A second mechanism for oxazoline formation involves the intervention of the unsaturated azetidinone **18** when **13** (R = $PhCH_2$) is dissolved in aqueous bicarbonate; in this case, cyclization to the oxazoline must generate the *R* configuration at the new asymmetric center, because the *trans*-fused bicyclic system is sterically impossible. Although, as discussed earlier, unsaturated azetidinones are hypothesized but not proven intermediates in the chlorinolysis, their formation in other types of reactions seems more secure. Thus, Corbett and Stoodley (17) have found that the oxazoline **19** is converted into *trans*-disubstituted azetidinones **20***a* upon treatment with alcohols in the presence of trace amounts of *p*-toluenesulfonic acid, or with various carboxylic acids and thioacids. More recently, the same workers (18) have observed that alkanethiols react with **19** to give mixtures of **20***a* and **20***b*. *Cis–trans* mixtures of 2-alkyloxy or acyloxyazetidinones were also obtained following reaction of either epimer of **21** with alcohols or carboxylic acids in the presence of Lewis acid catalysts (10*d*). It is evident that, under solvolytic conditions, there is a significant driving force for

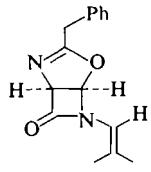
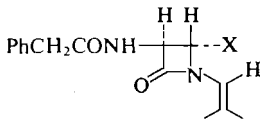
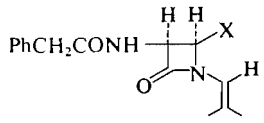
18



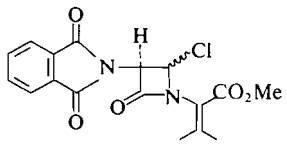
19



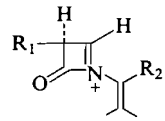
20*a*



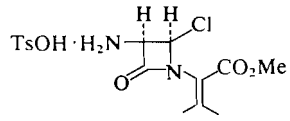
20*b*



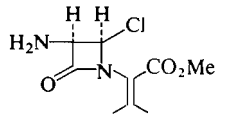
21



22



23



24

the cleavage of the C—O or C—Cl bonds of these azetidinones to form the cations **22**.

The conversion of **13** (R = $PhCH_2$) to **6** (R_1 = $PhCH_2$; R_2 = H) is performed in aqueous bicarbonate, a medium in which solvolytic cleavage of the C2—Cl bond is expected to be facilitated. The oxaanhydropenicillin **14** (R = $PhCH_2$) cannot be detected among the products of this reaction, even after a 1 min reaction time, at which point **13** has disappeared. We therefore consider that the cyclization of **13** (R = $PhCH_2$) to **6** (R_1 = $PhCH_2$; R_2 = H) proceeds via an unsaturated azetidinone intermediate. The cyclization of **17** on silica gel or alumina columns requires an analogous explanation, because oxaanhydropenicillin formation is precluded in the absence of a free carboxyl group.

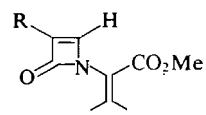
Compound **17** was synthesized either from **13** (R = $PhCH_2$) by methylation, or from **7** in three steps: (*i*) reaction with methanol at 0° to give **23** (67% from **5** (R = *p*-TsOH·H_2N)); (*ii*) bicarbonate (**23** → **24**); (*iii*) phenylacetylation of the free base (80%). The *trans*-2-chloro-3-aminoazetidinone **15** was obtained as the predominant epimer (5:1–6:1 by n.m.r.) following equilibration of **23** or **24** in chloroform solvent in the presence of excess tetramethylguanidinium chloride (**24** ⇄ **15**).

Four mechanisms can be considered for this and similar epimerizations (10*a*). Since what is actually observed by n.m.r. is not necessarily the interconversion of **15** and **24** but, rather, the interconversion of geometrical isomers, and C6 epimerization of penicillin (corresponding to C3 of these azetidinones) is well known (19), the reaction may, in principle, proceed by epimerization either at C2 or C3. Further, since unsaturated azetidinones of type **25** are also known (20), an elimination–addition sequence is also possible. However, **25** is achiral in this case and its intervention would lead to optically inactive products; this is not observed. Both the *cis* and *trans* isomers resulting from the epimerization reactions are optically active and have the same rotation as the materials prepared by chlorinolysis of the anhydropenicillins. This latter observation also rules out *cis–trans* isomerization by epimerization at C3. A third epimerization mechanism involves the unsaturated azetidinone **22**. In this case, however, generation of the cation **22** in the presence of a second nucleophile would be expected to afford two pairs of *cis–trans* isomers (10*d*). This is also not observed. Reaction of **15** with tetramethylguanidinium *azide* (21) leads smoothly to **26**, and **24** reacts similarly to give **27**.

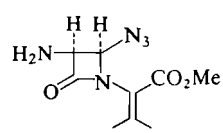
It must be concluded, therefore, that, in methylene chloride or chloroform solvents, epimerization and nucleophilic substitution at C2 of these 2-chloroazetidinones proceeds by an S_N2 mechanism, with inversion of configuration. It thus appears likely that, depending upon the experimental conditions, either stereospecific or nonstereospecific substitution can be achieved at the C2 position of these azetidinones.

Hydrolytic Opening of the Oxazoline Ring

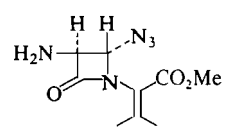
As noted above, Corbett and Stoodley (17) have found that treatment of **19** with *p*-toluenesulfonic acid in chloroform, alcohol, carboxylic



25



26



27

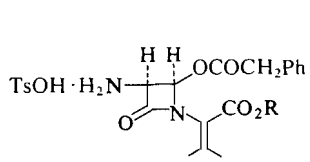
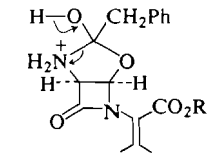
acid, or thioacid solvents leads to opening of the five-membered ring at the C5—O bond. We find that, in acetone solvent, the reaction takes a different course. As noted by Koe (22), the fact that *p*-toluenesulfonic acid is a monohydrate allows ready hydrolysis of acid-labile groups simply by addition of this reagent to the substrate *in acetone solvent* (11*b*). We considered that the analogous reaction in the case of **6** would consist of acid-promoted hydration of the imino group. In deuteroacetone solvent, the n.m.r. spectrum of **6** (R_1 = $PhCH_2$; R_2 = CH_3) shows, among other peaks (see Experimental), two doublets (J = 3.8 Hz) at 5.20 and 5.98 p.p.m. The doublet at 5.20 is assigned to the azetidinone proton geminal to nitrogen because it is coupled further (J = 0.5 Hz) to the methylene protons of the benzyl group. The doublet at 5.98 is assigned to the azetidinone proton geminal to oxygen. Addition of 1 molar-equiv. of *p*-toluenesulfonic acid monohydrate to this solution causes an immediate (< 1 min) change in the n.m.r. spectrum, characterized most noticeably by a downfield shift of the azetidinone proton geminal to oxygen. This new spectrum is not that of the *p*-toluenesulfonic acid salt of the oxazoline because neutralization of the solution does not regenerate this compound.

For preparative work, the oxazolines **6** (R_1 = $PhCH_2$; R_2 = CH_3 or CH_2Ph) were allowed to react with *p*-toluenesulfonic acid hydrate in dry acetone, and the solvent was then removed. In each case, a crystalline residue was obtained; recrystallization from acetone–hexane afforded the azetidinone **28** (R = CH_3) in 60% yield, and the azetidinone **28** (R = CH_2Ph) in quantitative yield. The compounds were identified by their spectroscopic properties (see Experimental) and by their chemical reactions, discussed below. Hydrogenolysis of **28** (R = CH_2Ph) produced the amino acid salt **28** (R = H). This novel procedure for hydrolytic ring opening of an oxazoline is presumed to involve the intermediate formation of the hydroxyoxazolidinium cation **29**, with the positive charge on nitrogen then directing the cleavage of the C—N bond, as shown.

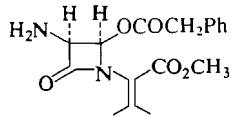
Neutralization of **28** (R = CH_3) and acylation of the free base **30** with benzoyl chloride or phenylacetyl chloride gave the diacylated azetidinones **31** (R = Ph, $PhCH_2$). It is known (23) that neutralization of the salt of a β-acyloxyethylamine does not lead to a β-acyloxyethylamine



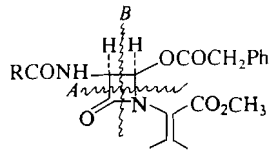
28



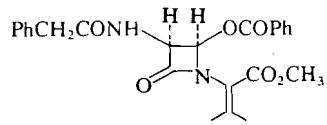
29



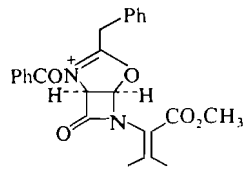
30



31



32



33

but, rather, to a β-acylaminoethanol. The O → N acyl transfer is intramolecular and proceeds via the cyclic hydroxyoxazolidine, so that the rate of the process in any given case depends upon the ease of formation of the five-membered ring intermediate. The structure of **31** (R = $PhCH_2$) is, therefore, secure, but it was necessary to prove that the benzoylation of **30** had given the *N*-benzoyl derivative **31** (R = Ph) and not its *O*-benzoyl isomer **32**. The spectroscopic properties of the compound were ambiguous; in particular, in the mass spectrum, fragmentation occurred principally by path *A* to give a parent ion of mass 281 which retains both acyl groups. The alternative fragmentation, by path *B*, was not observed. However, benzoylation of **6** (R_1 = $PhCH_2$; R_2 = CH_3), followed by hydrolysis of the *N*-benzoyloxazolinium salt **33** (24), afforded an *N*-benzoyl compound which was identical in all respects with the material prepared from **30**.

The neutralization of **28** (R = CH_3) thus proceeds without O → N acyl transfer. This is not

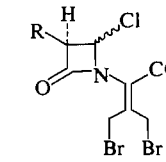
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

surprising; the acyl transfer is expected to be slow in this case because the reaction must take place via an intermediate hydroxyoxazolidine which is fused to the four-membered azetidinone ring. Indeed, delaying the benzoylation step for periods up to 5 h following the generation of **30** did not cause a change in the course of the reaction.

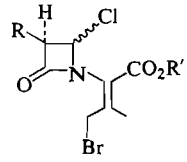
Oxidation and Rearrangement of ***28***

The methyl groups of azetidinones derived from **10** can be functionalized with *N*-bromosuccinimide (NBS) (10*b*). Either dibromo compounds (**34**) or approximately 1:1 mixtures of monobromo compounds (**35** and **36**) are obtained, depending on whether 2 molar-equiv. or 1 molar-equiv. of the reagent is employed. The azetidinones **28** were found to exhibit similar behaviour but some difficulty was experienced initially with the stoichiometry because the functionalization of the methyl group of the toluenesulfonate anion proceeded preferentially. Thus, 2 molar-equiv. of NBS were needed to generate the mixture **37** + **38** (R = *p*-$BrCH_2C_6H_4SO_3H$) and 3 molar-equiv. of NBS were needed to generate **39** (R = *p*-$BrCH_2C_6H_4SO_3H$). Although this result does not cause problems with the subsequent reactions of these compounds, alternative routes to these systems were sought. One consisted of bromination of the oxazoline **6** prior to the hydrolytic ring opening. However, although the allylic methyl groups were functionalized, the alpha carbon atom of the C2 substituent (*i.e.*, R_1) underwent substitution at the same time. A second and more successful alternative consisted of bromination of *benzenesulfonic* acid salts (**28**, $PhSO_3H$ in place of *p*-TsOH). These latter compounds could be prepared either from **30** or by reaction of **6** with the hydrate of benzenesulfonic acid in dry acetone.

