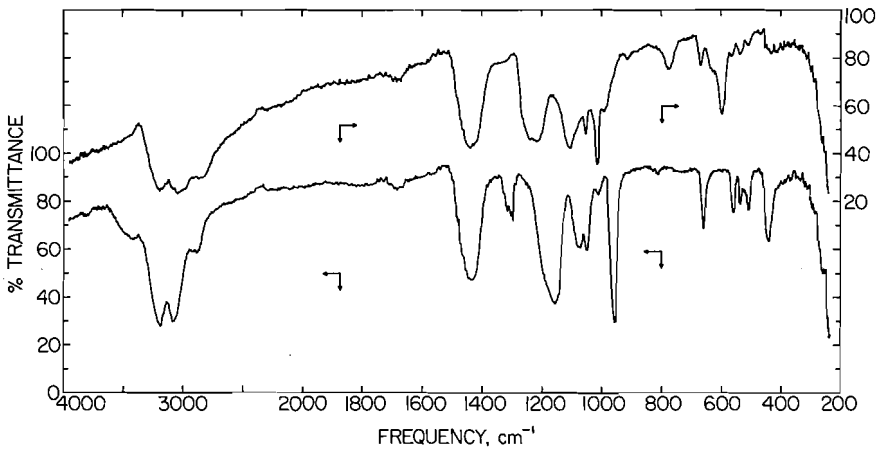

FIG. 3. Infrared spectra of residues from a solid state reaction between NH_3 and SO_2 in the presence of water. Lower curve, products from a solid sample with $[NH_3]:[SO_2]:[H_2O] = 0.68:1:0.52$ after warming to -65 °C and recooling to liquid nitrogen temperature; upper curve, residue at liquid nitrogen temperature from a sample with $[NH_3]/[SO_2] = 1.27$ after six warming and recooling cycles followed by overnight evacuation at room temperature.

over many hours, the water content appeared to increase and gave noticeable variations in the infrared spectra. Generally, the volatility of the residue appeared to decrease as the water content of the solid sample increased, and this decrease was accompanied by changes in the intensities of several infrared bands. A broad band at 1230 cm^{-1} and sharper bands near 1050, 1010, and 600 cm^{-1} increased in intensity while a prominent band at 960 cm^{-1} became weaker. At the same time the broad absorptions in the 1000 to 1200 cm^{-1} region showed changes in peak shapes and positions. The final spectrum of the residue is illustrated by the upper curve of Fig. 3. This sample was prepared by freezing the reactants with $[NH_3]/[SO_2] = 1.27$ in the storage vessel and then condensing the gas from this vessel on the low-temperature infrared window. The sample was subsequently carried through six warming and recooling cycles, warmed finally to room temperature, allowed to stand overnight while the cell was evacuated, and then recooled to obtain the spectrum shown in Fig. 3. The lower spectrum in this figure was obtained from a solid reaction mixture in which water was actually added. In this case, the gas from the storage vessel with $[NH_3]/[SO_2] = 0.68$ was condensed on the cell window and H_2O at $[NH_3]/[H_2O] = 1.30$ was condensed on top. The solid sample was warmed to -65 °C and then recooled to liquid nitrogen temperature to record the spectrum. The spectrum of this sample at room temperature was essentially the same except that it contained the *PQR*-structured 1360 cm^{-1} band of gaseous SO_2 and the doublet band of NH_4^+ near 1400 cm^{-1} had coalesced.

When more water was added to samples with $[NH_3]/[SO_2]$ of about one or less, the final residue was ammonium bisulfite. The infrared spectra of NH_4HSO_3 and ND_4DSO_3 taken at liquid nitrogen temperature are shown in Fig. 4. The frequencies of the bisulfite ion vibrational modes which involve the hydrogen atom were identified by exposing ND_4DSO_3 to H_2O vapor and NH_4HSO_3 to D_2O vapor. The hydrogen stretch and bend modes are at 2588 (1878) and 1123 (831) cm^{-1}, respectively. The values in parentheses are for the deuterium compound. Ammonium bisulfite is stable at room temperature. In the presence of pure oxygen gas, only a trace of sulfate ion was detected after overnight exposure at room temperature. Exposure of a sample to pure ozone at room temperature for about 30 min also produced no changes in its infrared spectrum. Neither did oxygen gas appear to affect the final results when it was present during the reactions to produce the residues shown by the lower spectrum of Fig. 3 and during the subsequent hydrolysis of this residue to ammonium bisulfite.

The residue from the hydrolysis of a solid reactant sample with $[NH_3]/[SO_2] > 2$ was ammonium sulfite, and its infrared spectrum is shown in

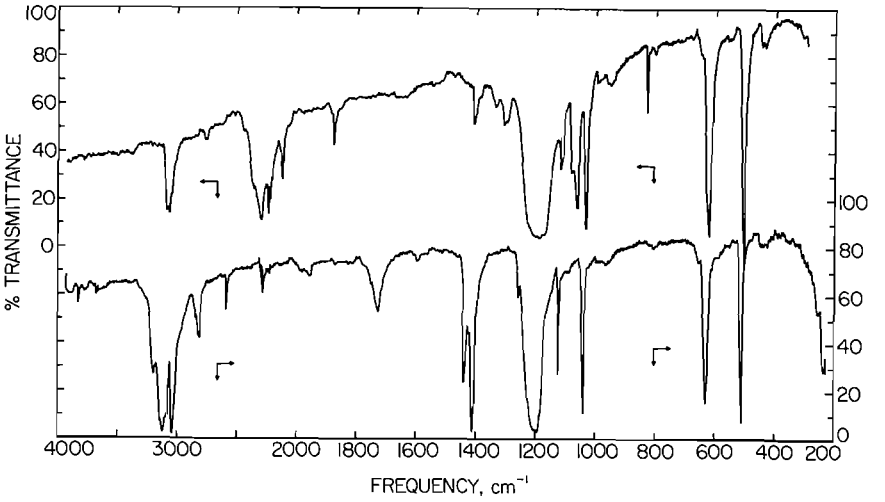

FIG. 4. Infrared spectrum of ammonium bisulfite at liquid nitrogen temperature. Lower curve, NH_4HSO_3; upper curve, ND_4DSO_3.

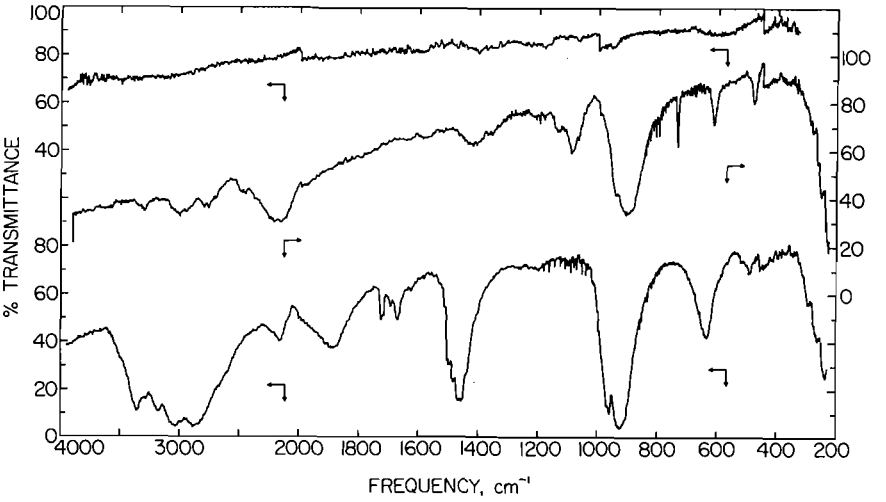

FIG. 5. Infrared spectrum of ammonium sulfite. Lower curve, $(NH_4)_2SO_3$ at room temperature; middle curve, $(ND_4)_2SO_3$ at room temperature; upper curve, $(ND_4)_2SO_3$ sample after short evacuation.

Fig. 5. This salt was very volatile at room temperature and could be pumped off the infrared window readily. The upper curve in Fig. 5 illustrates the loss of sample when the window with the $(ND_4)_2SO_3$ sample giving the middle spectrum was cooled with liquid nitrogen. During the cooling process of the cell, the infrared window is warmer than the metal window holder which comes in contact with the liquid nitrogen. Thus, samples with high vapor pressures are sublimed off the window during the recooling cycle.

When a solid sample prepared by depositing separate layers of NH_3 and SO_2 was allowed to warm slowly from liquid nitrogen temperature, NH_3 began to leave the window at about $-145\,°C$. Concomitantly, the sample started to show a light yellow coloration and a set of new absorption bands appeared in the spectrum, which did not depend on whether SO_2 was in excess or NH_3 was in excess in the original layer sample. From the rate of growth of the new peaks it was evident that a single primary product was being generated by the reaction

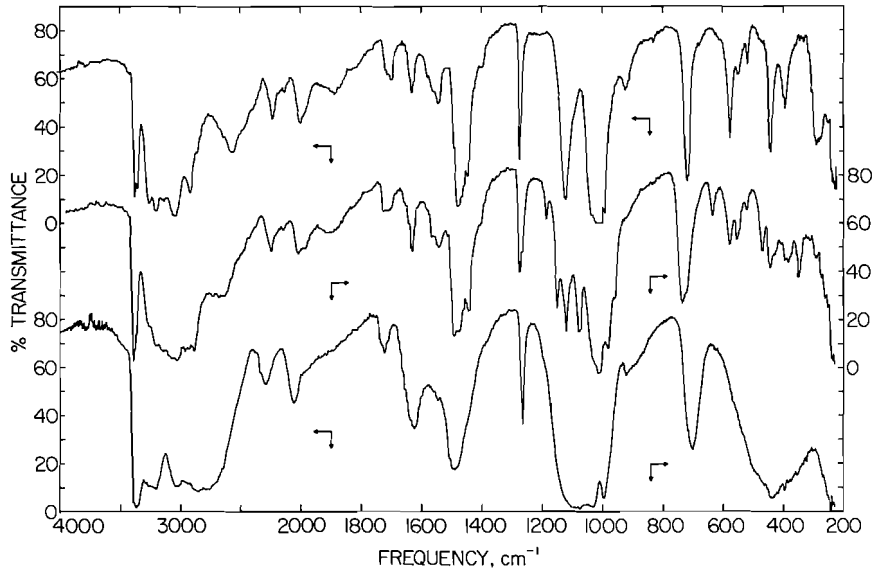

FIG. 6. Infrared spectra of NH_3–SO_2 matrix with $[NH_3]/[SO_2] = 2.67$. Lower curve, initial spectrum at liquid nitrogen temperature; middle curve, sample warmed to −90 °C and recooled; upper curve, sample warmed to −70 °C and recooled.

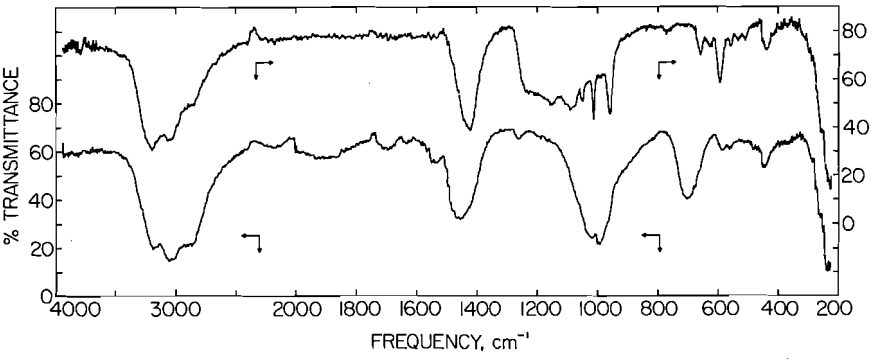

FIG. 7. Infrared spectra of NH_3–SO_2 matrix with $[NH_3]/[SO_2] = 2.67$ (continued from Fig. 6). Lower curve, sample warmed to −30 °C and recooled; upper curve, sample warmed to room temperature and evacuated for 2 h.

between SO_2 and NH_3 during the first warming sequence. The spectrum of this product consisted of broad peaks at 3190, 3050, and 2900 cm^{-1} in the N—H stretch region and at 1460 cm^{-1} in the NH_3 deformation region. Its modes associated with the SO_2 group were at 1017 cm^{-1} (stretch), 706 cm^{-1} (bend), and 446 cm^{-1} (bend). Interestingly, this spectrum was very similar to but not the same as that of ammonium sulfite. The primary product appeared to be stable to about −30 °C where its absorption bands began to weaken leaving behind a spectrum of the residues similar to those shown in Fig. 1. These changes were usually accompanied by the yellow color becoming white.

Samples prepared by condensing gaseous mixtures of NH_3 and SO_2 with $[NH_3]/[SO_2] \leq 1$ immediately showed the absorption bands of the primary product described above in the initial spectra recorded at liquid nitrogen temperature. However, with samples having $[NH_3]/[SO_2] > 2$, the initial spectra as well as many of the subsequent spectra obtained with warming were different from those described already. Figures 6 and 7 illustrate changes observed during warming of a typical sample prepared by

codepositing NH_3 and SO_2 on the low-temperature window. In this case, NH_3 and SO_2 at $[NH_3]/[SO_2] = 2.67$ were frozen separately in the storage vessel and then allowed to warm to room temperature. The gaseous mixture from this storage vessel was deposited directly in the low-temperature cell to obtain the spectra shown in Figs. 6 and 7. The lowest curve in Fig. 6 shows the initial spectrum of this white sample. There are no absorption bands which are characteristic of solid SO_2, so all SO_2 in the matrix must be coordinated to one or more ammonia molecules. Support for this interpretation also comes from the similarity of this spectrum to that obtained from the primary product of samples with $[NH_3]/[SO_2] < 1$. Warming of the matrix to $-90\,^{\circ}C$ and recooling produced the middle spectrum of Fig. 6. The sample color was still white, but the large decrease in intensity near 1070 cm^{-1} (NH_3 deformation) and 360 cm^{-1} (NH_3 lattice modes) indicated that most of the matrix NH_3 had sublimed off the sample window. The color of the sample was unchanged when the sample was warmed further to $-70\,^{\circ}C$ and recooled, but the spectrum was modified to that shown by the upper curve of Fig. 6. This spectrum and the middle spectrum in the figure each evidently represents a single compound since the major bands in each spectrum decayed together as the sample was warmed. The next warming sequence caused the sample color to become light yellow at about $-50\,^{\circ}C$, and the spectrum of this sample after recooling at $-30\,^{\circ}C$ is illustrated by the lower curve in Fig. 7. Within the limits of our experimental uncertainties, this spectrum was identical to that of the primary product obtained from reactant samples with $[NH_3]/[SO_2] \leq 1$. Finally, the compound giving rise to the lower spectrum of Fig. 7 started to decay noticeably at temperatures near $-20\,^{\circ}C$. The residue of the sample at room temperature after 2-h evacuation gave the spectrum represented by the upper curve in Fig. 7.

If water was added to the initial matrix, the compound represented by the upper spectrum of Fig. 6 still appeared as the sample was warmed to $-90\,^{\circ}C$. Further warming to $-80\,^{\circ}C$, however, caused the formation of ammonium sulfite whose spectrum is shown in Fig. 5. Changes in the spectra during the warming cycles of samples with ND_3 were more difficult to follow since the ND_3 deformation band overlapped with the S—O stretch region and there were also isotopic exchange reactions. Thus, only limited data were obtained with the ND_3 system.

Discussion

Since the chemical species which gave the lower spectrum of Fig. 7 was also the initial product in NH_3 matrices containing equimolar or excess SO_2, we conclude that this compound must be the adduct $NH_3 \cdot SO_2$. Thus, the principal reaction induced by warming a matrix with $[NH_3]/[SO_2] = 1$ is

$$[2] \qquad NH_3 + SO_2 \leftrightarrows NH_3 \cdot SO_2$$

Reaction 2 was reported to be exothermic by 9.5 kcal/mol (1), but the present work suggests in addition that its reaction activation energy must be very small. The exothermicity of this reaction presumably can cause the dehydration of $NH_3 \cdot SO_2$ in the gas phase to give HNSO which was observed by Hata (3). The initial spectra of samples prepared by the deposition of equimolar gaseous mixtures showed that $NH_3 \cdot SO_2$ was already formed at liquid nitrogen temperature, and the annealing of layers of solid NH_3 and SO_2 at $-150\,^{\circ}C$ readily generated this adduct. Under our experimental conditions, $NH_3 \cdot SO_2$ remained on the low-temperature infrared window to about $-30\,^{\circ}C$, above which temperature it decomposed evidently by the reverse of reaction 2.

Under anhydrous conditions, the decomposition of $NH_3 \cdot SO_2$ left no residue on the infrared window at room temperature. However, because of traces of water present on the walls of the low-temperature cell assembly, warming of a sample containing $NH_3 \cdot SO_2$ often led to some hydrolysis giving residues which were more difficult to remove by evacuation. The middle spectrum in Fig. 1 is due to such hydrolysis products. This spectrum is very similar to the one reported by Scargill (5) and assigned by him to the pyrosulfite salt $(NH_4)_2S_2O_5$. On the other hand, the upper spectrum of Fig. 1, which was obtained after evacuation of the same sample, is essentially the same as the spectrum of $(NH_4)_2S_2O_5$ reported by Hata (3). Although a comparison of Figs. 1 and 2 shows that, as expected for a pyrosulfite ion, the absorption bands other than those of the ammonium ion are not affected by deuterium substitution, these spectra are very different from the spectrum of $K_2S_2O_5$ reported by Buijs (14). In fact, the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

latter spectrum is closer to the one obtained by Hata (3) by aging $(NH_4)_2S_2O_5$ for 12 h in the infrared cell at room temperature. These discrepancies in the observed infrared spectrum of the pyrosulfite ion are due to the strong dependence of the results on the water content of the solid sample.

The infrared spectrum of the pyrosulfite salt prepared by the reaction

[3] $$2NH_3 + 2SO_2 + H_2O \leftrightarrows (NH_4)_2S_2O_5$$

is shown by the lower curve in Fig. 3. In this case a gaseous mixture with $[NH_3]/[SO_2] = 0.68$ was deposited first, water at $[H_2O]/[SO_2] = 0.52$ was condensed on top, and then the solid was allowed to warm to -65 °C. The spectrum obtained by recooling this sample to liquid nitrogen temperature is identical with that for $K_2S_2O_4$ as observed by Buijs (14) except that we have in our spectrum bands due to the ammonium ion and one band near 1300 cm^{-1} due to solid SO_2. The three most characteristic bands in this spectrum are the intense broad peak at 1160 cm^{-1}, another strong and sharper band at 960 cm^{-1}, and a moderately intense sharp peak at 660 cm^{-1}. These peaks are absent in the spectrum of a residue at liquid nitrogen temperature shown by the upper curve of Fig. 3. This residue came from a solid mixture with $[NH_3]/[SO_2] = 1.27$ after it was subjected to six warming and recooling cycles followed by an overnight evacuation at room temperature. For convenience, we will call this residue the β-pyrosulfite to distinguish it from the α-form which gave the lower spectrum of Fig. 3. Thus, β-$S_2O_5^{2-}$ is characterized by a strong broad band at 1230 cm^{-1}, another intense band at 1100 cm^{-1}, a pair of weak but very sharp peaks at 1050 and 1010 cm^{-1}, and a moderately strong peak at 600 cm^{-1}. Most conspicuous in this spectrum is the absence of the sharp strong peak at 960 cm^{-1} which the α-form possesses.

Once the two forms of hydrolysis product of $NH_3 \cdot SO_2$ have been recognized, the spectra of various residues obtained by warming $[NH_3]/[SO_2]$ solid mixtures can be interpreted. In Fig. 1, the room temperature sample displaying the middle spectrum contains mostly α-pyrosulfite. Evacuation of this sample caused much of the α-salt to disappear presumably by the reverse of reaction 3, and the absorption bands of the β-form have now become more distinct in the upper spectrum of Fig. 1. The latter spectrum as well as the upper spectrum of Fig. 7 appears to be characteristic for a hydrolysis residue containing both α- and β-forms of the pyrosulfite ion.

According to Hata (3), the aging of a hydrolysis residue containing both α- and β-pyrosulfite caused the mixture to change into predominantly the α-salt. On the other hand, the spectra shown in Fig. 1 suggest that a reverse change had taken place on evacuation of the residue. Thus, it appears that the β-pyrosulfite is a partially dehydrated form of the α-salt and that the aging phenomenon observed by Hata is a slow conversion of the β-form to the α-form by hydration. When more water was added to the α- or the β-pyrosulfite, the final hydrolysis product was the bisulfite ion formed by the reaction

[4] $$(NH_4)_2S_2O_5 + H_2O \rightarrow 2NH_4HSO_3$$

The infrared spectrum of ammonium bisulfite is shown in Fig. 4, and the assignment of the bisulfite ion according to a C_{3v} symmetry is summarized in Table 1. Frequency values and deuterium isotope exchange studies showed clearly that the hydrogen atom in the bisulfite ion is bonded to the sulfur and not the oxygen atom. Our infrared data gave no evidence that an ion of the form $HOSO_2^-$ was present in our samples. Earlier attempts (6, 8) to assign the spectrum of HSO_3^- were severely hampered by the presence of large amounts of pyrosulfite in the samples used.

The thermal history of a solid sample containing excess NH_3 is illustrated in Figs. 6 and 7. Since the product displaying the lower spectrum of Fig. 7 has been assigned to the adduct $NH_3 \cdot SO_2$, its precursor with the upper spectrum of Fig. 6 must be the adduct $(NH_3)_2 \cdot SO_2$. The observed color changes were also consistent with this interpretation. Based on the multi-

plicities of the absorption bands of NH_3 at 1500, 1100, and 400 cm^{-1}, we attribute the spectrum given by the middle curve of Fig. 6 to another 2:1 adduct in which the orientation of the ammonia groups are different. In the presence of excess water, the adduct $(NH_3)_2 \cdot SO_2$ gave ammonium sulfite by

[5] $$(NH_3)_2 \cdot SO_2 + H_2O \rightarrow (NH_4)_2SO_3$$

This salt, whose infrared spectrum is shown in Fig. 5, decomposes readily into NH_3, SO_2, and H_2O. The fundamental bands of the sulfite ion are summarized in Table 2. For comparison, the data for the sodium salt due to Evans and Bernstein (9) are also given in Table 2.

Although the assignments of the spectra of the sulfite and bisulfite ions were straightforward, the spectra of the adducts $NH_3 \cdot SO_2$ and $(NH_3)_2 \cdot SO_2$ as well as that of the pyrosulfite ions were more difficult to interpret. First, the experimental data for the adducts are limited to the normal infrared region and no Raman results are available for them. Other workers have reported more extensive experimental data

for the pyrosulfite, but unfortunately their samples were always contaminated with SO_3^{2-}, HSO_3^-, and possibly with other species. Thus, only a tentative assignment of the spectra of the various species will be presented here. In Table 3, we have listed the frequencies of the bands due to the adduct $NH_3 \cdot SO_2$ obtained at liquid nitrogen temperature. The strong resemblance of this spectrum (Fig. 7, lower curve) to that of ammonium sulfite (Fig. 5) suggests that the adduct $NH_3 \cdot SO_2$ must be like a sulfite ion in which one oxygen atom has been replaced with NH_3. Hence, the assignment summarized in Table 3 is based on a C_s symmetry for the adduct. The 2:1 adduct has similarly been treated as a disubstituted sulfate ion with a skeletal symmetry of C_{2v}. The assignment of $(NH_3)_2 \cdot SO_2$ is given in Table 4.

The infrared and Raman spectra of aqueous and solid potassium pyrosulfite obtained by Herlinger and Long (6), Simon and Waldmann (8), and Rocchiccioli (7) are given in Table 5. The pyrosulfite ion has a C_s symmetry (10), and its 15 fundamentals have been assigned as indicated in Table 5 from frequencies observed both by Herlinger and Long and by Simon and Waldmann. Previously, both of these research groups had assigned the medium intense polarized Raman line near 460 cm^{-1} to the bisulfite ion, but we have reassigned it to the pyrosulfite ion. Other minor differences between the present assignments and those of Herlinger and Long are: The 168 cm^{-1} Raman line was not assigned since it was not observed by Simon and Waldmann, and Herlinger and Long attributed the weak Raman line at 395 cm^{-1} to the bisulfite ion. The β-form of the pyrosulfite (Fig. 3, upper spectrum) is presumably a partially dehydrated salt, but we lack sufficient data to assign its spectrum.

Synthesis and Characterization of Cu(I) Complex Compounds With Methyl Isonicotinate

MOHAMED A. S. GOHER

Department of Inorganic Chemistry, Charles University, 128 40 Prague 2, Czechoslovakia[1]

Received January 31, 1975

MOHAMED A. S. GOHER. Can. J. Chem. **53**, 2657 (1975).

The preparation of Cu(I) complexes of methyl isonicotinate, MeIN, of the formula $(MeIN)_n$-CuX, in which $n = 1, 2, 3$, and 4 and X is Cl, Br, I, CN, SCN, and ClO_4, has been described. The isolated complexes are characterized by their analytical data, diamagnetism, and conductivity measurements. The $M \rightarrow L$ charge transfer bands in the visible spectra and the i.r. spectra of these complexes are discussed.

MOHAMED A. S. GOHER. Can. J. Chem. **53**, 2657 (1975).

On décrit la préparation de complexes du Cu(I), avec l'isonicotinate de méthyle (MeIN), de formule $(MeIN)_nCuX$ dans lesquels $n = 1, 2, 3$ et 4 et X = Cl, Br, I, CN, SCN et ClO_4. On a caractérisé les complexes par leurs données analytiques et des mesures de conductivité et de diamagnétisme. On discute des spectres i.r. ainsi que des bandes de transfert de charge $M \rightarrow L$ dans les spectres visibles de ces complexes. [Traduit par le journal]

Introduction

In a series of publications (1–3) we have reported the preparation and characterization of some Cu(I) complex compounds with pyridine monocarboxylic acids and their derivatives. As Cu(II) complexes of methyl isonicotinate have been studied from different points of view (4, 5), and as Cu(I) complexes of this ligand have not yet been mentioned, we tried to prepare these latter complex compounds. With methyl isonicotinate ligand we isolated Cu(I) complexes of Cu/L ratio 1:1, 1:2, 1:3, and 1:4 depending on the anion present.

Experimental

Chemicals and Apparatus

Methyl isonicotinate was g.l.c. purified. The other chemicals were analytical grade and commercially available.

Magnetic measurements were made by the Faraday method at room temperature. X-Ray powder patterns were taken on a Mikrometa 2 (Chirana, Prague) instrument, $\phi = 53.3$ mm, with λCuK_α radiation. Conductivity measurements were carried out at 25 °C on 10^{-3} *F* solutions in chloroform, nitrobenzene, and acetone under dry nitrogen with a Radiometer conductivity bridge model CDM 2e. Electronic spectra were recorded on a Unicam spectrophotometer SP 800. Reflectance spectra of the solids were measured over the 220–1000 nm range on a VSU-1 (Zeiss, Jena) instrument with MgO as a standard and diluent. Infrared spectra in the region 4000–400 cm^{-1} were measured on a UR-20 (Zeiss, Jena) spectrophotometer. The solid samples were measured as Nujol mulls or KBr pellets, and the liquid ligand as a capillary film. Far i.r. spectra have been measured on a Perkin-Elmer 325 spectrophotometer.

Analysis

Microanalysis of C, H, N were carried out on the Perkin-Elmer 240 elemental analyzer. Halogens were determined gravimetrically as AgX. Copper was determined either by titration against disodium EDTA or gravimetrically as CuSCN after degradation and oxidation of the complexes with boiling mixtures of concentrated H_2SO_4 and 30% H_2O_2.

Preparation of the Complexes

The complexes were prepared according to the procedure described previously (1, 3). Table 1 summarizes the elemental analysis and some properties of the prepared complexes.

The separation of pure Cu(I) perchlorate complexes caused some difficulties. However, the preparation of these complexes in such form was effected as follows. The 1:4 complex was prepared by mixing the ligand (six- to eightfold) with Cu(II) salt in aqueous medium, followed by addition of ascorbic acid and then sodium perchlorate pentahydrate. The final product was recrystallized from ethanol in presence of excess ligand and ascorbic acid to prevent air oxidation. The 1:3 complex was prepared from aqueous solutions of the ligand and copper in the exact molar ratio followed by slow addition of the perchlorate ion in the least amount of water. Care must be taken otherwise the complex will change immediately to one of the other two complexes. The white microcrystalline powder was prepared by mixing the ligand and copper ion in aqueous solution (Cu/L = 1:2). The faint yellow sheets were isolated by addition of an ethanolic solution of the ligand and an aqueous solution of $CuSO_4.5H_2O$ (Cu/L = 1:2) and after addition of ascorbic acid and the perchlorate ion the mixture was stirred about 15 min until faint yellow sheets isolated. This product was then recrystallized from ethanol.

Results and Discussion

The complexes were prepared simply by mixing ligand and $CuSO_4.5H_2O$ in the appropriate stoichiometric ratio in aqueous or ethanolic media followed by addition of ascorbic acid as the reducing agent and then the desired anion. By such a procedure Cu(I) nitrate complexes of MeIN have been prepared as yellow or red compounds, but they are too easily oxidized to permit their isolation and analysis. Alternatively, the halide complexes can be prepared by direct interaction between the components in suitable molar ratios. Because reactions leading to different stoichiometries are often competitive, pure samples are difficult to obtain. However, recrystallization could effect their purification.

Only in one case we isolated two isomers of the formula $(MeIN)_2CuClO_4$. One is white microcrystalline powder and not sufficiently stable and the other is faint yellow sheets and stable enough.

All the complexes isolated are colored, except the 1:2 perchlorate, diamagnetic compounds and are fairly stable in air except the 1:1 chloride and the white 1:2 perchlorate complexes. As was observed (2, 6) for Cu(I) halide complexes of other ligands, the stability with respect to air oxidation of the isolated Cu(I) complexes depends critically on the identity of the halogen and increases from chloride to iodide.

The X-ray powder patterns showed that the 1:1 bromide and iodide and the 1:2 halide complexes are isomorphous.

The Cu(I) perchlorate complexes behave in nitrobenzene (7) and acetone (8) as 1:1 electrolytes (see Table 2). The Cu(I) halide complexes, on the other hand, gave nonconducting solutions in chloroform and nitrobenzene. In acetone the measured conductivities are very small compared to those of 1:1 electrolytes (8). However, the results are reproducible for different samples and hence they are not due to impurities.

The Cu(I) halide complexes dissociate in solvents like chloroform, acetone, or alcohols to free ligand and complexes of lower ligand content or simple CuX. In general the intense red color of solutions of the 1:2 complexes obtained at higher concentrations changes very rapidly upon dilution. The faint yellow solutions obtained did not show the M → L charge transfer bands which are observed in the spectra of the solid samples.

Electronic Spectra

Table 2 summarizes the reflectance spectra data. In the u.v. region of the spectra of solutions of free ligand and complexes as well as in the spectra of the solid samples, an absorption band is observed around 275–280 nm. This band is attributed to a π–π^* transition in comparison with the assignment given for similar transition in the parent acid (9). Around 320–380 nm other absorption bands are observed in the reflectance spectra of some complexes,

but not in the spectra of their solutions. These bands cannot be assigned as X → M charge transfer bands since the perchlorate compounds also showed strong absorption in this region.

Intense absorption bands are observed in the visible region of the reflectance spectra of Cu(I)—MeIN complexes, except for the 1:2 perchlorates. These bands are assigned as M → L charge transfer from the completely filled d^{10} orbitals of the Cu(I) ion to an empty π^* orbital on the ligand. Similar M → L charge transfer bands are observed in the visible spectra of Cu(I) complexes of bipyridine and phenanthroline (10, 11).

The electron attracting carbomethoxy group causes the electron density to migrate from the delocalized system on the pyridine ring to the substituent and thus lowers the electron density on the nitrogen atom. Therefore, increasing the number of ligands per Cu(I) ion increases the reducing power, that is, its tendency to accept electrons, of the acceptor part in the complex molecule, and hence M → L charge transfer band shifts to longer λ_{max} as the number of ligands increased (12), as seen from Table 2.

The cation $[(MeIN)_2Cu]^+$ is white and does not exhibit an M → L charge transfer band. Therefore the structure $[(MeIN)_2Cu]^+[CuX_2]^-$ is not probable for (MeIN)CuX (X = halide, CN, or SCN) complexes. Since these latter complexes exhibit M → L bands similar to the trigonal cation $[(MeIN)_3Cu]^+$, structures involving trigonally coordinated Cu(I) ion are, therefore, proposed for these 1:1 complexes. Similarly, the reflectance spectra of the halides of 1:2 complexes are very similar to that of the cation $[(MeIN)_4Cu]^+$ in the u.v. and visible regions. Tetrahedral geometries are, therefore, postulated for the 1:2 complexes.

Infrared Spectra

Wong and Brewer (5, 13) have carried out the coordinate analysis calculations on 1:1 complex models between Cu(II) or Zn(II) ions and MeIN among other 4-substituted pyridines. Following them, we assign the in-plane vibrations as given in Table 3. In Table 4 the vibrational frequencies of the anions are tabulated.

At 668 cm^{-1} a new band appears in the spectra of the Cu(I) complexes. It may be attributed to ν_{6b} vibration since a similar band given the same assignment was observed in the spectrum of Cu(II)—MeIN complex (5). The ν_{6a} vibration mode has been calculated to be at 516 cm^{-1} and at 488 cm^{-1} for the 1:1 complex model of Cu(II) and Zn(II) with MeIN, respectively. No bands have been observed in the spectra of both compounds to be assigned for this vibration mode. However, a band of weak to medium intensity is observed at 485–507 cm^{-1} in the spectra of all Cu(I)—MeIN complexes. It may be attributed to ν_{6a} ring vibration mode. The positions of most frequencies observed in the spectra of Cu(I) complexes are in good agreement with those observed for Cu(II) and Zn(II) complexes of MeIN (5, 13).

The position of the C=O stretching vibration frequency, as seen from Table 3, is essentially constant in free and coordinated MeIN. On the other hand, the ring C—C, C—N stretching, ring C—H in-plane, and ring breathing ν_1 and ν_{12} vibration frequencies all are blue shifted upon coordination of MeIN. These shifts are in line with those observed for coordinated

$(MeIN)_2CuBr$	235 s, 200		

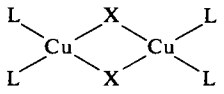
pyridine (14, 15), indicating the coordination of MeIN via the nitrogen atom. Taking the shifts of the ν_{12} vibration mode as a measure of the relative π-contribution to the coordination bond (4), we observe that the π-contribution in the case of Cu(I)—MeIN complexes is slightly higher than in the case of Cu(II) or Zn(II) complexes with MeIN (5, 13).

Examination of Table 4 shows that the perchlorates of 1:4, 1:3, and the white 1:2 MeIN complexes are ionic, since the vibrations of the perchlorate groups are consistent only with noncoordinated groups (ref. 16 and references cited therein). Therefore, these complexes are formulated as $[(MeIN)_4Cu]^+ClO_4^-$, $[(MeIN)_3Cu]^+ClO_4^-$, and $[(MeIN)_2Cu]^+ClO_4^-$ with tetrahedral, trigonal, and linear geometries respectively. In the spectrum of the faint yellow 1:2 Cu(I) perchlorate complex, ν_3, the antisymmetrical stretching, and ν_4, the antisymmetrical bending, vibration modes split into three components for each. The splitting of these modes in this manner is consistent only with a bidentate perchlorate group. This compound is, therefore, formulated as $[(MeIN)_2CuClO_4]$ in which Cu(I) ion is tetrahedrally coordinated in the solid state.

For the 1:1 cyanide complex, the appearance of a single ν(CN) at 2140 cm^{-1} which is higher than those of the terminal cyanide groups in the complex $K_3Cu(CN)_4$, 2075–2095 cm^{-1} (17), strongly suggests a bridging cyanide group (18, 19). The 1:1 thiocyanate complex showed two cyanide stretching frequencies. The higher frequency indicates an S-bonded, and the lower an N-bonded, thiocyanate group (20, 21). Therefore this compound is postulated to exhibit a bridging thiocyanate group.

In an attempt to obtain further information concerning the structures of the complexes, the low frequency (200–400 cm^{-1}) i.r. spectra of some of them were measured (Table 5).

Wong and Brewer (13) have assigned the two bands observed at 230 and 203 cm^{-1} in the spectrum of Zn(II)—MeIN complex as Zn(II)—N stretching vibrations in accordance with the calculated values. Similarly we have assigned the bands in the region 220–234 cm^{-1} and around 200 cm^{-1} in the spectra of Cu(I)—MeIN complexes as Cu(I)—N stretching vibrations. As expected the 1:2 halide complexes showed two Cu(I)—N stretching frequencies. However, there are no bands attributable to Cu(I)—Cl frequencies above 200 cm^{-1} in the spectrum of the 1:2 chloride. For the 1:2 halides a structure of the type



may account for these observations, with each metal atom having approximately tetrahedral geometry through halide bridges.

In the spectrum of the faint yellow Cu(I) perchlorate 1:2 compound, two bands have been observed at 251 and 264 cm^{-1}. Since these bands are absent from the spectra of all the measured complexes we attributed them to Cu(I)—O stretching vibrations. This observation confirms our conclusion that the perchlorate group acts as a bidentate ligand in this complex.

The author expresses his gratitude to Dr. M. Drátovský for valuable discussion and Dr. M. Ferles, Department of Organic Chemistry, Institute of Chemical Technology, Prague, who very kindly supplied methyl isonicotinate. His thanks are also due to Dr. Šilha and Mrs. Zemanová for their help with some measurements.

Chlorine-water Oxidation of Some α-Methylsulfonyl Sulfides

W. R. HARDSTAFF, R. F. LANGLER,[1] J. LEAHY, AND M. J. NEWMAN

Chemistry Department, Dalhousie University, Halifax, Nova Scotia B3H 3J5

Received February 11, 1975

W. R. HARDSTAFF, R. F. LANGLER, J. LEAHY, and M. J. NEWMAN. Can. J. Chem. **53**, 2664 (1975).

An examination of the chlorination of phenylmethyl, diphenylmethyl, and triphenylmethyl methylsulfonyl sulfides (**1**, **2**, and **3**) in aqueous acetic acid has provided indirect evidence for Pummerer rearrangement during the chlorination of an α-methylsulfonyl sulfinyl chloride. The results are discussed from both mechanistic and synthetic standpoints.

W. R. HARDSTAFF, R. F. LANGLER, J. LEAHY et M. J. NEWMAN. Can. J. Chem. **53**, 2664 (1975).

L'étude de la chloration des sulfures du phénylméthyle, du diphénylméthyle et du triphénylméthyle méthylsulfonyle (**1**, **2** et **3**) dans une solution aqueuse d'acide acétique fournit une preuve indirecte du réarrangement de Pummerer durant la chloration d'un chlorure de α-méthylsulfonyle sulfinyle. Les résultats sont discutés des points de vue du mécanisme et de la synthèse. [Traduit par le journal]

In recent years, a widespread interest in the chlorination of organosulfur compounds has become apparent. Research has been primarily directed at the chlorination of sulfides (1–6) and sulfoxides (7–19). Our own work (20, 21) has demonstrated that α-chlorodialkyl sulfides give rise to sulfonyl chlorides via sulfinyl chlorides upon chlorination in dilute aqueous acetic acid. We have proposed (21) that the sulfinyl chloride is hydrolyzed to the sulfinic acid which then reacts with chlorine to furnish the corresponding sulfonyl chloride.

The present report is the result of a desire to examine the behavior of chloro- and oxochlorosulfonium chloride salts in systems which may undergo either Pummerer rearrangement or dissociation to form carbonium ions and/or intimate ion pairs as well as sulfenyl or sulfinyl chlorides. Dissociation of this sort is not available to simple dialkyl chloro- and oxochlorosulfonium chloride salts.

The particular substrates chosen for examination (**1**, **2**, and **3**) offer two potentially useful features for such a study.

$$\overset{1}{CH_3}\cdot\overset{2}{SO_2}\cdot\overset{3}{CH_2}\cdot\overset{4}{S}\cdot\overset{5}{C}\,XYZ$$

1 X = Y = H; Z = Ph

2 X = H; Y = Z = Ph

3 X = Y = Z = Ph

[1]Enquiries should be directed to: Dr. R. F. Langler, Chemistry Department, Scarborough College, University of Toronto, West Hill, Ontario M1C 1A4.

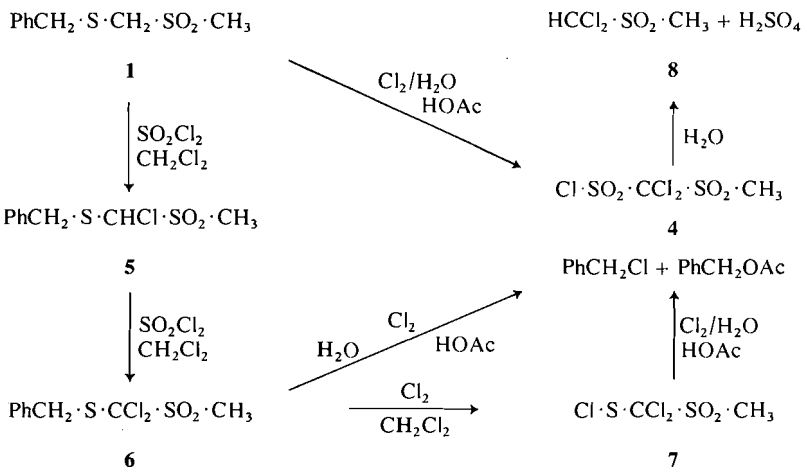
Pummerer rearrangement of intermediate chlorosulfonium chloride salts is directed to C-3 by the α-sulfonyl group (22) thus preventing chlorination on C-5, so that the polyphenylmethyl groups retain their ability to form carbonium ions (or intimate ion pairs) as the reaction proceeds. Secondly the regular increase of the number of phenyl groups on C-5 in the series **1** → **3** increased the propensity for cleavage at progressively earlier stages during the reaction in the event that some Pummerer rearrangement preceded cleavage in the reaction of the phenylmethyl sulfide (**1**).

The sulfone-sulfides (**1**, **2**, and **3**) were prepared by refluxing the appropriate thiol anion with chloromethyl methyl sulfone in absolute ethanol (*vide* Scheme 1). Although this reaction

$$RSH + ClCH_2\cdot SO_2\cdot CH_3 \xrightarrow[EtONa]{EtOH} R\cdot S\cdot CH_2\cdot SO_2\cdot CH_3$$

SCHEME 1

is precedented (22, 23), reports that α-halosulfones are inert to nucleophilic substitution can be found in the literature (24–27). Since these reports are based on the failure of non-sulfur containing nucleophiles to displace the α-halogen atoms of α-halosulfones, we decided to examine two sulfur-containing nucleophiles in this reaction. Both sodium bisulfide and thiourea failed to react with chloromethyl methyl sulfone in refluxing ethanol. It therefore appears that the electronic nature of the nucleophilic sulfur



SCHEME 2

atom is quite restricted if substitution reactions are to succeed on α-halosulfones.

Chlorination of the sulfone-sulfide (**1**) in aqueous acetic acid furnished the dichlorosulfone-sulfonyl chloride (**4**) in good yield. Two approaches were undertaken in order to establish the structure of **4**. Synthetic support was obtained by the unambiguous preparation of the dichlorosulfone-sulfenyl chloride (**7**) through the known compounds **1**, **5**, and **6** (28), followed by oxidation of **7** to **4** as shown in Scheme 2. Degradative support for the structure of **4** was obtained by its hydrolysis to give the dichlorosulfone (**8**) and an equivalent of sulfuric acid. This hydrolysis reaction appears to be new and is the subject of further studies, already underway, in our laboratories.

Once the structure of **4** had been established, we directed some effort towards elucidating the pathway by which it was formed from **1**. The reaction **1** → **4** was complete after chlorination for 0.75 h. The product contained approximately 5% of the sulfone-sulfenyl chloride (**7**) and 95% of the sulfone-sulfonyl chloride (**4**). When the sulfone-sulfenyl chloride (**7**) was chlorinated under the same conditions, the reaction was only 70% completed after 14.5 h. Clearly, then, short chlorinations leave almost all intervening sulfone-sulfenyl chloride (**7**) unreacted and therefore a direct determination of **7** in crude reaction mixtures is a good measure of the amount of starting material giving rise to it.

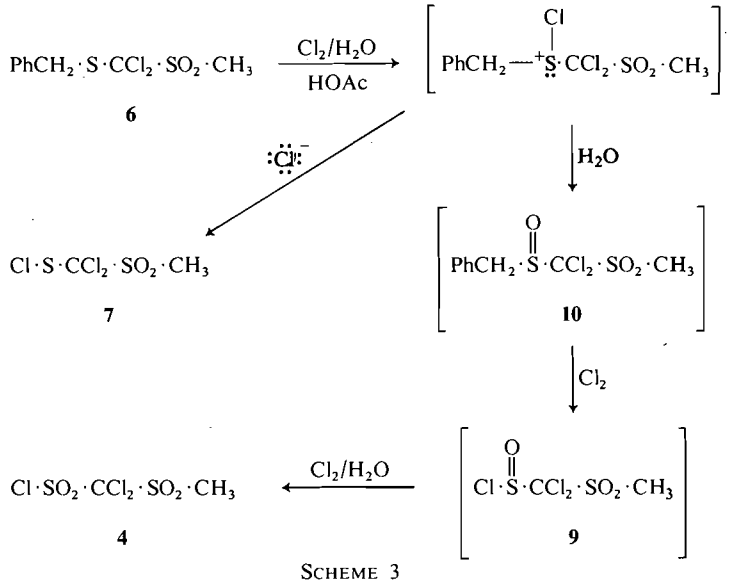
Therefore only 5% of **1** gives rise to **7** in the reaction **1** → **4** and **4** does not form via the intermediacy of **7**. From our previous studies (20, 21) it is clear that **4** must arise from the corresponding dichlorosulfone-sulfinyl chloride (**9**). It is now evident that **9** does not arise from the dichlorosulfone-sulfenyl chloride (**7**).

Chlorination of the dichlorosulfone-sulfide (**6**) in aqueous acetic acid furnished a mixture of the dichlorosulfone-sulfonyl chloride (**4**) and the dichlorosulfone-sulfenyl chloride (**7**) in the ratio 2:3 respectively. Since little dichlorosulfone-sulfonyl chloride (**4**) could have formed from **7** in such a short time, then **4** must have arisen from **9** and **10**[2] as depicted in Scheme 3. The relatively large amount of the dichlorosulfone-sulfenyl chloride (**7**) formed from the chlorination of **6** in aqueous acetic acid essentially precludes **6** from consideration as a principal intermediate in the conversion of **1** → **4**.

The presence of the dichlorosulfone-sulfenyl chloride (**7**) in the crude product obtained from the chlorination of **6** was established in part by its detection on t.l.c. After development and drying, the plate was sprayed with ammonium hexanitratocerate(IV) solution, a new spray reagent developed in these laboratories (31). This oxidizing spray is sensitive to the nature of the substituents on sulfur and visualizes the spots more slowly as the substituents on sulfur become more electron withdrawing. When a mixture is examined on t.l.c. using an authentic sample of a component for comparison, one can compare both the R_F and the appearance time of the component in question and the authentic sample. Thus the crude product from the chlorination of **6** contained a compound

[2]The intermediacy of the β-disulfone can be ruled out on the basis of results published elsewhere (30).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.



SCHEME 3

which was identical to **7** with respect to R_F and appearance time.

Two possibilities now remain for the pathway **1** → **4**. Either the benzylic sulfone-sulfide (**1**) cleaves directly after chlorosulfonium chloride formation or Pummerer rearrangement occurs leading ultimately to **4**.

If the longer pathway implicated by Pummerer rearrangement is occurring, then reaction times should be substantially shortened if the structure of the sulfone-sulfide (**1**) were modified in such a way as to facilitate direct cleavage of the chlorosulfonium chloride salt initially formed.

$$CH_3{\cdot}SO_2{\cdot}CH_2{\cdot}SO{\cdot}CH_2{\cdot}Ph$$
11

We have undertaken two approaches to facilitating immediate cleavage and suppressing Pummerer rearrangement. In our first approach, the sulfone-sulfoxide (**11**) was prepared. When **11** reacts with chlorine an oxochlorosulfonium chloride salt is formed. The sulfur atom in this case is more electron deficient than the sulfur atom in a chlorosulfonium chloride salt and should constitute a better leaving group, thereby facilitating direct cleavage without Pummerer rearrangement. Such an analysis is consistent with our previous results (20) in which we found that α-polychlorosulfoxides cleave to furnish sulfinyl chlorides upon treatment with molecular chlorine, whereas α-polychlorosulfides either react via a Pummerer rearrangement to furnish more highly chlorinated sulfides or do not react at all with molecular chlorine. Chlorination of **11** furnished **4** in the same yield with the same chlorination time as observed for **1**.

In our second approach, the diphenylsulfone-sulfide (**2**) and the triphenyl sulfone-sulfide (**3**) were prepared. The chlorosulfonium chloride salts of **2** and **3** would be expected to dissociate in an S_N1 type process more readily than the corresponding salt of **1** on the grounds that the resultant carbonium ion should be more stable as the number of phenyl rings on the central atom of the carbonium ion is increased. Again the chlorination times[3] and yields were essentially identical with those observed for **1**. These results suggest that there is no Pummerer rearrangement occurring prior to cleavage.

If, in any of these cases, cleavage is occurring prior to Pummerer rearrangement, then either or both of the intervening sulfenyl or sulfinyl chlorides must be undergoing Pummerer rearrangement in order for the dichlorosulfone-sulfonyl chloride (**4**) to be the observed product. Such a process is abnormal for sulfenyl or sulfinyl chlorides both of which are normally oxidized, under these conditions, to the corresponding sulfonyl chlorides. To examine the possibility that benzylic sulfides undergo direct cleavage upon chlorination under these reaction

[3]Exhaustive chlorinations were terminated when the reactions were no longer exothermic.

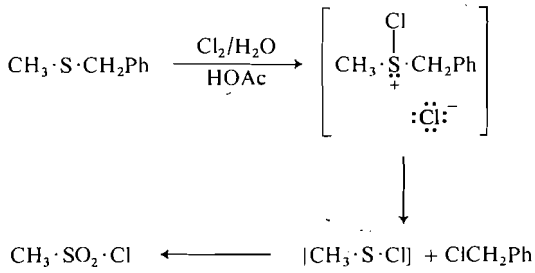

SCHEME 4

conditions, we decided to chlorinate a benzylic sulfide that would give rise to a sulfenyl and/or sulfinyl chloride which would be oxidized to the corresponding sulfonyl chloride without complicating Pummerer rearrangement. The experiment was carried out on benzyl methyl sulfide. The product obtained was an approximately equimolar mixture of methanesulfonyl chloride and benzyl chloride.[4]

Clearly the cleavage has occurred before any Pummerer rearrangement has occurred (see Scheme 4). Furthermore, it now appears likely that all three sulfone-sulfides **1**, **2**, and **3** have undergone direct cleavage upon chlorination in aqueous acetic acid.

Since the dichlorosulfone-sulfonyl chloride **4** must arise from the dichlorosulfone-sulfinyl chloride **9** and it seems very likely that chlorination of **1** leads to direct cleavage, then the precursor of **9** must be the monochlorosulfone-sulfinyl chloride **12** as shown in Scheme 5. As previously mentioned the dichlorosulfone-sulfenyl chloride (**7**) has been excluded as an intermediate.

A direct examination of the behavior of α-sulfonyl-sulfenyl and α-sulfonyl-sulfinyl chlorides cannot be undertaken until synthetic methods become available for their preparation.

Implicit in the results presented in this article is the fact that sulfonyl compounds with an α-sulfur atom are unsuitable for the preparation of simple α-sulfonyl-sulfonyl chlorides (*e.g.* methylsulfonylmethanesulfonyl chloride) because of the propensity of the intermediate species to undergo Pummerer rearrangements. The method of Opitz (32) by which sulfenes are dimerized and subsequently treated with HCl to provide α-sulfonyl-sulfonyl chlorides remains the only available method for their preparation.

[4]An immediate consequence of this result is the synthetic utility of benzylic sulfides as precursors for the preparation of sulfonyl chlorides. Further work on this method is already underway in our laboratories.

Experimental

General

The i.r. spectra were recorded on a Perkin-Elmer 237 B grating spectrophotometer. The n.m.r. spectra were obtained on a Varian T-60 instrument using TMS as the internal standard. The mass spectra were recorded on a Dupont-CEC model 21-104 mass spectrometer. The samples were directly introduced using an all glass probe and the spectra run at 30 eV with a source temperature of 150 °C. Melting points were determined on a Fisher-Johns melting point apparatus and are uncorrected. The t.l.c. was carried out on 5 × 20 cm analytical plates (0.75 mm thickness) spread with silica gel HF-254 (A.G. Merck). Spots were detected by spraying with ammonium hexanitratocerate(IV) spray (31) or by 250 nm u.v. light.

Chlorinations

Chlorine flow rates were standardized by the use of a rotameter. The rotameter was calibrated by bubbling chlorine into an aqueous solution of potassium iodide for a fixed period of time. The flow rate was calculated from the weight of chlorine trapped and the bubbling time using the ideal gas law.

Preparation of $PhCH_2{\cdot}S{\cdot}CH_2{\cdot}SO_2{\cdot}CH_3$ (1)

The preparation and properties of this compound have been described elsewhere (28).

Preparation of $Ph_2CH{\cdot}S{\cdot}CH_2{\cdot}SO_2{\cdot}CH_3$ (2)

Sodium metal (1.894 g) was dissolved in absolute ethanol (100 ml). Diphenylmethanethiol (33) (15.504 g) was added to the solution, followed by chloromethyl methyl sulfone (28) (8.028 g). The resultant reaction mixture was refluxed for 1 h. The reaction mixture was poured into ice–water (100 ml) and the resultant mixture extracted with chloroform (four 100 ml aliquots). The chloroform layers were combined, dried ($MgSO_4$), filtered, and rotary evaporated. The residue was recrystallized from benzene, furnishing **2** (14.890 g, 81.5%). The product had m.p. 118–120 °C and was homogeneous on t.l.c. (R_F, 0.29) when developed with chloroform. The i.r. bands were present ($CHCl_3$), 1325 and 1145 cm^{-1}. The n.m.r. spectrum ($CDCl_3$) showed signals at τ 2.70 (10H, m), 4.20 (1H, s), 6.40 (2H, s), and 7.03 (3H, s). The mass spectrum exhibited ions at *m/e* 215 (23%), 167 (100%), 105 (22%), 79 (9%), and 77 (14%).

Anal. Calcd. for $C_{15}H_{16}S_2O_4$: C, 61.61; H, 5.52. Found: C, 61.23; H, 5.72.

Preparation of $Ph_3C{\cdot}S{\cdot}CH_2{\cdot}SO_2{\cdot}CH_3$ (3)

Sodium metal (0.759 g) was dissolved in absolute ethanol (100 ml). Triphenylmethanethiol (9.518 g) was added to the solution, followed by chloromethyl methyl sulfone (4.030 g). The resultant reaction mixture was refluxed for 1 h. The reaction mixture was poured into ice–water (100 ml) and the resultant mixture extracted with chloroform (four 100 ml aliquots). The combined chloroform layers were dried ($MgSO_4$), filtered, and rotary evaporated. The dark brown resinous residue (12 g) was dissolved in chloroform (250 ml), boiled with norite (1 g), filtered, and the process repeated. The chloroform was evaporated furnishing a light brown resinous

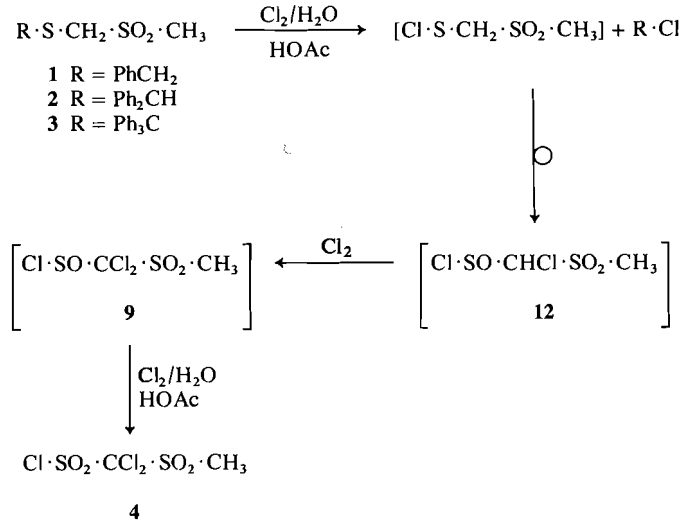

SCHEME 5

sample (10 g). This material was chromatographed on silica gel (720 g) with chloroform eluent (100 ml aliquots). Fractions 15–27 furnished the triphenylsulfone-sulfide (**3**) (5.3 g, 43.5%). After recrystallization from benzene, the product had m.p. 131.5–133.5 °C and was homogeneous on t.l.c. (R_F, 0.41) when developed with chloroform. The i.r. bands were present ($CHCl_3$), 1312 and 1130 cm^{-1}. The n.m.r. spectrum displayed signals at τ 2.80 (15H, m), 6.37 (2H, s), and 7.54 (3H, s). The mass spectrum showed ions at *m/e* 243 (100%), 166 (37%), and 79 (3%).

Anal. Calcd. for $C_{21}H_{20}S_2O_2$: C, 68.45; H, 5.55. Found: C, 68.09; H, 5.32.

Preparation of $PhCH_2{\cdot}S{\cdot}CHCl{\cdot}SO_2{\cdot}CH_3$ (5)

The sulfone-sulfide (**1**) (0.263 g) was added to methylene chloride (5 ml) and the solution brought to gentle reflux. A solution of sulfuryl chloride (0.165 g) in methylene chloride (5 ml) was added dropwise over 8 min. The reaction mixture was refluxed for 1 h. The methylene chloride was rotary evaporated and the residue spotted on two preparative t.l.c. plates. The plates were developed with chloroform and the lower band (R_F, 0.55) was scraped.

The silica gel was covered with chloroform (60 ml) and the mixture stirred for 1 h. The mixture was filtered and the chloroform rotary evaporated affording a colorless oil (0.149 g). The product had R_F 0.41 when developed with chloroform. The i.r. bands were present ($CHCl_3$), 1330 and 1135 cm^{-1}. The n.m.r. showed signals at τ 2.66 (5H, s), 4.56 (1H, s), 5.76 (2H, q, J = 13 Hz) and 6.93 (3H, s). The mass spectrum exhibited ions at *m/e* 250 (1.5%), 171 (21%), 91 (100%), and 65 (12%).

Anal. Calcd. for $C_9H_{11}ClS_2O_2$: C, 43.11; H, 4.42. Found: C, 43.31; H, 4.28.

Preparation of $PhCH_2{\cdot}S{\cdot}CCl_2{\cdot}SO_2{\cdot}CH_3$ (6)

The preparation and properties of this compound have been described elsewhere (28).

Preparation of $Cl{\cdot}S{\cdot}CCl_2{\cdot}SO_2{\cdot}CH_3$ (7)

The dichlorosulfone-sulfide (**6**) (4.941 g) was dissolved in methylene chloride (25 ml) and chlorine (232 ml/min) was bubbled through the reaction mixture for 1 h.

The methylene chloride was rotary evaporated furnishing a residue containing a 1:1 mixture of the dichlorosulfenyl chloride (**7**) and benzyl chloride. The benzyl chloride was distilled off and established as identical to authentic material by n.m.r., i.r., b.p., and t.l.c. The residue was distilled furnishing the sulfenyl chloride (**7**) (3.420 g), b.p. 128–130 °C/1.5 mm (86.1%). The sulfenyl chloride solidified and was recrystallized from carbon tetrachloride which furnished pale yellow needles. The recrystallized sulfenyl chloride had m.p. 55–57 °C and was homogeneous on t.l.c. (R_F, 0.51) when developed with chloroform. The i.r. bands were present ($CHCl_3$), 1350 and 1155 cm^{-1}. The n.m.r. spectrum displayed signals at τ 6.66 (s). The mass spectrum showed ions at *m/e* 193 (2.7%), 149 (100%), 79 (73%), 63 (21%), and 36 (30%).

Anal. Calcd. for $C_2H_3Cl_3S_2O_2$: C, 10.47; H, 1.32. Found: C, 10.62; H, 1.05.

Preparation of $PhCH_2{\cdot}SO{\cdot}CH_2{\cdot}SO_2{\cdot}CH_3$ (11)

The preparation and properties of this compound have been described elsewhere (28).

Chlorination of 1

The sulfone-sulfide (**1**) (5.003 g) was dissolved in glacial acetic acid (25 ml) and distilled water (5 ml) was added. Cl_2 (232 ml/min) was bubbled into the reaction mixture for 45 min. During the chlorination the temperature was maintained at 25–30 °C with an ice–water bath. The acetic acid was distilled off affording a residue containing benzyl chloride (1.293 g, 44%), benzyl acetate (0.845 g, 24%), and the dichlorosulfone-sulfonyl chloride (**4**) (5.659 g, 93.5%). The residue was carefully fractionated providing samples of benzyl chloride and benzyl acetate which were established as identical to authentic samples by n.m.r., i.r., b.p., and t.l.c. The dichlorosulfone-sulfonyl chloride (**4**) was distilled (b.p. 110–115 °C/1 mm). The distilled material was recrystallized from CCl_4 (5×) after which it had m.p. 72–74 °C. The i.r. bands were present ($CHCl_3$), 1390, 1355, 1180, and 1155 cm^{-1}. The n.m.r. spectrum displayed a signal at τ 6.50 (s). The mass spectrum has been discussed previously (34).

Anal. Calcd. for $C_2H_3Cl_3S_2O_4$: C, 9.19; H, 1.16. Found: C, 9.25; H, 1.16.

Chlorination of **6**

The dichlorosulfone-sulfide (**6**) (31.75 g) was dissolved in glacial acetic acid (150 ml) and distilled water (18 ml) was added. Cl_2 (448 ml/min) was bubbled through the reaction mixture for 30 min, during which the temperature was maintained at 25–30 °C. Distilled water (150 ml) was added and the resultant solution extracted with chloroform (six 100 ml aliquots). The combined chloroform layers were washed with aqueous sodium hydroxide (5%) until the aqueous layer remained basic. The chloroform was washed with distilled water (100 ml), dried ($MgSO_4$), filtered, and the chloroform rotary evaporated furnishing a residue containing benzyl chloride (4.322 g, 30.6%), benzyl acetate (2.871 g, 17%), the dichlorosulfone-sulfenyl chloride (**7**) (9.296 g, 36.4%), and the dichlorosulfone-sulfonyl chloride (**4**) (6.778 g, 23.8%). The benzyl chloride and benzyl acetate were distilled off and a sample of each shown to be identical to authentic material by i.r., n.m.r., b.p., and t.l.c.

The addition of a small portion of the dichlorosulfone-sulfenyl chloride (**7**) to a sample of the distillation residue showed the signal at 6.7 τ to have the same chemical shift as the methyl group of **7**. The distillation residue showed a compound present which was identical to **7** on t.l.c. by both R_F and appearance time ($(NH_4)_2Ce(NO_3)_6$ spray).

A portion of the distillation residue (8.004 g) was dissolved in glacial acetic acid (50 ml) and distilled water (6.6 ml) was added. Cl_2 (448 ml/min) was passed through the solution for 3 h. Water (100 ml) was added and the resultant solution extracted with chloroform (three 100 ml aliquots). The combined chloroform layers were washed with 2.5% NaOH (100 ml aliquots) until the aqueous layer was basic. The chloroform was washed with distilled water, dried ($MgSO_4$), filtered, and rotary evaporated furnishing impure **4** (6.981 g). The sample was dissolved in carbon tetrachloride, cooled, and seeded. Crystals identical to **4** (as obtained from **1**) by n.m.r., i.r., m.s., and m.p. were obtained.

Chlorination of **7**

The sulfone-sulfenyl chloride (**7**) (4.990 g) was dissolved in glacial acetic acid (25 ml) and distilled water (3.3 ml) was added. Cl_2 (232 ml/min) was bubbled through the reaction mixture for 14.5 h. The acetic acid was distilled off at reduced pressure affording a residue of the sulfone-sulfonyl chloride (**4**) (3.996 g, 70%) and unreacted sulfone-sulfenyl chloride (**7**) (1.019 g, 20%). A portion of the residue was crystallized, with seeding, from carbon tetrachloride. The first crop was shown to be identical to **4** (as obtained from **1**) by n.m.r., i.r., m.p., and mixture m.p.

Hydrolysis of **4**

The sulfone-sulfonyl chloride (**4**) (1.431 g) was added to distilled water (10 ml). The mixture was refluxed for 1 h. Shortly after reflux began the solution became homogeneous. Upon completion of the reflux, the solution was extracted with chloroform (five 15 ml aliquots) and *the aqueous phase* set aside. The combined chloroform layers were dried ($MgSO_4$), filtered, and the chloroform rotary evaporated yielding the dichlorosulfone (**8**) (0.700 g, 79%). The sulfone was recrystallized from 95% ethanol and established as identical to authentic material (29) by m.s., i.r., m.p., mixture m.p., and n.m.r.

The aqueous phase was diluted with distilled water to a volume of 200 ml. A standard gravimetric sulfate determination (35) furnished $BaSO_4$ (0.892 g, 70%). The $BaSO_4$ isolated was identical to authentic material by i.r. (KBr).

Chlorination of **11**

The sulfone-sulfoxide (**11**) (5.001 g) was dissolved in glacial acetic acid (25 ml) and distilled water (3.3 ml) was added. Cl_2 (232 ml/min) was bubbled through the reaction mixture for 45 min. The acetic acid was distilled off at reduced pressure giving a residue of crude dichlorosulfone-sulfonyl chloride (**4**) (5.259 g, 93.5%). A portion of the sample was crystallized from carbon tetrachloride furnishing **4** which was identical to previous samples by n.m.r., i.r., m.p., and mixture m.p.

Chlorination of **2**

The diphenylsulfone-sulfide (**2**) (6.006 g) was added to a solution of glacial acetic acid (25 ml) and distilled water (3.3 ml). Chlorine (232 ml/min) was bubbled through the reaction mixture for 45 min. The acetic acid was distilled off furnishing a residue containing diphenylchloromethane (2.989 g, 72%) and the dichlorosulfone-sulfonyl chloride (**4**) (4.4896 g, 84%). The crude mixture was stored in a freezer. After some time crystals of diphenylchloromethane appeared and were rapidly filtered. They were identical to authentic material by n.m.r., i.r., and b.p. The filtered solution was added to carbon tetrachloride (5 ml), stored in a freezer, and seeded with **4**. The crystals were filtered and shown to be identical to **4** by n.m.r., i.r., m.p., and mixture m.p.

Chlorination of **3**

The triphenylsulfone-sulfide (**3**) (10.7544 g) was added to a solution of glacial acetic acid (50 ml) and distilled water (6.6 ml). Cl_2 (232 ml/min) was bubbled into the reaction mixture for 45 min. During the chlorination a solid formed in the reaction mixture. At the end of the reaction the solid was filtered off and shown to be triphenylchloromethane (3.967 g). The acetic acid was distilled off affording a residue containing triphenylchloromethane (1.502 g, total 67%) and the dichlorosulfone-sulfonyl chloride (**4**) (5.497 g, 72%). The triphenylchloromethane was identical to authentic material by n.m.r., i.r., and t.l.c. The dichlorosulfone-sulfonyl chloride (**4**) was recrystallized from carbon tetrachloride (4×) and shown to be identical to previously isolated **4** by n.m.r., i.r., m.p., and mixture m.p.

Chlorination of Benzyl Methyl Sulfide

Benzyl methyl sulfide (7.706 g) was added to a solution of glacial acetic acid (25 ml) and distilled water (3.3 ml). Chlorine (232 ml/min) was bubbled into the reaction mixture for 30 min. Distilled water (35 ml) was added and the solution extracted with chloroform (three 50 ml aliquots). The combined chloroform layers were washed with 2½% w/v NaOH (two 50 ml aliquots), distilled water (75 ml), dried ($MgSO_4$), filtered, and the chloroform distilled off. The residue contained benzylsulfonyl chloride (0.368 g, 3.5%), benzyl chloride (5.958 g, 84%), and methanesulfonyl chloride (4.774 g, 75%).

After standing overnight, crystals formed, which were filtered off and shown to be identical to authentic benzylsulfonyl chloride by n.m.r., i.r., m.p., and t.l.c. Some of

the filtered residue (2.194 g) was chromatographed on silica gel (120 g) using carbon tetrachloride eluant. Elution with carbon tetrachloride (1.5 l) furnished benzyl chloride which was identical to authentic material by i.r., n.m.r., and b.p. Further elution with chloroform (500 ml) furnished methanesulfonyl chloride which was identical to authentic material by n.m.r., i.r., and b.p.

The authors are indebted to Mr. W. K. Jardine for technical assistance and to Mr. J. LeDue for running the mass spectra. We are grateful to Dalhousie University for some financial support.

New Access to Noradamantanes via Generation of Selectively Protected Bicyclic β-Diketones

D GRAVEL[1] AND S. RAHAL[2]

Department of Chemistry, University of Montreal, P.O. Box 6210, Montreal, Quebec H3C 3V1

Received May 8, 1975

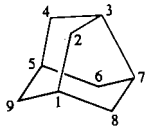
D. GRAVEL and S. RAHAL. Can. J. Chem. **53**, 2671 (1975).

The synthesis of 2,9-disubstituted and 2- and 9-monosubstituted noradamantanes is described starting from 4-acetoxycyclohexanone. The key step in this approach is the generation of selectively protected 7-acetoxybicyclo[3.3.1]nonane-2,9-dione by trapping the imminium salt precursor by an acetalyzing reagent.

D. GRAVEL et S. RAHAL. Can. J. Chem. **53**, 2671 (1975).

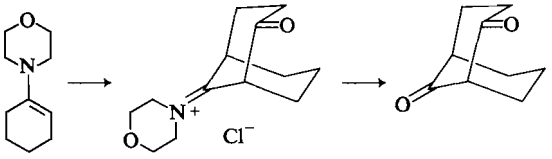
La synthèse des noradamantanes disubstitués en 2,9 ainsi que monosubstitués en 2 et 9 est décrite à partir de l'acétoxy-4 cyclohexanone. L'étape clé dans cette voie de synthèse et l'obtention de l'acétoxy-7 bicyclo[3.3.1]nonanedione-2,9 sélectivement protégée en position-9. Ceci est rendu possible en piégeant le sel d'immonium précurseur de la dione par un agent acétalisant.

Continuing interest in the synthesis of substituted noradamantanes (1), be it for physical organic or pharmacological studies, prompts us to report our results concerning a new mode of access to the noradamantane ring system **1**.



1

In 1967, Hickmott and Hargreaves (2) reported the condensation of the morpholine enamine of cyclohexanone with acryloyl chloride to yield bicyclo[3.3.1]nonane-2,9-dione after hydrolytic work up as depicted in Scheme 1. We were able to take advantage of the intermediate imminium salt in this reaction to devise a successful route to noradamantanes.



SCHEME 1

In the present communication we report the synthesis of 2,9-disubstituted and 2- and 9-monosubstituted noradamantanes starting from readily available 4-acetoxycyclohexanone (**2**)[3], as shown in Scheme 2.

The morpholine enamine of the starting ketone **2** is prepared in the usual manner and condensed *in situ* with acryloyl chloride following the procedure of Hickmott and Hargreaves (2) to yield the intermediate imminium salt **3** in the form of a dark solid. Whereas the usual (**2**) hydrolytic work up leads to β-diketone **4** which is a dead end in the projected synthesis[4], the simple filtration and washing of the precipitate with anhydrous benzene and then ether yields the white intermediate salt **3**, sufficiently pure for acetalyzation. Stirring of the imminium salt **3** in ethanedithiol or ethylene glycol for 20 h affords, after chromatography, either the monoethylenedithioacetal derivative **5**, yield[5] 15% based on **2**; b.p. 200 °C/0.1 Torr; i.r. 1705, 1730 cm^{-1}; n.m.r. singlet (3H) δ 2.07, singlet (4H) δ 3.37, multiplet (1H) δ 5.1 $W_{1/2}$ 10 Hz; or the monoethylenedioxyacetal derivative **10**, yield [5]10% based on **2**;

[2]C.I.D.A. Predoctorate Fellow, 1970–1975.

[3]Compound **2** is obtained from commercial 1,4-cyclohexanediol either by monoacetylation followed by chromic oxidation (8) or by selective oxidation with silver carbonate (9) followed by acetylation.

[4]As could be anticipated, attempts to saponify the acetate or selectively acetalyze the 9-keto group in **4** were unsuccessful.

[5]Yields reported are not optimized. Reported yields (2) of 45% in the synthesis of bicyclo[3.3.1]nonane-2,9-dione (Scheme 1) could not be repeated either by ourselves or by others (3).

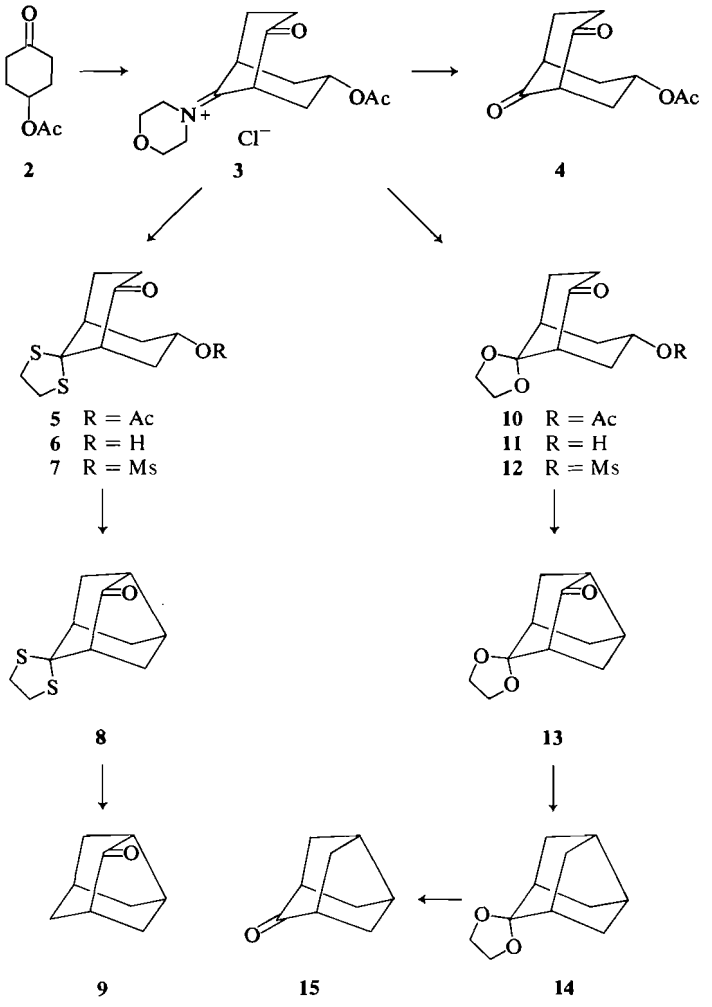

SCHEME 2

m.p. 86–87 °C; i.r. 1705, 1735 cm^{-1}; n.m.r. singlet (3H) δ 1.97, singlet (4H) δ 3.98, multiplet (1H) δ 4.97 $W_{1/2}$ 9 Hz. This procedure therefore allows the preparation from 4-acetoxycyclohexanone (**2**) of the selectively protected β-diketones **5** and **10** in essentially one step.[6]

Saponification of the ethylenedithioacetal-keto-ester **5** with aqueous sodium carbonate in refluxing methanol for 3 h gives the corresponding semisolid alcohol **6** (crude) which is mesylated under the usual conditions to give the ethylenedithioacetal-keto-mesylate **7**, yield 82% based on **5**; m.p. 104–105 °C; i.r. 1170, 1330, 1710 cm^{-1}; n.m.r. singlet (3H) δ 3.12, singlet (4H) δ 3.42, multiplet (1H) δ 5.06 $W_{1/2}$ 18 Hz. Ring closure of the precursor **7**, carried out in refluxing dioxane in presence of sodium hydride, affords 9,9-ethylenedithionoradamantane-2-one (**8**), yield 82%; m.p. 206–208 °C; i.r. 1740 cm^{-1}; n.m.r. unresolved peaks (6H) δ 2.02 and 2.17, unresolved multiplet (4H) δ 2.67, singlet (4H) δ 3.36; molecular ion, *m/e* 226.0487, calculated; 226.0485. Desulfurization of compound **8** in presence of Raney nickel under specific conditions; 35 °C, absolute ethanolic solution and vigorous stirring for 8 h gives noradamantane-2-one (**9**), yield 80%; m.p. 214–215 °C (lit. (4), 214.5–215 °C), i.r. 1748 cm^{-1}; n.m.r.: unresolved peaks δ 1.8 and 2.3; molecular ion *m/e* 136.0887, calculated 136.0888.

[6]It is important to note that this annellation method appears to be highly stereoselective yielding the desired isomer **5** or **10**. This fact is established firmly by the subsequent conversion of **7** to **8** or **12** to **13**.

In an analogous fashion the monoethylenedioxyacetal **10** may be converted into noradamantane-9-one (**15**). Saponification of **10** with methanolic sodium hydroxide at room temperature gives the corresponding alcohol **11** (crude) which is converted to the mesylate **12** in the usual manner, yield 74.5%, based on **10**; m.p. 121–122 °C; i.r. 1170, 1350, 1700 cm^{-1}; n.m.r. singlet (3H) δ 3.03, singlet (4H) δ 3.98, multiplet (1H) δ 4.95 $W_{1/2}$ 18 Hz. Cyclization of the ethylenedioxy-keto-mesylate **12** is carried out in presence of potassium *tert*-butoxide in refluxing *tert*-butanol to afford 9,9-ethylenedioxynoradamantane-2-one (**13**), yield 85%; i.r. 1745 cm^{-1}; n.m.r. three unresolved peaks (6H) δ 1.87, (2H) δ 2.30, (2H) δ 2.60, singlet (4H) δ 3.98; molecular ion *m/e* 194.0938, calculated 194.0942.

Treatment of keto-acetal **13** under the Huang-Minlon modification of the Wolff–Kishner method (5) leads to 9,9-ethylenedioxynoradamantane (**14**), yield 92%; m.p. 51–52 °C, (lit. (6, 7) 51–52 °C); i.r. 1080, 1125 cm^{-1}; n.m.r. four unresolved peaks (8H) δ 1.7 and 1.84, (2H) δ 2.05, (2H) δ 2.42, singlet (4H) δ 4.0; molecular ion *m/e* 180.1145, calculated 180.1149. Upon acid hydrolysis the acetal **14** gives noradamantane-9-one (**15**), yield 86%; m.p. 194–195 °C, (lit. (6, 7) 193–195 °C); i.r. 1715 cm^{-1}; n.m.r. two unresolved peaks (8H) δ 1.85 and (4H) δ 2.7; molecular ion *m/e* 136.0884, calculated 136.0887.

Further work is in progress to extend the use of the same starting material (**2**) to the synthesis of 1- and 3-substituted noradamantanes.

IAN A. OXTON, OSVALD KNOP, and MICHAEL FALK. Can. J. Chem. **53**, 2675 (1975).

Infrared spectra of polycrystalline $(NH_4)_2PtCl_6$ and $(NH_4)_2TeCl_6$ at various degrees of deuteration were recorded between 4000 and 1000 cm^{-1} at 30 and −165 °C. The stretching and bending vibrations of NH_4^+, NH_3D^+, $NH_2D_2^+$, NHD_3^+, and ND_4^+ ions in these two compounds were systematically examined. The observed fundamentals were unambiguously assigned by analogy with the vibrations of the partially deuterated methanes. The spectrum of isotopically dilute NH_3D^+ confirms the existence of only one crystallographically distinct type of ammonium ion in the structure, on sites of T_d symmetry. Vibrational coupling of neighboring ammonium ions was not detected.

IAN A. OXTON, OSVALD KNOP et MICHAEL FALK. Can. J. Chem. **53**, 2675 (1975).

Les spectres infrarouge de $(NH_4)_2PtCl_6$ et de $(NH_4)_2TeCl_6$ polycristallins à deutération variable ont été enregistrés entre 4000 et 1000 cm^{-1} à 30 °C et à −165 °C. Les vibrations de valence et de déformation des espèces ioniques NH_4^+, NH_3D^+, $NH_2D_2^+$, NHD_3^+ et ND_4^+ dans ces deux composés ont été systématiquement examinés. L'attribution exacte des vibrations fondamentales observées a été réalisée par analogie avec celle des méthanes partiellement deutérés. Le spectre de NH_3D^+ à dilution isotopique indique nettement l'existence d'un seul et unique type d'ion ammonium dans la structure cristalline, sur des sites de symétrie T_d. On n'a pas observé de couplage vibrationnel des ions ammonium voisins.

Infrared spectroscopy has been an important tool in the elucidation of the structural behavior of the ammonium ion in crystals (1–6) and especially useful in the detection of phase changes (7, 8). However, most of the published results are based on the spectra of undeuterated, or fully deuterated, samples and are thus limited in scope. The present study is the first in a series aimed at investigating the spectra of *all* the ionic species $NH_{4-n}D_n^+$ ($n = 0$ to 4) in various known crystalline environments, with particular attention to the spectra of the isotopically dilute NH_3D^+ and NHD_3^+ ions.

Three considerations suggest that spectra of the isotopically dilute ions may prove to be more informative than those of NH_4^+ or ND_4^+.

(*i*) Difficulty has been experienced in making the correct assignment of the stretching fundamentals ν_1 and ν_3. This basic problem may be illustrated by the assignments proposed for these modes in NH_4F by different authors:

[1]NRCC No. 14763.

	ν_1 (cm^{-1})	ν_3 (cm^{-1})
Plumb and Hornig (3)	2870	2810
Waddington (9)	—	3100
Mathieu (10)	2845	3100
Bovey (11)	3100, 3212	2725, 2830

This difficulty would not be encountered in the spectra of crystals containing a low deuterium concentration, since the N—D stretching fundamental $\nu_1(NH_3D^+)$ has a frequency far removed from the spectral region where NH_4^+ ions absorb. This should permit its unambiguous assignment. Similarly, an unambiguous assignment of the N—H stretching frequency $\nu_{3a}(NHD_3^+)$ should be possible in crystals containing a high deuterium concentration.[2]

(*ii*) The region 2700 to 3400 cm^{-1} in the i.r. spectra of undeuterated ammonium compounds is rich in absorption bands and it is likely that extensive Fermi resonance exists between many vibrational levels (3, 13). Among vibrations which may be expected to occur in this frequency range, depending upon the symmetry of the ion in each individual case, are ν_1, ν_3, $2\nu_4$, $\nu_2 + \nu_4$, $\nu_3 + \nu_6$, $\nu_1 + \nu_5$, etc. Judging by the medium-strong i.r. intensities of some of these modes, appreciable "borrowing" of intensity must take place, and the observed intensities will in general correspond to vibrational levels that are considerably perturbed (12, 13). This type of perturbation should be largely absent in the much simpler N—D (or N—H) stretching region of isotopically dilute NH_3D^+ (or NHD_3^+), so that $\nu_1(NH_3D^+)$ (or $\nu_{3a}(NHD_3^+)$) should reflect more directly the environment of the ammonium ion in the crystal.

(*iii*) Vibrational modes of neighboring ammonium ions may be coupled. In the spectra of the undeuterated or fully deuterated compounds the coupling, if present, may escape detection, but it would show up on comparing spectra of ammonium ions in crystals of suitably varied D content. Knowing whether or not vibrational coupling is present is required when ammonium frequencies in different crystal structures are to be compared. The magnitude of the frequency shifts produced by such coupling may be of structural significance, as has recently been found in the case of H_2O spectra in crystalline hydrates (14).

[2]Herzberg's nomenclature has been adopted for the vibrations of the $NH_{4-n}D_n^+$ ions (ref. 12, p. 238).

Vibrational spectra of the partially deuterated ammonium ions have not been tabulated with any completeness. Such data as exist are mainly due to the assignment of extraneous bands in the spectra of "fully" deuterated ammonium compounds (1–3, 6). Ananthakrishnan (15) tabulated some Raman frequencies of partially deuterated NH_4Cl many years ago. Recently Wiener *et al.* (16) presented some tentative assignments for the i.r. spectra of partially deuterated $NH_4H_2PO_4$ and $NH_4H_2AsO_4$. Oden and Decius (17) used an intermediate deuteration of NH_4NCS as a general illustration of the low site symmetry of the ammonium ion in this compound but made no detailed assignments.

For our first study we have selected $(NH_4)_2PtCl_6$ and $(NH_4)_2TeCl_6$. The ammonium ion in these two compounds has been shown to be located at sites of tetrahedral symmetry (see below). The various deuterated ammonium ions might thus be expected to obey the selection rules of their own molecular point groups. The expected correlation of the fundamental vibrations of these species is shown in Table 1.

The vibrational energy levels of a uniquely oriented NH_4^+ ion in a site of symmetry T_d would be expected to bear a close relationship to those of the isoelectronic ion BH_4^- (18) and molecule CH_4 (19, 20). This supposition will be examined in the light of the existing i.r. and Raman spectra of the $CH_{4-n}D_n$ (21–23) and $BH_{4-n}D_n^-$ species (18). We have also sought evidence for the vibrational coupling of neighboring, isotopically similar ammonium ions (*cf.* the coupling of the bending modes of isotopically similar water molecules in crystalline hydrates, ref. 14).

Crystallographic Features of $(NH_4)_2PtCl_6$ and $(NH_4)_2TeCl_6$

Ammonium hexachloroplatinate(IV) has the distinction of being the first reported case of coordination compound studied by X-ray diffraction (24). It is, apart from the H atoms, isostructural with the type compound K_2PtCl_6 (31) and a large number of other cubic compounds having the antifluorite-like structures $R_2[MX_6]$ of symmetry $Fm3m$ (No. 225) (Table 2). Each R atom is coordinated by 12 equivalent X atoms at the corners of a cuboctahedron of symmetry T_d (Fig. 1), $d(R\ldots X) = a_0[(x - \frac{1}{4})^2 + \frac{1}{8}]^{1/2}$. The value of x(Cl) in $(NH_4)_2PtCl_6$ is known only approximately, 0.240(5) (25). However,

$\partial d(\text{N}\ldots\text{Cl}) \sim -0.3\partial x$, so that d(N. . .Cl) is quite insensitive to uncertainties in x. An uncertainty ∂x of ± 0.01, which seems to correspond to the total range of variation of x in the cubic $R_2[MCl_6]$ (28, 30, 31), produces a change in d(N. . .Cl) of only about ± 0.003 Å. The N. . .Cl distance can thus be taken as 3.49 Å to within 0.01 Å. From the results of the neutron-diffraction study of the isostructural $(NH_4)_2SiF_6$ by Schlemper *et al.* (29) there seems little doubt that the H atoms in the hexachloroplatinate are to be looked for in the volumes defined by the N. . .3Cl trigonal pyramids shown in Fig. 1.

The isostructural (25, 30) $(NH_4)_2TeCl_6$ has been included to see what effect on the spectrum of the ammonium ion is produced by replacing the relatively small atom of a transition element, Pt, by a significantly larger atom of a non-transition element, Te. In this compound x(Cl) is 0.248(3) and d(N. . .Cl), 3.61(1) Å (30).

Experimental

$(NH_4)_2PtCl_6$ of high purity was recrystallized twice from cold water. Deuterated samples were obtained by crystallization from mixtures of H_2O and D_2O of the requisite compositions.

$(NH_4)_2TeCl_6$ was prepared by dissolving high-purity TeO_2 in concentrated HCl, adding a solution of the stoichiometric amount of NH_4Cl, and allowing the resulting solution slowly to crystallize on a hot plate. The greenish-yellow crystals were air dried. The sample of intermediate deuteration was prepared in a similar manner from 50% HCl–DCl.

Spectra were recorded at 30 and −165 °C on a Perkin-Elmer model 180 spectrophotometer in the region 4000 to 1000 cm^{-1}. Nujol mulls were supported on KBr windows. Fluorolube mulls were occasionally used to ensure that no bands were overlaid by Nujol bands. In each case the degree of deuteration was estimated from the integrated intensities of the N—H and N—D stretching absorptions at room temperature, assuming that N—D stretching bands have half the integrated intensity of the N—H stretching bands. This is known to be approximately true for D and H stretching vibrations of other systems (32).

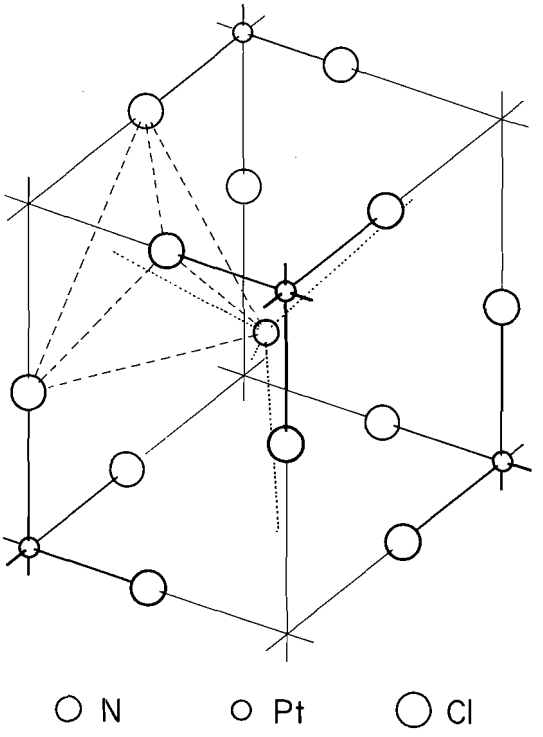

FIG. 1. One-eighth of the unit cell of $(NH_4)_2PtCl_6$. Dotted lines from the N atom indicate the averaged (equilibrium) directions of the N—H vectors.

Results and Discussion

In the room-temperature spectra the bands were broad, hence only a few absorption maxima could be located with accuracy and measurement of low-temperature spectra was essential. This was found to be especially true of the N—D stretching modes (Fig. 2). Where accurate frequency values were available for room temperature *and* liquid-nitrogen temperature, the difference due to temperature variation did not exceed 3 cm^{-1}.[3]

All frequencies quoted in the following (text and Table 3) refer to the low-temperature spectra. The accuracy of the bending frequencies is estimated to be about ± 0.5 cm^{-1} and that of the stretching frequencies, about ± 1 cm^{-1}. The hexachlorotellurate spectra were so similar to those of the hexachloroplatinate that the frequencies for the Te compound are tabulated without further comment.

Examination of the band intensities as a function of the D content of the sample allows assignment of all observed bands (Table 3). All but three of the i.r. active fundamentals predic-

[3]From his observations of the habit and optical properties of $(NH_4)_2PtCl_6$ crystals at different temperatures, Ries (33) proposed the existence of three, possibly four, polymorphs: a "probably O_h" form stable at liquid-air temperatures, a "pseudo-octahedral" form at intermediate low temperatures, and an O_h form stable from a few degrees below 0 °C to decomposition. However, he stated that a similar situation existed for K_2PtCl_6, hence his observations could not have had their cause in the temperature-dependent behavior of the NH_4^+ ion. There was no indication of polymorphism in our i.r. spectra of $(NH_4)_2PtCl_6$.

†This equipoint corresponds to the minimum multiplicity consistent with stoichiometry and with site symmetry T_d at the N atom. See ref. 29 for a discussion of the neutron-diffraction evidence bearing on the H atoms in the isostructural $(NH_4)_2SiF_6$.

ted by Table 1 have been located. The three remaining fundamentals, which are overlaid by more intense absorptions, have been placed by comparison with the spectra of related compounds, as outlined below. No splitting of any of the bands was observed and no fundamental frequency varied by more than 3 cm^{-1} over the whole range of deuterations.

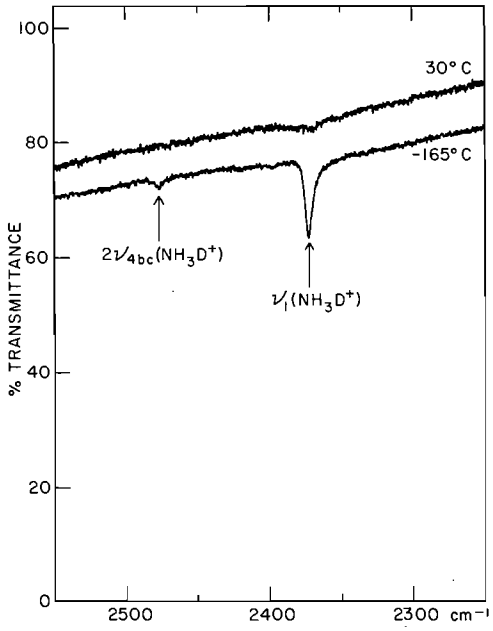

FIG. 2. The N—D stretching region of the i.r. spectrum of $(NH_4)_2PtCl_6$ (1% D) at room temperature and liquid-nitrogen temperature.

N—D Stretching Vibrations

Isotopically dilute NH_3D^+ gives rise to a sharp band at 2372 cm^{-1}, assigned unambiguously to the $\nu_1(a_1)(NH_3D^+)$ mode. The band is a singlet, which confirms the equivalence of hydrogen atom environments in the crystal structure. At intermediate D contents several bands appear in the 2500 to 2300 cm^{-1} region (Fig. 3). Inspection shows that the band assigned to $\nu_1(a_1)(NH_3D^+)$ reaches maximum intensity at a D concentration of about 25%, as would be expected from the statistical distribution of the $NH_{4-n}D_n^+$ species; the frequency of the band does not vary with the D content of the sample. The half-width of the band is 6 cm^{-1}.

At high D contents, when the predominant species is ND_4^+, a single band centered at 2430 cm^{-1} is observed, hence it is assigned to $\nu_3(t_2)(ND_4^+)$. The N—D stretching modes of the remaining species $NH_2D_2^+$ and NHD_3^+ are readily assigned to bands which reach maximum intensity at 50% D, at 2454 and 2398 cm^{-1}, and 75% D, at 2417 and 2314 cm^{-1}, respectively. The remaining bands in this region may be satisfactorily assigned to overtone and combination modes (*cf.* Table 3).

N—H Stretching Vibrations

The region 3300 to 3100 cm^{-1} (Fig. 4) is seen

to contain a multiple, broad absorption in the spectra of samples of intermediate D contents. At zero, or very high, D contents this absorption consists of a single, broad band centered at 3239 and 3240 cm^{-1}, assigned to $\nu_3(NH_4^+)$ and $\nu_{3a}(NHD_3^+)$ respectively.

The absorptions arising from the N—H stretching motions of $NH_2D_2^+$ are located at 3217 and 3204 cm^{-1}. Only one band arising from NH_3D^+, at 3195 cm^{-1}, is observed; the other N—H stretching fundamental is expected at about the same frequency as the more intense $\nu_3(NH_4^+)$ fundamental.

Bending Vibrations

The bending modes of the $NH_{4-n}D_n^+$ species give rise to absorptions in the region 1600 to 1050 cm^{-1} (Fig. 5). Ten bands are observed in this region (Table 3) whilst 12 i.r. active fundamentals are predicted by Table 1.

The $\nu_{4a}(NH_2D_2^+)$ fundamental has been calculated to have the frequency of about 1120 cm^{-1} in partially deuterated ammonium thiocyanate (17). Comparison of the vibrational frequencies of Table 3 with those of the thiocyanate leads us to expect this mode between 1110 and 1100 cm^{-1}. However, this region is dominated by an intense band, assigned to $\nu_{4bc}(NHD_3^+)$, whose maximum intensity occurs at about 75% D. The calculations of Oden and Decius (17) for ammonium thiocyanate place the frequencies of $\nu_{4a}(NH_2D_2^+)$ and $\nu_{4bc}(NHD_3^+)$ within 6 cm^{-1}. The corresponding frequencies of partially deuterated methanes fall within 12 cm^{-1} of each other (ref. 12, p. 309), while those in partially deuterated BH_4^- ions coincide within 0.2 cm^{-1} (18). It is thus concluded that the absorption at 1106 cm^{-1} results from both modes and that in ammonium hexachloroplatinate the frequencies of these two modes coincide.

It is not surprising that $\nu_{4a}(NH_3D^+)$ is not observed, since we expect its frequency to coincide with that of the very intense band arising from $\nu_4(NH_4^+)$. The frequencies of the two modes

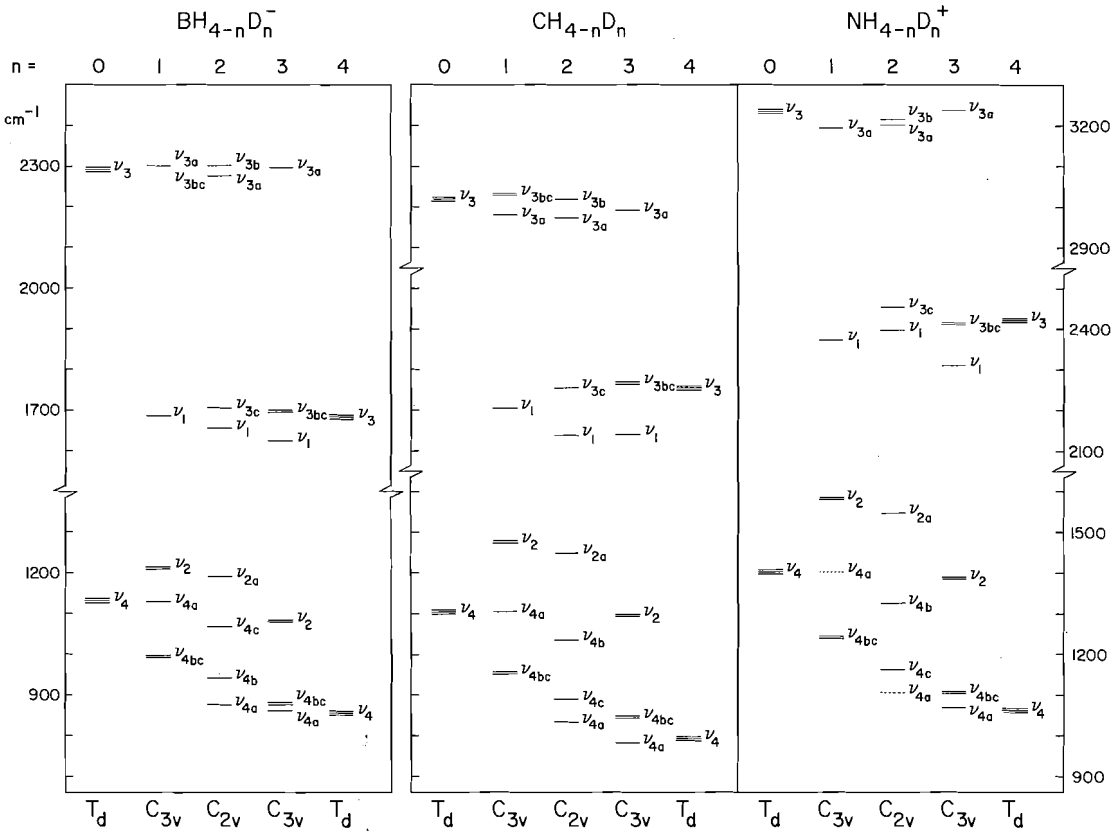

FIG. 6. Observed i.r.-active vibrational energy levels of the $BH_{4-n}D_n^-$, $CH_{4-n}D_n$, and $NH_{4-n}D_n^+$ species.

differ by only 0.4 and 1.4 cm^{-1} in the corresponding methane and borohydride species respectively.

Comparison with CH_4, CD_4, BH_4^-, and BD_4^-

The vibrational frequencies of the $NH_{4-n}D_n^+$ species are compared with those of the corresponding $CH_{4-n}D_n$ and $BH_{4-n}D_n^-$ species in Fig. 6. The overall similarity of the three sets of energy levels is striking.

For the triply degenerate modes of a tetrahedral XY_4 molecule and its isotopic counterpart $X^{(i)}Y_4^{(i)}$, the Teller–Redlich rule (ref. 12, p. 232) predicts

$$[1]\quad \omega_3^{(i)}\omega_4^{(i)}/\omega_3\omega_4 = (m_Y/m_Y^{(i)})[(m_X/m_X^{(i)})(m_X^{(i)} + 4m_Y^{(i)})/(m_X + 4m_Y)]^{1/2}$$

where ω_3 and ω_4 are the zero-order frequencies of ν_3 and ν_4 in XY_4, $\omega_3^{(i)}$ and $\omega_4^{(i)}$ are the corresponding frequencies of $X^{(i)}Y_4^{(i)}$, and m_X, m_Y, $m_X^{(i)}$, and $m_Y^{(i)}$ are the masses of the atoms X, Y, $X^{(i)}$, and $Y^{(i)}$, respectively. Hence, for the ammonium ions NH_4^+ and ND_4^+, we predict $\omega_3^{(i)}\omega_4^{(i)}/\omega_3\omega_4 = 0.553$. Setting $\nu_3 = 3239$ cm^{-1}, $\nu_4 = 1401$ cm^{-1}, $\nu_3^{(i)} = 2426$ cm^{-1}, and $\nu_4^{(i)} = 1062$ cm^{-1}, we find $\nu_3^{(i)}\nu_4^{(i)}/\nu_3\nu_4 = 0.566$. This agreement is reasonable (difference, 2.4%), since the product rule applies rigorously only for zero-order frequencies.

The corresponding values for CH_4 and CD_4 are 0.559 for the ω-product and 0.570 for the ν-product, *i.e.* in agreement to within about 2%.[4] The agreement obtained for NH_4^+ and ND_4^+ is viewed as comparable with that for CH_4 and CD_4. This suggests that no unduly large anharmonic terms are present in the vibrational potential energies of the ammonium ions as a result of their crystalline environments.

Comparison can also be made with the results

[4]Frequencies taken from ref. 12, p. 309.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

of Coker and Hofer (18) for $^{11}BH_4^-$ and $^{11}BD_4^-$. Here the right-hand side of [1] yields 0.563, while the $\nu_3^{(i)}\nu_4^{(i)}/\nu_3\nu_4$ product of the observed frequencies, 0.556, has a *smaller* value, contrary to expectation. One cannot, therefore, regard as justified the assumption made by these authors, *viz.* that ν_3 as the central component of a Fermi triplet is not seriously affected by Fermi resonance.

No evidence was found in the spectra of either $(NH_4)_2PtCl_6$ or $(NH_4)_2TeCl_6$ to support the presence of vibrational coupling between neighboring ammonium ions in the crystal structure. Since the unit-cell dimensions of the two compounds encompass those of most of the cubic $R_2[MCl_6]$ compounds (28, 25), it would appear that no appreciable coupling of vibrational modes exists in any of the ammonium hexachlorometallates.

Conclusions

Unambiguous assignment of the i.r. active bending and stretching modes of the $NH_{4-n}D_n^+$ species in ammonium hexachloroplatinate(IV) and hexachlorotellurate(IV) has been made by analogy with the partially deuterated methanes. The number of observed i.r. active fundamentals is consistent with the existence of only one crystallographically distinct type of ammonium ion in a site of T_d symmetry. The bending and stretching vibrations involving the D atom of isotopically dilute NH_3D^+ ions demonstrate the equivalence of the hydrogen atoms and their positions in the crystal in a strikingly direct manner: absorptions due to the $\nu_1(a_1)$ and $\nu_{4bc}(e)$ modes appear, at liquid-nitrogen temperatures, as clear-cut singlets with half-widths of 6 and 5 cm^{-1} respectively. Vibrational coupling of the ammonium ions was not detected and must be of the order of 1 cm^{-1} or less.

Hydration of Some Acids in Sulfolane

R. L. BENOIT AND S. Y. LAM

Département de Chimie, Université de Montréal, C.P. 6210, Montréal, Québec H3C 3V1

Received March 6, 1975

R. L. BENOIT and S. Y. LAM. Can. J. Chem. **53**, 2683 (1975).

Interaction between water at low concentrations and some carboxylic acids, methanesulfonic acid and picric acid, HA, have been studied in Sulfolane at 30 °C. Vapor pressure measurements and calorimetry were used. Results are interpreted in terms of hydration constants K_1 and enthalpy changes ΔH_1, for the 1:1 complexes $H_2O\cdots HA$. The values of K_1 are low and generally increase slightly with the strength of the acid HA from ~0.4 for acetic acid to 5.7 for methanesulfonic acid.

These results in conjunction with reported data in acetonitrile suggest that the basicity of water in Sulfolane and acetonitrile is lower than that of bromide ion. The hydration enthalpies ΔH_1 do not show any definite increase with the strength of the acids HA.

R. L. BENOIT et S. Y. LAM. Can. J. Chem. **53**, 2683 (1975).

On a étudié dans le sulfolane à 30 °C, et par mesure de pressions de vapeur et calorimétrie, les interactions entre l'eau aux faibles concentrations et des acides HA, HA étant des acides carboxyliques, méthanesulfonique et picrique. On interprète les résultats sur la base des constantes d'hydration K_1 et des variations d'enthalpie ΔH_1 des complexes $H_2O\cdots HA$. Les valeurs de K_1 sont faibles et augmentent peu dans l'ensemble avec la force des acides HA depuis 0.4 pour l'acide acétique jusque 5.7 pour l'acide méthanesulfonique. Ces résultats combinés à des données sur l'acétonitrile suggèrent que la basicité de l'eau dans le sulfolane et l'acétonitrile est inférieure à celle de l'ion bromure. Les enthalpies d'hydratation ΔH_1 ne croissent pas de façon marquée avec la force des acides HA.

While protonation of water has been widely studied, complexing of water by acids has received less attention. However, the presence of water hydrogen-bonded to acids in concentrated solutions of strong acids, such as H_2SO_4 and HNO_3, has been inferred from physicochemical measurements (1). Hydrogen-bonding equilibria between water and acids in nonpolar or slightly polar solvents have also been investigated (ref. 2 and references cited therein). Kolthoff and Chantooni have reported hydration constants for some acids in acetonitrile (3). Direct spectroscopic evidence for the existence of the complex $H_2O\cdots HCl$ in a nitrogen matrix at 15 K has recently been published (4).

During the course of a study of HCl solutions in Sulfolane (5), a weakly basic dipolar solvent, it became apparent from conductivity and near-infrared measurements that the reaction $2HCl + H_2O \rightleftarrows H_3O^+ + HCl_2^-$ did not fully account for the behavior of added water in these solutions, thus suggesting the presence of the $H_2O\cdots HCl$ complex. We have therefore carried out a thermodynamic study of the hydration of a series of acids in Sulfolane using vapor pressure and calorimetric measurements with a view to determining the influence of the strength of the acid HA on the stability of the complex $H_2O\cdots HA$. It was also hoped that such an investigation combined with some results from our current work on hydration of H^+ and anions A^- in Sulfolane (6) could help to provide an understanding of the influence of residual water on the dissociation of acids HA in Sulfolane and related solvents (7).

Experimental

Chemicals

Conductivity water was used. Purification of Sulfolane was given elsewhere (8). The freshly prepared solvent had a specific conductivity of 1.00×10^{-7} cm^{-1} Ω^{-1}, and a residual water content of 4.4×10^{-3} *M* as determined by Karl Fischer titration. Acids were analyzed by titration using standardized sodium hydroxide solution and appropriate indicators. Acetic acid (99.8%) was obtained from CIL. Chloroacetic (99.6%), 3,5-dinitrobenzoic (99.4%), and methanesulfonic acids (99.9%) were from Eastman. Dichloroacetic (99.8%), trichloroacetic (99.8%), and *o*-nitrobenzoic acids (99.5%) were Baker chemicals. Trifluoroacetic acid (99.8%) was from Aldrich. *m*-Nitrobenzoic acid (99.9%) was obtained from MC and B. Picric acid (99.9%) was recrystallized from the wet product of Anachemia using ethanol.

Vapor Pressure Measurements

The apparatus and procedure for vapor pressure measurements at 30 °C were similar to that given pre-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

viously (9) except that the concentrations of water after experiments were checked by Karl Fischer titration. Test solutions, 0.5 *M* in acid with variable concentrations of water, usually below 0.4 *M*, were made up in volumetric flasks by weighing. Concentrations are expressed on the molar scale.

Calorimetry

The calorimetric apparatus and procedure used have been reported previously (5). The heats of mixing known weights of water with 27 ml of 0.5 *M* acid solutions in Sulfolane at 30 °C were determined for water concentrations less than 0.12 *M*. The heats of solution in Sulfolane of acetic, dichloroacetic, and trifluoroacetic acids were also measured for concentrations less than 0.5 *M*.

Conductivity

The conductivity bridge has already been described (10). Measurements were made at 30 °C on Sulfolane solutions of 0.5 *M*, dichloro, trichloro, and trifluoroacetic, picric and methanesulfonic acids with successive additions of water from a microburette.

Results and Discussion

Vapor Pressures

The partial pressures of water for water–Sulfolane mixtures at low water concentrations were obtained by subtracting from the total pressure the very small vapor pressure of pure Sulfolane, 0.02 mm Hg determined previously (8). Measurements of partial pressures of water-free 0.5 *M* acid solutions showed that most of these had negligible pressures except in the case of acetic acid (0.33 mm Hg) and trifluoroacetic acid (0.08 mm Hg). Corrections were applied where necessary to yield the partial pressures of water plotted in Fig. 1 as a function of total water concentration.

For the binary system, water–Sulfolane, the measured vapor pressures of water are in good agreement with previous values (8). The Henry's law constant for water at infinite dilution (when only monomer is likely to be present) is calculated as 11.5 mm/*m*. If one assumes that the nonlinearity of the water vapor pressure plot is due to self-association of water, then from the water monomer concentration (given by the limiting slope of the plot of water vapor pressure *vs.* water concentration), calculated dimerization constants vary from 0.08 to 0.16 M^{-1} in passing from 0.2 to 0.7 *M* water. This water dimerization constant is close to that found in propylene carbonate (9). In order to simplify the interpretation of the vapor pressure data in the presence of water and acids, the water concentration was usually kept below 0.4 *M*, so that at least 95% of water molecules were present as monomer.

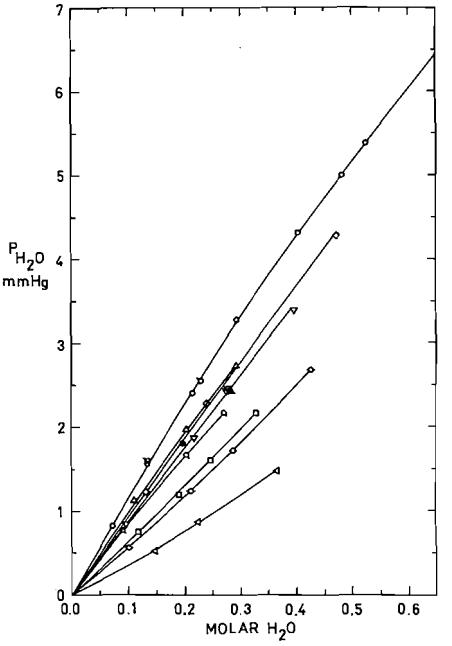

FIG. 1. Partial pressures of water for 0.5 *M* acid solutions in Sulfolane as a function of water concentration at 30 °C: ○, Sulfolane; ◔, 0.50 *M* 2,4,6-$(NO_2)_3C_6H_2OH$; △, 0.50 *M* CH_3COOH; ◇, 0.46 *M* *m*-$NO_2C_6H_4COOH$; ●, 0.48 *M* *o*-$NO_2C_6H_4COOH$; ▽, 0.50 *M* $CH_2ClCOOH$; ▲, 0.54 *M* 3,5-$(NO_2)_2C_6H_3COOH$; ◔, 0.50 *M* $CHCl_2COOH$; □, 0.50 *M* CCl_3COOH; –○–, 0.5 *M* CF_3COOH, ◁, 0.53 *M* CH_3SO_3H.

Concentration of Ionic Species

The conductivity results were used to estimate the extent to which water is protonated in side reactions such as

$$[1] \qquad HA + H_2O \rightleftarrows H_3O^+ + A^-$$

Among the acids, HA, studied here, methanesulfonic acid is the strongest acid in aqueous solution, although it is only partially dissociated in a basic dipolar aprotic solvent such as dimethylsulfoxide with a dissociation constant of 1.7×10^{-2} which is close to that of HCl (10). In Sulfolane, a much less basic solvent, the dissociation constant of methanesulfonic acid is expected to be in the order of 10^{-12} so that solutions of all the acids studied should show negligible conductivity in dry Sulfolane. However, the conductivity results plotted in Fig. 2 show that, in aqueous sulfolane, the specific conductance *L* of solutions of the acids HA, increases with the concentration of water, thus for 0.5 *M* HCH_3SO_3 it increases from 1.1×10^{-5} to 1.2×10^{-4} cm^{-1} Ω^{-1} with an increase in water concentration from 0.025 to 0.40 *M*.

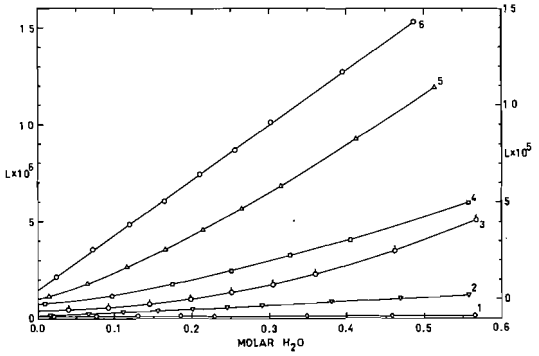

FIG. 2. Specific conductance L of 0.5 M acid solutions as a function of water concentrations at 30 °C: *1*, no acid; *2*, 0.53 M dichloroacetic acid; *3*, 0.48 M picric acid; *4*, 0.50 M trichloroacetic acid; *5*, 0.54 M trifluoroacetic acid; *6*, right-hand scale, 0.53 M methanesulfonic acid.

Calculations using an approximate limiting equivalent conductance of ~ 15 cm^2 Ω^{-1} equiv.$^{-1}$ for H_3O^+ and A^- (11) gave, for the concentrations of these ionic species, values which remain in the order of 2% of the concentration of added water. For the trifluoroacetic acid solutions, the concentrations of ionic species are reduced further by a factor of 10. It was therefore assumed that the concentration of water present as H_3O^+ in the solutions of all the acids HA could be neglected, although this leads to a small error for methanesulfonic acid.

Hydration Constants of the Acids

In order to analyze the vapor pressure data, the possibility of self association of the acids in Sulfolane has to be taken into account. Carboxylic acids are known to dimerize extensively in the vapor phase and in nonpolar or weakly polar solvents. However in solvents like Sulfolane and acetonitrile, it is expected that hydrogen-bonding of the monomer to the weakly basic solvent should favor dissociation of the dimer (12). It is generally agreed that the extent of dimerization of the carboxylic acids decreases with the introduction of electronegative substituents and there is an inverse correlation between the dimer association constant and the acid dissociation constant in water (ref. 13 and references cited therein). It was therefore thought that if CH_3CO_2H and $C_6H_5CO_2H$, the weakest acids studied, were mainly present as monomer in 0.5 M solutions in Sulfolane, then the other stronger acids would behave similarly. Precise and extensive cryoscopic determinations of molal freezing point depressions of organic solutes in Sulfolane by Della Monica *et al.* (14) revealed that the constants for benzoic acid from 0.1 to 1 M are identical to those of diphenylmethane, naphthalene, and benzene which are not expected to dimerize. We also found that the molal freezing point depression constant for 0.01 M acetic acid in Sulfolane as determined by using the LKB calorimeter was 64 $\pm$ 2° compared to normal values of 65° (14) and 64° (15) for nonassociating substances. Furthermore, the heats of mixing with Sulfolane given in Table 1 for acetic acid and the substituted acetic acids, in the range 0.02 to 0.4 M acid, are constant within $\pm$0.02 kcal per mol acid. The absence of concentration effects together with the cryoscopy results strongly suggest the presence of monomers as predominating species for the acids. We also noted that the n.m.r. chemical shift of the acidic proton of 0.1 to 0.5 M HCF_3CO_2 solutions in Sulfolane also remains constant at 11.2 $\pm$ 0.2 p.p.m., with respect to tetramethylsilane, once corrections are applied for residual water. However, it would have been difficult to draw any conclusion from this result alone since this chemical shift value is also close to that of the acid dimer (16). Having established that monomeric species predominate for both

acid and water (at low water concentrations), we were able to interpret our vapor pressure results in terms of the association reaction

[2] $$H_2O + HA \rightleftarrows H_2O\cdots HA$$

The water vapor pressure curves shown in Fig. 1 for 0.5 *M* acid solutions are lower than the water–Sulfolane curve, except for picric acid. For a given water vapor pressure, unbound and bound water concentrations were calculated. Possible interactions in the gas phase between carboxylic acids and water were neglected on the basis of existing data (17). The treatment described in the text of Rossotti and Rossotti (18) was used to calculate the association constants K_1 of [2]. However, as the lowering of the vapor pressure is small, the K_1 values are only approximate for acetic acid and little meaning should be attached to the K_2 constants found for the equilibrium $H_2O + H_2OHA \rightleftarrows (H_2O)_2HA$.

The values of K_1 are given in Table 2 together with the corresponding acid dissociation constant K_a in water (corresponding values of K_a in Sulfolane are not available). The hydration constants K_1 for the acids are remarkably low and tend to increase slightly with the strength of the acids, at least within the substituted acetic acids series. It is interesting to note that a similar pattern has been found for the association constants of carboxylic acids with charged bases, such as the dichloroacetate anion in nitrobenzene (19) and Cl^- and Br^- in nitrobenzene (20), acetonitrile (21), acetone, and dimethylsulfoxide (19). Our K_1 values for the nitrobenzoic acids when compared with those of Huyskens and co-worker (20), in acetonitrile, suggest that H_2O behaves as a H-bond acceptor weaker than Cl^- and also Br^-. The low "basicity" of isolated H_2O molecules compared with the high basicity of bulk water has already been remarked upon (22, 6). Our observed low sensitivity of K_1 to the Hammett σ parameters of the substituents, in the acetic acid series, is in line with Huyskens' results on the complexation of Cl^- and Br^- in acetonitrile with substituted benzoic acids (20). Our hydration constants K_1 for methanesulfonic, picric, and 3,5-dinitrobenzoic acids in Sulfolane are not too different from, but somewhat lower than the same constants K_1 in acetonitrile, which are respectively 14, 0.5, and 1.8 (3). This difference may result from slightly weaker interactions of the acids with acetonitrile than with Sulfolane since water interactions with both solvents are similar (6). However, in a more recent study Kolthoff and Chantooni concluded from near infrared measurements that picric acid is not hydrated in acetonitrile (7). Strong intramolecular H-bonding may explain the inability of picric acid to bind a water molecule in both acetonitrile and Sulfolane.

Hydration Enthalpies

The heats of mixing of water, acetic, dichloroacetic, and trifluoroacetic acids with Sulfolane are given in Table 1. The values which are reasonably independent of concentration in the ranges studied, are respectively +1.63, +0.90, −1.95, and −1.46 ± 0.02 kcal mol^{-1}. The heats of mixing of water with 0.5 *M* acid solution in Sulfolane are listed in Table 3. In the case of

	0.120	0.79		0.120	1.60

0.5 *M* picric acid, the heat of mixing remains unchanged thus confirming that this acid is not appreciably hydrated. In the presence of the other acids, the heats of mixing become less endothermic or even exothermic for the stronger acids. The experimental heat change was taken as the sum of two contributions, the enthalpy of mixing of water with Sulfolane and the hydration enthalpy of the acid. By calculating the concentrations of unbound and bound water (derived from the values of the hydration constants), the enthalpy of hydration ΔH_1, of the acids were obtained and are given in Table 2. A small correction was applied to ΔH_1 in the case of methanesulfonic acid to take into account [1]. In order to calculate this correction, −9.8 kcal mol^{-1} was used for the heat of protonation of water; this value was calculated from the heat of mixing in Sulfolane, of water with an excess of $HSbCl_6$ (a strong acid in this solvent).[1] The concentration of H_3O^+ was obtained from the conductivity data. The correction was 0.2 kcal per mol of water.

The hydration enthalpies, ΔH_1, listed in Table 2, although somewhat imprecise because of weak complexing, mainly emphasize the absence of a definite increase of ΔH_1 with the strength of the acids as indicated by the pK_a values. However, it has been shown by Kebarle and co-worker (23) that the enthalpies of the related reaction for complex formation between Cl^- and acids HA in the gas phase increase with the acid strength. Thus a similar increase of the enthalpy of the hydration reaction $H_2O + HA = H_2O\cdots HA$ with the strength of the acid HA could be expected in the gas phase, at least within the substituted acetic acid series. If this increase is not observed in the solvent phase, it is partly because the interaction between the solvent and HA also increases with the strength of HA, *i.e.* both the base, H_2O, and the slightly basic solvent compete effectively for the acid HA. The results of our analysis of the solvent effect on complex formation between Cl^- and acids HA (24) support this view.

Particle Motions in Sheared Suspensions. XXVIII. Configurations of Coiled Fibers in Shear Flow[1]

A. Okagawa and S. G. Mason

Pulp and Paper Research Institute of Canada and Department of Chemistry, McGill University, Montreal, Québec H3C 3G1

Received March 25, 1975

A. Okagawa and S. G. Mason. Can. J. Chem. **53**, 2689 (1975).

The coiling of elastomer filaments in liquids undergoing shear flow was studied experimentally. In the steady state the rotating coils were stretched along the axes of flow and vorticity, compacted along the third orthogonal axis, and became progressively more entangled as the velocity gradient increased. Although the coils did not possess spherical symmetry, the distribution of end-to-end distances and maximum projected dimensions projected on a given axis or plane corresponded closely to random coiling statistics.

A. Okagawa et S. G. Mason. Can. J. Chem. **53**, 2689 (1975).

On a étudié expérimentalement l'enroulement de filaments d'élastomère dans des liquides soumis au cisaillement d'écoulement. Dans l'état stationnaire les filaments en rotation sont allongés le long des axes d'écoulement et du rotationel comprimés le long du troisième axe orthogonal et deviennent de plus en plus enchevêtrés à mesure que le gradient de vitesse augmente. Quoique les filaments ne possèdent pas la symétrie sphérique, la distribution des distances entre les bouts de filaments et les dimensions maximales projetées sur un plan ou un axe donné correspondent de très près à une pelote statistique. [Traduit par le journal]

Introduction

Forgacs and Mason (1) have described some interesting observations of the rotational orbits of flexible threads suspended in viscous liquids subjected to simple shear flow. Three rotational orbits were observed (springy and snake, helical, and coiled) with the orbit class depending upon the amount of deformation (bending) of the thread, which in turn depended on the extended length of the thread, its bending modulus, and the deforming stresses generated by the flowing liquid.

Quantitative data was presented for the first two orbit classes, but the behavior of the entangled coils was only qualitatively described. In this brief communication we present measurements of dimensions of rotating coils and relate their statistical properties to those of random coils.

For our purposes we define several characteristic dimensions of coiled fibers as follows, using essentially the quantities as those for describing coiled linear macromolecules. Let a system of Cartesian coordinates X_i ($i = 1, 2, 3$) be fixed in space with the origin at one end of a coiled fiber as shown in Fig. 1. The end-to-end distance can be expressed by the projected lengths h_{ij} and h_i of the vector connecting the two ends of the filament on the coordinate plane X_iX_j and axis X_i respectively. The direction of h_{23} is given by the azimuthal angle ϕ_1 measured from the X_2-axis. Two of the maximum projected dimensions a_i along the coordinate axes are also defined in Fig. 1. The liquid in which the filament is suspended is subjected to a simple shear flow whose velocity components u_i are $u_1 = u_2 = 0$ and $u_3 = GX_2$ where G is the velocity gradient which together with the viscosity of the liquid determines the deforming stresses (1).

In our experiments we have measured distributions of ϕ_1, h_i, h_{ij}, and a_i at various values of G for coils which were in statistically steady states.

Experimental

The experiments were performed in a Couette apparatus described previously (2) but fitted with two counter-rotating transparent concentric cylinders. Single elastomer filaments of circular cross section (Lycra by DuPont) of diameter 40 μm cut to various lengths were suspended in a Newtonian silicone oil (Dow Corning 200; 100 stokes) and located (2) in the stationary layer ($u_3 = 0$) in the annular gap between the cylinders. The range of shear rates G was from 0.5 to 15 s^{-1}. Cinematographic records of the coil were made at 12 frames/s along the

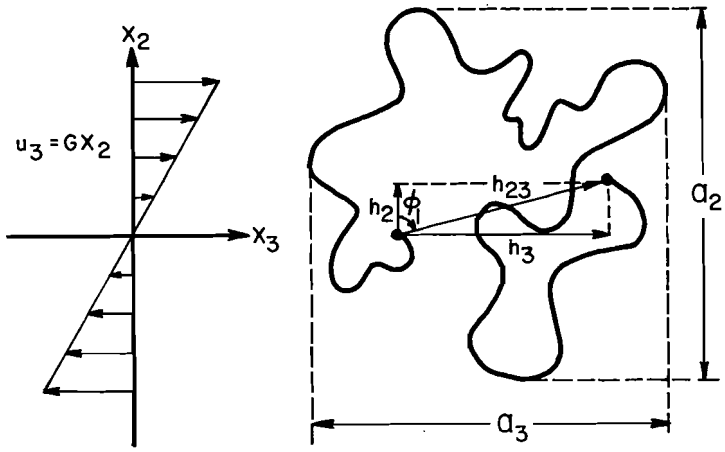

FIG. 1. Definition of end-to-end distances h_{23}, h_2, and h_3 projected on the X_2X_3-plane, X_2-axis, and X_3-axis respectively. The X_1-axis is normal to the page. The maximum projected dimensions a_2 and a_3 are also indicated. The shear field $u_3 = GX_2$ was applied as shown by the arrows. In conducting an experiment the speeds of the counter-rotating cylinders were adjusted so that the coil was located at $X_2 = 0$ and rotated (with a continuously changing configuration) in the clockwise direction about the X_1 (the vorticity) axis.

X_1-axis (viewing vertically down into the annulus) and along the X_2-axis (viewing horizontally through the transparent cylinders) and the various dimensions were measured in frame-by-frame analysis of the cine-films. The mean values obtained from more than 500 measurements at each value of G are thus the time-averaged values for a single coil rather than instantaneous number-averages for an assembly of coils.

Results and Discussion

Qualitatively, the observations were similar to those previously reported (1) with coiling and entanglement occurring over the range of G in the present experiments only with filaments longer than 20 mm. We therefore selected 25.0 mm filaments for the quantitative measurements. When the shear was applied the filament was initially aligned along the X_3-axis (*i.e.*, the initial values h_1, $h_2 = 0$, $h_3 = 25.0$ mm) after which deformation in the five successive stages previously described (1) occurred until a statistically steady state was attained in which the coiled filament rotated about the vorticity (X_1) axis with continuously changing configurations. Instantaneous photographs of typical coils in these steady states viewed along the X_1 and X_2 axes are shown in Fig. 2 for several velocity gradients. It is seen that the coils were extended along the axes of flow (X_3) and vorticity (X_1).

Projections of h_{23}, ϕ_1, a_2, and a_3 were measured from the photographic projections similar to those shown in upper part of Fig. 2, and h_2, h_3 were calculated from h_{23} and ϕ_1. In a similar way from the photographs along X_2-axis, h_1, h_3, a_1, and a_3 were obtained. As an example, $h_{23}/\bar{h}_{23}$ and ϕ_1 at $G = 3.12\ s^{-1}$ are plotted in a polar diagram in Fig. 3*A*. It is clearly seen that h_{23} exhibits a highly preferred orientation in the direction of flow. When the coil reached a statistically steady state each end of the coiled fiber appeared to behave independently of the other, with each end sometimes leading and at other times trailing. Once the coil formed, however, one end maintained an upper position along the X_1 axis with respect to the other.

In analyzing the cine-films one end of the coil was arbitrarily selected as the reference end and placed at the origin of Fig. 3*A*. Although one end or the other occasionally disappeared due to overlap with other segments of the coil, the reference end was easily identified when it reappeared several frames later. Analysis of diagrams like Fig. 3*A* showed that the distribution of ϕ_1 for h_{23} was symmetrical with respect to both the X_2 and X_3-axes. If n_{ϕ_1} is the number of configurations observed for h_{23} oriented between 0 and ϕ_1 and N is total number of observations, the cumulative distribution $P(\phi_1) = n_{\phi_1}/N$. Values of $P(\phi_1)$ for the coil at $G = 3.12\ s^{-1}$ are shown in Fig. 3*B* where for simplicity and because of symmetry mentioned above, the

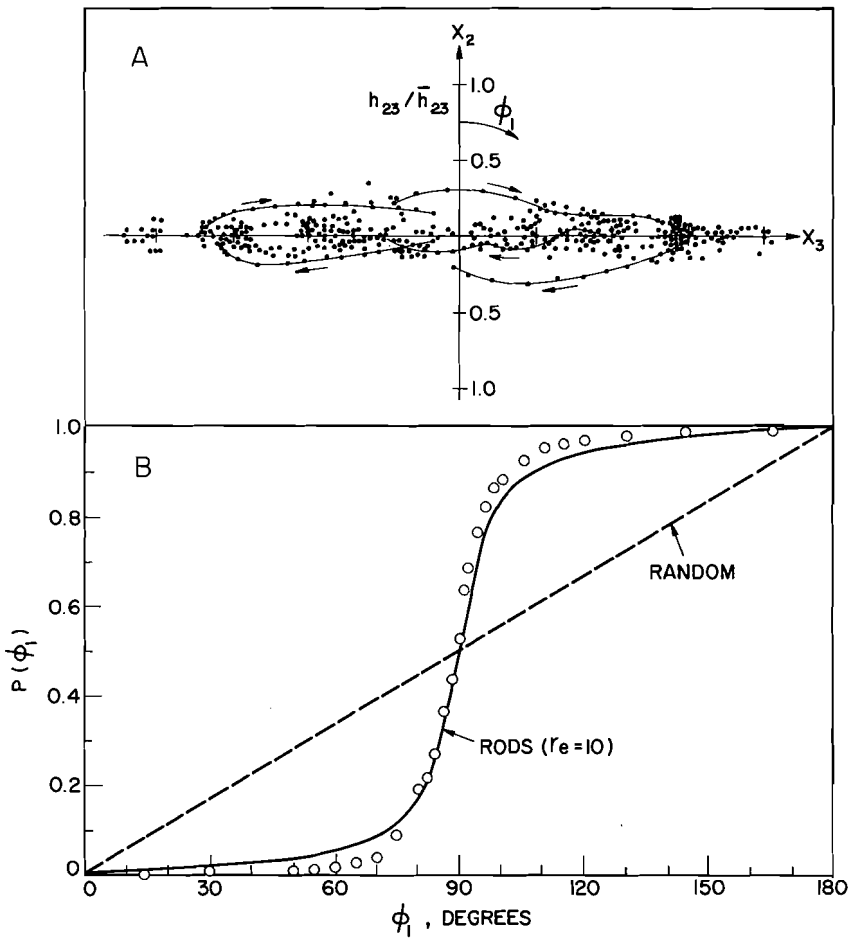

FIG. 3. (*A*) Polar plot of one end of a coil relative to the other (placed at the origin) at $G = 3.12\ s^{-1}$. Each point represents a frame of a cine film taken along the X_2-axis. (Fig. 2*B* being one such frame) when the two ends could be clearly identified. Short sections of successive points are joined and represent portions of the locus of the one end of the coil relative to the other in the directions shown by the arrows. (*B*) Integral distribution $P(\phi_1)$ of h_{23} at $G = 3.12\ s^{-1}$, plotted as points. The broken line corresponds to spherical symmetry, and the solid line is the steady state distributions for rigid prolate spheroids of $r_e = 10$ calculated from [4]. Because of symmetry about the X_2-axis in Part (A) the range of ϕ_1 for $P(\phi_1)$ has been taken to be 0 to 180°.

range of ϕ_1 was taken from 0 to 180°. $P(\phi_1)$ showed only a small increase at low ϕ_1 and increased rapidly around $\phi_1 = 90°$ indicating (as is obvious from Fig. 3*A*) that h_{23} was highly oriented in the direction of flow, and was symmetrical about $\phi_1 = 90°$ at which $P(\phi_1) = 0.5$.

Next the probability distributions $p(\alpha) = dP(\alpha)/d(\alpha/\bar{\alpha})$ of various coil dimensions were obtained graphically from the slopes of smoothed curves drawn to fit the experimental cumulative distribution functions $P(\alpha)$ when plotted against a reduced dimension $\alpha/\bar{\alpha}$, where α represents h_i, h_{ij} or a_i and $\bar{\alpha}$ is the corresponding time-averaged value.

Typical results are given in Fig. 4 where we have used $p(h_{23})$ and $p(a_3)$ at two values of G. The range of $h_{23}/\bar{h}_{23}$ varied from 0 to 2.6, and $a_3/\bar{a}_3$ from 0.4 to 2.0. The probability $p(h_{23})$ increased as h_{23} increased and reached a maximum at $h_{23}/\bar{h}_{23} = 0.8 \sim 0.9$, then decreased slowly until $p(h_{23})$ vanished at $h_{23}/\bar{h}_{23} = 2.6$. The probability $p(a_3)$ was zero up to $a_3/\bar{a}_3 = 0.4$ after which it increased sharply toward the maximum at $a_3/\bar{a}_3 = 0.8$, then decreased rapidly. Values of $p(\alpha)$ obtained in this way showed qualitatively similar distributions for the entire range of velocity gradients employed.

As a matter of interest, we have compared

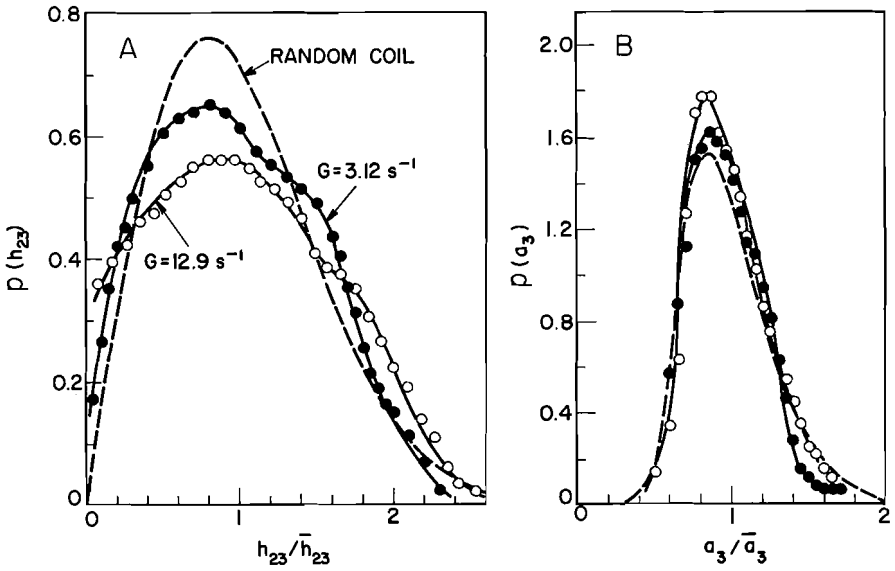

FIG. 4. Probability distributions $p(h_{23})$ and $p(a_3)$ at different values of G. The broken lines show the distributions for random coils calculated from [2] and [3].

these measured distributions with values for randomly coiled linear macromolecules in solutions at rest, when spherical symmetry should exist (3), *i.e.*, the orientation ϕ_1 is equally probable for all angles so that

$$[1] \qquad P(\phi_1) = \int_0^{\phi_1} p(\phi)\, d\phi = \phi_1/\pi$$

This is shown by the broken line in Fig. 3*B*, which of course deviates considerably from the experimental results. On the other hand, when expressed in the reduced dimensions employed above, $p(h_{23})$ corresponding to the random chain model (3) is given by

$$[2] \quad p(h_{23}) = \frac{dP(h_{23})}{d(h_{23}/\bar{h}_{23})} = \frac{\pi}{2}\left(\frac{h_{23}}{\bar{h}_{23}}\right)^2 \exp\left[-\frac{\pi}{4}\left(\frac{h_{23}}{\bar{h}_{23}}\right)^2\right]$$

As shown in Fig. 4*A*, it is striking that the measured probability distributions are qualitatively similar to those calculated from [2]. These similarities between the measured distributions for coiled fibers in shear flow and the theoretical distribution for random coils were also observed with $p(h_2)$ and $p(h_3)$. The corresponding probability $p(a_3)$ for the random chain model (3) is given by

$$[3] \quad p(a_3) = \frac{dP(a_3)}{d(a_3/\bar{a}_3)} = \pi\left(\frac{\bar{a}_3}{a_3}\right)^3 \sum_{i=1}^{\infty} \left\{\frac{\pi^3(2i+1)^2}{8}\left(\frac{\bar{a}_3}{a_3}\right) - 1\right\} \times \exp\left[\frac{-\pi^3(2i+1)^2}{16}\left(\frac{\bar{a}_3}{a_3}\right)^2\right]$$

which is plotted by the broken line in Fig. 4*B* and shows even better agreement with the experimental results.

The measured orientation distribution of ϕ_1 may be better approximated by the steady state orientation distribution of rigid prolate spheroids of axis ratio r_e subjected to a simple shear flow, which is given (4) by the theoretical equation

$$[4] \qquad P(\phi_1) = \frac{1}{\pi}\tan^{-1}\left(\frac{\tan\phi_1}{r_e}\right)$$

Although h_{23} is not constant, a value of $r_e = 10$ in [4] gave close agreement (Fig. 3*B*) with the experimental data. At this stage, we cannot assign any theoretical significance to this, but can merely regard [4] as a useful semi-empirical relation when it is applied to the coils and which indicates a highly preferred orientation of the end-to-end vector along the X_3-axis.

The effects of G on the dimensions of the coils are summarized in Table 1, where mean values of various dimensions are listed. As can

$\bar{h}_3$	−0.03	−0.06	0.01	0.03
$\lvert\bar{h}_1\rvert$	0.76	1.28	1.09	1.95
$\lvert\bar{h}_2\rvert$	0.39	0.38	0.25	0.26
$\lvert\bar{h}_3\rvert$	3.13	3.03	2.93	2.17
$\bar{a}_1$	3.64	3.71	3.27	4.25
$\bar{a}_2$	0.73	0.68	0.75	0.52
$\bar{a}_3$	7.11	6.41	4.72	4.01
$\bar{V}(mm^3)$	14.84	12.70	9.09	6.96

*All values except G and $\bar{V}$ are in mm; the extended length of the coil is 25.0 mm.

be seen from Fig. 3*A*, h_2 and h_3 can be either positive or negative and are equally probable, so that the mean values $\bar{h}_2$ and $\bar{h}_3$ were practically zero for the entire range of velocity gradient studied. On the other hand when observed along the X_2-axis, each end of the coil maintained its relative vertical position so that h_1 remained either positive or negative depending on which end was selected as the reference so that $\pm\bar{h}_1 = |\bar{h}_1|$. On the other hand, the absolute means $|\bar{h}_2|$ and $|\bar{h}_3|$ were nonzero; and as expected from the stretching along the X_3-axis $|\bar{h}_3| \geq |\bar{h}_2|$. The variations in $|\bar{h}_1|$ with G are shown in Fig. 5. While $|\bar{h}_2|$ showed little absolute change, $|\bar{h}_3|$ decreased with G. This confirms that the coils became more compacted in the X_2X_3 plane as G increased as may be seen from the photographs in Fig. 2. Other interesting observations are that (*1*) $|\bar{h}_1|$ was always greater than $|\bar{h}_2|$ and increased with G, and (*2*) at low G $|\bar{h}_3| > |\bar{h}_1|$ but $|\bar{h}_3|$ decreased and $|\bar{h}_1|$ increased on increasing G.

Generally parallel behavior with $|\bar{h}_i|$ was observed for $\bar{a}_i$ (Table 1). This indicates that just as in dealing with coiled linear macromolecules, the end-to-end distances are useful in describing the statistical shapes of the coils. Overall changes in coil dimensions can also be expressed by the effective coil volume $\bar{V}$ which we define as an elliptic cylinder of minor and major axes of $\bar{a}_2$ and $\bar{a}_3$, and of height $\bar{a}_1$ so that $\bar{V} = (\pi/4)\bar{a}_1\bar{a}_2\bar{a}_3$. Values of $\bar{V}$ calculated from the experimental values of $\bar{a}_i$ (Table 1 and Fig. 5) were approximately halved over the range of G, showing a compaction with increasing G which started to level off at the highest gradient (Fig. 5).

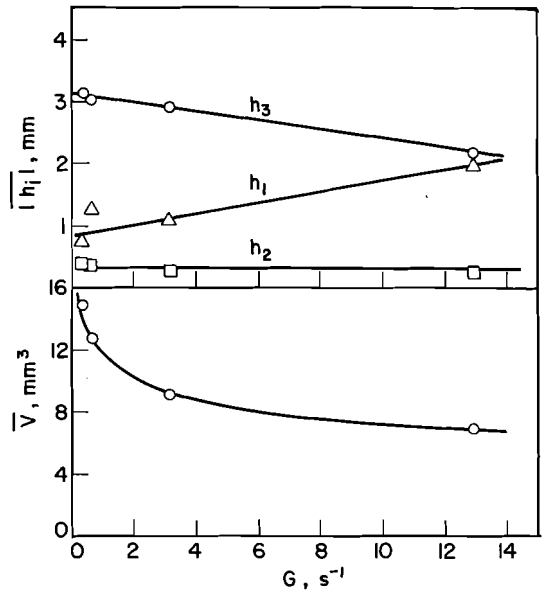

FIG. 5. Mean absolute values of end-to-end distances and the effective coil volume at various gradients.

Of all the observations, that which surprised us the most was the extension of the coil along the X_1 (vorticity) axis. Several possible explanations come to mind: firstly, in the initial stages of coiling both ends were leading (*1*) and the coil was in the X_2X_3 plane so that when the ends approached one another they deflected each other along the X_1-axis; secondly, as the coil bent it could also twist so that torques might be generated in the thread causing it to expand further along the X_1-axis.

Clearly, further experimental and theoretical investigations of these interesting phenomena are warranted, particularly on the effect of flexibility (or the bending modulus) and the torsional resistance of the thread on its configuration. However, it must be realized that theoretical studies will be complex and experimental studies very extensive, since the problem of an infinitesimally thin and infinitely flexible coil has yet to be solved.

SAUL GOLDMAN and LESTER R. MORSS. Can. J. Chem. 53, 2695 (1975).

An electrostatic hydration model, that had previously been developed for ions of the noble-gas structure, was applied to the trivalent lanthanide and trivalent actinide ions. For the trivalent lanthanides it was found that a single primary hydration number resulted in a satisfactory fit of the model to the experimental free energy and enthalpy data. Subsequently, the model was applied to the trivalent actinide ions with a view to predicting values for the free energy and enthalpy of hydration for this series. A primary hydration number for the actinide series was determined by fitting the model to existing experimental enthalpy data for Pu^{3+}. The predictions for this series were found to compare favorably with the few experimental and estimated values that exist.

SAUL GOLDMAN et LESTER R. MORSS. Can. J. Chem. 53, 2695 (1975).

On a appliqué aux ions trivalents des lanthanides et des actinides un modèle d'hydratation électrostatique qui avait été développé antérieurement pour des ions de structure semblable à celle des gaz rares. Pour les lanthanides trivalents, on trouve qu'un seul nombre d'hydratation primaire conduit à une corrélation satisfaisante du modèle avec les données d'enthalpie et d'énergie libre. Par la suite, on a appliqué le modèle aux ions trivalents d'actinides en vue de prédire les valeurs d'énergie libre et d'enthalpie d'hydratation de cette série. On a déterminé un nombre d'hydratation primaire pour la série des actinides en faisant une corrélation du modèle avec les valeurs expérimentales existantes pour Pu^{3+}. On a trouvé que les prédictions pour cette série se comparent avantageusement avec les quelques valeurs expérimentales et estimées qui existent. [Traduit par le journal]

Introduction

In a previous article (1), it was found that an electrostatic model could be used to account successfully for the Gibbs free energy ($\Delta G_t°$) and enthalpy ($\Delta H_t°$) associated with the transfer of 17 closed shell ions from their standard state in the gas to their standard state in water at 25 °C. An off-centered dipole model was used to characterize the permanent electrostatic properties of water in the primary hydration shell, and a Born continuum treatment was used to calculate secondary solvation effects. This model owed its success to the fact that the interactions of closed shell ions with water are largely electrostatic. Because the unfilled f-subshells in the lanthanide and actinide ions are inner orbitals, which do not interact significantly with surrounding molecules or ions, it can be anticipated that nonelectrostatic interactions should contribute relatively little to the thermodynamic functions of hydration for these ions. Therefore an extension of the calculations in ref. 1 to the lanthanide and actinide ions seemed worthwhile.

The calculations in ref. 1 were semi-empirical in the sense that an adjustable parameter (the primary hydration number n) was required in order to fit the model to the experimental free energies and enthalpies of hydration. (Experimental hydration data refer to those calculated from available experimental processes via a thermodynamic cycle.) Accordingly, some experimental hydration data are also needed here if we are to use the approach in ref. 1. There now exist experimental values for the enthalpies and free energies of hydration for all of the trivalent lanthanides and for trivalent plutonium. In this work we have combined the model in ref. 1 with the existing hydration data for the trivalent lanthanides and actinides in order to: (*1*) confirm that the electrostatic model used in ref. 1 can be used to account for experimental

[a]The values of $\Delta G_t°$ and $\Delta H_t°$ are for T = 298.15 K. The standard state in the gas is the hypothetical ideal ion gas at 1 atm. The standard state in solution is the hypothetical 1 m solution.

hydration data for these ions; (*2*) predict the free energies and enthalpies of hydration of the trivalent actinides for which (with the exception of Pu^{3+}) experimental values are unavailable.

Calculations and Results

The calculations performed here for the thermodynamic transfer functions $\Delta G_t°$ and $\Delta H_t°$ are identical to those described in ref. 1 (in the section "Calculation of the Thermodynamic Transfer Functions") except for one simplification. In this work the ion – primary water Lennard–Jones term is omitted. This simplification was made necessary by the unavailability of polarization and ionization potential data for the trivalent actinides. Because n, an adjustable parameter, absorbs errors in the model, and because the Lennard–Jones ion–water term contributes relatively little to the transfer functions $\Delta G_t°$ and $\Delta H_t°$ (~1% for La^{3+}), the effect of this simplification is negligible.

In all the calculations for $\Delta G_t°$ and $\Delta H_t°$ described below, the values of the parameters used for water (size, polarizability, effective charge distribution, moments of inertia) were those given in ref. 1.

Trivalent Lanthanides

With the simplification noted above, we require values for the crystallographic radius r_c, the gas-phase radius r_g, and the primary hydration number n, in order to calculate the sought thermodynamic transfer functions $\Delta G_t°$ and $\Delta H_t°$. The values used for r_c and r_g are given in columns 2 and 3 of Table 1. The values for r_c were taken from the literature (2) and the values of r_g were estimated by a method similar to one suggested by Stokes (3). Specifically, the gas-phase radius for each of the trivalent lanthanide ions was calculated by the equation (4)

$$[1] \qquad r_g = \frac{K}{(Z - S)}$$

where K is a constant, Z is the atomic number, and S is a screening constant. The values of S for each ion were obtained by Slater's rules (4), and K for the lanthanide series was determined by applying [1] to xenon for which r_g was taken to be 2.168 Å (5). Thus it was found that the value of K for the lanthanide series was 17.9 Å.

We have also included, in columns 5 and 7 of Table 1, our selected experimental values for the quantities $\Delta G_t°$ and $\Delta H_t°$. The values of $\Delta H_t°$ (6) are based on Halliwell and Nyburg's (7) recommended value for $\Delta H_t°$ (H^+).[1] The

[1]This value (−260.7 kcal mol^{-1}) is used here in order to be consistent with previously published work on these ions (8). There are a number of other values available in the literature for this quantity (see for example refs. 9 and 10). The interested reader who may favor a different value for $\Delta H_t°$ (H^+) can correct the values of $\Delta H_t°$ and $\Delta G_t°$ reported here by adding to them the difference between the reader's selected value of $\Delta H_t°$ (H^+) and ours.

experimental values of ΔG_t° were calculated by

$$[2] \qquad \Delta G_t^\circ = \Delta H_t^\circ - T\Delta S_t^\circ$$

using the experimental values of ΔH_t° in Table 1, and values of ΔS_t° calculated by

$$[3] \qquad \Delta S_t^\circ = \bar{S}_{soln}^\circ - \bar{S}_g^\circ$$

In [3] $\bar{S}_{soln}^\circ$ is the absolute standard ionic entropy in solution and $\bar{S}_g^\circ$ is the standard ionic entropy in the gas. Values for $\bar{S}_{soln}^\circ$ were obtained from experimental conventional entropies which were converted to absolute entropies by the equation (11)

$$[4] \quad \bar{S}_{soln}^\circ = \bar{S}_{soln}^\circ(\text{conventional}) + 3\bar{S}_{soln}^\circ(H^+)$$

In [4] the values of $\bar{S}_{soln}^\circ$ (conventional) were taken from published values (12) and $\bar{S}_{soln}^\circ$ (H^+) was taken to be -5.3 cal deg^{-1} mol^{-1} (9). The values of $\bar{S}_g^\circ$ required with [3] were obtained from the Sackur–Tetrode equation written for the conditions $T = 298.15$ K and $p = 1$ atm (13). The ground-state electronic degeneracies required with the Sackur–Tetrode equation were obtained in the usual way ($g = 2J + 1$) from published ground-state term values for these ions (14).

With the values of r_g and r_c given in Table 1, and the methods described in ref. 1, values were calculated for ΔG_t° and ΔH_t° with both $n = 4$ and $n = 6$ for each of the trivalent lanthanide ions. The results of these calculations are illustrated in Figs. 1 and 2. It is readily deduced from these figures, that for each of the trivalent lanthanide ions the value of n that would result in a fit of the model to the data lies between 4 and 6.

We obtained a value of n for the trivalent lanthanides by assuming that ΔH_t° for each ion varied linearly with n for n between 4 and 6. Thus a fitted value of n was obtained for each ion and subsequently an average value of n was determined. Thus n for the trivalent lanthanides was found to be 5.6. The calculated values of ΔH_t°, obtained with $n = 5.6$, are given in column 6 of Table 1, and are illustrated in Fig. 1.

We use the same interpolative procedure to obtain values for ΔG_t°. That is, by assuming that ΔG_t° varies linearly with n (for n between 4 and 6) and by using the value $n = 5.6$, we obtained the values of ΔG_t° given in column 4 of Table 1, and illustrated in Fig. 2. A comparison of the corresponding calculated and

[b]Estimated by extrapolation, using refs. 2 and 22.

experimental values for both $\Delta G_t°$ and $\Delta H_t°$ reveals that the average absolute error for all the trivalent lanthanides is about 1%, and the discrepancy for any particular ion is always within 2%. Discrepancies of this magnitude can be expected from the approximations inherent in the model, from the uncertainties in the values used for r_c and r_g, and from the uncertainties in the experimental values used for $\Delta G_t°$ and $\Delta H_t°$.

Our results for the trivalent lanthanides are noteworthy in several respects. First we point out that the value $n = 5.6$ is consistent with the value of 6 determined in ref. 1 for La^{3+} (in ref. 1 values of n were reported to the nearest integer). Second, whereas the value 5.6 is lower than other values that have previously been reported for the lanthanides (15–17), it is not necessarily inconsistent with these values. The point is that in this work n is a primary hydration number which does not include secondary hydration effects; these latter effects are accounted for separately in our calculations by a Born continuum treatment. Third, it should be pointed out that there is no agreement in the literature on whether the hydration number increases or decreases through the lanthanides. Some authors (16) consider it to decrease, while others (17) consider it to increase. Our result, a constant hydration number for the series, is therefore not at variance with what is known in this respect. Part of the problem in achieving concordant n values among various workers is that n is an operational quantity, and as such will vary somewhat from one application to another. In this work the value $n = 5.6$ is a reflection of our particular definition of n and of the approximations inherent in the model.

Despite the somewhat arbitrary character of n, our results for the trivalent lanthanides are useful. They illustrate how an electrostatic model can be used to account for the thermodynamic hydration functions for these ions, and they suggest a basis for predicting the values of $\Delta G_t°$ and $\Delta H_t°$ for the trivalent actinides, for which (except for Pu^{3+}) no experimental values exist.

Trivalent Actinides

We found that one value of n resulted in a reasonably good fit of our model to the $\Delta G_t°$ and $\Delta H_t°$ data for the trivalent lanthanides. Because of the similarity between the lanthanides and the actinides this suggests that a constant value of n should also obtain, as a good approximation, for the trivalent actinides. The assumption that n is a constant for all the trivalent actinides forms the basis of the predictions given below.

The crystallographic and gas-phase radii for the trivalent actinides that were used in

our calculations are given in Table 2. The crystallographic radii were taken from published values (2), and the gas-phase radii were calculated by [1]. The value of K in [1] for the actinide series was obtained by applying this equation to radon for which r_g was taken to be 2.315 Å (18). As with the lanthanides the values of S required for [1] were obtained by Slater's rules. Thus the value of K for the actinides was found to be 19.1 Å.

We determined the value of n for the actinide series by determining its value for Pu^{3+}. This was done by calculating values of ΔH_t° for Pu^{3+} with $n = 4$ and $n = 6$. Using the values of r_c and r_g for Pu^{3+} in Table 2, the results of these calculations were ΔH_t° $(n = 4) = -657.8$ kcal mol^{-1} and ΔH_t° $(n = 6) = -805.5$ kcal mol^{-1}. The experimental value for this quantity is -812.7 kcal mol^{-1} (ref. 19, corrected as follows: $\Delta H_f^\circ(Cs_2NaPuCl_6) = -546.0$ kcal/mol, using latest values for ΔH_f°(CsCl,c) and ΔH_f°(NaCl,c). The sum of the first three ionization potentials for Pu was recalculated (using most-recent auxiliary data) as 904.7 kcal/mol. Then, from eqs. 5 and 6 of ref. 8, $\Delta H_t^\circ(Pu^{3+}) = U_0(Cs_2NaPuCl_6) - 10RT + \Delta H^\circ$(soln,$Cs_2NaPuCl_6$) $- 2\Delta H_t^\circ(Cs^+) - \Delta H_t^\circ(Na^+) - 6\Delta H_t^\circ(Cl^-) = -1550 - 5.94 - 13.4 - 2(-64.6) - (-96.4) - 6(-88.5) = -812.7$ kcal/mol). Thus, using the linear interpolation described previously, $n = 6.1$. From the assumption that n is a constant for all the trivalent actinides, it follows that the value 6.1 can be used for n with the entire series.

With the values of r_g and r_c given in Table 2 and $n = 6.1$, values were calculated for ΔH_t° and ΔG_t°, by the methods described in ref. 1, for all the trivalent actinides. The results are given in columns 4 and 6 of Table 2.

Discussion

By analogy with what was found for the trivalent lanthanides, it is probable that most of the predictions given in Table 2 are correct to within 1%, and an upper limit on the error for any particular ion should be about 2%. Our predictions for the actinides are checked further below.

An experimental value is calculable for ΔG_t° for Pu^{3+}, and this value is entered in column 5 Table 2. It was obtained using the experimental value for ΔH_t° (-812.7 kcal mol^{-1}), $\bar{S}_{soln}^\circ$ (conventional) (20), the published ground-state term value (14), and eqs. 2–4. It is seen that the experimental and predicted values agree to well within 0.5%.

The values for ΔH_t° given in parentheses in column 7 of Table 2 for U^{3+}, Np^{3+}, Am^{3+}, Cf^{3+}, and Bk^{3+} were obtained as follows. The systematics of ref. 8 were extended from $Cs_2NaPuCl_6$ (for which ΔH_f° is known) to the corresponding isostructural compounds of Am and Bk (21) and to the presumed-isostructural compounds of U, Np, and Cm. The ionization potential sums ($\sum I = I_1 + I_2 + I_3$) thus calculated are given in Table 3. Using most-recent thermodynamic data, ΔH_t° for the ions was calculated by

$$[5]\quad \Delta H_t^\circ = \Delta H_f^\circ(M^{3+}, aq) - \Delta H(subl, M) - \sum I + 3\Delta H_f^\circ(H^+, aq, absolute) - 15/2RT = \Delta H_f^\circ(M^{3+}, aq) - \Delta H(subl, M) - \sum I + 314.9 \text{ kcal/mol}$$

For personal use only.

A comparison of our predicted values for ΔH_t° with these estimated experimental quantities reveals that the average absolute error is well within 0.5%. Clearly therefore, our predictions which can be tested are quite good.

Received March 10, 1975

GEORGE JUST and KARL GROZINGER. Can. J. Chem. **53**, 2701 (1975).

The synthesis of the title compound **5** was accomplished by a high-yield thermal rearrangement of the ozonide (**3**) of dimethyl 5,6-*O*-isopropylidene-7-oxabicyclo[2.2.1]hept-2-ene-*exo*-5,6-diol-2,3-dicarboxylate (**2***a*), which is obtained in 30% yield from the Diels–Alder adduct of furan and dimethyl acetylenedicarboxylate. Catalytic reduction of **5** gave methyl 2,3-*O*-isopropylidene-β-DL-talofuranuronate (**8**) as the major product, accompanied by a small amount of the *allo* isomer **9**.

GEORGE JUST et KARL GROZINGER. Can. J. Chem. **53**, 2701 (1975).

On a effectué la synthèse du composé mentionné dans le titre (**5**) grâce à un réarrangement thermique de l'ozonide (**3**) du *O*-isopropylidène-5,6 oxa-7 bicyclo[2.2.1] heptène-2 diol-5,6 *exo* dicarboxylate-2,3 de méthyle (**2***a*); ce réarrangement se produit avec un excellent rendement et **2***a* pu être obtenu avec un rendement de 30% par réaction de Diels-Alder entre le furanne et l'acétylènedicarboxylate de méthyle. La réduction catalytique de **5** conduit au *O*-isopropylidène-2,3 β-DL-talofuranneuronate de méthyle (**8**) comme produit majeur accompagné par une petite quantité de l'isomère *allo* **9**. [Traduit par le journal]

In connection with our investigations on *C*-nucleosides, we had occasion to study the reaction of the ozonide **3** of dimethyl 5,6-*O*-isopropylidene-7-oxabicyclo[2.2.1]hept-2-ene-*exo*-5,6-diol-2,3-dicarboxylate. This compound is obtained in good yield in the following manner: reaction of furan with dimethyl acetylenedicarboxylate gave Diels–Alder adduct **1**. Catalytic osmylation of **1** gave the *exo*-diol **2**, which was transformed to the corresponding isopropylidene derivative **2***a*, m.p. 60.5–62 °C, by treatment with acetone – dimethoxypropane – *p*-toluenesulfonic acid. Ozonolysis gave crystalline ozonide (**3**), m.p. 79–81 °C, in quantitative yield (1). Upon heating in various solvents, ozonide **3** rearranged predominantly to the stable oxalic ester **5**, m.p. 112–114 °C and to the mixed anhydride **6***a*, which was not isolated (2). Hydrolysis of the mixed anhydride led to **6**, m.p. 114–116 °C. Keto ester **6** was identified by comparison of its spectral data with those of an authentic sample described previously (1). There are many precedents for both types of rearrangements. In the furan series, oxygen insertion products of the Baeyer–Villiger type have been commonly observed (2–5).

The results of the thermal rearrangement of the ozonide **3** in various refluxing solvents are summarized in Table 1 and refer to isolated products.

The p.m.r. spectrum of **5** indicated the presence of two methoxy groups at 3.90 and 3.92 p.p.m., the anomeric proton as a singlet at 6.35 p.p.m., and an AB system corresponding to protons H_2 and H_3, centered at 5.09 p.p.m. H_3 is split into a double doublet $J_{3,2} = 6$ Hz and $J_{3,4} = 1$ Hz, H_4 appears as a doublet at 5.23 p.p.m. Mild hydrolysis of **5** gave oxalic acid monomethyl ester and further hydrolysis, followed by sublimation, gave oxalic acid. When **5** was allowed to stand in ethanol containing palladium-on-charcoal for a few hours a new product crystallized out. Spectral and analytical data indicate that the new product, m.p. 94–95 °C, is ketal-hemiketal of formula **4** or **4***a*. Although no rigorous proof is adduced, we prefer formula **4** for mechanistic reasons. A slight modification of the procedure permitted the isolation of **4** in 56% yield. Acetylation of **4** gave **7**, m.p. 147–148 °C, in 92% yield. Compound **7** is also formed by direct acetylation of **5**. Compound **7** was identified on the basis of spectroscopic evidence. The u.v. spectrum exhibited a maximum at 232 nm in ethanol and the i.r. spectrum (KBr) showed absorptions at 1782, 1769, 1748, 1725, and 1682 cm^{-1}, which is in

[1]This paper is dedicated to Professor C. A. Winkler of McGill University on the occasion of his sixty-fifth birthday by one of his colleagues (G.J.).

accord with the ester and C—C double bond absorption.

Catalytic hydrogenation, in the presence of a palladium catalyst, of **4** or **5** in ethanol gave two products that were isolated by column chromatography on silica with ethyl acetate – benzene (3:7). The major product was shown to be methyl 2,3-*O*-isopropylidene-β-DL-talofuranuronate **8**, m.p. 112–114 °C (67%), and gave upon acetylation a diacetate **8***a*, m.p. 77–79 °C. The minor product isolated was identified as the *allo* isomer **9**, m.p. 96–97 °C (22%). Acetylation of **9** gave the diacetate **9***a*, m.p. 133–134 °C.

These structures were established by the following reactions: **8** was heated in methanol in the presence of a catalytic amount of sulfuric acid for 2 h and the mixture separated on silica with ethyl acetate. The first product eluted was methyl (methyl 2,3-*O*-isopropylidene-β-DL-talofuranosid)uronate **10**, m.p. 63–64 °C (25%). Acetylation gave the oily monoacetate **10***a*. The next product eluted (R_f 0.5) gave the oily methyl (methyl-β-DL-talofuranosid)uronate **11** (46%). Treatment of **11** with acetone and 2,2-dimethoxypropane in the presence of *p*-toluenesulfonic acid for several hours gave a high yield of **10**, identified by p.m.r., i.r., t.l.c., m.p., and mixture m.p.

Acetylation of **11** gave the triacetate **11***a*, m.p. 105–107 °C. The p.m.r. spectrum of **11***a* proved to be slightly different from that of methyl (methyl 2,3,5-tri-*O*-acetyl-β-DL-allofuranosid)-uronate(6). A sample of this compound, m.p. 103–104 °C, obtained from Prof. Fukami, showed a m.p. depression with **11***a* and a dif-

TABLE 1. Solvent effect on product ratio

Solvent	% yield 5	6
Ethylacetate	93	0
Benzene	90	0
Acetone	90	0
Ether	10*	0
Isopropanol	60	10
Tetrahydrofuran	60	27
Water (phosphate buffer p*H* 6.0)	10†	20

*The balance consisted of recovered starting material.
†The balance consisted of unidentified products.

ferent pattern in the i.r. (KBr) spectrum. The α-isomer **12** was eluted last (R_f 0.2) in 29% yield. Treatment of **12** with acetone–dimethoxypropane in the presence of *p*-toluenesulfonic acid gave **12***b*, m.p. 112–113 °C. Reduction of the monoacetate **10***a* with lithium aluminum hydride in ether and direct acetylation of the reaction mixture, gave the monoacetate **13***a*, m.p. 64–65 °C, and the oily diacetate **13***b*. Compound **13** was obtained by sodium methoxide catalyzed methanolysis of **13***a* or **13***b*. Analytical data were in excellent agreement with the structures proposed.

A sample of methyl 2,3-*O*-isopropylidene-β-D-allofuranoside **15**, m.p. 94–96 °C, was not identical with **13**, nor the corresponding diacetate **15***a* with **13***b*. However when **13** was subjected to oxidative cleavage with periodate, the aldehyde **14**, m.p. 94–95 °C, showed identical i.r. (in chloroform), p.m.r., t.l.c., and retention time on g.l.c. with the aldehyde obtained from oxidative cleavage of **15**.

Experimental

Melting points were determined on an Electrothermal block and are corrected. Nuclear magnetic resonance spectra were recorded on a Varian Associates A-60 spectrometer. Infrared spectra were obtained on a Perkin-Elmer 267B spectrometer. Ultraviolet spectra were recorded on a Bausch & Lomb 505 spectrophotometer. Microanalyses were carried out by Micro-Tech. Laboratories Inc., Skokie, Illinois.

Dimethyl 7-Oxabicyclo[2.2.1]hept-2-ene-exo-5,6-diol-2,3-dicarboxylate (2)

To a solution of 42 g of crude dimethyl 7-oxabicyclo[2.2.1]hept-2,5-diene-2,3-dicarboxylate (**1**) in 80 ml of ether and 320 ml of acetone was added 40 ml of a solution made up from 1 g osmium tetroxide in 200 ml of *t*-butyl alcohol, followed by 40 ml of 30% hydrogen peroxide. After completion of the reaction as monitored by t.l.c. (chloroform–methanol 9:1) the reaction was quenched by addition of aqueous sodium bisulfite. Methylene chloride extraction gave crude **2** as an oily syrup; i.r. (film) 3425 (OH), 1710 (CO), 1620 cm^{-1} (C=C); p.m.r. ($CDCl_3$) δ 3.84 (s, OCH_3), 4.02 (s, OH), 5.00 (s, H_1, H_4).

Dimethyl 5,6-O-Isopropylidene-7-oxabicyclo[2.2.1]hept-2-ene-exo-5,6-diol-2,3-dicarboxylate (2a)

The crude diol (21 g, 0.0915 mol) was dissolved in acetone (500 ml) and dimethoxypropane (160 ml) and heated to reflux with a catalytic amount of *p*-toluenesulfonic acid for 3 h. After evaporation of the solvent, the residue was taken up in chloroform and washed with water (2 × 50 ml). The combined extracts were dried (Na_2SO_4) and concentrated. The residue was chromatographed on silicic acid using chloroform as eluent. Recrystallization of the first fraction (17.0 g, 64.5%) from isopropanol – petroleum ether gave colorless plates of **2***a*, m.p. 60.5–62 °C; i.r. (KBr) 1710 (CO), 1632 (C=C), 1360, 1370 cm^{-1} (*gem*-dimethyl); p.m.r. ($CDCl_3$) δ 1.32 (s, 3H), 2.50 (s, 3H), 3.83 (s, 3H), 4.60 (s, 2H), 5.08 (s, 2H).

Anal. Calcd. for $C_{13}H_{16}O_7$: C, 54.93; H, 5.67. Found: C, 54.82; H, 5.82.

Dimethyl 2,3-O-Isopropylidene-1-O-oxalyl-β-DL-ribo-hexofuran-5-ulosuronate (5)

An ethyl acetate (100 ml) solution of dimethyl 5,6-*O*-isopropylidene-7-oxabicyclo[2.2.1]hept-2-ene-*exo*-5,6-diol-2,3-dicarboxylate (10 g, 0.035 mol), was cooled to −60 °C and treated with ozone in oxygen at the rate of 7 mmol of ozone per hour. The reaction was continued until the blue color, characteristic of ozone, persisted. The reaction mixture was flushed with nitrogen and the solvent was evaporated at room temperature under reduced pressure to about 20 ml. The semicrystalline ozonide was heated in a water bath for 20 min until all the solvent evaporated. The product crystallized from ethyl acetate and ether, yield 10.9 g (93.2%), m.p. 114–116 °C; i.r. (KBr) 1760 (ester), 1720 (CO), 1380 cm^{-1} (*gem*-dimethyl); p.m.r. ($CDCl_3$) δ 1.39 (s, 3H), 1.56 (s, 3H), 3.90 (s, 3H), 3.92 (s, 3H), 4.83 (d, $J_{2,3}$ = 6 Hz, 1H), 5.23 (d, $J_{4,3}$ = 1 Hz, 1H), 5.36 (d, d, $J_{2,3}$ = 6 Hz, $J_{3,4}$ = 1 Hz, 1H), 6.35 (s, 1H); mass spectrum *m/e* 332 (M^+), 317 ($M^+ - CH_3$).

Anal. Calcd. for $C_{13}H_{16}O_{10}$: C, 47.22; H, 4.85. Found: C, 46.99; H, 4.85.

Alternatively, the ozonide, m.p. 79–81 °C, was isolated and the pure ozonide refluxed for 20 min and crystallized from ethyl acetate – ether to give **5**.

Treatment of Dimethyl 2,3-Di-O-isopropylidene-1-O-oxalyl-β-DL-ribo-hexofuran-5-ulosuronate (5) with Ethanol and Palladium

A solution of **5** (10.9 g, 0.033 mol) in ethanol (250 ml) was stirred with 5% palladium-on-charcoal (2 g) for 8 h.

The suspension was filtered through Celite and the catalyst washed with ethanol (5 × 25 ml). The filtrate and washings were combined and evaporated to dryness. Addition of ether afforded 7.0 g (56%) of **4**, m.p. 94–95 °C; i.r. (KBr) 3490 (OH), 1752, 1725 (ester), 1378 cm^{-1} (*gem*-dimethyl); p.m.r. ($CDCl_3$) δ 1.20 (t, J = 7 Hz, 3H), 1.35 (s, 3H), 1.45 (s, 3H), 3.82 (s, 3H), 3.97 (s, 3H), 4.60 (s, 1H), 4.85 (d, $J_{2,3}$ = 6 Hz, 1H), 5.10 (d, $J_{2,3}$ = 6 Hz, 1H), 6.21 (s, 1H); mass spectrum (70 eV) *m/e* 362 ($M^+ - CH_3$), 332 ($M^+ - C_2H_5OH$), 317, 303.

Anal. Calcd. for $C_{15}H_{22}O_{11}$: C, 47.62; H, 5.86. Found: C, 47.72; H, 5.91.

*Treatment of Dimethyl 2,3-Di-O-isopropylidene-1-O-oxalyl-β-*DL*-ribo-hexofuran-5-ulosuronate (5) with Acetic Anhydride*

A solution of **5** (166 mg, 0.5 mmol) in a mixture of acetic anhydride (1 ml) and pyridine (1 ml) was stirred for 12 h. After removal of the solvents, the oily residue was dissolved in chloroform, carefully washed with 1 *N* hydrochloric acid, and dried over sodium sulfate. Evaporation and crystallization from ether – petroleum ether gave 150 mg (80%) of **7**, m.p. 147–148 °C; i.r. (KBr) 1782, 1769, 1748, 1725 (ester), 1682 (C=C), 1437 (CH), 1389, 1370 cm^{-1} (*gem*-dimethyl); p.m.r. ($CDCl_3$) δ 1.43 (s, 3H), 1.45 (s, 3H), 2.20 (s, 3H), 3.83 (s, 3H), 3.92 (s, 3H), 4.81 (d, $J_{2,3}$ = 6 Hz, 1H), 5.90 (d, $J_{2,3}$ = 6 Hz, 1H), 6.50 (s, 1H); mass spectrum (70 eV) *m/e* 374 (M^+), 359 ($M^+ - CH_3$), 343 ($M^+ - OCH_3$), 315 ($M^+ - COOCH_3$).

Anal. Calcd. for $C_{15}H_{18}O_{11}$: C, 48.13; H, 4.85. Found: C, 48.32; H, 4.89.

Acetylation of 4

Compound **4** (500 mg, 1.34 mmol) was acetylated and purified as described above. There was obtained 465 mg (92%) of **7**, m.p. 147–148 °C; i.r. and p.m.r. spectra were identical with those of a sample obtained previously.

*Methyl 2,3-O-Isopropylidene-β-*DL*-talofuranuronate 8 and Methyl 2,3-O-Isopropylidene-β-*DL*-allofuranuronate 9, from 5*

A solution of **4** (7.0 g, 18.5 mmol) in ethanol (250 ml) containing 5% palladium-on-charcoal (2 g) was hydrogenated for 16 h at 50 p.s.i. The suspension was filtered through Celite and the catalyst washed with ethanol. The filtrate and washings were combined and evaporated to a syrup. The crude mixture showed two products on t.l.c. chromatography on a silica gel column (350 g) and elution with ethyl acetate – benzene (3:7) gave successively 3.1 g of **8** (67.5%), m.p. 112–114 °C (from acetone – petroleum ether), and 1.0 g of **9** (29%), m.p. 96–97 °C (from ether – petroleum ether).

Compound **8**: i.r. (KBr) 3400 (OH), 1745 (ester), 1442 (C—H), 1380, 1375 cm^{-1} (*gem*-dimethyl); p.m.r. (DMSO-d_6) δ 1.22 (s, 3H), 1.40 (s, 3H), 3.71 (s, 3H), 4.35 (d, $J_{2,3}$ = 6 Hz, 1H), 4.3–4.4 (m, 2H), 4.83 (d, $J_{2,3}$ = 6 Hz, 1H), 5.20 (d, $J_{1,OH}$ = 6 Hz, 1H), 5.63 (d, J = 9 Hz, OH), 7.10 (d, J = 6 Hz, OH); mass spectrum (70 eV) *m/e* 248 (M^+), 233 ($M^+ - CH_3$).

Anal. Calcd. for $C_{10}H_{16}O_7$ (248.2): C, 48.38; H, 6.50. Found: C, 48.14; H, 6.50.

Compound **9**: i.r. (KBr) 3240 (OH), 1740 (ester), 1470, 1440 (CH), 1380, 1370 cm^{-1} (*gem*-dimethyl); p.m.r. (DMSO-d_6) δ 1.30 (s, 3H), 1.40 (s, 3H), 3.70 (s, 3H), 4.10 (s, 2H), 4.47 (d, $J_{2,3}$ = 6 Hz, 1H), 4.80 (d, $J_{2,3}$ = 6 Hz, 1H), 5.20 (s, 1H), 6.23 (2 OH); mass spectrum: (70 eV) *m/e* 248 (M^+), 233 ($M^+ - CH_3$).

Anal. Calcd. for $C_{10}H_{16}O_7$ (248.2): C, 48.38; H, 6.50. Found: C, 48.49; H, 6.66.

*Methyl (2,3-O-Isopropylidene-1,5-di-O-acetyl-β-*DL*-allofuranosid)uronate (9a)*

A solution of **9** (100 mg, 0.4 mmol) in acetic anhydride (3 ml) and pyridine (3 ml) was stirred for 18 h at room temperature. After concentration to dryness, the residue was dissolved in chloroform, washed with dilute hydrochloric acid, dried (sodium sulfate), and the chloroform was evaporated. The product was crystallized from ether and petroleum ether, yield 100 mg (74%), m.p. 133–134 °C; i.r. (KBr) 1745 (ester), 1442 (C—H), 1380, 1360 cm^{-1} (*gem*-dimethyl); p.m.r. ($CDCl_3$): δ 1.35 (s, 3H), 1.46 (s, 3H), 2.08 (s, 3H), 2.19 (s, 3H), 3.79 (s, 3H), 4.59 (d, $J_{2,3}$ = 7 Hz, 1H), 4.80 (d, 2H), 5.02 (d, $J_{2,3}$ = 7Hz, 1H) 6.22 (s, 1H); mass spectrum (70 eV): *m/e* 332 (M^+), 317 ($M^+ - CH_3$), 301 ($M^+ - OCH_3$), 289 ($M^+ - CH_3CO$), 273 ($M^+ - CH_3COO$).

Anal. Calcd. for $C_{14}H_{20}O_9$ (332.3): C, 50.60; H, 6.07. Found: C, 50.51; H, 6.14.

*Methyl (2,3-O-Isopropylidene-1,5-di-O-acetyl-β-*DL*-talofuranosid)uronate (8a)*

Treatment of **8** (100 mg, 0.4 mmol) with a mixture of acetic anhydride and pyridine (1:1), under conditions identical with those described for the preparation of **9a**, gave 125 mg (93%) of **8a**, m.p. 77–79 °C; i.r. (KBr) 1770, 1755, 1742 (ester), 1433 (CH), 1378 cm^{-1} (*gem*-dimethyl); p.m.r. ($CDCl_3$) δ 1.36 (s, 3H), 1.50 (s, 3H), 2.05 (s, 3H), 2.17 (s, 3H), 3.80 (s, 3H), 4.70 (dd, $J_{2,3}$ = 6.5 Hz, $J_{3,4}$ = 1 Hz, 1H), 4.75 (d, $J_{4,5}$ = 6.5 Hz, 1H), 4.94 (dd, $J_{4,5}$ = 6.5 Hz, $J_{3,4}$ = 1 Hz, 1H), 6.20 (s, 1H); mass spectrum (70 eV) *m/e* 332 (M^+), 317 ($M^+ - CH_3$).

Anal. Calcd. for $C_{14}H_{20}O_9$ (332.3): C, 50.60; H, 6.07. Found: C, 50.61; H, 6.17.

*Methyl (Methyl 2,3-O-Isopropylidene-β-*DL*-talofuranosid)uronate (10), Methyl (Methyl β-*DL*-talofuranosid)uronate (11), and Methyl (Methyl α-*DL*-talofuranosid)uronate (12)*

A solution of 2.3 g (9.3 mmol) of **8** in methanol (100 ml) and a catalytic amount of sulfuric acid was boiled under reflux for 2 h, evaporated to dryness, and the residue chromatographed on silicic acid with ethyl acetate as eluent. Fractions (15 ml each) were collected and examined by t.l.c. Fractions 6–18 were combined and evaporated. Crystallization from hot petroleum ether yielded 610 mg (24%) of **10**, m.p. 63–64 °C; i.r. (KBr) 3435 (OH), 1743 (ester), 1455, 1442 (C—H), 1382, 1375 cm^{-1} (*gem*-dimethyl); p.m.r. ($CDCl_3$) δ 1.35 (s, 3H), 1.45 (s, 3H), 3.45 (s, 3H), 3.82 (s, 3H), 4.21 (s, 1 OH, 1H), 4.60 (d, $J_{2,3}$ = 6 Hz, 1H), 4.80 (d, $J_{4,5}$ = 2 Hz, 1H), 4.90 (d, $J_{2,3}$ = 6 Hz, 1H), 4.96 (s, 1H); mass spectrum (70 eV) *m/e* 262 (M^+), 261 ($M^+ - 1$), 247 ($M^+ - CH_3$).

*Methyl (Methyl 2,3-O-Isopropylidene-*β*-*DL*-talofuranosid)uronate (**10**) from **11***

A solution of **11** (500 mg, 2.25 mmol) in acetone (3 ml), 2,2-dimethoxypropane (5 ml), and a catalytic amount of *p*-toluenesulfonic acid was refluxed for 3 h. Chloroform extraction and crystallization from hot petroleum ether (b.p. 30–60 °C) gave 520 mg (88%) of **10**, m.p. 64–65 °C. The spectral data (i.r., p.m.r., m.s.) were identical with those of the product obtained before.

*Methyl (Methyl 2,3-O-Isopropylidene-5-O-acetyl-*β*-*DL*-talofuranosid)uronate (**10***a*)*

Compound **10** (400 mg, 1.52 mmol) was acetylated with acetic anhydride (4 ml) and pyridine (4 ml) in the usual manner. Chloroform extraction and column chromatography, using benzene–isopropanol (98:2) as eluent, gave 450 mg (97%) of **10***a*; i.r. (film) 1747 (ester), 1435 (CH), 1372 cm^{-1} (*gem*-dimethyl); p.m.r. ($CDCl_3$) δ 1.33 (s, 3H), 1.50 (s, 3H), 2.17 (s, 3H), 3.35 (s, 3H), 3.81 (s, 3H), 4.55 (dd, $J_{4,5}$ = 8 Hz, $J_{4,3}$ = 1 Hz, 1H), 4.60 (d, $J_{2,3}$ = 6 Hz, 1H), 4.90 (dd, $J_{3,4}$ = 1 Hz, $J_{3,2}$ = 6 Hz, 1H), 5.00 (s, 1H), 5.12 (d, $J_{5,4}$ = 8 Hz, 1H); mass spectrum (70 eV): *m/e* 304 (M^+), 289 ($M^+ - CH_3$), 273 ($M^+ - OCH_3$).

Anal. Calcd. for $C_{13}H_{20}O_8$ (304.3): C, 51.31; H, 6.63. Found: C, 51.67; H, 6.75.

*Methyl (Methyl 2,3,5-Tri-O-acetyl-*β*-*DL*-talofuranosid)uronate (**11***a*)*

Compound **11** (450 mg, 2 mmol) was acetylated with acetic acid (4 ml) and pyridine (4 ml) in the usual manner. Chloroform extraction and crystallization from chloroform – petroleum ether, gave 550 mg (78%), m.p. 105–107 °C; i.r. (KBr) 1763, 1740 (ester), 1440 (CH), 1375, 1368 cm^{-1} (*gem*-dimethyl); p.m.r. ($CDCl_3$) δ 2.07 (s, 3H), 2.12 (s, 3H), 2.21 (s, 3H), 3.41 (s, 3H), 3.82 (s, 3H), 4.60 (q, 1H), 4.90 (s, 1H), 5.19 (d, $J_{4,5}$ = 3.6 Hz, 1H), 5.22 (d, $J_{2,3}$ = 4.6 Hz, 1H), 5.44 (q, 1H); mass spectrum (70 eV) *m/e* 348 (M^+), 347 ($M^+ - 1$), 288 [($M^+ - 1$) – $COOCH_3$].

Anal. Calcd. for $C_{14}H_{20}O_{10}$ (348.3): C, 48.27; H, 5.79. Found: C, 48.26; H, 5.88.

*Methyl (Methyl 2,3,5-Tri-O-acetyl-*α*-*DL*-talofuranosid)uronate (**12***a*)*

A solution of **12** (100 mg, 0.45 mmol) in acetic anhydride (2 ml) and pyridine (2 ml) was stirred at room temperature for 20 h. After evaporation, the residue was purified on a silicic acid column using benzene–methanol (95:5) as eluent. The band R_f 0.5, gave triacetate **12***a*, 90 mg (57%); i.r. (film) 1750 (ester), 1435 (CH), 1370 (CH_3); p.m.r. ($CDCl_3$) δ 2.15 (s, 6H), 2.20 (s, 3H), 3.42 (s, 3H), 3.80 (s, 3H), 4.60 (m, 1H), 5.0–5.3 (m, 3H), 5.40 (d, $J_{1,2}$ = 2.5 Hz, 1H); mass spectrum (70 eV) *m/e* 317 ($M^+ - OCH_3$), 289 ($M^+ - COOCH_3$).

Anal. Calcd. for $C_{14}H_{20}O_{10}$ (348.3): C, 48.27; H, 5.79. Found: C, 48.60; H, 5.87.

*Methyl (Methyl 2,3-O-Isopropylidene-*α*-*DL*-talofuranosid)uronate (**12***b*)*

A solution of **12** (350 mg, 1.57 mmol) in acetone (5 ml) and 2,2-dimethoxypropane (10 ml), containing a catalytic amount of *p*-toluenesulfonic acid was refluxed for 2 h. Chloroform extraction and purification on a silicic acid column gave 345 mg (84%) of **12***b*, m.p. 111–112 °C as colorless needles; i.r. (KBr) 3435 (OH), 1745 (ester), 1450, 1431 (CH), 1380, 1370 cm^{-1} (*gem*-dimethyl); p.m.r. ($CDCl_3$) δ 1.38 (s, 3H), 1.58 (s, 3H), 3.05 (d, 1 OH), 3.45 (s, 3H), 3.84 (s, 3H), 4.30 (d, J = 1 Hz), 4.50 (dd, 1H), 4.6–4.8 (m, 2H), 4.93 (d, $J_{1,2}$ = 4 Hz, 1H); mass spectrum (60 eV) *m/e* 262 (M^+), 247 ($M^+ - CH_3$), 231 ($M^+ - OCH_3$), 203 ($M^+ - COOCH_3$).

Anal. Calcd. for $C_{11}H_{18}O_7$ (262.2): C, 50.37; H, 6.92. Found: C, 50.49; H, 6.97.

*Methyl 2,3-O-Isopropylidene-5,6-di-O-acetyl-*β*-*DL*-talofuranoside (**13***b*) and Monoacetate (**13***a*)*

To a slurry of lithium aluminum hydride (114 mg, 3 mmol) in anhydrous ether (50 ml) was added dropwise a solution of **10***a* (455 mg, 1.5 mmol) in ether (5 ml) at 20 °C. The mixture was refluxed for 3 h, cooled to 5 °C, and a mixture of pyridine – acetic anhydride (1:1, 10 ml) was slowly added. The reaction mixture was kept at room temperature for 20 h, poured on crushed ice, stirred for 15 min, and then extracted with three portions of chloroform. The extracts were combined, dried (sodium sulfate), and evaporated to a syrup. The residue was chromatographed on silicic acid with chloroform-methanol (98:2) for elution. Fractions (10 ml each) were collected and examined by t.l.c. The less polar oily diacetate **13***b* was eluted first. Yield of **13***b*, 180 mg (38%); i.r. (film) 1740 (ester), 1437 (CH), 1370 (CH_3) cm^{-1}; p.m.r. ($CDCl_3$) δ 1.34 (s, 3H), 1.50 (s, 3H), 2.07 (s, 3H), 2.10 (s, 3H), 3.34 (s, 3H), 4.02 (dd, 1H), 4.23 (d, 1H), 4.35 (d, 1H), 4.55 (d, J = 6 Hz, 1H), 4.75 (dd, $J_{3,2}$ = 6 Hz, $J_{3,4}$ = 2 Hz, 1H), 5.00 (s, 1H), 5.20 (m, 1H); mass spectrum (70 eV) *m/e* 318 (M^+), 317 ($M^+ - 1$), 303 ($M^+ - CH_3$), 287 ($M^+ - OCH_3$), 275 ($M^+ - COCH_3$).

Anal. Calcd. for $C_{14}H_{22}O_8$ (318.3): C, 52.82; H, 6.97. Found: C, 52.96; H, 7.03.

The more polar monoacetate **13***a* was eluted next and crystallized from hot petroleum ether (b.p. 30–60 °C). Yield 180 mg (43%), m.p. 64–65 °C; i.r. (KBr) 3380 (OH), 1742 (ester), 1462, 1437 (CH), 1375, 1365 cm^{-1} (*gem*-dimethyl); p.m.r. ($CDCl_3$) δ 1.33 (s, 3H), 1.50 (s, 3H), 2.09 (s, 3H), 3.50 (s, 3H), 3.60 (s, OH), 3.80 (m, 1H), 4.0–4.3 (m, 2H), 4.50 (s, 1H), 4.59 (d, $J_{2,3}$ = 6 Hz), 4.85 (d, $J_{2,3}$ = 6 Hz), 5.00 (s, 1H); mass spectrum (70 eV) *m/e* 276 (M^+), 261 ($M^+ - CH_3$), 245 ($M^+ - OCH_3$), 233 ($M^+ - COCH_3$).

Anal. Calcd. for $C_{12}H_{20}O_7$ (276.3): C, 52.16; H, 7.30. Found: C, 52.27; H, 7.32.

*Methyl 2,3-O-Isopropylidene-*β*-*DL*-talofuranoside (**13**)*

To a solution of **13***b* (180 mg, 0.56 mmol) in methanol (20 ml), was added a catalytic amount of sodium with stirring. After 18 h at room temperature, the mixture was neutralized with anhydrous hydrogen chloride in

ether and concentrated under reduced pressure to dryness. The residue was purified by filtration through a silica gel column using chloroform–methanol (98:2) as eluent. After combining the main fractions, **13** was obtained as a colorless syrup. Yield, 100 mg (75%); i.r. (film) 3420 (OH), 1372 cm^{-1} (*gem*-dimethyl); p.m.r. ($CDCl_3$) δ 1.32 (s, 3H), 1.50 (s, 3H), 2.90 (broad s, 2 OH), 3.48 (s, 3H), 3.65 (s, 3H), 4.50 (broad s, 1H), 4.60 (d, $J_{3,2}$ = 6 Hz, 1H), 4.85 (d, $J_{2,3}$ = 6 Hz, 1H), 5.00 (s, 1H); mass spectrum (60 eV) *m/e* 234 (M^+), 219 ($M^+ - CH_3$), 203 ($M^+ - OCH_3$), 173 ($M^+ - HO - CH_2 - CH - OH$).

Anal. Calcd. for $C_{10}H_{18}O_6$ (234.2): C, 51.27; H, 7.75. Found: C, 51.17; H, 7.81.

Treatment of **13***a* under conditions identical with those described above, gave pure **13** in 45% yield.

*Methyl 2,3-O-Isopropylidene-*β*-*DL*-ribo-pentodialdo-1,4-furanoside (**14**) from **13***

To a solution of **13** (46 mg, 0.2 mmol) in methanol (1 ml) and phosphate buffer p*H* 7.0 (0.2 ml) was added a solution of sodium metaperiodate (22 mg, 0.2 mmol) in water (1 ml). The mixture was stirred for 2 h at 20 °C. Evaporation, ether extraction, and partial evaporation of the ether gave 35 mg (89%) of **14**, m.p. 94–95 °C; i.r. ($CHCl_3$) 1730 (CO), 1372 cm^{-1} (*gem*-dimethyl; p.m.r. ($CDCl_3$) δ 1.35 (s, 3H), 1.50 (s, 3H), 3.37 (s, 3H), 4.50 (s, 1H), 4.55 (d, $J_{3,2}$ = 6 Hz, 1H), 5.05 (d, $J_{2,3}$ = 6 Hz, 1H), 5.10 (s, 1H); mass spectrum (70 eV) *m/e* 203 ($M^+ + 1$), 187 ($M^+ - CH_3$), 173 ($M^+ - CHO$).

Anal. Calcd. for $C_9H_{14}O_5$ (202.2): C, 53.46; H, 6.98. Found: C, 53.24; H, 7.12.

*Methyl (2,3-O-Isopropylidene-5,6-di-O-acetyl)-*β*-*D*-allofuranoside (**15***a*)*

Acetylation of **15** (117 mg, 0.5 mmol) in the usual manner gave 150 mg (94%), of **15***a* as a syrup; i.r. ($CHCl_3$): 1745 (CO), 1440 (CH), 1370 cm^{-1} (*gem*-dimethyl); p.m.r. ($CDCl_3$) δ 1.27 (s, 3H), 1.45 (s, 3H), 2.03 (s, 3H), 2.08 (s, 3H), 3.35 (s, 3H), 4.0–4.5 (m, 3H), 4.60 (s, 2H), 4.98 (s, OH), 5.01 (dd, 1H).

*Methyl 2,3-O-Isopropylidene-*β*-*DL*-ribo-pentodialdo-1,4-furanoside (**14**) from **15***

Compound **15**, m.p. 94–95 °C, was oxidized with sodium metaperiodate in methanol at p*H* 7 as described previously. The aldehyde **14** had identical i.r. and p.m.r. spectra, and g.l.c. and t.l.c. behavior as DL-**14**, obtained from **13**.

We thank Drs. A. S. Perlin and H. J. Koch for a sample of compound **15** and valuable discussions, and Dr. H. Fukami, Kyoto University, Kyoto, Japan, for a sample of methyl (2,3,5-tri-*O*-acetyl-β-DL-allofuranosid)uronate. We also wish to thank the National Research Council of Canada for financial support.

Received April 23, 1975

DEBBIE ALLEN, COLIN JAMES LYNE LOCK, GRAHAM TURNER, and JOHN POWELL. Can. J. Chem. **53**, 2707 (1975).

The crystal and molecular structures of pentane-2,4-dionato-(2,3,5,6-*tetrahapto*-2,3-dicarbomethoxo[2.2.1]bicycloheptadienerhodium(I), $Rh(C_5H_7O_2)(C_7H_6(CO_2CH_3)_2)$, have been measured by single crystal X-ray diffraction. The orange crystals are monoclinic, space group $P2_1/c$, $Z = 4$, $a = 9.245(4)$, $b = 9.003(4)$, $c = 21.680(15)$ Å, $\beta = 113.41(5)°$. The calculated and observed densities are 1.645 and 1.642(5) respectively. Intensity data were collected on a Syntex $P\bar{1}$ diffractometer and a full matrix least squares refinement on 3010 observed reflections leads to a conventional $R = 0.0660$. The structure can be considered as a roughly square planar arrangement of ligands around the rhodium atom composed of two β-ketoenolate oxygen atoms (Rh—O, 2.037(5) and 2.025(5) Å) and the centers of the two ethylenic groups. The Rh—C distances for the olefin group attached to the two carbomethoxo groups, 2.117(8), 2.108(8) Å, appear to be slightly larger than those for the other olefinic group, 2.087(7), 2.082(6), and the corresponding C=C distances of 1.375(10) and 1.410(9) Å are different at the 95% confidence level.

DEBBIE ALLEN, COLIN JAMES LYNE LOCK, GRAHAM TURNER, et JOHN POWELL. Can. J. Chem. **53**, 2707 (1975).

On a mesuré, par diffraction de rayons-X d'un cristal unique, les structures cristallines et moléculaires du pentanedionato-2,4 (*tétrahapto*-2,3,5,6 dicarbométhoxo-2,3 bicyclo[2.2.1] heptadiènerhodium(I), $Rh(C_5H_7O_2)(C_7H_6(CO_2CH_3)_2)$. Les cristaux oranges sont monocliniques avec un groupe d'espace $P2_1/c$, $Z = 4$, $a = 9.245(4)$, $b = 9.003(4)$, $c = 21.680(15)$ Å, $\beta = 113.41(5)°$. Les densités calculées et observées sont respectivement de 1.645 et 1.642(5). On a recueilli les données d'intensité avec un diffractomètre Syntex $P\bar{1}$ et la structure affinée par la méthode des moindres carrés (matrice complète) pour 3010 réflexions observées a conduit à une valeur de R conventionnelle de 0.0660. On peut considérer que la structure comporte en première approximation un arrangement plan carré des ligands autour de l'atome de rhodium; cet arrangement comporte deux atomes d'oxygène du β-cétoénolate (Rh—O, 2.037(5) et 2.025(5) Å) et le centre de deux groupes éthyléniques. Il semble que les distances Rh—C (2.117(8) et 2.108(8) Å) du groupe oléfinique attaché aux deux groupes carbométhoxo sont légèrement plus larges que celles (2.087(7) et 2.082(6) Å) de l'autre groupe oléfinique. Les distances C=C correspondantes, 1.375(10) et 1.410(9) Å sont différentes au niveau de confiance de 95%.

Introduction

Structural studies on the adduct of pyridine to 1,1,1,5,5,5-hexafluoropentane-2,4-dionato-(2,3,5,6-*tetrahapto*-2,3-dicarbomethoxo[2.2.1]-bicycloheptadienerhodium(I), $Rh(C_5HF_6O_2)(C_6H_7(CO_2CH_3)_2)$ (**1**), showed that the Rh—O bond lengths in the adduct, $Rh(C_5HF_6O_2)(C_6H_7(CO_2CH_3)_2)(C_5H_5N)$, were unusually long (1). It appeared that the bond-length anomaly was caused by pseudo-trigonal bipyramidal arrangement of the ligands around the rhodium atom since pentane-2,4-dionato-bis(ethylene)-rhodium(I) (2) and pentane-2,4-dionatoethylene-perfluoroethylenerhodium(I) (2) do not show abnormal Rh—O bond lengths. However, no structural studies had been made of a diene attached to rhodium in place of the two ethylene ligands. We intended to study the structure of

the parent compound, **1**, but it has proved impossible to grow crystals suitable for X-ray diffraction studies. Instead, we have studied the structure of pentane-2,4-dionato(2,3,5,6-*tetrahapto*-2,3-dicarbomethoxo[2.2.1]bicycloheptadiene)-rhodium(I), $Rh(C_5H_7O_2)(C_6H_7(CO_2CH_3)_2)$, and we report this work here.

Experiments

The Preparation of Pentane-2,4-dionato(2,3-dicarbomethoxo[2.2.1]bicycloheptadiene)rhodium(I)

Acetylacetonatothallium(I) (0.600 g) was added to a solution of di-μ-chlorobis(2,3-dicarbomethoxo[2.2.1]bicycloheptadiene)dirhodium(I) (0.650 g) (4) in dichloromethane (30 ml) and the reaction mixture shaken for 30 min and then evaporated to dryness under reduced pressure. The residue was extracted with pentane. Evaporation of the extract under reduced pressure gave the desired product as a yellow solid which recrystallized from *n*-pentane as orange prisms (0.712 g) m.p. 100–103 °C. Crystals, suitable for X-ray work, were grown from a pentane solution.

Anal. Calcd. for $C_{16}H_{19}O_6Rh$: C, 46.8; H, 4.6. Found: C, 46.5, H, 4.4.

X-Ray Crystallography

An orange crystal, selected after microscopic examination, was approximately a cylindrical bipyramid. The crystal was 1.0 mm in length and the maximum cylinder diameter was 0.25 mm. A series of precession and Weissenberg photographs suggested the crystal was monoclinic.

The crystal was transferred to a Syntex PĪ diffractometer and accurate unit cell parameters were obtained by least squares refinement from 15 centered medium angle reflections. Examination of the intensity of reflections in the region $0 < 2\theta < 25°$ showed the systematic absences $0k0$, $k = 2n + 1$ and $h0l$, $l = 2n + 1$, showing the crystal had the space group $P2_1/c$. The density of a few crystals was measured by flotation in a degassed aqueous zinc bromide solution. Crystal data were

$C_{16}H_{19}O_6Rh$ f.w. = 410.23

Monoclinic, $a = 9.245(4)$, $b = 9.003(4)$, $c = 21.680(15)$ Å, $\beta = 113.41(5)°$, $V = 1655.0$ Å^3, $P2_1/c$ (C_{2h}^5, No. 14), $\rho_o = 1.642(5)$, $Z = 4$, $\rho_c = 1.645$ (22 °C, MoKα, $\lambda = 0.71069$ Å, $\mu = 10.34$ cm^{-1}).

Intensity data were recorded on a Syntex PĪ diffractometer using graphite monochromatized MoKα radiation for the hemidemisphere defined by h, k, $-l$ to $+l$,[2] and up to $2\theta = 55°$. Data were collected by executing a coupled θ(crystal)–2θ(counter) scan 1° on either side of the peak, scan rates varying from 8 to 24 deg/min.

The stability of the system was monitored by measuring a standard reflection after each 50 reflections. The counting e.s.d. of the standard peak was 1.1% and an analysis of the standard counts showed an overall e.s.d. of 1.3% with no systematic variation with time. The intensity of a reflection, I, and its e.s.d., σ_I, were calculated as outlined previously (1). A total of 3758 symmetry-independent reflections were measured and 297 were rejected because they were "not significantly above background" ($I < \sigma_I$).

A further 453 reflections had $I < 3\sigma_I$ and were called unobserved. Such reflections were only used in the refinement if $F_c > F_o$ for the reflection. In the final refinement 216 unobserved reflections were used with the 3008 observed reflections. Corrections were made for absorption[3] assuming the crystal had the dimensions listed above and that it was bounded by the sets of faces {6 3 1}, {0 3 1}, {6 0 1}.

Unscaled structure factor amplitudes, F, and their standard deviations, σ_F, were calculated from the expression $F = (I/Lp)^{1/2}$, $\sigma_F = (1/2)(1/\sqrt{Lp})(\sigma_I/\sqrt{I})$, where Lp, the Lorentz-polarization factor is $(1 + \cos^2 2\theta)/(2 \sin 2\theta)$.

Solution of the Structure

The coordinates of the rhodium atom were found from a three-dimensional Patterson synthesis and the six atoms nearest the rhodium atom were found from a three-dimensional difference synthesis. All remaining nonhydrogen atoms were found from successive projection Fourier and electron density difference syntheses and calculations of the likely geometry of the ligands. At this stage the rhodium and oxygen atoms were given anisotropic temperature factors; previously all temperature factors had been treated isotropically. Successive cycles of full matrix least squares refinement were terminated at $R_1 = 0.0660$, $R_2 = 0.690$.[4] For the last cycle of refinement no parameter shifted by more than 0.1σ.

A three dimensional difference map showed no significant features, the largest residual peaks being $+0.43$ e/Å^3 at 0.23, 0.43, 0.23, between the β-ketoenolate ring and C13, O3, and at 0.27, 0.93, 0.30, the closest atoms being C9 and C11. The largest valley was -0.38 e/Å^3 at 0.08, 0.50, 0.50 lying between O3 and C4.

[2]Defined with respect to the $P2_1/n$ cell. This cell was converted to the cell used here by the matrix 00—1/010/101.

[3]All calculations were carried out on a CDC6400 computer. The programs DATCO3, ABSORB, and DATRDN from the X-RAY71 package were used for preliminary treatment of data. The full matrix least square program CUDLS and Fourier program SYMFOU were written locally by J. S. Stephens and J. S. Rutherford, respectively. Least squares planes were calculated by the local program PALS by P. G. Ashmore, and diagrams were prepared by the program ORTEP by C. K. Johnson (5).

[4]
$$R_1 = \frac{||F_o| - |F_c||}{\sum |F_o|}$$

$$R_2 = \left(\frac{\sum \omega(|F_o| - |F_c|)^2}{\sum \omega F_o^2}\right)^{1/2}$$

*Anisotropic temperature factors (Å$^2 \times 10^3$). The temperature factor parameters U_{ij} were obtained from $\beta_{ij} = 2\pi^2 b_i b_j U_{ij}$ where β_{ij}'s appear as a temperature effect through exp $[-(\beta_{11}h^2 + \ldots + 2\beta_{12}hk + \ldots)]$ in the structure factor expression b_i are the reciprocal lattice vectors.

Throughout the refinement, the scattering curves for C and O were those tabulated in the *International Tables for X-Ray Crystallography* (6), while that for Rh was taken from Cromer and Waber (7). Anomalous dispersion corrections were applied for Rh and were taken from Cromer (8). The final atom parameters are given in Table 1 and the values of the moduli of F_o and F_c are given in Table 2.[5]

Discussion

The molecule is illustrated in Fig. 1 and selected bond lengths and angles are given in Table 3. The rhodium atom could be considered as having rough square planar coordination,

the two β-ketoenolate oxygen atoms and the centers of the two olefinic groups occupying the corners of the square. Unlike the corresponding five coordinate pyridine adduct, Rh(hfac)py(NOR) (1),[6] the Rh—O distances were not unduly long.

Some bond lengths of interest are shown in Fig. 2*A*. Unfortunately, because of the size of the errors, one could not draw any positive conclusions about possible differences in pairs of equivalent bonds, except to say that C(1)—C(2) and C(2)—C(3) were probably of different

FIG. 2. Part of the $Rh(C_5H_7O_2)(C_7H_6(CO_2CH_3)_2)$ molecule showing bond lengths. C(A) and C(B) represent the centers of the ethylenic bonds, the $\cdot CO\cdot OCH_3$ groups being attached to the carbon atoms represented by C(B).

lengths. The other pairs did not differ by more than about 2σ. Thus, the following comments must be regarded as speculative.

We noted that the absolute values of the bond lengths formed a set which was reasonable in terms of conventional bonding models for *trans*-influence (9) and was consistent with some localization of multiple bonding in the β-ketoenolate ring. An M—X bond, where X has some π-acceptor properties, *trans* to an olefinic group substituted with electron-withdrawing ligand, (C(B)), should be longer than a similar bond *trans* to an unsubstituted olefinic group, (C(A)), because in the competition for d–π electrons, the increased π-back bonding to the olefin would weaken the *trans* π-bond (9). We have shown previously that β-ketoenolates in low valence compounds of rhenium were π-acceptors (22), and that when β-ketoenolate oxygen atoms were *trans* to a group with good π-acceptor ability (CO) the Re—O distance was larger than normal (23). Further, Mason and Towl (10), have suggested that, for a system L—M—X, a strong L—M bond caused the M—X bond to become more ionic, and weaker, giving rise to localization of negative charge on X. If negative charge were localized on O(1), this would cause consequent localization of the bonds in the β-ketoenolate ring and we should have the situation shown in Fig. 2*B*.

O(1) appeared to have two bonds which were longer than normal (to C(1) and Rh). Brown and Shannon (11), using the concept that the bond valence of oxygen should be two, have postulated that, under that circumstance, there should be abnormally short "nonbonding" interactions to compensate for the long bond distances. The nearest atoms to O(1) were the hydrogen atoms attached to C(7) and C(11), however, and although we have not calculated the O(1)—H distances, the corresponding O(1)—C(7) and O(1)—C(11) distances were 3.55 and 3.59 Å respectively, so no significant hydrogen bonding could be taking place.

Even with bond localization, suggested above, the β-ketoenolate ring, O(1)C(1)C(2)C(3)O(2), was essentially planar and it made a dihedral angle of 6.9° with the plane RhO(1)O(2). Thus, the rhodium atom was 0.17 Å out of the plane defined by the ring. In addition, C(5) was significantly out of the plane of the ring (0.16 Å) on the opposite side to the rhodium atom.

The two sets of Rh—C distances (Rh—C(6), Rh—C(7); Rh—C(8), Rh—C(9)) were different at the 95% confidence level and the olefin with the shorter Rh—C distances (C(8)—C(9)) had the longer C—C distance, (at the 99% confidence level) as would be expected from conventional pictures of the bonding of olefins to metals (12, 13). Within the norbornadiene group, all other distances agreed well with those found in free norbornadiene (14, 15), a norbornadiene–palladium complex (16), and Rh(hfac)py(NOR) (1).[6]

Comparison of the Rh—C bond lengths in Rh(hfac)py(NOR) and Rh(acac)NOR, shows that equivalent distances were not significantly different. This was despite the fact that, within a given compound, Rh—C distances for the two types of olefin group differed, that there was a marked change in the Rh—O bond lengths, and that there was a change in geometry from pseudo-trigonal bipyramidal to pseudo-square planar. It was quite clear, after examining a number of structures (2, 3, 16–20), that Rh—C distances were almost insensitive to geometry and could be predicted entirely on the basis of whether electron-withdrawing groups (*e.g.* F or CO_2Me) were attached to the olefin or not. In the former case, Rh—C distances were most likely 2.03(2) Å and in the latter 2.13(2) Å. It should be noted that, in Rh(hfac)py(NOR), the more electronegative group was in the equatorial plane, which was contrary to what is usually found in five-coordinate trigonal bipyramidal structures (21).

The packing of the molecules in the unit cell is shown in Fig. 3. In the ***b*** direction the molecules were stacked directly above each

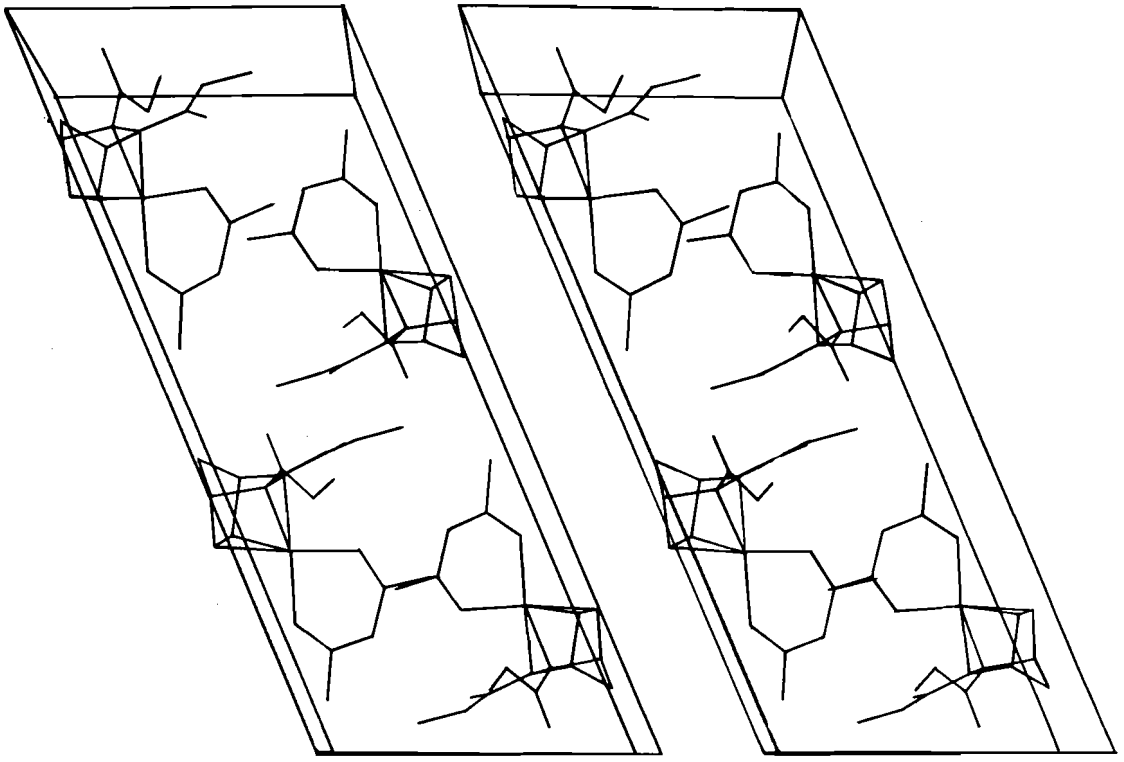

FIG. 3. Stereogram (stereoscopic pair of perspective projections) of the contents of the unit cell viewed down the ***b*** axis. The ***a*** axis is parallel to the top of the page and the c^* axis is parallel to the side of the page.

other and contact was between a carbomethoxo group on one molecule and the norbornadiene group of the next molecule. The space between the β-ketoenolate rings was occupied by the methyl group of the β-ketoenolate ring on the next molecule in the ***a*** direction. Thus, the β-ketoenolate rings of molecules related by x,y,z; $-x,\frac{1}{2}+y,\frac{1}{2}-z$, were interleaved in the ***b*** direction. For this same pair of molecules, the remaining contacts, in the ***a*** direction, were between the methyl group of a carbomethoxo unit on one molecule and a methyl group on the β-ketoenolate ring on the next molecule. The alternate set of contacts in the ***a*** direction was primarily between the norbornadiene group on one molecule and the β-ketoenolate ring in the next. In addition, there were contacts between the two norbornadiene groups. In the ***c*** direction, contact was between the methyl group on a carbomethoxo group on one molecule and the oxo unit of the carbomethoxo group on the next molecule. There was also contact between a β-ketoenolate methyl group on one molecule and the bridgehead hydrogen atoms of the norbornadiene group on the next. All contacts mentioned above were at or slightly more than the distances calculated for van der Waals contact.

Electron Mobilities and Ranges in Liquid Hydrocarbons: Cyclic and Polycyclic, Saturated and Unsaturated Compounds[1]

KYOJI SHINSAKA, JEAN-POL DODELET, AND GORDON R. FREEMAN
Chemistry Department, University of Alberta, Edmonton, Alberta T6G 2G2
Received March 24, 1975

KYOJI SHINSAKA, JEAN-POL DODELET, and GORDON R. FREEMAN. Can. J. Chem. **53**, 2714 (1975).

Penetration ranges b_{GP} of secondary electrons into 21 X-irradiated liquids were estimated from measured free ion yields. The density normalized ranges $b_{GP}d$ are independent of temperature. Increasing the molecular symmetry by creating one or more cycles in the molecule causes the normalized range to increase, provided that the amount of bond distortion due to strain remains small. Ranges are smaller in compounds that contain strained rings. Energy transfer from the secondary electrons to the molecules is enhanced by the presence of distorted bonds in the molecules. The ranges in olefins are affected by the same factors as those in saturated hydrocarbons, with the addition of a contribution of transient negative ion states to the energy transfer processes. Shielding the double bond by methyl groups is not effective; the effect of the added methyl groups on the molecular symmetry is a more important factor. The magnitude of the energy transfer interaction is an inverse function of molecular symmetry.

The general correlation between b_{GP} and thermal electron mobilities u_e in liquids contains significant variations within it. For a given value of b_{GP}, u_e in different liquids increases in the order *n*-alkane < cycloalkane < cycloalkene < 1,4-cyclohexadiene or benzene. Arrhenius plots of u_e in cyclic olefins curve downwards at low temperatures, due to the formation of a deeper trapped state of the electron. The trap is deepest in 1,4-cyclohexadiene (21 kcal/mol) and is attributed to an equilibrium between solvated electrons and anions at temperatures below about 280 K.

KYOJI SHINSAKA, JEAN-POL DODELET et GORDON R. FREEMAN. Can. J. Chem. **53**, 2714 (1975).

Les parcours des électrons secondaires, b_{GP}, ont été estimés d'après les rendements en ions libres mesurés dans 21 liquides irradiés aux rayons X. Normalisés pour la densité, ces parcours, $b_{GP}d$, deviennent indépendants de la température. Une augmentation de la symétrie moléculaire par cyclisation simple ou multiple entraîne une augmentation du parcours normalisé, tant que la distorsion des liaisons demeure faible. Un important transfert d'énergie des électrons secondaires est réalisé dans le cas de molécules à cycle tendu, ce qui réduit le parcours des électrons dans de tels liquides. Les parcours électroniques dans les oléfines sont fonction des mêmes facteurs que dans les alcanes, avec en plus la possibilité d'un transfert d'énergie via la tendance à former un ion négatif éphémère. L'addition de groupes méthyles ne protège pas une double liaison, mais affecte la symétrie moléculaire. L'importance de la quantité d'énergie transférée par collision est une fonction inverse de la symétrie moléculaire. La corrélation générale entre b_{GP} et la mobilité de l'électron thermique dans les liquides présente une structure fine. Pour une valeur de b_{GP} donnée, u_e augmente selon l'ordre suivant: *n*-alcane < cycloalcane < cycloalcène < cyclohexadiène-1,4 ou benzène. La courbe obtenue en portant u_e selon l'inverse de la température présente pour les oléfines cycliques une courbure importante à basse température, prouvant l'existence d'électrons piégés dans les trappes plus profondes. Une profondeur maximum de 21 kcal/mol dans le cas du cyclohexadiène-1,4 est attribuée à un équilibre entre l'électron solvaté et l'anion qui se manifeste aux environs de 280 K et moins.

Introduction

The mobilities of thermal electrons in liquid hydrocarbons and the penetration ranges of epithermal electrons in the liquids both tend to be larger when the constituent molecules are more highly branched (1, 2). The effect of branching is not basically understood, but it seems to be associated with the fact that the more highly branched molecules are more nearly spherelike in external shape (2, 3).

The correlations of electron mobility and range with molecular shape have mainly been determined using open chain molecules, with methyl groups branching outward from a central chain or core to increase the degree of sphericity. When the liquid is made up of large molecules the effective radius of interaction of

the electron does not encompass the whole molecule, but seems to be limited to groups containing only two carbon–carbon bonds in series (4). This includes groups up to neopentyl in size. The average interaction of an electron with a large open chain molecule in the liquid phase is therefore the average of the interactions with its constituent groups containing two C—C bonds in series.

As an alternative to chain branching, the degree of sphericity of molecules can be increased by constructing one or more rings in them. The small amount of information available about the effect of cyclic structures cannot be explained by one model alone, because the density-normalized range of epithermal electrons in cyclopropane is smaller than that in propane (5), whereas the normalized ranges cyclopentane and cyclohexane are slightly greater than those in the corresponding *n*-alkanes (6). In the present work the effect of cyclization has been investigated further by measuring electron ranges and mobilities in several mono- and polycyclic hydrocarbons. Both saturated and unsaturated compounds were used. The molecular structure dependence of electron behavior in liquid olefins (7, 8) is peculiar and is not even qualitatively understood. The search for a key to the understanding continues.

Experimental

Materials

The purities of the hydrocarbons obtained from the suppliers were ≥99%. Cyclopentane, cyclohexane, cyclopentene, and benzene were Phillips Research Grade. Cycloheptane, cyclooctane, bicyclo[2,2,1]heptane, bicyclo[2,2,2]octane, 1,2-dimethylcyclohexene, 1,3-dimethylcyclohexene, cycloheptene, *cis*-cyclooctene, bicyclo[2,2,1]-hept-2-ene, bicyclo[2,2,1]hepta-2,5-diene, 1,3-cyclohexadiene, and 1,4-cyclohexadiene were from Chemical Samples Co. Adamantane, α(+)pinene, and α(−)pinene were from Aldrich Chemicals Co.

The compounds were purified as follows.

Cyclopentane, cyclohexane, cycloheptane, cyclooctane, and benzene were shaken with concentrated sulfuric acid, washed with distilled water, dried over CaO, then stirred under vacuum successively with KOH pellets, $LiAlH_4$, and Na–K alloy. Each purification step lasted at least 3 h.

1,3-Cyclohexadiene and 1,4-cyclohexadiene reacted with Na–K alloy. The former reacted rapidly to form a heavy, brown precipitate. The latter reacted slowly to produce benzene and hydrogen. In preparation for the measurement of the free ion yields, both liquids were stirred under vacuum with KOH pellets, then with $LiAlH_4$, then electrolyzed under vacuum before the final distillation into the measurement cell. An electron conductance transient (e.c.t.) signal could not be obtained in the 1,3-diene, due to rapid reaction of the electrons with the diene to form negative ions. A large e.c.t. signal was obtained, however, in the 1,4-diene. To increase the half-life of the e.c.t., and thereby the accuracy of the mobility measurement, the 1,4-diene was stirred for about 2 h with Na–K alloy to reduce the concentration of electron scavengers. The amount of benzene in the resulting liquid was 1.7%, measured by gas chromatography. Various concentrations of purified benzene were also added to the 1,4-diene, to permit extrapolation of the electron mobility to that in pure diene.

Bicyclo[2,2,1]heptane was stirred with Na–K alloy and distilled under vacuum.

Bicyclo[2,2,2]octane and α(+)- and α(−)pinene were distilled under vacuum and electrolyzed for 1 h at 1 kV/cm.

Adamantane was recrystallized from *n*-heptane. All attempts to purify liquid adamantane, m.p. 541 K, were unsuccessful. The background conductance of the liquid at the high temperatures involved was too large to permit measurement of the free ion yield. Measurements were therefore made on a nearly saturated solution of adamantane in *n*-heptane.

Cyclopentene, 1,2-dimethylcyclohexene, 1,3-dimethylcyclohexene, cycloheptene, and *cis*-cyclooctene were stirred under vacuum successively with KOH pellets, $LiAlH_4$, and Na–K alloy.

Bicyclo[2,2,1]heptene and bicyclo[2,2,1]heptadiene reacted with Na–K alloy to form a brown precipitate. These olefins were simply stirred under vacuum with $LiAlH_4$ and distilled.

All of the compounds were degassed by vacuum distillation or sublimation. The pressure of gas that was not condensable at 77 K was reduced to $< 5 \times 10^{-6}$ Torr before the sample cell was sealed off.

The electrolysis step in the above purification procedures has been found to be unnecessary when the sample background conductance is low, and useless when the background conductance is high. The step was therefore abandoned in the latter part of the present work.

Apparatus and Techniques

The equipment and methods of measurement were described earlier (7, 8). Briefly, a 1 μs (or 0.1 μs) pulse of 1.7 MeV X-rays delivered 3×10^{10} eV/g (or 5×10^{9} eV/g) to the sample. The free ion yield G_{fi} was measured by the charge clearing technique. The value of the product of the free ion yield and the electron mobility, $G_{fi}u_e$, was obtained from the peak magnitude of the electron conductance transient (e.c.t.), corrected for decay during the radiation pulse if necessary. The positive ion mobility u_+ was assumed to be negligible in comparison to u_e. The value of u_e was calculated from the ratio $(G_{fi}u_e/G_{fi})$.

Physical Properties of the Liquids

The densities d (9–12) and dielectric constants ε (12–14) of the liquids were obtained from the references indicated or measured during the present work. Values are recorded in Table 1. The total ionization yields in the liquids are not known. For lack of better information they were taken equal to the average gas phase value for long chain alkanes, $G_{tot} = 4.3$ (15).

Results

Free Ion Yields

Free ion yields $G_{fi}{}^{E}$ were measured at applied electric field strengths E in the range 2 to 20 kV/cm. The yields increased with field strength in the manner illustrated in Figs. 1 and 2. The curves were extrapolated to zero field strength to obtain $G_{fi}{}^{0}$, using [1] (8, 16).

$$[1] \qquad G_{fi}{}^{E} = G_{tot} \int_0^\infty F(y)\phi(y,E)\,dy$$

where G_{tot} is the total number of ion–electron pairs generated per 100 eV absorbed by the liquid, $F(y)dy$ is the fraction of thermalized electron–ion pairs that have initial intrapair separation distances between y and $y + dy$, and $\phi(y,E)$ is the probability that a pair with a given separation distance y will escape geminate neutralization (become free ions) in the presence of an applied field E (V/cm).

$$[2] \qquad \phi(y,E) = e^{-r/y}\left[1 + e^{-\beta y}\sum_{n=1}^{\infty}\frac{(\beta y)^n}{(n+1)!}\sum_{j=0}^{n-1}(n-j)\frac{(r/y)^{j+1}}{(j+1)!}\right]$$

where $r = \xi^2/\varepsilon kT$, $\xi = 4.803 \times 10^{-10}$ e.s.u., k is Boltzmann's constant, T is the absolute temperature, and $\beta = (\xi E/300kT)$.

The distribution function $F(y)$ was taken to have the form [3], which has been shown to be suitable for many liquids and has been designated YGP (8, see also footnote 3 on p. 3500 of ref. 17).

$$[3] \qquad \begin{cases} F(y) = 0.96\ \mathrm{YG} & y < 2.4b_{GP} \\ F(y) = 0.96(\mathrm{YG} + 0.5b_{GP}{}^2/y^3) & y > 2.4b_{GP} \end{cases}$$

where 0.96 is a normalization factor, YG is the three dimensional Gaussian function $(4y^2/\pi^{1/2}b_{GP}{}^3)\exp(-y^2/b_{GP}{}^2)$, and b_{GP} is the adjustable dispersion parameter. The dispersion parameter is also equal to the most probable value of y. Distribution function [3] is a Gaussian that has been extended to larger y values by the addition of a more gently decreasing power function tail.

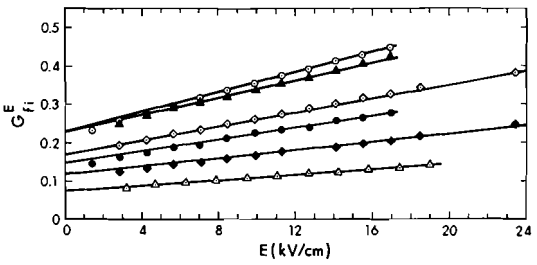

FIG. 1. Free ion yields $G_{fi}{}^{E}$ at field strength E in monocyclic hydrocarbons at 294 ± 2 K. ○, cyclopentane; ●, cyclopentene; ▲, 1,4-cyclohexadiene; △, 1,3-cyclohexadiene; ◇, cyclooctane; ◆, *cis*-cyclooctene. The lines were calculated from [1]–[3] using the parameter values in Table 1.

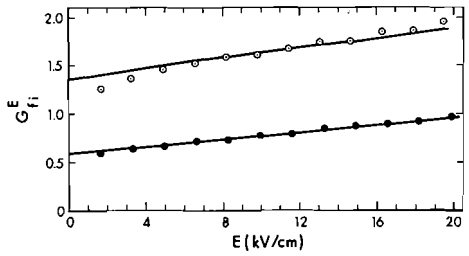

FIG. 2. Free ion yields $G_{fi}{}^{E}$ at field strength E in bicyclo[2,2,2]octane at 450 K (○), and in bicyclo[2,2,1]-heptane at 374 K (●). The lines were calculated from [1]–[3], using the parameter values in Table 1.

The terms in the infinite series in [2] display a maximum at some value of $n \geqslant 1$. The summation was terminated at $n = k$ such that the value of the kth term was $<10^{-3}$ of the maximum term value, or at $n = 55$, whichever came first. Termination at $n = 55$ was necessary because the computer saturated at (56!). The summation reached $n = 55$ when β or y was very large, in which case $\phi(y,E) = 0.999...$ and was placed equal to unity.

To fit a curve to a set of $G_{fi}{}^{E}$ *vs.* E results for a given liquid at a given temperature, a preliminary value of b_{GP} was chosen and $G_{fi}{}^{E}$ was calculated for each experimental value of E. Calculated and experimental yields were compared by calculating the average % error:

$$[4] \qquad \text{Average \% error} = 100\sum|G^E_{fi,calc} - G^E_{fi,exp}|/\sum G^E_{fi,exp}$$

The calculations were repeated with a series of b_{GP} values to find the one that gave the minimum

average % error. This value of b_{GP} was then used to calculate G_{fi}^0.

$$[5] \qquad G_{fi}^0 = G_{tot} \int_0^\infty F(y)\, e^{-r/y}\, dy$$

Examples of best-fit curves calculated for a number of liquids are shown in Figs. 1 and 2. Agreement between calculation and experiment became less good at high temperatures, where the calculated slope was somewhat lower than the experimental slope (*e.g.* bicyclo[2,2,2]octane curve in Fig. 2).

The values of b_{GP} and G_{fi}^0 obtained in the above manner for different compounds over a range of temperatures are listed in Table 1. To normalize the ranges b_{GP} for comparison between liquids, they were multiplied by the liquid density d. The density normalized range $b_{GP}d$ in a given liquid was essentially independent of temperature (Table 1).

In spite of extended attempts to purify adamantane and to degas it prior to melting, it always turned yellow upon melting (m.p. 541 K) and had a high background conductance. The free ion yields were therefore measured in a 35 wt.% solution of adamantane in *n*-heptane and in pure *n*-heptane, both at 396 K (Table 2). The density normalized range $b_{GP}d$ was extrapolated to pure adamantane with the aid of a plot of $(b_{GP}d)^{-2}$ against wt.% adamantane (6). The value so obtained, $b_{GP}d$(adamantane) = 90×10^{-8} g/cm^2, is included in Table 1.

Although the 99% pure 1,4-cyclohexadiene obtained from Chemical Samples Co. was adequate for the measurement of free ion yields, it had to be treated with Na–K alloy before electron mobilities could be measured in it. The alloy treatment generated benzene, so the e.c.t. measurements were actually made on benzene solutions. To extract electron mobilities from the e.c.t. measurements it was necessary to measure free ion yields in diene–benzene solutions. The results are listed in Table 2. The yields in benzene are in good agreement with those reported earlier from this laboratory (17). However, it is probably worth repeating that yields from this laboratory (4, 8, 17) are usually larger by a factor of 1.4 ± 0.2 than those reported by Schmidt and Allen (1, 6).

Electron Mobilities

Electron mobilities were measured in 13 of the present liquids and the values are listed in Table 3. The mobilities were independent of applied electric field strength over the range 2–20 kV/cm.

An e.c.t. signal could not be obtained in 1,3-cyclohexadiene, bicyclo[2,2,1]heptene, or bicyclo[2,2,1]heptadiene due to reaction of the electrons with the olefins. The lack of an e.c.t. signal in the adamantane–heptane solution was doubtless due to the presence of a trace of electron scavenging impurity, because the difficulty of transferring adamantane under vacuum prevented its purification with Na–K alloy. The pinenes were also difficult to purify and showed no e.c.t. signal.

The mobilities in pure 1,4-cyclohexadiene (Table 3) were estimated from those in the diene–benzene solutions by extrapolation of plots of log u_e against mole fraction of benzene (Fig. 3). The mobilities measured in the solutions are listed in Table 4. A given curve in Fig. 3 requires that the mobility in each solution be known at the same temperature, which was difficult to achieve experimentally. The mobilities in Fig. 3 were therefore taken at appropriate temperatures from the curves in Fig. 4.

[a]Reference 4.
[b]Reference 7.
[c]Extrapolated from the mobilities in 1,4-cyclohexadiene–benzene solutions presented in Table 4.

The mobilities in benzene obtained in the present work were on the average 7% higher than those reported earlier from this laboratory (17). The value at 300 K is fourfold lower than that given by Minday *et al.* (18) for that temperature. The latter measurements seem to have been affected by background currents.

Discussion

Free Ion Yields and Secondary Electron Ranges

One of the long term objectives of these studies is to learn about the processes that govern energy transfer from subelectronic excitation energy electrons to liquids (19). The processes are phase dependent (20). Preliminary information about the combined effects of inelastic and

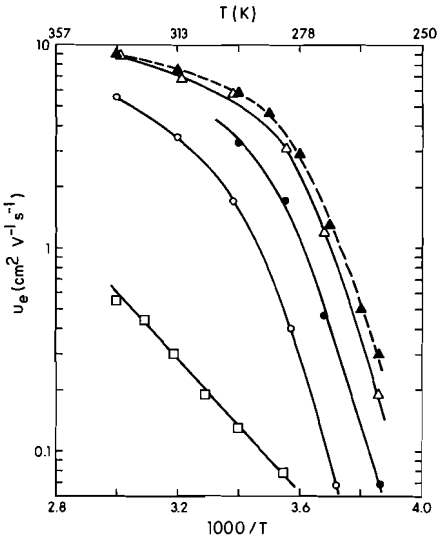

FIG. 4. Arrhenius plots of electron mobilities in 1,4-cyclohexadiene–benzene solutions and in pure benzene. Mol.% 1,4-cyclohexadiene: ▲, 100 (extrapolated u_e); △, 98.3; ● ,90.3; ○, 66.7; □, 0.0 (pure benzene). The curves were calculated using [12] and the parameter values in Table 5.

elastic scattering is obtained from the relative penetration ranges b_{GP} of secondary electrons into different liquids. The penetration ranges are inversely related to the efficiencies of the scattering processes.

The value of b_{GP} is calculated from $G_{fi}{}^{E}$ and G_{tot}. Values of G_{tot} in liquid alkanes might be about 25% greater than the corresponding gas phase values (21), but liquid phase values are in general not known. For the sake of consistency over a wide range of compounds, it is customary to take G_{tot} equal to the corresponding gas phase value (1, 4–6, 8).

To compare electron behavior in different liquids, a more convenient parameter than the range itself is the density-normalized range $b_{GP}d$. The density-normalized range in a given liquid is independent of temperature (Table 1) and compensates for the simple inverse variation of electron range with liquid density.

Monocyclic Alkanes

The density-normalized range of secondary electrons in cycloalkanes increases with increasing symmetry of the molecule, providing the strain in the C—C bonds remains small.

The normalized ranges in cyclopentane (56×10^{-8} g/cm^2) and cyclohexane (52×10^{-8} g/cm^2) are larger than those in *n*-pentane (44×10^{-8} g/cm^2) and *n*-hexane (46×10^{-8} g/cm^2) (8). The normalized ranges are essentially the same in cyclohexane, cycloheptane, and cyclooctane (Table 1), so the six-membered ring has no special properties in this regard (as it does in molecular packing, reflected in the melting points of the hydrocarbons (11)). The normalized ranges in the *n*-C_6–C_8 hydrocarbons are also equal (6) and uniformly lower than those in the cycloalkanes.

However, the range in cyclopropane (38×10^{-8} g/cm^2) is lower than that in propane (52×10^{-8} g/cm^2) (5). This is attributed to efficient energy transfer from the secondary electrons to the molecules by way of interaction with the peculiar bonds in the strained ring. Cyclopropane has a partially olefinic nature, which correlates with the fact that the normalized electron range in this liquid is intermediate between those in propane and propylene (5).

Polycyclic Alkenes

The large ranges in the polycyclic alkanes (Table 1) appear to be associated with the high degree of sphericity, relative rigidity, and lack of distorted orbitals (bond strain) in these molecules.

Bicyclo[2,2,2]octane is the most spherelike of the present molecules and the normalized range (117×10^{-8} g/cm^2) is the greatest in that liquid. It is nearly as great as that in neopentane (128×10^{-8} g/cm^2) (4). Therefore, the correlation between electron range in a liquid and the degree of sphericity of the molecules, that exists for branched chain molecules (1–4), extends to polycyclic hydrocarbons.

Monocyclic Alkenes

The density normalized ranges $b_{GP}d$ of secondary electrons in alkenes are affected by the same factors as those in alkanes, with the addition of a possible contribution of transient negative ion states to the energy transfer processes. The extra energy transfer mode tends to decrease the electron range.

The normalized ranges in all the monocyclic alkenes studied (Table 1) are larger than that in the open chain *cis*-hexene-3 (38×10^{-8} g/cm^2 (8)), but smaller than those in the corresponding monocyclic alkanes.

Either the range in cyclopentene is abnormally low by comparison with the rest of the series or that in cyclohexene is abnormally high (Fig. 5). A low range in cyclopentene might be attributed to efficient energy transfer associated with strain

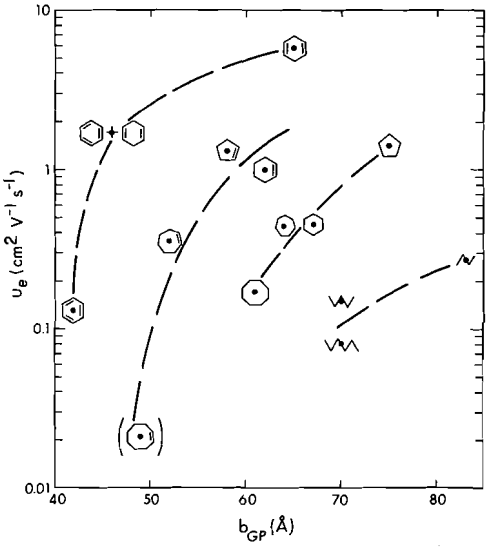

FIG. 5. Plots of u_e against b_{GP} for electrons in liquids at 295 ± 2 K, except for cyclooctene which was at 321 K. Values for the *n*-alkanes were taken from refs. 5–8 and 24. The symbols represent the carbon skeletons of the molecules. A point is included for the 66.7% cyclohexadiene solution in benzene.

in the olefinic five-membered ring, and an associated tendency of the molecule to accept an electron to form a negative ion. On the other hand, the relatively high degree of symmetry of cyclohexene might lead to a larger range in that liquid.

By analogy with behavior in *cis*-2-butene and 2,3-dimethyl-2-butene (8), it was suspected that shielding the double bond in cyclohexene might cause the electron range to increase. However, the normalized range in 1,2-dimethylcyclohexene is lower than that in cyclohexene (Table 1). Furthermore, the normalized range in 1,3-dimethylcyclohexene is essentially the same as that in the 1,2-isomer. Shielding the double bond by methyl groups is not important if it disrupts the symmetry of the molecule. Addition of methyl groups to the cyclohexene ring reduces the rotational symmetry of the molecule, which apparently increases the magnitude of the electron energy transfer interaction. It follows that the large range in 2,3-dimethyl-2-butene (72×10^{-8} g/cm^2) compared to that in *cis*-2-butene (46×10^{-8} g/cm^2) should be interpreted in terms of the greater molecular symmetry of the former, rather than in terms of shielding the double bond.

The present series of molecules have gas phase dipole moments ranging from 0.0 to 0.55 D (Table 1 and ref. 22). As noted previously (8), dipole moments were expected to influence the electron energy transfer interactions, but other effects apparently dominate that of the dipole moment in hydrocarbons. There is no detectable correlation between the electron normalized ranges $b_{GP}d$ and the gas phase molecular dipole moments (Table 1).

Polycyclic Alkenes

The ranges in the enantiomorphs α(+)- and α(−)pinene are the same, as expected. The normalized ranges in the pinenes are equal to those in the dimethylcyclohexenes (Table 1). The substituted cyclohexene character of the pinenes therefore appears to dominate in their interactions with low energy electrons in the liquid phase.

The normalized range in bicyclo[2,2,1]heptene is slightly smaller than that in cyclohexene, but is much smaller than that in bicyclo[2,2,1]heptane (Table 1). Putting a bridge methylene group between the 1- and 4-positions of cyclohexane increased $b_{GP}d$ from 52×10^{-8} g/cm^2 in cyclohexane to 76×10^{-8} g/cm^2 in bicyclo[2,2,1]heptane. The same procedure with cyclohexene decreased the normalized range from 51×10^{-8} to 48×10^{-8} g/cm^2. The effect of the bridge group on cyclohexane was in the expected direction, because adding the methylene bridge increased the degree of sphericity of the molecule. The bridge group decreased the range in the olefin in spite of the increased degree of sphericity. The fact that bicyclo[2,2,1]heptene reacts with Na–K alloy indicates that the ring strain (caused by the bridge) increases the reactivity of the molecule, somewhat analogous to the propane–cyclopropane and possibly the cyclohexene–cyclopentene case.

This supports the suggestion that one of the methods by which low energy electrons transfer energy to olefins in the liquid phase is through incipient negative ion formation. The electron and olefin coming together in collision approach the potential surface of a negative ion state. Upon separation after the collision the olefin may be left with more rotational or vibrational energy and the electron with less kinetic energy.

Monocyclic Alkadienes

The density-normalized range in 1,4-cyclohexadiene is somewhat larger than that in cyclohexene, whereas that in 1,3-cyclohexadiene is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

For personal use only.

much smaller than that in the mono-olefin (Table 1).

Introducing the second π bond in the nonconjugated 4-position increased the symmetry of the molecule, which decreased the strength of the electron–molecule energy transfer interaction. Introducing the second π bond in the conjugated 3-position increased the molecular reactivity to an extent that this effect dominated any other that the extra π bond might have had. The lower range in 1,3-cyclohexadiene is attributed to an increased electron energy loss interaction by way of negative ion states.

Polycyclic Alkadiene

The low range in bicyclo[2,2,1]heptadiene was unexpected, because the molecule is structurally related to 1,4-cyclohexadiene (Table 1). However, it turns out that bicyclo[2,2,1]heptadiene is conjugated through space (23), and the reactivity of this compound is similar to that of 1,3-cyclohexadiene. The equality of the normalized ranges in bicyclo[2,2,1]heptadiene and 1,3-cyclohexadiene is thereby explained. Negative ion states once again provide an important mode of energy transfer from the electrons to the molecules.

Benzene

The normalized range in benzene (37×10^{-8} g/cm^2) is only slightly greater than that in 1,3-cyclohexadiene (34×10^{-8} g/cm^2) and is much smaller than that in 1,4-cyclohexadiene (57×10^{-8} g/cm^2). This indicates that transient negative ion states are also important in the energy transfer mechanism for low energy electrons in liquid benzene.

Electron Mobilities

Correlation between u_e and b_{GP}

There is a general correlation between thermal electron mobilities and epithermal electron penetration ranges in liquids (4, 7). The correlation indicates that the gross properties of liquids that facilitate energy transfer from epithermal electrons also inhibit the migration of thermal electrons. However, the correlation is not perfect and it is fruitful to pick out variations within it.

The temperature dependence of u_e is much greater than that of b_{GP}, so comparisons are made between liquids at the same temperature when possible. An alternative is to compare the values obtained at the normal boiling points of the liquids. In the present work the same trends emerge from the two types of comparison, so only the former is given.

The general tendency is for u_e and b_{GP} to increase together, although the former changes much more quickly than the latter. Previously reported values of u_e in different liquids cover a range of seven orders of magnitude, while the corresponding values of b_{GP} cover a range of only two orders of magnitude. A log u_e *vs.* log b_{GP} plot was used to put all the data on a single graph (4, 7). However, to look for fine structure in the correlation it is convenient to expand the b_{GP} axis to an arithmetic scale and to use a limited range of u_e. To this end, a plot of log u_e *vs.* b_{GP} for cyclic hydrocarbons at 295 ± 2 K is shown in Fig. 5. Values for *n*-butane (5), *n*-pentane (7, 8), and *n*-hexane (6, 8, 24) are included for comparison. For a given value of b_{GP} the tendency is for u_e to increase in the order *n*-alkane < cycloalkane < cycloalkene < 1,4-cyclohexadiene or benzene.

The irregularity of shape of *n*-alkane molecules appears to have a greater effect on limiting the migration rate of thermal electrons than on de-energizing epithermal electrons. Solvent rearrangement probably makes a significant contribution to the formation of the equilibrium solvated state of electrons in hydrocarbons, as in other liquids. Solvent rearrangement increases the electron trap depth and decreases the mobility. The effect is greater in *n*-alkanes than in cycloalkanes.

By contrast, π bonds appear to have a greater effect on de-energizing epithermal electrons than on limiting the migration rate of thermal electrons. This applies only to compounds such as those in Fig. 5, which do not capture electrons to form stable negative ions. When negative ion formation is an endothermic process, epithermal electrons can interact more strongly than thermal electrons with the molecules. Interactions involving transient negative ion states thereby make a larger contribution to limiting b_{GP} than to limiting u_e in these liquids.

Temperature Dependence of u_e

Arrhenius plots of u_e in the olefins curve downwards at low temperatures (Figs. 4 and 6). The rapid change of slope indicates a change in transport mechanism.

The change of slope is particularly marked in 1,4-cyclohexadiene and the benzene–1,4-

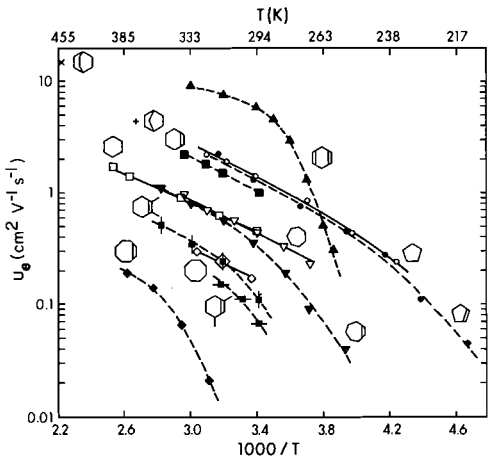

FIG. 6. Arrhenius plots of electron mobilities in cyclic hydrocarbons. The compounds are identified by their carbon skeletons on the graph. The filled points and dashed curves represent olefins. The open points and full curves represent cycloalkanes. The curves were calculated using [12] and the parameter values in Table 5.

cyclohexadiene solutions (Fig. 4). At temperatures below 280 K the Arrhenius temperature coefficient is 24–26 kcal/mol in all of the solutions. However, at about 330 K the coefficient is only 2 kcal/mol in the 98.3% diene solution and 4 kcal/mol in the 66.7% solution.

At high temperatures electron migration in hydrocarbons may occur mainly by thermal excitation from the solvated state to the conduction band.

[6] $$e^-_{solv} \rightleftharpoons e^-_{cb}$$

Optical excitation energies of solvated electrons in water and alcohols tend to decrease linearly with increasing temperature (25, 26), so the free energy and enthalpy of solvation would probably do likewise (27). By analogy, the free energy change of [6] in hydrocarbons is represented by [7].

[7] $$\Delta G_6 \approx \Delta G_6(0) - A_6T \approx \Delta H_6(0) - T\Delta S_6 - A_6T \approx \Delta H_6(0) - B_6T$$

where $\Delta H_6(0)$ is the enthalpy change extrapolated to zero Kelvin, A_6 is the temperature coefficient of the free energy change, and $B_6 = (\Delta S_6 + A_6)$. The temperature dependences of ΔS_6 and B_6 are neglected.

The large temperature coefficient of mobility at low temperatures is tentatively attributed to negative ion formation, by analogy with the reaction between solvated electrons and benzene in dimethoxyethane at low temperatures (28).

[8] $$e^-_{solv} + M \rightleftharpoons M^-_{solv}$$

Negative ion formation is negligible at high temperatures, where the slopes of the curves in Fig. 4 are small. The free energy change of [8] is assigned the same form as [7].

[9] $$\Delta G_8 \approx \Delta H_8(0) - B_8T$$

where $\Delta H_8(0)$ is the enthalpy change of [8] extrapolated to zero Kelvin and $B_8 = (\Delta S_8 + A_8)$.

$\Delta H_6(0)$ and $\Delta H_8(0)$ are opposite in sign, as are B_6 and B_8; [6] is endothermic to the right, whereas [8] is exothermic to the right.

Phenomenologically one cannot distinguish between [8] and the formation of a deeper trapped state of the electron. The present behavior is similar to that observed for electrical conduction in several liquid chalcogenides, such as As_2Te_3 (29). In those liquids the band gap is temperature dependent and has the form $E = E(0) - \gamma T$, with $E(0) \approx 20$ kcal/mol and $\gamma \approx 23$ cal deg^{-1} mol^{-1} (29).

The observed electron mobility u_e is equal to the product of the mobility u_{cb} in the conduction band and the fraction χ of the electrons that are in the conduction band. The mobilities of e^-_{solv} and M^- are considered to be negligible in the present systems.

[10] $$u_e = u_{cb}\chi$$

The fraction χ can be expressed in terms of the equilibrium constants or standard state free energy changes of [6] and [8].

[11] $$\chi = \{1 + K_6^{-1} + K_6^{-1}K_8[M]\}^{-1} = \{1 + e^{\Delta H_6^0(0)/RT}e^{-B_6^0/R} + [M]e^{(\Delta H_6^0(0) - \Delta H_8^0(0))/RT}e^{-(B_6^0 - B_8^0)/R}\}^{-1}$$

Under most conditions the first term on the right hand side of [11] is negligible and [10] may be approximated as [12].

[12] $$u_e \approx \frac{u_{cb}\, e^{B_6^0/R}\, e^{-\Delta H_6^0(0)/RT}}{1 + [M]\, e^{B_8^0/R}\, e^{-\Delta H_8^0(0)/RT}}$$

The mobility data in Figs. 4 and 6 were fitted to [12] and the values of the parameters so obtained are listed in Table 5.

98.3% CHD[c]	250	2.2	1.0×10^{-17}	−83	−21.8
90.3% CHD	700	3.0	7.5×10^{-17}	−79	−21.0
66.7% CHD	4100	4.4	5.5×10^{-17}	−79	−21.6
Benzene	5.4×10^4	7.6	—	—	—

[a]The value of $B_6{}^0$ is expected to be zero or positive, so these represent upper limits for u_{cb}.
[b]Estimated by taking $[M] \approx 10\,M$ for the pure solvent. 23 cal/deg mol $\equiv 1 \times 10^{-3}$ eV/deg electron.
[c]Parameters calculated using [10] and [11] instead of [12].

It is not possible to separately determine the factors u_{cb} and $e^{B_6{}^0/R}$ from mobility data alone. The value of $B_6{}^0$ is expected to be zero or positive, so $u_{cb}e^{B_6{}^0/R}$ gives an upper limit for the value of u_{cb}. In the 1,4-cyclohexadiene–benzene solutions the value of $u_{cb}e^{B_6{}^0/R}$ increases approximately exponentially with $\Delta H_6{}^0(0)$, which implies that $B_6{}^0$ increases with $\Delta H_6{}^0(0)$. Consistent with this, the values of u_{cb} in these nonspherelike hydrocarbons probably lie below that in neopentane, *i.e.* $u_{cb} \lesssim 100$ cm^2 V^{-1} s^{-1} (20).

The value of $\Delta H_8{}^0(0)$ is -21.4 ± 0.3 kcal/mol in all of the 1,4-cyclohexadiene solutions and it is attributed to an equilibrium between solvated electrons and negative ions. The temperature coefficient of $\Delta G_8{}^0$ in the diene is large, $B_8{}^0 = -81 \pm 2$ cal deg^{-1} mol^{-1} (Table 5), so the anion is relatively unstable even at the lowest temperature used: at 259 K, $\Delta G_8{}^0 = -21\,400 - (-81)259 = -400$ cal/mol.

The values of $\Delta H_8{}^0(0)$ and $B_8{}^0$ in the mono-olefins are smaller than those in the diene (Table 5). The small values in cyclopentane are attributed to the formation of a deeper trapped state of the electron in the liquid. The same may be true in the mono-olefins, without involving negative ion formation.

The authors wish to thank the personnel of the Radiation Research Center for help with the electronics.

The Catalytic Decomposition of 2-Propanol on Magnesium Oxide

IAN M. HOODLESS AND G. DOUGLAS MARTIN
Department of Chemistry, Lakehead University, Thunder Bay, Ontario P7B 5E1
Received October 18, 1973[1]

IAN M. HOODLESS and G. DOUGLAS MARTIN. Can. J. Chem. **53,** 2729 (1975).

The catalytic decomposition of 2-propanol on powders of "pure" and lithium oxide doped magnesium oxide has been investigated in the temperature range 300–450 °C by a pulse reactor technique. With the "pure" magnesium oxide samples the selectivity for dehydrogenation decreases with increasing temperature with an abrupt change in the region of 375 °C. The effect of the lithium oxide dopant is to depress the selectivity for dehydrogenation at the lower temperatures. The dopant does not appear to affect the dehydration activity and the decrease in selectivity is ascribed to the strong chemisorption of acetone at anion vacancies.

IAN M. HOODLESS et G. DOUGLAS MARTIN. Can. J. Chem. **53,** 2729 (1975).

On a étudié la décomposition du propanol-2 sur des poudres d'oxyde de magnésium "pur" et d'autres dopées par de l'oxyde de lithium; ces études ont été effectuées à des températures de 300–450 °C par une technique de réaction à pulsation. Avec des échantillons d'oxyde de magnésium "pur" la sélectivité pour la deshydrogénation diminue à mesure que la température augmente; il y a un changement subit dans la région de 375 °C. L'effet d'un dopage par l'oxyde de lithium est de diminuer la sélectivité pour la deshydrogénation aux températures inférieures. Il ne semble pas que le dopant affecte l'activité de deshydratation; on attribue la diminution dans la sélectivité à une forte chemisorption de l'acétone au niveau des anions disponibles.
[Traduit par le journal]

Introduction

The decomposition of 2-propanol has been widely used as a model reaction for studying the principles of catalyst selectivity and reactivity of metal oxides. Below 500 °C the predominant modes of decomposition are dehydration to give propene and dehydrogenation to give acetone. Several theories have been advanced linking the catalyst selectivity with geometric factors (1, 2), with electronic factors (3, 4), and with chemical factors (5). From the extensive data available Krylov (6) has examined the various theories by correlation analysis and, although there is considerable dispersion in the data points, he finds that the catalytic activity for dehydrogenation is a function of lattice parameter, type of conductivity, work function, and width of the forbidden zone. More recently a relationship between the selectivity for dehydrogenation and mobility of surface oxygen, as measured by isotopic exchange, has been proposed (7, 8).

In view of the correlation with the conduction characteristics of the oxides, the alkaline earth oxides are surprisingly active catalysts for the dehydrogenation reaction (6, 8). In the temperature range used in the catalysis investigations, these oxides are typical insulators and it is unlikely that their activity can be associated with electronic point defects. With semiconductor oxides it is frequently difficult to differentiate between the effects of electronic defects and other lattice defects on the catalytic activity but with the insulator oxides the influence of lattice vacancies on the decomposition reaction can be investigated. It has been suggested (9) that insulator oxides depend for their dehydration activity on the presence of these vacancies at the surface. This paper reports on a study of the effects of lattice vacancies on the decomposition of 2-propanol on MgO; the temperature range covered in these measurements is one in which previous work (8) would indicate a change in the activity of MgO from a dehydrogenation to a dehydration catalyst.

Experimental

Apparatus

The decomposition of 2-propanol was investigated by a micropulse reactor technique. A sample of the "spectra-analyzed" quality alcohol (1 μl) was injected into a dry, helium carrier-gas stream and passed over a 0.4 g sample of the catalyst in an all-glass reactor. The catalyst-bed temperature was controlled to ±1° by a Thermoelectric model 400 proportional controller which was initially calibrated with a second thermocouple embedded in the catalyst sample.

The reaction products and unreacted alcohol were quantitatively analyzed at 80 °C by a Hewlett–Packard model 5750 gas chromatograph using 6 ft long stainless

steel columns, 5 ft of which was packed with "Carbowax (20M)" on "Chromosorb G" and the final 1 ft packed with "Porapak Q". In most experiments the products passed directly from the reactor to the gas chromatograph but the apparatus could be modified to include a trapping system so that the products could be trapped out at liquid nitrogen temperatures for longer times prior to admission to the analytical column; the former will be referred to as partial recovery experiments. Independent measurements in which the flow rate was varied by a factor of three showed that this did not affect the selectivity. Several injections of 2-propanol were made at each reaction temperature, the time interval between injections being approximately 30 min.

Materials

Two samples of MgO were used. One sample was semiconductor grade MgO (>99.99% purity) supplied by Research Chemical Corporation. The other was prepared from magnesium nitrate solution (Baker Analyzed Reagent) by precipitation as hydroxide followed by thermal decomposition at 900 °C for 12 h. Li^+-doped samples were prepared by the same method, the dopant being added as lithium nitrate to the original nitrate solution. The lithium content of the samples was determined by atomic absorption spectrometry. Prior to any alcohol injections the catalysts were conditioned in the reactor by annealing at 600 °C for 6 h in the carrier gas stream. Surface areas of the samples, as measured by the BET method using krypton gas, were found to be 34 ± 3, 26 ± 3, and 31 ± 3 $m^2 g^{-1}$ for the MgO prepared by decomposition of the hydroxide, the 15.5×10^{-6} m.f. Li^+-doped MgO and the 45×10^{-6} m.f. Li^+-doped MgO respectively. The latter samples will be referred to as ML15.5 and ML45 respectively.

Results

Measurements of the catalyst selectivity were made over the temperature range 300–450 °C. At higher temperatures trace amounts of decomposition products of 2-propanol were detected in the absence of the catalyst. The major products of the catalytic reaction were acetone and propene, while, at temperatures above 400 °C, small amounts of propyne and a diene were also formed. The diene has been identified by mass spectroscopy and by its retention time on the analytical column as 2-methyl-1,3-pentadiene. In the temperature range investigated there was no evidence of the formation of ethers or mesityl oxide.

One advantage of the pulse technique is that it permits investigations of changes in selectivity in the catalyst prestabilization stages. De Vleesschauwer (10), who studied the reaction in a conventional flow system, reports that considerable time was required before a uniform decomposition rate of 2-propanol was obtained, presumably due to catalyst instability. We find little evidence of this in terms of the reaction products; in general the first injection of 2-propanol on to a fresh catalyst leads to a low recovery of products and reactant but there is no evidence of this behavior with subsequent injections. The variation in selectivity at each temperature for a series of alcohol injections is less than ± 0.03 and there is no significant trend in the selectivity as a function of the number of injections. Catalyst selectivities, defined as $C_{acetone}/(C_{acetone} + C_{propene})$ are shown in Table 1 and the fractional conversion to propene and acetone, based on the products and reactants recovered, are shown in Table 2 for the partial recovery experiments.

A number of studies have also been made of the effect of catalyst pretreatment on the selectivity for dehydrogenation of the alcohol. In these experiments, the catalysts, at the reaction temperature, were subjected to pulses of hydrogen, oxygen, and water vapor followed by injection of the alcohol approximately 10 s after the pretreatment pulse. Some results of these types of experiment on the ML15.5 catalyst are given

in Table 3. One significant feature regarding the pretreatment of the catalyst with water vapor is that the marked reduction in propene production is observed only with the first injection of alcohol after the pretreatment.

Discussion

The high selectivity of MgO for dehydrogenation observed at the lower temperatures, Table 1, is in good agreement with previous work (8, 10). De Vleesschauwer (10), who prepared the MgO by calcination of magnesite, reports a value of 0.92–0.96 for the selectivity at 350 °C of samples calcined at temperatures above 550 °C but found that lower calcination temperatures produce a dehydration catalyst. McCaffrey *et al.* (8) and De Vleesschauwer (10) report that the activation energy for the dehydration reaction is greater than that for the dehydrogenation reaction so that a decrease in the selectivity for dehydrogenation with increases in reaction temperature is to be expected. Selectivities at temperatures above 350 °C have been calculated by extrapolation of the results of McCaffrey *et al.* (8) for the rates of dehydration and dehydrogenation in the temperature range 270–350 °C and are shown in parentheses in Table 1. Above 400 °C the present results for MgO give a significantly higher value for the dehydrogenation selectivity than would be anticipated from the rate equations for lower temperature behavior (8).

The effect of Li^+-doping is to decrease the selectivity for dehydrogenation particularly at the lower temperatures. The level of dopant used is such that it would lead to changes in the point defect concentrations rather than new compound formation; X-ray diffraction data support this conclusion. Relatively few detailed studies have been made into the defect nature of MgO but, on the basis of theoretical estimates of defect formation energies (11) and diffusion measurements (12), it is believed that the predominant point defects are of the Schottky type. Incorporation of the dopant in the lattice would be achieved by the

following reaction

$$[1] \quad (Mg_1^{2+})(O_1^{2-}) + \tfrac{1}{2}nLi_2O \rightarrow (Mg_1^{2+}Li_n^{+})(O_{1+1/2n}^{2-}\boxed{a}_{1/2n})$$

where $\boxed{a}$ signifies an anion vacancy. The doped samples will therefore have an increased anion vacancy concentration and a decreased cation vacancy concentration relative to undoped MgO. The selectivity results for the doped samples do not support the proposal (9) that the dehydration activity of insulators is associated with cation vacancies. In Table 2 the fractional conversions to propene and acetone in partial recovery experiments on the catalysts are compared. The effect of Li^+-doping, apart from the results at 300 °C where low yields of products were obtained, is to decrease the yield of acetone particularly for reaction temperatures of 400 °C and below.

It seems unlikely that the reduction in acetone yield is directly associated with the reduced cation vacancy concentration in the doped samples. At the highest reaction temperature, 450 °C, there is good agreement in both the selectivity and the fractional conversion for all the catalysts yet, at this temperature, there should still be a depressed cation vacancy concentration in the doped samples relative to the undoped samples. It is possible that the decreased selectivity of the doped samples below 400 °C may be partially due to the strong chemisorption of acetone on the catalyst surface. Some controversy exists as to the rate-determining step in the dehydrogenation reaction on metal oxides; it has been suggested that either the reaction of the adsorbed alcohol on the surface (8, 13) or the desorption of acetone (6, 14) is rate limiting. It has been noted in the present work that in the experiments, in which the products are trapped out over a longer period of time prior to admission to the analytical column, there is an enhanced recovery of products, particularly acetone, relative to the partial recovery experiments for the lower reaction temperatures; for example with the ML45 catalyst at a reaction temperature of 350 °C the yield of acetone is approximately doubled in the trapping-out experiments while the yield of propene is essentially unchanged. Above 400 °C the selectivities obtained in the two types of experiment are the same.

Recent infrared studies of adsorption on MgO (15) have shown that acetone is strongly chemisorbed and at temperatures above 250 °C the spectra are consistent with the formation of a carboxylate ion at the surface. Since the surface of the MgO will be preferentially terminated by oxide ions (16), an anion vacancy, being a region of positive charge, is an ideal site for the chemisorption of acetone via its oxygen. It is therefore suggested that the decreased selectivity in the doped samples is, at least in part, due to the strong chemisorption of acetone at anion vacancies. In this connection it is interesting to note the effects of pretreatment of the catalyst with water vapor on the 2-propanol decomposition, Table 3. The inhibition of dehydration reaction on oxide catalysts by water vapor has been previously reported (8) but additionally we observe an enhanced recovery of acetone. Blocking of the anion vacancies by adsorption of some of the water at these sites would reduce the tendency for acetone chemisorption and hence increase the yield of acetone in the partial recovery experiments.

In the temperature range 375–400 °C there are significant changes in the dehydrogenation selectivity for all the catalysts; with MgO there is a "break" in the selectivity temperature trend in this region while for the doped samples a minimum in the selectivity is observed. Winter (17) has measured oxygen exchange on MgO and reports a marked change in the rate of exchange in the temperature region 390–410 °C; above these temperatures the activation energy for exchange is considerably lowered. The observation is interesting in light of the recent proposal (7, 8) linking high selectivity for dehydrogenation with a low activation energy for oxygen exchange on the catalyst. Winter (17) has interpreted the decrease in activation energy for exchange as indicative of the temperature of onset of significant oxide ion mobility at the surface. Following this interpretation, at temperatures above 400 °C the lifetime of individual anion vacancies will be decreased and this would lead to the observed increase in acetone desorption.

The present results do not permit identification of the active sites for the dehydration and dehydrogenation reactions. Because of the similar behavior of all the catalyst samples at 450 °C it appears that, although anion vacancies may act as trapping sites for acetone at lower temperatures, vacancies are not the active centers for catalysis. Also comparison of the yields of acetone for successive injections of 2-propanol at each temperature shows that the dehydrogenation sites are not readily poisoned. In terms of

For personal use only.

the dehydrogenation mechanism it has been proposed (18, 19) that chemisorbed oxygen may act as a hydrogen abstractor. The effects of oxygen pretreatment of the catalyst at higher temperatures, Table 3, are consistent with this suggestion. Keier *et al.* (20) have found that lithium doping increases both the rate and amount of oxygen adsorption on magnesium oxide in the temperature region around 500 °C. The enhanced yields of acetone on the pretreated catalyst could be due to chemisorbed oxygen. However the results at lower temperatures, *i.e.* below 400 °C, are surprising. Pretreatment of the catalyst with oxygen does not significantly affect the acetone yield but it has been observed that in this temperature range treating the catalyst with oxygen some 15 min after a 2-propanol injection leads to the release of acetone from the surface. Whether this is due to the reaction of the strongly adsorbed precursor to acetone with gaseous or physisorbed oxygen or due to the displacement of chemisorbed acetone by the relatively high concentration of oxygen present is not clear.

The Proton–Proton and Proton–Carbon-13 Spin–Spin Coupling Constants in 1,3-Dioxole and Bis-1,3-dioxolyl. Conformational Dependence

TED SCHAEFER, KALVIN CHUM, DAVID MCKINNON, AND M. S. CHAUHAN
Department of Chemistry, University of Manitoba, Winnipeg, Manitoba R3T 2N2

Received May 12, 1975

TED SCHAEFER, KALVIN CHUM, DAVID MCKINNON, and M. S. CHAUHAN. Can. J. Chem. **53**, 2734 (1975).

The carbon-13 satellite peaks in the proton magnetic resonance spectra of 1,3-dioxole and bis-1,3-dioxolyl are analyzed under single and double resonance conditions to yield the signs and magnitudes of proton–proton coupling constants over three, four, and five bonds, and of proton–carbon-13 coupling constants over one, two, and three bonds. The conformational behavior of bis-1,3-dioxolyl contrasts sharply with that of analogous *sym*-tetrasubstituted ethane derivatives. It is indicated that the two-bond proton–carbon-13 coupling in the ethanic fragment can be used for conformational analysis in a manner similar to vicinal proton–proton couplings. The vicinal three-bond proton–carbon-13 couplings are given for dihedral angles of 180 and 120° and their relative magnitudes are as expected from a Karplus relationship. The two-bond proton–carbon-13 coupling in the olefinic fragment is, at 20.0 Hz, the largest coupling known for such a bond.

TED SCHAEFER, KALVIN CHUM, DAVID MCKINNON et M. S. CHAUHAN. Can. J. Chem. **53**, 2734 (1975).

On a analysé les pics satellites causés par le ^{13}C dans les spectres r.m.p. du dioxole et du bis-dioxolyl-1,3; utilisant des conditions de résonance simple et de résonance double, on a pu déterminer le signe et l'amplitude des constantes de couplage proton–proton sur trois, quatre et cinq liens et les constantes de couplage proton–^{13}C sur un, deux et trois liens. Le comportement conformationnel du bis-dioxolyl-1,3 est en opposition flagrante avec celui de dérivés analogues de l'éthane tétrasubstitué d'une façon symétrique. Il ressort de ces travaux que le couplage proton–^{13}C sur deux liens de la fraction éthane pourrait être utilisé pour des besoins conformationnels de la même manière que les couplages proton–proton vicinaux. On donne les couplages vicinaux proton–^{13}C sur trois liens pour des angles dièdres de 180 et 120° et leurs amplitudes relatives correspondent à ce que l'on peut attendre à partir d'une relation de Karplus. Le couplage proton–^{13}C sur deux liens du fragment oléfinique est de 20.0 Hz qui est la valeur la plus élevée connue pour un tel couplage. [Traduit par le journal]

Introduction

The observation of ^{13}C satellite peaks in the proton magnetic resonance spectra of symmetrical molecules, and their use in obtaining spin–spin coupling constants, has a long history (1, 2). More recently, ^{13}C n.m.r. spectra have been used for this purpose and, when combined with enrichment of ^{13}C, allow the unambiguous identification of $^{13}C,H$ and $^{13}C,^{13}C$ couplings. Marshall *et al.* (3) use this approach in pursuing a relationship (4) between $^{13}C,H$ and analogous H,H couplings.

In a somewhat different approach (5), a comparison between $^2J(^{13}C,H)$ and $^1J(^{13}C,H)$ gave an indication of inductive and hyperconjugative substituent effects (6) on $^2J(^{13}C,H)$. In another study (7), a relationship between $^2J(^{13}C{=}C{-}H)$ and $^3J(H{-}C{=}C{-}H)$ in some ethylenic and aromatic systems was used as a tentative measure of delocalization in a cyclic compound.[1]

The previous work (7) included compounds **1**, **2**, and **3**. In the present paper 1,3-dioxole, **4**, and bis-1,3-dioxolyl, **5**, have their ^{13}C satellite spectra analyzed. The spectra of **5** are a good example of a system in which the ^{13}C side bands in a p.m.r. spectrum yield most of the interesting $^{13}C,H$ coupling constants, as well as the signs and magnitudes of very small (0.1 Hz) H,H couplings, in a relatively inexpensive manner. The conformational dependence of $^2J(^{13}C,H)$ in the ethanic fragment appears as a potential measure of conformational preferences in ethane derivatives but such studies will be much easier to perform with pulsed ^{13}C spectrometers.

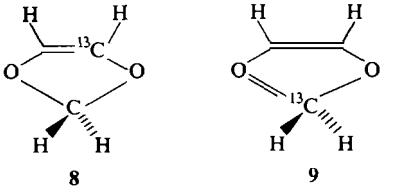
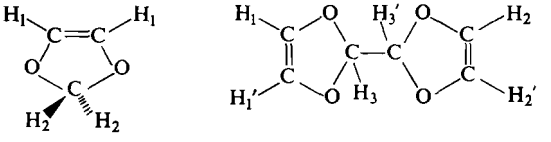
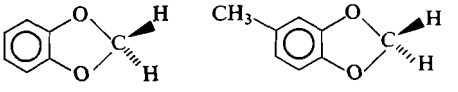
1 2 3



8 9



4 5



6 7

As a check on the $^{13}C,H$ parameters in **4**, the ^{13}C side bands of the methylene protons in **6** and **7** are also measured.

Experimental

Materials and Spectral Measurements

Compounds **4** and **5** were prepared by known methods (8, 9). Solutions of **4** (50 mol%) in acetone-d_6 and benzene-d_6 were degassed and their p.m.r. spectra were repeatedly calibrated at 5 Hz intervals in the frequency sweep mode of a H-100D Varian spectrometer. The scale was 1 Hz/cm and sweep times as low as 5000 s were employed. Similar statements apply to **5** as a 25 mol% solution in acetone-d_6 and as 10 mol% solutions in both acetone-d_6 and benzene-d_6. Compounds **6** and **7** were measured as 50 mol% solutions in carbon disulfide.

Molecular Orbital Calculations

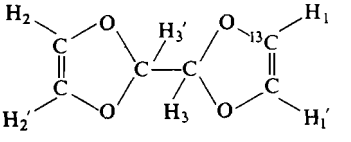
The spin–spin coupling constants were calculated by approximate molecular orbital theory (10) at the INDO MO FPT and CNDO/2 MO FPT levels (11), using the original parameterization (10). Convergence to 0.01 Hz in the couplings was demanded. The geometry of **4** was based on the microwave geometry of **1** (12) and a tetrahedral H—C—H bond angle was assumed for the methylene group. A similar geometry (coordinates available from the authors) was assumed for **5**, where *trans* and *gauche* orientations of the C—H bonds about the ethanic C—C bond were taken. The relevant calculated couplings are given in Tables 1 and 2.

Results and Discussion

Spectral Analysis

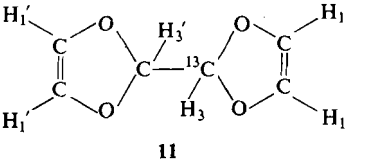
The p.m.r. spectrum of **4** is a rare example of an A_2B_2 (nearly A_2X_2) spectrum, as opposed to an $[AB]_2$ spectrum (13), whereas **8** and **9** yield A_2BCX and A_2B_2X spectra, respectively. Because all but two of the transitions in **8** and **9** are observable, iteration with the computer program LAME (14, 15) combined with tickling experiments (16), gave the parameters in Table 1. It is assumed that $^1J(^{13}C,H)$ and $^3J(H,H)$ are positive. The negative sign of $^4J(H_1,H_2)$ is confirmed by experiments on bis-1,3-dioxolyl.

The spectrum of **5** containing only ^{12}C is an example of an $X_2AA'X_2'$ or $[X_2A]_2$ spectrum (17) and, assuming that $^7J(H_1,H_2)$ is zero, the presence of very weak transitions (to be seen as sharp peaks in Fig. 1*A*) yields $^3J(H_3,H_3')$ as 4.27 ± 0.03 Hz, assumed positive. The magnitudes of $^4J(H,H)$ and $^5J(H,H)$ found below reproduced the spectrum of **5** only if their signs were opposite.



10

The spectrum of **10** was first analyzed as a first-order spectrum to give the coupling parameters in Table 2. Later its spectrum was simulated as a seven-spin system using input parameters from the analysis of **11** and good agreement with experiment was found on the basis of the isotope shifts implied by the data in Table 2.



11

The spectrum of **11** was most informative. In Fig. 1*A* the spectrum of H_1 is given. Because $^7J(H_1,H_1') < 0.03$ Hz, the separation between the midpoints of the two pairs of doublets on either side of the intense resonance of the ^{12}C

‡$\nu_1' = 647.97(4)$ Hz.
§$\nu_3' = 574.22(4)$ Hz.

molecule is $^3J(^{13}C,H_1) = 6.75 \pm 0.03$ Hz, this value agreeing with $^3J(^{13}C,H_1)$ found for the monocyclic compound, **9**. $^4J(^{13}C,H_1')$ must be less than 2.5 Hz in magnitude. The larger separation within the pairs on one side of the resonance from the ^{12}C molecule is $^4J(H_1,H_3) = \pm 0.28$ Hz and the smaller splitting is $^5J(H_1,H_3') = \pm 0.11$ Hz.

On the right hand side of Fig. 1 the spectrum of H_3' for **11** is given schematically but the long-range proton–proton splittings are omitted for reasons of clarity. It turns out that the magnitudes of $^2J(^{13}C,H_3')$ and $^3J(H_3,H_3')$ are almost equal and only the outside peaks of this multiplet are observable, the inner peaks being hidden in the intense resonance of the ^{12}C molecule. The spin states of $^{13}C,H_3$ and H_3' are indicated in the figure with the convention that a positive spin state corresponds to a high-field (low-frequency) peak for a positive coupling constant.

In Fig. 1*B*, 1*C*, and 1*D* the results of partial decoupling experiments (18) are displayed, the irradiations being indicated on the right. These experiments show that $^3J(^{13}C,H_1)/^2J(^{13}C,H_3') > 0$ and $^4J(H_1,H_3)/^3J(H_3,H_3') < 0$. In Fig. 1*E* and 1*F* the H_1 resonance is observed during irradiation of the high-field multiplet of H_3. The recorded spectra indicate $^3J(^{13}C,H_1)/^1J(^{13}C,H_3) > 0$ and $^3J(H_3,H_3')/^5J(H_1,H_3') > 0$. The results of these and other experiments are given in Table 2 on the assumption that $^1J(^{13}C,H)$ and $^3J(H_3,H_3')$ are positive. Final magnitudes of the parameters were found by successive simulations of the seven-spin spectra.

The Coupling Parameters

^3J(H—C=C—H) and $^2J(^{13}C$=C—H)

The value of 1.21 Hz for **4** and **5** falls on the previous plot (7) of ^3J(H—C=C—H) *vs.* $^2J(^{13}C$=C—H), characterizing **4** and **5** as ethylene derivatives and distinguishing them from delocalized species such as furan or benzene. The value of 1.21 Hz is the smallest known coupling of this nature. The value in cyclopropene is 1.3 Hz (19). ^3J(H—C=C—H) is 3 Hz in cyclopropenone (20). $^2J(^{13}C$=C—H), at +20.0 Hz in **4** and **5**, is the largest known coupling in olefinic systems, its value being −2.4 Hz in ethylene (21).

^3J(H—C—C—H) and the Conformation of Bis-1,3-dioxolyl

At 32 °C this coupling is $4.2_5 \pm 0.05$ Hz in 10 and 20 mol% solutions in acetone-d_6 and is 4.10 ± 0.05 Hz in a 10 mol% solution in benzene-d_6. In the 10 mol% acetone solution, ^3J(H—C—C—H) increases to 4.8 ± 0.1 Hz at −40 °C (precipitation occurs at lower temperatures). This behavior contrasts sharply with that observed for other *sym* tetrasubstituted ethanes.

Thus, the *gauche* conformation **12** is favored over the *trans* conformation **13** in acetone solution, the observed ^3J(H,H) being 4.4 Hz in *n*-hexane and 2.7 Hz in acetone (22). This

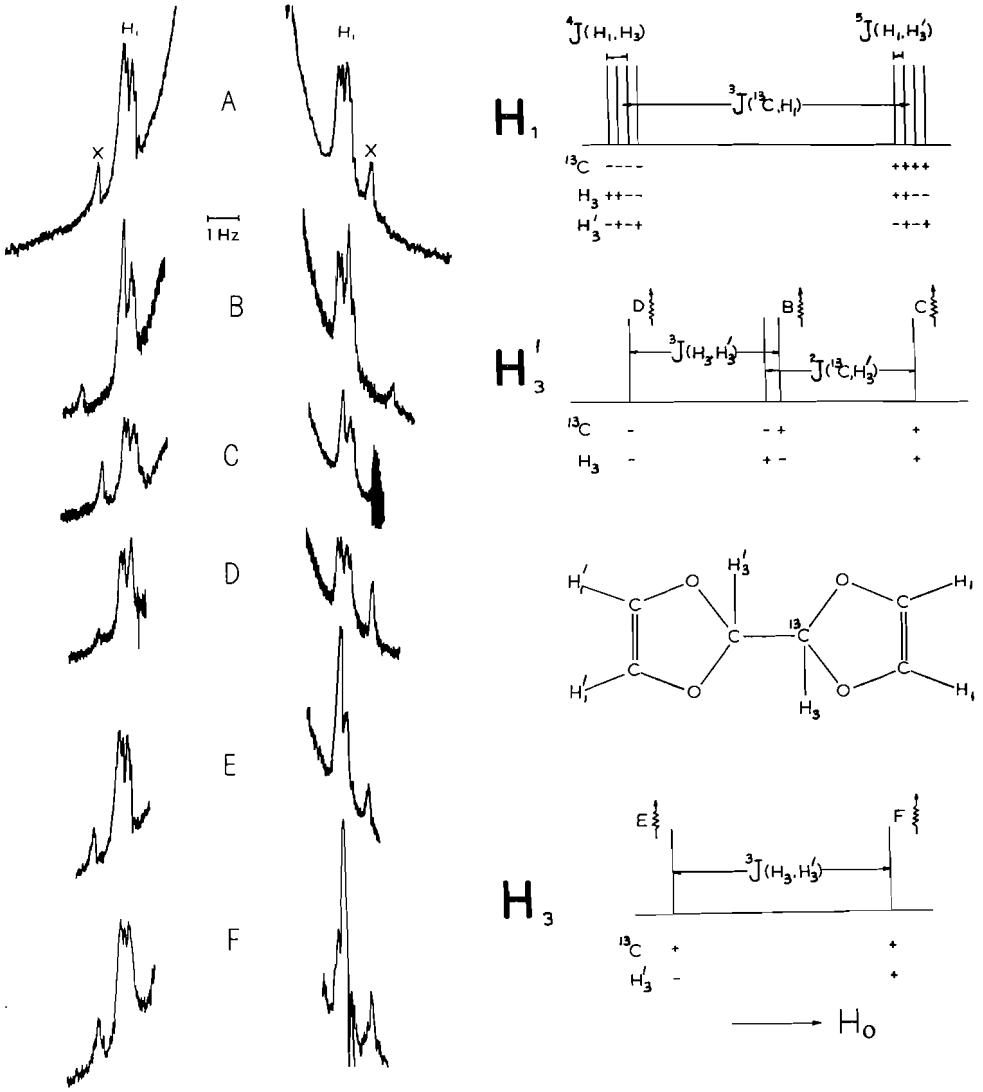

FIG. 1. On the left the H_1 proton resonance is displayed for bis-1,3-dioxolyl containing ^{13}C at one ethanic position. The intense peak from the ^{12}C molecule is flanked by two peaks marked with a cross and these peaks also arise from the ^{12}C molecule. The two pairs of doublets arise from the ^{13}C molecule. On the right the schematic resonance patterns are indicated for the protons as labelled in the formula. The vertical, curly, arrows indicate the peaks which are being irradiated while observing the lettered spectra on the left. The observed double resonance patterns are discussed in the text. The smallest splittings are 0.1 Hz in magnitude.

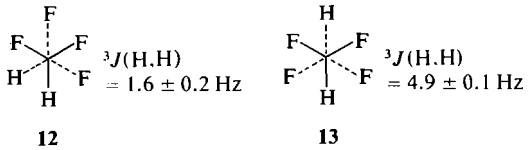


12 **13**

behavior is expected on the basis of Abraham's classical solvation theory (23), the more polar form **12** having a lower energy in the more polar medium. Similar observations are made for 1-chloro-1,2-dibromo-2-iodoethane (24), the *gauche* conformations becoming more abundant as the temperature decreases in an acetone–DME solution.

However, a less polar conformation can be stabilized by quadrupolar interactions of the solute molecule with the dielectric continuum (23), as has recently been shown for 3-pyridinealdehyde (25). The O,N-*trans* form of this molecule has a dipole moment more than 2 D

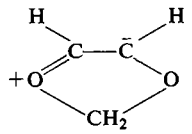
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

smaller than the O,N-*cis* form, yet is more stable in acetone solution by about 0.5 kcal/mol. It is clear that **5** is also behaving in this manner if ${}^3J^{H,H}_{trans} > {}^3J^{H,H}_{gauche}$.

In the absence of ${}^3J_t{}^{H,H}$ and ${}^3J_g{}^{H,H}$ values for **5** it is unreliable (25) to calculate[2] energy differences between the conformational isomers of **5** on the basis of the observed ${}^3J$(H,H). One may note, however, that the dipole moment of the *trans* form is zero while that of the *gauche* form is calculated as 1.52 D by INDO MO theory (see Experimental). As with other *sym*-tetrasubstituted ethanes (23), however, the quadrupole moment of the *trans* form is larger than that of the *gauche* form. Furthermore, INDO MO theory predicts the *gauche* form as 1.00 kcal/mol more stable than the *trans* form (see Experimental). Consequently, it may be concluded that, as the temperature decreases in the acetone solution, the quadrupolar interaction of the *trans* form with the dielectric medium outweighs both the dipolar interaction and the thermal preferences of the *gauche* form.[3] The present results emphasize that the conformational behavior of extended molecules need not follow that observed for smaller molecules of the same substitution pattern (23) about a given bond.

${}^4J(H,H)$ and ${}^5J(H,H)$

The closest useful analogy to ${}^4J$(H—C—O—C—H) in **4** is the allylic coupling in propene; particularly if the resonance structure **14** is considered, where the C=O$^+$ grouping now plays the role of the C=C double bond in propene. The relevant dihedral angle is 120°, which in propene is calculated (27) to lead to a



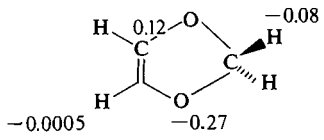
14

coupling constant of about −2 Hz, very much larger than the observed value of −0.29 Hz. However, the σ–π interaction between the C—H bond of the methylene group and the p_π orbital on oxygen presumably will be less effective than in propene (p_π orbital is contracted by the positive charge on oxygen). Furthermore, ${}^4J$(H,H) in **4** may be considered as the average of a negative allylic coupling and a positive ${}^5J$(H—C—O—C=C—H), possibly leading to the observed small, negative coupling. The INDO value, although positive (Table 1), is considerably smaller than the CNDO/2 prediction, possibly indicating the importance (10) of a π electron mechanism. ${}^4J$(H,H) in **4** is insensitive to substitution by carbon at the methylene group (*cf.* **5**).

${}^5J$(H,H) is +0.11 Hz in **5**. Comparison with the calculated values for the *trans* and *gauche* forms suggests the presence of a considerable amount of the latter in acetone solution, the calculated value for the *trans* form being 0.02 Hz at most. The coupling paths in the *gauche* form approximate more closely to an all-*trans* arrangement of bonds.

Solvent Dependence of ${}^1J({}^{13}C,H)$ in 4

The theoretical and experimental aspects of this dependence have been reviewed (28, 29). In **4** the coupling involving the olefinic carbon increases by 0.65 Hz in going from benzene to acetone solution, whereas the coupling involving the methylene carbon increases by only 0.25 Hz. In **15** the valence charge densities are given as calculated by INDO MO theory. The olefinic



15

hydrogen atoms carry less negative charge than do the methylenic hydrogens. Therefore the specific interaction with acetone molecules, known (30) to lead to increases in ${}^1J({}^{13}C,H)$, will be larger at the olefinic site and cause the greater change in ${}^1J(=^{13}C,H)$. The change observed for ${}^1J({}^{13}C,H)$ at the methylenic carbon is about 10

[2]In *sym*-tetrachloroethane it is estimated (26) that ${}^3J_t$ and ${}^3J_g$ are 10.5 and 2.2 Hz, respectively. If the estimations (22) of 4.9 and 1.6 Hz for ${}^3J_t$ and ${}^3J_g$, respectively, in *sym*-tetrafluoroethane are combined with these and a linear dependence of ${}^3J_t$ and ${}^3J_g$ on substituent electronegativity is assumed, one predicts ${}^3J_t$ = 7.6 Hz and ${}^3J_g$ = 2.0 Hz for **5**. Then, in acetone solution at 32 °C one has n_t = 0.4 and n_g = 0.6 whereas at −40 °C, n_t = 0.5 = n_g. Assuming no entropy difference between *gauche* and *trans* forms, *i.e.*, the *gauche* form is favored by a simple statistical factor of 2, the *trans* form has a lower enthalpy of 170 cal/mol at 32 °C and of 320 cal/mol at −40 °C. Note that none of these molecules have been 'frozen out' on the n.m.r. time scale, so that ${}^3J_t$ and ${}^3J_g$ have not been measured directly. INDO MO theory (Table 2) predicts quite different values than those quoted here.

[3]A thorough study of the solvent and temperature dependence of ${}^3J$(H—C—C—H) in **5** demands FFT equipment because of the low solubility of **5** in many solvents and because of the spectral characteristics.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

times smaller than for a molecule like CH_2Cl_2 (29). This can be qualitatively understood in terms of Barfield's calculations (29) in which a uniform electric field acting on the molecule causes a further transfer of charge from carbon to the substituent and to the hydrogen atom. In **15** the C—H bond is already considerably polarized, so that the reaction field due to the dielectric medium will be less effective in changing $^1J(^{13}C,H)$.

$^2J(^{13}C—C—H)$ in the Ethanic Fragment of **5**

$^2J(^{13}C—C—H)$ is +4.35 Hz in **5** while it is −4.5 Hz in ethane (21) and +1.1 Hz in *sym*-tetrabromoethane (31). The computed numbers in Table 1 demonstrate a dependence on conformation and imply that $^2J(^{13}C—C—H)$ depends on the orientation of the $^{13}C—O$ bond relative to the C—H bond, as well as on the electronegativity of the substituents attached to the $^{13}C—C—H$ fragment. Thus, in ethane the INDO value is −7.20 Hz (11), rises to +7.70 Hz in the *gauche* form of **5** where one C—O bond lies *trans* to the C—H bond in the $^{13}C—C—H$ fragment, but drops to +3.42 Hz when both C—O bonds are oriented to form dihedral angles of 60° with the C—H bond, *i.e.*, in the *trans* form.

The conclusion must be that $^2J(^{13}C,H)$ values in ethane derivatives can very likely be used in a fashion analogous to $^3J(H,H)$ in estimating conformational preferences. As with $^3J(H,H)$, the MO values are insufficiently reliable as reference points, so that ^{13}C n.m.r. measurements on compounds of known conformational preferences are necessary to establish calibration points. The intrinsic solvent dependence of $^3J(H,H)$ is apparently small (32). Such may not be true for $^2J(^{13}C,H)$.

Conformational Dependence of $^3J(^{13}C—O—C—H)$

$^3J(^{13}C—X—\overset{\|}{C}—H)$ in **1** to **4** is (5, 7) ±9.3, ±8.7, ±10.4, and +6.7 Hz, respectively. The first three numbers have been qualitatively interpreted (7) as being a consequence of the higher effective nuclear charge in the radial part of the 2s orbital on the ^{13}C atom. In this vein it is then reasonable that the coupling in **4** be smaller than in **1** to **3** because the ^{13}C atom is now formally sp^3 instead of sp^2 hybridized, thereby reducing the s electron density at the ^{13}C nucleus. The dihedral angle for this coupling path is 180° for all four compounds, expected to be a maximum for a Karplus relationship between angle and coupling. It follows that $^3J(^{13}C—X—\overset{\|}{C}—H)$ depends markedly on substituent effects and on the nature of X in addition to its dependence on dihedral angle. The INDO computations for **4** reproduce this coupling rather well.

$^3J(=^{13}C—O—C—H)$ in **4** is +2.4 Hz. The dihedral angle is 120°. It is remarkable that the ratio (0.36) of the two $^3J(^{13}C,H)$ values is nearly equal to the ratio (0.34) computed for these dihedral angles (180 and 120°) in propane (33), suggesting that $^3J(^{13}C,H)$ will follow a Karplus curve under diverse bonding conditions.

As a check on the magnitude of $^3J(=^{13}C—O—C—H)$ in **4**, the ^{13}C satellites of the methylenedioxybenzenes, **6** and **7**, were observed and gave values of ±2.05 ± 0.05 Hz for both compounds.

Isotope Shifts of the Proton Resonance

The carbon-13 isotope shifts of the proton resonance in **4** are very similar to those observed for **2** and **3** (7). They range from +0.0040 ± 0.0004 p.p.m. for directly bonded protons to 0.0008 ± 0.0004 p.p.m. for a proton separated by three bonds from ^{13}C. The measurements are not precise enough to distinguish clearly between the one-bond isotope shifts measured at olefinic or methylenic carbon centers.

Apparent Isotope Effect on $^4J(H,H)$

The data in Table 1 indicate a ^{13}C isotope effect of $+0.03 \pm 0.01_5$ Hz on $^4J(H,H)$ in **4**, this coupling being −0.30 ± 0.005 Hz in the ^{12}C molecule and −0.26 ± 0.01 Hz in the ^{13}C molecules, all in acetone-d_6. However, the spectral properties depend on solvent and concentration, to be discussed elsewhere, and suggest that the effect is an experimental artifact.

The Initial Stages of the Pyrolysis of Dimethyl Ether

PHILIP D. PACEY

Department of Chemistry, Dalhousie University, Halifax, Nova Scotia B3H 4J3

Received October 15, 1974[1]

PHILIP D. PACEY. Can. J. Chem. **53**, 2742 (1975).

Dimethyl ether was pyrolized in a flow system at 782–936 K and 25–395 Torr with conversions from 0.2–10%. Product analyses were consistent with a simple Rice–Herzfeld mechanism with most chain termination by the recombination of CH_3 radicals. The rate coefficients for both the initiation and termination reactions appeared to be slightly pressure dependent. The first-order rate constant for the initiation reaction,

$$CH_3OCH_3 \rightarrow CH_3O + CH_3$$

calculated from the rate of C_2H_6 formation, was $k_1 = 10^{15.0\pm0.5} \exp(-318 \pm 8 \text{ kJ mol}^{-1}/RT)$ s^{-1}, corresponding to $\Delta H_f^0(CH_3O) = -5 \pm 8$ kJ mol^{-1}. Comparison of CH_4 and C_2H_6 yields enabled calculation of the rate constant for the reaction of CH_3 with dimethyl ether. From 373–936 K, the Arrhenius plot for this reaction is a curve.

PHILIP D. PACEY. Can. J. Chem. **53**, 2742 (1975).

On a pyrolysé l'éther méthylique dans un système à flux à des températures allant de 782 à 936 K et des pressions allant de 25 à 395 Torr; les taux de conversions étaient de 0.2 à 10%. L'analyse des produits est en accord avec le mécanisme simple de Rice–Herzfeld impliquant que la plupart des terminaisons de chaîne s'effectuent par recombinaison de radicaux méthyles. Il semble que les coefficients de vitesse des réactions d'initiation et de terminaison dépendent en faible partie de la pression. La constante de vitesse du premier ordre pour la réaction d'initiation,

$$CH_3OCH_3 \rightarrow CH_3O + CH_3$$

calculée à partir de la vitesse de formation de C_2H_6, est $k_1 = 10^{15.0\pm0.5} \exp(-318 \pm 8$ kJ mol$^{-1}/RT)$ s^{-1}, correspondant à un $\Delta H_f^0(CH_3O) = -5 \pm 8$ kJ mol^{-1}. Une comparaison des rendements en CH_4 et en C_2H_6 permet de calculer la constante de vitesse pour la réaction du CH_3 avec l'éther méthylique. De 373 à 936 K, la relation d'Arrhénius pour cette réaction est courbe. [Traduit par le journal]

Introduction

There have been several studies of the pyrolysis of dimethyl ether (1–4) but the mechanism has not been established.

The concentration of methyl radicals in this system has recently been measured spectroscopically (5). This could help provide an especially detailed knowledge of the kinetics of this pyrolysis if other mechanistic features were understood.

The simplest proposed mechanism is the following:

[1] $$CH_3OCH_3 \rightarrow CH_3O + CH_3$$

[2] $$CH_3O \rightarrow CH_2O + H$$

[3] $$H + CH_3OCH_3 \rightarrow H_2 + CH_2OCH_3$$

[4] $$CH_2OCH_3 \rightarrow CH_2O + CH_3$$

[5] $$CH_3 + CH_3OCH_3 \rightarrow CH_4 + CH_2OCH_3$$

[6] $$2CH_3 \rightarrow C_2H_6$$

According to a recent review (6), this may be the correct mechanism, although the following evidence appears to contradict it: (*i*) The observed rates, activation energies, and Arrhenius preexponential factors were greater than predicted by the mechanism using measurements of the Arrhenius parameters for reactions 5 and 6 at low temperatures and thermochemical estimates of k_1. (*ii*) Anderson and Benson (3) observed the formation of 1,2-dimethoxyethane and observed that the concentration of methyl ethyl ether impurity did not decrease as rapidly as expected. They interpreted these observations in terms of two additional termination reactions:

[7] $$CH_3 + CH_2OCH_3 \rightarrow C_2H_5OCH_3$$

[8] $$2CH_2OCH_3 \rightarrow (CH_2OCH_3)_2$$

(*iii*) McKenney and Laidler (7) found that pyrolysis of mixtures of dimethyl ether with large amounts of H_2S could be explained by a mechanism which required that reaction 1 be second order and reaction 6 be third order.

These contradictions, however, do not rule out the simple mechanism [1–6]. For example, the arguments of McKenney and Laidler did not consider the effect of heterogeneous processes, which are believed to be important in the pyrolysis of pure H_2S (7). The concentrations of dimethoxyethane ($10^{-4} \times [CH_4]$) and methyl ethyl ether ($2 \times 10^{-4} \times [CH_4]$) observed by Anderson and Benson were much less than the concentration of ethane ($10^{-2} \times [CH_4]$); this suggests that reactions 7 and 8 may be minor relative to reaction 6.

One reason for the uncertainty about the mechanism is the lack of analytical data for the early stages of the reaction. For example, C_2H_6 analyses have been reported only at conversions of 29% and greater (1).

Analysis of the simple mechanism [1–6] leads to the following relationships between the initial rates, R°, of product formation and the rate constants, k_i, for individual reactions:

$$[9] \qquad k_1 = \frac{R_{H_2}{}^0}{[C_2H_6O]} = \frac{R_{C_2H_6}{}^0}{[C_2H_6O]}$$

$$[10] \qquad \frac{k_5{}^2}{k_6} = \frac{(R_{CH_4}{}^0)^2}{R_{C_2H_6}{}^0[C_2H_6O]^2}$$

The initiation rate constant, k_1, has not previously been measured; the ratio $k_5{}^2/k_6$ has been measured at temperatures below the pyrolytic range.

The present study, using a flow reactor system, has been undertaken to obtain the required initial rates to further investigate the mechanism and to calculate k_1 and $k_5{}^2/k_6$.

Experimental

The apparatus and most details of technique have been described previously (8).

Dimethyl ether (Matheson, 99.87%) was purified by trap-to-trap distillation and by degassing at −95 °C. The major impurity remaining was methyl ethyl ether (0.02%). Concentrations of CH_4, C_2H_6, and C_2H_4 as impurities were about 1 p.p.m. For calibration purposes, methyl ethyl ether was prepared by the Williamson reaction using methanol, sodium, and ethyl iodide, followed by distillation and degassing. 1,2-Dimethoxyethane (BDH, 99.5%) was purified by fractional distillation.

Two 75-cm long quartz reactors (see ref. 8) were used: reactor i, 1.7-cm inside diameter, surface to volume ratio (S/V) = 3.1 cm^{-1}, and reactor iii, 0.2-cm inside diameter, S/V = 23 cm^{-1}. Temperatures were measured at intervals along the reactor. For a typical experiment, the computer program described in ref. 9 indicated that 91% of the reaction occurred within ±7 °C of the average reaction temperature.

The flow rate of dimethyl ether was kept below 0.2 mol/h to prevent the cooler, entering gas from distorting the temperature profile. Conversions were kept to less than 10%.

Products were analyzed by gas chromatography with thermal conductivity and flame ionization detection. Hydrogen and hydrocarbons were separated at 0 °C or 50 °C on a 0.5-m 5% NaOH on alumina column with nitrogen carrier gas. Carbon monoxide was analyzed on the same column at 0 °C using hydrogen as carrier gas. Oxygen-containing compounds were separated at 25 or 50 °C on a 3-m column containing 10% polyethylene glycol (BDH 1540) on Chromosorb P (nonacid washed) and at 65 °C on a 2-m 10% 1,2,3-tris(2-cyanoethoxy)propane on Chromosorb W column in series with a 2-m 10% DC-200 silicone oil on Chromosorb W column.

Results

Experiments have been performed at reactor temperatures from 782 to 936 K and reactant pressures of 25–395 Torr at reactor residence times from 0.06 to 106 s, with resulting conversions from 0.2 to 10%.[2]

Dependence of Rates on Reaction Time

The dependence of the rates of formation of H_2, C_2H_6, CH_4, and CO on reaction time at fixed reaction temperatures and pressures are shown in Figs. 1 and 2. The straight lines were calculated by the method of least squares. The figures show that for C_2H_6 and CH_4 the rates of formation were almost independent of time as expected for primary products, whereas for H_2 and CO, the rates increased linearly with time, as expected for predominantly secondary products.

In Fig. 1, the data for H_2 and C_2H_6, both obtained at 50 Torr and 856 K, appear to extrapolate to a common intercept. The least-squares intercepts are 1.7 (±0.7) × 10^{-3} Torr s^{-1} for H_2 and 1.48 (±0.02) × 10^{-3} for C_2H_6, consistent with a single value, within experimental uncertainty. (Unless otherwise specified, stated uncertainties are standard deviations). This agreement, predicted by the simple Rice–Herzfeld mechanism, supports reaction 6 as the main termination reaction under these conditions. The C_2H_6 data, which were easier to extrapolate to initial rates than were the H_2 data, were used in most experiments to provide an estimate of the rates of initiation and termination.

In contrast to H_2, there is no evidence of an initial rate of formation of CO. (The intercept

[2]Tables of data are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Canada K1A 0S2.

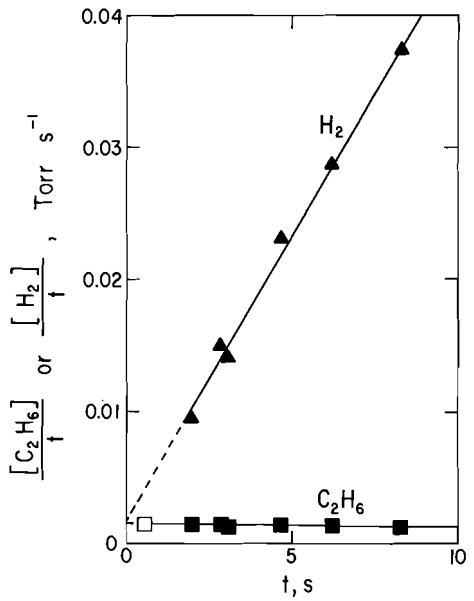

FIG. 1. Rates of formation of H_2 and C_2H_6 as a function of reactor residence time at 856 K and 50 Torr. Filled points, reactor i ($S/V = 3.1$ cm^{-1}); open point, reactor iii ($S/V = 23$ cm^{-1}). The lines were determined by the method of least squares.

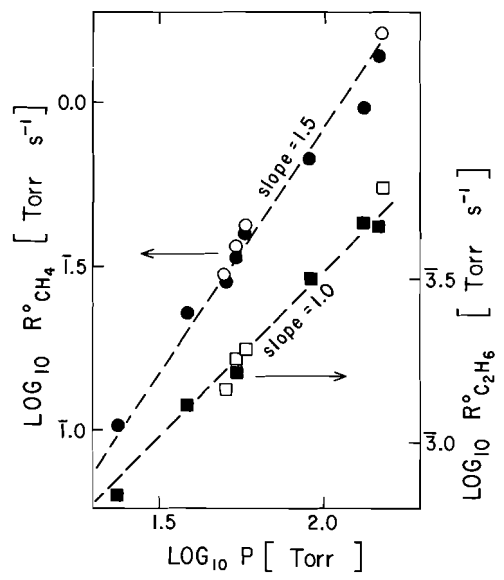

FIG. 3. Order plot for the initial rates of formation of CH_4 and C_2H_6 at 856–859 K. Filled points, reactor i; open points, reactor iii. The dashed lines have the slopes predicted by the mechanism 1–6, if reaction 1 is first order and reaction 6 is second order.

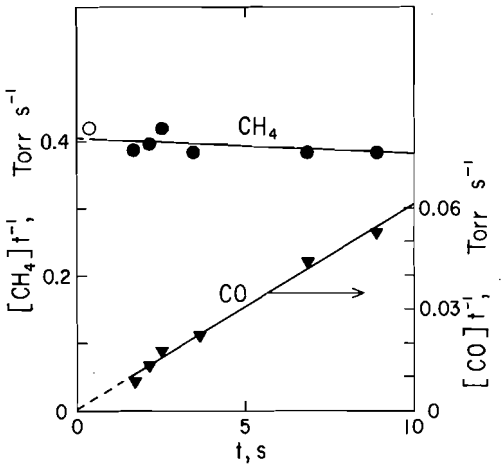

FIG. 2. Rates of formation of CH_4 and CO as a function of reactor residence time at 859 K and 58 Torr. Filled points, reactor i; open point, reactor iii. The lines were determined by the method of least squares.

in Fig. 2 is 0.5 ($\pm$1.2) $\times$ 10^{-3} Torr s^{-1}.) The secondary source of CO and H_2 is believed to be the decomposition of the product, formaldehyde (1).

Ethylene was a minor product; at 784 K and 288 Torr its initial rate of formation was 12% of that of C_2H_6 and 0.005% of the total rate of product formation; this would be expected from decomposition of methyl ethyl ether impurity.

As observed by Anderson and Benson (3), the concentration of methyl ethyl ether decreased during pyrolysis. Formation of methyl ethyl ether in amounts comparable to the C_2H_6 observed could have been masked by this impurity.

No dimethoxyethane product was observed; upper limits on the rate of formation of this substance have been established as 3% of $R_{C_2H_6}{}^0$ at 784 K and 348 Torr and 1% of $R_{C_2H_6}{}^0$ at 856 K and 50 Torr.

The major product, formaldehyde, which has been studied previously (1), was not measured in this work. No carbon deposits were observed.

Dependence of Rates on Pressure

The pressure dependences of the initial rates of formation of CH_4 and C_2H_6 at temperatures of 856–859 K are shown in the form of order plots in Fig. 3. The dashed lines have the slopes 1.5 and 1.0, respectively, predicted by the mechanism [1–6].

In view of the agreement observed thus far between the experimental results and the predictions of the simple mechanism [1–6] the rest

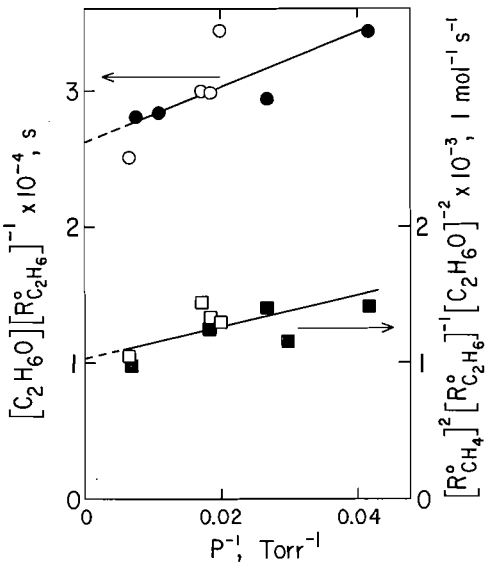

FIG. 4. Lindemann–Hinshelwood style plots for k_1^{-1} (calculated using [9]) at 858–859 K, upper line, and $k_5^2k_6^{-1}$ (calculated using [10]), at 856–859 K, lower line. The lines were obtained by the method of least squares. Solid points, reactor i; open points, reactor iii.

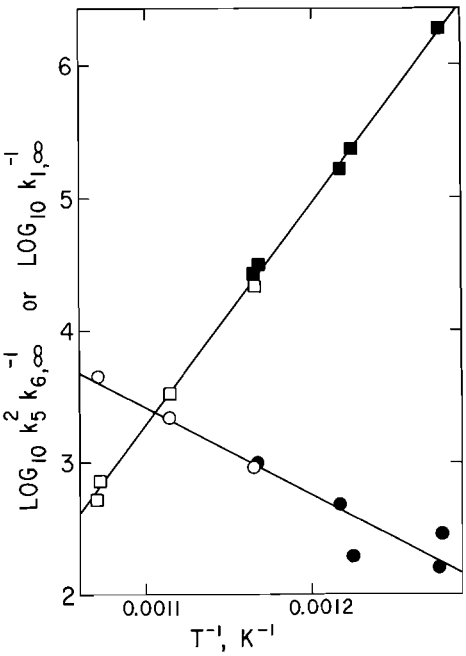

FIG. 5. Arrhenius plot of intercepts of plots like Fig. 4: ■, $\log k_1^{-1}$, reactor i; □, $\log k_1^{-1}$, reactor iii; ●, $\log k_5^2k_6^{-1}$, reactor i; ○, $\log k_5^2k_6^{-1}$, reactor iii. The lines were obtained by the method of least squares.

of the results will be interpreted in terms of this mechanism, and the possibility of errors in the mechanism will be considered in more detail in the Discussion.

There was a slight tendency for the C_2H_6 data to exhibit a slope greater than 1.0. This could be explained if k_1 is slightly pressure dependent. Values of k_1 have been calculated by means of [9] from data obtained at 858–859 K; the inverses of k_1 are plotted in the form of a Lindemann–Hinshelwood plot as the upper line in Fig. 4.

Studies with other systems (8–12) have indicated that k_6 is also pressure dependent. Values of k_5^2/k_6 have been calculated by means of [10] from the data in Fig. 3 and are plotted as the lower line in Fig. 4. Again a trend is evident.[3]

Dependence of Rates on Temperature

High pressure, extrapolated values of k_1^{-1} and k_5^2/k_6, from Fig. 4 and similar Lindemann–Hinshelwood plots, are shown in the form of Arrhenius plots in Fig. 5. Least-squares treatment of the data for k_1^{-1}, leads to an Arrhenius preexponential factor of $10^{15.2\pm0.2}$ s^{-1} and activation energy of 322 ± 4 kJ mol^{-1} for k_1 at infinite pressure.

Arrhenius parameters for reaction [5] are listed in Table 1. It can be seen that both the preexponential factor and the activation energy of the present work are substantially greater than values determined at lower temperatures.

Individual values of $k_5k_6^{-1/2}$ obtained in each of the studies in Table 1 (including square roots of the data in Fig. 5) are shown in the form of an Arrhenius plot in Fig. 6. The straight, dashed line is calculated from the Arrhenius parameters of ref. 17, which came closest to predicting the high temperature behavior. It can be seen that the overall Arrhenius plot is best described as a curve. Curved Arrhenius plots and large Arrhenius parameters at high temperatures have been observed using other techniques for several similar reactions (8, 9, 18–21); the curvature can be interpreted by means of activated complex theory (20).

Discussion

The main difficulty with the simple mechanism [1–6] has been the observation that overall Arrhenius parameters are greater than had been

[3]Half-quenching pressures obtained from Fig. 4 and similar figures at other temperatures are listed in the tables in the depository.

$(CH_3)_2O$ pyrolysis (this work)	783–935	10.5 ± 0.4	63 ± 7

*All values are based on a value of 2.43×10^{10} l mol^{-1} s^{-1} for $k_{6,\infty}$ (13).

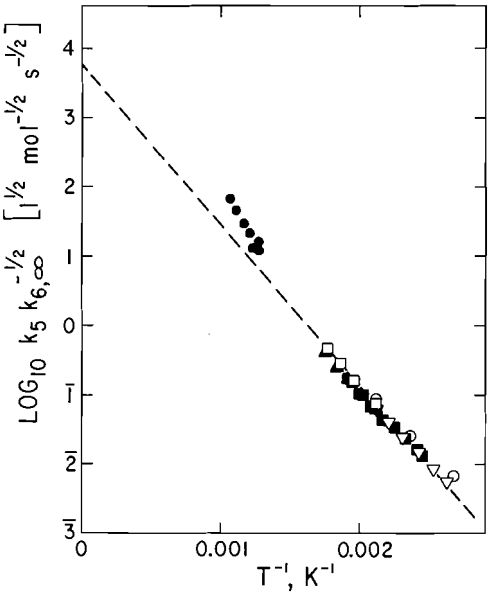

FIG. 6. Arrhenius plot for $k_5 k_6^{-1/2}$: ○, ref. 14; ▽, ref. 15; ■, ref. 16; □, ref. 17; ▲, ref. 10; ●, this work. The dashed, straight line is a least-squares fit to the data of ref. 17.

predicted. Observed overall activation energies, E_0, are 233(1), 228(2), 230(4), and 228 ± 2 (this work) kJ mol^{-1}. According to the mechanism 1–6, $E_0 = \frac{1}{2}E_1 + E_5 - \frac{1}{2}E_6$ or 224 ± 9 kJ mol^{-1}, if values of E_1 and $E_5 - \frac{1}{2}E_6$ from this work are used. In other words, the 'large' observed values of E_0 are consistent with the large E_5 of this work. Furthermore, the overall preexponential factor can be calculated from this work to be $10^{12.9 \pm 0.6}$ $l^{1/2}$ mol$^{-1/2}$ s^{-1}; this is consistent with observed values of $10^{13.6}$ (1), $10^{13.7}$ (2), $10^{13.0}$ (4), and $10^{13.2 \pm 0.2}$ (this work) $l^{1/2}$ mol$^{-1/2}$ s^{-1}.

Possible Competing Reactions

The calculation of k_5^2/k_6 assumed that reactions 5 and 6 were the only sources of CH_4 and C_2H_6 in this system. Some of the C_2H_4 formed probably results from decomposition of C_2H_5 radicals, which could also abstract hydrogen to form C_2H_6. In another system involving C_2H_5, the pyrolysis of *n*-butane (22), the rate of formation of C_2H_6 from this source was one-third the rate of formation of C_2H_4. As the rate constants for reaction of CH_3 with *n*-butane and dimethyl ether are very similar (18), it is likely that the rate constants for reaction of C_2H_5 with *n*-butane and dimethyl ether are as well. In the present system then, one can estimate that only 4% of the C_2H_6 results from this cause.

The absence of surface reactions is indicated by the insensitivity to surface-to-volume ratio illustrated in Figs. 1–5.

The calculation of k_1 assumed that reaction 6 was the only termination reaction. The similarity of $R_{C_2H_6}{}^0$ and $R_{H_2}{}^0$ and the nearly first order behavior of $R_{C_2H_6}{}^0$ were as expected if [6] were at least the major termination reaction. Nevertheless, if other radicals had concentrations comparable to CH_3, they could have been involved in minor termination reactions; the relative concentrations of these radicals can be estimated as follows: (*i*) Hydrogen atoms. If k_3 is taken from ref. 23 and k_5 from this work, the maximum initial ratio of $[H]/[CH_3]$ in these experiments can be calculated to be 2×10^{-4}, from $R_{H_2}{}^0/R_{CH_4}{}^0$ at 936 K and 51 Torr. (*ii*) Methoxy radicals. Anderson and Benson (3) found that the yield of CH_3OH (presumably from $CH_3O + C_2H_6O \rightarrow CH_3OH + CH_2OCH_3$) equalled $6 \times 10^{-4} \times [CH_4]$ at 799 K and 55 Torr. The compilation of Trotman-Dickenson and Milne (24) indicates that the abstraction reactions of CH_3O are generally faster than those of CH_3, hence 6×10^{-4} may be taken as an upper limit for $[CH_3O]/[CH_3]$. This ratio should increase at higher temperatures but should not become significant within the range of the present work. (*iii*) Methoxymethyl radicals. The upper limits es-

tablished herein for the rate of formation of dimethoxyethane by reaction 8 enable calculation of upper limits for the rate of reaction 7 with the use of the geometric mean rule, $k_7^2 = 4k_6k_8$. The greatest possible fraction of termination by reaction 7 in the present experiments is calculated to be 0.25 at 784 K and 348 Torr. Loucks and Laidler (25) have measured the rate constant ratio k_4^2/k_8 at 473–573 K. By combining their data and the data for k_5^2/k_6 from this work, it is possible to estimate that the maximum fraction of termination by reaction 7 is 0.29 at 784 K and 348 Torr.

In conclusion, reaction 6 appears to be the major termination reaction under these conditions, although reaction 7 and (to a lesser extent) reaction 8 are probably also significant. If the amount of reaction 7 predicted from Loucks and Laidler's data is taken into account, E_1 would be lowered by 8 kJ mol^{-1} and $\log_{10} A_1$ by 0.3 units. To allow for this, the Arrhenius expression could be rewritten as $k_1 = 10^{15.0\pm0.5} \exp(-318 \pm 8 \text{ kJ mol}^{-1}/RT)$ s^{-1}.

Thermochemistry of the Methoxy Radical

By assuming that k_{-1} is temperature independent, the heat of reaction for the initiation reaction, corrected to a standard state of 1 atm and 298 K, may be calculated from E_1 to be 325 ± 8 kJ mol^{-1}. With the heats of formation of CH_3 and $(CH_3)_2O$ from refs. 26 and 27, respectively, the heat of formation of CH_3O may be calculated to be -5 ± 8 kJ mol^{-1}. This may be compared with previous kinetic estimates from -3 to $+16$ kJ mol^{-1} (28, 29) and estimates from appearance potential measurements of -13 ± 13 kJ mol^{-1} (30).

With entropy data from Benson and O'Neal (29) and the value of $\log A_1$ from this work, it is possible to calculate that $\log_{10} A_{-1}$ should equal 9.1 ± 0.6.

The author wishes to thank the National Research Council of Canada for a grant in support of this research.

Carbon-13 Nuclear Magnetic Resonance Spectra of Some Dendroketose and Other Furanose Derivatives

DOLATRAI M. VYAS, HAROLD C. JARRELL, AND WALTER A. SZAREK[1]

Department of Chemistry, Queen's University, Kingston, Ontario K7L 3N6

Received April 7, 1975

D. M. VYAS, H. C. JARRELL, and W. A. SZAREK. Can. J. Chem. **53**, 2748 (1975).

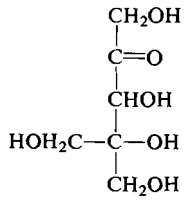
The carbon-13 n.m.r. spectra of derivatives of the branched-chain sugars apiose and dendroketose, and of other furanose sugars, are reported. The study has permitted assignment of the configuration at the branching carbon atom and at the anomeric center in the dendroketose derivatives.

D. M. VYAS, H. C. JARRELL et W. A. SZAREK. Can. J. Chem. **53**, 2748 (1975).

On rapporte les spectres r.m.n. du ^{13}C de dérivés des sucres à chaîne ramifiée, apiose et dendroketose, et d'autres sucres sous forme furannose. Cette étude a permis d'attribuer, pour les dérivés du dendroketose, la configuration au niveau de l'atome de carbone portant la ramification et au centre anomérique. [Traduit par le journal]

Introduction

Until recently, the bulk of the activity in the area of carbon-13 magnetic resonance (c.m.r.) spectroscopy of carbohydrates had centered about the study of pyranose sugars and their derivatives (1), since conformational and configurational effects on ^{13}C shieldings in these compounds generally followed trends analogous to those in the well-studied cyclohexane series (for examples see refs. 1*b* and 2). In contrast, furanose sugars and their derivatives have not been subjected to an extensive investigation by c.m.r. spectroscopy, presumably because of the dearth of knowledge concerning the ^{13}C chemical shift patterns associated with conformational and configurational changes in the tetrahydrofuran ring (for examples see ref. 3). Nevertheless, the furanoid derivatives warrant a detailed c.m.r. study, since biologically important compounds such as nucleosides and nucleotides possess a furanoid moiety. Moreover, an active field of research in many laboratories is the chemical modification of nucleosides, for example, the introduction of branching into the furanoid ring. In recent years the utility of c.m.r. spectroscopy for determination of the configurations of tertiary alcoholic centers in branched-chain pyranoid derivatives has been demonstrated (4). A project in this laboratory (5) is concerned with the stereospecific synthesis of derivatives, including nucleoside analogs, of one enantiomer of the branched-chain sugar dendroketose (**1**) (6).On conversion of the acyclic structure (**1**) into its furanoid form, C-4 becomes asymmetric, giving rise to four possible isomers for the D-form and four more for the L-form. Thus, the complete structural formulation of furanoid dendroketose derivatives requires the determination of the configuration at the anomeric center and also at the branching carbon atom (C-4). The present publication describes the application of c.m.r. spectroscopy to the solution of these stereochemical problems; as part of this work the c.m.r. spectra of 1,2-*O*-isopropylidene-D-apio-β-L-furanose (**7**) and of isopropylidene derivatives of some aldohexofuranoses are also reported.



1

Results and Discussion

The ^{13}C chemical shifts of the compounds studied in this research, namely, 1,2-*O*-isopropylidene-α-D-glucofuranose (**2**), 1,2-*O*-isopropylidene-α-D-allofuranose (**3**), 1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose (**4**), 1,2:5,6-di-*O*-isopropylidene-α-D-allofuranose (**5**), 2,3:5,6-di-*O*-isopropylidene-α-D-mannofuranose (**6**), 1,2-*O*-isopropylidene-D-apio-β-L-furanose (**7**), and

the ketofuranose derivatives **8–13** are documented in Table 1. The signal assignments were aided by the previous studies by Que and Gray (3*c*) on anhydro sugars and ketoses, by Usui *et al.* (3*d*) on the determination of anomeric configuration of furanoside derivatives, and by Perlin *et al.* (3*b*) on furanose sugars. In the spectra of all of the compounds listed in Table 1, the signal assignments of the anomeric carbons and of the 1,3-dioxolane-acetal carbons were readily made, since the signals appeared at low field; also, the isopropylidene-methyl signals and hydroxymethyl signals were readily identified, since they appeared at high field. The signal assignments of the remaining carbons were made as discussed below.

A comparison of the chemical-shift data reported (3*c*) for 1,4-anhydroglucitol (see footnote *b* of Table 1) with that of compound **2**[2] permitted the assignment of signals in the spectrum of the latter compound. Analogously, chemical-shift data reported (3*c*) for 1,4-anhydroallitol (see footnote *c* of Table 1) were employed for the assignment of signals in the spectrum of compound **3**. The C-2 and C-4 signals in the spectrum of compound **2** were unambiguously assigned on the expectation, based upon studies by Perlin *et al.* (3*b*) and by Que and Gray (3*c*), that the *cis* O-2,O-3 interaction in **3** should result in an upfield shift of ~5–6 p.p.m. of the C-2 signal in the spectrum of **3** relative to the corresponding signal in the spectrum of **2**. The signal assignments in the spectra of **2** and **3** were further corroborated by comparison of the chemical-shift data with that obtained for the di-*O*-isopropylidene derivatives **4** and **5**, respectively, since the shieldings of C-1, C-2, and C-3 in the mono-*O*-isopropylidene derivatives **2** and **3** should be very similar to those of the corresponding carbons in **4** and **5**. Finally, the signal assignments in the spectrum of 2,3:5,6-di-*O*-isopropylidene-α-D-mannofuranose (**6**) were made in the following manner. The C-1, C-5, and C-6 signals were readily assigned by comparison of the chemical-shift data with that of **4** and **5**. The C-2 signal was assigned on the expectation that it should occur at lower field than either the signal for C-3 or C-4, since O-2 is incorporated in a 1,3-dioxolane ring and is in a *trans* relationship with O-1. In confirmation of this reasoning is the observation of essentially identical chemical shifts for the C-2 signals in the spectra of compounds **2**, **4**, and **6**.

In a c.m.r. study of furanose sugars, Perlin *et al.* (3*b*) observed that the C-4 signal in the spectrum of methyl α-D-glucofuranoside resonated ~7 p.p.m. upfield relative to the corresponding signal in the spectrum of methyl α-D-allofuranoside. However, in the case of the spectra of 1,2-*O*-isopropylidene-α-D-glucofuranose (**2**) and 1,2-*O*-isopropylidene-α-D-allofuranose (**3**), the C-4 signals have almost identical chemical shifts, and, more surprizingly, C-4 in the allofuranose derivative **5** is shielded (2 p.p.m. upfield shift) relative to C-4 in the glucofuranose derivative **4**. The shielding of C-4 in 1,2:5,6-di-*O*-isopropylidene-α-D-allofuranose (**5**) may perhaps be partly attributed to a γ interaction between O-5 and H-4; such effects have been observed with 4,6-*O*-benzylidene derivatives of hexopyranose sugars (1*l*) and with methyl ethers of galactopyranosides (1*n*). It is possible that this γ interaction may be attenuated in 1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose (**4**) as a result of an influence of the C-3 hydroxyl group on the orientation of the 5,6-*O*-isopropylidene group.

In the case of the c.m.r. spectra of the branched-chain sugars **8–13** the signal assignments could be unequivocally made from the proton-coupled spectra; the signals for the anomeric carbon, the isopropylidene-acetal carbon, and the isopropylidene-methyl groups were readily assigned on the basis of their characteristic chemical shifts. The c.m.r. data obtained for these compounds, together with that obtained for 1,2-*O*-isopropylidene-D-apio-β-L-furanose (**7**), permitted assignment of the configuration at the branching carbon atom and at the anomeric center in compounds **8–13**.

A comparison of the chemical shifts of the C-2 signal in the spectra of 1,2-*O*-isopropylidene-D-apio-β-L-furanose (**7**), 1,2:5,6-di-*O*-isopropylidene-α-D-allofuranose (**5**), and 1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose (**4**) revealed some interesting trends which are pertinent to the assignment of the configuration at C-4 in compounds **8–13**. It was assumed that C-5 and C-6

[2]It should be noted that the spectrum of compound **2** was recorded in 1:1 (v/v) methanol–chloroform-*d*, whereas that of 1,4-anhydroglucitol (3*c*) was recorded in deuterium oxide. However, it is assumed that, in the present cases, such a solvent change does not result in an appreciable change in chemical shifts. Thus, it is found that the chemical shifts of the C-4, C-5, and C-6 signals in the spectra of the two compounds are almost identical.

have little or no effect on C-2 shieldings in compounds **4** and **5**,[3] and hence the C-2 chemical shifts in the spectra of compounds **4**, **5**, and **7** should reflect the nature and stereochemistry of the substituent at C-3. It is noteworthy that the C-2 chemical shifts are nearly identical in the spectra of 1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose (**4**) and **7**, whereas in the spectrum of 1,2:5,6-di-*O*-isopropylidene-α-D-allofuranose (**5**), the signal for C-2 is shifted upfield by ~5 p.p.m. relative to the corresponding signal in the spectrum of **7**; these observations imply that the *cis* O-2,O-3 interaction in **5** is a shielding one relative to the *cis* O-2,CH_2OH interaction in **7** (*cf.* refs. 3*b*–3*e*). In the spectrum of the dendroketose derivative **8** the C-3 and C-4 signals are shifted upfield by 4.4 and 2.8 p.p.m. relative to the corresponding signals (C-2 and C-3, respectively) in the spectrum of 1,2-*O*-isopropylidene-D-apio-β-L-furanose (**7**), an observation consistent with a *cis* O-3,O-4 arrangement in compound **8**; thus, the configuration at the branching carbon (C-4) in this dendroketose derivative is as shown in structural formula **8**. It follows also that the configuration at C-4 in the vinyl derivative **11** is as shown, since compound **8** was chemically derived from **11** by a procedure which is known not to affect the stereochemistry at C-4 (see ref. 5); in accordance with this conclusion is the observation of the upfield shift (5.8 p.p.m.) of the C-3 signal in the spectrum of compound **11** relative to the corresponding signal (C-2) in the spectrum of compound **7**.

The assignment of the configuration at the anomeric center in the dendroketose derivatives **9** and **10** was made as follows. It was observed that the C-4 signal in the spectrum of the 2,3-*O*-isopropylidene derivative **8** was shifted upfield by 13.1 p.p.m. relative to the corresponding signal in the spectrum of the 3,4-*O*-isopropylidene derivative **9**, whereas the C-2 signal in the spectrum of **9** was shifted upfield by 8.4 p.p.m. These observations are consistent with the anomeric configuration for compound **9** being as shown in the structural formula, since if **9** had possessed the opposite configuration at the anomeric center, then the C-2 signal would have been expected to have been shifted upfield by ~13 p.p.m. rather than the observed 8.4 p.p.m. shift. This conclusion is further corroborated by the chemical shift of the C-3 signal in the spectrum of **9**; this signal was shifted downfield by 6.4 p.p.m. relative to the corresponding signal in the spectrum of **8**. The structural feature responsible for the deshielding of C-3 in **9** relative to C-3 in **8** is the *cis* O-3,CH_2OH interaction as opposed to the *cis* O-3,O-4 interaction in **8**; in both of these compounds C-3 is part of a 1,3-dioxolane ring system. This reasoning is supported by the observation of Que and Gray (3*c*), in the case of the c.m.r. spectra of a series of ketohexofuranoses, that a *cis* O,CH_2OH interaction is a less shielding one relative to a *cis* O,O interaction. It is noteworthy that the chemical shift of the C-3 signal in the spectrum of **9** is almost identical to that of the corresponding signal (C-2) in the spectrum of 2,3:5,6-di-*O*-isopropylidene-α-D-mannofuranose (**6**) and differs by only 2 p.p.m. from that of the C-2 signal in the spectrum of 1,2-*O*-isopropylidene-D-apio-β-L-furanose (**7**); the similarities of these chemical shifts clearly reflect the nearly identical environments of the specified carbon atoms. In the case of the dendroketose derivative **10**, the configuration at the anomeric center was assigned as shown in the structural formula on the basis of the identity of the observed chemical shifts of the C-3 signals in the spectra of compounds **9** and **10**.

The c.m.r. spectroscopic data of the deuterated analog (**12**) of **10** are consistent with the assigned structure (see Table 1). In the spectrum of the phthalimido derivative (**13**) of **10** the only noteworthy features are the 23.9 and 1.9 p.p.m. upfield shifts of the C-4′ and C-4 signals, respectively, relative to the corresponding signals in the spectrum of **10**.

Experimental

The isopropylidenehexoses **2**, **4**, and **6** were prepared by procedures described by Schmidt (7); the isopropylideneallofuranoses **3** and **5** were prepared as described in refs. 8 and 9, respectively.[4] Procedures for the synthesis of compounds **8**–**13** are described in ref. 5.

Carbon-13 magnetic resonance spectra were recorded in chloroform-*d*, unless otherwise stated, on either a Varian CFT-20 spectrometer or a Bruker HX-60 spectrometer equipped with a FT60M Fourier transform accessory at 15.1 MHz, with tetramethylsilane (TMS) as internal standard; chemical shifts are given in parts per million downfield from TMS.

[3]This assumption was considered to be valid in the light of the c.m.r. study by Que and Gray (3*c*) on anhydro sugars; thus, it was found that the C-2 chemical shifts in the spectra of 1,4-anhydroerythritol, 1,4-anhydroribitol, and 1,4-anhydroallitol are 71.9, 72.0, and 72.5 p.p.m., respectively.

[4]An authentic sample of 1,2-O-isopropylidene-D-apio-β-L-furanose (7) was kindly provided by Dr. D. H. Ball, U.S. Army Natick Laboratories (see ref. 10).

The authors are grateful to the National Research Council of Canada for financial support in the form of a scholarship (to H.C.J.) and a grant (to W.A.S.), and to Professor J.K.N. Jones, F.R.S., for his interest and encouragement. They also thank Dr. B. K. Hunter of Queen's University and Dr. I. C. P. Smith of the National Research Council of Canada for recording the c.m.r. spectra.

The Use of Deuterium Magnetic Resonance in the Determination of the Structure and Location of the Anilinium Ion in an Aqueous Anisotropic Surfactant Solution

PETER DIEHL AND ALAN S. TRACEY

Department of Physics, The University of Basel, Klingelbergstrasse 82, CH-4056 Basel, Switzerland

Received April 1, 1975

P. DIEHL and A. S. TRACEY. Can. J. Chem. **53**, 2755 (1975).

Anisotropic soap solutions containing the anilinium ion have been studied by n.m.r. techniques. The partially averaged proton–proton dipole couplings were used to obtain the relative positions of the hydrogen nuclei of the phenyl ring. Deuterium quadrupole splittings from the deuterium enriched ion provided information concerning the quadrupole coupling constant, Q_D, the asymmetry parameter, η, and the angles that the C—D bonds make with the coordinate systems axes. Quadrupole splittings from the deuterium enriched decylsulfate simultaneously with those from the anilinium ion established that the C_2 axis of the ion on an average lies parallel to the decylsulfate chain axis and is ordered to a similar extent. It is concluded that the aromatic ring is incorporated into the superstructure of the soap solution and that the $-NH_3^+$ group protrudes into the electrical double layer where it interacts with the oppositely charged decylsulfate and with water.

P. DIEHL et A. S. TRACEY. Can. J. Chem. **53**, 2755 (1975).

On a étudié, par r.m.n., des solutions anisotropiques de savon contenant l'ion anilinium. On a utilisé les valeurs partiellement moyennées des couplages dipolaires proton–proton pour obtenir les positions relatives de l'atome d'hydrogène du noyau phényle. Les couplages quadrupolaires du deutérium dans des ions enrichis en deutérium ont permis d'obtenir des informations relatives à la constante de couplage quadrupolaire, Q_D, au paramètre d'asymétrie, η, et aux angles que font les liens C—D avec les axes du système de coordonnées. Les couplages quadrupolaires de sulfate de décyle enrichi en deutérium observés simultanément avec ceux de l'ion anilinium ont permis d'établir que l'axe C_2 de l'ion à l'état moyen est parallèle à l'axe de la chaîne du sulfate de décyle et que l'ion est ordonné jusqu'à un degré semblable. On en conclut que le noyau aromatique est incorporé dans la superstructure de la solution de savon et que le groupe $-NH_3^+$ se trouve dans la double couche électrique où il interagit avec l'eau et avec le sulfate de décyle de charge opposée.

[Traduit par le journal]

Introduction

Recent work has established the applicability of nematic anisotropic soap solutions to the determination of ionic structures in aqueous solution (1, 2). These studies have taken advantage of the partially averaged internuclear dipole–dipole coupling in a homogeneously ordered system. Such structure determination of molecular or ionic species from n.m.r. techniques has, until the present time, utilized almost exclusively the direct dipolar coupling between proton and proton or between carbon-13 and proton. Couplings to other nuclei such as phosphorus-31 or nitrogen-15 have been used to a more limited extent.

Deuterium magnetic resonance, until the present time, has received relatively little attention as a structural tool although it has been used as a probe into the structural characteristics of macroscopically oriented smectic (3–5) and nematic (6–8) lyotropic phases. In the case of hydrocarbons, the major quadrupolar axis of deuterium deviates only slightly from the C—D bond axis and the quadrupole coupling tensor has a small asymmetry parameter. As a consequence deuterium has potentially an important role to play in structural work.

The deuterium quadrupole splitting can, in principle, provide some of the information obtained from ^{13}C substituted species. In cases where ^{13}C substitution is difficult, often the replacement of hydrogen by deuterium is a straightforward process.

The effects of many surfactants in micellar solution on the rates of reaction of various aromatic and aliphatic compounds have been extensively investigated (9, 10). These studies are important in understanding factors which influence chemical reactions and as such may provide information concerning processes in bio-

*Prepared with D_2O.
†Prepared with anilinium-d_5.
‡This phase was prepared with H_2O acidified to 0.1 *N* with HCl. All other phases were prepared with water acidified to 0.1 *N* with H_2SO_4.
§This sodium decylsulfate consists of 41% 2,2,3,3-tetradeuterated, 30% 2,2-dideuterated, and 29% 9,9,10,10,10-pentadeuterated sodium decylsulfate.
‖Prepared with H_2O.

logical systems. Unfortunately much of this work is hampered by a lack of definitive knowledge concerning the relative orientations of the reacting species with each other and, most particularly, with the micellar superstructure of the solution. The location of ionic species in lyotropic liquid crystals is then of interest since this information may be useful in understanding the various properties of such systems. Since dipole couplings and quadrupole splittings provide information concerning the orientation of species in anisotropic solution we have an opportunity to obtain this information quantitatively.

The anilinium ion offers a particularly good system for the demonstration of the value of quadrupole coupling constants for structure determination and simultaneously allows conclusions to be drawn about the location of this ion. In this study the anilinium ion, the pentadeuteroanilinium ion, and deuterium labelled decylsulfate, all in nematic solution, were investigated.

Experimental

Anilinium Decylsulfate

Anilinium chloride (2 gm) was added to sodium decylsulfate (4 gm), then combined with chloroform (200 ml). Water (1 ml) was added and the mixture refluxed until all sodium decylsulfate went into solution. The water was removed by codistillation with chloroform. Carbon was added to the product, then it was filtered through celite. The resultant solution was evaporated to approximately 50 ml and light petroleum (200 ml) was added. The solution was cooled to −20 °C and the product obtained by filtration, then recrystallized from chloroform – petroleum ether. The yield was quantitative.

Anilinium-d_5 Decylsulfate

Pentadeuteroaniline (1.25 gm) in methanol (20 ml) was neutralized with decylsulfuric acid prepared by passing sodium decylsulfate (3.5 gm) in water (10 ml) through a Dowex 50-H^+ column (20 ml). The product was evaporated with aliquots (100 ml) of chloroform–ethanol (99%) until the water was removed. The product was recrystallized from chloroform – petroleum ether. The yield was quantitative.

Nematic Liquid Crystals

The compositions of the nematic phases are given in Table 1. They were prepared by weighing the various components into a small test tube then alternately stirring and centrifuging until dissolution was complete. Slight warming to ~50° aided the process considerably.

Nuclear Magnetic Resonance Spectra

Proton spectra were obtained either in the FT mode at 60 MHz (samples 1 and 2, Table 1) from a Bruker spectrometer or at 100 MHz (sample 3, Table 1) from a Varian HA-100 continuous wave spectrometer. Deuterium spectra were obtained from a Bruker Hx-90 modified to pulse 50 kHz spectral widths. Operating temperatures were ~27°.

Results

It has recently been shown that nematic soap solutions are not of a single type but that at least two nematic phases occur (11, 12). The nematic Type I phase orients with its uniaxial direction parallel to the magnetic field. As a consequence when in a conventional spectrometer, this phase gives a rotation diagram according to $\frac{1}{2}(3\cos^2\phi - 1)$ where ϕ is the angle of rotation from the equilibrium angle of 0°. The nematic Type II phase orients with the hydrocarbon superstructure perpendicular to H_0. This is the usual phase which has been used as an orienting medium in lyotropic work. After prolonged spinning the uniaxial direction of this phase is parallel to the spinning axis and the spectrum is independent of rotation angle.

The nematic phases which were used in this

study were of Type I. This was established by observing the n.m.r. signal from the anilinium ion on the oscilloscope of the spectrometer, then rotating the sample and observing the variation in the spectral width. The maximum width was found to occur at 0° of rotation. A typical proton spectrum is displayed in Fig. 1. The spectral analysis was straightforward and similar for all phases. The results are tabulated in Table 2. All nematic phases were prepared with water (or D_2O) acidified to approximately pH 1 with either H_2SO_4 or HCl. This pH insured that no significant quantities of free aniline were present in solution.

Figure 2 shows a deuterium spectrum obtained from the deuterated anilinium ion. The large quadrupolar doublet of 36 kHz splitting arises from D_4 and demonstrates the high degree of order along the C_4—D_4 bond (*i.e.* the C_2 axis). The next quadrupole doublet, split further by

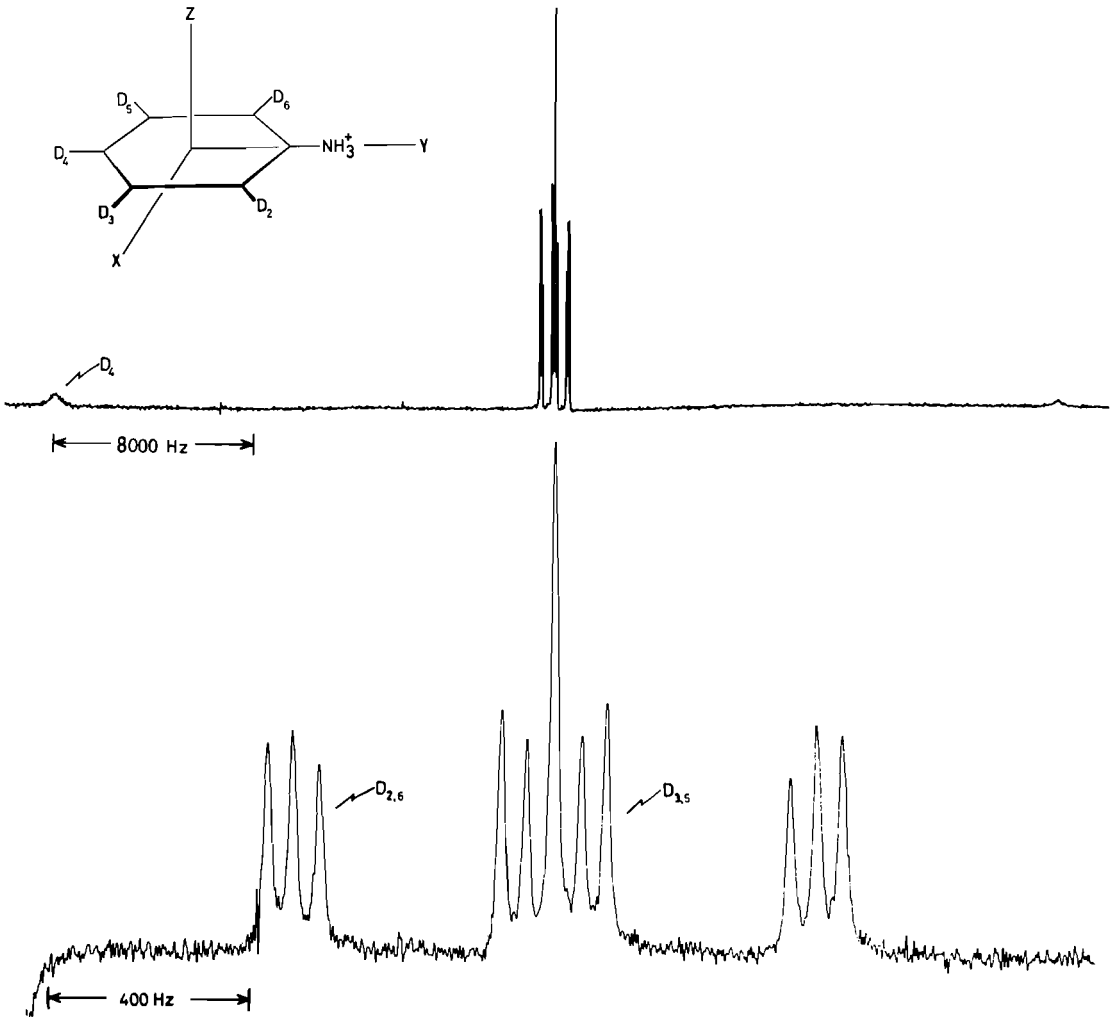

FIG. 2. A deuterium magnetic resonance spectrum from the deuterated anilinium ion in anisotropic solution. The upper trace shows the complete spectrum, the lower only the central resonances of the upper spectrum. The quadrupole doublets are labelled according to the position in the ion that they arise from (spectrum from phase 4, Table 1).

dipole couplings, arises from deuteriums 2 and 6, the overlapping triplets from deuteriums 3 and 5. The small quadrupole splittings of these two sets of deuteriums, ~ 100 and ~ 1200 Hz respectively, indicate the very small degrees of order along these C—D bonds.

Normally in nematic phases it is difficult to change the relative degrees of order along different axes significantly. In this system the quadrupolar axes of deuteriums 2,6 and 3,5 were directed along an axis so close to the zero transition angle that very small changes in S_{xx} relative to S_{yy} had a significant effect on the relative magnitudes of the quadrupolar splittings as is evident from Table 3.

The quadrupole splittings for each position are given by equations similar to [1].

$$[1]\quad \Delta\nu_D = \frac{3}{2}Q_D\left(S_{zz}' + \frac{\eta}{3}(S_{xx}' - S_{yy}')\right)$$

where $\Delta\nu_D$ is the quadrupole splitting and S_{zz}' is the degree of order along the major quadrupole axis which is assumed to be along the C—D bond. Q_D, the quadrupole coupling constant, was assumed to be equal for the three nonequivalent positions and determined from the

quadrupole splittings and the dipole coupling D_{23}. D_{23}, within a very small error is directed along the y axis. The assumption that the three Q's are equal has a negligibly small effect on any parameters obtained. The deuterium and proton spectral parameters were obtained with the aid of a modified UEA (13) n.m.r. computer program. The modified program iterates on all parameters, chemical shifts, indirect couplings, direct couplings, and quadrupole splittings.

Discussion

The Structural Information Provided by the Internuclear Proton–Proton Dipole Couplings

No structural information concerning the $-NH_3^+$ was obtainable since the NH exchange could not be slowed enough for observation of the NH_3 protons. Information concerning the positions of the aromatic protons was obtainable.

The phenyl ring has C_{2v} symmetry, so two orientation parameters are necessary to define its order while three distance ratios are required for a description of its structure. As a consequence five dipole couplings are needed for a complete analysis of the system. Since the spectrum provides six dipole couplings the system is overdetermined by one D value. The iterative least squares computer program SHAPE (14) was used to obtain the optimal structure parameters. Three independent structure determinations were made. The coordinate system was chosen so that the y axis was along the C_2 symmetry axis, the x axis in the plane of the ring, and the z axis perpendicular to the plane.

The results are summarized in Table 4. The benzene proton–proton distance of 2.481 Å was used as a reference distance to obtain the orientation constants. It is evident that the proton structure deviates only slightly from a regular hexagonal geometry. The distance r_{26} is increased by the factor 1.0065 ± 0.0028 from the

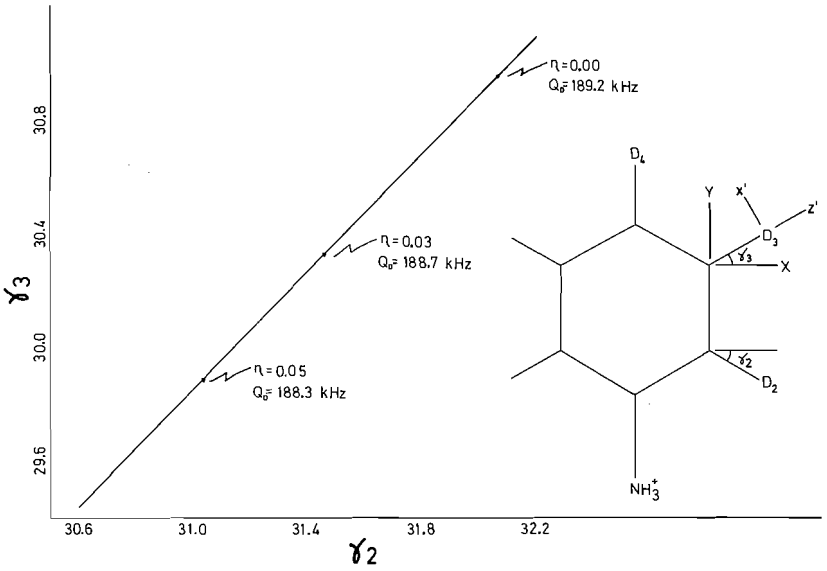

FIG. 3. This diagram shows the coordinate system employed to describe the quadrupole splittings. The angles γ_2 and γ_3 are used so that the quadrupole coordinates x', y', and z' can be easily related to the coordinate system of the ion, x, y, and z. The relationship between γ_2 and γ_3 is shown on the graph for the region of interest. Values which correspond to specific angles are also shown.

distance r_{35}. The ratio $r_{35}/r_{34} = 1.7343 \pm 0.0002$ is slightly larger than that of a true hexagon where this value is $\sqrt{3} = 1.7320$ while the value $r_{26}/r_{34} = 1.7231 \pm 0.0048$ is smaller. The values of the distances r_{23} and r_{34} are nearly equal ($r_{23}/r_{34} = 1.0009 \pm 0.0005$) as required for hexagonal geometry.

The proton evidence thus indicates that the aromatic hydrogens are arranged in a nearly hexagonal geometry but with a slight displacement of the hydrogens 2 and 6 towards the nitrogen.

The Information Provided by the Deuterium Quadrupole Splittings

With the assumptions that the quadrupole coupling constants Q_D and the asymmetry parameters η vary insignificantly with position within the aromatic ring and that a principal axis of the quadrupole coupling tensor is directed along the C—D bond axis it is possible to derive eqs. 2 to 4 from [1] where the $\Delta\nu_i$ are the observed quadrupole splittings for positions i.

$$[2]\quad \Delta\nu_2 = \frac{3}{2}Q_D\Big[S_{yy} - \cos^2\gamma_2(S_{yy} - S_{xx}) + \frac{\eta}{3}(2S_{xx} + S_{yy} + \cos^2\gamma_2(S_{yy} - S_{xx}))\Big]$$

$$[3]\quad \Delta\nu_3 = \frac{3}{2}Q_D\Big[S_{yy} - \cos^2\gamma_3(S_{yy} - S_{xx}) + \frac{\eta}{3}(2S_{xx} + S_{yy} + \cos^2\gamma_3(S_{yy} - S_{xx}))\Big]$$

$$[4]\quad \Delta\nu_4 = \frac{3}{2}Q_D\Big[S_{yy} + \frac{\eta}{3}(2S_{xx} + S_{yy})\Big]$$

The angles γ_2 and γ_3 are shown in Fig. 3 as is the axis system for deuterium 3. The transformation from the quadrupolar coordinate system to the ionic coordinate system is straightforward and utilizes equations of the type [5]

$$[5]\quad S_{zz}' = \cos^2\phi_{xx}S_{xx} + \cos^2\phi_{yy}S_{yy}$$

where ϕ_{xx} and ϕ_{yy} are the angles that the quadrupolar axes make with the coordinate axes of the ion and are given by the angles γ_i.