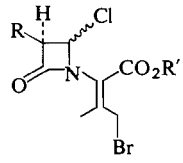
Exposure of the mixture **37** + **38** to 2 molar-equiv. of triethylamine in methylene chloride solvent caused a rapid and deep-seated rearrangement to a crystalline compound $C_{17}H_{18}N_2O_5$, to which structure **40** is assigned. The i.r. and n.m.r. spectra of the crude product, obtained in 94% yield, were identical to those of the crystalline material isolated in 64% yield following chromatography. The compound is optically inactive, shows amide and ester absorption in the i.r., and the n.m.r. spectrum in deuteriochloroform displays two broad one-



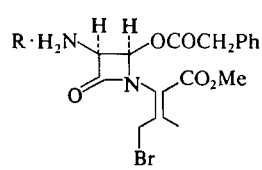
34



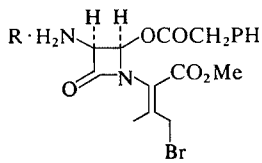
35



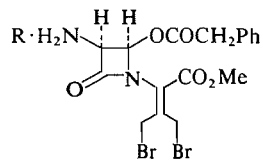
36



37



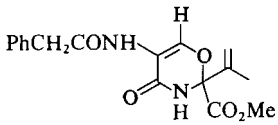
38



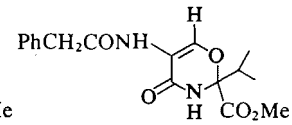
39

proton singlets at 6.80 and 7.43 p.p.m. which exchange with D_2O. The n.m.r. spectrum also contains, in addition to phenylacetyl and methoxycarbonyl signals, a one-proton singlet at 8.24 and a slightly broadened two-proton doublet at 5.21 and 5.26 coupled to a slightly broadened three-proton singlet at 1.84 p.p.m. The compound is stable to the action of excess acetyl chloride, indicating the absence of hydroxyl groups, and it affords a dihydro derivative **41** upon catalytic hydrogenation. The n.m.r. spectrum of this latter compound reveals the presence of an isopropyl group while retaining the phenylacetyl and methyl peaks and the one-proton singlet at low field. Consequently **40** must contain an isopropenyl group, a methoxycarbonyl group, a phenyl*acetamido* group, and an additional amide proton. The structure shown is consistent with all of these data.

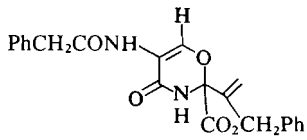
Since the 1:1 mixture of **37** + **38** affords **40** in greater than 50% yield, it follows that both geometrical isomers have rearranged to the same compound, presumably via a common intermediate. It is also evident that the rearrangement proceeds with O → N acyl transfer. Scheme 1 illustrates, for the *E* isomer **37**, the mechanism proposed for this reaction, and for the analogous result in the benzyl ester series, which affords the



40



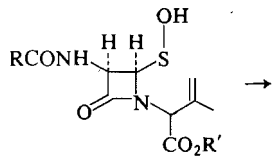
41



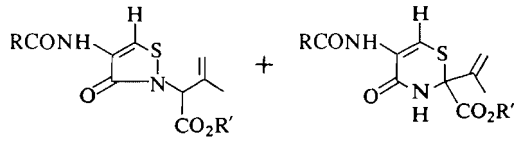
42

oxazinone **42**. Neutralization of **37** gives the free base **43** which, *in contrast to the unbrominated base 30*, undergoes acyl transfer to yield **44**; the second equivalent of triethylamine now induces fragmentation of this carbinolamide (25) to give the aldehyde **45**, which eliminates bromide ion to form the dehydroacylimine **46**. Application of the same reaction sequence to the *Z* isomer **38** also leads to **46**, which cyclizes to **40** via the enol tautomer **47**.

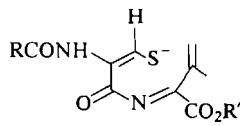
There is precedent for the sequences just proposed in the behaviour of the unsaturated sulfenic acids **48** (26), which are intermediates (27) in the Morin reaction. Among the products of this rearrangement are the isothiazolone **49**



48



49 50



51

and the thiazinone **50**, the sulfur analog of the oxazinone **40**. The isothiazolone rearranges to **50** upon treatment with base (28) and the intermediate proposed for this rearrangement is the acylimine **51**, the sulfur analog of **47**.

Acylimines have recently been the subject of much discussion, in connection with partial

syntheses of cephamycin derivatives (29), and as the hypothetical intermediates in penicillin biosynthesis (30, 31). The present work, in conjunction with the studies of Morin *et al.* (26, 28, 30*a*, 32) and Baldwin *et al.* (30*b*), may permit the development of rational procedures for the study of these compounds under non-enzymatic conditions.

Experimental

Melting points were obtained on Fisher-Johns or Mel-Temp equipment and are uncorrected. Nuclear magnetic resonance (n.m.r.) spectra were recorded on Varian A60 or T60 or Bruker HX60 spectrometers; TMS and TSS were employed as internal standards, and all spectra were obtained in $CDCl_3$ or D_2O, unless stated otherwise. Chemical shifts are reported as p.p.m. downfield from the internal standard. Infrared (i.r.) spectra were recorded on Beckman 5A or Perkin Elmer 180 spectrometers; data from the Beckman instrument are reported in microns, and those from the Perkin Elmer instrument are reported in cm^{-1}. Column chromatography was performed on Woelm alumina (neutral, Activity II), or on Silica Gel 60, obtained from Brinkmann Instruments. Thin-layer chromatography was performed on Eastman Chromatoplates; preparative-layer chromatography (p.l.c.) was performed on Merck precoated t.l.c. plates having a 0.25 mm layer thickness. Optical rotations were measured on a Perkin Elmer Model No. 141 Polarimeter.

Chlorination of **5** *(R = p-TsOH·H_2N)*

The salt (328 mg, 0.89 mmol) was suspended in methylene chloride (30 ml), the mixture cooled to 0°, and gaseous chlorine was introduced for 15 s. Dry nitrogen was passed through the resulting yellow solution for 15 min to remove excess chlorine and the solution was evaporated to dryness. Trituration of the residue with dry ether afforded a quantitative yield of **7**. This material was a stable (below 20°) white powder, m.p. 148–149° dec. The i.r. spectrum showed peaks at 5.55 and 5.62 μ. The 2′*R* isomer (formed in 80% yield) showed n.m.r. absorption ($CDCl_3$) at 7.80 (2H, d), 7.20 (2H, d) 5.98 (1 H, d, 4.2 Hz), 5.18 (1 H, d, 4.2 Hz), 2.37 (3 H), 2.20 (3 H), 2.00 (3 H). (The NH_2 protons were not observed.) The 2′*S* isomer (formed in 20% yield) showed n.m.r. absorption at 7.80 (2 H, d), 7.20 (2 H, d), 5.18 (2 H, m), 2.37 (3 H), 2.17 (3 H), 2.00 (3 H).

Chlorination of anhydro-6-tritylamino penicillin, the precursor of the *p*-toluenesulfonic acid salt, was unsuccessful using Cl_2, SO_2Cl_2, pyrrolidone hydrotrichloride, pyridinium trichloride, PCl_5, and $(C_6H_5O)_3PCl$. In each case a reaction of the desired type occurred but the trityl group was then lost and the product decomposed.

Hydrolysis of **7** *to* **11**

The salt (200 mg) was chlorinated as described above and, after removal of the solvent, the residue was maintained under high vacuum for 30 min. It was then dissolved in a mixture of D_2O (2 ml) and CD_3COCD_3 (2 ml), cooled to 0°, and the n.m.r. spectrum was recorded at intervals. Hydrolysis was complete after 3 h, and the solvent was, therefore, removed by lyophilization. The resulting foam was redissolved in D_2O. The n.m.r. spectrum of this solution indicated that quantitative conversion to a 4:1 mixture of 2′*R*:2′*S* chloro acids had been achieved. The 2*R*-chloro acid showed n.m.r. absorptions at 7.63 (2H, d), 7.22 (2H, d), 6.22 (1H, d, 4.0 Hz), 5.07 (1H, d, 4.0 Hz), 2.23 (3H), 2.12 (3H), 1.91 (3H). The epimeric 2′*S*-chloro acid had n.m.r. absorption at 7.63 (2H, d), 7.22 (2H, d), 5.47 (1H, d, 2.0 Hz), 5.43 (1H, d, 2.0 Hz), 2.23 (3H), 2.02 (3H), 1.76 (3H).

Phenylacetylation of **11**

The *p*-toluenesulfonic acid salt of anhydro-6-amino penicillin (242 mg, 0.65 mmol) was chlorinated and the product hydrolyzed in aqueous acetone as already described. To the resulting solution (volume 20 ml) at 0° was added in portions sodium bicarbonate (275 mg, 3.27 mmol) followed by a solution of phenylacetyl chloride (152 mg, 0.98 mmol) in acetone (5 ml) in one portion. The mixture was stirred for 30 min and then diluted with water and extracted with methylene chloride; this extract was discarded. The aqueous phase was brought to p*H* 3 and extracted with methylene chloride. This extract was dried over anhydrous magnesium sulfate and evaporated to give **13** (R = $PhCH_2$).

Conversion of **7** *to the Methyl Ester* **23**

The anhydropenicillin salt **5** (3.80 g, 10.3 mmol) was suspended in methylene chloride (150 ml), the mixture was cooled to −5°, and a slow stream of dry nitrogen was passed through it. Gaseous chlorine was passed into the mixture for 30 s and the nitrogen stream was then continued for 15 min. Methanol (75 ml) was added and the resulting yellow solution was swept with nitrogen at 0 °C for 20 min. The cooling bath was then removed and, after 15 min, the solvent was removed under reduced pressure at 25°. The residue was treated with 5 ml of methylene chloride and the resulting solution was re-evaporated; this procedure was repeated three times and at this point the pale yellow foam had no odor of chlorine or HCl. The foam was dissolved in dry acetone, the orange solution was filtered to remove a small amount of insoluble material, and petroleum ether (30–60°) was added to the cloud point. A few drops of acetone were then added to clarify the solution and crystallization was allowed to proceed at 10 °C. The white crystals thus obtained were washed with cold 1:1 acetone – petroleum ether and dried in vacuo. The yield was 2.7 g (67%), m.p. 125–130° dec.

Anal. Calcd. for $C_{16}H_{21}N_2O_6Cl$: C, 47.48; H, 5.23. Found: C, 47.62; H, 5.54.

The n.m.r. spectrum shows peaks at 7.78 (2H, d), 7.10 (2H, d), 5.98 (1H, d, 4.0 Hz), 5.13 (1H, d, 4.0 Hz), 3.52 (3H), 2.35 (3H), 2.22 (3H), 1.85 (3H).

Neutralization of **23**

The methyl ester, in methylene chloride (50 ml), was shaken with ice-cold sodium bicarbonate solution. Evaporation of the methylene chloride layer gave the free base, a crystalline compound, m.p. 67–70° dec. The compound was not stable in the solid state and darkened perceptibly after 10 min at room temperature.

The n.m.r. spectrum of the compound has peaks at 6.03 (1H, d, 4.1 Hz), 4.62 (1H, d, 4.1 Hz), 3.78 (3H), 2.30 (3H), 2.00 (3H). The position of the NH_2 protons varies with time; although these peaks shift, no other changes occur in the spectrum. The i.r. spectrum of the com-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

pound has peaks at 2.94, 5.60, 5.80, 6.12 μ which (in CH_2Cl_2) do not change with time.