If we substitute eq. 4 into [2] and [3] and let $k_0 = S_{yy} - S_{xx}$, $p = \cos^2\gamma_2$, and $p' = \cos^2\gamma_3$ we obtain the expressions [6] and [7].

$$[6]\quad 2(\Delta\nu_2 - \Delta\nu_4) = Q_D p k_0(\eta - 3)$$

$$[7]\quad 2(\Delta\nu_3 - \Delta\nu_4) = Q_D p' k_0(\eta - 3)$$

Q_D, p, p', k_0, and η are the unknowns of interest. Unfortunately, as may be seen from the equations, the unknowns always arise as products so

For personal use only.

that individual determination is not possible. Furthermore additional spectra from ions with different relative orientations will not help the analysis since for each new equation there is also a new unknown. This situation is quite similar to that encountered when attempting to obtain internuclear distances from dipolar couplings. Only the ratios of S_{ij} to r_{ij}^3 can be obtained and consequently only relative distances within a system of interacting nuclei. It occurs similarly in the problem of obtaining relative populations in an equilibrating system. Here only the product of relative population and degree of order is obtainable even though the geometry of the individual components may be known.

In the present problem only the ratio (p/p') can be determined from [6] and [7], that is, the ratio of the angles γ_2 to γ_3 is defined very accurately. The value $\cos\gamma_2/\cos\gamma_3 = 0.98817 \pm 0.00004$ was found. A plot of γ_3 *vs.* γ_2 is shown in Fig. 3.

The η and Q_D values corresponding to the individual points on this plot can be obtained by the following procedure. S_{yy} is given by the observed direct deuterium–deuterium dipolar coupling (Table 3), the geometric relationships of Table 4, and an assumed r_{34} of 2.481 Å. S_{xx} can then be obtained on the basis of the argument that the S_{yy}/S_{xx} ratio is the same for the deuterium spectra as from the proton spectra. As can be seen from Table 4 the variation of the ratio is small between different phases. From S_{xx} and S_{yy} as well as a chosen value of η the corresponding Q_D was provided by [4]. Finally substitution of S_{xx}, S_{yy}, η, and Q_D into [6] and [7] gives the angles γ_2 and γ_3 which match the η and Q_D values. In practice the four deuterium spectra were fitted simultaneously and the less stringent requirement, that the average value S_{yy}/S_{xx} for the deuterium spectra was the same as the average from the proton spectra, was imposed. The errors quoted for γ_2 were obtained mainly from the extreme deviation of the ratio S_{yy}/S_{xx} from its average value *i.e.* $S_{yy}/S_{xx} = -2.818 \pm 0.030$ from Table 4.

As shown in Fig. 3 a value of $\eta = 0$ (often assumed) leads to the angles $\gamma_2 = 32.0 \pm 0.13°$ and $\gamma_3 = 30.96°$. These angles when combined with the relevant proton data lead to a highly distorted carbon skeleton for the ring. As a consequence $\eta = 0$ is highly improbable. The asymmetry parameter has been obtained experimentally for several aromatic systems and found to be approximately 0.04 to 0.06 (15). Using the value $\eta = 0.05$ the angles $\gamma_2 = 31.05 \pm 0.13°$ and $\gamma_3 = 29.89°$ as well as $Q_D = 188.3 \pm 1.3$ kHz were obtained. This gives a reasonable carbon skeleton and also agrees well with the values for similar compounds in the literature (16, 17). An estimation of the vibrational corrections to γ_2 and γ_3 indicate that they are negligible.

The Orientation and Location of the Anilinium Ion

It has been established that the nematic phases in this study give rotationally dependent spectra from a conventional spectrometer. The angular dependence of quadrupole splittings from various monatomic ions (11) and of methanol (11) in various similar phases has been found to be identical. That is, all species behave similarly with respect to their orientation. Such a result would be anticipated if the hydrocarbon superstructure is not significantly different on going from one Type I phase to another and if the phases are composed of hydrocarbon layers separated by interstitial water and oriented so that the plane of hydrocarbon superstructure is perpendicular to H_0. The axis of an extended decyl chain then is parallel to H_0. Information about the degree of order of this axis was obtained by observing the deuterium spectrum from specifically labelled decylsulfate. Simultaneously the spectrum from the deuterated anilinium ion was obtained. The order of the chain axis (S_{Ch}) is given by

$$[8] \qquad \Delta\nu_D = \tfrac{3}{2}Q_D\tfrac{1}{2}(3\cos^2 90° - 1)S_{Ch}$$

where it is assumed that one S value is sufficient to describe the orientation of the chain as has been established for lamellar phases prepared from sodium decanoate (5). The term $\frac{1}{2}(3\cos^2 90° - 1) = -0.5$ transfers the order from the C—D bond to the chain axis to which it is perpendicular. Q_D is ~170 kHz for methylene groups.

Deuterium quadrupole splittings of 20.42, 18.82, and 9.70 kHz were obtained for positions 2, 3, and 9 of the decyl chain respectively, corresponding to order parameters S_{Ch}, of 0.1613, 0.1489, and 0.0761. The degree of order of the long axis (S_{yy}) of the anilinium ion in the same phase was 0.1528. This large degree of order is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

almost identical to that of the hydrocarbon chains at the 2 and 3 positions and twice as large as that at the 9 position.

Several ionic species have been investigated in Type II phases. One characteristic in common with all oriented species was their rather low degrees of order [$(-1$ to $-10) \times 10^{-3}$] along a C_3 axis (12). The degree of order of the major axis of the anilinium ion ranges between $+0.13$ and $+0.19$ dependent on the particular phase. This is much larger than has been observed for other ions and similar to that of the degree of order of the hydrocarbon chains in the superstructure.

It has been found that substitution of other ions for sodium generally converts Type I phases into Type II (11). A survey of the literature shows that sodium sulfate (or occasionally another inorganic salt) has almost invariably been used as an additive in the preparation of nematic phases since this insures the formation of Type II phases. For this anilinium case it was found that addition of sodium sulfate did not convert the Type I into a Type II phase. When attempts were made to use more anilinium decylsulfate and less sodium decylsulfate (see Table 1 for the proportions used for the nematic phases), nematic phases would no longer be prepared but only smectic phases. These results indicate that the anilinium ion is a strong structure building component of the phase which stabilizes the lamellar structure.

It is clear from the results that the anilinium ion has become an integral part of the phase superstructure with its C_2 (or long axis) directed preferentially perpendicular to the surface of the lamellae. A positive or negative direction of the order axis cannot be assigned. However, since the aromatic ring is quite hydrophobic it can be expected that the phenyl ring penetrates into the superstructure and the charged $—NH_3^+$ group sits in the electrical double layer where it interacts efficiently with water and negatively charged decylsulfate headgroups. The opposite sense to the order, that is with the $—NH_3^+$ penetrating into the superstructure is not reasonable. That the degree of order of the C_2 axis of the ion is so much larger than that obtained from position 9 of the decyl chain shows that the ion does not spend a significant amount of its time in the interior of the superstructure.

The relative magnitudes of S_{xx} and S_{zz} indicate that the C_2 axis of the ion oscillates about H_0 more freely in the xy than in the zy plane. This result might be anticipated since oscillation in the xy plane would require substantially less free volume than that in the yz plane.

We would like to thank Dr. S. Sýkora of Bruker for obtaining the 60 MHz proton spectra for us and Bruker for providing the facility. We would also like to thank M. Reinhold for obtaining the deuterium spectra and the Swiss National Foundation for the Advancement of Science for the financial support.

Mechanisms of Acylal Hydrolysis in Sulfuric Acid Solutions

ROBERT ALLAN MCCLELLAND
Department of Chemistry, University of Toronto, Toronto, Ontario M5S 1A1
Received March 3, 1975

ROBERT ALLAN MCCLELLAND. Can. J. Chem. **53**, 2763 (1975).

The acid-catalyzed hydrolysis (in aqueous H_2SO_4) of acylals $ArOCH_2OAc$ is reported, and compared with that of normal acetate esters. On the basis of *r* plot behavior and the effects of the aromatic substituents, an A_{Ac}-2 ester hydrolysis mechanism is shown to occur in dilute acids, with a changeover to a mechanism analogous to A_{A1}-1 ester hydrolysis (intermediate cation $ArOCH_2^+$) in more concentrated acids, the position of the changeover being dependent on the substituent. Methylene diacetate is also investigated and shown to display the same behavior, with an A-1 mechanism involving an intermediate $CH_3COOCH_2^+$ becoming important at about 75% H_2SO_4. The relative A_{A1}-1 reactivities for acetates ROAc, R = CH_3OCH_2, *tert*-butyl, $C_6H_5OCH_2$, $C_6H_5CH_2$, 4-$NO_2C_6H_4OCH_2$, CH_3COOCH_2, isopropyl, are 6×10^3, 5×10^2, 1, 7×10^{-2}, 4×10^{-2}, 1.1×10^{-2}, 1.3×10^{-4} respectively.

ROBERT ALLAN MCCLELLAND. Can. J. Chem. **53**, 2763 (1975).

On rapporte l'hydrolyse acido-catalysé (dans l'acide sulfurique aqueux) d'acylals du type $ArOCH_2OAc$ et on compare ces hydrolyses à celles d'esters acétiques normaux. En se basant sur le comportement des courbes *r* et les effets des substituants aromatiques, on démontre qu'un mécanisme A_{Ac}-2 d'hydrolyse d'ester se produit en milieux acides dilués; en milieux acides plus concentrés, un mécanisme similaire à un mécanisme A_{A1}-1 d'hydrolyse d'ester (cation $ArOCH_2^+$ intermédiaire) devient prépondérant. La position du changement de mécanisme dépend du substituant. On a aussi examiné le diacétate de méthylène et on a démontré qu'il réagit de la même manière; le mécanisme A-1 impliquant un intermédiaire $CH_3COOCH_2^+$ devient important dans l'acide sulfurique 75%. Les réactivités A_{A1}-1 relatives des acétates ROAc où R = CH_3OCH_2, *tert*-butyle, $C_6H_5OCH_2$, $C_6H_5CH_2$, 4-$NO_2C_6H_4OCH_2$, CH_3COOCH_2, *iso*-propyle sont respectivement de 6×10^3, 5×10^2, 1, 7×10^{-2}, 4×10^{-2}, 1.1×10^{-2}, 1.3×10^{-4}.

[Traduit par le journal]

The class of organic molecules known as acylals (*e.g.* $ROCH_2OOCR'$) has received attention recently as suspected intermediates in enzymatic processes (1). These are somewhat unusual species in that they can be regarded both as carboxylate esters and as acetals. Thus, three reasonable mechanistic possibilities for their acid-catalyzed hydrolysis can be proposed (Scheme 1); as esters, an A_{Ac}-2 hydrolysis, and as acetals two A-1 reactions (2).[1]

In previous investigations, all three have been found or proposed, particularly when the acylal is incorporated in a cyclic system (4). Acyclic acylals seem however to prefer the A-1(b) pathway (2, 5–7) whose ease can be attributed to the resonance stabilization in the incipient oxycarbonium ion **1***b*. A mixture of A-1(b) and A_{Ac}-2 reactions has been suggested with formic acid acylals (5, 6) (more efficient bimolecular attack) and with 2-chloroethoxy acylals (8) (destabilized oxycarbonium ion). Methylene diacetate and ethylidene diacetate follow only the bimolecular route (9), presumably in order to avoid the formation of an acyloxycarbonium ion. No A-1(a) process has been observed with acyclic acylals; this also involves an intermediate acyloxycarbonium ion **1***a*.

Our interest in this system stems from the fact that the A-1(b) pathway can also be looked upon as an A_{A1}-1 ester hydrolysis,[2] so that the hydrolysis of the acyclic acylals can in a sense be regarded as a competition between unimolecular and bimolecular ester hydrolysis. This is the same type of competition that has been investigated in some detail for normal esters (11, 12),

[1]Recently a number of acetals have been encountered which show general acid-catalyzed hydrolysis (2, 3). For our purposes, we will not distinguish this from the above specific acid-catalyzed reactions, since the same intermediate carbonium ion is formed in both cases. In any event the acylals considered here do not possess the structural features that are likely to lead to the general catalysis.

[2]This hydrolysis can proceed with protonation at either oxygen of the carboxylate group. At present, no distinction can be made, although the carbonyl oxygen is the more basic site (10).

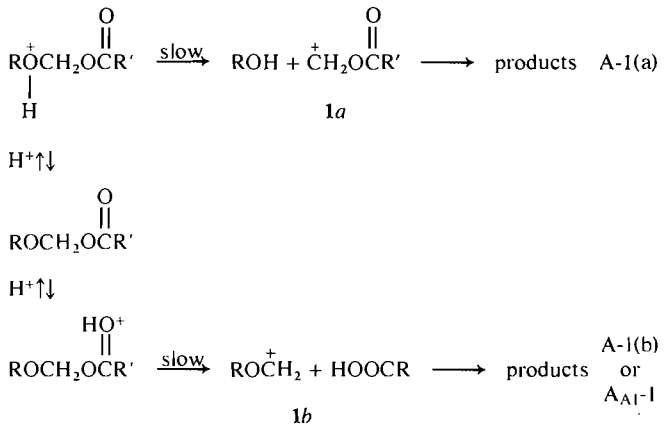
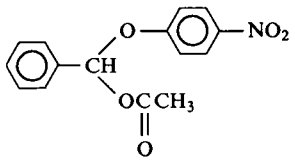


SCHEME 1

and we decided therefore to see if similar considerations apply in the acylal system. In particular this paper centers mainly on acylals of the type $ArOCH_2OAc$, in which the effects of the phenyl and its substituents are evaluated. We have also extended the study of methylene diacetate to more concentrated acid solutions.

The aryl acylals have seen little prior investigation. Fife and De have recently reported on the hydrolyses of a pair of *p*-nitrophenyl acylals (1). In acidic solutions the cyclic acylal 3-(*p*-nitrophenoxy)phthalide seemed to hydrolyze via a bimolecular mechanism, while its acyclic analog **2** was suggested to follow a unimolecular route; there were however certain ambiguities in both cases.



2

Results

In Table 1, first-order rate constants at 25 °C for the hydrolysis of a series of aryloxymethyl acetates are reported as a function of sulfuric acid concentration. Also included are data for methylene diacetate and methoxymethyl acetate. For the latter compound the literature values (determined by analysis of liberated formaldehyde (5)) show excellent agreement with those measured in this work (by following the u.v. absorbance change at 205 nm).

For the two activated aromatics, and to some extent the unsubstituted and 4-chloro compounds, considerable decomposition was observed above a certain acidity. This is probably caused by condensation reactions between the phenol and formaldehyde products since in the absence of formaldehyde the phenol is stable under the same conditions. This prevented extension of the study for the 4-methoxy and 4-methyl compounds to any higher acidity than that reported in Table 1. With the other two where the decomposition was less severe, rate constants in the more concentrated acids were calculated by the Guggenheim method.

In Table 2, second-order rate constants obtained on hydrolysis in aqueous sodium hydroxide at 25 °C are reported for the aryl acylals. These were obtained by following the hydrolysis under pseudo-first-order conditions in excess base (10^{-2} *M* NaOH, 10^{-4} *M* substrate). In the case of the unsubstituted compound, a number of sodium hydroxide concentrations were employed, and the rate was shown to be first order in base as well.

Discussion

In sulfuric acid solutions acetate esters have generally been found (11) to hydrolyze via the $A_{Ac}2$ mechanism in the dilute acid region, followed at some acidity by a changeover to one of two A-1 mechanisms, the type of A-1 and the position of changeover being dependent on the ester structure. With the exception of simple primary alkyl acetates and phenyl acetates, an $A_{Al}1$ reaction is involved, and a considerable variety of behavior can be observed, depending essentially on the stability of the carbonium ion

so formed. For example, in the series 4-methoxybenzyl acetate, benzyl acetate, 4-nitrobenzyl acetate, the acid concentration at which the A_{Al}-1 reaction becomes important (20%, 60%, 80% H_2SO_4 respectively (11)) is a direct reflection of the stabilization in the benzylic carbonium ions. In the case of strongly stabilized carbonium ions, the unimolecular process can predominate even in dilute acids and no bimolecular hydrolysis is observed, as for example with *tert*-butyl acetate (13).

In this sense then, an acylal like methoxymethyl acetate can be seen to fit this latter category, the methoxymethyl carbonium ion is stabilized sufficiently that only the unimolecular hydrolysis is observed (5, 6). With the aryloxymethyl acetates however, the intermediate oxycarbonium ion should be considerably less stabilized due to the competition for the oxygen electron pairs between the phenyl ring and the cationic center. In consequence the bimolecular hydrolysis becomes a very real possibility, particularly in the more dilute acids, and by analogy with normal esters, the A_{Al}-1 mechanism might be expected to occur only in more concentrated acids, the acidity being dependent on the actual stability of this cation.

In Fig. 1 the rate–acidity profiles obtained with the aryloxymethyl acetates are shown and compared with that of methoxymethyl acetate. Although all the curves exhibit a monotonic increase in rate with increasing acidity, there are considerable differences. Methoxymethyl acetate, like *tert*-butyl acetate (13), shows an immediate rapid increase in rate even in dilute acids. With the phenyl acylals, however, the rise in rate in the dilute acids is quite moderate; this is followed at some intermediate acid concentration by a much more pronounced increase, similar to that of the methoxymethyl compound. We will show that these profiles are reflecting precisely the con-

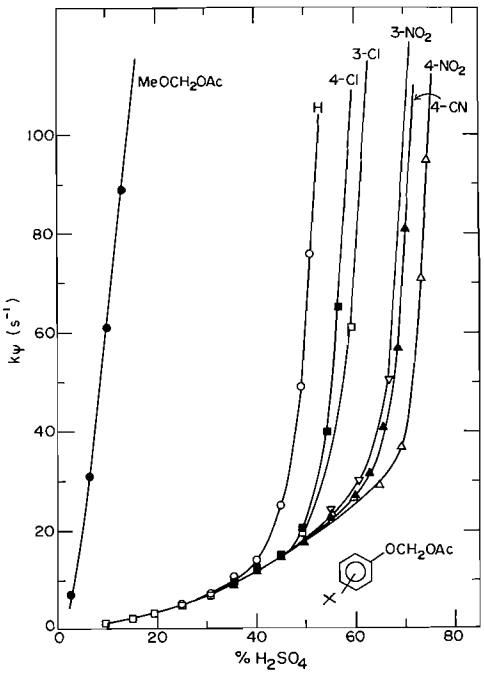

FIG. 1. Rate variation as a function of acidity for aryloxymethyl acetates at 25 °C.

siderations of the previous discussion, *i.e.* an A_{Ac}-2 hydrolysis in dilute acids giving way to an A_{Al}-1 hydrolysis at intermediate acidity, this mechanistic changeover being characterized by the change in the rate of increase of k_ψ.

The first piece of evidence for this behavior comes upon application of the *r* hydration treatment (11) to the rate–acidity data. Although the significance of the *r* values obtained from this approach is open to question (14), it has proven successful in suggesting mechanisms and mechanistic changes, in particular when applied to the hydrolysis of esters (11, 12). The *r* plots obtained with the acylals are depicted in Fig. 2. These take the form $\log k_\psi - \log (h_0^m/h_0^m + K_{SH^+})$ *vs.* $\log a_{H_2O}$ (11), where *m* and K_{SH^+} are parameters pertaining to the protonation step ($\log [BH^+]/[B] = m(-H_0) + pK_{SH^+}$). These terms could not be obtained with the acylals, since hydrolysis in the concentrated acids is too rapid. Consequently these plots are based on protonation data previously obtained with other acetate esters (11, 15), $m = 0.60$, $pK_{SH^+} = -4$.[3] Small devia-

[3]In acids below 65% H_2SO_4 the ordinate of the *r* plot then is equivalent to $\log k_\psi + mH_0 +$ constant.

tions from this behavior will not affect the following qualitative interpretations in any way.

The plots can be seen to be of the form that has been generally observed for simple acetates (11). The aryl acylals exhibit initially a linear region of positive log a_{H_2O} dependence; this is characteristic of the A_{Ac}-2 hydrolysis. At some acidity there is a pronounced break to another linear region which shows a negative log a_{H_2O} dependence; this is characteristic of a mechanistic changeover to an A-1 reaction. The magnitudes of the slopes (*i.e.* r values) in this latter region ($r = -0.6$ to -0.9) are furthermore those found for A_{Al}-1 hydrolysis rather than A_{Ac}-1 hydrolysis (r values normally around -0.2 (11)). Methoxymethyl acetate produces a plot with a strongly negative log a_{H_2O} dependence beginning in dilute acids, consistent with its unimolecular character throughout. The r values calculated for the linear regions of these plots and the mechanistic conclusions are summarized in Table 3. Significantly the acidities where the mechanistic changeovers are predicted to occur are those where the rate profiles also show their changes in behavior.

With the aryl acylals, further evidence for these mechanistic assignments can be seen in the effect of the substituents. In Fig. 3 are plotted log k_ψ values at various acidities as a function of the Hammett σ constant. In dilute acids (up to *ca.* 25% H_2SO_4), there is very little difference in the rates across the entire range of substituents; the ρ value for the hydrolysis at these acidities is -0.03 (± 0.01). This is what is normally found for A_{Ac}-2 ester hydrolysis (*e.g.* phenyl acetates, $\rho = -0.17$ (16); benzyl acetates, $\rho = -0.05$ (16)) and can be attributed to the near cancellation of the substituent effects on the two steps in the hydrolysis (12). With these acylals a further factor contributing to the very small ρ value lies simply in the remoteness of the substituent from the reaction center. This consideration is borne out by the base hydrolysis, which follows a normal ester B_{Ac}-2 mechanism (1, 17). For the acylals of this study a ρ value of $+0.41$ is obtained (Fig. 4). This can be compared to values obtained in systems in which the substituent change is occurring closer to the reaction center: benzyl acetates $\rho_{base} = +0.8$ (12); phenyl ace-

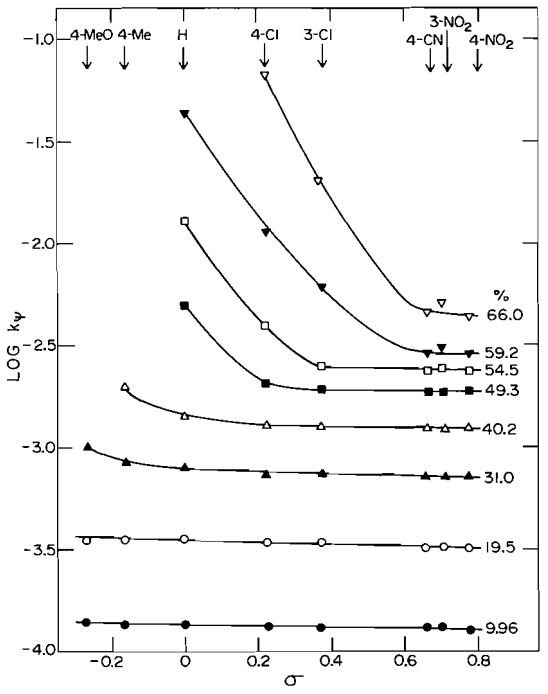

FIG. 3. Log k_ψ versus σ for hydrolysis of $ArOCH_2OAc$ at varying concentrations of H_2SO_4.

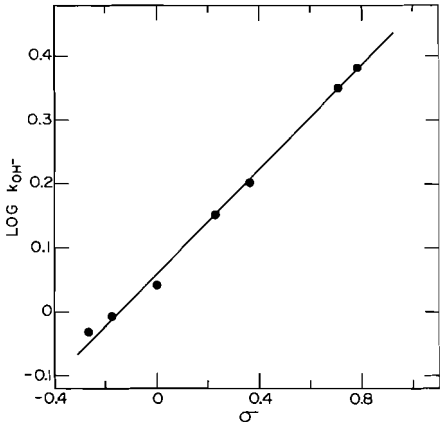

FIG. 4. Hammett σ plot for base hydrolysis of $ArOCH_2OAc$.

tates, $\rho_{base} = +1.5$ (12). In fact, for these series in which the substituent change is occurring in the alkyl portion of the ester, the ratio ρ_{base}/ρ_{acid} is quite similar.

In more concentrated acids, the plots for the acylals no longer show a linear behavior. As the A-1 reaction becomes important for each compound, its point on the σ plot shows a positive deviation from the line of the A_{Ac}-2 hydrolysis. Again, the acidities where these deviations first occur correspond to the acidities where the *r* plots and rate profiles show the mechanistic changeover.

A direct estimate of the ρ value for the unimolecular reaction is difficult with the competing bimolecular hydrolysis. In principle this could be determined at an acidity where only the former is occurring (*i.e.* very concentrated acids), but this is impossible in the present case since at such an acidity the rates for most of the acylals would be far too rapid to measure.

An alternative approach involves measuring the relative rates for pairs of compounds of overlapping A_{Al}-1 reactivity, and by a stepwise technique similar to that used to determine relative basicities in acidity function studies (18), extending this over the entire range of substituents. This is illustrated in Fig. 5, in which values of log k_ψ are plotted as a function of acidity for those regions where the *r* plots predict that only the A-1 hydrolysis is occurring. Parallel lines are obtained, and the reactivities relative to the unsubstituted acylal can be estimated by proceeding in a stepwise manner from this compound. (A slight extrapolation is required at the 3-chloro : 3-nitro pair). These relative rates are listed in Table 4, and plotted as a function of σ in Fig. 6. A reasonably linear plot (correlation coefficient = 0.996) results with a slope $\rho = -3.02$, showing a relatively strong retardation by electron-withdrawing substituents. Qualitatively the same effect is seen in the considerably later acidities at which the A-1 reaction first occurs for the acylals with electron-withdrawing substituents.

This substantial dependence on the aryl substituent is completely consistent with the unimolecular hydrolysis proceeding via the A_{Al}-1

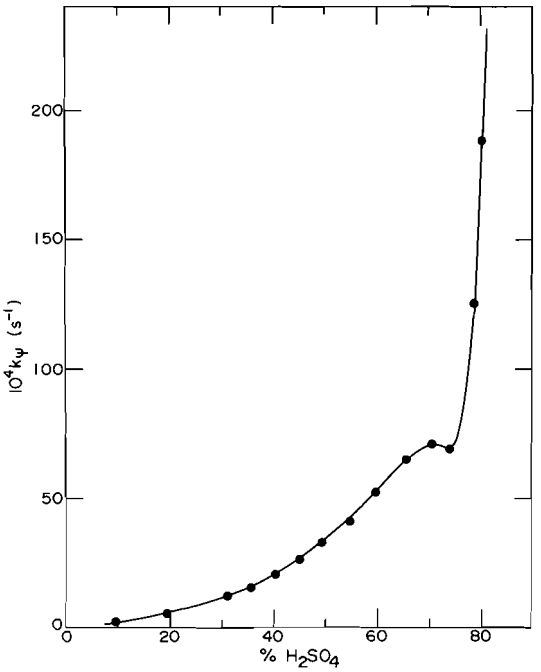

FIG. 7. Rates of hydrolysis of methylene diacetate in sulfuric acid solutions at 25 °C.

pathway, in which an $ArOCH_2^+$ carbonium ion would be formed in the rate-determining step. A comparison can be made with the hydrolysis of a series of alkoxymethyl acetates ($ROCH_2OAc$), which like methoxymethyl acetate hydrolyze by this route even in dilute acids, forming $ROCH_2^+$ (7). Based on σ* substituent constants for the varying R groups, this series is found to have a ρ* value of −3.42 (2), *i.e.* very similar to that of the aromatic compounds. Furthermore, the effect is inconsistent with the alternate A-1(a) pathway, in which a neutral phenol (plus a carbonium ion) would be formed in the slow step. A number of acetal hydrolyses proceed in this fashion (*e.g.* $ArOCH_2OMe$) and exhibit considerably smaller ρ values, although in the same direction (ρ values in the range 0 to −1 (see section C of Table II, ref. 2.)). Finally an A_{Ac}-1 ester hydrolysis reaction can be ruled out again, since this has been shown to be favored by electron-withdrawing groups in the neutral departing molecule (11).

The observation that these phenyl acylals hydrolyze via the A_{Al}-1 mechanism in moderately concentrated sulfuric acid leads to methylene diacetate, from which an acyloxycarbonium ion must be produced by this reaction. The previous study (9) on this compound was carried out in aqueous hydrochloric acid, and was therefore not extended to media of high acidity. Accordingly we have measured the rates of hydrolysis in sulfuric acid over a considerably wider range of acid concentration, and so obtained the rate profile of Fig. 7. Behavior similar to the aryloxymethyl acetates is observed, in this case with a hint perhaps of the rate maximum often found with A_{Ac}-2 ester hydrolysis (11, 12, 19).[4] The *r* plot (Fig. 2) and derived parameters (Table 3) confirm this similarity, and show that although the A_{Ac}-2 hydrolysis is preferred in dilute acids as noted before (9), by increasing the acidity sufficiently the reaction involving the acyloxycarbonium ion does occur.

Thus, in summary, the hydrolysis of these acetate acylals does follow the same trends observed with simple acetates; a conventional A_{Ac}-2 ester hydrolysis in dilute acids with a changeover at some acidity to an A-1 reaction. It is interesting in this respect to compare reactivities in the two types of compound. In

[4]Such maxima are not observed with the aryloxymethyl acetates because of the earlier changeover to the unimolecular hydrolysis.

[a]Interpolated from plots of k_4 *vs.* $\%H_2SO_4$.
[b]$k_4/2$, since there are two acetate groups in the molecule.

Table 5, a number of A_{Ac}-2 hydrolysis rates (in 15% H_2SO_4) are listed. As is expected from the great deal of study which has been devoted to this reaction (12), the effect of these structural variations is very small, and is probably mainly steric in origin. Certainly the additional oxygen in the acylals has introduced no new effect.

On the other hand a wide variety of behavior is observed for the A_{Al}-1 reactions, being due to the considerable differences in the stabilities of the intermediate carbonium ions. Relative A_{Al}-1 reactivities for a number of acetates are summarized in Table 6. As with the aryloxymethyl acetates (Table 4) these data are not based on direct comparison, but on an extension of the stepwise technique. The measurable A_{Al}-1 rates for benzyl acetate, methylene diacetate, and isopropyl acetate overlap with one (or more) of the aryloxymethyl acetates. In the following paper (20) is reported the hydrolysis of a series of thioacylals with A_{Al}-1 reactivities which cover the dilute acid region (0–60% H_2SO_4), allowing the relative rates for the more reactive acetates of Table 6 to be estimated.[5] Unfortunately a simple primary alkyl group cannot be included in Table 6, since such acetates hydrolyze by an A_{Ac}-1 mechanism in concentrated acids (11).

A number of points arise from these comparisons. The first is the variation within the acylals themselves. The phenyl ring does show its predicted effect when compared with methyl, a considerable rate decrease due to the lesser availability of the oxygen lone pairs for stabilization of the adjacent cationic center. In this respect it can be seen that the acetoxymethyl carbonium ion derived from methylene diacetate is the least stable of the oxycarbonium ions, although there is not a great deal of difference with that derived from the 4-nitrophenoxy compound.

[5]See Fig. 6 and Table 8 of ref. 20.

Significantly however this study reveals that these "destabilized" oxycarbonium ions are still comparable to what are normally regarded as moderately stable carbonium ions, for example isopropyl and benzyl. This illustrates the very large conjugative stabilizing effect of oxygen lone pairs adjacent to a positive carbon, even in cases in which there is a considerable competition for these electrons with another π system.

In the light of such comparisons, the behavior of the acetate acylal **2** is interesting.[6] This compound would give a carbonium ion bearing two moderately stabilizing groups, phenyl and 4-nitrophenoxy. In consequence the combined effects of the two results apparently in sufficient stabilization to make this compound the most reactive acetate in Table 6, even when compared with $MeOCH_2OAc$.

Finally, we can comment on the behavior of cyclic acylals (1, 4). On the basis of our results, all such compounds to date investigated would be expected to hydrolyze as simple A_{Al}-1 esters, particularly since there is usually some additional substituent such as phenyl present to stabilize the intermediate carbonium ion of that reaction. The occurrence then of other pathways[7] must be due to some factor or factors associated with the cyclic nature of these compounds, as have been discussed in previous studies (1, 4).

Experimental

Materials

Sulfuric acid solutions were prepared and standardized as previously described (21). The preparation of the aryloxymethyl acetates has been reported elsewhere (22). Standard procedures were used for the preparation of methylene diacetate (9) and methoxymethyl acetate (5).

Kinetics

Rates were obtained on a Cary 16 spectrophotometer equipped with an external recorder and a thermostatted cell compartment. With the aryloxymethyl acetates, stock solutions were prepared in methanol, and reactions initiated by addition of 3 μl of these solutions to pre-equilibrated cuvettes containing 3 ml of aqueous solution. Final concentrations of substrates were $1–5 \times 10^{-4}$ *M*. Reactions were monitored by following the absorbance increase at the wavelengths given in Table 7. For methoxymethyl acetate and methylene diacetate, the substrate was added directly to the solution in the cuvette (concen-

[6]Based on the data of Table 5 and accompanying discussion, the conclusion of an A_{Al}-1 hydrolysis for this compound appears valid, since its rate is far too rapid for an A_{Ac}-2 acetate hydrolysis.

[7]As has been recognized in the reports on these hydrolyses (1, 4) there are definite uncertainties in the mechanistic assignments.

4-NO_2	340	395

tration 2×10^{-2} *M*), and the absorbance decrease at 205 nm was followed (11).

First-order rate constants were calculated from plots of ln $(A_\infty - A_t)$ (or ln $(A_t - A_\infty)$) *vs.* time. With the exceptions noted below, these plots are linear to several half-lives.

Above a certain acidity, stable infinity values could not be obtained with some of the aryloxymethyl acetates. In fact, these solutions can be observed to go cloudy during hydrolysis. This problem is most severe with the activated compounds, and the rates can not be measured above the acidities for which data are reported in Table 1. With the unsubstituted and 4-chloro compounds, decomposition is less serious, and the hydrolysis could be followed for 3–4 half-lives, and the rates were calculated by the Guggenheim method. This applies to the data above 45% H_2SO_4 for the unsubstituted compound, and above 55% H_2SO_4 for 4-chloro.

Products of Hydrolysis

Hydrolysis of the aryloxymethyl acetates produces the phenol. The u.v. spectrum of the product is quantitatively superimposable (within ±2%) on the u.v. spectrum of the phenol in the same solution. With methylene diacetate and methoxymethyl acetate, the u.v. spectrum of the hydrolysis product is identical to that of acetic acid under the same conditions.

Mechanisms of Thioacylal Hydrolysis in Sulfuric Acid Solutions

ROBERT ALLAN MCCLELLAND
Department of Chemistry, University of Toronto, Toronto, Ontario M5S 1A1
Received March 3, 1975

ROBERT ALLAN MCCLELLAND. Can. J. Chem. **53**, 2772 (1975).

The acid-catalyzed hydrolysis (aqueous H_2SO_4) of thioacylals CH_3SCH_2OAc and $ArSCH_2OAc$ is reported. The former is shown to react solely by an A-1 mechanism proceeding via an intermediate $CH_3SCH_2^+$ cation. In the latter series hydrolysis in dilute acids involves both this A-1 mechanism and a normal A_{Ac}-2 ester hydrolysis mechanism occurring simultaneously; as the acidity is increased the proportion of A-1 reaction increases until it completely dominates. The A-1 reaction shows lesser importance with electron-withdrawing substituents. The 4-nitro compound in fact shows no A-1 mechanism until about 40% H_2SO_4. These hydrolyses are compared with those of the corresponding acylals, which show a similar mechanistic behavior. Relative A-1 reactivities for $RXCH_2OAc$, RX = CH_3O, CH_3S, C_6H_5S, C_6H_5O are 81, 49, 1, 0.022, relative to $C_6H_5SCH_2OAc$. Discussions pertaining to the effects of the oxygen and the sulfur in these systems are presented.

ROBERT ALLAN MCCLELLAND. Can. J. Chem. **53**, 2772 (1975).

On rapporte l'hydrolyse acido-catalysée (H_2SO_4 en milieu aqueux) de thioacylals du type CH_3SCH_2OAc et $ArSCH_2OAc$. On démontre que le premier réagit uniquement par un mécanisme A-1 se produisant par l'intermédiaire d'un cation $CH_3SCH_2^+$. Dans la deuxième série, l'hydrolyse par des acides dilués implique à la fois ce mécanisme A-1 et un mécanisme d'hydrolyse A_{Ac}-2 normal pour les esters et se produisant d'une façon simultanée; à mesure que l'acidité du milieu augmente, la proportion de réaction se produisant par un mécanisme A-1 augmente jusqu'à ce qu'elle devienne prédominante. Lorsque les groupes portent des substituants électro-attracteurs, l'importance de la réaction A-1 diminue. En fait dans le cas du composé portant un groupe nitro en position 4, le mécanisme A-1 ne commence à intervenir que dans l'acide sulfurique à 40%. On compare ces hydrolyses avec celles des acylals correspondants qui, du point de vue mécanistique, réagissent d'une façon similaire. Les réactivités A-1 relatives (au $C_6H_5SCH_2OAc$) pour $RXCH_2OAc$ où RX = CH_3O, CH_3S, C_6H_5S, C_6H_5O sont respectivement 81, 49, 1, 0.022. On présente une discussion relative aux effets de l'oxygène et du soufre dans ces systèmes. [Traduit par le journal]

In the previous paper (1) an investigation into the sulfuric acid catalyzed hydrolysis of acylals of the type CH_3OCH_2OAc and $ArOCH_2OAc$ was reported. In this paper the study is extended to the sulfur analogs of these compounds, CH_3SCH_2OAc and $ArSCH_2OAc$. No prior investigation into the acid hydrolysis of any such thioacylal appears to have been carried out. Fife and De (2) have recently looked into the hydrolysis in buffered and basic solutions, and concluded that their behavior is similar to that of the corresponding acylals.

Results

The rates of hydrolysis of five thioacylals are reported in a number of sulfuric acid solutions in Table 1. No aromatic with an electron-releasing substituent is included because extensive decomposition occurred during the kinetic runs, even in dilute acids. Kinetics were followed by u.v. spectroscopy for the four aromatic compounds: a hydroxamic acid – ferric chloride assay (3) was used with methylthiomethyl acetate. With the aromatics the appropriate benzenethiols were shown to be formed on hydrolysis by comparison of the u.v. spectra of the products with those of authentic samples. This was confirmed in the case of the unsubstituted compound where a quantitative yield of benzenethiol was found by g.c. analysis.

In Fig. 1, these rates are plotted as a function of the sulfuric acid concentration; also included are the profiles previously obtained for methoxymethyl acetate and phenoxymethyl acetate (1). All compounds exhibit a similar behavior in the sense of a monotonic rate increase with increasing acidity. The aromatic compounds, however, are characterized by a more moderate rate increase in the dilute acids followed by a change at some acidity to a more pronounced increase.

Rates of hydrolysis as a function of temperature are listed for selected thioacylals (and one

acylal) in Table 2. Plots of log (k_ψ/T) *vs.* $1/T$ are depicted in Fig. 2, and the derived activation parameters given in Table 3. Of particular significance is the observation that the two plots for phenylthiomethyl acetate show curvature, particularly the one in the more dilute acid (the deviation from linearity in 24.9% H_2SO_4 is probably not outside the limit of experimental error).

In Table 4, second-order rate constants for the basic hydrolysis of the aromatic thioacylals are given. These were obtained under pseudo-first-order conditions in 0.01 *N* aqueous sodium hydroxide. In Fig. 3, a plot of log k_{OH^-} *vs.* the Hammett substituent constant is shown; from this a ρ value of +0.44 is obtained. This is very similar to values observed for the base hydrolysis of 3-(*para*-substituted thiophenyl) phthalides (2), as well as the aryloxymethyl acetates (1) (+0.42 and +0.41 respectively). The base hydrolysis of these thioacylals and acylals has been shown to proceed by a normal B_{Ac}-2 ester hydrolysis mechanism (2, 4).

In addition the products of solvolysis of two of the thioacylals in acidic (0.02 $M[H^+]$) methanol

were determined. Methylthiomethyl acetate was found to give a quantitative yield of the thioacetal **1**.

$$CH_3SCH_2OAc \xrightarrow[CH_3OH]{H^+} CH_3SCH_2OCH_3 \quad (1)$$

No methanethiol could be detected; acetic acid is also formed but is rapidly esterified to methyl acetate. In the same solution phenylthiomethyl acetate gives benzenethiol (95%) and thioacetal **2** (5%).

$$C_6H_5SCH_2OAc \xrightarrow[CH_3OH]{H^+} C_6H_5SH(95\%) + C_6H_5SCH_2OCH_3(5\%) \quad (2)$$

Control experiments demonstrated that both products are stable under the reaction conditions. Methyl acetate and a trace of acetic acid are also formed; again the latter is converted to the former during the solvolysis.

In order to determine the effect of a change from water to methanol on the solvolysis rate for an acetate whose hydrolysis proceeds by the A_{Ac}-2 mechanism, the rate of *trans*-esterification of *p*-nitrophenyl acetate was determined in acidic methanol. First-order rate constants were measured at three acid concentrations from 0.01 to 0.06 $M[H^+]$; these give a value for the second-

TABLE 4. Hydrolysis of arylthiomethyl acetates ($ArSCH_2OAc$) in aqueous NaOH at 25 °C

Ar	$k_2(M^{-1}\,s^{-1})$
$4\text{-}MeOC_6H_4$	0.521
C_6H_5	0.712
$4\text{-}ClC_6H_4$	0.827
$3\text{-}ClC_6H_4$	1.021
$4\text{-}NO_2C_6H_4$	1.531

order rate constant ($k_2 = k_\psi/[H^+]$) of 0.0015 $M^{-1}\,s^{-1}$. Coupled with data for the hydrolysis reaction (3), the ratio $k_2(CH_3OH)/k_2(H_2O)$ is 25. For an acetate whose hydrolysis proceeds via the A_{Al}-1 route this rate ratio is 6, based on literature data for the methanolysis (5) and hydrolysis (6) of methoxymethyl acetate. Thus although both types are faster in methanol, the effect is greater for the bimolecular reaction.

Discussion

From the previous study of the acylals (1) the mechanistic behavior of the thioacylals is expected to revolve around a competition between a normal A_{Ac}-2 ester hydrolysis and a unimolecular process analogous to an A_{Al}-1 ester hydrolysis, involving in this case a carbonium ion center adjacent to sulfur. We will show in the following discussion that this is the case, permitting in consequence a comparison to be made of the ability of oxygen and sulfur to form such stabilized cationic species.

[1] $CH_3\overset{\overset{O}{\|}}{C}OCH_2SR \overset{H^+}{\rightleftarrows} CH_3\overset{\overset{{}^+OH}{|}}{C}OCH_2SR \rightarrow CH_3COOH + {}^+CH_2SR \rightarrow$ product

Methylthiomethyl Acetate

The oxygen analog of this compound is well known to hydrolyze solely via a unimolecular pathway similar to [1] (1, 6) and the results for the thioacylal suggest an identical behavior. Thus, there is a striking similarity in the rate–acidity profiles of the two compounds (Fig. 1), as well as their entropies of activation (Table 3). The latter values are small and slightly positive as is characteristic of A-1 hydrolysis reactions (7). Particularly conclusive evidence is afforded by the methanolysis experiment, where the thioacetal $CH_3SCH_2OCH_3$ arises from methanol attack on the intermediate carbonium ion $CH_3SCH_2^+$. A bimolecular solvolysis (*trans*-esterification) would be expected to yield (eventually) methanethiol.[1] (A similar experiment has been carried out with methoxymethyl acetate; $CH_3OCH_2OCH_3$ is formed in quantitative amounts (5).)

4-Nitrophenylthiomethyl Acetate

In the oxygen series replacement of the methyl group of CH_3OCH_2OAc by aryl results in sufficient destabilization of the oxycarbonium ion intermediate of the A-1 hydrolysis that in dilute acids the reaction proceeds by an A_{Ac}-2 ester hydrolysis mechanism, while the unimolecular process only becomes important in some more concentrated acid. The 4-nitrophenyl thioacylal appears to behave similarly, with the mechanistic changeover at *ca.* 40–50% H_2SO_4. Thus, when the relative rates of hydrolysis of this compound and its oxygen analog (A-2 until 65% H_2SO_4) are compared (Table 5) the ratio of reactivities is found to be essentially constant up to 40% H_2SO_4, implying a common mechanistic behavior. At this point as the A-1 process takes over with the thioacylal the rate ratio increases dramatically. In addition, the *r* hydration plot (8) exhibits the form characteristic of such a mechanistic behavior, a linear region of positive slope (+1.37) up to 40% H_2SO_4 (A_{Ac}-2 reaction), followed by a changeover to another linear region of negative slope (−1.01) (A-1 reaction). Finally the entropy of activation (Table 3) for the hydrolysis in 10% H_2SO_4 is large and negative, as is consistent with A-2 hydrolysis (7). The $\Delta S^{\neq}$ value is in fact very similar to that of phenoxymethyl acetate in the same acid.

TABLE 5. A comparison of the rates of hydrolysis of $4\text{-}NO_2C_6H_4OCH_2OAc$ and $4\text{-}NO_2C_6H_4SCH_2OAc$ in sulfuric acid solutions at 25 °C

Other Arylthiomethyl Acetates

For the other three aromatic thioacylals, it appears as if the decrease in A-1 reactivity due to the aromatic ring is not sufficient to completely inhibit this reaction even in the dilute acids. However, the decrease is enough to allow the A_{Ac}-2 reaction to compete, and what is occurring is a mixture of the two, up until some intermediate acidity (40–50% H_2SO_4) where the A-1 reaction finally dominates.

This behavior is seen particularly in the effect of the aromatic substituents. In the previous paper it was shown that the A_{Ac}-2 hydrolysis rates for $ArOCH_2OAc$ depend very little on the nature of Ar ($\rho = -0.03$), while the A-1 hydrolysis demonstrates a strong dependence ($\rho = -3$). A similar behavior should occur here, as for example in their base hydrolyses, where the two series $ArXCH_2OAc$ give very similar ρ values. In Fig. 5 are depicted plots at four acidities of $\log k_\psi$ for the thioacylals as a function of σ. Two features are apparent, the substantial and changing slopes, and the curvature. A hydrolysis proceeding solely via the A_{Ac}-2 mechanism would have resulted in lines of very small slope passing through the 4-nitro points (for example the dotted line in 9.96% H_2SO_4). The deviations from such lines are caused by the A-1 reaction. These deviations fall in the order H > 4-Cl > 3-Cl as is consistent with the substituent dependence for that reaction, and

[1]The comparison of unimolecular and bimolecular reactivities in methanol and water rules out the possibility of a mechanistic difference between the two solvents, since the bimolecular reaction would be favored in methanol. That is, if the solvolysis in methanol is unimolecular, hydrolysis likely follows the same route.

40.2	95	90	77

[a]Log $k_\psi(A_{Ac}\text{-}2) = \log k_\psi(4\text{-}NO_2) + 0.03(0.78 - \sigma)$; $k_\psi(A\text{-}1) = k_\psi(obs.) - k_\psi(A_{Ac}\text{-}2)$.

become more serious as the acidity is increased and the A-1 reaction assumes a greater importance. The amount of hydrolysis proceeding through each of the two pathways can in fact be approximated on the basis of such considerations, evaluating the A_{Ac}-2 rates from the rates of the 4-nitro compound with small corrections for the substituent dependence of that reaction. This is illustrated in Table 6, using the ρ value of −0.03 observed in the oxygen series.

The substituent effects not only point to the occurrence of an A-1 process, but also provide

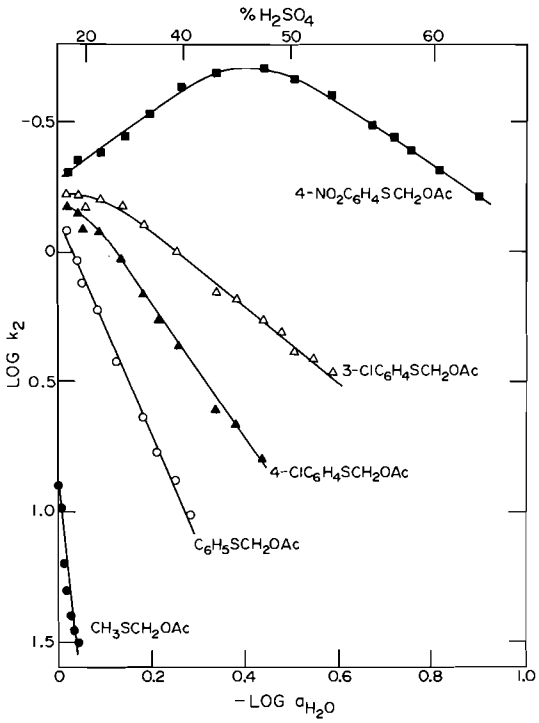

FIG. 4. r Hydration plots for the hydrolysis of thioacylals in aqueous sulfuric acid. Log k_2 = log k_ψ + mH_0, m = 0.60 (1). (No correction for protonation is necessary (8).)

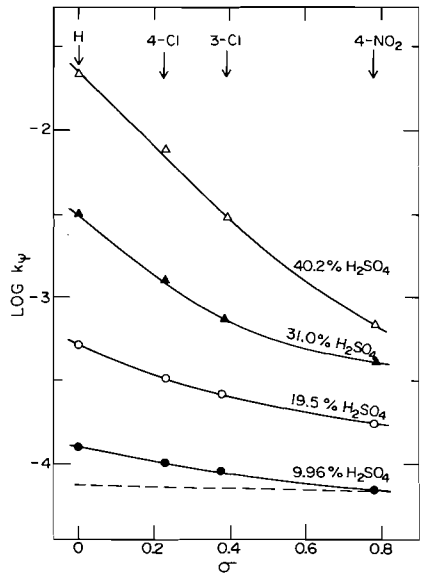

FIG. 5. Plots of log k_ψ for the acid hydrolysis of $ArSCH_2OAc$ as a function of σ. The dotted line is drawn with a slope of −0.03, and represents approximately the behavior that is expected if hydrolysis in 9.96% H_2SO_4 is occurring solely by the bimolecular pathway.

evidence that this is proceeding via the pathway of [1], with an intermediate of the form $ArSCH_2^+$. As will be described later a ρ value of −2.6 can be calculated for this reaction, *i.e.* of the same order as that of the acylals. This value is also similar (in fact, identical) to that obtained in the hydrolysis of $ArSCH_2Cl$ in 50% aqueous dioxane, a reaction which produces the same cationic intermediate (9). Moreover such a value makes unlikely a route involving protonation on sulfur followed by C—S cleavage to give ArSH and CH_2OAc^+. Such reactions occur with certain thioacetals and give ρ values of the order −0.9 (10), *i.e.* considerably less negative.

Further evidence is obtained in the methanolysis of $C_6H_5SCH_2OAc$. The benzenethiol product arises from a bimolecular process (via an intermediate $C_6H_5SCH_2OH$) while the thioacetal is the result of A-1 solvolysis. In addition the relative proportion of the two is in fairly good agreement with the situation in water. Assuming that the effect of changing solvent is that described previously, then the 5:95 proportion of A-1:A-2 in methanol implies a ratio of 18:82 in water. This applies to hydrolysis in very dilute acid and will increase as the acidity is increased. The ratio in the most dilute aqueous acid studied,

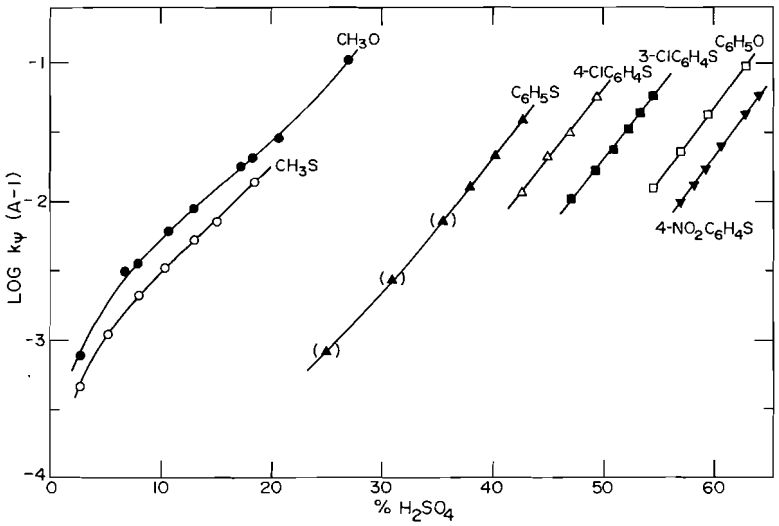

FIG. 6. A-1 hydrolysis rates for thioacylals and acylals ($RXCH_2OAc$). The points in parentheses for C_6H_5S— have been corrected for the A_{Ac}-2 contribution (Table 6).

9.96% H_2SO_4, is 41 : 59 (Table 6). In addition the actual observation of the thioacetal is significant, since this provides further strong evidence for the intermediacy of the thiocarbonium ion $C_6H_5SCH_2^+$ in the A-1 solvolysis reactions of this thioacylal.

Finally, with the considerable difference in the entropies of activation for A-1 and A-2 reactions, if a compound is undergoing hydrolysis by both routes simultaneously, it should exhibit some curvature in its activation plot. This is the case for $C_6H_5SCH_2OAc$ hydrolysis (Fig. 2). The curvature is particularly serious in 9.96% H_2SO_4 where at 25 °C there is a very close balance between the two reactions; it is less serious in 24.9% H_2SO_4 where the A-1 route predominates at 25 °C (and will become even more favored as the temperature is increased).

In concluding this section, a word should be said about the r plots for these compounds (Fig. 4). At first glance their behavior appears to be that of typical A-1 acetates, *i.e.* negative slopes. However, what is occurring here is that the substantial water activity dependence for the A-1 reaction in dilute acids (*e.g.* $r = -14$ for CH_3SCH_2OAc) has the dominating influence on the r plot behavior, even where the reaction itself is only a minor component. A similar situation arises with 4-methoxybenzyl acetate, where again there are competing hydrolyses in dilute acids (8, 11). These cases represent a serious breakdown of this mechanistic criterion for acid-catalyzed reactions, although such failures are probably restricted to the more dilute acid region where log a_{H_2O} does not change very greatly.

Relative A-1 Reactivities for Acylals and Thioacylals

In summary the thioacylals are exhibiting the same mechanistic behavior as the acylals (1), namely a competition between what are essentially A_{Ac}-2 and A_{A1}-1 ester hydrolysis reactions. The differences lie only in the acidities at which the latter reaction becomes important.[2] In previous investigations it has been established (1, 8, 11) that the determining factor in this is the stability of the intermediate carbonium ion, and in consequence the A-1 behavior of the thioacylals and acylals is a reflection of the relative stabilities of thiocarbonium ions and oxycarbonium ions, *i.e.* the relative stabilizing effect of sulfur and oxygen adjacent to a cationic center. These relative A-1 reactivities can be estimated quantitatively using the stepwise procedure outlined previously (1), employing Fig. 6 where the rates of hydrolysis are plotted in acids where the reaction is substantially unimolecular. The rates relative to $C_6H_5SCH_2OAc$ are listed in Table 7. (From this table, a ρ value of −2.6 for A-1 hydrolysis of $ArSCH_2OAc$ is obtained (Fig. 7).)

The most surprising result is the very close

[2]There is only a small difference in $A_{Ac} = 2$ hydrolysis rates (see for example Table 5 and the discussion in the previous paper (1)).

reactivity of the two aliphatic compounds. Previous solution studies would suggest a considerably greater stabilizing effect of oxygen, as for example in the S_N1 solvolysis of CH_3XCH_2Cl where $k_{-O-}/k_{-S-} \approx 1500$ (12), or in comparing σ^+ substituent constants, CH_3O, −0.78; CH_3S, −0.60 (13). On the other hand gas phase investigations (14, 15) (as well as a recent theoretical study (16)) imply an opposite behavior. Thus our result actually lies somewhat intermediate between these two extremes. No simple explanation is apparent; a number of factors are important in determining the solution reactivity (*e.g.* solvation and extent of charge development), and it is probable that these are responsible for the various behaviors. Certainly in our system there is an inherent difference in that the heterolysis starts with a cationic (protonated) species[3] and furthermore involves an excellent leaving group in the neutral acetic acid molecule.

The second intriguing observation of this work involves the results obtained on replacing methyl by phenyl. As is expected the rate is decreased in both cases. However, the decrease is far greater with oxygen than with sulfur. With the similarity in the two aliphatic compounds this means that for the aromatic pair $C_6H_5SCH_2OAc$ and $C_6H_5OCH_2OAc$ the sulfur compound is considerably more reactive. In this comparison, the situation is complicated by the adjacent aromatic ring which is also conjugated with the heteroatom and the difference in behavior undoubtedly involves this consideration in some way. However, again, no simple explanation offers itself, and we will refrain from further speculation until more experimental and theoretical results become available.

[3]It is highly unlikely that there is much difference in the protonation step (11, 17).

Experimental

Materials

Sulfuric acid solutions were prepared and standardized as previously described (18). The preparation of the arylthiomethyl acetates has been reported elsewhere (19). Standard procedures were used for the preparation of CH_3SCH_2OAc (14) and $CH_3SCH_2OCH_3$ (20).

$C_6H_5SCH_2OCH_3$ (2) was prepared using the method of Dunn and Bruice (21) and had b.p. 110 (11 mm); n.m.r. (CCl_4, TMS): δ 7.5–7.1 (5H, m, ArH); 4.85 (2H, s, CH_2); 3.32 (3H, s, CH_3).

Kinetics

Rate data for the aromatic thioacylals were obtained from the u.v. spectral change, as described in the previous paper (1). Wavelengths used are listed in Table 8. With methylthiomethyl acetate, the hydroxamic acid – ferric chloride method for the analysis of esters (3) was employed. Control experiments demonstrated that there were no problems associated with the measurements because of the fact that this substrate is not a simple ester.

Products of Hydrolysis

For the arylthiomethyl acetates the u.v. spectra of the products were found to be identical to those of the appropriate benzenethiols in the same acid. In the case of the unsubstituted compound, the quantitative formation of this product was confirmed by g.c. analysis. Solutions of the thioacylal in various acids were allowed to react for

TABLE 8. Wavelengths employed to follow hydrolysis of arylthiomethyl acetates

	λ (nm)	
Substituent	Acid	Base
4-MeO	—	280
H	230	280
4-Cl	240	285
3-Cl	235	285
$4\text{-}NO_2$	330	385

7–10 half-lives, and then extracted with methylene chloride. A known amount of naphthalene was added and the methylene chloride layer was analyzed by g.c. This was performed on a Carlo-Erba model 61 chromatograph, with a column (2 m × 6 mm) of 30% Carbowax 20M on Chromosorb P operating at 130 °C. The amount of benzenethiol present was determined from its peak area relative to that of naphthalene. The relative response of the two was determined from synthetic mixtures. In all acids, a 95–105% yield based on thioacylal was obtained, *i.e.* quantitative within experimental error.

Methanolysis

In a methanol solution containing 0.02 *M* benzenesulfonic acid (monohydrate) were placed the thioacylal (0.02 *M*) and g.c. standard (for the CH_3SCH_2OAc experiment, chlorobenzene; for $C_6H_5SCH_2OAc$, naphthalene). At appropriate intervals this solution was injected directly into the gas chromatograph (conditions as above, the temperature for CH_3SCH_2OAc was 60 °C). The products were identified by comparison of retention times with those of authentic samples. Their yields were calculated from peak areas relative to that of the standard, again referenced to a relative response determined from synthetic mixtures. Control experiments were carried out in the same fashion starting with authentic samples of the products.

The kinetics for the methanolysis of *p*-nitrophenyl acetate were studied in solutions which were 0.01 *M*, 0.03 *M*, and 0.05 *M* in benzenesulfonic acid, by following the increase in u.v. absorbance at 305 nm. The concentration of ester was 2×10^{-4} *M*. Excellent first-order plots of ln $(A_\infty - A_t)$ *vs.* *t* were obtained.

Proton Magnetic Resonance Studies of Dinucleotide Conformation in Aqueous Solution. 2′-Deoxythymidylyl-(3′,5′)-2′-deoxy-3′-thymidylate, d(TpTp)

DONALD J. WOOD,[1] KELVIN K. OGILVIE,[2] AND FRANK E. HRUSKA
Department of Chemistry, University of Manitoba, Winnipeg, Manitoba R3T 2N2

Received January 31, 1975

DONALD J. WOOD, KELVIN K. OGILVIE, and FRANK E. HRUSKA. Can. J. Chem. **53**, 2781 (1975).

Proton magnetic resonance studies of 2′-deoxythymidine, its 3′- and 5′-monophosphate, its 3′,5′-diphosphate, and the dimer molecules d(TpT) and d(TpTp) in aqueous solution are described. Spectral analysis yields ^1H–^1H and ^1H–^{31}P coupling constants and ^1H chemical shifts which can be discussed in terms of the conformational properties of the nucleoside fragments. An important observation is the apparent phosphate–phosphate interaction in a 3′,5′-diphosphate fragment which stabilizes the *gauche-gauche* conformation about the $C_{4'}$—$C_{5'}$ bond.

DONALD J. WOOD, KELVIN K. OGILVIE et FRANK E. HRUSKA. Can. J. Chem. **53**, 2781 (1975).

On décrit des études r.m.p. sur des solutions aqueuses de déoxy-2′ thymidine, de ses monophosphates-3′ et -5′, de son diphosphate-3′,5′ et des molécules dimères d(TpT) et d(TpTp). L'analyse des spectres fournit les constantes de couplage ^1H–^1H et ^1H–^{31}P et les déplacements chimiques du ^1H qui peuvent être discutés en termes de propriétés conformationnelles de fragments nucléosides. Une observation importante est l'interaction apparente phosphate–phosphate dans le fragment diphosphate-3′,5′ qui stabilise la conformation *gauche-gauche* autour du lien $C_{4'}$—$C_{5'}$. [Traduit par le journal]

Introduction

The study by spectroscopic and theoretical methods of the physicochemical properties of nucleosides and their monophosphate derivatives is one approach towards the understanding of the properties of polynucleotides (1–7). These monomer studies do not, however, allow for the evaluation of factors such as internucleoside interactions, phosphate–phosphate interactions etc., which might influence polymer stereochemistry. Studies on 3′,5′-diphosphates (7), however, do provide information on the interactions between adjacent phosphates. Dinucleoside mono-, di-, and triphosphates possessing a 3′,5′-phosphodiester linkage are better model systems. Recent X-ray studies (8–13) have revealed features of dimer stereochemistry in the solid state. Solution studies at the dimer level have been concerned primarily with the problems of base-stacking forces and geometry. Several groups (14–20) have attempted complete analysis of the complex ^1H and ^{13}C spectra of the sugar-phosphate moiety of several dinucleoside monophosphates and discussed the effect of formation of the 3′,5′-phosphodiester linkage upon sugar-phosphate conformation. As a sequel to our study on 2′-deoxythymidylyl-(3′,5′)-2′-deoxythymidine, d(TpT) (17–19), and its u.v. damaged derivative (18, 19), we present here the p.m.r. data of its phosphorylated derivative, d(TpTp) (Fig. 1). Data for 2′-deoxythymidine (dT), its 3′- and 5′-monophosphates (3′dTMP, 5′dTMP), and its 3′,5′-diphosphate (pdTp) (Fig. 2) are also presented. Comparison of all the data

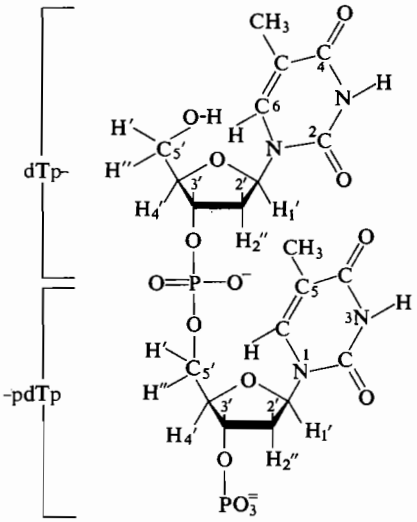

FIG. 1. Structural formula of 2′-deoxythymidylyl-(3′,5′)-2′-deoxy-3′-thymidylate, d(TpTp). dTp- and -pdTp refer to the free 5′- and 3′-terminal fragments of d(TpTp), respectively.

allows us to assess the effect of 3′- and 5′-phosphorylation and incorporation into the nucleoside mono- and diphosphates upon the conformation of dT. An observation of particular interest is the *concerted* enhancement of the *gauche-gauche* conformer population by the 3′- and 5′-phosphates in a nucleoside-3′,5′-diphosphate fragment.

Experimental

The compounds d(TpTp) and pdTp were prepared and purified by the method of Letsinger *et al.* (21). dT was obtained from the Sigma Chemical Co., and used without further purification. The p.m.r. samples were lyophilized three times from D_2O and then were dissolved in 100% D_2O to a concentration of 0.10 *M*. The p*D* of the samples (dT, d(TpTp): 7.0; pdTp: 5.8) was adjusted with NaOD or DCl. Sodium 3-trimethylsilylpropionate-2,2,3,3-d_4 (TSP) was used as an internal reference.

The p.m.r. spectrum of dT was recorded on a Varian HD 100 MHz spectrometer; the spectra of pdTp and d(TpTp) (Fig. 3) were recorded at the Canadian 220 MHz Centre, Sheridan Park, Ontario, on a Varian HR 220 MHz spectrometer. All spectra were analyzed using the computer program LAME (22) and computer simulations (Fig. 3) were used as a final test of the derived chemical shift (δ) and coupling constant (*J*) data. The *J* (H–H and H–P) and δ values (along with data for 3′dTMP, 5′dTMP and d(TpT) from ref. 17) are given in Table 1; the δ data also appear in Fig. 4.

Spectra for pdTp and d(TpTp) were recorded at 65 °C, whereas for dT a slightly higher temperature (70 °C) was required to expose the $H_{3'}$ resonances obscured at 65 °C by the HDO resonance. The relatively high temperature was needed owing to the broadness of the resonances[3] for pdTp and d(TpTp) at ambient (and lower) temperatures. However, except for this line broadening, the general features of the spectra are very similar in the temperature interval examined (30–70 °C). Thus, our main conclusions regarding molecular conformation should apply at the lower temperatures.

In the discussion section dTp- and -pdTp will be used to designate the 5′- and 3′-*terminal* fragments of d(TpTp), respectively. For the corresponding fragments of d(TpT), dTp- and -pdT will be used. Wherever confusion from the use of dTp- might occur, the appropriate dimer, d(TpT) or d(TpTp), will be indicated.

We must also point out here that at our experimental temperatures the dimers are unstacked. Our conformational conclusions apply, therefore, strictly to the extended molecules. In the transition to the folded forms the conformational distributions about the P—O bonds, in particular, and about the $C_{4'}$—$C_{5'}$ and $O_{5'}$—$C_{5'}$ bonds to a lesser extent, will change.

Results and Discussion

Spectral Assignment

The spectral assignments for dT, 3′dTMP, 5′dTMP, and d(TpT) have been presented (17). The assignment of the spectra of pdTp was facilitated by comparison with those of the other monomers (dT, etc.) and confirmed by decoupling experiments. In the 2′,2″ region of the pdTp spectrum, $H_{2''}$ was assigned to the low-field portion on the basis of arguments by Fang *et al.* (23) concerning the deshielding influence of a 3′-phosphate on the *cis* ($H_{2''}$) hydrogens. In the 5′,5″ region of all molecules examined here, $H_{5'}$ was assumed to be to low field of $H_{5''}$ (following Remin and Shugar (24)).[4]

The assignment of the various bands in the spectrum of d(TpTp) was initiated with the assumption that the quartets at 6.37 and 6.25 p.p.m. were attributable to the 1′-hydrogens of the -pdTp and dTp- fragments, respectively. This assumption is made reasonable by the appearance of $H_{1'}$ (pdTp) at 6.37 p.p.m. and $H_{1'}$ (3′dTMP) at 6.28 p.p.m. Spin decoupling experiments facilitated the location of bands attributable to other hydrogens on the two fragments. Differentiation between the 2′- and 2″-hydrogens on the dTp- fragment and between the 2′- and 2″-hydrogens on -pdTp was first made with the assumption that the deshielding effect on 3′-phosphorylation at the monomer level (dT → 3′dTMP; 5′dTMP → pdTp) was similar to its effect at the dimer level (d(TpT) → d(TpTp)). The assignment made on this basis is

[3]Extensive hydration may contribute to the line broadening; the dinucleotide d(pTpT) is extensively hydrated in the solid state (13).

[4]We cannot be certain that the Remin and Shugar assignment applies to each of the molecules examined here. However, because we are concerned, in the $C_{4'}$—$C_{5'}$ conformational problem, primarily with the *gg* population, any misassignment is not serious since the calculated P_{gg} values are invariant with change in 5′,5″ assignment. See footnote 1 in ref. 25 for comments on 5′,5″ assignment in 2′-deoxyriboses.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

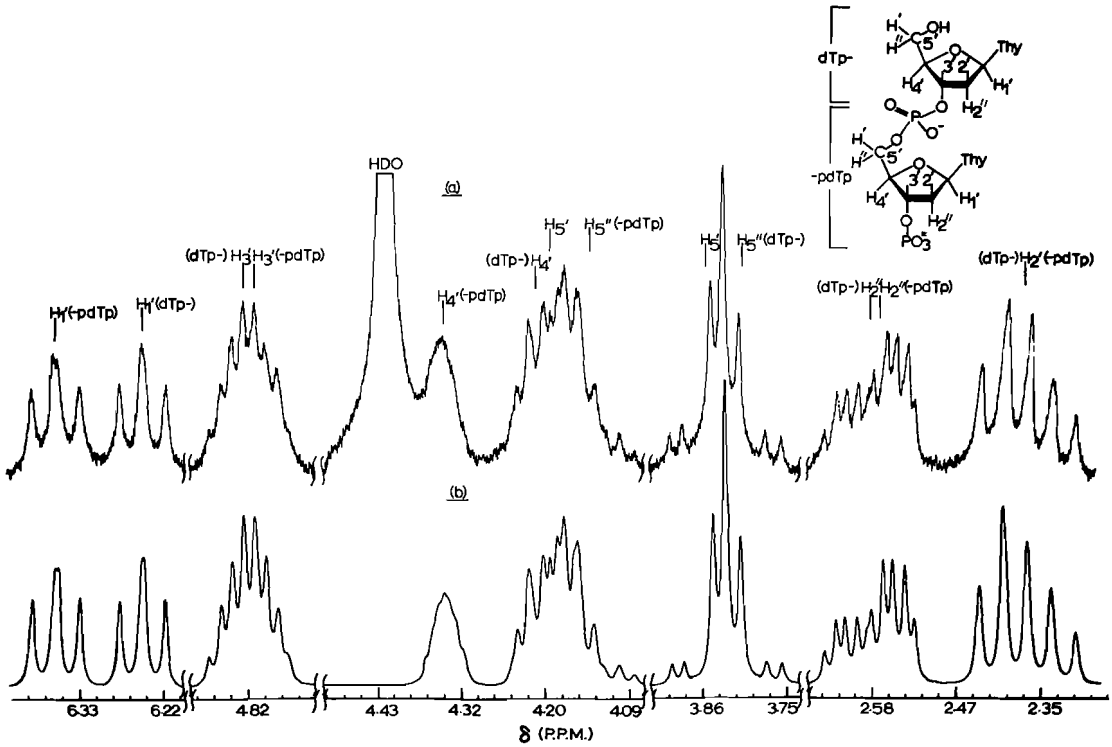

FIG. 3. (*a*) Single scan, continuous-wave, 220 MHz spectrum of d(TpTp) (p*D* 7.0, 65 °C, 0.1 *M* in D_2O). Sweep width 250 Hz. (*b*) Computer simulated spectrum. Included for simulation were $J_{2',P_3'} = 0.7$ Hz and $J_{4',P_3'} = 0.5$ Hz for both 3′-nucleotide fragments and $J_{3',5''} = 0.9$ Hz for -pdTp. Similar magnitudes are indicated for these coupling constants in the spectrum of pdTp.

consistent with a 2′,2″ assignment based on the assumptions that $J_{2'',3'} \simeq J_{3',4'}$ and $J_{1',2''} \simeq J_{2',3'}$ for 'normal' (26, 27) 2′-deoxyriboses (17).

The 2′,2″ assignments for all entries (except those for 5′dTMP and the -pdT fragment of d(TpT)) in Table 1 adhere to the proposal that $J_{2'',3'} \simeq J_{3',4'}$ and $J_{1',2''} \simeq J_{2',3'}$. In the exceptional cases $H_{2'}$ and $H_{2''}$ are too strongly coupled for meaningful assignment and only the sums $J_{1',2'} + J_{1',2''}$ and $J_{2',3'} + J_{2'',3'}$ can be obtained; in Table 1 one-half of the appropriate sum has been arbitrarily entered for these four coupling constants.

The Sugar-Base Torsion Angle (χ)

Accurate χ values (2, 13, 28, 29) for crystalline 2′-deoxythymidine residues (dT, 39.3 °C; 5′dTMP, 43.5 °C; pdTp- of d(pTpT), 27 °C; -pdT of d(pTpT), 34 °C) reveal a remarkable degree of conformational similarity in dT fragments and the absence of drastic changes in χ(*anti*) upon 3′- or 5′-phosphorylation of dT or upon its incorporation into a dimer molecule. In *solution* the chemical shift of the 6-hydrogen should be sensitive to changes in χ (30). The striking similarity in the δ_6 values for the series dT, 3′dTMP, dTp- of d(TpT) and dTp- of d(TpTp) argues, therefore, that extension of the dT molecule in the 5′ → 3′ direction by sequential addition of a 3′-phosphate, a dT fragment, etc., has little effect on the χ-value distribution under our experimental conditions. This suggestion is supported by the relative invariance, for this same series, of the $\delta_{1'}$ values which fall in the narrow range from 6.24 to 6.28 p.p.m. Similarly, the relative invariance of the δ_6 data on the one hand and the $\delta_{1'}$ data on the other for the 5′-phosphorylated fragments (5′dTMP, -pdT of d(TpT)) and for the 3′,5′-phosphorylated fragments (pdTp and -pdTp of d(TpTp)) indicates that extension in the 3′ → 5′ direction has little influence on χ(dT). The remarkable

[a]Chemical shifts reported in p.p.m. from TSP. Coupling constants reported in Hz. Estimated errors: J, ±0.3 Hz; δ, ±0.01 p.p.m.
[b]See experimental for abbreviations.
[c]dT at 70 °C.
[d]Data from ref. 17.
[e]All J_{Pi} are ^3J except $J_{P4'}$ ($=^4J$) which involves the P atom and $H_{4'}$ displaced in the 5′ → 3′ sense.
[f]$\Sigma = J_{4'5'} + J_{4'5''}$.
[g]$\Sigma' = J_{P5'} + J_{P5''}$.
[h]Not observed or not applicable.
[i]The 0.01 p.p.m. shift is arbitrary *i.e.* $\delta_i \simeq \delta_j$.
[j]Owing to near equivalence of chemical shifts, only the sum of connected ([) coupling constants is significant.
[k]Arbitrary. When $\delta_i \simeq \delta_j$, the spectrum is independent of J_{ij}.
[l]Owing to overlap of resonances, these values are less certain.

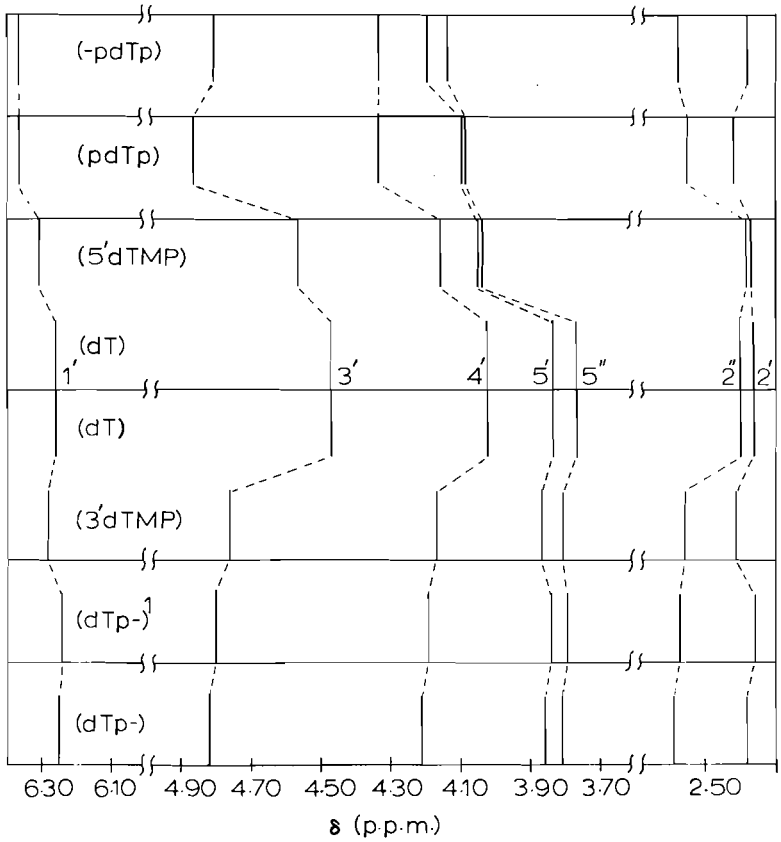

FIG. 4. Chemical shifts of the deoxyribo hydrogens of dT, 3′dTMP, 5′dTMP, pdTp, d(TpT), and d(TpTp) in p.p.m. relative to internal TSP. Plotted data from Table 1. $(dTp-)^1$ and (dTp-) refer, respectively, to the dTp- fragment of d(TpT) and d(TpTp). In comparing $\delta_{3'}$ for -pdTp and pdTp, bear in mind that the acidity conditions (experimental section) were such that the 3′-phosphate in the former is diionized and monoionized in the latter. At $pD < 5.5$, $H_{3'}$(-pdTp) is located 0.09 p.p.m. to lower field.

conservation of χ(dT) values in the solid state is apparently achieved in aqueous solution as well.

Puckering of the 2′-Deoxyribose

The magnitudes of the *trans* coupling constants ($J_{1'2'}$, $J_{2''3'}$, $J_{3'4'}$) and the *cis* coupling constants ($J_{1'2''}$, $J_{2'3'}$) are related to the mode and extent of puckering of the 2′-deoxyribose ring (26, 27). A striking feature of these data in Table 1 is the similarity in corresponding values for all entries. Thus we must conclude that the puckering of a dT fragment is little affected by 3′- or 5′-phosphorylation or by incorporation into the dimer molecules. What little variation there is in the *J* values conforms, however, with our expectations based on a 2′-*endo* (S) ↔ 3′-*endo* (N) model. Firstly, we note that the overall range for the *trans* coupling constants is consistently larger ($J_{1'2'}$ = 1.3 Hz; $J_{2''3'}$ = 2.3 Hz; $J_{3'4'}$ = 1.0 Hz) than that for the *cis* coupling constants ($J_{1'2''}$ = 0.6 Hz; $J_{2'3'}$ = 0.7 Hz). This is expected since, whereas the *cis* pairs of hydrogens (1′2″, 2′3′) assume a quasi-axial-equatorial (*ae*) disposition in both the 2′- and 3′-*endo* modes, the disposition of the *trans* pairs (1′2′, 2″3′, 3′4′) alters from *aa* (or *ee*) to *ee* (or *aa*) in the 2′-*endo* to 3′-*endo* change. Thus any shift in the 2′-*endo* ↔ 3′-*endo* balance should be manifest in proportionate changes in the *trans* coupling constants and (somewhat) attenuated changes in the *cis* values (26, 27). Secondly, there is a prevailing tendency for $J_{2''3'}$ and $J_{3'4'}$ to increase concomitantly with decreases in $J_{1'2'}$. These inverse relations are best revealed by the relative constancy of the sums $J_{1'2'} + J_{3'4'}$ which lie in the range 11.0 ± 0.3 Hz for our molecules and by the sums $J_{1'2'} + J_{2''3'}$ which, with pdTp excepted, lie in the range 11.1 ±

0.2 Hz. The larger deviation from the norm for $J_{1'2'} + J_{2''3'}$ for pdTp (10.3 Hz) might be a consequence of a somewhat less accurate value for $J_{2''3'}$ owing to obscured fine structure in the 3′ region of its proton spectrum, though a conformational interpretation cannot be discounted (see below).

An approximation of the relative contributions to the 2′-*endo* ↔ 3′-*endo* blend can be obtained from [1].

$$[1] \qquad \% \text{ 3′-}endo = 10J_{3'4'}$$

In Table 2 we have entered the % populations of the predominant (2′-*endo*) form. A bias of 60–70% for 2′-*endo* is evident in each instance. At the monomer level phosphorylation appears to enhance the 2′-*endo* bias within the small overall range. Incorporation into the dinucleoside mono- or diphosphate does not produce significant further change in this bias. This conservation of structure is also apparent in the crystal state; with only two exceptions (2, 31, 32) 2′-deoxyribo rings favor the 2′-*endo* pucker in the solid state.

One further trend appears in the data in Table 1. For dT we find that $J_{2''3'}$ is *larger* than $J_{3'4'}$ by 0.6 Hz; for the 3′-phosphorylated species (3′dTMP, dTp- of d(TpT) and of d(TpTp)), $J_{2''3'}$ and $J_{3'4'}$ differ by only 0.1 Hz whereas in the 3′,5′-phosphorylated species (pdTp and -pdTp of d(TpTp)) $J_{2''3'}$ is *smaller* than $J_{3'4'}$ by 0.6–0.7 Hz. Thus there appears to be a significant (1.3 Hz) spread in the difference $J_{2''3'} - J_{3'4'}$ in this series of molecules. This trend is understood (26, 27) if, in the sequence from dT to 3′-phosphorylated fragments to 3′,5′-phosphorylated fragments, the characteristic P_N values increase and/or the P_S values decrease.[5] If this is the appropriate interpretation of the trend in the value of $J_{2''3'} - J_{3'4'}$, then we must further predict, following Altona and Sundaralingam (27), that for 2′-*endo* decreases in $J_{2''3'} - J_{3'4'}$ should be coupled to decreases in $J_{1'2''}$ and to increases in $J_{2'3'}$ values. Trends in the *cis* couplings are less clear because of their small overall variation but it is interesting nevertheless to observe (Table 1) that, as $J_{2''3'} - J_{3'4'}$ *decreases* by 1.3 Hz as we pass from dT to pdTp, $J_{1'2''}$ *decreases* by 0.6 Hz while $J_{2'3'}$ *increases* by 0.4 Hz. In fact for the entries in Table 1 there is the prevailing tendency for $J_{1'2''} - J_{2'3'}$ to decrease with $J_{2''3'} - J_{3'4'}$. These correlated decreases are expected for a decrease in phase angle of pseudorotation P in 2′-*endo*, the favored pucker of 2′-deoxyriboses (26, 27). To summarize in conformational terms, we state that our data are consistent with shifts towards lower P_S values upon phosphorylation of a dT fragment. Granted, this statement follows from interpretation of small changes in coupling. Nevertheless it will be interesting to see whether similar trends can be observed in the more accurately-determinable crystal conformations. This comparison awaits evaluation of the effects of phosphorylation (and incorporation into dimer molecules) on the phase angle of pseudorotation in crystalline 2′-deoxyribosides.

[5] P_N and P_S are the so-called 'phase angles of pseudorotation' for the N and S ranges (26, 27).

Conformation about the Exocyclic $C_{4'}$—$C_{5'}$ Bond

The $J_{4'5'}$ and $J_{4'5''}$ data can be translated into approximate values of the *gauche-gauche* (*gg*), *gauche-trans* (*gt*), and *trans-gauche* (*tg*) populations (Fig. 5) according to ref. 17. The main trends in the calculated populations (P_{gg}, P_{gt}, P_{tg} in Table 2) are as follows. (*i*) In the series dT, 3′dTMP, dTp- of d(TpT) and dTp- of d(TpTp) which progresses by extension in the 5′ → 3′ direction, we find little change in the $C_{4'}$—$C_{5'}$ rotamer population for the free 5′-terminal hydroxymethyl group. The *gg* conformation in this series is slightly favored but remains in the nar-

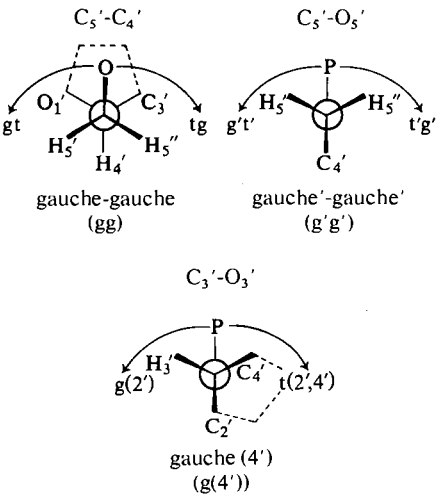

FIG. 5. Dominant conformations viewed along the $C_{5'}$–$O_{5'}$ bond (*gauche'-gauche'* (*g'g'*), *gauche'-trans'* (*g't'*), *trans'-gauche'* (*t'g'*)), the $C_{4'}$—$C_{5'}$ bond (*gauche-gauche* (*gg*), *gauche-trans* (*gt*), *trans-gauche* (*tg*)), and the $C_{3'}$—$O_{3'}$ bond (*gauche* (2′) (*g*(2′)), *gauche* (4′) (*g*(4′)), *trans* (2′,4′) (*t*(2′,4′))).

row range from 41–48%. (*ii*) 5′-Phosphorylation of dT enhances the *gg* bias (5′dTMP: 55%) and (*iii*) this bias is further enhanced by subsequent phosphorylation at the 3′-position (pdTp: 64%). (*iv*) Incorporation of 5′dTMP into the dimer d(TpT) has little effect on P_{gg} (-pdT: 55%). However, 3′-phosphorylation of d(TpT) enhances noticeably the P_{gg} value for this fragment (-pdTp of d(TpTp): 64%) in line with observations at the monomer level (point *iii*). We should point out here that both dimer molecules are probably predominantly in the extended form at our experimental (65 °C) temperature. For dimer molecules in a stacked conformation, larger calculated P_{gg} values (100%?) are expected. (*v*) The extension of a 5′-thymidylyl fragment in the 3′ → 5′ direction has little effect upon P_{gg} for this fragment. (Compare data for 5′dTMP and -pdT of d(TpT) and for pdTp and -pdTp of d(TpTp).)

The observed trends (points *i–v*) are, for the most part, in agreement with X-ray data. Thus, *gg* appears most often in 2′-deoxyriboses at the monomer level (2) and at the dimer level (13). The increase in P_{gg} with 5′-phosphorylation (point *ii*) and the absence of significant variation in P_{gg} for dT, 3′dTMP, dTp- of d(TpT) and of d(TpTp) (point *i*) are consistent with the "rigid nucleotide" concept (2, 33) which proposes that 5′- (but not 3′-phosphorylation *by itself*) will enhance the *gg* conformer population.

The effect of 3′-phosphorylation upon P_{gg} of a 5′-nucleotide (points *iii* and *v*) is interesting since it must (in view of the absence of a similar effect at the nucleoside level (point *i*)) be a manifestation of an interaction between the phosphates on a 3′,5′-diphosphate. Estimations of the magnitude of this interaction can be made using the P_{gg} etc., values for -pdT of d(TpT) and for -pdTp of d(TpTp); they reveal a destabilizing effect of the 3′-phosphate of 250 and 500 cal/mol, respectively, upon the *gt* and *tg* conformers *relative* to the energy of *gg*. That the destabilization is larger for *tg* is reasonable since the negatively charged phosphates can be at minimum separation when the 3′,5′ diphosphate is *tg*. However, the destabilization of *gt* relative to *gg* can not be related simply to separation of charges since it is in *gt* rather than in *gg* that the maximum phosphate–phosphate separation is obtained. It should be of interest to compare the 3′-phosphate effect noted here with the calculations by Yathindra and Sundaralingam (7) on 5′dTMP and pdTp. These authors have estimated for the $C_{2'}$-*endo* situation that the *gg* conformation is slightly destabilized (0.3–0.4 kcal) by 3′-phosphorylation; this translates into a reduction from 94 to 90% in their estimated *gg* population. For $C_{3'}$-*endo* sugars the calculations reveal a larger decrease from 90 to 62% in the *gg* population resulting from 3′-phosphorylation.

Conformation about the $O_{5'}—C_{5'}$ Bond

The $J_{5'P}$ and $J_{5''P}$ values can be translated (17) into values of the *gauche'-gauche'* (*g'g'*), *gauche'-trans'* (*g't'*), and *trans'-gauche'* (*t'g'*) conformer populations ($P_{g'g'}$, $P_{g't'}$, $P_{t'g'}$) of a 5′-nucleotidyl fragment (Fig. 5). In 5′dTMP and pdTp the 5′- and 5′′-hydrogens are strongly coupled; thus

only the sum, $\sum'$ ($= J_{5'P} + J_{5''P}$) can be determined and translated into $P_{g'g'}$ and $P_{g't'} + P_{t'g'}$ values (17). The important conclusions which may be drawn from the calculated rotamer populations (Table 2) are as follows. Firstly, all 5′-nucleotide fragments (5′dTMP, pdTp, -pdT of d(TpT), -pdTp of d(TpTp)) show a pronounced preference for $g'g'$. This is consistent with previous work (34) that revealed in 5′-nucleotides a bias for $g'g'$ that surpassed their bias for gg. The $g'g'$ conformation is found in all crystalline 5′-nucleotides studied.

Second, in ref. 34 a linear correlation between $\sum(P_{gg})$ and $\sum'(P_{g'g'})$ values for the 5′-monophosphates was revealed; it is consistent with the view that a $g'g'$ conformation is a required feature of a gg oriented molecule, whereas for gt (or tg), $g'g'$ is no longer required but is nevertheless still preferred. Interestingly the $\sum,\sum'$ data for the 5′-nucleotide fragments studied here fall near to the correlation line. Through a consideration of space-filling models, this correlation between the conformer distribution about $C_{4'}$—$C_{5'}$ and $O_{5'}$—$C_{5'}$ may be rationalized. When any β-5′-nucleotide is rotated into its gg form, unfavorable close-contact interactions between the phosphoryl oxygens and the furanose and base substituents preclude rotation into the $g't'$ and $t'g'$ conformations. However, if we rotate the molecule into either the gt or tg forms, the hindrance from the base to rotation about $O_{5'}$—$C_{5'}$ is removed and that from the sugar ring substituents becomes less severe. On this basis the $g't'$ and $t'g'$ modes are expected to become more accessible in a gt or tg orientation. Furthermore, it is reasonable to postulate *similar* conformational distributions about $O_{5'}$—$C_{5'}$ for all gt (tg) oriented β-5′-nucleotides since the important distinguishing feature (the base) now lies distant from the 5′-phosphate. In other words, it appears that the conformational state of the $C_{4'}$—$C_{5'}$ bond is of foremost importance insofar as the conformational preferences about $O_{5'}$—$C_{5'}$ are concerned. The location of $\sum,\sum'$ data for -pdT of d(TpT) and -pdTp of d(TpTp) near to the $\sum,\sum'$ correlation plot defined originally by a collection of 5′-monophosphates must mean, therefore, that addition of a dT fragment onto the 5′-phosphate of 5′dTMP or of pdTp does not lead to any *new steric* interactions which might influence the $O_{5'}$—$C_{5'}$ conformational distribution. This is again clear from space-filling models of a dimer. When the 5′-nucleotide fragment of d(TpT) or d(TpTp) is oriented gg (and necessarily $g'g'$) or when it is oriented $gt(tg)$ (and preferentially but not necessarily $g'g'$), the dT fragment on the 5′-phosphate is distant from the sugar and thus can introduce no new steric interactions.

Third, we note that 3′-phosphorylation enhances $P_{g'g'}$ at the monomer level. (Compare $P_{g'g'}$ for 5′dTMP and pdTp.) This is expected in view of the influence that 3′-phosphorylation has on P_{gg} of 5′dTMP and the demonstration that $g'g'$ is excluded in gg oriented 5′-nucleotides. However, though we expect an increase of $P_{g'g'}$ for -pdTp of d(TpTp) relative to -pdT of d(TpT) this is not observed.

The four-bond $^4J_{P4'}$ couplings provide information about the $C_{4'}$—$C_{5'}$ and $O_{5'}$—$C_{5'}$ bond conformations (35) although they are expected to be less reliable than $\sum$ and $\sum'$ as conformational (P_{gg} and $P_{g'g'}$) probes owing to their small magnitudes. Using the correlation plots of P_{gg} and $P_{g'g'}$ *vs.* $^4J_{P4'}$ (35) and the values of $^4J_{P4'}$ (Table 1), we estimate the P_{gg} ($P_{g'g'}$) values: 5′dTMP, 63% (81%); -pdT, 68% (83%); pdTp, 63% (81%); -pdTp, 72% (84%). Considering the uncertainty in translating coupling constants into populations, we feel the agreement is good between these estimates and those made from the magnitudes of the vicinal coupling constants (Table 2). Thus our data support the contention that 5′-monophosphates and 5′-nucleotidyl fragments of oligonucleotides possessing the thymine base show a bias for the gg conformation and a stronger bias for the $g'g'$ conformation. One should bear in mind that under the experimental conditions employed ($T \simeq 70$ °C) the dimers are largely destacked. Helical polynucleotides are expected to assume in solution the gg, $g'g'$ combination with the virtual exclusion of any of the *trans* conformers about the $O_{5'}$—$C_{5'}$ and $C_{5'}$—$C_{4'}$ bonds. Our findings for the dimers should be useful in any discussion of the conformational consequences of the denaturation of an ordered oligonucleotide. Further, our data reveal a prevailing tendency towards the gg, $g'g'$ combination as the chain is elongated with phosphate and nucleoside fragments. Recent n.m.r. studies (36) have revealed that base stacking in dinucleoside monophosphates enhances the gg, $g'g'$ bias.

Conformation about the $C_{3'}$—$O_{3'}$ Bond

The magnitude of the vicinal $J_{P3'}$ is related to the conformation about $C_{3'}$—$O_{3'}$ of a 3′-nucleotide fragment (Fig. 5). All values lie in the nar-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

row range from 6.4 to 7.6 Hz. However, these values cannot be interpreted in an unambiguous way if one expects a 3–5 Hz value for a *gauche* $J_{P3'}$ and 23–25 Hz value for a *trans* $J_{P3'}$. Previously (5, 15–17) 6.0–9.0 Hz values have been interpreted as evidence for the $g(2')$ and/or $g(4')$ conformational ranges. However, one cannot rule out contributions from $t(2',4')$ on the basis of $J_{P3'}$ coupling constants of this magnitude.

Chemical Shifts

The trends in the δ values for the hydrogens of the deoxyribo moieties are consistent with our spectral assignment and conformational conclusions. The 'stick' representation (Fig. 4) facilitates discussion. Centered in the diagram is the data for dT. Upon 3′-phosphorylation (3′dTMP) downfield shifts are observed for the 3′-hydrogen and the *exo* hydrogens near to the 3′-position ($3' > 4' \simeq 2''$) whereas the *endo* hydrogens (2′, 5′, and 5″) are considerably less influenced by 3′-phosphorylation. The *exo*-$H_{1'}$ is also little affected as might be predicted from the 1′–3′ separation. Extension in the 5′ → 3′ direction to dTp- of d(TpT) and of d(TpTp) produces little further change in δ for any hydrogen. This is to be expected since this extension does not result in major conformational changes in the original dT fragment. Furthermore, in the *unfolded* dimer conformation no significant shielding effects from the 3′-terminal base is expected. The similarity in the δ values for 3′dTMP and dTp- of the dimers, coupled with the similarity in their $J_{P3'}$ values suggests that 5′ → 3′ extension has not drastically altered their $C_{3'}$—$O_{3'}$ conformational distribution.

5′-Phosphorylation of dT produces large changes in δ(5′,5″) and smaller changes in δ(3′,4′), as expected from distance considerations. Considerably smaller effects (<0.05 p.p.m.) are noted for δ(1′,2′,2″). It is interesting to point to the absence of any influence of 5′-phosphorylation on $\delta_{2'}$ since rotation of 5′-dTMP in the *gg*, *t′g′* conformation places $H_{2'}$ near to the negative charge. However, earlier solution studies (35, 36) revealed that the *trans* conformations (*t′g′* and *g′t′*) are not likely in *gg* oriented 5′-monophosphates; they have never been observed in the crystal state under any circumstances (2, 3, 37). 3′-Phosphorylation of 5′dTMP (pdTp) parallels in a striking manner its influence on the δ values of dT. This is best seen from comparison of δ(dT-3′dTMP) and δ(5′dTMP-pdTp) values for each hydrogen (in p.p.m.): 1′(0.02, 0.06); 2′(0.05, 0.05); 2″(0.16, 0.17); 3′(0.29, 0.30); 4′(0.14, 0.18); 5′(0.03, 0.05); 5″(0.04, 0.05), respectively. Extension of pdTp to -pdTp has little effect on the shifts except for the 0.1 p.p.m. downfield shift of $H_{5'}$.

Conclusions

The p.m.r. data of dT, 3′dTMP, 5′dTMP, -pdTp, d(TpT), and d(TpTp) in aqueous solution are discussed. They reveal that the conformation of the dT nucleoside fragment is similar in this series of molecules. However, 5′-phosphorylation, but not 3′-phosphorylation, of dT enhances the population of the *gg* conformer. This observation is consistent with the rigid nucleotide concept. 3′-Phosphorylation of a 5′-nucleotidyl fragment (5′dTMP → pdTp; d(TpT) → d(TpTp)) enhances the population of the *gg* conformation. This enhancement suggests the presence of a through-space interaction between a 3′-phosphate and a 5′-phosphate which stabilizes the *gg* conformer relative to the *gt* and *tg* conformers. During the course of this study several n.m.r. papers on nucleotide stereochemistry have appeared (38–40). Their results are in good agreement with our discussion of mononucleotides.

This research was supported by grants from the National Research Council of Canada, The North Atlantic Treaty Organization, and The Faculty of Graduate Studies. We thank Dr. A. A. Grey and Mrs. Valerie Robinson of the Canadian 220 MHz Centre for obtaining the 220 MHz spectra and the members of the n.m.r. group in Manitoba for valuable discussions.

A new stereoelectronic theory for the cleavage of the tetrahedral intermediate (hemiorthoamide) in the hydrolysis of amides is presented. In this new theory, the precise conformation of the tetrahedral intermediate controls the nature of the hydrolysis products. It is postulated that the breakdown of the tetrahedral intermediate depends upon the orientation of the lone pair orbitals of the heteroatoms. Specific cleavage of a carbon–oxygen or a carbon–nitrogen bond in any conformer is allowed only if the other heteroatoms (oxygen and nitrogen) each have an orbital oriented antiperiplanar to the leaving *O*-alkyl or *N*-alkyl group. Experimentally, a study of the basic hydrolysis of a variety of *N,N*-dialkylated imidate salts having either a *syn* or an *anti* conformation demonstrates clearly that there is a stereoelectronic control in the cleavage of the hemiorthoamide.

PIERRE DESLONGCHAMPS, SERGE DUBÉ, CLAUDE LEBREUX, DENNIS R. PATTERSON et ROLAND J. TAILLEFER. Can. J. Chem. **53**, 2791 (1975).

Une nouvelle théorie stéréoélectronique sur la décomposition de l'intermédiaire tétrahédrique (hémi-orthoamide) au cours de l'hydrolyse des amides est présentée. Dans cette nouvelle théorie, il y a une relation directe entre la conformation précise de l'intermédiaire tétrahédrique et la nature des produits d'hydrolyse. Il est aussi postulé que c'est l'orientation des paires d'électrons libres sur les hétéroatomes qui contrôle la décomposition de l'intermédiaire. La coupure d'un lien carbon–oxygène ou d'un lien carbone–azote d'un intermédiaire est permise lorsque les deux autres hétéroatomes possèdent chacun une orbitale d'électrons libres orientée d'une manière antipériplanaire au groupe partant (*O*-alkyl ou *N*-alkyl). On démontre expérimentalement par l'hydrolyse en milieu basique sur des sels imidates ayant une conformation *syn* ou *anti* qu'il y a effectivement un contrôle stéréoélectronique lors de la décomposition d'un hémiorthoamide.

Introduction

We have recently reported a new stereoelectronic theory for the hydrolysis of esters (1, 2) and amides (2, 3). In this new theory, the nature of the products formed from the hydrolysis of an ester or amide depends upon the conformation of the tetrahedral hemiorthoester or hemiorthoamide intermediate formed in the reaction. It is further postulated that the breakdown of a tetrahedral conformer depends upon the orientation of the lone pair orbitals of the heteroatoms; specific cleavage of a carbon–oxygen or a carbon–nitrogen bond being allowed only if the other two heteroatoms (oxygen or nitrogen) of the tetrahedral intermediate each have an orbital oriented antiperiplanar to the leaving *O*-alkyl or *N*-alkyl group.

We have reported in detail our experiments which show that there is indeed a stereoelectronic control in the cleavage of hemiorthoesters (1). We have also obtained experimental evidence that there is a stereoelectronic control in the cleavage of hemiorthoamides (3), based on a study of the basic hydrolysis of some *N,N*-dialkylated imidate salts. These results were published in a preliminary form (3). We have now completed this work with a variety of imidate salts and wish to detail our results.[2]

When we started this investigation, it was clear to us that we could obtain experimental evidence for the new stereoelectronic theory by observing the products formed from the cleavage of a hemiorthoamide such as **2**. Consequently, it was first important to find a method for the generation of a hemiorthoamide which would then break down to products (ester or amide) in an irreversible manner. It is not possible to produce

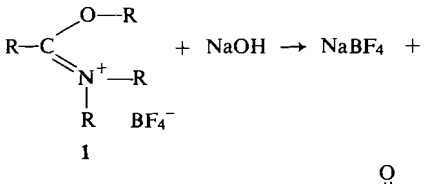
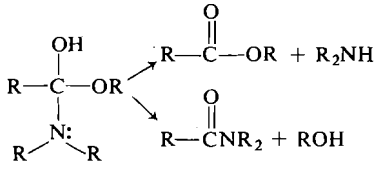
such a hemiorthoamide in a mild and irreversible fashion by treating an amide with an alkoxide (hydroxide) ion. Similarly, it cannot be obtained by treating an ester with an amide anion. It was therefore desirable to find an alternative precursor to the hemiorthoamide. An ideal precursor appeared to be an *N,N*-dialkylated imidate salt, which can be considered to be an activated amide. Indeed, it is known that imidate salts are rapidly hydrolyzed under basic conditions, at room temperature, to give ester and amine or amide and alcohol as products (7).



1



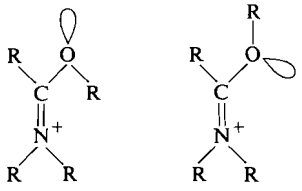
2

When a fluoroborate imidate salt such as **1** reacts with sodium hydroxide, it forms sodium fluoroborate and the intermediate **2** which rapidly breaks down to the products of the reaction. The amide and alcohol products will always completely predominate over the ester and amine products under equilibrating conditions. The amide and alcohol products are therefore the thermodynamic products resulting from the cleavage of the intermediate **2**. If ester and amine are obtained as products, it is clear that it is the result of kinetically controlled cleavage of **2** and will indicate that the transition state leading to those products is of lower energy than the one leading to the more stable amide and alcohol products. However, it is possible that in some cases, the amide and alcohol are also the kinetic products of the cleavage of the intermediate **2**. In such a circumstance, it is in principle possible to use the result as evidence for the new stereoelectronic theory, if it can be clearly established that the reaction is kinetically controlled. If the corresponding ester and amine are not converted into the thermodynamic products under the experimental conditions, it demonstrates that the formation of amide and alcohol is the result of a kinetically controlled cleavage of the intermediate **2**.

It is experimentally very difficult to know the precise conformation of a hemiorthoamide such as **2**. However, the conformation of **2** can be obtained indirectly by the utilization of the new stereoelectronic theory and the knowledge of the precise conformation of the starting imidate salt **1**. If a good correlation between the proposed conformation of **2** and its cleavage is obtained, it constitutes experimental evidence in favor of the new stereoelectronic theory. Thus, the conformation of the imidate salts must first be taken into consideration.

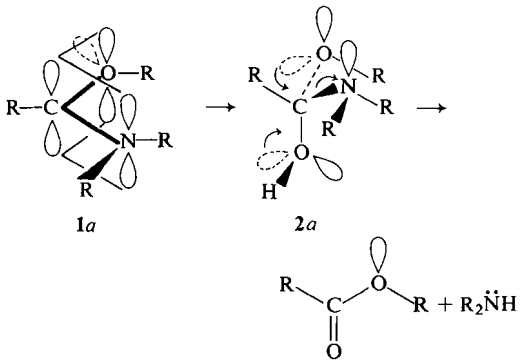
Stereoelectronic Control in the Cleavage of Hemiorthoamide

We believe that imidate salts are planar and thus can exist in two different conformations, the *anti* (**1***a*) or the *syn* (**1***b*) form. In the *anti* conformation **1***a*, the O—R bond is antiperiplanar to the C—R bond. In the *syn* conformation **1***b*, the O—R bond is *cis* to the C—R bond. Application of the new stereoelectronic theory on each type of imidate salt leads to the following predictions concerning the precise conformation of the intermediate **2** and to the manner by which each conformer of **2** should then break down.



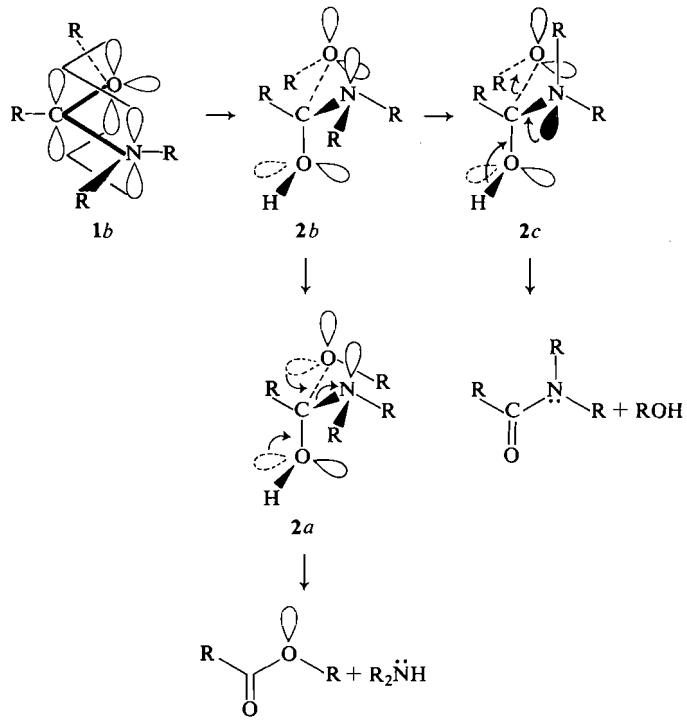
1*a* **1***b*

According to this theory, the reaction of hydroxide ion with the *anti* form **1***a* of an imidate salt should give the tetrahedral conformer **2***a* specifically (Scheme 1). Conformer **2***a* is the



1*a* **2***a*

SCHEME 1



SCHEME 2

result of hydroxide ion attack perpendicular to the plane of the salt **1***a*. The conformation of the starting imidate salt **1***a* is thus transposed to the intermediate **2***a*; the R—C bond in **2***a* is antiperiplanar to the O—R bond and to one of the N—R bonds as in the *anti* imidate **1***a*.[3] As a consequence of the stereoelectronic theory, one of the lone pair orbitals of the oxygen of the OR group and the lone pair orbital of the nitrogen must be oriented antiperiplanar to the new carbon–oxygen bond. Thus, the reverse reaction, the ejection of the hydroxyl group can be achieved by an orbital assisted mechanism because there are two heteroatoms each having a lone pair orbital properly oriented antiperiplanar to the leaving group. The principle of microscopic reversibility is thus adhered to.

One more assumption has to be made to render the preceding theory valid. Whenever a tetrahedral intermediate possesses proper orbital orientation, its half-life is very short and it breaks down to products immediately. This implies that the energy barrier for conformational changes by rotation of C—N and C—O bonds in **2***a* is higher than the energy barrier for its breakdown. With such a condition, no tetrahedral conformer other than **2***a* must be taken into consideration.

Examination of the orientation of the lone pair orbitals in **2***a* indicates that this conformer should break down to yield the ester and the amine only. The nitrogen orbital is not properly oriented to assist in expelling the OR group. At the same time, both oxygens have a lone pair orbital oriented antiperiplanar to the C—N bond to permit a facile ejection of the amino group. Consequently, it is predicted that the basic hydrolysis of the *anti* form **1***a* of an imidate salt should lead to the exclusive formation of ester and amine as a result of the cleavage of conformer **2***a*.

If the preceding stereoelectronic theory is valid, the reaction of hydroxide ion on the *syn* form **1***b* will give specifically the conformer **2***b* (Scheme 2). Again, **2***b* is the result of an attack perpendicular to the plane of the salt **1***b* by hydroxide ion. The conformation of **1***b* has also been retained in the intermediate **2***b*. There are lone pair orbitals on

[3]In principle, hydroxide ion attack on the imidate can either lead to conformer **2***a* or two other conformers which differ in the orientation of the O—H bond. These three conformers can be interconverted by proton transfer. This interconversion occurs at a diffusion controlled rate (8). Since we assume that the breakdown of the tetrahedral intermediate is a slower process than proton transfer, the three conformers are therefore equivalent as far as the theory is concerned.

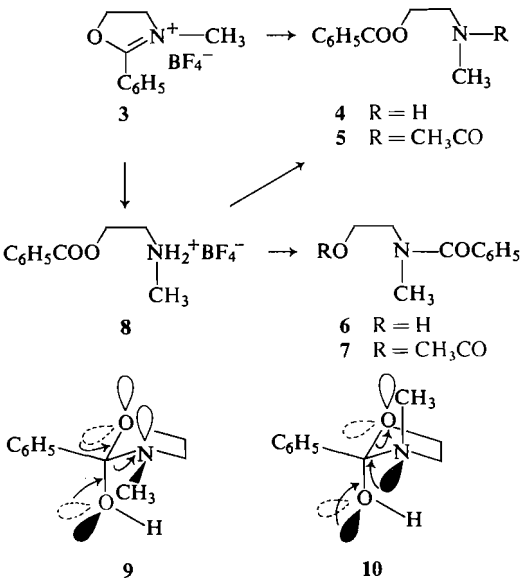
the nitrogen and on the oxygen of the OR group which are each oriented antiperiplanar to the C—OH bond.

It is interesting to note that conformer **2***b* cannot break down to products by an orbital assisted mechanism; the nitrogen nonbonded orbital is not antiperiplanar to the C—OR bond. Similarly, the oxygen atom of the OR group does not have a nonbonded orbital properly oriented antiperiplanar to the C—N bond. In this case, we postulate that rotation of C—N and C—O bonds in conformer **2***b* becomes more facile than its breakdown to products and new conformers must be considered. If these new conformers have their orbitals properly oriented, they will break down immediately to give products. The energy barrier for carbon–nitrogen rotation should be of the same order of magnitude as the one for carbon–oxygen rotation. Both types of rotation must therefore be taken into consideration.

For example, by rotation of the carbon–nitrogen bond, conformer **2***b* can give a new conformer such as **2***c*. In conformer **2***c*, the hydroxyl oxygen and the nitrogen each have a lone pair orbital oriented antiperiplanar to the C—OR bond. Intermediate **2***c* should thus immediately produce the amide and alcohol products. By rotation of the C—OR bond in **2***b*, a new conformer such as **2***a* can also be obtained. We have already described that **2***a* should give the ester and amine products. Other conformers can be obtained by other rotations in **2***b*. The relative proportions of ester and amine products *vs.* amide and alcohol products will thus depend on the new conformers that will be formed by bond rotation in conformer **2***b*. Consequently, it is predicted that the basic[4] hydrolysis of the *syn* form **1***b* of an imidate salt will give in principle mixtures of products.

Hydrolysis of *Anti* Imidate Salts

We will first describe the results obtained from the basic hydrolysis of imidate salts having an *anti* conformation. The first substrate selected was the five-membered ring imidate salt **3** in which the *anti* conformation is assured by the cyclic structure. Hydrolysis of **3** with 3 equiv. of sodium carbonate in a mixture of acetonitrile and water gave the benzoate amine **4** exclusively. The reaction was followed by proton n.m.r. spectroscopy and was complete after 10 min at room temperature. Compound **4** was isolated as the acetamide derivative **5** by treating the reaction mixture with an excess of pyridine and acetic anhydride. If the reaction mixture was left at room temperature for a period of 24 h, the aminobenzoate **4** was completely converted into the more stable benzamide alcohol **6**. This product was isolated also as its acetate derivative **7**.



These experimental results can be easily explained by the stereoelectronic theory. The salt **3** forms the hemiorthoamide intermediate **9** in which the energy barrier for fragmentation is lowered by the alignment of the orbitals on both oxygen atoms. Indeed, under kinetically controlled conditions, the ester amine product **4** is the only product formed.[5] It is possible that the ex-

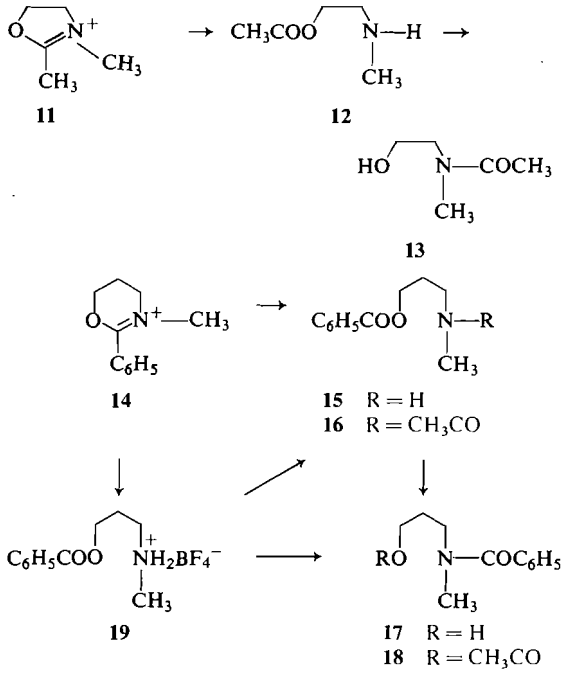
[4]It should be emphasized that this prediction is valid in basic medium only. This condition is important because the protonation of the basic nitrogen of the tetrahedral intermediate effectively ties up its lone pair orbital (7). Thus the nitrogen atom cannot participate in an orbital assisted decomposition of the tetrahedral intermediate under acidic conditions.

[5]The basic hydrolysis of **3** was also carried out with sodium hydroxide. Under these conditions, the imidate salt **3** gave directly the benzamide alcohol **6**, while the benzoate amine **4** was not detected. This unexpected result can be explained if the transformation of the benzoate amine **4** into the more stable benzamide alcohol **6** is very rapid in the presence of sodium hydroxide. This assertion was shown to be true in the following way. The benzoate ammonium salt **8** was prepared by the hydrolysis of **3** in neutral water. When the ammonium salt **8** was treated with sodium hydroxide under the conditions described for the hydrolysis of **3**, it gave directly the benzamide alcohol **6**. Treatment of **8** with sodium carbonate gave the benzoate amine **4**.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

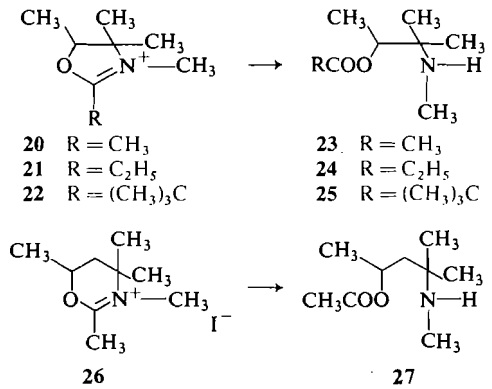
perimental conditions used favor the reformation of tetrahedral intermediates by an attack of the amino group on the ester function of **4**. Compound **4** can either reform **9** or form a new intermediate such as **10**, which has its orbitals properly aligned to yield the more stable product, the amide alcohol **6**. Consequently, the final result will be the exclusive formation of the thermodynamic product under those equilibrating conditions. These conditions were obtained after a period of 24 h with sodium carbonate; they were immediately obtained when sodium hydroxide was utilized.[5]

The hydrolysis of imidate salt **11** was also carried out with sodium carbonate. After 10 min, it gave mainly the acetate amine **12** which was then slowly converted into the acetamide alcohol **13** after standing for 1.5 h at room temperature. It is interesting to note that the conversion of **12** into **13** in the presence of sodium carbonate occurs at a much faster rate than the conversion of **4** into **6** under similar conditions. This result, however, can be easily explained by the fact that **12** is an acetate ester, thus more reactive than **4** which is a benzoate ester.



The basic hydrolysis of a six-membered ring imidate salt was also performed. After 15 min at room temperature, the hydrolysis of **14** with sodium carbonate gave the benzoate amine **15** exclusively. The presence of benzamide alcohol **17** was not detected in the reaction mixture even after a period of 5 h. Compound **15** was isolated and characterized as its corresponding acetamide derivative **16**.

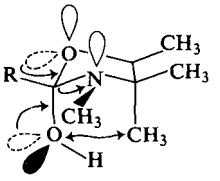
The hydrolysis of **14** was also carried out with sodium hydroxide. The imidate salt was completely hydrolyzed after a few minutes and it yielded mainly the benzoate amine **15** (≃95%) with a small quantity of the benzamide alcohol **17** (≃5%). After standing for a period of 30 min at room temperature, the reaction mixture consisted of the benzamide alcohol **17** only, which was isolated as its acetate derivative **18**. This result indicates again that the ester **15** is first formed and then converted into the more stable amide product **17**. This assumption was verified by treating the ammonium salt **19** under identical basic conditions. Like the imidate **14**, **19** also gave the benzoate amine **15** first, which was then completely converted into the benzamide alcohol **17** within a period of 30 min. The ammonium salt **19** had been obtained by the hydrolysis of **14** in neutral water.



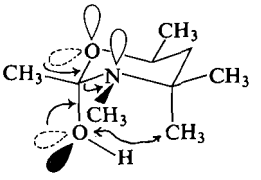
The basic hydrolysis of the imidate salts **20**, **21**, and **22** has been previously reported by Allen and Ginos (9). These salts gave the corresponding ester amine products **23**, **24**, and **25** in basic conditions. We have also carried out the basic hydrolysis of imidate salt **26** (10) and it gave the ester amine **27**. There are two factors which help the cleavage of the C—N bond in the hydrolysis of **20**, **21**, **22**, and **26**. According to the theory, **20**, **21**, and **22** should form the intermediate **28** which has proper orbital alignment to yield the corresponding ester amine products. In **28**, there is also a pseudo 1,3-diaxial type of interaction between the OH group and one of the methyl groups which promotes the cleavage of the carbon–nitrogen bond. Compound **26** should give the intermediate **29** in which there is again a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

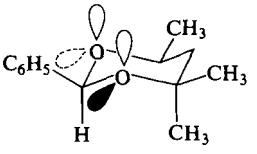
similar steric compression factor. This, combined with the orbital orientation factor, favors the carbon–nitrogen bond cleavage.



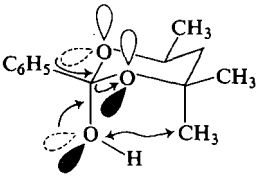
28



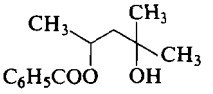
29



30



31

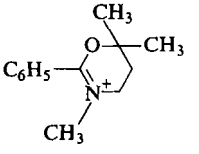


32

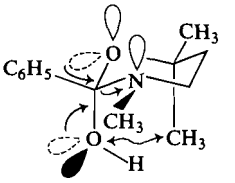
It was of interest to find out if this steric compression factor was important enough to direct the cleavage of the intermediate exclusively in one direction. We have verified experimentally that this factor is indeed important by carrying out the ozonolysis of the acetal **30** (11). Oxidation of **30** by ozone gave the ester **32** exclusively. During this reaction, it is postulated that the intermediate **31** is formed. In **31** the orientation of the nonbonded orbitals favors the opening in both directions equally well. Consequently, the experimental results demonstrate that the interaction between the OH group and the axial methyl group in **31** is strong enough to allow a specific cleavage in one direction. This result is in agreement with the minimum value of 2.4 kcal/mol which has been estimated for 1,3-diaxial interaction between a hydroxyl and a methyl group.[6]

Having a good estimate for the importance of the steric decompression factor, it is in principle possible to obtain some idea about the magnitude of the orbital orientation effect by opposing these two factors in the same system. The salt **33** was therefore prepared for that purpose. Its reaction with hydroxide ion should give the intermediate **34**, in which the orbital orientation promotes the cleavage of the C—N bond, while the 1,3-diaxial methyl–hydroxyl steric interaction favors the cleavage of the C—O bond. Hydrolysis of **33** with sodium carbonate gave exclusively the ester amine product **35** which was characterized as its acetamide derivative **36**. Additionally, salt **37** was also prepared. Its hydrolysis yielded first the ester amine **38** which was rapidly transformed under the experimental conditions into the benzamide alcohol **39**. In the above examples, the reaction was still specific despite an opposing steric factor (estimated to be $\geq$2.4 kcal/mol) which had first to be surmounted. It is considered that a reaction path is specific when it is favored by at least 2.4 kcal/mol. The minimum value for the orbital orientation effect can therefore be estimated to be at least 5 kcal/mol.

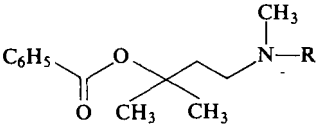
So far, we have described the hydrolysis of rigid *anti* imidate salts. These compounds were predicted to give the ester amine products exclusively. The preceding experimental results



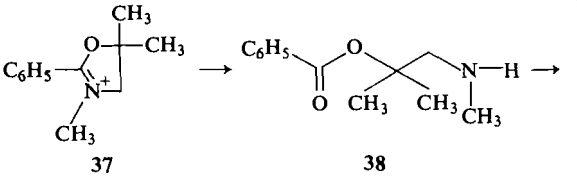
33



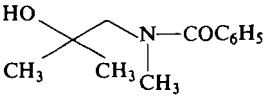
34



35 R = H
36 R = CH_3CO



37 38



39

[6]The energy difference between the two conformers of *cis*-3-methylcyclohexanol can be estimated at about 3.8 kcal/mol and an experimental value of 2.4 kcal/mol (12) is taken as the basis for the 1,3-diaxial methyl–hydroxyl interaction (13).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

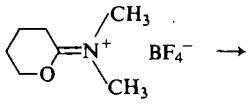
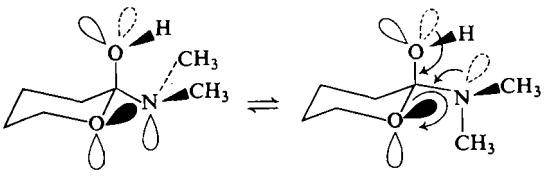
clearly demonstrate that, indeed, the ester amine products are the only products observed under kinetically controlled conditions. We must conclude that orbital orientation is an important factor in lowering the energy barrier for the breakdown of a tetrahedral intermediate. In fact, we believe that it is the determining factor.

Hydrolysis of *Syn* Imidate Salts

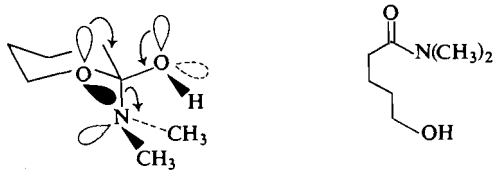
We have also undertaken the basic hydrolysis of the imidate salts **40** and **41** which have a *syn* conformation owing to their cyclic structure. The hydrolysis of **40** should give the intermediate **42** which is equivalent to **2***b*. Thus, **42** cannot break



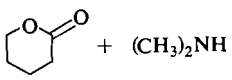
40



42 **43**

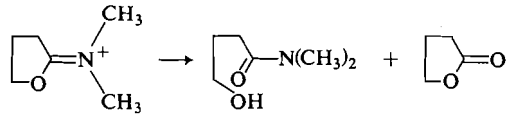


44 **46**



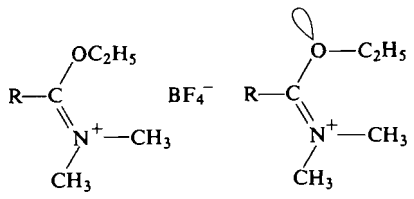
45

down easily if the stereoelectronic theory is valid. However, intermediate **42** can undergo conformational changes to yield either **43** by carbon–nitrogen rotation or **44** by chair inversion. Conformer **43** has its orbitals properly oriented to give the hydroxy amide **46** whereas conformer **44** should yield the lactone **45** and dimethylamine. Thus, the stereoelectronic theory predicts a mixture of products **45** and **46** from the basic hydrolysis of **40**. The hydrolysis of **40** was carried out with sodium hydroxide in aqueous acetonitrile. Indeed, the imidate salt **40** gave a mixture of hydroxy amide **46** (66%) and δ-valerolactone (**45**, 33%) and dimethylamine (33%). The relative proportion of products was determined directly in the reaction mixture by measuring (n.m.r.) the relative proportion of dimethylamine and *N*,*N*-dimethylamide produced. Likewise, the hydrolysis of the imidate salt **41** gave a one to one mixture of the corresponding hydroxy amide **47** and γ-butyrolactone (**48**).

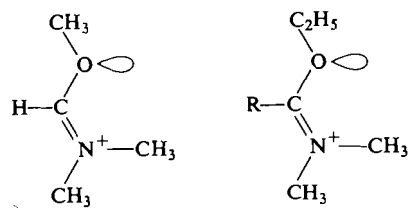


41 **47** **48**

We have also studied the basic hydrolysis of a series of imidate salts **49**, in which the R group was varied (R = hydrogen, methyl, isopropyl, cyclohexyl, *t*-butyl, and phenyl). Such salts can exist in principle in the *anti* (**49***a*) or the *syn* (**49***b*) form. The extent of the electronic interaction which stabilizes or destabilizes either of these two forms is as yet unknown. There is, however, a steric repulsion between the R group and the ethyl group in the *syn* form *b*. There is also a 1,3-synperiplanar interaction between the ethyl and the methyl groups in the *anti* form *a*. When R is a small group, one can postulate that the *syn* form *b* might be favored since it avoids the rather strong interaction which exists in the *anti* form *a*. However, when R is a large group such as



49 **49***a*



50 **49***b*

‡Yields were estimated by v.p.c. analysis.

the *t*-butyl or the planar phenyl group, the *anti* form *a* might predominate so that the rather severe interaction between the ethyl group and the large group R is now avoided. If this assumption is valid, it would indicate that **49** (R = H) exists mainly as the *syn* form. A nuclear Overhauser effect study on the salt **50** indicates that it exists mainly in the *syn* conformation.[7] When R is a methyl, an isopropyl, or a cyclohexyl group, **49** would exist either as the pure *syn* form or as an equilibrium mixture of the *syn* and the *anti* forms. Finally, when R is a *t*-butyl or a phenyl group, **49** would exist in the pure *anti* form.

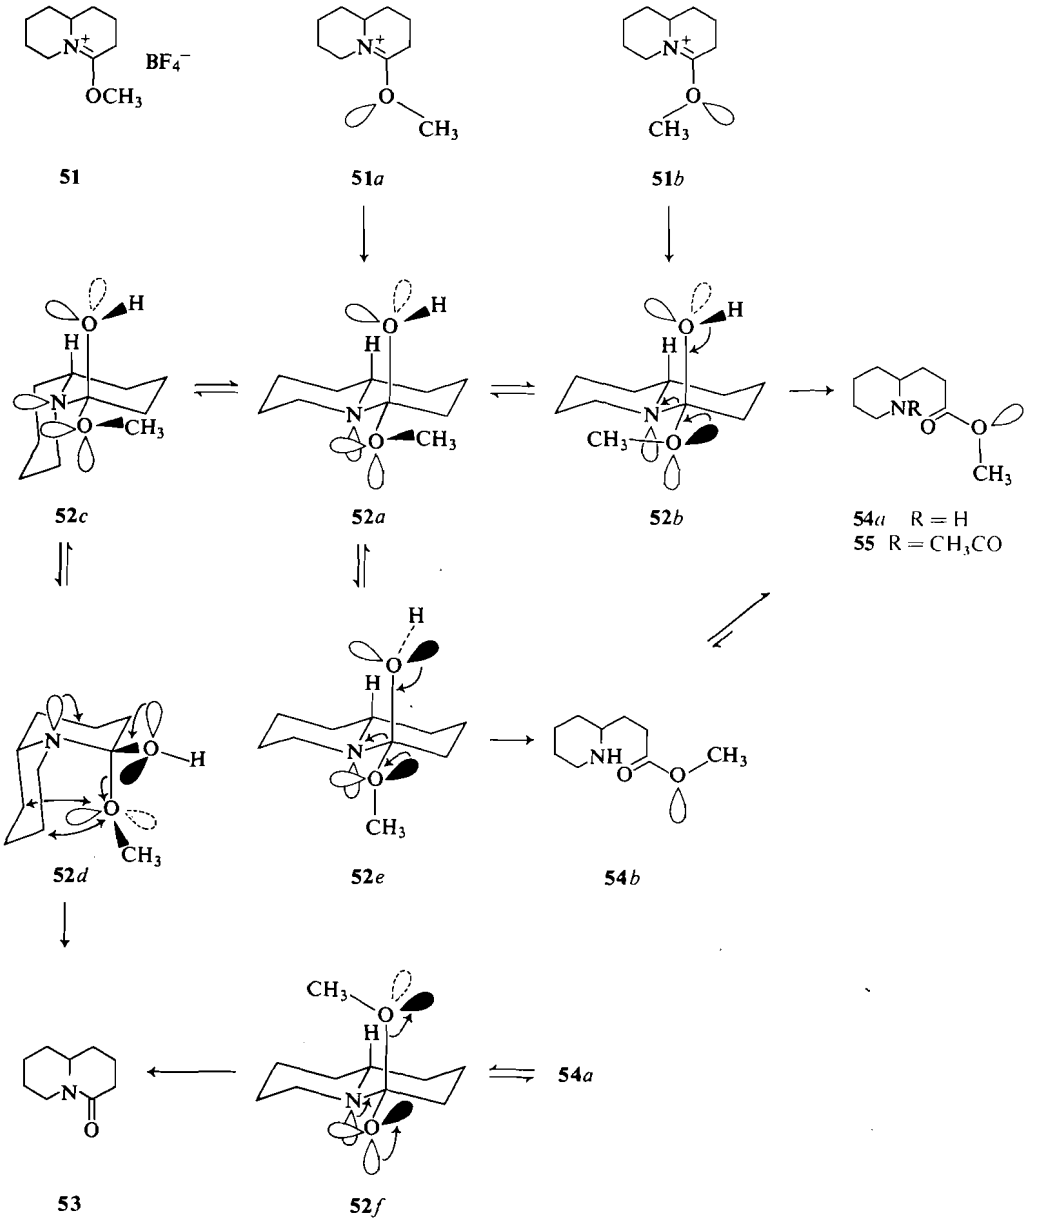
The above reasoning, in conjunction with stereoelectronic theory predicts that mixtures of ester amine and amide alcohol products should be observed in the hydrolysis of **49** when R is a hydrogen, a methyl, an isopropyl, and a cyclohexyl group. It also predicts that the basic hydrolysis of **49** when R is a *t*-butyl or a phenyl group should give the ester and amine products exclusively. The result of the hydrolysis of those salts (carried out with sodium hydroxide) is described in Table 1. This data is in striking accord with the preceding discussion.

We have also studied the bicyclic imidate salt **51**; imidate **51** can exist either in the *syn* (**51***a*) or the *anti* (**51***b*) form. Steric interactions in **51** are similar to those of salt **49** (R = CH_3). Application of the stereoelectronic theory to this system leads to the following conclusions. We assume that the *syn* conformation **51***a* must be predominant. Reaction of **51***a* with hydroxide ion should yield the conformer **52***a* specifically. Since conformer **52***a* cannot break down by an orbital assisted mechanism, conformational changes should take place. Nitrogen inversion is possible in **52***a* to give the new conformer **52***c*. However, this new conformer, like **52***a*, does not have proper orbital orientation to break down. Since **52***c* is equivalent to a *cis*-decalin system, it can undergo a chair inversion to give conformer **52***d*. Conformer **52***d* should break down to give the lactam product **53** in a stereoelectronically controlled fashion. However, in conformer **52***d*, there are two severe 1,3-diaxial steric interactions between two methylene groups of ring A and the oxygen of the OCH_3 group. The energy barrier for the conversion of **52***a* into **52***d* will be increased accordingly. Thus, if **52***a* can undergo other conformational changes having a lower energy barrier and leading to a new conformer which can break down via stereoelectronic control, the pathway through **52***d* can be eliminated from consideration.

Conformer **52***a* can also change its conformation by rotation of the O—CH_3 bond. In this fashion, it can give either **52***b* or **52***e*. (In principle, **52***b* could also be obtained directly from the *anti* form **51***b*.) These two conformers have proper orbital orientation to break down to yield the ester amine product **54**. The magnitude of the anomeric effect (15), which occurs whenever two lone pair orbitals are in a 1,3-synperiplanar arrangement is approximately the same in **52***b* and **52***e*. However, on steric grounds, **52***e* should be more stable than **52***b* since there is a 1,3-synperiplanar interaction[8] between the OCH_3 group and the methylene group adjacent to the nitrogen atom in **52***b*. Conformer **52***b* should give the ester amine in its thermodynamically more stable *E* form (**54***a*), whereas **52***e* should yield the same product in its less stable *Z* form **54***b* (14). If the route **52***a* → **52***e* → **54***b* were operative, **54***b* would be converted by bond rotation into the more stable *E* form **54***a*. If the instability of the *Z* ester relative to the *E* ester (11) is transposed to the energy barrier for the cleavage of the more stable conformer **52***e*, one must conclude that the hydrolysis of **51** could very well occur via both intermediates **52***b* and **52***e*. These two intermediates lead to the ester

[7]Saturation of the OCH_3 absorption (δ = 4.8) causes an area enhancement of 15% of the methine proton (δ = 8.8). Irradiation of the N—CH_3 group *cis* to the methine proton (doublet, J = 2 Hz, δ = 3.6) resulted in a 16% area increase of this absorption, whereas saturation of the *trans* N—CH_3 group (singlet, δ = 3.8) had no effect. We are grateful to professor J. K. Saunders for this experiment.

[8]A 1,3-synperiplanar interaction is identical to a 1,3-diaxial interaction in a cyclohexane ring.



amine **54***a*. Formation of **54***a* via **52***b* and **52***e* is an easier process than formation of the lactam **53** via the sterically unfavored **52***d*. The kinetic product of the hydrolysis reaction of **51** must therefore be the ester amine **54***a*.

In the experiment, the imidate salt **51** was hydrolyzed with sodium carbonate and gave the ester amine **54***a* exclusively after 15 min of reaction. The ester amine **54***a* was then slowly converted into the lactam **53** in the reaction mixture (66% of conversion after 76 h). In another experiment, the hydrolysis of **51** was allowed to proceed for 15 min, then the reaction mixture was treated with a large excess of acetic anhydride and pyridine. The ester amine **54***a* was trapped as the acetamide ester **55** in good yield. Thus, it appears that the formation of lactam **53** via stereoelectronic control must occur by the new tetrahedral conformer **52***f* which can be easily formed from the ester amine **54***a*.

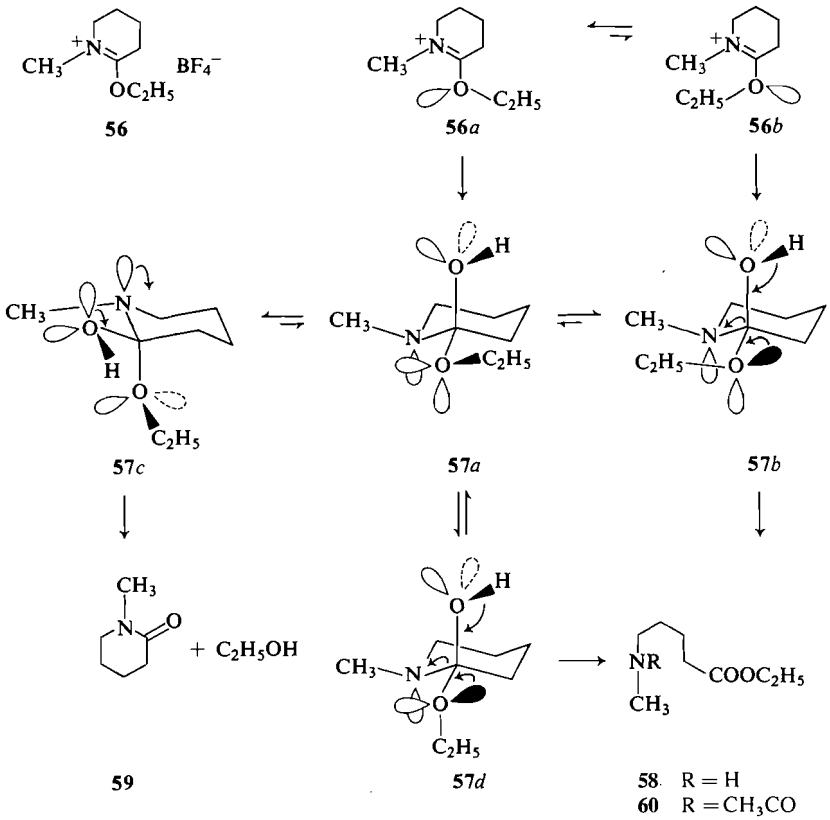
For personal use only.



The hydrolysis of the imidate salt **56** was also carried out. It gave a mixture of ester amine **58** (83%) and lactam **59** (17%). The ester amine **58** was isolated as its acetamide derivative **60**. The salt **56** can be considered as the monocyclic version of the bicyclic salt **51** that gives tetrahedral intermediates (**52**) which cannot undergo a proper nitrogen inversion without creating severe steric interactions. The salt **56** can form tetrahedral intermediates (**57***a*, *b*, *c*, and *d*) in which proper nitrogen inversion can occur as well as rotation of the C—OCH_3 bond. Thus, we should expect some lactam product from **56**. This prediction is in agreement with the experimental result. A similar result was obtained from the hydrolysis of the salt **61** which also gave a mixture of ester amine **63** (65%) and lactam **62** (35%). The ester amine **63** was isolated and characterized as its acetamide derivative **64**.

The hydrolysis of the bicyclic imidate salt **65** was also investigated. Its hydrolysis with aqueous sodium carbonate gave directly the lactam **66**, while none of the expected amine ester **67** was detected. However, hydrolysis of **65** in aqueous acid gave the ester ammonium salt **68**. On treatment of **68** with aqueous sodium carbonate only the lactam **66** was obtained. The amine ester **67** was not observed. Consequently, the above result cannot be used against the stereoelectronic theory, because the basic hydrolysis of **65** gives directly the thermodynamic product (**66**) under

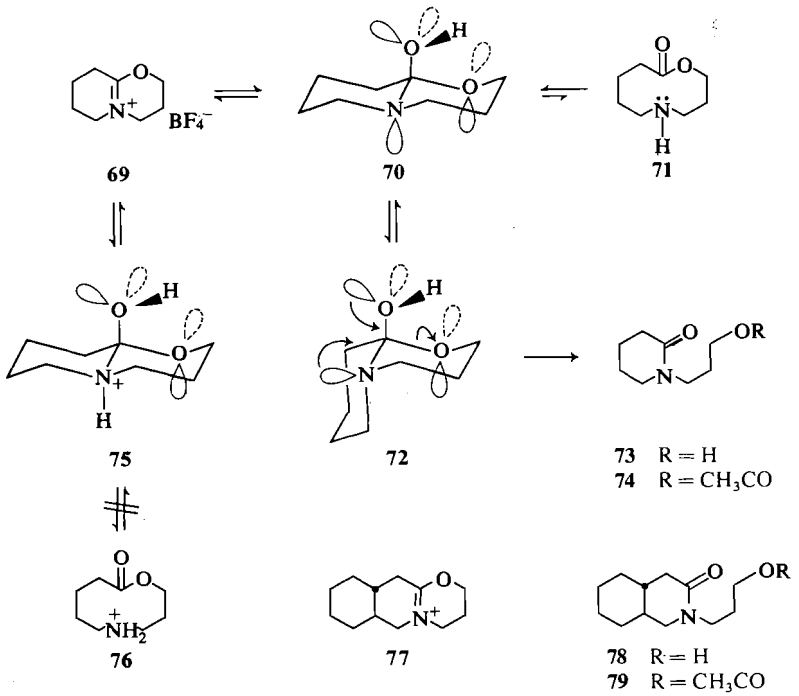
For personal use only.



conditions where the kinetic product (**67**) cannot long survive.

Hydrolysis of Bicyclic Imidate Salts 69 and 77

The hydrolysis of the *anti* bicyclic imidate salt **69** was also examined. If the stereoelectronic rule is followed, the salt **69** should give the intermediate **70** which has its orbitals properly aligned to yield the amino lactone **71**. The presence of the large ring in **71** keeps the nitrogen in close proximity to the carbonyl of the ester function. It is therefore logical to expect that the reformation of intermediate **70** from **71** should be especially facile. If **70** has a sufficient lifetime because it is in mobile equilibrium with **71**, it can undergo a conformational change to **72** by nitrogen inversion. Stereoelectronically controlled cleavage of **72** yields the hydroxy lactam **73** which is the thermodynamic product of the reaction. So, even if the conversion of **70** into **72** is a much slower process than its breakdown into **71**, once **72** is obtained, it represents a means by which the reaction can become thermodynamically controlled. Consequently, kinetically controlled conditions should be difficult to obtain in this case. Accordingly, the basic hydrolysis of salt **69** was carried out and it led to the exclusive formation of hydroxy lactam **73** which was characterized by its acetate derivative **74**.

On the other hand, the reaction of **69** in acidic medium should give the intermediate **75** which can break down into the lactonium ammonium salt **76** by an orbital assisted mechanism. The intermediate **75** cannot undergo a conformational change to give the protonated form of **72**; the nitrogen in **75** cannot be inverted because its lone pair orbital is now protonated. The formation of hydroxy lactam **73** should therefore not be observed in acidic medium. The hydrolysis of **69** was attempted in aqueous hydrochloric acid (0.1 *N*) and this compound was found to be completely stable under those conditions for a period of 8 months. Thus, not only the hydroxy lactam product **73** was not formed but the ammonium salt **76** was not even produced. The stability of **69** in aqueous acid can be explained in two ways: (*a*) the salt **69** does not react with water to form a tetrahedral intermediate and it is therefore stable; (*b*) it does react with water to form the intermediate **75** but it prefers to give back the starting salt **69**, for the reason that **69** is more stable than the ammonium salt **76**. We think that the first explanation is not valid. It is difficult to find one good reason to explain the resistance of **69** to form a tetrahedral inter-

For personal use only.

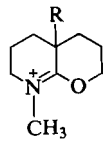
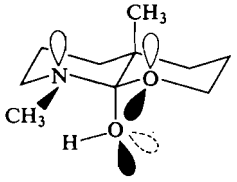
mediate in acidic medium. All other imidate salts that we have reported in this article do form an intermediate since they are all hydrolyzed in aqueous acid. We have prepared the tricyclic imidate salt **77** which has a structure similar to **69** and we should thus expect the same kind of reactivity. In aqueous base, **77** gave the expected hydroxy lactam **78** which was characterized by its acetate derivative **79**. In aqueous acid, it was found to be completely stable.

Hydrolysis of Imidate Salts 80 and 86

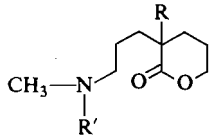
The basic hydrolysis of the bicyclic imidate salt **80** was undertaken next. Reaction of **80** with hydroxide ion should give the intermediate **81**



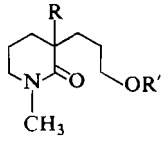
80 R = CH_3
86 R = H



81



83 R = CH_3, R′ = H, HBF_4
84 R = CH_3, R′ = CH_3CO
89 R = H, R′ = H, HBF_4
90 R = H, R′ = CH_3CO



82 R = CH_3, R′ = H
85 R = CH_3, R′ = CH_3CO
87 R = H, R′ = H
88 R = H, R′ = CH_3CO

which cannot break down in a stereoelectronically controlled fashion unless considerable twisting of the molecule can occur. It was therefore of interest to find out if the tetrahedral intermediate **81** could be detected in the reaction mixture since the energy barrier for its breakdown must be abnormally high. The hydrolysis of **80** was carried out in aqueous sodium carbonate. This imidate gave the hydroxy lactam **82** which was also isolated as its acetate derivative **85**. We have found that **80** is hydrolyzed in aqueous acid to the lactone ammonium salt **83** which was further transformed into its acetamide derivative **84**. When **83** was treated with aqueous base, it gave directly the hydroxy lactam **82**. This result shows that the products of the basic hydrolysis of **80** were those of thermodynamic control. (The fact that **80** is hydrolyzed in aqueous acid brings additional support that **69** is in equilibrium with the intermediate **75** under the same conditions.) The specific formation of the lactone ammonium salt **83** shows that the nitrogen lone pair in the tetrahedral intermediate is always protonated under acidic conditions; the lone pair is, therefore, never available to expel an OR group. The successful hydrolysis of **80** under basic conditions indicates that the breakdown of a tetrahedral intermediate can be accomplished without the help of two lone pair orbitals acting synergistically. The tetrahedral intermediate can be cleaved through a higher energy barrier. If the cleavage of **81** had become the slow step of the reaction, its presence could have been detected.

We have also prepared the closely related imidate salt **86** and have obtained a similar result. Under basic conditions, **86** gave the hydroxy lactam **87** which was also characterized as its acetate derivative **88**. Under acidic conditions, **86** gave the lactone ammonium salt **89** which was transformed into the hydroxy lactam **87** by treatment with aqueous sodium carbonate. Treatment of the salt **89** with pyridine and acetic anhydride gave the lactone acetamide **90**.

Conclusion

The products of hydrolysis of the imidate salts examined were accurately predicted by application of the straightforward argument presented here. The application of the postulate of conformational changes combined with the principle of stereoelectronic control provide a very attractive mechanism to explain the products formed in the hydrolysis of imidate salts under basic conditions. We believe that the preceding results combined with our work on the oxidation of acetals (11) and the hydrolysis of orthoesters (1) constitute strong experimental evidence which support this new stereoelectronic theory.[9]

Experimental

The i.r. spectra were taken on a Perkin-Elmer 257 spectrophotometer. Proton n.m.r. spectra (δ value) were

[9]In this work, we have not taken account of the p*H* of the reaction medium, except that we have tried to use the most basic conditions which allow a kinetically controlled reaction. So, whenever possible, sodium hydroxide was used. In other cases, the less suitable sodium carbonate had to be used. We also used mixed aqueous–organic solvents so that the products of the reaction could be conveniently analyzed by n.m.r. spectroscopy. We have also undertaken the hydrolysis of some *N,N*-dialkylated imidate salts in aqueous solution over a range of p*H* values. The results obtained confirm the conclusion of this work and will be reported in the near future.

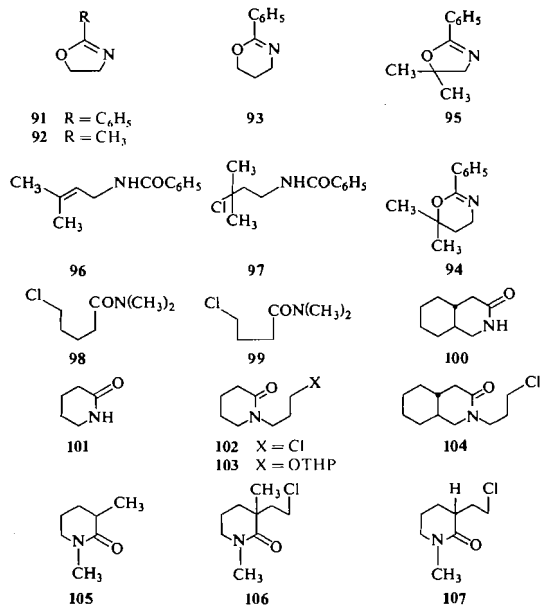
recorded on a Varian A-60 spectrometer in solvent indicated. All chemical shifts are recorded relative to internal TMS as standard. The vapor phase chromatographic analyses were done on Varian chromatographs models 600-D and 2800. Mass spectra were run on a Hitachi-Perkin-Elmer RMU-6 spectrometer. Microanalyses were performed by Dr. C. Daesslé, Organic Microanalyses, Montreal and by Mr. J. Tamas, Laboratoire de Microanalyse, Université de Sherbrooke.

The imidate salts **3**, **11**, **14**, **33**, and **37** were obtained by alkylation with trimethyloxonium tetrafluoroborate (16) of compounds **91**, **92**, **93**, **94**, and **95**, respectively. Compound **94** was prepared from the chloroamide **97** which was obtained from the olefinic amide **96**. The imidate salt **40** was prepared from δ-valerolactone via intermediates **46** and **98**. Similarly, the salt **41** was obtained from γ-butyrolactone via compounds **47** and **99**. The imidate salts **49**, **50**, **51**, **56**, **61**, and **65** were prepared by alkylation with the appropriate trialkyloxonium tetrafluoroborate of the corresponding amides or lactams. The lactam **66** was prepared from lactam **100**. The salt **69** was prepared by cyclization of **102** which was obtained by *N*-alkylation of **101** with 1-bromo-3-chloropropane. An authentic sample of **73** was prepared by alkylation of **101** with 3-chloro-1-propanol tetrahydropyranyl ether (**103**) followed by acid hydrolysis. The salt **77** was obtained by a similar route using **100** and **104** as intermediates. The salts **80** and **86** were prepared by cyclization of **106** and **107**. *C*-Alkylation of **105** and **59** gave the chloroamides **106** and **107** respectively. Finally, alkylation of **59** gave **105** (17).



General Method of Preparation of Imidate Salts

The imino ether, amide, or lactam (1 equiv.) was treated with trialkyloxonium tetrafluoroborate (1 equiv.) in anhydrous dichloromethane. The solution was kept at room temperature for 12 h. The solvent was removed *in vacuo*. The reactions are essentially quantitative. When the imidate salt could not be obtained crystalline, it was used directly without further purification. The structure and purity of such salts can be easily verified by n.m.r. and i.r. spectroscopic analysis.[10]

A Typical Procedure for the Basic Hydrolysis of Cyclic Imidate Salts

Imidate Salt 3

Procedure A—Imidate salt **3** (50 mg, 0.20 mmol) was dissolved in deuterated acetonitrile (0.3 ml). Sodium carbonate (0.66 mmol) in deuterated water (0.3 ml) was added. After 10 min, analysis by n.m.r. spectroscopy indicated the presence only of benzoate amine **4** (n.m.r. (CD_3CN—D_2O): δ 7.55–8.05 (5H, multiplet, aromatic protons), 4.45 (2H, triplet, J = 5.5 Hz, CH_2O), 3.02 (2H, triplet, J = 5.5 Hz, CH_2N), and 2.48 (3H, singlet, CH_3N). The reaction mixture was left at room temperature for 24 h. Nuclear magnetic resonance analysis indicated the presence of benzamide alcohol **6** as the sole product. The solvent was removed *in vacuo*, brine was added, and the mixture was extracted with chloroform. The organic phase was dried over magnesium sulfate, filtered, and evaporated to dryness to yield crude benzamide alcohol **6**; i.r. ($CHCl_3$): 3520–3200 and 1615 cm^{-1}; n.m.r. ($CDCl_3$): δ 7.45 (5H, singlet, aromatic hydrogens), 3.76 (5H, multiplet, OCH_2CH_2N and OH), 3.21 (3H, singlet, CH_3N), and 3.09 (3H, singlet, CH_3N). Acetylation of benzamide alcohol **6** with pyridine and acetic anhydride gave benzamide acetate **7**; i.r. ($CHCl_3$): 1625 and 1740 cm^{-1}; n.m.r. ($CDCl_3$): δ 7.44 (5H, aromatic hydrogens), 4.33 (2H, unresolved triplet, CH_2O), 3.72 (2H, unresolved triplet, CH_2N), 3.08 (3H, singlet, CH_3N), and 2.09 (3H, singlet, CH_3CO).

Procedure B—Imidate salt **3** (200 mg, 0.8 mmol) was dissolved in acetonitrile (5 ml) and sodium carbonate (44 mmol) in water (2 ml) was added. After 10 min at room temperature, acetic anhydride (50 ml) and pyridine (10 ml) were added. The reaction was left for 12 h at room temperature. It was cooled to 0 °C and methanol (50 ml) was added. Water was then added and the mixture was extracted with dichloromethane. The organic phase was washed with water, dried, and evaporated to dryness to yield pure benzoate acetamide **5** (180 mg, 100%); i.r. ($CHCl_3$): 1635 and 1715 cm^{-1}; n.m.r. ($CDCl_3$): δ 7.55–8.10 (5H, multiplets, aromatic hydrogens), 4.50 (2H, triplet, J = 6 Hz, CH_2O), 3.70–3.80 (2H, two triplets, J = 6 Hz, CH_2N), 3.06–3.12 (3H, two singlets, CH_3N), and 2.11–2.18 (3H, two singlets, CH_3CO).

Procedure C—Imidate salt **3** (50 mg, 0.20 mmol) was dissolved in deuterated acetonitrile (0.3 ml). Sodium carbonate (0.66 mmol) in deuterated water (0.3 ml) was added. After 10 min, n.m.r. analysis indicated the presence of only benzoate amine **4**. Sodium hydroxide in deuterated water (1 *N*, 0.3 ml) was added. Nuclear magnetic resonance analysis of this solution showed only benzamide alcohol **6**.

Procedure D—Imidate salt **3** (30 mg, 0.20 mmol) was dissolved in acetonitrile (0.3 ml) and deuterated water (0.1 ml). The reaction is complete after 10 h at room temperature and gives the ammonium salt **8** n.m.r.

[10]The experimental procedures and spectroscopic data for the imidate salts and the various compounds described in this work are available, at a nominal charge, from the Depository for Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Canada KIA 0S2.

(CD_3CN—D_2O): δ 7.65–8.10 (5H, multiplet, aromatic hydrogens), 4.53 (2H, multiplet, CH_2O), 3.48 (2H, multiplet, CH_2N), and 2.83 (3H, singlet, CH_3N). A solution of sodium hydroxide (0.25 ml, 1 *N*) is added. Nuclear magnetic resonance analysis indicated the presence of benzamide alcohol **6** only.

Procedure E—Imidate salt **3** (30 mg, 0.12 mmol) was dissolved in acetonitrile (0.3 ml) and deuterated water (0.1 ml). After 18 h at room temperature, sodium carbonate (0.66 mmol) in deuterated water (0.3 ml) was added. Nuclear magnetic resonance analysis indicated the presence of benzoate amine **4**. After standing for 100 h, n.m.r. analysis indicated the presence of benzamide alcohol **6**.

Hydrolysis of Imidate Salt ***11***

Acetate amine ***12***—n.m.r. (CD_3CN–D_2O): δ 4.15 (2H, triplet, J = 6 Hz, CH_2O), 2.77 (2H, triplet, J = 6 Hz, CH_2N), and 2.32 (3H, singlet, CH_3N).

Acetamide alcohol ***13***—i.r. ($CHCl_3$): 3200–3550 and 1630 cm^{-1}; n.m.r. ($CDCl_3$): δ 4.70 (1H, broad singlet, OH), 3.60 (4H, multiplet, NCH_2CH_2O), 2.95–3.10 (3H, two singlets, CH_3N), and 2.08–2.14 (3H, two singlets, CH_3CO).

Hydrolysis of Imidate Salt ***14***

Benzoate amine ***15***—n.m.r. (CD_3CN–D_2O): δ 7.55–7.90 (5H, two multiplets, aromatic hydrogens), 4.35 (2H, triplet, J = 6 Hz, CH_2O), 2.88 (2H, triplet, J = 7 Hz, CH_2N), 2.42 (3H, singlet, CH_3N), and 2.02 (2H, multiplet, CH_2).

Benzoate acetamide ***16***—i.r. ($CHCl_3$): 1630 and 1715 cm^{-1}; n.m.r. ($CDCl_3$): δ 7.57–8.10 (5H, two multiplets, aromatic hydrogens), 4.40 (2H, triplet, J = 6 Hz, CH_2O), 3.52–3.58 (2H, two triplets, J = 6 Hz, CH_2N), 2.98–3.06 (3H, two singlets, CH_3N), 2.10–2.11 (3H, two singlets, CH_3CO), and 2.11 (2H, multiplet, CH_2).

Acetate benzamide ***18***—i.r. ($CHCl_3$): 1620 and 1730 cm^{-1}; n.m.r. ($CDCl_3$): δ 7.45 (5H, singlet, aromatic hydrogens), 4.11 (2H, multiplet, CH_2O), 3.55 (2H, multiplet, CH_2N), 3.05 (3H, singlet, CH_3N), and 2.02 (5H, multiplet, CH_2 and CH_3CO).

Benzoate ammonium salt ***19***—n.m.r. (CD_3CN): δ 7.65–8.10 (5H, two multiplets, aromatic hydrogens), 4.41 (2H, triplet, J = 6 Hz, CH_2O), 3.20 (2H, triplet, J = 7 Hz, CH_2N), 2.70 (3H, singlet, CH_3N), and 2.11 (2H, multiplet, CH_2).

(90 MHz, CH_2Cl_2): δ 4.11 (2H, quartet, J = 7 Hz, OCH_2CH_3), 2.54 (2H, triplet, J = 7 Hz, CH_2N), 2.34 (3H, singlet, CH_3N), 2.30 (2H, triplet, J = 7 Hz, CH_2CO), 1.21 (3H, triplet, J = 7 Hz, OCH_2CH_3).

Lactam ***62***—i.r. (neat): 1670 cm^{-1}; n.m.r. ($CDCl_3$): δ 3.41 (2H, triplet, J = 7 Hz, CH_2N), 2.85 (3H, singlet, CH_3N), 2.30 (4H, multiplet).

Acetamide ester ***64***—n.m.r. ($CDCl_3$): δ 4.18 (2H, quartet, J = 7 Hz, OCH_2CH_3), 3.40 (2H, multiplet, CH_2N), 2.94–3.02 (3H, two singlets, CH_3N), 2.08–2.10 (3H, two singlets, CH_3CO), 2.10 (4H, multiplet), and 1.28 (3H, triplet, J = 7 Hz, OCH_2CH_3).

Hydrolysis of Imidate Salt ***65***

Basic conditions—Imidate salt ***65*** (93 mg, 0.345 mmol) was dissolved in acetonitrile-d_3 (300 μl) in an n.m.r. tube. Dry sodium carbonate (79 mg, 0.744 mmol) was added, along with deuterium oxide (700 μl). The heterogeneous

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

mixture was shaken for 10 min at room temperature. The n.m.r. spectrum at this time showed no resonances due to starting material. Solvent was removed *in vacuo* and the residue was triturated with chloroform. The triturant was concentrated *in vacuo* to leave a clear oil which was the lactam **66** (60 mg, 100%). This material was homogeneous by t.l.c. and identical to the lactam prepared via methylation of lactam **100** by n.m.r., i.r., and t.l.c. comparison.

Acidic Conditions—Imidate salt **65** (43 mg, 0.16 mmol) was dissolved in aqueous hydrochloric acid (1 *N*, 300 μl) in an n.m.r. tube. The sample was allowed to stand at room temperature for 5 days. At the end of this time no resonances due to starting material remained. New resonances characteristic of the ester ammonium salt **68** at δ 3.80 (singlet) and 2.80 p.p.m. (triplet, $J = 3$ Hz) had appeared. Solvent was removed *in vacuo*. The i.r. of the semisolid thus obtained in chloroform showed absorptions at 3500–3000 (NH), 1720, and 1625 cm^{-1}.

Ammonium ester **68** (25 mg, 0.067 mmol) was placed in an n.m.r. tube along with deuteriochloroform (300 μl). Aqueous sodium carbonate (1 *N*, 300 μl) was added and the tube was shaken vigorously. Within 3 min the n.m.r. spectrum was essentially that of lactam **66**. Solvent was removed *in vacuo*. The oily solid which remained was triturated with methylene chloride and the triturant was dried over sodium sulfate. Solvent was removed *in vacuo* to give the lactam **66** (10 mg, 90%) as a clear oil. The t.l.c., i.r., and n.m.r. characteristics of this sample were identical to an authentic sample.

Hydrolysis of Imidate Salt 69

Basic Conditions—Imidate salt **69** ($X = ClO_4^-$) (59 mg, 0.247 mmol) was dissolved in acetonitrile-d_3 (300 μl) in an n.m.r. tube. Aqueous sodium carbonate (4 *N* in D_2O, 250 μl, 1 mmol) was added. The heterogeneous mixture thus obtained was stirred vigorously and the progress of the reaction was followed by n.m.r. The hydrolysis was judged complete after 15 h at room temperature. The contents of the n.m.r. tube were extracted with chloroform and the extract dried over sodium sulfate. Removal of solvent *in vacuo* gave hydroxy lactam **73** in good yield. The hydroxy lactam **73** obtained from this experiment was identical to hydroxy lactam prepared from the tetrahydropyranyl ether **103**.

Imidate salt **69** ($X = ClO_4^-$) (62 mg, 0.260 mmol) was dissolved in acetonitrile-d_3 (30 μl) in an n.m.r. tube. Aqueous sodium hydroxide (4 *N*, 65 μl, 0.26 mmol) was added, and the resulting heterogeneous mixture was shaken vigorously. The progress of the reaction was followed by n.m.r. After 19 min at room temperature the salt **69** was completely hydrolyzed to hydroxy lactam **73**. As in the previous experiment, **73** was isolated in good yield. The basic hydrolysis of **69** ($X = BF_4^-$) also gives the hydroxy lactam **73**.

Acidic Conditions—Imidate salt **69** ($X = BF_4^-$) (21 mg, 0.09 mmol) was dissolved in aqueous hydrochloric acid (300 μl, 0.1 *N* in D_2O) in an n.m.r. tube. During 8 months at room temperature, there was no change in the n.m.r. spectrum of this sample. At the end of this time solvent was removed *in vacuo*. The residue (31 mg) was triturated with dichloromethane. The triturant was concentrated *in vacuo* to give the imidate salt **69** (13 mg, 62%). Crystallization from dichloromethane – ethyl ether gave pure **69** (11 mg); m.p. 161–163 °C. A 50:50 w/w mixture of authentic **69** and **69** recovered from the aqueous acidic reaction gave m.p. 162–163 °C.

Hydrolysis of Imidate Salt 77

Basic Conditions—Imidate salt **77** (57 mg, 0.196 mmol) was dissolved in acetonitrile-d_3 (300 μl). Aqueous sodium carbonate (4 *N* in deuterium oxide, 200 μl) was added. At this point some sodium carbonate precipitated and the solution was filtered into an n.m.r. tube. After 19 h at room temperature the salt **77** had been completely hydrolyzed, as shown by n.m.r. The resulting solution was extracted with chloroform and the extract was dried over potassium carbonate. Removal of solvent *in vacuo* left an oil (40 mg). Preparative t.l.c. (silica gel, $CHCl_3$ – 6% (v/v) CH_3OH, R_f 0.2) gave the hydroxy lactam **78** (30 mg, 70%) as a clear oil; i.r. (CCl_4): 3400 and 1630 cm^{-1}; n.m.r. ($CDCl_3$): δ 4.20 (1H, singlet, OH), 3.9–2.6 (6H, multiplet), 2.5–0.6 (14 H, multiplet); m.s.: *m/e* 211 (M^+), 193 ($M^+ - H_2O$).

Hydroxy lactam **78** (255 mg, 1.21 mmol) was dissolved in acetic anhydride (2 ml) and dry pyridine (2 ml). This mixture was stirred overnight at room temperature, under nitrogen. Solvent was removed *in vacuo* to leave a yellow oil (280 mg). Preparative t.l.c. (silica gel, $CHCl_3$ – 6% (v/v) CH_3OH, R_f 0.5) gave the acetoxy lactam **79** (240 mg, 78%). Low temperature crystallization from hexane gave **79** as a white solid; m.p. 27 °C; i.r. (CCl_4): 1745 and 1650 cm^{-1}; n.m.r. ($CDCl_3$): δ 4.15 (2H, triplet, $J = 7$ Hz, CH_2O), 3.7–2.5 (4H, multiplet), 2.4–0.8 (14 H, multiplet), and 2.05 (3H, singlet, CH_3CO); m.s.: *m/e* 253 (M^+), 210 ($M^+ - CH_3CO$), 193 ($M^+ - CH_3COOH$).

Anal. Calcd. for $C_{14}H_{23}NO_3$: C, 66.37; H, 9.15. Found: C, 66.29; H, 9.17.

Acidic Conditions—Tricyclic salt **77** (25 mg, 0.089 mmol) was dissolved in hydrochloric acid (0.1 *N* in deuterium oxide, 300 μl) in an n.m.r. tube. There was no appreciable change in the n.m.r. spectrum of this sample during 8 months at room temperature. At the end of this time solvent was removed *in vacuo* and the residue was triturated with dichloromethane. The triturant was concentrated *in vacuo* to give the imidate **77** (16 mg, 65%) as an oil. This material crystallized from cold absolute ethanol to give pure **77** (12 mg); m.p. 78–80 °C. A 1:1 (w/w) mixture of authentic **77** and **77** isolated from aqueous acid showed m.p. 78–79.5 °C.

Hydrolysis of Imidate Salt 80

Basic Conditions—Imidate salt **80** (60 mg, 0.236 mmol) was dissolved in deuteriochloroform (400 μl), in an n.m.r. tube. Aqueous sodium carbonate (300 μl, 0.270 mmol, 0.9 *N* in D_2O) was added and the reaction was followed by n.m.r. After 2.5 h approximately 10% of the imidate remained; after standing 12 h at room temperature, no starting material was detectable by n.m.r. Solvent was removed *in vacuo*. The residue obtained was triturated with chloroform. The triturant was concentrated *in vacuo* to leave a yellow oil (50 mg). Trituration with diethyl ether gave pure lactam alcohol **82** (33 mg, 75%) as a clear, ether soluble, oil; t.l.c.: R_f 0.5 on silica gel using $CHCl_3$ – 7% (v/v) CH_3OH eluent; i.r. (CCl_4): 3450 and 1640 cm^{-1}; n.m.r. ($CDCl_3$): δ 3.8–3.5 (2H, multiplet), 3.5–3.15 (2H, multiplet), 2.90 (3H, singlet), 2.2–1.25 (9H, multiplet), and 1.20 (3H, singlet); m.s.: *m/e* 186 (M^+).

In another experiment the hydrolysis of imidate salt **80** was carried out in aqueous sodium carbonate with no cosolvent. Work-up as described above gave the hydroxy lactam **82** in quantitative yield. The hydrolysis was complete within 5 min after mixing the reagents.

Hydroxy lactam **82** (115 mg, 0.62 mmol) was dissolved

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

in a mixture of acetic anhydride (1 ml) and dry pyridine (1 ml), under argon. This was allowed to stand overnight at room temperature. Solvent was removed *in vacuo* to leave a slightly yellow oil (137 mg). Short path distillation gave pure acetoxy lactam **85** (95 mg, 68%) as a clear oil; b.p. 80 °C/0.1 Torr; i.r. (CCl_4): 1740 and 1640 cm^{-1}; n.m.r. ($CDCl_3$): δ 4.2–3.9 (2H, multiplet), 3.5–3.1 (2H, multiplet), 2.90 (3H, singlet, CH_3N), 2.05 (3H, singlet, CH_3CO), 2.0–1.3 (8H, multiplet), and 1.20 (3H, singlet, CH_3C); m.s.: *m/e* 227 (M^+).

Anal. Calcd. for $C_{12}H_{21}NO_3$: C, 63.41; H, 9.31. Found: C, 63.18; H, 9.38.

Acidic Conditions—Imidate salt **90** (106 mg, 0.416 mmol) was dissolved in aqueous fluoroboric acid (86 mg, 48% HBF_4–H_2O, 0.50 mmol) in an n.m.r. tube. Deuterium oxide (300 μl) was added and the solution was allowed to stand at room temperature for 3 months. No resonances owing to starting material could be detected in the n.m.r. spectrum of the sample at this time. Solvent was removed *in vacuo* and the residue was triturated with chloroform. The triturant gave an oil (110 mg) whose i.r. spectrum in acetonitrile showed an absorption due to the presence of the lactone function at 1720 cm^{-1} corresponding to compound **83**. The oil was stirred at room temperature in a mixture of acetic anhydride (1 ml) and dry pyridine (1 ml), under argon, overnight. Solvent was removed *in vacuo* to leave a brown oil. Preparative t.l.c. (silica gel, $CHCl_3$ – 6% (v/v) CH_3OH, R_f 0.2) gave pure lactone **84** (40 mg, 43%), as a clear oil; i.r. (CCl_4): 1730 and 1640 cm^{-1}; n.m.r. ($CDCl_3$): δ 4.5–4.2 (2H, multiplet), 3.5–3.1 (2H, multiplet), 3.1–2.8 (3H, two lines due to CH_3NCO), 2.7–1.0 (11H, multiplet), and 2.10 (3H, singlet, CH_3CO); m.s.: *m/e* 227 (M^+).

Hydrolysis of Imidate Salt 86

Basic Conditions—Imidate salt **86** (21 mg, 0.091 mmol) was dissolved in acetonitrile-d_3 in an n.m.r. tube. Aqueous sodium hydroxide (4 *N* in deuterium oxide, 50 μl) was added and the n.m.r. spectrum was run immediately. Resonances due to the imidate **86** had completely disappeared. One new resonance, at 2.9 p.p.m., was particularly diagnostic of the methyl group of a 1-methyl-2-piperidone. No further changes occurred in the n.m.r. spectrum of this sample during 1 h of intermittent observation. In another experiment, imidate **86** (21 mg, 0.091 mmol) was dissolved in aqueous sodium carbonate (1 g Na_2CO_3 – 10 ml D_2O, 0.94 *N*, 300 μl) in an n.m.r. tube. The n.m.r. spectrum of this sample was run within 5 min after mixing. No resonances from **86** remained and the spectrum obtained was identical to the one obtained in the previous experiment.

To fully characterize the product of the basic hydrolysis of imidate **86**, the reaction was scaled up. Imidate salt **86** (91 mg, 0.395 mmol) was dissolved in aqueous sodium hydroxide (1 *N*, 5 ml). The mixture was stirred at room temperature for 30 min. The resulting solution was saturated with sodium chloride, then extracted with chloroform. The extract was dried over sodium sulfate, then solvent was removed *in vacuo* to leave a clear oil (75 mg). Preparative t.l.c. (silica gel, $CHCl_3$ – 5% (v/v) CH_3OH, R_f 0.2 gave the hydroxy lactam **87** ((18), 60 mg, 87%) as an oil which crystallized from cold diethyl ether; m.p. 56–56.5 °C; i.r. (CCl_4): 3400 and 1630 cm^{-1}; n.m.r. ($CDCl_3$): δ 3.85–3.55 (3H, multiplet), 2.95 (3H, singlet, CH_3N), and 2.6–1.2 (11H, multiplet); m.s.: *m/e* 153 ($M^+ - H_2O$).

Anal. Calcd. for $C_9H_{17}NO_2$: C, 63.13; H, 10.01. Found: C, 63.07; H, 10.48.

Hydroxy lactam **87** (12 mg, 0.07 mmol) was dissolved in a mixture of acetic anhydride (2 ml) and dry pyridine (1 ml). This solution was stirred at room temperature, under nitrogen, for 3 h. Solvent was removed *in vacuo* to leave a clear oil (13 mg). After preparative t.l.c. (silica gel, $CHCl_3$ – 6% (v/v) CH_3OH, R_f 0.8) this oil gave pure lactam acetate **88** (6 mg, 40%) as a clear oil; i.r. (CCl_4): 1740 and 1640 cm^{-1}; n.m.r. ($CDCl_3$): δ 4.18 (2H, triplet, J = 6 Hz, CH_2O), 3.6–3.2 (2H, multiplet), 3.00 (3H, singlet, CH_3N), 2.5–1.4 (9H, multiplet), and 2.10 (3H, singlet, CH_3CO); m.s.: *m/e* 213 (M^+).

Acidic Conditions—Imidate tetrafluoroborate salt **86** (100 mg, 0.434 mmol) was dissolved in deuterium oxide (300 μl) along with aqueous tetrafluoroboric acid (86 mg of 48% HBF_4–H_2O, 0.5 mmol HBF_4). The progress of the reaction was followed by n.m.r. After 1 month at room temperature, solvent was removed *in vacuo* to leave a clear oil (148 mg). This oil was dissolved in acetonitrile and the solution dried over sodium sulfate. Solvent was removed *in vacuo* to leave a waxy semisolid (142 mg). This was triturated extensively first with dichloromethane, then with acetonitrile. The dichloromethane was evaporated *in vacuo* to leave a clear oil (29 mg) which consisted for the most part of unreacted imidate **86**. The acetonitrile solution was diluted with diethyl ether. Upon cooling in the refrigerator, the desired lactone ammonium salt **89** (79 mg, 100%) precipitated as a waxy semisolid; i.r. (CH_3CN): 1730 cm^{-1}; n.m.r. (CD_3CN): δ 7.3–6.3 (1H, multiplet), 4.5–4.25 (2H, multiplet), 3.8–3.4 (1H, multiplet), 3.3–2.9 (2H, multiplet), 2.72 (3H, triplet, J = 5 Hz), and 2.2–1.3 (partially obscured by solvent).

Ammonium lactone salt **89** (113 mg, 0.455 mmol) was dissolved in acetic anhydride (5 ml) under nitrogen. Dry pyridine (1 ml) was added with vigorous stirring. This was stirred for 3 h at room temperature, then solvent was removed *in vacuo*. The residue was triturated with dichloromethane. Evaporation of the dichloromethane *in vacuo* left crude **90** (54 mg) as an oil. Preparative t.l.c. (silica gel, $CHCl_3$ – 6% (v/v) CH_3OH, R_f 0.6) gave pure **90** (10 mg, 10%) as a clear oil (the crude yield is reasonable but the recovery off the t.l.c. plate is inexplicably poor); i.r. (CCl_4): 1740 and 1650 cm^{-1}; n.m.r. ($CDCl_3$): δ 4.40 (1H, triplet, J = 5 Hz), 4.3–4.00 (1H, multiplet), 3.8–3.20 (2H, multiplet), 3.2–2.95 (3H, singlet, CH_3NCO), 2.7–1.10 (9H, multiplet), and 2.18 (3H, singlet, CH_3CO); m.s.: *m/e* 213 (M^+), 170 ($M^+ - CH_3CO$).

Basic Hydrolysis of Lactone Ammonium Salt 89

Lactone ammonium salt **89** (10 mg) was dissolved in deuterium oxide in an n.m.r. tube. One drop of sodium hydroxide in deuterium oxide (4 *N*) was added, then the n.m.r. spectrum of this solution was run immediately. The spectrum showed no resonance due to starting material, and the spectrum did not change during 30 min. Solvent was removed *in vacuo* to leave a clear oil whose t.l.c. retention time and spectral characteristics (i.r. and n.m.r.) were identical to those of a sample of hydroxy lactam **87**.

The Equilibrium Constant for the Formation of $Al_2(OH)_2^{4+}$ in Aqueous Solutions[1,2]

R. C. TURNER[3]

Soil Research Institute, Agriculture Canada, Ottawa, Canada K1A 0C6

Received April 16, 1975

R. C. TURNER. Can. J. Chem. **53**, 2811 (1975).

The equilibrium constant for the formation of the aluminum hydroxy dimer, $Al_2(OH)_2^{4+}$, was calculated from measured values of p*H* and the concentrations of the dimer and trivalent aluminum in aqueous solutions at 25 °C. The concentrations of $Al_2(OH)_2^{4+}$ was determined by a method based on its rate of reaction with an 8-hydroxyquinoline – sodium acetate solution. Experiments were made with various concentrations of aluminum and different ionic strengths. With an ionic strength of 0.06, the equilibrium constant was $10^{-7.42}$ and increased with decreasing ionic strength. The negative log of the equilibrium constant when the ionic strength approaches zero was estimated to be 6.95 ± 0.05.

R. C. TURNER. Can. J. Chem. **53**, 2811 (1975).

On a calculé la constante d'équilibre pour la formation du dimère alumino-hydroxy, $Al_2(OH)_2^{4+}$ à partir des valeurs mesurées du p*H* et des concentrations de dimère et d'aluminium trivalent dans des solutions aqueuses à 25 °C. On a déterminé les concentrations de $Al_2(OH)_2^{4+}$ par une méthode basée sur son taux de réaction avec une solution d'hydroxy-8 quinoléine et d'acétate de sodium. On a fait des expériences à différentes concentrations d'aluminium et différentes forces ioniques. A une force ionique de 0.06, la constante d'équilibre est de $10^{-7.42}$ et cette valeur augmente au fur et à mesure que la force ionique diminue. On estime à 6.95 ± 0.05 la valeur du logarithme négatif de la constante d'équilibre quand la force ionique approche zéro.

[Traduit par le journal]

There is considerable variation in the published values for the equilibrium constant for the formation of the aluminum hydroxy dimer, $Al_2(OH)_2^{4+}$. The largest value, $10^{-6.27}$ with ionic strength μ approaching zero, found by Kubota (1) was calculated from p*H* values after making the NaOH/Al mole ratio 0.25. Faucherre (2), using the slope of p*H* *vs.* dilution, calculated values of $10^{-8.06}$ and $10^{-8.24}$ for μ equal to 0.12 and 0.06 respectively. Greenwald and Fong (3) reported a value of $10^{-7.45}$ as μ approaches zero at 30 °C, derived from the slope of p*H* *vs.* amount of acid added at the p*H* of a pure $AlCl_3$ solution. Kenttamaa (4) using the slope of p*H* *vs.* amount of base added arrived at a value of $10^{-7.55}$ with μ between 0.048 and 0.03. Aveston (5) used ultracentrifugation and acidity measurements to calculate a value of $10^{-7.07}$ (μ = 1). Mesmer and Baes (6) reported $10^{-7.45}$ at 25 °C in 1 *M* KCl. None of these values were calculated from direct measurements of the concentration of $Al_2(OH)_2^{4+}$ in solution. In the work reported here an attempt was made to measure the concentration of the dimer in solution and from this to calculate the equilibrium constant for its formation.

It has been shown (7) that it is possible to differentiate between mononuclear and poly-

nuclear hydroxyaluminum cations by using an 8-quinolinolate extraction technique. Turner and Sulaiman (8) showed that the polynuclears reacted with a standard 8-quinolinol – sodium acetate solution via a pseudo first order process with a specific rate constant of 0.16 min^{-1} at 26 °C. It was observed in subsequent work, however, that with very low mole ratios of NaOH to total aluminum in the solution the reaction was first order with the usual rate constant after the first 2 min but during the first 2 min it was much faster. An investigation of this anomaly led to a method for determining the concentration of $Al_2(OH)_2^{4+}$ by a kinetic technique.

Experimental

The concentrations used were approximately 10^{-2}, 10^{-3}, 5×10^{-4}, and 10^{-4} *M* $AlCl_3$ all adjusted to an ionic strength of 0.06 with NaCl. The latter three concentrations were also used with μ equal to that imposed by the aluminum salt, and $Al(ClO_4)_3$ as well as $AlCl_3$ was used at 10^{-2} *M*. Reagent grade sodium hydroxide, at concentrations 10 times that of the Al salt solution, was added dropwise slowly, while the solutions were stirred vigorously with a magnetic stirrer. The NaOH/Al mole ratio was 0.116 in all cases. After the addition of the base, the solutions were aged at 25 °C with gentle agitation for one month before the measurements were made. The p*H* of the solutions were then measured with an expanded scale p*H* meter and the rate of reaction studies were done.

Rate of reaction studies were made by placing 10 ml of chloroform in a dry separatory funnel to which was then added the appropriate volume of the test solution. Two and one-half millilitres of 8-quinolinol stock solution (10 gm 8-quinolinol dissolved in 25 ml of glacial acetic acid and diluted to 1000 ml) was mixed with H_2O and 2.5 ml of *N* NaOAc added; the amount of H_2O used was such that the total volume was 25 ml less the volume of the test solution added to the chloroform. The 8-quinolinol–NaOAc solution was then added to the chloroform plus test solution in the separatory funnel and shaken vigorously by hand for 10 s. The two liquids were allowed to separate and the chloroform layer drained off through the drainage tube which contained a dry cotton plug to remove H_2O. The concentration of Al in the chloroform was determined by the depth of color of the Al–quinolinolate complex. Because the reactions are essentially stopped immediately shaking in the separatory funnel begins, the Al in the chloroform layer was considered to be that which reacted immediately. The chloroform extraction was repeated except that this time the test solution was placed in a dry separatory funnel. The 8-quinolinol–NaOAc solution was added and the combined solutions were allowed to react with gentle agitation for the desired length of time. Chloroform (10 ml) was then added followed by vigorous shaking and the chloroform layer was drawn off as before. The lengths of time of reaction were ½, 1, 2, 15, and 30 min. The above was replicated 10 times for each concentration and ionic strength.

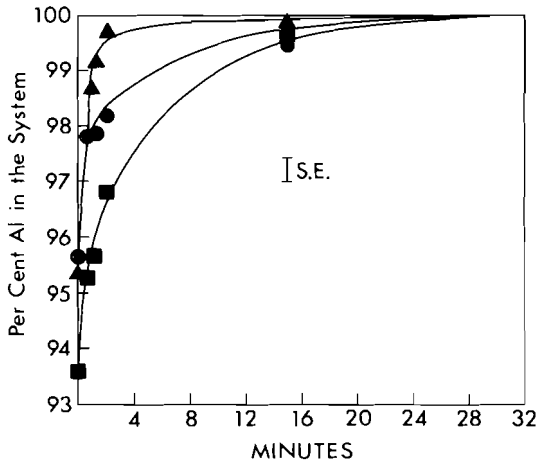

FIG. 1. Percent of the total aluminum in the system measured after increasing lengths of time of reaction. Each point is the mean of 10 replicates. The smooth curves were calculated from [2]. S.E.: standard error of the means, ▲, 10^{-2} *M*; ●, 10^{-3} *M*; ■, 10^{-4} *M*; ionic strength 0.06.

Results and Discussion

Figure 1 shows the mean of 10 determinations for each of three concentrations, 10^{-2}, 10^{-3}, and 10^{-4} *M* with $\mu = 0.06$, as the percent of the aluminum in the solutions measured after the different lengths of time of reaction. The smooth curves were calculated from [2]. When the concentration was 10^{-2} *M* practically all of the Al in the solution, 99.5%, was measured after only 2 min reaction, whereas with the 10^{-3} and 10^{-4} *M* solutions 98.3 and 96.4%, respectively, were measured. It should also be noted that, because the NaOH/Al mole ratio was very small, most of the Al was measured at zero time of reaction, causing the large standard error of the means shown in the figure. The standard error was the same on a percent basis for the three concentrations. This also indicates why it was necessary to use ten replicates rather than the usual two or three and to apply statistics in the interpretation of the data.

Assuming a first order process, a first approximation to the specific rate constant, k_1, for the very fast reaction was estimated from the results at ½ min reaction time with 10^{-2} *M* $AlCl_3$; *i.e.*, as near zero time as possible with the Al concentration at which the very fast one represented most of the reaction (Fig. 1). The mean of k_1's found for the 10 replicates was 3.1 min^{-1}. From this result and published data (8), the least

number of reactions possible is two, with specific rate constants of 3.1 and 0.16 min^{-1}.

The slower reaction represents reaction with the polynuclear cations (8) which have an OH/Al mole ratio of approximately 2.5 (5, 9, 10).[4] Assuming these two reactions, the fraction of Al remaining to react, R, at any time t is

$$[1] \qquad R = ae^{-3.1t} + (1 - a)e^{-0.16t}$$

where a is the fraction of aluminum in the reacting material represented by the fast reaction and $(1 - a)$ that represented by the slower one. The values of a were calculated by means of [1] at $t = \frac{1}{2}$, 1, and 2 min for 10 replicates for each of 10^{-2} M $AlCl_3$ and $Al(ClO_4)$ and 20 replicates for 10^{-3} M $AlCl_3$ ($\mu = 0.06$). The means of a for the three reaction times for each replicate were then used to recalculate k_1 at ½ min reaction for the 40 replicates. The mean of these 40 gave a second approximation for k_1 equal to 3.6 min^{-1}. A third approximation was not different from the second.

Equation 1 was changed to

$$[2] \qquad R = ae^{-3.6t} + (1 - a)e^{-0.16t}$$

and a was calculated at $t = \frac{1}{2}$, 1, and 2 min for each of the replicates for all concentrations and ionic strengths. The means for a and their standard errors from these calculations are presented in Table 1. An analysis of variance showed that there was no difference even at $P_{0.50}$ in the values due to the length of time of reaction used in the calculations. The results strongly support the hypothesis that [2] represents the reactions occurring. Furthermore, the fraction represented by the fast reaction was greatest for the highest concentrations and least for the lowest concentration when the ionic strength was 0.06 and was generally higher for the lower ionic strengths at the same concentration. Although this does not prove that the fast reaction represented reaction with the dimer $Al_2(OH)_2^{4+}$, the results are at least in accordance with the hypothesis.

Assuming that the fast reaction was in fact reaction with $Al_2(OH)_2^{4+}$ and the slower one the reaction with the polynuclear cations (8), it was possible to calculate the concentrations of the dimer for each replicate of each experiment at reaction times of ½, 1, and 2 min. The means of the replicates and their standard errors calculated from the results for the three reaction times are presented in Table 2. The differences between the means for the different lengths of time of reaction were not significant at $P_{0.20}$ level, except in one case out of the 24 possible comparisons. Consequently, the means of the values calculated for the three lengths of time of reaction were used to calculate a value for K_{2c} for each replicate in each experiment, where

$$[3] \qquad K_{2c} = \frac{[Al_2(OH)_2^{4+}](H^+)^2}{[Al^{3+}]^2}$$

and the square brackets and parenthesis denote concentrations and activities respectively.

It was necessary to know the concentration of Al^{3+} before K_{2c} could be calculated. The values from zero time of reaction with 8-quinolinol are not represented entirely by Al^{3+}. As a first approximation, it was assumed that

$$[4] \qquad [Al_0] = [Al^{3+}] + [AlOH^{2+}]$$

where $[Al_0]$ is the total concentration of Al measured at zero time of reaction. Using $10^{-5.00}$ as the thermodynamic hydrolysis constant for $AlOH^{2+}$ (11, 12), it was possible to calculate the concentration of $AlOH^{2+}$ and therefore the concentration of Al^{3+} from the measured $[Al_0]$. The Al^{3+} concentrations calculated in this way were used to calculate the pK_{2c}'s and the results were essentially the same as those reported in Table 3. It was observed, however, that only about 65% of the base added could be accounted for with the 10^{-2} M Al concentrations.

According to the assumptions used so far, the total OH in the system is represented by the equation

$$[5] \quad [B] + [H^+] = [AlOH^{2+}] + 2[Al_2(OH)_2^{4+}] + 2.5[Al_p]$$

where B represents base added and $[Al_p]$ is the concentration of Al in the polynuclear cations. As stated above, only about 65% of the base added could be accounted for when [5] was used for the 10^{-2} M Al concentrations with either $AlCl_3$ or $Al(ClO_4)_3$. As the concentration of Al was decreased with μ maintained at 0.06, this discrepancy decreased and essentially disappeared with the 10^{-4} M concentration. It appeared, therefore, that there was some other aluminum hydroxy species that became appreciable in amount, and was measured at zero time of reaction, at the higher Al concentrations only. The only conceivable product was Al_2OH^{5+}. It was decided, therefore, to calculate K_{1c} for $AlOH^{2+}$ from the results for the lowest Al concentration, 10^{-4} M, with μ equal to 0.06, where

$$[6] \quad K_{1c} = \frac{[AlOH^{2+}](H^+)}{[Al^{3+}]}$$

assuming at this low Al concentration that Al_2OH^{5+} could be ignored. The concentration of $AlOH^{2+}$ was calculated by means of [5] and then [4] was used to calculate the concentration of Al^{3+}. The mean value for pK_{1c} from the ten replicates with 10^{-4} M $AlCl_3$ and μ equal to 0.06 was 5.26 with a standard error of 0.02.

‡$Al(ClO_4)_3$. The others are $AlCl_3$.
§Calculated from the means.

The concentrations of Al^{3+}, $AlOH^{2+}$, and Al_2OH^{5+} for each of the replicates of the 10^{-2} M $AlCl_3$ and $Al(ClO_4)_3$ experiments were calculated, using [6] with K_{1c} equal to $10^{-5.26}$ and [7] and [8], shown below.

$$[7] \quad [Al_0] = [Al^{3+}] + [AlOH^{2+}] + 2[Al_2OH^{5+}]$$

$$[8] \quad [B] + [H^+] = [AlOH^{2+}] + [Al_2OH^{5+}] + 2[Al_2(OH)_2^{4+}] + 2.5[Al_p]$$

The value of K_{3c} was then calculated for each replicate, where

$$[9] \qquad K_{3c} = \frac{[Al_2OH^{5+}](H^+)}{[Al^{3+}]^2}$$

The difference between the means of pK_{3c} for the two salts, $AlCl_3$ and $Al(ClO_4)_3$, was not significant at the $P_{0.20}$ level, the overall mean being 3.1 (Table 3).

The value of pK_{1c} was then calculated, using pK_{3c} equal to 3.1, for the 10^{-3} and 5×10^{-4} M solutions with μ equal to 0.06. The difference between the means for the two Al concentrations was not significant at the $P_{0.20}$ level, the overall mean for pK_{1c} being 5.25 (Table 3). Introducing K_{3c} into the calculations for the 10^{-4} M solutions had no effect on the calculated value for K_{1c}. Thus the mean value for pK_{1c} for all concentrations of Al with μ equal to 0.06 was 5.25 with a standard error of 0.02. The mean values for pK_{1c} for all the Al concentrations and ionic strengths are shown in Table 3. The values for K_{1c} for the different ionic strengths are in general agreement with published results (1, 11, 12) arrived at by different techniques. This is rather convincing evidence that the assumptions concerning the various products used in the above are correct. As a further test of the assumptions, the equilibrium constant for one of the formulaes proposed for the polynuclears, and for which an equilibrium constant was reported, was calculated for all of the replicates where this was possible.

It was suggested by Aveston (5) that the most probable formula for the polynuclear cations is $Al_{13}(OH)_{32}^{7+}$ with pK_{4c} equal to 104.5 at an ionic strength of 1.0, where

$$[10] \qquad K_{4c} = \frac{[Al_{13}(OH)_{32}^{7+}](H^+)^{32}}{[Al^{3+}]^{13}}$$

Using this formula the mean value for K_{4c} with μ equal to 0.06 was $10^{-103.4}$, with higher values for the lower ionic strengths, the highest value being $10^{-100.7}$ for the lowest ionic strength (Table 3). These values are in general agreement with that found by Aveston, which was arrived at by entirely different methods. Thus all of the experimental evidence supports the interpretation regarding the three hydroxyaluminum species, $AlOH^{2+}$, Al_2OH^{5+}, and the polynuclear cations in addition to the dimer, $Al_2(OH)_2^{4+}$, which will be dealt with now.

The concentration of Al^{3+} for each replicate was calculated with pK_{1c} equal to 5.26 and pK_{3c} equal to 3.1 for the 10^{-2} M Al concentrations and for 10^{-3} and 5×10^{-4} M Al concentrations with μ equal to 0.06, *i.e.* using [6], [7], and [9]. Introducing K_{3c} into the calculations for the 10^{-4} M solutions at μ equal to 0.06 had no effect whatever. At the lower ionic strengths, [4], [5], and [6] were used, *i.e.*, K_{3c} was ignored because no value for it could be obtained and the values for K_{1c} and K_{4c} were not out of line, indicating that K_{3c} had little effect. The mean values of Al^{3+} and $Al_2(OH)_2^{4+}$ concentrations are presented in Table 4. The value of K_{2c} was calculated for each replicate. The mean values for

*Linear regression coefficient of pK_{2c} on $pf(\mu)$.
†Calculated from the results of each individual replicate. All others calculated from the means of the 10 replicates for each concentration and ionic strength.

pK_{2c} (Table 4) were relatively independent of Al concentration providing the ionic strength was kept constant at 0.06; none of the differences between the different concentrations were significant at the $P_{0.05}$ level. The mean of all the replicates for μ equals 0.06 was 7.42 with a standard error of 0.04. With the lower ionic strengths, pK_{2c} was significantly lower. Thus the assumption that the fast reaction involved the dimer and not some other hydrolysis product is in fact consistent with the experimental results. Further support for the assumption was that no other single species would give a K_{2c} value that was independent of concentration at constant ionic strength and show higher values when the ionic strength was decreased at a given concentration.

The pK_{2c}'s can be calculated from the mean values for the concentrations of Al^{3+} and $Al_2(OH)_2^{4+}$ shown in Table 4 for each concentration and ionic strength rather than for the individual replicates. The values calculated in this way, shown in the last column of Table 4, are essentially the same as the means of the individual replicates shown in next to the last column.

An approximation of the value for pK_{2c} as μ approaches zero can be made using the Debye-Hückel equation

$$[11] \qquad -\log f_1 = \frac{0.5 z_i^2 \mu^{1/2}}{1 + A_i \mu^{1/2}}$$

where z_i is the charge on the ith ion, f_i its activity coefficient, and A_i is a constant for a given ion species, the magnitude of which depends on the distance of closest approach between the ions. Using [11] and K_0 for K_{2c} as μ approaches zero, A_1 for Al^{3+}, and A_2 for $Al_2(OH)_2^{4+}$, it follows that

$$[12] \qquad pK_0 = pK_{2c} - pf(\mu)$$

where

$$[13] \quad pf(\mu) = \frac{\mu^{1/2} + (9A_2 - 8A_1)\mu}{1 + (A_1 + A_2)\mu^{1/2} + A_1 A_2 \mu}$$

The problem is to assign values to A_1 and A_2. An approximation to [11], suggested by Kielland (13), is to replace A_i with z_i. This gives A_1 a value of 3 and A_2 a value of 4. Kubota (1) however, used 2.47 for A_1 and Greenwald and Fong (3) claimed that it should be assigned the value 2. It is possible to estimate the value of A_2 for any given value of A_1 from the pK_{2c}'s in Table 4. Thus there are a number of possibilities which are summarized, along with the results obtained for each possibility, in Table 5.

From the results in Table 5, it is obvious that Kielland's approximation (14), A_1 and A_2 equal to 3 and 4 respectively, gave the regression coefficient of pK_{2c} on $pf(\mu)$ too much greater than unity to be in accordance with [12]. All of the other combinations of A_1 and A_2, with the possible exception of 2.47 and 4.0, gave regression coefficients very near unity, and pK_2 calculated for $pf(\mu)$ equals zero for these combinations varied from 6.94 and 6.96. The results in Table 5, except those designated †, were calculated using the means of the 10 replicates in each case. The values designated † were obtained by using each individual pK_{2c} for all replicates in order to get a fair estimate of the standard deviation of the calculated regression coefficients. From the last four pK_0's in Table 5 and the standard deviation designated † the value for pK_0 was estimated to be 6.95 ± 0.05.

Reductive Cleavage of Acetals and Ketals by Borane. Part II. The Kinetics of the Reaction[1,2]

HENRY I. BOLKER AND BRUCE I. FLEMING

Pulp and Paper Research Institute of Canada, and Department of Chemistry, McGill University, Montreal, Quebec H3C 3GI

Received March 21, 1975

HENRY I. BOLKER and BRUCE I. FLEMING. Can. J. Chem. **53**, 2818 (1975).

The reductive cleavage of acetals with borane in tetrahydrofuran was found to be first order in acetal and close to third order in borane. The high order in borane may be due to the participation of three BH_3 units in the transition state with subsequent formation of a $B_2H_7^-$ ion. All the hydrogen atoms of borane are available for the reduction of excess acetal at 30 °C.

HENRY I. BOLKER et BRUCE I. FLEMING. Can. J. Chem. **53**, 2818 (1975).

On a trouvé que la scission réductrice des acétals par le borane dans le tétrahydrofuranne est du premier ordre en acétal et près d'ordre trois en borane. L'ordre élevé en borane pourrait être dû à la participation de trois unités de BH_3 dans l'état de transition avec une formation subséquente d'un ion $B_2H_7^-$. A 30 °C, tous les atomes d'hydrogène du borane sont disponibles pour la réduction d'un excès d'acétal.

[Traduit par le journal]

In a previous publication (1) we discussed the possibility of complex borohydride formation during the cleavage of acetals by borane in tetrahydrofuran (THF). We now present evidence to support this hypothesis.

Two acetals, one simple (benzaldehyde dimethylacetal) and one cyclic (2-phenyl-1,3-dioxolane), were chosen to exemplify the kinetics of the reaction between acetals and borane in THF. In the procedure used for benzaldehyde dimethylacetal, standard dilutions of borane taken from a stock solution (1.15 *M*) were made with dry THF. When the solution had equilibrated in a constant temperature bath for a few minutes, sufficient acetal was added to bring the concentration to 0.025 *M*. The ratio of borane to acetal was made as high as possible to achieve pseudo first-order conditions, for which rate equation [1] is simplified to [2].

$$[1] \qquad \frac{d[\text{Product}]}{dt} = k[\text{Acetal}]^m[BH_3]^n$$

$$[2] \qquad \frac{d[\text{Product}]}{dt} = k_{obsvd}[\text{Acetal}]^m$$

$$[3] \qquad k_{obsvd} = \frac{1}{t}\log_e \frac{A}{A - x}$$

$$[4] \qquad k_{obsvd} = k[BH_3]^n$$

After fixed time intervals samples of the reaction mixture were removed, quenched by addition of aqueous sodium carbonate, and the organic material was analyzed by gas liquid chromatography (g.l.c.). Figure 1 shows the results obtained, plotted according to the integrated first-order equation [3] where A is the initial concentration of acetal and x is the product concentration at time t.

The majority of the experimental points lie very close to straight lines of zero intercept and we may conclude that the reduction is first order in acetal. Towards the end of the reaction the plots exhibit a slight tendency to zero order.

The slopes of the pseudo first-order graphs yielded the rate constants k_{obsvd}. The dramatic effect of reducing the borane concentration can be seen from the values of k_{obsvd} and the half-life periods shown in Table 1. A log–log plot of k_{obsvd} *vs.* borane concentration yielded a straight line graph of slope 2.9.[3] This is the value of n (eq. 4). The intercept of the graph yielded a k value of 5.4×10^{-2} min^{-1} mol$^{-2.9}$.

[1]Taken from the Ph.D. Thesis of B. I. Fleming, McGill University, Montreal, Quebec, 1974.

[2]This paper is dedicated to Professor C. A. Winkler of McGill University on the occasion of his sixty-fifth birthday by one of his colleagues (H.I.B.).

[3]A slope of 2.91 was calculated by the least-squares method; standard error around the fitted line = 0.058.

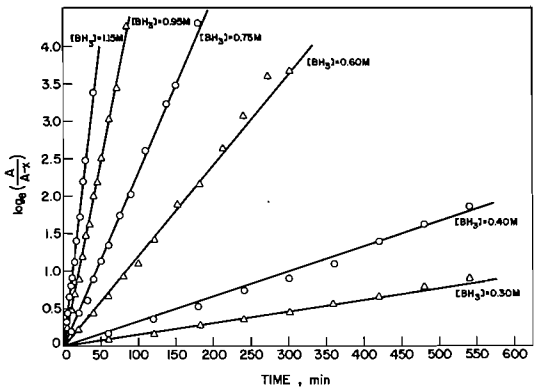

FIG. 1. Pseudo first-order plot for the reaction of benzaldehyde dimethylacetal with borane in THF at 17 °C.

TABLE 1. Rates of reduction of 0.025 *M* benzaldehyde dimethylacetal by borane in THF at 17 °C

[Borane] (*M*)	Half-life (min)	k_{obsvd} (min^{-1})	k (min^{-1} $mol^{-2.9}$)
1.15	9	0.079	5.7×10^{-2}
0.95	14	0.049	5.7×10^{-2}
0.75	30	0.023	5.3×10^{-2}
0.60	57	0.012	5.3×10^{-2}
0.40	200	0.0035	5.0×10^{-2}
0.30	400	0.0017	5.7×10^{-2}

The values for the rate constant k given in Table 1 were calculated from [4] using $n = 2.9$.

Thus, within error limits, the reductive cleavage of benzaldehyde dimethylacetal appeared to be third order in borane. Such a high order in borane was unexpected and further experiments were therefore initiated to check the observation. This time a fresh batch of borane in THF and a different acetal, 2-phenyl-1,3-dioxolane, were employed. After cleavage and hydrolysis, this acetal yields an alcohol which shows a slightly tailing peak in the gas chromatogram and thus causes some difficulty in analyzing very small amounts of product. It was therefore necessary to work with higher (0.208 *M*) concentrations of acetal. Since the borane was no longer in large excess, pseudo first-order conditions did not obtain; therefore, the initial reaction rate was used to determine the order of reaction. Table 2 shows the initial rates over the region zero to 0.5 mmol of product formed (5% of the total reaction). A plot of $\log_e$ (initial rate) *vs.* $\log_e$ [BH_3] yielded a straight line of slope 2.8.[4] The slope agrees well with that found for benzaldehyde dimethylacetal.

TABLE 2. Rates of reduction of 0.208 *M* 2-phenyl-1,3-dioxolane by borane in THF at 0 °C

[Borane] (*M*)	Time taken to form 0.5 mmol product, Δt (min)	Initial rate, dx/dt* (mmol/min)
1.15†	6	0.085
0.95	10	0.052
0.75	19	0.026
0.60	33	0.015
0.40	117	0.0043
0.30	243	0.0020

*Over the range 0–0.5 mmol, $\Delta x/\Delta t$ is assumed equal to dx/dt.
†The nominal concentration of the stock solution from which accurate dilutions were made.

Some of these experiments were repeated with redistilled cyclic acetal and a third batch of borane in THF. The results gave, within error limits, the same slope (2.73, with standard error of 0.12).

One possible interpretation of the high observed order in borane is that in some way three BH_3 units participate in the transition state (eq. 5). Such a situation would certainly lead

[5] 
to borane species of high stability: the alkoxyborane being stabilized by pπ–pπ double bonding, and $B_2H_7^-$ being more stable than BH_4^- when an excess of borane is present (2–4). Since BH_4^- reduces borane to $B_2H_7^-$ in ether solvents (5*a*), it would not be surprising if the more powerful hydride donor $ROBH_3^-$,[5] which tends to form as the C—O acetal bond cleaves (eq. 6), is likewise capable of reducing borane species.

Transition states involving the concatenation of several borane units are probably not uncom-

[4]Calculated slope; 2.80, standard error; 0.045.
[5]Alkoxyboranes have resonance contributions which reduce their Lewis acidities compared to BH_3 (see ref. 5*b*). Consequently alkoxyborohydride should be a better hydride donor than BH_4^-.

§When the reagents were mixed, 3.1 mmol of H_2 was evolved, possibly because of moisture in the system, thus diminishing the hydride available for reduction.

[6] 
mon. For example, the hydride exchange between $B_2H_7^-$ and B_2H_6, known from n.m.r. observations to be rapid in ether solvents at room temperature (6), presumably passes through such a transition state. Also analogous is the proposed mechanism for the formation of certain polyhedral borane anions (7), which involves sequential addition of borane units to an adduct formed from a base and borane.

The nature of the reacting species shown as "BH_3—THF" in [5] is open to speculation. Three possible candidates are B_2H_6, H_3B—H—BH_2·THF and BH_3·THF; these species are all likely to be in equilibrium in THF solvent. The first two could be directly attacked by $ROBH_3^-$ to yield $ROBH_2$ and $B_2H_7^-$, whereas BH_3·THF could give the same products after two sequential additions to $ROBH_3^-$.

An unexpectedly high order was found once before for a borane reduction: Klein and Dunkelblum (8) observed that the reduction of carbonyl groups was $\frac{3}{2}$ order in "B_2H_6" (THF solution), showing this reduction to be much more complex than the originally proposed hydride transfer by a single borane unit (*5b*).

The Reaction of Borane with Excess Acetal

In this experiment the tables were turned: an excess of acetal, not borane, was employed. Thus, from the yield of reduced product it is possible to determine whether all three hydrogens of borane are available for acetal reduction.[6] The results (Table 3) revealed that for every available hydrogen atom initially present in the borane solution, one molecule of acetal was reduced to ether after 18 h at 30 °C. Consequently, under these conditions, all three hydrogens of borane are available for acetal reduction.

Selectivity in Borane Reductions

In ref. 5, page 250, Brown states: "....carboxylic acid and aldehyde groups possess reactivities that would be competitive with the hydroboration reaction. Fortunately....aldehyde groups can be protected as the acetals." It is clear from the work presented here and in the previous article (1) that this protection will not be complete under all experimental conditions. However, it should generally be easy to effect selective hydroborations on molecules possessing both olefinic double bonds and acetal groups provided that low temperatures are employed and an excess of borane is avoided. The rate of hydroboration is immeasurably fast even at temperatures below zero, whereas cyclic acetal cleavage requires hours at 30–50 °C for completion. Selectivity could be further improved by using dilute THF solutions, since acetal reduction is close to third order in borane and hydroboration of olefins is first order in diborane (8).

Descriptions of such selective reductions are to be found in the literature. For example, Lehmann (10) has been successful in the hydro-

[6]Brown and Korytnyk (9) have shown that the third hydrogen of borane reacts very slowly with ketones and nitriles.

boration of carbohydrate derivatives having a double bond and isopropylidene groups. He employed a slight excess of borane for 2 h at room temperature. Likewise hydroboration of unsaturated steroids has been accomplished when ketal groups were present in the molecule (11). Complications may arise however, if the acetal group is a substituent on the double bond, see, for example, ref. 13.

Carboxylic acid groups are also extremely reactive to borane (5, 9) and selective reduction in presence of acetals should present no problem. However, no generalizations can be made for more slowly reacting groups such as nitriles, epoxides and esters. For these compounds, selective reduction in the presence of acetals will depend on the particular structures concerned.

Experimental

Kinetic Studies of the Reaction between Excess Borane and Acetals

A solution of borane was diluted to the required concentration with dry tetrahydrofuran[7] (THF) and placed in a constant temperature bath, and the acetal (10 mmol) was added. The solution in the reaction flask was stirred with a magnetic stirrer and was protected by a calcium chloride tube. Aliquots (0.2 ml) removed after fixed times were dropped into saturated aqueous sodium carbonate (0.2 ml) to quench the reaction.

Gas–liquid chromatographic analysis of the samples so obtained was effected on a 120-cm SE-30 column at 110 °C (see ref. 1 for details). The g.l.c. system gave a slightly greater molar response for the acetal than for its cleavage product. From injections of equimolar amounts of acetal and its reduction product, response factors of 0.94 for benzyl methyl ether and 0.98 for 2-(benzyloxy)ethanol (relative to the corresponding acetal) were obtained.

As the mole percentage of product formed, calculated from the ratio of the product peak area to the total area, was independent of the size of the injected sample, the results were highly replicable. Four injections of the same sample (Fig. 1, $[BH_3] = 0.6\ M$ curve, 60 min sample) indicated the following amounts of benzyl methyl ether: 4.93, 4.81, 4.69, and 4.93 (mmol), a relative standard deviation of $\pm 2.4\%$.

The Reaction of Borane with Excess Benzaldehyde Dimethylacetal

Borane (12.2 mmol) in THF (10 ml) was added to an excess of the acetal (53 mmol) in a flask attached to a gas burette. There was an exothermic reaction and some hydrogen (3.1 mmol) was evolved. As the reaction proceeded, aliquots (2 ml) were withdrawn by syringe through a septum for (*i*) analysis of boron and hydrogen content[8] and (*ii*) g.l.c. analysis of the organic fraction. The results are shown in Table 3. Analysis of the standard borane solution prior to reaction showed it to have the empirical formula $BH_{2.7}$. Therefore the borane taken initially contained 33.0 mmol of hydride. Discounting the initial hydrogen evolution, 30 mmol of hydride are theoretically available for reduction. After 18 h at 30 °C, a sample of reaction mixture evolved no hydrogen gas upon addition of water and the yield of benzyl methyl ether was found to be 30 mmol. Therefore all the hydrogens of borane were consumed in the reduction of excess acetal at 30 °C.

The source of the acetals and of their reduction products was given in ref. 1.

The authors are indebted to Dr. I. S. Butler for help and advice during preparation of the manuscript and to the National Research Council of Canada for financial support.

[8]Hydrogen was estimated as H_2 by adding water to the borane solution in a flask attached to a gas burette. Mannitol in excess was then added to the boric acid residue in the flask and the mixture was titrated with potassium hydroxide to phenolphthalein end point (12).

Free Ion Yields and Electron Ranges in X Irradiated Simple Liquids: Unusual Behavior in Carbon Dioxide and Carbon Disulfide[1]

TERANCE E. M. SAMBROOK AND GORDON R. FREEMAN

Chemistry Department, University of Alberta, Edmonton, Alberta T6G 2G2

Received April 22, 1975

TERANCE E. M. SAMBROOK and GORDON R. FREEMAN. Can. J. Chem. **53**, 2822 (1975).

The radiolysis free ion yields G_{fi}^0 and electron penetration ranges b_{GP} in the liquids carbon dioxide and carbon disulfide are much larger than would be predicted by extrapolation from earlier studies of unsaturated hydrocarbons. In the isoelectronic, nonpolar compounds carbon dioxide and propadiene at 212 ± 4 K $G_{fi}^0 = 0.19$ and 0.022, respectively, with $b_{GP} = 116$ and 37 Å. In carbon disulfide $G_{fi}^0 = 0.44 \pm 0.02$, independent of temperature over the range 169 to 354 K; the electron penetration range appears to increase with decreasing temperature in this liquid. In the unsymmetrical, polar compound carbonyl sulfide, $G_{fi}^0 = 0.089$ and $b_{GP} =$ 37 Å at 214 K; the behavior is similar to that in ethers.

TERANCE E. M. SAMBROOK et GORDON R. FREEMAN. Can. J. Chem. **53**, 2822 (1975).

Les rendements en ions libres, G_{fi}^0, et les parcours des électrons, b_{GP}, dans le dioxyde et le disulfure de carbone liquides sont beaucoup plus importants qu'on aurait pu le prévoir en extrapolant les études antérieures sur les hydrocarbures non saturés. Pour le dioxyde de carbone et le propadiène qui sont non polaires et isoélectroniques, on trouve à 212 ± 4 K: $G_{fi}^0 = 0.19$ et 0.022, respectivement, avec un parcours b_{GP} de 116 et 37 Å. Pour le disulfure de carbone, $G_{fi}^0 = 0.44 \pm 0.02$ est indépendant de la température depuis 169 jusqu'à 354 K; le parcours électronique dans ce liquide semble augmenter lorsque la température diminue. Pour l'oxysulfure de carbone, composé non symétrique et polaire, $G_{fi}^0 = 0.089$ et $b_{GP} = 37$ Å à 214 K. Son comportement est semblable à celui des éthers.

Introduction

In studies of the behavior of electrons in liquids, one of the subjects of major interest is processes that govern energy transfer from low energy ($\lesssim 1$ eV) electrons to the molecules of the liquid. Preliminary information about the processes is obtained from the relative penetration ranges of secondary electrons into X irradiated liquids (1, 2). The ranges are inversely related to the rates of energy loss of the electrons.

Penetration ranges in liquid hydrocarbons depend on the molecular structure. In saturated compounds the ranges increase with increasing degree of sphericity of the molecules (1, 2). If the molecules are large, the range correlates with the average sphericity of groups containing two carbon–carbon bonds in series (3). In unsaturated hydrocarbons the correlation between molecular structure and electron penetration is obscure (4). For example, the presence of dipole moments up to 0.6 D seem to have negligible influence, whereas an electron–dipole interaction might have been expected to reduce the electron penetration range.

Most organic molecules have relatively complex structures. In the present work a series of three simple triatomic compounds containing π bonds were studied. They are carbon dioxide (O=C=O), carbonyl sulfide (O=C=S), and carbon disulfide (S=C=S), all comprised of linear molecules.

Penetration ranges are estimated from the radiolysis free ion yields in the liquids (1–4).

Experimental

Materials

The three compounds were obtained from Matheson Co.

Spectral grade carbon disulfide was dried over either anhydrous magnesium carbonate or anhydrous calcium chloride, fractionally distilled (retaining the central portion), then thoroughly degassed by distillation under vacuum.

Carbonyl sulfide was purified by bubbling the gas through two concentrated potassium hydroxide solutions, then two solutions of lead acetate. The gas was then passed through a 30 cm column of potassium hydroxide pellets and eight 40 cm columns of Drierite, then condensed in a cold trap. The compound was thoroughly degassed by successive distillations into cold traps from which gases noncondensable at 77 K were continuously removed by the vacuum system.

Carbon dioxide gas was passed through a 50 cm column of Drierite. Gases noncondensable at 77 K were

removed by successive sublimations of the carbon dioxide into traps that were continuously pumped on.

Apparatus and Techniques

The equipment and methods of measurement were the same as those described elsewhere (4). Briefly, a 1 μs pulse of 1.7 MeV X-rays delivered 3×10^{10} eV/g to the sample. The free ion yield $G_{fi}{}^{E}$ was measured by the charge clearing technique, normally using applied electric field strengths E in the range 1–60 kV/cm.

The measured yields were extrapolated to zero applied field strength by using [1] (4, 5).

$$[1] \qquad G_{fi}{}^{E} = G_{tot} \int_0^\infty F(y)\phi(y,E)\,dy$$

where G_{tot} is the total number of ion–electron pairs generated per 100 eV absorbed by the liquid, $F(y)dy$ is the fraction of thermalized electron–ion pairs that have initial intrapair separation distances between y and $y + dy$, and $\phi(y,E)$ is the probability that a pair with a given separation distance y will escape geminate neutralization (become free ions) in the presence of an applied field E.

$$[2] \quad \phi(y,E) = e^{-r/y}\left(1 + e^{-\beta y}\sum_{n=1}^{\infty}\frac{(\beta y)^n}{(n+1)!} \times \sum_{j=0}^{n-1}(n-j)\frac{(r/y)^{j+1}}{(j+1)!}\right)$$

where $r = \xi^2/\varepsilon kT$, $\xi = 4.803 \times 10^{-10}$ e.s.u., ε is the dielectric constant of the liquid, k is Boltzmann's constant, T is the absolute temperature, and $\beta = (\xi E/300kT)$.

The distribution function $F(y)$ was taken to have the form [3], which has been designated YGP (4).

$$[3] \quad F(y) = 0.96(4y^2/\pi^{1/2}b_{GP}{}^3)\exp(-y^2/b_{GP}{}^2) \qquad y < 2.4b_{GP}$$

$$F(y) = 0.96[(4y^2/\pi^{1/2}b_{GP}{}^3)\exp(-y^2/b_{GP}{}^2) + 0.5b_{GP}{}^2/y^3] \qquad y > 2.4b_{GP}$$

where 0.96 is a normalization factor and b_{GP} is the adjustable dispersion parameter. The latter is also the most probable value of y. At $E = 0$, [1] reduces to

$$[4] \quad G_{fi}{}^{0} = G_{tot} \int_0^\infty \exp(-\xi^2/\varepsilon kTy)F(y)\,dy$$

Physical Properties of the Liquids

The densities d (6–8) were obtained by interpolation or extrapolation of data in the references quoted. The dielectric constant of carbon disulfide was similarly obtained from ref. 6*b*. That for carbon dioxide was calculated from the Clausius–Mosotti equation and the molar polarization listed for the liquid in ref. 9. The dielectric constant of carbonyl sulfide was measured at 0.4 and 4 kHz, using a capacitance bridge (Electroscientific Inc.) and a standard capacitor (General Radio 1422 CD). Values are recorded in Table 1.

The total ionization yields G_{tot} in the liquid are not known. As a first approximation they were taken equal to the gas phase yields, which are 3.0 ion pairs/100 eV in carbon dioxide (10–12), 3.8 in carbon disulfide[2] (13), and ~3.5 in carbonyl sulfide. The last value was interpolated with the aid of the ionization potentials of the three gases, which are respectively 13.8, 10.1, and 11.2 eV (14).

Results and Discussion

Free Ion Yields

The yields in the different liquids at the same temperature increase in the order OCS < OCO < SCS. Yields at 210 ± 6 K are included in Fig. 1. The difference between the yields in carbon dioxide and carbon disulfide is due mainly to the greater dielectric constant of the latter ([4] and Table 1). The yield in carbonyl sulfide is smaller than those in the other liquids in spite of the larger dielectric constant of the former. The small yield must be attributed to a small electron range y, to be discussed later.

There is relatively little effect of temperature on the yields in carbonyl sulfide over the region measured (Fig. 1). This is similar to the behavior in ethers (15). It has been attributed to the magnitude of the increase of the dielectric constant of the polar liquid with decreasing temperature; the product εT is nearly independent of temperature.

In carbon disulfide the free ion yields $G_{fi}{}^{E}$ *increase* with *decreasing* temperature (Fig. 2). This is opposite to the direction of change expected for a nonpolar liquid. The influence of temperature is relatively small at $T > 295$ K, but is marked at $T < 295$ K. The effect is attributed to unusual electron penetration ranges, discussed in the next section. Earlier estimates of $G_{fi}{}^{0}$ at 296 K (1, 16) were 30–40% smaller than the present value of 0.44 (Table 1). The discrepancy is a general one that exists between free ion yield measurements in the Brookhaven and Edmonton laboratories and is not understood (4, 5).

Electron Ranges

The values of the most probable electron ranges b_{GP} were obtained by fitting eqs. 1–3 to the experimental yields $G_{fi}{}^{E}$, and are listed in Table 1.

The range in carbon dioxide ($b_{GP} = 116$ Å) is much greater than that in the isoelectronic hydrocarbon propadiene ($b_{GP} = 37$ Å (17)), and is greater even than that in the analogous saturated hydrocarbon (propane, $b_{GP} = 84$ Å (17)). Carbon dioxide in dilute solution in either a polar (18) or nonpolar (19) solvent is an efficient

[2]Gas phase ion yield estimated from the results of J. J. Thomson.

scavenger of electrons. One might have expected that the electron capturing property of carbon dioxide would enhance the electron energy transfer cross section of the molecule via negative ion states. The penetration range of low energy electrons into liquid carbon dioxide might therefore have been expected to be smaller than that in propane. However, the reverse is true, so the contribution of negative ion states to the electron energy transfer cross section of carbon dioxide in the liquid phase appears to be negligible.

The symmetry and degree of sphericity of carbon dioxide are greater than those of propadiene which partly rationalizes the larger electron range in the former liquid (3). However, the apparent lack of influence of the double bonds in carbon dioxide, evidenced by the ranges

falling in the order carbon dioxide > propane > propadiene (Table 1), is surprising.

Electron behavior in carbon disulfide is similar to that in carbon dioxide. Both compounds are efficient electron scavengers when present as a dilute solute in water (18), yet electron ranges in both pure liquids are large (Table 1). The high vapor pressure of liquid carbon dioxide prevented the temperature dependence of $G_{fi}{}^{E}$ being measured in that liquid. However, peculiar temperature effects were found in carbon disulfide. The *increasing* free ion yield with *decreasing* temperature displayed in Fig. 2 can only be explained by an increasing electron range with decreasing temperature (Table 1). The yield extrapolated to zero field strength, $G_{fi}{}^{0}$, is nearly independent of temperature (Table 1 and Fig. 2), which is different from the behavior in hydrocarbons (1, 3–5, 20).

The yields $G_{fi}{}^{E}$ calculated as a function of E, using eqs. 1–3 and $G_{tot} = 3.8$, agreed with the experimental results only at the highest temperature. At lower temperatures the calculated field dependence of $G_{fi}{}^{E}$ was too large. To obtain agreement at the lower temperatures, either the range distribution function $F(y)$ had to be altered to decrease less rapidly at large y, or the assumed value of G_{tot} had to be reduced. It is improbable that G_{tot} in the liquid is temperature dependent. However, it is impractical to develop a new distribution function $F(y)$ on the basis of a single compound, so the assumed value of G_{tot} was decreased to determine the magnitude of the problem. The "best fit" value of G_{tot} obtained using the distribution function [3] was ~4 at 354 K and it reduced gradually to 1.6 at 169 K. The sensitivity of the curve fitting to the assumed value of G_{tot} increased with decreasing temperature.

Yields calculated using $G_{tot} = 2.0$ are shown in Fig. 2 to demonstrate the variation of agreement or disagreement with temperature. The curves were selected by adjusting the value of b_{GP} in [3] to give the minimum average deviation from the experimental points, with the restriction that G_{tot} be held at 2.0. If the calculated curves had been fitted to the experimental yields at high field strengths, the calculated yields at low field strengths would have been too large at high temperatures and too small at low temperatures.

The simple exponential distribution function[3] (21, 22) and the exponential function with the power tail (designated YEP, 22) are also inappropriate. All decrease too rapidly at large y. Other compounds will have to be studied before distribution functions for nonhydrocarbons can be devised with confidence.

Mohler and Taylor measured the steady state X radiation induced electrical conductance of liquid carbon disulfide at field strengths up to 70 kV/cm, presumably at room temperature (13). The shape of their curve at $E > 20$ kV/cm was the same as that of the 295 K curve in Fig. 2. At lower fields the Mohler and Taylor curve fell more rapidly than the present one, due to greater ion loss by second order neutralization in the steady state system. The early authors (13) used Jaffe's theory of columnar ionization (23) to extrapolate the ion current to infinite field strength. Then using a comparison of the ionization produced in the liquid with that produced in air they estimated $W(CS_2$ liquid) = 24 eV/ion pair, or G_{tot} (liquid) = 4.2 ionizations/100 eV. This yield seems reasonable by comparison with the gas phase value G_{tot} (gas) = 3.8 (13), but the treatment was inaccurate on two counts: (*a*) the columnar ionization model does not apply to X or γ irradiated systems; (*b*) extrapolation of the high field current-voltage curve to zero field strength and comparison of that value with the Jaffe extrapolation to infinite field strength gives $G_{fi}{}^{0}/G_{tot} = 0.3$, which would indicate $G_{fi}{}^{0} = 1.2$ from their treatment. That value of $G_{fi}{}^{0}$ is 3–5 times greater than the present and the Brookhaven (1, 16) determinations.

It must be concluded that electrons behave differently in carbon disulfide than in liquids previously studied. Other similar systems should be sought.

The range in carbonyl sulfide is much smaller than those in carbon dioxide and carbon disulfide (Table 1). The smaller range ties in with more efficient electron de-energization by molecules that lack symmetry and have a large dipole moment (Table 2). However, it should be noted that there is no detailed correlation between electron ranges in different liquids and the molecular dipole moments or anisotropies of polarizability (Table 2). The inverse correlation between range and anisotropy of polarizability that was noted for simple alkanes (3) is not a general property.

Dipole moment and polarizability relate to long range electrostatic interactions, so these do not govern low energy electron energy loss pro-

cesses in liquids. The nature of the controlling short range interactions remains obscure. The peculiar temperature effect in carbon disulfide seems to be a clue. It should be sought in other liquids.

We would like to thank the personnel of the Radiation Research Center for aid with the electronics.

Stereoselective Total Synthesis of Copa and Ylango Sesquiterpenoids: Preparation of (−)-(1*S*,4*S*,5*R*,7*R*)-1,7-Dimethyl-4-isopropylbicyclo[3.2.1]octa-6,8-dione and (+)-(1*R*,4*S*,5*S*,7*S*)-1,7-Dimethyl-4-isopropylbicyclo[3.2.1]octa-6,8-dione

Received May 15, 1975

EDWARD PIERS, RONALD W. BRITTON, M. BERT GERAGHTY, ROBERT J. KEZIERE, and R. DEAN SMILLIE. Can. J. Chem. **53**, 2827 (1975).

The efficient, stereoselective syntheses of two diastereomeric bicyclo[3.2.1]octadiones (**23** and **24**) are described and the potential use of these materials for the synthesis of the copa (**1–5**) and the ylango (**7–11**) sesquiterpenoids, respectively, is outlined. Conversion of (+)-carvomenthone (**26**) into the corresponding *n*-butylthiomethylene derivative **28**, followed by alkylation of the latter with ethyl 2-iodopropionate, gave compound **29**. Removal of the blocking group from the latter was accompanied by ester hydrolysis and afforded keto acid **30**. An efficient intramolecular Claisen condensation of the corresponding ester **31** yielded (−)-(1*S*,4*S*,5*R*,7*R*)-1,7-dimethyl-4-isopropylbicyclo[3.2.1]octa-6,8-dione (**23**). Conversion of the known octalone **39** into the cross-conjugated keto aldehyde **41** was accomplished by standard reactions. Treatment of the latter with lithium dimethylcuprate, followed by trapping of the resultant enolate anion with acetyl chloride gave compound **42**. Oxidative ozonolysis of this material yielded the keto acid **43**. Esterification of the latter, followed by intramolecular Claisen condensation of the resulting keto ester **45**, afforded (+)-(1*R*,4*S*,5*S*,7*S*)-1,7-dimethyl-4-isopropylbicyclo[3.2.1]octa-6,8-dione (**24**).

EDWARD PIERS, RONALD W. BRITTON, M. BERT GERAGHTY, ROBERT J. KEZIERE et R. DEAN SMILLIE. Can. J. Chem. **53**, 2827 (1975).

On a décrit les synthèses efficaces et stéréosélectives des deux bicyclo[3.2.1]octanediones (**23** et **24**) et leurs usages potentiels pour la synthèse de sesquiterpenoides copa (**1–5**) et ylango (**7–11**). La conversion de la (+) carvomenthone (**26**) en dérivé butylthiométhylène correspondant (**28**) suivie d'une alkylation de ce dernier par l'iodo-2 propionate d'éthyle conduit au composé **29** qui après élimination du groupe protecteur et hydrolyse de l'ester fournit le céto-acide **30**. Une condensation de Claisen intramoléculaire et efficace effectuée sur l'ester correspondant **31** conduit à la (−) (1*S*,4*S*,5*R*,7*R*) diméthyl-1,7 isopropyl-4 bicyclo[3.2.1]octanedione-6,8 (**23**). On a transformé l'octalone connue **39** en céto-aldéhyde **41** par des techniques standards. Le traitement de **41** par du diméthylcuprate de lithium suivi par le piégeage de l'anion énolate qui en résulte par du chlorure d'acétyle conduit au composé **42** qui par ozonolyse oxydante fournit le céto-acide **43**. L'estérification de ce dernier suivie par une conduisation de Claisen intramoléculaire du céto-ester **45** conduit à la (+) (1*R*,4*S*,5*S*,7*S*) diméthyl-1,7 isopropyl-4 bicyclo[3.2.1]-octanedione-6,8 (**24**).

[Traduit par le journal]

The structurally related series of compounds (+)-copacamphor (**1**), (+)-copaborneol (**2**), (+)-copaisoborneol (**3**), (−)-copacamphene (**4**), and (−)-cyclocopacamphene (**5**) together make up part of the copa[1] group of sesquiterpenoids. In similar fashion, the structurally related substances (−)-ylangocamphor (**7**), (−)-ylangoborneol (**8**), (−)-ylangoisoborneol (**9**), (+)-sativene (**10**), and (+)-cyclosativene (**11**) together constitute part of the ylango[1] group of sesquiterpenoids. These two series of compounds can be considered as 'isoprenologs' of the well-known series of monoterpenoids camphor (**13**), borneol (**14**), isoborneol (**15**), camphene (**16**), and tricyclene (**17**) (see Chart 1).

Of the copa and ylango sesquiterpenoids listed in Chart 1, only four have as yet been isolated from naturally occurring sources. Thus, (+)-

[1]The terms 'copa' and 'ylango' have by convention been derived from the sesquiterpenoids (−)-α-copaene (**6**) (1, 2) (structurally related to **1–5**), and (+)-α-ylangene (**12**) (3) (structurally related to **7–11**). On the basis of this structural analysis and system of nomenclature, the more consistent names for sativene (**10**) and cyclosativene (**11**) would be ylangocamphene and cycloylangocamphene, respectively.

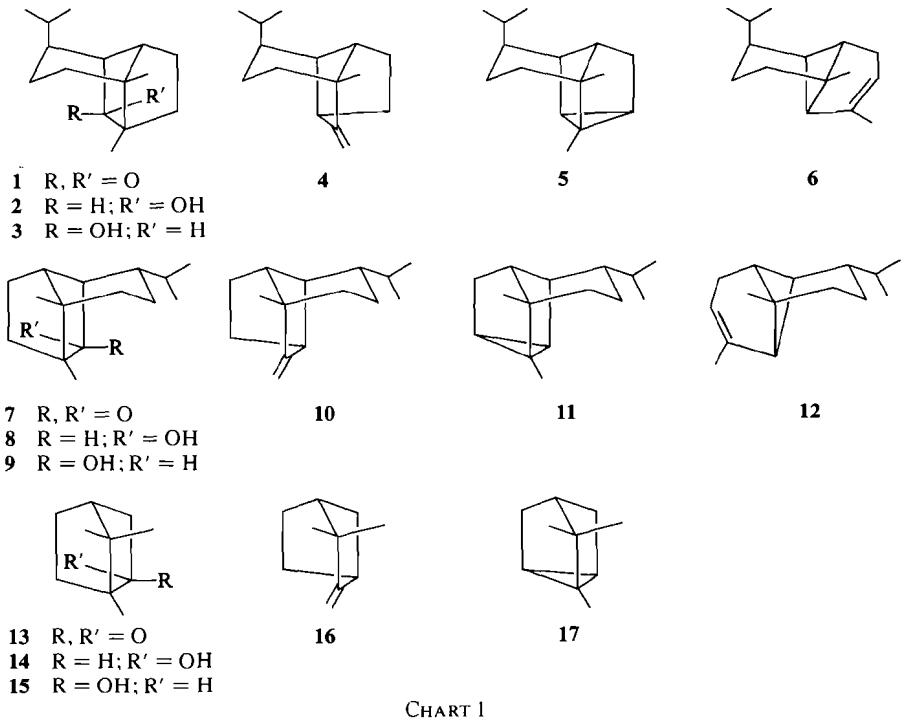

CHART 1

copaborneol (**2**) was found to be the major sesquiterpenoid alcohol occurring in the wood of *Pinus silvestris* L. and in Swedish sulfate turpentine (4–6), while several vetiver oils have been shown to contain (+)-cyclocopacamphene (enantiomer of **5**) (7). The latter has also been obtained by chemical conversion from cyclocopacamphenic acids (8). Although (+)-copacamphor (**1**), (+)-copaisoborneol (**3**), and (−)-copacamphene (**4**) have not as yet been obtained from living systems, they have been acquired by chemical transformation from (+)-copaborneol (6).

(−)-Sativene (enantiomer of **10**) has been isolated from *Helminthosporium sativum*, a fungus responsible for widespread destruction and loss of cereal crops (9). The enantiomer, (+)-sativene (**10**), as well as the structurally and configurationally related tetracyclic compound (+)-cyclosativene (**11**), have been acquired from the cortical turpentine of a number of different *Abies* species (10–12). The remaining three ylango sesquiterpenoids (**7**, **8**, and **9**) have yet to be isolated as natural products and were, in fact, unknown compounds until the completion of our synthetic work.

A careful analysis of the structure of the various copa and ylango sesquiterpenoids listed in Chart 1 reveals a number of different approaches which might be employed to carry out the stereoselective synthesis of these compounds.[2] Our own work was based upon the observation that all of these substances can, from a structural point of view, be considered as derivatives of two diastereomeric substituted bicyclo[3.2.1]octanes. For example, the copa compounds would have as the parent structure the bicyclooctane **18** and each of the specific sesquiterpenoids (+)-copacamphor, (−)-copacamphene, and (−)-cyclocopacamphene would have the two additional

[2]At the time that our work was initiated, relatively little synthetic work had been done in this area. In this connection, the very elegant synthesis of racemic sativene by McMurry (13) deserves special mention. During the time that our studies were underway, and after their completion, several reports concerning the synthesis of one or more of the copa and/or ylango sesquiterpenoids appeared. These reports involved, in each case, synthetic routes very different from those employed in our work. In summary, the following syntheses have been reported: partial synthesis of (+)-copacamphor, (+)-copaborneol, (+)-copaisoborneol (6), and (+)-sativene (9); total synthesis of (±)-sativene (13,14), (±)-cyclosativene (15,16), (±)-copacamphene (17,15*b*), (±)-copacamphor (18,14), (±)-ylangocamphor (18,14), (−)-sativene, (−)-copacamphene, (+)-ylangocamphor, and (+)-copacamphor (19).

18 19 20 21 22 23 24 25

required carbon atoms attached in a different way from the one-carbon bridge to the two-carbon bridge (*cf.* **19**, **20**, and **21**). A similar analysis can be made for the ylango sesquiterpenoids, with the parent bicyclo[3.2.1]octane being **22**. Therefore, more explicitly, our synthetic plan was to attempt the stereoselective synthesis of two substituted bicyclo[3.2.1]octadiones, one (**23**) to serve as the synthetic precursor to the copa sesquiterpenoids and the other (**24**) to be employed as the starting point for the preparation of the ylango sesquiterpenoids. In each case, the carbonyl group contained in the one-carbon bridge (C-8) was to serve as a 'handle' for the introduction of the additional two carbon atoms necessary to complete the various 15-carbon skeletons. Similarly, the carbonyl group present in the two-carbon bridge (at C-6) was to be employed to effect directly a necessary mode of cyclization or to introduce appropriate functionality to allow for the necessary mode(s) of ring closure.

In this paper we report the stereoselective total synthesis of (−)-(1*S*,4*S*,5*R*,7*R*)-1,7-dimethyl-4-isopropylbicyclo[3.2.1]octa-6,8-dione (**23**) and of (+)-(1*R*,4*S*,5*S*,7*S*)-1,7-dimethyl-4-isopropylbicyclo[3.2.1]octa-6,8-dione (**24**).[3] Interestingly, the readily available monoterpenoid (−)-carvone (**25**), a substance of known absolute configuration, served as the starting material for the synthesis of both **23** and **24**. In subsequent papers (22,23) we describe the conversion of the bicyclic ketones **23** and **24** into the copa and ylango sesquiterpenoids, respectively.

Synthesis of (−)-(1S,4S,5R,7R)-1,7-Dimethyl-4-isopropylbicyclo[3.2.1]octa-6,8-dione (23) (see Scheme 1)

Conversion of (+)-carvomenthone (**26**)[4] into the corresponding *n*-butylthiomethylene derivative **28**, via the hydroxymethylene compound **27**, was accomplished in 69% overall yield by standard procedures (25). Alkylation of the blocked ketone **28**[5] with ethyl 2-iodopropionate in the presence of potassium *t*-butoxide in *t*-butyl alcohol was highly regioselective[6] and stereoselective, producing in 73% yield the alkylated product **29**.[7] Treatment of the latter with potassium hydroxide in refluxing aqueous diethylene glycol (25) concomitantly resulted in removal of the *n*-butylthiomethylene blocking group and hydrolysis of the ester functionality. Esterification (ethereal diazomethane) of the resulting crude keto acid **30** afforded in 85% overall yield (from **29**) the keto ester **31**. As might be expected, spectral and gas–liquid chromatographic analysis of this material revealed that it consisted of a mixture of two diastereomers (with respect to the chiral center in the ester-bearing side chain) in a ratio

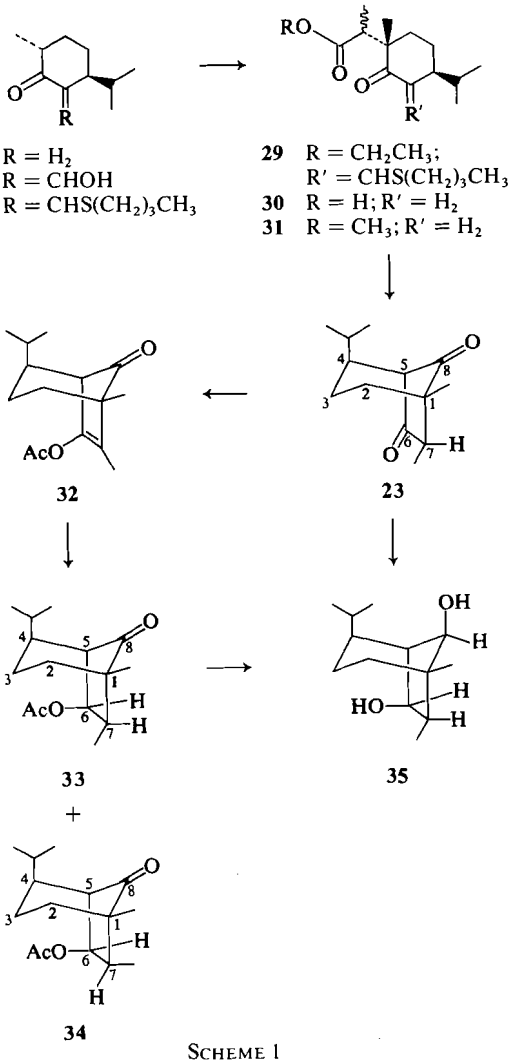
[3]For preliminary reports regarding part of this work, see refs. 20 and 21.

[4]This compound can readily be obtained by hydrogenation of (−)-carvone (**25**); see ref. 24.

[5]Extensive experimentation on the direct alkylation of (+)-carvomenthone (**26**) with ethyl 2-halopropionates under a variety of conditions did not produce synthetically useful yields of desired product.

[6]Interestingly, alkylation of **28** with ethyl 2-bromopropionate under a variety of conditions (including potassium *t*-butoxide in *t*-butyl alcohol) consistently afforded mixtures of *O*- and *C*-alkylation products, in a ratio of approximately 1:1. It is known, however, that changing the leaving group of the alkylating agent from bromide to iodide favors, relatively speaking, *C*-alkylation. For an excellent discussion regarding the various structural and experimental factors which influence *O*- *vs.* *C*-alkylation of ambident anions, see ref. 26.

[7]A discussion of the stereochemistry of **29** and the subsequent synthetic intermediates is deferred until a later section of the paper (*vide infra*).



SCHEME 1

of approximately 1 : 1. However, no attempt was made to separate these epimers, since it was anticipated that this stereochemical ambiguity would disappear upon successful completion of the next synthetic step.

Conversion of the keto ester **31** into the desired bicyclic diketone **23** required an intramolecular Claisen condensation reaction. To this end, keto ester **31** was treated with sodium hydride in dimethoxyethane[8] under a variety of experimental conditions. However, only very poor yields of the desired diketone were obtained. Therefore, the use of alternative bases was investigated and it was eventually found that the desired condensation could be accomplished conveniently and efficiently by treatment of the keto ester **31** with slightly more than 2 equiv. of sodium bis(trimethylsilyl)amide (28) in refluxing dimethoxyethane for 1 h, followed by quenching the reaction mixture with aqueous acetic acid. In this manner, the desired levorotatory bicyclic diketone **23** was obtained in 90% yield as a crystalline, sharp-melting solid.

Although the success of the intramolecular Claisen condensation was very gratifying, there were at this stage of the planned synthetic sequence two stereochemical features of the condensation product (**23**) which required further investigation. Firstly, the stereochemical orientation of the secondary methyl group at C-7 was not known. Although this point was not crucial to any of the subsequent proposed syntheses, it was nevertheless of interest to us to determine whether the methyl group at C-7 was *endo* or *exo* to the bicyclooctane ring system. Secondly, and much more importantly, the stereochemistry at C-1 of compound **23** was also uncertain. This point was directly related, of course, to the question of whether or not one could predict with certainty the stereochemical outcome of the alkylation of the blocked ketone **28**, since it was at this stage of the synthetic sequence that the chiral center under discussion (C-1 of **23**) was formed. In this connection, a perusal of the chemical literature dealing with many different ketone alkylations, along with our own experiences in this area, clearly indicated that, in fact, very little certainty could be ascribed to any predictions which might be made concerning the stereochemistry of the conversion of **28** into **29**. Therefore, it was felt that independent unambiguous evidence concerning this point would have to be obtained.

The stereochemistry at C-7 in the bicyclic diketone **23** was shown as follows. First of all, this material was recovered unchanged from treatment with potassium carbonate in aqueous dioxan. However, an identical treatment with deuterium oxide in the place of water effected the incorporation of one deuterium atom (at C-7). Therefore, it was clear that we were dealing with the thermodynamically more stable epimer.

Conversion of the diketone **23** into the corresponding enol acetate **32** was accomplished in high yield by heating the former with isopropenyl

[8]For a similar type of intramolecular condensation leading to a substituted bicyclo[4.2.1]nonadione, see ref. 27.

acetate in the presence of a catalytic amount of sulfuric acid.[9] Hydrogenation of the carbon–carbon double bond of **32** would be expected to take place primarily with *cis* stereochemistry from the less hindered *exo* face of the bicyclic system, to afford predominantly the keto acetate **33**. In the event, hydrogenation of **32** over 5% palladium-on-barium sulfate in ethanol gave a very high yield (97%) of two products, in a ratio of approximately 9:1. These compounds were separated by preparative g.l.c. The spectral properties of the major product were found to be in complete accord with those expected for the keto acetate **33**. Of particular importance was the p.m.r. spectrum in which the C-6 proton adjacent to the acetoxy functionality appeared as a pair of doublets at τ 4.61. The observed coupling constants ($J_{5,6}$ = 7.0 Hz, $J_{6,7}$ = 10.0 Hz)[10] were in full agreement with structure **33**. Explicitly, molecular models clearly indicated that if the proton at C-6 had been *endo* to the bicyclic system, the coupling constant between the C-5 and C-6 protons would have been very small (dihedral angle ~ 80–90°). However, the coupling constant between the C-5 proton and a C-6 *exo* proton (as in structure **33**) was expected to be in the 6–8 Hz region (dihedral angle ~ 20–30°).[11] Similarly, the coupling constant between the C-6 and C-7 protons in **33** was expected to be quite large (dihedral angle ~ 0°), whereas $J_{6,7}$ of the epimeric compound (at C-7) would presumably be significantly smaller (dihedral angle ~ 120°).

A similar analysis of the p.m.r. spectrum of the minor hydrogenation product led to the conclusion that this material possessed structure **34**. Thus, the C-6 proton adjacent to the acetoxy group in this compound appeared as a pair of doublets at τ 5.30, with coupling constants $J_{5,6}$ = 7.0 Hz and $J_{6,7}$ = 4.0 Hz.[10] On the basis of an argument similar to that used above in the case of keto acetate **33**, these observed coupling constants were consistent only with structure **34**. Although the formation of this compound in the hydrogenation reaction was initially unexpected, its appearance as a minor product is not inconsistent with mechanistic proposals for hydrogenations (29).

Reduction of the major hydrogenation product, keto acetate **33**, with lithium aluminum hydride in refluxing ether afforded, in 92% yield, the crystalline diol **35**. The *same* diol could also be obtained by a similar reduction of the original bicyclic diketone **23**. In each of these reductions, one would expect that the ketone carbonyl group at C-8 would be reduced from the less hindered side, away from the axially oriented isopropyl group at C-4. Thus, the stereochemistry of the chiral center at C-8 in the product could be confidently assigned as shown in structure **35**. Furthermore, the p.m.r. spectrum (C-6 proton as a pair of doublets at τ 5.71, with $J_{5,6}$ = 7.0 Hz and $J_{6,7}$ = 10.5 Hz) of the latter was again in full accord with the assigned structure. Therefore, assuming that our conclusions regarding the structure of the keto acetate **33** were correct, the fact that the same diol **35** was obtained by reduction of either **33** or the diketone **23** led automatically to the conclusion that the methyl group at C-7 in the dione **23** was *endo* to the bicyclic system.

The stereochemistry at C-1 of the dione **23** was shown indirectly by an independent, unambiguous synthesis of the diastereomeric dione **24**. Not only did this synthesis supply the required information regarding the stereochemistry of **23** but it also produced the precursor (**24**) necessary for the projected syntheses of the ylango sesquiterpenoids **7–11**.

Synthesis of (+)-(1R,4S,5S,7S)-1,7-Dimethyl-4-isopropylbicyclo[3.2.1]octa-6,8-dione (24) (see Scheme 2)

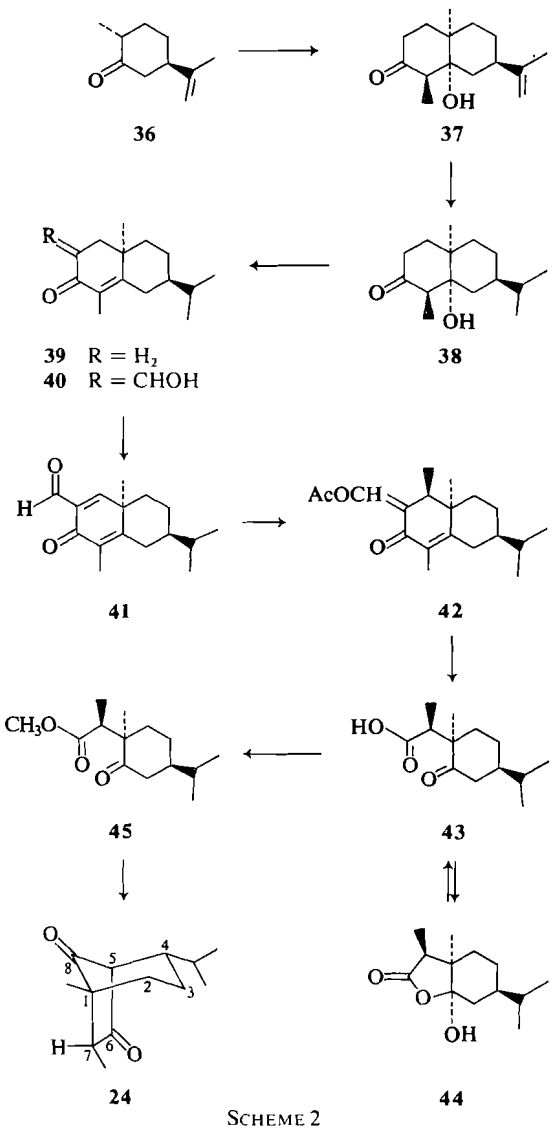
It is well known that Robinson annelation of (+)-dihydrocarvone (**36**)[12] with 1-diethylamino-3-pentanone methiodide affords a mixture of products, of which the crystalline, easily isolable ketol **37** predominates (an average of ~65% isolated yield in our experiments) (31,32). For our synthetic purposes, the established *trans* configurational relationship between the isopropenyl group and the angular methyl group was of crucial importance. Hydrogenation of the ketol

[9]This transformation could also be conveniently carried out by treatment of the dione **23** with sodium bis(trimethylsilyl)amide in benzene, followed by trapping of the resultant enolate with acetyl chloride or acetic anhydride.

[10]These coupling constants were confirmed by appropriate decoupling experiments. See Experimental for details.

[11]In this connection, it should be noted that the proton adjacent to the hydroxyl group in (+)-copaisoborneol (**3**) appeared in the p.m.r. spectrum as a doublet with J = 8.0 Hz, while the corresponding proton in (+)-copaborneol (**2**) produced a broad singlet (6).

[12]This compound can readily be obtained by appropriate reduction of (−)-carvone (**25**) (30).



SCHEME 2

37 over palladium-on-charcoal, followed by base-promoted dehydration of the resultant product **38**, afforded in greater than 95% yield the known levorotatory octalone **39** (33).

It can readily be seen that introduction of a methyl group at C-1[13] of compound **39**, followed by oxidative cleavage of the C-2—C-3 and the C-4—C-5 bonds would result in the formation of a keto acid of known absolute configuration. In order to accomplish the first transformation (introduction of a methyl group at C-1), it was necessary to convert **39** into a compound in which the C-1 center became electrophilic. To this end, compound **39** was transformed into the hydroxymethylene derivative **40** and the latter was subjected to dehydrogenation with 2,3-dichloro-5,6-dicyanobenzoquinone (DDQ) (34) in dioxan. The resultant product, the crystalline cross-conjugated keto aldehyde **41**, was formed in 91% overall yield from **39**.[14] Treatment of compound **41** with excess lithium dimethylcuprate (37) in ether at 0 °C, followed by quenching of the resultant enolate with acetyl chloride, gave the somewhat unstable enol acetate **42**[15] in good yield. Ozonolysis of the crude material in methylene chloride at −78 to −25 °C, followed by oxidative decomposition of the resulting ozonide with hydrogen peroxide and base, afforded the crude keto acid **43**. Although the bulk of this material was used directly for the next synthetic step, a small sample crystallized on standing and could readily be recrystallized from hexane – ethyl acetate. The resulting crystalline material exhibited interesting spectral properties. The i.r. spectrum in Nujol showed strong absorption bands at 3415 (OH stretch) and at 1750 cm^{-1} (C=O stretch). On the other hand, the i.r. spectrum in chloroform exhibited a hydroxyl absorption at 3590, a broad band at 3560–2500 characteristic of a carboxylic acid, and two carbonyl absorptions at 1760 and 1705 cm^{-1}. These data clearly indicated that the keto acid **43** crystallized in the lactol form **44**, while in chloroform solution there existed an equilibrium between **43** and **44**. A careful analysis of the p.m.r. spectrum of this material in deuteriochloroform at 40 °C indicated that the ratio of the two compounds in solution was approximately 1:1.

Esterification of the crude keto acid **43** with ethereal diazomethane gave the keto ester **45** in

[13]The numbering system used here is that normally employed for eudesmane-type sesquiterpenoids.

[14]Direct dehydrogenation of **39** with DDQ produced only low yields of the corresponding cross-conjugated dienone (see ref. 35). The described sequence (octalone → hydroxymethylene derivative → cross-conjugated keto aldehyde) had been employed previously in our laboratory (36) in a related case.

[15]The stereochemistry of the newly introduced chiral center (at C-1) of this compound was not rigorously established. However, considerable literature precedent (38, 39) for this type of reaction clearly indicated that the product should have the stereochemistry as shown in **42**. In any event, this point was not crucial to the subsequent syntheses, since the stereochemical integrity of this center would be lost at a later stage of the projected synthetic sequence.

60% overall yield from the dienone aldehyde **41**. It is important to note that spectral and g.l.c. properties of the keto ester **45** clearly showed that this material was different from *both* of the epimeric keto esters **31** obtained by alkylation of blocked (+)-carvomethone (**28**). Since the stereochemistry of **45** was on firm ground, this comparison clearly established the stereochemistry of **31** and, by implication, the configuration at C-1 of the bicyclic diketone **23**. The latter point was further verified by the successful cyclization of **45** into the dione **24** (*vide infra*), which was clearly diastereomeric with the previously prepared dione **33**.

The intramolecular Claisen condensation of the keto ester **45** proved to be much more troublesome and capricious than expected on the basis of our earlier experience with keto ester **31**. Thus, subjection of the former compound **45** to condensation conditions similar to those used previously for **31** resulted in the formation of only poor yields of the desired bicyclic ketone **24**. The crude product of the reaction consisted largely of unidentified high-boiling material. At this stage, considerable effort was expended to find conditions which would provide increased yields of the dione **24**. A number of different bases (sodium hydride, sodium and lithium bis(trimethylsilyl)amide, trityllithium, tritylsodium) and/or different solvents (benzene, dimethoxyethane, tetrahydrofuran) were employed under a variety of conditions. In general, although the degree of success varied somewhat from experiment to experiment, most of the attempted reactions proved unsatisfactory. Eventually, it was found that the conditions which afforded by far the highest yield (75%) and which gave reproducible results, were the following. A benzene solution of the keto ester **45** was added over a period of 65 min to a solution of sodium bis(trimethylsilyl)amide (2.6 equiv.) in benzene kept at 79–80 °C (internal temperature). This temperature was maintained for a further 75 min and the reaction mixture was then poured into aqueous acetic acid. It was found that the choice of reaction temperature was crucial. At lower temperatures, some starting material was recovered, whereas at higher temperatures the crude product contained considerable amounts of high-boiling material. Similarly, longer reaction times also gave appreciable quantities of undistillable products.

The crystalline, dextrorotatory diketone **24** obtained from the above-described condensation reaction was, as previously mentioned, clearly diastereomeric with the dione **23** obtained earlier. Although the stereochemistry at C-7 of **24** was not rigorously demonstrated[16], it could be assigned as shown by analogy with **23**. In this connection, it should be pointed out that the p.m.r. spectra of both **23** and **24** showed that there existed, in each case, a small coupling (J = 1.5 Hz) between the protons at C-5 and C-7.[17] This similarity strongly indicated that the stereochemical relationship between the two protons was the same for both compounds.

Experimental

General[18]

Melting points, which were determined on a Kofler block, and boiling points are uncorrected. The u.v. spectra were, unless otherwise noted, measured in methanol solution on either a Cary, model 14, or a Unicam, model SP 800, spectrophotometer. Optical rotations were obtained at the sodium D line, using a Rudolph polarimeter, model 219, a Bendix ETL-NPL automatic polarimeter, type 143A, or a Perkin-Elmer model 141 automatic polarimeter. Routine i.r. spectra were recorded on a Perkin-Elmer model 710 spectrophotometer, while comparison spectra were recorded on a Perkin-Elmer model 457 spectrophotometer. Proton magnetic resonance spectra were, unless otherwise noted, taken in deuteriochloroform solution on Varian Associates spectrometers, models A-60, T-60, and/or HA-100 or XL-100. Signal positions are given in the Tiers scale, with tetramethylsilane as an internal standard; the multiplicity, integrated peak areas, and proton assignments are indicated in parentheses. High resolution mass spectrometric measurements were carried out on an AEI type MS-9 mass spectrometer. Gas–liquid chromatographic analyses were carried out on Varian Aerograph g.l.c. units, models 700 or 90-P. The following columns were employed, with the inert supporting material being, in each case, 60–80 mesh Chromosorb W (unless otherwise noted): column A (10 ft × ¼ in.), 20% SE 30; column B (10 ft × ¼ in.), 15% Ionox 330; column C (10 ft × ⅜ in.), 30% SE 30; column D (5 ft × ¼ in.), 20% SE 30; column E (10 ft × ¼ in.), 20% Carbowax 20M; column F (10 ft × ¼ in.), 10% OV-210; column G (10 ft × ¼ in.), 8% FFAP on 60–80 mesh Chromosorb G; column H (5 ft × ¼ in.), 3% SE 30; column I (10 ft × ¼ in.), 20% Apiezon J; column J (20 ft × ⅜ in.), 30% SE 30; column K (10 ft × ⅜ in.), 30% Apiezon J; column L (10 ft × ⅜ in.), 8% FFAP on 60–80

[16]Complete recovery of **24** from epimerizing reaction conditions (potassium carbonate in aqueous dioxan) clearly demonstrated that we were again dealing with the thermodynamically more stable C-7 epimer.

[17]In the case of compound **24** this was confirmed by an appropriate decoupling experiment. See Experimental for details.

[18]This general section is applicable to the two succeeding, accompanying papers (22, 23) as well as to the present paper.

mesh Chromosorb G; column M (10 ft × ¼ in.), 20% FFAP. The specific column used, along with the column temperature and carrier gas (helium) flow rate (in ml/min), are indicated in parentheses. Microanalyses were performed by Mr. P. Borda, Microanalytical Laboratory, University of British Columbia, Vancouver, B.C.

Preparation of the Hydroxymethylene Derivative ***27***

To an ice-cooled, stirred suspension of powdered sodium methoxide (81.5 g, 1.51 mol) in 300 ml of dry benzene, kept under an atmosphere of dry nitrogen, was added a solution of 77.2 g (0.502 mol) of (+)-carvomethone **26** in 300 ml of dry benzene. The resulting mixture was stirred for 10 min and then a solution of 112 g (1.51 mol) of ethyl formate in 60 ml of dry benzene was added. The mixture was warmed to room temperature and allowed to stir overnight. Water was added, the mixture was thoroughly shaken, and the layers were separated. The organic layer was extracted with two portions of 10% aqueous sodium hydroxide. The combined aqueous layer and alkaline extracts were cooled, acidified with concentrated hydrochloric acid, and thoroughly extracted with ether. The combined ethereal extracts were washed with water and brine, and dried over anhydrous magnesium sulfate. Removal of solvent, followed by distillation of the residual oil under reduced pressure, gave 75.3 g (83%) of the hydroxymethylene derivative **27** as a pale yellow oil, b.p. 89–93 °C at 1.0 Torr; n_D^{21} 1.4936; u.v. λ_{max} 291 nm (ε 6570), λ_{max} (NaOH added) 317 nm (ε 17 000); i.r. (film) ν_{max} 1730, 1701, 1629, 1582, 1453, 1360 cm^{-1}.

Preparation of the n-Butylthiomethylene Derivative ***28***

A solution of the hydroxymethylene derivative **27** (62.0 g, 0.341 mol), *n*-butanethiol (36.8 g 0.408 mol), and *p*-toluenesulfonic acid (40 mg) in 400 ml of dry benzene was refluxed in a nitrogen atmosphere under a Dean–Stark water separator overnight, at which time 6 ml of water had been collected. The cooled solution was washed with saturated aqueous sodium bicarbonate, then with water, and finally dried over anhydrous magnesium sulfate. Removal of the solvent gave an oil, which, upon distillation under reduced pressure, afforded 72.1 g (83%) of the *n*-butylthiomethylene derivative **28**, b.p. 120–126 °C at 0.2 Torr; n_D^{21} 1.5252; u.v. λ_{max} 302 nm (ε 11 700); i.r. (film) ν_{max} 1667, 1536, 1450, 1165, 799 cm^{-1}.

Anal. Calcd. for $C_{15}H_{26}OS$: C, 70.82, H, 10.30; S, 12.58. Found: C, 70.57; H, 10.42, S, 12.40.

Alkylation of the n-Butylthiomethylene Derivative ***28*** *with Ethyl 2-Iodopropionate*

The *n*-butylthiomethylene derivative **28** (101.6 g, 0.40 mol) was added to 1 l of dry *t*-butyl alcohol containing 46.0 g (0.46 mol) of potassium *t*-butoxide and the resulting solution was stirred at room temperature for 10 min and then cooled to 0 °C. Ethyl 2-iodopropionate (228 g, 1.0 mol) was added slowly and the reaction mixture was stirred at room temperature under an atmosphere of dry nitrogen overnight. Most of the solvent was removed under reduced pressure and the residue was diluted with water. The resulting mixture was extracted with ether and the organic layer was washed with water and brine, and dried over anhydrous magnesium sulfate. Removal of the solvent gave an oil, which upon distillation under reduced pressure, afforded 103.2 g (73%) of the desired alkylated product **29**, b.p. 172–180 °C at 0.8 Torr; n_D^{24} 1.5181; u.v. λ_{max} 301 nm (ε 10 300); i.r. (film) ν_{max} 1727, 1667, 1536, 1453, 1176 cm^{-1}.

Preparation of Keto Ester ***31***

To a solution of the alkylated *n*-butylthiomethylene derivative **29** (103 g) in 450 ml of diethylene glycol was added 450 ml of 25% aqueous potassium hydroxide and the resulting solution was refluxed under nitrogen for 22 h. The reaction mixture was cooled, acidified with concentrated hydrochloric acid, and then thoroughly extracted with ether. The ethereal layer was dried over anhydrous magnesium sulfate and then concentrated. The crude acid **30** thus obtained was reacted with excess ethereal diazomethane and the excess diazomethane was destroyed by the addition of acetic acid. The ethereal layer was washed with water, a 10% sodium carbonate solution, brine, and then dried over anhydrous magnesium sulfate. Removal of the solvent followed by distillation of the residual oil gave 61.2 g (85%) of the desired keto ester **31** (epimeric mixture of diastereomers), b.p. 120–126 °C at 0.2 Torr; n_D^{21} 1.4722; i.r. (film) ν_{max} 1733, 1701, 1456, 1193 cm^{-1}; p.m.r. τ 6.34, 6.36 (s, s, 3H, methyl ester protons), 7.00, 7.13 (q, q, 1H, protons adjacent to the ester carbonyls, J = 7.5, 7.0 Hz, respectively), 8.76, 8.87 (s, s, 3H, tertiary methyls), 8.84, 8.89 (d, d, 3H, secondary methyls, J = 7.5, 7.0 Hz, respectively), 9.09 (d, 6H, isopropyl methyls, J = 6.0 Hz).

*(−)-(1S,4S,5R,7R)-1,7-Dimethyl-4-isopropylbicyclo-[3.2.1]octa-6,8-dione (****23****)*

To a solution of 80.6 g (0.44 mol) of sodium bis(trimethylsilyl)amide in 900 ml of dry dimethoxyethane was added a solution of 48.0 g (0.20 mol) of the keto ester **31** in 100 ml of dry dimethoxyethane, and the resulting mixture was refluxed under an atmosphere of dry nitrogen for 1.0 h. The reaction mixture was cooled and poured into a rapidly stirred solution of 27.0 g (0.45 mol) of glacial acetic acid in 300 ml of ice water. The resultant mixture was concentrated and the residue was thoroughly extracted with ether. The ethereal extracts were combined and washed with water, a 10% sodium bicarbonate solution, brine, and then dried over anhydrous magnesium sulfate. Removal of the solvent afforded a crystalline material which was recrystallized from petroleum ether (b.p. 60–110 °C) to yield 37.4 g (90%) of the desired diketone **23**, m.p. 76–77 °C; $[\alpha]_D^{20}$ −56° (*c*, 4.0 in $CHCl_3$); i.r. ($CHCl_3$) ν_{max} 1767, 1727, 1453, 1182 cm^{-1}; p.m.r. τ 7.08 (broadened d, 1H, bridgehead proton, J = 4.8 Hz), 7.66 (q of d, C-7 H, $J_{5,7}$ = 1.5 Hz, $J_{7\text{-}CH_3}$ = 7.0 Hz), 8.75 (d, 3H, secondary methyl, J = 7.0 Hz), 8.90 (s, 3H, tertiary methyl), 9.00, 9.10 (d, d, 6H, isopropyl methyls, J = 6.3 Hz).

Preparation of the Keto Acetate ***32***

A stirred mixture of the bicyclic diketone **23** (2.94 g, 15 mmol), isopropenyl acetate (25 ml), and concentrated sulfuric acid (0.06 ml) was placed under an atmosphere of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

nitrogen and then heated gently. An acetone enriched distillate was collected in a Dean–Stark water separator. After 4 h, an additional 0.06 ml of concentrated sulfuric acid was added and heating was continued for a further 2 h. The reaction mixture was cooled and poured into ice water. The resulting mixture was extracted thoroughly with ether. The combined extracts were washed successively with cold dilute aqueous sodium bicarbonate, cold water, and brine, and then dried over anhydrous magnesium sulfate. Removal of the solvent, followed by distillation (air-bath temperature 110–112 °C at 0.2 Torr) of the residual oil afforded 3.3 g (87%) of a pale yellow oil. Analysis of this material by g.l.c. (column A, 200 °C, 100) indicated that the enol acetate **32** and the diketone **23** were present in a ratio of 97:3. An analytical sample of the enol acetate **32**, collected by preparative g.l.c. (column A, 200 °C, 100), exhibited n_D^{20} 1.4830; $[\alpha]_D^{22}$ −10.4° (*c*, 0.55 in $CHCl_3$); i.r. (film) ν_{max} 2940, 1755, 1675, 1450, 1365, 1205, 1175, 1090, 876 cm^{-1}; p.m.r. τ 6.97 (unresolved m, 1H, C-5 H), 7.85 (s, 3H, $COCH_3$), 8.42 (d, 3H, vinyl methyl, J = 0.8 Hz), 8.99 (s, 3H, tertiary methyl), 9.05, 9.11 (d, d, 6H, isopropyl methyls, J = 6.0 Hz). In a decoupling experiment, irradiation of the multiplet signal at τ 6.97 (C-5 H) effected collapse of the doublet at τ 8.42 to a sharp singlet, thus demonstrating the presence of homoallylic coupling between the vinyl methyl group at C-7 and the bridgehead proton at C-5.

Anal. Calcd. for $C_{15}H_{22}O_3$: C, 71.97; H, 8.86. Found: C, 72.16; H, 8.67.

Hydrogenation of the Keto Acetate 32

To a solution of the enol acetate **32** (5.63 g, 22.6 mmol) in 340 ml of 100% ethanol was added 2.26 g of 5% palladium-on-barium sulfate. The reaction mixture was stirred vigorously under hydrogen for 5 h. At this time, an additional amount of hydrogenation catalyst was added and hydrogenation was continued for a further 4 h. After filtration through Celite, the reaction mixture was concentrated under reduced pressure and the residue was distilled (air-bath temperature 120–124 °C, 0.15 Torr) to afford 5.5 g (97%) of a colorless oil. Gas–liquid chromatographic analysis (column B, 220 °C, 90) of this material indicated the presence of the two keto acetates **33** and **34**, in a ratio of 9:1, respectively. Analytical samples of the two isomers were obtained by preparative g.l.c. (column B, 220 °C, 90).

The major product **33** exhibited n_D^{20} 1.4793; $[\alpha]_D^{22}$ +43.8° (*c*, 0.40 in $CHCl_3$); i.r. (film) ν_{max} 2975, 1735, 1465, 1385, 1368, 1235, 1038 cm^{-1}; p.m.r. τ 4.61 (d of d, 1H, C-6 H, $J_{5,6}$ = 7.0 Hz, $J_{6,7}$ = 10.0 Hz), 7.15 (d of d, 1H, C-5 H, $J_{4,5}$ = 3.0 Hz, $J_{5,6}$ = 7.0 Hz), 7.91 (s, 3H, $COCH_3$), 8.94 (d, 3H, secondary methyl, J = 7.4 Hz), 9.05, 9.15 (d, d, 6H, isopropyl methyls, J = 6.3 Hz), 9.15 (s, 3H, tertiary methyl). In decoupling experiments, irradiation of the C-5 proton signal (τ 7.15) effected collapse of the C-6 proton signal (τ 4.61) to a doublet ($J_{6,7}$ = 10.0 Hz). Similarly, irradiation at τ 4.61 caused collapse of the C-5 proton signal to a doublet ($J_{4,5}$ = 3.0 Hz). Finally, irradiation of the somewhat masked C-7 proton multiplet at τ 7.87 produced collapse of the C-7 methyl doublet (τ 8.94) to a sharp singlet, as well as the collapse of the C-6 proton signal to a doublet ($J_{5,6}$ = 7.0 Hz).

Anal. Calcd. for $C_{15}H_{24}O_3$: C, 71.39; H, 9.59. Found: C, 71.10; H, 9.38.

The minor keto acetate **34** exhibited $[\alpha]_D^{22}$ +55.8° (*c*, 0.50 in $CHCl_3$); i.r. (film) ν_{max} 2975, 1735, 1470, 1450, 1383, 1368, 1245, 1142, 1087, 1038 cm^{-1}; p.m.r. τ 5.30 (d of d, 1H, C-6 H, $J_{5,6}$ = 7.0 Hz, $J_{6,7}$ = 4.0 Hz), 7.12 (d of d, 1H, C-5 H, $J_{4,5}$ = 3.0 Hz, $J_{5,6}$ = 7.0 Hz), 7.90 (s, 3H, $COCH_3$), 9.00 (d, 3H, secondary methyl, J = 7.4 Hz), 9.03, 9.09 (d, d, 6H, isopropyl methyls, J = 7.0 Hz), 9.13 (s, 3H, tertiary methyl). A series of decoupling experiments similar to those carried out on the keto acetate **33** (see above) fully corroborated the p.m.r. assignments.

Anal. Calcd. for $C_{15}H_{24}O_3$: C, 71.39; H, 9.59. Found: C, 71.23; H, 9.41.

Preparation of the Diol 35

(a) By Lithium Aluminum Hydride Reduction of Diketone 23

To a solution of lithium aluminum hydride (50 mg) in anhydrous ether (5 ml) was added 208 mg (1.0 mmol) of the bicyclic diketone **23**. The resulting solution was refluxed for 4.5 h and then cooled to 0 °C. Excess hydride was quenched by careful addition of water and the resulting mixture was filtered. The aqueous layer of the filtrate was washed thoroughly with ether, the combined extracts were washed with water and brine, and then dried over anhydrous magnesium sulfate. Removal of the solvent afforded 192 mg (91%) of a colorless crystalline material. Recrystallization of a small sample gave an analytical sample of the diol **35**, m.p. 175–176 °C; $[\alpha]_D^{22}$ −9.8° (*c*, 0.60 in $CHCl_3$); i.r. ($CHCl_3$) ν_{max} 3640, 1460, 1025 cm^{-1}; p.m.r. τ 5.71 (d of d, 1H, C-6 H, $J_{5,6}$ = 7.0 Hz, $J_{6,7}$ = 10.5 Hz), 6.58 (d, 1H, C-8 H, $J_{5,8}$ = 5.0 Hz), 7.48 (broad m, 1H, C-5 H), 9.03, 9.09 (d, d, 6H, isopropyl methyls, J = 6.5 Hz), 9.06 (d, 3H, secondary methyl, J = 7.5 Hz), 9.19 (s, 3H, tertiary methyl).

Anal. Calcd. for $C_{13}H_{24}O_2$: C, 73.54; H, 11.39. Found: C, 73.39; H, 11.48.

(b) By Lithium Aluminum Hydride Reduction of Keto Acetate 33

The reduction of the keto acetate **33** was carried out under conditions identical with those described for the reduction of **23** (see above). From 26 mg of **33** there was obtained 20 mg (92%) of the crystalline diol **35**. This material was identical (m.p., mixture m.p., i.r., p.m.r.) with the diol obtained by hydride reduction of the diketone **23**.

Preparation of the Hydroxymethylene Derivative 40

To a stirred suspension of powdered sodium methoxide (102.5 g, 1.9 mol) in 1400 ml of dry benzene containing 153 ml (2.25 mol) of ethyl formate was added, at 0 °C, a solution of 140 g (0.635 mol) of the (−)-octalone **39** in 1400 ml of dry benzene. The cooling bath was removed and the reaction mixture was stirred at room temperature in an atmosphere of nitrogen for 4 days. The cooled mixture was acidified with 6 *N* hydrochloric acid, the layers were separated, and the aqueous layer was extracted with ether. The combined organic extracts were washed twice with brine and dried over anhydrous magnesium sulfate. Removal of the solvent gave 157 g (98%) of the hydroxymethylene derivative **40** as yellow crystals. An analytical sample of this material, obtained by recrystallization of a small amount of the crude product from hexanes, exhibited m.p. 64.5–65 °C; $[\alpha]_D^{27}$ −8.5° (*c*, 2.5 in $CHCl_3$); i.r. ($CHCl_3$) ν_{max} 1638, 1563 cm^{-1};

p.m.r. (CCl_4) τ −3.73 (broad signal, 1H, exchangeable, =CHO*H*), 2.68 (d, 1H, =*CH*OH, J = 1.6 Hz), 8.17 (d, 3H, vinyl methyl, J = 1.2 Hz), 8.90 (s, 3H, tertiary methyl), 9.01, 9.07 (d, d, 6H, isopropyl methyls, J = 6.0 Hz).

Anal. Calcd. for $C_{16}H_{24}O_2$: C, 77.38; H, 9.74. Found: C, 77.31; H, 9.86.

Preparation of the Dienone Aldehyde 41

A solution of 2,3-dichloro-5,6-dicyanobenzoquinone (5.0 g, 22.0 mmol) in 75 ml of dry dioxan was added to a solution of the hydroxymethylene derivative **40** (5.0 g, 20.1 mmol) in 75 ml of dry dioxan. The resulting mixture was stirred at room temperature in an atmosphere of nitrogen for 10 min and then 300 ml of methylene chloride was added. The precipitate was removed by filtration and the filtrate was passed quickly through a short column of neutral alumina (activity III). The column was thoroughly eluted with methylene chloride. Removal of the solvents gave 4.6 g (93%) of the desired dienone aldehyde **41** as pale yellow crystals. An analytical sample, obtained by recrystallization of a small amount of the crude material from hexanes, exhibited m.p. 78.5–79 °C; $[\alpha]_D^{27}$ +161° (*c*, 2.5 in $CHCl_3$); u.v. λ_{max} 228 (ε 10 200), 239 (ε 9800) (shoulder), 266 nm (ε 6800) (shoulder); i.r. ($CHCl_3$) ν_{max} 1700, 1648, 1623, 1600, 855, 824 cm^{-1}; p.m.r. τ −0.31 (s, 1H, aldehydic H), 2.51 (s, 1H, vinyl H), 8.03 (d, 3H, vinyl methyl, J = 1.2 Hz), 8.67 (s, 3H, tertiary methyl), 9.04, 9.17 (d, d, 6H, isopropyl methyls, J = 6.0 Hz).

Anal. Calcd. for $C_{16}H_{22}O_2$: C, 78.01; H, 9.00. Found: C, 78.18; H, 9.09.

Preparation of the Keto Ester 45

To a stirred suspension of anhydrous cuprous iodide (15.6 g, 82.0 mmol) in 300 ml of anhydrous ether at −25 °C was added, over a period of 5 min, 73.7 ml of 2.2 *M* ethereal methyllithium. The resulting solution was stirred in an atmosphere of nitrogen for 10 min and then the temperature was raised to 0 °C. A solution of the dienone aldehyde **41** (11.6 g, 47.0 mmol) in 300 ml of anhydrous ether was added over a period of 40 min and the resulting mixture was stirred at 0 °C for 2 h. A solution of acetyl chloride (12 ml) in 240 ml of anhydrous ether was then added over a period of 5 min and stirring was continued at 0 °C for a further 10 min, by which time the reaction mixture was composed of a clear supernatant and a sticky precipitate. The clear solution was poured into a rapidly stirred mixture (1200 ml) of concentrated ammonium hydroxide and crushed ice (1:2) and the ether layer was quickly separated. The aqueous layer was rapidly extracted twice with cold ether and the combined ether extracts were washed with cold brine until neutral, dried over anhydrous magnesium sulfate, and concentrated to give 11.1 g of the enol acetate **42** as a viscous oil. This material was somewhat unstable and was used without further purification in the next reaction (ozonolysis). It exhibited i.r. (film) ν_{max} 3110, 1768, 1672, 1612 cm^{-1}; p.m.r. τ 1.85 (s, 1H, vinyl H), 7.12 (q, 1H, CH_3CH—, J = 7.0 Hz), 7.76 (s, 3H, CH_3COO—), 8.13 (s, 3H, vinyl methyl), 8.82 (s, 3H, tertiary methyl), 8.96 (d, 3H, secondary methyl, J = 7.0 Hz), 9.06 (poorly resolved multiplet, 6H, isopropyl methyls).

The solid residue remaining in the reaction flask was treated with 500 ml of concentrated ammonium hydroxide and crushed ice (1:1) and 500 ml of ether. This mixture was stirred vigorously for 15 min, sodium chloride was added, and the layers were separated. The aqueous layer was extracted twice with cold ether and the combined ether extracts were washed with cold brine until neutral. Drying over anhydrous magnesium sulfate and removal of the solvent gave 3.0 g of a gum-like material. Infrared and p.m.r. spectra indicated that about one-half of this material was the desired enol acetate **42** so it was combined without further purification with the material obtained above.

A solution of the combined crude enol acetate product (14.1 g) in 200 ml of methylene chloride was treated with ozone at −78 °C until the solution turned blue and then for a further 30 min at −25 °C. The cooling bath was removed and 300 ml of a 5% solution of sodium hydroxide in methanol–water (7:1) was added, followed by the careful addition of 120 ml of 30% hydrogen peroxide. The resulting mixture was gradually heated, effecting distillation of the methylene chloride. The temperature of the remaining mixture was raised to reflux and refluxing was continued until foaming ceased. The solution was cooled to 40 °C and 60 ml of 30% hydrogen peroxide was added, followed by refluxing as before. This process was repeated once more with a further 60 ml of hydrogen peroxide. The methanol was removed at aspirator pressure, the residue was diluted with water and acidified with 6 *N* hydrochloric acid. The resulting mixture was thoroughly extracted with ether and the combined ether extracts were washed twice with brine and then dried over anhydrous magnesium sulfate. Removal of the solvent gave 10.9 g of a viscous oil which solidified overnight. A small sample of this solid was recrystallized from hexanes and then from hexanes – ethyl acetate to give an analytical sample of the lactol **44** which exhibited m.p. 83.5–84 °C; i.r. ($CHCl_3$) 3590, 3560–2500, 1760, 1705 cm^{-1}; i.r. (Nujol) 3415, 1750 cm^{-1}; p.m.r. τ 6.88, 7.13 (q, q, 1H, CH_3CHCO_2H and $CH_3CHCO_2C(OH)$— (lactol), J = 7.2, 7.2 Hz).

Anal. Calcd. for $C_{13}H_{22}O_3$: C, 68.99; H, 9.80. Found: C, 69.03; H, 9.83.

The total crude keto acid **43** – lactol **44** product was esterified by treatment with excess ethereal diazomethane. The excess diazomethane was then destroyed with acetic acid, the mixture was washed with sodium bicarbonate solution, with brine, and dried over anhydrous magnesium sulfate. Removal of the solvent and distillation (air-bath temperature 98–106 °C/0.15 Torr) of the residual oil gave 6.75 g (60% overall from the dienone aldehyde **41**) of the desired keto ester **45**. An analytical sample, obtained by preparative g.l.c. (column C, 205 °C, 180), exhibited n_D^{20} 1.4699; $[\alpha]_D^{25}$ +151° (*c*, 2.0 in $CHCl_3$); i.r. (film) ν_{max} 1732, 1705 cm^{-1}; p.m.r. τ 6.30 (s, 3H, $-OCH_3$), 6.91 (q, 1H, $CH_3CHCO_2CH_3$, J = 7.1 Hz), 9.00 (s, 3H, tertiary methyl), 9.03 (d, 3H, secondary methyl, J = 7.1 Hz), 9.07, 9.08 (d, d, 6H, isopropyl methyls, J = 6.3 Hz).

Anal. Calcd. for $C_{14}H_{24}O_3$: C, 69.96; H, 10.07. Found: C, 69.93; H, 9.93.

(+)-(1R,4S,5S,7S)-1,7-Dimethyl-4-isopropylbicyclo-[3.2.1]octa-6,8-dione (24)

To a solution of sodium bis(trimethylsilyl)amide (30g,

164 mmol) in 400 ml of dry benzene, kept at 79–80 °C (internal temperature) under an atmosphere of nitrogen, was added over a period of 65 min a solution of the keto ester **45** (15.0 g, 62.5 mmol) in 650 ml of dry benzene. This temperature was maintained for a further 75 min, then the reaction mixture was cooled and poured into 1000 ml of cold water containing 30 ml of acetic acid. The layers were separated and the aqueous layer was extracted once with ether. The combined organic layers were washed twice with sodium bicarbonate solution, with brine, and dried over anhydrous magnesium sulfate. Removal of the solvent and distillation (air-bath temperature 90–105 °C/0.2 Torr) of the resulting crystalline residue gave 10.9 g of the crystalline diketone **24**. Analysis of this material by g.l.c. (column A, 165 °C, 110) showed that it consisted of 91% diketone and two unidentified minor components. Recrystallization of this material from hexane yielded 9.8 g (75%) of pure diketone. This compound exhibited m.p. 77.5–78 °C; $[\alpha]_D^{27}$ +102° (*c*, 1.6 in $CHCl_3$); i.r. ($CHCl_3$) ν_{max} 1765, 1725 cm^{-1}; p.m.r. τ 7.07 (broad s, 1H, C-5 H, width at half-height 3.5 Hz), 7.68 (q of d, 1H, C-7 H, J = 7.1, 1.5 Hz), 8.80 (d, 3H, secondary methyl, J = 7.1 Hz), 8.88 (s, 3H, tertiary methyl), 8.99, 9.12 (d, d, 6H, isopropyl methyls, J = 6.0 Hz). A frequency-swept decoupling experiment in which the proton at τ 7.07 was irradiated, thus causing the quartet of doublets at τ 7.68 to collapse to a quartet (J = 7.1 Hz), showed that the C-7 proton was coupled with the bridgehead C-5 proton (J = 1.5 Hz).

Anal. Calcd. for $C_{13}H_{20}O_2$: C, 74.96; H, 9.68. Found: C, 74.98; H, 9.80.

Stereoselective Total Synthesis of Copa and Ylango Sesquiterpenoids: (+)-Copacamphor, (+)-Copaborneol, (+)-Copaisoborneol, (−)-Ylangocamphor, (−)-Ylangoborneol, (−)-Ylangoisoborneol

EDWARD PIERS, RONALD W. BRITTON, M. BERT GERAGHTY, ROBERT J. KEZIERE, AND FUSAO KIDO

Department of Chemistry, University of British Columbia, 2075 Wesbrook Place, Vancouver, British Columbia V6T 1W5

Received May 15, 1975

EDWARD PIERS, RONALD W. BRITTON, M. BERT GERAGHTY, ROBERT J. KEZIERE, and FUSAO KIDO. Can. J. Chem. **53**, 2838 (1975).

Efficient, stereoselective syntheses of the tricyclic sesquiterpenoids (+)-copacamphor (**3**), (+)-copaborneol (**4**), (+)-copaisoborneol (**5**), (−)-ylangocamphor (**6**), (−)-ylangoborneol (**7**), and (−)-ylangoisoborneol (**8**) are described. Conversion of the keto acetate **9** (previously synthesized from the dione **1**) into the keto tosylate **17** was accomplished via an eight-step sequence. Intramolecular alkylation of **17** afforded, in high yield, (+)-copacamphor (**3**), which had previously been converted into the corresponding alcohols **4** and **5** by Kolbe-Haugwitz and Westfelt. Alkylation of the enolate anion of the bicyclic dione **2** with 2-bromopropane in hexamethylphosphoramide gave mainly the *O*-alkylation product **19**. Conversion of **19** into the keto mesylate **29** was carried out in 5 synthetic steps. Intramolecular alkylation of **29** afforded (−)-ylangocamphor (**6**). Reduction of the latter with calcium in liquid ammonia gave (−)-ylangoborneol (**7**), while reduction with lithium aluminum hydride yielded (−)-ylangoisoborneol (**8**).

EDWARD PIERS, RONALD W. BRITTON, M. BERT GERAGHTY, ROBERT J. KEZIERE et FUSAO KIDO. Can. J. Chem. **53**, 2838 (1975).

On décrit des synthèses efficaces et stéréosélectives des sesquiterpenoides tricycliques (+) copacamphre (**3**), (+) copabornéol (**4**), (+) copaisobornéol (**5**), (−) ylangocamphre (**6**), (−) ylangobornéol (**7**) et (−) ylangoisobornéol (**8**). Huit étapes sont nécessaires pour effectuer la conversion du céto-acétate (**9**) (synthétisé antérieurement à partir de la dione **1**) en céto-tosylate **17**. Une alkylation intramoléculaire de **17** fournit, avec un bon rendement le (+) copacamphre (**3**) qui avait été transformé antérieurement en alcools **4** et **5** correspondants par Kolbe-Haugwitz et Westfelt. L'alkylation de l'anion énolate de la dione bicyclique (**2**) par le bromo-2 propane dans l'hexaméthylphosphoramide conduit principalement au produit de *O*-alkylation **19**. On a effectué la transformation de **19** en céto-mésylate **29** en cinq étapes. L'alkylation intramoléculaire de **29** fournit le (−) ylangocamphre (**6**) qui par réduction avec du calcium dans l'ammoniac liquide conduit au (−) ylangobornéol (**7**) alors que la réduction de **6** par $LiAlH_4$ fournit le (−) ylangoisobornéol (**8**).

[Traduit par le journal]

In the preceding paper (1) we described the stereoselective total synthesis of both (−)-(1*S*,4*S*,5*R*,7*R*)- and (+)-(1*R*,4*S*,5*S*,7*S*)-1,7-dimethyl-4-isopropylbicyclo[3.2.1]octa-6,8-dione (**1** and **2**, respectively), and indicated in general terms how these two diastereomeric compounds could potentially serve as excellent precursors for the total synthesis of a number of copa and ylango sesquiterpenoids, respectively. In this paper we report the successful completion of a portion of this overall goal. Specifically, we describe here: (*a*) the conversion of the diketone **1** into the sesquiterpenoids (+)-copacamphor (**3**), (+)-copaborneol (**4**), and (+)-copaisoborneol (**5**), and (*b*) the conversion of diketone **2** into (−)-ylangocamphor (**6**) and the two corresponding epimeric alcohols (−)-ylangoborneol (**7**) and (−)-ylangoisoborneol (**8**).[1] As noted in the preceding paper (1), only one ((+)-copaborneol (**4**)) of these six sesquiterpenoids has, up to the present time, been isolated from naturally occurring sources (4–6). However, at the time we began our synthetic work, (+)-copacamphor (**3**) and (+)-copaisoborneol (**5**) were also known compounds, having been obtained, by appropriate chemical transformations, from the natural product **4** (6). The three remaining sesquiterpenoids (**6**–**8**) were, until completion of our synthetic work, unknown compounds.

[1]For preliminary communications regarding portions of this work, see refs. 2 and 3. For a summary of other synthetic work done in this general area, see ref. 1, footnote 2.

Conversion of Diketone 1 into (+)-Copacamphor (3), (+)-Copaborneol (4), and (+)-Copaisoborneol (5) (see Scheme 1)

Comparison of the structure of the synthetic intermediate **1** with that of (+)-copacamphor (**3**) clearly showed that in any planned overall conversion of **1** into **3**, the carbonyl group at C-6 (in **1**) should be retained. At the same time, the ketone functionality at C-8 would have to serve as a 'handle' for the introduction of the two additional carbon atoms necessary to complete the required 15-carbon skeleton. Clearly, then, it was necessary at the outset to distinguish chemically between the two carbonyl groups present in **1**. Although, theoretically, there were potentially a number of alternative routes open to us via which this could be accomplished, we had already carried out, in a fairly efficient manner, the conversion of **1** into the keto acetate **9**, (1). Therefore, in the portion of our synthetic work presently being discussed, compound **9** served as the starting material.

Treatment of the keto acetate **9** with methoxymethylenetriphenylphosphorane in ether afforded the enol ether acetate **10** (mixture of geometric isomers), accompanied by some of the corresponding alcohols **11**.[2] Direct subjection of this mixture to reduction by lithium aluminum hydride effected the transformation of the remaining **10** into the enol ether alcohol **11**. As shown by the p.m.r. spectrum, the latter material consisted of a mixture of geometric isomers, in a ratio of approximately 3:1. Hydrolysis of **11** with aqueous perchloric acid in ether at room temperature produced an epimeric mixture of the two hydroxy aldehydes **12** and **13**. On the basis of conformational analysis and on the fact that the relative proportion of these two epimers in the product varied appreciably from experiment to experiment, it was clear that we were not dealing with a fully equilibrated mixture. Presumably, the double bond of the enol ether moiety in **11** was, at least to some extent, kinetically protonated from the less hindered

[2]The ratio of **10** to **11** in the product varied somewhat from experiment to experiment. However, since the next synthetic step involved reduction of the acetate functionality, no attempt was made to experimentally control the reaction in the sense of avoiding the formation of the alcohols **11**.

side (equatorial to the six-membered ring, away from the axially oriented isopropyl group) to afford initially the hydroxy aldehyde **12**. Obviously, compound **12** would, owing to the 1,3-diaxial interaction between the isopropyl group and the aldehyde moiety, be considerably less stable than the epimeric aldehyde **13** and one would thus expect complete equilibration to largely favor the latter isomer. Therefore, the mixture of hydrolysis products (**12** and **13**) was subjected to treatment with potassium carbonate in aqueous methanol. The product, formed in 91% overall yield from **11**, was shown by g.l.c. and spectral analysis to be homogeneous and, on the basis of the conformational analysis argument mentioned above, was assigned structure **13**. When the latter was allowed to react with methylenetriphenylphosphorane in dry dimethyl sulfoxide (7), the crystalline olefinic alcohol **14** was produced in 92% yield.

It should be noted that a number of possible synthetic pathways can be envisaged whereby the two carbon atoms (vinyl group in **14**) would be introduced into the keto acetate **9** in one step, rather than in two separate synthetic transformations as outlined above. However, we chose the latter route for stereochemical reasons. That is, use of the hydroxy aldehydes **12** and/or **13** as synthetic intermediates ensured, in either case, the possibility of epimerizing the center adjacent to the carbonyl group, thus allowing for stereochemical control at this center. This was particularly advantageous in the present synthesis, since the desired hydroxy aldehyde **13** was, as mentioned above, obviously more stable than the epimeric compound **12**. Therefore, it was not at all difficult to predict that subjection of a mixture of the two epimers **12** and **13** to epimerizing conditions would afford, irregardless of the initial ratio of the two compounds, a product consisting largely or entirely of the desired intermediate **13**.

Hydroboration of the olefinic alcohol **14** with borane in tetrahydrofuran, followed by oxidation of the resulting organoborane intermediate with alkaline hydrogen peroxide (8), afforded the diol **15**. Treatment of this material with slightly more than 1 equiv. of *p*-toluenesulfonyl chloride in pyridine at room temperature effected selective tosylation of the primary alcohol functionality, thus producing the hydroxy tosylate **16**. Oxidation of this material with chromium trioxide – pyridine complex in dichloromethane (9, 10) gave, in 72% overall yield from the olefinic alcohol **14**, the crystalline keto tosylate **17**.

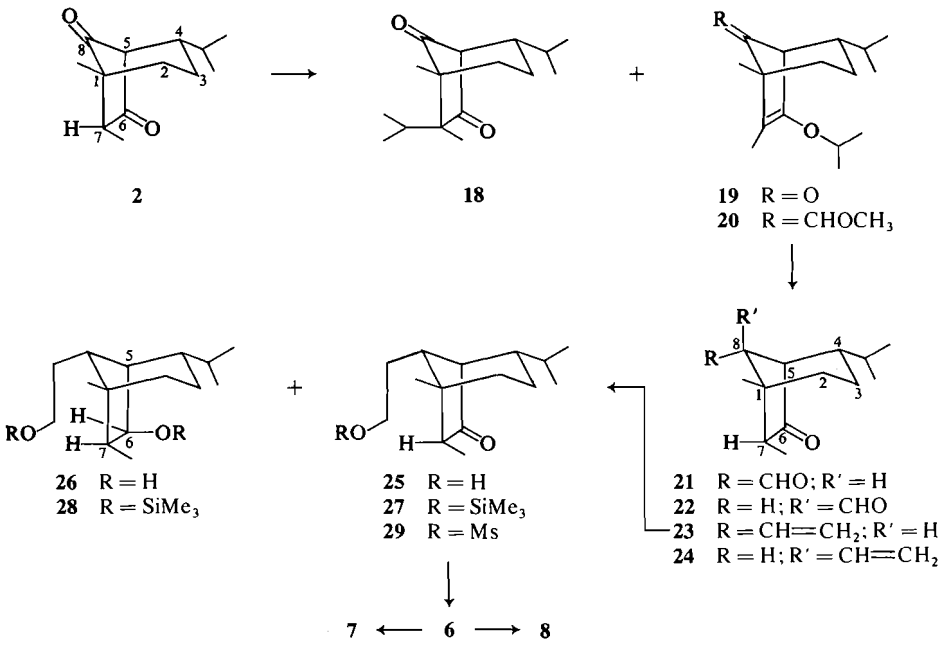
The final synthetic transformation necessary to complete the total synthesis of (+)-copacamphor (**3**) involved the intramolecular alkylation of the keto tosylate **17**. This proved to be a very facile process. Thus, when a solution of compound **17** in dimethyl sulfoxide containing sodium methylsulfinylmethide (11) was allowed to stand at room temperature for 35 min, (+)-copacamphor (**3**) (6) was produced in 87% yield. This material exhibited the expected physical and spectral properties and was shown to be identical in every respect with an authentic sample of (+)-copacamphor.[3] Since Kolbe-Haugwitz and Westfelt (6) had already described the conversion of (+)-copacamphor (**3**) into both (+)-copaborneol (**4**) and (+)-copaisoborneol (**5**), the total synthesis of **3** described above also constitutes a formal total synthesis of the other two sesquiterpenoids (**4** and **5**).

Conversion of Diketone 2 into (−)-Ylangocamphor (6), (−)-Ylangoborneol (7), and (−)-Ylangoisoborneol (8) (see Scheme 2)

The conversion of the second totally synthetic bicyclic diketone **2** (1) into the three ylango sesquiterpenoids **6**, **7**, and **8** was accomplished via a route which was in some of the individual synthetic steps quite similar to that described above for the overall transformation of **1** into **3**. However, there were also aspects in which the two synthetic sequences significantly differed and these features will be stressed in the following discussion.

The two carbonyl groups of the bicyclic dione **2** were chemically differentiated in a manner different from and more efficient than that used in the case of the dione **1**. Obviously, in both of these compounds, only the C-6 carbonyl group was capable of enolate anion formation and there existed, therefore, the possibility of directly protecting this keto group via a corresponding enol ether. The latter functionality appeared to be an ideal protecting group, since it would be stable to the conditions of the next proposed synthetic step (Wittig reaction) and would also, presumably, be easily reconverted by simple acid hydrolysis into the ketone. To this end, the diketone **2** was allowed to react with excess sodium bis(trimethylsilyl)amide (12) in hexamethylphosphoramide and the resulting solution

[3]We are very grateful to Dr. L. Westfelt for a generous sample of (+)-copacamphor.



SCHEME 2

of enolate anion was treated with excess 2-bromopropane. After a reaction time of 45 min at room temperature, there was obtained, in addition to some starting material (approximately 10%), a near quantitative yield of a mixture of two products in a ratio of approximately 8:1. Separation of the three components was efficiently accomplished by a combination of distillation and column chromatography. Spectral analysis of the resulting pure compounds clearly showed that the major product was the desired *O*-alkylated material **19**, while the minor product **18**, was the result of *C*-alkylation. Although the configuration at C-7 of the latter compound was not unequivocally established, it was assigned as shown on the basis of the prediction that the alkylating agent (2-bromopropane) would approach the enolate anion from the less hindered *exo* side of the molecule.

It should be noted that it was important to use hexamethylphosphoramide as the solvent in the alkylation described above. It is known that this polar, aprotic solvent, along with others such as dimethyl sulfoxide and sulfolane, promotes *O*-alkylation of enolate anions.[4] However, in the present instance, it was found that dimethyl sulfoxide and sulfolane were considerably inferior to hexamethylphosphoramide. Thus, although the alkylation reaction proceeded smoothly in the two former solvents, in each case the proportion of the desired *O*-alkylated material in the product was significantly less than when the reaction was carried out in hexamethylphosphoramide.

Treatment of the keto enol ether **19** with excess methoxymethylenetriphenylphosphorane in refluxing ether for 30 min afforded, in essentially quantitative yield, compound **20** as a mixture of two geometric isomers. Since both of these diastereomers gave rise to the same products in the next synthetic step, no attempt was made to effect their separation. Hydrolysis of both of the enol ether functionalities in **20** was accomplished by exposure of this material to aqueous perchloric acid in ether. The resultant mixture of keto aldehydes **21** and **22** (ratio approximately 1:1) was equilibrated (potassium carbonate in aqueous methanol), thus affording in 80% yield from **20** a mixture of **21** and **22** in a ratio of 84:16, respectively. Since attempted separation of these epimers by column chromatography led to considerable loss of both compounds, the next reaction was performed on the equilibrium mixture of the two materials. Accordingly, treatment of the mixture with methylenetri-

[4]For an excellent discussion regarding the various structural and experimental factors which influence *C- vs. O*-alkylation of ambident anions, see ref. 13.

phenylphosphorane in dimethyl sulfoxide (7) produced in very high yield[5] a mixture of the epimeric keto olefins **23** and **24**, in the expected ratio of approximately 84:16, respectively. These two materials were cleanly separated by column chromatography. The major product **23** was an oil at room temperature, while the minor component was a low-melting, crystalline solid.

The stereochemical assignment made with respect to the two keto olefins **23** and **24** merits comment. It had been assumed, on the basis of conformational analysis, that in the mixture of keto aldehydes **21** and **22**, the major component at equilibrium would be the desired compound **21**, with the formyl group in an equatorial orientation with respect to the six-membered ring. Consequently, the major product in the corresponding mixture of keto olefins **23** and **24** was assumed to be **23**. The first indication that this assumption was indeed correct was provided by a comparison of the p.m.r. spectra of the two epimers. The C-5 proton of the major, oily compound **23** appeared as a broad singlet (width at half-height = 4.5 Hz) at τ 7.41. Obviously, therefore, there was very little coupling between the protons on C-5 and C-8.[6] On the other hand, the C-5 proton of the minor, crystalline epimer **24** produced a broadened doublet (τ 7.42) and was thus clearly coupled with the C-8 proton ($J_{5,8}$ = 5.6 Hz).[6] These observations were fully in line with what would be expected on the basis of the dihedral angles involved. That is, a molecular model of the keto olefin **23** showed that the dihedral angle between the protons on C-5 and C-8 was approximately 75–80° and, on the basis of the Karplus equation (14), only a very small coupling constant would be expected. On the other hand, the dihedral angle between the C-5 and C-8 protons of the keto olefin **24** was, on the basis of a molecular model, approximately 40–45° and the Karplus equation (14) predicts a coupling constant of magnitude similar to that observed (5.6 Hz). That these initial conclusions regarding the stereochemistry of **23** and **24** were indeed correct was shown unambiguously by the subsequent successful conversion of the former compound into (−)-ylangocamphor (**6**) (*vide infra*).

Subjection of the major keto olefin **23** to hydroboration with disiamylborane (15) in tetrahydrofuran at 0 °C afforded, in 81% yield, a mixture of the desired keto alcohol **25** and the diol **26**, in a ratio of approximately 85:15. Since direct separation of these two compounds proved troublesome, they were eventually separated by preparative g.l.c. on the corresponding trimethylsilyl ether derivatives **27** and **28**. The spectral data obtained from pure samples of the keto alcohol **25** (regenerated from **27**) and the diol **26** (regenerated from **28**) were in complete accord with the assigned structures. In particular, it is pertinent to note that the p.m.r. spectrum of the diol **26** fully corroborated the proposed stereochemistry.[7] Thus, the C-6 proton appeared as a pair of doublets at τ 5.60, with $J_{5,6}$ = 6.9 Hz and $J_{6,7}$ = 10.6 Hz. The former coupling constant was in agreement with that expected on the basis of the Karplus equation (14), since molecular models indicated that the dihedral angle between the C-5 proton and a C-6 *exo*-proton (as in **26**) was approximately 15–25°. If the configuration at C-6 of the diol had been epimeric with that shown in **26**, the dihedral angle between the C-5 and C-6 protons would have been approximately 90° and a very small coupling constant would have been expected.[8] Furthermore, molecular models indicated that the dihedral angle between the C-6 and C-7 protons in **26** was near 0° and the observed coupling constant (10.6 Hz) was therefore also in good agreement with that expected (14).

Treatment of the pure keto alcohol **25** with methanesulfonyl chloride in pyridine at room

---

[5]When the Wittig reaction was carried out in ethyl ether or other ether solvents, only poor yields of product were formed.

[6]It is important to note that the p.m.r. spectra of a number of compounds in this series (**2**, **18**, **19**, **23**, **24**) consistently showed that the coupling between the C-4 and C-5 protons was very weak. For example, in compounds **2**, **18**, and **19**, the bridgehead proton at C-5 appeared, in each case, as a broad singlet, with half-height width in the range of 3.5–4.5 Hz.

[7]This stereochemical assignment was initially made on the basis of steric approach control. That is, it seemed highly likely that the reducing agent (disiamylborane) would approach the carbonyl group (of **23**) from the less hindered *exo* side of the bicyclic system, thus producing the *endo* alcohol.

[8]In this connection, it had already been noted in the chemical literature (6) that the carbinol proton in copaborneol (**4**) appeared as a broad singlet, while that in copaisoborneol (**5**) appeared as a doublet with J = 8.0 Hz.

temperature gave the keto mesylate **29**, which was subjected to intramolecular alkylation without extensive purification. Thus, exposure of **29** to sodium bis(trimethylsilyl)amide (12) in dimethoxyethane at room temperature smoothly afforded, in 84% yield from the keto alcohol **25**, pure (−)-ylangocamphor (**6**). This material, which crystallized on cooling, exhibited m.p. 25–25.5 °C, $[\alpha]_D^{26}$ −58°, and produced spectra data which were very similar to, but clearly different from, those obtained from (+)-copacamphor (**3**).

It is pertinent to note that (−)-ylangocamphor (**6**) could also be conveniently obtained from the 85:15 mixture of the keto alcohol **25** and the diol **26**, and the rather tedious (although efficient) separation of these two materials could, therefore, be avoided. Thus, treatment of the mixture of **25** and **26** with excess methanesulfonyl chloride in pyridine, followed by exposure of the resultant mixture of mesylate derivatives to sodium bis(trimethylsilyl)amide in dimethoxyethane, gave a crude product which upon simple distillation afforded pure (−)-ylangocamphor (**6**) in 50% overall yield from the keto olefin **23**.

Two highly stereoselective reductions effected the conversion of (−)-ylangocamphor (**6**) into the two corresponding alcohols **7** and **8**. Thus, treatment of **6** with calcium in anhydrous liquid ammonia (16, 17) afforded, in 95% yield, (−)-ylangoborneol (**7**) as the only detectable product. This crystalline material exhibited spectral data in full accord with the assigned structure. Of particular note was the p.m.r. spectrum in which the proton on the hydroxyl-bearing carbon appeared as a broad singlet at τ 6.26 (see footnote 8). Reduction of **6** with lithium aluminum hydride in refluxing ether gave, in 91% yield, (−)-ylangoisoborneol (**8**). This compound produced spectra very similar to, although clearly different from, those obtained from the epimeric material **7**. In the p.m.r. spectrum of **8**, the carbinol proton produced, as expected (see footnote 8), a doublet (τ 6.27) with a coupling constant of 7.7 Hz.

The synthetic work described in this paper not only provides unambiguous evidence for the structure and absolute stereochemistry of the six sesquiterpenoids **3**–**8**, inclusive, but may also be an example of the total synthesis of one or more natural products before actual isolation from natural sources.

Experimental[9]

Preparation of the Hydroxy Enol Ether 11

To a stirred slurry of methoxymethyltriphenylphosphonium chloride (54.5 g, 159 mmol) in 350 ml of anhydrous ether at room temperature under a nitrogen atmosphere was added 69.2 ml of 2.3 *M* *n*-butyllithium (159 mmol) in hexane. The resulting dark red solution was cooled to −25 °C and 8.0 g (31.8 mmol) of keto acetate **9** was added dropwise over a period of 10 min. The reaction mixture was stirred at −20 to −30 °C for 1 h, at room temperature for 2 h, and then filtered through Celite. The filtrate was washed with cold water, with brine, and then concentrated. The residual material was diluted with water and the resulting mixture was thoroughly extracted with hexane. The combined extracts were washed with brine and dried over anhydrous magnesium sulfate. Removal of the solvent afforded an orange oil which, on the basis of spectral data, was shown to contain a mixture of the enol ether acetates **10** and the enol ether alcohols **11**. This material was dissolved in anhydrous ether (175 ml), lithium aluminum hydride (1.5 g) was added, and the resulting solution was refluxed under nitrogen for 4 h. The reaction mixture was cooled to 0 °C, the excess hydride was destroyed by careful addition of water, and the mixture was filtered through Celite. The filtrate was diluted with additional water and was then thoroughly extracted with ether. The combined extracts were washed with brine and dried over anhydrous magnesium sulfate. Removal of the solvent, followed by distillation (air-bath temperature 130–135 °C; 0.5 Torr) of the residual oil afforded 4.2 g (55%) of the hydroxy enol ether **11** (mixture of geometric isomers) as a colorless oil, n_D^{20} 1.5048; i.r. (film) ν_{max} 3450, 2940, 1695, 1460, 1383, 1370, 1235, 1215, 1110, 1035 cm^{-1}; p.m.r. τ 4.30, 4.34 (s, s, 1H, $=CHOCH_3$ of isomers, ratio 1:3), 5.66 (d of d, 1H, C-6 H, $J_{5,6}$ = 7.0 Hz, $J_{6,7}$ = 11.0 Hz), 6.54, 6.57 (s, s, 3H, $=CHOCH_3$ of isomers, ratio 1:3), 7.45 (m, 1H, C-5 H).

Anal. Calcd. for $C_{15}H_{26}O_2$: C, 75.58; H, 10.99. Found: C, 75.44; H, 11.01.

Preparation of Hydroxy Aldehyde 13

To a mixture of 35% aqueous perchloric acid (135 ml) and ether (675 ml) was added 5.06 g (21.3 mmol) of the hydroxy enol ethers **11**. The reaction mixture was stirred at room temperature for 2.5 h and was then neutralized by careful addition of solid potassium carbonate. The aqueous layer was thoroughly extracted with ether; the combined ether extracts were washed with brine and dried over anhydrous magnesium sulfate. Removal of the solvent afforded an oil which, as shown by spectral analysis, consisted of a mixture of the two epimeric aldehydes **12** and **13**. This material was dissolved in 550 ml of 1:10 water–methanol containing 5.4 g of potassium carbonate and the resulting solution was stirred at room temperature for 2.5 h. Most of the methanol was removed under reduced pressure, the residue was diluted with water, and the resulting mixture was thoroughly extracted with ether. The combined extracts were washed with water and brine and then dried over anhydrous magnesium sulfate.

[9]For pertinent general information, see the preceding paper (ref. 1).

Preparation of the Olefinic Alcohol ***14***

A solution of methyltriphenylphosphonium bromide (25.8 g, 72.2 mmol) in anhydrous dimethyl sulfoxide (70 ml) was added to a solution of sodium methylsulfinylmethide (7.14 g, 71.4 mmol) in anhydrous dimethyl sulfoxide (70 ml). The solution was stirred for 15 min and then a solution of 4.15 g (18.5 mmol) of the hydroxy aldehyde **13** in 90 ml of dry dimethyl sulfoxide was added. The reaction mixture was maintained at 40–50 °C for 1 h, cooled, and diluted with water. The resulting mixture was extracted thoroughly with hexane. The combined extracts were washed with brine and dried over anhydrous magnesium sulfate. Removal of the solvent, followed by distillation (air-bath temperature 100–102 °C; 0.3 Torr) of the residual oil gave 3.78 g (92%) of the olefinic alcohol **14** as a colorless oil. This material crystallized on standing. An analytical sample, obtained by sublimation (40–50 °C/0.35 Torr) of a small sample of this material exhibited m.p. 56.5–57 °C; $[\alpha]_D^{20}$ +43.2° (*c*, 4.0 in $CHCl_3$); i.r. ($CHCl_3$) ν_{max} 3525, 2940, 1637, 1462, 1385, 1115, 1040, 985, 908 cm^{-1}; p.m.r. τ 4.04–4.42 (m, 1H, C*H*=CH_2), 4.86–5.12 (m, 2H, CH=C*H*$_2$), 5.42 (d of d, 1H, C-6 H, $J_{5,6}$ = 7.0 Hz, $J_{6,7}$ = 11.0 Hz), 9.04, 9.12 (d, d, 6H, isopropyl methyls, J = 6.2 Hz), 9.08 (d, 3H, secondary methyl, J = 7.5 Hz), 9.20 (s, 3H, tertiary methyl).

Anal. Calcd. for $C_{15}H_{26}O$: C, 81.02; H, 11.79. Found: C, 80.92; H, 11.75.

Conversion of the Olefinic Alcohol ***14*** *into the Keto Tosylate* ***17***

To a cold (0 °C), stirred solution of the olefinic alcohol **14** (1.0 g, 4.5 mmol) in dry tetrahydrofuran (90 ml), under an atmosphere of nitrogen, was added 7.2 ml of 1.25 *M* borane (9.0 mmol) in tetrahydrofuran. The resulting solution was stirred at room temperature for 1.5 h and then cooled to 0 °C. After successive careful additions of 3 *N* aqueous sodium hydroxide (13.5 ml) and 30% hydrogen peroxide (13.5 ml), the reaction mixture was stirred at room temperature for 1 h, diluted with water, and then thoroughly extracted with ether. The combined extracts were washed with brine and dried over anhydrous magnesium sulfate. Removal of the solvent afforded 1.2 g of the diol **15** as a colorless, viscous oil (i.r. (film) ν_{max} 3390, 1465, 1385, 1145, 1120, 1040 cm^{-1}) which was used directly for the next step.

To a solution of the crude diol **15** in 45 ml of dry pyridine was added 2.25 g of *p*-toluenesulfonyl chloride and the resulting solution was stirred at room temperature, under nitrogen, for 3 h. The reaction mixture was diluted with ether and the resultant solution was successively washed with dilute aqueous sodium bicarbonate, water, and brine, and then dried over anhydrous magnesium sulfate. Removal of the solvent afforded a viscous yellow oil which was subjected to chromatography on neutral silica gel (125 g). Elution of the column with 1:1 chloroform–ether gave 1.4 g (79%) of the hydroxy tosylate **16**, as a viscous oil, i.r. (film) ν_{max} 3510, 1605, 1465, 1365, 1190, 1183, 943 cm^{-1}; p.m.r. τ 2.19, 2.67 (d, d, 4H, aromatic protons, J = 8.5 Hz), 5.44–6.02 (complex m, 3H, C-6 H, and —C*H*$_2$OTs), 7.56 (s, 3H, aromatic methyl), 9.09, 9.22 (d, d, 6H, isopropyl methyls, J = 6.0 Hz), 9.13 (d, 3H, secondary methyl, J = 7.5 Hz), 9.25 (s, 3H, tertiary methyl).

To a stirred solution of dry pyridine (3.42 ml) in anhydrous methylene chloride (95 ml) at room temperature was added 2.14 g of anhydrous chromium trioxide. The solution was stirred at room temperature for 15 min and then a solution of 1.4 g of the hydroxy tosylate **16** in 5 ml of methylene chloride was added. The reaction mixture was stirred for 15 min and then decanted. The black residue was washed thoroughly with ether and the combined organic solutions were successively washed with 5% aqueous sodium hydroxide, 5% hydrochloric acid, dilute aqueous sodium bicarbonate, and brine, and then dried over anhydrous magnesium sulfate. Removal of the solvent afforded 1.25 g (72%, based on olefinic alcohol **14**) of the crude keto tosylate **17** as a semicrystalline material. An analytical sample of the keto tosylate **17**, obtained by recrystallization of a small sample of this material from pentane–ether, exhibited m.p. 117–119 °C; $[\alpha]_D^{25}$ −13.1° (*c*, 1.1 in $CHCl_3$); i.r. ($CHCl_3$) ν_{max} 1733, 1608, 1473, 1368, 1175, 1100 cm^{-1}; p.m.r. τ 2.19, 2.66 (d, d, 4H, aromatic protons, J = 8.5 Hz), 5.80–6.04 (complex m, 2H, —C*H*$_2$OTs), 7.55 (s, 3H, aromatic methyl), 7.70 (m, 1H, C-5 H), 9.00 (d, 3H, secondary methyl, J = 7.2 Hz), 9.02 (s, 3H, tertiary methyl), 9.10, 9.21 (d, d, 6H, isopropyl methyls, J = 6.3 Hz).

Anal. Calcd. for $C_{22}H_{32}O_4S$: C, 67.30; H, 8.22; S, 8.18. Found: C, 67.05; H, 8.05; S, 8.01.

(+)-Copacamphor (3)

To a stirred solution of sodium methylsulfinylmethide (0.21 g, 2.1 mmol) in dry dimethyl sulfoxide (21 ml) at room temperature under nitrogen, was added a solution of the keto tosylate **17** (0.41 g, 1.1 mmol) in 4 ml of dimethyl sulfoxide. The solution was stirred at room temperature for 35 min and then poured into cold water. The resulting mixture was thoroughly extracted with hexane. The combined extracts were washed with brine and dried over anhydrous magnesium sulfate. Removal of the solvent, followed by distillation (air-bath temperature 95–100 °C; 0.5 Torr) of the residual oil afforded 0.20 g (87%) of (+)-copacamphor (**3**) as a colorless oil, $[\alpha]_D^{25}$ +106° (*c*, 1.05 in $CHCl_3$) (lit. (6) $[\alpha]_D$ +98.7° (*c*, 1.7 in $CHCl_3$)); i.r. (film) ν_{max} 1739, 1473, 1450, 1390, 1326, 1300, 1272, 1042, 1013 cm^{-1}; p.m.r. τ 9.06, 9.10 (s, s, 6H, tertiary methyls), 9.09, 9.11 (d, d, 6H, isopropyl methyls, J = 6.4 Hz).

Anal. Calcd. for $C_{15}H_{24}O$: C, 81.76; H, 10.98. Found: C, 81.70; H, 10.95.

Preparation of the Keto Enol Ether ***19***

A solution of the bicyclic diketone **2** (10.4 g, 50 mmol) in 100 ml of dry hexamethylphosphoramide was added to a solution of sodium bis(trimethylsilyl)amide (25 g,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

136 mmol) in 150 ml of dry hexamethylphosphoramide. This mixture was stirred at room temperature in an atmosphere of nitrogen for 15 min, then cooled to 0 °C, and 25 ml of 2-bromopropane was added over a period of 3 min. The cooling bath was removed and stirring was continued at room temperature for 45 min. The reaction mixture was poured into cold brine and the resulting mixture was thoroughly extracted with ether. The combined ether extracts were washed three times with brine and dried over anhydrous magnesium sulfate. Removal of the solvent gave 12.3 g of a mobile oil. A g.l.c. analysis of this material (column D, 168 °C, 100) showed the presence of three components. These were shown to be starting material (diketone **2**), the desired *O*-alkylated product **19**, and the *C*-alkylated product **18** in the ratio of approximately 1:8:1, respectively. Distillation of this crude product through a 2-in. Vigreux column gave 11.0 g of material (b.p. 73–81 °C at 0.025 Torr), which consisted of the starting material, the desired *O*-alkylated product, and a trace of the *C*-alkylated product. The keto enol ether **19** was readily separated from this mixture by chromatography of the latter on activity III neutral alumina. Elution of the column with 2–15% benzene in petroleum ether (b.p. 65–110 °C) afforded 9.55 g (88% based on unrecovered starting material) of pure keto enol ether **19**. This material exhibited n_D^{20} 1.4747; $[\alpha]_D^{25}$ + 145° (*c*, 2.0 in $CHCl_3$); i.r. (film) ν_{max} 1760, 1660 cm^{-1}; p.m.r. τ 5.95 (septet, 1H, $-OCH(CH_3)_2$, J = 6.1 Hz), 6.99 (broad s, 1H, C-5 H, $w_{\frac{1}{2}}$ = 3.3 Hz), 8.32 (d, 3H, vinyl methyl, J = 0.9 Hz), 8.74, 8.89 (d, d, 6H, $-OCH(CH_3)_2$, J = 6.1 Hz), 8.98 (s, 3H, tertiary methyl), 9.04, 9.13 (d, d, 6H, isopropyl methyls, J = 6.4 Hz).

Anal. Calcd. for $C_{16}H_{26}O_2$: C, 76.75; H, 10.47. Found: C, 76.55; H, 10.46.

Further elution of the column with 15–50% benzene in petroleum ether (b.p. 65–110 °C) gave 1.37 g of the crystalline starting material (diketone **2**), containing a very small amount of *C*-alkylated material. A pure sample of the latter compound was obtained as follows. Hot box distillation (air-bath temperature 115 °C; 0.3 Torr) of the still-pot residue of the original distillation (see above) yielded 1.2 g of crystalline material. Recrystallization of this material from hexanes gave an analytical sample of **18**, which exhibited m.p. 60.5 °C; i.r. ($CHCl_3$) ν_{max} 1758, 1722 cm^{-1}; p.m.r. τ 7.15 (broad s, 1H, C-5 H, $w_{\frac{1}{2}}$ = 4.3 Hz), 8.85, 8.90 (s, s, 6H, tertiary methyls), 8.97, 9.12 (d, d, 6H, isopropyl methyls, J = 6.9 Hz).

Anal. Calcd. for $C_{16}H_{26}O_2$: C, 76.75; H, 10.47. Found: C, 76.60; H, 10.55.

Preparation of the Diethers ***20***

A slurry of methoxymethyltriphenylphosphonium chloride (71.5 g, 208 mmol) in 615 ml of anhydrous ether was cooled to 0 °C under an atmosphere of nitrogen. To this stirred mixture was added, via a syringe, 73.5 ml of a 2.34 *M* hexane solution of *n*-butyllithium over a period of 2 min. The resulting phosphorane solution was stirred for a further 10 min. A solution of the keto enol ether **19** (11.65 g, 46.5 mmol) in 170 ml of anhydrous ether was then added over a period of 4 min, the cooling bath was removed, and the reaction mixture was refluxed for 30 min. The cooled solution was poured into cold water, the layers were separated, and the aqueous layer was extracted once with ether. The combined ether layers were washed twice with brine and dried over anhydrous magnesium sulfate. Removal of the solvent and distillation of the resultant crude material (55.0 g) gave 14.2 g of colorless oil with b.p. 94–103 °C at 0.2 Torr. Analysis by g.l.c. (column D, 155 °C, 110) showed that this material contained three unidentified minor components to the extent of approximately 10%, thus indicating that the desired diethers **20** were formed in quantitative yield. The ratio of the component diastereomers **20** as determined by g.l.c. (same column and conditions) varied somewhat from experiment to experiment but the average ratio was approximately 65:35, with the same isomer always predominating. Attempts to remove the impurities from this distilled material by column chromatography (neutral alumina, activity I or III, or Florisil) were unsuccessful because of poor recovery of the diethers from the columns and/or owing to poor separation. Consequently, this mixture was used in the next reaction without further purification. An analytical sample of the diastereomeric diether mixture **20**, was obtained, however, by preparative g.l.c. (column E, 185 °C, 105) and it exhibited i.r. (film) ν_{max} 1707, 1664 cm^{-1}; p.m.r., τ 4.43, 4.52 (s, s, 1H, vinyl protons), 5.92, 5.97 (septets, 1H, J = 6.1, 6.1 Hz), 6.49, 6.56 (s, s, 3H, methoxy methyls).

Anal. Calcd. for $C_{18}H_{30}O_2$: C, 77.65; H, 10.86. Found: C, 77.52; H, 11.11.

Preparation of the Keto Aldehydes ***21*** *and* ***22***

A solution of the impure diethers **20** (10.8 g) in 180 ml of ether was added to a solution of 70% perchloric acid (120 ml) in 700 ml of ether. The resulting mixture was stirred at room temperature under a nitrogen atmosphere for 1.5 h. It was then washed successively with ice water, with dilute sodium bicarbonate solution, and with brine, and dried over anhydrous magnesium sulfate. Removal of the solvent and distillation of the residual oil gave 7.7 g of material with b.p. 108–110 °C at 0.07 Torr. A g.l.c. analysis (column F, 168 °C, 110) of this material showed that the ratio of the keto aldehydes **21** and **22** was approximately 1:1.

This material (7.7 g) was dissolved in 325 ml of methanol and the resulting solution was added to a solution of anhydrous potassium carbonate (9.5 g) in 800 ml of water. The resultant mixture was stirred at room temperature under a nitrogen atmosphere for 1.5 h. It was then diluted with water and extracted three times with petroleum ether (b.p. 68 °C) – ether (4:1). The combined extracts were washed with water, with brine, and dried over anhydrous magnesium sulfate. Removal of the solvent and distillation of the residue gave 7.05 g of a colorless oil, b.p. 106–109 °C at 0.05 Torr. A g.l.c. analysis (column F, 168 °C, 110) of this material showed that it was composed of the desired products (88%), keto aldehydes **21** and **22** in a ratio of 84:16, respectively, and impurities (12%) which were not identified but were presumably related to those in the starting material. Thus the effective overall yield for the hydrolysis and epimerization reactions was 80%. Owing to the unstable nature of the epimeric keto aldehydes **21** and **22**, it was not possible to separate these epimers from each other or from the other contaminants by column chromatography (silica gel or activity III neutral alumina). Consequently, this material was used in the next reaction without further

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

purification. The impure keto aldehyde product mixture exhibited i.r. (film) ν_{max} 2745, 1735, 1715 (shoulder) cm^{-1}; p.m.r. τ −0.10, −0.03 (d, d, 1H, aldehydic protons, J = 1.0, 2.0 Hz, respectively).

Preparation of Keto Olefins ***23*** *and* ***24***

To a stirred solution of sodium methylsulfinylmethide (2.25 g, 22.5 mmol) in dry dimethyl sulfoxide (52 ml) at 20 °C, under an atmosphere of nitrogen, was added 9.64 g (27.0 mmol) of methyltriphenylphosphonium bromide and the resulting solution was stirred at room temperature for 10 min. To this solution was added, over a period of 3 min, a solution of 1.046 g (approximately 4.15 mmol) of the impure keto aldehyde mixture (**21** and **22**) in 26 ml of dry dimethyl sulfoxide. Stirring was continued for a further 1 h at room temperature. The solution was poured into ice water and the resulting mixture was extracted three times with petroleum ether (b.p. 68 °C). The combined extracts were washed with brine and dried over anhydrous magnesium sulfate. Removal of the solvent and distillation (air-bath temperature 82–95 °C; 0.07 Torr) of the residue gave 991 mg of a colorless oil. A g.l.c. analysis (column G, 175 °C, 110) showed that this material was composed of a mixture of the keto olefins (92%), **23** and **24** in a ratio of 84:16, respectively, and unidentified minor components (8%). This represents a quantitative yield of keto olefins based on pure starting material. The two epimers were only partially separated by column chromatography on silica gel. However, total separation was achieved by column chromatography using Camag Kieselgel for t.l.c. (without binder) and 98:2 petroleum ether (b.p. 68 °C) – ether as eluting solvent. A positive pressure (nitrogen) was required to maintain a reasonable flow rate. The ratio of compound to silica gel was 1:100. The recovery of both keto olefins from the column was quantitative. However, while the minor epimer **24**, a colorless crystalline compound, was obtained in pure form, the major epimer **23** contained minor impurities (approximately 4% as determined by g.l.c.). Therefore, an analytical sample of the keto olefin **23** was obtained by preparative g.l.c. (column C, 198 °C, 170) of the material obtained from chromatography on silica gel. This analytical sample, a colorless oil, exhibited $[\alpha]_D^{25}$ +51.5° (*c*, 2.0 in $CHCl_3$); i.r. (film) ν_{max} 3080, 1730, 1634, 910 cm^{-1}; p.m.r. τ 3.99–4.37 (m, 1H, $-CH{=}CH_2$), 4.86–5.10 (m, 2H, $-CH{=}CH_2$), 7.41 (broad s, 1H, C-5 H, $w_{\frac{1}{2}}$ = 4.5 Hz), 7.79 (d, 1H, C-8 H, J = 7.9 Hz), 7.97 (q, 1H, C-7 H, J = 7.2 Hz), 8.99 (s, 3H, tertiary methyl), 8.99, 9.20 (d, d, 6H, isopropyl methyls, J = 6.2 Hz), 9.06 (d, 3H, secondary methyl, J = 7.2 Hz).

Anal. Calcd. for $C_{15}H_{24}O$: C, 81.76; H, 10.98. Found: C, 81.64; H, 11.07.

The crystalline keto olefin **24** (the minor component) was recrystallized from pentane and exhibited m.p. 28.5–29 °C; $[\alpha]_D^{25}$ +130° (*c*, 2.5 in $CHCl_3$); i.r. ($CHCl_3$) ν_{max} 3080, 1724, 1633, 916 cm^{-1}; p.m.r. τ 3.71–4.08 (m, 1H, $-CH{=}CH_2$), 4.68–4.92 (m, 2H, $-CH{=}CH_2$), 7.42 (broadened d, 1H, C-5 H, $J_{5,8}$ = 5.6 Hz), 7.64 (d of d, 1H, C-8 H, J = 8.3, 5.6 Hz), 8.17 (q, 1H, C-7 H, J = 7.0 Hz), 9.01 (d, 3H, secondary methyl, J = 7.0 Hz), 9.05 (s, 3H, tertiary methyl), 9.05, 9.18 (d, d, 6H, isopropyl methyls, J = 5.9 Hz).

Anal. Calcd. for $C_{15}H_{24}O$: C, 81.76; H, 10.98. Found: C, 81.52; H, 11.10.

Preparation of the Keto Alcohol ***25***

To a stirred solution of disiamylborane (1.8 g, 12.7 mmol) in dry tetrahydrofuran (16 ml) at 0 °C under a nitrogen atmosphere was added a solution of the keto olefin **23** (0.66 g, 3 mmol) in 7 ml of dry tetrahydrofuran and the resulting reaction mixture was stirred for 45 min at 0 °C. The reaction was quenched by the careful addition at 0 °C of 6 ml of 3 *N* aqueous sodium hydroxide followed by 6 ml of 30% hydrogen peroxide. The cooling bath was removed and stirring was continued at room temperature for 1 h. The tetrahydrofuran was removed at aspirator pressure, water was added to the residue, and the resulting mixture was thoroughly extracted with ether. The combined organic extracts were washed with brine and dried over anhydrous magnesium sulfate. Removal of the solvent and distillation (air-bath temperature 135–145 °C; 0.2 Torr) of the residue gave 579 mg (81%) of a viscous oil. A g.l.c. analysis (column H, 175 °C, 100) of this material indicated the presence of two components in the approximate ratio of 85:15. Chromatography of this mixture on silica gel or activity III neutral alumina afforded no useful separation of the two products.

Pure samples of the desired keto alcohol **25** and of the contaminating diol **26** were obtained for analytical purposes via their silyl ether derivatives. Thus, a solution of 239 mg (1.0 mmol) of the product mixture in 2 ml of dry pyridine containing 0.4 ml of hexamethyldisilazane and 0.2 ml of trimethylchlorosilane was stirred in an atmosphere of nitrogen at room temperature for 15 min. This mixture was filtered, the solvent was evaporated, and the residue was distilled (air-bath temperature 125–130 °C; 0.25 Torr) to give 323 mg of a mobile oil. This material was shown by g.l.c. analysis (column D, 190 °C, 100) to consist of a mixture of two components in a ratio of 85:15. An attempt to separate the components on a silica gel column resulted in the partial hydrolysis of the silyl ether blocking groups but an efficient separation was effected by preparative g.l.c. (column C, 220 °C, 200). Thus, 300 mg of the mixture yielded, after collection and distillation, 204 mg of the pure keto trimethylsilyl ether **27** and 44 mg of the bistrimethylsilyl ether derivative **28**. The keto trimethylsilyl ether **27** exhibited i.r. (film) ν_{max} 1727, 1250, 1090, 840, 745 cm^{-1}; p.m.r. τ 6.39 (complex m, 2H, $-CH_2OTMS$), 7.45 (broad s, 1H, C-5 H, $w_{\frac{1}{2}}$ = 4.6 Hz), 8.97 (s, 3H, tertiary methyl), 9.00, 9.18 (d, d, 6H, isopropyl methyls, J = 6.1 Hz), 9.04 (d, 3H, secondary methyl, J = 7.0 Hz), 9.88 (s, 9H, $-OSi(CH_3)_3$).

Hydrolysis of the keto trimethylsilyl ether **27** gave the desired keto alcohol **25**. Thus, a solution of the silyl ether (220 mg, 0.71 mmol) in 3 ml of ethanol and 0.1 ml of water was refluxed in an atmosphere of nitrogen for 4 h. The solvent was removed at aspirator pressure and the residue was distilled (air-bath temperature 127–130 °C; 0.04 Torr) to give 150 mg (89%) of a viscous oil. Analysis of this material by g.l.c. (column H, 175 °C, 100) showed that it was one component. It exhibited $[\alpha]_D^{25}$ +30.5° (*c*, 0.7 in $CHCl_3$); i.r. (film) ν_{max} 3400, 1724 cm^{-1}; p.m.r. τ 6.34 (complex m, 2H, $-CH_2OH$), 7.46 (broad s, 1H, C-5 H, $w_{\frac{1}{2}}$ = 4.8 Hz), 7.87 (s, 1H, exchangeable, —OH), 8.96 (s, 3H, tertiary methyl), 8.99, 9.18 (d, d, 6H, isopropyl methyls, J = 6.1 Hz), 9.03 (d, 3H, secondary methyl, J = 7.1 Hz).

Anal. Calcd. for $C_{15}H_{26}O_2$: C, 75.58; H, 10.99. Found: C, 75.32; H, 11.19.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

The minor component **28** in the silyl ether mixture was also collected by preparative g.l.c., as mentioned above. It exhibited i.r. (film) ν_{max} 1250, 1060, 840, 750 cm^{-1}; p.m.r. τ 5.53 (d of d, 1H, —C*H*OTMS, J = 6.8, 10.5 Hz), 6.40 (complex m, 2H, —CH_2OTMS), 7.73 (broadened d, 1H, C-5 H, J = 6.8 Hz), 9.10, 9.20 (d, d, 6H, isopropyl methyls, J = 6.5 Hz), 9.15 (s, 3H, tertiary methyl), 9.23 (d, 3H, secondary methyl, J = 7.0 Hz), 9.89, 9.95 (s, s, 18H, —OTMS groups). This material was hydrolyzed to the diol **26** in a manner similar to that used for the hydrolysis of the keto silyl ether **27**. From 44 mg of **28** there was obtained 25 mg of the viscous diol **26** which exhibited i.r. (film) ν_{max} 3350 cm^{-1}; p.m.r. τ 5.60 (d of d, 1H, —C*H*OH, J = 6.9, 10.6 Hz), 6.41 (complex m, 2H, —CH_2OH), 7.83 (broadened d, 1H, C-5 H, J = 6.9 Hz), 9.18, 9.28 (d, d, 6H, isopropyl methyls, J = 6.6 Hz), 9.25 (s, 3H, tertiary methyl), 9.29 (d, 3H, secondary methyl, J = 7.1 Hz). This diol decomposed slowly on standing in deuteriochloroform solution at room temperature.

(−)-Ylangocamphor (6)

(a) From the Pure Keto Alcohol 25

A solution of the keto alcohol **25** (109 mg, 0.458 mmol) in 3.5 ml of dry pyridine containing 229 mg (1.0 mmol) of methanesulfonyl chloride was stirred in an atmosphere of nitrogen at room temperature for 2.25 h. The reaction mixture was then poured into 25 ml of cold water and the aqueous layer was extracted three times with ether. The combined ether extracts were washed with cold 10% hydrochloric acid, with water, and with brine, and dried over anhydrous magnesium sulfate. Removal of the solvent gave 173 mg of a viscous oil which exhibited i.r. (film) ν_{max} 1728 cm^{-1}. A solution of this crude keto mesylate in 2 ml of dry dimethoxyethane was added to a solution of sodium bis(trimethylsilyl)amide (450 mg, 2.46 mmol) in 5 ml of dry dimethoxyethane at 0 °C. The cooling bath was immediately removed, the reaction mixture was stirred at room temperature in an atmosphere of nitrogen for 40 min, and was then poured into 25 ml of cold water. The resulting mixture was thoroughly extracted with hexane. The combined extracts were washed with water and brine and dried over anhydrous magnesium sulfate. Removal of the solvent and distillation (air-bath temperature 72–74 °C; 0.04 Torr) of the residue gave 85 mg (84% from the keto alcohol **25**) of (−)-ylangocamphor (**6**). This material was pure by gas–liquid chromatographic analysis (columns: A, 170 °C, 115; E, 190 °C, 110; I, 201 °C, 118) and it crystallized on refrigeration. A sample was recrystallized from hexanes at −35 to −40 °C yielding colorless crystals with m.p. 25–25.5 °C; $[\alpha]_D^{26}$ −58° (*c*, 1.0 in $CHCl_3$); i.r. (film) ν_{max} 1733 cm^{-1}; p.m.r. τ 7.76 (broad s, 1H, bridgehead H adjacent to —C=O, $w_{\frac{1}{2}}$ = 3.0 Hz), 9.02, 9.19 (d, d, 6H, isopropyl methyls, J = 6.5 Hz), 9.10, 9.11, (s, s, 6H, tertiary methyls).

Anal. Calcd. for $C_{15}H_{24}O$: C, 81.76; H, 10.98. Found: C, 81.91; H, 11.18.

(b) From the Mixture of Keto Alcohol 25 and Diol 26

The keto alcohol – diol mixture (239 mg) obtained from hydroboration of the keto olefin **23** (*vide supra*) was converted into the mesylate derivative mixture by a procedure identical with that used in the case of the pure keto alcohol. Similarly, the crude mixture of mesylate derivatives thus obtained was cyclized (without purification) as above, using 915 mg (5 mmol) of sodium bis(trimethylsilyl)amide and 14 ml of dry dimethoxyethane. Simple distillation of the product (hot box) yielded 135 mg (50% overall from the keto olefin **23**) of pure (−)-ylangocamphor (**6**). This material exhibited physical and spectral properties identical with those recorded above.

(−)-Ylangoborneol (7)

To a reaction vessel containing 12.5 ml of refluxing anhydrous ammonia was added 50 mg (1.25 mmol) of calcium metal followed, 5 min later, by a solution of (−)-ylangocamphor (**6**) (57 mg, 0.259 mmol) in 1.1 ml of anhydrous ether. The resulting mixture was stirred at reflux temperature for 30 min and 150 µl of anhydrous ethanol was then added. Care was taken at all times to exclude water from the system. When the blue color was discharged, ether was added and the mixture was poured into water. The water layer was thoroughly extracted with ether and the combined extracts were washed with brine until neutral and then dried over anhydrous magnesium sulfate. Filtration through Celite and removal of the solvent from the filtrate gave a residue which was distilled (air-bath temperature 108 °C; 0.04 Torr) to yield 55 mg (96%) of crystalline (−)-ylangoborneol (**7**). This material consisted of only one component by gas–liquid chromatographic analysis (columns: E, 188 °C, 110; D, 168 °C, 100; I, 195 °C, 105. Note: columns E and I resolve a mixture of ylangoborneol and ylangoisoborneol). Recrystallization from hexanes gave a sample exhibiting m.p. 60.5–61 °C; $[\alpha]_D^{25}$ −23° (*c*, 0.4 in $CHCl_3$); i.r. ($CHCl_3$), ν_{max} 3610, 3460 cm^{-1}; p.m.r. (*i*) ($CDCl_3$) τ 6.17 (broad s, 1H, —C*H*OH, $w_{\frac{1}{2}}$ = 3.2 Hz), 8.60 (s, 1H, exchangeable, —OH), 9.05, 9.15 (d, d, 6H, isopropyl methyls, J = 6.4 Hz), 9.13, 9.19 (s, s, 6H, tertiary methyls); (*ii*) (CCl_4) 6.26 (broad s, 1H, —C*H*OH, $w_{\frac{1}{2}}$ = 3.2 Hz), 8.90 (s, 1H, exchangeable, —OH), 9.06, 9.14 (d, d, 6H, isopropyl methyls, J = 6.5 Hz), 9.15, 9.19 (s, s, 6H, tertiary methyls).

Anal. Calcd. for $C_{15}H_{26}O$: C, 81.02; H, 11.79. Found: C, 80.75; H, 11.69.

(−)-Ylangoisoborneol (8)

An anhydrous ether solution (5 ml) of (−)-ylangocamphor (**6**) (110 mg, 0.5 mmol) containing 25 mg of lithium aluminum hydride was refluxed under an atmosphere of nitrogen for 1 h. The reaction mixture was cooled to 0 °C, 1 ml of saturated aqueous ammonium chloride solution was added, and stirring was continued for 45 min at room temperature. The mixture was filtered through Celite and the Celite was thoroughly washed with ether. The filtrate was washed with brine and dried over anhydrous magnesium sulfate. Removal of the solvent followed by distillation (air-bath temperature 100–102 °C; 0.12 Torr) of the residue gave 101 mg (91%) of (−)-ylangoisoborneol (**8**). This material consisted of only one component on analysis by g.l.c. (columns and conditions: same as for (−)-ylangoborneol) and it crystallized on refrigeration. Recrystallization from hexanes at −10 °C gave colorless crystals which were somewhat soft at room temperature (22 °C) and exhibited m.p. 31.5–32.5 °C; $[\alpha]_D^{26}$ −28° (*c*, 1.0 in $CHCl_3$); i.r. (film) ν_{max} 3630, 3495 cm^{-1}; p.m.r. (*i*)

($CDCl_3$) τ 6.22 (d, 1H, —C*H*OH, J = 7.6 Hz), 7.88 (broadened d, 1H, bridgehead H adjacent to —CHOH, J = 7.6 Hz), 8.68 (s, 1H, exchangeable, —OH), 9.04, 9.17 (d, d, 6H, isopropyl methyls, J = 6.5 Hz), 9.15, 9.21 (s, s, 6H, tertiary methyls); (*ii*) (CCl_4) τ 6.27 (d, 1H, —C*H*OH, J = 7.6 Hz), 7.91 (broadened d, 1H, bridgehead H adjacent to —CHOH, J = 7.6 Hz), 8.87 (s, 1H, exchangeable, —OH), 9.08, 9.20 (d, d, 6H, isopropyl methyls, J = 6.5 Hz), 9.18, 9.22 (s, s, 6H, tertiary methyls). The chemical shift assigned to the bridgehead proton adjacent to the —CHOH was confirmed by a frequency-swept decoupling experiment in which the proton at τ 6.27 was irradiated, thus causing the doublet at τ 7.91 to collapse to a broadened singlet.

Anal. Calcd. for $C_{15}H_{26}O$: C, 81.02; H, 11.79. Found: C, 80.99; H, 11.86.

Received May 15, 1975

EDWARD PIERS, M. BERT GERAGHTY, R. DEAN SMILLIE, and MARCEL SOUCY. Can. J. Chem. **53**, 2849 (1975).

Stereoselective total syntheses of the tricyclic sesquiterpenoids (−)-copacamphene (**1**) and (+)-sativene (**3**) and of the related tetracyclic compounds (−)-cyclocopacamphene (**2**) and (+)-cyclosativene (**4**) are described. An efficient four-step synthetic sequence was employed to convert the bicyclic dione **5** into the olefinic ketone **8**. The latter compound was converted in four steps into the olefinic alcohol **23**. Eliminative cyclization of the corresponding tosylate **25** gave (−)-copacamphene (**1**) in high yield. In similar fashion, (+)-sativene (**3**) was obtained by cyclization of the olefinic tosylate **42**, which in turn was derived via a four-step synthetic sequence from the olefinic ketone **9**. Oxidation of the olefinic alcohol **23** afforded the aldehyde **34**. Conversion of the latter compound into the *p*-tosylhydrazone **35**, followed by pyrolysis of the corresponding lithium salt **36**, gave the pyrazoline **37**. Photolysis of **37** afforded, in high yield, (−)-cyclocopacamphene (**2**). Similarly, (+)-cyclosativene (**4**) was obtained from the olefinic alcohol **41** via the pyrazoline **46**.

EDWARD PIERS, M. BERT GERAGHTY, R. DEAN SMILLIE et MARCEL SOUCY. Can. J. Chem. **53**, 2849 (1975).

On décrit des synthèses totales et stéréosélectives des sesquiterpénoides tricycliques (−) copacamphène (**1**) et (+) sativène (**3**) et des composés tétracycliques (−) cyclocopacamphène (**2**) et (+) cyclosativène (**4**) qui leur sont reliés. On a utilisé une séquence de synthèse efficace impliquant 4 étapes pour transformer la dione **5** en cétone non-saturée **8**. On a converti ce dernier composé en alcool oléfinique **23** en quatre étapes. L'élimination cyclisante du tosylate correspondant **25** donne le (−) copacamphène (**1**) avec un bon rendement. De la même manière, on obtient le (+) sativène (**3**) par cyclisation du tosylate non-saturé **42**, qui dérive de la cétone non-saturée **9** par l'intermédiaire d'une séquence de synthèse en 4 étapes. L'oxydation de l'alcool insaturé **23** fournit l'aldéhyde **34** qui est transformé en *p*-tosylhydrazone **35**. La pyrolyse du sel de lithium de cette dernière (**36**) donne la pyrazoline **37** qui par photolyse conduit, avec un bon rendement, au (−) cyclocopacamphène (**2**). On obtient le (+) cyclosativène (**4**) de la même manière à partir de l'alcool **41** par l'intermédiaire de la pyrazoline **46**.

[Traduit par le journal]

The tricyclic olefinic sesquiterpenoid (−)-copacamphene (**1**) has not as yet been directly isolated from a naturally occurring source, although it has been obtained by rearrangement of a derivative of (+)-copaborneol (1).[1] The structurally related tetracyclic compound (+)-cyclocopacamphene (enantiomer of **2**) has been obtained by chemical conversion from cyclocopacamphenic acids (2) and has been shown to occur in a number of vetiver oils (3). The corresponding ylango sesquiterpenoids are known natural products. (−)-Sativene (enantiomer of **3**) is a well-known compound first isolated in 1965 from the fungus *Helminthosporium sativum* (4), while (+)-sativene (**3**), as well as the structurally and configurationally related tetracyclic compound (+)-cyclosativene (**4**), have been acquired from the cortical turpentine of a number of different *Abies* species (5–7).

In a previous paper (8) we described the stereoselective total synthesis of the diastereomeric bicyclic diketones **5** and **6**. Both of the compounds were prepared from the well-known monoterpenoid (−)-carvone (**7**) and were thus of known absolute stereochemistry. We report herein the

[1]Although Kolbe-Haugwitz and Westfelt (1) were correct in their assignments regarding absolute stereochemistry, it is now clear that copacamphene of absolute configuration as shown in **1** is levorotatory ($[\alpha]_D^{21}$ −159°, *vide infra*) and not dextrorotatory ($[\alpha]_D$ +28.9°) as reported (1). It has not been possible to trace the reason for this discrepancy (private communication from Dr. Westfelt).

total synthesis of (−)-copacamphene (**1**), (−)-cyclocopacamphene (**2**), (+)-sativene (**3**), and (+)-cyclosativene (**4**) via synthetic routes which unambiguously establish the structure and absolute configuration of all four sesquiterpenoids.[2] More explicitly, we describe in this paper (*a*) the conversion of the bicyclic diketone **5** into the olefinic ketone **8**, (*b*) the transformation of compound **8** into the sesquiterpenoids **1** and **2**, and (*c*) the conversion of the olefinic ketone **9** (obtained, as described previously (11), from the bicyclic dione **6**) into the natural products **3** and **4**.

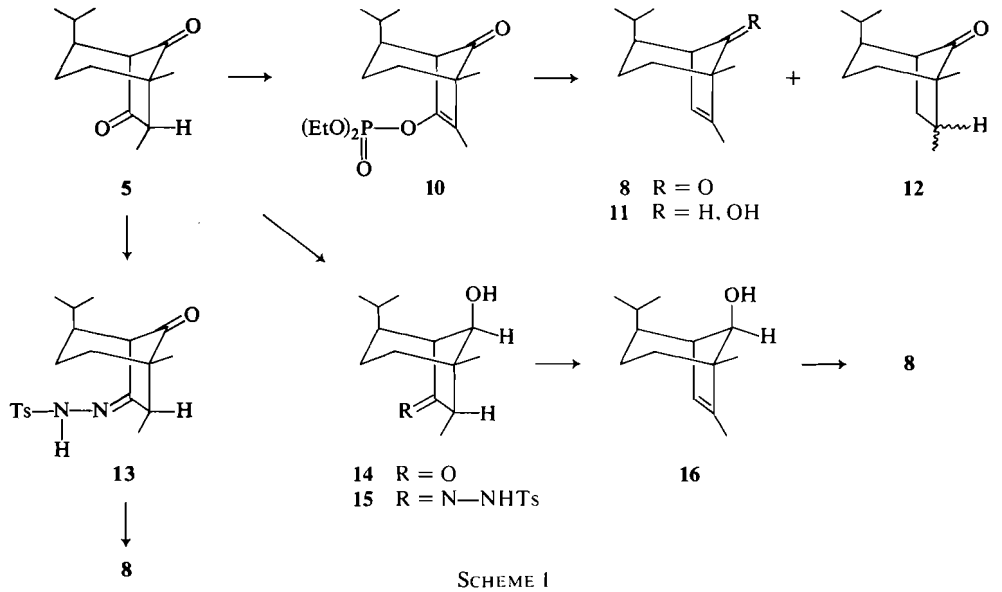
Conversion of Diketone 5 into Olefinic Ketone 8 (see Scheme 1)

The synthetic plan for the overall synthesis of (−)-copacamphene (**1**) and (−)-cyclocopacamphene (**2**) from the bicyclic diketone **5** involved in the early stages the conversion of the latter compound into the olefinic ketone **8**. The carbonyl group of this material was to be employed for the subsequent introduction of the two necessary additional carbon atoms, suitably functionalized to allow for the completion of the carbon skeletons of **1** and **2**.