Chlorination of Anhydrobenzylpenicillin (5, R = $PhCH_2CONH$)

Anhydropenicillin G (176 mg, 0.56 mmol) was dissolved in methylene chloride (7 ml) and the solution was chlorinated at room temperature for 30 s with a strong sweep of chlorine. The solvent was then removed immediately at 20° under reduced pressure to give a pale yellow foam. The i.r. spectrum of this foam showed peaks at 2.92, 5.5, 5.95 μ. The n.m.r. spectrum showed that the product was a 4:1 mixture of 2-(2′*R*-chloro-3′*S*-phenylacetamido-4′-oxo)azetidinyl-3-methyl-2-butenoyl chloride and its 2′*S* epimer. The major isomer has the following n.m.r. spectrum: 7.29 (5H), 6.93 (1H, d, 9 Hz), 6.03 (1H, d, 4.5 Hz), 5.48 (1H, q, 4.5, 9 Hz), 3.63 (2H), 2.22 (3H), 2.08 (3H). The minor isomer has peaks at: 7.29 (5H), 6.93 (1H, d, 9 Hz), 5.88 (1H, d, 2 Hz), 4.83 (1H, q, 2, 9 Hz), 3.56 (2H), 2.22 (6H).

Synthesis of 13 (R = $PhCH_2$) from Anhydrobenzylpenicillin

The above-mentioned mixture of dichlorides (from 176 mg of anhydropenicillin) was dissolved in acetone (6 ml) and water (4 ml) was added followed, at 0°, by excess sodium bicarbonate. The mixture was stirred for 2.3 h and then diluted with water (50 ml) and extracted thrice with methylene chloride and once with ether. Acidification of the aqueous phase to p*H* 2.5, extraction with methylene chloride and evaporation of the dried methylene chloride extract afforded 36 mg of an oil whose i.r. and n.m.r. spectra indicated it to consist mainly of unhydrolyzed acid chloride.

In a second experiment anhydropenicillin G (105 mg) was chlorinated; the resulting white foam was dissolved in ice-cold tetrahydrofuran (3 ml), and cold water (1 ml) was added. The clear yellow solution was maintained at 0° for 2 h and then poured into a mixture of water and ice, and extracted with methylene chloride. Evaporation of the dried methylene chloride extract afforded 113 mg (98%) of a chloro acid whose i.r. and n.m.r. spectra showed it to have structure **13**, R = $PhCH_2$. The i.r. spectrum showed peaks at 3.05, 5.62, 5.90, 5.95 μ. The n.m.r. spectrum showed peaks at 7.28 (5H), 6.90 (1H, d, 8 Hz), 6.07 (1H, d, 4.5 Hz), 5.58 (1H, q, 4.5, 8 Hz), 3.68 (2H), 2.28 (3H), 1.99 (3H).

In a third experiment, the chloro acid from 333 mg of anhydropenicillin G was treated in ether with an excess of ethereal diazomethane. The solution was stirred for 2 h at room temperature and then evaporated to dryness. The residue was left in the refrigerator overnight and then, in methylene chloride, shaken with 5% bicarbonate, dried and evaporated. The residue was chromatographed on silica gel; elution with 1:1 petroleum ether – ethyl acetate afforded 189 mg (51%, m.p 110.5–111°) of the methyl ester and 40 mg (12%) of the oxazoline **6** (R_1 = $PhCH_2$; R_2 = CH_3).

Chlorination of Anhydrocarbobenzoxypenicillin (5, R = $PhCH_2OCONH$)

The anhydropenicillin (470 mg, 1.47 mmol) was chlorinated in methylene chloride for 15 s. After an additional 30 s the solvent was removed to give a white foam which consisted of a 77:23 mixture of dichlorides, the compound having the 2′*R*-chloro configuration predominating. The n.m.r. spectrum of this compound has peaks at 7.31 (5H), 6.86 (1H, d, 9 Hz), 6.07 (1H, d, 4 Hz), 5.25 (1H, q, 4.9 Hz), 5.17 (2H), 2.20 (3H), 2.10 (3H). The minor isomer has peaks at 7.31 (5H), 6.86 (1H, d, 9 Hz), 5.90 (1H, d, 2 Hz), 5.16 (2H), 4.83 (1H, d, 2 Hz), 2.20 (6H).

Hydrolysis of the Anhydrocarbobenzoxypenicillin Chlorination Product

The dichloride (a 77:23 2′*R*:2′*S* mixture from 470 mg of the anhydropencillin) was dissolved in cold tetrahydrofuran (10 ml), and ice-cold water (1 ml) was added. The mixture was left for 3 h at 0° and then added to ice-cold saturated sodium chloride solution. Extraction with methylene chloride and evaporation of the dried methylene chloride extract afforded 535 mg of the chloro acids. The major isomer has peaks at 7.32 (5H), 6.37 (1H, d, 10 Hz) 6.13 (1H, d, 4 Hz), 5.45 (1H, q, 4, 10 Hz), 5.17 (2H), 2.28 (3H), 2.02 (3H).

Chlorination of Anhydro-6-phthalimidopenicillin (5, R = phthalimido)

Chlorine gas was passed at room temperature into a solution of anhydro-6-phthalimidopenicillin (500 mg, 1.52 mmol) in methylene chloride (15 ml). The gas introduction was terminated after 3 min and, after an additional 5 min, the yellow solution was evaporated to dryness. The resulting white foam was crystallized from a mixture of chloroform and petroleum ether to give a total of 250 mg (32%) of material in two crops, m.p. 210° dec. The i.r. spectrum of the residual mother liquor was identical to that of the crystalline material, summarized below.

Anal. Calcd. for $C_{16}H_{12}N_2O_4Cl_2$: C, 52.3; H, 3.31; N, 7.69; Cl, 19.4. Found: C, 52.03; H, 2.96; N, 7.76; Cl, 19.53.

The i.r. spectrum shows peaks in the carbonyl region at 5.48, 5.55, 5.62, and 5.79 μ. The n.m.r. spectrum shows peaks at 7.87 (4H), 6.22 (1H, d, J = 4.2 Hz), 5.76 (1H, d, J = 4.2 Hz), 2.40 (3H), 2.31 (3H). The u.v. spectrum shows λ_{max}(EtOH) 242 (10 000).

Hydrolysis of the Anhydrophthalimidopenicillin Chlorination Product

The dichloride (500 mg, 1.36 mmol), in dimethyl sulfoxide, (500 ml) was treated, dropwise at 0°, with 50 ml of a p*H* 7.95 buffer (prepared by diluting 50 ml of 0.1 *M* boric acid and 2.6 ml of 0.1 *M* NaOH to 100 ml). At the end of the addition, the p*H* of the reaction mixture was 6.8. This mixture was allowed to warm to room temperature, and stirring was continued for 3.25 h. Then ice-cold water (300 ml) was added, the mixture brought to p*H* 3 with ice-cold *N* HCl, and extracted with five 100 ml portions of methylene chloride. The combined extracts were washed twice with water (100-ml portions) and dried over anhydrous sodium sulfate. Evaporation under reduced pressure at 40° afforded a mobile liquid which contained a considerable amount of DMSO. This was redissolved in chloroform (60 ml) and the solution washed 10 times with water (10-ml portions). After drying and evaporation there was obtained from the chloroform phase 0.59 g of a crystalline white solid. This was recrystallized from a mixture of chloroform and petroleum ether giving a total of 350 mg (73%) of short white needles, m.p. 168–174° dec.

Anal. Calcd. for $C_{16}H_{13}N_2O_5Cl$: C, 55.05; H, 3.76; N, 8.02; Cl, 10.02. Found: C, 54.65; H, 3.79; N, 8.46; Cl, 10.53.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

The i.r. spectrum shows peaks in the carbonyl region at 5.52, 5.60, 5.80, and 5.85 μ. The n.m.r. spectrum shows peaks at 7.87 (4H), 6.22 (1H, d, J = 4.1 Hz), 5.71 (1H, d, J = 4.1 Hz), 2.33 (3H), 2.31 (3H). The u.v. spectrum shows λ_{max}(EtOH) 236 (7400), 296 (1800).

Conversion of the Acid to the Methyl Ester

The acid (200 mg, 0.57 mmol) was dissolved in 30 ml of a 1:1 mixture of methylene chloride and ether. The solution was cooled and treated with excess ethereal diazomethane. The solution which resulted was stirred for 0.5 h, allowed to warm to room temperature during an additional 1 h, and then evaporated at 40° to a white crystalline residue. Recrystallization from a mixture of chloroform and petroleum ether gave 0.20 g (97%) of colorless fine needles, m.p. 178–180° dec.

Conversion of the Acid Chloride to the Methyl Ester

The crystalline acid chloride (500 mg, 1.43 mmol) was dissolved in methylene chloride (10 ml) and absolute methanol (10 ml) was added. The mixture was stirred at room temperature for 30 min, then diluted with methylene chloride (50 ml) and washed successively with ice-cold 5% bicarbonate solution (10 ml) and water. After drying over anhydrous magnesium sulfate and removal of the solvent a crystalline residue was obtained. This was recrystallized from methylene chloride – petroleum ether to give 463 mg (93%) of methyl ester identical to that described above.

Anal. Calcd. for $C_{17}H_{15}N_2O_5Cl$: C, 56.3; H, 4.16; N, 7.71; Cl, 9.78. Found: C, 56.58; H, 4.37; N, 7.55; Cl, 9.82.

The n.m.r. spectrum shows peaks at 7.90 (m, 4H), 6.23 (1H, d, J = 4.1 Hz), 5.77 (1H, d, J = 4.1 Hz), 3.82 (3H), 2.43 (3H), 2.34 (3H).

Direct Conversion of Anhydro-6-phthalimidopenicillin into a Mixture of Methyl 2-(2′R-Chloro-3′S-phthalimido-4′-oxo)azetidinyl-3-methyl-2-butenoate and its 2′S Epimer

Chlorine gas was passed at room temperature into a solution of anhydro-6-phthalimidopenicillin (1.0 g, 3.04 mmol) in methylene chloride (30 ml). After 3 min the gas introduction was terminated and, after an additional 5 min, the solvent was removed under reduced pressure at 30°. The solid residue was redissolved in methylene chloride (20 ml) and absolute methanol (20 ml) was added. This solution was stirred at room temperature for 30 min and then evaporated to dryness under reduced pressure at 40°. The residue was crystallized from chloroform – petroleum ether to give 600 mg (55%) of the ester having the 2′*R*-chloro configuration. The mother liquor was chromatographed on a 1.5 × 14 cm column of alumina (Woelm, grade II). Elution with 1:1 methylene chloride – benzene afforded 202 mg (18%) of a new compound in the first 25 ml, followed by 93 mg of a mixture of the 2′*R* ester and the new compound in the next 25 ml. Elution with methylene chloride (40 ml) then afforded an additional 68 mg of the 2′*R* ester.

The new compound was crystallized from methylene chloride – petroleum ether to give the ester having the 2′*S*-chloro configuration, m.p. 192–194°.

Anal. Calcd. for $C_{17}H_{15}N_2O_5Cl$: C, 56.3; H, 4.16; N, 7.71; Cl, 9.78. Found: C, 56.42; H, 4.43; N, 7.68; Cl, 9.60.

The n.m.r. spectrum shows peaks at 7.83 (4H, m), 6.23 (1H, d, J = 2.0 Hz), 5.60 (1H, d, J = 2.0 Hz), 3.83 (3H), 2.30 (3H), 2.08 (3H).

When chlorination was performed for 10 s with a slow stream of chlorine, and the mixture then immediately evaporated to dryness, a single new compound was obtained. The n.m.r. spectrum of this new compound showed peaks at ($CDCl_3$) 7.9 (4H, d), 5.99 (2H, s), 2.40 (3H), 2.36 (3H). In CD_3COCD_3 the two-proton singlet at 5.99 showed slight splitting to a doublet. The compound is assigned structure **9**. That it is an intermediate in the chlorination of the anhydropenicillin was shown by its conversion, on standing, to the 2′*R* and 2′*S* dichlorides.