A number of different routes for the overall conversion of **5** into **8** were investigated. The first of these was based on the known reduction of enol phosphate derivatives to the corresponding olefin (12–14). Thus, treatment of the dione **5** with sodium bis(trimethylsilyl)amide (15) in tetrahydrofuran, followed by quenching of the resultant enolate anion by addition of a solution of diethyl phosphorochloridate in pyridine, afforded in 94% yield the enol phosphate derivative **10**. Reduction of this material with lithium in ethylamine containing *t*-butyl alcohol (12) gave, in mediocre yield, a mixture of products consisting of the desired olefinic ketone **8**, the olefinic alcohol **11**, the saturated ketone **12**, and a number of minor unidentified components. This reduction reaction was studied in considerable detail and the effect of varying a number of reaction parameters (reactant concentration, reaction temperature, proton source, reaction time) was investigated. However, the reaction proved to be capricious and the maximum yield of desired product **8** obtained was about 25%. Furthermore, although subjection of the crude product to oxidation effected conversion of the olefinic alcohol **11** into the desired ketone **8** and thus reduced the number of individual components in the mixture, a rather tedious preparative g.l.c. procedure was necessary to effect final isolation of the desired product. In view of these difficulties, an alternative synthetic route to **8** was sought.

It is known that pyrolysis of salts of *p*-toluenesulfonylhydrazone derivatives of aldehydes and ketones produces the corresponding diazo compounds, which, depending mainly upon the character of the solvent employed, can decompose *in situ* by carbenic or cationic processes (16). In many cases, this process, known as the Bamford–Stevens reaction, results in the formation of the



SCHEME 1

corresponding alkene as the major product. When the bicyclic dione **5** was allowed to react with *p*-toluenesulfonylhydrazide in methanol in the presence of an acid catalyst, the required mono *p*-tosylhydrazone **13** was produced in good yield. Although the crude material was used directly for the next synthetic step, an analytical sample of **13** was obtained by column chromatography of a small sample of the crude product and exhibited spectral data in full accord with the assigned structure. Subjection of the crude *p*-tosylhydrazone **13** to the Bamford–Stevens reaction under protic conditions (sodium ethylene glycolate in ethylene glycol) produced in low yield a crude product consisting of many components. However, use of aprotic conditions proved to be more successful. Thus, when the sodium salt of **13** (formed by reaction of **13** with sodium bis(trimethylsilyl)amide in tetrahydrofuran) was mixed with a small amount of Nujol and the resulting mixture was heated under reduced pressure to 125 °C with direct distillation of product, a clear oil was obtained in reasonably good yield. Analysis of this material by g.l.c. indicated that although the major product was the desired olefinic ketone **8**, a number of minor unidentified components were also present. Again, purification of this material by a combination of column chromatography and g.l.c. proved to be quite tedious and the isolated yield of pure **8** was only ~40%. Although this was a definite improvement over the enol phosphate reduction route, it remained synthetically unsatisfying.

Another, more recently developed method for the conversion of a *p*-tosylhydrazone into an alkene involves treatment of the former with an excess of an alkyllithium reagent (17–21). Obviously, however, this method would not be directly applicable to the *p*-tosylhydrazone **13**, since the alkyllithium reagent would presumably add to the carbonyl group in addition to effecting decomposition of the hydrazone moiety. This undesirable possibility was avoided by employing a somewhat circuitous, albeit very efficient, route.

It was found that the two carbonyl groups of the bicyclic dione **5** could be differentiated by selective reduction. Thus, when **5** was allowed to react with one equivalent of sodium borohydride in ethanol at 0 °C, the C-8 carbonyl group was preferentially reduced. The reaction appeared to be completely stereoselective as well as siteselective and the keto alcohol **14** could be isolated in 89% yield. The p.m.r. spectrum of the product was in full accord with structure **14**. In particular, the carbinol proton at C-8 appeared as a doublet (J = 5.5 Hz) at τ 6.12. Clearly, had preferential reduction of the C-6 carbonyl group of **5** taken place, the carbinol proton of the product would have appeared as a pair of doublets. Furthermore, the stereochemistry of the reduction

5 17 18

14 19 13

product, expected to be as shown in **14** on the basis of approach of the reducing agent from the less hindered side of the carbonyl group, was also confirmed by the p.m.r. spectrum. Explicitly, the observed coupling constant (5.5 Hz) between the protons on C-5 and C-8 was in good agreement with that predicted by the Karplus equation (22) for a dihedral angle of about 40–45°. Had the reduction reaction produced the epimeric alcohol, the dihedral angle between these two protons would have been approximately 75–80° and a very small coupling constant would have been expected.

Conversion of the keto alcohol **14** into the corresponding *p*-tosylhydrazone **15**, followed by treatment of the latter with 8 equiv. of methyllithium in tetrahydrofuran–ether at 0 °C (21), afforded, in 86% overall yield, the levorotatory olefinic alcohol **16**. Oxidation of this material with either Collins' reagent (23, 24) or with Jones' reagent (25) produced good yields (about 90% in each case) of the desired keto olefin **8**. Even though this overall conversion of **5** into **8** involved more synthetic steps than either of the two previously described methods, it was considerably more efficient on two counts. Firstly, the overall yield was 69%, a notable improvement over previous yields. Secondly, a simple distillation of the crude product obtained from oxidation of **16** produced pure **8**, and tedious separation procedures could therefore be avoided.

At this point a brief diversion is in order. It is interesting to note that whereas borohydride reduction of the bicyclic dione **5** selectively produced the keto alcohol **14** (reaction at C-8), reaction of **5** with *p*-toluenesulfonylhydrazide regioselectively afforded the *p*-tosylhydrazone **13** (reaction at C-6). Although it is perhaps difficult to delineate all of the reasons underlying this interesting difference, it is nevertheless tempting to propose that the major cause is to be found in the obvious angle strain associated with an sp^2 center at C-8. Molecular models of **5** clearly show that the angle traced in going from C-1 to C-8 to C-5 is constrained to a value significantly less than 120°. The resulting strain, which would obviously be relieved by conversion of the C-8 carbon from an sp^2 center into an sp^3 center, could largely account for the fact that with respect to (irreversible) borohydride reduction, the C-8 carbonyl group of **5** was considerably more reactive than the C-6 carbonyl group. If one accepts this argumentation, then it appears likely that *p*-toluenesulfonylhydrazide should also preferentially attack the C-8 carbonyl group. However, conversion of the resultant intermediate **17** into the corresponding *p*-tosylhydrazone **18** would not only reintroduce the above-mentioned angle strain but would also result in $A^{1,3}$ steric strain (26) between the C-5 proton and the NH—Ts moiety. Therefore, this step would be energetically unfavorable with respect to the reverse reaction (**17** → **5**). The alternative mode of reaction, involving (slower) attack at C-6, followed by loss of water from the resultant intermediate **19**, would not be subject to the same difficulties. Therefore, the observation that the *p*-tosylhydrazone **13** was the only observed prod-

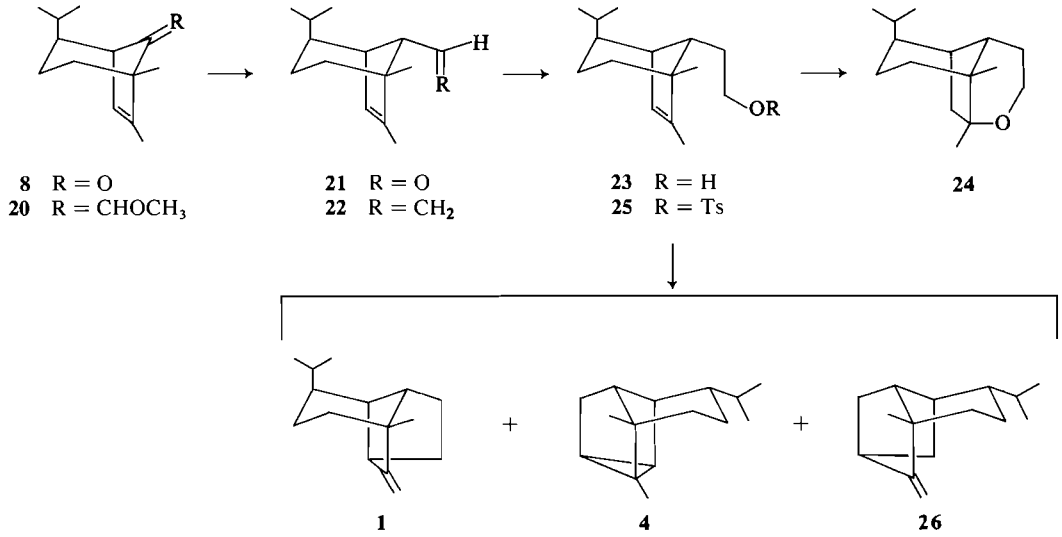

SCHEME 2

uct presumably reflected the fact that, overall, the reaction was thermodynamically controlled and that compound **13** was significantly more stable than the isomeric material **18**.

Synthesis of (−)-Copacamphene (1) (see Scheme 2)

The keto olefin **8** already contained 13 of the 15 carbons necessary for the synthesis of (−)-copacamphene (**1**). The two additional carbons necessary to complete the carbon skeleton were added via a synthetic route very similar to that already employed in a related case (11). Thus, reaction of **8** with methoxymethylenetriphenylphosphorane in dimethyl sulfoxide (27) gave, in 71% yield, a diastereomeric mixture of the corresponding enol ethers **20**. Hydrolysis of this material with aqueous perchloric acid in ether at room temperature, followed by equilibration (potassium carbonate in aqueous methanol) of the initially formed product (see ref. 11), afforded the olefinic aldehyde **21** in 86% yield. Treatment of the latter compound with methylenetriphenylphosphorane in dimethyl sulfoxide (27) gave the diene **22** (83% yield).

Conversion of the diene **22** into an intermediate suitable for eliminative cyclization to (−)-copacamphene (**1**) required initially the selective functionalization of the vinyl group at the terminal carbon atom. This was efficiently accomplished by hydroboration of the diene **22** with disiamylborane in tetrahydrofuran (28), followed by the usual oxidative work-up. The resulting olefinic alcohol **23**, formed in 91% yield, was somewhat unstable and, even in the presence of only a trace of acid, readily cyclized to the corresponding cyclic ether **24**. However, when the freshly isolated olefinic alcohol **23** was immediately treated with *p*-toluenesulfonyl chloride in pyridine, the corresponding olefinic *p*-tosylate **25** could be isolated in high yield. This material, presumably largely owing to the proximity of the *p*-tosylate functionality and the olefinic double bond, exhibited a high propensity towards eliminative cyclization. Indeed, it was found that when the freshly prepared compound was transferred to the top of a silica gel column and the column was eluted with pentane, a clear oil could be isolated (89% yield) from the eluant. Analysis of this material by g.l.c. showed that it consisted of a mixture of three compounds, in a ratio of approximately 98:1:1. The major component, isolated in pure form by column chromatography of the mixture on silver nitrate impregnated silica gel, was shown to be (−)-copacamphene (**1**), $[\alpha]_D^{21}$ −159°. This compound exhibited spectral data which were in excellent agreement with those published for copacamphene (1) and showed g.l.c. retention times and spectral data identical with those of racemic copacamphene (29, 30).[3] The two minor compounds formed during the eliminative cycliza-

[3]We are very grateful to Professor J. E. McMurry for a sample of (±)-copacamphene.

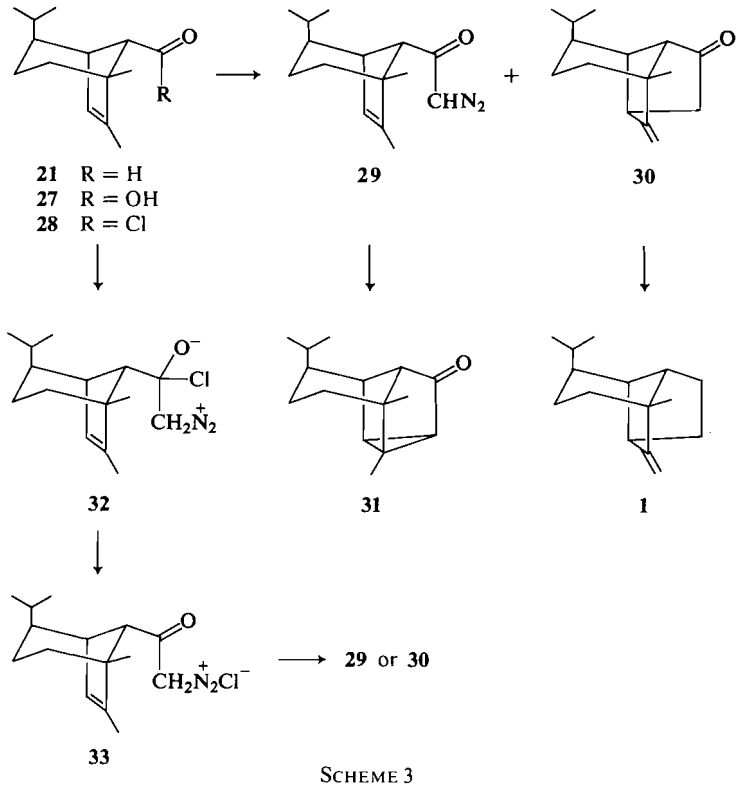
For personal use only.



SCHEME 3

tion of the olefinic tosylate **25** were isolated by subjection of the appropriate fractions from the above-mentioned column chromatography to preparative g.l.c. and were identified (g.l.c. retention times and i.r. spectra) as (+)-cyclosativene (**4**) and (−)-isosativene (**26**) (31, 30). The formation of these two compounds was explicable on the basis of the known acid-catalyzed rearrangement of copacamphene to a mixture of sativene, cyclosativene, and isosativene (31, 30).

Synthesis of (−)-Cyclocopacamphene (2)

The synthetic route which was initially chosen for the preparation of (−)-cyclocopacamphene (**2**) involved in the early stages the projected conversion of the olefinic aldehyde **21** into the diazoketone **29** (see Scheme 3). Appropriate carbenoid cyclization of **29**, followed by removal of the carbonyl group from the resulting tetracyclic ketone **31**, would then afford the sesquiterpenoid.

Oxidation of the olefinic aldehyde **21** with chromium trioxide in pyridine containing a small amount of water (32) gave, in 80% yield, the crystalline acid **27**. A suspension of the dry sodium salt of this material in anhydrous ether at 0 °C was treated with oxalyl chloride. The crude acid chloride **28** (ν_{max} 1812 cm^{-1}) thus obtained was dissolved in dry ether and the resulting solution was added slowly to excess alcohol-free ethereal diazomethane. However, an i.r. spectrum of the resulting crude product revealed that the desired diazoketone **29** was present in only minor amounts, since the appropriate absorptions (ν_{max} 2130, 1656 cm^{-1}) were very weak. The most notable absorptions in the i.r. spectrum were at 1745, 1665, and 879 cm^{-1}, indicating that the major product contained a cyclopentanone carbonyl group and an exocyclic methylene double bond. The most likely structure for this material was **30** and this was subsequently shown to be correct (*vide infra*).

When a cyclohexane solution of the crude product obtained from the attempted diazoketone formation was heated in the presence of cupric sulfate (33), a colorless oil was produced (60% yield from the olefinic acid **27**). Analysis of this material by g.l.c. showed that it contained about 84% of the keto olefin **30**, 8% of the tetra-

For personal use only.

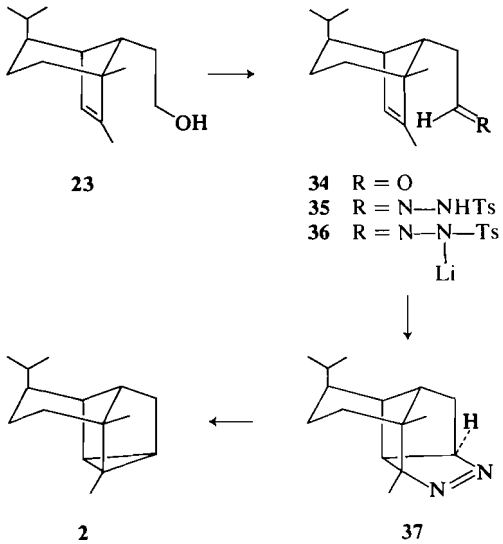
cyclic ketone **31**, and a number of minor unidentified components. Analytical samples of compounds **30** and **31**, obtained by preparative g.l.c., exhibited spectral properties in full accord with the assigned structures. The structure of the major product was further confirmed by its conversion, via Huang-Minlon reduction (34), into (−)-copacamphene (**1**).

It is appropriate to comment briefly regarding the possible pathway involved in the formation of the keto olefin **30**. Attack of diazomethane on the carbonyl group of the acid chloride **28**, followed by expulsion of chloride ion from the resultant intermediate **32**, would afford the charged species **33**. Abstraction of a proton from the nitrogen-bearing carbon of the latter would produce, in addition to hydrogen chloride (presumably rapidly destroyed by the excess diazomethane), the diazoketone **29**. However, because of the possibility of close proximity between the olefinic double bond and the electrophilic carbon adjacent to the carbonyl group, intermediate **33** could also undergo rapid eliminative cyclization to produce compound **30**. Apparently, this intramolecular cyclization was energetically favored over intermolecular proton abstraction. Some support for this proposal was obtained as follows. When the crude product obtained by a repetition of the acid chloride – diazomethane reaction was subjected to treatment with *p*-toluenesulfonic acid in benzene, the initially present i.r. absorptions due to the diazoketone moiety disappeared almost immediately. Analysis (g.l.c.) of the product showed that it consisted mainly (~90%) of the keto olefin **30** and contained none of the tetracyclic ketone **31**. Presumably, the small amount of diazoketone **29** originally present was protonated and the resulting intermediate (like **33**) cyclized to compound **30**. In this connection, it should be noted that, recently, the noncarbenoid, acid-catalyzed intramolecular cyclization of olefinic diazoketones has been demonstrated by a number of other research groups (35–38).

Although the work just described resulted in an interesting alternative preparation of (−)-copacamphene (**1**), the sequence was clearly unsatisfactory for the synthesis of (−)-cyclocopacamphene (**2**). Therefore, an alternative route was considered, based upon the possibility of achieving an intramolecular carbenoid-type cyclization of an olefinic diazoalkane, rather than a diazoketone. For this purpose, the previously

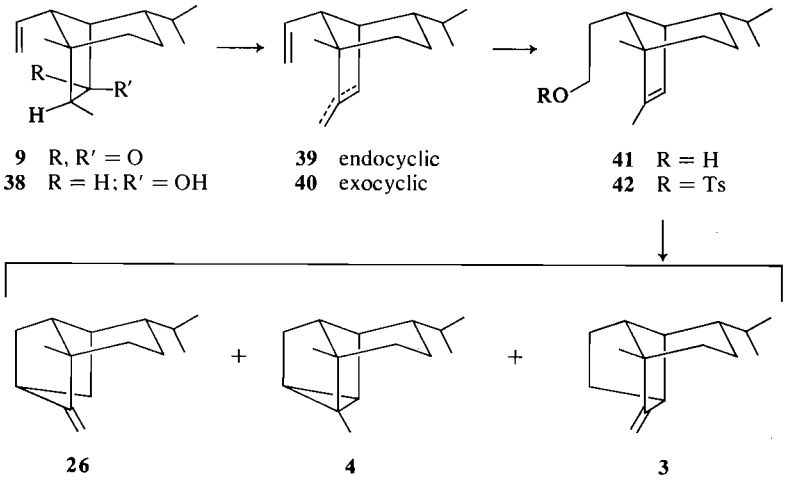


23 **34** R = O; **35** R = N—NHTs; **36** R = N—N(Li)—Ts; **2** **37**

SCHEME 4

synthesized olefinic alcohol **23** served as the starting material (see Scheme 4).

Oxidation of compound **23** with chromium trioxide-pyridine in dichloromethane (23, 24) gave the olefinic aldehyde **34** in 91% yield. The latter compound was, particularly in the presence of traces of acid, quite susceptible to intramolecular cyclization (internal Prins reaction (39)) and was therefore not amenable to storage. However, when the freshly prepared material was allowed to react with *p*-toluenesulfonylhydrazide in refluxing benzene for 5 min, the *p*-tosylhydrazone **35** was smoothly formed. Since compound **35** was also somewhat unstable, it was immediately converted (*n*-butyllithium in tetrahydrofuran) into the corresponding lithium salt **36**. Pyrolysis of this material at 120–140 °C under reduced pressure (0.25 Torr) with direct distillation of the product (40) afforded, in 81% yield, a clear colorless oil. This material, not unexpectedly, proved to be the pyrazoline **37**, obviously formed by intramolecular 1,3-dipolar cycloaddition of the initially formed (40) olefinic diazoalkane. The facility with which this reaction took place was presumably a function of the potential proximity of the two reacting functional groups and of the fairly strained nature of the carbon–carbon double bond (see ref. 41). The regioselectivity of the cycloaddition reaction was clearly shown by the p.m.r. spectrum of the product **37**, which showed that there was only one proton (multiplet at τ 5.11) adjacent to the —N=N— moiety (42).



SCHEME 5

An ether solution of the pyrazoline **37** was irradiated at room temperature for approximately 1 h, using a Rayonet reactor equipped with 3500 Å lamps and a Pyrex filter. The product, formed in 92% yield, was (−)-cyclocopacamphene (**2**). The i.r. and p.m.r. spectra of this material were identical with those of authentic (+)-cyclocopacamphene (47).[4]

Synthesis of (+)-Sativene (3) (see Scheme 5)

The synthesis of (+)-sativene (**3**) was achieved via a sequence which was in the later steps very similar to the preparation of (−)-copacamphene (**1**). However, the required bicyclic diene **39** was prepared via a route quite different from that employed for the corresponding compound **22** in the copa series. Thus, for the synthesis of (+)-sativene (**3**) the immediate starting material was the keto olefin **9**, a compound which had previously been prepared from the dione **6** (11) and which already contained the 15 carbon atoms necessary to complete the carbon skeleton of the natural product.

Initial investigations showed that a number of potentially suitable routes for the conversion of **9** into **39** were unsatisfactory. For example, we were unable to effect the transformation of **9** into the corresponding *p*-tosylhydrazone, even under quite drastic reaction conditions (43). Furthermore, conversion of **9** into a corresponding enol phosphate derivative, followed by reduction (12–14) of the latter with lithium in ethylamine – *t*-butyl alcohol under a variety of conditions, failed to produce synthetically acceptable yields of the desired diene **39**. In view of our previous difficulties in a related case (*vide supra*), this difficulty was perhaps not entirely unexpected.

The desired transformation (**9** → **39**) was finally accomplished as follows. Lithium aluminum hydride reduction of the olefinic ketone **9** afforded in nearly quantitative yield, the corresponding alcohol **38**. The stereochemistry of the latter compound was expected to be as shown (steric approach control) and this was fully corroborated by the p.m.r. spectrum of the reduction product. Dehydration of compound **38** with 6 equiv. of thionyl chloride[5] in pyridine at 40–45 °C for 3 h gave, in 75% yield, a mixture of the two isomeric dienes **39** and **40**, in a ratio of about 2:1, respectively. Attempts to avoid the formation of the unwanted diene **40** by employing alternative conditions and/or methods for the dehydration of **38** proved unsuccessful. In short, whenever dehydration did occur, both of the dienes **39** and **40** were produced. However, the two isomeric compounds could readily be separated by subjection of the mixture to column chromatography over silver nitrate impregnated silica gel. Furthermore, the overall efficiency of the process was improved by the discovery that the undesired diene **40**, upon treatment with a

[4]We are very grateful to Dr. Kido for his help in carrying out this comparison.

[5]Use of 1 equiv. of thionyl chloride produced mainly the corresponding sulfite ester (see ref. 44). Dehydration occurred most efficiently when a fairly large excess of reagent was employed.

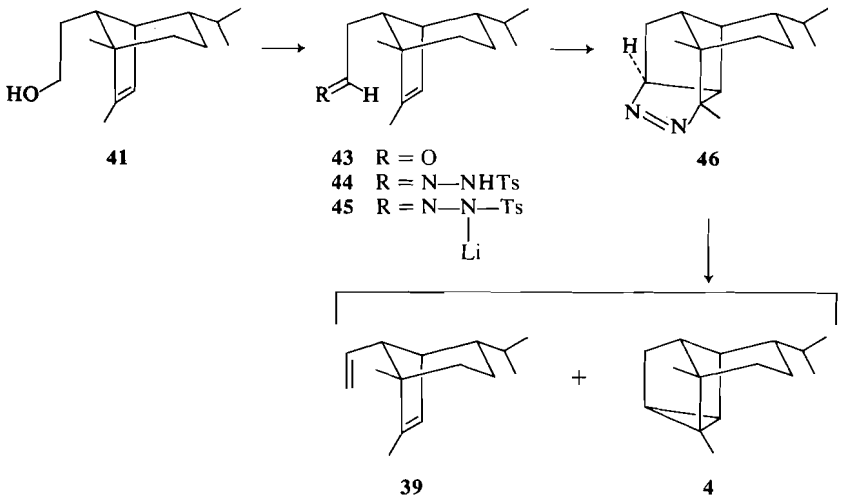

SCHEME 6

catalytic amount of *p*-toluenesulfonic acid in refluxing benzene for 30 min produced, in 94% yield, a mixture of **39** and **40** in a ratio of 7:3, respectively.

The synthetic route employed for the conversion of the diene **39** into (+)-sativene (**3**) paralleled that described previously (*vide supra*) for the transformation of diene **22** into (−)-copacamphene (**1**). Briefly, successive subjection of **39** to hydroboration–oxidation (disiamylborane in tetrahydrofuran; alkaline hydrogen peroxide), *p*-tosylation (*p*-toluenesulfonyl chloride in pyridine), and eliminative cyclization (silica gel column) afforded, in order, the primary alcohol **41**, the corresponding *p*-tosylate **42**, and a clear, colorless oil (58% overall yield). Analysis of the latter material by g.l.c. showed that it consisted of a mixture of three compounds, in a ratio of approximately 75:22:3. The minor component (3%) was identified (g.l.c. retention times on three different columns) as cyclosativene (**4**). Pure samples of the other two components were obtained by preparative g.l.c. The major compound (75%) was (+)-sativene (**3**), identified by direct comparison (i.r., p.m.r.) with an authentic sample.[6] The remaining component (22%), again identified by direct comparison with an independently synthesized sample, was (−)-isosativene (**26**) (31, 30). The formation of compounds **26** and **4** during the eliminative cyclization of olefinic tosylate **42** is explicable on the basis of the known acid-catalyzed interconversion of sativene, isosativene and cyclosativene (45), the mechanism of which has been discussed in detail by McMurry (30).

Synthesis of (+)-Cyclosativene (4) (see Scheme 6)

The conversion of the olefinic alcohol **41** into (+)-cyclosativene (**4**) was accomplished via a synthetic route which was fully analogous to that previously employed for the synthesis of (−)-cyclocopacamphene (**2**) from the bicyclic alcohol **23** (*vide supra*). Oxidation (23, 24) of **41** afforded the aldehyde **43**, which in turn was converted into the *p*-tosylhydrazone **44**. Pyrolysis (105–130 °C) of the corresponding lithium salt **45** under reduced pressure (0.1 Torr) with direct distillation of the product gave the pyrazoline **46** (50% overall yield from **41**). Photolysis of **46** in dry ether afforded in high yield an oil which was shown by g.l.c. analysis to consist of two compounds in a ratio of 11:1. This mixture was separated by preparative g.l.c. and the major product was identified (i.r., p.m.r.) as (+)-cyclosativene (**4**).[6] The minor product was shown (i.r.) to be identical with the diene **39**, presumably formed from the pyrazoline **46** by retro-1,3-dipolar addition, followed by carbene formation and insertion into an adjacent C—H bond (see ref. 46).

[6]We are very grateful to Professor J. E. McMurry for samples of sativene and cyclosativene.

Experimental[7]

Preparation of the Keto Enol Phosphate ***10***

To a solution of 6.6 g (36 mmol) of sodium bis(trimethylsilyl)amide in 90 ml of dry tetrahydrofuran was added a solution of 5.0 g (24 mmol) of the bicyclic diketone **5** in 10 ml of dry tetrahydrofuran. The reaction mixture was stirred at room temperature under an atmosphere of dry nitrogen for 20 min and then a solution of 10.7 g (62 mmol) of diethyl phosphorochloridate in 30 ml of dry pyridine was added. After the resulting mixture had been stirred at room temperature for 30 min it was concentrated under reduced pressure. The residual material was diluted with water and the resulting mixture was thoroughly extracted with ether. The combined ethereal extracts were washed with water and saturated brine, and dried over anhydrous magnesium sulfate. Removal of the solvent, followed by distillation (air-bath temperature 135–145 °C; 0.25 Torr) of the residual oil under reduced pressure afforded 7.8 g (94%) of the desired keto enol phosphate **10**, n_D^{21} 1.4722; $[\alpha]_D^{25}$ −5.8° (*c*, 1.4 in $CHCl_3$); i.r. (film) ν_{max} 1755, 1678, 1270, 1094, 1025, 960, 876, 833 cm^{-1}; p.m.r. τ 4.82 (d of q, 4H, $-OCH_2CH_3$, J = 7.0 Hz, $J_{H\text{-}P}$ = 1.0 Hz), 8.30 (d of d, 3H vinyl methyl, $J_{5\text{-}CH_3}$ = 1.0 Hz, $J_{H\text{-}P}$ = 2.2 Hz), 8.63 (d of t, 6H, $-O-CH_2CH_3$, J = 7.0 Hz, $J_{H\text{-}P}$ = 1.0 Hz), 8.98 (s, 3H, tertiary methyl), 9.08 (d, 6H, isopropyl methyls, J = 6.3 Hz).

Anal. Calcd. for $C_{17}H_{29}O_5P$: C, 59.29; H, 8.49. Found: C, 59.18; H, 8.45.

Preparation of the Keto Alcohol ***14***

A solution of the bicyclic diketone **5** (14.0 g, 67.3 mmol) in 170 ml of ethanol was cooled to 0 °C and a solution of 825 mg (21.8 mmol) of sodium borohydride in 30 ml of ethanol was added. The resulting solution was stirred at 0 °C for 15 min and then 4.4 g (74.0 mmol) of acetic acid was added. The reaction mixture was concentrated under reduced pressure, the residue was diluted with water, and the resulting mixture was thoroughly extracted with ether. The combined ethereal extracts were washed with a saturated sodium carbonate solution and brine, and then dried over anhydrous magnesium sulfate. Removal of the solvent followed by distillation of the residual oil under reduced pressure afforded 12.5 g (89%) of the desired keto alcohol **14**, b.p. 125–130 °C at 0.4 Torr; n_D^{25} 1.4916; $[\alpha]_D^{25}$ −69° (*c*, 1.0 in $CHCl_3$); i.r. (film) ν_{max} 3475, 1725, 1460, 1110, 1100 cm^{-1}; p.m.r. τ 6.12 (d, 1H, C-8 H, J = 5.5 Hz), 7.30 (m, 1H, C-5 H), 8.92 (d, 3H, secondary methyl, J = 7.0 Hz), 8.97 (s, 3H, tertiary methyl), 9.02, 9.13 (d, d, 6H, isopropyl methyls, J = 6.5 Hz).

Anal. Calcd. for $C_{13}H_{22}O_2$: C, 74.24; H, 10.54. Found: C, 74.12; H, 10.50.

Preparation of the Olefinic Alcohol ***16***

To a hot (90 °C) solution of the keto alcohol **14** (12.0 g, 57.2 mmol) and *p*-toluenesulfonylhydrazide (11.7 g, 62.8 mmol) in 9.0 ml of methanol was added 300 μl of acetyl chloride. The reaction mixture was stirred under an atmosphere of dry nitrogen at 90–100 °C for 3 h, cooled, and diluted with water. The resulting mixture was thoroughly extracted with ether. The combined ethereal extracts were washed with 10% aqueous sodium bicarbonate, then with brine, and finally dried over anhydrous magnesium sulfate. Removal of the solvent under reduced pressure yielded 21.2 g (98%) of the *p*-toluenesulfonylhydrazone **15** as a viscous yellow oil (i.r. (film) ν_{max} 3620, 3355, 3320, 1655, 1600, 1170 cm^{-1}). This material was used without further purification.

To an ice-cooled solution of the *p*-toluenesulfonylhydrazone **15** (21.2 g, 56.2 mmol) in 1100 ml of dry tetrahydrofuran was added 214 ml of 2.1 *M* ethereal methyllithium over a period of 30 min. The reaction mixture was allowed to warm to room temperature and was stirred under an atmosphere of dry nitrogen for an additional 3 h. The solution was then cooled to 0 °C and the excess methyllithium was destroyed by the careful addition of water. The reaction mixture was concentrated, the residue was diluted with water, and the resulting mixture was thoroughly extracted with ether. The combined ethereal extracts were washed with brine and dried over anhydrous magnesium sulfate. Removal of the solvent followed by distillation of the residual oil under reduced pressure afforded 9.57 g (88%) of the desired olefinic alcohol **16** as a colorless oil, b.p. 80 °C at 0.25 Torr; n_D^{25} 1.4898; $[\alpha]_D^{25}$ −61° (*c*, 0.7 in $CHCl_3$); i.r. (film) ν_{max} 3400, 3050, 1620, 1450, 1090, 1066, 805 cm^{-1}; p.m.r. τ 4.60 (unresolved m, 1H, vinyl proton), 5.57 (s, 1H, hydroxyl proton), 6.36 (d, 1H, C-8H, J = 5.5 Hz), 7.34 (m, 1H, C-5H), 8.38 (d of d, 3H, vinyl methyl, $J_{6\text{-}CH_3}$ = 1.6 Hz, $J_{5\text{-}CH_3}$ = 1.0 Hz), 9.10 (s, 3H, tertiary methyl), 9.03, 9.13 (d, d, 6H, isopropyl methyls, J = 6.5 Hz).

Anal. Calcd. for $C_{13}H_{22}O$: C, 80.35; H, 11.41. Found: C, 80.16; H, 11.27.

Preparation of the Keto Olefin ***8***

(a) By Lithium–Ethylamine Reduction of the Keto Enol Phosphate ***10***

A solution of 1.38 g (200 mmol) of lithium metal in approximately 70 ml of dry ethylamine was stirred at room temperature for 20 min. To this solution was added dropwise, over a period of 10 min, a solution of the keto enol phosphate **10** (3.43 g, 10.0 mmol) and *t*-butyl alcohol (1.48 g, 20.0 mmol) in 10 ml of dry ether. The reaction mixture was stirred for an additional 5 min and was then filtered through a small glass wool plug into a rapidly stirred ether–water mixture. The resulting mixture was extracted twice with ether, the combined ethereal extracts were washed with water and brine, and dried over anhydrous magnesium sulfate. The ether was removed at aspirator pressure and the crude product was distilled (air bath temperature 65–75 °C; 0.5 Torr) under reduced pressure to afford 900 mg of a yellow oil. Gas–liquid chromatographic analysis (column A, 170 °C, 95) of the distilled product indicated that it consisted of a mixture of approximately 50% of the keto olefin **8**, 20% of the corresponding alcoholic olefin **11**, 10% of the saturated ketone **12**, and several minor, unidentified components.

Standard chromic acid solution (25) was added to a solution of the distilled reduction product (900 mg) in acetone (25 ml) at 0 °C until the orange color persisted. Isopropyl alcohol was added to destroy the excess oxidizing reagent, and the solution was evaporated under reduced pressure. The residual material was diluted with water and thoroughly extracted with ether. The combined ethereal extracts were dried over anhydrous magnesium

[7]For pertinent general information, see ref. 8.

For personal use only.

sulfate and the ether was removed at aspirator pressure. The desired keto olefin **8** was obtained from the resulting mixture by means of preparative g.l.c. (column J, 230 °C, 200). The keto olefin **8** thus obtained (500 mg, 26%) was a colorless oil and exhibited n_D^{23} 1.4789; $[\alpha]_D^{23}$ −29° (*c*, 1.3 in $CHCl_3$); i.r. (film) ν_{max} 3040, 1750, 1630, 1060, 818 cm^{-1}; p.m.r. τ 4.13 (unresolved m, 1H, vinyl proton), 7.17 (unresolved m, 1H, C-5 H), 8.25 (d of d, 3H, vinyl methyl, $J_{6\text{-}CH_3}$ = 1.6 Hz, $J_{5\text{-}CH_3}$ = 1.0 Hz), 9.00 (s, 3H, tertiary methyl), 9.00, 9.09 (d, d, 6H, isopropyl methyls, J = 6.0 Hz).

Anal. Calcd. for $C_{13}H_{20}O$: C, 81.20; H, 10.48. Found: C, 81.30; H, 10.59.

(b) By Bamford–Stevens Reaction of the p-Toluenesulfonylhydrazone 13

To a solution of the bicyclic diketone **5** (11.6 g, 56.0 mmol) in 10 ml of methanol was added *p*-toluenesulfonylhydrazide (13.0 g, 70.0 mmol) and the resulting mixture was heated and stirred under an atmosphere of dry nitrogen until a homogeneous solution was obtained. Acetyl chloride (100 µl) was added to the solution and the reaction mixture was stirred at room temperature for 3 h. The methanol was removed under reduced pressure, the residue was diluted with water, and the resulting mixture was thoroughly extracted with ether. The ethereal extracts were washed with a 10% solution of sodium bicarbonate and brine, and dried over anhydrous magnesium sulfate. Removal of the solvent under reduced pressure yielded 21.1 g (100%) of the crude *p*-toluenesulfonylhydrazone **13**. In general, this material was used for the next reaction without further purification. However an analytical sample of compound **13**, obtained by recrystallization of a small amount of this material from methanol exhibited m.p. 77–80 °C; i.r. ($CHCl_3$) ν_{max} 3520, 3205, 1745, 1653, 1600, 1165 cm^{-1}; p.m.r. τ 2.18, 2.72 (d, d, 4H, aromatic protons, J = 9.0 Hz), 7.50 (s, 3H, aromatic methyl), 8.82 (d, 3H, secondary methyl, J = 7.0 Hz), 9.05 (s, 3H, tertiary methyl), 9.02, 9.19 (d, d, 6H, isopropyl methyls, J = 6.0 Hz).

To a solution of the crude *p*-toluenesulfonylhydrazone **13** (21.1 g, 56.0 mmol) in 150 ml of dry tetrahydrofuran was added a solution of 10.7 g (58.7 mmol) of sodium bis(trimethylsilyl)amide and 2.2 ml of high boiling Nujol (> 210 °C at 0.2 Torr) in 50 ml of dry tetrahydrofuran, and the resulting reaction mixture was stirred under an atmosphere of dry nitrogen for 1 h. The reaction mixture was then concentrated under reduced pressure. The remaining mixture of Nujol and the sodium salt of the *p*-toluenesulfonylhydrazone was heated slowly to 125 °C under reduced pressure (water aspirator, 10–20 Torr) at which temperature decomposition of the salt was observed to take place. At this temperature, direct distillation of the product was accomplished by application of a vacuum pump (0.3 Torr) to the reaction system. The product thus obtained was redistilled (air-bath temperature 75–80 °C; 0.5 Torr) and those distillation fractions containing significant amounts of keto olefin (g.l.c. analysis, column A, 170 °C, 95) were chromatographed on silica gel. Elution with 10:1 petroleum ether (b.p. 30–60 °C) – ether afforded fractions containing significant amounts of keto olefin (g.l.c. analysis, column A, 170 °C, 95). These fractions were then subjected to preparative g.l.c. (column J, 230 °C, 150) and 4.0 g (38%) of the pure keto olefin **8** was obtained in this manner. This material was identical (g.l.c. retention time, i.r., and p.m.r. spectra) with the keto olefin **8** prepared previously.

(c) By Jones Oxidation of the Olefinic Alcohol 16

Standard chromic acid solution (25) was added to a solution of the olefinic alcohol **16** (1.94 g, 10 mmol) in acetone (50 ml) at 0 °C, until the orange color persisted. Isopropyl alcohol was added to destroy the excess oxidizing agent and the solution was evaporated under reduced pressure. The residual material was diluted with water and the resulting mixture was thoroughly extracted with ether. The combined ethereal extracts were washed with brine and dried over anhydrous magnesium sulfate. Removal of the solvent, followed by distillation (air bath temperature 70–75 °C; 0.5 Torr) of the residual oil under reduced pressure afforded 1.71 g (89%) of the keto olefin **8**. This material was identical (g.l.c. retention time, i.r., and p.m.r. spectra) with the keto olefin **8** prepared previously.

Preparation of the Olefinic Enol Ethers 20

To a stirred solution of sodium methylsulfinylmethide (0.84 g, 8.4 mmol) in 9 ml of dry dimethyl sulfoxide at room temperature, under an atmosphere of dry nitrogen, was added a solution of methoxymethyltriphenylphosphonium chloride (3.07 g, 10 mmol) in 12 ml of dry dimethyl sulfoxide. The resulting solution was stirred for 10 min and then a solution of the keto olefin **8** (320 mg, 1.67 mmol) in 9 ml of dimethyl sulfoxide was added. The reaction mixture was heated at 40–50 °C for 1.5 h, then cooled, diluted with water, and the resulting mixture was thoroughly extracted with petroleum ether (b.p. 30–60 °C). The combined extracts were washed twice with water, once with saturated brine, and then dried over anhydrous magnesium sulfate. Removal of the solvent, followed by distillation (air-bath temperature 75–80 °C; 0.5 Torr) of the residual oil under reduced pressure yielded 262 mg (71%) of the olefinic enol ethers **20** as a colorless oil, n_D^{21} 1.4927; u.v. λ_{max} 208 nm (ε 8030); i.r. (film) ν_{max} 3030, 1700, 1450, 1236, 1215, 1112 cm^{-1}; p.m.r. τ 4.43 (broad signal, 2H, vinyl protons), 6.51, 6.54 (s, s, 3H, —OCH_3), 7.23 (broad s, 1H, C-5H).

Anal. Calcd. for $C_{15}H_{24}O$: C, 81.76; H, 10.98. Found: C, 82.00; H, 11.11.

For personal use only.

under reduced pressure yielded 202 mg (86%) of the olefinic aldehyde **21** as a colorless oil, n_D^{21} 1.4931; $[\alpha]_D^{22}$ −20° (*c*, 1.7 in $CHCl_3$); i.r. (film) ν_{max} 3030, 2725, 1715, 1645, 1450, 1380, 808 cm^{-1}; p.m.r. τ 0.40 (d, 1H, aldehydic proton, J = 4.2 Hz), 4.56 (unresolved m, 1H, vinyl proton, $w_{\frac{1}{2}}$ = 6.0 Hz), 7.53 (unresolved m, 1H, C-5 H), 7.80 (d, 1H, C-8 H, J = 4.2 Hz), 8.38 (d of d, 3H, vinyl methyl, $J_{6\text{-}CH_3}$ = 1.6 Hz, $J_{5\text{-}CH_3}$ = 1.0 Hz), 8.97 (s, 3H, tertiary methyl), 9.08, 9.16 (d, d, 6H, isopropyl methyls, J = 6.2 Hz).

Mol. Wt. Calcd. for $C_{14}H_{22}O$: 206.167. Found (high resolution mass spectrometry): 206.166.

Preparation of the Diene 22

To a stirred solution of sodium methylsulfinylmethide (2.25 g, 22.5 mmol) in dry dimethyl sulfoxide (27 ml) at room temperature, under an atmosphere of nitrogen, was added a solution of methyltriphenylphosphonium bromide (9.65 g, 27.0 mmol) in 36 ml of dimethyl sulfoxide. The solution was stirred for 10 min and then a solution of the olefinic aldehyde **21** (900 mg, 4.5 mmol) in 27 ml of dimethyl sulfoxide was added. The reaction mixture was heated at 40–50 °C for 1 h, cooled, and diluted with water and the resulting mixture was thoroughly extracted with petroleum ether (b.p. 30–60 °C). The combined petroleum ether extracts were washed twice with water, once with saturated brine, and then dried over anhydrous magnesium sulfate. Removal of the solvent, followed by distillation (air-bath temperature 90–95 °C; 0.3 Torr) of the residual oil under reduced pressure afforded 740 mg (83%) of the desired diene **22**, n_D^{26} 1.4820; $[\alpha]_D^{21}$ +4.3° (*c*, 1.5 in $CHCl_3$); i.r. (film) ν_{max} 3030, 1640, 1450, 997, 906, 842, 806 cm^{-1}; p.m.r. τ 4.00–4.42 (m, 1H, —C*H*=CH_2), 4.67 (unresolved m, 1H, C-6H, $w_{\frac{1}{2}}$ = 6.0 Hz), 4.84–5.24 (m, 2H, —CH=CH_2), 7.67 (unresolved m, 1H, C-5 H, $w_{\frac{1}{2}}$ = 8 Hz) 7.83 (d, 1H, C-8 H, J = 9.0 Hz), 8.42 (d of d, 3H, vinyl methyl, $J_{6\text{-}CH_3}$ = 1.6 Hz, $J_{5\text{-}CH_3}$ = 1.0 Hz), 9.07, 9.15 (d, d, 6H, isopropyl methyls, J = 6.5 Hz), 9.16 (s, 3H, tertiary methyl).

Anal. Calcd. for $C_{15}H_{24}$: C, 88.16; H, 11.84. Found: C, 88.08; H, 12.00.

Preparation of the Olefinic Alcohol 23

To a stirred solution of 0.51 g (3.3 mmol) of disiamylborane in 8 ml of dry tetrahydrofuran at 0 °C, under an atmosphere of dry nitrogen, was added a solution of the diene **22** (306 mg, 1.5 mmol) in 6 ml of tetrahydrofuran. The reaction mixture was stirred at room temperature for 1.5 h. The reaction mixture was cooled to 0 °C and 2 ml of 3 *N* NaOH was added slowly, followed by addition of 2 ml of 30% hydrogen peroxide. The resulting mixture was warmed to room temperature, stirred for 1 h, and then concentrated. The residual material was diluted with water and thoroughly extracted with ether. The combined ether extracts were washed with a saturated brine solution and dried over anhydrous magnesium sulfate. Removal of the solvent, followed by distillation (air-bath temperature 115–120 °C; 0.2 Torr) of the residual material under reduced pressure afforded 300 mg (91%) of the desired olefinic alcohol **23** as a colorless oil. An analytical sample was obtained by preparative g.l.c. (column A, 210 °C, 100) and exhibited n_D^{24} 1.4936; $[\alpha]_D^{20}$ +8.5° (*c*, 5.6 in $CHCl_3$); i.r. (film) ν_{max} 3300, 3020, 1642, 1450, 1375, 1055 cm^{-1}; p.m.r. τ 4.68 (unresolved m, 1H, vinyl proton, $w_{\frac{1}{2}}$ = 4.2 Hz), 6.38 (m, 2H, —CH_2OH), 7.63 (unresolved m, 1H, C-5H), 8.44 (d of d, 3H, vinyl methyl, $J_{6\text{-}CH_3}$ = 1.6 Hz, $J_{5\text{-}CH_3}$ = 1.0 Hz), 9.08, 9.14 (d, d, 6H, isopropyl methyls, J = 6.0 Hz), 9.10 (s, 3H, tertiary methyl).

Mol. Wt. Calcd. for $C_{15}H_{26}O$: 222.198. Found (high resolution mass spectrometry): 222.198.

Preparation of the Olefinic Acid 27

A solution of 206 mg (10.0 mmol) of the olefinic aldehyde **21** in 1.5 ml of pyridine was added to a solution of 1.2 g of chromium trioxide in 12 ml of pyridine. Five drops of water were added and the resulting dark mixture was stirred for 18 h at room temperature. The reaction mixture was diluted with water and extracted with ether. The combined ethereal extracts were washed with water, with a dilute hydrochloric acid, and then extracted with 10% aqueous sodium hydroxide. The alkaline extracts were cooled, acidified with 6 *N* hydrochloric acid, and the resulting mixture was thoroughly extracted with ether. The combined ethereal extracts were washed with water and dried over anhydrous magnesium sulfate. Removal of the solvent afforded 174 mg (82%) of the crystalline olefinic acid **27**, m.p. 138–139.5 °C; $[\alpha]_D^{26}$ −16.7° (*c*, 1.2 in $CHCl_3$); i.r. ($CHCl_3$) ν_{max} 1704 cm^{-1}; p.m.r. τ 0.18 (very broad signal, 1H, acid proton), 4.55 (unresolved m, 1H, vinyl proton, $w_{\frac{1}{2}}$ = 6.0 Hz), 7.19 (unresolved m, 1H, C-5 H), 7.50 (s, 1H, C-8 H), 8.40 (d of d, 3H, vinyl methyl, $J_{6\text{-}CH_3}$ = 1.6 Hz, $J_{5\text{-}CH_3}$ = 1.0 Hz), 8.89 (s, 3H, tertiary methyl), 9.07, 9.11 (d, d, 6H, isopropyl methyls, J = 6.0 Hz)..

Anal. Calcd. for $C_{14}H_{22}O_2$: C, 75.63; H, 9.97. Found: C, 75.33; H, 9.98.

Preparation of the Tricyclic Keto Olefin 30

The olefinic carboxylic acid **27** (111 mg, 0.5 mmol) was dissolved in aqueous sodium hydroxide (0.55 mmol), the water was evaporated under reduced pressure, and the residue was dried in a vacuum oven at 70 °C. A stirred suspension of the resulting dry sodium salt in 10 ml of anhydrous ether containing 20 μl of dry pyridine was cooled to 0 °C and 640 mg (5.0 mmol) of oxalyl chloride was added. The reaction mixture was stirred at 0 °C for 15 min under an atmosphere of dry nitrogen, then filtered, and concentrated under reduced pressure (vacuum pump). The solution was kept at 0 °C during this process. The crude acid chloride **28** (i.r. (film) ν_{max} 1812 cm^{-1}) thus obtained was dissolved in 15 ml of anhydrous ether and the resulting solution was added to excess alcohol-free ethereal diazomethane which had been dried over potassium hydroxide. The resulting reaction mixture was stirred at 0 °C for 2.5 h, then the excess diazomethane and solvent was removed under reduced pressure. The crude reaction product (i.r. (film) ν_{max} 1745 cm^{-1} (strong), 2130, 1656 cm^{-1} (weak)) was dissolved in 15 ml of dry cyclohexane and cupric sulfate (400 mg) was added. The resulting suspension was refluxed, with stirring, for 3 h. The cooled reaction mixture was filtered, the filtrate was washed with saturated aqueous sodium bicarbonate, water, and brine, and then dried over anhydrous magnesium sulfate. Removal of the solvent, followed by distillation (air-bath temperature 110–115 °C; 0.25 Torr) of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

the residual material under reduced pressure, yielded 66 mg (60%) of a colorless oil. This material was shown by g.l.c. analysis (column I, 200 °C, 95) to consist mainly (~84%) of the keto olefin **30**. In addition, the tetracyclic ketone **31** (~8%) and a number of minor unidentified compounds were also present. Compounds **30** and **31** were isolated by preparative g.l.c. (column K, 240 °C, 200). The tetracyclic ketone **31** thus obtained exhibited i.r. (film) ν_{max} 3058, 1745, 876, 831 cm^{-1}; p.m.r. τ 8.82, 9.08 (s, s, 6H, tertiary methyls), 9.12, 9.15 (d, d, 6H, isopropyl methyls, J = 6.0 Hz).

The keto olefin **30** exhibited n_D^{24} 1.5036; $[\alpha]_D^{26}$ −100° (*c*, 1.0 in $CHCl_3$); i.r. (film) ν_{max} 3065, 1745, 1665, 1462, 1170, 879 cm^{-1}; p.m.r. τ 5.03, 5.27 (s, s, 2H, vinyl protons), 7.13 (unresolved m, 1H, allylic proton), 8.99 (s, 3H, tertiary methyl), 9.12 (d, 6H, isopropyl methyls, J = 6.0 Hz).

Mol. Wt. Calcd. for $C_{15}H_{22}O$: 218.167. Found (high resolution mass spectrometry); 218.165.

The attempted formation of the diazoketone **29** was repeated employing a reaction procedure identical with that just described. The crude product (i.r. (film) ν_{max} 1745 (strong), 2130, 1656 (weak) cm^{-1}) obtained by reaction of the acid chloride **28** with diazomethane was dissolved in approximately 1 ml of dry benzene, and the resulting solution was added to 25 ml of a 5.0 m*M* solution of *p*-toluenesulfonic acid in benzene. The reaction mixture was stirred for 30 min at room temperature under an atmosphere of dry nitrogen. Appropriate analysis of an aliquot showed that the i.r. absorptions due to the diazoketone moiety had disappeared after a period of a few minutes. The solution was washed with saturated aqueous sodium bicarbonate, water and brine, and then dried over anhydrous magnesium sulfate. Removal of the solvent, followed by distillation of the residual material under reduced pressure yielded 65 mg (60%) of a colorless oil. Analysis of this material by g.l.c. (column I, 200 °C, 95) indicated the presence of the keto olefin **30** (~90%), along with a number of minor components (unidentified). The keto olefin **30** was obtained by preparative g.l.c. (column K, 240 °C, 200) and was shown (g.l.c. retention time, i.r., and p.m.r. spectra) to be identical with the material prepared previously.

(−)-Copacamphene (1)

(a) From the Olefinic Alcohol 23

To a solution of 200 mg (0.9 mmol) of the olefinic alcohol **23** in 4 ml of dry pyridine was added a solution of 342 mg (1.8 mmol) of *p*-toluenesulfonyl chloride in 1 ml of dry pyridine. The reaction mixture was stirred under an atmosphere of dry nitrogen for 2.5 h. The solution was diluted with hexane and the resulting mixture was washed with aqueous sodium bicarbonate, water and brine, and dried over anhydrous magnesium sulfate. The solvent was removed first at water aspirator pressure and finally the last traces of pyridine were removed by application of a vacuum pump. The residual oil (the crude *p*-tosylate **25**) was transferred to the top of a silica gel column (5.0 g) and the column was eluted with approximately 50 ml of pentane. Removal of the solvent from the eluant, followed by distillation (air-bath temperature 75–80 °C; 0.25 Torr) of the residual oil afforded 164 mg (89%) of a colorless oil. Gas–liquid chromatographic analysis (column G, 135 °C, 85) of this material indicated that it consisted of a major component (98%) accompanied by two minor components (in a ratio of approximately 1:1) that comprised 1–2% of the total mixture. Final purification was effected by column chromatography of the mixture on 10% silver nitrate impregnated silica gel. Elution with 25:1 pentane–ether afforded pure (−)-copacamphene (**1**) $[\alpha]_D^{21}$ −159° (*c*, 2.2 in $CHCl_3$); i.r. (film) ν_{max} 3065, 1658, 1389, 1370, 876 cm^{-1}; p.m.r. τ 5.21, 5.49 (s, s, 2H, vinyl protons), 7.54 (broad signal, 1H, allylic proton), 9.00 (s, 3H, tertiary methyl), 9.10 (d, 6H, isopropyl methyls, J = 6.0 Hz). This material was found to be identical (g.l.c. retention time, i.r.) with authentic (±)-copacamphene.

Mol. Wt. Calcd. for $C_{15}H_{24}$: 204.188. Found (high resolution mass spectrometry): 204.188.

The minor components from the reaction described above were collected by preparative g.l.c. (column L, 145 °C, 120) and were identified as (+)-cyclosativene (**4**) and (−)-isosativene (**26**) by direct comparison (g.l.c. retention time, i.r. spectra), in each case, with an authentic sample.

(b) By Reduction of the Keto Olefin 30

A solution of 50 mg of the keto olefin **30** in 2.0 ml of ethylene glycol containing 0.1 ml of 85% hydrazine hydrate and 100 mg of potassium hydroxide was refluxed for 2 h. The reflux condensor was removed and replaced by a distillation head and the temperature of the reaction mixture was slowly raised to 200 °C and maintained at this temperature for 3 h. The distillate was collected in a Dry Ice – acetone cooled receiver and combined with the cooled reaction mixture. This solution was diluted with water and the resulting mixture was thoroughly extracted with petroleum ether (b.p. 30–60 °C). The combined petroleum ether extracts were washed with water and brine and dried over anhydrous magnesium sulfate. The dried petroleum ether extracts were filtered through 2 g of silica gel and the column was further eluted with petroleum ether. Removal of the solvent from the eluant followed by distillation of the residual oil produced 27 mg (58%) of (−)-copacamphene (**1**). This material was identical (g.l.c. retention time, specific rotation, i.r., and p.m.r. spectra) with the (−)-copacamphene prepared as described above.

Preparation of the Olefinic Aldehyde 34

To a solution of 286 mg (3.6 mmol) of dry pyridine in 4.0 ml of dry methylene chloride was added 180 mg (1.8 mmol) of dry chromium trioxide. The solution was stirred under an atmosphere of dry nitrogen at room temperature for 15 min. To this mixture was added a solution of 64 mg (0.3 mmol) of the olefinic alcohol **23** in 0.5 ml of methylene chloride. The reaction was allowed to proceed for 15 min, then approximately 10 ml of ether was added and the resulting solution was washed with saturated aqueous sodium carbonate, with water, and then dried over anhydrous magnesium sulfate. Removal of the solvent followed by distillation (air-bath temperature 80–85 °C; 0.25 Torr) of the residual oil yielded 58 mg (91%) of the desired olefinic aldehyde **34**, as a colorless oil, n_D^{24} 1.4906; $[\alpha]_D^{21}$ −39° (*c*, 1.6 in $CHCl_3$); i.r. (film) ν_{max} 3040, 2715, 1724, 1675, 1458, 1385 cm^{-1}; p.m.r. τ 0.20 (t, 1H, aldehydic proton, J = 2.5 Hz), 4.60 (unresolved m, 1H, vinyl proton), 8.42 (d of d, 3H, vinyl methyl, $J_{6\text{-}CH_3}$ = 1.6 Hz, $J_{5\text{-}CH_3}$ = 1.0 Hz), 9.07, 9.13

For personal use only.

(d, d, 6H, isopropyl methyls, J = 6.5 Hz), 9.10 (s, 3H, tertiary methyl).

Anal. Calcd. for $C_{15}H_{24}O$: C, 81.76; H, 10.98. Found: C, 81.45; H, 10.98.

Preparation of the Pyrazoline 37

In a 5-ml flask equipped with a Dean–Stark water separator there was placed 58 mg (0.26 mmol) of the olefinic aldehyde **34** and 49 mg (0.263 mmol) of *p*-toluenesulfonylhydrazide in 2.5 ml of dry benzene. The reaction mixture was refluxed in an atmosphere of dry nitrogen for 5 min. The solvent was then removed, and replaced with 2.5 ml of dry tetrahydrofuran. To the resulting stirred solution was added 0.13 ml of 2 *M* *n*-butyllithium in hexane. After 30 min, the solvent was removed and the residual lithium salt of the *p*-toluenesulfonylhydrazone (**36**) was heated slowly under reduced pressure (0.25 Torr). Between the temperatures of 120 and 140 °C, 50 mg (81% yield from the aldehyde **34**) of the pyrazoline **37** was collected as a colorless oil, n_D^{24} 1.5042; $[\alpha]_D^{22}$ +95° (*c*, 1.0 in $CHCl_3$); u.v. λ_{max} 334 nm (ε 232); i.r. (film) ν_{max} 1550, 1456, 1377, 1122 cm^{-1}; p.m.r. τ 5.11 (m, 1H, proton adjacent to the —N=N— moiety), 8.42, 9.18 (s, s, 6H, tertiary methyls), 9.14 (d, 6H, isopropyl methyls, J = 6.0 Hz).

The instability of this material precluded the acquisition of satisfactory analytical data.

(−)-Cyclocopacamphene (2)

A solution of 35 mg of the pyrazoline **37** in 35 ml of dry ether was irradiated in a Rayonet Reactor, using 3500 Å lamps and a Pyrex filter, for 1 h. Removal of the solvent, followed by distillation (air-bath temperature 80 °C) of the residual oil under reduced pressure (0.3 Torr) afforded 30 mg (93%) of pure (−)-cyclocopacamphene (**2**), $[\alpha]_D^{21}$ −42° (*c*, 1.1 in $CHCl_3$); i.r. (film) ν_{max} 3039, 1460, 1387, 862, 847, 826 cm^{-1}; p.m.r. τ 8.99, 9.26 (s, s, 6H, tertiary methyls), 9.10, 9.13 (d, d, 6H, isopropyl methyls, J = 6.5 Hz), 9.32, 9.37 (broad signals, 2H, cyclopropyl protons). The i.r. and p.m.r. spectra of this material were identical with those of authentic (+)-cyclocopacamphene.

Anal. Calcd. for $C_{15}H_{24}$: C, 88.14; H, 11.84. Found: C, 88.35; H, 11.90.

Preparation of the Olefinic Alcohol 38

To a solution of lithium aluminum hydride (75 mg) in dry ether (5 ml) was added 330 mg of the keto olefin **9** and the resulting solution was refluxed gently for 1 h. The reaction mixture was cooled in an ice water bath and 3 ml of saturated aqueous ammonium chloride was added. The mixture was stirred at room temperature for 30 min and filtered through Celite. The filtrate was washed with brine and dried over anhydrous magnesium sulfate. Removal of the solvent, followed by distillation (air-bath temperature 86–89 °C; 0.08 Torr) of the residual oil, gave 325 mg (98%) of the olefinic alcohol **38** as a clear colorless oil, $[\alpha]_D^{25}$ −30° (*c*, 0.63 in $CHCl_3$); i.r. (film) ν_{max} 3510, 3105, 1640, 1460, 1383, 1132, 1110, 1016, 910 cm^{-1}; p.m.r. τ 3.92–4.50 (m, 1H, —C*H*=CH_2), 4.83–5.17 (m, 2H, —CH=C*H*$_2$), 5.37 (d of d, 1H, C-6 H, $J_{5,6}$ = 7.0 Hz, $J_{6,7}$ = 10.7 Hz), 9.04, 9.16 (d, d, 6H, isopropyl methyls, J = 6.7 Hz), 9.12 (d, 3H, secondary methyl, J = 7.5 Hz), 9.18 (s, 3H, tertiary methyl).

Anal. Calcd. for $C_{15}H_{26}O$: C, 81.02; H, 11.79. Found: C, 80.80; H, 11.61.

Dehydration of the Olefinic Alcohol 38

To a solution of the olefinic alcohol **38** (3.0 g, 13.5 mmol) in 125 ml of dry pyridine was added 9.6 g of redistilled thionyl chloride. The resulting mixture, under an atmosphere of nitrogen, was heated to 40 °C and then kept at this temperature for 3 h. The solution was cooled and poured into rapidly stirred ice-cold dilute hydrochloric acid. The resulting mixture was extracted thoroughly with 1:1 ether – petroleum ether (b.p. 65–110 °C). The combined extracts were successively washed with cold dilute hydrochloric acid, aqueous sodium bicarbonate, and brine, and then dried over anhydrous magnesium sulfate. Removal of the solvents afforded 2.7 g of a crude yellow oil which was subjected to column chromatography on 210 g of 15% silver nitrate impregnated silica gel. The column was eluted with petroleum ether (b.p. 65–110 °C) containing increasing amounts of ether. From the earlier fractions there was obtained 0.75 g (27%) of the pure diene **40**, which was distilled under reduced pressure (0.25 Torr) at an air-bath temperature of 69–71 °C, and exhibited $[\alpha]_D^{26}$ −6.3° (*c*, 0.8 in $CHCl_3$); i.r. (film) ν_{max} 3085, 1650, 1640, 990, 910, 870 cm^{-1}; p.m.r. τ 4.03–4.63 (m, 1H, —C*H*=CH_2), 4.90, 5.01 (d, d, 2H, $\diagdown$C=C*H*$_2$, J = 2.5 Hz), 5.08–5.37 (m, 2H, —CH=C*H*$_2$), 9.03 (s, 3H, tertiary methyl), 9.09, 9.12 (d, d, 6H, isopropyl methyls, J = 6.0 Hz).

Anal. Calcd. for $C_{15}H_{24}$: C, 88.16; H, 11.84. Found: C, 88.37; H, 11.91.

From the later petroleum ether – ether fractions in the above-mentioned chromatography 1.32 g (48%) of the pure diene **39** was obtained, which was distilled under reduced pressure (0.3 Torr) at an air-bath temperature of 70–72 °C, and exhibited $[\alpha]_D^{26}$ +37° (*c*, 0.64 in $CHCl_3$); i.r. (film) ν_{max} 3095, 3060, 1640, 1450, 1380, 1365, 995, 910 cm^{-1}; p.m.r. τ 3.98–4.35 (m, 1H, —C*H*=CH_2), 4.72 (unresolved m, 1H, C-6 H, $w_{\frac{1}{2}}$ = 6.0 Hz), 4.96–5.21 (m, 2H, —CH=C*H*$_2$), 7.64 (unresolved m, 1H, C-5H, $w_{\frac{1}{2}}$ = 5.0 Hz), 8.09 (d, 1H, C-8 H, J = 9.0 Hz), 8.42 (unresolved m, 3H, vinyl methyl, $w_{\frac{1}{2}}$ = 3.5 Hz), 9.12, 9.21 (d, d, 6H, isopropyl methyls, J = 6.5 Hz), 9.16 (s, 3H, tertiary methyl).

Acid-catalyzed Isomerization of the Diene 40

To a solution of the diene **40** (170 mg) in 3 ml of dry benzene was added a few crystals of *p*-toluenesulfonic acid and the resulting solution was refluxed for 30 min. The solution was cooled, washed successively with aqueous sodium bicarbonate and brine, and dried over anhydrous magnesium sulfate. Removal of the solvent yielded 160 mg (94%) of an oil which was shown by g.l.c. analysis (column A, 160 °C, 100) to consist of a mixture of the two dienes **39** and **40**, in a ratio of 7:3, respectively. These two materials could be separated by column chromatography as described above.

Preparation of the Olefinic Alcohol 41

To a stirred solution of disiamylborane (0.32 g, 2.1 mmol) in dry tetrahydrofuran (6 ml) at 0°, under an atmosphere of nitrogen, was added a solution of 204 mg (1.0 mmol) of the diene **39** in 4 ml of tetrahydrofuran. The solution was stirred at room temperature for 2.5 h and then cooled to 0 °C. There was successively added

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

2 ml of 3 *N* aqueous sodium hydroxide and 2 ml of 30% hydrogen peroxide, and the resulting mixture was stirred at room temperature for 60 min. After being diluted with water, the reaction mixture was thoroughly extracted with a 2:1 petroleum ether (b.p. 65–75 °C) – ether mixture. The combined extracts were washed with brine and dried over anhydrous magnesium sulfate. Removal of the solvents afforded an oil (340 mg) which was subjected to column chromatography on Florisil (48 g). Elution of the column with petroleum ether (b.p. 65–75 °C) containing increasing amounts of ether afforded 158 mg (71%) of the pure olefinic alcohol **41**, which was distilled under reduced pressure (0.1 Torr) at an air-bath temperature of 105–107 °C. Compound **41** exhibited $[\alpha]_D^{23}$ +45° (*c*, 0.31 in $CHCl_3$); i.r. (film) ν_{max} 3355, 3075, 1460, 1380, 1040, 1015 cm^{-1}; p.m.r. τ 4.73 (unresolved m, 1H, C-6 H, $w_{\frac{1}{2}}$ = 6.0 Hz), 6.20–6.73 (m, 2H, —C*H*$_2$OH), 7.58 (unresolved m, 1H, C-5 H, $w_{\frac{1}{2}}$ = 5.5 Hz), 8.41 (unresolved m, 3H, vinyl methyl, $w_{\frac{1}{2}}$ = 4.0 Hz), 9.08 (s, 3H, tertiary methyl), 9.09, 9.18 (d, d, 6H, isopropyl methyls, *J* = 6.0 Hz).

Anal. Calcd. for $C_{15}H_{26}O$: C, 81.02; H, 11.79. Found: C, 80.79, H, 11.85.

(+)-Sativene (3)

To a solution of the olefinic alcohol **41** (45 mg) in 1 ml of dry pyridine was added 90 mg of *p*-toluenesulfonyl chloride. The solution was stirred at room temperature for 2.5 h and then diluted with petroleum ether. The resulting solution was extracted with aqueous sodium bicarbonate and brine, and dried over anhydrous magnesium sulfate. Removal of the solvent afforded 56 mg of the crude olefinic tosylate **42**. The latter was transferred to the top of a small column of silica gel (4 g) and the column was eluted with petroleum ether. Evaporation of the eluant gave an oil which, upon distillation (air-bath temperature 50–52 °C; 0.08 Torr) afforded 34 mg (82%) of a clear colorless oil. Analysis of the latter by g.l.c. (column M, 120 °C, 90) indicated that it consisted of a mixture of three components in a ratio of approximately 3:75:22. Coinjection with an authentic sample indicated that the minor component was (+)-cyclosativene (**4**). The major component was collected by preparative g.l.c. and was identified as (+)-sativene (**3**): $[\alpha]_D^{24}$ +185°; i.r. (film) ν_{max} 3110, 1660, 1470, 1450, 1380, 1365, 870 cm^{-1}; p.m.r. τ 5.27, 5.60 (s, s, 2H, =CH_2), 7.41 (unresolved m, 1H, $w_{\frac{1}{2}}$ = 6 Hz), 8.98 (s, 3H, tertiary methyl), 9.11, 9.15 (d, d, 6H, isopropyl methyls, *J* = 6.0 Hz).

Anal. Calcd. for $C_{15}H_{24}$: C, 88.16; H, 11.84. Found: C, 88.31; H, 12.00.

The third component was isolated by preparative g.l.c. and was identified as isosativene (**26**): i.r. (film) ν_{max} 3090, 1650, 1455, 1377, 1359, 860 cm^{-1}; p.m.r. τ 5.25, 5.53 (s, s, 2H, =CH_2), 7.39 (unresolved m, 1H, $w_{\frac{1}{2}}$ = 9.0 Hz), 9.08 (s, 3H, tertiary methyl), 9.17 (d, 6H, isopropyl methyls, *J* = 6.0 Hz).

Preparation of the Olefinic Aldehyde 43

To a solution of 474 mg (6.0 mmol) of dry pyridine in 8 ml of dichloromethane was added 300 mg (3.0 mmol) of dry chromium trioxide. The mixture was stirred under an atmosphere of nitrogen at room temperature for 15 min and then a solution of the olefinic alcohol **41** (111 mg, 0.5 mmol) in 0.4 ml of dichloromethane was added. The reaction mixture was stirred at room temperature for 15 min and then diluted with ether. The organic solution was washed with saturated aqueous potassium carbonate and brine, and then dried over anhydrous magnesium sulfate. Removal of the solvent, followed by distillation (air-bath temperature 85–88 °C; 0.1 Torr) of the residual material under reduced pressure, afforded 84 mg (76%) of a clear oil. The latter was shown by g.l.c. analysis (column F, 130 °C, 100) to consist of the olefinic aldehyde **43** and an unidentified component in a ratio of 92:8. An analytical sample of compound **43**, collected by preparative g.l.c., exhibited $[\alpha]_D^{24}$ +71 (*c*, 0.64 in $CHCl_3$); i.r. (film) ν_{max} 3060, 2740, 1726, 1455, 1440, 1380, 1365 cm^{-1}; p.m.r. τ 0.23 (t, 1H, —C*H*O, *J* = 2.0 Hz), 4.70 (unresolved m, 1H, C-6 H, $w_{\frac{1}{2}}$ = 12 Hz), 7.53–7.67 (m, 2H, —C*H*$_2$CHO), 8.06 (d, 1H, C-5 H, *J* = 6.5 Hz), 8.42 (unresolved m, 3H, vinyl methyl, $w_{\frac{1}{2}}$ = 3.0 Hz), 9.09 (s, 3H, tertiary methyl), 9.12, 9.17 (d, d, 6H, isopropyl methyls, *J* = 6.0 Hz).

Mol. Wt. Calcd. for $C_{15}H_{24}O$: 220.183. Found (high resolution mass spectrometry): 220.184.

Preparation of the Pyrazoline 46

A solution of the olefinic aldehyde **43** (80 mg, 0.36 mmol) and *p*-toluenesulfonylhydrazide (67 mg, 0.36 mmol) in 6 ml of dry benzene was refluxed under a Dean–Stark water separator for 15 min. The solution was cooled and the solvent was evaporated under reduced pressure. The residual crude *p*-toluenesulfonylhydrazone **44** was dissolved in 4 ml of dry tetrahydrofuran and the resulting solution was treated with a solution of *n*-butyllithium (1 equiv.) in hexane. The solution was stirred at room temperature under nitrogen for 90 min and then the solvents were removed under reduced pressure. The residual lithium salt **45** was heated slowly under reduced pressure (0.1 Torr), with direct distillation of the product. Between 105 and 130 °C, 88 mg of a colorless oil was collected. The latter was redistilled (air-bath temperature 110–115 °C; 0.1 Torr) to afford 64 mg (72%) of the pure pyrazoline **46**, which exhibited u.v. λ_{max} 334 nm (ε 235); i.r. (film) ν_{max} 1550, 1460, 1370 cm^{-1}; p.m.r. τ 4.98 (m, 1H, proton adjacent to the —N=N— group), 8.33, 9.20 (s, s, 6H, tertiary methyls), 9.16 (d, 6H, isopropyl methyls, *J* = 6.0 Hz).

The instability of this compound precluded the acquisition of satisfactory analytical data.

(+)-Cyclosativene (4)

A solution of the pyrazoline **46** (50 mg) in 50 ml of dry ether was irradiated in a Rayonet Reactor (3500 Å lamps, Pyrex filter) for 90 min. Removal of the solvent, followed by distillation (air-bath temperature 70–75 °C; 0.1 Torr) of the residual oil gave 36 mg of a clear oil. Gas–liquid chromatographic analysis of the latter (column M, 120 °C, 100) showed that it consisted of a mixture of two components, in a ratio of approximately 11:1. The two compounds were collected by preparative g.l.c. The minor product was identified (i.r.) as the bicyclic diene **39**. The major product (30 mg, 68%) was identified as (+)-cyclosativene (**4**): $[\alpha]_D^{24}$ +84° (*c*, 0.36 in $CHCl_3$); i.r. (film) ν_{max} 3075, 1450, 1380, 1362, 845, 826 cm^{-1}; p.m.r. τ 9.03, 9.26 (s, s, 6H, tertiary methyls), 9.11, 9.14 (d, d, 6H, isopropyl methyls, *J* = 6.0 Hz).

Mol. Wt. Calcd. for $C_{15}H_{24}$: 204.188. Found (high resolution mass spectrometry): 204.189.

Oxidation of Hydrocarbons. VII. Kinetics of the Oxidation of Naphthalenes by Ruthenium Tetroxide[1]

UDO A. SPITZER AND DONALD G. LEE
Department of Chemistry, The University of Regina, Regina, Saskatchewan S4S 0A2

Received May 12, 1975

UDO A. SPITZER and DONALD G. LEE. Can. J. Chem. 53, 2865 (1975).

The kinetics of the oxidation of naphthalene by ruthenium tetroxide have been investigated. When the reaction was monitored using an absorption band at 385 nm it was possible to detect two processes; the first, a rapid second-order reaction which yielded a ruthenium(VI) moiety, was followed by a much slower first-order decomposition of this intermediate. The initial reaction exhibited an inverse isotope effect when naphthalene-d_8 was used as a substrate and was accelerated by the introduction of electron donating substituents. The decomposition of the intermediate was not sensitive to the presence of substituents, but involved carbon–hydrogen bond cleavage as indicated by the occurrence of a primary deuterium isotope effect.

UDO A. SPITZER et DONALD G. LEE. Can. J. Chem. 53, 2865 (1975).

On a étudié la cinétique de l'oxydation du naphtalène par le tétroxyde de ruthénium. Quand on suit l'évolution de la réaction en examinant la bande d'absorbtion à 385 nm, on peut détecter deux processus; le premier, une réaction rapide du deuxième ordre, conduit à une portion contenant du ruthénium (VI) et le deuxième, beaucoup plus lent et du premier ordre, correspond à la décomposition de l'intermédiaire. La première réaction montre un effet isotopique inverse lorsque du naphtalène-d_8 est utilisé comme substrat et est accélérée par l'introduction de substituants électro-donneurs. La décomposition de l'intermédiaire n'est pas sensible à la présence de substituants mais elle implique un bris du lien carbone–hydrogène tel qu'on peut le mettre en évidence par la présence d'un effet isotopique primaire du deutérium.

Introduction

Although a variety of oxidants are capable of converting substituted naphthalenes into the corresponding phthalic acids (1) or phthalic anhydrides (2), the use of ruthenium tetroxide for these purposes is attractive because it does not result in the destruction of alkyl side chains and because it can be used in conjunction with other, less expensive co-oxidants (3). Previous publications (4, 5) have shown that ruthenium tetroxide can be used catalytically (along with sodium hypochlorite) for the oxidation of substituted naphthalenes. Phthalic acid is the sole product obtained from naphthalene and its derivatives bearing electron donating substituents (4, 5). However, mixtures of substituted and unsubstituted phthalic acids are obtained if the substituents are electron withdrawing (4). Hence the reaction is of practical importance because of the commercial value of the products and theoretically interesting because of the large changes in oxidation number which occur in both the oxidant and the reductant.

In this paper we wish to describe the kinetics which are observed when a limited amount of ruthenium tetroxide is allowed to react with naphthalene and naphthalene derivatives in carbon tetrachloride solutions.

Experimental

All kinetic determinations were made by following changes in absorbance at 385 nm. A Perkin-Elmer 356 double wavelength spectrophotometer equipped with a thermostated cell compartment and a rapid mixing device was used. With this instrument spectrophotometric measurements can be made despite the presence of precipitates because the sample may be placed close to a large collimating lens which directs scattered energy to the photomultiplier. Consequently, the precipitation of ruthenium dioxide from these solutions did not interfere seriously with the kinetic determinations.

Spectral grade carbon tetrachloride reacts slowly with ruthenium tetroxide; however, it can be purified by repeated treatment with ruthenium tetroxide until no ruthenium dioxide is observed to precipitate, followed by distillation.

As indicated in Fig. 1 the reactions were all characterized by a rapid initial increase in absorbance, followed by a much slower decrease. Attempts to fit these curves

[1]For parts V and VI see refs. 4 and 23, respectively.

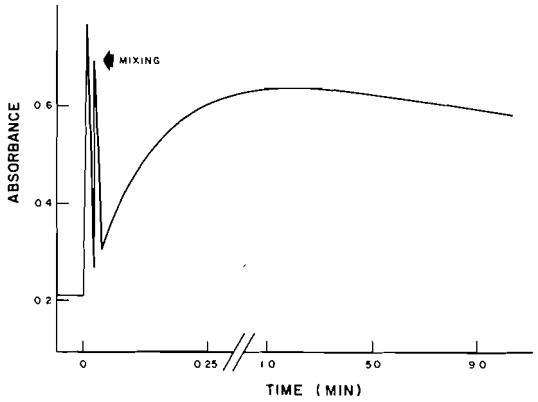

FIG. 1. Time *vs.* absorbance for a typical kinetic determination.

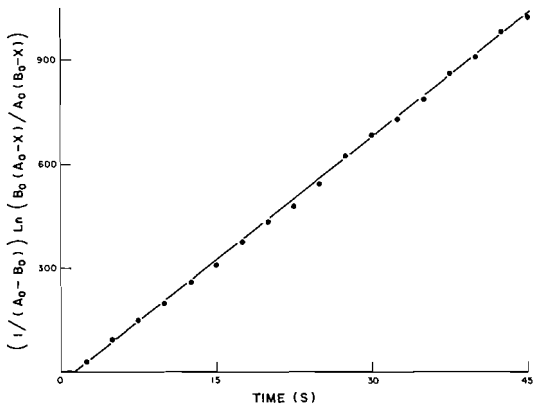

FIG. 2. Typical second-order plot: A_0 = [Naphthalene]$_0$ = 2.15×10^{-3} M; B_0 = [Ruthenium tetroxide]$_0$ = 1.8×10^{-4} M; X = [Intermediate]; temperature = 25.0 °C; correlation coefficient = 0.999.

quantitatively to integral rate laws indicated that the initial reaction was first order in both oxidant and reductant. As indicated by the following equations, the resulting second-order rate law can be expressed in terms of the extinction coefficient of ruthenium tetroxide (ε_R), the extinction coefficient of the intermediate (ε_I), the initial absorbance (A_0) and the absorbance at time t, (A_t).

$$[1] \qquad A_t = [RuO_4]_t\varepsilon_R + [I]_t\varepsilon_I$$

$$[2] \qquad A_t = [RuO_4]_0\varepsilon_R - [I]_t\varepsilon_R + [I]_t\varepsilon_I$$

$$[3] \qquad [I]_t = \frac{A_t - [RuO_4]_0\varepsilon_R}{\varepsilon_I - \varepsilon_R} = \frac{A_t - A_0}{\varepsilon_I - \varepsilon_R}$$

$$[4] \qquad \frac{-d[RuO_4]}{dt} = k_2[RuO_4][C_{10}H_8]$$

$$[5] \qquad \frac{1}{[RuO_4]_0 - [C_{10}H_8]_0} \times \ln \frac{[C_{10}H_8]_0([RuO_4]_0 - [I]_t)}{[RuO_4]_0([C_{10}H_8]_0 - [I]_t)} = k_2t$$

Plots of the left hand side of [5] against time consistently gave good straight lines. A typical example has been reproduced in Fig. 2.

The spectrum of ruthenium tetroxide was similar to that previously reported (6) and the spectrum of the intermediate could be easily obtained because the second reaction is comparatively slow (Fig. 1). The absorbance of the intermediate at 385 nm was observed to obey Beer's law if it was assumed that 1 mol of intermediate formed from each mole of oxidant present: apparently the intermediate is generated irreversibly from ruthenium tetroxide and naphthalene and its concentration is limited by the oxidant which was always present in lower molar amounts.

Decomposition of the intermediate was found to be a first-order process, but because of complications owing to precipitate formation in latter stages of the decomposition, it was most convenient to obtain these rate constants from initial reaction rates.

An attempt was made to detect the presence of free radicals in these solutions by use of a Varian 100 kHz electron paramagnetic resonance spectrophotometer. Solutions were prepared and placed immediately in the instrument but no free radical signals were ever obtained.

Results and Discussion

The excellent correlation of experimental data with a second-order equation for the formation of the intermediate and with a first-order relationship for its decomposition is consistent with a reaction sequence such as that given in [6] and [7].

$$[6] \qquad RuO_4 + \text{Naphthalene} \xrightarrow{k_2} \text{Intermediate}$$

$$[7] \qquad \text{Intermediate} \xrightarrow{k_1} \text{Products}$$

The lack of a primary deuterium isotope effect (Table 1) on the initial reaction indicates that no carbon–hydrogen bonds are appreciably cleaved in the transition state and the effect of substituents suggests that the organic moiety has acquired some positive charge. It is likely that the intermediate is formed in a two- rather than a one-electron transfer step. If only one electron had been transferred the products would have been ruthenium(VII) and the naphthyl radical cation. However, no e.s.r. signals could be obtained under conditions where ruthenium(VII) and the naphthalene radical cation had previously been detected. Furthermore the characteristic color associated with the naphthyl radical cation was not observed (7) nor is the spectrum of the intermediate characteristic of perruthenate (Fig. 3).

TABLE 1. Summary of kinetic data[a]

Compound	$k_2(s^{-1}\,M^{-1})$	$k_1(s^{-1}) \times 10^4$
Naphthalene	24.1	3.2
Naphthalene-d_8	27.7	1.3
2-Chloronaphthalene	6.54	1.9
1-Chloronaphthalene	7.57	1.7
1-Fluoronaphthalene	10.1	2.1
1-Methylnaphthalene	71.5	3.2
2-Methylnaphthalene	79.8	2.5
1,4-Dimethylnaphthalene	147	1.4
2,3-Dimethylnaphthalene	139	1.5
2-Methoxynaphthalene	168[b]	2.9
1-Methoxynaphthalene	652[b]	3.2

[a]Temperature = 25.0 ± 0.1 °C; $[RuO_4] = 2.40 \times 10^{-4}$ *M*; [Naphthalene] = 2–50 × 10^{-4} *M*.
[b]For these very fast reactions the number of experimental points was rather small (4–6); in all other cases at least 15 points were obtained in each determination.

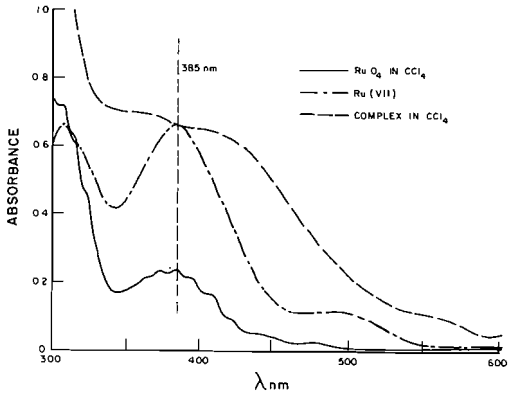

FIG. 3. Spectra of RuO_4 in CCl_4 before and after addition of naphthalene. RuO_4^- spectrum as reported in ref. 6.

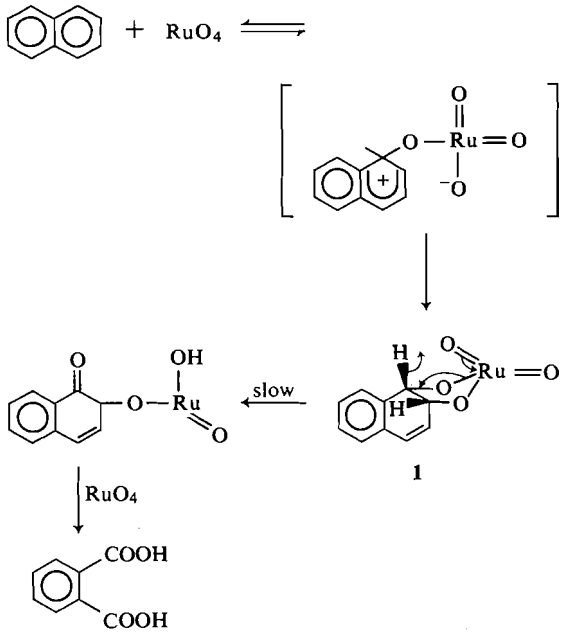
The observation of an inverse isotope effect for the initial step of the reaction indicates that one or more carbon atoms are undergoing a change in hybridization from sp^2 to sp^3 (8, 9). This in turn suggests that the reaction sequence may be initiated by an electrophilic aromatic substitution reaction as indicated in Scheme 1. (Other electrophilic aromatic substitutions are also known to exhibit inverse isotope effects (10).) The dipole structure formed would then very likely condense to give a cyclic ruthenate diester (**1**), which must subsequently decompose by a slower first-order reaction in which C—H bond cleavage occurs. One possibility (involving the internal transfer of a hydride ion) is shown in Scheme 1.

It is not possible to apply an exact linear free energy correlation to the effect of substituents because the oxidant does not attack the substituted ring exclusively when it bears electron withdrawing substituents (4). However, if it is assumed that reaction will take place most readily at the 1-position of naphthalene and at the 4-position of 1-methyl- and 1-methoxynaphthalene (11), an approximate Hammett ρ value can be calculated (12). If σ_R^0 substituent parameters (13) are used a ρ value of about −3.5 is obtained. This result is also consistent with an electrophilic aromatic substitution reaction in which a partial positive charge is developed in the transition state (14).



SCHEME 1

The electrophilic aromatic substitution reaction which would be most directly comparable with the mechanism depicted in Scheme 1 is sulfonation by sulfur trioxide in a nonaqueous medium. A neutral electrophile (SO_3) is believed to attack the aromatic ring and in so doing undergoes reduction (15). Consequently one method of testing the proposed mechanism would be to compare the activation parameters of reaction 6 with those observed during sulfonation reactions. When the effect of temperature on the rate of the reaction between ruthenium tetroxide and naphthalene was investigated the activation parameters were found to be $\Delta H^{\ddagger} = 11.3 \pm 0.4$ kcal/mol and $\Delta S^{\ddagger} = -15 \pm 5$ e.u. (or $E^* = 12$ kcal/mol and $\log A =$

For personal use only.

9.9). These values are similar to those which have been reported for the sulfonation of a variety of aromatic compounds in oleum (16) and identical, within the limits of experimental error, with those obtained for the sulfonation of *p*-dichlorobenzene in trichlorofluoromethane (17).

When considering possible mechanisms for the second step of the process it should be noted that this reaction is quite insensitive to the effects of substituents (Table 1) and that it exhibits a substantial deuterium isotope effect. The latter observation indicates that a carbon–hydrogen bond is likely broken in this step. Such a cleavage can take place coincidentally with reduction of the ruthenium(VI) moiety by either hydrogen atom or hydride ion transfer. Although it is difficult to distinguish between these two processes the observed activation parameters ($\Delta H^{\ddagger} = 15.9 \pm 0.4$ and $\Delta S^{\ddagger} = -20 \pm 5$ e.u.) are more similar to those obtained for a number of other oxidation reactions which are presumed to proceed by way of hydride transfers (18). Such reactions are usually characterized by a negative entropy of activation of about −20 e.u., whereas oxidations by cobaltic (19), manganic (20), and ceric (21) salts as well as by halogen atoms (22) which are considered to be reacting by free radical steps usually exhibit much larger (positive) entropies of activation.

If the second step is taken to be a hydride transfer the product would be a keto derivative which would be subject to second stage oxidation, eventually leading to formation of phthalic acid if sufficient oxidant is available.

The authors gratefully acknowledge the financial assistance of the National Research Council of Canada. We also thank Dr. J. A. Weil and Mr. B. D. Perlson for assistance in obtaining the e.s.r. spectra.

Synthesis of Methyl 12*S*- and 12*R*-Hydroxylabd-8(17)-en-19-oates

RUSSELL A. BELL, MICHAEL B. GRAVESTOCK, AND VINCENT Y. TAGUCHI

Department of Chemistry, McMaster University, Hamilton, Ontario L8S 4M1

Received September 5, 1974[1]

RUSSELL A. BELL, MICHAEL B. GRAVESTOCK, and VINCENT Y. TAGUCHI. Can. J. Chem. **53**, 2869 (1975).

A formal total synthesis using podocarpic acid as the relay of methyl 12*S*- and 12*R*-hydroxylabd-8(17)-en-19-oates, **7** and **8** respectively, has been achieved. Carbons 13 → 16 of the labdane side chain were formed by the nucleophilic addition of *s*-butyllithium to the bicyclic acid **5***a* or the aldehyde **4**, and the configuration of the alcohols assigned from a consideration of product distributions and physical and spectroscopic properties. The spectroscopic properties of the synthetic alcohols were in agreement with those reported for two alcohols isolated from *Juniperus phoenicea* L. and assigned structures **7** and **8**.

RUSSELL A. BELL, MICHAEL B. GRAVESTOCK et VINCENT Y. TAGUCHI. Can. J. Chem. **53**, 2869 (1975).

On a réussi une synthese totale formelle des hydroxy-12*R* (et 12*S*) labdène-8(17) oates-19 de méthyle **7** (et **8**) en utilisant l'acide podocarpique comme relais. On a introduit les carbones 13 → 16 de la chaîne latérale du labdane par addition nucléophile du *s*-butyllithium sur l'acide bicyclique **5***a* ou sur l'aldéhyde correspondant **4**; on a attribué la configuration des alcools en se basant sur la distribution des produits et aussi sur leurs propriétés physiques et spectroscopiques. Les propriétés spectroscopiques des alcools de synthèse sont en accord avec celles rapportées pour deux alcools isolés du *Juniperus phoenicea* L. et auxquels les structures **7** et **8** avaient été attribuées. [Traduit par le journal]

The reported isolation in 1968 of two isomeric 12-hydroxylabd-8(17)-en-19-oic acids by Tabacik-Wlotzka and Laporthe (1) from *Juniperus phoenicea* L. led us to undertake a partial synthesis of these two compounds from podocarpic acid **1***a*. The interest in these two diterpenes lies in the positioning of the hydroxyl group at carbon 12 which is an unusual site of oxidation for simple labdane diterpenoids.[2] The synthesis of such 12-hydroxylabdenes appeared attractive because of the ready availability of the bicyclic acid **5***a* and the aldehyde **4**, both of which possessed electrophilic centers at C-12.

Podocarpic acid as its methyl ester **1***b* had previously been transformed (3) by ozonolysis into the hydroperoxide **2** and this material on catalytic reduction to the keto acid **3**. A standard Reformatsky reaction and decarboxylation sequence converted **3** into the olefin acid **5***a* in overall yields of 43% (4). The aldehyde **4** was available from the diester **5***b* by a simple oxidation reduction sequence (4). The remaining step to

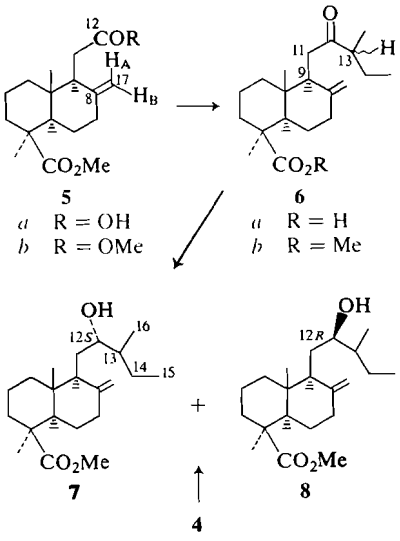
generate the labdene skeleton was then the straightforward addition of a *s*-butyl group and this was carried out in two ways using *s*-butyllithium as the nucleophile.

Firstly, the *s*-butyl group was introduced by the action of *s*-butyllithium (*s*-BuLi) on the free acid **5***a* at room temperature to give the keto acid **6***a*, but the purification of this acid proved difficult and conversion to the ester with diazomethane gave, after chromatography, a 50% yield of the keto ester **6***b*. It is interesting to note here that *s*-BuLi has behaved in a manner analogous to other strong bases in aprotic solvents (5) in completely demethylating the hindered C-19 methyl ester of **5***a*. The purified keto ester **6***b* obtained was expected to be a mixture of two diastereomers that are epimeric at C-13, since the nucleophilic reagent was racemic *s*-BuLi, but in our hands the diastereomers proved inseparable and **6***b* always behaved as a single species. The $NaBH_4$ reduction of **6***b* gave rise to two easily separable 12-alcohols, **7** and **8**, in a ratio of 70:30. The same two alcohols were obtained more directly in a second experiment in 60% yield in a ratio of 75:25 by the selective addition of *s*-BuLi to the aldehyde **4** at −70 °C (see Scheme 1).



SCHEME 1

This latter low temperature addition showed no hydrolysis of the C-19 methyl noted in the room temperature reactions and more importantly it showed clearly that although two C-12 alcohols could be readily separated, each alcohol remained a mixture of two diastereomers which were epimeric at C-13 since again racemic *s*-BuLi was the reagent. In a number of thin-layer chromatographic (t.l.c.) experiments no physical differences could be observed between these 13-epimers, a fact which suggests that the configuration at C-13 has a very small influence on the properties of either of the alcohols **7** or **8**, or the ketone **6***b*.

Before commenting in more detail on the assignment of the configuration at C-12 in **7** and **8**, it should be noted that neither of the synthetic alcohols possessed spectroscopic properties exactly identical with the *erythro* and *threo* stereoisomers isolated by Tabacik-Wlotzka and Laporthe[3] and proposed to have structures **7** and **8**. The differences particularly in the proton magnetic resonance (p.m.r.) spectra of the naturally occurring and synthetic alcohols initially led us to suppose that the proposed structures for the natural alcohols were incorrect, despite the fact that we had been unable to separate the 13*S* and 13*R* stereoisomers of **7** and **8**. While the natural alcohols are most likely to possess a single configuration at C-13, our experience noted above suggests that any p.m.r. or i.r. spectroscopic differences should not be apparent if the synthetic alcohols differ from the natural compounds merely in their configurations at C-13. However, the natural alcohols were reported to be isolated in a ratio of 65:35, virtually identical with that obtained in our reduction experiments on the synthetic ketone **6**. We now consider that the isolated alcohols do in fact have structures **7** and **8** and that the spectroscopic differences arose from the presence of impurities (benzene) in the synthetic samples used for p.m.r. spectra. The most disturbing feature was the occurrence of a doublet at 4.14 p.p.m. in the p.m.r. spectrum of natural **8** which was not present in synthetic **8**. The absorption was assigned (1) to H-12, but in our view, the lines are better assigned to the proton of the OH group which would then allow the movement of its lines underneath the methylene envelope in the synthetic **8** by exchange with any traces of acids or bases present in the sample. The H-12 in the

[3]We thank Mme Tabacik-Wlotzka for copies of the i.r. and p.m.r. spectra in addition to the reported physical data. Samples of either alcohol were unfortunately not available.

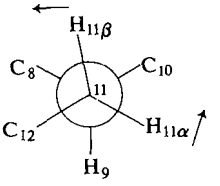


FIG. 1. Conformational torsion about the 9,11-bond of labd-8(17)-enes.

natural material should then be assigned to a broad absorption between 3.27 and 3.77 p.p.m. which is partly masked by the ester methyl group at 3.6 p.p.m.[4]

To place the position of the hydroxyl group in synthetic **7** and **8** on even firmer ground, the high resolution mass spectra of both alcohols were recorded. The expected fragmentation α to the hydroxyl occurred and strong ions were observed at *m/e* 279 showing the loss of carbons 13 → 16 and at *m/e* 87 showing the OH group was contained in the fragment of carbons 12 → 16.

The assignment of the configuration of C-12 in **7** and **8** was based largely on standard conformational analysis coupled with close scrutiny of Dreiding molecular models. X-Ray structural studies on 8α-hydroxylabdanes (6) indicated that there was torsion about the 9,11-bond which moved H-11β away from the 20-methyl and H-11α away from H-1β. While such torsion need not be so pronounced in the present molecules with their 8(17)-double bonds, the presence of some twisting about the 9,11-bond as shown in Fig. 1 does relieve the serious H-11α, H-1β interaction and places C-12 at more acceptable distances from C-17. Taking a rotation of 15–30° about the 9,11-bond as reasonable, the conformers about the 11,12-bond of ketone **6** can be represented as in Fig. 2. Even if it is assumed that the carbonyl group can move away somewhat from an eclipsing orientation when steric forces demand it, it is clear from molecular models that conformer **c** is prohibited because of the *s*-butyl group being thrust into the vinylic hydrogen H-17A. The two remaining conformers **a** and **b** have their topsides or β faces completely shielded by H-17A and thus undergo attack by

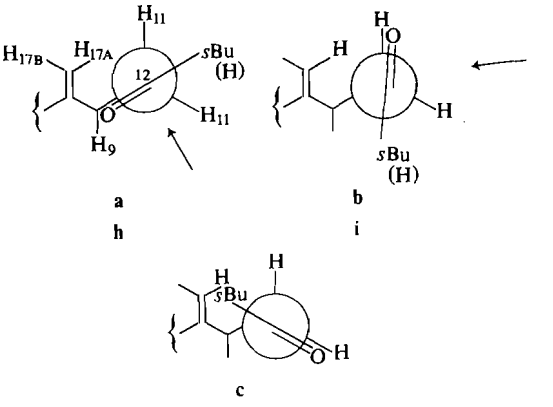

FIG. 2. Conformers of ketone **6** about 11,12-bond, **a**, **b**, and **c**; and conformers about 11,12-bond of aldehyde **4**, **h** and **i**, where *s*-Bu is replaced by H.

hydride from the α face as illustrated in Fig. 2. Both transition states from **a** and **b** result in the development of O,H-17A interactions, but in conformer **b** the O atom of the carbonyl is always closer to H-17A by some 0.3–0.4 Å than is the O atom in conformer **a** no matter how much rotation occurs about the 9,11-bond. Thus the transition state resulting from conformer **b** will be of higher energy than the transition state from conformer **a** and, therefore, the major product will be that derived from hydride ion attack on the α face of conformer **a**; that is, the major product has the 12*S* configuration and is assigned structure **7**.[5] Further support for **7** possessing the 12*S* configuration was found in the chromatographic and spectroscopic properties of this isomer. Thus it was more polar than the 12*R* isomer **8** and was eluted last on column chromatography; it showed the vinylic proton H-17A at low field, 4.72 p.p.m., in its p.m.r. spectrum, whereas the 12*R* isomer showed H-17A at 4.40 p.p.m., the same shift as observed for H-17A in aldehyde **4**; and it showed the presence of strong intermolecular hydrogen bonding in its i.r. spectrum, while the 12*R* isomer showed very weak intermolecular hydrogen bonding at normal concentrations. These differences in properties are

[4]That the 12-hydrogens in both the 12*S* and 12*R* isomers should have similar chemical shifts was further supported by the shifts of the two 12-alcohols **9** and **10** prepared during a synthesis of lambertianic acid (4), where H-12 of **9** and **10** absorbed at 4.48–4.85 p.p.m.

[5]Crams rule (7) as applied to conformer **a** does in fact predict the 12*S* stereoisomer as the major product but in the present case the rule is a simplification of the reasons for the observed product distribution. Hydrogen-17A so effectively shields the β face of the carbonyl group in **a** that the rule would predict the formation of no 12*R* stereoisomer at all.

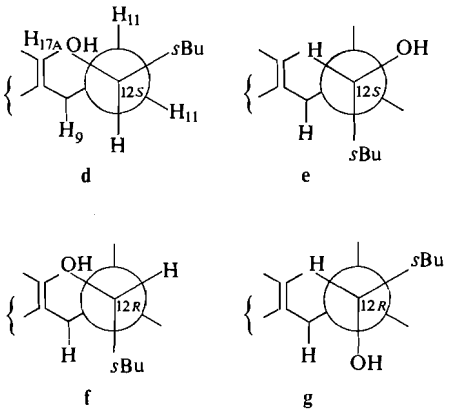

FIG. 3. Stable conformers of 12*S*-alcohol **7**, **d** and **e**; and stable conformers of 12*R*-alcohol **8**, **e** and **f**.

readily rationalized upon inspection of the conformers about the 11,12-bond for **7** and **8** (see Fig. 3). For simplicity the conformers where the *s*-butyl group is juxtaposed to H-17A are omitted since the liklihood of these conformers being significantly populated is negligible. The two 12*S* conformers **d** and **e** are probably fairly evenly populated as the O,H-17A interaction in **d** is roughly counterbalanced by the H-9,*s*-Bu *gauche* interaction in **e** but the populations of the 12*R* isomer should show a strong preference for conformer **g** since there are OH,H-17A and H-9,*s*-Bu interactions present in **f** and only a *gauche* H-9,OH interaction present in **g**. Conformer **d** of the 12*S* isomer is well populated and therefore the OH can be expected to deshield H-17A as is observed, whereas conformer **e** leaves the OH group relatively exposed on the outskirts of the molecule and thus readily able to bind to chromatographic absorbents and to undergo intermolecular hydrogen bonding. The main populated conformer **g** of the 12*R* isomer on the other hand has the OH removed from H-17A and therefore having no deshielding effect on it. In addition this OH is effectively buried within the molecule, firstly by H-9 and secondly by the *s*-butyl group. Thus the 12*R* isomer **8** should show less polar behavior on chromatographic adsorbents and less intermolecular hydrogen bonding in its i.r. spectrum than **7**.

The product-distribution argument used above to assign the configurations of **7** and **8** received further support from the addition of *s*-butyllithium to the aldehyde **4** where a similar product ratio of **7**:**8** was obtained. This experiment confirmed the view that it is the O,H-17A interaction in the transition states derived from conformers **h** and **i** (see Fig. 2) that determine the product distribution rather than any interactions of the *s*-butyl group, for it would be unlikely that the aldehyde hydrogen of **4** and the *s*-butyl group of **6** would experience transition state interactions so identical that they would lead to the same product distribution. Furthermore, the same product ratio of 12*S*:12*R* alcohols was observed when 3-furyllithium was employed as the nucleophile (4) which again suggests that the nucleophile is unimportant and the O,H-17A interaction is the controlling influence over the products. It is pertinent to note here that the two stereoisomers **9** and **10** obtained from **4** and 3-furyllithium (4) exhibited the same chromatographic and spectroscopic behavior as the isomers **7** and **8**, and their assignments were based on the arguments presented here.

In summary, methyl 12*S*-hydroxylabd-8(17)-en-19-oate (**7**) and methyl 12*R*-hydroxylabd-8(17)-en-19-oate (**8**) have been synthesized from the acid **5***a* by *s*-butyllithium addition to the acid **5***a* and reduction of the resulting ketone with $NaBH_4$. The addition of *s*-butyllithium to the aldehyde **4** furnished the alcohols **7** and **8** in the same ratio as the $NaBH_4$ reduction and this fact is used in a stereochemical argument to assign the configurations of **7** as 12*S* and **8** as 12*R*. The observed spectroscopic properties of **7** and **8** are closely similar to those recorded for two alcohols isolated from *Juniperus phoenicea* L. and it is concluded that the natural products possess the proposed structures **7** and **8**.

Experimental

Spectra were recorded in the following solvents and instruments: i.r. ($CHCl_3$) Perkin-Elmer 337; p.m.r. ($CDCl_3$) Varian Associates T-60 and A-60, tetramethylsilane as internal standard; mass spectra, Hitachi Perkin-Elmer RMU-6A (at 80 eV) and C.E.C. 21-110. In the experimental descriptions to follow, the organic substrates were isolated by extraction with the appropriate solvent (2×) followed by washing of the combined solvent layer with water, saturated brine, and finally drying with anhydrous Na_2SO_4. The solvents were removed by evaporation at reduced pressure on a Buchi Rotavapor.

Methyl 12-Oxolabd-8(17)-en-19-oate (6b)

The olefin acid **5***a*, 0.114 g (0.39 mmol; m.p. 153–155 °C (4)) was dissolved in 5 ml of anhydrous ether in a flask under nitrogen sealed with a septum inlet. Two millilitres of *s*-butyllithium (2.4 mmol) in hexane were added to the stirred solution cooled to 0 °C in an ice bath and after stirring for 6 h at 0 °C, a further 1 ml of reagent was added and the stirred solution allowed to warm to room temperature overnight. The reaction mixture was quenched

with 5% NaH_2PO_4 solution, extracted with benzene, and worked up in the usual way to give 130 mg of colorless oil. The p.m.r. spectrum of the crude reaction mixture showed the presence of 60% of keto acid **6***a* and 40% of starting material accompanied by some quantity of butyl telomeric material. Separation of **6***a* from starting material proved troublesome even after extensive sodium bicarbonate extraction and the oil was esterified with diazomethane in ether and chromatographed on Florisil. Elution with 50% petroleum ether (30–60 °C) – benzene gave unwanted telomer and benzene elution yielded 65 mg (50%) of keto ester **6***b* (mixture of epimers at C-13) as a colorless oil; i.r. ν_{max} 3015, 2940, 2885, 2880, 1720, 1650, 1470, 1220, 1165, 878 cm^{-1}; u.v. λ_{max} 265 (40) nm; p.m.r. δ 0.54 (s, 3H, C-20 CH_3), 1.20 (s, 3H, C-18 CH_3), 3.60 (s, 3H, C-19 CO_2CH_3) 4.30 (s, 1H, $W_{h/2}$ = 3 Hz, H-17A), 4.73 (s, 1H, $W_{h/2}$ = 3 Hz, H-17B) p.p.m.; mass spectrum, *m/e* 334 (M^+), 319 (M − 15), 302 (M − 32), 275 and 277 (M − 59/57) ($COOCH_3$ and *s*-C_4H_9), 235 (M − 57 − 42), 176 (M − 57 − 42 − 59). Thin-layer chromatography on alumina and SiO_2 supports in various solvents always showed **6***b* as one spot.

Methyl 12S-Hydroxylabd-8(17)-en-19-oate (7) and Methyl 12R-Hydroxylabd-8(17)-en-19-oate (8)

By reduction of 6 with $NaBH_4$

A sample of 0.03 g (0.09 mmol) of the keto ester **6***b* was dissolved in 2 ml of absolute ethanol, 0.150 g $NaBH_4$ added, and the whole heated at reflux for 30 min. The reaction mixture was quenched with 5% NaH_2PO_4 solution and the organic material extracted with benzene to yield 31 mg of the alcohols as a colorless oil. The p.m.r. spectrum of the crude reaction product showed the presence of only two alcohols and triangulation of the absorptions in the vinylic region (4.2–5.0 p.p.m.) showed them to be present in a ratio of 70±5:30±5. The alcohols were separated by chromatography on Florisil and identified as given below.

By Addition of s-BuLi to Aldehyde 4

To a solution of 0.183 g (0.66 mmol) of the aldehyde **4** (4) in 15 ml of dry ether under a nitrogen atmosphere at −70 °C were added 2.2 ml (2.65 mmol, 4.0 equiv.) of a 1.2 *M* solution of *s*-butyllithium in hexane. After 5 min the reaction was quenched with 25 ml of a 5% solution of NaH_2PO_4 and the whole allowed to warm to room temperature. The products were isolated via benzene extraction in the usual way to give 191 mg of a yellow oil. The p.m.r. spectrum of the crude product showed the presence of 81% alcohols and 19% unreacted aldehyde **4**, and the products from two experiments were combined (280 mg) and chromatographed on 28 g Florisil. Elution with benzene gave initially aldehyde and then the less polar 12*R*-alcohol, **8**, contaminated with aldehyde. Final purification of the 12*R*-alcohol was achieved by gas–liquid chromatography (Varian Aerograph A90-P) when only one peak was observed for the alcohol. The 12*R*-alcohol, **8**, was obtained as a colorless oil, 34 mg (15% based on recovered aldehyde) and showed: i.r. ν_{max} 3600 (non-bonded OH), 2965, 2930, 2875, 2850, 1715 (C=O), 1640 (C=C), 1460, 1380, 1206, 1154, 1134, 1092, 1031, 986, 971, 891 cm^{-1}; p.m.r. δ 0.50 (s, 3H, C-20 CH_3), 1.17 (s, 3H, C-18 CH_3), 3.58 (s, 3H, C-19 CO_2CH_3), 3.52 (br, 1H, H-12 α to OH), 4.40 (s, 1H, $W_{h/2}$ = 4 Hz, H-17A), 4.83 p.p.m. (s, 1H, $W_{h/2}$ = 3.5 Hz, H-17B); u.v. featureless; mass spectrum, *m/e* 336 (M^+, calcd. for $C_{21}H_{36}O_3$: 336.2658; found: 336.2652), 318 (M − H_2O), 279 (M − C_4H_9, calcd. for $C_{17}H_{27}O_3$: 279.1998; found: 279.2036), 277 (M − CO_2CH_3); 261 (M − H_2O − C_4H_9), 259 (M − H_2O − CO_2CH_3), 235 (M − H_2O − C_6H_{11}; allylic 9(11)-bond cleavage), 87 (M − $C_{16}H_{25}O_2$, calcd. for $C_5H_{11}O$: 87.0831; found: 87.0853). Further elution of the chromatographic column with benzene gave the pure 12*S*-alcohol (7), 104 mg (45% based on recovered aldehyde) as a colorless oil which showed i.r. ν_{max} 3680 (non-bonded OH), 3540 (bonded OH), 2960, 2940, 2875, 2850, 1715 (C=O), 1635 (C=C), 1465, 1380, 1206, 1154, 1135, 1093, 1031, 984, 894 cm^{-1}; p.m.r. δ 0.50 (s, 3H, C-20 CH_3), 1.17 (s, 3H, C-18 CH_3), 3.58 (s, 3H, C-19 CO_2CH_3), 3.52 (br, 1H, H-12 α to OH), 4.72 (s, 1H, $W_{h/2}$ = 4 Hz, H-17A), 4.88 p.p.m. (s, 1H, $W_{h/2}$ = 3.5 Hz H-17B); mass spectrum, *m/e* 336 (M^+, calcd. for $C_{21}H_{36}O_3$: 336.2664; found: 336.2664), 318 (M − H_2O, calcd. for $C_{21}H_{34}O_2$: 318.2516; found: 318.2472), 279 (M − C_4H_9, calcd. for $C_{17}H_{27}O_3$: 279.1973; found: 279.1986), 277 (M − CO_2CH_3), 261 (M − H_2O − C_4H_9), 259 (M − H_2O − CO_2CH_3), 249 (M − $C_5H_{11}O$, calcd. for $C_{16}H_{25}O_2$: 249.1853; found 249.1851), 235 (M − H_2O − C_6H_{11}, allylic 9(11)-bond cleavage), 87 (M − $C_{16}H_{25}O_2$, calcd. for $C_5H_{11}O$: 87.0763; found: 87.0716). Thin-layer chromatography on alumina and SiO_2 supports in a variety of solvents always showed **7** and **8** to behave as single species.

12-Hydroxylabd-8(17)-en-19-oic Acid

The mixed 12 and 13 *S* and *R* stereoisomers of the acids corresponding to **7** and **8** were prepared by treating a 20 mg sample of **7** and **8** (ratio 7:3) dissolved in anhydrous ether with 2 ml of *s*-BuLi (1.2 *M* in hexane) at 0 °C for 2 h. The reaction mixture was quenched with 5% NaH_2PO_4 solution and worked up via benzene to give 18 mg of the mixed acids (C-19 CO_2H) as a colorless oil. The acids showed i.r. ν_{max} 3600–2800, 1720 (COOH), 1640 (C=C), 1460, 1230, 1160, 900 cm^{-1}; u.v., featureless; p.m.r. δ 0.565 (s, 3H, C-20 CH_3), 1.18 (s, 3H, C-18 CH_3), 3.56 (m, 1H, $W_{h/2}$ = 30 Hz, H-12's α to OH), 4.40 (s, 0.15 H, $W_{h/2}$ = 4 Hz, H-17A of 12*R*-epimer), 4.70 (s, 0.35 H, $W_{h/2}$ = 4 Hz, H-17A of 12*S*-epimer), 4.80 (s, 0.15 H, $W_{h/2}$ = 3.5 Hz, H-17B of 12*R*-epimer), 4.87 p.p.m. (s, 0.35 H, $W_{h/2}$ = 3.5 Hz, H-17B of 12*S*-epimer). The COOH/OH peak was located by D_2O exchange at 1.5–1.7 p.p.m. beneath the methylene envelope.

We wish to thank the National Research Council of Canada for financial support of this work and for a Fellowship to M.B.G. and an NRCC Bursary to V.Y.T. (1970–1971).

Acylsilane Photolyses: 1,1-Diphenyl-1-Silacyclohexanone-2 in Cyclohexane

A. G. BROOK, J. B. PIERCE, AND J. M. DUFF[1]

Department of Chemistry, University of Toronto, Toronto, Ontario M5S 1A1

Received March 11, 1975

A. G. BROOK, J. B. PIERCE, and J. M. DUFF. Can. J. Chem. **53**, 2874 (1975).

Photolysis of the cyclic acylsilane 1,1-diphenyl-1-silacyclohexanone-2 yields 1,1-diphenyl-1-silacyclopentane and two dimeric products whose structures were established by chemical and spectroscopic methods. A mechanism involving a siloxycarbene intermediate which is trapped by a second acylsilane molecule, is proposed for the formation of the dimers.

A. G. BROOK, J. B. PIERCE et J. M. DUFF. Can. J. Chem. **53**, 2874 (1975).

La photolyse de l'acylsilane cyclique, diphényl-1,1 sila-1 cyclohexanone-2, conduit au diphényl-1,1 sila-1 cyclopentane et à deux produits dimères dont les structures ont été établies par des méthodes chimiques et spectroscopiques. Pour la formation des dimères, on propose un mécanisme impliquant un intermédiaire siloxycarbène qui est piégé par une seconde molécule d'acylsilane. [Traduit par le journal]

Over the past few years we have been engaged in elaborating the photochemical behavior of acylsilanes (R_3SiCOR'). It has been shown that depending on the structure of the acylsilane and particularly on the solvent employed, two types of reaction can occur. These are (*i*) the photoisomerization of the acylsilane to a siloxycarbene which may revert back to acylsilane in a dark reaction if not trapped by a suitable reagent, and (*ii*) a radical type process which generally occurs less readily than reactions involving the siloxycarbene. Our findings are summarized in Scheme 1.

Most acylsilanes studied to date show this dual photochemical behavior. The photochemically formed siloxycarbenes insert into the polar bonds of protic solvents to give adducts (1), form cyclopropanes with suitably reactive alkenes (2), or form oxiranes (or their hydrolysis products) on reaction with certain carbonyl compounds (3). When photolyzed in halogenated solvents, acylsilanes yield radical type products (which may arise through exciplex formation (4)), including R_3SiCl and R'COCl (5). More recently it was found that when acyclic acylsilanes such as acetyl- or phenylacetyltriphenylsilane were photolyzed in cyclohexane, a solvent unreactive towards silyl radicals or siloxycarbenes, a variety of products was obtained whose mode of formation was best explained as arising from the initial addition of silyl radicals to the carbonyl oxygen of a second molecule of acylsilane followed by normal radical behavior (6).

We now wish to report a new photochemical behavior of acylsilanes, namely photodimerization, which was observed when the cyclic acylsilane 1,1-diphenyl-1-silacyclohexanone-2 was photolyzed in cyclohexane. This investigation was actually one of the earliest studies in our laboratory of the photochemical behavior of acylsilanes (7), but because the structures of the two main products could not be assigned unambiguously from the available chemical and physical data, we deferred publication until the structures of the photodimers were confirmed recently by X-ray structure analysis by Nyburg *et al.* (8) of our department.

Irradiation of diphenylsilacyclohexanone **1** in

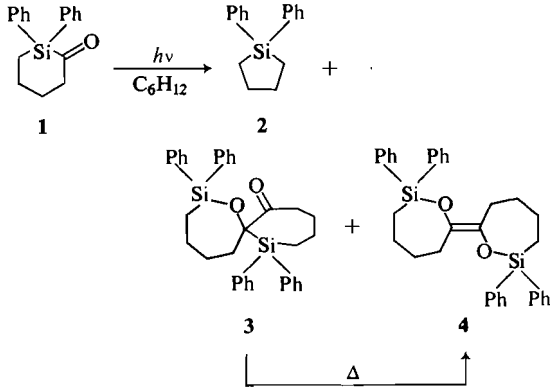
dry, oxygen-free, cyclohexane with a mercury spot lamp ($\lambda_{max} \simeq 360$ nm) gave three main products, 1,1-diphenyl-1-silacyclopentane, **2** (18–22%), and two dimers, **3** (20–53%) and **4** (9–12%), whose structures are given below.



The photolysis appeared to be quite clean and the low yield of isolated products in some cases was due more to the difficulty in isolating pure compounds than to the presence of significant amounts of unidentified products.

It was noted that **3** was thermally labile, the β-ketosilane functionality being quantitatively converted into the siloxyalkene functionality in **4** in less than 20 h at reflux in cyclohexane.[2] In accord with this observation, if the photolysis was carried out with cooling, higher yields of **3** (55%) were obtained, compared to the 20% isolated from photolysis at ambient temperature (35–40 °C). However, even at low temperatures, significant amounts of **4** were obtained and hence **4** is believed to arise, at least in part, directly as a result of the photolysis.

The diphenylsilacyclopentane may result from a Norrish type I cleavage to a diradical, followed by loss of carbon monoxide and ring closure. However, since none of the other types of products usually obtained from the photolysis of cycloalkanones were obtained (aldehydes, alkenes) and since none of the usual products resulting from silyl radicals were obtained (6), it is possible that the diphenylsilacyclopentane arose from a concerted extrusion of carbon monoxide.

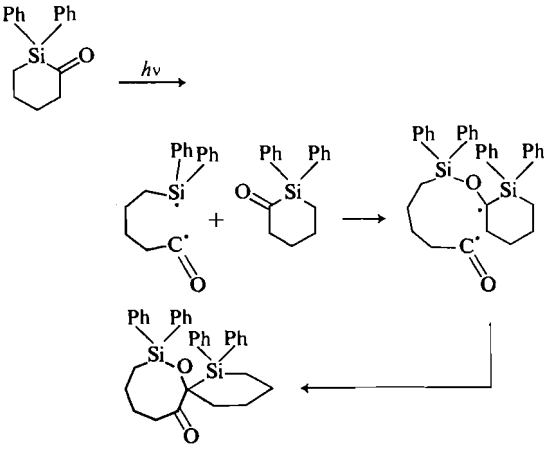
It seems unlikely that **3** (and **4**) arise from a radical process, since, by analogy with previous studies (6), the silyl radical resulting from cleavage of the acylsilane (Scheme 2) would be expected to attack the carbonyl oxygen of a second acylsilane molecule and the resulting diradical would then presumably close to the 8,6-spiro compound **3***b*, shown in Scheme 2; in fact the 7,7-spiro compound **3** (Scheme 1) is the observed product.

The formation of the dimeric products can be explained logically as arising from attack of a cyclic siloxycarbene, which is nucleophilic in character, on the carbonyl group of a second molecule of the silacyclohexanone, analogous to the observed addition reactions of siloxycarbenes with other carbonyl compounds such as acetaldehyde, acetone, and cyclohexanone (3). The resulting intermediate, **5**, could then react by any of the three routes shown in Scheme 3.

Unlike the reaction with acetaldehyde (3), there was no evidence obtained for the closure of the intermediate **5** to give the oxirane **6**. However a 1,2-migration of silicon to the electron deficient center in **5**, accompanied by reformation of the carbonyl group accounts for the formation of **3** (route *b*). Alternatively, the attack of the oxyanion center on the neighboring silicon atom, with displacement of electrons toward the electron deficient center, forming a carbon–carbon double bond, accounts for the formation of **4** directly from the intermediate (route *c*).

This behavior attributed to **5**, reacting by routes *b* and *c*, follows closely the behavior of the intermediate formed between acylsilanes and diazomethane, where β-ketosilanes and siloxyalkenes are likewise formed competitively (10, 11).

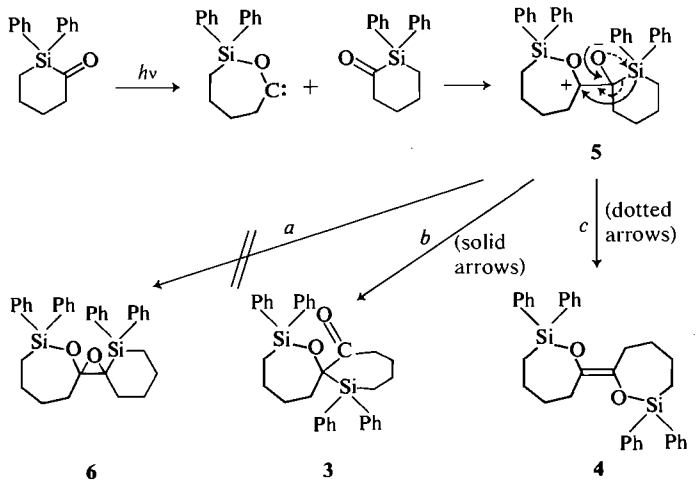
Other routes to **3** and **4** can be envisioned but



3*b*

SCHEME 2

[2]This was the first observed case of a β-ketosilane to siloxyalkene thermal rearrangement (9, 10).



SCHEME 3

appear less likely. Thus **3** could arise by direct insertion of the siloxycarbene into the silicon–acyl bond of the second acylsilane molecule but this is unprecedented. Compound **4** could arise by direct coupling of two siloxycarbenes but the probable concentration of siloxycarbene in the system makes the formation of **4** in significant amounts by this route unlikely.

Therefore it appears that the photodimers formed in the photolysis of diphenylsilacyclohexanone in cyclohexane arise from siloxycarbenes, in contrast to the behavior of acyclic acylsilanes whose photolysis in cyclohexane led to radical-derived products (6). A similar tendency for cyclic acylsilanes to react via siloxycarbenes under conditions where acyclic acylsilanes are either unreactive or react by radical pathways has been observed previously (in reactions with C=C and C=O) but it is not yet clear whether this difference arises because the cyclic siloxycarbenes are more reactive, are more readily formed, or are longer-lived than their acyclic counterparts.

The structures of products **3** and **4** were originally assigned partly on the preceding mechanistic arguments and also on the basis of chemical and spectroscopic data. Thus **3** was believed to be a β-ketosilane by virtue of the relatively long wavelength carbonyl absorption at 5.90 μm (11). No other functional groups appeared to be present. Hydrolysis of **3** gave a compound formulated as **7** (Scheme 4), containing silanol and α-hydroxyketone groups. Isolation of such a product fails to distinguish between **3** and **3***b*, whose possible modes of formation were described earlier in Schemes 2 and 3. The identity of **7** was confirmed by its reduction to the diol and cleavage with lead tetraacetate to give the known 5-(diphenylhydroxysilyl)pentanal, **8**, and the related acid, **9** (12).

Compound **4** (or its possible alternative **4***b*) derived either directly from the photolysis or indirectly by the thermolysis of **3** (or **3***b*) showed no OH, C=O, or C=C i.r. absorption although its Raman spectrum showed a band at 5.93 μm (symmetrical ). Mild acid hydrolysis of this dimer similarly gave **7** but this fact again failed to distinguish unambiguously between the possible structures **4** and **4***b*.

In an attempt to distinguish **4** from **4***b* the compound was treated with ozone, followed by careful anhydrous work-up using triphenylphosphine to destroy the ozonide. The product isolated, contaminated with some triphenylphosphine oxide, was the silalactone **10**, expected from **4**. However, the possibility that the macrocyclic bis-lactone derivable from **4***b* might have broken down to give **10** during work-up could not be ruled out.

Numerous other attempted structure-proving reactions, including reduction, and reaction with methylmagnesium iodide, failed to distinguish between the possible pairs of isomers and hence it was necessary to confirm the proposed structures for **3** and **4** by X-ray diffraction techniques.

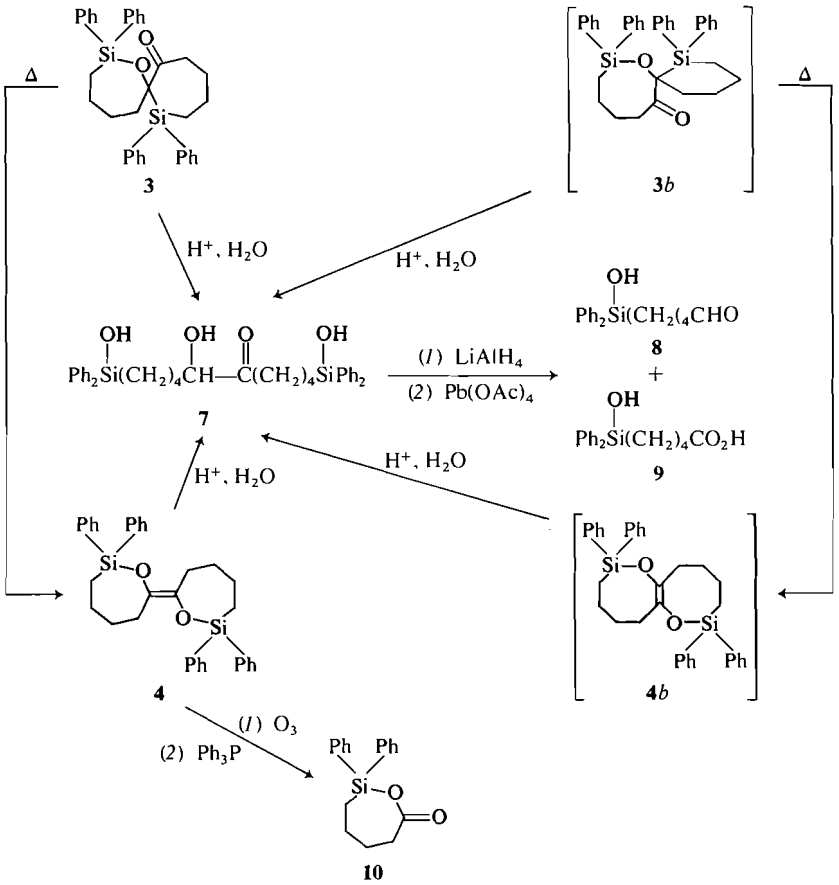
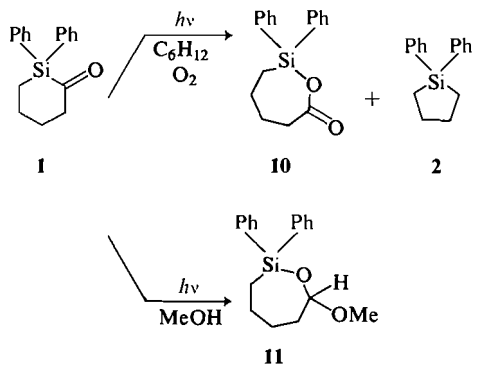


SCHEME 4

The silalactone **10** was also formed in significant yield along with silacyclopentane **2** when the cyclic acylsilane **1** was photolyzed in cyclohexane saturated with oxygen. When **1** was photolyzed in methanol, the cyclic acetal **11**, expected from trapping of the siloxycarbene (1), was obtained.



One major question remaining is the apparent ease (80 °C, <20 h) with which the β-ketosilane **3** rearranges to siloxyalkene **4**. Other than this case, the most facile β-ketosilane–siloxyalkene rearrangement known is that of triphenylsilylacetophenone, which required about 18 h at 100 °C for complete rearrangement; only 10% rearrangement occurred in 18 h at 80 °C (13). It is known that incorporation of a β-ketosilane functionality into a seven-membered ring considerably reduces the ease of thermal rearrangement compared to acyclic systems. For example, 1,1-dimethyl-1-silacycloheptanone-3 rearranged about 5 times more slowly than trimethylsilylacetone and 170 times more slowly than triphenylsilylacetophenone (13). This appears to be reasonable since models suggest that approach of the carbonyl oxygen to the β-silicon atom is more difficult in the cyclic system. The difficulty of such an approach in the spiro compound **3** appears to be even more pronounced. Therefore,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

the observed ease of rearrangement of **3** suggests that the α-siloxy functionality is playing an important role, not yet understood, in facilitating the β-ketosilane to siloxyalkene rearrangement; the fact that the siloxy-silicon atom of **3** is somewhat closer (3.02 Å) to the carbonyl oxygen than is the β-silicon atom with which bonding ultimately occurs (3.77 Å) is probably of some relevance.

Experimental

The synthesis of 1,1-diphenyl-1-silacyclohexanone-2 has been described previously (12).

Photolyses were carried out in Pyrex flasks using a Westinghouse PAR 38 100 W mercury spot lamp. Solvents were carefully dried by standard methods and photolysis solutions were deoxygenated by bubbling dry nitrogen through them. The extent of photolyses was determined by withdrawing small samples and following the disappearance of the carbonyl absorption of the acylsilane at 6.08 μm.

Nuclear magnetic resonance spectra were recorded on a Varian A60 instrument, i.r. spectra on a Beckman IR8. Column chromatography used Grace activated silica gel, grade 923, 100–200 mesh. Melting points are uncorrected.

*Photolysis of **1** in Cyclohexane*

This reaction was carried out many times and variations in the conditions and work-up procedure significantly affected the results. The isolations of the three photolysis products are described separately.

*Photolysis at 0 °C. Isolation of Dimer **3**, 2,2,8,8-Tetraphenyl-1-oxa-2,8-disilaspiro[7.7]tridecanone-13*

A solution of 4.4 g of **1** in 80 ml of cyclohexane, cooled to 0 °C in an ice bath, was irradiated for 8 h. The solution was evaporated to dryness at reduced pressure without heating and the residue was dissolved in 30 ml of dry hexane. The solution was stored at room temperature for 20 h to give 2.41 g (54.8%) of dimer **3** as white crystals. The product was recrystallized by dissolving it in a minimum of cold dichloromethane and reprecipitating it with hexane; m.p. 152–154 °C; i.r. (CCl_4) 5.90 (Si—C—C=O) 7.0, 9.0 μm (Si—Ph); n.m.r. ($CDCl_3$) δ 7.0–7.85 (m, 20H, Ph), 2.15–2.96 (broad, 2H, CH_2CO), 0.85–2.1 p.p.m. (m, 14H, ring protons).

Mol. Wt. Calcd. for $C_{34}H_{36}O_2Si_2$: 532. Found (osmometry): 544.

Anal. Calcd. for $C_{34}H_{36}O_2Si_2$: C, 76.65; H, 6.76. Found: C, 76.93; H, 6.83.

*Photolysis at 15 °C; Isolation of Dimer **4**, trans-7,7′-Bicyclo(2,2-diphenyl-1-oxa-2-silacycloheptylidene)*

Photolysis of 2.0 g of **1** in cyclohexane cooled by a cold finger condenser (solution temperature *ca.* 15 °C) followed by crystallization from hexane, as above, gave a total of 1.06 g (53%) of dimer **3**. The mother liquor was then evaporated to dryness and the oily residue was taken up in a small amount of diethyl ether. This solution was stored at −20 °C to yield 0.17 g (9%) of dimer **4**. This compound, which was more readily obtained from thermolysis of **3** (see below), had the following properties: m.p. 149–151 °C; i.r. (CCl_4) 7.0, 9.0 μm (Si—Ph); Raman (powder) 5.93 μm (O—C=C—O); n.m.r. ($CDCl_3$) δ 7.2–7.75 (m, 20H, Ph), 2.3–2.6 (m, 4H, CH_2—C=C—CH_2), 1.1–2.0 p.p.m. (m, 12H, ring protons).

Mol. Wt. Calcd. for $C_{34}H_{36}O_2Si_2$: 532. Found (osmometry): 527.

Anal. Calcd. for $C_{34}H_{36}O_2Si_2$: C, 76.65; H, 6.76. Found: C, 76.78; H, 6.93.

*Photolysis at Ambient Temperature; Isolation of **2**, 1,1-Diphenyl-1-silacyclopentane*

Following the photolysis of 4.3 g (0.016 mol) of **1** in cyclohexane at ambient temperature (solution temperature *ca.* 40 °C) and crystallization of dimer **3** (1.06 g, 25%) from petroleum ether (b.p. 60–70 °C) the residual product was distilled. This afforded 0.70 g (18%) of 1,1-diphenyl-1-silacyclopentane, b.p. 115–120 °C/0.2 Torr, which was identified by comparison with the authentic material (14).

*Thermal Rearrangement of **3** to **4***

A solution of 1.06 g of **3** in 50 ml of cyclohexane was refluxed for 20 h by which time the i.r. carbonyl absorption of **3** (5.90 μm) had disappeared. Removal of solvent gave a solid which was washed twice with cold ether to give 0.92 g (90%) of **4**, m.p. 150–150.5 °C, identical to the material obtained from the photolysis. An additional 0.06 g (total yield 93%) was crystallized from the ether washings.

*Hydrolysis of **3** with Aqueous Acid; Isolation of **7***

A solution of 0.5 g (0.96 mmol) of **3** in 25 ml of acetone containing 10 drops of 5% aqueous hydrochloric acid was stirred at room temperature for 2 days. The acetone was evaporated and the residue was extracted with ether and water. The organic product was chromatographed on silica gel. Elution with ether gave an oil which was identified as pure **7** (0.53 g, 97%) on the basis of the following data: i.r. (CCl_4) 2.70 (Si—OH), 2.90 (broad, C—OH), 5.85 (C=O), 7.0, 9.0 μm (Si—Ph); n.m.r. (DMSO) δ 6.48 (s, 2H, SiO*H*), 5.10 p.p.m. (d, 1H, CHO*H*).

Anal. Calcd. for $C_{34}H_{40}O_4Si_2$: C, 71.80; H, 7.09. Found: C, 72.02; H, 7.01.

*Reduction and Cleavage of **7** to **8**, 5-(Diphenylhydroxysilyl)pentanal*

To 0.25 g (0.44 mmol) of **7**, obtained as above, in ether solution was added 0.20 g (5.3 mmol) of lithium aluminum hydride. After 18 h at reflux, normal aqueous work-up yielded material having both Si—H (i.r. 4.7 μm) and Si—OH groups present. The Si—H function was hydrolyzed to SiOH by brief treatment of the product in aqueous alkaline ethanol. Work-up gave an oil (0.26 g, 96%) presumed to be the expected bis(diphenylhydroxysilyl)-diol; i.r. (CCl_4) 2.70 (Si—OH) 2.98 μm (broad, strong, C—OH).

To 0.14 g (0.25 mmol) of the above in 25 ml of benzene was added 0.13 g (0.29 mmol) of freshly recrystallized lead tetraacetate. After 18 h at room temperature saturated aqueous sodium bicarbonate was added and the solution was extracted with ether to give a mixture of 5-(diphenylhydroxysilyl)pentanal, **8**, and the corresponding acid, **9**. The acid was removed by extraction with sodium bicarbonate to give 0.066 g (39%) of the pure aldehyde, the spectra of which were identical to those of the authentic material (12).

Acidification of the sodium bicarbonate solution and extraction with ether afforded 0.053 g (31%) of 5-(diphenylhydroxysilyl)pentanoic acid, **9**, m.p. 102–104 °C,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

which was identified by mixture m.p. with the authentic material (12).

A control experiment showed that the aldehyde, **8**, was partly converted by lead tetraacetate into the acid, **9**, under the conditions of the reaction.

Hydrolysis of Dimer 4

Hydrolysis of dimer **4** in dilute aqueous acidic acetone for 4 days at room temperature gave the hydroxyketone, **7** (identical to the above), in almost quantitative yield.

Ozonolysis of Dimer 4; Isolation of Silalactone 10

A solution of 1.12 g (2.11 mmol) of **4** in cyclohexane was treated with ozone under anhydrous conditions. Following completion of the reaction 0.53 g (2.11 mmole) of pure dry triphenylphosphine was added and the solution was concentrated and then distilled under vacuum (175–187 °C/0.05 Torr) to give a mixture of 5-(diphenylhydroxysilyl)pentanoic acid lactone, **10**, and triphenylphosphine oxide which were identified spectroscopically.

The mixture was hydrolyzed with dilute acid and the resultant product was chromatographed. Elution with chloroform yielded 0.23 g (37%) of triphenylphosphine oxide, m.p. 155–157 °C, and 0.29 g (21%) of 5-(diphenylhydroxysilyl)pentanoic acid, **9**, m.p. 102–102.5 °C.

Photolysis of 1 in the Presence of Oxygen

The acylsilane **1** (2.55 g, 9.58 mmol) was irradiated in 40 ml of cyclohexane through which oxygen was bubbled. After completion of the photolysis (6 h) the solvent was removed and the residue (i.r. 5.76 μm) was distilled to give 0.40 g (18%) of 1,1-diphenyl-1-silacyclopentane, **2**, (102–112 °C/0.03 Torr), and 0.72 g (27%) of lactone **10** (180–185 °C/0.25 Torr).

The above lactone was hydrolyzed in wet ether to give crystalline 5-(diphenylhydroxysilyl)pentanoic acid (73% yield) which was identified by mixture m.p. with authentic material.

Preparation of 5-(Diphenylhydroxysilyl)pentanoic Acid Lactone, 10

A solution of 0.75 g of the acid, **9**, in 25 ml of acetic anhydride was slowly distilled at atmospheric pressure until the acetic acid and anhydride were largely removed. The residue was distilled to give 0.33 g (47%) of the expected lactone, **10**; b.p. 150–152 °C/0.005 Torr; n_D^{25} 1.5814; i.r. (CCl_4) 5.76 μm (C=O); n.m.r. (CCl_4) δ 7.2–7.7 (m, 10H, Ph), 1.21–2.24 p.p.m. (m, 8H, ring protons).

Anal. Calcd. for $C_{17}H_{18}O_2Si$: C, 72.3; H, 6.38. Found: C, 71.9; H, 6.30.

This lactone slowly hydrolyzed to the acid, **9**, in moist air.

Photolysis of 1 in Methanol; Formation of 11

The photolysis of a solution of 1.0 g of **1** in 25 ml of methanol was complete in 0.5 h. Removal of the solvent gave an oil, the spectra of which indicated it to consist of over 95% of the cyclic acetal, **11**, contaminated with the corresponding open-chain aldehyde. Distillation gave a sample of pure acetal (0.40 g, 36%); b.p. 130–132 °C/0.04 Torr; i.r. (CCl_4) 3.51 (OCH_3), 7.0, 9.0 μm (SiPh); n.m.r. (CCl_4) δ 7.1–7.75 (m, 10H, Ph), 4.9 (broad, t, 1H, O—CH—O), 3.23 (s, 3H, OCH_3), 0.91–2.15 p.p.m. (m, 8H, ring protons).

Anal. Calcd. for $C_{18}H_{22}O_2Si$: C, 72.43; H, 7.43. Found: C, 72.70; H, 7.48.

This acetal was readily converted to the aldehyde, **8**, in aqueous alkaline tetrahydrofuran.

^{13}C Nuclear Magnetic Resonance Spectra of Organic Sulfur Compounds: Cyclic Sulfides, Sulfoxides, Sulfones, and Thiones

M. S. CHAUHAN AND I. W. J. STILL

Department of Chemistry, University of Toronto, Toronto, Ontario M5S 1A1

Received April 21, 1975

M. S. CHAUHAN and I. W. J. STILL. Can. J. Chem. **53**, 2880 (1975).

^{13}C Chemical shift data have been obtained for more than 50 thiochromanone and related sulfoxide and sulfone derivatives. The assignments of the various resonances in the most important of these have been made using the limited data already available and also by comparison with certain model compounds, such as thioanisole, diphenyl sulfide, and the corresponding sulfoxides and sulfones.

Within each of these three series and in a fourth which comprises derivatives of thiochromone, including three α,β-unsaturated thiones, we have examined the effects on ^{13}C chemical shift of substitution at various positions in the thiochromanone skeleton. Among the substituents examined in this context are methyl, phenyl, methoxyl, bromine, and carbomethoxyl. Attempts to compare the ^{13}C chemical shifts for the thiochromanone series with those in a few oxygen containing analogs and in a small number of structurally similar analogs are also discussed.

M. S. CHAUHAN et I. W. J. STILL. Can. J. Chem. **53**, 2880 (1975).

On a déterminé les déplacements chimiques du ^{13}C de plus de 50 thiochromanones ainsi que des sulfoxydes et sulfones correspondantes. On a attribué les positions principales de résonance en faisant appel aux quelques données disponibles et aussi par comparaison avec divers composés modèles comme le thioanisole et le sulfure de diphényle ainsi que les sulfoxydes et les sulfones correspondantes.

Dans chacune de ces trois séries et dans une quatrième comprenant des dérivés de la thiochromone incluant trois thiones α,β non-saturées, on a examiné les effets, sur le déplacement chimique du ^{13}C, de substitutions à diverses positions sur le noyau thiochromanone. Dans ce contexte, on a examiné l'influence des substituants méthyle, phényle, méthoxyle, bromure et carbométhoxyle. On discute des essais que nous avons faits afin de comparer les déplacements chimiques du ^{13}C dans la série de la thiochromanone avec ceux de quelques analogues contenant de l'oxygène et d'un petit nombre d'analogues de structures similaires.

[Traduit par le journal]

Our recent application of ^{13}C n.m.r. chemical shifts to the elucidation of the structure of an unusual rearrangement product from the base-catalyzed methylation of 3-methylthiochroman-4-one (1) demonstrated to us the scarcity of ^{13}C n.m.r. data for even the most common types of sulfur-containing functionality. By way of an example, one (3) of several excellent introductory texts on ^{13}C n.m.r. to appear recently (2–4) contains 500 spectra but reports data for only one sulfone, one thione, and not one sulfoxide. The availability in our laboratory of a considerable number of sulfides, sulfoxides, and sulfones which had been synthesized as part of a continuing investigation of the photochemical behavior of such compounds (5–7) prompted us to undertake an extensive compilation of ^{13}C n.m.r. data for these compounds, and a few related thiones, under identical experimental conditions, the results of which we now wish to discuss.

Experimental

The i.r. spectra were recorded as neat films or Nujol mulls on a Perkin-Elmer 337 grating spectrophotometer and the u.v. spectra on a Unicam SP8000 instrument. ^1H Nuclear magnetic resonance spectra were recorded on Varian T-60 or HA-100 spectrometers with tetramethylsilane (TMS) as internal reference. Mass spectra were recorded on a Bell and Howell 21-490 spectrometer and accurate mass measurements on the A.E.I. MS-902 machine. Elemental analyses were performed by the Scandinavian Microanalytical Laboratory, Box 25, Herlev, Denmark or by A. B. Gygli, 329 St. George St., Toronto. All melting and boiling points are uncorrected. Satisfactory spectral and analytical data were obtained for all new compounds.

The ^{13}C n.m.r. spectra were obtained in 12–15% $CDCl_3$ solution for natural abundance compounds on a Varian Associates XL-100-15 instrument at 25.16 MHz, with approximately 5% TMS added as internal reference. The deuterium of the solvent was used as lock and primary reference and the chemical shifts were obtained from listings supplied by the 16K-620i computer, with an accuracy of ±0.1 p.p.m. Normal operating conditions included an acquisition time of 0.9 s/transient with a delay of 0.3 s and a routine spectral width of 6000 Hz, at an r.f. pulse width of 35 μs and a probe temperature of

32 ± 3 °C. Off-resonance proton decoupled spectra were obtained for all compounds. Of the model compounds for which data are recorded in Table 1, the diphenyl sulfide, sulfoxide, and sulfone were used as commercially supplied. Thiobenzophenone was prepared from benzophenone by refluxing with P_2S_5 in toluene.

Thiochroman-4-one (now commercially available) and its 5-, 6-, 7-, and 8-methyl analogs, as well as the 6-methoxy derivative were all prepared by the base-catalyzed reaction of the appropriate benzenethiol with β-propiolactone, followed by ring closure of the resulting acid with concentrated sulfuric acid (5). The preparation of the 2- and 3-methyl and the 2- and 3-methoxycarbonyl analogs of **1**, and of isothiochromanone **4** also followed our previously outlined procedures (5). The preparation of 3-bromothiochroman-4-one (8), thiochroman-3-one (9), and 2-phenylthiochroman-4-one (10) closely followed the literature methods, although a modified procedure for 6-methyl-2-phenylthiochroman-4-one is described below. 3,3-Dimethylthiochroman-4-one was prepared by methylation of **1** with sodium hydride – methyl iodide, and similar methylation of isothiochroman-4-one and of 2,2-dimethylthiochroman-4-one produced 3,3-dimethylisothiochromanone and 2,2,3,3-tetramethylthiochroman-4-one respectively.

2,2-Dimethylthiochroman-4-one

A mixture of thiophenol (30 g), β,β-dimethylacrylic acid (20 g) and hydrobromic acid in acetic acid (30%, 100 ml) was heated under reflux for 12 h after which it was diluted with water and extracted with ether. The ether extract was washed, dried, and evaporated. The oil obtained was distilled under reduced pressure. Distillate collected up to 120 °C (2 Torr) was discarded. This was found to be a mixture of thiophenol and some products arising from reactions of the unsaturated acid. The temperature was maintained at 120 °C until no more distillate collected. The residue in the flask was cooled, extracted with ether and the ether solution was then extracted four times with saturated sodium bicarbonate solution. The bicarbonate extracts were combined, acidified with concentrated hydrochloric acid, and the precipitated acid was extracted with ether, washed, and dried. The product (17.6 g, 42%) obtained on evaporation of the solvent was recrystallized from petroleum ether, m.p. 60–61 °C. Infrared 3300–2500, 1705 cm^{-1}; n.m.r. δ 1.4 (s, 6H), 2.55 (s, 2H), 7.15–7.65 (m, 5H), 12.9 (s, 1H) p.p.m. This acid, 3-methyl-3-phenylthiobutanoic acid, was cyclized to 2,2-dimethylthiochroman-4-one by the following procedure.

The acid (15.5 g) was dissolved in dry benzene (60 ml). A paste of phosphorus pentoxide (25 g) and Hyflo Super Cel (15 g) was prepared with dry benzene (80 ml) and the paste was added in small amounts to the solution of the acid with stirring. The mixture was then heated under reflux at 100 °C for 5 h, stirring all the time. The solution was filtered and the residue was extracted with boiling benzene three times. The benzene solutions were combined, washed with water, sodium hydroxide solution, and again water, dried and evaporated. The oil so obtained crystallized (8.0 g, 56%) and was recrystallized from petroleum ether, m.p. 44–45 °C Infrared, 1680, 1590, and 1315 cm^{-1}; n.m.r. δ 1.45 (s, 6H), 2.85 (s, 2H), 7.25 (m, 3H), 8.15 (br d, 1H) p.p.m.

Anal. Calcd. for $C_{11}H_{12}OS$: C, 68.73; H, 6.29; S, 16.64. Found: C, 68.49; H, 6.29; S, 16.65.

6-Methyl-2-phenylthiochroman-4-one

A mixture of *p*-thiocresol (30 g), methyl cinnamate (33 g), absolute ethanol (100 ml), and piperidine (4.0 g) was heated under reflux at 100 °C for 72 h. The unreacted thiocresol was removed from the mixture by steam distillation. Hydrochloric acid (6 *N*) (350 ml) and acetone (20 ml) were then added and the mixture was heated under reflux for 12 h; on cooling, crystals of the acid, 3-[*p*-methylphenylthio]hydrocinnamic acid, were formed. The product was filtered off and purified by dissolving it in saturated sodium bicarbonate solution and reprecipitating with concentrated hydrochloric acid. Recrystallization from petroleum ether – benzene gave the pure product (28 g, 52%), m.p. 106–107 °C, lit. (8) m.p. 106 °C.

The acid (13 g) was mixed with phosphorus oxychloride (60 g) and heated on a steam bath for 25 min after which the mixture was cooled and then poured over ice. Extraction with ether gave an impure product (8 g, 66%) which was recrystallized from ethanol, m.p. 95–96 °C, lit. (8) m.p. 96 °C. Infrared 1670, 1600, 1465, 1400, 1300, 1280 cm^{-1}; n.m.r. δ 2.30 (s, 3H), 3.2 (m, 2H), 4.65 (m, 1H) 7.15–7.45 (m, 7H), 8.0 (m, 1H) p.p.m.

2,3-Dimethylthiochroman-4-one

A mixture of tiglic acid (2-methyl-*cis*-2-butenoic acid) (15.0 g), thiophenol (12.0 g), and piperidine (6 drops) was heated at 170–180 °C for 12 h and then distilled under vacuum to remove unreacted thiophenol and tiglic acid. The fraction collected at b.p. 170–172 °C/0.5 Torr was the required acid (23.0 g, 85%). Infrared 3600–2500, 1700 cm^{-1}; n.m.r. δ 1.17–1.40 (m, 6H), 2.62 (m, 1H), 3.51 (m, 1H), 7.10–7.57 (m, 5H), 11.65 (br s, 1H) p.p.m.

The thioacid (5.0 g) and concentrated sulfuric acid (40 g) were kept at room temperature for 4 h. The viscous reddish brown mixture was poured over ice and the solution extracted with ether. The combined ether extracts were dried ($MgSO_4$) and then evaporated. The residue was chromatographed on silica, elution with benzene affording 2,3-dimethylthiochromanone (3.0 g, 64%). Infrared 1670 cm^{-1}; n.m.r. δ 1.14–1.47 (m, 6H), 2.33–3.74 (m, 2H), 6.84–7.42 (m, 3H), 7.99 (br d, 1H) p.p.m.

1-Thiaindan-3-one (6)

This was prepared essentially by the route described in the literature (11, 12) via cyclization of the acid chloride of *S*-phenylthioglycolic acid (prepared from thiophenol and bromoacetic acid in alkali) using aluminum chloride as the catalyst. Yields of the acid chloride (attempted with various chlorinating agents) and of the final product were invariably poor. The product was recrystallized from *n*-hexane – petroleum ether as a pink solid, m.p. 67–69 °C (lit. (13) m.p. 71 °C), which rapidly turned purple if allowed to stand at room temperature. Infrared 1665 cm^{-1}; n.m.r. δ 3.7 (s, 2H), 6.95–7.55 (m, 3H), 7.6–7.85 (m, 1H) p.p.m.

The preparations of thiochromone **7***a* and of 4*H*-thiochromene-4-thione **9** described below illustrate the general methods also used to prepare the 2- and 3-methyl and the 2,3-dimethyl analogs of **7***a*, and the other thiones listed in Table 3, respectively.

Thiochromone (7a) (14)

The crude red triphenylmethyl perchlorate (prepared just before use by dissolving triphenylmethanol (13.0 g) in 60% perchloric acid (50 ml), warming briefly, cooling, and filtering) was added to thiochroman-4-one (6.0 g) in

TABLE 1. Carbon-13 chemical shifts[a] and aromatic shielding parameters[b] of model compounds

Compound[c]	C-1	C-2, 6(*o*)	C-3, 5(*m*)	C-4(*p*)
Thioanisole (3)	138.6[d]	126.6	128.7	124.9
(—S—)	(+10.0)	(−2.0)	(+0.1)	(−3.7)
Diphenyl sulfide	135.8	131.0	129.1	127.0
(—S—)	(+7.2)	(+2.4)	(+0.5)	(−1.6)
Methyl phenyl sulfoxide	145.9[e]	123.4	129.7	130.8
(—SO—)	(+17.3)	(−5.2)	(+0.6)	(+2.2)
Diphenyl sulfoxide	145.7	124.7	129.2	131.0
(—SO—)	(+17.1)	(−3.9)	(+0.6)	(+2.4)
Methyl phenyl sulfone	140.6[f]	127.1	129.3	133.6
($—SO_2—$)	(+12.0)	(−1.5)	(+0.7)	(+5.0)
Diphenyl sulfone	141.6	127.6	129.3	133.2
($—SO_2—$)	(+13.0)	(−1.0)	(+0.7)	(+4.6)
Thiobenzophenone	147.2	129.5	127.9	131.9
(—CS—)	(+18.6)	(+0.9)	(−0.7)	(+3.3)

[a]In p.p.m. downfield from TMS. [b]In p.p.m. from benzene (128.6). Positive value indicates a downfield shift, relative to TMS. [c]In $CDCl_3$ solution. [d]Methyl, 15.6q. [e]Methyl, 43.7q. [f]Methyl, 44.2q.

glacial acetic acid (60 ml). After addition of acetic anhydride (9 ml) an exothermic reaction occurred and the mixture was then boiled for 10 min before cooling in ice and filtering off the yellow 4-hydroxy-1-thiobenzo[*b*]pyrylium perchlorate. This salt, after being washed with anhydrous ether, was stirred briefly with saturated sodium bicarbonate solution and the liberated thiochromone filtered off in almost quantitative yield. Recrystallization from petroleum ether – benzene (4:1) gave white prisms, m.p. 78–80 °C, lit. (8) m.p. 78 °C. Infrared 1635, 1590 cm^{-1}; u.v. $\lambda_{max}^{CH_3OH}$ 248 (ε, 11 100), 256sh (ε, 10 900), 280 (ε, 4300), 333 (ε, 9500) nm; n.m.r. δ 6.9 (d, J = 10 Hz, 1H), 7.8 (d, J = 10 Hz, 1H) 7.5–7.6 (m, 3H), 8.4–8.6 (m, 1H) p.p.m.

4H-Thiochromene-4-thione (9)

Thiochromone (3.24 g) was refluxed in dry benzene for 4 h with phosphorus pentasulfide (4.45 g). The red solution was cooled, filtered, and the solvent evaporated. The crude residue was extracted with boiling petroleum ether (60–80 °C). Filtration of the hot solution and concentration gave red crystals of the thione (2.89 g, 81%), m.p. 90–91 °C, lit. (15) m.p. 91 °C. Infrared 1150 cm^{-1} (C=S); u.v. $\lambda_{max}^{CH_3OH}$ 236 (ε, 16 000), 289 (ε, 6450), 405 (ε, 15 400) nm; n.m.r. δ 7.3 (d, J = 9 Hz, 1H), 8.1 (d, J = 9 Hz, 1H), 7.5–7.7 (m, 3H), 8.9–9.1 (m, 1H) p.p.m.

Using the general procedure illustrated below for the case of 3-methylthiochroman-4-one we have experienced no difficulty in converting the thiochromanones into the corresponding sulfoxides in yields (isolated) ranging from 43–90% with virtually no contamination by the corresponding sulfones. Similarly, the general procedure previously described (5) converted the sulfides into the corresponding sulfones in isolated yields of 42–91%.

3-Methylthiochroman-4-one 1-oxide

A solution of 3-methylthiochroman-4-one (9.0 g) in acetic acid (35 ml) was cooled in an ice bath and 30% hydrogen peroxide (6.4 g) was added slowly with stirring. The mixture was allowed to remain for 12 to 16 h at 25 °C before dilution with water and extraction with ether to remove unreacted sulfide. Extraction with methylene chloride, followed by washing ($NaHCO_3$, water) and drying gave the sulfoxide (6.0 g, 66%). Final purification was achieved by chromatography on silica (eluting with 30% acetone – methylene chloride) and recrystallization from *n*-hexane–benzene, m.p. 116–117 °C. Infrared 1689, 1031 cm^{-1}.

Anal. Calcd. for $C_{10}H_{10}O_2S$: C, 61.86; H, 5.15; S, 16.49. Found: C, 61.64; H, 5.17; S, 16.62.

Results and Discussion

Carbon-13 chemical shift data for a series of cyclic keto-sulfides derived mainly from thiochroman-4-one (**1**) and including also the isomeric isothiochromanone (**4**) and thiochroman-3-one (**5**), as well as 1-thiaindan-3-one (**6**) and the oxime derived from **1**, are collected in Table 2. A number of other oximes were also available but their insolubility in $CDCl_3$ rendered them unsuitable for the present study. The simple oxygen analogs of **1** and of thioflavanone (**3***a*) (chromanone (**2**) and flavanone (**3***b*)) are also included to provide some comparisons between S- and O-series of compounds.

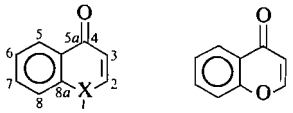
For personal use only.

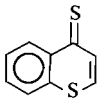
aromatic shielding parameters of the $COCH_3$ group (2) and by subtracting from the various chemical shifts of thioanisole (3) (Table 1) the chemical shift of benzene, which was 128.6 p.p.m. under the present conditions. This rather simplifying assumption gave remarkably good agreement between theory and prediction for the four unsubstituted carbons, C-5 to C-8, none of the deviations exceeding 1.0 p.p.m. Not unexpectedly, as other authors have noted (16), the agreement between prediction and observation for C-5*a* and C-8*a* was much poorer, the deviations being 4.8 and 3.4 p.p.m., respectively. The relative lack of data for the shielding parameters of sulfur-containing substituents as compared to the carbonyl substituent and the presence of the second (heterocyclic) ring may account for this result. Results from the 6-methyl and 6-methoxy analogs, however, reveal *para*-substituent effects of −3.3 and −8.7 p.p.m. respectively and give excellent corroboration of the correctness of the C-5*a* and C-8*a* assignments in **1**. A similar procedure was carried out for chromanone using the well documented aromatic shift parameters for $COCH_3$ and OCH_3 (2) groups. The maximum deviation observed was 3.6 p.p.m. (for C-8), while the agreement for the ring fusion carbons C-5*a* and C-8*a* was very good in this case, neither of the deviations exceeding 2.0 p.p.m. The assignment of the resonance at 26.2 to C-2 and that at 39.5 p.p.m. to C-3 in thiochromanone was obvious from an examination of the chemical shifts in tetrahydrothiophene, cyclopentanone and cyclopentane, as well as being in accord with the substituent effects produced in the C-2 and C-3 methylated analogs.

The 2-methyl, 3-methyl, 2,2-dimethyl, and 3,3-dimethyl analogs of **1** were also examined in the analogous sulfoxide (Table 5) and sulfone (Table 6) series and the substituent effects have been compared in Table 7 for all three series. Generally speaking, methyl substitution at C-2 produces a more pronounced downfield shift at that carbon than does methyl substitution at C-3, α to the carbonyl group. Roberts and Weigert (17) observed this effect in simple methylcyclohexanones. As Table 7 reveals, however, there are a number of curious variations in the methyl substituent effect pattern and the likelihood that the heterocyclic ring may exist in both the half-chair and the sofa conformations, as well as the widely different electronic effects of S, SO, and SO_2 and the existence of diastereomeric sulfoxides (in some cases) make rationalization difficult. As expected, substitution of methyl (or phenyl) groups on C-2 or C-3 has in general no significant influence on the chemical shifts of C-5*a*, C-8*a* or the carbonyl carbon (C-4). The one exception to this is in the downfield shift of the carbonyl carbon in the 3-methyl compound (+2.4 p.p.m.) and in the 3,3-dimethyl compound (+4.5 p.p.m.). The shift of the carbonyl carbon on going from cyclohexanone to 2-methylcyclohexanone is +1.5 p.p.m. Significant shifts in the position of the carbonyl carbon were noted in thiochroman-3-one (**5**), where the downfield shift is attributable to the loss of conjugation with the aromatic ring, and in 1-thiaindan-3-one (**6**), where the downfield shift is due to the five-membered ring. In thiochroman-4-one oxime the C-2 and C-3 signals had almost identical chemical shifts and the C-4 carbon appeared in the normal range for oximes (2) at 153.6 p.p.m.

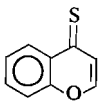


7*a* X = S
7*b* X = SO_2

8



9



10

The 10 compounds appearing in Table 3 under the generic heading 'thiochromones' strictly include only four members of that class of compound. However, the three thiones **9**, **10**, and the 2-phenyl analog of **10**, the thiochromone sulfone (**7***b*), and the oxygen analogs chromone (**8**) and flavone all possess as a common structural feature a double bond between C-2 and C-3 and furthermore all contain an α,β-unsaturated ketone (or thione) moiety in a six-membered ring, with an electron-withdrawing group (O, S, SO_2) attached to the β-carbon, and we have thus felt justified in treating them for the present purpose as a related group of compounds. Finding suitable model compounds is more difficult for this series, but at least for the ketone members of the series we have utilized the well-documented effects of α- and β-methyl substitution in 2-cyclohexen-1-one (2) and the generally much lower field position observed for the β-carbon in assigning the C-2 and C-3 resonances. In assigning the aromatic carbon reson-

TABLE 4. Shielding parameters[a] in α,β-unsaturated cyclic ketones

Substituent	Effect on β-carbon[b]	Effect on α-carbon[b]
β-Methyl(2-methyl-7*a*)	+13.1 (+11.5)	−2.0 (−2.8)
α-Methyl(3-methyl-7*a*)	−5.2 (−5.2)	+6.4 (+6.5)
α,β-Dimethyl(2,3-dimethyl-7*a*)	+6.4 (+3.9)	+3.2 (+1.6)

[a]In $CDCl_3$ solution. [b]In p.p.m. from corresponding values in thiochromone (7*a*) and cyclohexenone (in parentheses), respectively. Positive value indicates a downfield shift, relative to TMS.

ances, for example in the parent thiochromone and chromone systems, (7*a* and **8**), we have adopted the guideline that those carbon atoms whose resonances are significantly shifted (upfield or downfield) from the 128.6 p.p.m. value for benzene in $CDCl_3$ will experience much the same electronic effects as those in the saturated analogs, **1** and **2**, and have assigned them accordingly. The carbonyl carbon atoms (C-4) in the first seven members of the series all appear within the narrow range 177.6–179.9 p.p.m., thus indicating that not only methyl substitution (α- or β-), but also β-phenyl substitution or even the replacement of the cyclic β-sulfur substituent with oxygen or sulfone groups, produces little effect at C-4. The same situation occurs for the thiones **9**, **10**, and 2-phenyl-**10**, where the carbon of the C=S group appears within the range 201.4–204.4 p.p.m. Comparison of the chemical shifts in chromone and thiochromone with those in the corresponding thiones, **10** and **9** respectively, reveals a general similarity in the α,β-unsaturated ketone and thione systems. Indeed, in the thiochromone ketone and thione pair the only significant change is a downfield shift of +4.8 p.p.m. in the C-3 resonance on going from the ketone to the thione. A similar downfield shift was observed for C-3 of the alicyclic thione, thiocamphor, compared to C-3 in camphor itself, in an earlier study by Demarco *et al.* (18). In the ketone and thione of the chromone series, where the electronic influence of the ring oxygen is much greater, the corresponding downfield shift of the C-3 signal is +13.2 p.p.m. in going from C=O to C=S. Attempts to prepare thiones corresponding to the thiochromanone series of compounds in Table 2 unfortunately met with no success.

Some justification for comparing the thiochromone ring system with the simple cyclohexenone system is obtained by examining the effects of α- and β-(C-3 and C-2)methyl-substitution. Table 4 shows the remarkably good agreement between the shielding parameters for the thiochromones and the corresponding cyclohexenones. As expected, methyl substitution at C-2 and C-3 exerted little effect on the aromatic carbon atoms. The methyl resonance in 3-methylthiochromone appeared at 4.1 p.p.m. upfield relative to that in the 2-methyl analog. Once again this follows the pattern observed for the 2- and 3-methylthiochromanones in Table 2 and is attributable to the alignment of the 3-methyl substituent in the plane of the carbonyl group (17).

Comparison of the two 2-phenyl substituted compounds in Table 3 with their unsubstituted analogs **8** and **10** reveals that substitution at C-2 (or C-3), as already observed for the methyl derivatives, produces no significant alteration in the chemical shift of any of the aromatic carbon atoms, including C-5*a* and C-8*a*; indeed this consistency was of some assistance in making the given assignments. The (downfield) shift of the C-2 carbon differs considerably, however, being +17.8 for 2-phenyl substitution in the chromone and only +7.8 for the analogous thione. The upfield shift observed at C-3 is almost the same on the other hand, −5.4 and −6.1 respectively. The larger deshielding effect observed for phenyl substitution at C-2 in the ketone may reflect the greater electronegativity of the (carbonyl) oxygen or a greater degree of conjugation in the ketones than in the thiones.

The difference in chemical shift between C-2 and C-3 is, as expected, greater for the chromenethione (**10**) than the thiochromene-thione (**9**) (19.8 *vs.* 6.2 p.p.m.)just as the presumably greater

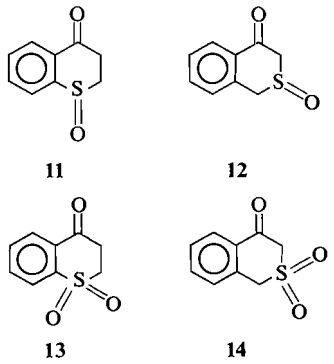
degree of conjugation in chromone (**8**) accounts for a C_β–C_α chemical shift difference of 32.5 p.p.m., compared with 11.3 p.p.m. for thiochromone (*7a*). Chemical shifts of the aromatic carbon atoms in the pair of compounds **8** and **10** and also in *7a* and **9** are generally very similar. The chemical shift difference between the ring fusion positions (C-8*a* – C-5*a*) is, however, much greater in chromone (31.6 p.p.m.) than in the corresponding thione (20.5 p.p.m.), reflecting once more perhaps the greater degree of conjugation in the unsaturated ketones referred to above.

Chemical shift data for the cyclic sulfoxides and sulfones in our study are collected in Tables 5 and 6, respectively. The electron-withdrawing character of the sulfoxide and sulfone functionalities is reflected in the downfield shifts at C-2, relative to thiochromanone itself, of +20.5 p.p.m. in thiochroman-4-one 1-oxide (**11**) and of +22.7 p.p.m. in thiochroman-4-one 1,1-dioxide (**13**). Interestingly, the replacement of the cyclic sulfur atom in thiochroman-4-one by the sulfoxide functionality produces an *upfield* shift at C-3 of −8.8 p.p.m., whereas in the corresponding sulfone the upfield shift at C-3 is only −2.7 p.p.m. The C-4 (carbonyl) carbon is not greatly affected by these changes, showing upfield shifts of −1.9 p.p.m. in the sulfoxide and a further −1.8 p.p.m. in the sulfone. The assignment of the aromatic carbon resonances, including the ring junctions, C-5*a* and C-8*a*, in **11** and **13** was carried out using information obtained from the model compounds in Table 1 and the shielding parameters of aromatic $COCH_3$ substituents (2), as well as by comparison with thiochroman-4-one itself. Our assignments are further supported by the generally good agreement between the observed aromatic resonances in the 6- and 8-methyl- and 6-methoxythiochroman-4-one 1-oxides and in the 5-, 6-, and 7-methylthiochroman-4-one 1,1-dioxides with the values calculated using the known aromatic substituent effects of CH_3 and OCH_3 (2).

In the series diphenyl sulfone, diphenyl sulfoxide, thiobenzophenone (Table 1), and benzophenone (19) the *p*-substituent (deshielding) effects are in the order $SO_2 > C{=}O > C{=}S > S{=}O$, being (+) 4.6, 3.7, 3.3, and 2.4 p.p.m. respectively. In diphenyl sulfide, of course, the *p*-effect is in the opposite sense, although the shift of −1.6 p.p.m. is considerably less than the −3.7 p.p.m. observed in thioanisole (3). A similar reduction in the upfield shift at the *p*-position



11 **12** **13** **14**

is observed in diphenyl ether as compared to anisole. The *o*-effects in the above series (*cf.* Table 1) show much less consistency, being small and in the downfield direction in thiobenzophenone and benzophenone (+0.9 and +1.3 p.p.m., respectively), whereas in diphenyl sulfoxide and diphenyl sulfone they are in the upfield direction, being −3.9 and −1.0 p.p.m., respectively. In diphenyl sulfide, the *o*-effect is +2.4 p.p.m.

The effects of methyl-substitution at C-2 and C-3 in the sulfide, sulfoxide, and sulfone series (Tables 2, 5, 6) show interesting variations and the data for the three series has been collected in Table 7. Although general trends are difficult to discern, it does appear that substitution of a methyl group at C-2 produces more 'normal' shifts at both C-2 and C-3 than is the case for the corresponding 3-methyl and 3,3-dimethyl series. In fact, downfield shifts at C-3 are generally small, the single exception being in going from the 3-methyl to the 3,3-dimethyl sulfoxide where a change of +10.9 p.p.m. is observed. Once again, in both the sulfoxide and sulfone series, the tendency of α-methyl (C-3) substitution to produce downfield shifts of the C-4 (carbonyl) resonance is just as pronounced as it was for the sulfides in Table 2. The differences in chemical shifts for the methyl resonances themselves at C-2 and C-3, referred to in the discussion of Table 2, are no longer so evident in Tables 5 and 6, not only because of the non-equivalence of methyl groups in 2,2- and (to a lesser extent) 3,3-dimethylthiochroman-4-one 1-oxides, but also no doubt because of the shielding influence, not present in the thiochromanones, of the S=O bond(s) on the C-2 methyls. In general, as was the case for the corresponding sulfides, the effect of C-2 or C-3 methyl substitution on even the closest aromatic (ring-junction) carbon atoms is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

not very great, as expected, and is probably attributable to steric crowding of one or both of the polar functionalities at C-1 and C-4, which reaches its maximum expression in 2,2,3,3-tetramethylthiochroman-4-one 1-oxide.