Equilibration of Methyl 2-(2′R-Chloro-3′S-phthalimido-4′-oxo)azetidinyl-3-methyl-2-butenoate and its 2′S Epimer

Starting with the 2′R Isomer

The pure 2′*R* ester (100 mg, 0.28 mmol) was added to a warm solution of tetraethylammonium chloride (95.2 mg, 0.57 mmol; 2 molar-equiv.) in acetone (15 ml). The solution was refluxed for 2 h, and then cooled to room temperature and poured onto a mixture of water and ice. Extraction with methylene chloride, followed by washing of the extract with water, drying over anhydrous magnesium sulfate, and evaporation afforded a crystalline residue. The n.m.r. spectrum of this residue was identical to that of the starting material except for the appearance of a weak doublet at 5.6 (J = 2 Hz). The substance was therefore redissolved in acetone containing tetraethylammonium chloride (95.2 mg), and refluxing was continued for an additional 14 h. Isolation in the same manner as described above afforded a residue whose n.m.r. spectrum showed it to be a 1:1 mixture of 2′*R* and 2′*S* esters.

The experiment was repeated with 100 mg (0.28 mmol) of the pure 2′*R* ester and 238 mg (5 molar-equiv.) of tetraethylammonium chloride in methyl ethyl ketone (10 ml). After 4 h of refluxing the product was isolated and found to be a 3:2 mixture of 2′*R* and 2′*S* esters. This ratio did not change when the material was refluxed for a further 8.5 h in methyl ethyl ketone containing 5 molar-equiv. of tetraethylammonium chloride.

The experiment was repeated with 100 mg of the pure 2′*R* ester in acetone (15 ml) containing 5 molar-equiv. of tetraethylammonium chloride. After 12 h and after 24 h refluxing a 3:2 2′*S*:2′*R* ratio of esters was observed. The product of a 12 h reaction was chromatographed on alumina (Woelm, grade II). Elution with benzene – methylene chloride (1:1), as already described, afforded 40 mg of the 2′*R* compound in the first 25 ml followed by 34 mg of the 2′*S* compound in the next 45 ml of eluate.

After 6 h in refluxing chloroform (30 ml) containing 5 molar-equiv. of tetraethylammonium chloride, the 2′*R* ester (430 mg) was converted into a 2:1 2′*R*:2′*S* mixture.

Starting with the 2′S Isomer

The 2′*S* ester (40 mg) was refluxed for 12 h in a mixture of acetone (10 ml) and methylene chloride (5 ml) containing 2 molar-equiv. of tetraethylammonium chloride. The product was a 1:2 2′*R*:2′*S* mixture.

Conversion of Methyl 2-(2′R-Chloro-3′S-phthalimido-4′-oxo)azetidinyl-3-methyl-2-butenoate into Methyl 2-(2′S-Azido-3′S-phthalimido-4′-oxo)azetidinyl-3-methyl-2-butenoate

Sodium azide (10.1 mg, 0.16 mmol) was dissolved in DMF (15 ml) by brief warming on the steam bath and to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

this solution was added the methyl ester having the 2′*R*-chloro configuration (50 mg, 0.14 mmol). The resulting solution was stirred at room temperature for 24 h and then diluted with water and extracted with methylene chloride. The methylene chloride extract was washed thoroughly with water, dried over anhydrous magnesium sulfate, and evaporated to dryness. The resulting white crystalline solid was recrystallized from chloroform – petroleum ether to give 42 mg of unreacted 2′*R* ester.

In a second experiment the reaction mixture was heated on the steam bath for 5 h, by which time the color had become a deep yellowish-orange. Isolation of the product as described above afforded 38 mg of a solid residue whose i.r. spectrum showed azide absorption at 4.7 μ and carbonyl peaks at 5.58, 5.62, 5.79, and 5.82 μ. The n.m.r. spectrum showed, in the β-lactam region, one-proton absorptions at 5.78 and 5.29 (d, J = 2.0 Hz).

In a third experiment, sodium azide (20.2 mg, 0.31 mmol) was dissolved in 10 ml of freshly distilled DMF, the 2′*R* ester (100 mg, 0.28 mmol) was added, and the solution was heated for 5 h on the steam bath. The product was isolated in the usual manner and was crystallized from 2-butanone–ethanol to give 25 mg of 2′*S*-azido ester (first crop), m.p. 142–144°.

Anal. Calcd. for $C_{17}H_{15}N_5O_5$: C, 55.29; H, 4.09; N, 18.97. Found: C, 55.45; H, 4.02; N, 18.68.

The n.m.r. spectrum shows peaks at 7.78 (4H, d), 5.78 (1H, d, J = 2.0 Hz), 5.29 (1H, d, J = 2.0 Hz), 3.83 (3H), 2.30 (3H), 2.09 (3H).

In a further experiment sodium azide (20.2 mg, 0.28 mmol) was dissolved in freshly distilled DMF (10 ml) by heating on the steam bath for 0.5 h. Then the 2′*R*-chloro ester (100 mg, 0.28 mmol) was added, followed by an additional 20.2 mg of sodium azide. The resulting mixture was heated at 90° for 3 h, with stirring. Isolation as described above yielded a semi-solid residue which weighed 68.2 mg (67%) and whose n.m.r. spectrum was identical to that described above. Chromatography on a 1 × 2 cm column of alumina (Woelm, grade II) and elution with methylene chloride afforded 62 mg of crystalline material. Recrystallization from methylene chloride – petroleum ether afforded 38 mg in the first crop, m.p. 144–145° (colorless prisms).

Conversion of Methyl 2-(2′S-Chloro-3′S-phthalimido-4′-oxo)azetidinyl-3-methyl-2-butenoate into Methyl 2-(2′R-Azido-3′S-phthalimido-4′-oxo)azetidinyl-3-methyl-2-butenoate

The pure 2′*S*-chloro ester (100 mg, 0.28 mmol) was reacted with sodium azide (2 molar-equiv.) in DMF (10 ml) as in the last experiment described above. Isolation in the same manner afforded 52.2 mg of material. This material was chromatographed on a 4.5 × 1 cm column of alumina (Woelm, activity II). Elution with methylene chloride afforded no material in the first 10 ml followed by 13.0 and 11.1 mg of crystalline material in each of the next 10 ml. Both residues had the same n.m.r. spectrum. They were therefore combined and recrystallized from chloroform – petroleum ether to give 19 mg of colorless needles, m.p. 183–187° dec.

The n.m.r. spectrum shows peaks at 7.90 (4H, d), 5.82 (1H, d, 4.0 Hz), 5.67 (1H, d, 4.0 Hz), 3.90 (3H), 2.53 (6H).

Anal. Calcd. for $C_{17}H_{15}N_5O_5$: C, 55.29; H, 4.09; N, 18.97. Found: C, 55.06; H, 4.25; N, 19.10.

Conversion of ***23*** *into* ***15***

The 2′*R*-chloro-3′*S*-aminotosylate (440 mg, 1.09 mmol) and tetramethylguanidinium chloride (1.387 g, 9.1 mmol, 9 molar-equiv.) were refluxed in spectroscopic grade chloroform (9 ml) for 4.5 h. The solution was then cooled to 0°, washed with ice-cold 5% bicarbonate solution, dried over anhydrous magnesium sulfate, and evaporated to dryness under reduced pressure at 25°. The n.m.r. spectrum of the residue indicated it to be a 5:1 mixture of the 2′*S* and 2′*R* epimers, the predominant isomer being the 2′*S* compound. The n.m.r. spectrum of this compound shows peaks at 5.55 (1H, d, 1.8 Hz), 4.37 (1H, d, 1.8 Hz), 3.82 (3H), 2.30 (3H), 2.00 (3H). The position of the NH_2 protons depends upon the age of the solution.

Complete separation of the two epimers could be achieved by alumina chromatography and elution with 1:1 benzene – ethyl acetate. However, because of the instability of these compounds it was usually more convenient to separate at a later stage.

Conversion of ***23*** *into* ***27***

The crystalline methyl ester having the 2′*R*-chloro-3′*S*-TsOH·H_2N configuration (448 mg, 1.1 mmol) and tetramethylguanidinium azide (347 mg, 2.2 mmol, 2 molar-equiv.) were refluxed for 75 min in 20 ml of anhydrous chloroform. The solution was allowed to cool and excess anhydrous ether was added to precipitate tetramethyl guanidinium chloride, which was removed by filtration. The resulting material, after removal of the solvent, was the desired 2′*S*-azido-3′*S*-amino ester (237 mg, 90%) which appeared pure by t.l.c. and n.m.r. The n.m.r. spectrum had peaks at 5.03 (1H, d, 1.8 Hz), 4.13 (1H, d, 1.8 Hz), 3.80 (3H), 3.00 (2H), 2.28 (3H), 1.98 (3H).

The compound could also be isolated by washing the chloroform reaction mixture with cold water, drying, and evaporating. Tetraethylammonium azide (in various solvents) and sodium azide (in DMF) were less effective for this reaction.

Conversion of ***15*** *into* ***26***

A 4:1 mixture of 2′*S*- and 2′*R*-chloro-3′*S*-amino esters from an epimerization of the 2′*R*-chloro compound (532 mg, 2.29 mmol), and tetramethylguanidinium azide (500 mg, 3.2 mmol), was refluxed in pure chloroform (10 ml) for 4.5 h. The mixture was then washed with ice-cold 5% bicarbonate solution, dried over anhydrous magnesium sulfate, and evaporated to give 465 mg (85%) of a 3.3:1 mixture of 2′*R*- and 2′*S*-azido-3′*S*-amino methyl esters. This mixture was separated by chromatography on neutral alumina (Woelm, activity II). Elution with benzene – ethyl acetate (2:3) afforded the pure 2′*R*-azido-3′*S*-amino ester as a crystalline compound. Recrystallization from chloroform – petroleum ether gave long needles, m.p. 116–117°.

Anal. Calcd. for $C_9H_{13}N_5O_3$: C, 45.19; H, 5.48; N, 29.28. Found: C, 45.42; H, 5.24; N, 28.81.

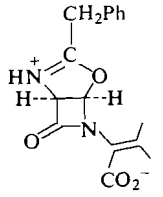
The i.r. spectrum has peaks at 4.72, 5.62 and 5.80 μ. The n.m.r. spectrum shows peaks at 6.03 (1H, d, 4.1 Hz), 5.62 (1H, d, 4.1 Hz), 3.78 (3H), 2.40 (2H), 2.30 (3H), 2.00 (3H).

Conversion of ***13*** *to the Oxazoline* ***6*** *(R_1 = $PhCH_2$; R_2 = H)*

The chloro acid prepared from 640 mg of anhydropenicillin G was dissolved in 5% bicarbonate solution. This was extracted with methylene chloride and then

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

acidified to p*H* 2. Extraction with methylene chloride and evaporation of the dried extract afforded a crystalline residue. Recrystallization from ethyl acetate gave 320 mg (53%) of the oxazoline carboxylic acid, m.p. 119–122° dec. The i.r. spectrum shows a broad peak at 4 μ, as well as peaks at 5.64, 5.92, 6.1 μ, consistent with the zwitterionic structure



The n.m.r. spectrum (in D_2O) shows peaks at 7.33 (5H), 6.12 (1H, d, 3.8 Hz), 5.25 (1H, d, 3.8 Hz), 3.75 (2H), 1.91 (3H), 1.31 (3H).

Anal. Calcd. for $C_{16}H_{16}N_2O_4$: C, 63.99; H, 5.37; N, 9.33. Found: C, 64.26; H, 4.89; N, 9.54.

Phenylacetylation of ***24***

The free 2′*R*-chloro-3′*S*-amino ester, obtained from 722 mg (1.78 mmol) of the *p*-toluenesulfonic acid salt, was dissolved in methylene chloride (15 ml) and phenylacetic acid (242 mg, 1.78 mmol) was added. This solution was treated, dropwise with stirring, with a solution of dicyclohexylcarbodiimide (405 mg, 1.96 mmol) in methylene chloride (5 ml). Precipitation of dicyclohexylurea commenced before the addition was complete. The reaction mixture was allowed to stand at room temperature for 3 h, by which time no free amine remained (by t.l.c.). Most of the urea was then removed by filtration and the filtrate was washed with ice-cold 5% bicarbonate solution. After drying over anhydrous magnesium sulfate, the organic phase was evaporated to give a solid residue. This was dissolved in boiling chloroform and an equal volume of petroleum ether (30–60°) was added, whereupon crystallization occurred. The crude product weighed 700 mg. One more recrystallization from the same solvent mixture gave 500 mg (80%) of methyl 2-(2′*R*-chloro-3′*S*-phenylacetamido-4′-oxo)azetidinyl-3-methyl-2-butenoate, m.p. 111–115° dec. The n.m.r. spectrum of this compound shows peaks at 7.38 (5H), 6.90 (1H, d, 10 Hz), 6.06 (1H, d, 4.2 Hz), 5.66 (1H, q, 4.2, 10 Hz), 3.78 (3H), 3.69 (2H), 2.30 (3H), 1.98 (3H). The same compound could be obtained, but in slightly lower yield, using diisopropylcarbodiimide or phenylacetyl chloride and triethylamine.

Phenylacetylation of ***15***

The *p*-toluenesulfonic acid salt **23** (651 mg, 1.6 mmol) and tetramethylguanidinium chloride (1.210 g, 5 molar-equiv.) were refluxed in spectroscopic grade chloroform (9 ml) for 4.5 h. The resulting solution was cooled, washed successively with ice-cold 5% bicarbonate, ice-cold saturated sodium chloride, dried over anhydrous magnesium sulfate, and then used immediately for the next step (previous experiments had indicated that the above procedure leads to a 5:1 or 6:1 excess of the 2′*S*-chloro-3′*S*-amino compound over the 2′*R*-chloro-3′*S*-amino compound). To the solution were added phenylacetic acid (228 mg, 1.7 mmol), diisopropylcarbodiimide (222 mg, 1.8 mmol), and methylene chloride (20 ml) and this solution was refluxed for 1 h. Removal of the solvent gave a residue whose n.m.r. spectrum showed peaks at 7.27 (phenyl), 5.28 (d, 1.9 Hz), 4.67 (d, 1.9 Hz), 3.70 (OCH_3), 3.53 (CH_2), 2.20 (CH_3), 1.95 (CH_3), corresponding to the amide **16**.

The spectrum also showed peaks at 5.98 (d, 3.8 Hz), 5.20 (d, 3.8 Hz), 3.67, 2.17, 1.57. This is the spectrum of **6**, *i.e.*, 2-benzyl-6-(1′-methoxycarbonyl-2′-methylprop-1′-enyl)-1-oxa-3,6-diaza-4*S*,5*R*-bicyclo[3,2,0]hept-2-en-7-one, which is formed by intramolecular cyclization of the preceding compound. The cyclization occurs on standing, but is facilitated by heating of a solution of the chloro compound, by shaking with bicarbonate, or by chromatography on alumina or silica gel of either epimeric 2′-chloro-3′-acylamino ester, as will be described below.

Chromatography of the above mixture on silica gel and elution with petroleum ether – ethyl acetate (1:1) afforded the oxazoline. Recrystallization from ethyl acetate gave 240 mg (49% from the *p*-toluenesulfonic acid salt), m.p 126.5–127°.

The n.m.r. spectrum of the pure compound shows peaks at 7.27 (5H), 5.98 (1H, d, 3.8 Hz), 5.20 (1H, d, 3.8 Hz), 3.70 (3H), 3.67 (2H), 2.17 (3H), 1.57 (3H).

Conversion of ***17*** *to the Oxazoline*

The crystalline *cis* compound (100 mg) was chromatographed on alumina (Woelm, grade II). Elution with carbon tetrachloride – benzene (1:1) gave 38 mg of the oxazoline in the first fractions, followed by uncyclized *cis* compound.

In a second experiment, the *cis* compound (1.0 g) was chromatographed on 37 g of silica gel, elution being performed with 1:1 petroleum ether (30–60°) – ethyl acetate. There were obtained in successive fractions 450 mg of recovered *cis* compound, 140 mg of a mixture of the *cis* compound and oxazoline, and 210 mg of oxazoline.

In a third experiment the crystalline methyl ester **24** (157 mg, 0.68 mmol), in dry methylene chloride (8 ml), was treated successively with phenylacetic acid (92 mg, 0.68 mmol) and diisopropylcarbodiimide (93 mg, 0.74 mmol). The solution was stirred at room temperature for 22 h, and the precipitated diisopropylurea was then collected by filtration. Addition of ether to the mother liquor completed the precipitation of the urea. Evaporation of the filtrate, followed by chromatography on a 1.0 × 7 cm column of alumina (activity II) gave, with 1:1 benzene – methylene chloride, 83 mg of crystalline material. This was found, by n.m.r. and t.l.c., to be a mixture of oxazoline and **17**.

Conversion of the Mixture ***15*** *+* ***24*** *to Oxazoline and* ***31*** *(R = PhCH₂)*

The *p*-toluenesulfonic acid salt **23** (4.428 g, 10.9 mmol) and 8.260 g (54.5 mmol) of freshly prepared tetramethylguanidinium chloride were refluxed for 2 h in spectroscopic grade chloroform (65 ml). The cooled solution was washed successively with ice-cold 5% bicarbonate solution, ice-cold saturated sodium chloride solution, and then dried over anhydrous magnesium sulfate. Then a solution of phenylacetic acid (1.490 g, 11 mmol) and diisopropylcarbodiimide (1.500 g, 11.9 mmol) in methylene chloride (25 ml) was added, and the mixture was refluxed

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

for 2 h. The n.m.r. spectrum of the reaction product showed only a small amount of the oxazoline (based on the peaks at 2.17 and 1.57). The solution was then washed with ice-cold 5% bicarbonate, dried over anhydrous magnesium sulfate, and evaporated. The n.m.r. spectrum of this residue now showed oxazoline as the major product. Thus, washing with bicarbonate had caused cyclization. The product was left at 10° overnight, then redissolved in methylene chloride and shaken again with bicarbonate solution. After drying and evaporation of the organic layer the n.m.r. spectrum of the residue was redetermined; it now indicated that the mixture contained 70% of oxazoline. The mixture, in 1:1 ethyl acetate – petroleum ether, was filtered through 50 g of silica gel and then chromatographed carefully on 110 g of silica gel. Elution was performed with graded mixtures of petroleum ether and ethyl acetate (250 ml of 20% ethyl acetate, followed by 200 ml of 30% ethyl acetate, followed by 200 ml of 35% ethyl acetate, followed by 200 ml of 45% ethyl acetate, followed by 50% ethyl acetate); 40-ml fractions were collected. Fractions 1–3 afforded 100 mg of **17**. Fractions 5–12 afforded 1.475 g of oxazoline. Fractions 13–15 were rechromatographed and yielded, besides an additional 150 mg of oxazoline (total 1.625 g, 48%), 240 mg of **31** (R = $PhCH_2$; see below).

*Preparation of **14** (R = $PhCH_2O$)*

The chloro acid from 470 mg of the anhydropenicillin, in acetone (5 ml), was added to a solution of sodium bicarbonate (247 mg, 2.94 mmol) in water (10 ml). After 1 min, crystallization began. The mixture was stirred for 15 min and then diluted with saturated sodium chloride solution (20 ml) and extracted twice with methylene chloride (10 ml each) and once with ether (10 ml). The combined organic extracts were dried over anhydrous magnesium sulfate and evaporated. The crystalline residue weighed 216 mg. Chromatography on silica gel afforded 185 mg of material which was recrystallized to give **14** (R = $PhCH_2O$), m.p. 170–172° dec., $[\alpha]_D^{25}$ −64.5° (*c* 0.45, $CHCl_3$). Anhydrocarbobenzoxypenicillin has $[\alpha]_D^{25}$ +259° (*c* 1, $CHCl_3$). The 5-epioxaanhydropenicillin has i.r. absorption at 2.98, 5.55, 5.65, 5.88, and 6.51 μ. The n.m.r. spectrum has peaks at 7.56 (6H), 5.86 (1H, d, 1.8 Hz), 5.18 (2H), 5.02 (1H, q, 1.8, 8 Hz), 2.18 (3H), 2.12 (3H). The mass spectrum shows the molecular ion at *m/e* 316.

Anal. Calcd. for $C_{16}H_{16}N_2O_5$: C, 60.75; H, 5.10; N, 8.86. Found: C, 60.67; H, 5.20; N, 8.99.

*Preparation of **28** (R = CH_3)*

The oxazoline (500 mg, 1.6 mmol) and *p*-toluenesulfonic acid monohydrate (300 mg, 1.6 mmol) were stirred in dry acetone (20 ml) for 30 min. The solvent was then removed below 40° to give a colorless foam which was crystallized from acetone–hexane to give 480 mg (60%) of methyl 2-(2′*R*-phenylacetoxy-3′*S*-amino-4′-oxo)azetidinyl-3-methyl-2-butenoate *p*-toluene-sulfonate as colorless fine needles, after washing with cold ethyl acetate, m.p., 145–146°, $[\alpha]_D^{EtOH}$ +40.1 (*c* 0.17).

Anal. Calcd. for $C_{24}H_{28}N_2O_8S$: C, 57.14; H, 5.56. Found: C, 56.75; H, 5.85.

The n.m.r. spectrum has peaks at 7.83 (2H, d, 9 Hz), 7.06 (5H, s) 7.06 (2H, d, 9 Hz), 6.30 (1H, d, 4.0 Hz), 4.90 (1H, d, 4.0 Hz), 3.62 (3H, s), 3.52 (2H, s), 2.30 (3H, s), 2.03 (3H, s), 1.88 (3H, s). In KBr, the i.r. spectrum has peaks at 1800, 1776, 1728, 1690 cm^{-1}.

*Preparation of **28** (R = CH_2Ph)*

The oxazoline **6** (R_1 = $PhCH_2$; R_2 = H) (1.0 g, 3.33 mmol), in ether (50 ml), was treated dropwise with stirring with a solution of phenyldiazomethane in ether. The pink color of the phenyldiazomethane disappeared immediately, and a gas was evolved. When a permanent pink solution was obtained, the mixture was stirred for an additional hour and then evaporated to dryness to give a pale orange oil. This was chromatographed on silica gel and the column eluted with graded mixtures of petroleum ether – ethyl acetate. The fractions obtained with a 60:40 solvent mixture afforded 1.21 g (93%) of **6** (R_1 = $PhCH_2$, R_2 = CH_2Ph); n.m.r.: 7.33 (5H, s), 7.27 (5H, s), 5.88 (1H, d, 4 Hz), 5.17 (2H, s), 5.07 (1H, d, 4 Hz), 3.57 (2H, s), 2.17 (3H, s), 1.55 (3H, s). The benzyl ester (1.1 g, 2.8 mmol) and *p*-toluenesulfonic acid monohydrate (532 mg, 2.8 mmol) were stirred in dry acetone (50 ml) for 30 min. Removal of the solvent afforded a quantitative yield of **28** (R = CH_2Ph), m.p., 128–130° dec., after crystallization from ethyl acetate – petroleum ether. The n.m.r. spectrum has peaks at 7.68 (2H, d, 8 Hz), 7.15 (5H, s), 6.97 (5H, s), 6.93 (2H, d, 8 Hz), 6.23 (1H, d, 4 Hz), 5.02 (s, 2H), 4.73 (br d, 4 Hz), 3.43 (2H, s), 2.23 (3H, s), 1.97 (3H, s), 1.50 (3H, s). The ester (100 mg) was hydrogenated at 15 p.s.i. in absolute ethanol (20 ml) containing 5% palladium-on-charcoal (10 mg) to give **28** (R = H). The n.m.r. spectrum has peaks at 7.67 (2H, d, 8 Hz), 7.17 (5H, s), 7.00 (2H, d, 8 Hz), 6.35 (1H, d, 4 Hz), 4.97 (1H, d, 4 Hz), 3.47 (2H, s), 2.23 (3H, s), 2.00 (3H, s), 1.58 (3H, s).