In thioflavanone 1-oxide and thioflavanone 1,1-dioxide, the effect of phenyl substitution at C-2 is to produce downfield shifts of +15.9 (taking the mean value for the two diastereoisomers) and +14.7 p.p.m. respectively. The corresponding shifts so produced at C-3 amount to +6.0 and +6.3 p.p.m., respectively, much the same behavior as was observed in thioflavanone itself. In all three 2-phenyl substituted compounds, the increased complexity of the aromatic region of the ^{13}C n.m.r. spectra prevented the individual assignment of all signals. This problem becomes particularly acute in the case of 2-phenylthiochroman-4-one 1-oxide and 2-phenyl-6-methylthiochroman-4-one 1-oxide owing to the existence of diastereoisomers, since the separation of lines (due to configurational isomerism) becomes quite small for the aromatic carbons which are relatively remote from the chiral centers, leading to much overlapping of neighboring peaks in the relatively narrow region of the spectrum involved. The spectrum of 3-bromothiochroman-4-one 1-oxide reveals that the α-effect produced by replacing hydrogen by bromine is +11.4 and the β-effect +7.8 p.p.m. which, at least as far as the α-effect is concerned, seems to agree well with results quoted by Levy and Nelson (2). The effect of introducing a bromine α to the carbonyl group produces an upfield shift of −5.8 p.p.m. in the resonance due to the C-4 carbon. This compares favorably with the value of −5.3 p.p.m. reported for 3-*endo*-bromocamphor (20). As usual, the signals due to the aromatic carbons were not greatly affected by introduction of the bromine although a general drift downfield of approximately 1 p.p.m. was noted.

The two sulfones which bear an ester functionality in the heterocyclic ring (Table 6) deserve comment. In 2-methoxycarbonylthiochroman-4-one 1,1-dioxide, the α-effect of the ester group is +14.8 p.p.m. and the β-effect +3.0. Very recently, Gordon *et al.* (21) have reported their results from a ^{13}C n.m.r. study of a series of methyl esters in which the α-effect was +15.4 p.p.m. and the β-effect +1.3 p.p.m. for the cyclohexyl system. In our 2-methoxycarbonyl substituted case, the only other significant effect was to produce an upfield shift of −2.0 p.p.m. in the carbonyl carbon (Gordon *et al.* (21) report a γ-effect for simple cyclohexanes of −2.3 p.p.m.). In distinct contrast to the rather routine effects observed in the 2-substituted case, the 3-methoxycarbonylthiochroman-4-one 1,1-dioxide produced a quite unexpected result. It will be noted that this is in fact a β-keto ester and the ^{13}C n.m.r. spectrum indicates quite clearly that in $CDCl_3$ solution at the concentration used (12–15% w/v) enolization is complete. Thus, the C-3 signal appears as a singlet rather than a doublet, as a value of 93.2 p.p.m., far removed from the 36.8 p.p.m. observed in the unsubstituted sulfone, whereas the position of the C-2 signal is altered only slightly. The electron-releasing effect of the enolic OH group, enhanced by the electron-withdrawing effect of the COOMe group, accounts for the unusually high field location for the sp^2 carbon at C-3. As expected, the C-4 carbon shows a chemical shift closer to what one would expect for an sp^2 carbon bonded to oxygen, appearing at 171.0 p.p.m. The methyl and ester carbonyl signals, as well as the signals for the aromatic carbons in the two ester derivatives, are virtually identical.

The remaining compounds for which data are included in Tables 5 and 6 are isothiochromanone 2-oxide (**12**) and isothiochromanone 2,2-dioxide (**14**) and its 3,3-dimethyl derivative. The assignment of the C-1 and C-3 signals in **12** and in **14** as well as in isothiochromanone (**4**) itself was made initially in the expectation that the signal due to C-3, α to the carbonyl, would be downfield from that due to C-1, which is a benzylic methylene, and the assumption that the C-3 signal in particular would not be greatly changed in position from C-3 of thiochroman-4-one. In the sulfoxide (**12**) the C-1 and C-3 signals are shifted downfield by +21.7 and +21.8 p.p.m., respectively, while in the sulfone (**14**) the corresponding shifts are +25.0 and +25.4 p.p.m. These values are very similar to the effects observed at C-2 in the analogous thiochromanones, in proceeding through the series sulfide, sulfoxide, sulfone. Further evidence in support of these assignments comes from a consideration of 3,3-dimethylisothiochromanone 2,2-dioxide (Table 6), where the change in chemical shift at C-3 between this compound and the unsubstituted analog is +5.8 p.p.m., while the corresponding change in chemi-

TABLE 7. Methyl substituent effects[a] at C-2 and C-3

Series	Substituent	Effect at C-2[b]	Effect at C-3[b]
Thiochromanones	2-Methyl	+9.6	+8.1
	2,2-Dimethyl	+17.9	+14.3
	3-Methyl	+6.4	+2.6
	3,3-Dimethyl	+12.5	+1.4
	2,3-Dimethyl[c]	+14.6	+8.3
Thiochromanone sulfoxides	2-Methyl[c]	+6.1	+8.0
	2,2-Dimethyl	+9.4	+15.0
	3-Methyl	+4.7	+1.4
	3,3-Dimethyl	+13.6	+12.3
	2,2,3,3-Tetramethyl	+16.3	+20.5
Thiochromanone sulfones	2-Methyl	+5.2	+7.4
	2,2-Dimethyl	+9.3	+13.7
	3-Methyl	+6.3	+4.6
	3,3-Dimethyl	+10.4	+8.3

[a]In p.p.m.; positive values indicate downfield shifts.
[b]All shifts are related to values for C-2 and C-3 in the parent compounds (**1**, **11**, or **13**), including those for the dimethyl substituted derivatives.
[c]Mean value taken for diastereoisomers.

cal shift at C-3 between thiochroman-4-one 1,1-dioxide and its 3,3-dimethyl analog is +8.3 p.p.m. In general the C-4 (carbonyl) carbon appears at higher field in isothiochromanone and its sulfoxide and sulfone, the differences ranging between 3–4 p.p.m. Once again, however, in the case of 3,3-dimethylisothiochromanone 2,2-dioxide, the characteristic downfield shift in the C-4 (carbonyl) frequency produced by α-methylation is observed. The numerical value of this shift, 6.0 p.p.m., is exactly the same as that observed in 3,3-dimethylthiochroman-4-one 1,1-dioxide. The removal of the electron-withdrawing sulfur group at C-1 in isothiochromanone sulfoxide and sulfone to the C-2 position produces a very marked closing of the gap in chemical shifts between C-5*a* and C-8*a* observed in the analogous thiochromanone sulfoxide and sulfone to about 2 p.p.m. and furthermore greatly reduces the spread in chemical shifts arising from the carbons 5, 6, and 8 to the point at which attempts to make individual assignments become somewhat nebulous.

In Table 7 are gathered data on the effects of methylation at C-2 and C-3 in the thiochromanone and related sulfoxide and sulfone series, calculated from the chemical shifts in Tables 2, 5, and 6. It may be noted that for 2,3-dimethylthiochroman-4-one the total downfield shift observed at C-2 and C-3 approximates quite closely that obtained by simply adding the contributions from the 2-methyl and 3-methyl derivatives. This additivity is not so apparent in 2,2,3,3-tetramethylthiochroman-4-one 1-oxide, where the steric crowding must cause considerable distortion of the heterocyclic ring. Even in this case, however, the relative magnitude of the shifts at C-2 and C-3 is correctly predicted by summing the values from the 2,2-dimethyl and 3,3-dimethyl sulfoxides.

We thank Mr. N. Plavac of this department for his help and cooperation in recording the ^{13}C n.m.r. spectra. We wish to acknowledge also the experimental contributions of Dr. M. T. Thomas, Miss M. H. Kwan, and Mr. Peter Lau in making available some of the compounds included in this study.

Certain bisaziridinopyrrolidinoquinone analogs, which contain the structural moieties essential for physiological activity in the parent antitumor agent mitomycin C, have been synthesized. These compounds efficiently induce covalent cross-links in DNA as shown by the ethidium fluorescence assay which was confirmed by an independent S_1-endonuclease assay. The interaction of clinically active and structurally related antitumor aziridinoquinones with DNA have been examined similarly. The aziridinoquinones cross-link DNA efficiently with a marked p*H* dependence. Parallel dependence is observed on p*H* and concentration of alkylating species in the concomitant alkylation which does not result in cross-linking as measured by the suppression of the before heat fluorescence. The latter phenomenon was shown by the application of radiolabelled polynucleates not to be accompanied by depurination. A direct correlation exists between the extent of covalent cross-linking and (G + C) content of various DNA's of comparable molecular weight as in the case of mitomycin C. Estimates of the average number of cross-links per DNA molecule range from 0.61 to 1.71 depending on (G + C) content. The rate of acid assisted opening of a model aziridinoquinone measured spectrophotometrically at different p*H* values parallels the observed rate of covalent cross-linking and alkylation. It was shown independently that the intermediate 2,5 bis(2-acetoxyethylamino)-3,6-dimethoxy-1,4-benzoquinone does not cross-link DNA. A correlation is made of antineoplastic activity against a variety of tumors with covalent cross-linking ability using λ-DNA.

On a synthétisé certains analogues de la bis-aziridinopyrrolidinoquinone qui contiennent la fraction structurale essentielle pour l'activité physiologique de la mitomycine C, agent actif contre les tumeurs. Ces composés induisent d'une façon efficace des liaisons transversales covalentes dans l'ADN; on a pu démontrer cette propriété par les tests de fluorescence à l'éthidium et la confirmer par un test indépendant avec la S_1-endonuclease. On a examiné, de la même manière, l'interaction entre l'ADN et les aziridinoquinones de structures semblables, actives du point de vue clinique contre les tumeurs. Les aziridinoquinones provoquent d'une façon efficace des liaisons transversales dans l'ADN; ce processus varie d'une façon importante avec le p*H* et la concentration des espèces alkylantes dans l'alkylation concomitante qui ne conduit pas à une liaison transversale telle que mesurée par la suppression de la fluorescence d'avant chauffage. On a démontré ce dernier phénomène par l'application de polynucléates marqués qui n'est pas accompagnée d'une dépurination. Une corrélation directe existe entre la quantité de liaisons transversales covalentes et le contenu (G + C) de divers ADN de poids moléculaires comparables à ceux utilisés dans le cas de la mitomycine C. On évalue que le nombre moyen de liaisons transversales par molécule d'ADN varie de 0.61 à 1.71 suivant le contenu (G + C). Le taux d'ouverture, aidée par les acides, de l'aziridinoquinone modèle, tel que mesuré spectrophotométriquement à divers p*H*, est parallèle au taux observé pour la formation de liaisons transversales covalentes et l'alkylation. On a démontré d'une façon indépendante que l'intermédiaire bis(acétoxy-2 éthylamino)-2,5 diméthoxy-3,6 benzoquinone-1,4 ne cause pas de liaisons transversales dans l'ADN. On présente une corrélation entre l'activité antinéoplastique contre une variété de tumeurs avec l'habilité de causer des liaisons transversales covalentes dans la λ-ADN.

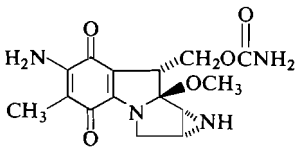
Introduction

In the alkylating class of antitumor antibiotics the most effective are bifunctional including many chemically important agents such as mitomycin C and synthetic agents *e.g.* Trenimon (1*a*). There is much evidence to indicate that DNA is the cell component most sensitive to the attack of such agents (2). As we described in Part V of this series the method of fluorescence enhancement employing the intercalative trypanocidal dye ethidium bromide which specifically detects double stranded DNA is a convenient procedure for investigating many aspects of the interaction of alkylating agents with the cell's genetic material (3). We describe the application of this technique to a study of the rate, extent, geometrical, substituent, and purine base specificity requirements for the covalent cross-linking of polynucleates, and attempt to correlate such factors with their antineoplastic properties.

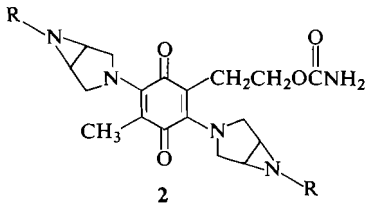
Results and Discussion

Synthesis of Analogs of Mitomycin C which Covalently Cross-link DNA

In their studies on the mode of action of mitomycin C, **1**, Szybalski and Iyer (4) showed that the rate of cell death correlated well with the degree of DNA cross-linking and have calculated that one cross-link per genome is sufficient to cause cell death. An examination of the literature of cancer chemotherapy reveals that many effective bifunctional agents have quite widely different geometries (1*a*). To examine further the characteristics of cross-linking of DNA with a view ultimately of establishing a rapid and convenient screen for potential antitumor agents, we sought initially a group of analogs of mitomycin C. Despite intensive and ongoing efforts by several groups of workers, mitomycin C has not as yet yielded to a total synthesis (5). There is also interest in chemically modified forms of mitomycin C



1

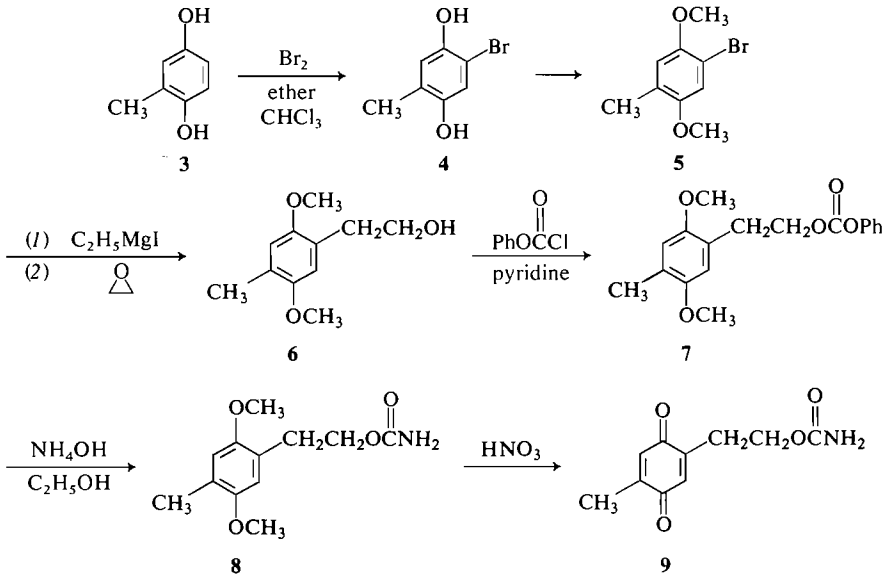


2

(5*h*). We have prepared a group of analogs which possess what are regarded as the essential structural moieties for physiological activity, *i.e.* the bisaziridinopyrrolidinoquinones, **2**.

The rationale is that compounds **2** retain the reactive aziridine and carbamate functions which separately have been shown to alkylate DNA (1*b*, 6). The distance between the two potential aziridine alkylating centers in **2** is comparable with that of the clinically useful 2,5-diaziridinoquinones (1). In addition, the greater conformational flexibility between the alkylating centers of **2** with the concomitant increase in the number of possible alkylating sites on DNA may compensate for the reduction in reactivity resulting from the loss of conjugative enhancement afforded by the indole nucleus in **1**. It has not been demonstrated that the rate of alkylation is significant in determining antitumor activity. The quinone function is retained for two reasons (*i*) so that the structure of analogs **2** should resemble **1** for possible intercalative properties (7) and (*ii*) we have established that mitomycin (3) in common with the structurally related antibiotic streptonigrin (8) degrades DNA employing its oxidative capacity which contributes significantly to their cytotoxic properties. In this connection there is much accumulated evidence that quinone containing substances display marked antibacterial and antitumor activity (5*h*, 9). In the event, analogs of type **2** proved to be quite efficient cross-linking agents which are useful in delineating the geometrical and conformational constraints in cross-linking of DNA.

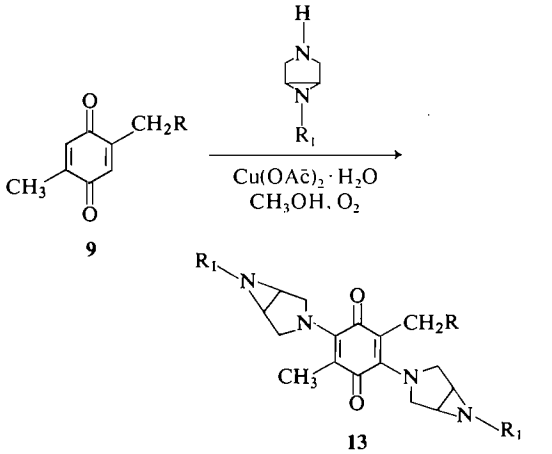
Functionalized quinones bearing the required carbamate side chain were prepared by the route illustrated in Scheme 1. The required bicyclic aziridines were prepared via 1,3-dipolar azide addition to 3-pyrroline and subsequent photolysis of the triazolines (10) (Scheme 2). The bicyclic aziridines were then coupled to the functionalized quinones using copper acetate as catalyst (11) (Scheme 3).



SCHEME 1

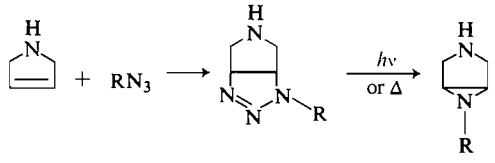
Detection of Covalent Cross-linking of DNA by Bicycloaziridinoquinones and Confirmation by S_1-Endonuclease

When the synthetic analogs **13** were incubated in 20% aqueous pyridine with λ-phage DNA (mol. wt. = 31 × 10^6) in an acetate buffer the induction of covalent cross-links was detected as summarized in Table 1. It is evident from the results that covalent cross-linking to the DNA is occurring quite efficiently across the two aziridine positions (compare **13***d* with **13***b*). The span between C_1 and C_{10} of the activated form of mitomycin is *ca.* 4.3 Å compared with the span between the alkylating centers of **13***d* of 10.1–10.8 Å indicating bifunctional agents of quite different dimensions may be accommodated by cross-linked DNA. Secondly, an electron-withdrawing group in R_1 enhances the efficiency of covalent cross-linking.



a R = CH_2OCONH_2; R_1 = C_6H_5
b R = CH_2OCONH_2; R_1 = $pBrC_6H_5$
c R = CH_2OCONH_2; R_1 = $pCH_3OC_6H_4$
d R = H; R_1 = $pBrC_6H_4$

SCHEME 3



a R = $pBrC_6H_4$
b R = C_6H_5
c R = $pCH_3OC_6H_4$

SCHEME 2

The induction of CLC sequences with compounds **13***d* received independent confirmation by the use of the S_1-endonuclease assay described previously employing *Escherichia coli* DNA (3) (see Table 2).

The substantially lower values for the induction of covalent cross-linking reflects the use of *E. coli* DNA of much lower molecular weight (14.8 × 10^6) than that of λ-DNA (31 × 10^6). Since only one cross-link is re-

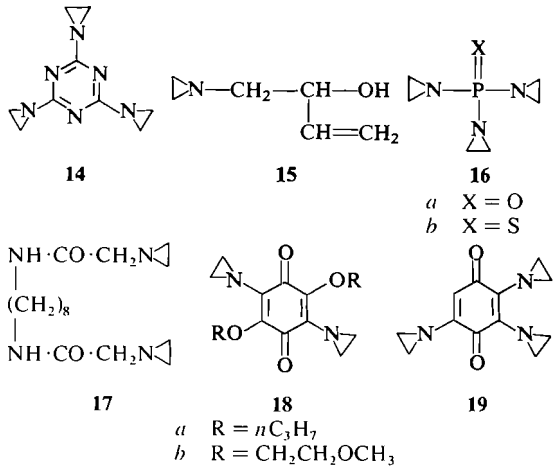
	Time (min)			
	10	90	195	270
% cross-linking by CLC assay	16	20	27	25
% cross-linking by S_1-endonuclease assay	9	15	19	16

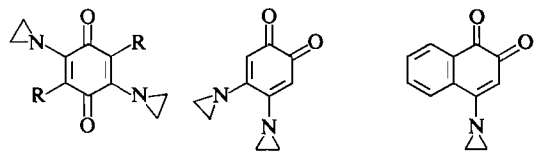
quired per molecule to be detected by the CLC assay, a given concentration of alkylating agent will induce proportionately fewer cross-links in the *E. coli* DNA. The S_1-endonuclease assay gives lower values because the time required for digestion permits a small amount of spontaneous renaturation of the *E. coli* DNA especially at the neutral p*H* used to be compatible with the enzyme. In addition the ambient temperature used in the enzyme digestion probably permits some slow degradation of double stranded DNA presumably via the natural 'breathing' mechanism which produces transient single strand regions (12). There was no evidence of radical induced single strand cleavage of PM2 circular DNA by **13***d* as has been found for mitomycin C and streptonigrin (3).

Mode of Cytotoxic Action of Structurally Related Aziridinoquinones

Many aziridine containing compounds of quite different structures have useful antitumor properties (1*b*). Thus TEM (**14**, 2,4,6-tris(1-aziridinyl)-*s*-triazine) was the first alkylating agent found suitable for oral administration and is still in clinical use (13). Also included are tetramin (**15**) active against leukemia L1210 (14), TEPA (**16***a*), phosphoramides like tris(1-aziridinyl)phosphine oxide triethylene phosphoramide and thio-TEPA the sulfur analog **16***b* which effect complete regression of Flexner-Jobling rat carcinoma (15), and *N,N'*-octamethylenebis-1-aziridineacetamide (**17**) which is active against Ehrlich ascites carcinoma in mammals (16). Interest in the antitumor properties of the above compounds led to the synthesis and evaluation of many aziridinoquinones from which many effective agents were found including the clinically active benzoquinones 2,5-bis(1-aziridinyl)-3,6-dipropoxy-*p*-benzoquinone (**18***a*), 2,5-bis(1-aziridinyl)-3,6-bis(2-methoxyethoxy)-*p*-benzoquinone (**18***b*) (17), and tris(1-aziridinyl)-*p*-benzoquinone, Trenimon (**19**) (18). In common with other alkylating agents, they exhibit greatest effectiveness against leukemias and other lymphomas such as Hodgkin's disease. The mechanisms by which aziridine containing agents exert their antitumor activity cannot as yet be stated with confidence. Among the suggestions that have been made include (*i*) their alkylating ability (2*a*), (*ii*) their covalent cross-linking of DNA (1, 2), and (*iii*) that hydrogen peroxide or other oxidizing species formed by intracellular redox reactions of quinones are the real cytostatic agent (19). Efforts have been made, without notable success, to correlate antitumor activity with magnetic susceptibility and electron delocalization



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.



20 21 22

(20), and with partition coefficients between benzene and aqueous phosphate buffer solutions (21).

The convenience of the ethidium fluorescence assay described above offers a means for investigating many of the suggestions that have been made with respect to the modes of action. Three general types of aziridinoquinones were synthesized **20**, **21**, and **22**. The induction of CLC sequences in λ-DNA was established for compounds of the type **20** and **21** in the concentration range 0.05–1.00 μg/μl using the ethidium assay (3, 22) as illustrated in Fig. 2 and Tables 6 and 7 where agents are listed in order of cross-linking ability. Independent confirmation that this assay detects CLC sequenced DNA for this group of bifunctional alkylating agents was obtained by the S_1-endonuclease assay (3) as summarized in Table 3.

A correspondence is again noted for these independent assays bearing in mind the remarks about the S_1 assay made earlier. It may be seen that for 1,4-benzoquinones alkoxy substituents enhance both antineoplastic activity and cross-linking efficiency whereas chloro substituents suppress both these phenomena. A carbamate side chain, unless activated as in the mitomycin C structure does not contribute to increased DNA cross-linking. *Ortho* substituted bifunctional agents are particularly effective in cross-linking and *in vivo* antitumor data are awaited with interest. The monofunctional aziridine *ortho* and *para* substituted naphthoquinones are included as controls and, as expected, do not exhibit cross-linking.

pH Dependence of Covalent Cross-Linking and Alkylation without Depurination of DNA by Aziridinoquinones

As has been observed with the antitumor antibiotic mitomycin C (3), the detection of CLC sequenced DNA is accompanied by a suppression of the before heat denaturation fluorescence reading. A synthetic polynucleotide containing selective radioactive labels in the purine and pyrimidine bases was treated with an aziridinoquinone to the stage where in a control experiment an appreciable decrease in before-heat fluorescence value was observed. The alkylated DNA's were washed with trichloroacetic acid and counted. The results summarized in Table 4 show that no depurination accompanies alkylation or covalent cross-linking as

TABLE 3. Confirmation of covalent cross-linking of DNA by aziridinoquinone (**20**) with S_1-endonuclease assay

	Time (min)		**20** R = CH_3

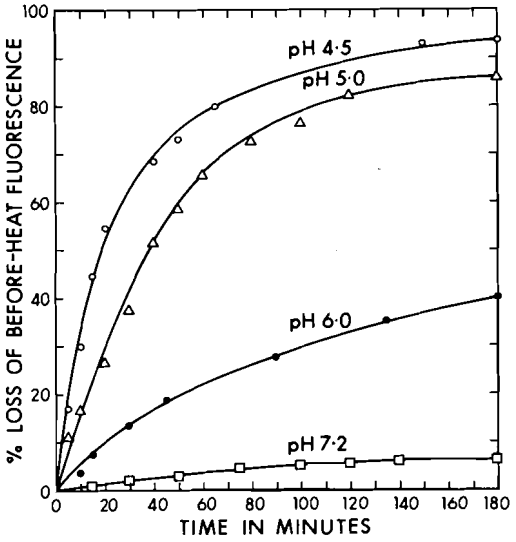

FIG. 1. The p*H* dependence of alkylation of λ-DNA by 2,5-bis(aziridinyl)-3,6-dimethoxy-1,4-benzoquinone at a final concentration of 0.8 μg/μl. Reactions were performed in 1.0 *M* buffered aqueous solutions at 37 °C with a final DNA concentration of 1.40 O.D.$_{260}$ units.

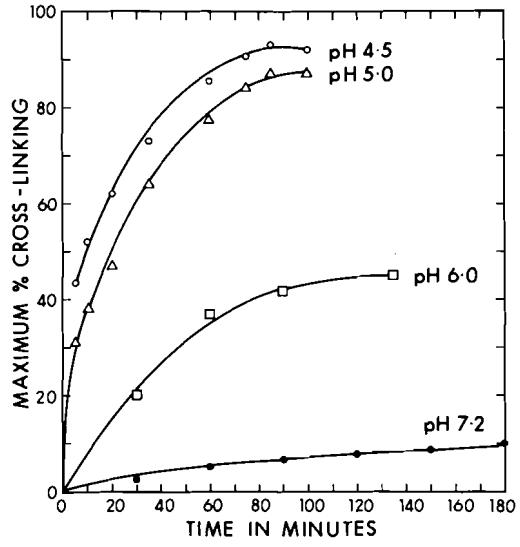

FIG. 2. The p*H* dependence of covalent cross-linking of λ-DNA by 2,5-bis(aziridinyl)-3,6-dimethoxy-1,4-benzoquinone at a final concentration of 0.05 μg/μl. Reactions were carried out in *ca.* 1.0 *M* buffered aqueous solutions at 37 °C with a final DNA concentration of 1.40 O.D.$_{260}$ units.

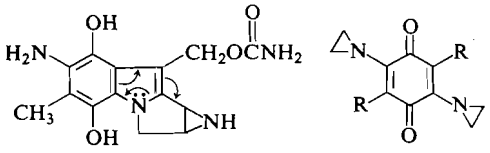
was found for the antibiotic mitomycin C. This evidence together with the close parallel between cross-linking and suppression of before-heat fluorescence (see Figs. 1 and 2) strongly suggest that the latter phenomenon is due to alkylation of DNA which does not lead to cross-links and is manifest by a destruction of potential ethidium intercalation sites. Several physical explanations are possible for the latter phenomenon, for example steric hindrance to approach of the ethidium or a referee has suggested quenching of the ethidium fluorescence by nearby bound drug or by drug modified bases. We are currently examining the physical cause by employing a range of ethidium analogs but meanwhile the decrease in before-heat fluorescence is used as a measure of single covalent attachment of drugs to DNA.

Freese and Cashel (23) have reported a small amount of induced cross-links in DNA by low p*H* alone. For example at p*H* 4.2 and at 25 °C their sample was cross-linked to the extent of 11% over a 2 h period. In our studies of p*H* dependence (Figs. 1 and 2) strict controls were run with λ-DNA at the corresponding p*H* but in the absence of the substrate. Over the time scale of our experiments no acid induced cross-linking was detected by the CLC assay.

The extent of alkylation as measured by the decrease in before-heat fluorescence showed a much more pronounced p*H* dependence than was found with mitomycin C (see Fig. 1). Similarly the concomitant covalent cross-linking of DNA by the aziridinoquinones shows a much more marked p*H* dependence than reduced mitomycin C (see Fig. 2). This reflects the structural differences; while the aziridine moiety of the activated mitosene **23** receives assistance to opening by conjugative interaction of the indole nitrogen lone pair at any p*H* value (4), the aziridine groups in **24** require protonation to assist alkylation.



23 **24**

Dependence of Extent of Covalent Cross-linking of DNA's by Aziridinoquinones on (G + C) Content of DNA

No evidence has as yet been presented for any base preference in the alkylation of DNA by aziridinoquinones. Therefore we examined

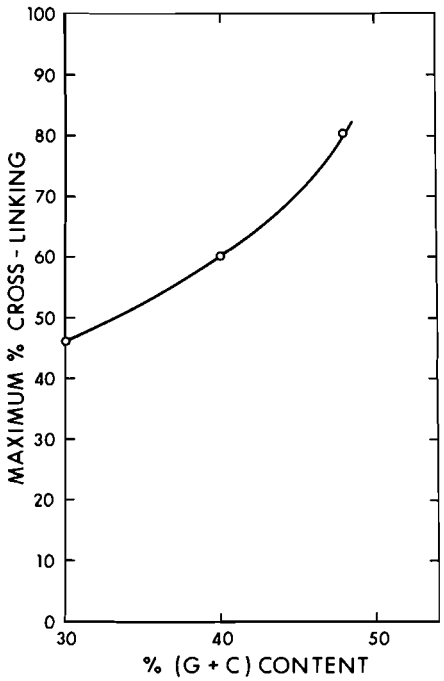


FIG. 3. The dependence of maximum percentage covalent cross-linking of DNA's by 2,5-bis(aziridinyl)-3,6-dimethoxy-1,4-benzoquinone (0.05 μg/μl) on the percentage (G + C) content of the DNA. The DNA's used were, *Clostridium perfringens* (30% G + C), mol. wt. 11.4×10^6; calf thymus (40% G + C), mol. wt. 10.8×10^6; *E. coli* (50% G + C), mol. wt. 14.8×10^6, with final concentrations respectively of 1.40, 1.145, and 1.03 $O.D._{260}$ units.

the interaction of **20** ($R = OCH_3$) with three different natural DNA's of different (G + C) content: *Clostridium perfringens*, 30%; calf thymus, 40%; and *E. coli* 50%. These three DNA's had comparable molecular weights as determined by sedimentation velocity studies and therefore their reactivity towards the aziridinoquinone could be compared directly. It may be seen from Fig. 3 that a direct correlation obtains between maximum extent of covalent cross-linking with higher (G + C) content for a given concentration of the cross-linking agents. Assuming a Poisson's distribution of the links and further that one link is sufficient to permit the spontaneous renaturation of the molecule an estimate of the average number of cross-links per molecule was made, $m = \ln(1/P_0)$ where P_0 is the proportion of the molecules unlinked as 0.62, 0.93, and 1.71 for the three DNA's. These are closely comparable with similar estimates made by Iyer and Szybalski (24) for mitomycin cross-linking. Recent work by Tomasz (25) rules out direct alkylation of the N-7 position of guanine by mitomycin C but does not exclude reaction at O-6 as originally suggested by Szybalski and Iyer (4). This may then apply to the aziridinoquinones.

Kinetics of Acid Assisted Ring Opening of Aziridinoquinones

The rate of acid assisted opening of **20** in 1 *M* sodium acetate buffers in the range p*H* 4.0 to 6.0 in 25% tetrahydrofuran – 75% water was determined spectrophotometrically employing concentrations comparable with those used for DNA cross linking by measuring the rate of appearance of the ring opened species **26** at 380 nm. Since attempts at product isolation at intermediate stages afforded only **20** or **26** it was concluded that the lifetime of **25** was very short under the solvolysis conditions and therefore its equilibrium contribution to the absorbance at 380 nm could be neglected to a first approximation (Scheme 4).

The pseudo unimolecular rate constants at different p*H* values are listed in Table 5. It may be seen that the p*H* dependence of the aziridine opening parallels the rate of covalent cross-linking (Table 5 and Fig. 2) and of alkylation of DNA (Fig. 1). It was shown in an independent experiment that the diacetate **26** in which the aziridine rings were opened did not cross-link DNA. Therefore the strong p*H* dependence of the cross-linking suggests, as expected, that the active species involved directly in covalent bonding to DNA is the intermediate aziridinium ion.

Correlation of Covalent Cross-Linking with Antineoplastic Activity

Having established a convenient procedure for detecting alkylation and covalent cross-linking of various DNA's by aziridinoquinones and other alkylating agents it is encouraging to observe that a fairly good correlation exists between the extent and rate of covalent cross-linking of DNA and antineoplastic activity against leukemia L1210 and several solid tumors (see Table 6). This parameter may prove useful for prescreening antitumor agents for clinical trials. It is recognized that other biological and pharmacological parameters, in addition to DNA covalent cross-linking (*i.e.* drug uptake,

partition, metabolism, and toxicity) contributes to the ultimate effectiveness of cancer inhibitory properties. Table 7 lists covalent cross-linking results for additional aziridinoquinones for which, as yet, no *in vivo* antitumor data is available.

Experimental

Melting points were determined on a Fisher-Johns apparatus and are uncorrected. The i.r. spectra were recorded on a Perkin-Elmer model 421 spectrophotometer and only the principal, sharply defined peaks are reported. The n.m.r. spectra were recorded on Varian A-60 and A-100 analytical spectrometers. The spectra were measured on approximately 10–15% (w/v) solutions usually in $CDCl_3$, with tetramethylsilane as a standard. Line positions are reported in p.p.m. from the reference. Mass spectra were determined on an Associated Electrical Industries MS-9 double focusing high resolution mass spectrometer. The ionization energy, in general, was 70 eV. Peak measurements were made by comparison with perfluorotributylamine at a resolving power of 15000. Kieselgel DF-5 (Camag, Switzerland) and Eastman Kodak precoated sheets were used for thin-layer chromatography. Microanalyses were carried out by Mrs. D. Mahlow of this department. First derivative e.p.r. spectra were measured on a Varian V-2503 spectrometer fitted with a V-4532 dual cavity operating at a nominal frequency of 9.5 GHz. The microwave power incident on the cavity was attenuated to 10 dB below maximum. Hyperfine couplings were measured by comparison with a peroxylamine disulfonate solution in the audio cavity. The triplet spacing of the standard was taken to be 13.0 Oe.

Materials

Ethidium bromide, calf thymus DNA, and α-amylose powder were purchased from Sigma Chemical Co., Sephadex G-100 superfine was from Pharmacia and DEAE cellulose was obtained from Whatman and washed before use.

4-Phenyl-2,3,4,7-tetraazobicyclo[3.3.0]oct-1-ene

A mixture of 6.14 g (60 mmol) of phenylazide and 5.60 g (60 mmol) of 3-pyrroline (75% pure) was set aside in the dark at ambient temperature for 3 weeks. The resulting precipitate was collected, washed with light petroleum, and recrystallized from ethyl acetate – petroleum ether to give **11***b* 6.75 g (57% yield) as a tan solid m.p. 111–112 °C.

Anal. Calcd. for $C_{10}H_{12}N_4$ (mol. wt. 188.1062): C, 63.81; H, 6.43; N, 29.76. Found 188.1072 (mass spectrum): C, 63.80; H, 6.19; N, 29.45.

The i.r. spectrum $\nu_{max}(CHCl_3)$: 3323 (NH); 1590 cm^{-1} (N=N). The n.m.r. spectrum $\delta_{TMS}(CDCl_3)$: 1.43 (s, 1H, NH); 2.68–3.60 (m, 4H, CH_2); 4.32 (dd, 1H, H_1, $J_{15} = 10$ Hz, $J_{18'} = 4$ Hz), 5.15 (dd, 1H, H_5, $J_{56'} = 6$ Hz); 6.80–7.60 (m, 5H, ArH).

*4-(p-Methoxyphenyl)-2,3,4,7-tetraazabicyclo[3.3.0]-oct-1-ene (**11***c*)

This compound was prepared in a similar fashion from 2.2 g (15 mmol) of *p*-methoxyphenylazide and 1.4 g (15 mmol) of 3-pyrroline (75% pure) in 30% yield as a white crystalline solid m.p. 108.5–109 °C.

6-Phenyl-3,6-diazabicyclo[3.1.0]hexane

A solution of 2.60 g (14 mmol) of 4-phenyl-2,3,4,7-tetraazabicyclo[3.3.0]oct-1-ene in 280 ml of tetrahydrofuran under nitrogen was irradiated with a Hanovia high pressure mercury lamp (200 W) fitted with a Pyrex filter with stirring and cooling for 6 h. The solvent was removed *in vacuo* and the residue extracted with hot ether (6 × 100 ml). The ether extracts were concentrated giving **12***b* as a red brown oil, 1.95 g (87% yield).

Mol. Wt. Calcd. for $C_{10}H_{12}N_2$: 160.1001. Found (mass spectrum): 160.1007.

The n.m.r. spectrum $\delta_{TMS}(CDCl_3)$: 1.65–2.07 (broad 1H, NH), 2.66 (s, 2H, methine); 2.75 (AB quartet, 4H, CH_2, $J = 12.5$ Hz); 6.65–7.34 (m, 5H, ArH). The absorption spectrum: 239 (log ε 4.75), 277 nm (log ε 3.90).

6-(p-Methoxyphenyl)-3,6-diazabicyclo[3.1.0]hexane

A solution of 0.906 g (4 mmol) of 4-(*p*-methoxyphenyl)-2,3,4,7-tetraazabicyclo[3.3.0]oct-1-ene in 120 ml of tetrahydrofuran under nitrogen was irradiated as described in the above procedure. The solvent was evaporated and the residue treated with 100 ml of ether. The resulting precipitate was filtered. The filtrate was evaporated and the residue crystallized from benzene – light petroleum affording **12***c* 0.742 g (98% yield) as an off-white solid, m.p. 36–38 °C.

Anal. Calcd. for $C_{11}H_{14}N_2O$ (mol. wt. 190.1106); C, 69.45; H, 7.42; N, 14.72. Found 190.1105 (mass spectrum): C, 68.90; H, 7.57; N, 14.67.

The n.m.r. spectrum $\delta_{TMS}((CD_3)_2CO)$: 2.79 (s, 2H, methine); 3.70 (s, 3H, OCH_3) 2.82 (AB quartet, 4H, methylenes, $J = 12.5$ Hz, 6.41–7.08 (m, 4H, ArH). The absorption spectrum (CH_3CN): 238 (log ε 4.21), 295 nm (log ε 3.30).

2,5-Bis-3'[-6'-p-bromophenyl-3',6'-diazabicyclo[3.1.0]-hexane]3-(β-carbamoyloxyethyl)-6-methyl-1,4-benzoquinone

A solution of 0.400 g (2.0 mmol) of freshly crushed cupric acetate monohydrate and 1.800 g (7.5 mmol) of 6-(*p*-bromophenyl)-3,6-diazabicyclo[3.1.0]hexane (23)

in 40 ml of methanol was purged with oxygen. While bubbling oxygen through the stirred solution, a solution of 0.313 g (1.5 mmol) of 2-(β-carbamoyloxyethyl)-5-methyl-1,4-benzoquinone (24) in 75 ml of methanol was added. The reaction mixture was stirred at room temperature for 2 days, then was concentrated to *ca.* 5 ml and subjected to chromatography on a neutral alumina (Woelm) column eluting with methanol. The dark red band was collected and concentrated and the residue was crystallized from ethyl acetate – light petroleum to afford **13***b* as a purple solid, m.p. 111–113 °C, which slowly turned brown on exposure to light and air.

Anal. Calcd. for $C_{30}H_{29}Br_2N_5O_4$ (mol. wt. 683): N, 10.25; Br, 23.39. Found (683, ebullioscopic): N, 9.89; Br, 23.05.

The i.r. spectrum ν_{max}($CHCl_3$): 3544, 3434 (NH_2), 1720 (carbamate C=O), 1585 cm^{-1} (quinone C=O). The absorption spectrum (CH_3CN): 248 (log ε 4.26), 282 (log ε 3.67), 396 (log ε 3.09), 503 nm (log ε 2.57). The e.p.r. spectrum (generated by treating a 1.2×10^{-2} *M* methanolic solution of **13***b* with sodium methoxide in air), developed a signal of maximum intensity in 30 min which persisted for 2½ h consisting of 10 lines h.f.s. 1.4–1.8 Oe of spectrum width 12.3 Oe.

2,5-Bis-3′-[6′-p-bromophenyl-3′,6′-diazabicyclo[3.1.0]-hexane]-3,6′dimethyl-1,4-benzoquinone

A similar reaction between 0.300 g (1.5 mmol) of freshly crushed cupric acetate monohydrate and 1.800 g (7.5 mmol) of 6-(*p*-bromophenyl)-3,6-diazabicyclo[3.1.0]-hexane (26) with 0.204 g (1.5 mmol) of 2,5-dimethyl-1,4-benzoquinone in methanol afforded **13***d* 0.511 g (56% yield) as a brownish purple solid, m.p. 107–110 °C, which slowly changed to a brown solid on exposure to light and air.

Anal. Calcd. for $C_{28}H_{24}Br_2N_4O_2$: N, 9.18, Br, 26.18. Found: N, 9.06; Br, 27.89.

The i.r. spectrum ν_{max}($CHCl_3$): 1588 cm^{-1} (C=O). The absorption spectrum (CH_3CN): 250 (log ε 4.70), 285 (log ε 3.88), 328 (log ε 3.63), 395 (log ε 3.33), 501 nm (log ε 2.76). The e.p.r. spectrum (generated by treating a 1.2×10^{-2} *M* methanolic solution of **13***d* with sodium methoxide in air), developed a signal of maximum intensity within 30 min which persisted for 2½ h and consisted of 11 lines, h.f.s. 1.4–1.7 Oe of total spectrum width 14.2 Oe.

2,5-Bis-3′-[6′-phenyl-3′,6′-diazabicyclo[3.2.0]hexane]-3-(β-carbamoyloxyethyl)-6-methyl-1,4-benzoquinone

A similar reaction between 0.400 g (2.0 mmol) of cupric acetate and 1.60 g (10.0 mmol) of 6-phenyl-3,6-diazabicyclo[3.1.0]hexane with 0.418 g (2.0 mmol) of 2-(β-carbamoyloxyethyl)-5-methyl-1,4-benzoquinone(24) in methanol afforded **13***a* as a red-brown solid from ethyl acetate – light petroleum, 0.892 g (85% yield), m.p. 80–83 °C, which slowly turned brown on exposure to air and owing to its instability was characterized spectroscopically.

The i.r. spectrum ν_{max}($CHCl_3$): 3546, 3426 (NH_2); 1725 (carbamate C=O); 1595 cm^{-1} (quinone C=O). The absorption spectrum (CH_3CN): 241 (log ε 4.58), 282 (log ε 3.92), 394 (log ε 3.22), 503 nm (log ε 2.72). The e.p.r. spectrum (generated from **13***a* as described above) developed a signal due to the semiquinone of maximum intensity in 30 min which persisted for 2½ h and consisted of 10 lines h.f.s. 1.5–1.8 Oe of total spectrum width 12.5 Oe.

2,5-Bis-3′-[6′-p-methoxyphenyl-3′,6′-diazabicyclo[3.1.0]-hexane]-3-(β-carbamoyloxyethyl)-6-methyl-1,4-benzoquinone

A similar reaction of 0.400 (2.0 mmol) of cupric acetate and 1.900 g (10 mmol) of 6-*p*-methoxyphenyl-3,6-diazabicyclo[3.1.0]hexane in 50 ml of methanol with 0.418 g (2.0 mmol) of 2-(β-carbamoyloxyethyl)-5-methyl-1,4-benzoquinone (27) afforded **13***c* 0.199 g (17% yield) as a purple solid from ethyl acetate, m.p. 98–103 °C which slowly turned brown on exposure to light and air.

Anal. Calcd. for $C_{32}H_{35}N_5O_6$: C, 65.63; H, 6.02; N, 11.96. Found: C, 65.11; H, 6.41; N, 9.99.

The i.r. spectrum ν_{max}($CHCl_3$): 3520 and 3418 (NH_2); 2826 (OCH_3), 1723 (carbamate C=O), 1568 cm^{-1} (quinone C=O). The absorption spectrum (CH_3CN): 242 (log ε 4.52), 290 (log ε 3.97), 397 (log ε 3.47), 506 nm (log ε 2.94). The e.p.r. spectrum (generated from **13***c* as described above) developed a signal of the semiquinone within 30 min which persisted for over 2 h and consisted of an unresolved singlet of spectrum width 5.8 Oe.

Synthesis of Aziridinoquinones

Most of the aziridinoquinones studied were prepared by published procedures (17). The general method is illustrated by the following example.

Preparation of Tetramethoxy-1,4-benzoquinone

A slurry of 24.5 g (0.1 mol) of chloranil in 75 ml of methanol was added to a solution of 9.8 g (0.42 mol) of sodium in 250 ml of methanol. During addition the temperature of the reaction mixture was kept at 15–25 °C by means of external cooling. The reaction mixture was then heated on a steam bath for 6 h. The cooled reaction mixture deposited bright orange crystals which were collected, washed with cold water, and taken up in dichloromethane. The solution was decolorized with charcoal, filtered and the solvent removed *in vacuo* to give bright orange crystals of the product, 16.7 g (73.2% yield), m.p. 133–134 °C (lit. (28) m.p. 135–136 °C).

Reaction of Tetramethoxy-1,4-benzoquinone with Aziridine

To a suspension of 1.05 g (5 mmol) of tetramethoxy-1,4-benzoquinone in 30 ml of methanol was added a solution of 0.280 g (65 mmol) of aziridine in 10 ml of methanol. The reaction mixture was stirred at room temperature for 2 days. The resulting reddish-brown 2,5-bis(aziridinyl)-3,6-dimethoxy-1,4-benzoquinone was collected by filtration, 0.875 g (79% yield), m.p. 189–190 °C (lit. (17*a*) m.p. 193–194.5 °C). The n.m.r. spectrum: δ_{TMS}($CDCl_3$): 2.28 (s, 8H, aziridinyl protons) and 3.92 (s, 6H, OCH_3).

New compounds prepared using these procedures include:—

(i) 2,5-Bis(2-methylaziridinyl)-3,6-dimethyl-1,4-benzoquinone in 63% yield, m.p. 147–150 °C.

Anal. Calcd. for $C_{14}H_{18}N_2O_2$: C, 68.29, H, 7.31, N, 11.38. Found: C, 68.21, H, 7.61; N, 11.72.

(ii) 2,5-Bis(2-ethylaziridinyl)-3,6-dimethyl-1,4-benzoquinone in 50% yield, m.p. 125–126 °C.

Anal. Calcd. for $C_{16}H_{22}N_2O_2$: C, 70.44; H, 8.03; N, 10.08. Found: C, 70.04; H, 8.54; N, 10.38.

For personal use only.

(iii) 4,5-Bis(2-methylaziridinyl)-1,2-benzoquinone in 47% yield, m.p. 135–138 °C.

Anal. Calcd. for $C_{12}H_{14}N_2O_2$: C, 66.05; H, 6.42; N, 12.85. Found: C, 65.85; H, 6.51; N, 13.01.

Fluorescence Assay for Detecting CLC Sequences and Monoalkylation

The general procedure employing a G. K. Turner and associates model 430 spectrofluorometer has been described previously. The assay mixture was prepared by mixing 2 ml of a 1 *M* K_2HPO_4–KOH buffer (at p*H* 12.0) with 0.2 ml of a 0.2 *M* solution of EDTA disodium salt (buffered at p*H* 8 with 2 *M* K_3PO_4) and with 0.05 ml of a 1 mg/ml solution of ethidium bromide in water. The resulting mixture was made up to 100 ml with distilled water and was covered with aluminum foil to protect it from the light. The instrument was blanked using 2 ml of the above solution. The cross-linking assays were carried out as follows.

Bicycloaziridinobenzoquinones

The cross-linking agents were added as 5 μg/μl solutions in 40% pyridine – 60% water. DNA was added as an aqueous solution. Reactions were buffered to p*H* 4.5 with 1 *M* sodium acetate – acetic acid buffer. Cross-linking reactions were carried out on a 60 μl scale. The reaction solutions were incubated at 37 °C and had concentrations of 1.06 $O.D._{260}$ units of λ-DNA, 0.05 *M* of buffer, 2.5 μg/μl of cross-linking agent and 20% pyridine; 10 μl aliquots were removed at timed intervals and analyzed for the extent of cross-linking by CLC assay described previously (3). A control reaction mixture prepared exactly as above but containing no cross-linking agent was run with each experiment. In no case was there evidence for acid induced covalent cross-linking.

Bisaziridinoquinones

A 10 μl aliquot of the cross-linking reaction mixture (*ca.* 5 μg/μl of alkylating agent in 25% tetrahydrofuran – 75% water, 1 *M* sodium acetate buffer and DNA) was diluted in 2 ml of the solution. Similarly a 10 μl aliquot was withdrawn from a reaction mixture containing no alkylating agent (control) and was diluted in 2 ml of the assay solution. The solutions were analyzed by the CLC assay described previously (3). A typical run is given in complete form for 2,5-bis(aziridino)-3,6-dimethoxy-1,4-benzoquinone at p*H* 5.0 with a concentration of 0.8 μg/μl.

Time (min)	Before-heat fluorescence*	After-heat fluorescence	% Cross-linking
0	70	3.5	0
5	64	12.5	19.5
10	60	17	28.3

150	10	8	80
180	9	6	67

*Control fluorescence = 70 constant throughout experiment.

Covalent Cross-Linking of DNA's with Different (G + C) Content with 2,5-Bis(aziridino)-3,6-dimethoxy-1,4-benzoquinone

The CLC assays were performed at p*H* 4.5 and 37 °C as described above using the following solutions of natural DNA's.

Clostridium perfringens DNA (30% G + C)

The assay mixture was prepared using 7 μl of the DNA stock solution ($O.D._{260}$ = 20), 5 μl of 1 *M* sodium acetate buffer p*H* 4.5, 8 μl of water, and 80 μl of a solution of **20** (R = OCH_3) in 25% aqueous tetrahydrofuran (final concentration of agent 0.05 μg/μl and final concentration of DNA was 1.40 $O.D._{260}$). The control was similar but lacked **20** (R = OCH_3).

Calf Thymus DNA (40% G + C)

The assay mixture was prepared using 30 μl of the DNA stock solution ($O.D._{260}$ = 4.58), 5 μl of 1 *M* sodium acetate buffer p*H* 4.5, 5 μl of water, and 80 μl of the solution of agent **20** (R = OCH_3) (final concentration of agent was 0.05 μg/μl and of DNA 1.145 $O.D._{260}$). Control as above.

E. coli DNA (50% G + C)

The assay mixture was prepared using 25 μl of the DNA stock solution ($O.D._{260}$, 1.03), 5 μl of 1 *M* sodium acetate p*H* 4.5, 5 μl of water, and 40 μl of a 25% aqueous solution of **20** (R = OCH_3) (final concentration of agent 0.05 μg/μl, and final concentration of DNA was 1.03 $O.D._{260}$). Control as above.

Assay for Covalent Cross-Linking of E. coli DNA using S_1-Endonuclease

E. coli DNA which had been covalently cross-linked with the bifunctional alkylating agent was dialyzed overnight at 40 °C *vs.* 10 m*M* potassium phosphate at p*H* 11.5, 0.1 m*M* EDTA, neutralized with 0.5 *M* tris hydrochloride p*H* 7.5 (~25 m*M*), and heat denatured (5 min at 95 °C then ice treatment). To 80 μl were added 20 μl 5 × S_1 buffer p*H* 4.5 (final p*H* about 4.6). After removal of the first aliquot, 2 μl of purified S_1-endonuclease (610 U/mg, 1.28 mg/ml) was added and the mixture incubated at 45 °C. Aliquots were removed and examined with ethidium bromide solution p*H* 8.0 and read as described previously. Heat denatured and native *E. coli* DNA's were incubated as controls.

Assay for Depurination of Radioactively Labelled Polynucleates Treated with 2,5-Bis(aziridino)-3,6-dimethoxy-1,4-benzoquinone

Poly dG.dC(^{14}CG).d(^{3}HC) 0.339 A_{260}/ml was incubated at 37 °C in 50 m*M* sodium buffer p*H* 5.0 with 360 μg/ml of 2,5-bis(aziridino)-3,6-dimethoxy-1,4-benzoquinone in 18% aqueous tetrahydrofuran. At intervals duplicate samples were removed, placed on Whatman filter discs, washed with 5% trichloroacetic acid, then twice with ethanol, dried, and counted. The results summarized in Table 4 show no loss of purine or pyrimidine bases accompany treatment of the DNA by the aziridinoquinone.

Kinetic Studies of the Rate of Acid Catalyzed Ring Opening of Aziridinoquinones

A 1.04 × 10^{-3} *M* solution of the 2,5-bis(aziridinyl)-3,6-dimethoxy-1,4-benzoquinone was prepared in 25% THF – 75% H_2O at room temperature and transferred in 160 μl aliquots to reaction tubes and then 10 μl of water, 20 μl of λ-DNA, and 10 μl of 1 *M* sodium acetate

buffer (of the appropriate p*H*) were added. The tubes were sealed with Parafilm and placed in a constant temperature bath. Several reaction tubes were withdrawn at convenient intervals, diluted with 25% THF – 75% H_2O to 5 ml and the concentration of 2,5-bis(2-acetoxyethylamino)-3,6-dimethoxy-1,4-benzoquinone was established by its absorbance at 380 nm. It was demonstrated that both the aziridinoquinone and the 2-acetoxyethylaminoquinone obeyed the Beer–Lambert Law in the optical density range of 0.02–0.4. Allowance was made for residual absorption at 380 nm due to the aziridine (see Table 8).

The reaction followed good first-order (pseudo unimolecular) kinetics for the formation of the diacetate the time dependence of which is shown in full for the run at p*H* 4.5 (see Table 9).

This research was supported by grants to J. W. L. from the National Cancer Institute of Canada, the National Research Council of Canada, and by the Department of Chemistry, University of Alberta. We thank Dr. A. Hogg and Mr. R. Swindlehurst for the mass and n.m.r. spectra, and Mrs. Talat Akhtar for the preparation of many intermediates.

General-base-catalyzed Proton Exchange in Glycocyamidiniom Ions: A Comparison of Activation by Protonation and by Alkylation

ROSS STEWART AND R. SRINIVASAN

Department of Chemistry, University of British Columbia, Vancouver, British Columbia V6T 1W5

Received April 28, 1975

ROSS STEWART and R. SRINIVASAN. Can. J. Chem. **53**, 2906 (1975).

The rates of exchange of methylene protons in seven glycocyamidinium ions in formate and chloroacetate buffers were measured in D_2O by means of proton magnetic resonance spectroscopy. When protonation and methylation of glycocyamidines occur at the same site the methylated products react faster than the protonated products by factors of 1.8–1.9. Replacing ring protons in glycocyamidinium ions by methyl groups causes small increases in the methylene exchange rate whereas corresponding substitution at the exocyclic nitrogen causes small rate decreases. It is concluded that in this reaction a quaternary ion ZR^+ can serve as a satisfactory model for the analogous conjugate acid ZH^+.

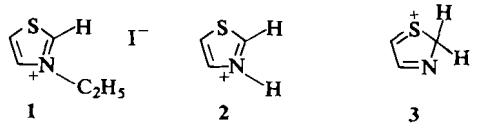
ROSS STEWART et R. SRINIVASAN. Can. J. Chem. **53**, 2906 (1975).

Faisant appel à la résonance magnétique nucléaire du proton, on a mesuré, dans des tampons de formiate et de chloracétate dans D_2O, les vitesses d'échange des deux protons du méthylène de sept ions glycocyamidinium. Lorsque la protonation et la méthylation des glycocyamidines se produisent au même niveau, les produits méthylés réagissent environ 1.8–1.9 fois plus rapidement que les produits protonés. Lorsqu'on remplace les protons du cycle d'ions glycocyamidinium par des groupes méthyles, il y a une légère augmentation dans la vitesse d'échange au niveau du méthylène; par ailleurs une substitution correspondante au niveau de l'azote exocyclique conduit à une faible diminution. On en conclut que dans cette réaction, un ion quaternaire ZR^+ peut servir comme modèle satisfaisant pour l'acide conjugué analogue ZH^+.

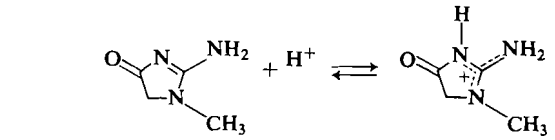
[Traduit par le journal]

The rate-controlling step in general-acid-catalyzed hydrogen exchange reactions can be either protonation of the substrate by general acids or abstraction of a proton from the conjugate acid of the substrate by general bases (1). Many heterocyclic compounds undergo exchange by the latter route and the reasonable assumption has sometimes been made that a quaternary salt ZR^+ can serve as a model for the corresponding conjugate acid ZH^+, and that the rate of proton abstraction from ZR^+ by a base will be equal to that for the conjugate acid. Thus, Coburn *et al.* (2) used the agreement between the directly measured rate of hydrogen exchange at the 2-position of 3-ethylthiazolium iodide, **1**, and the value calculated for protonated thiazole, **2**, in aqueous buffers, to support the idea that the exchange in thiazole occurs through **2** and not through the tautomeric *C*-protonated form **3**.

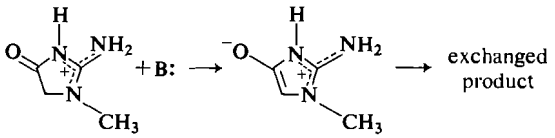
Other examples in heterocyclic chemistry of the use of quaternary salts as surrogates for conjugate acids are to be found in the work of Olofson and co-workers (3) on isothiazole exchange, Cox (4) on iodination of acetylpyridines, and Katritzky and co-workers (5) on exchange and substitution reactions of several heteroaromatic systems.



1 **2** **3**



[1] **4** **5**



We have previously studied the exchange of the methylene protons in creatinine, **4**, catalyzed by general acids and general bases. The general-acid route was rationalized in terms of eq. 1 and rates were obtained for the rate-controlling step, abstraction of a proton from position 5 of **5** by various bases (6). (The ring is numbered starting with the alkylated nitrogen atom.)

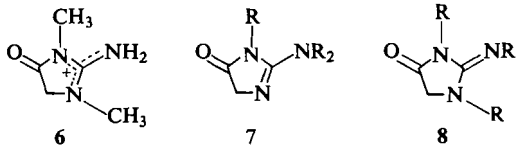
We now compare these rates with those for proton abstraction from the corresponding *N*-methylated quaternary salt **6**.



6 **7** **8**

The glycocyamidine system (7, 8), to which creatinine belongs, also includes compounds of type **7** and **8** and since these can give rise to cations having the same charge distribution as **5** and **6** we have also examined the reactivity of several of the protonated and alkylated derivatives of these compounds. The bases used in this work were formate ion and chloroacetate ion and the rates of proton abstraction from the methylene group of the various glycocyamidinium ions were determined in buffered D_2O by means of n.m.r. spectroscopy, as before (6).

Experimental

Acidity measurements were made on buffer solutions containing the dissolved substrate using a Radiometer model 26 p*H* instrument with an aqueous glass–calomel assembly. The electrode was calibrated with standard aqueous buffers; the p*D* values were obtained from the relationship p*D* = 'p*H* reading' + 0.40 (9).

Solvents and Reagents

The deuterated solvents, D_2O (99.7 atom% D) and aqueous solutions of NaOD were obtained from Merck, Sharp and Dohme of Canada Limited. Prior to use D_2O was heated to boiling and allowed to cool with a slow stream of nitrogen bubbling through it.

Chloroacetic acid and formic acid were purified by crystallization from benzene – petroleum ether and by distillation, respectively.

1-Methyl-2-amino-2-imidazolin-4-one (creatinine) (**4**) was purchased from Matheson, Coleman and Bell and purified by crystallization from aqueous ethanol.

2-Amino-2-imidazolin-4-one (9) hydrochloride was prepared as described previously (10), m.p. 208–210 °C dec. (lit. (7) m.p. 211–212 °C dec.).

1-Methyl-2-amino-2-imidazolin-5-one (**10**) was obtained by methylation of 2-amino-2-imidazolin-4-one (**9**) with iodomethane followed by neutralization of the resulting hydriodide salt, m.p. 228–231 °C dec. (lit. (8) 233–235 °C dec.).

1,3-Dimethyl-2-iminoimidazolidin-4-one (**11**) hydriodide was obtained by methylating creatinine (**4**) with iodomethane (8), m.p. 213–215 °C dec. (lit. (8) m.p. 213–215.5 °C dec.).

1,3-Dimethyl-2-methyliminoimidazolidin-4-one (**13**) hydriodide was obtained as described previously (8) and identified by conversion to its conjugate base (**13**), m.p. 72–74 °C (lit. (8) m.p. 71–73 °C).

1-Methyl-2-methylamino-2-imidazolin-4-one (**12**) was synthesized by isomerization of **11** (8), m.p. 197–199 °C (lit. (8) m.p. 196.5–198.5 °C).

2-Dimethylamino-2-imidazolin-4-one (**14**) hydriodide was prepared as described previously (8) and converted to its conjugate base (**14**) for purposes of identification, m.p. 228–232 °C dec. (lit. (8) m.p. 230–232 °C dec.).

Rate Measurements

The exchange of methylene protons was followed to about 70% completion at 34.5 °C (the probe temperature) with a Varian T-60 MHz spectrometer at a sweep width of 100 Hz, using the procedure outlined previously (6). The ionic strength was kept constant at 1.2 by addition of sodium chloride. The exchange rate measurements were made by dissolving the substrate in the conjugate acid form (**9′**, **10′**, **11′**, and **13′**) or in the free base form (**4**, **12**, and **14**). The concentration of the substrate was kept at about 0.32 *M*.

The exchange of methylene protons was followed by integrating the methylene proton signal periodically, the signal of non-exchanging *N*-Me protons serving as reference. If the n.m.r. tube was kept in the probe during the reaction with all the conditions held constant the intensity of the reference signal was found to be practically invariant. Consequently, the exchange of **9′** was followed by integrating only the methylene signal. The acidity of the medium did not change during the course of the reaction.

The exchange followed first-order kinetics. The observed first-order exchange constant, k_{obs}, was obtained by plotting the data according to equation 2.

$$[2] \qquad \ln \frac{R_t}{S_t} = k_{obs}t$$

R_t = average area of *N*-methyl peak(s) and S_t = average area of methylene peak both at time t. With **9′**, R_t was arbitrarily assigned a constant value. The reproducibility was better than ±10%.

Results and Discussion

On protonation or alkylation all three kinds of glycocyamidines represented by **4**, **7**, and **8** would be expected to give resonance-stabilized guanidinium cations, of which **6** is an example. Kenyon and Rowley (8) and others (6) have shown this to be so in several instances and, for protonation at least, is probably always the case.

The second-order exchange constant, k_2, for abstraction of proton from glycocyamidinium ion by carboxylate is obtained from k_{obs} (Equation 3) (6).

$$[3] \qquad k_{obs} = k_2\left(\frac{[D^+]}{[D^+] + K'_{SD^+}}\right)[A^-]$$

K'_{SD^+} = the equilibrium constant for dissociation of glycocyamidinium ion at 34.5 °C in D_2O, ionic strength 1.2 and $[A^-]$ = the concentration of carboxylate anion. Since the required pK'_{SD^+} values are available for creatininium ion (**4′**) only (pK'_{SD^+} = 5.41) (6) the difference between the pK'_{SD^+} and thermodynamic pK_{SD^+} value (water, 25 °C) (8) for cations **9′**, **12′**, and **14′** is assumed to be the same as that for creatininium ion (**4′**).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Rate measurements in formate and chloroacetate buffers were made at pD 4.3 and 3.8 respectively and at these pD values K'_{SD^+} is sufficiently smaller than $[D^+]$ that significant errors in k_2 are not introduced by the use of this assumption. The ratio, $[D^+]/[D^+] + K'_{SD^+}$, is taken to be unity for compounds **10′**, **11′**, and **13′**. For each of these $[D^+] \gg K'_{SD^+}$ (8). The pK_{DA} values for formate and chloroacetate were calculated from the general relation $pK_{DA} = 1.02\ pK_{HA} + 0.41$ (11).

It is found that under experimental conditions the exchange is almost completely accounted for by the loss of proton by glycocyamidinium ion to the carboxylate and self-catalysis is negligible as shown by studies of exchange rates at different concentrations of carboxylate (Table 1).

Scheme 1 shows the structures of the seven cations whose exchange rates in formate and chloroacetate buffers are given in Table 2 together with the structures of the neutral compounds that can give rise to them through protonation or methylation. Also listed are the average relative rates, based on the cation **9′**, calculated by averaging the relative rates found with formate and chloroacetate ions.

A number of interesting comparisons can be made using the results shown in Scheme 1.

1. When protonation and methylation occur at the same site, as they do for compounds **9**, **4**, and **12**, the alkylated products react faster than the protonated products by factors of 1.81, 1.73, and 1.89. (Compare cations **9′** and **10′**, **4′** and **11′**, and **12′** and **13′**.)

2. The effect of replacing the proton at position 1 in **9′** by a methyl group is to increase the rate by a factor of 1.68 (compare **9′** and **4′**) and the effect of a similar substitution at position 3 is 1.81 (compare **9′** and **10′**). The similarity in these two quantities suggests that any steric effects that might have been expected to be present because of the proximity of the N-1 alkyl group and the reactive methylene at C-5 are small.

3. The effects of alkyl substitution at the ring nitrogens is cumulative. The 1,3-dimethyl cation **11′** reacts 2.91 times as fast as the unsubstituted cation **9′**, which is close to the expected value of 3.04 (the product of the rates of the two monomethyl cations, **4′** and **10′**). Similarly the rate of 2.00 for the trimethyl cation **13′** is close to the expected value of 1.92 (the product of the rates of the monomethyl cation **10′** and the dimethyl cation **12′**).

4. Methyl substitution at the exocyclic nitrogen lowers the reactivity of the cation. The effects are smaller and less regular than those found

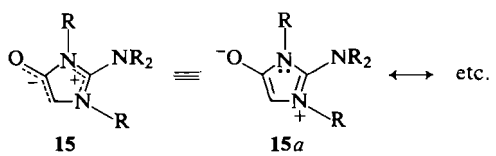
for substitution at the ring nitrogens but in all cases they are negative. (Compare cations **4′** and **12′**, **11′** and **13′**, and **9′** and **14′**.)

The modest deactivating effect on the rate of proton abstraction from the ring methylene group that results from substituting methyl for hydrogen in the exocyclic amino group of glycocyamidinium ions is not unreasonable. The cations would be expected to be stabilized by the inductive effect of methyl and, since the intermediate that is formed by proton loss is formally neutral, methylation should decrease the rate, as is observed. The intermediate, and the transition state leading thereto, is highly polar (see below) and the fact that a large amount of positive charge remains in the guanidinium portion of the system is doubtless the cause of the modest effects referred to in point 4, above .Two other systems that undergo analogous reactions, 4-acetylpyridinium ions (4) and 1,4,6-trimethylpyrimidonium ions[1] also show rate decreases when methyl replaces hydrogen.

In terms of the discussion above, the uniform rate increases that accompany methyl substitution at *ring* nitrogens are anomalous. A possible explanation for this effect follows. The formally neutral intermediate formed by proton loss from the methylene group of glycocyamidinium ions is, in fact, mesoionic, as shown in **15**.



[1]R. Srinivasan and R. Stewart. Unpublished results.

The aromatic character of the intermediate is apparent from a scrutiny of the canonical form **15*a***, which is a substituted imidazolium ion. The aromaticity of such species depends on the availability of an unshared pair of electrons on nitrogen and it is interesting to speculate that the inductive effect of methyl groups attached to the ring nitrogen atoms stabilizes the intermediate by this means. Though the effects are small they are regular and, regardless of the validity or otherwise of the above rationalization, the system provides an interesting example of alkyl substitution stabilizing neutral compounds to a greater degree than cations.

The results presented herein are in agreement with the generally held notion that quaternization activates a substrate towards proton loss elsewhere in the system to roughly the same degree as does protonation. The span of reactivities among the seven cations studied is a factor of less than four, with substitution of methyl for hydrogen increasing the reactivity of the ion in some cases and decreasing it in others.

The financial support of the National Research Council of Canada is gratefully acknowledged.

Reçu le 1 Avril 1975

J.-R. LLINAS, D. ROARD, M. DERBESY et E.-J. VINCENT. Can. J. Chem. **53**, 2911 (1975).

L'analyse de l'essence d'*Eriocephalae punctulactus* a permis d'isoler deux composés azuléniques. Leur structure a été déterminée sans ambiguité par spectroscopie r.m.n. comme étant celle du diméthyl-1,4 azulène et du diméthyl-1,4 éthyl-7 azulène. La r.m.n. du carbone-13 a confirmé ces structures et nous a permis de mettre en évidence sur ces composés ainsi que sur le guaiazulène (diméthyl-1,4 isopropyl-7 azulène) des effets de substitution du noyau azulénique.

J.-R. LLINAS, D. ROARD, M. DERBESY, and E.-J. VINCENT. Can. J. Chem. **53**, 2911 (1975).

Two azulene compounds were isolated from the extract of *Eriocephalae punctulactus*; their structures were determined unambiguously by n.m.r. as those of 1,4-dimethylazulene and 1,4-dimethyl-7-ethylazulene. These structures were confirmed by ^{13}C n.m.r. The effects of substitution in the azulene ring on the ^{13}C n.m.r. spectra were demonstrated using these compounds as well as guaiazulene (1,4-dimethyl-7-isopropylazulene).

[Journal translation]

Dans le cadre de l'analyse effectuée sur l'essence d'*Eriocephalae punctulactus* (encore appelée "plante bleue") en vue de déterminer ses principaux constituants (11), nous avons isolé et étudié deux composés présentant les charactéristiques principales des dérivés azuléniques (coloration bleue, absorption à 596–603 nm). La séparation de ces produits nécessite un fractionnement par distillation sur colonne bande tournante suivi d'une chromatographie sur colonne complété enfin par chromatographie préparative sur couche mince (11). Par spectroscopie d'absorption dans le visible, les concentrations dans l'essence ont été évaluées à 0.07% pour le dérivé **1** et 0.32% pour le dérivé **2**. L'analyse en résonance magnétique nucléaire du proton et du carbone-13 que nous allons décrire, nous a permis d'identifier ces deux produits comme étant le diméthyl-1,4 éthyl-7 azulène (dérivé **1**) et le diméthyl-1,4 azulène (dérivé **2**).

Partie expérimentale

Les spectres de résonance ^1H ont été enregistrés sur spectromètre R 32 opérant en mode locké à la fréquence de 90 MHz, en solution dans CCl_4 (15% v/v) et en présence de TMS pris comme référence interne. La température de la sonde est de 30 °C. Les déplacements chimiques ont été évalués avec une précision de ± 0.01 p.p.m. et les constantes de couplage à 0.1 Hz près, par simulation de spectre sur ordinateur HP 2100 à l'aide d'une version adaptée du programme LAOCOON III (9). Dans certains cas, la précision des mesures a été limitée par la présence de nombreux couplages à longue distance inférieurs à 0.2 Hz. Les mises en évidence d'effet Overhauser nucléaire ont été réalisées sur des solutions identiques préalablement dégazées. Les exaltations d'intensités observées ont été rapportées aux intensités maximales des signaux obtenus soit en l'absence d'irradiation, soit en présence d'une irradiation de même puissance à une fréquence nettement décalée par rapport à la résonance du pic irradié. Les valeurs obtenues ont été évaluées sur une dizaine d'intégrations.

Les déplacements chimiques du carbone-13 ont été obtenus à partir des spectres totalement découplés par bruit. Nous avons opéré sur un spectromètre NV-14 équipé d'une unité à transformée de FOURIER (8192 points) opérant à la fréquence de 15.087 MHz. Les composés ont été étudiés en solution dans $CDCl_3$, en présence de TMS choisi comme référence interne. Le spectre ^{13}C du dérivé **2** est rapporté dans la figure 4.

Analyse des spectres de resonance du ^1H

Les résultats sont consignés dans le tableau 1. L'analyse des spectres des dérivés **1** et **2** a été réalisée à partir des attributions relatives aux spectres de l'azulène (1, 5, 13) et de certains de ses dérivés (1, 2, 12, 13) et les dernières am-

biguités ont été levées à l'aide de manipulations de double irradiation.

Dérivé 1

Le spectre obtenu est très voisin de celui du guaiazulène (diméthyl-1,4 éthyl-7 azulène):

Région aromatique

On observe le même type de superposition de deux figures de type AB et ABX. Dans le système AB, le couplage J_{AB} (3.6 Hz) est caractéristique des couplages $^3J_{HH}$ mesurés sur les cycles à cinq chainons du noyau azulénique alors que dans le système ABX, le couplage J_{AB} obtenu (10.5 Hz), est lui caractéristique du cycle à sept chainons (1, 3).

Région aliphatique

Deux groupements méthyles résonnent aux mêmes fréquences que les homologues du guaiazulène, un groupement éthyle se substituant dans le spectre au groupement isopropyle. Le spectre ayant été totalement analysé, l'attribution de chacun des signaux a été faite en plusieurs étapes.

(*i*) L'irradiation du méthyle résonnant à 2.64 p.p.m. provoque, par suppression du couplage à distance, un affinement important du doublet à champ fort du système AB. Le méthyle irradié étant fixé en position 1, le proton observé est en position 2 sur le cycle à cinq chainons.

(*ii*) Le déplacement chimique très important du proton X du système ABX est caractéristique des positions 4 ou 8 (1). D'autre part, le couplage J_{AX} observé (1.9 Hz) est comparable au couplage $^4J_{H_6H_8}$ du guaiazulène (2.0 Hz). Il permet d'attribuer au proton A la position 6 et par conséquent, au proton B la position 5 si X est en 8, ou la position 7 si X est en 4.

(*iii*) L'ambiguité précédente a pu être levée en mettant en évidence la proximité du proton X et du groupement méthyle en position 1, à l'aide de l'effet Overhauser nucléaire. Une irradiation de faible puissance appliquée à 2.64 p.p.m. se traduit par une augmentation moyenne d'intensité de 12% au niveau du proton X. Cette valeur, bien qu'éloignée de l'effet n.O.e. maximum, est toutefois suffisante pour conclure à la proximité de ces groupements ce qui permet d'affecter la position 8 au proton X et donc aux protons A et B les positions respectives 6 et 5 (*cf.* Fig. 1).

(*iv*) L'attribution de la position 4 au second groupement méthyle repose sur la valeur très

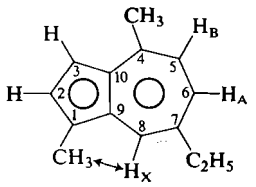

FIG. 1. Diméthyl-1,4 ethyl-7 azulène (dérivé **1**).

élevée de son déplacement chimique (2.80 p.p.m.), valeur comparable à celle observée pour le guaiazulène (2.73 p.p.m.) et pour le triméthyl-4,6,8 azulène (2.98 p.p.m.) (4). Cet effet de déblindage s'explique essentiellement par une densité électronique réduite en position 4 et 8 (4, 1, 5).

Il en résulte que le groupement éthyle restant est fixé en position 7. Ces dernières attributions seront confirmées par l'analyse des effets de substitution observés en r.m.n. du ^{13}C. La structure ainsi déterminée est celle du chamazulène (diméthyl-1,4 éthyl-7 azulène).

Dérivé 2

La partie aliphatique du spectre du dérivé **2** fait uniquement apparaître deux groupements méthyles résonant aux mêmes fréquences que ceux du chamazulène et guaiazulène. Les six protons aromatiques constituent un massif complexe qui peut être analysé en deux figures superposées (*cf.* Fig. 2): (*a*) un sous-spectre de type AB: le couplage J_{AB} observé (3.8 Hz) permet de caractériser deux protons vicinaux du cycle à cinq chainons, un groupement méthyle étant donc substitué en position 1 sur

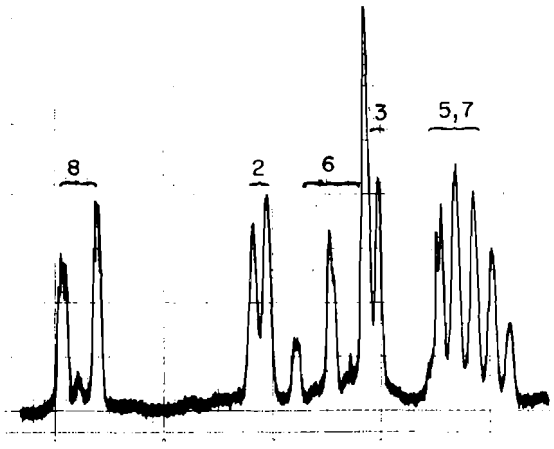

FIG. 2. Etalement de la partie aromatique du spectre ^1H du dérivé **2**.

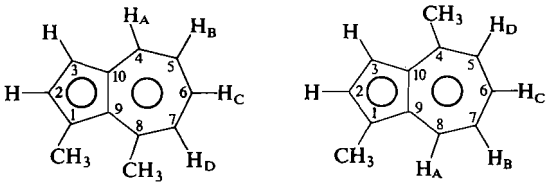

FIG. 3. Diméthyl-1,4 azulène (dérivé **2**).

le cycle. L'irradiation du groupement méthyle à 2.63 p.p.m. permet de mettre en évidence un couplage à distance entre ce méthyle et le proton à champ fort du système AB; ce groupement méthyle a été ainsi attribué à la position 1, et les positions 2 et 3, aux protons A et B. (*b*) Un sous-spectre ABCD pour lequel une analyse au second ordre nous a donné les couplages suivants:

$$J_{AB} = J_{BC} = 10.0 \text{ Hz}$$

$$J_{CD} = 9.7 \text{ Hz}$$

Ces couplages ne peuvent être que des couplages vicinaux $^3J_{HH}$ entre protons fixés sur le cycle à sept chainons. Deux structures restent alors possibles **2***a* et **2***b* (Fig. 3).

Cette dernière ambiguité a été levée par la mise en évidence d'un effet Overhauser nucléaire significatif entre le méthyle en position 1 et le proton A, le plus déblindé du système ABCD. Lorsqu'on irradie faiblement le groupement méthyle à 2.63 p.p.m., l'augmentation moyenne d'intensité du signal du proton A est de 15%, mesurée sur plusieurs intégrations. Cet effet n.O.e. traduit la proximité des deux espèces en présence; nous avons donc affecté la position 8 au proton A et les positions 7, 6 et 5 aux protons B, C et D.

Le dérivé **2** est donc identifié comme étant le diméthyl-1,4 azulène. L'analyse de certaines bandes d'absorption caractéristiques en spectroscopie u.v. est en accord avec les observations déjà réalisées sur le diméthyl-1,4 azulène et le diméthyl-1,4 éthyl-7 azulène (10). Toutefois, afin de confirmer la position des divers substituants fixés sur le noyau azulènique, nous avons étudié les mêmes molécules en r.m.n. du carbone-13.

Analyse des spectres de resonance du ^{13}C

Les résultats de l'analyse des spectres ^{13}C de l'azulène, du guaiazulène et des dérivés A et B sont consignés dans le tableau 2. L'identification des positions des substituants (sites 1, 4 et 7) a été réalisée à partir du spectre de l'azulène (4, 5,

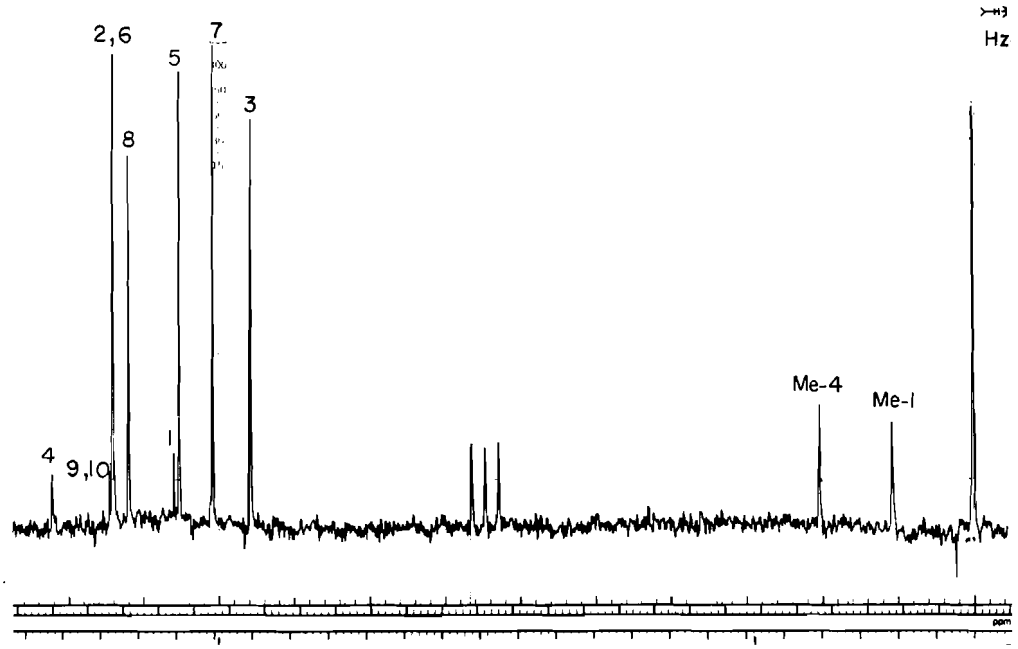

FIG. 4. Spectre ^{13}C du dérivé **2** totalement découplé en proton.

TABLEAU 3. Effets de substitution sur les déplacements chimiques des carbones 1, 4 et 7 rapportés aux carbones homologues de l'azulène

Composés	C_1	C_4	C_7
Azulène (δ ^{13}C)	118.1	136.5	122.7
Di-Me-1,4 azulène	+8.4	+9.5	−2.4
Di-Me-1,4 Et-7 azulène	+7.2	+7.8	+13.2
Di-Me-1,4 *i*Pr-7 azulène	+7.0	+7.7	+17.2

8) en tenant compte des observations suivantes. (*i*) La substitution d'un groupement méthyle sur le noyau azulénique se traduit par un déblindage d'environ 8 p.p.m. du carbone porteur, comme cela a été observé pour le triméthyl-4,6,8 azulène (4). (*ii*) Le déblindage est amplifié dans le cas de substitution par des radicaux éthyle ou isopropyle (14). (*iii*) L'intensité des signaux des carbones substitués est nettement plus faible que celle des carbones non substitués. Cette différence s'expliquant par la diminution du processus de relaxation de type dipole–dipole.

Les effets de substitution sur les carbones 1, 4 et 7 rapportés dans le tableau 3 sont très proches de ceux qui ont déjà été évalués sur les noyaux aromatiques (14). La valeur négative observée pour le carbone 7 du diméthyl-1,4 azulène traduit un effet de blindage en position δ des groupements méthyles. Pour chaque composé, les signaux intenses correspondants aux carbones 2, 6, 8, 3, 5 ont été attribués par des découplages sélectifs des différents protons liés à ces carbones. Les carbones 9 et 10 n'ont pu être définitivement attribués. L'étude en r.m.n. du carbone-13 vient donc compléter et confirmer sans aucune ambiguité les résultats acquis en r.m.n. du proton pour établir la structure des composés azuléniques extraits de la plante bleue.

Thermal Decomposition of Ammonium Metavanadate

K. C. KHULBE AND R. S. MANN

Chemical Engineering Department, University of Ottawa, Ottawa, Canada K1N 6N5

Received February 4, 1975

K. C. KHULBE and R. S. MANN. Can. J. Chem. **53**, 2917 (1975).

X-Ray, infrared, and electron spin resonance (e.s.r.) studies were made on the samples prepared by the thermal decomposition of ammonium metavanadate at various temperatures between 100 and 700 °C. A new intermediate compound has been identified to be formed between 100 and 150 °C. This new compound is stable up to 200 °C, and is a complex ammonium–vanadyl compound, since while the infrared studies showed the presence of an NH_4 group, and V—N bond, the e.s.r. gave the signal of VO^{2+} ions ($V^{4+} + O^{2-} = VO^{2+}$). A mechanism of the decomposition of ammonium metavanadate has been given.

K. C. KHULBE et R. S. MANN. Can. J. Chem. **53**, 2917 (1975).

On a étudié par rayons-X, infra-rouge et résonance paramagnétique électronique (r.p.e.) des échantillons préparés par décomposition thermique, à diverses températures entre 100 et 700 °C, de métavanadate d'ammonium. On a identifié qu'un nouveau composé intermédiaire se forme entre 100 et 150 °C. Ce nouveau composé est stable jusqu'à 200 °C et il s'agit d'un composé complexe de vanadyl–ammonium; cette conclusion découle des études i.r. qui montrent la présence d'un groupe NH_4 et d'un lien V—N et des études r.p.e. qui présentent un signal dû aux ions VO^{2+} ($V^{4+} + O^{2-} = VO^{2+}$). On donne un mécanisme de décomposition du métavanadate d'ammonium.

[Traduit par le journal]

Introduction

Ammonium metavanadate is generally the starting material in the preparation of vanadium compounds. The manufacture of vanadium pentoxide from ammonium metavanadate involves a series of chemical reactions (1–5). Although the thermal decomposition of ammonium metavanadate has been studied by several investigators, yet there is no general agreement on the course of the reaction. It has been established that a stable intermediate is formed, but it has not been positively identified and its physical characteristics are not reported. No electron spin resonance (e.s.r.) or infrared studies have been reported on the products formed by the thermal decomposition of ammonia metavanadate at various temperatures. In the present paper, we report the results obtained by e.s.r., X-ray, and infrared techniques on the vanadium compounds prepared by the thermal decomposition of ammonium metavanadate between 100 and 700 °C.

Experimental

Vanadium pentoxide was prepared by the thermal decomposition of ammonium metavanadate (Sample A). Ammonium metavanadate (Baker Analyzed Reagent) was dissolved in a minimum quantity of warm distilled water, and the solution evaporated over a hot plate with a magnetic stirrer, at low heat. The residue was dried for 12 h at 60 °C. The temperature was increased in stages to 100, 150, 200, 250, 300, 400, 500, 600, and 700 °C and maintained at each of the temperatures for 24 h. The samples were taken from the bulk at these temperatures before the temperature was raised to the next level, Samples B, C, D, E, F, G, H, I, and J refer to the samples obtained by the decomposition of ammonium metavanadate at 100, 150, 200, 250, 300, 400, 500, 600 and 700 °C respectively. The e.s.r. measurements were carried out using a Bruker 416 spectrometer in which the microwave frequency was in the X-band, g value was calculated by comparison with the g value of the free radical DPPH (2.003). The Phillips defractometer was used for the X-ray analysis of the samples. Measurements were carried out by the Debye–Sherrer method at room temperature using a Cobalt target and an iron filter. Infrared absorption spectra were observed on a Perkin-Elmer model 421 spectrophotometer. The samples were formed into discs with KBr (0.5% sample in KBr).

Results and Discussion

X-Ray Analysis

Table 1 gives the results of the X-ray analysis of the samples prepared by the thermal decomposition of ammonium metavanadate at various temperatures. At 250 °C, all ammonium metavanadate was decomposed and pure V_2O_5 was formed. No other phases (that is other oxides of vanadium) appeared to be present at or above 250 °C. The color of the mass changed from light yellow to dark yellow as the temperature

TABLE 1. X-Ray analysis of the products obtained by thermal decomposition of ammonium metavanadate at different temperatures and g value of different samples

Samples	Temperature (°C)	Identified phases	g
A (ammonium metavanadate)	Room temperature	Ammonium metavanadate	
B	100	Ammonium metavanadate	
C	150	Unidentified (X)	1.968
D	200	Unidentified (same as C)	1.965
E	250	Vanadium pentoxide	1.965
F	300	V_2O_5	1.965
G	400	V_2O_5	1.964
H	500	V_2O_5	1.965
I	600	V_2O_5	1.965
J	700	V_2O_5	1.968

was raised. The products obtained by the decomposition of ammonium metavanadate at 150 and 200 °C could not be identified specifically by X-ray analysis, though they appeared to be the same as indicated by their similar X-ray diffraction pattern. Table 2 shows the d-values and intensity of lines of the unidentifiable product. Thus X-ray analysis showed beyond doubt that a new compound really formed between 100 and 200 °C, though it could not be specifically identified. Lamure and Colin (5) studied the pyrolysis of ammonium metavanadate and reported the formation of bivanadate ($2V_2O_5 \cdot O(NH_4)_2$) and trivanadate ($3V_2O_5 \cdot O(NH_4)_2$) preceding the formation of V_2O_5. Taniguchi and Ingraham (1) studied the thermal decomposition of ammonium metavanadate at 225 °C and reported the compound's formula as $(NH_4)_2 \cdot O \cdot V_2O_5$. But the X-ray analysis data obtained for $(NH_4)_2 \cdot O \cdot V_2O_5$ was not the same as that obtained in the present investigation. It

is possible that the compound obtained by the decomposition of ammonium metavanadate in the temperature range of 150 to 200 °C was not the same as identified by Lamure and Colin (5) and Taniguchi and Ingraham (1).

Infrared Absorption Measurements

Figure 1 *a* and *b* show the infrared absorption spectra obtained for various samples. The spectra for sample A were very similar to that observed for sample B, which indicated that there was no structural change, when the temperature of pure ammonium metavanadate was raised to 100 °C and maintained at that temperature for 24 h. However when the temperature of ammonium metavanadate was raised to 150 °C and its (sample C) spectra observed, a definite change in its structure was noticed. The spectra for sample C was different from that observed for sample B. The spectra for samples C and D were identical, indicating that when the decomposition temperature was raised from 150 to 200 °C no noticeable structural change took place. When the decomposition temperature was raised from 200 to 250 °C a change in the structure and formation of a new compound was indicated by the spectra for sample E, which was different from the one observed for sample D. The spectra of all samples prepared by the decomposition of ammonium metavanadate at temperatures greater than 250 °C were identical to the one observed for sample E. This indicated that no structural change took place when the decomposition temperature was increased from 250 to 700 °C. The infrared spectra for samples B, C, and D show that as the temperature of decomposition was raised from 100 to 200, two new bands appeared. This band is entirely different from the one observed for ammonium

metavanadate in the region 600 to 1000 cm^{-1}. The peak observed at about 1010 cm^{-1} for samples B, C, and D is possibly due to V=O (6). This peak shifts towards higher frequency on raising the decomposition temperature on the formation of V_2O_5 (characteristic peak of V=O in V_2O_5 is 1020 cm^{-1}) (6–9) which indicates that the band strength of V=O strengthens with the increase of the decomposition temperatures. The characteristic peak of ammonia (NH_4), 1397 to 1400 cm^{-1} (10), disappeared totally at 250 °C. A comparison of the intensity and shape of the peak at 1010–1020 cm^{-1} for the samples B, C, D, and E indicates that the product obtained by the decomposition of ammonium metavanadate in the temperature range of 100–200 °C cannot be a mixture of the compound and V_2O_5. The peak observed for samples C and D at about 980 cm^{-1} may be attributed to V—O band with slightly weaker bonding strength (characteristic peak of V^+:O is 990 cm^{-1}) (6). The observed 825 cm^{-1} band in Figs. 1 and 2 is apparently due to the vibrations of the V—O—V bond (8, 9). The band in the region of absorption at 640–400 cm^{-1} is assigned to lattice vibrations. The band observed at around 750 cm^{-1} in samples C and D may be due to the V—N bond (11–13) but it is not possible to postulate at present as to what exactly is bonded to N, *i.e.* V—NO, V—NH_2, etc. (10, 11). Usually covalent nitrite gives a peak in this region (R—O—NO) (14). Taniguchi and Ingraham (1) observed that the

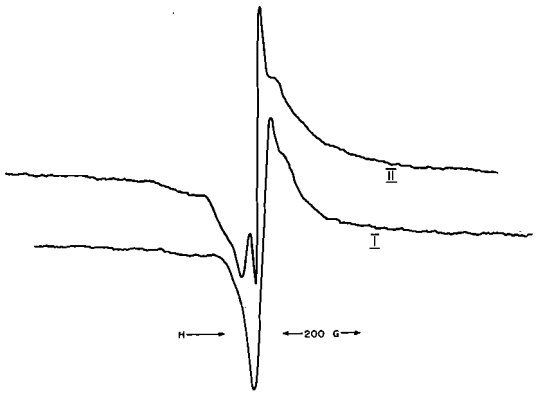

FIG. 2. Electron spin resonance spectra for samples C (I) and D (II).

amount of ammonia fell short of the theoretical value, *i.e.* some part of ammonia changed into nitrogen through either its oxidation or decomposition (15). The loss in weight of ammonium metavanadate to vanadium pentoxide was very small in the temperature range between 100 and 200 °C. Thus it can be concluded from infrared measurements that the compound formed during the thermal decomposition of ammonium metavanadate at temperatures greater than 100 °C and less than 200 °C should be a new compound of ammonia–vanadium–nitrogen–oxygen or a mixture of ammonia–vanadium–oxygen and vanadium–oxygen–nitrite.

Electron Spin Resonance Measurements

All samples gave e.s.r. signals except samples A and B. The thermal decomposition of ammonium metavanadate started at temperatures higher than 100 °C. Representative spectra for the samples C, D, H, and J are shown in Figs. 2 and 3. In studying the sequence of the spectra of the samples prepared by the thermal decomposition of the ammonium metavanadate at temperatures between 100 and 700 °C, it was observed that the two lines (a–a′) observed for samples D broadened to form a large broad line near the center of the spectral pattern (Fig. 2). The spectra observed for samples E, F, G, and H contained some broad lines (h.f.s.) (Fig. 3). These also disappeared as the samples were heated over 500 °C (samples H, I, and J). The spectra obtained for samples I and J were essentially similar.

Vanadium contains 99.8% of an isotope with a spin of 7/2 and should either give a spectrum consisting of eight components or one broad line of about 80 G observed in the absence of exchange interaction. The e.s.r. spectra in V_2O_5 is due to VO^{2+} ion in the unit structure VO^{2+}-$5O^{2-}$ (16). The VO^{2+} ion (3d′ electron configuration) is formed when a V^{4+} ion is bound to an oxygen ion by a strong, double covalent bond. The nature of this bond has been described in terms of molecular orbitals of the vanadyl pentahydrate complex ($VO^{2+}\cdot 5H_2O$) by Ballhausen and Gray (17). Table 2 gives the *g* values calculated (16) for all the samples. It appears that in all cases the spectra is due to VO^{2+} ions ($V^{4+} + O^{2-} = VO^{2+}$). The two lines observed at low temperature (*i.e.* 200 °C) are due to VO^{2+} ions. The sharp line (a) corresponds to perpendicular orientation of the internal magnetic field (*H*) and the electric field (*E*) of the VO^{2+} ions, whereas the broad, (a′), line corresponds to parallel orientation of (*H*) and (*E*). The lines are due to V^{4+} ions in the compound surrounded by six distorted O atoms. It seems from the i.r. and e.s.r. study that the new compound should be an ammonium vanadyl compound.

The line width increased for the samples C, D, E, and F; for samples G, H, I, and J, the line width remained constant. There are various factors affecting the line width. The magnetic dipole interaction is assumed to be the major factor (16). In other words the local fields produced by the nearest V^{4+} ions contribute mainly to the line width. The concentration of V^{4+} ions increases with the increase of temperature up to 300 °C and then remains constant.

Conclusion

During the thermal decomposition of ammonium metavanadate between 100 and 200 °C, a new intermediate compound has been identified

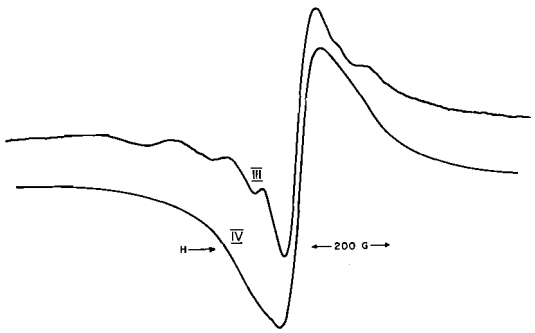

FIG. 3. Electron spin resonance spectra for samples H (III) and J (IV).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

from e.s.r., infrared, and X-ray studies. This new compound is stable up to 200 °C. While the infrared studies showed the presence of an NH_4 group and N—V bond, the e.s.r. gave the signal of VO^{2+} ions. It can thus be concluded that the new intermediate identified in the present study is a complex of vanadyl compound.

The following mechanism is possible for the decomposition of ammonium metavanadate.

The authors are grateful to the National Research Council of Canada for financial assistance for the project (A-1125). The authors wish to express their gratitude to Dr. A. Manoogian, Physics Department and Dr. J. L. Argo, Chemical Engineering Department, Ottawa University for useful discussions. The authors are also indebted to Mr. E. J. Murray of the Mineral Science Division of Mines Branch, Department of Energy, Mines and Resources for the X-ray analysis.

Electrochemistry of Ruthenium Ammine Complexes

C. M. ELSON,[1] I. J. ITZKOVITCH,[2] J. MCKENNEY,[3] AND JOHN A. PAGE
Department of Chemistry, Queen's University, Kingston, Ontario K7L 3N6

Received April 24, 1975

C. M. ELSON, I. J. ITZKOVITCH, J. MCKENNEY, and JOHN A. PAGE. Can. J. Chem. **53**, 2922 (1975).

The electrochemistry of ruthenium(III) penta- and tetraammine chloro complexes has been investigated. In each case, the ruthenium(III) species was found to undergo an initial one electron reduction step, followed by hydrolysis of the chloride(s) in the ruthenium(II) product. The rate constants for the substitution steps were evaluated by cyclic voltammetry. An aqueous 0.30 *M* methane sulfonate electrolyte of p*H* 2.0 was used at 25 °C.

Values for the reversible "$E_{1/2}$" (V *vs.* SCE) and first order rate constants for the (stepwise) replacement of the Cl^- are: $Ru(NH_3)_5Cl^+$, −0.282 V and 17 s^{-1}; *cis*-$Ru(NH_3)_4Cl_2^+$, −0.328 V, 80 s^{-1}, and 5 s^{-1}; *trans*-$Ru(NH_3)_4Cl_2^+$, −0.412 V, 2 s^{-1}, and 0.4 s^{-1}.

The electrochemistry of $Ru(NH_3)_5SO_2^{2+}$ was also investigated. In a 0.10 *M* CH_3SO_3H – 0.20 *M* CH_3SO_3Na electrolyte the ruthenium(II) species was found to undergo an initial one electron oxidation step with "$E_{1/2}$" = +0.50 V, followed by a slow hydrolysis of the SO_2 in the ruthenium(III) product with $k = 2.4 \times 10^{-2}$ s^{-1} at 25 °C.

C. M. ELSON, I. J. ITZKOVITCH, J. MCKENNEY et JOHN A. PAGE. Can. J. Chem. **53**, 2922 (1975).

On a étudié l'électrochimie des complexes penta- et tétraammine chloro du ruthénium(III). On a trouvé, dans chaque cas, que les espèces ruthénium(III) subissent en premier lieu une réduction impliquant un électron et que celle-ci est suivie par une hydrolyse des chlorures dans le produit ruthénium(II). On a évalué les constantes de vitesse des étapes de substitution par voltamètrie cyclique. On a utilisé une solution aqueuse 0.30 *M* d'électrolyte de méthane sulfonate à un p*H* de 2.0 et une température de 25 °C.

Les valeurs pour le réversible "$E_{1/2}$" (V *vs.* SCE) et les constantes de vitesse du premier ordre pour les remplacements successifs de Cl^- sont: $Ru(NH_3)_5Cl^+$, −0.282 V et 17 s^{-1}; *cis*-$Ru(NH_3)_4Cl_2^+$, −0.328 V, 80 s^{-1} et 5 s^{-1}; *trans*-$Ru(NH_3)_4Cl_2^+$, −0.412 V, 2 s^{-1} et 0.4 s^{-1}.

On a aussi étudié l'électrochimie du $Ru(NH_3)_5SO_2^{2+}$. On a trouvé que, dans un électrolyte 0.10 *M* CH_3SO_3H – 0.20 *M* CH_3SO_3Na, les espèces ruthénium(II) subissent en premier lieu une oxydation impliquant un électron avec un "$E_{1/2}$" = +0.50 V, et que celle-ci est suivie par une hydrolyse lente du SO_2 dans le produit ruthénium(III) avec $k = 2.4 \times 10^{-2}$ s^{-1} à 25 °C.

[Traduit par le journal]

Introduction

The solution chemistry of ruthenium ammine complexes has had considerable recent attention (1) and a number of recent papers have been concerned with the electrochemistry of these species (2–6). This paper extends the previous work and reports new electrochemical and kinetic results for $Ru(NH_3)_6^{3+}$, $Ru(NH_3)_5Cl^{2+}$, *cis*- and *trans*-$Ru(NH_3)_4Cl_2^+$, and $Ru(NH_3)_5SO_2^{2+}$.

Experimental

The electrochemistry experiments were carried out using a PAR Model 170 unit. The cell had an internal Pt counter electrode and a Luggin probe to a saturated calomel reference electrode. All potentials are relative to this reference. The cell was thermostatted at 25 °C and purified Ar (4) was used for deaeration.

The voltammetry with the hexaammine and Cl substituted species was carried out at a hanging mercury drop electrode (h.m.d.e.) formed at a Metrohm E410 Kemula type electrode assembly. The area of the electrode, calculated from the weight of the mercury and assuming a simple sphere, was 0.0355 cm^2. The voltammetry of the SO_2 substituted species involved more positive potentials and was carried out at a Pt disk electrode of area 0.0557 cm^2.

The voltammograms were recorded without filtering over a range of scan rates (v) and switching potentials (E_λ), with i.r. compensation at the faster scan rates. At high scan rates (0.1 V s^{-1} < v < 200 V s^{-1}) the output of the PAR 170 instrument was recorded using a Biomation Model 1015 Waveform Recorder (4096 words × 10 bits/word; 0.01 to 100 kHz sample rates). The compensation of the resistance between the reference electrode probe and the working electrode was achieved with the positive feedback network of the 170 instrument using

an oscilloscope to monitor the summing amplifier output. For a particular current range the compensation was adjusted to the maximum value consistent with amplifier stability under conditions of "zero" faradaic current through the cell. The voltammograms obtained were corrected for residual and charging current contributions by running the blank electrolyte at the same scan rate, then subtracting the observed currents from those obtained with the ruthenium ammines present in the electrolyte. The polarography at the dropping mercury electrode was done in the sampled mode without filtering. The drop time was controlled (t = 2 s) and a slow scan rate was used (v = 0.002 V s^{-1}). The apparatus and cell used for the controlled potential coulometric analysis have been described together with the specific ion electrode and cell used to monitor displaced Cl^- (7).

The starting material for the preparation of the various species was pure $Ru(NH_3)_6 \cdot Cl_3$ obtained from Johnson Matthey Chemicals Limited (Lot B/8). The preparation and characterization of the $Ru(NH_3)_5Cl \cdot Cl_2$ and the *cis*-$Ru(NH_3)_4Cl_2 \cdot Cl$ has been described (7) while the *trans*-$Ru(NH_3)_4Cl_2 \cdot Cl$ was prepared by the method of Gleu and Breuel (8) using an ICl oxidation of the *trans*-$Ru(NH_3)_4(SO_2)Cl \cdot Cl$. The absorption spectra of the chlorotetraammines was in agreement with the literature values (9). The *cis* isomer gave twin peaks at 312 and 352 nm (ε 1500 and 1300) and the *trans* isomer a peak at 330 nm (ε 4700).

The $Ru(NH_3)_5SO_2 \cdot Cl_2$ was prepared from the *trans*-$Ru(NH_3)_4(SO_2)Cl \cdot Cl$ again using a method of Gleu and Breuel (10). The procedure involved preparation of $Ru(NH_3)_5SO_3 \cdot 2H_2O$ by reaction of the starting material with dilute aqueous ammonia and precipitation from a cold solution with ethanol. The freshly prepared pentaammine derivative was then reacted with aqueous 3 *M* HCl at the boiling point, and the dark red $Ru(NH_3)_5SO_2 \cdot Cl_2$ precipitated from cold solution with ethanol.

The electrochemistry was studied in a noncomplexing methane sulfonate electrolyte prepared from reagent CH_3SO_3H and reagent NaOH. The work with the SO_2 complex was carried out in an acid 0.10 *M* CH_3SO_3H – 0.20 *M* CH_3SO_3Na electrolyte, while all the other complexes were studied in a 0.30 *M* CH_3SO_3Na electrolyte adjusted to p*H* 2.0 ± 0.1.

The solutions were prepared using weighed amounts of the salts and were 1–1.5 m*M* in ruthenium. The purity of the ruthenium(III) salts was verified by coulometric assay. In each case, electrolysis at a Hg cathode controlled at −0.50 V was clean and rapid with a negligible background. Results, expressed as apparent n values, for triplicate analyses with ~10 C amounts of the ruthenium(III) species were: $Ru(NH_3)_6Cl_3$ (1.03 ± 0.02), $Ru(NH_3)_5Cl \cdot Cl_2$ (1.02 ± 0.02), *cis*-$Ru(NH_3)_4Cl_2 \cdot Cl$ (0.98 ± 0.04) and *trans*-$Ru(NH_3)_4Cl_2 \cdot Cl$ (0.92 ± 0.05). Some water of hydration is indicated in the *trans* isomer.

The composition of the $Ru(NH_3)_5SO_2 \cdot Cl_2$ was verified by chemical analysis of the prepared salt. The results (N 21.6%, Cl 21.8%, S 10.0%) indicated a high degree of purity.

Results

The polarographic data are given in Table 1 while Figs. 1 and 2 show data obtained at various scan rates by cyclic voltammetry. The polarographic $E_{1/2}$ were determined from the intercept of a plot of log $(i/(i_d - i))$ *vs.* E_{dme}. The slopes of the plot are given for comparison with the expected −59.2 mV for a reversible one electron reduction process. The diffusion coefficients given were calculated from the observed i_d and the simple Ilkovic relation. In each case they agreed closely (±5%) with values calculated from the observed voltammetric $(i_p)_c$ and the Randles–Sevcik relation (11).

Ru(NH₃)₆³⁺

The behavior was consistent with a one electron charge transfer and a stable product

$$Ru(NH_3)_6^{3+} + e \rightleftarrows Ru(NH_3)_6^{2+}$$

Polarography of the ruthenium(III) species gave a well defined reduction wave, while cyclic voltammetry gave one cathodic peak on the forward scan with one anodic peak on the reverse scan. Over the range of scan rates studied $(i_p)_c$ varied directly as $v^{1/2}$, and both the peak current ratio $((i_p)_c/(i_p)_a)$ and the peak potential separation $(\Delta E_p = (E_p)_c - (E_p)_a)$ were just equal

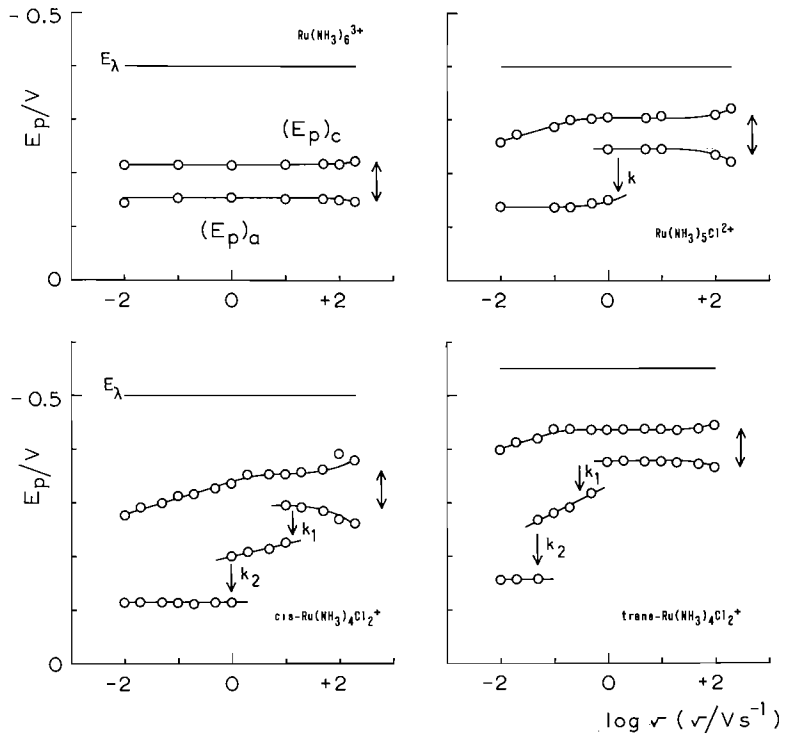

FIG. 1. Cyclic voltammetry of ruthenium(III) ammines: upper curve gives $(E_p)_c$ on forward scan, upper line indicates E_λ and lower curve(s) give $(E_p)_a$ on reverse scan, $\xrightarrow{k}$ indicates v leading to half reaction of ruthenium(II) products.

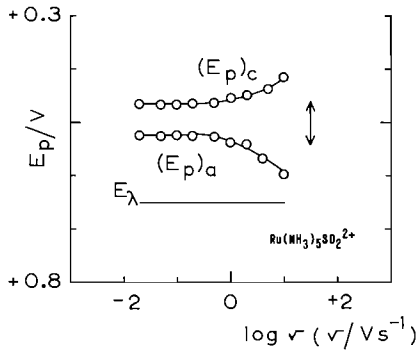

FIG. 2. Cyclic voltammetry of $Ru(NH_3)_5SO_2^{2+}$: lower curve gives $(E_p)_a$ on forward scan, lower line gives E_λ, and upper curve gives $(E_p)_c$ on reverse scan.

to those expected for a reversible cyclic process. There was some increase in ΔE_p at the highest scan rates, but this is probably an instrument response artifact. Controlled potential electrolysis at a Hg cathode at -0.50 V was found to produce $Ru(NH_3)_6^{2+}$ quantitatively. The quantity of electricity required was reproducible and in close agreement with the amount of $Ru(NH_3)_6Cl_3$ taken, while polarography of the resultant solution gave a well defined oxidation wave for the ruthenium(II) species.

$Ru(NH_3)_5Cl^{2+}$

The behavior was consistent with the steps:

$$Ru(NH_3)_5Cl^{2+} + e \rightleftarrows Ru(NH_3)_5Cl^+$$

$$Ru(NH_3)_5Cl^+ + H_2O \xrightarrow{k_1} Ru(NH_3)_5H_2O^{2+} + Cl^-$$

Polarography of the ruthenium(III) species gave a well defined reduction wave while cyclic voltammetry gave just one cathodic peak on the forward scan. With increasing scan rate $(E_p)_c$ shifted to more negative potentials although $(i_p)_c$ remained proportional to $v^{1/2}$. At the higher scan rates one anodic peak, assigned to the oxidation of the $Ru(NH_3)_5Cl^+$, was apparent on the reverse scan. Here the peak current ratio and the separation of the peak potentials were near the reversible value. As the scan rate was decreased the cathodic peak moved to less negative potentials and on the reverse scan an anodic peak

assigned to the oxidation of $Ru(NH_3)_5H_2O^{2+}$ appeared. This second anodic peak grew at the expense of the first so that at the slower scan rates only one anodic process was apparent on the reverse scan with a peak current equivalent to that of the cathodic peak on the forward scan.

Multicycle experiments on the $Ru(NH_3)_5Cl^{2+}$ at 0.1 V s^{-1} resulted in a limiting situation characterized by a major cathodic peak at −0.19 V, a minor cathodic peak at −0.29 V, and one major anodic peak at −0.13 V. This is in keeping with a reaction involving the oxidation and reduction of aquo species present in the layer of solution adjacent to the electrode. The reduction peak at −0.29 V persists as fresh $Ru(NH_3)_5Cl^{2+}$ is continually supplied by diffusion from the bulk solution.

Controlled potential coulometric electrolysis of the $Ru(NH_3)_5Cl^{2+}$ at −0.50 V was found to result in the displacement of the Cl^- and the quantitative formation of $Ru(NH_3)_5H_2O^{2+}$ (4). Polarography of the resultant solution gave one well defined oxidation wave while cyclic voltammetry at 0.1 V s^{-1} gave two peaks with $(E_p)_a = -0.132$ V, $(E_p)_c = -0.194$ V, and $(i_p)_a/(i_p)_c$ equal to the reversible value. Reoxidation of the solution by controlled potential coulometric electrolysis at −0.05 V was found to result in the quantitative formation of $Ru(NH_3)_5H_2O^{3+}$. Polarography of the oxidized solution gave one well defined reduction wave while cyclic voltammetry at 0.1 V s^{-1} gave two peaks with $(E_p)_c = -0.192$ V, $(E_p)_a = -0.120$ V, and $(i_p)_c/(i_p)_a$ equal to the reversible value.

cis and trans-$Ru(NH_3)_4Cl_2^+$

The behavior was consistent with the steps:

$$Ru(NH_3)_4Cl_2^+ + e \rightleftarrows Ru(NH_3)_4Cl_2$$

$$Ru(NH_3)_4Cl_2 + H_2O \xrightarrow{k_1} Ru(NH_3)_4(H_2O)Cl^+ + Cl^-$$

$$Ru(NH_3)_4(H_2O)Cl^+ + H_2O \xrightarrow{k_2} Ru(NH_3)_4(H_2O)_2^{2+} + Cl^-$$

For each isomer, polarography of the ruthenium(III) species gave a well defined reduction wave while cyclic voltammetry always gave one cathodic peak on the forward scan with $(i_p)_c$ proportional to $v^{1/2}$. At the higher scan rates only one current peak assigned to the reoxidation of the $Ru(NH_3)_4Cl_2$ was apparent on the reverse scan. Under these conditions the separation of the peak potentials were close to the reversible value. As the scan rate was continually decreased from the higher values a more positive anodic second peak assigned to the oxidation of $Ru(NH_3)_4(H_2O)Cl^+$ grew at the expense of the first peak and, in turn, this peak was eventually replaced by a still more positive third peak assigned to the oxidation of $Ru(NH_3)_4(H_2O)_2^{2+}$. At the lower scan rates only this third anodic peak was present with height equivalent to that of the cathodic peak on the forward scan.

Multicycle experiments were also carried out at 0.1 V s^{-1}. In the case of the *cis* isomer these gave, in the limit, a major cathodic peak at −0.18 V, a minor cathodic peak at −0.32 V, and one (major) anodic peak at −0.11 V. The behavior of the *trans* isomer was similar with the major cathodic peak at −0.23 V, the minor cathodic peak at −0.42 V, and the one (major) anodic peak at −0.16 V. These results are again in keeping with a situation where the cyclic processes giving the major peaks involve aquo species within the layer next to the electrode surface and the minor cathodic peaks result from the continual diffusion of fresh $Ru(NH_3)_4Cl_2^+$ to the electrode surface. The potentials associated with the various *cis* and *trans* isomers are sufficiently distinct that isomerization during the voltammetric experiment should be detectable. However experiments involving 20 consecutive cyclic scans at 0.02 V s^{-1} showed no current peaks other than those for the isomer taken.

Controlled potential coulometric electrolysis of the *cis*-$Ru(NH_3)_4Cl_2^+$ at −0.50 V was found to result in the quantitative formation of *cis*-$Ru(NH_3)_4(H_2O)_2^{2+}$. The substitution of the Cl^- groups evidently involves a ruthenium(II) catalyzed substitution in the ruthenium(III) species (7). Polarography of the reduced solution gave a well defined oxidation wave, while cyclic voltammetry at 0.1 V s^{-1} gave $(E_p)_a = -0.11$ V and $(E_p)_c = -0.18$ V with $(i_p)_a/(i_p)_c$ equal to the reversible cyclic value. A further electrolysis of the solution at −0.05 V resulted in quantitative oxidation to *cis*-$Ru(NH_3)_4(H_2O)_2^{3+}$.

Attempts to prepare *trans*-$Ru(NH_3)_4(H_2O)_2^{2+}$ by electrolysis of *trans*-$Ru(NH_3)_4Cl_2^+$ resulted in a displacement of the Cl^- and quantitative formation of ruthenium(II), but the cyclic voltammetric experiment on the reduced solution at 0.1 V s^{-1} gave two pairs of major peaks with $(E_p)_a = -0.11$ and −0.16 V and $(E_p)_c = -0.18$ and −0.24 V. If the peaks at −0.16 and −0.24 V are assigned to the *trans*

species, the peaks at −0.11 and −0.18 V would indicate some isomerization has taken place over the relatively long time required for the controlled potential reduction. Polarography of the reduced solution gave a well defined but drawn out oxidation wave with $E_{1/2} = -0.20$ V.

$Ru(NH_3)_5SO_2^{2+}$

The behavior was consistent with the steps:

$$Ru(NH_3)_5SO_2^{2+} - e \rightleftarrows Ru(NH_3)_5SO_2^{3+}$$

$$Ru(NH_3)_5SO_2^{3+} + H_2O \xrightarrow{k_1} Ru(NH_3)_5H_2O^{3+} + SO_2$$

The aquation of the ruthenium(III) species was found to be slow, and the aquo substituted product was not observed over the range of voltammetric experiments. At low scan rates the charge transfer step (on Pt) appeared reversible but irreversibility was indicated as the separation of the anodic and cathodic potentials increased with scan rate. However $(i_p)_a$ varied directly as $v^{1/2}$ over the range of scan rates, and the ratio $(i_p)_a/(i_p)_c$ remained near that for a reversible process.

The slow aquation step could be observed after a controlled potential electrolysis of the $Ru(NH_3)_5SO_2^{2+}$. Oxidation at a Pt anode at +0.64 V proceeded smoothly with a rapid exponential decay in i_a (Fig. 3). The solution color turned from brick red to purple, and coulometry indicated just *over* 1*F* of electricity per mol of ruthenium(II) taken. The solution, maintained with Ar bubbling through the electrolyte and the Pt electrode at +0.64 V, then slowly decolorized and the formation of the $Ru(NH_3)_5H_2O^{3+}$ was followed by analytical voltammetry at a h.m.d.e. Small portions of the electrolyte were withdrawn at intervals, and scanned from 0 to −1.0 V using a scan rate of 0.1 V s^{-1} after an initial hold at 0 V.

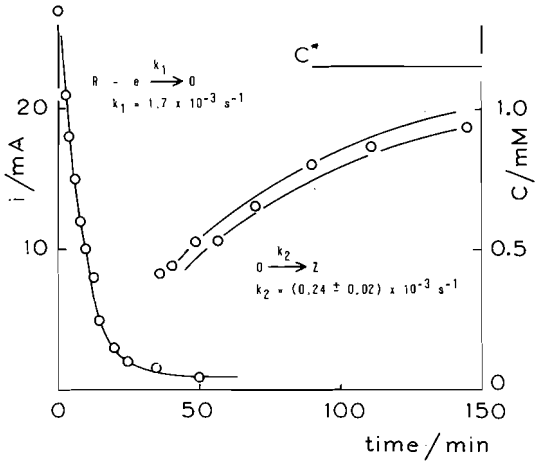

FIG. 3. Controlled potential oxidation of $Ru(NH_3)_5SO_2^{2+}$: Pt anode at +0.64 V; 1.15 m*M* $Ru(NH_3)_5SO_2^{2+}$. Left hand curve gives i_a as function of time. Right hand points give $Ru(NH_3)_5H_2O^{3+}$ concentration as function of time.

A well defined peak for the reduction of the ruthenium(III) aquo species was obtained and $(i_p)_c$ was related to the concentration through a calibration curve. Quantitative substitution without side reactions was indicated, and the nature of the product was confirmed both by the peak potentials on cyclic voltammetry and the u.v. absorption spectra of the solution. The substitution process was accompanied by small anodic electrolysis currents and this could be accounted for by the direct oxidation of the displaced SO_2 at the Pt anode. Most of the SO_2 would be removed from the system by the Ar gas flow, but some would be expected to react directly at the electrode. This possibility was indicated by voltammetry on SO_2 dissolved in the methane sulfonic acid electrolyte. On a Pt electrode the SO_2 gave an anodic peak with $(E_p)_a = +0.56$ V at a scan rate of 0.1 V s^{-1}. Integration of the electrolysis current over the whole experiment gave (in duplicate) 1.4 *F* of electricity per mol of ruthenium(II) taken.

It was found that the stepwise process occurring on electrolysis could be chemically reversed. A solution of $Ru(NH_3)_5(H_2O)^{3+}$ was prepared in the methane sulfonic acid electrolyte and SO_2 was passed through the solution. It immediately turned purple indicating the formation of $Ru(NH_3)_5SO_2^{3+}$, and then as bubbling continued it slowly turned to the brick red of $Ru(NH_3)_5SO_2^{2+}$.

Rate Constants

The first order rate constants for the substitution steps can be calculated from the voltammetric data and the values are given in Table 2.

For a reversible charge transfer step, followed by an irreversible chemical reaction (Nicholson and Shain, Case VI (12)):

$$O + e \rightleftarrows R \quad R \xrightarrow{k} Z$$

it can be shown that at 25 °C

$$(E_p)_c = \left\{E_{1/2} - 0.06708 \text{ V} + \frac{0.05916}{2} \text{V} \log k_1\right\} - \frac{0.05916}{2} \text{V} \log v$$

TABLE 2. Rate constants for substitution in ruthenium(II) ammines

	$E_{1/2}$* (V)	k_1 (s^{-1})	k_2 (s^{-1})
$Ru(NH_3)_5Cl^+$	−0.282	17 ± 2†	
		10 ± 4‡	
cis-$Ru(NH_3)_4Cl_2$	−0.328	81 ± 8†	6.0–4.5§
		73 ± 24‡	
trans-$Ru(NH_3)_4Cl_2$	−0.412	2.2 ± 0.2†	0.36–0.27§
		4.4 ± 2.1‡	

*$E_{1/2}$ estimated from rev $(E_p)_c$; $E_{1/2} = (E_p)_c + 0.028$ V.
†k_1 from [1]; limits correspond to ±0.005 V in $((E_p)_c - E_{1/2})$.
‡k_1 from v giving $(i_p)_a/(i_p)_c = 0.5$; limits correspond to ±0.1 v.
§k_2 from v giving $(i_p)_a' = (i_p)_a''$; limits correspond to $(\tau/1\text{–}\tau/0.75)$.

The relation assumes that there is no significant contribution from reoxidation of the substituted ruthenium(II) product at $(E_p)_c$. For each of the ruthenium(III) chloro species $(E_p)_c$ was plotted as a function of log v and a best straight line of slope −0.05916/2 V fitted to the data at low scan rates. Values of k_1 were calculated from the intercept of these plots and the estimated $E_{1/2}$.

The rate constant for the first substitution step can also be calculated from the peak current ratios observed on cyclic voltammetry. There is some difficulty in estimating $(i_p)_a$ since the reoxidation of the immediate product overlaps that of the substituted ruthenium(II) species but the scan rate that gave $(i_p)_a/(i_p)_c = 0.5$ was estimated. This corresponds to a value of $k_1\tau = 1.00$, where τ is the time in seconds required to scan forward from $E_{1/2}$ to E_λ on the cyclic voltammogram.

For the second substitution step in the ruthenium(II) tetraammines the same relations were used. In this case the scan rate that produced nearly equal peak heights for the oxidation of $Ru(NH_3)_4(H_2O)Cl^+$ and $Ru(NH_3)_4(H_2O)_2^{2+}$ was estimated from the cyclic voltammograms. A first estimate of the rate constant was then made on the assumption that this corresponded to a value of $k_2\tau = 1.00$. This assumes that the first substitution step is fast relative to the second; the assumption will give an estimate of the rate constant that is too large since ~25% more time is consumed in scanning from $E_{1/2}$ to the anodic peaks than is allowed for in the Nicholson and Shain relations. The rate constant was assumed to lie within the limits $1/\tau$ and $0.75/\tau$.

The rate constant for the aquation of the $Ru(NH_3)_5SO_2^{3+}$ was estimated from the voltammetric data obtained after controlled potential electrolysis of the $Ru(NH_3)_5SO_2^{2+}$. The results were fitted to the case:

$$R - e \xrightarrow{k_1} O \quad O \xrightarrow{k_2} Z$$

according to Frost and Pearson (13). A value of the electrolytic rate constant $k_1 = 1.7 \times 10^{-3}$ s^{-1} was first estimated from the slope of the linear ln i_a *vs.* t plot, and k_2 was then estimated by generating Z *vs.* t plots corresponding to various values of k_2. A value of $k_2 = (2.4 \pm 0.2) \times 10^{-4}$ s^{-1} was found to match the duplicate experimental results as shown in Fig. 3. The calculation ignored any back reaction involving the Z, it being assumed that the free SO_2 concentration was negligible as a result of displacement and electrolytic oxidation.

Discussion

The ruthenium(III) complexes were all found to undergo an initial one electron reduction process and formal reduction potentials derived from the observed peak potentials are listed in Table 3. The reduction process has been discussed by Movius and Linck (9) and involves a change in the metal from a t_{2g}^5 to a t_{2g}^6 electron configuration. The values reported are close to those reported by Lim *et al.* in a previous tabulation (5).

In these complexes it is seen that the presence of one or two Cl^- groups stabilizes the ruthenium(III) relative to the ruthenium(II) and this can be related to the σ donating ability of the Cl^-. The replacement of the Cl^- with neutral non-π-bonding species gives ruthenium(III) species that are more easily reduced with the H_2O more effective than the NH_3. This can be related to an inductive effect since H_2O is more capable of withholding electron density from the metal center. A comparison of the $Ru(NH_3)_4Cl_2^+$ species shows that the *trans* ruthenium(III) is more difficult to reduce than the *cis* isomer; here in the *trans* case there would be competition for the same metal electrons in σ bonding to the two Cl^-, but in the *cis* isomer this competition

TABLE 3. Formal reduction potentials of ruthenium complexes

*Value is average of $(E_p)_c$ and $(E_p)_a$ at scan rates where reversible behavior indicated (Fig. 1, 2).
†Value is average of $(E_p)_c$ and $(E_p)_a$ obtained at 0.1 V s^{-1} (see text).
‡$(E_p)_c$ not observed, value is $(E_p)_a$ −0.03 V (Fig. 1).
§Values in parentheses are previously reported values in noncomplexing electrolytes (5). All values will differ from actual E by 0.030 log $\{D_{ox}/D_{red}\}$ V (12).

would be minimized and the metal center would be more highly charged.

With the SO_2 ligand the ruthenium(II) pentaammine is highly stabilized relative to the ruthenium(III) species. The SO_2 group is sulfur bonded to the metal center (14) and the ruthenium(II) is stabilized by π back bonding from the metal to the ligand.

The rate constants for the hydrolysis reactions are given in Table 2 and are consistent with previous reports. For $Ru(NH_3)_5Cl^{+}$ Coleman *et al.* (2) have estimated $k = 6.3 \pm 0.3\ s^{-1}$ (25°) by voltammetry in a 0.171 *M* *p*-toluene sulfonic acid electrolyte. They found the rate constant to increase with decreasing acidity but interpreted the change as an ionic strength effect. Baxendale *et al.* (15) had previously estimated $k = 4.7 \pm 0.4\ s^{-1}$ (20°) using a pulse radiolysis technique and an aqueous 0.1 *M* methanol electrolyte. Our results were correspondingly reproducible and precise, but the larger spread reported results from the introduction of an estimate of the uncertainty in determining the peak potentials or the critical scan rate.

As far as the tetraammines are concerned previous estimates are uncertain. Movius and Linck (9) have estimated values from the slow absorptivity changes that followed the vanadium(II) reduction of the ruthenium(III) species. For the *cis*-ruthenium(II) species values of $k_1 = 16 \pm 8$ and $k_2 = 4 \pm 2\ s^{-1}$ were obtained. For the *trans* species estimates of $k_1 < 0.1$ and $k_2 < 0.1\ s^{-1}$ were made. These results were obtained in a 0.1 *M* *p*-toluene sulfonic acid electrolyte at 25°.

The present study gives significantly higher rates for the hydrolysis of the *trans* species although these remain significantly less than the rates for the corresponding *cis* species. Using the peak potentials observed in the cyclic voltammetry as a criteria, the reactions are stereospecific as observed by Ford and Sutton (16) in other ruthenium(II) substitution reactions. The hydrolysis rate observed with the *cis*-$Ru(NH_3)_4(H_2O)Cl^{+}$ is greater than that observed with the *trans*-$Ru(NH_3)_4(H_2O)Cl^{+}$ but comparable to that observed with $Ru(NH_3)_5Cl^{+}$. Thus the substitution of an NH_3 for an H_2O in a position *trans* to the Cl^{-} significantly increases the hydrolysis rate but substitution in the *cis* position has little effect. This is contrary to the behavior noted with $Co^{III}(en)_2XCl$ species (17, 18) but interpretation will require data for the hydrolysis of other $Ru^{II}(NH_3)_4XCl$ species.

The ruthenium(II) SO_2 species is stable to hydrolysis, but the ruthenium (III) complex undergoes a slow substitution in the acid solution in contrast to the inert ruthenium(III) chloro species.

Financial support in the form of a grant from the National Research Council of Canada and a graduate scholarship (C.M.E.) from the Province of Ontario are gratefully acknowledged.

The Crystal and Molecular Structures of Pyrazolyl-, 3-Methylpyrazolyl-, and Indazolylgallium Dimethyl Dimers

DAVID F. RENDLE, ALAN STORR, AND JAMES TROTTER

Department of Chemistry, University of British Columbia, 2075 Wesbrook Place, Vancouver, British Columbia V6T 1W5

Received April 7, 1975

DAVID F. RENDLE, ALAN STORR, and JAMES TROTTER. Can. J. Chem. **53**, 2930 (1975).

Crystals of the pyrazolylgallium dimethyl dimer (**1***a*) are monoclinic, $a = 16.914(3)$, $b = 21.747(6)$, $c = 8.117(2)$ Å, $\beta = 92.09(3)°$, $Z = 8$, space group $P2_1/c$, those of the 3-methylpyrazolylgallium dimethyl dimer (**1***b*) are also monoclinic, $a = 13.473(6)$, $b = 7.162(2)$, $c = 18.468(4)$ Å, $\beta = 113.78(2)°$, $Z = 4$, space group $P2_1/c$, and those of the indazolylgallium dimethyl dimer (**1***c*) are orthorhombic, $a = 8.909(2)$, $b = 27.463(3)$, $c = 15.738(2)$ Å, $Z = 8$, space group *Pbca*. All three structures were solved by Patterson and Fourier methods and were refined by full-matrix least-squares methods to final R values of 0.065, 0.061, and 0.036 for 2542, 2011, and 1986 reflections with $I \geq 3\sigma(I)$ respectively. The three crystal structure analyses emphasize the critical role of steric interaction in determining the molecular geometry for these molecules. The results clearly demonstrate that changing deuterium for methyl groups on the gallium atoms and introducing substituents on the bridging 'pyrazolyl' ligands in the $[D_2Ga{\cdot}N_2C_3H_3]_2$ dimer cause a pronounced flattening of the central Ga—(N—N)$_2$—Ga boat conformation and a noticeable lengthening of the Ga—N bonds. Average Ga—N distances are 1.996, 1.986, 1.996 Å, and V-angles (the angle between the $Ga_2N_2C_3$ moieties) are 131.5, 139.5, and 147.8° in **1***a*, **1***b*, and **1***c* respectively.

DAVID F. RENDLE, ALAN STORR et JAMES TROTTER. Can. J. Chem. **53**, 2930 (1975).

Les cristaux du dimère du complexe (**1***a*) du pyrazolyle avec le diméthyl gallium sont monocliniques, $a = 16.914(3)$, $b = 21.747(6)$, $c = 8.117(2)$ Å, $\beta = 92.09(3)°$, $Z = 8$, groupe d'espace $P2_1/c$ alors que ceux du dimère du complexe (**1***b*) du méthyl-3 pyrazolyle avec le diméthyl gallium sont aussi monocliniques, $a = 13.473(6)$, $b = 7.162(2)$, $c = 18.468(4)$ Å, $\beta = 113.78(2)°$, $Z = 4$, groupe d'espace $P2_1/c$ et ceux du dimère du complexe (**1***c*) de l'indazolyle avec le diméthyl gallium sont orthorhombiques $a = 8.909(2)$, $b = 27.463(3)$, $c = 15.738(2)$ Å, $Z = 8$, groupe d'espace *Pbca*. On a résolu ces trois structures par les méthodes de Patterson et de Fourier et on les a affinées par la méthode des moindres carrés (matrice complète) jusqu'aux valeurs finales respectives de R de 0.065, 0.061 et 0.036 pour 2542, 2011 et 1986 réflexions avec $I \geq 3\sigma(I)$. L'analyse de ces trois structures cristallines met en relief que les interactions stériques jouent un rôle critique pour déterminer la géométrie moléculaire de ces molécules. Les résultats permettent aussi de démontrer sans ambiguité que le remplacement, au niveau des atomes de gallium, de deutérium par des groupes méthyles et que l'introduction de substituants sur les ligands pyrazolyles dans le dimère $[D_2Ga{\cdot}N_2C_3H_3]_2$ produit premièrement un applatissement notable de la conformation bateau du Ga—(N—N)$_2$—Ga central et deuxièmement un allongement important des liens Ga—N. Pour les composés **1***a*, **1***b* et **1***c* respectivement, les distances Ga—N moyennes sont 1.996, 1.986 et 1.996 Å et les angles V (l'angle entre les deux portions de $Ga_2N_2C_3$) sont de 131.5, 139.5 et 147.8°.

[Traduit par le journal]

Introduction

A previous report (1) presented the first structural characterization of a member of the class of symmetrical dimeric compounds, *viz.* $[D_2Ga{\cdot}N_2C_3H_3]_2$, involving pyrazole ligands and Group III moieties, and containing as the central feature a six-membered M—(N—N)$_2$—M ring (where M = B, Al, or Ga). Crystal structures of numerous related pyrazolyl–borate and –gallate transition metal complexes have been published (refs. 2 and 3 and references therein) but these differ from the title compounds in having unsymmetrical six-membered M—(N—N)$_2$—M′ rings (where M = B, or Ga; M′ = transition metal) incorporating the Group III atom. The present investigation probes the steric effects of substituents, on both the gallium atoms and on the 'pyrazolyl' bridging moieties, on the geometry of the central symmetrical Ga—(N—N)$_2$—Ga rings in this class of compound. Three crystal structure determinations are described, pyrazolylgallium dimethyl dimer, $(Me_2Ga{\cdot}N_2C_3H_3]_2$, **1***a*; 3-methyl pyrazolylgallium dimethyl dimer, $[Me_2Ga{\cdot}N_2C_4H_5]_2$, **1***b*; and indazolylgallium dimethyl

dimer, $[Me_2Ga{\cdot}N_2C_7H_5]_2$, **1***c*. The results clearly demonstrate that changing deuterium for methyl groups on the gallium atoms and introducing substituents on the bridging ligands cause a pronounced flattening of the Ga—(N—N)$_2$—Ga boat conformation found in the original $[D_2Ga{\cdot}N_2C_2H_3]_2$ dimer (1).

Experimental

The three compounds studied were prepared[1] by reacting stoichiometric ratios of trimethylgallium and the "active-hydrogen" containing ligand in refluxing benzene solvent under an atmosphere of dry nitrogen. On cessation of methane evolution the benzene solvent was removed and the products recrystallized from toluene. The three compounds were air-stable and no precautions were necessary in mounting crystal samples for X-ray study.

*Crystallographic Studies of the Pyrazolylgallium Dimethyl Dimer (**1a**)*

The crystal chosen for study was mounted with c^* parallel to the goniostat axis and had dimensions of *ca.* 0.25 × 0.29 × 0.42 mm^3. Unit cell and space group data were obtained from film and diffractometer measurements. The unit cell parameters were refined by a least-squares treatment of $\sin^2\theta$ values for 16 reflections measured on a diffractometer with CuK$_\alpha$ radiation. Crystal data are: $C_{10}H_{18}Ga_2N_4$ f.w. = 333.7 Monoclinic, a = 16.914(3), b = 21.747(6), c = 8.117(2) Å, β = 92.09(3)°, V = 2983.5 Å^3, Z = 8 (2 molecules per asymmetric unit), ρ_c = 1.485 g cm^{-3}, $F(000)$ = 1344 (20 °C, CuK$_\alpha$, λ = 1.5418 Å, μ = 46.5 cm^{-1}.) Absent reflections: $0k0$, $k \neq 2n$ and $h0l$, $l \neq 2n$ define uniquely the space group $P2_1/c$ (C_{2h}^5, No. 14).

Intensities were measured on a Datex-automated General Electric XRD 6 diffractometer equipped with a scintillation counter, nickel filter, and pulse height analyzer. The θ–2θ scan technique was employed at a rate of 2° min^{-1} in 2θ. Data were measured to 2θ = 115° and a standard reflection was monitored every 40 reflections. The data were accordingly scaled, Lorentz and polarization corrections were applied, and the structure amplitudes derived. No absorption correction was applied because of the irregular crystal surface. Of the 4091 independent reflections measured, 1536 had intensities less than $3\sigma(I)$ above background where $\sigma^2(I) = S + B + (0.05S)^2$ with S = scan count and B = time averaged background count. These reflections were given zero weight in the refinement.

The structure was solved via the Patterson function and successive difference-Fourier syntheses. Two cycles of full-matrix least-squares refinement in which all nonhydrogen atoms were permitted anisotropic thermal motion reduced R to 0.070. A difference-Fourier synthesis at this point failed to reveal the majority of the hydrogen atom positions and so positions for the hydrogens were calculated assuming C—H 1.0 Å and ideal sp^2 and sp^3 geometry about the appropriate carbon atoms. Hydrogen atoms were placed in these positions, included in structure factor calculations (B = 6 Å^2), but not refined. Refinement converged with R 0.065 and R_w 0.085 [$R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$] for 2542 reflections with $I \geq 3\sigma(I)$. Thirteen reflections (−1 0 2, −1 −1 1, −5 −1 1, 2 0 0, 4 0 0, 6 0 0, 2 1 0, 4 1 0, 6 3 0, 0 4 0, 4 1 1, 5 1 1, and 4 0 2) were given zero weight in the last cycle of refinement because of suspected extinction effects. The function minimized in the refinement was $\Sigma w(|F_o| - |F_c|)^2$ with weights w derived from counting statistics. The scattering factors for the nonhydrogen atoms were taken from ref. 4 and those for H from ref. 5. Those for Ga were corrected for the real and imaginary parts of anomalous dispersion (6). The maximum shift to error ratio in the refined parameters at convergence was 0.95 (the U_{13} term of atom C(17)) while the average value was 0.21. The error in an observation of unit weight was 1.48.

*Crystallographic Studies of the 3-Methylpyrazolylgallium Dimethyl Dimer (**1b**)*

Experimental details for **1***b* are the same as for compound **1***a* except where noted. The crystal was mounted with b parallel to the goniostat axis and had dimensions of *ca.* 0.32 × 0.61 × 0.30 mm^3. Seventeen reflections measured with CuK$_\alpha$ radiation were employed in the refinement of the unit cell parameters. Crystal data are: $C_{12}H_{22}Ga_2N_4$ f.w. = 361.8 Monoclinic, a = 13.473(6), b = 7.162(2), c = 18.468(4) Å, β = 113.78(2)°, V = 1630.9Å^3, Z = 4, ρ_c = 1.473 g cm^{-3}, $F(000)$ = 736 (20 °C, CuK$_\alpha$, λ = 1.5418 Å, μ = 43.0 cm^{-1}). Absent reflections: $0k0$, $k \neq 2n$ and $h0l$, $l \neq 2n$ define uniquely the space group $P2_1/c$ (C_{2h}^5, No. 14).

Of the 2416 independent reflections measured with $2\theta \leq 120°$, 398 had intensities less than $3\sigma(I)$ above background.

The coordinates of the gallium atoms were deduced from a three-dimensional Patterson function, and the remainder of the atomic positions from successive difference-Fourier syntheses. The nonhydrogen atoms were refined with anisotropic temperature factors and R fell to 0.072. A difference-Fourier synthesis revealed the positions of the hydrogen atoms and these were included in the refinement with isotropic thermal parameters. Convergence was reached with R 0.061 and R_w 0.078 for 2011 reflections with $I \geq 3\sigma(I)$. Seven reflections (2 0 −6, 1 1 −5, 2 0 −4, 2 0 −2, 4 0 −2, 0 0 2, and 0 0 4) were given zero weight in the final cycle because of suspected extinction errors. The error in an observation of unit weight was 2.29. The mean shift to error ratio in the refined parameters was 0.48 and the largest was 1.98 (the temperature factor of H(9*c*)).

*Crystallographic Studies of the Indazolylgallium Dimethyl Dimer (**1c**)*

Experimental details for **1***c* are the same as for **1***a* again, except where noted. The crystal was mounted with a parallel to the goniostat axis and had dimensions of *ca.* 0.40 × 0.21 × 0.25 mm^3. Twelve reflections measured with CuK$_\alpha$ radiation were employed in the refinement of the unit cell parameters. Crystal data are: $C_{18}H_{22}Ga_2N_4$ f.w. = 433.8 Orthorhombic, a = 8.909(2), b = 27.463(3), c = 15.738(2) Å, V = 3850.7 Å^3, Z = 8, ρ_c = 1.496 g cm^{-3}, $F(000)$ = 1760 (20 °C, CuK$_\alpha$, λ = 1.5418 Å, μ = 37.5 cm^{-1}). Absent reflections: $0kl$, $k \neq 2n$, $h0l$, $l \neq 2n$, $hk0$, $h \neq 2n$ define uniquely the space group $Pbca$ (D_{2h}^{15}, No. 61).

Of the 2635 independent reflections measured with $2\theta \leq 115°$, 643 had intensities less than $3\sigma(I)$ above background.

The coordinates of the gallium atoms were again deduced from the Patterson function, difference-Fourier syntheses revealing the remainder of the molecule. The nonhydrogen atoms were refined with anisotropic temperature factors and R fell to 0.055. A difference-Fourier synthesis at this point revealed all the hydrogen atoms and they were included in the refinement with isotropic thermal parameters. At convergence R was 0.036 and R_w 0.052 for 1986 reflections with $I \geq 3\sigma(I)$. Six reflections (2 0 0, 0 4 0, 1 2 1, 0 0 2, 0 6 2, and 0 6 4) were given zero weight in the final cycle because of suspected extinction errors. The error in an observation of unit weight was 1.47 and the mean shift to error ratio in the refined parameters was 0.419. The largest ratio was 2.22 (the temperature factor of H(16*b*)). Measured and calculated structure factors have been placed in the Depository of

Unpublished Data.[2] Final atomic coordinates and thermal parameters for all three compounds are listed in Tables 1 and 2 respectively.

Results and Discussion

The three compounds contain as the central feature a six-membered Ga—(N—N)$_2$—Ga ring in the boat conformation. A previous study (1) reported the first example of this class of compound and the present investigation emphasizes the critical role of steric interactions, between the gallium methyl groups and substituents on the pyrazolyl rings, in determining the molecular geometry for these molecules. Stereoscopic views of the three molecules are shown in Fig. 1. Figure 2 shows stereoscopic views of the three unit cells. Bond lengths and valency angles are given in Tables 3 and 4 respectively and Table 5 gives selected mean planes and dihedral angles. Table 6 compares a number of parameters with similar data obtained for $[D_2Ga{\cdot}N_2C_3H_3]_2$ (1) and $[Me_2Ga{\cdot}N_2C_5H_7]_2$ (7), and Table 7 lists some important intramolecular nonbonded distances. As there are no significant differences of real importance between the two independent molecules in **1***a*, only one is shown in Fig. 1 and referred to in the tables of bond distances and valency angles.

[2]The structure factor table is available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Canada K1A 0S2.

[a]Distances quoted for one independent molecule only.

The three molecules exhibit structures predicted on the basis of the previous study on the dimer, $[D_2Ga{\cdot}N_2C_3H_3]_2$ (1). They all contain a central boat conformation for the Ga—(N—N)$_2$—Ga ring with a planar arrangement of bonds about the four nitrogen atoms and planar 'pyrazolyl' or 'indazolyl' groupings. This molecular arrangement allows delocalization of π-electrons in each of the bridging ligand moieties with consequent gain in stabilization energy. The deviation from a totally planar configuration for the molecules, an arrangement which would also allow delocalization of the π-electrons but one which is somewhat more strained, is indicated by the V-angles listed in Table 6. The larger the V-angle observed for a particular compound the flatter the boat conformation for the Ga—(N—N)$_2$—Ga ring, until at a V-angle of 180° a planar arrangement is attained. This trend to flatter boats and eventual planarity is thought to be the result of increasing steric demands within the molecules. The increasing steric requirements are reflected also in trends to larger values for the N—Ga—N angles and to longer Ga...Ga nonbonded distances. It may be noteworthy that generally in the molecules having the larger V-angles, the Ga—N distances are longer than the distance of 1.97 Å found normally in four-coordinate gallium compounds (8, 9). This may reflect a tendency in these systems to reduce steric interactions by *both* a flattening of the boat conformation *and* a lengthening and weakening of the Ga—N bond. Supportive evidence for this hypothesis is forthcoming in the observation that the most strained molecule, the planar $[Me_2Ga{\cdot}N_2C_5H_7]_2$ (7), having long Ga—N bonds, is slowly attacked by water to remove one of the bridging 'pyrazolyl' groups and thereby relieve steric tension. In contrast the three complexes of the present report are moisture stable.

Another aspect of this qualitative argument concerns the proximity of the equatorial gallium methyl groups to the carbon atoms in the ligands. These nonbonded distances in **1***a*, *b*, *c* are compared in Table 7 (the distances listed are not necessarily the shortest in each molecule, but involve equivalent atoms in all three molecules). In **1***a*, one might expect all distances quoted to be the same. They are slightly different, and the reason is probably that Ga(1) is not as far above the plane through N(3), N(4), N(6), N(7) as is Ga(4) (Table 5). In **1***b* and **1***c* marked differences in C...C distances appear. Instead of the distances associated with one gallium methyl group being approximately the same (as in **1***a*) they occur as one long and one short distance. In both cases the longer distance is the one associated with the substituted carbon in the 'pyrazolyl' ring, and the shorter distance with the unsubstituted carbon atom. The equatorial methyl groups on the gallium atoms are effectively crowded toward

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

the unsubstituted part of a bridging ligand. This effect is stronger in the case of **1***b* presumably because of the larger substituent (methyl group) on the 'pyrazolyl' ring. There are no intermolecular nonbonded contacts ≤ 3.5 Å in any of the structures. The failure to locate the hydrogen atoms in **1***a* may probably be attributed to, amongst other things, a lack of short inter- and intramolecular nonbonded contacts with consequent high thermal motion in the methyl groups. It is interesting to note that the calculated density of **1***c* is the highest of the three compounds, an unexpected occurrence, since the light atom/heavy atom ratio is higher than in **1***a* or **1***b*. This seemingly more efficient molecular packing in **1***c* would account for the ease with which all the hydrogen atoms in **1***c* were located and their superior refinement.

Received April 7, 1975

DAVID F. RENDLE, ALAN STORR, and JAMES TROTTER. Can. J. Chem. **53**, 2944 (1975).

Crystals of the 3,5-dimethylpyrazolylgallium dimethyl dimer $[Me_2Ga \cdot N_2C_5H_7]_2$ (**1***a*) are monoclinic, $a = 8.660(3)$, $b = 13.776(1)$, $c = 8.443(2)$ Å, $\beta = 112.45(2)°$, $Z = 2$, space group $P2_1/c$, and crystals of the hydroxy-bridged species $[Me_2Ga(OH)(N_2C_5H_7)GaMe_2 \cdot 2N_2C_5H_8]$ (**1***b*) are monoclinic, $a = 28.778(3)$, $b = 9.098(3)$, $c = 20.222(2)$ Å, $\beta = 100.72(1)°$, $Z = 8$, space group $C2/c$. Both structures were solved by Patterson and Fourier methods and were refined by full-matrix least-squares methods to final R values of 0.071 and 0.045 for 1443 and 2746 reflections with $I \geq 3\sigma(I)$ respectively. Molecules of **1***a* lie on crystallographic centers of symmetry, the central Ga—(N—N)$_2$—Ga ring being almost planar as a result of steric interactions between gallium-methyl groups and those on the 'pyrazolyl' rings. The mean Ga—N and Ga—C distances are 1.993 Å and 1.962 Å respectively. Compound **1***b* was formed by the attack of moisture on the strained dimer **1***a*. The central feature is a five-membered Ga_2N_2O ring, with two 3,5-dimethylpyrazole molecules hydrogen-bonded to it (N—H...O, O—H...N, 2.851 and 2.892 Å) and to each other (N—H...N, 2.907 Å). The five-membered ring adopts a slightly distorted envelope conformation, the angle between the Ga_2N_2 and N_2O moieties being 13.9°. The mean Ga—N and Ga—O distances are 1.989 and 1.934 Å respectively.

DAVID F. RENDLE, ALAN STORR et JAMES TROTTER. Can. J. Chem. **53**, 2944 (1975).

Les cristaux du dimère du complexe (**1***a*) du diméthyl-3,5 pyrazolyle avec le diméthyl gallium $[Me_2Ga \cdot N_2C_5H_7]_2$ sont monocliniques, $a = 8.660(3)$, $b = 13.776(1)$, $c = 8.443(2)$ Å, $\beta = 112.45(2)°$, $Z = 2$, groupe d'espace $P2_1/c$ et les cristaux des espèces (**1***b*) comportant des ponts hydroxyles $[Me_2Ga(OH)(N_2C_5H_7)GaMe_2 \cdot 2N_2C_5H_8]$ sont monocliniques, $a = 28.778(3)$, $b = 9.098(3)$, $c = 20.222(2)$ Å, $\beta = 100.72(1)°$, $Z = 8$, groupe d'espace $C2/c$. Chaque structure a été résolue par les méthodes de Patterson et de Fourier et on les a affinées par la méthode des moindres carrés (matrice complète) jusqu'à des valeurs finales de R respectives de 0.071 et 0.045 pour 1443 et 2746 réflexions avec $I \geq 3\sigma(I)$. Les molécules de **1***a* reposent au centre cristallographique de symétrie; le noyau Ga(N—N)$_2$Ga central est presque plan à cause des interactions stériques entre les groupes méthyles du gallium et ceux des cycles pyrazolyles. Les distances moyennes Ga—N et Ga—C sont respectivement de 1.993 et 1.962 Å. Le composé **1***b* se forme par attaque de l'humidité sur le composé **1***a* qui est très tendu. La caractéristique centrale de **1***b* est un cycle à cinq chaînons formé par Ga_2N_2O; deux molécules de diméthyl-3,5 pyrazole y sont liées par des ponts hydrogènes (N—H...O, O—H...N de 2.851 et 2.892 Å) qui les lient aussi entre elles (N—H...N, 2.907 Å). Le cycle à cinq chaînons existe sous forme d'enveloppe déformée; l'angle entre la position Ga_2N_2 et N_2O est de 13.9°. Les valeurs moyennes des distances Ga—N et Ga—O sont respectivement de 1.989 et 1.934 Å.

[Traduit par le journal]

Introduction

The preceding paper (1) describes the structural effects of substituting bulkier groups on both the gallium atoms and the pyrazolyl fragments in the dimer, $[D_2Ga \cdot N_2C_3H_3]_2$. In the three structures described, a pronounced flattening of the boat conformation of the central six-membered Ga—(N—N)$_2$—Ga rings was noted when compared to the arrangement observed in the deuterio complex (2). The present report describes, firstly, the structure of the 3,5-dimethylpyrazolylgallium dimethyl dimer, $[Me_2Ga \cdot N_2C_5H_7]_2$, **1***a*, in which the boat conformation of the central Ga—(N—N)$_2$—Ga ring is lost and, instead, an almost planar arrangement is adopted by the two gallium and four nitrogen atoms. Secondly, the report describes the structure of a novel compound $[Me_2Ga(OH)(N_2C_5H_7)GaMe_2 \cdot 2N_2C_5H_8]$, **1***b*, formed by the attack of moisture on the above strained dimer, $[Me_2Ga \cdot N_2C_5H_7]_2$. Steric interactions in this dimer are reduced by replacement of one of the bridging 3,5-dimethylpyrazolyl moieties with a bridging hydroxy group. The

novel structure which results has, as the central feature, a nonplanar, five-membered Ga_2N_2O ring. The molecular unit is completed by two hydrogen-bonded 3,5-dimethylpyrazole molecules which form a large heterocyclic ring incorporating the bridging hydroxy group and positioned approximately at right angles to the bridging 3,5-dimethylpyrazolyl moiety.

Experimental

Preparative and analytical data for the two compounds of this study, together with similar data for the three compounds of the preceding report, will be published in a forthcoming article.[1] Briefly, the 3,5-dimethylpyrazolylgallium dimethyl dimer was prepared by refluxing a benzene solution containing 1:1 stoichiometric amounts of gallium trimethyl and 3,5-dimethylpyrazole, the reaction being performed under a nitrogen atmosphere. The white solid product was recrystallized from toluene and a crystal, suitable for X-ray study, was mounted in a capillary tube under nitrogen. The tube was flame sealed to prevent reaction of the sample with atmospheric moisture.

The hydroxy species was first isolated when a sample of the dimer $[Me_2Ga{\cdot}N_2C_5H_7]_2$ which had been air-exposed for several months, was recrystallized from toluene solution. The crystals which were deposited were the hydroxy-bridged species, $[Me_2Ga(OH)(N_2C_5H_7)GaMe_2{\cdot}2N_2C_5H_8]$ rather than the expected dimer. This hydroxy-bridged species has since been prepared less serendipitously by reacting the original dimer with water and 3,5-dimethylpyrazole in toluene. Fractional crystallization of the resultant solution yields, firstly, unreacted 3,5-dimethylpyrazole (m.p. 107–108 °C), secondly, the hydroxy-bridged compound (m.p. ~87 °C), and, finally, unreacted dimer (m.p. 110–111 °C). A crystal of the hydroxy-bridged compound was mounted in a capillary tube for X-ray study.

Crystallographic Studies of the 3,5-Dimethylpyrazolylgallium Dimethyl Dimer (1a)

The crystal chosen for study was mounted with a^* parallel to the goniostat axis and had dimensions of *ca.* 0.51 × 0.23 × 0.45 mm³. Unit cell and space group data were obtained from film and diffractometer measurements. The unit cell parameters were refined by a least-squares treatment of $\sin^2\theta$ values for 16 reflections measured on a diffractometer with CuK_α radiation. Crystal data are:

$C_{14}H_{26}Ga_2N_4$ f.w. = 389.8

Monoclinic, $a = 8.660(3)$, $b = 13.776(1)$, $c = 8.443(2)$ Å, $\beta = 112.45(2)°$, $V = 930.9$ Å³, $Z = 2$, $\rho_c = 1.391$ g cm^{-3}, $F(000) = 400$ (20 °C, CuK_α, $\lambda = 1.5418$ Å, $\mu = 38.1$ cm^{-1}). Absent reflections: $0k0$, $k \neq 2n$ and $h0l$, $l \neq 2n$ define uniquely the space group $P2_1/c$ (C_{2h}^5, No. 14).

Intensities were measured on a Datex-automated General Electric XRD 6 diffractometer equipped with a scintillation counter, nickel filter, and pulse height analyzer. The θ–2θ scan technique was employed at a rate of 2 deg min^{-1} in 2θ. Data were measured to $2\theta = 145°$ and a standard reflection was monitored every 40 reflections. The data were accordingly scaled, Lorentz and polarization corrections were applied, and the structure amplitudes derived. No absorption correction was applied because of the irregular crystal surface. Of the 1841 independent reflections measured, 392 had intensities less than $3\sigma(I)$ above background where $\sigma^2(I) = S + B + (0.05S)^2$ with S = scan count and B = time averaged background count. These reflections were given zero weight in the refinement.

The structure was solved via the Patterson function and successive difference-Fourier syntheses. Two cycles of full-matrix least-squares refinement in which all non-hydrogen atoms were permitted anisotropic thermal motion reduced R to 0.086. A difference-Fourier synthesis at this point revealed the hydrogen atom positions and they were included in the refinement with isotropic thermal parameters. Refinement converged with R 0.071 and R_w 0.086 [$R_w = \Sigma w(|F_o| - |F_c|)^2 / \Sigma w|F_o|^2$] for 1443 reflections with $I \geq 3\sigma(I)$. Six reflections (1 0 0, 2 0 0, 4 0 0, 6 0 0, 8 0 0, and 0 2 0) were given zero weight in the final cycle because of suspected extinction errors. The function minimized in the refinement was $\Sigma w(|F_o| - |F_c|)^2$ with weights w derived from counting statistics. The scattering factors for the nonhydrogen atoms were taken from ref. 3 and those for H from ref. 4. Those for Ga were corrected for the real and imaginary parts of anomalous dispersion (5). The maximum shift to error ratio in the refined parameters at convergence was 1.45 (the x coordinate of H(3*a*)) while the average value was 0.16. The error in an observation of unit weight was 2.41.

Crystallographic Studies of the Hydroxy-bridged Species $[Me_2Ga(OH)(N_2C_5H_7)GaMe_2{\cdot}2N_2C_5H_8]$ (1b)

Experimental details for **1b** are the same as for compound **1a** except where noted. The crystal was mounted with b parallel to the goniostat axis and had dimensions of *ca.* 0.20 × 0.51 × 0.18 mm³. Twenty reflections measured with CuK_α radiation were employed in the refinement of the unit cell parameters. Crystal data are:

$C_{19}H_{36}Ga_2N_6O$ f.w. = 504.0

Monoclinic, $a = 28.778(3)$, $b = 9.098(3)$, $c = 20.222(2)$ Å, $\beta = 100.72(1)°$, $V = 5202$ Å³, $Z = 8$, $\rho_c = 1.287$ g cm^{-3}, $F(000) = 2096$ (20 °C, CuK_α, $\lambda = 1.5418$ Å, $\mu = 29.0$ cm^{-1}). Absent reflections: hkl, $h + k \neq 2n$ and $h0l$, $l \neq 2n$ define the space groups $C2/c$ (C_{2h}^6, No. 15) and Cc (C_s^4, No. 9).

Of the 3564 independent reflections measured with $2\theta \leq 115°$, 818 had intensities less than $3\sigma(I)$ above background. Intensity statistics (6) were calculated and they heavily favored the centrosymmetric space group $C2/c$. The vector distribution in the Patterson function was concurrent with this choice, providing the coordinates of both gallium atoms. All nonhydrogen atoms were refined with anisotropic thermal parameters and R fell to 0.065. A difference-Fourier synthesis revealed all the hydrogen atoms associated with carbon atoms and they were refined with isotropic temperature factors. The highest peaks in a subsequent difference-Fourier synthesis were close to O, N(3), and N(5) suggesting that hydrogen atoms were localized on these atoms. However, smaller peaks (approximately half the height of those mentioned above) were also found, close to O, N(4), and N(6) suggesting that throughout the crystal some asymmetric units may have hydrogen atoms localized on O, N(3), and N(5), and others may have them localized on O, N(4), and N(6). An attempt to include six hydrogen atoms in the refinement

with half-occupancies failed. With all other atoms fixed, a further attempt was made to obtain meaningful parameters for the six 'half-hydrogen' atoms by refining their coordinates, temperature factors, and occupancy factors. This resulted in occupancy factors of 0.75, 0.33, 0.75, 0.39, 0.57, and 0.30 for H(O1), H(O2), H(N3), H(N4), H(N5), and H(N6) respectively. The corresponding isotropic temperature factors were: 6.2, 0.1, 5.8, 2.6, 5.2, and 12.7 Å^2. This result certainly agrees with our assumption that the three hydrogen atoms assumed to be present are associated with atoms O, N(3), and N(5), and O, N(4), and N(6) throughout the crystal in the approximate ratio 2:1. This would appear to be a more feasible explanation than, say, rapid hydrogen exchange between O and N(3), O and N(6), and N(4) and N(5), a situation which would require elongated peaks of electron density between the three sets of atoms concerned, or at least a 1:1 correspondence in the peak heights of the two 'half-hydrogen' atoms localized on O and the single 'half-hydrogen' atoms localized on N(3), N(4), N(5), and N(6).

Since no real advantage was to be gained by refining six hydrogen atoms with partial occupancies, refinement was continued with three localized hydrogens on O, N(3), and N(5). Several low angle, high intensity reflections appeared to suffer extinction effects and, unlike compound **1***a*, the introduction and refinement of an extinction coefficient proved successful. The function now minimized was: $\Sigma w(|F_o| - \{|F_c|/(1 + gI)\})^2$ where g is the extinction coefficient and I is the uncorrected intensity of reflection. Two cycles of refinement brought convergence at R 0.045 and R_w 0.058. The average shift/error ratio in the refined parameters was 0.38 and the largest was 2.57 (the z coordinate of H(N5)). The final value for the extinction coefficient was $0.72(3) \times 10^{-6}$ and the error in an observation of unit weight was 1.66. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[2] Final atomic coordinates and thermal parameters for the two compounds are listed in Tables 1 and 2 respectively.

Results and Discussion

Numerous crystal structures of compounds incorporating pyrazolyl–borate (7) and pyrazolyl–gallate (8, 9) ligands in transition metal complexes have been reported recently. In addition, several crystallographic studies have been concerned with the related class of symmetrical dimer molecules incorporating a central Ga—(N—N)$_2$—Ga ring (1, 2). The present study is concerned with a member of this latter class of

compound, $[Me_2Ga{\cdot}N_2C_5H_7]_2$, and a novel hydroxy species derived from it, $[Me_2Ga(OH)(N_2C_5H_7)GaMe_2{\cdot}2N_2C_5H_8]$. The two molecules are shown in stereo in Fig. 1 and stereoscopic views of the unit cells for the two compounds are shown in Fig. 2. Bond lengths and valency angles are collected in Tables 3 and 4 respectively. Table 5 lists selected mean planes and dihedral angles whilst Table 6 collects important non-bonded distances for the molecules.

$[Me_2Ga{\cdot}N_2C_5H_7]_2$

Most 'pyrazolyl'-based structures determined to date display a central six-membered M—(N—N)$_2$—M′ ring in a boat conformation (where M = B or Ga; M′ = transition metal or Ga) (1, 2, 7–9). This arrangement allows planarity to be maintained about the nitrogen atoms with consequent gain in stabilization energy stemming from an ability to delocalize π-electrons in the bridging 'pyrazolyl' units. A planar central ring would also allow such π-electron delocalization but the environment of the Group III atoms is somewhat more strained. Two previous examples have shown nonboat conformations for the central six-membered

M—(N—N)$_2$—M′ ring. The first example was reported by Cotton *et al.* (10) *viz.* $[Et_2B(N_2C_3H_3)_2](h^3\text{-}C_3H_5)(N_2C_3H_4)(CO)_2Mo$, and the shallow chair conformation adopted by the B—(N—N)$_2$—Mo ring was argued to result from severe steric interactions. The second example (9) involves the bis[dimethylbis(3,5-dimethyl-1-pyrazolyl)gallato]copper(II) complex,

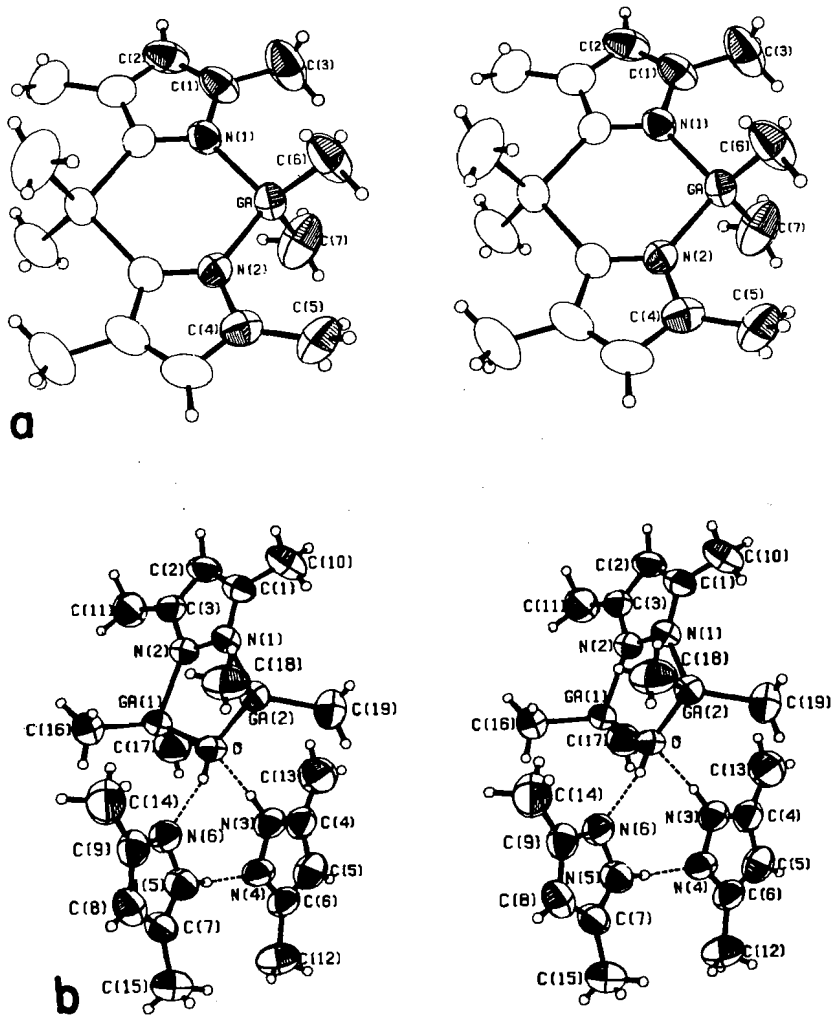

FIG. 1. Stereoscopic views of the molecules **1***a* and **1***b*.

$[Me_2Ga(N_2C_5H_7)_2]_2Cu$, in which steric requirements necessitate an almost planar arrangement for the two Ga—(N—N)$_2$—Cu six-membered rings. The present dimer structure represents the third example where steric requirements dictate a nonboat conformation for the central six-membered ring; the first example in the case of a symmetrical six-membered Ga—(N—N)$_2$—Ga ring. In the present example a shallow chair conformation is adopted but the deviation from planarity is small, the two gallium atoms being 0.131 Å above and below the mean plane through the four nitrogen atoms in the molecule. The almost planar arrangement for the tricyclic system incorporating the two bridging 3,5-dimethylpyrazolyl ligands and the two gallium atoms (see Table 5), and the positioning of the two GaC units at right angles to this plane, minimizes the steric interactions between adjacent methyl groups on the gallium atoms and on the bridging 'pyrazolyl' moieties. The relevant nonbonded C...C distances are collected in Table 6 and range from 3.51 to 3.80 Å. In addition to the planarity adopted by the Ga—(N—N)$_2$—Ga ring the Ga—N distances in the molecule (1.988, 1.998 Å) are longer than the distance of 1.97 Å normally observed in four-coordinate gallium compounds (11, 12). Both

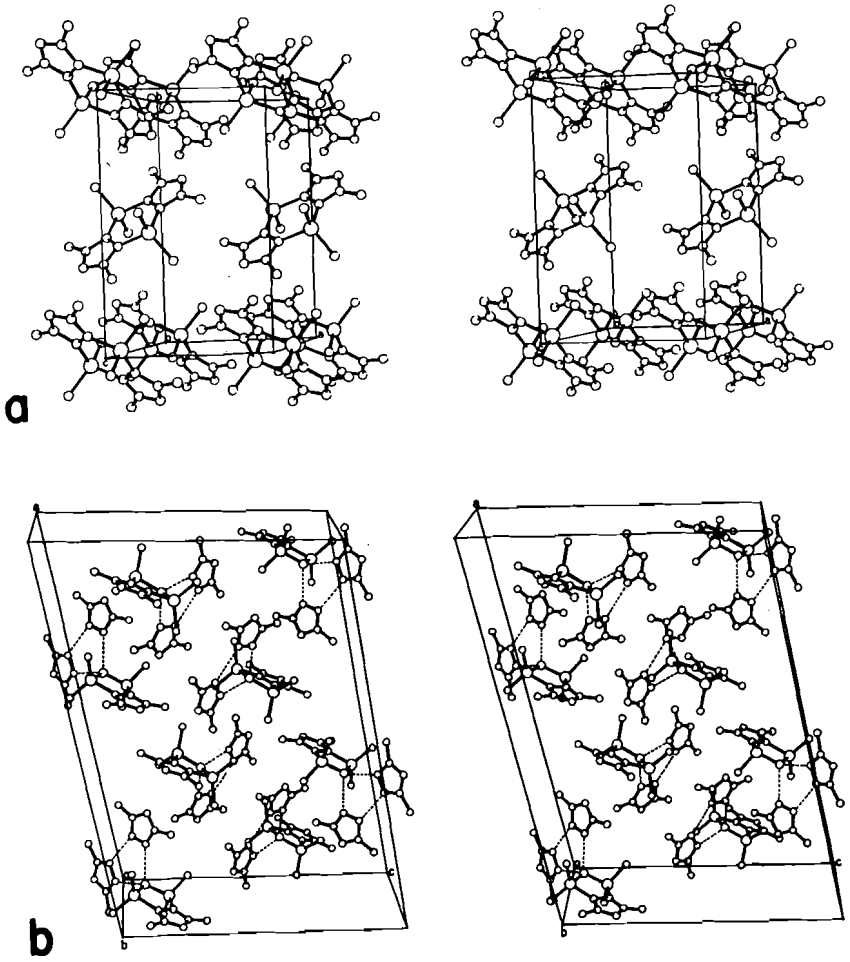

FIG. 2. Stereoscopic views of the unit cells for **1***a* and **1***b*.

these factors, the imposed planarity with consequent strain about the gallium atoms, and the long and probably weak Ga—N bonds, may contribute to the willingness of this particular dimer to react with water and thereby allow replacement of a bridging 3,5-dimethylpyrazolyl group with a bridging hydroxy group. Such a transformation relieves the steric interactions, still inherent in the planar dimer, between the methyl groups on the gallium atoms and on the bridging 'pyrazolyl' units. The planar dimer molecules occur as discrete entities in the unit cell with no intermolecular nonbonded contacts of less than 3.5 Å.

$[Me_2Ga(OH)(N_2C_5H_7)GaMe_2 \cdot 2N_2C_5H_8]$

The formation of this compound from the above dimer is probably encouraged by the reduction of steric strain which occurs as a result of the transformation. Thus nonbonded C...C distances in the hydroxy species between the Ga—Me and the 3-methyl and 5-methyl groups on the bridging 'pyrazolyl' moiety are increased over those found in the dimer molecule and now have the range 3.82–4.18 Å (*cf.* 3.51–3.80 Å) (Table 6). The molecule incorporates a bridging hydroxy function between the two gallium dimethyl units and this part of the structure may be compared with the $[Me_2GaOH]_4$

tetramer (13). The Ga—O distances of 1.932 and 1.936 Å of the present structure are shorter, though probably not significantly so, than the 1.94 and 1.98 Å Ga—O distances found in the tetramer, and somewhat longer than the tetrahedral Ga—O distances of 1.879 and 1.869 Å reported recently in the structure of a Ga,O,N cage compound (14). The latter structure, however, displays triply bridging oxygen atoms rather than doubly bridging hydroxy groups found in the present structure and in the tetramer, $[Me_2GaOH]_4$. The novel five-membered Ga_2N_2O ring is nonplanar with a dihedral angle of 13.9° between the mean planes through the atoms Ga(1), O, Ga(2) and Ga(1), N(1), N(2), Ga(2) respectively (Table 5). This folding about the gallium atoms results in the GaC_2 planes deviating from a 90° angle to the mean plane through the bridging 'pyrazolyl' unit, with consequent nonequivalent C...C nonbonded distances between the Ga—Me and the 3-Me and 5-Me groups (Table 6). The structure is completed by two hydrogen-bonded 3,5-dimethylpyrazole molecules which form a large heterocyclic ring incorporating the bridging hydroxy group, and which is approximately at right angles to the bridging 3,5-dimethylpyrazolyl moiety (see mean planes, Table 5). This arrangement 'staggers' the Ga—Me and the adjacent Me groups on the hydrogen-bonded 'pyrazoles' and thereby minimizes steric interactions between them. The relevant C...C nonbonded distances are listed in Table 6 and range from 4.01 to 4.21 Å, significantly longer than the nonbonded distances in the dimer molecule between neighboring Me groups.

The hydrogen-bonding system alone provides an interesting topic for discussion. Pyrazole itself has been the subject of a number of crystallographic studies (15–17) and it has been concluded that the tautomeric NH proton is localized on one of the nitrogen atoms in the solid state, and shows no tendency to migrate to the other nitrogen atom. In contrast, a crystal structure determination of 3-methyl-5-phenylpyrazole (18) failed to locate the NH hydrogen atoms and it was concluded that they exist as a loose association within molecular groupings. Our findings in this study appear to fall midway between the results of the pyrazole and 3-methyl-5-phenylpyrazole studies. Figure 1 shows only the hydrogen atoms associated with the major component of the two systems discussed in the Experimental section. There is one N—H...O hydrogen bond (N(3)...O 2.851(6), N(3)—H(N3) 0.84(6), O...H(N3) 2.03(6) Å, and N(3)—H(N3)...O 165(6)°), one O—H...N hydrogen bond (O...N(6) 2.892(6), O—H(O1) 0.60(6), N(6)...H(O1) 2.31(6) Å, and O—H(O1)...N(6) 164(8)°), and one N—H...N hydrogen bond (N(4)...N(5) 2.907(7), N(5)—H(N5) 0.72(7), N(4)...H(N5) 2.19(7) Å, N(5)—H(N5)...N(4) 178(7)°). Of these bonds the N—H...N bond is the strongest and the O—H...N bond the weakest when compared with documented distances for such bonds (19). Indeed, the N(4)...N(5) contact is quite short at 2.907 when one considers the sum of the van der Waals radii is 3.0 Å (20). Corresponding N...N contacts in 3-methyl-5-phenylpyrazole are even shorter still and lie in the range 2.824–2.913 Å.

The multicyclic molecules are quite well separated in the unit cell, there being only two intermolecular nonbonded contacts less than 3.5 Å: N(5)...C(11)[$x,y-1,z$] 3.46(1) Å, and N(6)...C(11)[$x,y-1,z$] 3.33(1) Å.

On a préparé le bis(phénylglyoxyloyl)-1,7 *m*-carborane par différentes méthodes, le meilleur rendement étant obtenu en faisant réagir le dilithio-1,7 *m*-carborane et le diméthoxy-2,2 phénylglyoxal. Opposé à l'*o*-phénylènediamine, ce nouveau composé ne donne pas la quinoxaline attendue mais un mélange de *m*-carborane, de phényl-3 quinoxalinone-2 et de benzoyl-2 benzimidazole. Il réagit également avec les bases pour donner du *m*-carborane et de l'acide phénylglyoxylique. L'étude théorique de la molécule par la méthode CNDO/2 indique une grande différence de réactivité entre les carbonyles situés en α et β du noyau carborane.

GUY RABILLOUD, BERNARD SILLION, JEAN ROSSARIE, MONIQUE BLAIN, and SIMONE ODIOT. Can. J. Chem. **53**, 2955 (1975).

1,7-Bis(phenylglyoxyloyl)-*m*-carborane has been prepared by different methods but the best yield was obtained with 1,7-dilithio-*m*-carborane and 2,2-dimethoxyphenylglyoxal. Mixed with *o*-phenylenediamine this new compound failed to yield the expected quinoxaline but afforded *m*-carborane, 3-phenyl-2-quinoxalinone, and 2-benzoylbenzimidazole. Moreover, under the action of bases, we observed a cleavage of the carbon–carbon bond giving *m*-carborane and phenylglyoxylic acid. A theoretical study of the molecule by CNDO/2 indicated a significant difference between chemical reactivities of the α and β carbonyl groups.

Introduction

La chimie des composés organiques contenant un noyau carborane s'est considérablement développée au cours de ces dix dernières années, soit à partir du dicarba-1,2-closo-dodécaborane-12 (*ortho*-carborane), soit avec le dicarba-1,7-closo-dodécaborane-12 (*méta*-carborane). En particulier, la synthèse des alkyl et aryl carboranylcétones a été réalisée par condensation des métallocarboranes sur les chlorures d'acides carboxyliques (1), sur les esters et les anhydrides d'acides aliphatiques et aromatiques (2) ou encore par oxydation des alcools secondaires obtenus dans la réaction d'un aldéhyde sur un lithiocarborane (3).

Ces méthodes générales semblent, à priori, utilisables pour fixer sur le noyau carborane le radical phénylglyoxyloyle (C_6H_5—CO—CO—) mais, dans la plupart des cas, nous avons observé la formation de produits secondaires ou de substances résineuses en quantités très importantes qui limitent considérablement les voies d'accès au bis(phénylglyoxyloyl)-1,7 *m*-carborane (**1**).

$$C_6H_5—CO—CO—CB_{10}H_{10}C—CO—CO—C_6H_5$$
1

Synthèse du bis(phénylglyoxyloyl)-1,7 *m*-carborane

L'introduction des substituants organiques sur les deux atomes de carbone du noyau carborane est effectuée à partir du dilithio-1,7 *m*-carborane (**2**) obtenu par transmétallation du *m*-carborane avec le butyllithium.

$$HCB_{10}H_{10}CH + 2C_4H_9Li \rightarrow 2C_4H_{10} + LiCB_{10}H_{10}CLi$$
2

A l'aide du dilithien **2** ainsi formé, quatre voies de synthèse ont été étudiées. L'ensemble de ces réactions est représenté dans la fig. 1.

[1]Nouvelle adresse: Centre de Recherches de la Compagnie Française de Raffinage, Gonfreville l'Orcher 76700, France.

[2]Revision reçue le 16 juin 1975.

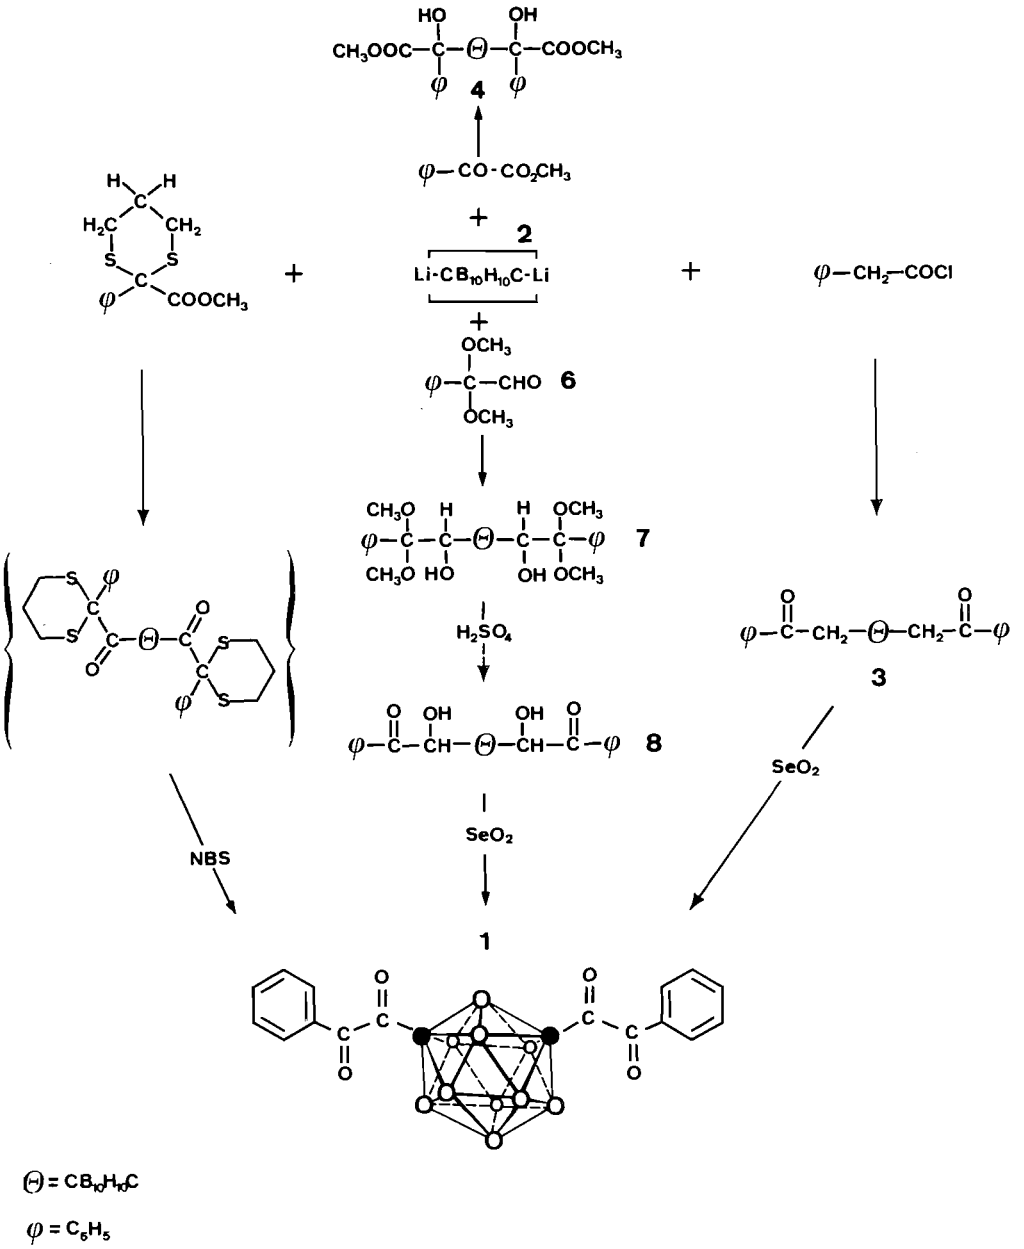

FIG. 1. Synthèse du bis(phénylglyoxyloyl)-1,7 *m*-carborane; θ = —$CB_{10}H_{10}C$—; φ = C_6H_5—.

(*i*) La condensation du composé **2** sur le chlorure de phénacétyle donne 12% seulement de bis(phénacétyl)-1,7 *m*-carborane (**3**) accompagné de *m*-carborane, d'acide mandélique, d'acide phénylacétique et de résidus lourds non identifiés. L'oxydation ultérieure de la cétone **3** par l'oxyde de sélénium permet de préparer le composé **1** avec un rendement global d'environ 4–5%.

(*ii*) En remplaçant le chlorure de phénacétyle par le phénylglyoxylate de méthyle on n'observe pas la formation de la tétracétone **1** mais il est possible d'isoler une petite quantité de l'ester alcool **4** qui proviendrait d'une attaque du composé métallique au niveau du carbonyle cétonique.

(*iii*) Pour éviter ce genre de réaction, la fonc-

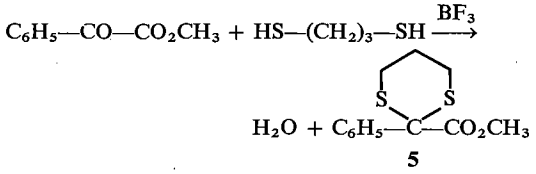
tion cétone du phénylglyoxylate de méthyle est protégée par le propanedithiol-1,3. Le méthoxy-



carbonyl-2 phényl-2 dithiane-1,3 (**5**) est alors opposé au dilithio-1,7 *m*-carborane (**2**) dans un mélange éther–hexane à 40 °C. Le traitement final permet de récupérer 90% des réactifs de départ inchangés et 10% d'un composé impur qui est directement oxydé par la méthode de Corey et Erickson (4) en tétracétone **1**.

(*iv*) L'absence de sélectivité de ces différentes synthèses nous a conduit à étudier une nouvelle séquence réactionnelle basée sur le diméthoxy-2,2 phénylglyoxal (**6**) préparé lui-même à partir de la dichloro-1,1 acétophénone (5). La fonction aldéhyde du dérivé **6** réagit de façon normale sur le lithien **2** pour donner le bis(hydroxy-1 diméthoxy-2,2 phénéthyl)-1,7 *m*-carborane (**7**). L'hydrolyse des fonctions acétals par l'acide sulfurique dans le dioxanne régénère les groupes carbonyles avec un rendement de 90% en bis(benzoylhydroxyméthyl)-1,7 *m*-carborane (**8**). L'oxydation de ce composé par l'oxyde de sélénium en suspension dans le toluène à reflux, en présence d'une faible quantité d'acide acétique, conduit au bis(phénylglyoxyloyl-)1,7 *m*-carborane (**1**) avec un rendement de 75%.

Les spectres i.r. des composés **1**, **7** et **8**, réunis sur la fig. 2, permettent de suivre les étapes de la réaction. Les transitions vibrationnelles de valence ν_{BH} (2650–2500 cm^{-1}) subissent d'importantes modifications selon la nature des substituants fixés sur les atomes de carbone de la cage carboranique. La structure fine des bandes d'absorption correspondantes a été récemment étudiée par cryospectrophotométrie i.r. et Raman (6).

La vibration de valence ν_{OH}, sensible à l'encombrement stérique autour de la liaison C—OH, est une bande fine très intense à 3525 cm^{-1} dans le dialcool **7** et une bande d'association large mal résolue (3530–3150 cm^{-1}) pour le céto alcool **8**. Le phénomène marquant est la valeur élevée de la fréquence de vibration de valence $\nu_{C=O}$ des carbonyles en α de la tétracétone **1** (1730 cm^{-1}) qui est à rapprocher de celle des carbonyles du diacétyl-1,7 *m*-carborane (1730 cm^{-1}) (3). Pour les carbonyles en β, la position de la bande à 1675 cm^{-1} est comparable à celle des composés aromatiques comme le benzile (1670 cm^{-1}).

Réaction du bis(phénylglyoxyloyl-1,7 *m*-carborane avec l'orthophénylène-diamine

La réaction de condensation des α-dicétones sur l'*o*-phénylènediamine est une voie assez générale de synthèse des quinoxalines et nous attendions de la tétracétone **1** qu'elle conduise dans ces conditions au bis(phényl-3 quinoxalinyl-2)-1,7 *m*-carborane (**9**). Or, quelles que soient les méthodes expérimentales, nous n'avons jamais pu mettre en évidence la présence d'une quinoxaline fixée au noyau carborane.

Dans les solvants neutres (benzène, chloroforme, dioxanne, éthanol) ou modérément acides (*m*-crésol, acide acétique) chauffés au reflux, on isole, à la fin de la réaction, du *m*-carborane et deux hétérocycles isomères: la phényl-3 1*H*-quinoxalinone-2 (**10**) accompagné d'une faible quantité de benzoyl-2 benzimidazole (**11**). Ces deux derniers composés ont été identifiés par comparaison avec les produits préparés séparément par des méthodes connues: oxydation du benzyl-2 benzimidazole avec l'anhydride chromique (7) et condensation de l'acide phénylglyoxylique sur l'*o*-phénylènediamine (8).

A température ambiante, dans ces mêmes solvants, il se forme progressivement un précipité très coloré qu'il n'est pas possible de purifier car les essais de cristallisation ou de sublimation induisent, au chauffage, une transformation en *m*-carborane et en composés hétérocycliques **10** et **11**. Les spectres i.r. (fig. 2) et r.m.n. sont loin d'être une superposition des spectres individuels des corps **10** et **11**. Cependant les données spectroscopiques ne permettent pas d'établir la structure de cet intermédiaire instable.

Enfin, si la réaction entre la tétracétone **1** et l'*o*-phénylènediamine est conduite dans un solvant basique comme la diméthylaniline, connue pour favoriser la formation des quinoxalines (9), les seuls produits isolés avec un rendement de 90% sont le *m*-carborane et la phényl-3 quinoxalinone-2 **10**.

Acétalisation et clivage par les bases

Les réactions du composé **1** *vis à vis* de l'*o*-phénylènediamine sont nettement différentes de celles des α-dicétones aromatiques et afin de poursuivre cette comparaison, nous avons étudié

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

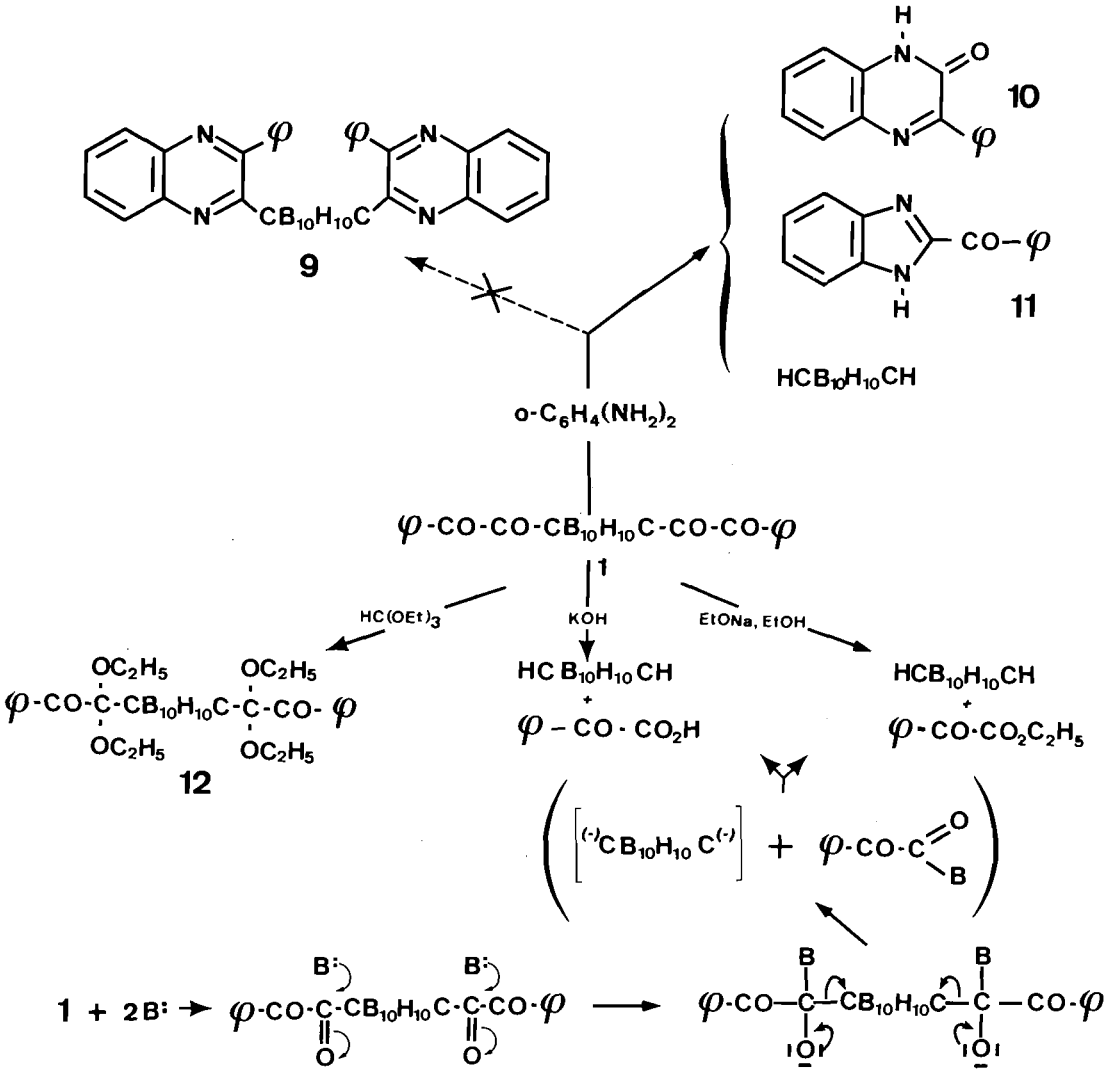


FIG. 3. Réactions du bis(phénylglyoxyloyl)-1,7 *m*-carborane.

son comportement avec les bases et les réactifs d'acétalisation.

L'acétalisation de la tétracétone **1** par l'orthoformiate d'éthyle se fait uniquement sur la fonction carbonyle située en α du carborane. En effet, on observe sur le spectre i.r. une disparition progressive de la bande d'absorption à 1730 cm^{-1} alors que le pic du carbonyle en β à 1680 cm^{-1} ne subit pas de modification sensible. La réaction est pratiquement achevée au bout de 2 h et les spectres i.r. et r.m.n. du produit brut correspondent bien à la structure **12** du bis(diéthoxy-1,1 phénylglyoxyloyl)-1,7 *m*-carborane (fig. 3).

On sait que, *vis à vis* des bases les α-dicétones aromatiques comme le benzile peuvent subir deux réactions principales: la coupure entre les deux carbonyles conduisant au benzaldéhyde et à l'acide benzoïque et le réarrangement benzilique. Dans le cas de la tétracétone **1** on n'observe aucune de ces réactions.

Dans les conditions du réarrangement benzilique dans la potasse éthanolique, il y a formation de *m*-carborane et d'acide phénylglyoxylique. De la même manière, l'action de traces d'éthylate de sodium dans l'éthanol absolu conduit au *m*-carborane et au phénylglyoxylate de méthyle (fig. 3).

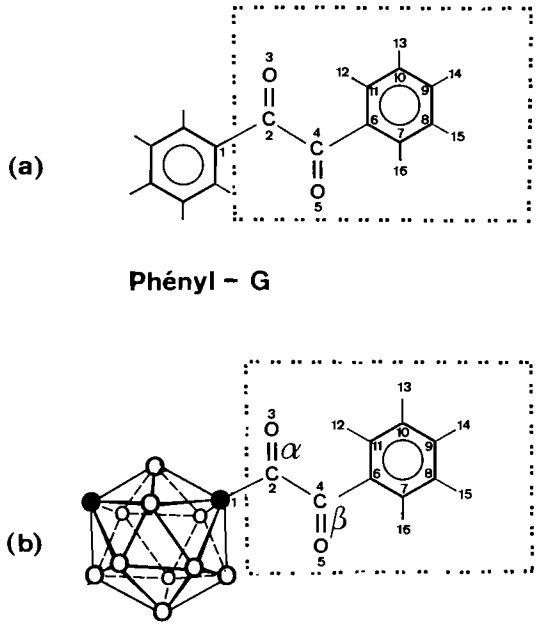

FIG. 4. Numérotation des centres pour le calcul des charges.

Conclusion

L'ensemble de ces résultats met en évidence la sensibilité de cette tétracétone carboranique à l'action des agents basiques organiques et minéraux. Il semble que l'attaque nucléophile se situe toujours sur les carbonyles en α du noyau carborane avec, ultérieurement, un clivage des liaisons C—C entre les atomes de carbone de ces carbonyles et ceux de la cage carborane qui stabiliserait le dianion $CB_{10}H_{10}C$ (fig. 3).

Ces résultats peuvent être rapprochés de ceux qui ont été observés dans la coupure alcaline de certains composés fonctionnels carbonylés des *o*- et *m*-carboranes (10, 11).

Interprétation théorique dans l'approximation des orbitales moléculaires

Les structures géométriques et électroniques d'une série de carboranes, isomères et dérivés substitués, ont été particulièrement bien analysées (12), à l'aide de la méthode CNDO/2 (13).

Néanmoins, dans cette approximation, la validité que l'on attache aux nombres, éléments de la matrice densité, reste relative. Ils doivent être considérés comme compléments d'information aux données expérimentales pour exprimer une tendance phénoménologique.

TABLEAU 1. Indices de liaison π* des deux liaisons C—C de la chaîne cétonique et des deux groupements C=O en position α et β

Indices de liaison π	a	b
$P_{C_2—C_4}$	0.2538	0.2548
$P_{C_4—C_6}$	0.2972	0.2998
$P_{C=O(\alpha)}$	0.9026	0.9174
$P_{C=O(\beta)}$	0.9026	0.9036

$P_{AB\pi_l} = 2\,\Sigma_{l\,occ} C^l_{2pz_A} C^l_{2pz_B}$ où $C^l_{2pz_{A\text{ ou }B}}$ est le coefficient affecté à l'orbitale atomique $2pz_{A\text{ ou }B}$ dans le développement de la *l*ème orbitale moléculaire occupée.

Le choix de cette méthode semi-empirique à l'égard des méthodes *ab initio* est économiquement imposé ici par la taille des composés, dans le cadre d'une étude de la restructuration électronique des dérivés fonctionnels par l'introduction du noyau *m*-carborane-1,7 $C_2B_{10}H_{12}$.

Les composés étudiés et la numérotation des centres sont représentés sur la fig. 4. La géométrie adoptée pour les calculs est la géométrie standard. Les résultats des calculs sont rassemblés dans les tableaux 1, 2 et 3. Dans le tableau 1 sont mentionnés les indices de liaison (*i*) entre les deux carbones qui assurent la conjugaison du groupe phényle d'une part et de la liaison entre les deux carbonyles d'autre part, avec le système moléculaire **a** ou **b**, et (*ii*) entre le carbone et l'oxygène des deux C=O. Le tableau 2 donne la distribution des charges nettes électroniques, sur chaque centre numéroté selon la fig. 4, ainsi que les charges nettes globales portées par les groupements G (*cf.* fig. 4), phényle de G et *m*-carboranyle. Dans le tableau 3 figurent les polarités des deux liaisons C=O en absence ou en présence de *m*-carborane. La polarité de la liaison C=O est mesurée par la différence entre les charges nettes du carbone et de l'oxygène.

Si l'on examine les tableaux 1 et 3, on constate que lors du remplacement d'un phényle par un noyau *m*-carboranique: (*i*) Les deux groupements carbonyles se différencient l'un de l'autre. Les indices de liaison ($P_{C=O}$) sont différents tout comme leur polarité. Le C=O en α du carborane devient plus réactif que celui en β (indice de liaison et polarité plus élevés). L'attaque nucléophile par un groupement basique doit toucher

TABLEAU 2. Distribution des charges électroniques

	Charges nettes	
Centres	a	b
2	0.1882	0.2034
3	−0.2407	−0.2172
4	0.1882	0.1914
5	−0.2407	−0.2237
6	−0.0077	−0.0060
7	0.0222	0.0254
8	−0.0006	0.0012
9	0.0209	0.0251
10	0.0021	0.0044
11	−0.0001	0.0023
12	0.0306	0.03
13	−0.0049	0.0003
14	−0.0050	−0.0003
15	−0.0042	0.0005
16	0.0031	0.006
G	−0.0486	0.0428
ϕ	+0.048	0.0889
m-Carborane		−0.0416

TABLEAU 3. Polarité des liaisons carbonyles

	Polarité	
Liaisons	a	b
C=O (α)	0.4289	0.4206
C=O (β)	0.4289	0.4151

en tout premier lieu le C=O en α. (*ii*) L'indice de liaison de C=O en β augmente de façon peu significative, mais par contre, sa polarité diminue. Une réaction d'addition sur ce carbonyle est alors défavorisée par rapport à l'addition sur le composé phénylé (**a**), en accord avec les observations expérimentales.

L'analyse des résultats du tableau 2 souligne une fois de plus le caractère attracteur d'électrons du *m*-carborane qui prend une charge égale à −0.04 *e*. Lorsque l'on passe du composé **a** au composé **b** on constate sur le tableau 2 que le groupement G primitivement chargé négativement (−0.0486) devient positif (+0.0428) et que le groupe phényle cède des électrons puisque sa charge passe de +0.048 à +0.0889 et ceci d'autant plus aisément que l'indice de liaison $\pi,P_{C_4-C_6}$ augmente (0.2972–0.2998 (tableau 1)), assurant une meilleure conjugaison.

Conditions expérimentales de synthèse

Les spectres i.r. ont été réalisés sur pastilles de KBr avec un appareil Perkin-Elmer 257. Les spectres r.m.n. ont été effectués à l'aide d'un Perkin-Elmer R-24 de 60 MHz et sont donnés en unités δ par rapport au TMS utilisé comme étalon interne. Les températures de fusion instantanées ont été mesurées avec un banc Kofler. Le *m*-carborane utilisé dans les synthèses de composés fonctionnels est commercialisé par Research in Inorganic and Organic Chemicals et par Ventron Chemical Corp.—Alfa Products Division. Ce produit est utilisé sans purification supplémentaire quand sa pureté, contrôlée par chromatographie en phase gazeuse est de 99.7%. Les lots de *m*-carborane contenant de l'*o*-carborane sont isomérisés à 600 °C dans un appareil en quartz identique à celui qui est décrit dans la littérature (14).

Synthèse du bis(phénacétyl)-1,7 m-carborane (3)

Le *m*-carboranyldilithium **2** est préparé dans un ballon de 500 ml équipé d'un agitateur, d'un thermomètre, d'une ampoule d'addition à robinet et d'une arrivée d'argon. On introduit dans le ballon 137 ml d'une solution 1.61 *M* de butyllithium dans l'hexane et 100 ml d'éther anhydre. L'ampoule d'addition est chargée avec une solution de *m*-carborane (14.4 g, 0.1 mol) dans 100 ml d'éther. Le *m*-carborane est ajouté goutte à goutte, avec une forte agitation, au butyllithium refroidi à 0 °C en 1 h environ puis le mélange est agité une nuit à température ambiante pour compléter la réaction de transmétallation.

A cette suspension de dilithiocarborane refroidie à −50 °C on ajoute peu à peu une solution de chlorure de phénacétyle (31 g, 0.2 mol) dans 80 ml d'éther. Le mélange réactionnel est ensuite laissé 5 h à 20 °C puis hydrolysé avec de la glace et de l'acide chlorhydrique dilué. La phase organique est lavée à l'eau, séchée sur Na_2SO_4 et les solvants sont évaporés sous pression réduite. Le résidu est une huile jaune très visqueuse constituée de plusieurs produits parmi lesquels on identifie par chromatographie en couche mince du *m*-carborane, de l'acide mandélique, de l'acide phénylacétique, des alcools carboraniques tertiaires non identifiés et 4.56 g (12%) de bis(phénacétyl)-1,7 *m*-carborane. Ce composé recristallisé de l'hexane a les caractéristiques suivantes: p.f. 95 °C; i.r. (cm^{-1}): 2670–2550 (ν_{B-H}), 1740 ($\nu_{C=O}$).

Masse moléculaire calc.: 380.6. Trouvé (tonométrie): 378.

Anal. calc. pour $C_{18}H_{24}B_{10}O_2$: C, 56.80; H, 6.35; B, 28.43. Trouvé: C, 56.96; H, 6.51; B, 28.22.

Oxydation du composé 3

Le composé **3** (3.8 g, 0.01 mol) est chauffé à reflux pendant 5 h dans 40 ml d'anhydride acétique avec un excès d'oxyde de sélénium (3.5 g). A la fin de la réaction, le sélénium est éliminé par filtration et le solvant est distillé sous pression réduite. Le résidu est repris au chloroforme et chromatographié sur une colonne d'alumine acide de 20 × 100 mm (éluant $CHCl_3$). Les fractions contenant la tétracétone **1** sont réunies et donnent après évaporation du solvant 1.84 g de produit qui est purifié par cristallisation de l'heptane, p.f. 100–101 °C.

Condensation du phénylglyoxylate de méthyle sur le m-carboranyldilithium

Une solution de 8.2 g de phénylglyoxylate de méthyle dans 50 ml d'éther est ajoutée peu à peu à une suspension

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

de *m*-carboranyldilithium (0.01 mol) dans l'éther–hexane refroidie à −80 °C. A la fin de la réaction exothermique on laisse revenir à température ambiante en une heure et on hydrolyse sur un mélange glace–HCl. Les produits de réaction sont principalement des oligomères infusibles contenant le noyau carborane. Par chromatographie sur colonne d'alumine d'activité III, on sépare 200 mg d'un ester alcool carboranique dont les caractéristiques analytiques et spectroscopiques sont en accord avec la formule **4** du bis(méthoxycarbonyl-α hydroxy-α benzyl)-1,7 *m*-carborane, p.f. 85 °C; i.r. (cm^{-1}): 3450 (ν_{OH}), 3030 (ν_{CH} aromatique), 2970 et 2870 (ν_{CH_3}), 2550 (ν_{BH}), 1720 ($\nu_{C=O}$).

Masse moleculaire calc.: 472.6. Trouvé (tonométrie): 484.

Anal. calc. pour $C_{20}H_{28}B_{10}O_6$: C, 50.82; H, 5.97; B, 22.89. Trouvé: C, 50.68; H, 5.78; B, 22.96.

Méthoxycarbonyl-2 phényl-2 dithiane-1,3 (5)

Un mélange de phénylglyoxylate de méthyle (2 ml), de propanedithiol-1,3 (2 ml), d'acide acétique (5 ml), et de BF_3 éthérate dans l'éther éthylique (3 ml) est chauffé 3 h à 100 °C. En diluant à l'eau, il se forme un précipité blanc cristallin qui est filtré et lavé plusieurs fois avec du méthanol aqueux; i.r. (cm^{-1}): 3100 et 3030 (ν_{CH} aromatique), 2950, 2900 et 2830 (ν_{CH} aliphatique), 1730 ($\nu_{C=O}$); r.m.n. ($CDCl_3$): 3.67 (s, 3H, CH_3O), 1.7–2.2 (m, 2H, dithiane), 2.5–2.4 (m, 4H, dithiane), 7.2–7.9 (m, 5H, aromatique).

Anal. calc. pour $C_{12}H_{14}O_2S_2$: C, 56.65; H, 5.54; S, 25.21. Trouvé: C, 56.69; H, 5.70; S. 25.58.

Condensation du composé 5 sur le m-carboranyldilithium

Une solution du composé **5** (2.54 g) dans 40 ml de benzène est ajoutée peu à peu à une suspension de *m*-carboranyldilithium (5 mmol) dans 20 ml d'éther–hexane. Après 1 h de réaction à température ambiante, le mélange est chauffé à 40 °C (30 min) puis hydrolysé avec 150 ml d'acide chlorhydrique dilué. Le produit brut obtenu par le traitement habituel est chromatographié sur une colonne de silice (éluant, benzène–hexane 30:70). Les trois fractions principales correspondent au *m*-carborane et au composé **5** (90% des quantités de départ) et à un composé brut qui est dissous dans 4 ml d'acétone et oxydé par une solution de *N*-bromosuccinimide (2.85 g) dans 30 ml d'acétone contenant 3% d'eau. A la fin de la réaction, on isole par chromatographie 282 mg de tétracétone **1**, p.f. 99–101 °C.

Diméthoxy-2,2 phénylglyoxal (6)

Ce composé est préparé par la méthode de Henery-Logan et Fridinger (5) modifiée de la façon suivante. Une solution de méthylate de sodium est préparée en ajoutant à 1.5 l de méthanol anhydre refroidi à 0 °C 120 g de suspension d'hydrure de sodium à 50% dans l'huile lourde. Quand le dégagement d'hydrogène cesse, on additionne peu à peu 209.5 g de dichloro-1,1 acétophénone en refroidissant pour maintenir le mélange à 35–40 °C. Après une nuit à température ambiante, le chlorure de sodium est filtré et la plus grande partie du méthanol distillée sous vide. Le résidu est repris à l'éther et traité avec de l'acide chlorhydrique dilué jusqu'à neutralité. La phase éthérée est lavée à l'eau, séchée sur Na_2SO_4 et le solvant est évaporé sous pression réduite.

Le produit de réaction est distillé à 60–62 °C sous 0.15 Torr; rendement, 164.8 g (83%). Les spectres i.r. et r.m.n. sont identiques à ceux qui ont été publiés (5).

Bis(diméthoxy-2,2 hydroxy-1 phénéthyl)-1,7 m-carborane (7)

Dans un réacteur de 500 ml tenu sous atmosphère inerte, on prépare du *m*-carboranyldilithium en ajoutant une solution de 14.4 g (0.1 mol) de *m*-carborane dans 200 ml d'éther à 165 ml de butyllithium 1.52 *N* dans l'hexane. On ajoute ensuite peu à peu 43 g de diméthoxy-2,2 phénylglyoxal à 20 °C et la réaction est poursuivie pendant 1 h après la fin de l'addition.

Le mélange est hydrolysé sur de la glace, extrait à l'éther et lavé à l'eau jusqu'à neutralité. Une partie des sous-produits de la réaction est éliminée par distillation sous vide ($p.é._{0.1}$ 80–100 °C). Le résidu, repris par le pentane, donne un solide blanc qui est cristallisé d'un mélange benzène (100 ml) – hexane (150 ml). On isole 25 g (50%) de diol **7** qui n'a pas de température de fusion franche; spectre de masse, pic moléculaire *M* 506 (^{11}B); i.r. (cm^{-1}): 3520 (ν_{OH}), 3090, 3065, 3050, 3030 et 3018 (ν_{CH} aromatique), 2960, 2940, 2900 et 2830 (ν_{CH} de CH_3O), 2692, 2662, 2658, 2643, 2638, 2624, 2610, 2600, 2578 et 2558 (ν_{BH} 10 bandes fines bien résolues), 1448 et 1380 (δ_{CH_3}).

Masse moleculaire calc.: 504.7. Trouvé (tonométrie): 502.

Anal. calc. pour $C_{22}H_{36}B_{10}O_6$: C, 52.35; H, 7.19; B, 21.43. Trouvé: C, 52.48; H, 7.31; B, 21.12.

Bis(benzoylhydroxyméthyl)-1,7 m-carborane (8)

A une solution de 13 g de composé **7** dans 300 ml de tétrahydrofuranne on ajoute 300 ml d'une solution aqueuse à 48% d'acide sulfurique. Le mélange est agité pendant une nuit à 20 °C. Le précipité qui s'est formé est isolé par filtration, lavé à l'eau jusqu'à neutralité et séché, rendement 10.6 g (100%). Une cristallisation du benzène donne 9 g de produit pur, p.f. 192–195 °C; spectre de masse, pic moléculaire *M* 414 (^{11}B); i.r. (cm^{-1}): 3500 à 3300 (bande large ν_{OH} associé), 3080, 3060, 3020 (ν_{CH} aromatique), 2644, 2630, 2620, 2612, 2584, 2575, 2565, 2548 et 2538 (ν_{BH}), 1688 (ν_{CO}); r.m.n. ($CDCl_3$–DMSO-d_6 60:40) δ: 5.16 (s, —CH—), 6.57 (s large, —OH), 7.20–7.70 (m, 3H, aromatique), 7.80–8.05 (m, 2H, aromatique en *ortho* du carbonyle).

Anal. calc. pour $C_{18}H_{24}B_{10}O_4$: C, 52.40; H, 5.86; B, 26.22. Trouvé: C, 52.36; H, 5.80; B, 26.28.

Bis(phénylglyoxyloyl)-1,7 m-carborane (1)

On chauffe à reflux pendant 24 h un mélange de 10 g de composé **8**, 60 ml de toluène anhydre, 6.2 g d'oxyde de sélénium et 10 gouttes d'acide acétique glacial. A la fin de la réaction, le sélénium métallique est isolé par filtration et lavé avec deux fois 20 ml de toluène. Les phases organiques sont réunies, lavées à l'eau et séchées sur sulfate de sodium. L'évaporation du toluène laisse un résidu marron qui est purifié par cristallisation de 50 ml d'heptane en présence de charbon décolorant. Le rendement en composé **1** est de 7.4 g (74%); p.f. 101 °C; spectre de masse, pic moléculaire *M* 410 (^{11}B); i.r. (cm^{-1}): 3066 et 3012 (ν_{CH} aromatique); 2650, 2638, 2629, 2618, 2609, 2589, 2580, 2578 et 2562 (ν_{BH}), 1723, 1732, 1736 (ν_{CO} en α du carborane), 1675, 1677, 1687 (ν_{CO} en β du carborane); r.m.n. ($CDCl_3$) δ: 7.2–7.7 (m, 3H), 7.8–8.05 (m, 2H en *ortho* du carbonyle).

Anal. calc. pour $C_{18}H_{20}B_{10}O_4$: C, 52.92; H, 4.93; B, 26.48. Trouvé: C, 53.08; H, 5.11; B, 26.57.

*Condensation de la tétracétone **1** avec l'o-phénylènediamine*

Dans 50 ml de *m*-crésol désaéré on ajoute successivement 2.16 g (20 mmol) d'*o*-phénylènediamine et 4.08 g (10 mmol) de tétracétone **1**. Après 1 h de réaction à température ambiante, le mélange est porté à 200 °C en 2 h et laissé 1 h à cette température. Le solvant est ensuite évaporé sous pression réduite et le résidu est repris avec 100 ml de pentane–éther (80:20). La fraction soluble, purifiée par chromatographie sur colonne d'alumine donne 1.3 g de *m*-carborane identifié par spectrométrie de masse et i.r. Le résidu insoluble dans le pentane est extrait à l'éther. La fraction qui se dissout dans ce solvant est ensuite isolée et cristallisée du benzène. On obtient ainsi environ 0.3 g d'un composé hétérocyclique dont la température de fusion et les caractéristiques spectroscopiques (i.r., r.m.n.) sont identiques à celles du benzoyl-2 benzimidazole (**11**) synthétisé séparément ci-dessous. Le résidu insoluble dans l'éther est cristallisé de l'alcool, puis sublimé à 230 °C sous vide. On isole ainsi 3.7 g d'un second composé hétérocyclique isomère du précédent qui est identifié par comparaison avec un échantillon authentique de phényl-3 1*H*-quinoxalinone-2 (**10**).

Par rapport aux quantités de réactifs utilisées, le bilan de la réaction s'établit ainsi: 90% de **1** est transformé en *m*-carborane, l'*o*-phénylènediamine donnant 83.5% de quinoxalinone **10** et 6.7% de benzimidazole **11**.

*Phényl-3 quinoxalinone-2 **10***

Le produit est obtenu en faisant réagir l'acide phénylglyoxylique et l'*o*-phénylènediamine (8), p.f. 251 °C; u.v. (éthanol) λ_{max} en nm (ε_{max}): 207 (32 400), 222–228 (23 900), 307.5 (12 360), 365 (12 100); i.r. (cm^{-1}): 3150–2715 (11 bandes ν_{N-H}), 1670 et 1660 ($\nu_{C=O}$), 1610 ($\nu_{C=N}$), 1598, 1535, 1480, 1448, 1432; r.m.n. (DMSO) δ: 7.15 (dd, H8), 7.25–7.45 (m, 5H), 7.3 (dd, H5), 8.1–8.45 (m, H2′ et 6′), 12.55 (s, NH).

*Benzoyl-2 benzimidazole **11***

Ce composé est préparé par oxydation du benzyl-2 benzimidazole par CrO_3 dans l'acide acétique (7); p.f. 214–215 °C; i.r. (cm^{-1}): 3220–2200 (ν_{NH}), 1660 ($\nu_{C=O}$), 1600, 1590, 1515, 1485, 1430; r.m.n. (DMSO) δ: 7.2–7.8 (m, 7H), 8.4–8.65 (m, H2′ et 6′), 13.45 (s large, NH).

Le processus réactionnel de condensation entre la tétracétone **1** et l'*o*-phénylènediamine est identique à celui que nous venons de décrire lorsque la réaction est effectuée au reflux dans d'autres solvants tels que le dioxanne, le tétrahydrofuranne, l'éthanol, le chloroforme ou l'acide acétique pendant plusieurs heures. Par contre, si la réaction est conduite dans les mêmes solvants entre 0–20 °C, on isole au bout d'une dizaine d'heure 90% d'un composé intermédiaire instable qui ne peut être purifié ni par cristallisation, ni par sublimation. Le produit brut a les caractéristiques suivantes: p.f. ≃190 °C; analyse élémentaire: $C_{30}H_{32}B_{10}N_4O_2$; masse moléculaire par tonométrie dans le THF, *M* 590; i.r. (cm^{-1}): 3500–3300 (ν_{NH} ou ν_{OH}), 3100, 3060 (ν_{CH}), 3000–2700 (ν_{NH} ou ν_{OH} associé), 2665, 2620, 2605, 2580, 2570, 2560 (ν_{BH}), 1670 large ($\nu_{C=O}$); r.m.n. ($CDCl_3$) δ: 5.08 (s large, 2H, NH et/ou OH), 7.1–7.6 (m, 6H), 7.6–8.15 (m, 3H).

En chauffant 250 mg de ce produit dans 4 ml de *m*-crésol pendant 1 h à 200 °C, on isole 50–60 mg de *m*-carborane et 150 mg d'un mélange des hétérocycles **10** et **11** qui sont séparés par cristallisation fractionnée en benzoyl-2 benzimidazole (10 mg) et phényl-3 quinoxalinone-2 (140 mg).

Dans la diméthylaniline

En faisant réagir 4 h à 20 °C les mêmes proportions de réactifs dans 4 ml de diméthylaniline, on obtient quantitativement un précipité de phényl-3 quinoxalinone-2 **10**. La solution traitée à l'acide chlorhydrique dilué et extraite à l'éther donne la quantité correspondante de *m*-carborane.

*Bis(diéthoxy-1,1 phénylglyoxyloyl)-1,7 m-carborane (**12**)*

Un mélange de tétracétone **1** (204 mg), d'orthoformiate d'éthyle (500 mg), d'alcool éthylique absolu (3 ml) et d'acide chlorhydrique concentré (1 goutte) est agité à température ambiante. L'avancement de la réaction est suivi en i.r. sur la bande à 1730 cm^{-1}. L'intensité de celle-ci diminue rapidement pour devenir nulle après 2 heures environ. L'évaporation des solvants à 100 °C sous vide laisse un résidu vitreux transparent qui n'a pas été purifié en raison des difficultés de recristallisation. Les caractéristiques spectroscopiques de ce composé sont les suivantes: i.r. (cm^{-1}): 2990, 2960, 2940, 2835 (ν_{C-H}), 2690, 2660, 2640, 2625, 2600, 2580, 2559 (ν_{B-H}), 1675 ($\nu_{C=O}$), 1477 (δ CH_2), 1440, 1400 (δ CH_3), 1110 (ν_{C-O-C}); r.m.n. ($CDCl_3$) δ: 1.22 (t, CH_3), 3.62 (m, CH_2), 7.2–7.7 (m, H3′, 4′, 5′ aromatique), 7.92 (dd, H2′, 6′).

*Réaction de la tétracétone **1** avec la potasse éthanolique*

Une solution de potasse (30 mg) dans 0.5 ml d'éthanol est ajoutée à 204 mg de tétracétone **1** dans 8 ml d'éthanol absolu chauffé à 80 °C. Après 30 min de réaction, le solvant est évaporé sous pression réduite et le résidu est extrait avec de l'hexane chaud. La fraction soluble dans l'hexane, purifiée par chromatographie sur colonne d'alumine, donne 62 mg de *m*-carborane. Le résidu insoluble dans l'hexane est acidifié avec de l'acide chlorhydrique dilué, extrait à l'éther et, après évaporation de l'éther, cristallisé du tétrachlorure de carbone. On isole ainsi 120 mg environ d'acide phénylglyoxylique qui est identifié par comparaison avec un échantillon commercial.

*Réaction de la tétracétone **1** avec l'éthylate de sodium*

A une solution de **1** (408 mg) dans 13 ml d'éthanol absolu on ajoute une solution d'éthylate de sodium préparée en faisant réagir 4 mg de sodium dans 2 ml d'éthanol. Le mélange est agité 6 h à 20 °C et le solvant évaporé sous pression réduite. Par chromatographie en couche mince on identifie deux constituants: le *m*-carborane et le phénylglyoxylate d'éthyle. Ces composés sont ensuite séparés par chromatographie préparative en phase gazeuse qui donne en une seule injection 100 mg de *m*-carborane et 250 mg d'ester.

Ce travail a été effectué dans le cadre d'un contrat avec la Direction des Recherches et Moyens d'Essais que nous tenons à remercier ici.

Relation between van der Waals and Partial Molal Volumes of Organic Molecules in Water[1]

JOHN T. EDWARD AND PATRICK G. FARRELL

Department of Chemistry, McGill University, P.O. Box 6070, Station A, Montreal, Quebec H3C 3G1

Received April 3, 1975

JOHN T. EDWARD and PATRICK G. FARRELL. Can. J. Chem. **53**, 2965 (1975).

The partial molal volumes $\bar{v}$ of nonpolar organic molecules (*i.e.* those having more than three aliphatic carbon atoms per polar hydroxyl, ether, amine, amide, or urea group) in water at 25 °C are given by their van der Waals volumes v_w plus the additional empty volume provided by an enclosing shell 0.53 Å thick. An equation relates $\bar{v}$ to v_w. More polar compounds (*i.e.* those having fewer than two or three aliphatic carbon atoms per polar group) have $\bar{v}$ smaller than calculated by the equation; the shrinkage in $\bar{v}$ from that computed is linearly related to the fraction of the total surface area of the molecule occupied by the polar group.

JOHN T. EDWARD et PATRICK G. FARRELL. Can. J. Chem. **53**, 2965 (1975).

Les volumes molaires partiels $\bar{v}$ de composés organiques non-polaires (*i.e.* ceux contenant plus que trois atomes de carbone aliphatique pour chaque groupement hydroxyle, éther, amine, amide ou urée) dans l'eau à 25 °C sont égaux à leurs volumes van der Waals v_w avec l'incrément du volume vide donné par une enveloppe d'une épaisseur de 0.53 Å. La relation entre $\bar{v}$ et v_w est contenue dans une équation. Les composés plus polaires (ayant moins d'atomes de carbone aliphatique) ont $\bar{v}$ plus petit; la diminution fractionnelle en $\bar{v}$ est liée à la proportion de la surface moléculaire occupée par le groupement polaire.

In connection with other work, we needed to know the densities of aqueous solutions of various organic compounds. In principle, such values could be derived from the apparent molal volumes of the compounds, which were shown many years ago by Traube (1) to be given by the summation of atomic or group increments plus a covolume of about 13 ml/mol. In this paper we devise a simple model for calculating partial molal volumes $\overline{V}$ of organic molecules in water from their van der Waals volumes; we defer for a later paper a comparison of our results with those of Traube.

Stillinger (2) has pointed out that $\overline{V}$ "represents three distinct contributions:

1. The first is the volume increase that would result even for a point particle (not interacting with solvent molecules) on account of its kinetic contribution to the pressure . . . . .

2. The second is just the geometric volume occupied by the solute particle. In the general case, there may be some ambiguity about the precise magnitude of this volume . . . . .

3. Finally, one expects that solvent molecule rearrangement to accommodate the solute particle will normally result in a change in packing efficiency for those solvent molecules . . . . ."

Stillinger's first contribution represents the empty volume (3) required to accommodate any kinetic particle in a liquid, and is akin to Traube's covolume. In our model we identify the second contribution with the van der Waals' volume of the molecule, as defined by various authors (4–6). We discuss below the varying extents to which the volumes of solids, liquids, and solutions are made up in part of the van der Waals volumes of their constituent molecules, and in part of empty volume.

The Varying Proportion of the Volume of Solids and Liquids Made Up of Empty Volume

In a crystalline solid made up of spherical molecules at 0 K the centers of the molecules are separated by a distance which we may define as $2r_w$, r_w being the van der Waals radius of the molecule. This radius in turn defines a spherical van der Waals surface of area A_w, enclosing the van der Waals volume v_w of the molecule. The molar volume V of the solid may be considered to be made up of a molar van der Waals volume $V_w = Nv_w$ of Avogadro's number N of touching spheres, packed in a regular lattice arrangement, and of the void or "empty volume" (3) between the spheres.

[1]Dedicated to Professor C. A. Winkler of McGill University on the occasion of his sixty-fifth birthday by two of his colleagues, one of whom is also a former student (J.T.E.).

The van der Waals surface areas A_w and volumes v_w of most organic molecules can be computed by addition of the van der Waals increments of their constituent atoms or groups listed in the literature (4, 5). From the v_w thus computed we can obtain $r_w \equiv (3v_w/4\pi)^{1/3}$. Even though all molecules (with the exception only of noble gas atoms) are not perfect spheres, this parameter, which treats the molecule as a sphere of equivalent volume, proves useful in calculations of various molecular properties such as diffusion coefficients (4) and ion conductances (7) when the molecules or ions are roughly spherical.

The proportion of the volume of a crystalline solid made up of empty volume depends on how the molecules are packed in the crystal. The closest possible packing of spheres or ellipsoids, when each particle is in contact with 12 nearest neighbors, gives a packing density ρ^* ($\equiv Nv_w/V$) of 0.74, and in spite of their nonspherical shapes, most complex organic molecules pack into crystals with 12 nearest neighbors so that at 0 K they have $\rho^* = 0.74 \pm 0.4$ (6).

The expansion of a solid when it warms up from 0 K involves an increase in empty volume, because of the increasing amplitude of molecular vibrations; when the solid melts, there is usually a further increase of 10–15%. At the boiling point the molal volume of most liquids made up of small molecules is about half empty volume.

The Volume of the Solvent Cavity Containing the Solute Molecule

The volume of a solution obtained by dissolving a solid or liquid solute in a solvent is usually (although not always) greater than the original volume of the solvent; however, the increase is not necessarily equal to volume of the added solute, because of variations in the empty volume associated with each molecule of solute in its old and its new environment. If the apparent molal volume at different concentrations is extrapolated to zero concentration we obtain the partial molal volume $\bar{V}$ of the solute at infinite dilution;[2] this is the product of N times the partial molal volumes $\bar{v}$ for a single molecule.

[2]Some of the data from the literature which we have used are for very dilute solutions rather than for infinite dilution; however, the differences are within the accuracy to be expected for our model. Similarly, in a few cases experimental values are recorded for 20° or 30° rather than 25°; again the difference will usually be negligible for our purposes.

Now consider the volume changes $\bar{v}$ accompanying the dissolution of the molecules of two solids, B and C, in a liquid (Fig. 1). For simplicity we postulate spherical molecules and, more importantly, molecules of *the same chemical character*, so that the attraction of molecules of both B and C for solvent molecules will be similar. In such a case, the *average separation of the solvent from solute molecules B and C should be the same* (Stillinger's first contribution). This is represented in Fig. 1 by having molecules of B and of C in cavities having the same separation Δ of the solute molecule from the solvent (represented in Fig. 1, for convenience only, as a continuum); *i.e.*, having $\bar{r} = r_w + \Delta$, where $\bar{r} \equiv (3\bar{v}/4\pi)^{1/3}$. Since $\bar{r}/r_w = 1 + \Delta/r_w$, we come to the important relationship

$$[1] \qquad \left(\frac{\bar{v}}{v_w}\right)^{1/3} = 1 + \frac{\Delta}{r_w}$$

A test of this relation is shown in Fig. 2 in which $(\bar{v}/v_w)^{1/3}$ is plotted against $1/r_w$ for five aliphatic and aromatic hydrocarbons. As required by [1], the points lie close to a straight line having an intercept = 1 and a slope $\Delta = 0.53$ Å. This last can be considered a measure of the separation of solute hydrocarbon molecules from solvent water molecules, the latter perhaps being organized into a quasi-clathrate "cage." We shall accordingly use [2] with $\Delta = 0.53$ Å to

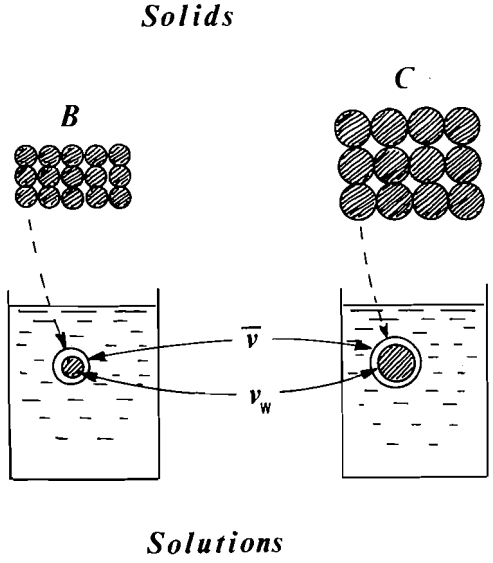

FIG. 1. Schematic representation of volume changes accompanying the dissolution of one molecule of B or of C in a solvent.

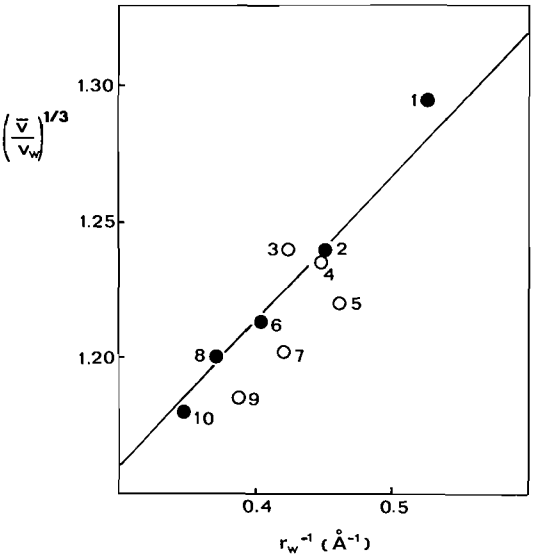

FIG. 2. Dependence of $(\bar{v}/v_w)^{1/3}$ on $1/r_w$ for hydrocarbons (●) and haloalkanes (○) in water at 25°. Curve: theoretical for eq. 1 with $\Delta = 0.53$ Å. Points: experimental data for: 1, methane (refs. 8, 9); 2, ethane (ref. 8); 3, methyl iodide (ref. 10); 4, methyl bromide (ref. 10); 5, methyl chloride (ref. 10); 6, propane (ref. 8); 7, methylene chloride (ref. 11); 8, benzene (ref. 8); 9, chloroform (ref. 12); 10, toluene (ref. 13).

calculate $\bar{v}$ (and thence $\overline{V}$) of hydrophobic molecules from r_w

$$[2] \qquad \bar{v} = \tfrac{4}{3}\pi(r_w + \Delta)^3$$

This equation shows that even for a point molecule $\bar{v}$ would be finite ($=\frac{4}{3}\pi\Delta^3$), corresponding to Stillinger's first contribution. While for small molecules the difference between $\bar{v}$ and v_w is considerable, for large molecules the difference disappears as $\Delta/r_w \to 0$. It may be noted that the cavities associated with hydrocarbon molecules in other solvents can be much greater than those in water. Thus the apparent molal volume of methane in hexane (8) indicates $\Delta = 0.88$ Å. The closer wrapping of the water molecules about hydrocarbons has been attributed to the greater internal pressure of water (8), or to a volume loss due to the partial fit of hydrocarbon molecules into the cavities of an icelike component of water (19).

Shrinkage of the Solvent Cavity When It Contains Hydrophilic Molecules

Stillinger (2) has pointed out that for the majority of water molecules in a clathrate cage surrounding a hard-sphere solute molecule the dipole moment direction cannot point either towards or directly away from the center of the solute molecule. Consequently, such a cage should be partially disrupted when the solute particle is an ion or a strong dipole (Stillinger's third "contribution" to volume). This may account for the alkyl chlorides in Fig. 2 having values of $\bar{v}/v_w$ slightly less than expected; *i.e.* Δ is slightly less than 0.53 Å, so that water molecules are packed more closely in the immediate environment of the solute molecule. This accords with other indications (*e.g.* from Hansch's π values (15)) that chloroalkanes are less hydrophobic than alkanes.

We may, then, expect [2] to hold only for preponderantly hydrophobic molecules. In fact, we find that for molecules containing three or more alkyl carbon atoms for each hydrophilic group (hydroxyl, ether, amine, amide, or urea) [2] with $\Delta = 0.53$ Å works reasonably well. This is illustrated for eight apolar molecules in Table 1; other molecules having $\overline{V}$ agreeing to within 4% of that predicted by [2] are: 1-propanol (11, 14, 21), 2-propanol (14, 21), 1-butanol (11, 12, 14, 21), 2-butanol (14, 21), 2-methyl-1-propanol (14), 1-pentanol (11, 14), 2,2-dimethyl-1-propanol (12), cyclohexanol (12, 16), cycloheptanol (16), benzyl alcohol (14), tetrahydropyran (12, 18, 24), dioxane (18, 24), *n*-propylamine (16), *n*-butylamine (16), *t*-butylamine (12), *n*-pentylamine (16), *n*-hexylamine (16), *n*-heptylamine (16), diethylamine (16), di-*n*-propylamine (16), diethylmethylamine (16), piperidine (16), heptamethyleneimine (16), *N*-methylpyrrolidine (16), *N*-methylpiperidine (16), isopropyl urea (21), *n*-butylurea (21), 1,1-diethylurea (21), 1,3-diethylurea (21), and tetramethylurea (21, 23).

With hydrophilic molecules having less than two alkyl carbon atoms per polar group, on the other hand, [2] fails badly. This is illustrated for eight polar molecules in Table 1; in all cases $\overline{V}$ is 10–20% smaller than calculated from [2], the solvent cavity shrinking for reasons discussed above.

The extent of shrinkage might be expected to vary, depending on (*a*) the differing abilities of different polar groups to form hydrogen bonds to water, and (*b*) the differing extent to which the surface area of the molecule is occupied by these polar groups. These surface areas can be computed by addition of the van der Waals surface increments given for different atoms and groups

[a]At 20 °C.

by Bondi (5). An example of their use is given in Fig. 3; it is assumed that the polar surface area (p.s.a.) of methanol and of 1-propanol is made up of the hydroxyl group, and the nonpolar surface area (n.p.s.a.) of the methyl or *n*-propyl group. The shrinkage of $\overline{V}$ of various alcohols in water is found to be a linear function of the percentage of the molecular surface area occupied by the hydroxyl group, as shown in Fig. 4*A*.

Similar relations are found to hold for amines, amides, and ureas (Fig. 4*B–E*). While the example of 1,3-dioxolane (Table 1) indicates that the ether oxygen atom can be effective in hydrogen-bonding to water and thus shrinking the solvent cavity, the example of trimethylamine (Table 1) indicates that hydrogen-bonding by the amine nitrogen is comparatively ineffective. Consequently, in calculating the polar surface area (% p.s.a.) for primary and secondary amines in Fig. 4*B* and *C* we have taken account only of the surface area of the hydrogen atoms attached to

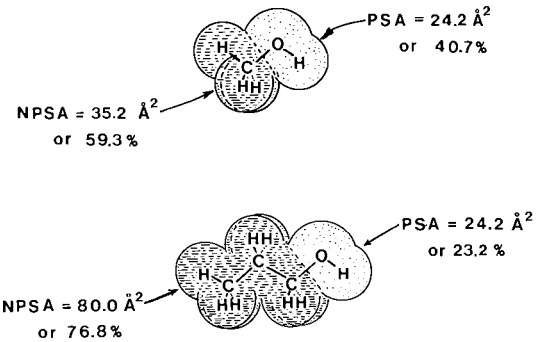

FIG. 3. Comparison of the polar surface area (p.s.a.) and nonpolar surface area (n.p.s.a.) of methanol and of 1-propanol as a percentage of the total surface of the molecule.

nitrogen groups. This is the reason for the apparently small % p.s.a. of these compounds; if the p.s.a. were taken as the total areas of the $-NH_2$ or —NH— groups, the % p.s.a. of the primary amines (*e.g.*, methylamine, compound 2

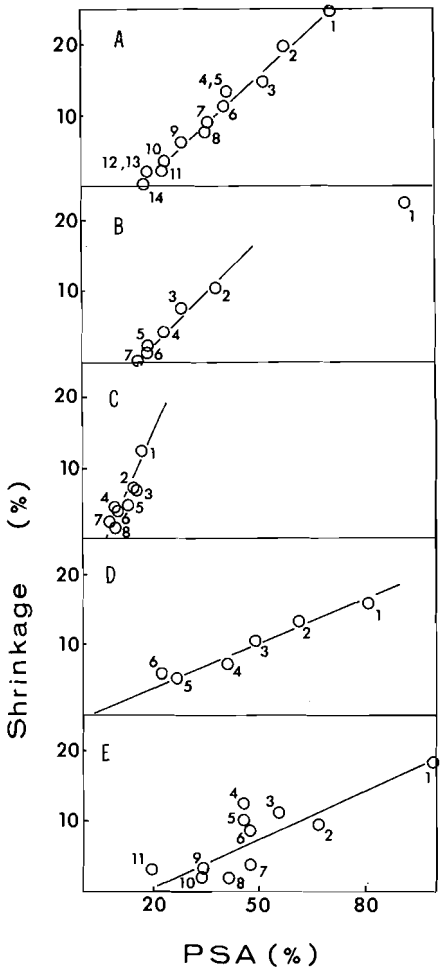

FIG. 4. Effect of percentage of polar surface area (p.s.a.) of a molecule on the shrinkage of $\bar{v}$ in water: (*A*) (Alcohols): 1, erythritol (ref. 25); 2, glycerol (ref. 12); 3, ethylene glycol (ref. 22); 4, 1,2-propanediol (ref. 22); 5, 1,3-propanediol (ref. 22); 6, methanol (refs. 11, 14); 7, 1,4-butanediol (ref. 22); 8, 1,3-butanediol (ref. 22); 9, ethanol (refs. 11, 14); 10, 2-propanol (ref. 14); 11, 1-propanol (refs. 11, 14); 12, 1-butanol (refs. 11, 12, 14); 13, 2-butanol (ref. 14); 14, *tert*-butyl alcohol (refs. 12, 17). (*B*) (Ammonia and primary amines); 1, ammonia (ref. 16); 2, methylamine (ref. 16); 3, ethylamine (ref. 16); 4, *n*-propylamine (ref. 16); 5, *t*-butylamine (ref. 12); 6, *n*-butylamine (ref. 16); 7, *n*-pentylamine (ref. 16). (*C*) (Secondary amines): 1, aziridine (ref. 18); 2, dimethylamine (ref. 16); 3, azetidine (ref. 18); 4, hexamethyleneimine (ref. 18); 5, pyrrolidine (ref. 18); 6, piperidine (ref. 18); 7, heptamethyleneimine (ref. 18); 8, diethylamine (ref. 16). (*D*) (Amides): 1, formamide (refs. 12, 21); 2, acetamide (ref. 21); 3, propionamide (ref. 21); 4, *n*-butyramide (ref. 21); 5, *N*,*N*-dimethylformamide (ref. 21); 6, *N*,*N*-dimethylacetamide (ref. 21). (*E*) (Ureas): 1, urea (refs. 12, 21, 23); 2, methylurea (ref. 21); 3, ethylurea (ref. 21); 4, 1,1-dimethylurea (refs. 21, 23); 5, 1,3-dimethylurea (refs. 21, 23); 6, *n*-propylurea (ref. 21); 7, isopropylurea (ref. 21); 8, *n*-butylurea (ref. 21); 9, 1,1-diethylurea (ref. 21); 10, 1,3-diethylurea (ref. 21); 11, tetramethylurea (refs. 21, 23).

of Fig. 4*B*) would be greater than those of the corresponding alcohols (*e.g.*, methanol, compound 6 of Fig. 4*A*). Obviously, our definition of polar surface is somewhat arbitrary, but at least it has the virtue of affording very simply a quantitative measure of polar character which is consistent as long as it is restricted to a single class of compounds.[3]

The limited data in the literature indicate that the % n.p.s.a. correlates roughly with Hansch's π values (15), with the *h* values of Cabani *et al.* (16, 18), and with Neal and Goring's $d\phi_2/dT$ values (12), all of which have been proposed as quantitative measures of hydrophobic character; however, further work will be required to discover how generally useful it is.

Limitations of the Model

The foregoing model has been tested only with fairly small molecules, none of which departs too far from a spherical shape. Thus, if *n*-pentane is considered to be a prolate ellipsoid having a volume equal to that of its spherical isomer, neopentane, but an axial ratio of 2.3, its surface is only 11% greater than that of neopentane, and consequently the empty volume surrounding the molecule should be only about 11% greater. However, for more extended molecules [1] and [2] become increasingly inadequate; the problem of such molecules will be dealt with in a later paper. For relatively simple and compact water-soluble molecules (ketones, ethers, esters, amino acids, carbohydrates [2] has proved moderately successful, as will be shown in subsequent papers of this series.

We are indebted to two referees for most helpful criticism, which has led to substantial modification of this paper, to Dr. D.A.I. Goring for encouragement and discussion, and to the National Research Council of Canada for financial support of our experimental work.

[3]We have chosen to consider the entire surface of urea as polar, so that % p.s.a. = 100% in Fig. 4*E*. Roseman and Jencks (26) argue that the flat upper and lower surfaces of the urea molecule, covered by the π-orbitals, are apolar, the polar character residing only in the hydrogen-bonding capabilities of the hydrogen and oxygen atoms in an equatorial plane of the molecule. Such an approach would shift the points of Fig. 4*E* to the left and increase the slope of the line.

Regioselective *O*-Alkylation of Sterically Hindered Steroidal Ethynyl Carbinols

Z. G. HAJOS AND G. R. DUNCAN

Faculty of Pharmacy, University of Toronto, Toronto, Ontario M5S 1A1

Received March 3, 1975

Z. G. HAJOS and G. R. DUNCAN. Can. J. Chem. **53**, 2971 (1975).

A synthetic method is described for the direct regioselective *O*-alkylation of sterically hindered acetylenic carbinols in the presence of other alcoholic functional groups. The method is not sensitive to the configuration of the latter or to the stereochemistry of ring fusion; the preparation of 5β- and 5α- 20α-ethynyl-20β-methoxy-pregnan-3β-ol **1***b* and **2***b* from the corresponding 20-ols is exemplary. In addition, a straightforward high yield four-step procedure is described for the preparation of the regio-isomer, 20α-ethynyl-3β-methoxy-5β-pregnan-20β-ol **1***c* from 5β-pregnan-3β-ol-20-one **3***a* via **3***b*, **3***c* and **3***d*.

Z. G. HAJOS et G. R. DUNCAN. Can. J. Chem. **53**, 2971 (1975).

On décrit une méthode de synthèse pour la *O*-alkylation directe et régiosélective de carbinols acétyléniques stériquement empêchés en présence d'autres groupes fonctionnels hydroxylés. La méthode n'est pas sensible à la configuration de ces derniers ou à la stéréochimie de la fusion des cycles; on propose à titre d'exemple la préparation des éthynyl-20α méthoxy-20β 5β- (et 5α-)pregnanols-3β (**1***b* et **2***b*) à partir des composés hydroxy-20 correspondants. De plus on décrit une méthode simple en quatre étapes permettant d'obtenir avec un bon rendement le régioisomère éthynyl-20α méthoxy-3β 5β-pregnanol-20β (**1***c*) à partir de la 5β-pregnanol-3β one-20 (**3***a*) par l'intermédiaire de **3***b*, **3***c* et **3***d*.

[Traduit par le journal]

During the course of the investigation of the physiological activity of norcholane analogs of cucurbitacins the problem of regioselective *O*-alkylation of the previously reported (1) diol (**1***a*) arose. Based on electronic considerations we expected the acetylenic carbinol to be the more reactive alcoholic group in **1***a*. Dreiding model studies, however, of the steric arrangment (2) of the molecule indicated a rather hindered C-20 hydroxyl group. Thus one could not predict with certainty which of the two factors would prevail. Rotation around the C_{17}–C_{20} axis would result in even more serious interactions between the C_{13}-methyl and the C_{20}-methyl or ethynyl groups, respectively. Alkylation of a sterically less hindered 17α-ethynyl, 17β-steroidal alcohol using an equimolecular amount of sodamide in liquid ammonia has been previously reported in the patent literature (3), however, no yields were given.

We formed the anion of **1***a* with 2 molecular equiv. of sodium hydride in dry *N*,*N*-dimethyl formamide at 20 °C, and monoalkylated it with an excess of methyl iodide to give exclusively 20α-ethynyl-20β-methoxy-5β-pregnan-3β-ol (**1***b*), m.p. 126–136 °C (91%). A comparison of its n.m.r. spectrum with that of the starting material (**1***a*) revealed that no methylation of the 3β-axial hydroxyl group occurred under the aforementioned reaction conditions. In agreement with the indicated stereochemistry the signal of the C-3 equatorial proton appeared as a relatively narrow multiplet at about 4.1 p.p.m. in both compounds (4).

Since it has been known that equatorial alcohols are more reactive in esterification reactions than their axial counterparts (5), it was of interest to find out if the observed selectivity of ethynyl ether formation could be maintained in the presence of the more reactive equatorial hydroxyl group. Alkylation of the previously reported (1) diol **2***a* with methyl iodide under the above described reaction conditions (**1***a* → **1***b*) gave exclusively 20α-ethynyl-20β-methoxy-5α-pregnan-3β-ol (**2***b*), m.p. 166–178 °C (92.5%).

In comparison with the n.m.r. spectra of **1***a* and **1***b* the signal of the C-3 axial proton of **2***b* appeared at higher field, δ 3.57 (m, 3*a*-H), essentially at the same position as in the starting material (**2***a*) as a broad multiplet due to large diaxial coupling constants. This showed that the 3β-equatorial alcohol had not been alkylated under the above reaction conditions.

These results provide a new and simple procedure for the regioselective *O*-alkylation of

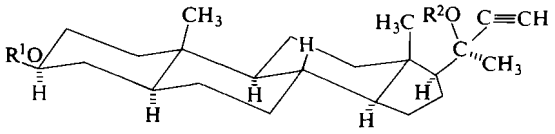
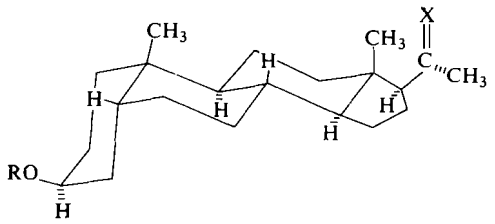
1*a* $R^1 = R^2 = H$
1*b* $R^1 = H; R^2 = CH_3$
1*c* $R^1 = CH_3; R^2 = H$



2*a* $R^1 = R^2 = H$
2*b* $R^1 = H; R^2 = CH_3$



3*a* $R = H; X = O$
3*b* $R = H; X = N{-}OCH_3$
3*c* $R = CH_3; X = N{-}OCH_3$
3*d* $R = CH_3; X = O$

gem-substituted sterically hindered ethynyl carbinols. It avoids the alkylation of the non-acetylenic alcoholic function regardless of its axial or equatorial orientation. No elimination of water was observed, which would have led to undesired enyne formation. The reaction proceeded in good yield and high regioselectivity with both A/B-*cis* (**1***a*) and A/B-*trans* (**2***a*) steroids.

It became evident that in order to achieve the regioselective *O*-alkylation of the cyclohexanol-type oxygen function at the steroidal C-3 position, the C-20 position would have to be protected. Therefore, the keto alcohol **3***a* (1) was converted to its C-20 oxime ether **3***b*. The signal of the C-3 equatorial proton appeared as a relatively narrow multiplet at about 4.1 p.p.m., similar to the signal found in compounds **1***a* and **1***b*.

Methylation under the aforementioned reaction conditions (**1***a* → **1***b*) gave the methyl ether **3***c* in excellent yield (94%). The relatively narrow multiplet of the C-3 equatorial proton appeared at higher field in agreement with the literature (4).

Hydrolysis of the oxime ether group of **3***c* under mild reaction conditions to avoid isomerization at the steroidal C-17 position (6) gave 3β-methoxy-5β-pregnan-20-one (**3***d*) in 97% yield. The compound appeared to be a waxy solid, which resisted all attempts at purification by crystallization or by preparative thin layer chromatography. It has been identified by infrared and by n.m.r. spectroscopy. The 21-H signal of **3***d* was shifted downfield to 2.10 p.p.m. as expected from data obtained with **3***a* (1) and showed no trace of the oxime-ether methyl signal at 3.80 p.p.m.

The addition of acetylene to the 20-keto group of **3***d* gave **1***c*, the 3-methyl ether derivative of the acetylenic carbinol **1***a*. The synthesis of the regio-isomer of **1***b* has thus been accomplished. The high yield (94%) and the good quality of the crude product (**1***c*) is due to the reaction conditions, *i.e.* the introduction of acetylene gas during the reaction of **3***d* with the lithium acetylide – ethylene diamine complex (7). This optimized the yield of conversion and minimized undesired dimer formation as shown by thin layer chromatography.

The observed n.m.r. data are in good agreement with the structural differences between the regio-isomers **1***b* and **1***c*, as shown by the shift in the positions of the 21 and of the 3*e*-H signals. The assignment of the 18- and 19-H signals, on the other hand, has been derived from the n.m.r. spectrum of a mixture containing **1***c* and the 17α-isomer of **1***c*. This fraction, a very minor side product of the acetylene reaction (4.6%), has been obtained by preparative thin layer chromatography of the combined mother liquors of crystallization. It showed the three C-19 protons at 0.95 p.p.m., while the signal of the three C-18 protons appeared at 0.83 as well as at 0.81 p.p.m. respectively, indicating an approximately 1:1 mixture of **1***c* and its 17α-epimer in this particular fraction. The 17β → 17α isomerization is well known from the literature (6), and it has been maintained at a minimum by the introduction of acetylene gas (*C*-acidic compound) during the execution of the reaction.

Experimental

Melting points were determined on a Kofler block and are corrected. Absorption spectra were determined in absolute $CHCl_3$ using a Beckman IR-8 i.r. spectrophotometer, and in $CDCl_3$ with TMS as internal standard using a Varian HA-100 or a T-60 n.m.r. spectrophotometer, as indicated in the discussion part of this paper. Elemental analyses were performed by A. B. Gygli, Microanalysis Laboratory, Toronto, Ontario. "Worked up as usual" will mean a solution of the reaction mixture in a water immiscible organic solvent was washed with saturated NaCl in water (two or three times), dried over anhydrous Na_2SO_4, filtered through Celite, and evaporated *in vacuo*.

*20α-Ethynyl-20β-methoxy-5β-pregnan-3β-ol (**1b**)*

To a 50% dispersion of sodium hydride in mineral oil (11.0 mg, 0.23 mmol) was added 35.0 mg (0.1 mmol) of the acetylenic diol **1***a* dissolved in 0.4 ml of dry *N,N*-dimethyl formamide (DMF). It was stirred under nitrogen for approximately 2 min. Methyl iodide (0.2 ml, treated with CaH_2 at 20 °C for 24 h) was added to 1.0 ml anhydrous DMF, and 0.2 ml of this solution ($\simeq$0.5 mmol of CH_3I) was added to the anion of **1***a* in dry DMF. The system was stirred under nitrogen at 20 °C for 24 h. It was then poured into 0.5 ml of water, and worked up as usual with $CHCl_3$ to give 33.1 mg (92%) of crude, crystalline methyl ether **1***b*; ν_{max} 3700, 3650 (OH), 3333 (—C≡CH), 1060 cm^{-1} (—OCH_3). Recrystallization from ether–hexane gave analytically pure **1***b*; m.p. 126–136 °C. The ^1H n.m.r. spectrum of **1***b* (100 MHz) showed δ 0.90 (s, 3, 18-H), 0.98 (s, 3, 19-H), 1.40 (s, 3, 21-H), 2.45 (s, 1, —C≡C—H), 3.36 (s, 3, —OCH_3), and 4.14 (m, 1, 3*e*-H).

Anal. Calcd. for $C_{24}H_{38}O_2$: C, 80.39; H, 10.68. Found: C, 80.89; H, 10.81.

*20α-Ethynyl-20β-methoxy-5α-pregnan-3β-ol (**2b**)*

To a 50% dispersion of sodium hydride in mineral oil (22.7 mg, 0.47 mmol) was added 61.0 mg (0.18 mmol) of the acetylenic diol **2***a* dissolved in 1.0 ml dry DMF. It was stirred under nitrogen for 5 min. Methyl iodide (0.2 ml, treated with CaH_2 at 20 °C for 24 h) was added to 1.0 ml anhydrous DMF and 0.4 ml of this solution (approximately 1.0 mmol CH_3I) was added to the anion of **2***a* in dry DMF. The system was stirred under nitrogen at 20 °C for 1 h. It was then poured into 1.0 ml of ice water, and worked up as usual with benzene. The solid residue (65.0 mg) was placed under high vacuum to remove traces of DMF and gave 58.0 mg of the methyl ether **2***b* (92.5%), identified by n.m.r. spectroscopy (*vide supra*). Recrystallization from ether gave analytically pure **2***b*; m.p. 166–178 °C. The ^1H n.m.r. spectrum of **2***b* (60 MHz) showed δ 0.90 (s, 3, 18-H), 0.81 (s, 3, 19-H), 1.45 (s, 3, 21-H), 2.45 (s, 1, C≡CH), 3.36 (s, 3, —OCH_3), and 3.57 (m, 1, 3*a*-H).

Anal. Calcd. for $C_{24}H_{38}O_2$: C, 80.39; H, 10.68. Found: C, 80.21; H, 10.67.

*3β-Methoxy-20-methoxyimino-5β-pregnane (**3c**)*

A 50% dispersion of sodium hydride in mineral oil (542 mg, 11.3 mmol) was washed free of oil with dry petroleum ether. To this was added while stirring under nitrogen at 20 °C, 622.0 mg (1.8 mmol) of the oxime ether alcohol **3***b* dissolved in 12.0 ml of dry DMF. The addition took approximately 3 min and it was then stirred under nitrogen at 20 °C for 50 min. Methyl iodide (1.25 ml, treated with CaH_2 at 20 °C for 24 h) was added to 1.0 ml dry DMF. This solution (approx. 18.7 mmol of CH_3I) was added within 5 min while stirring under nitrogen to the anion of **3***b* in dry DMF. Stirring was continued for 16 h with the exclusion of moisture. A few drops of methanol were then added, and it was poured into 50 ml of ice water and worked up as usual with $CHCl_3$. The resulting oil was placed under high vacuum to remove traces of DMF. The oily residue crystallized upon the addition of 1.0 ml of methanol to give 612.1 mg (94%) of the methyl ether **3***c*, identified by n.m.r. spectroscopy. Recrystallization from methanol gave analytically pure **3***c*; m.p. 84–86 °C. The ^1H n.m.r. spectrum of **3***c* (60 MHz) showed δ 0.60 (s, 3, 18-H), 0.93 (s, 3, 19-H), 1.78 (s, 3, 21-H), 3.26 (s, 3, 3β-OCH_3), 3.50 (m, 1, 3*e*-H), and 3.80 (s, 3, =N—OCH_3).

Anal. Calcd. for $C_{23}H_{39}NO_2$: C, 76.40; H, 10.87. Found: C, 76.36; H. 10.43.

*20-Methoxyimino-5β-pregnan-3β-ol (**3b**)*

The 20-keto steroid **3***a* (193 mg, 0.61 mmol) was dispersed in 2.0 ml of methanol. Methoxylamine hydrochloride (73.0 mg, 0.87 mmol) was added in 3.0 ml of methanol, followed by 92.0 mg (1.06 mmol) of anhydrous sodium acetate and 3.0 ml of methanol. The reaction mixture was stirred for 16 h, water (15.0 ml) was then added, and the crystalline precipitate was filtered off. It was then dissolved in $CHCl_3$, and worked up as usual to give 257.7 mg of a solid. This was broken up in methanol and filtered to give 199.4 mg (94%) of the oxime ether **3***b*. Recrystallization from methanol gave analytically pure **3***b*; m.p. 136–139.5 °C; ν_{max} 3750, 3500–3650 (OH), 1660, 1600 (weak C=N bands), 1060 cm^{-1} (—OCH_3). The ^1H n.m.r. spectrum of **3***b* (60 MHz) showed δ 0.62 (s, 3, 18-H), 0.97 (s, 3, 19-H), 1.83 (s, 3, 21-H), 3.85 (s, 3, =N—OCH_3), and 4.12 (m, 1, 3*e*-H).

Anal. Calcd. for $C_{22}H_{37}NO_2$: C, 76.03; H, 10.73; N, 4.03. Found: C, 76.24; H, 10.61; N, 4.00.

*20α-Ethynyl-20β-hydroxy-3β-methoxy-5β-pregnane (**1c**)*

a. Hydrolysis of the 20-methoxyimino compound 3c to the 20-keto compound 3d

The oxime ether **3***c* (612 mg, 1.69 mmol) in 45.0 ml of 0.066 *N* HCl in acetone–water (40.4 ml of acetone and 4.5 ml of 0.66 *N* aqueous HCl) was refluxed for 4 h. It was then allowed to stand at 20 °C for 18 h. Thin layer chromatography showed the presence of some residual starting material (benzene/ethyl acetate, 9:1 on Silica Gel; R_f of **3***c* 0.4; of **3***d* 0.29). Therefore, 1.0 ml of 2.0 *N* aqueous HCl was added, and refluxing continued for 4 h; it was then allowed to stand at 20 °C for 18 h. No starting material (**3***c*) was indicated by t.l.c. The clear solution was evaporated *in vacuo* at 20 °C to remove the acetone. The usual work up with $CHCl_3$ gave 549.0 mg (97%) of the desired 20-keto compound **3***d* in the form of a waxy solid; ν_{max} 1705 (20-CO) and 1088 cm^{-1} (—OCH_3); n.m.r. spectrum (*vide supra*). It was rather insoluble in methanol, slightly more soluble in ethyl alcohol, soluble in acetone, in ether, and in *n*-hexane. It resisted all attempts at crystallization. A 63.0 mg sample of **3***d* was dissolved in $CHCl_3$, and applied to two 20 × 20 cm,

1.0 mm thick SiO_2-gel plates with fluorescence indicator; it was developed with anhydrous ether. A 1.0 cm wide strip of each plate was cut away and sprayed with phosphomolybdic acid. Based on this 4 zones have been marked and separated into fronts 1–4. Fraction 2 gave 31.0 mg of clean (by t.l.c. developed with ether or benzene/ethyl acetate, 1:1 and 9:1 respectively) 20-keto compound **3***d*, which could be broken up with methanol into a waxy solid, but still resisted all attempts at crystallization. The ^1H n.m.r. spectrum of **3***d* (60 MHz) showed δ 0.60 (s, 3, 18-H), 0.90 (s, 3, 19-H), 2.10 (s, 3, 21-H), 3.30 (s, 3, 3β-OCH_3), and 3.50 (m, 1, 3*e*-H).

b. Acetylene addition to 5β-pregnan-3β-ol-20-one-3-methyl ether (3d) to give 1c

Into a 50.0 ml 3-necked flask equipped with magnetic stirring bar, serum cap, gas inlet tube, and reflux condenser with $CaCl_2$ filled tube at the top was placed 5.0 ml of anhydrous DMSO (dimethylsulfoxide). Acetylene gas (cooled to −75 °C and purified with two H_2SO_4, one $CaO/CaCl_2$ and one fritted-glass filter tower) was introduced over the DMSO level while stirring for 40 min at 20 °C. Lithium-acetylide – ethylenediamine complex (stored under Argon, freshly opened bottle; 460 mg, 4.8 mmol) was added at once; it dissolved to give a light brown solution. To this was added 526.7 mg (1.59 mmol) of crude, unpurified 20-keto compound **3***d* dissolved in 6.0 ml of anhydrous DMSO with the help of a syringe through the serum cap within 10 min while stirring under a continuous flow of acetylene gas for an additional 4 h. The dark brown solution was sealed under acetylene, and it was stirred at 20 °C for 16 h. It was then cooled with ice water, and 600 mg of ammonium chloride in 4 ml of water was added to it dropwise. Approximately 300 mls of benzene and 100 ml of water was added, and the mixture was carefully acidified with 2 *N* HCl. The benzene solution was then worked up as usual to give 650.5 mg of crude **1***c*, a dark brown solid. This was dissolved in 60.0 ml of $CHCl_3$ and treated with Darco G-60 at 20 °C for 30 min. It was filtered through Celite, and evaporated *in vacuo* to give 535.0 mg (94%) of light yellow, crystalline ethynyl carbinol **1***c*; t.l.c. on 0.25 mm thick SiO_2-gel developed with benzene/ethyl acetate, 9:1 showed R_f 0.18; spraying with vanillin–H_3PO_4 and heating to 80 °C gave a cherry red colour; it showed some slower moving impurities, n.m.r. spectrum (*vide infra*).

Due to the slower moving impurity the compound (**1***c*) was dissolved in 25 ml of benzene, 7.0 g of Silicagel III (Woelm, for dry column chromatography) was added, and the solvent evaporated *in vacuo*. The dry SiO_2 powder and **1***c* were placed on top of an 87 cm long column of the same absorbent of 2.5 cm diameter. It was developed with 300 ml of anhydrous ether in 3.0 ml fractions. The first ten fractions contained the desired material as shown by t.l.c., and gave 496.6 mg of almost colorless **1***c* (87%). Thin layer chromatography indicated no slower moving impurities. Recrystallization from ethyl acetate and petroleum ether (b.p. 30–60 °C) gave analytically pure ethynyl carbinol **1***c* 305.9 mg m.p. 150–156 °C; t.l.c. (*vide supra*); ν_{max} 3400–3550, 3330 (OH), 3270 (—C≡CH), 1100 and 1075 cm^{-1} (—C—O-stretching). The ^1H n.m.r. spectrum of **1***c* (60 MHz) showed δ 0.83 (s, 3, 18-H), 0.95 (s, 3, 19-H), 1.50 (s, 3, 21-H), 2.48 (s, 1, —C≡CH), 3.30 (s, 3, 3β-OCH_3), and 3.50 (m, 1, 3*e*-H).

Anal. Calcd. for $C_{24}H_{38}O_2$: C, 80.39; H, 10.68. Found: C, 80.19; H, 10.65.

The mother liquors of crystallization were combined and evaporated *in vacuo* to give 140 mg of crude **1***c*. This was dissolved in 1.0 ml CH_2Cl_2 and applied to two 20 × 20 cm, 1.0 mm thick SiO_2-gel plates with fluorescence indicator. They were developed with anhydrous ether. A 1.0 cm wide strip of each plate was cut away and sprayed with vanillin–H_3PO_4 (desired band turned pink). Work up of the desired band gave 90.0 mg of a crystalline fraction, which was indistinguishable from **1***c* by t.l.c. in different solvent systems (one spot in benzene/ethyl acetate, 1:1, in ether, and in ethyl acetate). It showed, however, m.p. 100–110 °C. It was extracted with refluxing petroleum ether (b.p. 30–60 °C) to give 34.6 mg of **1***c* (insoluble in petroleum ether) m.p. 150–156 °C; n.m.r. spectrum superimposable to that of authentic **1***c*. Total yield of pure, crystalline acetylenic carbinol **1***c* was thus 340.5 mg (59.5%). The anomalous n.m.r. spectrum of the petroleum ether soluble fraction (55.0 mg) has been described in the discussion part of this paper.

The authors wish to express their thanks to the Medical Research Council of Canada (MA 2996) for supporting this investigation.

The Preparation and Synthetic Utility of *tert*-Butyldiphenylsilyl Ethers[1]

STEPHEN HANESSIAN AND PIERRE LAVALLEE[2]
Department of Chemistry, University of Montreal, Montreal, Quebec H3C 3V1
Received June 27, 1975

STEPHEN HANESSIAN and PIERRE LAVALLEE. Can. J. Chem. **53**, 2975 (1975).

The utility of *tert*-butyldiphenylsilyl chloride as a reagent for the protection of hydroxyl groups was explored. The corresponding *tert*-BDPSi ethers have much greater stability to acids, and under conditions of hydrogenolysis, than related silyl and trityl ethers. Preferential removal of trityl, tetrahydropyranyl, benzyl, and other silyl ethers and acetals can be effected in presence of *tert*-BDPSi ethers. Treatment with fluoride ion causes smooth cleavage of the latter.

STEPHEN HANESSIAN et PIERRE LAVALLEE. Can. J. Chem. **53**, 2975 (1975).

L'utilité synthétique du chlorure de *tert*-butyldiphenylsilyle pour la protection temporaire des fonctions hydroxyles a été explorée. Les éthers *tert*-BDPSi démontrent une stabilité supérieure dans des conditions acides et d'hydrogénolyse, par rapport à d'autres éthers silylés analogues, et aux éthers de triphenylméthyle, tétrahydropyrannyle, et benzyle. Plusieurs fonctions y inclus des acétals, peuvent être préférentiellement hydrolysés en présence de la fonction *O-tert*-BDPSi.

The availability of appropriate protecting groups for hydroxyl, and related functions (1, 2) is oftentimes a crucial problem in the planning and execution of a synthetic stratagem involving polyfunctional molecules. Silyl ethers, and in particular, *tert*-butyldimethylsilyl ethers, have been extensively used in recent synthetic work related to the prostaglandins (3), and also in the deoxynucleoside series (4).

We wish to report on the protection of hydroxyl groups as *tert*-butyldiphenylsilyl ethers (*tert*-BDPSi). In addition to retaining all the known features that are associated with silyl ethers, such as their ease and selectivity of formation, their adaptability to various analytical techniques, and their compatibility with a variety of conditions or synthetic transformations in organic chemistry (3), the *tert*-BDPSi group offers some unique and novel features that constitute a significant improvement over the existing related groups, and warrants their communication at this time.

Selectivity—Primary hydroxyl groups are silylated preferentially to secondary, as indicated by the following examples. Treatment of methyl α-D-glucopyranoside with 1.1 equiv. of *tert*-butyldiphenylsilyl chloride[3] in DMF containing 2.2 equiv. of imidazole (3) (25 °C, 4 h[4]), afforded the corresponding 6-*O*-*tert*-DBPSi derivative as an amorphous solid, (75–80%); m.p. 119–121 °C; $[\alpha]_D^{23}$ +61.6° (*c* 1.15, $CHCl_3$).[5] Similar silylation of methyl 2-benzyloxycarbonylamino-2-deoxy-α-D-glucopyranoside (25 °C, 4 h) gave the corresponding crystalline 6-*O*-*tert*-DBPSi derivative (84%); m.p. 90.5–91.5 °C (ether–hexane); $[\alpha]_D^{23}$ +34.4° (*c* 1.16, $CHCl_3$).[6]

Silylation was equally effective in the case of secondary hydroxyl groups, including axially

[2]NRCC and Quebec Ministry of Education predoctoral fellow.

[3]Prepared from dichlorodiphenylsilane and *tert*-butyl lithium in refluxing pentane; b.p. 90 °C/0.015 Torr; 95%.

[4]Silylation could also be accomplished in pyridine, in the absence of imidazole, but the reaction times were longer.

[5]The presence of the phenyl chromophore in the *tert*-BDPSi group greatly facilitates the detection of products on chromatograms by spectrophotometric methods, a feature which is not shared by the related *O-tert*-butyldimethylsilyl group. Also in many instances there was no need for chromatographic separations.

[6]Satisfactory spectroscopic (i.r., n.m.r., mass) data were obtained for the compounds described herein. Crystalline compounds gave correct microanalyses.

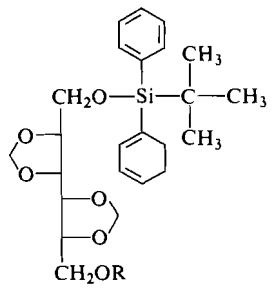
For personal use only.

disposed groups, utilizing the same combination of reagents and at temperatures ranging from 25–60 °C.

Stability and Compatibility—The *O-tert*-BDPSi group offers unique acid stability properties relative to related analogs. Thus, it is virtually unaffected under conditions that cause complete cleavage of *O*-trityl, *O-tert*-butyldimethylsilyl, and *O*-tetrahydropyranyl groups. In such a study, 2,3:4,5-di-*O*-methylene-D-mannitol was monosilylated as usual, and the resulting syrupy *O-tert*-BDPSi ether, $[\alpha]_D^{23}$ +32.3° (*c* 1.34, $CHCl_3$), was converted into the corresponding 6-*O*-trityl, 6-*O*-tetrahydropyranyl, and 6-*O-tert*-butyldimethylsilyl ethers. Treatment of these derivatives individually with 80% acetic acid caused selective cleavage of the 6-ether groups, and the 6-*O-tert*-BDPSi derivative was recovered in each case in over 96% yield.



R = H, Tr, THP, $Si(CH_3)_2C(CH_3)_3$

A distinctive feature of the *O-tert*-BDPSi group is its compatibility under conditions required for the acid-catalyzed formation, and cleavage of acetals. The following synthetic transformation will illustrate this point. Silylation of cytidine (1.1 equiv. *tert*-BDPSiCl, 2.2 equiv. imidazole, 25 °C, 3 h) gave the 5′-*O-tert*-BDPSi derivative (87%); m.p. 223–226 °C ($CHCl_3$); $[\alpha]_D^{23}$ +56.5° (*c* 1.14, MeOH). Treatment of the former with 2,2-dimethoxypropane and concentrated hydrochloric acid (25 °C, 24 h), followed by conventional workup, gave the corresponding 5′-*O-tert*-BDPSi-2′,3′-*O*-isopropylidene derivative (95.5%); m.p. 138–143 °C ($CHCl_3$–ether–hexane); $[\alpha]_D^{23}$ +30.3° (*c* 1.08, $CHCl_3$); M^+ 521; 506 (*M* − 15); 464 (*M* − 57), etc. Treatment with 50% aqueous trifluoroacetic acid – dioxane (25 °C, 15 min) gave the starting crystalline silyl ether derivative (64%). Benzylidene acetals of the 2-phenyl-1,3-dioxane type could also be preferentially hydrolyzed in the presence of secondary *O-tert*-BDPSi groups.[7]

The *tert*-BDPSi group is unaffected under conditions of hydrogenolysis.[8] Thus, benzylation of methyl 6-*O-tert*-butyldiphenylsilyl-α-D-glucopyranoside ($PhCH_2Br$, NaH, DMF) gave the corresponding crystalline tribenzyl ether; m.p. 115.5–116 °C; $[\alpha]_D^{23}$ +18.7° (*c* 1.04, $CHCl_3$). Catalytic hydrogenolysis in the presence of 20% palladium hydroxide-on-charcoal (6) gave the starting silyl ether, m.p. 117–118 °C, in 93% yield. The *O-tert*-BDPSi group was also found to be stable under the following conditions: 25–75% aqueous formic acid – dioxane, 25 °C, 2–6 h (90% recovery); 50% aqueous trifluoroacetic acid – dioxane, 25 °C, 15 min; hydrogen bromide in glacial acetic acid (2 equiv.), 12 °C, 2 min; catalytic amounts of sodium methoxide in methanol, 25 °C, 24 h (95% recovery); 9 *M* ammonium hydroxide – dioxane, 60 °C 2 h (96% recovery).

Upon treatment with a *M* solution of tetra-*n*-butyl-ammonium fluoride in THF (2 equiv.) (3), smooth cleavage occurred within 1–5 h at 25 °C to regenerate the parent alcohol in over 90% yield in all cases studied.[9] Hydrolysis could also be brought about in 3% methanolic hydrogen chloride (25 °C, 3 h, 71%), and in 2 *N* sodium hydroxide containing 50% ethanol (25 °C, 7 h, 93%).

Thus, the novel *tert*-BDPSi group becomes an important complement to the trityl and other silyl groups, for the selective protection of primary hydroxyl groups, with the added advantage of much greater stability under acidic and hydrogenolytic conditions. It is also a convenient and versatile protecting group for secondary hydroxyl groups, and as

[7]Little, if any migration of silyl groups was observed under these conditions. When kept in solution (CH_2Cl_2, etc.) for prolonged periods of time, some change (t.l.c.) was observed presumably due to a migration to suitably disposed primary hydroxyl groups. This possibility is presently under study.

[8]Some silyl ethers are susceptible to hydrogenolysis (3); see also ref. 5.

[9]Partial migration of ester (acetate, benzoate) groups occurs during the desilylation reaction in compounds where the esters functions are suitably disposed. This observation has been recently recorded by others also (5).

such, complements the tetrahydropyranyl and benzyl groups in a variety of synthetic transformations. Other applications are presently under study.

Kinetics and Equilibrium of Binding of Fe^{3+} by a Fulvic Acid: A Study by Stopped Flow Methods[1]

COOPER H. LANGFORD[2] AND TAHIR R. KHAN
Department of Chemistry, Carleton University, Ottawa, Canada K1S 5B6

Received June 3, 1974[3]

COOPER H. LANGFORD and TAHIR R. KHAN. Can. J. Chem. **53**, 2979 (1975).

The first report of a rate of binding of a metal ion (Fe^{3+}) by a soluble fulvic acid is derived from stopped flow measurements. The rate of complex formation is normal in Wilkins' sense and similar to that for sulfosalicylic acid. Dissociation is slow ($t_{1/2} > 10$ s). The binding of Fe^{3+} by the fulvic acid in acid solution, pH = 1–2.5, was investigated by kinetic analysis in which the reaction of free Fe^{3+} with sulfosalicylic acid was followed by stopped flow spectrophotometry on a time scale short compared to release of Fe^{3+} by fulvic acid. Conditional equilibrium constants found were $1.5 \pm 0.3 \times 10^4$ at pH = 1.5 and 2.5, and $2.8 \pm 0.3 \times 10^3$ at pH = 1.0 at 25 °C (ionic strength 0.1).

COOPER H. LANGFORD et TAHIR R. KHAN. Can. J. Chem. **53**, 2979 (1975).

On dérive de mesures à flux stoppé le premier rapport d'une vitesse de fixation d'un ion métallique (Fe^{3+}) par l'acide fulvique soluble. La vitesse de formation du complexe est normale dans le sens de Wilkins et semblable à celle rapportée pour l'acide sulfosalicylique. La dissociation est lente ($t_{1/2} > 10$ s). On a étudié la fixation du Fe^{3+} par l'acide fulvique en milieu acide, pH = 1–2.5, par une analyse cinétique dans laquelle la réaction du Fe^{3+} libre avec l'acide sulfosalicylique est déterminée par spectrophotométrie à flux stoppé sur une échelle de temps faible comparée à la vitesse de libération du Fe^{3+} par l'acide fulvique. On a trouvé que les constantes d'equilibre conditionnel sont de $1.5 \pm 0.3 \times 10^4$ à pH = 1.5 et 2.5 et $2.8 \pm 0.3 \times 10^3$ à pH = 1.0 à 25 °C (force ionique = 0.1).

[Traduit par le journal]

Introduction

Eigen (1) introduced the concept of 'kinetic spectrometry' which refers to the description of a complex chemical system in terms of a set of rate constants characteristic of its components. These rate constants are, of course, reciprocals of a set of frequencies which may be said to form a spectrum. The metaphor is especially appealing when relaxation techniques such as ultrasonic absorption are used to study kinetics because the kinetic spectrum is seen directly in the instrumental output.

For purposes of analysis of mixtures, the kinetic spectrum supplies an interesting set of frequencies by which different components may be recognized and estimated. The idea has been successfully exploited recently by groups in the United States (2, 3) and the Soviet Union (4). The most promising experimental approach is stopped flow spectrometry where a concentration pulse is applied and the system is followed during the time course of the relaxation of the components of interest to a common product by

following changes in the visible–ultraviolet spectrum.

So far, such studies have usually prepared a set of components (*e.g.* metal ions, M^{2+}) as some favorable molecular species (*e.g.* EDTA complexes) and reacted them with a common reagent (*e.g.* Cu^{2+}) to produce a common product (*e.g.* CuEDTA) which is monitored at a characteristic wavelength. Our interest is similar with one exception. We are interested in reagents which react with the analyte *without* prior treatment of the analyte. In this way, we seek to develop analysis for the *molecular species* originally in the *analyte*, as they are characterized by their rate constants for reaction with a given reagent.

This paper reports a *primitive* example of the above program. We analyze equilibrium mixtures of aquoiron(III) (aquo Fe(III)) species and a soluble fulvic acid to determine conditional average binding constants. In this case, the unbound aquo Fe(III) species react rapidly with the reagent (excess sulfosalicylic acid) such that the free iron can be determined prior to significant perturbation of the iron – fulvic acid complex. We have only one kinetically important species. To establish this point, some investigations were made of the kinetics of interaction of Fe(III) with fulvic acid using the (small!) absorbance changes in the spectrum of the fulvic acid. Also, one run used an excess of fulvic acid.

The system under study is difficult for alternative methodologies and some significant interest attaches to the results. The binding of iron by fulvic acids is thought to be quite important to iron dissolution and transport in fresh water. Moreover, metal – fulvic acid complexes have sometimes been referred to as 'non-labile' without detailed evidence. The present study contains, to our knowledge, the first direct examination of the kinetics of such an interaction.

Experimental

Materials

The fulvic acid sample was generously supplied by D. S. Gamble, Soil Research Institute, Agriculture Canada (5). It is a sample extracted from the Bh horizon of an imperfectly drained podzol soil in Prince Edward Island. The number average molecular weight is approximately 900. It contains 3.3 mequiv./dry g of phenolic sites *ortho* to carboxylic acid sites (salicylic acid type sites) and an additional 4.4 mequiv./dry g of carboxylic acid sites. Alcoholic, ketonic, and quinoid functionality is also present (5). Stock solutions were prepared and stored in the dark. They were found to be stable (no spectral change) for periods much longer than the storage time allowed prior to any of the experiments reported.

Iron(III) solutions were prepared from A.R. Grade metal by dissolution in nitric acid. The p*H* of the stock solutions was checked with a Fisher 'accumet' p*H* meter. Dilute Fe(III) solutions of specified p*H* were prepared by diluting the Fe(III) stock with water and precisely calculated (comparatively large) amounts of standardized $HClO_4$ solution.[4] The ionic strength was maintained at 0.10 using $NaClO_4$ solutions.

Recrystallized Baker 'analyzed' sulfosalicylic acid (SSA) was used to prepare stock solutions. These were found to be stable (no change in spectrum) for periods of over three months.

Kinetics

There were three types of kinetic measurements: (*1*) reaction between fulvic acid and Fe(III); (*2*) reaction between SSA and Fe(III); (*3*) reaction between SSA and the equilibrated Fe(III) – fulvic acid mixtures. All were made on a Durrum-Gibson stopped flow spectrometer thermostatted by circulating water at 25.0 °C. Two modes of data recording were employed. In most runs, the data were recorded conventionally on photographs of the record displayed on the Durrum-Gibson device's storage oscilloscope. In later runs, data were stored in six-bit digital form by a Biomation 610B Transient Recorder and read out on a teletype. There is no substantial difference in resolution between the two cases when only one rate constant is involved.

The data treatment for experiments of type (*1*) was necessarily simple. Good data for these experiments are very difficult to obtain, mainly due to two factors. One is that fulvic acid gives an almost flat absorption band starting from 900 nm and rising into the ultraviolet. The other is that the total change in absorbance due to binding with iron is very small (maximally 0.05 absorbance units). Kinetic runs under the most favorable conditions (540 nm) do not produce enough well resolved points for a fully meaningful pseudo first order (in fulvic acid) plot, although such plots were 'satisfactorily' linear. Thus, rate constants were calculated from half lives which in turn were estimated assuming absorbance proportional to transmittance. This implies that results are of low precision. The implication is valid! In type (*2*) experiments, conventional first order plots were constructed on the absorbance data at 500 nm (the product absorbs) over more than four half lives. Rate constants were obtained from least-squares fits. Type (*3*) experiments were similar except that the fulvic acid (free and complexed) added a constant absorbance. The data were analyzed using the multicomponent program suggested by Willis *et al.* (6) with the fulvic acid plus fulvic acid complex functioning as the constant concentration and considering only free Fe(III) as the time varying component.

The data are processed by fitting under a least-square criterion (6) the following equation for the observed absorbance, *P*.

$$P = A_0(1 - e^{-kt}) + X$$

[4]Note that p*H* is precisely determined by this procedure.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

where A_0 is the absorbance proportional to the initial concentration of free Fe(III) and X is all time invariant contributions (especially that due to fulvic acid and its Fe complex). k is the known rate constant for reaction between sulfosalicylic acid and aquo Fe(III) calibrated directly in conjunction with the run on the mixture. The use of the methodology of ref. 6 allows for maximal use of the information in the early time part of the runs before there can be any complication due to a slight reaction of the fulvic acid complex with SSA. At the same time, this analysis does not overweight early points.

Results

First order rate constants for reaction of fulvic acid with excess Fe(III) at pH = 1.65 are shown in Fig. 1. Fe^{3+} is in excess and the plot gives pseudo first order rate constants for rate of approach to equilibrium. Under these circumstances $k_{obs} = k_d + k_f[Fe^{3+}]$ where $[Fe^{3+}]$ is a constant in any run (k_d is the rate constant for dissociation, k_f is for complex formation). The first order rate constant for reaction of Fe(III) with 1.00×10^{-2} M sulfosalicylic acid (a large excess) was estimated at the three pH values, 1.00, 1.50, and 2.50. The rate constants found were 0.89 ± 0.04, 3.81 ± 0.13, and 10.60 ± 0.35 s^{-1}, respectively. These values are in satisfactory agreement with higher ionic strength studies (7). The values are averaged over runs at concentrations from 1.0×10^{-4} to 1.0×10^{-5} M Fe(III). The error specified is the standard deviation of eight runs. It is also possible to calculate an extinction coefficient for the sulfosalicylic acid complex essentially from infinity time absorbance which will be useful for comparison with non-kinetic data to indicate accuracy in Fe(III) concentration determination. Values at pH 1.0, 1.5, and 2.5 are 159_1, 185_0, and 170_8 respectively.

In experiments on the equilibrium mixture, free Fe(III) is the directly evaluated quantity. In order to ensure that SSA is not attacking fulvic acid bound Fe and what we are measuring is free Fe only, the rate of Fe–SSA formation was observed over a time scale five to ten times longer than the time scale used in actual measurements and T_∞'s were closely observed. In each case, (Fe – fulvic acid solutions at pH 1.0, 1.5, and 2.5) simple exponential decays were observed with a constant T_∞. The kinetics of a typical run, for 1:1 Fe – fulvic acid concentration higher than used in the present work (2.5×10^{-4}), is shown in Fig. 2. In addition, an experiment with fulvic acid increased ten times in concentration compared to other runs at pH = 1.5 was carried out. The free Fe^{3+} concentration found was 7.7×10^{-5} M which yields a calculated equilibrium constant of 1.7×10^4. *If any iron bound to fulvic acid were contributing to reaction with SSA, the value calculated should be low.* It is not (*vide infra*). These experiments were not elaborated because of difficulties associated with high absorbance when fulvic acid is large. The main results are presented in terms of free (unbound) Fe(III) con-

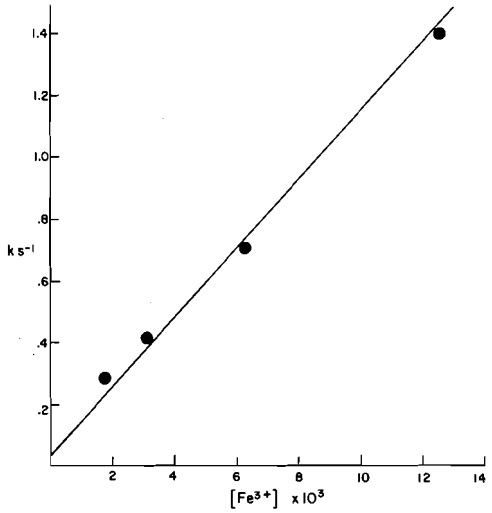

FIG. 1. Dependence of observed rate constants on Fe(III) concentration for the reaction of Fe(III) and fulvic acid. The effective fulvic acid concentration is approximately 3×10^{-4} M; pH = 1.65.

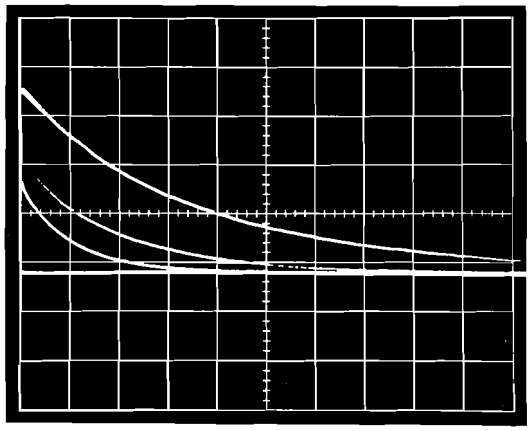

FIG. 2. A stopped flow photograph showing a 1:1 mixture of Fe^{3+} (2.5×10^{-4} M) with fulvic acid reacting at pH = 1.5 with 1.0×10^{-2} M SSA. Runs are at 50, 100, and 200 ms per division. Note the stability of the infinity. Wavelength is 500 nm and T = 25 °C (0.1 M $NaClO_4$).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

centration as a function of total Fe(III) introduced. Such free Fe(III) concentration values are plotted against total Fe(III) in Fig. 3. It is clear that differences between free Fe(III) and total Fe(III) are not large in the range of these experiments. Lower total Fe(III) would not be advantageous because the extinction coefficient of the analytical product is not large enough. We have chosen to fit data in the figures by a straight line because a more than one parameter representation of the function does not seem justified experimentally.

Assuming a linear relationship, corrected values for free Fe(III) are read from these plots and are used to calculate conditional formation constant K defined as usual as [Fe – fulvic acid]/-[Fe(III)-free][fulvic acid] at the pH specified and an overall ionic strength of 0.1 where brackets represent concentration. Initial fulvic acid concentration is calculated on the basis of a molecular weight 900 offering 3 mequiv./g of binding sites.

The results in Fig. 3 have been converted in Fig. 4 into plots of the binding function which is *commonly* presented for discussion of binding of fulvic acid (5). This is a plot of moles of

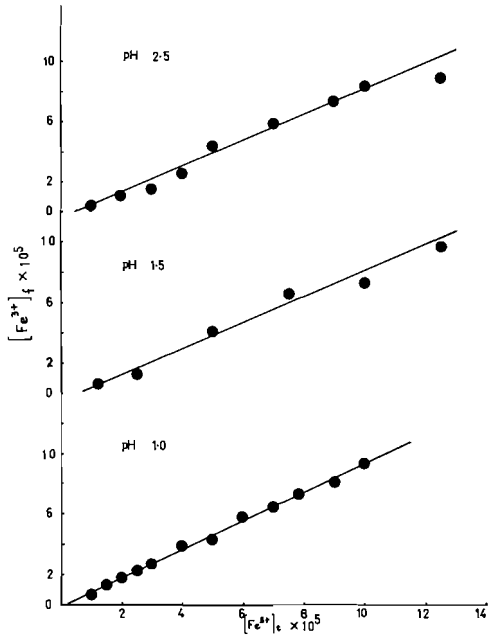

FIG. 3. Measured free Fe(III) concentration plotted *vs.* total Fe(III) concentration in equilibrium mixtures of Fe(III) and a fixed fulvic acid concentration 3.0×10^{-5} M.

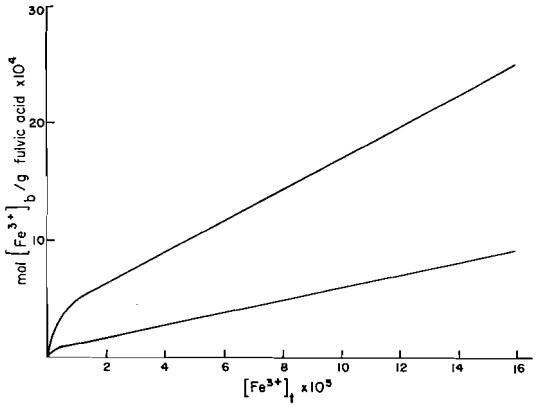

FIG. 4. Plot of the conventional binding function *vs.* total Fe(III) concentration in various mixtures of Fe(III) and fulvic acid. Top curve represents binding at pH 2.50 and 1.50 and bottom curve represents binding at pH 1.00.

bound metal ion per gram of fulvic acid plotted against total Fe(III) concentration. The ordinate in the plot also provides a scale for the measure of binding sites of fulvic acid available to Fe(III). The highest ordinate value on the figure represents 3 mequiv./g fulvic acid which approached the limit of available type I functional groups. Below this limit, as the plot shows, binding continues to increase.

The conditional formation constants at 25 °C, ionic strength 0.1, are:

K	pH
$2.8 \pm 0.3 \times 10^4$	1.0
$1.5 \pm 0.3 \times 10^4$	1.5
$1.5 \pm 0.3 \times 10^4$	2.5

Discussion

Analytical Aspects

The accuracy with which A_0 can be estimated depends heavily but not uniquely upon the measurement of infinity transmittance in kinetic runs. The value for the spectrophotometrically least sensitive kinetic curve is reproducible within 1%. Averaged T_∞ (converted to A_∞) when plotted against respective Fe(III) concentrations to obtain the extinction coefficient at pH 1.5 gave 185_0, which is to be compared with 187_0 obtained on a Cary 14, a difference of 1.2%. The rate constant values themselves exhibited a maximum standard deviation of 3.6% at pH 2.5. Our situation is analytically favorable in that there is only one kinetically important

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

component. We are intending to proceed to two and three components. For two or three component mixtures, precision similar to that of Pausch and Margerum (8) (~3%) can be anticipated in concentration if other rate constants can be determined as accurately as that for free aquo iron.

It is not easy to check precision in the equilibrium fulvic acid system, since concentration of any reference solution is determined by the fulvic acid equilibria. Inferred precision is similar to that for Fe(III) only solutions. One confirmation arises from looking at estimated values of bound Fe(III) in solutions of highest total Fe(III) concentration (10^{-4} *M*) where most Fe(III) is (and should be) free. The difference of the two large numbers is small and allows for only a few percent deviation in free iron.

Binding "Constant"

It should be made clear at the outset that *K* values are not true thermodynamic constants for the reaction of Fe(III) and fulvic acid. They represent ratio of bound Fe(III) to free over the range of binding sites available at the experimental ligand concentration (3×10^{-5} *M*). For a polyelectrolyte with more than one functional group the experimentally measured constant is a function of extent of participation by functional groups and charge accumulated on the polymeric molecule. These constants are thus regarded as weighted average values for the range investigated.

Results show that the binding constant at p*H* 1.0 is slightly larger than at p*H* 1.5 and 2.5. This pattern may be explained *qualitatively* by considering the nature of Fe(III) and fulvic acid species present. Solutions of Fe(III) would contain predominantly a mixture of Fe_{aq}^{3+} and $Fe(OH)^{2+}$. In the most strongly acidic solutions Fe_{aq}^{3+} is predominant and decreases towards higher p*H* values. Hydrolysis equilibria from data of Bray and Hershey (9) and Lamb and Jacques (10) were corrected to our ionic strength (11) and used to estimate the ratio of $FeOH^{2+}$ to Fe_{aq}^{3+}. The ratio is plotted against p*H* in Fig. 5. The degree of ionization of fulvic acid (α_1), presumably deprotonation of type I carboxyl groups as defined by Gamble and Schnitzer (5), in 0.1 *M* KCl close to ionic strength of present solutions is also plotted in the figure. The ratios of free to total Fe(III) (results from present study) are shown at the top left in the figure. The p*H* 1.0 value of the ratio of $FeOH^{2+}$ to Fe^{3+} (9×10^{-3}) increases four times at p*H* 1.5 and about 30 times at p*H* 2.5. Extrapolation of the fulvic acid plot shows that ionization of fulvic acid is negligible at p*H* 1.0 but significant at higher p*H*. At higher p*H* overall charge on Fe species decreases steadily due to larger proportions of $FeOH^{2+}$ but cumulative charge on fulvic acid increases. These two opposing factors (see Fig. 5) approximately compensate and qualitatively explain why the binding of Fe(III) by fulvic acid remains relatively insensitive to p*H* in these acidic media.

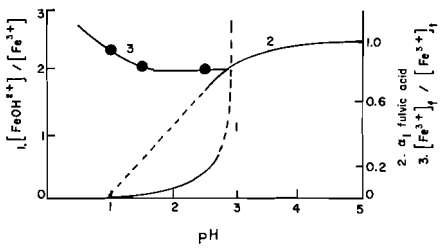

FIG. 5. The hydrolysis of Fe_{aq}^{3+} to $FeOH^{2+}$ is shown in curve *1* as the ratio $[FeOH^{2+}]/[Fe^{3+}]$. The first acid ionization of our fulvic acid is shown in curve *2* as α_1 fulvic acid, the fraction of strong acid sites ionized. These two factors contribute to an understanding of the small p*H* dependence of the ratio of free to total Fe(III) in the equilibrium system of Fe(III) with fulvic acid illustrated by curve *3*.

Kinetic Aspects

First, it must be observed that the small absorbance changes available limit precision. Especially, the intercept of Fig. 1 is of *no great significance*. (It could be zero!) The dissociation rate is less than 0.1 s^{-1}. A more meaningful estimate will be derived below from a combination of k_f with the conditional stability constant. It is worth observing next that the rate of formation of the fulvic acid complex is similar to that for sulfosalicylic acid and 'normal' (12) in the sense that it is comparable to rate of complex formation with monodentate ligands.[5] This suggests strongly that substitution of a first iron site by a binding site on fulvic acid is rate determining and that completion of the chelate ring is relatively rapid (12). We do not observe the slower complex formation commonly associated with rate limiting ring closure (12).

With respect to dissociation of the complex, the intercept in Fig. 1 showed that it was small

[5]See for a review ref. 13.

compared to the formation rate. Using the conditional stability constant to try to obtain a more precise value, we estimate 7×10^{-3} s^{-1}. This rate is slow but certainly faster than dissociation of small molecule chelates of high stability such as $FeEDTA^-$. It has sometimes been suggested that humic ligands play a role in rendering metal ions 'nonlabile in aqueous systems.' If this is the case in the sense of making them slowly available on time scales of hours to days, it does not seem that the effect arises from simple complex formation–dissociation reactions. Such a statement does not exclude nonlability due to mass transport rates in heterogeneous systems where humic ligands are suspended.

Arene Derivatives of Bis(trichlorogermanium)tetracarbonylruthenium(II)[1]

ROLAND K. POMEROY AND WILLIAM A. G. GRAHAM
Department of Chemistry, University of Alberta, Edmonton, Alberta T6G 2E1

Received June 4, 1975

ROLAND K. POMEROY and WILLIAM A. G. GRAHAM. Can. J. Chem. **53**, 2985 (1975).

Arenes react with *trans*-$Ru(CO)_4(GeCl_3)_2$ at 150 °C or higher to form the very stable complexes (η-arene)$Ru(CO)(GeCl_3)_2$ (arene = benzene, toluene, *o*-, *m*-, and *p*-xylene, mesitylene). The reactions may proceed via the more reactive *cis*-isomer, as suggested by a study of the reaction of benzene with *trans*-$Ru(CO)_4(SiCl_3)_2$ at 80 °C to form (η-C_6H_6)$Ru(CO)(SiCl_3)_2$. Benzene is displaced from (η-C_6H_6)$Ru(CO)(GeCl_3)_2$ by CO or mesitylene forming *trans*-$Ru(CO)_4(GeCl_3)_2$ and (η-mesitylene)$Ru(CO)(GeCl_3)_2$, respectively.

ROLAND K. POMEROY et WILLIAM A. G. GRAHAM. Can. J. Chem. **53**, 2985 (1975).

A des températures de 150 °C ou plus, les arènes réagissent avec le *trans*-$Ru(CO)_4(GeCl_3)_2$ pour conduire à des complexes très stables de formule (η-arène)$Ru(CO)(GeCl_3)_2$ (arène = benzène, toluène, *o*-, *m*-, ou *p*-xylène et mésitylène). Les réactions se produisent par l'intermédiaire de la forme *cis* qui est plus réactive; cette conclusion est basée sur une étude de la réaction, à 80 °C, du benzène avec le *trans*-$Ru(CO)_4(SiCl_3)_2$ conduisant au (η-C_6H_6)$Ru(CO)(SiCl_3)_2$. Le benzène du complexe (η-C_6H_6)$Ru(CO)(GeCl_3)_2$. est déplacé par le CO ou par le mésitylène pour conduire suivant le cas au *trans*-$Ru(CO)_4(GeCl_3)_2$ ou au (η-mésitylène)-$Ru(CO)(GeCl_3)_2$.

[Traduit par le journal]

Introduction

Energy-factored carbonyl stretching force constants for *cis*-$Ru(CO)_4(GeCl_3)_2$ are high and very nearly equal for the axial and equatorial sets of carbonyls.[2] The *trans influence* of a trichlorogermanium group, as inferred from this parameter, is very similar to that of the carbonyl group.[3] The molecule might accordingly be expected to resemble $Mo(CO)_6$ in some respects, and the reactions reported here with various benzene derivatives were undertaken to develop this analogy.

Results and Discussion

We have found that *trans*-$Ru(CO)_4(GeCl_3)_2$ (more readily available than this *cis* form, but *vide infra*) reacts with many arenes to form compounds of the type (η-arene)$Ru(CO)(GeCl_3)_2$. This is entirely analogous to the well-known reaction of molybdenum hexacarbonyl with arenes to form (arene)$Mo(CO)_3$ derivatives (4). Reactions were carried out in evacuated sealed tubes for the low boiling arenes, but simple refluxing in the appropriate ligand was sufficient for the xylene and mesitylene derivatives.

Although *trans*-$Ru(CO)_4(GeCl_3)_2$ was used in the reactions, it is known to isomerize at reaction temperatures (5), and we consider it likely, in analogy to $Ru(CO)_4(SiCl_3)_2$,[3] that the *cis* form would more readily dissociate carbon monoxide. The reaction between benzene and *trans*-$Ru(CO)_4(SiCl_3)_2$ was better suited for the elucidation of this point.[4] At 80 °C, *trans*-$Ru(CO)_4(SiCl_3)_2$ isomerizes at a moderate rate (6), and (η-C_6H_6)$Ru(CO)(SiCl_3)_2$ was formed at this temperature. The reaction was monitored by infrared, and only carbonyl stretching bands of starting material and product were observed; no bands due to *cis*-$Ru(CO)_4(SiCl_3)_2$ were observed, indicating its preferential reaction with benzene.

All of the (η-arene)$Ru(CO)(GeCl_3)_2$ complexes prepared in this work are colorless or

[1]Organometallic Compounds Having Metal–Metal Bonds, Part XX. For part XIX, see ref. 1.

[2]The values are k_{eq} = 18.1, k_{ax} = 18.2 mdyn Å^{-1} (2). The two force constants are also nearly equal to one another in the case of *cis*-$Ru(CO)_4(SiCl_3)_2$ (3).

[3]The *trans effect* (from ^{13}CO exchange rates) is in contrast much greater for $GeCl_3$ than for CO in this molecule, which has been ascribed to different relative stabilities of possible five-coordinate transition state isomers (3).

[4]*trans*-$Ru(CO)_4(GeCl_3)_2$ was not suitable because the equilibrium *trans:cis* ratio was *ca.* 98:3, so that the *cis*-isomer would have been difficult to detect even if it did not react preferentially. The equilibrium *trans:cis* ratio for $Ru(CO)_4(SiCl_3)_2$ is 65:35 (decalin, 84.6 °C) (6).

TABLE 1. Melting points and carbonyl stretching bands

Compound	Melting point (°C)	ν(CO) (cm^{-1})	
		CH_2Cl_2	Nujol
$(C_6H_6)Ru(CO)(GeCl_3)_2$	>300	2040	2048
$(CH_3C_6H_5)Ru(CO)(GeCl_3)_2$	236	2037	2030, 2020*
$[o\text{-}(CH_3)_2C_6H_4]Ru(CO)(GeCl_3)_2$	221–222	2031	2026
$[m\text{-}(CH_3)_2C_6H_4]Ru(CO)(GeCl_3)_2$	246–248	2032	2018
$[p\text{-}(CH_3)_2C_6H_4]Ru(CO)(GeCl_3)_2$	240–242	2034	2037, 2024
$[(CH_3)_3C_6H_3]Ru(CO)(GeCl_3)_2$	>300	2029	2027, 2020
$(C_6H_6)Ru(CO)(SiCl_3)_2$	203 (dec)	2016	—
$[(CH_3)_3C_6H_3]Ru(CO)(GeBr_3)_2$	—	2027	—

*A very weak band also observed at 2035 cm^{-1}.

pale yellow solids of remarkable thermal stability; they exhibit no decomposition before their melting points, which range from 200 °C to over 300 °C. The solids are stable in air, although $(\eta\text{-}C_6H_6)Ru(CO)(GeCl_3)_2$ showed some surface darkening. They are insoluble in nonpolar solvents, and sufficiently insoluble in polar solvents that n.m.r. spectra could not be obtained in all cases. The low solubility, high melting point, and lack of volatility of these complexes are perhaps due to dipole–dipole interactions; $(arene)Cr(CO)_3$ complexes have large dipole moments directed from arene towards the metal (7), and these would be expected to be larger in the present compounds due to the electronegative groups on germanium.

Molecular ions are observed in the mass spectra of the compounds, although at low intensity; the peak due to $[P—Cl]^+$ is much more intense (in $(\eta\text{-}C_6H_6)Ru(CO)(GeCl_3)_2$, the intensities of P and P—Cl are 2.3:87). This is reminiscent of $(\eta\text{-}C_5H_5)Fe(CO)H(SiCl_3)_2$ (8), in which the heaviest ion observed was $[P—Cl]^+$. Nuclear magnetic resonance spectra were obtained only for the benzene and mesitylene complexes; ring proton resonances were shifted to higher field than in the free ligands, while the methyl resonance of the latter complex occurred at higher field than in the free ligand.

Infrared carbonyl stretching frequencies (Table 1) shift to lower frequencies with increasing methyl substitution, consistent with greater electron release by methyl groups. Solubility requirements necessitated the use of a polar solvent (CH_2Cl_2) for infrared studies, and the broad bands encountered under these conditions were not useful in determining the possible existence in solution of isomers. We refer here to different orientations of the arene ring about an axis from its midpoint to the ruthenium atom. Although two bands were observed in the mull spectra of several of the compounds, the splitting could result from nonequivalent molecular environments in the crystal lattice so the results are ambiguous.

Two reactions involving displacement of arene were carried out, which further illustrate the analogy with arenetricarbonylmolybdenum compounds. Thus, $(\eta\text{-}C_6H_6)Ru(CO)(GeCl_3)_2$ with carbon monoxide (50 atm, 150 °C) was converted to *trans*-$Ru(CO)_4(GeCl_3)_2$ (the immediate displacement product may have been *cis*, which isomerized to the equilibrium mixture),[4] while refluxing in mesitylene afforded $[\eta\text{-}(CH_3)_3C_6H_3]Ru(CO)(GeCl_3)_2$. The latter reacted with benzene (150 °C, sealed tube) to reform the benzene complex.

The compounds reported here belong to the class of arene complexes of ruthenium(II), of which few examples were known until recently. Two investigations have now been reported of complexes of the type $(arene)RuX_2L$ (X = halogen, L = phosphine) (9–11); the route by which they were obtained was quite different, involving the dehydrogenation of cyclic 1,3-dienes by ethanolic ruthenium trichloride. It is of interest that Zelonka and Baird (10) found evidence for a very unstable compound, presumed to be $(\eta\text{-}C_6H_6)Ru(CO)Cl_2$, when carbon monoxide was bubbled into a solution of $(C_6H_6)RuCl_2$ in acetonitrile.

There seemed little doubt that the complexes reported here would have a half-sandwich structure similar to that of the benzenechromium tricarbonyl. This has now been confirmed by an X-ray study of $(\eta\text{-}C_6H_6)Ru(CO)(GeCl_3)_2$ (12).

Details of the structure, and a comparison with reported (11) structures of two (arene)-$Ru[P(CH_3)_2C_6H_3]Cl_2$ complexes will be presented elsewhere (12).

Experimental Section

Reactions were carried out under a nitrogen atmosphere or in evacuated sealed tubes. Melting points were measured using a microscope with Kofler hot stage. Infrared carbonyl stretching frequencies were recorded and calibrated as previously described (8). Analyses (Table 2) were carried out by the Microanalytical Laboratory of this department and by Pascher Mikroanalytisches Laboratorium, Bonn, West Germany. The synthesis of *trans*-$Ru(CO)_4(GeCl_3)_2$ and *trans*-$Ru(CO)_4(SiCl_3)_2$ will be described elsewhere (5).

Preparation of $(\eta\text{-}C_6H_6)Ru(CO)(GeCl_3)_2$

Benzene (25 ml) and *trans*-$Ru(CO)_4(GeCl_3)_2$ (0.57 g, 1.0 mmol) were heated in an evacuated sealed tube at 150 °C for 6 days. Approximately every 12 h during this period the tube was cooled (care!) and reevacuated. After this time the tube was allowed to stand at *ca.* 6 °C for 24 h. The benzene was then removed from the large, pale yellow needles of the product, $(\eta\text{-}C_6H_6)$-$Ru(CO)(GeCl_3)_2$ (0.41 g, 72%). The mother liquor contained $Ru_2(CO)_5GeCl_6$ (5) as well as this product. The crystals were washed with two 10-ml portions of *n*-hexane, and appeared from infrared examination to be pure at this stage. Analytical samples were recrystallized from benzene or *n*-hexane – dichloromethane; n.m.r. (dichloromethane): singlet, τ 3.38.

The corresponding toluene derivative, $(\eta\text{-}CH_3C_6H_6)$-$Ru(CO)(GeCl_3)_2$ was prepared in the same manner. An attempt to prepare $(\eta\text{-}C_6H_6)Ru(CO)(GeBr_3)_2$ by the same method led to isolation of 25 mg of greenish-yellow crystals which had the expected i.r. spectrum (2037 cm^{-1}, CH_2Cl_2 solution), but which did not give a satisfactory analysis. An infrared spectrum of the benzene solution showed mainly $Ru_2(CO)_5GeBr_6$ (5). A similar experiment using *trans*-$Ru(CO)_4(SnCl_3)_2$ gave only $Ru_2(CO)_5SnCl_6$ (13).

Preparation of $(\eta\text{-}C_6H_6)Ru(CO)(SiCl_3)_2$

Benzene (10 ml) and *trans*-$Ru(CO)_4(SiCl_3)_2$ (0.241 g, 0.5 mmol) were refluxed under a nitrogen atmosphere for 48 h. Infrared spectra taken during this time showed only starting material and product *i.e.*, no *cis*-$Ru(CO)_4$-$(SiCl_3)_2$ was present. After 2 days the solution was filtered and evaporated to dryness to give an almost quantitative yield of crude product. The analytical sample, in the form of white crystals, was obtained by two recrystallizations from CH_2Cl_2 – *n*-heptane; n.m.r. ($CDCl_3$): singlet, τ 3.42.

Preparation of $[\eta\text{-}(CH_3)_3C_6H_3]Ru(CO)(GeCl_3)_2$

A solution of *trans*-$Ru(CO_4)(GeCl_3)_2$ (0.57 g, 1.0 mmol) in mesitylene was refluxed for 11 h. The solution was then filtered and placed in the refrigerator overnight. The product (0.45 g, 75%) was separated from mesitylene, washed with hexane, and dried under vacuum. Recrystallization from benzene or CH_2Cl_2–*n*-hexane gave the analytical sample; n.m.r. ($CDCl_3$): τ 3.68 (s, 1), 7.36 (s, 3). Reaction times much longer than 11 h led to extensive decomposition and reduced yields.

Xylene Derivatives

The xylene derivatives were prepared in a similar manner only with reflux times of 70 to 90 h; n.m.r. spectra of these compounds could not be obtained due to their insolubility.

$[\eta\text{-}(CH_3)_3C_6H_3]Ru(CO)(GeBr_3)_2$

The bromo derivative $[\eta\text{-}(CH_3)_3C_6H_3]Ru(CO)(Ge$-$Br_3)_2$ was prepared in the same way as the chloro analog; the yield, however, was low (12%).

Reaction of $(\eta\text{-}C_6H_6)Ru(CO)(GeCl_3)_2$ *with Carbon Monoxide*

An autoclave containing $(\eta\text{-}C_6H_6)Ru(CO)(GeCl_3)_2$ (0.057 g) in *n*-heptane was pressurized with carbon monoxide (50 atm) and heated at 150 °C for 24 h. The autoclave was cooled and the gas vented. An infrared spectrum of the *n*-heptane solution showed only *trans*-$Ru(CO)_4(GeCl_3)_2$.

Reaction of $(\eta\text{-}C_6H_6)Ru(CO)(GeCl_3)_2$ *with Mesitylene*

A solution of $(C_6H_6)Ru(CO)(GeCl_3)_2$ (0.057 g, 0.1 mmol) in mesitylene (10 ml) was refluxed for 20 min, filtered, and allowed to cool. Crystals of $[\eta\text{-}(CH_3)_3$-$C_6H_3]Ru(CO)(GeCl_3)_2$ (0.040 g, 66%) were washed with *n*-hexane and dried under vacuum. The product was identified by its infrared spectrum.

In a similar reaction $[\eta\text{-}(CH_3)_3C_6H_3]Ru(CO)(GeCl_3)_2$ was heated in benzene at 150 °C in an evacuated sealed tube for 12 h. The product was found to be $(\eta\text{-}C_6H_6)$-$Ru(CO)(GeCl_3)_2$.

Détermination du pouvoir sulfonant des acides disulfurique et chlorosulfurique dans le sulfolane

PATRICK PIERENS, YVES AUGER, JEAN CLAUDE FISCHER ET MICHEL WARTEL
Université de Lille I, Laboratoire de Chimie Minérale I, Bâtiment C8, BP. 36, 59650 Villeneuve d'Ascq, France
Reçu le 10 mars 1975

PATRICK PIERENS, YVES AUGER, JEAN CLAUDE FISCHER et MICHEL WARTEL. Can. J. Chem. **53**, 2989 (1975).

L'étude du système électrochimique dans le sulfolane

$$AgCl + SO_3 + e^- \rightleftarrows Ag + SO_3Cl^-$$

a permis de calculer la constante de dissociation de l'ion chlorosulfate suivant: $SO_3Cl^- \rightleftarrows SO_3 + Cl^-$ ($K_{SO_3Cl^-} = 10^{-14.3}$) le chlorodisulfate $S_2O_6Cl^-$ étant entièrement dissocié en SO_3Cl^- et SO_3. Les constantes des équilibres

$$H_2S_2O_7 \rightleftarrows H_2SO_4 + SO_3 \ (K_{H_2S_2O_7} = 10^{-1.45})$$

$$HSO_3Cl \rightleftarrows HCl + SO_3 \ (K_{HSO_3Cl} = 10^{-4.2})$$

ont été déterminées, l'une par complexation de SO_3 par H_2SO_4, l'autre à partir de la différence d'acidité entre HCl et HSO_3Cl. Le pouvoir sulfonant des composés étudiés varie selon $S_2O_6Cl^- > H_2S_2O_7 > HSO_3Cl \gg SO_3Cl^-$. La constante d'acidité de l'acide chlorosulfurique est $k = 10^{-4.4}$, supérieure à celle de $H_2S_2O_7$ ($k = 10^{-5}$).

PATRICK PIERENS, YVES AUGER, JEAN CLAUDE FISCHER, and MICHEL WARTEL. Can. J. Chem. **53**, 2989 (1975).

On the basis of potentiometric study of the system

$$AgCl + SO_3 + e^- \rightleftarrows Ag + SO_3Cl^-$$

in sulfolane, the dissociation constant of the reaction $SO_3Cl^- \rightleftarrows SO_3 + Cl^-$ has been found to be $K_{SO_3Cl^-} = 10^{-14.3}$ assuming that the chlorodisulfate ion is completely dissociated to SO_3Cl^- and SO_3. The equilibrium constants of the reactions

$$H_2S_2O_7 \rightleftarrows H_2SO_4 + SO_3 \ (K_{H_2S_2O_7} = 10^{-1.45})$$

$$HSO_3Cl \rightleftarrows HCl + SO_3 \ (K_{HSO_3Cl} = 10^{-4.2})$$

have been determined on the one hand by complexation of SO_3 with H_2SO_4, and on the other by the difference of acidity between HCl and HSO_3Cl. The acidity constant of HSO_3Cl ($k = 10^{-4.4}$) is slightly higher than that of $H_2S_2O_7$ ($k = 10^{-5}$). The sulfonating power of some compounds have been found to follow the order $S_2O_6Cl^- > H_2S_2O_7 > HSO_3Cl \gg SO_3Cl^-$.

Introduction

Dans la préparation des dérivés sulfonés, utilisés comme colorants et détergents, on emploie l'acide sulfurique, l'acide chlorosulfurique ou plus souvent les oléums sulfuriques à des concentrations variables. Parmi ces oléums, il existe des composés définis $H_2SO_4 \cdot nSO_3$, le plus connu étant l'acide disulfurique ($H_2SO_4 \cdot SO_3$ ou $H_2S_2O_7$). Il était intéressant de déterminer le pouvoir sulfonant d'un tel composé, et de le comparer à celui de HSO_3Cl. La mesure de ce pouvoir ne peut être effectuée que si l'on connaît un composé SO_3X très stable et une méthode permettant de suivre la dissociation en SO_3 et X. S'il semble difficile de suivre la variation de concentration en SO_3, la détermination de X peut être facilement réalisée si $X = Cl^-$. En effet, nous avons montré que dans le nitrométhane, les chlorosulfates SO_3Cl^- sont peu dissociés (1) (la constante de l'équilibre

[1] $$SO_3Cl^- \rightleftarrows SO_3 + Cl^-$$

y est égale à $10^{-14.1}$). Les solutions concentrées de SO_3 dans ce solvant étant peu stables (2), nous avons choisi un autre solvant de constante diélectrique très voisine, le sulfolane. Les caractéristiques sont: $t_f^0 = 28$ °C, $t_e^0 = 285$ °C, $\varepsilon = 43.3$ à 30 °C, viscosité = 0.1029 poise (3). En raison de la valeur élevée de la viscosité les constantes de diffusion sont faibles (4). Nous avons donc, pour l'étude voltampérométrique, utilisé des solutions plus concentrées que dans le nitro-

For personal use only.

méthane (supérieures à 10^{-3} mol/l) ce qui diminue l'effet parasite de l'eau.

Partie expérimentale

Reactifs

Le sulfolane est un produit Merck. Nous avons repris, pour la purification les méthodes préconisées par Coetzee *et al.* (3) et Benoit et Choux (5) en y apportant quelques modifications. Le mode opératoire adopté est le suivant: le solvant mis à reflux pendant 18 h environ, puis distillé sous pression réduite est placé sur carbone actif à 40 °C, pendant une journée. Après filtration, le sulfolane incolore est distillé une seconde fois sous pression réduite. Sa teneur en eau est alors de 15 à 30 p.p.m. Les dernières traces d'eau sont éliminées par passage sur une colonne remplie d'alumine neutre d'activité 1 (séchée à 350° sous pression réduite), adaptée directement sur la cellule de mesure. Le solvant ainsi obtenu a une conductivité inférieure à 10^{-8} Ω^{-1} cm^{-1} (limite de l'appareillage dont nous disposons) et sa teneur en eau est inférieure à 10 p.p.m. (méthode de Karl Fischer).

L'acide chlorosulfurique Carlo Erba est utilisé sans purification.

L'acide sulfurique 100% est préparé par addition d'oléum (suivie par conductimétrie) à de l'acide sulfurique R.P. prolabo.

L'acide disulfurique est synthétisé par addition de SO_3 pur à de l'acide sulfurique 100%. Les solutions de cet acide ou d'oléums dans le sulfolane sont stables, contrairement aux observations de Benoit *et al.* (15).

Les solutions d'acide chlorhydrique anhydres sont obtenues par passage dans le solvant de HCl gaz (libéré par chauffage d'un mélange de H_3PO_4 anhydre et NaCl). La solution est titrée dans l'eau.

Le chlorosulfate de tétraéthylammonium est préparé par neutralisation d'un solution de HSO_3Cl dans le nitrométhane avec le chlorure de tétraéthylammonium. Le solide est extrait par évaporation du solvant sous pression réduite (6).

Le chlorure de tétraéthylammonium, le perchlorate de tétraéthylammonium sont des produits Eastman Kodak, ils sont séchés à 80° sous pression réduite.

Le perchlorate d'argent Flucka est deshydraté à 60° sous pression réduite.

Le chlorodisulfate d'ammonium est préparé par action de SO_3 sur NH_4Cl en proportions stoechiométriques dans SO_2 liquide (7).

Mesures: toutes les mesures sont effectuées à 30 ± 0.1 °C

Les courbes voltampérométriques sont réalisées à l'aide d'un ensemble Tacussel comprenant un potentiostat PRT 20.2.X, un correcteur de chute ohmique C.D.C.O., un pilote $GSTP_3$, un millivoltmétre et un enregistreur XY LUXY TRACE.

Potentiométrie: les mesures potentiométriques ont été faites avec un millivoltmétre Tacussel ISIS 4000, suivi d'un enregistreur permettant d'apprécier la stabilité des potentiels.

L'électrode de réf. 8 est constituée par la demi-pile $Ag/AgClO_4$ $N/10$. Un pont rempli d'une solution de perchlorate de tétraéthylammonium $N/10$ la relie à la cellule de mesure. Le potentiel de cette électrode très stable, est néanmoins contrôlé après chaque expérience en mesurant le potentiel de demi vague d'une solution de ferrocène, pris comme origine des potentiels.

Les solutions étudiées ont généralement une concentration voisine de 10^{-2} *M*. Le réactif est ajouté à l'aide d'une micro burette Gilmont (2 cm^3).

Résultats et discussion

Détermination de la constante de dissociation de l'ion SO_3Cl^- dans le sulfolane

L'ion SO_3Cl^- se dissocie selon

$$[1] \qquad SO_3Cl^- \rightleftarrows SO_3 + Cl^-$$

La mesure de l'activité de Cl^- conduit à la détermination de la constante d'équilibre

$$K_{SO_3Cl^-} = \frac{[SO_3][Cl^-]}{[SO_3Cl^-]}$$

Si l'électrode d'argent est bien indicatrice de Cl^- dans ce solvant (9), il fallait montrer qu'elle l'était encore pour le complexe SO_3Cl^- c'est à dire étudier le système oxydoréducteur

$$[2] \qquad SO_3 + AgCl\downarrow + e^- \rightleftarrows Ag\downarrow + SO_3Cl^-$$

dans l'hypothèse ou les chloropolysulfates sont totalement dissociés en SO_3Cl^- et SO_3 en solution. Le potentiel normal E_2^0 de ce système défini pour $[SO_3] = [SO_3Cl^-]$ dépend de P, produit de solubilité du chlorure d'argent, de K la constante de dissociation de l'ion chlorosulfate suivant

$$E_2^0 = E_{Ag/Ag^+}^0 + 0.06 \log \frac{P}{K}$$

où E_{Ag/Ag^+}^0 est le potentiel normal du système $Ag^+ + e^- \rightleftarrows Ag$.

En vue d'étudier la réversibilité du système, nous avons tracé les courbes voltampérométriques à l'électrode d'argent des solutions de chlorosulfate de tétraéthylammonium en présence de perchlorate de tétraéthylammonium comme électrolyte indifférent. Les vagues d'oxydation obtenues sont reproductibles et bien définies si la teneur en eau du solvant est très faible, mais la proximité du mur d'oxydation rend difficile l'évaluation du courant limite de diffusion. En traçant cependant la transformée logarithmique de la courbe intensité potentiel, correspondant au couple oxydo réducteur [2], on obtient une droite de pente 65 mV. En présence de SO_3 et SO_3Cl^-, la détermination du courant limite d'oxydation est encore plus difficile et ne peut plus être évaluée avec précision.

Cependant, en réduction on constate que le courant limite de diffusion i_{SO_3} est proportionnel à la concentration de l'anhydride sulfurique. Pour confirmer l'hypothèse initiale de dissocia-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

tion élevée des chloropolysulfates selon:

$$(SO_3)_nCl^- \rightleftarrows (n-1)SO_3 + SO_3Cl^-$$

nous avons tracé les courbes intensité potentiel sur platine d'une solution de chlorodisulfate d'ammonium. Nous observons une vague d'oxydation avec passivation. Ce phénomène a déjà été observé par Marchon et Badoz (10) lors de l'oxydation du chlorure sur électrode de platine dans le nitrométhane. Cette vague correspondrait soit à

[3] $$SO_3 + \tfrac{1}{2}Cl_2 + e^- \rightleftarrows SO_3Cl^-$$

soit à

[4] $$2SO_3 + \tfrac{1}{2}Cl_2 + e^- \rightleftarrows (SO_3)_2Cl^-$$

En réduction, nous notons une vague identique à la réduction des solutions de SO_3 seul, ce qui élimine la complexation de SO_3 par SO_3Cl^- (les potentiels de demi vague sont identiques pour des solutions de même concentration). L'addition de $N(C_2H_5)_4{}^+SO_3Cl^-$ modifie uniquement la hauteur du palier correspondant au courant limite d'oxydation. Ces résultats montrent donc qu'en solution seul le couple oxydo réducteur [3] intervient et que le chlorodisulfate est donc dissocié totalement en SO_3Cl^- et SO_3. L'écriture du couple [2] est donc justifiée.

Pour déterminer le potentiel normal du couple [1], nous avons suivi par potentiométrie le dosage d'une solution de chlorosulfate de tétraéthylammonium par une solution de perchlorate d'argent (fig. 1). L'étude mathématique de la courbe obtenue montre que

$$E = f\left(\log \frac{|[SO_3]|}{|[SO_3Cl^-]|}\right)$$

est une droite de pente 62 mV (fig. 2), confirmant ainsi la dissociation du chlorodisulfate, et que le potentiel normal du couple [2] est de 123 ± 5 mV par rapport au potentiel normal du couple ferrocène ferricinium pour une température de 30 °C (en assimilant concentration et activité pour des molécules neutres. L'activité des ions est calculée à partir de la formule de Debye–Hückel avec $a = 4$ Å (9)).

Nous avons redéterminé le produit de solubilité de AgCl et le potentiel normal du couple Ag^+/Ag; les valeurs trouvées sont $P_{AgCl} = 3.7 \times 10^{-19}$ et $E_{Ag^+/Ag}{}^0 = 0.373$ V. Ces valeurs sont comparables à celles trouvées par Benoit *et al.* (9) $P_{AgCl} = 8 \times 10^{-19}$ et $E_{Ag/Ag^+}{}^0 = 0.380$ V. La constante de l'équilibre $SO_3Cl^- \rightleftarrows SO_3 +$

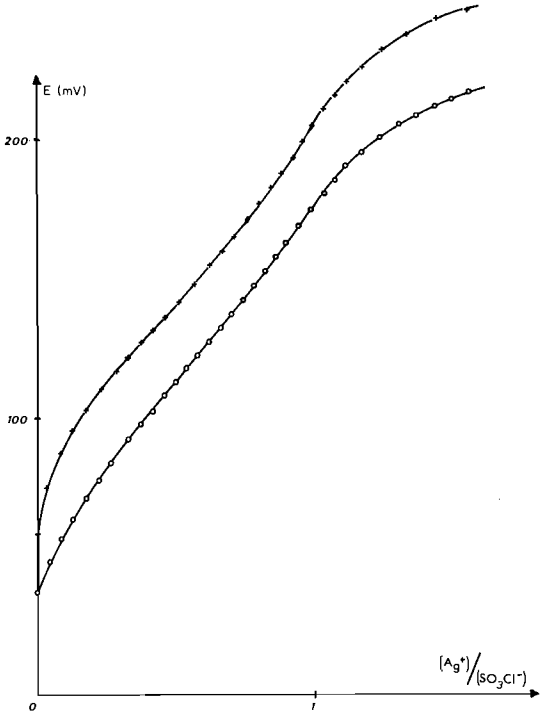

FIG. 1. Courbe potentiométrique de titrage d'une solution de $(C_2H_5)_4N\,SO_3Cl$ par une solution de $AgClO_4$ en milieu $(C_2H_5)_4ClO_4$ $N/10$, courbe (+); courbe (○), en présence de H_2SO_4.

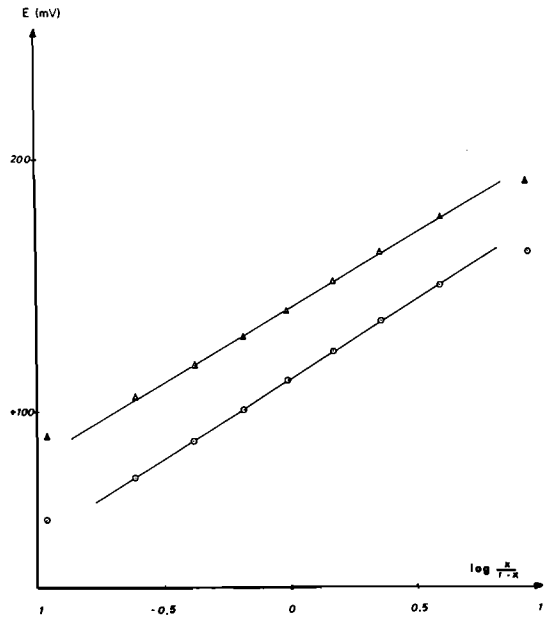

FIG. 2. Analyse mathématique des courbes représentées sur la fig. 1. $x = (Ag^+)/(SO_3Cl^-)$ initial; Δ, $(C_2H_5)_4NSO_3Cl + AgClO_4$; ○, $(C_2H_5)_4NSO_3Cl + H_2SO_{4(excès)} + AgClO_4$.

Cl^- est donc égale à $10^{-14.3\pm0.2}$ mol/l avec $E_2{}^0 = 123 \pm 5$ mV.

Cette valeur est très proche de celle trouvée dans le nitrométhane. Dans ce dernier solvant, en utilisant le potentiel de demi vague déduit des courbes $i = f(E)$ du couple [2] nous trouvons $pK = 14.1$. Ces résultats confirment les propriétés très voisines de ces deux solvants. Le chlorosulfate est donc un donneur très faible de SO_3, et la réaction

$$SO_3A + Cl^- \rightleftarrows SO_3Cl^- + A$$

devrait permettre de déterminer le pouvoir donneur de SO_3 des composés SO_3A à condition que les propriétés basiques de Cl^- n'interfèrent pas.

Détermination des constantes de dissociation des acides $H_2S_2O_7$ et HSO_3Cl dans le sulfolane

Il est connu depuis très longtemps (11) que l'acide chlorosulfurique peut être préparé en faisant passer du gaz chlorhydrique dans les oléums et en particulier dans l'acide disulfurique selon

$$H_2S_2O_7 + HCl \rightarrow HSO_3Cl + H_2SO_4$$

L'acide disulfurique est un meilleur donneur de SO_3 que l'acide chlorosulfurique. Cette réaction ne permet pas une détermination directe de la constante de dissociation de $H_2S_2O_7$ suivant

[5] $$H_2S_2O_7 \rightleftarrows H_2SO_4 + SO_3$$

elle nécessite en outre la connaissance du pouvoir sulfonant de HSO_3Cl. Pour atteindre cette constante nous avons étudié le système électrochimique

[6] $$AgCl\downarrow + H_2S_2O_7 + e^- \rightleftarrows H_2SO_4 + SO_3Cl^- + Ag\downarrow$$

en réalisant en présence d'un excès connu de H_2SO_4($C = 0.1$ mol/l) (fig. 1) la réaction

$$(C_2H_5)_4N^+SO_3Cl^- + Ag^+ClO_4^- + H_2SO_4 \rightleftarrows AgCl + H_2S_2O_7 + (C_2H_5)_4N^+ClO_4^-$$

L'analyse mathématique de la courbe potentiométrique obtenue (fig. 2) permet par comparaison avec le potentiel normal du système (2) d'atteindre la constante de dissociation de $H_2S_2O_7$ selon l'équilibre (5)

$$K_{H_2S_2O_7} = \frac{[H_2SO_4][SO_3]}{[H_2S_2O_7]} = 10^{-1.45\pm0.30} \text{ mol/l}$$

avec $E_6{}^0 = 36 \pm 5$ mV déterminé pour $[SO_3Cl^-] = [H_2S_2O_7]$ et $[H_2SO_4] = 0.1 f_\pm$ ($f_\pm$ étant le coefficient d'activité moyen).

Cerfontain (12) a montré par des mesures spectrométriques que cette constante dans l'acide sulfurique est inférieure ou égale à $10^{-0.7}$, valeur proche de celle trouvée dans le sulfolane. Les réactions de sulfonation réalisées dans l'acide sulfurique en utilisant l'acide disulfurique ou les oléums plus concentrés (que l'on peut considérer comme donneurs de SO_3 plus forts que $H_2S_2O_7$) peuvent être effectuées dans le sulfolane, solvant dont l'étendue des domaines d'électroactivité et de pH utilisables est beaucoup plus importante que celle dont on peut disposer dans l'acide sulfurique. Le sulfolane devrait donc permettre de différencier plus facilement les différents donneurs de SO_3, afin de les classer sur une échelle pSO_3.

L'acide chlorosulfurique étant également très souvent utilisé comme agent sulfonant il était intéressant de le comparer à l'acide disulfurique dans le sulfolane. La constante de dissociation de HSO_3Cl selon

[7] $$HSO_3Cl \rightleftarrows SO_3 + HCl$$

c'est à dire

$$K_{HSO_3Cl} = \frac{[SO_3][HCl]}{[HSO_3Cl]}$$

dépend de la constante de dissociation de l'ion SO_3Cl^- et du rapport des constantes d'acidité de HCl et de HSO_3Cl.

$$K_{HSO_3Cl} = (K_{SO_3Cl^-})\frac{k_{HSO_3Cl}}{k_{HCl}}$$

k_{HSO_3Cl} et k_{HCl} étant les constantes d'acidité des acides HSO_3Cl et HCl.

L'acide chlorhydrique étant associé dans le sulfolane (13) nous avons, pour déterminer la différence de pK de ces deux acides, étudié le couple électrochimique

[8] $$AgCl\downarrow + HSO_3Cl + e^- \rightleftarrows Ag\downarrow + SO_3Cl^- + HCl$$

en titrant une solution de HCl par une solution de perchlorate d'argent, l'électrolyte étant le chlorosulfate de tétraéthylammonium (fig. 3). (Une étude conductimétrique en cours montre que les constantes de dissociation de $N(C_2H_5)_4ClO_4$ et $N(C_2H_5)_4SO_3Cl$ sont très voisines.)

En comparant les potentiels normaux $E_{Ag/Ag^+}{}^0 = 373$ mV et $E_8{}^0 = 125 \pm 5$ mV (calculé en tenant compte de la concentration de $N(C_2H_5)_4SO_3Cl$,: $c = 0.08$ mol/l) et un utilisant le produit de solubilité de AgCl ($P = 3.7 \times 10^{-19}$) nous

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

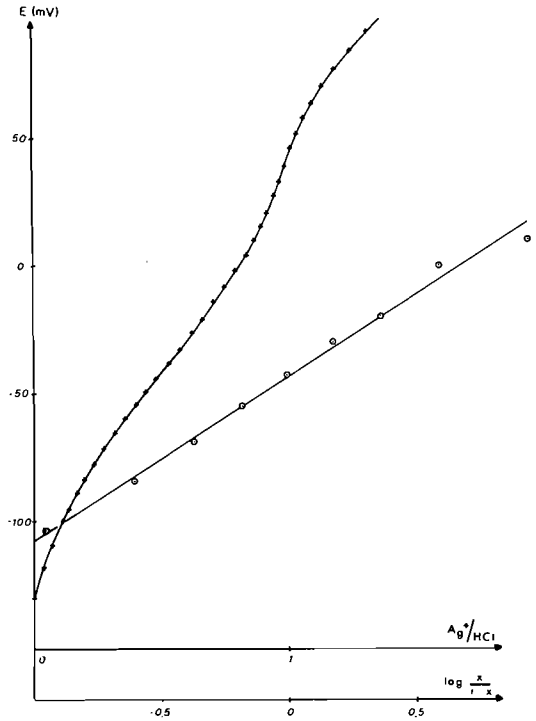

FIG. 3. Courbe potentiométrique de titrage d'une solution de HCl par une solution de $AgClO_4$ en milieu $(C_2H_5)_4NSO_3Cl$ $N/10$. ○, analyse mathématique de la courbe potentiométrique. $x = (Ag^+)/(HCl)$ initial.

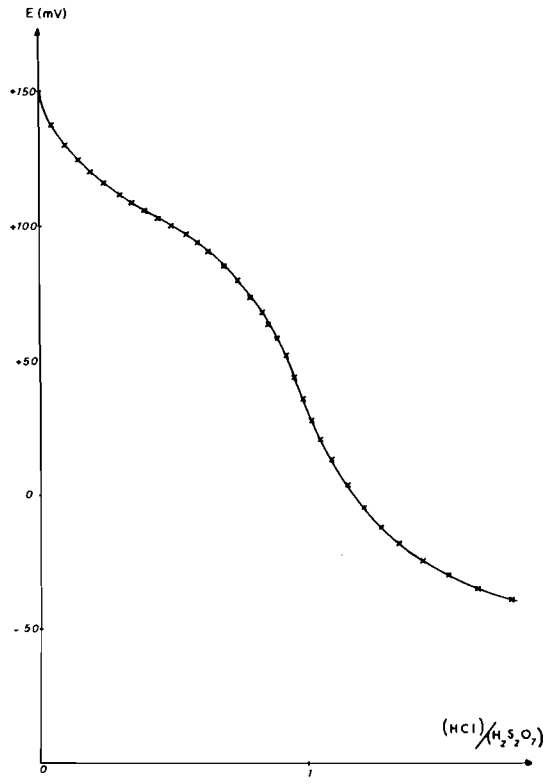

FIG. 4. Courbe potentiométrique de titrage d'une solution de $H_2S_2O_7$ par une solution de HCl en milieu $(C_2H_5)_4ClO_4$ $N/10$.

obtenons $pk_{HCl} - pk_{HSO_3Cl} = 10.1 \pm 0.2$. Dans l'hypothèse où les acides ne donnent pas d'hétéroconjugaison entre HCl et SO_3Cl^-, la constante de dissociation de HSO_3Cl est donc:

$$K_{HSO_3Cl} = \frac{[SO_3][HCl]}{[HSO_3Cl]} = 10^{-4.2\pm0.5} \text{ mol/l}$$

Richards et Woolf (14) ont déterminé cette constante dans HSO_3Cl par des mesures calorimétriques et trouvé $10^{-5.3}$. Le chlorure de sulfuryle étant moins donneur de Cl^- que SO_3Cl^- l'équilibre $2HSO_3Cl \rightleftarrows H_2SO_4 + SO_2Cl_2$ n'intervient pas ici. Cette valeur plus faible que celle de l'acide disulfurique, justifie l'obtention de HSO_3Cl à partir de $H_2S_2O_7$ et la possibilité de doser des solutions de $H_2S_2O_7$ ou d'oléums par des solutions d'acide chlorhydrique, en suivant cette réaction à l'aide d'une électrode d'argent comme indicatrice (fig. 4). Un travail doit être publié prochainement sur ce sujet.

En conclusion, les composés étudiés dans ce travail peuvent être classés d'une part suivant leur pouvoir sulfonant croissant selon $SO_3Cl^- \ll HSO_3Cl < H_2S_2O_7 < (SO_3)_2Cl^-$ et d'autre part, en utilisant les résultats de Coetzee *et al.* (4) et ceux de Benoit *et al.* (15) suivant leur caractère acide $pk_{HClO_4} = 3$ (4) ou 2.7 (15), $pk_{HSO_3F} = 3.3$ (15), $pk_{HSO_3Cl} = 4.4$, $pk_{H_2S_2O_7} = 5$ (15), $pk_{HCl} = 14.5$ (4).

Les acides chlorosulfurique et fluorosulfurique sont plus forts que l'acide disulfurique, contrairement à ce que l'on observe dans d'autres solvants de constantes diélectriques voisines comme le nitrométhane (16) ou le nitrobenzène (17, 18), les ions SO_3Cl^- et SO_3F^- devant être moins solvatés, dans ces deux derniers solvants que $HS_2O_7^-$ plus volumineux.

Nous nous proposons de compléter ces échelles d'acidité et de pSO_3 dans le but de permettre un choix plus judicieux de l'agent de sulfonation.

Nous remercions la Délégation Générale à la Recherche Scientifique et Technique, pour l'aide financière apportée à ces travaux. Contrat D.G.R.S.T CN 73-7-1827. Laboratoire de Chimie Minérale I-C8-59650, Villeneuve D'Ascq.

The Systems Indium Trichloride – Pyridine and Indium Trichloride – Pyridine – Water: Equilibrium Diagrams and Heat of Formation of $InCl_3.3C_5H_5N$

ELINOR M. KARTZMARK

Department of Chemistry, University of Manitoba, Winnipeg, Manitoba R3T 2N2

Received May 8, 1975

ELINOR M. KARTZMARK. Can. J. Chem. **53**, 2995 (1975).

The equilibrium diagram of the system indium trichloride – pyridine – water, at 25 °C, shows the existence of two compounds, $InCl_3.C_5H_5N.2H_2O$ and $InCl_3.3C_5H_5N$. The melting point diagram shows that the compound $InCl_3.3C_5H_5N$ melts incongruently at 242 °C. The heat of the reaction

$$InCl_3 + 3C_5H_5N \rightarrow InCl_3.3C_5H_5N$$

is $\Delta H = -34.6$ kcal/mol and the heat of formation of $InCl_3.3C_5H_5N$ is -137.0 kcal/mol.

ELINOR M. KARTZMARK. Can. J. Chem. **53**, 2995 (1975).

Le diagramme d'équilibre du système trichlorure d'indium – pyridine – eau à 25 °C montre l'existence de deux composés: $InCl_3.C_5H_5N.2H_2O$ et $InCl_3.3C_5H_5N$. Le diagramme de point de fusion montre que le composé $InCl_3.3C_5H_5N$ fond d'une façon non congruente à 242 °C. La chaleur de la réaction

$$InCl_3 + 3C_5H_5N \rightarrow InCl_3.3C_5H_5N$$

est $\Delta H = -34.6$ kcal/mol et la chaleur de formation de $InCl_3.3C_5H_5N$ est de -137.0 kcal/mol.

[Traduit par le journal]

Introduction

It is well known that indium trichloride has an appreciable solubility in many organic solvents, *e.g.* 51% in methanol, 38% in acetone (1). In an earlier paper (2) this author reported the formation of compounds between indium trichloride and *p*-dioxane, which have an appreciable solubility in water. In 1903 Renz (3) and subsequently in 1904 Dennis and Geer (4) reported the formation of a white crystalline compound when indium trichloride dissolved in absolute alcohol, was treated with pyridine. Renz gave a formula $InCl_3.3C_5H_5N$ and reported a melting point of 253 °C. The present paper deals with the phase diagram for the system indium trichloride – pyridine – water at 25 °C and the freezing point diagram of the binary system indium trichloride – pyridine. The heat of formation of the anhydrous compound from its constituents was also determined.

Experimental

Materials

For much of the solubility work, a concentrated acid-free solution (58 wt.%) of indium trichloride in water, provided without charge by Cominco, was used. Indium trichloride trihydrate was also prepared by refluxing pure indium metal with excess concentrated hydrochloric acid until solution was complete. The product was evaporated on a steam bath until on cooling it solidified. The salt was dissolved in water and crystallization repeated. The resulting salt gave a solution neutral to litmus. Analysis showed it to be pure indium trichloride. The anhydrous trichloride cannot be obtained pure by heating above 100 °C, because hydrolysis occurs. When the anhydrous salt was required for the measurements of heat of formation and the melting point diagram, BDH laboratory reagent indium trichloride was used. The pyridine was obtained from the Fisher Scientific Company, Certified ACS, and used without further purification. Conductance water was used throughout.

Analysis of the System Indium Trichloride – Pyridine – Water

The chloride was estimated gravimetrically as silver chloride, and pyridine by distillation from a strong sodium hydroxide solution, followed by titration with standard hydrochloric acid, using a conductimetric technique. The method for pyridine was tested by analysis of a known sample and gave an accuracy of $\pm 0.5\%$. This error is magnified in the drawing of tie-lines, as a means of determining composition of compounds, especially if the "wet residue" is appreciably damp. Because of the difference in molecular weights, there is no doubt of the indium trichloride to pyridine ratio in the compound, but the degree of hydration, if any, presents some difficulty. All solutions, except those high in pyridine, were very viscous and slow to filter. While the "wet residue"

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

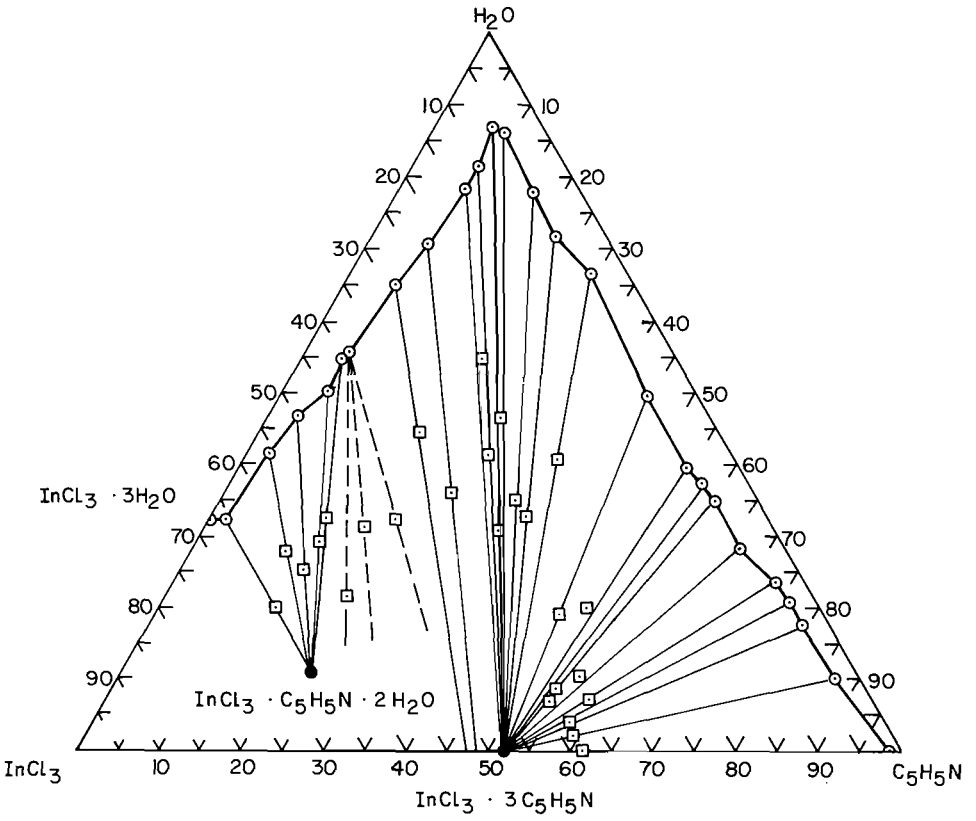

FIG. 1. Equilibrium diagram for the system indium trichloride – pyridine – water at 25 °C.

appeared to be sufficiently free from mother liquor, it was found necessary to separate them further by placing the filtered residue between thick layers of filter paper and subjecting it to a hydraulic pressure (2000 psi). Despite this treatment, the lever rule indicated that about 50% mother liquor was still present.

Calorimetry

The heat of reaction between indium trichloride (anhydrous) and pyridine was determined in a stoppered Dewar flask, fitted with thermistor, stirrer, and heating coil. Weighed amounts of indium trichloride were added intantaneously to about 300 g of well stirred pyridine. Anhydrous indium trichloride is very hygroscopic so all transfers were done in a dry-box before weighing. Reaction is rapid and therefore no attempt was made to exclude the atmosphere during measurements. The average was taken over ten measurements with a reproducibility of ±3%.

Freezing Point Diagram

Because pyridine is volatile, it was necessary to make the measurements in a closed system. A thermal analysis technique was tried unsuccessfully, because of extreme supercooling, which could not be overcome in a sealed vessel. Thick-walled glass tubes were charged with weighed quantities of the components and sealed off. Owing to the possibility of explosion on heating above 100 °C, the tubes were heated in an apparatus used previously to determine critical temperature (5). The temperatures of initial thawing and final disappearance of solid were measured using a copper–constantan thermocouple, calibrated with the freezing points of pure pyridine (−42 °C), water, and tin (231.9 °C). The tubes were removed from time to time during the heating and shaken vigorously.

Experimental Results

The solubility data are given in Table 1,[1] and are plotted in Fig. 1. The freezing point diagram, Fig. 2, is based on the measurements shown in Table 2.