*Preparation of Diacylated Azetidinones **31** from **28** (R = CH_3)*

The salt (500 mg, 1.0 mmol) in CH_2Cl_2 (40 ml), cooled to 0°, was shaken vigorously for 30 min in an ice-bath with an ice cold solution of sodium bicarbonate (263 mg, 3.0 mmol) in water (20 ml). Then a solution of benzoyl chloride (280 mg, 2.0 mmol) in CH_2Cl_2 (10 ml) was added dropwise during 5 min and stirring was continued at 0° for an additional 2 h. The layers were then separated and the aqueous layer extracted twice with CH_2Cl_2. Evaporation of the combined dried CH_2Cl_2 layers afforded 550 mg of a colorless solid. Recrystallization from CH_2Cl_2 – petroleum ether gave 330 mg (75.5%) of **31** (R = Ph) as colorless prisms, m.p. 139–141°. The i.r. spectrum (KBr) has peaks at 1777, 1722, 1669 cm^{-1}. The n.m.r. spectrum has peaks at 7.78–6.97 (6H, m), 7.13 (5H, s), 6.37 (1H, d, 4 Hz), 5.58 (1H, q, 2, 8 Hz), 3.73 (3H, s), 3.57 (2H, s), 2.18 (3H, s), 1.83 (3H, s).

To prove the structure of this compound, **6** (R_1 = $PhCH_2$; R_2 = CH_3) was converted directly into the same material. The oxazoline (100 mg, 0.3 mmol) and benzoyl chloride (140 mg, 1 mmol) were stirred in tetrahydrofuran (5 ml) at room temperature for 24 h. Then water (2 ml) and sodium bicarbonate (100 mg, 1.2 mmol) were added, and stirring continued for a further 30 min. The mixture was then diluted with water and extracted with CH_2Cl_2. After drying of this extract, evaporation yielded 140 mg of a yellow oil, whose n.m.r. spectrum showed it to be a mixture of oxazoline and the above-mentioned *N*-benzoyl compound. This latter material was isolated by p.l.c. on silica gel (elution with 1:2 ethyl acetate – hexane) and crystallized from ethyl acetate – hexane. Its i.r., n.m.r. spectra, m.p., and mixture melting point with the *N*-benzoyl compound showed the two to be identical.

The diacylated azetidinone **31** (R = $PhCH_2$), prepared

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

from **28** as described above has i.r. absorption at 2.9, 3.0, 5.60, 5.70, 5.80, 5.98, 6.06, 6.65 μ. The n.m.r. spectrum has peaks at 7.35–7.25 (10H, m), 6.74 (1H, d, 9.5 Hz), 6.32 (1H, d, 4.1 Hz), 5.47 (q, 4.1, 9.5 Hz), 3.73 (3H), 3.57 (2H), 3.46 (2H), 2.18 (3H), 1.72 (3H). The mass spectrum shows a molecular ion at *m/e* 450.

Allylic Bromination of Methyl 2-(2'R-Chloro-3'S-phthalimido-4'-oxo)azetidinyl-3-methyl-2-butenoate

To a suspension of the methyl ester (100 mg, 0.276 mmol) in carbon tetrachloride (7.5 ml) were added *N*-bromosuccinimide (108 mg, 0.61 mmol) and benzoyl peroxide (2 mg). When this mixture was brought to reflux, the ester dissolved; the heat source was then replaced by a 100 W Photoflood No. 2 lamp and reflector mounted close to the reaction flask and stirring was continued until the reaction was complete (10 min). The resulting suspension was cooled, diluted with a small amount of chloroform, and the precipitated succinimide was removed by filtration. Evaporation of the filtrate gave a white crystalline solid residue whose n.m.r. spectrum showed no absorption in the region of the allylic methyl groups (2.5 to 2.0), but did show succinimide absorption at 2.8. This was removed, in part, by trituration with carbon tetrachloride and methylene chloride, and the total product was then chromatographed on neutral alumina (Woelm, activity II). Elution with methylene chloride afforded a crystalline dibromo compound which, after recrystallization from carbon tetrachloride – petroleum ether, melted at 65°–70° dec. and weighed 116 mg (80%).

Anal. Calcd. for $C_{17}H_{13}N_2O_5ClBr_2$: C, 39.22; H, 2.52; N, 5.38. Found: C, 38.95; H, 2.36; N, 5.40.

The n.m.r. spectrum has peaks at 7.87 (4H), 6.20 (1H, d, 4.2 Hz), 5.79 (1H, d, 4.2 Hz), 4.93 (1H, d, 10.2 Hz), 4.77 (1H, d, 10.9 Hz), 4.73 (1H, d, 10.2 Hz), 4.67 (1H, d, 10.9 Hz), 3.89 (3H). The spectrum appears unusually complex because one of the $-CH_2Br$ groups is *cis* to the methoxycarbonyl substituent and the other is *trans*; and, in each $-CH_2Br$ group, the methylene protons are magnetically nonequivalent. The i.r. spectrum has peaks at 5.55, 5.62, and 5.79 μ.

Allylic Bromination of Methyl 2-(2'S-Chloro-3'S-phthalimido-4'-oxo)azetidinyl-3-methyl-2-butenoate

The compound (100 mg) was reacted with 2 molar-equiv. of *N*-bromosuccinimide in exactly the same manner as described above. Chromatography on alumina (Woelm, activity II) and elution with methylene chloride afforded 122 mg (84%) of the desired compound, m.p. 164–167 °C. The n.m.r. spectrum shows peaks at 7.92 (4H), 6.38 (1H, d, 1.7 Hz), 5.73 (1H, d, 1.7 Hz), 4.95 (1H, d, 10.0 Hz), 4.64 (1H, d, 10.0 Hz), 4.62 (1H, d, 11.0 Hz), 4.43 (1H, d, 11.0 Hz), 3.96 (3H).

Reaction of Methyl 2-(2'R-Chloro-3'S-phthalimido-4'-oxo)azetidinyl-3-methyl-2-butenoate with One Molar-equiv. of N-Bromosuccinimide

A suspension of the *cis* compound (75 mg, 0.207 mmol), *N*-bromosuccinimide (36.9 mg, 0.207 mmol), and benzoyl peroxide (1.5 mg) in carbon tetrachloride (5 ml) was heated to reflux until a clear solution resulted. The heat source was then removed and the mixture was stirred while being illuminated with a 100 W Photoflood No. 2 lamp. After 10 min the reaction was terminated and the mixture was cooled to room temperature and filtered to give succinimide (17 mg, 85% of the theoretical amount), identified by its melting point and i.r. spectrum. The filtrate was evaporated to dryness to give a white solid residue which, on the basis of its n.m.r. spectrum contained a small amount of succinimide and an exactly 1:1 mixture of the two possible monobrominated compounds. The solid was chromatographed on alumina to remove the succinimide. Elution with methylene chloride afforded the 1:1 mixture of monobrominated compounds as a white foam (87.5 mg, 96%). The n.m.r. spectrum of this mixture shows peaks at 7.80 (4H), 6.17 (0.5H, d, 4.2 Hz), 6.13 (0.5H, d, 4.2 Hz), 5.72 (0.5H, d, 4.2 Hz), 5.68 (0.5H, d, 4.2 Hz), 4.90–4.12 (2H, m, overlapping AB quartets), 3.85 (1.5H), 3.83 (1.5H), 2.45 (3H).

Reaction of Methyl 2-(2'S-Chloro-3'S-phthalimido-4'-oxo)azetidinyl-3-methyl-2-butenoate with One Molar-equiv. of N-Bromosuccinimide

A mixture of the pure *trans* methyl ester (165 mg, 0.455 mmol), *N*-bromosuccinimide (81 mg, 0.455 mmol), and benzoyl peroxide (4 mg), in carbon tetrachloride (12 ml), was brought to reflux. The heat source was then removed and replaced with a 100 W Photoflood No. 2 lamp. Illumination of the stirred reaction mixture was maintained for 15 min. The suspension was then cooled, filtered, and the filtrate evaporated to a white foam. This was chromatographed on a 0.5 × 13 cm column of 3.0 g of neutral alumina (Woelm, activity II). Elution with methylene chloride afforded 206 mg of a 60:40 mixture of monobromo compounds. The n.m.r. spectrum of this mixture has peaks at 7.83 (4H), 6.27 (1H, d, 2 Hz), 5.63 (1H, d, 2 Hz), 4.73–4.35 (2H, m, two overlapping AB quartets), 3.85 (3H), 2.41 (1.2H), 2.18 (1.8H).

*Oxidative Rearrangement of **28** ($R = CH_3$) to **40***

The toluenesulfonic acid salt (504 mg, 1 mmol) was brominated for 15 min in CCl_4 (50 ml) with NBS (356 mg, 2 mmol). The product was dissolved in CH_2Cl_2 (30 ml) containing triethylamine (202 mg, 2 mmol) and this solution was stirred at room temperature for 1 h and then evaporated to dryness. The residue was triturated with methylene chloride and water and the dried methylene chloride phase was evaporated to give 310 mg of a white foam. The n.m.r. spectrum of this foam was identical to that of crystalline material, m.p. 151–152°, obtained as follows. The crude product was chromatographed on silica gel and eluted with 1:1 petroleum ether – ethyl acetate. Crystallization from petroleum ether – CH_2Cl_2 afforded 210 mg of the dehydrooxazinone.

Mass Calcd. for $C_{17}H_{18}N_2O_5$ (M + 1): 330.1205. Found: 330.1216.

Anal. Calcd. for $C_{17}H_{18}N_2O_5$: C, 61.81; H, 5.49; N, 8.48. Found: C, 61.76; H, 5.52; N, 8.45.

The n.m.r. spectrum has peaks at 8.04 (1H, s), 7.30 (5H, s), 5.24 (2H, d), 3.74 (3H, s), 3.66 (2H, s), 1.81 (3H, s) at 100 MHz in DMSO-d_6 containing a drop of D_2O.

The compound gave a dihydro derivative, m.p. 178–180° upon hydrogenation in ethanol over 5% palladium-on-charcoal. Its n.m.r. spectrum shows the following peaks: 8.28 (1H, s), 7.38 (1H), 7.23 (5H), 7.18 (1H), 3.76 (3H), 3.63 (2H), 2.24 (1H, m), 1.00 (3H, d, 7 Hz), 0.94 (3H, d, 7 Hz).

Oxidative Rearrangement of 28 ($R = CH_2Ph$) to 42

The *p*-toluenesulfonic acid salt (100 mg, 0.17 mmol) was suspended in CCl_4 (spectroscopic grade, 20 ml) containing *N*-bromosuccinimide (62 mg, 0.35 mmol) and benzoyl peroxide (2 mg). The mixture was heated to reflux with mechanical stirring. After 2 min, the heat source was removed and the stirred mixture was irradiated with a 100 W Photoflood No. 2 lamp for 8 min. Irradiation was then discontinued and the reaction mixture was evaporated to dryness. The residue was dissolved in methylene chloride (15 ml) and triethylamine (35 mg) was added. This solution was stirred at 20° for 1.5 h and then evaporated. The residue was dissolved in methylene chloride, and this solution was washed with water, dried, and evaporated. The 42 mg of material thus obtained was chromatographed on silica gel. Elution with graded mixtures of petroleum ether and ethyl acetate afforded 7 mg of material with the 1:1 mixture. This material crystallized when triturated with ether. Recrystallization from methylene chloride – petroleum ether afforded 2-isopropenyl-2-benzyloxycarbonyl-5-phenylacetamido-5,6-dehydrooxazine-4-one, m.p. 162–163°. The n.m.r. spectrum shows peaks at 8.33 (1H, s), 7.53 (10H, s), 5.50 (4H, br s), 3.93 (2H, s), 1.98 (3H, s). The i.r. spectrum shows carbonyl absorptions at 1725, 1690, and 1642 cm^{-1}.

We thank the National Research Council of Canada and Bristol Laboratories for financial support of this research, and Drs. G. N. Knaus, Queen's University, and P. A. Hart, School of Pharmacy, University of Wisconsin-Madison, for assistance with some of the experimental work. Numerous discussions with Dr. R. B. Morin concerning the structure of the oxazinone **40** and the role of acylimines in penicillin biosynthesis are also gratefully acknowledged.