Discussion

The existence of two compounds of indium trichloride and pyridine is shown in the ternary phase diagram; $InCl_3.C_5H_5N.2H_2O$, incongruently saturating, decomposes on addition of water to give a solution of composition 39.5%

TABLE 2. Melting points in the system indium trichloride – pyridine

Wt.% pyridine	Peritectic temperature (°C)	Temperature of liquidus (°C)
40	240	330
45	245	315
52	242	295
60	242	242
70	—	178
80	—	132
85	—	124
90	—	100
95	−42 (eutectic)*	74
100	−42	−42

*The temperature and composition of the eutectic are very nearly those of pure pyridine.

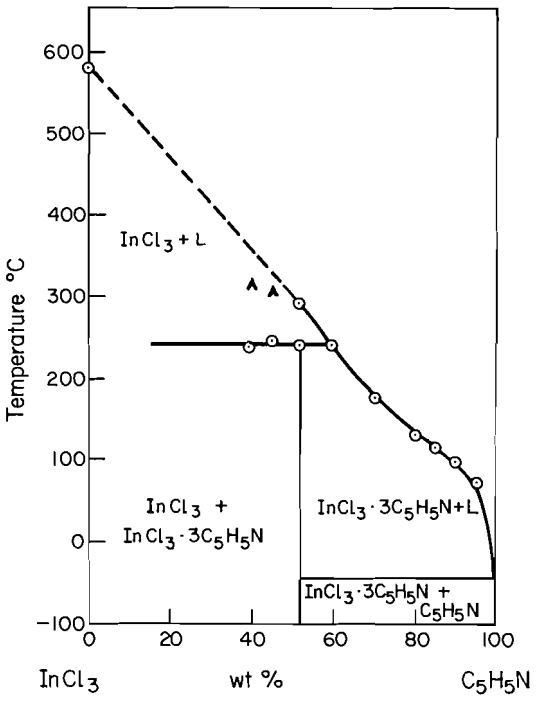

FIG. 2. Melting point diagram for the system indium trichloride – pyridine.

$InCl_3$, 5.3% C_5H_5N, and a second, anhydrous, compound, $InCl_3.3C_5H_5N$. The latter compound has very limited solubility in pyridine (1.0%) and is congruently saturating in water, with a solubility of 13 g per 100 g solution. The phase diagram indicates some slight solubility of indium chloride in the compound, to a maximum of about 6%.

The compound $InCl_3.3C_5H_5N$ forms with marked evolution of heat. A calorimetric study gave a value of -34.6 ± 1.0 kcal, for the reaction

$$InCl_3(s) + 3C_5H_5N(l) \rightarrow InCl_3.3C_5H_5N(s)$$

Using the value of −154.2 kcal given by Campbell *et al.* (6) for the heat of formation of $InCl_3(s)$ and a value of +17.2 kcal for pyridine, one obtains a value of −137.0 kcal per mol for the heat of formation of $InCl_3.3C_5H_5N(s)$.

Renz (3) reported a congruent melting of $InCl_3.3C_5H_5N$ at a temperature of 253 °C. The phase diagram, Fig. 2, indicates a peritectic temperature at 242 °C, at which decomposition occurs to anhydrous indium chloride and a liquid of 60 wt.% pyridine.

From a simple interpretation of the formulae of the compounds in the ternary system, it appears that pyridine replaces water in the solvation of $InCl_3.3H_2O$, resulting in the compounds $InCl_3.C_5H_5N.2H_2O$ and $InCl_3.3C_5H_5N$. There is no evidence for the existence of the third possible compound, *viz.* $InCl_3.2C_5H_5N.H_2O$. Systems in this region were stirred for several days to rule out the possibility of metastability. In the corresponding system, indium trichloride – dioxane – water, the trihydrate retains its water of crystallization and adds three molecules of dioxane (2, 7).

Studies of Ternary Nematic Phases by Nuclear Magnetic Resonance. Alkali Metal Decyl Sulfates/Decanol/D_2O[1]

KEITH RADLEY[2] AND LEONARD WALLACE REEVES

Chemistry Department, University of Waterloo, Waterloo, Ontario N2L 3G1

Received February 26, 1975

KEITH RADLEY and LEONARD WALLACE REEVES. Can. J. Chem. **53**, 2998 (1975).

The nematic regions of the ternary phase diagram for alkali metal decyl sulfates/decanol/D_2O have been investigated. The lithium detergent system has a very restricted region of type I nematic phase which orients parallel to the magnetic field with a long time constant. The sodium detergent also forms a rather restricted nematic region which may be type II, oriented perpendicular to the magnetic field or type I oriented parallel to the magnetic field, depending on the decanol content. The rubidium and potassium detergents were insufficiently soluble to form phases while the cesium detergent forms a very extensive type II nematic phase region with wide variations in water contents and with decanol between 2 and 7 wt.%. It is clear that the cesium decyl sulfate system has considerable advantage over the sodium detergent in forming nematic phases for use as orienting media for small molecules and ions in n.m.r. studies.

The partially averaged nuclear quadrupole coupling constants of Li-7, Na-23, and Cs-133 in ions and D-2 in the D_2O have been used as the primary tool in investigating the phase behavior. Quadrupole couplings have been reduced to unit quadrupole moment for the nucleus. The resultant quantity "E_s" in Hz b^{-1} reflects the strongly increasing electric field gradient induced in the monatomic ions by the nematic medium in going from Li^+ to Cs^+. The partially averaged quadrupole splittings which appear for the alkali metal ions in these uniaxial media are the result of distortion of the spherical symmetry of the ion and should not be interpreted in terms of degrees of orientation of the ion.

KEITH RADLEY et LEONARD WALLACE REEVES. Can. J. Chem. **53**, 2998 (1975).

On a étudié les régions nématiques du diagramme de phase ternaire: sulfates de décyle de métaux alcalins/décanol/D_2O. Le système comprenant un sel de lithium du détergent possède pour une région très restreinte, une phase nématique de type I qui s'oriente parallèlement au champ magnétique et qui possède une longue constante de temps. Le détergent sous forme de sel de sodium possède aussi, sur une région relativement restreinte, une phase nématique de type II orientée perpendiculairement au champ magnétique ou de type I orientée parallèlement au champ magnétique; les variations dépendent du contenu en décanol. Les sels de rubidium et de potassium du détergent ne sont pas suffisamment solubles pour former des phases; les sels de césium du détergent possèdent une phase nèmatique de type II sur une région très large impliquant de grandes variations dans le contenu en eau et à des concentrations de décanol allant de 2 à 7% en poids. Il est donc évident que le système contenant des sels de césium du sulfate de décyle possède des avantages marqués sur les sels de sodium lorsqu'il s'agit de former des phases nématiques destinées à orienter des petites molécules et des ions pour étude r.m.n.

Le principal outil utilisé pour étudier le comportement des phases a été les constantes de couplage quadrupolaires nucléaires partiellement moyennées des ions ^7Li, ^{43}Na et ^{133}Cs et de ^2D dans D_2O. Pour le noyau on a réduit les couplages quadrupolaires au moment quadrupolaire unitaire. La quantité "E_s" qui en résulte et qui s'exprime en Hz b^{-1} montre qu'il y a une augmentation importante de gradient de champ électrique induit dans les ions monoatomiques par le milieu nématique lorsque l'on passe di Li^+ à Cs^+. Les couplages quadrupolaires partiellement moyennés qui apparaissent pour les ions des métaux alcalins dans ces milieux uniaxiaux résultent d'une distorsion de la symétrie sphérique de l'ion et ne devraient pas être interprétés en termes de degrés d'orientation de l'ion.

and sodium sulfate. This phase (2–14) or small variations of it (12, 15) has proved to be a useful orienting medium for small molecules but to a much more restricted extent than the thermotropic liquid crystal solvents (16, 17). Most solute molecules in greater than 1 wt.% concentration in the lyotropic phase destroy the nematic properties, but this becomes less and less a limitation as the Fourier transform technique with rapid signal enhancement becomes a standard accessory to n.m.r. spectrometers (18) and dilute solutes can be reliably observed.

The lyotropic liquid crystal systems used in n.m.r. studies have been further generalized by Reeves *et al.* (19, 20) by substituting the simple counter ion for complex ions in both anionic detergent and cationic detergent phases. In this event the concentration of the complex ion can be high enough to allow study with the most elementary n.m.r. teaching instrument. The flexibility of these nematic phases with respect to counter ion exchange, variation of temperature, variation of detergent used, the use of mixed detergents, variation of p*H* in the water component etc., has prompted a series of studies from this and the São Paulo laboratory (21–30). The present study is a systematic investigation of the alkali metal decyl sulfates as components of ternary phases with decyl alcohol and water to probe the extent of nematic phase formation and type of nematic phase formed. The n.m.r. tool is applied to measure partially averaged nuclear quadrupole coupling constants and their variation with composition. The results should be a good guideline for those contemplating use of these mixtures as media for orienting solute molecules.

Experimental Section

The general methods developed for the preparation of alkali metal decyl sulfates have been previously described (19, 28, 30) and were followed in this study. The Varian VF16 variable frequency 2–16 MHz broad line spectrometer used to observe spectra was driven by a Schomandl ND30M frequency synthesizer to eliminate frequency drift of the variable frequency oscillator (v.f.o.) and to provide easy calibration by changing frequency after completing a sweep of the spectrum. The observation of one nucleus after another on the same oriented sample was facilitated by choosing a magnetic field where the nuclei observed had n.m.r. frequencies in the range 4–8.5 MHz. In this manner the optimum field was not used, but minor adjustments of the probe, v.f.o., and frequency synthesizer sufficed to observe one nucleus after the other. Li-7 fell outside this frequency range at all fields which were suitable for D-2, Na-23, and Cs-133. A probe change to 8–16 MHz was necessary in this case. The standard observation frequencies were Li-7 10.214 MHz, Na-23 8.300 MHz, Cs-133 4.120 MHz, and D-2 4.822 MHz. The H_1 field and modulation widths were adjusted optimally for each nucleus and sample (30) as before. Modulation frequencies were 40 Hz.

Nematic phases were prepared by the usual techniques described before (19, 21, 30). The cesium decyl sulfate (CsDS) formed by far the most extensive birefringent phases in the nematic region of the phase diagram. The compositions of these phases are described in Fig. 1. All phases contained 50 parts by weight of CsDS and $a \rightarrow f$ in the diagram describes increasing decanol content. Figure 1*a* is 2 parts by weight decanol, (*b*) 3 parts, (*c*) 4 parts, (*d*) 5 parts, (*e*) 6 parts, and (*f*) 7 parts. The horizontal lines indicate the extent of variation of water content in the nematic phases. The first line (*f*) indicates mesophases formed between 120 and 88 parts water (D_2O), 7 parts decanol, and 50 parts CsDS. As the decanol content decreases at constant weight of CsDS the extent of mesophase existence with variation of water content decreases and the amount of water required to form the mesophase decreases. To the lower left of the diagram an isotropic phase forms, to the bottom right a solid is formed, to the top right a birefringent phase occurs which is not oriented by a magnetic field and yields a powder pattern spectrum (30), and to the top left two phases separate, the upper one yielding a powder pattern spectrum (30) and the lower phase isotropic. Some of the above solid samples near the phase change, changed to nematic phases when stored in sealed tubes over a three month period thermostated at 27 °C.

Lithium decyl sulfate/decanol/water systems have an extremely limited range of nematic behavior with composition changes. A deuterium doublet for D_2O was obtained for birefringent phases with 32.5 parts by weight LiDS, 76–84 parts D_2O, and between 9.5 and 10.5 parts by weight decanol. The phases were never clear but had a very light milky appearance even after orienting in the magnet and this is unusual in our experience. The range of existence of nematic phases in the sodium decyl sulfate NaDS/decanol/D_2O was also very limited but more extensive than the LiDS system. Samples were prepared in a region with decanol 2.5 to 8.5 parts by weight, D_2O 44 to 62 parts, and NaDS 35 parts. In all cases where the magnetic field failed to orient the samples to give single crystal spectra and powder pattern spectra persisted indefinitely, it was assumed that lamellar type phases had formed. The samples were thermostated in a water bath at 27 °C the temperature of the n.m.r. measurements. Marked deterioration of the LiDS samples occurred over a four month period. All but a few of the samples initially nematic and birefringent phases became isotropic. Being an ion which generates the hydronium ion in water, it is probable that some hydrolysis of the decyl sulfate ion occurs with loss of weighed compositions. The solid samples formed, remained solid and birefringent when stored in sealed tubes over the same period of time. Similar aging was observed with NaDS sample although not as extensive.

The rubidium and potassium decyl sulfates prepared were insufficiently soluble in water to form mesophases. The most extensive work reported here therefore will describe the behavior of CsDS/decanol/water systems.

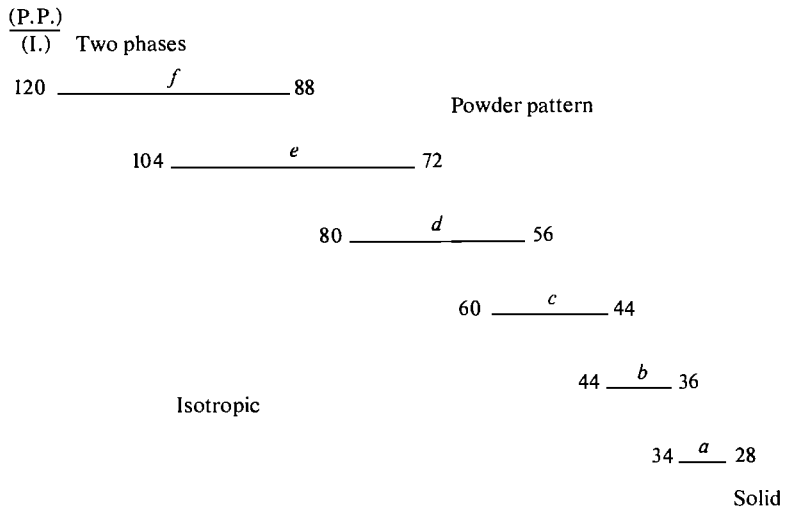

FIG. 1. Compositions of nematic mixtures in the cesium decyl sulfate/decanol/D_2O system. All phases were prepared by weighing 50 parts of cesium decyl sulfate. The decanol weighings were (*a*) 2 parts, (*b*) 3 parts, (*c*) 4 parts, (*d*) 5 parts, (*e*) 6 parts, and (*f*) 7 parts. Horizontal bars indicate the variation in heavy water content within the nematic region, *e.g.* nematic phases are staple for 80 to 56 parts by weight D_2O, 5 parts by weight decanol, and 50 parts by weight cesium decyl sulfate (horizontal bar *d*). To the top right powder pattern spectra were observed at the bottom extreme solid samples, to the left isotropic phases and upper left two phases. The upper phase gave a powder pattern spectrum, the lower one was isotropic.

Results

Mixtures containing Lithium and Sodium Decyl Sulfate

The Na-23 and D-2 n.m.r. spectra of the ternary nematic phases NaDS/decanol/D_2O were observed with nonspinning samples and after some time in the magnet became homogeneously oriented along the direction of the magnetic field (20). Single crystal spectra which were 1:1 doublets for deuterium and 3:4:3 triplets for the Na-23 n.m.r. were recorded. For low decanol contents the quadrupole splittings were in the range 700–1000 Hz for D-2 and 20–24 kHz for Na-23 while at higher decanol content the separations of transitions were 150–400 Hz for D-2 and 7–12 kHz for Na-23. These two types of phases formed have been identified with those previously reported (30) with mixed detergents as (*a*) type I orienting parallel to the magnetic field (*b*) type II orienting perpendicular to the field respectively. It is interesting that partial substitution of counter ions previously studied (30), and variation of the decanol content reported here, can induce phase changes from type I to type II. Low angle X-ray diffraction on magnetically oriented samples is required to fully interpret the changes in superstructure array. This change in phase has been explained (30) in terms of small alterations in the micro degrees of order of phase components but with a perpendicular change in the nematic direction. The quadrupole couplings in the two types of phases are thus related by a factor $\frac{1}{2}$ and a sign change in the degree of order at the coexistence point. In the solid samples formed with low water and low decanol, which were transparent and birefringent, the D-2 n.m.r. spectra were "powder pattern" type. The doublet separation was in the range 400–600 Hz for these samples.

After storing for four months, only six of the samples in the LiDS ternary system were homogeneous, transparent, and birefringent, while a large number were isotropic and a lesser number were solids. The Li-7 and D-2 n.m.r. spectra were investigated on these samples and the Li-7 signal was the expected 3:4:3 triplet with splittings between the outer peaks in the range 250 to 350 Hz and a 1:1 doublet with a separation of 450–650 Hz respectively. The D-2 n.m.r. of some of the birefringent and transparent solid phases formed in a region with low decanol and low water content was a powder pattern with a doublet spitting between 430–500 Hz. If the ratio of the Li-7 to D-2 splitting is compared to the ratio in our previous investigation (and identification of two types of phases) these six

nematic phases can be considered to be of type I (30).

The nematic ternary component mesophases of LiDS and NaDS were not investigated in great detail but results are cited here to serve as guidelines to those interested in using these phases as orienting media.

Cesium Decyl Sulfate/Decanol/D_2O System

The range of nematic mesophase formation in this system is so extensive that it is now the preferred solvent medium in our laboratory for orienting small molecules and ions. These CsDS phases are always of type II and no phase change is induced when small quantities of electrolyte or solute are added. After an initial orientation time which is very short the sample may be rotated in both cryogenic and convention magnet spectrometers to improve resolution (30).

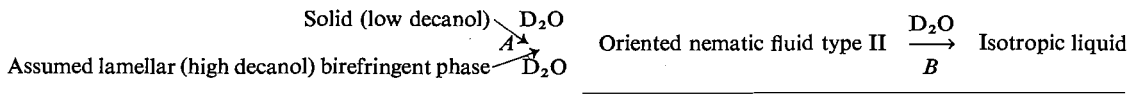
The Cs-133 spectrum in single crystal nematic samples appears as a septet with intensity ratios 7:12:15:16:15:12:7 for first order quadrupolar perturbation on the Zeeman spectrum with spin $I = 7/2$ (30). The quadrupole splittings were measured as separations of adjacent peaks for both deuterium and cesium spectra and are reported in Fig. 2 for the phase compositions summarized in Fig. 1.

The Cs-133 splittings in Fig. 2*A* follow quite closely the form of the D-2 splittings in Fig. 2*B* as a function of composition. Figure 2 (*a*) to (*f*) in each subfigure indicates increasing decanol content as in Fig. 1 while the horizontally displaced curves go from low water contents with large Cs-133 and D-2 splittings to low Cs-133 and D-2 splittings with higher water content. The decanol and water content of the phases has large effects on the local degrees of order. The characteristic dependence of these splittings is further illustrated in Fig. 2*C* where the ratio of cesium to deuterium quadrupole splittings is set out as a function of decanol and water content of the nematic phases. In Fig. 2*D* the deuterium quadrupole splittings are shown to be related in a linear fashion with zero intercept at low decanol contents to the cesium quadrupole couplings but this relationship becomes increasingly nonlinear as the decanol content of the phase increases. This nonlinearity at high decanol contents as the water composition is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

changed may be associated with the influence of chemical exchange between the water deuterium and the decanol-OD deuterium, which is much more highly ordered in the head groups of the hydrophobic/hydrophillic interface. All the nematic phases of CsDS are of type II with orientation of the uniaxial direction perpendicular to the magnetic field.

The phase transitions in the CsDS/decanol/D_2O system can be described as



At low decanol contents with little D_2O the system is solid and with water addition passes directly to the type II nematic phases whose behavior was described above. At high decanol contents a lamellar phase is probably formed which also passes on addition of further D_2O into the type II nematic phase. On further addition of D_2O the nematic phase undergoes a transition to an isotropic micellular solution.

Both the solid phase at low decanol content and the lamellar phase exhibit n.m.r. spectra, which are powder pattern type. The quadrupole splitting of the powder doublet (30) varied from 1000 to 500 Hz at the phase change *A* for 27 °C. In the isotropic micellular phase the quadrupole splitting was zero and typical single line spectra were observed for deuterium and sodium resonances.

Discussion

Nuclear Quadrupole Couplings

The nuclear quadrupole couplings in spherical or cubic symmetries are known to be zero (31). The appearance of a quadrupole coupling energy which has a nonzero average on the time scales of the n.m.r. experiment (the inverse of the quadrupole coupling energy in radians in the present case), must indicate a distortion of the spherical symmetry of the alkali metal ions in the nematic phase (23). In a nematic medium, it is most reasonable to assume a statistically uniaxial distortion into an ellipsoidal shape with two equal axis leading to a quadrupole coupling tensor with no asymmetry parameter. This is consistent with previous experiments (27, 30).

The effective Hamiltonian, which leads to the nuclear quadrupole splitting, in the n.m.r. spectra of a uniaxially distorted spherical ion is (27)

$$[1] \quad H_Q = \sum_i \left[\frac{e^2Q^{(i)}\langle q_{zz}{}^{(i)}\rangle}{4I^{(i)}(2I^{(i)}-1)}\right] \times [3I_z{}^{(i)2} - I^{(i)}(I^{(i)}+1)]$$

where the superscript (i) refers to nucleus i and $-e\langle q_{zz}{}^{(i)}\rangle$ is the nonzero averaged value of the principal electric field gradient (e.f.g.) which we have shown to be along the nematic axis (27, 30). $eQ^{(i)}$ is the nuclear quadrupole moment of nucleus i, $I^{(i)}$ its spin quantum number, and $I_z(i)$ the z component of the spin angular momentum. The spacing of the quadrupolar split lines in the spectrum is

$$\nu_Q{}^{(i)} = \left|\frac{3e^2Q^{(i)}\langle q_{zz}{}^{(i)}\rangle}{2I^{(i)}(2I^{(i)}-1)h}\right| \text{ Hz}$$

The evaluation of $-e\langle q_{zz}{}^{(i)}\rangle$ requires a knowledge of the contribution of p states, which must necessarily become mixed with the s ground states in order to accommodate the distortion of the ion, as well as further antishielding effects (31). As was recently pointed out (27) there is no degree of orientation involved but merely a distortion of cubic or spherical symmetry around the nuclear site over a sufficiently long period of time to lead to secular perturbation of the Zeeman energies by a quadrupole coupling energy. The relaxation of Na-23 nuclei in the simple ion in a aqueous solution is dominated by the fluctuating electric quadrupole coupling (32–34).

$$[2] \quad \frac{1}{T_1} = \frac{2\pi^2}{5}\left(\frac{e^2q_{zz}}{h}\right)^2 T_c$$

T_c is a local correlation time for the appropriate fluctuating motion which is of the order 10^{-11} to 10^{-12} s though the value cannot actually be determined. The quadrupole coupling term which occurs in [2] has been the subject of estimates only. The quadrupole coupling constants measured for sodium in solid materials are highly temperature dependent and vary a great deal with the crystal (31). These couplings in solids are characteristic of the local forces at the crystalline site which distort the ion from spherical symmetry. There has been a tendency

to assign degrees of orientation of the sodium ion e.f.g. vector (26, 35, 36) by relating the quadrupole couplings in lyotropic phases to those in solids by the equation

$$[3] \qquad \Delta\nu = 2\nu_Q S_{zz}$$

where $\Delta\nu$ is the quadrupole splitting between outer transitions in the lyotropic phase and ν_Q is a value typical for solids. S_{zz} has been interpreted (26, 35, 36) as an approximate degree of orientation of the e.f.g. for the sodium ion but it is much better interpreted as some measure of the distortion of the spherical electron distribution in the ion (27). The relaxation time T_1 of sodium in aqueous isotropic solution is approximately 50 ms and decreases to about 5 ms in the electrical double layer (e.d.l.) of lamellar phases (32, 37).[3] This decrease may of course be derived from larger fluctuating quadrupole coupling energies in the e.d.l. as well as longer T_c values.

The distortion of the spherical ions as manifested in the quadrupole splitting in these nematic phases does follow quite closely the variation of the degree of orientation of the deuterium in the water of the phase (26, 31). The relationship between the two quantities is in principle a complex one. It is the purpose of this experimental study to use the quadrupole couplings as a tool in the investigation of the e.d.l. and the nematic phases, so that apart from the above clarifying discussion on those couplings no attempt will be made to quantify them in a theoretical manner.

The quadrupole couplings of the alkali metal ions can be reduced by taking into account the quadrupole moments on the respective nuclei, which are now more precisely known (38). In units of barns (10^{-24} cm^2) the values of Q are: Li-7 3×10^{-2}, Na-23 0.14 to 0.15, Cs-133 -3×10^{-3}, and D-2 2.73×10^{-3}. The D_2O is the immediate neighbor of the alkali metal ions and thus the degree of order associated with the local nematic axis at the ion is represented in the deuterium quadrupole coupling. The results section and previous studies (30) indicate that the quadrupole couplings of the alkali metal nuclei are approximately proportional to that of deuterium in the immediate water environment. A proper measure to compare e.f.g.'s in different alkali metal ions would be to reduce the measured quadrupole couplings from the nuclear quadrupole moments. A quantity defined as E_s indicating a value in Hz b^{-1} can be defined.

$$[4] \qquad E_s = \left[\frac{\nu_Q(i)}{Q^{(i)}}\right] \text{Hz b}^{-1}$$

where (i) refers to the alkali metal nucleus, $eQ^{(i)}$ is the nuclear quadrupole moment of the alkali metal nucleus, and $\nu_Q{}^{(i)}$ is the quadrupole coupling splitting observed in Hz.

In Table 1 the values of E_s are given for each alkali metal nucleus in typical nematic phases encountered. Middle of range values are selected in each case and the third column lists the nuclear quadrupole coupling constant for deuterium in the D_2O of the same phases. Multiplying the magnitude of the deuterium quadrupole coupling of type II phases by two to correct for perpendicular alignment of the nematic axis, it is evident that the middle of the range values do not differ a great deal from phase to phase. The degree of orientation of the water surrounding the alkali metal ions varies by less than $\pm 35\%$ from 800 Hz with respect to a corrected common parallel axis direction. The reduced quadrupole coupling E_s for the alkali metal nuclei represents a quantity proportional to the electric field gradient $\langle eq_{zz} \rangle$ and this increases by a factor more than 10^2 in going from lithium to cesium. This increase is understandable qualitatively in terms of the binding energy of the hydration sphere and its increasing tendency to distort easily from cubic symmetries in the uniaxial medium as the alkali metal ion becomes larger.

The e.d.l. has been treated by macroscopic theories and divided between the adsorbed or Stern counter ion layer and a more diffuse Gouy layer which extends into the aqueous division of the interface (39). In all cases the D_2O and monatomic ions in the n.m.r. experiment are observed in average environments, since exchange processes between different portions of the aqueous electrical double half layer are rapid compared to the inverse frequency differences of quadrupole coupling constants and chemical shift changes. The monatomic ions have in principle a strongly decreasing concentration gradient from the negative interface outward. In recent work we have shown to a good degree of

[3]More recent preliminary measurements by L. A. Wilson and L. W. Reeves indicate a $T_1 \sim 38$–40 ms in nematic media for Na-23. (Unpublished work.)

approximation that the distribution of ions within the alkali metal series for mixed counter ion double layers is essentially independent of the ion (30). The quadrupole coupling ratios for phases of type I and II with varying contents of Li^+, Na^+, and Cs^+ change less than 8% in the whole nematic range. This is considerable evidence that the ion charges alone are the major determining effect in a distribution function of concentration from the surface outward.

Stéréochimie de l'addition homolytique de l'acide thioacétique à des dérivés méthylènes cyclohexaniques[1]

JEAN-CLAUDE RICHER ET CLAUDE LAMARRE[2]

Département de Chimie, Université de Montréal, B.P. 6210, Montréal, Québec, H3C 3V1

Reçu le 15 avril 1975

JEAN-CLAUDE RICHER et CLAUDE LAMARRE. Can. J. Chem. **53**, 3005 (1975).

On a examiné la stéréochimie de l'addition homolytique de l'acide thioacétique au *tert*-butyl-4 diméthyl-2,2 méthylène-1 cyclohexane, au triméthyl-3,3,5 méthylène-1 cyclohexane, au β-pinène et, pour fins de comparaison, au *tert*-butyl-4 méthylène-1 cyclohexane. Les résultats obtenus au cours de cette étude sont comparés à ceux obtenus lors de la réduction des cétones correspondantes par $LiAlH_4$.

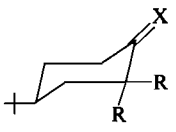
JEAN-CLAUDE RICHER and CLAUDE LAMARRE. Can. J. Chem. **53**. 3005 (1975).

The stereochemistry of the homolytic addition of thioacetic acid to 4-*tert*-butyl-2,2-dimethyl-1-methylenecyclohexane, to 3,3,5-trimethyl-1-methylenecyclohexane, to β-pinene and, for comparison purposes, to 4-*tert*-butyl-1-methylenecyclohexane has been examined. The results obtained during this study are compared to those obtained from the reduction of the corresponding ketones by $LiAlH_4$.

[Journal translation]

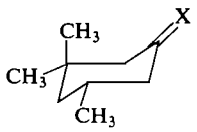
Introduction

Dans le cadre de nos travaux sur la stéréochimie des réactions d'addition sur des cétones cycliques (1), sur des carbocations contenus dans des systèmes cycliques (2) et sur des doubles liaisons endo- et exocycliques (3, 4*a* et *b*, 5), nous avons été amenés à examiner la stéréochimie des réactions d'addition homolytique d'acide thioacétique aux dérivés méthylènes cyclohexaniques (**1***a*, **2***a*, **3***a*). Ce sont les résultats obtenus au cours



1

a R = CH_3; X = CH_2
b R = H; X = CH_2
c R = CH_3; X = O
d R = H; X = O



2

a X = CH_2
b X = O

3

a X = CH_2
b X = O

de cette étude qui font l'objet de la présente communication. Pour fins de comparaison nous avons repris les travaux de Bordwell *et al.* (6) impliquant une telle addition sur le *tert*-butyl-4 méthylène-1 cyclohexane (**1***b*). Alors que le présent travail était terminé, Claise *et al.* (7) ont rapporté l'étude de l'addition homolytique de l'acide thioacétique au β-pinène (**3***a*) en utilisant le peroxyde comme initiateur. Ces auteurs ont analysé le mélange réactionnel par c.p.g.; la distribution des produits est dans un rapport de 3:1 mais la stéréochimie des thioacétates obtenus n'a pas été déterminée. Les résultats rapportés dans le présent travail confirment ces données et les complètent.

Partie expérimentale

Les instruments utilisés pour déterminer les propriétés physiques des produits obtenus au cours de cette étude ont été décrits dans une publication précédente (4*a*). Les poids moléculaires ont été déterminés au moyen d'un osmomètre à pression de vapeur de la compagnie Perkin-Elmer modèle 115 en utilisant le chloroforme comme solvant. La précision est de ±2%. Les spectres u.v. ont été mesurés dans l'éthanol 95% à l'aide d'un appareil Bausch and Lomb Spectronic 505. Les indices de rotation ont été déterminés à l'aide d'un spectropolarimètre photoélectrique Rudolph modèle 80.

Synthèse des méthylènes exocycliques ***1a, 1b et 2a***

Les méthylènes exocycliques sont préparés par l'action du méthylène de la triphénylphosphine sur la cétone correspondante selon la méthode de Wittig et Schöllkopf (8). Les propriétés physiques de chaque oléfine sont semblables à celles rapportées dans la littérature: **1***a* (3), **1***b* (9, 10) et **2***a* (4*b*, 10). Le β-pinène (**3***a*) est obtenu commercialement et purifié par distillation.

Synthèse des alcools primaires ***4a–11a***

Les alcools primaires **4***a*–**7***a* ainsi que **10***a* et **11***a* ont déjà été synthétisés par l'addition du diborane, préparé *in situ*, dans le diglyme à 0 °C, sur le méthylène correspon-

[1]Les résultats rapportés dans cette communication sont tirés en partie dans la thèse de doctorat présentée par Claude Lamarre, Université de Montréal, Montréal, Québec 1971.

4 5 6 7 8 9 10 11

a R = OH; *b* R = OTs; *c* R = S—C(=O)—CH$_3$

dant selon la méthode de Brown et Zweifel (11). Les propriétés physiques des alcools primaires **4***a*–**7***a* ainsi que celles du **10***a* et **11***a* sont connues (4*b*, 12).

Le *cis*-myrtanol (**8***a*) est obtenu par hydroboration du β-pinène (**3***a*) dans le tétrahydrofuranne selon la technique de Brown et Zweifel (13). Le *trans*-myrtanol (**9***a*) est obtenu par une isomérisation du *cis*-myrtanylborane à 135–140 °C suivie par une hydrolyse alcaline et d'une oxydation par l'eau oxygénée à 30%. Les propriétés physiques des alcools primaires **8***a* et **9***a* ont déjà été décrites (14, 15).

Synthèse des tosylates **4***b*–**11***b*

De façon générale, 5 mmol d'alcool primaire et 6 mmol de chlorure de tosyle sont dissous dans 4 ml de pyridine anhydre et abandonnés 3 jours au réfrigérateur. Le mélange est versé sur une solution glacée d'acide chlorhydrique à 25% et extrait à l'éther. La phase éthérée est lavée par de l'eau jusqu'à neutralité, séchée sur Na_2SO_4 anhydre et évaporée. Le résidu est cristallisé jusqu'à un point de fusion constant. Les propriétés physiques des tosylates **4***b*–**9***b* sont consignées dans le tableau 1; celles des tosylates **10***b* et **11***b* ont déjà été rapportées dans la littérature (12).

Synthèse des thioacétates **4***c*–**11***c*

De façon générale, 3 mmol de tosylate et 10 mmol du sel de potassium de l'acide thioacétique sont dissous dans 9 ml d'éthanol absolu et chauffés à reflux pendant 6 h sous une atmosphère d'azote. Le sel de potassium de l'acide *para*-toluènesulfonique se dépose durant la réaction. Après refroidissement, le thioacétate est extrait par le pentane. Les propriétés physiques des thioacétates **4***c*–**9***c* sont consignées dans le tableau 2; celles des thioacétates **10***c* et **11***c* sont déjà connues.

Addition homolytique de l'acide thioacétique aux méthylènes exocycliques **1***a*, **1***b*, **2***a* *et* **3***a*

Dans une expérience type, l'acide thioacétique est ajouté au dérivé méthylène cyclohexanique dans un tube de quartz et la solution est refroidie sous l'eau du robinet avec agitation pendant 15 min avant irradiation. Une lampe u.v. Hanovia 450 W, sans filtre, est utilisée pour irradier la solution et sa durée est de 30 min. Après ce temps, les produits de la réaction sont isolés par l'éther; la phase éthérée est lavée par une solution sursaturée de bicarbonate de sodium, lavée à l'eau jusqu'à neutralité, séchée sur Na_2SO_4 anhydre et évaporée. Le résidu est analysé par c.p.g. ou par r.m.n. Les résultats des additions homolytiques sont résumés dans les tableaux 3, 4, 5 et 6. Les pourcentages relatifs des thioacétates consignés dans les tableaux 3, 4 et 5 ont été déterminés par c.p.g. Dans le but de vérifier si tous les pourcentages relatifs sont exacts, des mélanges connus d'épimères ont été préparés par pesée et analysés par c.p.g. Dans chaque cas, le pourcentage obtenu par c.p.g. s'est avéré exact. Les pourcentages relatifs des thioacétates **8***c* et **9***c* consignés dans le tableau 6 ont été déterminés par r.m.n. de la façon suivante: le glissement chimique des groupements *gem*-diméthyles en position 7 sont respectivement de 1.20 et 1.05 p.p.m. et 1.20 et 0.80 p.p.m. pour les épimères **8***c* et **9***c*. Chaque groupement *gem*-diméthyle possède donc un méthyle dont le glissement chimique (1.20) est identique pour les deux épimères. Le rapport des intégrations des glissements chimiques situés à 1.20 p.p.m. et à 1.05 p.p.m. permet d'effectuer un dosage du pourcentage du thioacetate-*cis* **8***c* (moyenne de 10 déterminations du rapport des intégrations). Un mélange étalon, préparé par pesée, des thioacétates **8***c* et **9***c*, a démontré que le dosage par r.m.n. permet une détermination précise de la composition du mélange réactionnel.

Stabilité des thioacétates

Chaque thioacétate pur (45 mg) a été irradié pendant 30 min en présence de 60 mg d'acide thioacétique. Les analyses par c.p.g. ou par r.m.n. indiquent que le thioacétate de départ est récupéré intact; aucune transformation n'est observée.

Résultats et discussions

La stéréochimie de l'addition homolytique de l'acide thioacétique aux alcènes **1***a*, **1***b*, **2***a* et **3***a* est résumée dans le tableau 7; l'attribution des configurations relatives des divers produits d'addition se fait par leur comparaison, en chromatographie en phase gazeuse ou par r.m.n., avec des produits authentiques obtenus à partir d'alcools primaires (**4***a*–**11***a*) dont la configuration a été démontrée précédemment. Les résultats rapportés dans ce tableau correspondent à un contrôle cinétique de la réaction puisque les produits n'évoluent pas lorsque remis dans les conditions de la réaction. Les résultats obtenus pour l'addition sur le *tert*-butyl-4 méthylène-1

TABLEAU 1. Propriétés physiques des tosylates 4*b*–9*b*

cyclohexane (**1***b*) sont en parfait accord avec ceux rapportés par Bordwell *et al.* (6).

Les quantités relatives d'esters **8***c* et **9***c* formées lors de l'addition homolytique, induite photochimiquement, de l'acide thioacétique sur le β-pinène (**3***a*) sont en accord avec les valeurs obtenues par Claise *et al.* (7) pour l'addition homolytique de l'acide thioacétique au β-pinène (**3***a*) utilisant le peroxyde de benzoyle comme initiateur; dans le présent travail, nous pouvons attribuer les configurations relatives aux deux esters formés (**8***c* et **9***c*) et confirmer que, contrairement à ce qui est généralement observé (16–19), cette addition homolytique de l'acide thioacétique ne provoque pas une ouverture du β-pinène (**3***a*) pour conduire à des produits de structure *p*-menthénique du type **12**.

D'une manière générale, le mécanisme de l'addition homolytique d'un thiol sur une double liaison peut être représenté par la série d'équations du schéma 1 proposée par Kharash *et al.* (20).

L'addition du radical $CH_3COS\cdot$ (éq. 2) sur la double liaison s'effectue de façon inverse à celle prédite par la règle de Markonikoff et elle peut être reversible. L'abstraction d'un radical H· (éq. 3) de la molécule de thiol par le radical intermédiaire conduit au produit de la réaction; on considère généralement que cette étape détermine la vitesse de la réaction et qu'elle est irréversible (21).

Walling et Helmreich (22) et Huyser et ses collaborateurs (23, 24) ont démontré que si la réversibilité de la réaction est une étape importante, la distribution des produits de la réaction varie

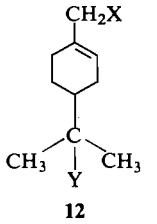
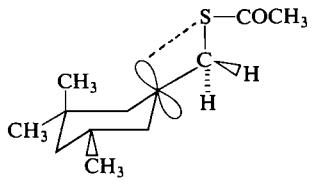
SCHÉMA I

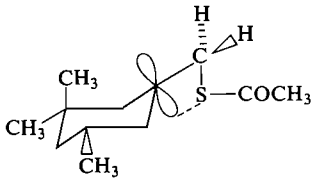
avec la concentration du thiol. Les résultats consignés dans les tableaux 3, 4, 5 et 6 indiquent que la distribution des produits n'est pas influencée par la variation de la concentration de l'acide thioacétique. Cette observation suggère que la vitesse d'élimination du radical CH_3COS· des radicaux intermédiaires (type A) représentés par une hybridisation planaire (voir réf. 25–28), est plus lente que la vitesse de la réaction des radicaux du type A avec l'acide thioacétique qui cède un H· pour donner les produits de la réaction. La distribution des thioacétates isomères est donc déterminée par l'approche de la molécule de l'acide thioacétique qui cède H· aux radicaux du type A au cours de l'étape représentée par [3]. Si l'on admet que l'acide thioacétique se comporte, au cours de ce transfert de H·, comme un réactif peu volumineux, l'approche axiale ou équatoriale de la molécule d'acide thioacétique à chaque centre radicalaire pourrait donc être comparée à l'approche d'un ion hydrure à la cétone correspondante. La stéréochimie des additions homolytiques de l'acide thioacétique serait donc déterminée par des facteurs stériques (1) et torsionnels (29) similaires à ceux proposée pour expliquer la stéréochimie des réductions des cétones par les hydrures complexes. Le tableau 7 résume les résultats stéréochimiques observés au cours du présent travail et permet la comparaison avec les résultats stéréochimiques obtenus lors de la réduction des cétones **1***c*, **1***d*, **2***b* et **3***b* par $LiAlH_4$ dans l'éther. Le parrallélisme entre ces deux séries de résultats stéréochimiques ressort d'une manière évidente. La proportion plus grande d'attaque axiale lors de l'addition homolytique de l'acide thioacétique sur l'alcène **2***a* par opposition à la stéréochimie de la réduction de la cétone **2***b* par $LiAlH_4$ pourrait être rationalisée en faisant appel aux conclusions de Kawamura *et al.* (30) qui suggèrent que la conformation privilégiée du radical intermédiaire, lors de l'addition de thiols sur des oléfines, est celle où la liaison C_β—S est parallèle à l'orbitale p du centre radicalaire. Dans de tels cas, il peut y avoir participation de l'électron célibataire avec l'atome de soufre pour former un pont dans les intermédiaires (**13***a* et **13***b*) issus de l'alcène **2***a*. Le conformère A, impliquant une interaction 1:3 diaxiale avec le groupe méthyle en position 3, serait défavorisé par rapport au conformère B qui conduirait ainsi, par rapport à la réduction de la cétone **2***b*



12



13*a*
Conformère A



13*b*
Conformère B

par $LiAlH_4$, à une attaque en proportions plus élevées par la face axiale.

Les résultats présentés dans le travail actuel suggèrent donc que l'addition homolytique de l'acide thioacétique sur des doubles liaisons exocycliques se fait par l'intermédiaire de radicaux du type A, que cette addition n'est pas reversible et que la stéréochimie des produits formés par le transfert du H· de l'acide thioacétique, peut être expliquée en faisant appel à des facteurs stériques et torsionnels.

Reduction of Some Alkylisoxazoles with Lithium Aluminum Hydride

A. L. KHURANA AND A. M. UNRAU

Department of Chemistry, Simon Fraser University, Burnaby, British Columbia V5A 1S6

Received February 17, 1975

A. L. KHURANA and A. M. UNRAU. Can. J. Chem. **53**, 3011 (1975).

Lithium aluminum hydride reduction of alkyl substituted isoxazoles gave a variety of products. The major constituent was identified (i.r., n.m.r., m.s.) as hydroxyethylaziridine. Specifically, reduction of 3,4,5-trimethylisoxazole gave as the major product 2,3-dimethyl-3-β-hydroxyethylaziridine. Two of the more prominent minor products were identified as 2,3-dimethyl-3-ethylaziridine and 4-amino-3-methyl-2-pentanol. The corresponding products were identified when 3,5-dimethylisoxazole was reduced with LAH.

A. L. KHURANA et A. M. UNRAU. Can. J. Chem. **53**, 3011 (1975).

La réduction, par $LiAlH_4$, d'isoxazoles substitués par des groupes alkyles conduit à une variété de produits. Le constituant principal, identifié par i.r., r.m.n. et s.m., est l'hydroxyéthylaziridine. D'une façon spécifique, la réduction de la triméthyl-3,4,5 isoxazole conduit, comme produit majeur, à la diméthyl-2,3 β-hydroxyéthyl-3 aziridine. On a identifié deux des produits mineurs les plus importants comme étant la diméthyl-2,3 éthyl-3 aziridine et l'amino-4 méthyl-3 pentanol-2. On a identifié les produits correspondants lorsque la diméthyl-3,5 isoxazole a été réduite par LAH.

[Traduit par le journal]

The reduction of isoxazolines with lithium aluminum hydride (LAH) has been described by Kotera *et al.* (1, 2). Whereas previous reports (3–6) described the formation of only the 1,3-amino alcohol, Kotera *et al.* (1) obtained significant yields (20–80%) of aziridine as well as the corresponding amino alcohol. The relative proportion of aziridine to amino alcohol was found to be solvent dependant (1). The stereochemistry of the substituted aziridines obtained was deduced from n.m.r. data for the proteo and corresponding deuterio compounds (1).

We have previously described the mechanism of 3,4,5-trimethylisoxazole (**1**) formation from nitroethane as well as that for 3,4-dimethylisoxazole (**2**) using ^{14}C- and ^{2}H-labelled precursors (7). Among alternate methods considered for the location of label in the isoxazoles thus formed, lithium aluminum hydride reduction appeared as a viable procedure for the conversion of the heterocyclic compounds to the corresponding alicyclic 1,3-amino alcohols.

Treatment of 3,4,5-trimethylisoxazole (**1**) and 3,5-dimethylisoxazole (**2**) with LAH in tetrahydrofuran for 48 h resulted in greater than 80% conversion of isoxazole to products. Analysis of the reaction mixtures by g.l.p.c. employing low inlet (120–130 °C) and detector (t.c.) (130–140 °C) temperatures together with column temperature programming (55–145 °C) gave in the case of trimethylisoxazole, a spectrum of more than eight peaks with one component constituting about 50% of the total peak area. The major as well as some of the more prominent minor constituents were collected in sufficient quantity to facilitate spectral analysis and consequent structure assignment. In some instances, the major component was collected and converted directly to the corresponding ester by trapping in a pyridine solution of *p*-nitrobenzoylchloride.

Using the general procedure indicated, 3,4,5-trimethylisoxazole gave as the major product 2,3-dimethyl-3-β-hydroxyethylaziridine (**3**). Two minor products were identified by spectroscopic means as 2,3-dimethyl-3-ethylaziridine (**4**) and 4-amino-3-methyl-2-pentanol (**5**). Similarly, 3,5-dimethylisoxazole (**2**) was converted to 2-methyl-3-β-hydroxyethylaziridine (**6**). Two minor products were identified as 2-methyl-3-ethylaziridine (**7**) and 4-amino-2-pentanol (**8**). It has been reported that 3,4-diphenylisoxazole will not undergo LAH reduction (1). This apparent difference in reactivity is probably due to inductive effects of the differing ring substituents.

The stereochemistry of the products resulting from the LAH reduction of the isoxazoles was deduced from a comparison of our n.m.r. data with those of Kotera *et al.* (1) and a consideration of the likely mechanisms involved. In the case of hydroxyaziridine formation, hydride attack apparently occurs at C_5 followed by $C_4 \rightarrow N$ cyclization and N–O bond fission. The

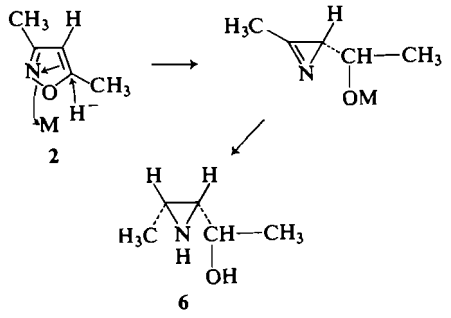
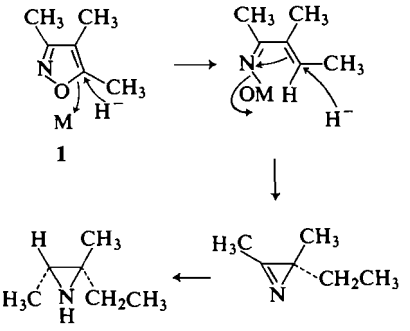


SCHEME 1



SCHEME 2

intermediate hydroxyazirine is then reduced by hydride attack on the least hindered side to the corresponding hydroxyaziridine (Scheme 1). The formation of the norhydroxyaziridine may be visualized to proceed by hydride attack at C_5 followed by C_5—O bond fission. Hydride attack at C_5 of the noncyclic oximino intermediate followed by $C_4 \rightarrow N$ cyclization and N—O bond fission would again generate the intermediate azirine. Preferential hydride attack would be expected on the less hindered side of the intermediate azirine although in this case, selectivity should be somewhat reduced (Scheme 2).

Experimental

Melting points were determined on a Fisher-Johns apparatus and are uncorrected. The n.m.r. spectra were obtained on a Varian A56-60 instrument with tetramethylsilane as internal standard (chemical shifts expressed on the δ scale and J values in Hz). Peak multiplicity is indicated as s, singlet; d, doublet; t, triplet; q, quartet; and m, multiplet. Infrared spectra were obtained using a Perkin-Elmer 427 and Beckman IR-12 grating instruments. Mass spectra were obtained from a Perkin-Elmer-Hitachi double focusing RMU-D6 instrument (electron ionization voltage 75 eV).

LAH Reduction Products of 2,3,5-Trimethylisoxazole (1). General Procedure

To a solution (200 ml) of lithium aluminum hydride (20 g) in THF was slowly added with stirring a solution (50 ml) of the isoxazole (5 g) in THF. The mixture, which became hot during addition of the solution of isoxazole, was cooled (ice water) for 1 h followed by refluxing for 40 h. Excess LAH was decomposed by addition of sodium sulfate and ethyl acetate. After filtration, solvent was removed by column distillation and the residual liquid distilled under reduced pressure yielding a pale yellow oil (2–3 g). The product was examined by vapor phase chromatography using two different columns: (*a*) A1 column, 1/4 in. × 5 ft, 15% SE550 on HMDS-Chromosorb W, He carrier gas, inlet and detector (t.c.) temperature 135 °C. column temperature programmed from 50 to 140 °C at 10 °C/min; (*b*) A1 column 1/4 in. × 5 ft, 20% Versamid on HMDS-Chromosorb W, otherwise conditions as in *a*. The latter column was utilized in preparative separation of components for spectral analysis. Analysis of the LAH reduction products from 3,4,5-trimethylisoxazole (**1**) on column *a* indicated six components, one of major (50%) proportion. Analysis on column *b* showed 11 components with retention indices (R_I, THF as reference) of 1.76 (2.1%); 2.50, 2.63 (4.4%); 3.03 (0.6%); 3.33, 3.50 (5.8%); 4.20 (7.7%, starting compound); 5.00 (14.5%, aziridine); 5.18 (5.8%); 5.83 (48.2%, hydroxyaziridine); and 6.36 (3.5%, amino alcohol). Repeated injection and collection of components gave sufficient quantities for characterization of four components (R_I 5.00, 4.20, 5.83, and 6.36).

2,3-Dimethyl-3-β-hydroxyethylaziridine (3) (R_I, 5.83)

The spectral data (i.r., n.m.r., m.s.) were consistent with the proposed structure; i.r. ν_{max} (liquid film), 3260–3300 (broad OH and NH), 1460, 1290, 1085, 1030, 970, 940, 890, and 840 cm^{-1}; n.m.r., C_2-*H*, 1.98, q, J = 5.5 (1H); C_2-C*H*$_3$, 1.05, d, J = 5.5 (3H); C_3-C*H*$_3$, 1.1, s (3H); C_4-*H*, 3.49, q, J = 7.2 (1H); C_5-*H*$_3$, 1.18, d, J = 7.2 (3H); N*H*–O*H*, broad region at 3.49 (2H), D_2O exchangeable; mass spectrum M^+ 115; $C_6H_{13}ON$ requires 115.

Anal. Calcd. for $C_6H_{13}ON$: C, 62.61; H, 11.30; N, 12.17. Found: C, 62.82; H, 11.25; N, 11.95.

N,O-Di-p-nitrobenzoyl-2,3-dimethyl-3-β-hydroxyethylaziridine (3a)

The v.p.c. effluent, R_I 5.83, was directly passed through a solution of *p*-nitrobenzoyl chloride in pyridine. The mixture was poured into a saturated aqueous solution of $NaHCO_3$ and the precipitated ester recrystallized from ethyl acetate, m.p. 163–165 °C. Infrared spectrum showed absence of OH and NH; n.m.r., OH and NH region absent, low-field aromatic protons, 7.6–7.7 (8H), except for slight shifts, spectrum otherwise similar to that of the parent compound; mass spectrum M^+ = 413; $C_{20}H_{19}O_7N_3$ requires 413.

Anal. Calcd. for $C_{20}H_{19}O_7N_3$: C, 58.11; H, 4.60; N, 10.17. Found: C, 58.06; H, 4.67; N, 10.05.

2,3-Dimethyl-3-ethylaziridine (4) (R_I 5.00)

The spectral characteristics were consistent with the proposed structure; i.r., ν_{max} (liquid film), 3260 cm^{-1} (relatively sharp NH), similar in other respects to the

For personal use only.

spectrum of the hydroxy analog (**3**); n.m.r., C_2-*H*, 1.95, q, J = 5.5 (1H); C_2-CH_3, 0.95, d, J = 5.5 (3H); C_3-CH_3, 1.05, s (3H); C_4-H_2, 2.05, J = 7.1 (2H); C_5-H_3, 0.98, t, J = 7.1 (3H); mass spectrum M^+ = 99; $C_6H_{13}N$ requires 99.

Anal. Calcd. for $C_6H_{13}N$: C, 72.73; H, 13.13; N, 14.14. Found: C, 72.65; H, 13.19; N, 13.89.

The aziridine (**4**) was converted to the corresponding *N-p*-nitrobenzoyl ester (**4***a*) which after recrystallization (ether) had m.p. 108–110 °C; i.r. spectrum, NH absorption absent; n.m.r., the D_2O exchangeable NH proton absent, low-field aromatic protons, 7.6–7.7 (4H), rest of the spectrum was basically similar to that of the parent compound; mass spectrum M^+ = 248; $C_{13}H_{16}O_3N_2$ requires 248.

Anal. Calcd. for $C_6H_{15}ON$: C, 61.53; H, 12.82, N, 11.96. Found: C, 61.66; H, 12.65; N, 11.80.

LAH Reduction Products of 2,5-Dimethylisoxazole (2)

2-Methyl-3-β-hydroxyethylaziridine (6) (R_I 5.12)

The spectral characteristics were consistent with the proposed structure; i.r., broad band for NH and OH at 3260–3400 cm^{-1}; n.m.r., C_2-*H*, 2.05, m, J = 5.5, 6.5 (1H); C_2-CH_3, 1.02, d, J = 5.5 (3H); C_3-*H*, 1.72, q, (AXY), J = 6.5, 7.8 (1H); C_4-*H*, 3.44, m, J = 7.8, 7.2 (1H); C_5-H_3, 1.15, d, J = 7.2 (3H); D_2O exchangeable N*H* and O*H*, (2H); mass spectrum M^+ = 101; $C_5H_{11}ON$ requires 101.

Anal. Calcd. for $C_5H_{11}ON$: C, 59.40; H, 10.89; N, 13.86. Found: C, 59.22; H, 10.95; N, 13.70.

2-Methyl-3-ethylaziridine (7) (R_I 4.10)

Spectral characteristics were consistent with the proposed structure; i.r. (liquid film, NaCl plate) relatively sharp NH absorption 3280 cm^{-1}; n.m.r., C_2-*H*, 2.05, m, J = 5.5, 6.5 (1H); C_2-CH_3, 0.93, d, J = 5.5 (3H); C_3-*H*, 2.32, q, (AXY), J = 6.5, 7.3 (1H); C_3-ethyl-(CH_2), 2.15, m, J = 7.3, 7.1 (2H); C_3-ethyl-(CH_3), 0.96, t, J = 7.1 (3H); mass spectrum M^+ = 85; $C_5H_{11}N$ requires 85.

Anal. Calcd. for $C_5H_{11}N$: C, 70.58; H, 12.94; N, 16.47. Found: C, 70.72; H, 12.81, N, 16.66.

4-Amino-2-pentanol (8) (R_I 6.28)

The tentative identity of this compound was established from the following spectroscopic characteristics: i.r. broad absorption band 3260–3400 cm^{-1}; n.m.r., overlapping CH_3 doublets, 0.96–1.2 (6H); CH_2, 2.3, m, (2H); C-*H*, broad, overlapping at 3.3 (2H); mass spectrum M^+ = 103; $C_5H_{13}ON$ requires 103.

Photoreaction of Nitroso Compounds in Solution. Part XXXI. Mechanisms of Intramolecular Acid Catalyzed Cleavage Reactions and a Hydride Initiated Rearrangement of *C*-Nitroso Alkanes[1]

K. Somosekharen Pillay, Shi C. Chen, Thomas Mojelsky, and Yuan L. Chow

Department of Chemistry, Simon Fraser University, Burnaby, British Columbia V5A 1S6

Received February 4, 1975

K. Somosekharen Pillay, Shi C. Chen, Thomas Mojelsky, and Yuan L. Chow. Can. J. Chem. **53**, 3014 (1975).

Two novel rearrangements of nitroso alkanes, one intramolecular acid catalyzed cleavage reaction and the other ring enlargement during hydride reduction, are described. Aminium radical initiated addition to norbornene under nitrogen gave *cis-exo-* and *trans*-2-nitroso-3-ammonium norbornanes in a good yield. Whereas the *trans* isomer underwent the usual nitroso group reactions, *i.e.*, tautomerization, dimerization, and HNO addition, the *cis-exo* isomer and its hydroxy analog cleaved extremely readily to give 1,3-bisformylcyclopentane derivatives. The stereoelectronic driving force in this cleavage is interpreted as the intramolecular proton transfer and the electron reorganization via a cyclic transition state. Metal hydride reduction of the *trans* isomer was accompanied by ejection of the neighboring amino group and an expansion of the ring to form an azabicyclic compound. A sequence involving an intramolecular displacement to form aziridine followed by the reductive cleavage is proposed.

K. Somosekharen Pillay, Shi C. Chen, Thomas Mojelsky et Yuan L. Chow. Can. J. Chem. **53**, 3014 (1975).

On décrit deux nouveaux réarrangements des nitroso alkanes: une réaction de coupure intramoléculaire catalysée par les acides et une autre impliquant une expansion de cycle au cours d'une réduction par les hydrures. L'addition au norbornène initiée par le radical amminium, se fait sous atmosphère d'azote et conduit, avec de bons rendements, aux *cis-exo-* et *trans*-nitroso-2 ammonium-3 norbornanes. Alors que le groupe nitroso de l'isomère *trans* réagit normalement, à savoir tautomérisation, dimérisation et addition de HNO, l'isomère *cis-exo* et son analogue hydroxylé se coupent extrêmement facilement pour conduire aux dérivés bisformyl-1,3 cyclopentanes. On suggère que la force stéréoélectronique aidant cette rupture est le transfert intramoléculaire d'un proton et la réorganisation électronique par l'intermédiaire d'un état de transition cyclique. La réduction de l'isomère *trans* par les hydrures complexes est accompagnée par une expulsion du groupe amino voisin et par une expansion de cycle conduisant à un composé azabicyclique. On propose un mécanisme impliquant un déplacement intramoléculaire conduisant à une aziridine qui serait ensuite coupée lors de la réduction.

[Traduit par le journal]

Introduction

Radical additions to norbornene are complicated by nonbonded interaction, steric strain, and torsional effects and their stereochemistry have been the subject of considerable studies (1–4). For relatively larger addends, the radical attack occurs without exception from the less hindered *exo* side (1); however, small addends, such as HBr, involve some initial *endo* attack (5, 6). The direction of the radical combination step (or chain transfer process) is controlled by two factors, namely those of nonbonded interaction from 5- and 6-hydrogens and torsional effects from the bridgehead 4-hydrogen to give 2-*exo*-3-*exo*(*cis-exo*) and 2-*exo*-3-*endo* (*trans*) orientations (1–4). Inspection of the literature shows that the distribution of this stereochemistry varies widely, ranging from a 100% *trans* product on the addition of *p*-tosyl chloride (7) to a 100% *cis-exo* product in the addition of ethyl α-bromoacetate (8). It is noteworthy that the additions of nitrosyl halides (9) and formate (10) to norbornene give the *cis* adducts in good yields and have been suggested to follow a four-centered addition mechanism. The further striking features of these additions are (*i*) that no skeletal rearrangement occurs despite the fact that these addends can undergo ionic reaction (9) and (*ii*) that the *trans* adducts are absent (9, 10). These reports intensified our interest in the stereochemical aspects of the study of nitrosamine

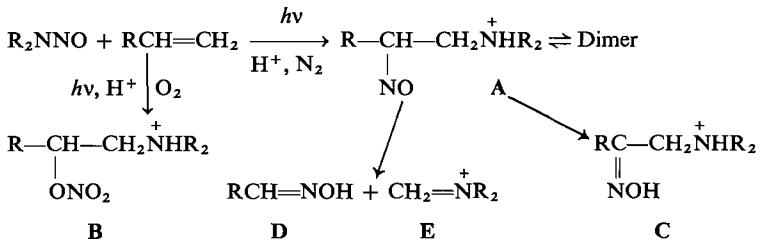

SCHEME 1

addition to norbornene that was then in progress.

Photoaddition of *N*-nitrosopiperidine (NNP) or *N*-nitrosodimethylamine (NND) in an acidic solution to an olefin (for example $RCH{=}CH_2$) gives a 1-nitroso-2-ammonium alkane, **A** (Scheme 1). It has been shown that the primary photoprocess is the dissociation of the nitrosamines to give the aminium and nitric oxide radicals and that the former initiates the addition to the olefin (11). In the presence of oxygen, the photoreaction is not quenched but nitric oxide is efficiently oxidized to the $\cdot NO_3$ radical; this leads to the clean formation of 1-nitrato-2-ammonium alkanes, **B** (12). The *C*-nitroso compound **A** is generally not stable under the experimental conditions and undergoes various competing secondary reactions; the common ones are tautomerization (**A** → **C**) and dimerization (13).

Our initial objective was to determine the stereochemical distribution of the nitrosamine photoaddition to norbornene in order to elucidate the nature of the radical pair generated in nitrosamine photolysis (12) and to compare the results with those obtained in the nitrosyl derivative additions (9, 10). While these aims were only partially fulfilled, we have gained some insight into the relatively obscure chemistry of *C*-nitroso compounds. These investigations also enable us to propose a mechanism for the novel cleavage reaction of 1-nitroso-2-ammonium alkanes (**A** → **D** + **E**).

Results

Photoaddition of NND to norbornene under nitrogen in the presence of hydrochloric acid exhibited the emergence of the u.v. absorption typical of a *C*-nitroso dimer at 290 nm similar to those observed in some previous cases (12–14). The photolysate, after the usual work up, gave an unusually large amount of the neutral fraction. The basic fraction contained the *anti* dimer of *endo*-2-nitroso-*exo*-3-dimethylaminobicyclo[2.2.1]norbornane (**1**) and *syn-exo*-3-dimethylaminobicyclo[2.2.1]norbornanone oxime (**2**) and its *anti* isomer (**3**).

The neutral fraction consisted of at least five compounds as shown by v.p.c. examinations and appeared to change composition on attempted chromatographic separations. With some difficulties as described in the Experimental, the examinations of the i.r. and n.m.r. spectra of semipure fractions obtained from chromatography allowed us to identify the following compounds, 1,3-bisdimethoxymethylcyclopentane (**5**), 1-formyl-3-dimethoxymethylcyclopentane (**6**) and its oxime (**7**), 1,3-bisformylcyclopentane (**8**) and its monooxime (**9**). These compounds[2] were identified by the typical spectral data of the functional groups. An aldoxime group exhibited i.r. peaks at 1630 and 900 ~ 1000 cm^{-1} and a n.m.r. doublet at *ca.* τ 2.5, a formyl group at 2700 and 1715 cm^{-1} and a weakly split doublet at *ca.* τ 0.0, and a dimethyl acetal group 1060 cm^{-1} and a doublet at *ca.* τ 6.0 and a singlet at *ca.* τ 6.5 in the ratio of 1:6. Both **6** and **7** showed a very strong mass peak at 75 corresponding to the $(CH_3O)_2CH^+$ species. All of these semipure fractions or the crude neutral fraction gave good yields of the bis-2,4-DNPH of **8** (15) on treatment with Brady's reagent.

A similar photolysis with three fold excess of NND was carried out until most of NND was consumed. The reaction gave 2-*endo*-(*N*-nitrosohydroxylamino)-3-*exo*-dimethylaminobicyclo-[2.2.1]heptane (**10**, 17%) in addition to oximes **2** and **3** and the 'neutral fraction.' In spite of some

[2]While these cyclopentane derivatives should have the *cis* configuration, acid catalyzed isomerization might have occurred changing the configuration of the isolated products. In some v.p.c. of such fractions, isomeric compounds were detected (see Experimental).

5 $R_1, R_2 = CH(OCH_3)_2$
6 $R_1 = CHO; R_2 = CH(OCH_3)_2$
7 $R_1 = CH(OCH_3)_2; R_2 = CH{=}NOH$
8 $R_1, R_2 = CHO$
9 $R_1 = CHO; R_2 = CH{=}NOH$

searching, the 2-*exo*-isomer corresponding to **10** could not be found in the photolysate.

The structure and stereochemistry of the basic products **2**, **3**, **10** and the dimer of **1** were determined primarily by spectral data particularly by the n.m.r. parameters that were elicited, in some cases, from decoupling experiments at 100 MHz. The common feature for all these compounds was the *exo* configuration of the dimethylamino group at the C-3. The 3-proton, which must have the *endo*-configuration, was shown to couple with the *anti*-7-proton through a W-plan and to have insignificant spin interaction with the 4-proton (16). The *exo* configuration of the 2-proton in **10** and the dimer of **1** was indicated by the coupling constants of $J_{1,2}$ and $J_{2,3}$ of *ca.* 4 Hz.

The *syn* and *anti* isomeric relation of oximes **2** and **3** was indicated by the following: (*i*) the dimer of *C*-nitroso compound **1** was converted quantitatively to **2** and **3** and a small amount of 3-*exo*-dimethylaminobicyclo[2.2.1]heptan-2-one (**11**); (*ii*) ketone **11** was oximated to give **2** and **3** in a ratio of 5:1; (*iii*) either isomeric oxime could be isomerized by a dilute acid to the other isomer; (*iv*) the mass spectra of oximes **2** and **3** were indistinguishable. Comparisons of the proton chemical shifts at the C-1 (τ 7.53 and 7.12) in oximes **2** and **3** and those at the C-3 for the same oximes (τ 6.58 and 6.67) indicated that **2** must have the *syn* and **3** the *anti* configuration because of the inverse chemical shift relation which had ample precedent from our publication (17). Further the chemical shift difference at

For personal use only.

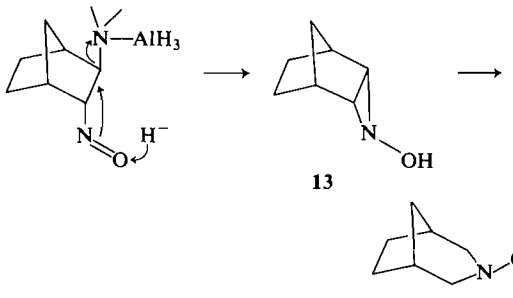
the C-1 (0.41 p.p.m.) of this oxime pair (**2** and **3**) compared favorably with that of the oxime pair derived from norcamphor (0.52 p.p.m.). However, both oximes exhibited a green color on dissolution in cupric sulfate solution; this was the only case so far in which the cupric ion test failed to distinguish the *syn* and *anti* oximes (17).

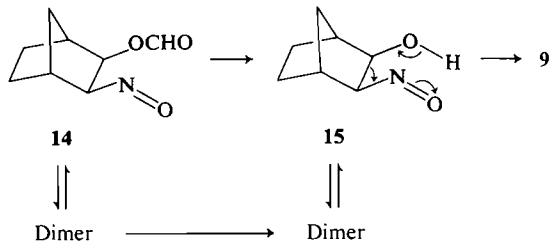
A crude hydrochloride salt of the dimer of **1** was readily precipitated on evaporation of a photolysate. The free base of the dimer liberated from this salt fraction was virtually pure and exhibited a clean n.m.r. spectrum. This implied that the crude product contained the single dimer, namely that of **1**, out of three possible diastereoisomeric dimers that could be generated from the adducts. The unique stereochemical purity of the 2-*endo*-3-*exo*- configuration was also observed in **10**. It was noteworthy that hydroxylamine **10** exhibited the 3-proton at the unusually low τ value of 6.00 for a proton geminal to an amine. This suggested that **10** might be a zwitterion in which the amine group was protonated by the weakly acidic *N*-nitroso-hydroxylamine group. The high solubility of **10** in water is suggested by the difficulty of its recovery from aqueous mother liquors.

The dimer of **1** possessed the expected i.r. absorption at 1210 cm^{-1} and the u.v. band at 295 nm. Whereas catalytic hydrogenation of the dimer in the presence of PtO_2 was unsuccessful, LAH reduction in ether gave a complex mixture



from which a small amount of *N*-hydroxy-3-azabicyclo[3.2.1]octane (**12**) was obtained. However, when a THF solution of the dimer was added to an ether solution of LAH, hydroxylamine **12** was obtained as the major product. The n.m.r. spectrum exhibited the signals at τ 6.82, 7.45, and 7.75 in 1:1:1 ratio. The lowest field signal was assigned to the equatorial protons at C-2 and C-4 which were coupled geminally to the axial protons (J = 10 Hz) and vicinally to the bridgehead proton (C-1 and C-5, τ 7.75). The doublet (J = 10 Hz) of the axial protons at τ 7.45 was only slightly coupled to the C-1 and C-4 bridgehead protons.

In the next phase of the study, the *anti* dimer of 2-*exo*-nitroso-3-*exo*-formyloxybicyclo[2.2.1]-heptane (**14**) was synthesized by addition of nitrosylformate to norbornene (10) and was purified by recrystallization without decomposition. Treatment of the dimer in 0.02% KOH solution at room temperature gave a mixture which showed the presence of aldehyde and aldoxime groups as judged by its n.m.r. and i.r. spectra. This mixture gave an essentially quantitative yield of bis-2,4-DNPH of **8** on treatment with Brady's reagent (15). In addition, the formate group of the dimer of **14** was hydrolyzed with a HCN—CN^- solution in methanol to give the sparingly soluble *anti* dimer of 2-*exo*-nitroso-3-*exo*-hydroxybicyclo[2.2.1]heptane (**15**). Prolonged heating of the dimer of **15**



in methanol slowly gave an oily mixture of **8** and **9**. However, the dimer dissolved in trifluoroacetic acid from which the bis-2,4-DNPH of **8** was obtained quantitatively on addition of the hydrazine. The results demonstrated that, whatever the conditions were, the formation of hydroxy nitroso compound **15** was immediately followed by an extremely facile cleavage pathway to give **9**.

Discussion

That *trans* addition has occurred in the photoaddition is proven by isolation of the dimer of **1** and *N*-nitrosohydroxylamine **10**, both of which have the 2-*endo*-3-*exo*-configuration. The latter compound is stable and derived from the addition of HNO generated *in situ* to **1** (13). Under the photolysis conditions, **1** tautomerizes concurrently to oximes **2** and **3** as demonstrated. From the reported patterns of radical additions to norbornene (1–4), it should be expected that

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

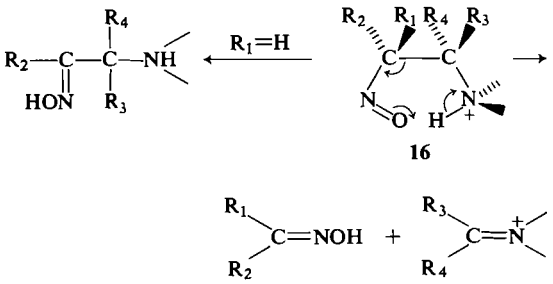
not only *trans* **1** but *cis-exo*-**4** also can be formed though *a priori* the ratio is unknown. Significantly, the dimer and the *N*-nitrosohydroxylamine derived from *cis-exo* isomer **4** are not isolated indicating **4** may react very efficiently by other pathways. The observations that the yields of the 'basic fraction' are always low and that **1** exclusively tautomerizes to *syn* and *anti* oximes **2** and **3** strongly suggest that the neutral products **5**–**9** are derived from the second photoadducts, *cis-exo* isomer **4**. Precedents for such a cleavage reaction in acyclic 1-nitroso-2-ammonium alkanes have been reported (18, 19) and they have been assumed to occur by the intramolecular proton transfer and electron shifts as indicated in **4** (18). In the present case it is unusual that the cleavage reaction appears to occur exclusively over the tautomerization and dimerization pathways.

While it is desirable to prove that *cis*-*C*-nitroso compound **4** exclusively undergoes the cleavage reaction, the dimer of **4** is not available. Hydroxy nitroso compound **15** is an ideal model compound since it can be obtained from its stable *anti* dimer which is prepared from the hydrolysis of the dimer of formate **14**. The extreme facility of **15** to cleave cleanly to **9** is in sharp contrast to the stability of its dimer and formate **14** and to the exclusive tautomerization of **1**. Undoubtedly it is the ready proton transfer from the hydroxyl group to the nitroso group in the *cis-exo* configuration (see **15**) that makes the remarkable cleavage pathway possible. The propensity to undergo this pathway is also shown by the absence of competing tautomerization under neutral, acidic, or basic conditions.

Judging from the extent of dissociation, a protonated amino group is expected to donate a proton more readily than a hydroxyl group. Extension of the above argument leads us to conclude that the *cis*-*C*-nitroso compound **4** has been formed during photoaddition and undergoes the cleavage reaction so rapidly that neither the dimer nor the *N*-nitrosohydroxylamine corresponding to **10** can be isolated. Although there is no direct proof that **4** does not tautomerize to give oximes **2** and **3**, it can be safely assumed to be so in view of its facile cleavage reaction.

This cleavage reaction is a new type broadly classified as 'heterolytic fragmentation' (20). Generally, stereochemical requirements are critical for this type of reaction. The evidence presented above indicates that in this cleavage reaction a *cis*-coplanar configuration of the functional group, such as in **4** and **15**, is a precondition which allows the intramolecular proton transfer to occur through a cyclic transition state though the process may not necessarily be a concerted one as represented in **16**. The *trans* orientation, as in **1**, and in *trans*-2-dimethylamino-1-nitrosocyclohexane (12), does not meet the stereochemical requirements and fails to undergo the cleavage reaction but preferentially tautomerizes to give the corresponding oximes.

After the first suggestion of the cyclic cleavage mechanism had been made, Pritzkow and Thieme (19) stated that such a mechanism was not necessarily operating on the basis of an undocumented acidity effect on the cleavage of three acyclic 2-piperidinonitrosoalkanes. For the flexible acyclic nitrosoalkanes, a *cis*-coplanar orientation of the functional groups results in an eclipsing conformation of the substituents R^1, R^2, R^3, R^4, and the *N*-alkyl groups as shown in **16**. The cleavage of such compounds is expected to require an additional activation energy to overcome the steric requirements. This explains why cleavage of acyclic 1-ammonium-2-nitrosoalkanes scarcely competes successfully with tautomerization as observed previously (12, 18). The amino groups in these compounds ($pK_a \cong 10$) are completely protonated under the



16

conditions of Pritzkow's experiments as well as our photoaddition. An increased acidity may strengthen the polarity of the solvent and increase solvation of the functional groups; this may conceivably reduce the rate of the cleavage pathway by disfavoring the required conformation. However such effects are expected to be small.

The ring enlargement observed in the LAH reduction of the dimer of **1** is a new rearrangement involving a nitroso group. It is assumed that aziridine derivative **13** serves as a probable intermediate as such derivatives are known in LAH reduction of nitroso and nitro compounds

For personal use only.

(21) and oximes (22). While it is uncertain whether the dimer or monomer is involved in the reduction, it is likely that the *trans* configuration in **1** facilitates the displacement of the coordinated amino group.

Experimental

General

Microanalyses were performed by Dr. A. Bernhardt, Engelskirschen, West Germany, and Mr. M. K. Yang, Department of Biological Science, Simon Fraser University. The n.m.r. spectra were taken with a Varian A56/60 spectrometer using TMS as the internal standard in $CDCl_3$ solution or the solvent specified. The n.m.r. data are expressed in τ values and coupling patterns (s = singlet, d = doublet, t = triplet, m = multiplet, b = broad), coupling constants and the protons are given in the brackets. Unless specified, the i.r. spectra were measured in a Perkin-Elmer Model 457 in Nujol mulls or liquid film, the u.v. spectra with an Unicam SP-800 spectrophotometer, and the mass spectra with a Hitachi RMU-6E at 80 eV using a heated inlet. The melting points were determined in a Fischer-Johns hot stage and are uncorrected. Nitrosamines (Eastman Kodak Co.) and norbornene (Aldrich Chemical Co.) were redistilled and stored in a refrigerator.

Addition of NND to Norbornene

A solution of norbornene (7.2 g, 76 mmol), NND (5.2 g, 70 mmol), and concentrated hydrochloric acid (6 ml, 72 mmol) in methanol (120 ml) was externally cooled with an acetone–CO_2 bath and was irradiated with a 450-W Hanovia u.v. lamp for 1 h. The photolysate was evaporated (*ca.* 40 ml) and cooled to give the dimeric hydrochloride of *endo*-2-nitroso-*exo*-3-dimethylaminonorbornane dimer (**1**) (1.2 g, 8.2%) as crystals: m.p. 122–123 °C (dec.); i.r. 2650, 1425, 1310, 1230, and 1175 cm^{-1}; n.m.r. (D_2O) τ 4.50 (t, J = 4 Hz, 1H), 6.00 (m, 1H), and 7.60 (s, 6H). Attempts to recrystallize this compound resulted in decomposition. Upon treatment with saturated $NaHCO_3$ solution, the hydrochloride gave the free basic dimer of **1** which was recrystallized at room temperature by dissolving the crystals in one portion of CH_2Cl_2 and subsequently pouring in five portions of ether. Repetition of the recrystallization afforded fine needles: m.p. 112–113 °C; i.r. 2765, 1470, 1300, 1270, 1210, and 1150 cm^{-1}; n.m.r., τ 4.90 (t, J = 4 Hz, H_2), 7.10 (dd, J = 4 and 1 Hz, H_3), 7.15 (m, H_1), 7.55 (d, J = 4 Hz, H_4), 8.15 (d, J = 10.5 Hz, H_{7s}), 8.74 (md, J = 10.5 Hz, H_{7a}), 7.85 (s, 6H); *m/e* (%) 168(15), 151(18), 96(50), 84(100); u.v. (MeOH) 295 nm (ε 9 × 10^3).

Anal. Calcd. for $C_{18}H_{32}N_4O_2$: C, 64.25; H, 9.59; N, 16.65. Found: C, 64.47; H, 9.65; N, 16.83.

After removal of the hydrochloride of the dimer the filtrates were worked-up in the usual manner (18) to give a neutral fraction and a basic fraction.

The 'neutral' ether extract gave a clear liquid (3.9 g), which was a mixture containing more than five compounds as indicated by t.l.c. This mixture was roughly separated into two fractions by passing through a neutral alumina column (120 g). The first fraction eluted with 50% CH_2Cl_2 in benzene (500 ml) gave a colorless liquid (*ca.* 600 mg), which showed a single spot on silicic acid t.l.c. However, it exhibited two major peaks of ratio *ca.* 1:6 in v.p.c. This mixture contained exclusively 1,3-bis-dimethoxymethylcyclopentane (**5**) as indicated by the n.m.r. signals at τ 6.12 (d, J = 7 Hz, 2H), 6.87 (s, 12H), and 7.90–9.10 (m, 8H) and i.r. absorptions at 2940, 2830, 1450, 1060, and 930 cm^{-1}. This substance was hydrolyzed in 0.5 *N* methanolic hydrochloric acid solution (5 ml) at room temperature overnight. The resultant solution was diluted with water (5 ml) and extracted with ether. The ether was dried ($MgSO_4$) and evaporated to give a colorless liquid (280 mg), which was identified as 1,3-bisformylcyclopentane (**8**): i.r. 2708, 1720, 1105, and 1060 cm^{-1}; n.m.r. 0.44 (d, J = 2 Hz, 2H), 7.17 (t, unresolved, 2H), 7.70–9.20 (m, 6H); *m/e* (%) 126(8), 124(8), 98(30), 68(40), and 58(100). The 2,4-DNPH derivative was recrystallized from tetrahydrofuran–ethanol, m.p. 224–225 °C (dec.) (lit. (15) m.p. 225–226 °C). The second fraction (*ca.* 1.5 g) was rechromatographed on silicic acid repeatedly furnishing three pure compounds in small amounts. The least polar compound was found to be 1-formyl-3-dimethoxymethylcyclopentane (**6**): i.r. 2710, 1720, 1450, 1060 cm^{-1}; n.m.r. τ 0.1 (d, J = 2 Hz, 1H), 5.72 (d, J = 7 Hz, 1H), 6.55 (s, 6H); *m/e* (%) 172(7), 140(10), and 75(100). The more polar compound was identified as 1-formyl-3-dimethoxymethylcyclopentane oxime (**7**): i.r. 3350, 1640, 1050, and 930 cm^{-1}; n.m.r. τ 2.36 (d, J = 7 Hz, 1H), 5.67 (d, J = 7 Hz, 1H), 6.54 (s, 6H); *m/e* (%) 187(2), 141(6), 81(26), and 75(100).

Anal. Calcd. for $C_9H_{17}NO_3$: C, 57.73; H, 9.15; N, 7.48. Found: C, 57.59; H, 8.95; N, not analyzed.

The most polar eluate was found to be impure 1,3-diformylcyclopentane monoxime (**9**): i.r. 2700, 1715, 1630, and 950 cm^{-1}; n.m.r. τ 0.36 (s, 1H, D_2O exchangeable), 2.68 (d, J = 7 Hz, 1H), 5.85 (d, J = 7 Hz, 1H); *m/e* (%) 141.

The basic extract (2.1 g) was dissolved in ether and chromatographed on a basic alumina column (59 g). The first fraction eluted with ether (100 ml) gave a mixture (300 mg) which contained *ca.* 70% of the dimer of **1** and 30% of the decomposition products as indicated by n.m.r. and t.l.c. Subsequent eluates from ether and CH_2Cl_2 were mixtures, which were combined (1.4 g) and further purified by chromatography on a silicic acid column (70 g). Elution with 2% methanol in CH_2Cl_2 (699 ml) gave *anti-exo*-3-dimethylamino-2-norbornanone oxime (**3**) (250 mg, 2%). Sublimation afforded an analytically pure sample: m.p. 72–73 °C; i.r. 1665, 950, 935, and 855 cm^{-1}; n.m.r. τ 0.8 (s, OH), 6.67 (d, J = 2 Hz, H_3), 7.1 (m, H_1), 7.36 (m, H_4), and 7.57 (s, 6H); *m/e* (%) 168(4), 151(100), 123(8), 95(12), and 82(16).

Anal. Calcd. for $C_9H_{16}N_2O$: C, 64.24; H, 9.55; N, 16.65. Found: C, 64.13; H, 9.40; N, 16.54.

Further elution with 1% methanol in CH_2Cl_2 (100 ml) gave *syn-exo*-3-dimethylamino-2-norbornanone oxime (**2**) (1.1 g, 9%): n.m.r. τ 6.58 (bs, H_3), 7.48 (d, J = 1 Hz, H_4), 7.53 (d, J = 2 Hz, H_1), 8.05 (md, J = 10.5 Hz, H_{7s}), 8.71 (md, J = 10.5 Hz, H_{7a}), 7.7 (S, 6H); m.p. 142–143 °C; i.r. 1660, 1003, 964, 950, and 936 cm^{-1}; *m/e* (%) 168(4), 151(100), 123(8), 95(12), and 82(16).

Anal. Calcd. for $C_9H_{16}N_2O$: C, 64.24; H, 9.55; N, 16.65. Found: C, 64.47; H, 9.67; N, 16.70.

A solution of an excess of NND (3.71 g, 50 mmol) and norbornene (1.89 g, 20 mmol) in methanolic hydrochloric acid (0.43 *N*, 135 ml, 58 mmol) was irradiated using a 200-W Hanovia lamp with a uranium glass filter. The

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

photocell was cooled externally in an acetone–CO_2 bath. The u.v. absorption at 295 nm increased to a maximum at 3 h irradiation, and then slowly decreased. At 11 h, the 295 nm absorption still persisted. Therefore, an additional portion of the nitrosamine (742 mg, 10 mmol) and enough acid was added and the acetone–CO_2 bath replaced by an ice bath. The absorption at 295 nm disappeared after further irradiation for 8 h without the filter. The photolysate was made strongly basic ($pH \sim 10$) and extracted with CH_2Cl_2 (30 ml × 3) to give a viscous liquid, which contained mostly oximes **2** and **3** as indicated by t.l.c. and n.m.r. analysis. The aqueous solution was neutralized with 4 *N* hydrochloric acid and stirred overnight. The solution was readjusted to pH 7 next day and treated with charcoal, filtered, and the filtrate extracted with CH_2Cl_2 (40 ml × 3). The extract was worked-up in the usual manner to afford a brownish viscous liquid, which on standing overnight partially crystallized to give *endo*-2-*N*-nitrosohydroxylamino-*exo*-3-dimethylaminonorbornane (**10**) (483 mg, 16.6%). Sublimation gave a white solid which recrystallized from isopropanol to furnish an analytical sample: m.p. 212–213 °C (dec.); i.r. 3400, 1500, 1320, and 930 cm^{-1}; *m/e* (%) 182, 169(72), 151(7), 84(100), and 58(20); n.m.r. (D_2O) τ 5.45 (dd, J = 4 and 4.5 Hz, H_2), 6.00 (dd, J = 4.5 and 1.5 Hz, H_3), 7.10 (m, H_1), 7.24 (m, H_4), 7.15 (s, 6H).

Anal. Calcd. for $C_9H_{17}N_3O_2$: C, 54.25; H, 8.60; N, 21.09. Found: C, 54.13; H, 8.72; N, 20.90.

Acid Treatment of the Dimer of 1

A 2 *N* HCl solution (20 ml) of the dimer (780 mg, 2.3 mmol) in an Erlenmeyer flask was stirred at room temperature for 60 h. The resultant solution was extracted with ether (30 ml × 3). Nothing was obtained in the ether extract. The aqueous layer was then made basic with saturated Na_2CO_3 solution to give a crystalline precipitate, which was filtered and shown to be recovered dimer (70 mg, 9%). The aqueous filtrate was extracted with CH_2Cl_2 (30 ml × 3) to give a viscous substance (595 mg) which partially crystallized on standing overnight. The t.l.c. of this substance showed three spots, of which two in the lower R_f region corresponded to oximes **2** and **3**. This mixture was chromatographed on a silicic acid column (37 g). The first fraction eluted with $CHCl_3$ (500 ml) was shown to be *exo*-3-dimethylamino-2-norbornanone (290 mg, 45%) (**11**): i.r. 2815, 2770, 1742, and 1045 cm^{-1}; n.m.r. τ 7.25 (m, 2H), 7.55 (s, 6H), 7.80 (m, 2H). The 2,4-DNPH derivative was recrystallized from ethanol: m.p. 240 °C (dec.); *m/e* (%) 333(17), 316(9), 290(5), 151(100). The second fraction eluted with 5% methanol in $CHCl_3$ (550 ml) afforded the oxime **3** (90 mg, 13%). Subsequent elution with 10% methanol in $CHCl_3$ (600 ml) gave the isomeric oxime **2** (140 mg, 20%).

Oximation of Ketone 11

Ketone **11** (114 mg, 0.75 mmol) and a large excess of hydroxylamine hydrochloride (400 mg, 57.5 mmol) in ethanol (5 ml) and 2 *N* NaOH solution (10 ml) was refluxed for 4 h. The resultant solution was concentrated *in vacuo* to remove ethanol and made basic with Na_2CO_3 solution to give a crystalline precipitate. The crystals were removed by filtration to give the oxime **2** (70 mg). The filtrate was extracted and worked-up to give a solid (41 mg), which exhibited two spots of approximately the same size on a t.l.c. plate, corresponding to isomeric oximes **2** and **3**.

Isomerization of Oxime 2

A solution of **2** in 2 *N* HCl solution (5 ml) was stirred at room temperature for 10 h. A drop of the solution was pipetted out and made basic, spotted on a silica gel t.l.c. plate, and eluted with 10% methanol in $CHCl_3$. In addition to a large spot of starting material, two spots corresponding to **11** and **3** appeared in higher R_f regions. After stirring for 45 h, the acidic solution was worked-up to recover a liquid (41 mg). Thin-layer chromatographic analysis indicated that the mixture contained **2**, **3**, and **11** in much the same ratio as that from the hydrolysis of the dimer.

Isomerization of 3

In a procedure similar to that described above, oxime **3** (21 mg) was treated with 2 *N* hydrochloric acid (0.5 ml) and stirred at room temperature. Thin-layer chromatographic analysis was carried out at 7 h intervals. Estimation of the composition of the products was made by comparison of t.l.c. spot areas with those from the mixtures obtained from the acid hydrolysis of dimer. Within 7 h, nearly equal amounts of **2** and **3** were obtained and after 14 h the spot corresponding to **11** appeared and grew bigger as the reaction proceeded.

LAH Reduction of the Dimer of 1

A solution of the dimer (300 mg) in THF (20 ml) was added to a LAH (170 mg) suspension in boiling ether (20 ml) and the mixture was refluxed for 2 h. The mixture was decomposed with water (0.6 ml) and the precipitate was washed with ether. The combined organic layer was worked-up in the usual manner to give a liquid (258 mg) which was chromatographed on silicic acid. The oil recovered from 1% MeOH in CH_2Cl_2 eluent was sublimed at 60 °C to give hydroxylamine **12** (41 mg): m.p. 86–87 °C; i.r. 3180, 1450, 1212, 1205, and 877 cm^{-1}; n.m.r. τ 2.40 (OH), 6.82 (dd, J = 10 and 4 Hz, 2H), 7.45 (d, J = 10 Hz, 2H), and 7.75 (m, 2H); *m/e* (%) 127(4), 110(14), 81(15), 79(14), 67(29), 60(71), 44(74), and 41(100).

Preparation and Decomposition of the Dimer of 14

The *anti* dimer of nitroso formate **14** was prepared by the known method (10). The crude product was recrystallized from ethyl acetate to afford white crystals of the dimer: m.p. 161–162 °C; i.r. 1725, 1385, 1240, and 1165 cm^{-1}; n.m.r. τ 4.71 (md, J = 7 and 1 Hz, H_2), 5.18 (md, J = 7 and 0.5 Hz, H_3), 7.14 (m, H_1), 7.59 (m, H_4), 7.95 (md, J = 11 Hz, H_{7a}). Decoupling at 100 MHz showed that the 2- and 3-protons formed a AB quartet each of which was further coupled to the *anti*-7-proton slightly. Further, these two protons were not coupled with the bridgehead protons at τ 7.14 and 7.59.

A suspension of the dimer of **14** (400 mg) was stirred in methanol (100 ml) containing potassium hydroxide (0.05 g) overnight. The homogeneous reaction mixture was diluted with water and extracted with CH_2Cl_2 to afford a crude oil (308 mg); n.m.r. τ 0.5, 2.5 and 3.0; i.r. 3300, 1725, 1630, 780, 760, and 700 cm^{-1}. The bis-2,4-DNPH of 1,3-diformylcyclopentane **8** (340 mg) was prepared from the oil (150 mg) and was recrystallized from an ethyl acetate – ethanol mixture, m.p. 226–228 °C.

Mild Hydrolysis of the Dimer of 14

The dimer (200 mg) was stirred in a solution consisting of concentrated hydrochloric acid (0.19 ml), potassium cyanide (230 mg), and methanol for 18 h. The precipi-

tate (70 mg) was filtered and was recrystallized from ethyl acetate to give the *anti* dimer of **15**; m.p. 170–171 °C; i.r. 3390, 1235, 1085, 875, and 795 cm^{-1}; *m/e*(%) 282 (M^+), 264(1), 142(41), 124(14), 111(32), 93(55), 72(73), 67(100). The methanol solution was evaporated and was worked-up in the usual manner to afford an oil which gave the 2,4-DNPH of **8** on treatment with Brady's reagent.

The dimer of **15** (30 mg) dissolved in trifluoroacetic acid (1 ml) exhibited an n.m.r. spectrum very similar to that of **8** and **9** in the same solvent. This solution was stirred into an ethanol solution of 2,4-dinitrophenylhydrazine to give a yellow precipitate of the 2,4-DNPH of **8** (115 mg).

The dimer of **15** (70 mg) was refluxed in ethanol. The solid gradually dissolved. At the end of 24 h, the remaining solid (22 mg) was filtered and the ethanol solution was treated with Brady's reagent to afford the *bis*-2,4-DNPH of **8** (220 mg).

Photoreaction of Nitroso Compounds in Solution. Part XXXII. Synthesis and Reaction of 2-Nitrato-3-Aminonorbornanes[1]

K. Somosekharen Pillay, Kaoru Hanaya,[2] and Yuan L. Chow
Department of Chemistry, Simon Fraser University, Burnaby, British Columbia V5A 1S6

Received February 4, 1975

K. Somosekharen Pillay, Kaoru Hanaya, and Yuan L. Chow. Can. J. Chem. **53**, 3022 (1975).

Oxidative photoaddition of nitrosamines to norbornene gave both *cis-exo-* and *trans*-2-nitrato-3-aminonorbornanes that were stable in their protonated form under photolysis conditions. The free bases underwent a novel cleavage reaction assisted by the lone pair of the amino group to give 1,3-bis(formyl)cyclopentane. In addition these nitrates also underwent solvolysis to give *cis-exo*-2-hydroxy-3-aminonorbornane. The mechanisms of these basic decompositions are discussed.

K. Somosekharen Pillay, Kaoru Hanaya et Yuan L. Chow. Can. J. Chem. **53**, 3022 (1975).

La photoaddition oxydative des nitrosamines au norbornène conduit aux *cis-exo-* et *trans*-nitrato-2 amino-3 norbornanes; dans les conditions de la photolyse, ces deux isomères sont stables sous leur forme protonée. Les bases libres subissent une nouvelle réaction de fission aidée par le doublet libre du groupe amino et fournissent le bis(formyl)1,3 cyclopentane. De plus ces nitrates subissent une solvolyse pour conduire aux *cis-exo*-hydroxy-2 amino-3 norbornane. On discute des mécanismes de ces décompositions en milieu basique.

Previously we discovered that oxygen does not quench nitrosamine photoaddition to cyclohexene but instead diverts the reaction cleanly to form 1-nitrato-2-aminoalkanes (3). It is suggested that oxygen intercepts photolytically generated nitric oxide to form a nitrogen trioxide radical which is scavenged by a *C*-radical intermediate. This remarkably efficient process, which is termed an oxidative photoaddition, is by far the mildest and simplest method of synthesizing nitrate esters and has been investigated in our laboratory. While such addition to simple olefins generally proceeds readily to give the expected amino nitrates which can be reduced by LAH to amino alcohols, the addition to norbornene gives amino nitrates that exhibit an interesting new cleavage reaction. This novel cleavage pathway and an application of the oxidative photoaddition are described in this paper.

Results

Photolysis of a methanolic solution of NND, norbornene, and hydrochloric acid under oxygen exhibited clean zero-order decreases of the nitrosamine n–π^* band at 335 nm in contrast to the emergence of the 290 nm band due to the *anti* dimer of *C*-nitroso alkanes in the non-oxidative photoaddition (3). The colorless photolysate, however, turned to a dark brown solution rapidly on addition of base and gave a complex mixture with the usual work up.

In the initial phase of the experiments, it was hoped to isolate stable salts of the photoadduct by running the photoaddition of NNP to norbornene under oxygen in the presence of perchloric acid. This oxidative photoaddition gave a mixture of the perchlorate (19%) of *exo*-2-nitrato-*exo*-3-piperidinobicyclo[2.2.1]heptane (**2**) and *endo*-2-nitrato-*exo*-3-piperidinobicyclo[2.2.1]heptane (**1**) in a 1:1 ratio. Attempts to recrystallize this mixture resulted in darkening of the solutions. Basification of the above photolysate at 0 °C followed by a quick extraction and work up gave a crude mixture showing strong i.r. absorption at 1620, 1275, and 865 cm^{-1} for a nitrate and 1720 cm^{-1} for an aldehyde group. Immediate reduction with LAH gave a complex mixture of products from which a small amount of 3-*exo*-piperidino-*endo*-bicyclo[2.2.1]heptan-2-ol (**7**, $R_2 = -(CH_2)_5-$) was isolated as the hydrochloride salt. To avoid the decomposition

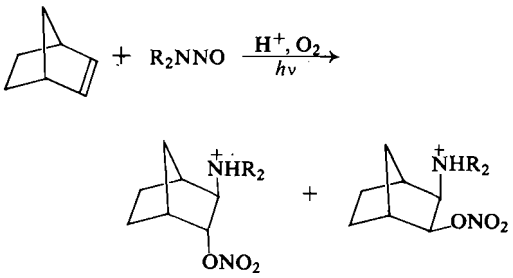
on basification, hydrogenation of the acidic photolysate in the presence of various catalysts was examined but failed to give clean reduction. For the convenience of n.m.r. analysis the major work was carried out using NND as the addend.



$R_2 = -(CH_2)_5-$ **1** **2**

$R = CH_3$ **3** **4**

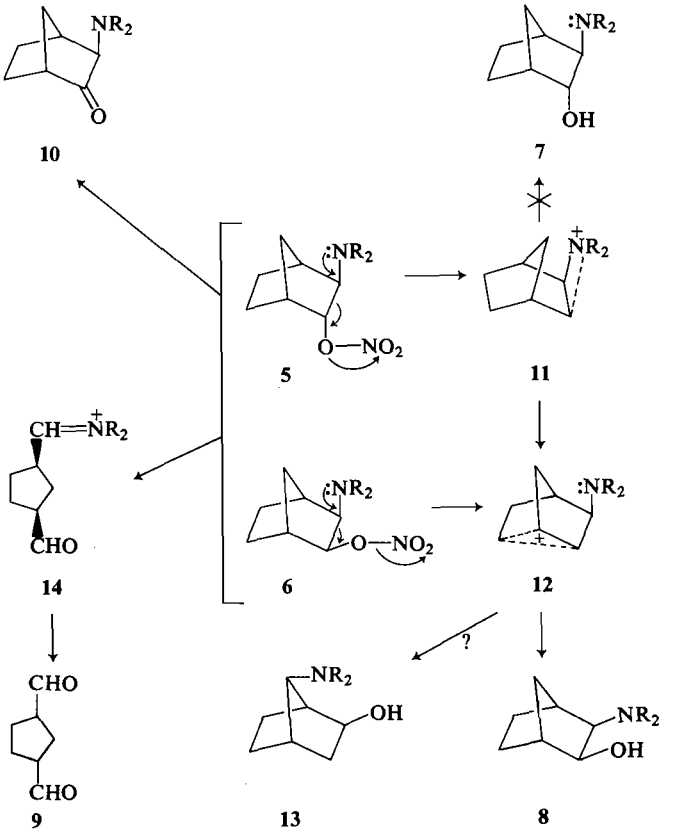
A similar oxidative photoaddition of NND gave the hydrochloride (the acid used in the reaction) of *endo*-2-nitrato-*exo*-3-dimethylaminobicyclo[2.2.1]heptane (**3**). Efforts to isolate the corresponding *exo*-nitrato isomer **4** were not successful. However when the photolysate was worked-up immediately under mild conditions, the 'first basic fraction' contained *endo*-nitrate **5** ($R = CH_3$), *exo*-2-dimethylamino-*exo*-bicyclo-[2.2.1]heptan-2-ol (**8**, $R = CH_3$), and *exo*-nitrate **6** ($R = CH_3$) as shown by the n.m.r. singlets at τ 7.78, 7.69, and 7.52 in nearly equal intensities. The n.m.r. and i.r. spectra also showed the presence of 1,3-bisformylcyclopentane (**9**, τ 0.22 and 0.35, and 1720 and 2720 cm^{-1}) and a small amount of *exo*-3-dimethylaminobicyclo[2.2.1]hepta-2-one (**10**, 1740 cm^{-1}).

Immediate reduction of the 'basic fraction' with LAH gave a 'second basic fraction' which accounted for only 50% of the 'first basic fraction' and contained *endo*-alcohol **7** and *exo*-alcohol **8** in a ratio of 3:7 as indicated by the intensity ratio of the N–CH_3 singlets at τ 7.80 and 7.71. Extensive chromatography of this mixture afforded *exo*-alcohol **8**, but the *endo*-alcohol **7** was isolated only as a mixture with **8**.

Subsequently the 'first basic fraction' was allowed to decompose in an aqueous solution at p*H* 10 and the recovered oil was reduced with LAH as above. The basic portion from this reduction was only 5% of the theoretical yield and contained only *exo*-alcohol **8**; *endo*-alcohol **7** was not found from chromatography and n.m.r. examinations. The major product after decomposition and reduction was recovered as the 'neutral fraction' and was shown to be 1,3-bis-dihydroxymethylcyclopentane which was isolated as the *p*-nitrobenzoyl derivative. This indicated that dialdehyde **9** was obtained in the decomposed mixture which indeed afforded a good yield of the bis-2,4-DNPH on treatment with Brady's reagent.

Summarizing these observations, it could be concluded that both *trans*-nitrates (**1** and **3**) and *cis*-nitrates (**2** and **4**) were formed in the oxidative photoaddition and that the nitrates were decomposed by bases to give mainly *exo*-alcohol **8** and dialdehyde **9** in addition to a small amount of ketone **10**. To clarify the stereochemical requirements of the basic decomposition, the pure hydrochloride of *endo*-nitrate **3** was neutralized in an aqueous solution and the total recovered oil was allowed to decompose in neat liquid. Immediately after the recovery the oil exhibited strong i.r. and n.m.r. absorptions for *endo*-nitrate **5** (1625, 1285, and 870 cm^{-1}, and τ 5.03 and 7.78) and for dialdehyde **9** (1720 cm^{-1} and τ 0.37); a small amount of *exo*-alcohol **8** (τ 6.41 and 7.60) and ketone **10** (1745 cm^{-1}) were also noted. As the nitrate absorptions gradually diminished, those absorptions due to dialdehyde **9** and *exo*-alcohol **8** built up considerably; the ketone absorption at 1745 cm^{-1} however remained static and finally showed as a faint shoulder. Gas chromatographic – mass spectral analysis of this final product showed that it contained dialdehyde **9** (61%), *exo*-alcohol **8** (31%), and other products (8%).

The structures of the products were determined by combinations of spectroscopic data. In particular the stereochemistry of the bicyclic derivatives was decided by the n.m.r. coupling patterns of the 2- and 3-protons and was, in many cases, clarified by decoupling experiments. From considerations of steric hindrance (4–6), an aminium radical would be expected to attack from the *exo* face of norbornene. In the case of **3** and **8**, the *endo*-3-proton was shown to couple with the 7-*anti*-proton through the long range W-plan and was not (or very weakly) coupled to the 4-proton (7). Since the 2-protons were generally shifted more downfield, analysis of their coupling patterns was much easier than were those of the 3-proton. The *trans* configuration such as in **1**, **3**, and **7** exhibited the 2-*exo*-proton as a triplet ($J = 4$ Hz) indicating the expected spin interaction with 1- and 3-*endo*-



$R_2 = -(CH_2)_5-$ or $(CH_3)_2$

SCHEME I

protons. The *exo-cis* configuration in **2**, **4**, and **8** showed that the 2-*endo*-proton coupled with the 3-*endo*-proton ($J \cong 6$ Hz) and the 7-*anti*-proton ($J = 1$–2 Hz) but not with the 1-proton.

The mass spectral fragmentation also showed a common pattern typical for the bicyclic systems; for example both alcohols **7** ($R_2 = -(CH_2)_5-$) and **8** ($R = CH_3$) gave strong peaks for the following fragments.

	7 (%)	8 (%)
	138(100)	98(54)
	124(55)	84(44)
	111(87)	71(48)
$R_2\overset{+}{N}=CH_2$	98(93)	58(100)

Discussion

From our observations it is concluded that the oxidative photoaddition of NND or NNP to norbornene clearly gave both *trans* and *cis* isomeric salts of the nitrate esters **1**–**4** and that, whereas these nitrate esters **5** and **6** are stable under acidic conditions in the protonated forms, they decompose rapidly under basic conditions. The formation of *exo*- and *endo*-nitrates is in agreement with the reported patterns of radical addition to norbornene (4–6); however, our efforts to determine the ratio of the isomers have been unsuccessful. Nitrate esters have been shown to undergo various basic decompositions (8, 9); among them are hydrolysis (10) or bimolecular nucleophilic substitution (11) by hydroxide to give alcohols and α-elimination of nitrite to give ketones (12). The presence of the neighboring amino group and the bicyclic

structure are expected to influence strongly the decomposition pathways.

The probable decomposition pathways of the nitrate isomers **5** and **6** are summarized in Scheme 1. While some pathways are established, *e.g.*, those of **5** → **8** and **5** → **9**, others are rationalized on the basis of the well-investigated solvolytic chemistry of norbornyl systems (13) and neighboring-group participation (14). Solvolysis of *endo*-nitrate **5**, which occurs only with the free base, is no doubt facilitated by participation of the neighboring amino group and the intermediate aziridinium ion **11** may be postulated. The aziridinium ion **11** may convert rapidly to the nonclassical carbonium ion **12** and eventually to **8** instead of directly reacting with hydroxide ion to give *endo*-alcohol **7** as this compound was not isolated from a prolonged basic decomposition. The ionization of *exo*-nitrate **6** to **12** is believed to be facile owing to the well established σ-bond participation in a norbornyl system (13). The cationic charge may be stabilized by the nitrogen lone pair but only to a slight extent, since subsequently hydroxide ion should be able to approach stereospecifically from the *exo* face at the 2-position to give **8**. The merit of the pathway **12** → **8** may be questioned in regard to the absence of the rearrangement products such as **13** which may have been formed as a very minor product but has escaped isolation. Alternatively, it may be suggested that the 3-amino group affects the position of entry of hydroxide ion.

endo-Alcohol **7** is derived solely from the immediate LAH reduction of *endo*-nitrate **5** before its exclusive solvolysis by the route of **5** → **11** → **12** → **8**. It is known that LAH reduction of nitrate esters gives alcohols without isomerization at the carbon center (3). In theory, *endo*-alcohol **7** can also be obtained from LAH reduction of ketone **10**. As demonstrated, the very low yield of ketone **10** during basic decomposition may be the reason why the *endo*-alcohol has not been obtained.

The α-elimination of HNO_2 from a nitrate ester is generally a minor side reaction under basic conditions (15). Such an elimination in nitrates **5** and **6** obviously requires the assistance of hydroxide ion since it occurs only in aqueous basic solution, but not in the neat liquid, to give a small yield of ketone **10**. Alternatively, nitrates **5** and **6** can eliminate nitrite ion by the electron shifts shown to give the immonium salt **14** (the precursor of **9**); this process obviously requires assistance from the lone pair of the amino group since it occurs only with the free bases. In view of the high yield of **9**, this cleavage pathway apparently requires a much lower activation energy than other decomposition processes mentioned.

The cleavage pathway of amino nitrates described above is also a novel reaction among heterolytic fragmentation reactions (16). In contrast to the facile cleavage of 2-ammoniumnitrosoalkanes (1), 2-amino nitrates are stable in their protonated forms but undergo cleavage reaction from the free bases. This strongly hints that the stereoelectronic requirements for 2-amino nitrate cleavage are an *anti*-periplanar arrangement of the functional groups (17, 18) as opposed to a *cis*-coplanar arrangement in 2-ammoniumnitrosoalkane cleavage (1). This has support from the result that *trans*-amino nitrate **5** readily cleaves to give dialdehyde **9**. While there is no positive proof, it is believed 2-amino nitrate **6** with the *cis-exo*-arrangement also cleaves in the same way in view of the copious yield of **9**, though this cleavage may not be as extensive as that of **5**.

The strained bicyclic structural features no doubt greatly facilitate the cleavage of amino nitrates **5** and **6**. It is also found now that in an aqueous basic solution, 1-piperidino-2-nitratocyclohexane (**15**) also undergoes the same type of cleavage to the extent of 10% in addition to the major pathways reported previously (3). Careful examination of the decomposition products shows the presence of 1,6-hexanedial (**16**) and 1-cyclopentenecarboxaldehyde (**17**) in addition to the products identified in our previous report. Oxidative photoaddition of NND to *trans*-2-octalin gave a mixture of various possible stereoisomeric amino nitrates. Decomposition of this mixture under basic conditions, however, gave no corresponding dialdehyde as shown by the i.r. and n.m.r. examinations. The major products[3] are cyclohexanol and cyclohexanone derivatives that resist attempts at purification.

[3]The details of the synthesis of *trans*-2-octalin, the photoaddition and isolation are described in the Ph.D. thesis of K. S. Pillay, Simon Fraser University, presented to the Faculty of Graduate Studies, September, 1975.

Experimental

The general experimental conditions are the same as those described in the preceding paper (1).

Oxidative Addition of NNP to Norbornene

A methanol solution (300 ml) of NNP (6.84 g, 0.06 mol), norbornene (3.76 g, 0.04 mol), and perchloric acid (60%, 10 ml) was irradiated (200-W Hanovia lamp) through a Nonex filter under an oxygen atmosphere at 0 °C for 4.5 h. At the end of the photolysis, the absorption at 345 nm had disappeared completely and a colorless solution was obtained. The solvent was distilled under reduced pressure at 10 °C. The residue was crystallized from ethyl alcohol – petroleum ether to give a white solid (2.61 g, 19%). This solid was recrystallized from methanol to give a mixture of the perchlorates of *endo*-2-nitrato-*exo*-3-piperidinobicyclo[2.2.1]heptane (**1**) and *exo*-2-nitrato-*exo*-3-piperidinobicyclo[2.2.1]heptane (**2**): m.p. 130–162 °C (decomposition with evolution of gas); i.r. 1645(s), 1275(s), 1110(s), 1080(s), 1065(s), and 840(s) cm^{-1}; n.m.r. (DMSO-d_6) τ 1.0 (D_2O exchangeable), 4.58 (t, J = 4 Hz), 4.73 (d, J = 7 Hz). The intensity ratio of the last two signals was 1:1.

After separating the salts, the filtrate was evaporated under vacuum. The residue was washed with ether and neutralized with saturated K_2CO_3 solution to p*H* 7.5. This was extracted with methylene chloride to give a reddish oil (4.81 g): i.r. 1740, 1720, 1620, 1275, and 865 cm^{-1}. This oil was not investigated further.

A methanol solution (300 ml) of NNP (5.47 g, 0.048 mol), norbornene (3.76 g, 0.04 mol), and concentrated hydrochloric acid (4.8 ml) was irradiated as described above. After the completion of the photolysis (2 h), the photolysate was immediately worked-up in the usual manner (3) to give a basic fraction.

A crude basic fraction (7 g) dissolved in anhydrous THF (50 ml) was added to a suspension of LAH (3.04 g, 0.08 mol) in THF (50 ml). The grey suspension was stirred for 24 h. The resultant reaction mixture was decomposed with water and filtered. The solid was washed thoroughly with THF. The filtrate and washings were combined and dried over anhydrous magnesium sulfate. The solvent was evaporated to give a thick colorless oil (6.25 g): i.r. 3360(s), 1105(m), 1050(s), and 1010(m) cm^{-1}; n.m.r. τ 5.93(m), 6.35 (m, partially D_2O exchangeable), 7.63(m), and 8.5(m).

The crude mixture was treated with ether containing a small amount of HCl to give a crystalline solid (500 mg, 5%). This solid was recrystallized from methanol to give the hydrochloride of *exo*-3-piperidino-*endo*-bicyclo[2.2.1]-heptan-2-ol (**7**): sublimes at 165 °C; i.r. 3345(s), 3295(s), 2660(s), 2550(m), 1090(s), 1080(s), and 1070(s) cm^{-1}; n.m.r. (D_2O) τ 5.76 (t, J = 4 Hz, H_2), 6.70 (m, 4H), 7.36 (d, J = 4 Hz, H_3), 7.38 (m, H_1), 7.58 (m, H_4), and 8.30 (m, 12H); *m/e*(%) 195(24), 194(6), 178(8), 138(88), 124(42), 111(73), 98(100), and 84(30). Decoupling experiments confirmed that the signal at τ 5.76 was coupled to the signals at τ 7.36 and 7.38 (J = 4 Hz).

M^+ Calcd. for $C_{12}H_{21}NO$: 195.1623. Found (high resolution mass spectrum): 195.1633.

Anal. Calcd. for $C_{12}H_{22}NOCl$: C, 62.19; H, 9.57; N, 6.05. Found: C, 61.91; H, 9.67; N, 6.16.

The hydrochloride (30 mg) was dissolved in saturated Na_2CO_3 solution and extracted with methylene chloride to give the free base of alcohol **7** (20 mg): m.p. 95–97 °C; i.r. 3200(sb), 2830(s), 1060(s), and 1045(s) cm^{-1}; *m/e*(%) (M^+, 41), 194(10), 178(11), 152(22), 138(100), 124(55), 111(87), 110(27), 98(93), and 84(33).

Oxidative Addition of NND to Norbornene

A solution of NND (3.552 g, 0.048 mol), norbornene (3.76 g, 0.04 mol), and concentrated hydrochloric acid (4.8 ml) in methanol (320 ml) was photolysed in a similar manner as described above. After irradiation (2 h), the methanol was removed at 10 °C. The residual solution was diluted with water and extracted with ether to give an oil (480 mg). This oil showed several spots on a t.l.c. plate and a complex n.m.r. spectrum containing no absorptions due to the N—CH_3 group. The aqueous solution was made basic with saturated Na_2CO_3 solution (p*H* 8.5) and extracted with methylene chloride to give a yellow oil (4.51 g): i.r. 2830(m), 2780(m), 2720(m), 1745(m), 1720(s), 1625(s), 1280(s), and 870(m) cm^{-1}; n.m.r. τ 0.22 (d, J = 2 Hz), 0.35 (d, J = 2 Hz), 7.52(s), 7.69(s), and 7.78(s). The g.c. analysis (20% SE-30, 150 °C) gave more than 10 peaks.

The crude basic fraction was reduced with LAH (3.42 g, 0.09 mol) in THF (100 ml) for 24 h. The reduced product was isolated in the usual manner to give an oil (3.5 g) which exhibited i.r. absorptions at 3400, 1050, and 1035 cm^{-1} due to a hydroxyl function. This oil was separated by extraction to the neutral (350 mg) and the basic fraction (1.76 g, 19%). The basic fraction contained *exo*-3-dimethylamino-*endo*-bicyclo[2.2.1]-heptan-2-ol (**7**) and *exo*-2-dimethylamino-*exo*-bicyclo[2.2.1]heptan-2-ol (**8**) in a ratio of 3:7 as shown by the intensities of the N—CH_3 singlets at τ 7.80 and 7.71: i.r. 3400(s), 2830(s), 2780(s), 1140(m), 1050(s), and 1035(s) cm^{-1}. The t.l.c. of this mixture showed two strong spots.

A portion of this mixture (500 mg) was chromatographed on neutral alumina (45 g). Elution with 0–10% chloroform in benzene gave an oil (92 mg) which showed one spot on a t.l.c. plate and a single peak on g.c. analysis (20% SE-30, 150 °C). This oil was distilled at 25 °C/0.03 Torr to give *exo*-alcohol **8** as a colorless oil: i.r. 3300(m), 2830(m), 2785(m), 1050(s), and 1035(s) cm^{-1}; n.m.r. τ 6.40 (dd, J = 1.3 and 6.3 Hz, H_2), 7.62 (s, 6H), 7.73 (m, H_3), 7.80 (m, 1H), 8.23–8.79 (m, 4H), 8.88 (m, 2H), 8.95 (m, H_{7s}), and 5.18 (D_2O, exchangeable); *m/e*(%) at 90 °C, 155(M^+, 15), 154(21), 126(38), 124(15), 98(54), 84(44), 71(48), and 58(100). Decoupling experiments showed that the signals at τ 6.40 and 7.73 were coupled mutually (J = 6.3 Hz) and also to the signal at τ 8.95 (J = 1.3 Hz).

Anal. Calcd. for $C_9H_{17}NO$: C, 69.63; H, 11.04; N, 9.02. Found: C, 69.30; H, 11.01; N, 9.20.

Subsequent fractions (392 mg) eluted with 20–50% chloroform in benzene gave mixtures of *endo*-alcohol **7** and *exo*-alcohol **8**: i.r. 3400(s), 1050(s), and 1035(s)

cm^{-1}; n.m.r. τ 7.73(s) and 7.79(s). The g.c. analysis (20% SE-30, 150 °C) showed two peaks at 5.3 and 5.7 min.

In a separate experiment, a solution of NND (3.55 g, 0.048 mol), norbornene (3.76 g, 0.04 mol) and concentrated hydrochloric acid (4.8 ml) in methanol (320 ml) was irradiated as described above. The methanol was distilled under reduced pressure, and the residue was washed with ether and made basic to p*H* 10 with saturated Na_2CO_3 solution. The aqueous solution was left for 24 h and extracted with methylene chloride to give a reddish oil (2.3 g) which was reduced with LAH (1.52 g, 0.04 mol) in ether for 24 h. The reduced product was isolated in the usual manner to give a basic fraction (310 mg, 5%): i.r. 3350(s), 1050(s), and 1030(s) cm^{-1}; n.m.r. τ 6.55 (dd, J = 1.5 and 6.5 Hz) and 7.67(s). This oil was purified on a neutral alumina column to give *exo*-alcohol **8**. No *endo*-alcohol **7** was detected in the n.m.r. spectrum.

The neutral fraction from LAH reduction was isolated in the usual manner. A part (233 mg) of this oil was heated with *p*-nitrobenzoyl chloride (555 mg, 0.003 mol) in pyridine (10 ml) on a steam bath for 1 h. The reaction mixture was poured into ice water. A solid was separated which was washed thoroughly with Na_2CO_3 solution followed by water. The solid was recrystallized from methanol to give the bis-*p*-nitrobenzoate of 1,3-bis(hydroxymethyl)cyclopentane (356 mg, 46%): m.p. 117–118 °C; i.r. 1720(s), 1605(m), 1530(s), 1520(s), 1345(s), 1285(s), 1275(s), 1120(s), 1100(s), and 720(s) cm^{-1}; n.m.r. τ 1.74 (m, 8H), 5.65 (m, 4H), 7.48 (m, 2H), and 7.25–9.11 (m, 6H); *m/e*(%) at 240 °C 428 (M^+, <0.1), 261(4), 150(63), 104(22), 94(100), and 79(56).

Exact Mass Calcd. for $C_7H_4NO_3$: 150.0191. Found (high resolution mass spectrum at *m/e* 150): 150.0228.

Exact Mass Calcd. for C_7H_{10}: 94.0782. Found (high resolution mass spectrum at *m/e* 94): 94.0762.

Anal. Calcd. for $C_{21}H_{26}N_2O_8$: C, 58.88; H, 4.71; N, 6.54; Found: C, 58.86; H, 4.64; N, 6.70.

A portion of the crude basic oil (300 mg) from the photolysate was treated with 2,4-dinitrophenylhydrazine solution in ethanol. The yellow solid (821 mg, 71%) was recrystallized from acetone to give the 2,4-DNPH of 1,3-bisformylcyclopentane **9**: m.p. 224–225 °C (lit. (19) m.p. 225–226 °C).

Decomposition of endo-2-Nitrato-exo-3-dimethylamino-bicyclo[2.2.1]heptane (5)

A methanol solution (320 ml) of NND (3.55 g, 0.048 mol), norbornene (3.76 g, 0.04 mol) and concentrated hydrochloric acid (4.8 ml) was photolyzed under an oxygen atmosphere as described earlier. The methanol was evaporated to a small volume at 10 °C. This solution was then diluted with ether and left at −5 °C for several months to give a small amount of a solid (600 mg) which was recrystallized from 2-propanol to give the hydrochloride of *endo*-2-nitrato-*exo*-3-dimethylaminobicyclo-[2.2.1]heptane (**3**) as a white crystalline compound: m.p. 161–162 °C (dec.); i.r. 3100(w), 1645(s), 1310(s), 1285(s), 1100(sb), and 850(s) cm^{-1}; n.m.r. (methanol-d_4) τ 4.65 (t, J = 4.0 Hz, H_2), 6.82 (dd, J = 4.0 and 2.5 Hz, H_3), 7.03 (S, 6H), 7.24 (m, 2H), and 7.95–8.74 (m, 6H). Decoupling experiments showed that the signals at τ 6.82 and 7.24 were not coupled to each other but coupled to the signals at τ 4.65 (J = 4.0 Hz) and at τ 7.95–8.74 (J = 2.5 Hz).

The HCl salt **3** (300 mg) dissolved in water was made basic with saturated Na_2CO_3 solution to p*H* 10 at 0 °C. The solution was immediately extracted with methylene chloride and the extract was washed with cold water and dried over anhydrous magnesium sulfate and was evaporated to give an oil (238 mg): i.r. 3350(w), 2830(s), 2780(s), 1745(w), 1720(m), 1625(s), 1285(s), 870(s), and 855(s) cm^{-1}; n.m.r. τ 0.37(m), 5.03 (t, J = 3.5 Hz), and 6.41 (d, J = 6.0 Hz) in the ratio 3.5:4.5:2. This oil was left at room temperature (color darkened) from which samples were withdrawn at different intervals (17, 24, and 44 h) and analyzed by i.r., n.m.r., and g.c.–m.s. (20% SE-30).

After 17 h, the sample showed strong i.r. absorptions at 1720 cm^{-1} for dialdehyde **9**, at 1625, 1285, 870, and 855 cm^{-1} for *endo*-nitrate **5**, and a weak peak at 3350 cm^{-1} for *exo*-alcohol **8**. The ratio of **9**:**5**:**8** was estimated to be 3.5:4:2 from the n.m.r. signals at τ 0.37, 5.02, and 6.35.

After 24 h, the intensity of absorption at 3350 cm^{-1} remained weak and that at 1720 cm^{-1} increased considerably compared to that of the nitrate peaks. The corresponding n.m.r. peak ratio was 5:4:4.

After 44 h, the absorption at 3350 cm^{-1} remained weak; the intensity at 1720 cm^{-1} increased enormously while that of the nitrate group decreased. The weak carbonyl absorption of **10** (1745 cm^{-1}) present at the zero-hour sample was now a barely visible shoulder merging with the 1720 cm^{-1} band. This sample was analyzed by g.c.–m.s. (100–200 °C, programmed at 10°/min) and was found to be a mixture of four compounds: 1.03 min (30.5%, *cis*-**9**), *m/e*(%) 126 (M^+, 47), 108(11), 98(26), 97(27), 80(23), 79(100), 70(48), 69(30), 67(88), and 57(52); 1.07 min (30.5%, *trans*-**9**) *m/e*(%) 126 (M^+, 6), 98(48), 80(22), 79(30), 67(43), and 57(100); 1.27 min (8.4%, unknown) *m/e*(%) 125(21), 85(10), and 84(100); 1.33 min (30.5%; **8**) *m/e*(%) 155 (M^+, 35), 140(26), 126(49), 98(100), 84(74), 71(81), 58(86), 45(27), 44(42), and 42(37).

The authors are grateful to the National Research Council of Canada for the financial support.

The Mechanism of Hydrolysis of Imidate Salts. The Importance of Stereoelectronic Control and p*H* of the Reaction Medium on the Cleavage of Tetrahedral Intermediates

PIERRE DESLONGCHAMPS AND ROLAND J. TAILLEFER

Laboratoire de synthèse organique, Université de Sherbrooke, Sherbrooke, Québec J1K 2R1

Received April 22, 1975

PIERRE DESLONGCHAMPS and ROLAND J. TAILLEFER. Can. J. Chem. **53**, 3029 (1975).

Hydrolysis of *anti* imidate salts give the ester amine products exclusively over the entire range of p*H*. Hydrolysis of *syn* imidate salts in acidic and neutral conditions give the ester amine products only; in basic conditions, mixtures of ester amine and amide alcohol products are observed. These results are explained by the application of the new theory of stereoelectronic control on the various ionic forms T^+, $T^\pm$, and T^- of the tetrahedral intermediate. For *syn* imidate salts, conformational changes of the tetrahedral intermediate must occur in order to have cleavage with stereoelectronic control.

PIERRE DESLONGCHAMPS et ROLAND J. TAILLEFER. Can. J. Chem. **53**, 3029 (1975).

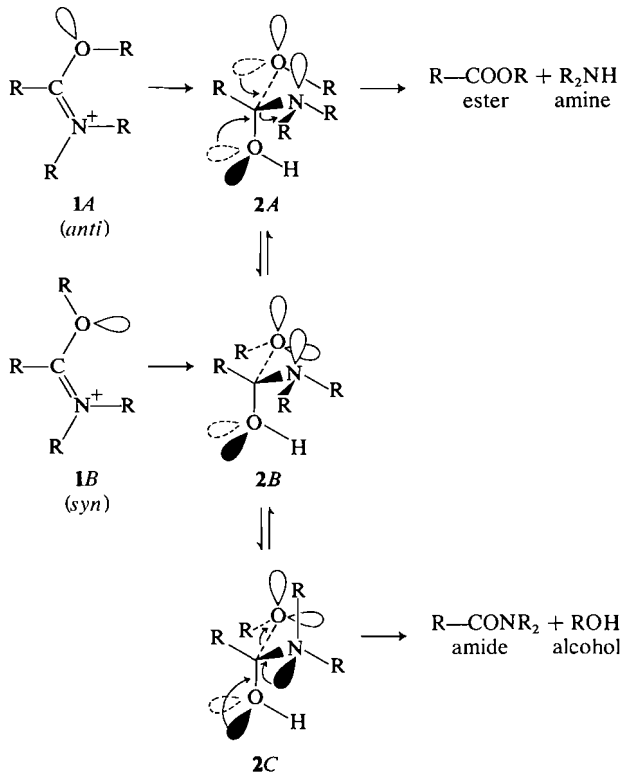
L'hydrolyse des sels imidates *anti* conduit toujours aux produits ester amine quelque soit le p*H* du milieu réactionnel. En milieu acide ou légèrement basique, les sels imidates *syn* donnent uniquement les produits ester amine. En milieu basique, ils donnent des mélanges des produits ester amine et amide alcool. Ces résultats sont expliqués par la nouvelle théorie de contrôle stéréoélectronique au niveau de l'intermédiaire tétrahédrique et par les diverses formes ioniques T^+, $T^\pm$ et T^- que peut prendre cet intermédiaire. De plus, dans le cas des imidates *syn*, il faut aussi postuler des changements conformationnels de l'intermédiaire tétrahédrique pour qu'il puisse se briser avec contrôle stéréoélectronique.

We have described recently a new theory of stereoelectronic control for the cleavage of tetrahedral intermediates which are formed during the hydrolysis of esters (1), and amides (2–4). In this new theory, the precise conformation of the tetrahedral intermediate (hemiorthoester or hemiorthoamide) plays a major role in determining the products formed. It is postulated that the precise conformation of the tetrahedral intermediate is transmitted into the products of the reaction and that the specific decomposition of such an intermediate is controlled by the orientation of the lone pair orbitals of the heteroatoms. Stereoelectronic cleavage of a tetrahedral intermediate is defined in the following way: specific cleavage of a carbon–oxygen or a carbon–nitrogen bond which occurs when two heteroatoms (oxygen or nitrogen) of the tetrahedral intermediate each have an orbital oriented antiperiplanar to the departing *O*-alkyl or *N*-alkyl leaving group.[1]

We have reported a study of the basic hydrolysis of several imidate salts having either a *syn* or an *anti* conformation (2, 3). The stereoelectronic theory predicts that an imidate salt having an *anti* conformation such as **1***A* (Scheme 1) will react with hydroxide ion to give the tetrahedral conformer **2***A*. Conformer **2***A* has a lone pair orbital on each oxygen properly oriented so that it can be cleaved with stereoelectronic control to yield the ester amine products. The theory also implies that when a tetrahedral intermediate can break down in a stereoelectronically controlled fashion, the energy barrier for its cleavage is much lower than that for rotation to give other conformers. So, there is no need to consider conformers other than **2***A* with an *anti* imidate salt. Such salts should therefore yield the ester amine products exclusively. We have obtained experimental results which support this prediction completely.

The theory also predicts that an imidate salt having a *syn* conformation such as **1***B* will react with hydroxide ion to give the tetrahedral conformer **2***B*. Conformer **2***B* does not have its orbitals properly aligned to allow a breakdown via an orbital-assisted mechanism. We have therefore postulated that the barriers of rotation of the C—O and the C—N bonds will be lower than the barrier for the cleavage of **2***B*. Thus, **2***B* will undergo conformational changes

[1]Theoretical calculations have been carried out and support this theory (5).

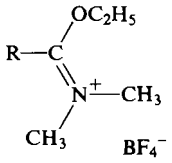


SCHEME I

by rotation to give new conformers such as **2***A* and **2***C* which can break down with stereoelectronic control yielding the ester amine and amide alcohol products, respectively. Conformer **2***C* has a lone pair orbital on one oxygen (the OH group) and on the nitrogen which are both properly oriented to eject the OR group with stereoelectronic control yielding the amide alcohol products. Since the barrier to rotation of the C—O and the C—N bonds must be of the same order of magnitude, **2***A* and **2***C* will be formed competitively from **2***B*. Mixtures of ester amine and amide alcohol products should therefore be observed in the basic hydrolysis of *syn* imidate salts. We have obtained experimental results which support this conclusion.

During our previous study on the basic hydrolysis of imidate salts, we have not taken account of the exact p*H* of the reaction medium. We have however used such basic conditions as to allow a kinetically controlled reaction and to suppress the protonation of the nitrogen in the tetrahedral intermediate. We had also to use a mixed aqueous–organic solvent so that the products of the reaction could be directly analyzed by n.m.r. spectroscopy. It was important to follow the reaction directly in the reaction mixture in order to ensure that the observed results were produced by a kinetically controlled reaction. To complete this investigation, we have undertaken a study of the products formed in the hydrolysis of some *N,N*-dialkylated imidate salts in aqueous solvent over a range of p*H* values. We wish to describe this work and to discuss the new stereoelectronic theory with respect to the generally accepted mechanism for the hydrolysis of imidate salts in acidic and basic media.

We have selected for this study, the imidate salts **3**, **4**, **5**, and **6**. The results of their hydrolyses as a function of p*H* are shown in Fig. 1. At p*H*



3 R = CH_3
4 R = C_6H_{11}(cyclohexyl)
5 R = C_6H_5
6 R = $(CH_3)_3C$

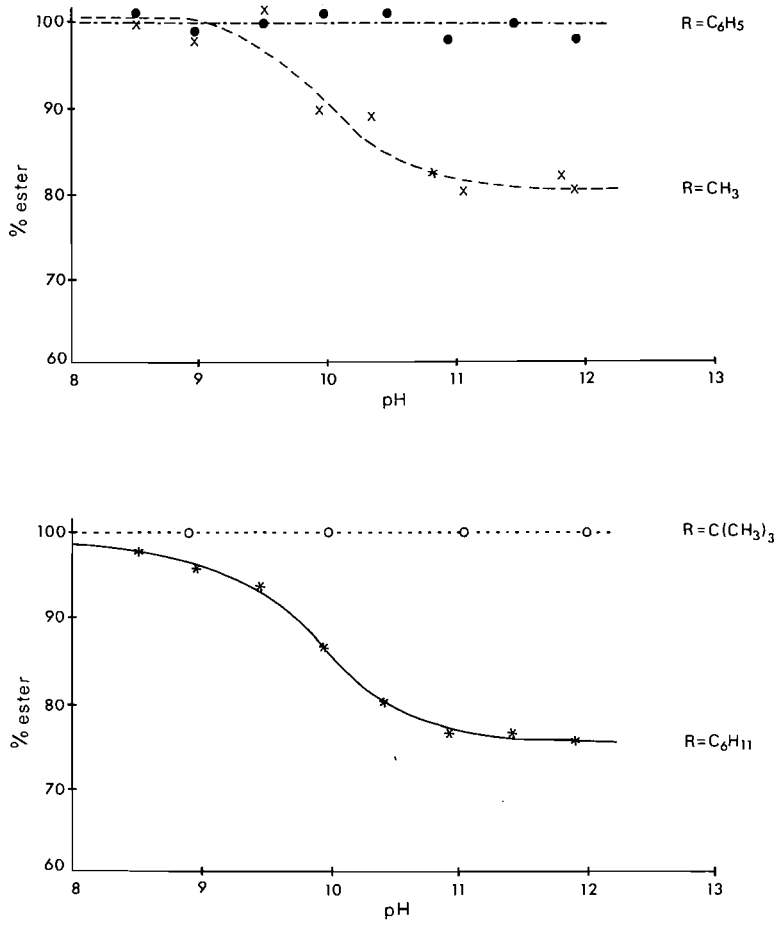


FIG. 1. Products of the hydrolysis of salts **3** (×), **4** (*), **5**(●), and **6** (○) as a function of p*H*. Buffer concentrations were 0.05 *M* (except for NaOH buffers) and the ionic strength was 1.0 *M* (maintained with KCl). In the case of **4**, the amide was assayed and the percentage ester was obtained by subtraction from 100.

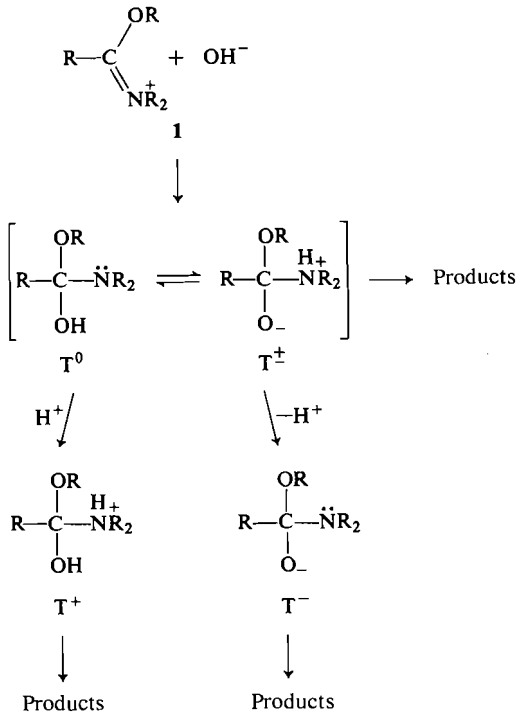
8.5 or lower, the four imidate salts yield the ester amine products exclusively. The imidate salts **5** and **6** yield the ester amine products over the entire range of p*H* values. At p*H* greater than 8.5, imidate salts **3** and **4** start to produce the amide alcohol products which reach a maximum yield at p*H* 11 (20% for **3** and 25% for **4**) and that value remains unchanged at higher p*H*. These results are essentially identical with those obtained in our previous study using mixed aqueous–organic solvents.

Several previous studies on the hydrolysis of imidate salts have resulted in the following proposed mechanism (6, 7). Hydroxide ion reacts with an imidate salt such as **1** (Scheme 2) to give the tetrahedral intermediate T^0. It is assumed that proton transfer on the tetrahedral intermediate is faster than its breakdown, thus, T^0 is kinetically equivalent to $T^{\pm}$. Consequently, T^0 will also exist as $T^{\pm}$ at the p*H* corresponding to the pK_a of the tetrahedral intermediate (p$H \simeq 10$). At low p*H*, T^0 will exist as T^+ and at high p*H* as T^-. The variation in product formation with p*H* was thus explained by the various charged forms of T^0.[2] It was proposed that T^+ and $T^{\pm}$ expel amine to form the ester[3] while T^- could

[2]The breakdown of $T^{\pm}$ should be much easier than that of T^0. The R_2NH^+ group in $T^{\pm}$ is a much better leaving group than the R_2N group in T^0. Also, the negatively charged oxygen in $T^{\pm}$ must be an extra driving force to facilitate the cleavage of the intermediate. Since $T^{\pm}$ and T^0 are kinetically equivalent, T^0 can therefore be neglected.

[3]The R_2NH^+ group is a better leaving group than the OR group, so the cleavage of the C—N bond in T^+ and $T^{\pm}$ should be a more facile process than that of the C—OR bond.



SCHEME 2

expel the alkoxide ion only with the consequent formation of amide.[4]

The results that we have obtained in the hydrolysis of imidate salts **2**, **4**, **5**, and **6** in acidic and slightly basic media can be explained by the preceding mechanism. However, the observed results in strongly basic medium cannot be rationalized by the same mechanism. The exclusive formation of the ester amine products from imidate salts **5** and **6** cannot be explained. Similarly, this mechanism does not offer an explanation for the partial formation of the ester amine products in the basic hydrolysis of imidate salts **3** and **4**. New parameters must be considered in order to explain the observed apparent anomalies. Clearly, the conformation of the tetrahedral intermediate must be one of the key points. Indeed, the application of the new stereoelectronic theory which we have developed appears to offer a complete explanation of the observed results.

We will first consider an imidate salt having an *anti* conformation such as **1***A*. According to the theory, **1***A* will form the intermediate **2***A*. In acidic medium, **2***A* will exist as the protonated form T^+, in slightly basic medium (near the pK_a of T^0, $pH \simeq 10$), it will exist as $T^{\pm}$ and in basic medium ($pH > 11$), it will exist as T^-. Again, $T^{\pm}$ is considered to be equivalent to T^0, thus T^0 can be neglected. Conformer **2***A* in the ionic form T^+, $T^{\pm}$, and T^- has proper orbital orientation to break down via stereoelectronic control to yield the ester amine products only.[5] *Anti* imidate salts should therefore yield ester amine products only, regardless of the pH of the reaction media.

The imidate salts **5** and **6** are considered to exist in the *anti* conformation[6] and indeed they give ester and amine as products of their hydrolysis over the complete range of pH values. We have also studied the hydrolysis in mixed aqueous–organic solvents of several cyclic imidate salts which can only exist in the *anti* conformation and these salts gave the ester amine products exclusively.[7]

When an imidate salt is in the *syn* conformation, it will first form the tetrahedral conformer **2***B* which will exist either as the T^+, $T^{\pm}$, or T^- form depending on the pH of the reaction medium. Since conformer **2***B* cannot break down via stereoelectronic control, we propose that conformational changes by rotation to give **2***A* (C—O bond rotation) or **2***C* (C—N bond rotation) will occur prior to cleavage.

When conformer **2***C* is in the T^+ or $T^{\pm}$ ionic form, it cannot be cleaved with stereoelectronic control because the nitrogen of the hemiorthoamide is sufficiently basic to be always protonated and its lone pair orbital is therefore not available to expel the OR group. Consequently, in media which favor T^+ or $T^{\pm}$, conformer **2***B* can be converted to either **2***A* or **2***C* but cleavage with stereoelectronic control can occur with con-

[4]The OR group is a better leaving group than the R_2N group, so the cleavage of the C—OR bond in T^- should be easier than that of the C—N bond.

[5]This implies that complete proton transfer can occur before cleavage even with tetrahedral intermediates which have two antiperiplanar lone pairs. It has also been suggested that the cleavage of some intermediates could occur prior to the proton transfer equilibrium giving different results (8).

[6]For a discussion concerning the conformation of these salts, see refs. 2 and 3.

[7]A study of the pH–product profile in an aqueous solution cannot be conveniently carried out with these cyclic salts. Under basic conditions, the ester amine products which are formed from these salts are very rapidly transformed into their corresponding amide alcohol products directly in the reaction mixture. It is, therefore, difficult to analyze the products resulting from the reaction under kinetically controlled conditions.

former **2***A* only. Thus, under those conditions, *syn* imidate salts should yield the ester amine products only.

When intermediate **2***C* exists in the T^- ionic form, it can be cleaved with stereoelectronic control. Consequently, in media which favor T^-, conformer **2***B* can be either converted to **2***A* or **2***C*; **2***A* yielding the ester amine products and **2***C* the amide alcohol products. Thus, in strong basic medium, *syn* imidate salts can give the amide alcohol as well as the ester amine products.

Thus, in acidic or neutral media which favor the formation of T^+ and $T^\pm$, *syn* imidate salts should only give the ester amine products. When the reaction medium becomes basic enough to allow the existence of T^-, the amide alcohol products should start to be formed. When the medium becomes strongly basic, T^- is then the only ionic species which should yield both the ester amine and amide alcohol products at a constant ratio for a given substrate. The ratio of products will depend on the relative energy barriers of rotation of the C—O and C—N bonds. One should therefore expect that the value of the ratio will vary with different *syn* imidate salts.

The imidate salts **3** and **4** are considered to exist in the *syn* conformation[6,8] and they do indeed exhibit the following behavior. They give the ester amine products in acidic and neutral conditions, and, starting at p*H* 8.5, the amide alcohol products which reach a constant maximum yield at p*H* 11 and above. In our previous investigation with mixed aqueous–organic solvents, we studied the basic hydrolysis of some cyclic imidate salts which can only exist in the *syn* conformation and a mixture of ester amine and amide alcohol products was also obtained (2, 3).

We would like to emphasize that the stereoelectronic theory permits the understanding of why a tetrahedral intermediate would prefer to eject the R_2N group in presence of the OR group, a normally better leaving group under basic conditions. Thus, the application of the postulate of conformational changes in tetrahedral intermediates combined with the theory of stereoelectronic control on the various ionic forms T^+, $T^\pm$, and T^- of such intermediates provide a very attractive mechanism to explain the products formed in the hydrolysis of imidate salts at various p*H* values.

In the course of the presentation of this new theory, we had to make several postulates concerning conformational changes during reactions and also about the relative energy barriers of bond rotation and cleavage of the intermediate (9).[9] These postulates remain to be supported by direct experimental evidence.

We have postulated that the energy barrier for the stereoelectronic cleavage of a tetrahedral intermediate such as **2***A* and **2***C* in the T^- ionic form, is much lower than that for rotation to give other conformers. The fact that *anti* imidate salts (which generate **2***A*) give the ester amine products, can be considered as experimental evidence for that postulate. However, it would be desirable to find an experiment which can show that conformational changes do not take place in the hydrolysis of *anti* imidate salts. Also, we have not yet obtained any experimental support that conformer **2***C* in the ionic form T^- behaves in a similar way. Good arguments can be brought to show that the energy barrier for the cleavage of **2***C* should be lower than that for **2***A*, thus indicating that if **2***A* does not undergo conformational changes, **2***C* will certainly not. The cleavage of the C—OR bond in **2***C* ought to be easier than that for the C—NR_2 bond in **2***A*.[4] It is also reasonable to assume that the lone pair orbital of the nitrogen in **2***C* must be a more powerful one to eject a leaving group than that of the oxygen of the OR group in **2***A*.

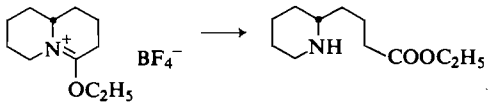
We have also postulated that the energy barrier for a nonstereoelectronically controlled cleavage of a tetrahedral intermediate is higher than that for rotation to give new tetrahedral conformers. Experimental evidence for the conformational change of **2***B* in the T^+ or $T^\pm$ forms

[8]It is possible that the salts **3** and **4** exist to some extent in the *anti* form which would be in equilibrium with the *syn* form (2, 3). This new situation does not change the above conclusion. The *syn* form would still produce the amide alcohol products and a certain percentage of the ester amine products. The remaining portion of ester amine products observed would come from the *anti* form.

[9]This implies that the energy barrier for conformational changes in tetrahedral intermediates must be relatively high. The energy barrier for rotation and inversion in benzyl-*t*-butylmethylamine have been found to be 6.4 and 6.3 kcal/mol, respectively (10). In tetrahedral intermediates, the anomeric effect (11) must also play an important role which could very well increase the energy barrier for conformational changes. For instance, dimethoxymethane is known to exist preferentially in the *gauche-gauche* conformation (12), thus its energy barrier for rotation must be high (it has been estimated to be $\simeq 3.0$ kcal/mol (13)).

has not yet been obtained. If the stereoelectronic theory is neglected, one can still predict on the basis of the ability of the two leaving groups[3] that an intermediate such as **2***B* should yield the ester amine products exclusively under acidic or slightly basic conditions. So, the fact that *syn* imidate salts yield only the ester amine products under those conditions does not constitute evidence for a conformational change of the tetrahedral intermediate prior to cleavage.

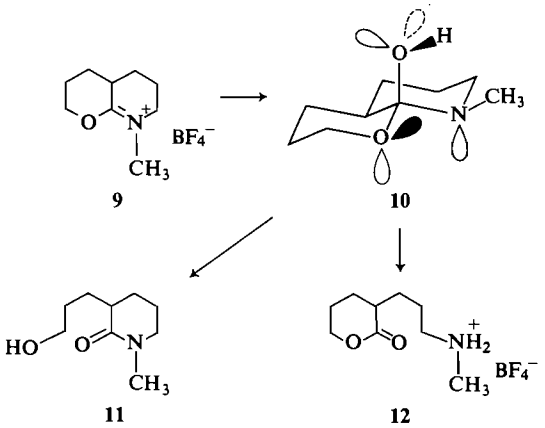
Similarly, we have not yet described an experiment to show that when conformer **2***B* exists in the ionic form T^-, it prefers to undergo conformational changes to **2***A* and **2***C* before cleavage.[10] The fact that *syn* imidate salts yield a mixture of products under basic conditions is very well explained by this postulate and the present level of knowledge does not present any alternative explanation. The hydrolysis of imidate salt **7** that we have recently reported (3) provides additional evidence for conformational changes. This *syn* salt produces a tetrahedral intermediate which is equivalent to **2***B*. However, only the C—O bond rotation is allowed in this intermediate, as the C—N bond rotation is a much more difficult process. Therefore, the intermediate can change only to new conformers which can produce the ester amine products. Indeed, the basic hydrolysis of this salt gave the ester amine **8** only, despite its *syn* conformation (Scheme 3).



7 8

SCHEME 3

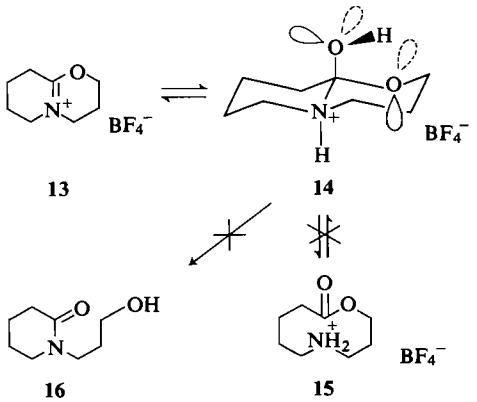
The bicyclic *syn* imidate salt **9** must form the intermediate **10** which is equivalent to **2***B* but **10** cannot undergo rotation of either the C—O or the C—N bond unless considerable twisting of the molecule could take place. This salt is thus an ideal model to find out if cleavage can occur without stereoelectronic control. In the absence of cleavage, the intermediate **10** would be isolated. We have found (3) that compound **9** is hydrolyzed under basic conditions to give the lactam alcohol product **11**; under acidic conditions, it gave the lactone ammonium salt **12** (Scheme 4). These results indicate that cleavage without stereoelectronic control can occur. The energy barrier of such a cleavage is simply higher than that for a cleavage with stereoelectronic control. However, when conformational changes to new conformers are possible, such high energy processes are of course avoided.



9 10 11 12

SCHEME 4

All the imidate salts described gave the ester amine products in acidic or neutral media. This result shows that when an intermediate exists in the T^+ or $T^\pm$ form, it prefers to eject the R_2NH^+ group instead of the OR group. The bicyclic *anti* imidate salt **13** was shown to be stable under acidic conditions (3). This salt must form the intermediate **14** in which the expected cleavage of the C—N bond would produce the large ring amino lactone **15** (Scheme 5). The formation of **15** is apparently not favored and **16** is not observed. Therefore, the intermediate **14** can only revert to starting material **13**. This result shows that a tetrahedral intermediate in the ionic form T^+ or $T^\pm$ cannot eject the OR group even when the normally competing ejection of the R_2NH^+ group is forbidden.



13 14 16 15

SCHEME 5

[10]When **2***B* exists as T^-, the energy barrier for its cleavage must be higher than when it exists as $T^\pm$ (and possibly as T^+). The R_2N group in T^- is a poorer leaving group than the R_2NH^+ group in $T^\pm$. Thus, conformational change is more likely to occur when **2***B* exists as T^-.

TABLE 1. Ester formed during the hydrolysis of **3**[a]

[f]Dimethyl glycine buffer at pH 10.9 and containing 0.1 *M* triethylamine.
[g]The yield in ester in the standard was 92%.
[h]The yield in ester in the standard was 95%.

We would like to emphasize that when a tetrahedral intermediate such as **2***A* exists in the T^- ionic form, it does not first eject the amide ion to be protonated by the solvent to give the secondary amine. Both, the protonation and the ejection processes must be synchronized (14). In aqueous solution, the nitrogen lone pair orbital of **2***A* must first be hydrogen bonded with the solvent. When the cleavage starts to occur, the C—N bond becomes longer and weaker, the nitrogen atom becomes more basic, the nitrogen–hydrogen bond must become shorter and stronger. When the cleavage is almost complete, the nitrogen–hydrogen bond must be near the length of a full bond, so that the group can leave as a secondary amine.

We have stressed the fact that conformational changes of the tetrahedral intermediate have not yet been rigorously established experimentally. We think that this should be done because it is a fundamental principle of the stereoelectronic theory. Furthermore, this principle of conformational change can become a crucial point when the stereoelectronic theory is applied to the mechanism of hydrolysis by enzymes. For instance, it could lead to the prediction that conformational changes are necessary for the stereoelectronic assistance of hydrolysis by enzymes.

Work is now in progress to demonstrate that conformational changes do indeed take place in such reactions.

Experimental

The imidate salts have been obtained as described elsewhere (3). Buffers were commercial products and were used without purification. Their concentrations were normally 0.05 *M* and the ionic strength was 1.0 *M*, maintained with potassium chloride.

Calorimetric determinations were done with a Zeiss PMQ II spectrophotometer or a Varian Techtron spectrophotometer model 634. Vapor phase chromatographic analyses were done on a Varian model 2800 instrument, with thermal conductivity detection and temperature programming when necessary. Columns used were 10% SE-30 on Chromosorb W or 10% Apiezon L on Chromosorb W. Proton n.m.r. spectra were recorded on a Varian A-60 spectrometer using TMS as the internal standard.

*Hydrolysis of Salts **3** and **5** and Product Analysis*

The ester produced during the hydrolysis of salts **3** and **5** was assayed using the hydroxamic acid method (8, 15). In a typical experiment, 100 μl of the imidate solution (0.15–0.25 *M* in acetone) were introduced using a rapid-injection syringe (Hamilton push-button syringe) into 10 ml of buffer solution. After an appropriate time, a 2.0 ml aliquot was withdrawn and added to 1.0 ml of alkaline hydroxylamine (prepared hourly by adding 1 volume of NH_3OH–HCl, 8 *M*, and 1.2 volumes of sodium hydroxide, 7 *N*). After 20 min, 4.0 ml of a ferric chloride solution ($FeCl_3$ $6H_2O$, 10% in hydrochloric acid, 0.7 *N*) were added. The optical density was determined after 10 min at 520 (**5**) or 540 nm (**3**) and compared against a standard curve.

Each hydrolysis was done in duplicate and was accompanied by a duplicate sample of pure ester of similar concentration treated under the same conditions of hydrolysis and analysis. Corrections for ester hydrolysis were made when necessary. Optical densities were measured against a blank consisting of 100 μl of acetone treated in the same manner as the imidate sample. The results are shown in Tables 1 and 2.

*Hydrolysis of Salt **4** and Product Analysis*

In a typical experiment, 100 μl of the imidate solution (0.185 *M* in acetonitrile) were introduced using a rapid-injection syringe (Hamilton push-button syringe) into 10 ml of buffer solution. A few seconds before the hydrolysis ended, 100 μl of a solution of a standard (*n*-propyl benzoate, 0.168 *M* in acetonitrile) were added and the reaction solution was extracted with methylene chloride

(3 × 3–4 ml). The extracts were dried over Na_2SO_4, filtered, concentrated, and assayed by vapor phase chromatography. The percentage amide produced was obtained by comparison of the weight (in mg) of the amide peak with that of the standard peak. The method (extraction and chromatographic analysis) was calibrated using pure amide treated in the same conditions as the hydrolysis[11] (a 1:1 molar correspondence was obtained between amide and standard).

Each hydrolysis was done in duplicate and was accompanied by a duplicate sample of pure amide of similar concentration and treated with the same conditions of hydrolysis. The results are shown in Table 3.

Hydrolysis of Salt 6 and Product Analysis

The product of the hydrolysis of salt **6**, pivalic acid ethyl ester, is very volatile (b.p. 118 °C (16)) such that a normal concentration procedure would involve some loss of the compound. Accordingly, in a typical experiment, the solid salt (150–200 mg) was added to the buffer solution (30 ml) and was stirred vigorously for an appropriate amount of time. The solution was then extracted with methylenechloride (5 ml). After drying (Na_2SO_4), a sample was removed and analyzed directly by n.m.r. spectroscopy using added TMS as an internal standard and by vapor phase chromatography. The results are shown in Table 4.

The extraction procedure was checked as follows: in a separate experiment, when 4.1 mol% of amide was present with the starting imidate, there was 3.6 mol% of amide present with ester after hydrolysis at pH 12, as detected by n.m.r. spectroscopy.

Mixing Experiments

Since imidate salts are very reactive in alkaline solutions (7), mixing problems could have arisen when the salt, dissolved in an organic solvent, is introduced into the buffer solution. The salt could react before complete mixing of the organic solvent and the buffer has occurred.

TABLE 4. Ester formed during the hydrolysis of **6**[a]

pH	Buffer	Reaction time	% ester
1	HCl	12.5 h	100
7	KCl	18 h	100

12	NaOH	0.5 min	100

[a]Hydrolysis performed at room temperature, at buffer concentration of 0.05 *M* (except for hydrochloric acid and sodium hydroxide buffers) and at ionic strength 1.0 *M*, maintained with potassium chloride.
[b]A trace of amide (< 1%) was consistently obtained at this pH.
[c]Dimethyl glycine.

[11]The ester could not be assayed at the same time because some of it was lost during the sample concentration procedure.

TABLE 5. Influence of the mode of addition of the imidate **3** solution into the buffer solution on the product composition[a]

Mode of addition[b]	% ester
1	76
2	82
3	85
4	84
5	79
6	82

[a]Hydrolysis performed at room temperature, at buffer concentration of 0.05 *M* at p*H* 10.9 (dimethyl glycine buffer) and at 1.0 *M* ionic strength maintained with potassium chloride.
[b]*1*, graduated pipette; *2*, Hamilton syringe; *3*, rapid injection syringe (Hamilton push-button syringe); *4*, rapid injection syringe with vortex stirring, *5*, rapid injection syringe with vortex stirring; 5 ml of reacting solution; *6*, rapid injection syringe in a buffer solution containing 0.1 *M* triethylamine (p*H* 11.9); the ester yield was 92%.

TABLE 6. Effect of buffer concentration on the hydrolysis of salt **3**[a]

[Buffer] (*M*)[b]	% ester	Deviation[c]
0.01	80	4
0.05	80	2
0.10	82	4

[a]Hydrolysis performed at room temperature and at ionic strength of 1.0 *M*, maintained with potassium chloride.
[b]Dimethyl glycine buffer at p*H* 11.0.
[c]Deviation from average of two results.

The net result of such a situation would be that the salt initially is hydrolyzed at a given p*H*, but as base is removed locally, the p*H* falls and hydrolysis would continue. Thus, some of the ester product could come from neutral or even acid hydrolysis of the salt. To check this possibility, a number of methods for adding the salt into the buffer solution were tried in which the rapidity of the mixing process varies considerably. Salt **3** was used and the procedure for the hydrolysis and product analysis was carried out as described above for this salt. The results are shown in Table 5.

Entry 6 of Table 5 is quite significant. If penetration of the base into the droplets of organic solvent during the initial mixing process would have caused local initial changes in p*H*, triethylamine should have been more efficient than hydroxide ion. Thus, these experiments show that no problems occur with mixing in these reactions.

Effect of Buffer Concentration

The effect of buffer concentration was investigated for the hydrolysis of salt **3**. Hydrolysis and product analysis was carried out in the same way as described above for this salt. The results are shown in Table 6. A variation by a factor of 10 in the buffer concentration does not influence the product composition.

Support for this work by the National Research Council of Canada, and by the Ministère de l'Education, Quebec, is gratefully acknowledged.

We also thank professor W. P. Jencks (Brandeis University) who kindly accepted one of us (R.J.T.) in his laboratory for a period of one month to learn various experimental techniques. We also deeply appreciate his help and encouragement through several discussions.

The Preparation of Hexamethylcyclotriphosphazene

RICHARD T. OAKLEY AND NORMAN L. PADDOCK[1]

Department of Chemistry, University of British Columbia, 2075 Wesbrook Place, Vancouver, British Columbia V6T 1W5

Received April 10, 1975

RICHARD T. OAKLEY and NORMAN L. PADDOCK. Can. J. Chem. **53**, 3038 (1975).

Dimethyltrichlorophosphorane reacts with methylamine hydrochloride to give an oil which decomposes on heating, yielding the quaternary chloride $N_3P_3Me_6 \cdot MeCl$ as the principal product. The controlled pyrolysis of this salt gives $N_3P_3Me_6$ in high yield. A simple method for the separation of $N_3P_3Me_6$ and $N_4P_4Me_8$ is described, based on the different solubilities of their salts in acetonitrile.

RICHARD T. OAKLEY et NORMAN L. PADDOCK. Can. J. Chem. **53**, 3038 (1975).

Le diméthyltrichlorophosphorane réagit avec le chlorhydrate de méthylamine pour conduire à une huile qui se décompose, sous l'influence de la chaleur, pour donner, comme produit principal, le chlorure quaternaire $N_3P_3Me_6 \cdot MeCl$. La pyrolyse controlée de ce sel fournit le $N_3P_3Me_6$ avec un bon rendement. On décrit une méthode simple permettant de séparer $N_3P_3Me_6$ et $N_4P_4Me_8$; cette méthode fait appel à la différence de solubilité de leurs sels dans l'acétonitrile.

[Traduit par le journal]

Although the methylphosphazenes $(NPMe_2)_{3,4}$ have been known for many years (1), studies of their chemistry have been based mainly on the tetramer. Both compounds are produced as hydrochlorides (2, 3) in the reaction between dimethyltrichlorophosphorane and ammonium chloride in tetrachloroethane, according to eq. 1

[1] $$Me_2PCl_3 + NH_4Cl \rightarrow 1/n(NPMe_2)_n + 4HCl \quad (n = 3, 4)$$

the molar ratio (trimer:tetramer) being about 1:4 (3); if the solvent is omitted, the dihydrochloride of the tetramer is the sole product (4). The neutral compounds can be released either by a tertiary amine (3, 4) or aqueous alkali (2). Mixtures of $N_3P_3Me_6$ and $N_4P_4Me_8$ are also formed by heating $Me_2P(NH_2)_2Cl$ (4, 5) but, however the mixture is produced, the separation of the individual components is tedious. The tetramer is the more easily obtained, because it is the major product of such reactions and forms good crystals. It can also be prepared in high yield by the methylation of the corresponding fluoride (6), a method which fails for the trimer (7). The present paper is intended to help in two ways. It describes in the Experimental (*a*) a convenient preparation of $N_3P_3Me_6$ in high yield and (*b*) a method for separating the trimer and tetramer, which can be usefully applied to mixtures produced in other ways.

The preparative method described below is a modification of that first used (1), with the substitution of methylamine hydrochloride for ammonium chloride. An oily intermediate is formed, which has not been characterized but, by analogy with the comparable reactions of PCl_5 (8) and $PhPCl_4$ (9) probably contains the dimeric phosphazane $(Me_2PCl \cdot NMe)_2$. Pyrolysis of the oil *in vacuo* gives a mixture of the quaternary chloride $N_3P_3Me_6 \cdot MeCl$ and a small amount of the diquaternary salt $N_4P_4Me_8 \cdot 2MeCl$, which can be separated by taking advantage of the solubility of the former compound in acetonitrile. The neutral $N_3P_3Me_6$ is obtained from $N_3P_3Me_6 \cdot MeCl$ by heating it *in vacuo*. There appears to be a similarity, in principle, to the formation of $N_3P_3Ph_6$ by the dehydrohalogenation of $(Ph_2PF \cdot NH)_2$ (10).

We add three comments: (*i*) The oily product should not be heated for too long in the presence of the solvent. If it is, increasing quantities of the tetramer are eventually formed, possibly as a result of the polymerization of the dimeric phosphazane, known to occur (11) on prolonged heating of the analogous $(F_3P \cdot NMe)_2$. (*ii*) The insolubility of the diquaternary salt $N_4P_4Me_8 \cdot 2MeCl$ in acetonitrile is a result of the double positive charge on the cation. Since $N_3P_3Me_6$ forms a monohydrochloride (2, 3), mixtures of the hydrochlorides can similarly be separated more easily than the neutral compounds prepared from them by the addition of a

base. (*iii*) There is an interesting difference from the behavior of $(Cl_3P{\cdot}NMe)_2$, prepared from methylamine hydrochloride and PCl_5 (8). On pyrolysis, this compound does not give a quaternary salt, presumably because the chlorophosphazenes are too weakly basic; a high polymer of composition $NPCl_2$ is formed instead (12). The positive charge on the quaternized methylphosphazenes would tend to prevent such polymerization.

Experimental

Reaction of Dimethyltrichlorophosphorane with Methylamine Hydrochloride

Dimethyltrichlorophosphorane was prepared by the chlorination of tetramethyldiphosphine disulfide (13) in carbon tetrachloride and was dried *in vacuo* for 24 h. The methylamine hydrochloride, a commercial product, was dried at 120 °C for 24 h.

Dimethyltrichlorophosphorane (32.0 g, 191 mmol) was added to a slurry of methylamine hydrochloride (12.0 g, 191 mmol) in 125 ml chlorobenzene and the mixture heated to reflux. When this temperature was reached, evolution of hydrogen chloride commenced and the reactants rapidly fused into a pale yellow oil which was immiscible with the solvent. After heating for 1 h under reflux, the solvent was distilled off, leaving a viscous oil. (As stated above, prolonged heating under reflux reduces the relative yield of trimer; it also lowers the overall yield of phosphazenes.) The oil was then heated at 165 °C/0.05 Torr for 4 h. During this time the oil solidified to an off-white powdery solid. After cooling, the solid was extracted with 3 × 200 ml hot acetonitrile. The extracts were combined and concentrated, whereupon a white slightly hygroscopic solid (11.94 g) crystallized out. A further 0.84 g of the same solid was obtained by evaporation of the mother liquor under N_2. The whole was recrystallized from acetonitrile and identified by its analysis and ^1H n.m.r. spectrum as the quaternary salt $N_3P_3Me_6{\cdot}MeCl$; m.p. 195–200 °C (dec.) (12.8 g, 73%); ^1H n.m.r., 100 MHz (δ, CD_3CN, internal TMS) 2.94 (3H, triplet, J_{PH} = 10.5 Hz), 1.87 (12H, doublet, J_{PH} = 13.5 Hz), 1.57 (6H, doublet, 14.5 Hz, long range J_{PH} = 1.5 Hz); i.r. ν(P=N) 1190, 1245 cm^{-1} (Nujol mulls for all compounds; assignments provisional).

Anal. Calcd. for $C_7H_{21}ClN_3P_3$: C, 30.5; H, 7.7; Cl, 12.9; N, 15.2. Found: C, 30.9; H, 7.75; Cl, 13.0; N, 14.8.

Slow pyrolysis of $N_3P_3Me_6{\cdot}MeCl$ at 200 °C/0.1 Torr decomposed the salt and $N_3P_3Me_6$ was collected, in nearly quantitative yield, by sublimation on to a water-cooled cold finger; m.p. 187–188 °C, (lit. (1) 195–195 °C, (5) 187–190 °C (dec.)); i.r. ν(P=N) 1180 cm^{-1} (lit. (1) 1180 cm^{-1}).

Anal. Calcd. for $C_6H_{18}N_3P_3$: C, 32.0; H, 8.0; N, 18.7. Found: C, 32.1; H, 8.0; N, 18.8.

The residue from the acetonitrile extraction (2.76 g) was dried *in vacuo* and recrystallized from hot methanol–chloroform. The hygroscopic solid was identified by its analysis and ^1H n.m.r. spectrum as the diquaternary salt $N_4P_4Me_8{\cdot}2MeCl$ (6.9 mmol, 15%); m.p. >275°; ^1H n.m.r., 60 MHz, (δ, D_2O, internal DSS) 2.93 (6H, triplet, J_{PH} = 11.5 Hz), 2.03 (24H, doublet, J_{PH} = 13.5 Hz); i.r.: ν(P=N), 1350 cm^{-1}.

Anal. Calcd. for $C_{10}H_{30}Cl_2N_4P_4$: C, 29.9; H, 7.5; Cl, 17.7; N, 14.0. Found: C, 29.7; H, 7.7; Cl, 18.0; N, 13.8.

Separation of Hexamethylcyclophosphazene and Octamethylcyclotetraphosphazene

A mixture of $N_3P_3Me_6$ (1.34 g, 5.94 mmol) and $N_4P_4Me_8$ (1.41 g, 4.71 mmol) was dissolved in 200 ml diethyl ether. Hydrogen chloride gas was bubbled through the solution until precipitation of the methylphosphazene hydrochlorides was complete. The resulting white precipitate was filtered off and dried *in vacuo* (3.36 g). The solid was shaken with 100 ml of hot acetonitrile and the mixture filtered. The residual $N_4P_4Me_8{\cdot}2HCl$ (1.78 g, quantitative) was identified by its i.r. spectrum: ν(P=N) 1282, 1322 cm^{-1} (lit. (2) 1286 cm^{-1}, (4) 1278, 1320 cm^{-1}).

Anal. Calcd. for $C_8H_{26}Cl_2N_4P_4$: C, 25.8; H, 7.0; Cl, 19.0; N, 15.0. Found: C, 25.6; H, 6.8; Cl, 18.9; N, 15.1.

Evaporation of the acetonitrile from the filtrate gave $N_3P_3Me_6{\cdot}HCl$ (1.51 g, 97%) m.p. 247–249 °C: i.r. ν(P=N) 1170, 1230 cm^{-1}.

Anal. Calcd. for $C_6H_{19}ClN_3P_3$: C, 27.5; H, 7.3; Cl, 13.6; N, 16.1. Found: C, 27.3, H, 7.4; Cl, 13.3; N, 16.2.

The neutral methylphosphazenes can be regenerated from their hydrochlorides by treatment with a base; triethylamine (3, 4) and aqueous alkali (2) have both been used.

The C—O and C—S bond lengths of the cations, radicals, and anions CH_3O, CH_3S, CH_2OH, and CH_2SH have been found not to correlate with the overlap populations of the C—X bonds. On the other hand, very satisfactory linear relations are observed with the *ionic* bond orders of the C—X bonds. It is suggested that, in certain molecular systems, it may be more meaningful to associate shortening of a bond A—B with greater coulombic attraction (or smaller coulombic repulsion) between the two point charges represented by the net atomic charges on the atoms A and B than with an increase in the overlap population between these atoms. It is noted that such an interpretation can account for the short C—P bond in a phosphonium ylide without resort to $(p \rightarrow d)_\pi$ conjugation.

MYUNG-HWAN WHANGBO, SAUL WOLFE et FERNANDO BERNARDI. Can. J. Chem. **53**, 3040 (1975).

On a trouvé qu'il n'y a pas de corrélation entre les longueurs des liaisons C—O et C—S des cations, radicaux et anions CH_3O, CH_3S, CH_2OH et CH_2SH et les populations de recouvrement des liens C—X. Par ailleurs on a trouvé qu'il existe des relations linéaires très satisfaisantes avec les ordres de liaison *ionique* des liens C—X. On suggère que, dans certains systèmes moléculaires, il pourrait s'avérer plus significatif d'associer le racourcissement d'un lien A—B avec une attraction coulombique plus grande (ou une répulsion coulombique plus petite) entre les deux charges ponctuelles représentées par les charges atomiques nettes sur les atomes A et B que par une augmentation dans la population de recouvrement entre ces atomes. On note qu'une telle interprétation peut rendre compte de la longueur plus courte de la liaison C—P de l'ylure de phosphonium sans avoir recours à la conjugaison $(p \rightarrow d)_\pi$.
[Traduit par le journal]

One of the important objectives of bonding theory is to relate the length of a chemical bond to some property of the atoms that form this bond. For the most part, theoretical (1) and empirical (2) approaches to this problem have assumed that the length of the bond A—B can be correlated with some property related to the electron distribution *between* the nuclei A and B. In π-electron theories, this property of the charge distribution has been taken to be the covalent bond order (3) of the bond population (4), and very good linear relations are observed between covalent bond orders and bond lengths (2*a*, 5). In LCAO–MO theories, which take overlap into account explicitly, the overlap population (6) has commonly been employed as a measure of the covalent bond order. However, the precise relationship between these two quantities is not clear, as can be seen from the number of definitions of bond order that exist (3, 4, 6, 7).

Ideally, any property of the atoms A and B that is to rationalize the length of the bond A—B should be permitted to vary as the molecular environments of A and B are varied. However, although r_{AB} is known to depend upon whether A and B are neutral, positive, or negative (8, 9), systematic studies of such bond length alterations, and the properties of A and B to which these alterations might be related, appear to be lacking.

In connection with other work, we have recently performed *ab initio* SCF–MO computations on the anion (10), radical (11), and cation (12) species CH_3X and CH_2XH, as well as

*Experimental value from Ivash and Dennison (21).
†Values in parentheses are taken from Yarkony *et al.* (20).

the neutral molecules CH_3XH, in which X is sulfur and oxygen. Restricted and unrestricted Hartree–Fock formalisms (13) were employed to calculate the total energies of closed shell and open shell species, respectively. In each case, the geometry was optimized by minimization of the total energy with respect to all bond lengths, valence angles, and dihedral angles. Table 1 summarizes the optimized C—O and C—S bond lengths of these systems (r_{BC}) and, in addition, lists q_i, the net atomic charge on the ith atom (or group of atoms) and p'_{BC}, the ionic bond order.[1]

The data of Table 1 permit the relationship between lengths and overlap populations of C—O and C—S bonds in different environments to be examined. In the two series CH_2OH (cation, radical, and anion) and CH_3S (cation, radical, and anion), the C—X bond length decreases as its overlap population increases. In these cases, therefore, overlap population seems to be a reliable measure of the bond order. However, in the series CH_3O and CH_2SH, no correlation between these quantities is evident.

The ionic bond order of the bond A—B is defined (14) as $p'_{AB} = -q_A q_B / r_{AB}$. This quantity represents the interaction energy of the net charges on atoms A and B and is attractive when $p'_{AB} > 0$, and repulsive when $p'_{AB} < 0$. Figure 1 shows plots of C—X bond length *vs.* ionic bond order for each of the series CH_3X and CH_2XH. In contrast to the absence of a uniform correlation with overlap population, there is in all cases a fairly good linear relation between r_{CX} and p'_{CX}. These findings indicate that, in each series, it may be physically more meaningful to associate a shorter C—X bond length with greater coulombic attraction (or smaller coulombic repulsion) between the two point charges represented by the net atomic charges on the atoms C and X than with an

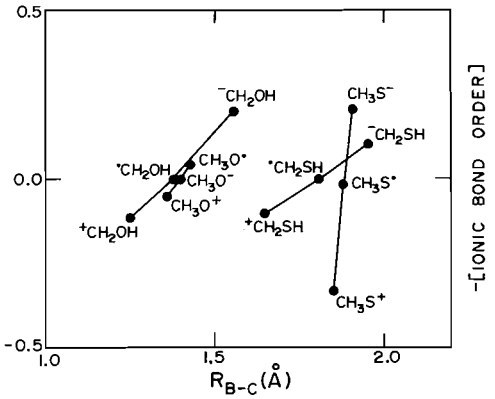

FIG. 1. The relationship between ionic bond order and C—X bond length in the various species CH_3X and CH_2XH (X = O, S). Data taken from Table 1.

[1]In the present work, the C—O bond length of CH_3O is computed to be 0.005 Å shorter than that of methanol. A recent study by D. R. Yarkony *et al.* (20) finds the C—O bond of CH_3O to be longer than that of methanol by 0.006 Å.