Deacylation of Fluorine-substituted *trans*-Cinnamoyl-α-chymotrypsins[1]

J. T. GERIG AND R. S. MCLEOD

Department of Chemistry, University of California, Santa Barbara, Santa Barbara, California 93106

Received July 23, 1974

J. T. GERIG and R. S. MCLEOD. Can. J. Chem. **53**, 513 (1975).

Deacylation of unsubstituted and of *o*-F-, *m*-F, *p*-F, α-F, pentafluoro-, *p*-methyl-, and *p*-trifluoromethyl-substituted *trans*-cinnamoyl-α-chymotrypsins has been studied from p*H* 4 to 8. The deacylation rate constants were found to depend upon the ionization state of a group on the enzyme with an apparent p*K* in the range 6.3–7.3. The hydrolysis rates of the correspondingly substituted *p*-nitrophenylcinnamate esters were determined at p*H* 10.6. Correlation of the data for these model reactions with the corresponding rates of enzyme deacylation suggests that the *p*-methyl-substituted acylenzyme is about an order of magnitude more reactive than expected while *p*-trifluoromethyl substitution results in deacylation at a rate 10 times slower than expected. The remaining substituents exert about the anticipated rate effect on deacylation.

J. T. GERIG et R. S. MCLEOD. Can. J. Chem. **53**, 513 (1975).

On a étudié, entre les p*H* 4 et 8, la réaction de déacylation de *trans*-cinnamoyl-α-chymotrypsines non-substitués et substitués par des groupes *o*-F, *m*-F, α-F, pentafluoro, *p*-méthyle et *p*-trifluorométhyle. Les constantes de vitesse de déacylation dépendent de l'état d'ionisation d'un groupe de l'enzyme ayant un p*K* apparent entre 6.3 et 7.3. On a déterminé, à p*H* de 10.6, les vitesses d'hydrolyse des esters *p*-nitrophénylcinnamates substitués d'une façon correspondantes. La corrélation des données pour les réactions de ces modèles avec les vitesses des réactions de déacylation correspondantes catalysées par les enzyme suggère que l'acyle-enzyme substitué par un groupe *p*-méthyle est environ 10 fois plus réactif que l'on aurait pu l'attendre alors que la substitution par un groupe *p*-trifluorométhyle conduit à des résultats de déacylation qui sont environ 10 fois plus lent que prévu. Les autres substituants exercent sur la déacylation les effets anticipés. [Traduit par le journal]

Numerous studies have been carried out to elucidate the properties as well as the catalytic mechanism of the proteolytic enzyme, α-chymotrypsin (1–5). Equation 1 represents the minimal features of this mechanism in which enzyme (E) and substrate (S) first combine to form a Michaelis complex (ES). The substrate is pre-

$$[1] \quad E + S \rightleftarrows ES \rightarrow ES' \rightarrow EP_2 \rightleftarrows E + P_2 + P_1$$

sumed to consist of an alcohol, amine, or thiol moiety symbolized P_1 which is present as a derivative of a carboxylic acid (P_2). A large body of evidence points to the appearance of a covalent enzyme–substrate intermediate (ES′) along the reaction pathway, likely one in which the acyl group of the substrate is attached to serine-195 of the enzyme (6, 7). Generally, nonspecific substrates produce acylchymotrypsins that are relatively stable and, in several studies, these species have been directly observed or isolated (8–12). Acylenzymes have also been detected in the reactions of specific ester substrates but more rarely or under unusual conditions (13, 14). Hydrolysis of the intermediate enzyme–ester gives initially an enzyme–acid product complex (EP_2) which, upon dissociation, regenerates the native enzyme.

The goal of a program in our laboratory is to compare the structures of acylenzyme intermediates with the structures of the corresponding enzyme–P_2 complexes. Fluorine n.m.r. spectroscopy should be useful in such studies since fluorine chemical shift and relaxation time data can provide information about the local environment of the fluorine 'reporter' nuclei (15, 16).

The purpose of the present work was to determine the stabilities of various fluorine-substituted cinnamoyl-α-chymotrypsins in the hope that some of these acylenzymes would prove amenable to study by fluorine n.m.r.; experiments

with the corresponding cinnamate–enzyme complexes are already underway (17). Previous kinetic investigations have shown that the electronic nature of the acyl group as well as its size are important in determining the rate of deacylation of the corresponding acylenzyme (11*a*, 18–20). In some cases unexpectedly large or small rates are observed, especially if fluorine substituents are present (20*b*). A second thrust of this work, then, was to compare the rates of deacylation of the fluorinated derivatives to their nonfluorinated analogs; such comparisons may give some indication of how representative of the nonfluorinated acylenzymes are the fluorine-containing ones.

Experimental

Materials

trans-Cinnamic acid (Matheson, Coleman and Bell), α-fluorocinnamic acid (Aldrich), and 4-methylcinnamic acid (Aldrich) were obtained commercially.

The other substituted cinnamic acids were prepared by heating at reflux the appropriate benzaldehyde (0.02 mol) and malonic acid (0.022 mol) in a solvent composed of pyridine (0.6 ml) and ethanol (0.4 ml). Upon heating, the malonic acid slowly dissolves; as the product forms, it precipitates from the solution until the mixture is pasty. At this point a few additional drops of ethanol can be added to maintain fluidity. Typical reaction times were 5–6 h. The cinnamic acids so produced were recrystallized from ethanol–water. Table 1 gives yields and melting points for these materials. Proton magnetic resonance spectra of these compounds uniformly showed a coupling constant between the vinyl protons of 15–17 Hz indicating a *trans* double bond.

The corresponding cinnamoyl chlorides were prepared by treating the appropriate cinnamic acid (0.03 mol) with thionyl chloride (0.11 mol, *ca.* 8 ml). After heating at reflux for 2 h and removal of excess thionyl chloride at atmospheric pressure, the products were distilled under vacuum. Table 1 records the boiling points and yields observed in these preparations.

p-Nitrophenylcinnamates were synthesized by dissolving the desired cinnamoyl chloride (0.006 mol) in dry benzene (25 ml) containing pyridine (1.2 ml). *p*-Nitrophenol (0.84 g, 0.006 mol) was added and the mixture heated at reflux for 1 h. Upon cooling the reaction mixture was washed five times with 5% potassium carbonate solution and then with water. (Addition of a small amount of ether was helpful when emulsion formation was a problem during these extractions.) After drying over anhydrous sodium sulfate, the solvent was stripped off *in vacuo* and the crystalline residue recrystallized from chloroform–cyclohexane. Data regarding yield, melting point, and microanalyses of these esters are given in Table 1.

The α-chymotrypsin used was a Worthington three-times crystallized product. Matheson spectroquality acetonitrile was used as co-solvent. Buffers were 0.05 *M* in buffer salts and contained 0.1 *M* KCl. Potassium phosphate was used at p*H* 6–8; at p*H* values lower than 6, acetate was used.

Kinetic Methods

Except for pentafluorocinnamoylchymotrypsin, the rates of deacylation of the various substituted cinnamoyl-enzymes were followed by monitoring the disappearance of the acylenzyme (12) at the wavelength indicated in Table 2 with a Beckman Model DUR spectrophotometer equipped with a Gilford 2000 recorder accessory. The temperature in the cell compartment was maintained at 30.2° by circulating thermostated water (±0.05°) through spacers on each side of the cell compartment. Stock solutions of the *p*-nitrophenyl esters at 0.54 m*M* were prepared

in acetonitrile. An α-chymotrypsin stock solution at 1.37 m*M*, p*H* 3, was prepared assuming a molecular weight of 25 200 (21). An aliquot of the enzyme stock solution (0.4 ml) was diluted to 10 ml with the appropriate buffer solution; 3-ml aliquots of this solution were added to each cuvette, including the reference cell; 0.2 ml of acetonitrile was also added to the reference cell. The contents of the cells were allowed to reach thermal equilibrium at 30.2°. To initiate a reaction 0.2 ml of ester stock solution was added to a sample cuvette. The final reaction mixture thus had a total volume of 3.2 ml and was 0.034 m*M* in substrate, 0.051 m*M* in enzyme, and 6.25% in acetonitrile. Depending upon p*H* an initial change in absorbance due to acylation was noted followed by a slower exponential loss of absorbance as a result of deacylation.

Plots of ln ($A_\infty - A_t$), where A_∞ is the observed absorbance at infinite time and A_t is the observed absorbance at time t, *vs.* t were linear; least squares analysis of the data, using a program prepared for a Hewlett-Packard 9820A calculator, gave correlation coefficients in excess of 0.999. The slope of such a plot gives the apparent first-order rate constant, k_ψ, for deacylation.

Deacylation of the pentafluoro derivative was followed by a dye displacement technique (11*b*) using the dye Biebrich scarlet (22). Reaction conditions identical to those described above were used except that the dye was present in the reaction mixture and reference cell at a concentration of 5.96×10^{-5} *M*. With this technique no enzyme was added to the reference cuvette and the reappearance of the enzyme–dye complex as deacylation proceeded was followed at 550 nm.

The kinetics of base-catalyzed hydrolysis of the *p*-nitrophenyl esters were carried out as follows. Twenty milliliters of acetonitrile was diluted to 100 ml with 0.05 *M* potassium carbonate buffer. A 3-ml aliquot of this solution was placed in a cuvette and allowed to equilibrate at 30.2 °C. To start the reaction a 0.2-ml aliquot of the ester stock solution described above was added (because of decreased solubility, with the *p*-methyl compound 0.1 ml of stock solution and 0.1 ml of acetonitrile was used); an equivalent amount of acetonitrile was added to the reference cell. Total acetonitrile in the reaction system was 25%. The evolution of *p*-nitrophenol was followed at 400 nm and was strictly first order. The measured p*H* of the reaction medium was 10.59 and the pseudo first-order rate constants obtained were thus divided by $[OH^-] = 3.89 \times 10^{-4}$ *M* to obtain the second-order rate constant, k_{OH}, for hydroxide reaction.

Results

The kinetics of deacylation of *o*-fluoro-, *m*-fluoro-, *p*-fluoro-, α-fluoro-, *p*-methyl-, *p*-trifluoromethyl-substituted and unsubstituted cinnamoyl-α-chymotrypsins have been studied by direct spectrophotometric observation over the p*H* range 4–8. The α-fluoro derivative was examined only from p*H* 4 to 6 because the reaction is too rapid at higher p*H* values to be followed by the present techniques. An appropriate wavelength at which to observe the pentafluoro-substituted cinnamoylenzyme could not be found and a dye displacement method was used in this case. Deacylation in this system was also too rapid to be measured above p*H* 6 and at p*H* values below 5 the dye displacement technique was not usable because the dye precipitates from solution under these conditions. The results of these kinetic experiments are assembled in Table 2.

As expected, the deacylation reactions with all groups were found to be p*H* dependent. A mechanism of the form shown in eq. 2 was assumed where EH^+A and EA represent forms of the acylenzyme in which a critical group is proton-

$$\begin{array}{ccc} EA & \xrightarrow{k_3} & E + A \\ K \Big\| & & \\ EH^+A & \xrightarrow{k_3'} & EH^+ + A \end{array} \qquad [2]$$

ated or not protonated, respectively. For this mechanism, the observed first-order rate constant k_ψ is given by eq. 3*a*.

$$[3a] \qquad k_\psi = \frac{k_3 + \frac{k_3'[H^+]}{K}}{1 + \frac{[H^+]}{K}}$$

$$[3b] \qquad k_\psi = k_3 + \frac{k_3'}{K}[H^+] - \frac{k_\psi[H^+]}{K}$$

The available rate data were used to calculate the parameters k_3, k_3', and K which characterize the assumed mechanism by a least-squares technique using the rearranged form, eq. 3*b*. With the pentafluoro-substituted acylenzyme, data at only two pH values were available. In this case, k_3' was assumed to be zero in order to obtain an estimate of the equilibrium constant K and the first-order rate constant for deacylation, k_3. Table 3 presents the parameters found to describe the reaction of each cinnamoylchymotrypsin; these values for k_3, k_3', and K reproduce the experimentally observed rate constants well, usually with an accuracy of 5% or better. It should be noted that the accuracy of k_3' depends critically upon the accuracy of K (*cf.* eq. 3*b*).

The rates of hydroxide ion catalyzed hydrolysis of the *p*-nitrophenyl esters of the cinnamic acids used in this work were determined. At pH 10.59, these reactions are pseudo first-order with hydroxide ion in large excess concentration over the ester substrate. The second-order rate constants obtained from these experiments are recorded in Table 3.

Discussion

An unexpected aspect of our results in this work is the apparently substantial contribution reaction of the protonated form of the enzyme (EH^+A in eq. 2) makes to the overall deacylation process. While the rate constant, k_3', for this step is very small relative to k_3, at pH values below 6 this pathway for deacylation appears to generate an appreciable fraction of the total reaction observed. Although others have included steps analogous to the one defined by k_3' in eq. 2 in discussions of the chymotrypsin mechanism (23) we are unaware of estimates for the relative magnitudes of k_3 and k_3' from previous work. Rather, the usual assumption appears to be that $k_3' = 0$. Our results suggest that this assumption should be made with caution. However, it is possible that the complete mechanism for deacylation under our conditions is inadequately represented by eq. 1 and that additional terms perhaps involving the buffer components or other ionization constants may become necessary in a more refined description of this reaction.

The rate constants k_3 and k_3' for deacylation define steps in the mechanism that are essentially ester hydrolyses. A linear free energy relation between k_3, for example, and the rate constant for attack of hydroxide on a corresponding simple ester analog of the acylenzyme is expected and has been observed in a number of cases (18, 19). Substantial deviations from the regression line in these correlations can be taken to indicate interactions between an acyl group and the protein structure which significantly affect the enzyme reaction; previous work has shown that remote fluorine substitution can have an accelerating, a decelerating or no effect on the hydrolysis of acylchymotrypsins (20*b*).

Figure 1 shows a plot of the logarithm of k_3 for substituted cinnamoylchymotrypsin deacylation *vs.* the logarithm of k_{OH}, the rate constant for basic hydrolysis of the corresponding *p*-nitro-

phenylcinnamate esters. Excepting the data points for the methyl and trifluoromethyl derivatives, a reasonably linear relationship is found. This indicates that the steric and electronic effects of the other various fluorine substituents on the cinnamoyl group are being felt in both types of ester hydrolyses to about the same extent. The kinetics of deacylation of the various monofluorine substituted and the pentafluorinated cinnamoylchymotrypsins thus appear to be 'normal' by this criterion.

Placement at the *para* position of the cinnamoyl group of a methyl or trifluoromethyl group has unexpected kinetic consequences. Using the correlation shown in Fig. 1 as a guide, it appears that the *p*-methyl compound deacylates about a factor of 10 more rapidly than anticipated on the basis of the model reaction while the *p*-trifluoromethyl derivative reacts about a factor of 10 more slowly than expected. These results may be related in some way to the prior observation that a *p*-trimethylammonium substituent greatly retards the rate of deacylation (24), although there is no evidence that the acyl groups of these three *para*-substituted cinnamoylchymotrypsins are in similar environments at the enzyme active site.

A plot of the logarithm of k_3' against the logarithm of k_{OH} gives a plot similar to Fig. 1. The points for the *p*-methyl- and *p*-trifluoromethyl-substituted compounds again lie off the correlation line but the deviations are not so large as those in Fig. 1.

p*H*-reactivity studies of the action of α-chymotrypsin have repeatedly implicated a group on the enzyme with a p*K* of approximately 7 in the catalytic mechanism (4, 23). This group, which controls the rate of deacylation, has usually been assigned to histidine-57 (25, 26) although more recent evidence indicates that the buried carboxyl group of aspartate-102 may be this group (27). Interestingly, the apparent p*K* of the group involved in enzyme deacylation (determined kinetically) changes with the structure of the acyl group (11, 18, 23, 29). Bernhard *et al.* have indicated, for a variety of acyl groups, that this p*K* is linearly related to the p*K* of the corresponding free acid: the more acidic is the free acid, the lower is the p*K* observed in the deacylation reaction of the corresponding acylenzyme (11). Although we do not have available p*K* data for the acids employed in this study under our experimental conditions, the data in Table 3 are qualitatively consistent with the observations of

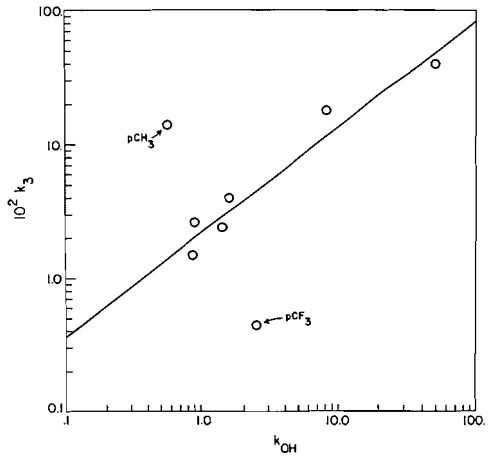

FIG. 1. Correlation of the rate of basic hydrolyses of various cinnamate *p*-nitrophenyl esters (k_{OH}) with the rate of deacylation of the corresponding acylchymotrypsin (k_3) (data from Table 3).

the Bernhard group. The pentafluoro- and α-fluorocinnamic acids are expected to be the most acidic of the group studied here because of the inductive effects of the fluorine atoms; in each of these cases the observed p*K* which determines the kinetics of deacylation of the corresponding acylenzyme is low. Similarly, the observed p*K*'s for the remaining cinnamoyl systems correlate reasonably well with Hammett's σ parameters.

There is little indication from this work that single substitution of fluorine atoms on the carbons of the double bond or the aromatic ring of the cinnamoyl group produce any special enzyme–cinnamoyl interaction that has kinetic consequences. In these cases, except for their electronic effect, fluorine atoms appear to be able to masquerade as hydrogen atoms. Substituents at the *para* position more bulky than a single fluorine do have an unexplained influence on the rate of deacylation; a methyl group in this location has an accelerating effect but if the hydrogen atoms of the methyl group are replaced by fluorine atoms, a substantial slowing of the deacylation reaction results. It seems likely, therefore, that contacts between the enzyme and the aromatic end of the cinnamoyl group are sufficient to significantly modify the positions of the atoms at the site of reaction for these cases. The abnormally low reactivity of the *p*-trifluoromethyl cinnamoyl enzyme warns that spectroscopic investigations of this protein by u.v. or magnetic resonance techniques may

not provide data that are particularly relevant to the nature of the other acylenzymes examined in this work. We hope that fluorine n.m.r. experiments in progress will illuminate this point.

TAKASHI TSUCHIYA and VICTOR SNIECKUS. Can. J. Chem. **53**, 519 (1975).

Sodium borohydride reduction of the 1,2(1*H*)-diazepines **1***a–e* and **7**, and the 1,2(1*H*)-diazepine iron tricarbonyl complexes **4***a–b* provides the 2,3-dihydro-1,2(1*H*)-diazepines **2***a–e* and **8**, and the (2,3-dihydro-1,2(1*H*)-diazepine)$Fe(CO)_3$ derivatives **5***a–b*, respectively. $Fe(CO)_3$ complexes **5***a* and **6***a* may be also directly obtained from the 1,2(1*H*)-diazepines **2***a* and **3***a*, respectively. A number of diacylated compounds (**3***a–c*, **6***a–b*, and **9**) are prepared some of which (**2***a*, **3***a*, **8**, and **9**) are readily converted into their corresponding $(4 + 2)\pi$ cycloadducts (**14***a–d*). Treatment of the borohydride reduction products **2***a–c* with sodium methoxide in methanol gives the 3,4-dihydro-1,2(2*H*)-diazepines **15***a–c*. Acetylation of **15***a* affords the 2-acetyl derivative **16***a* which may also be prepared by sodium methoxide deacetylation of either **3***a* or **9**. 2-Tosyl-3,4-dihydro-1,2(2*H*)-diazepine (**18**) is obtained from **2***a* by a similar tosylation and deacetylation sequence. When either **2***a* or **3***a* are subjected to sodium methoxide in methanol-*O-d*, compounds **15***a* and **16***a*, respectively, are produced which show high deuterium incorporation at C_4 and C_6 (n.m.r. analysis). Photolysis of the 2,3-dihydro-1,2(1*H*)-diazepines **2***a*, **3***a*, **8**, and **9** and the 3,4-dihydro-1,2(2*H*)-diazepine **16***a* affords the unstable 2,3-diazabicyclo[3.2.0]hept-6-ene **23***a*, **23***b*, **25***a*, and **25***b* and 1,2-diazabicyclo[3.2.0]hept-6-ene **27** derivatives, respectively. Treatment of either **25***a* or **25***b* with sodium methoxide results cleanly in N_2-deacylation to give compound **26**.

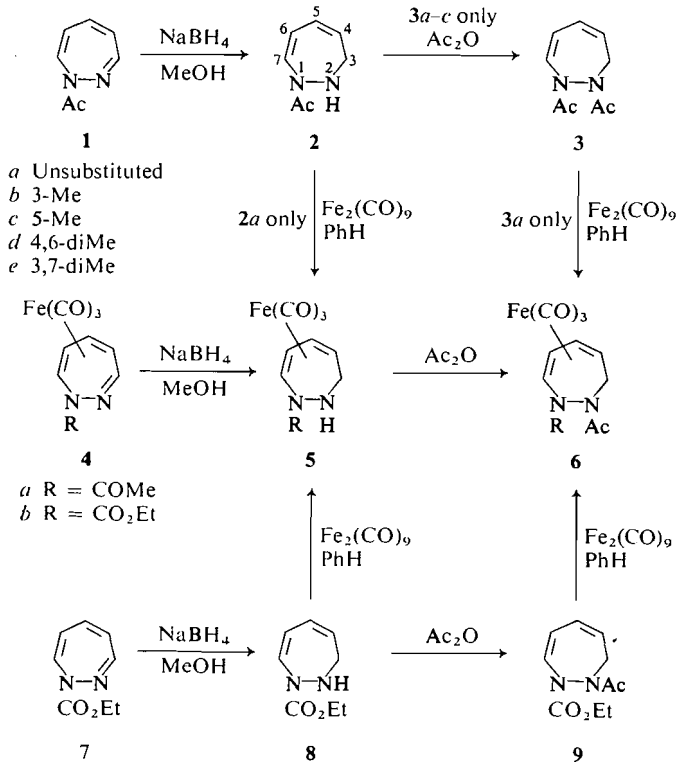
TAKASHI TSUCHIYA et VICTOR SNIECKUS. Can. J. Chem. **53**, 519 (1975).

La réduction des (1*H*)-diazépines-1,2 (**1***a–e* et **7**) de même que les complexes fer-tricarbonyl des (1*H*)-diazépines-1,2 (**4***a* et **4***b*), par le borohydrure de sodium, conduit dans le premier cas aux dihydro-2,3(1*H*)-diazépines-1,2 (**2***a–e* et **8**) et dans le deuxième cas aux complexes fer-tricarbonyl des dihydro-2,3 (1*H*) diazépines-1,2 (**5***a–b*). Les complexes fer-tricarbonyl de **5***a* et de **6***a* peuvent aussi tre obtenus d'une façon directe à partir des (1*H*)-diazépines-1,2, **2***a* et **3***a*. On a préparé un certain nombre de dérives diacétylés (**3***a–c*, **6***a–b* et **9**); la cycloaddition $(4 + 2)\pi$ des composés **2***a*, **3***a*, **8** et **9** conduit facilement aux produits (**14***a–d*) correspondants. Le traitement, des produits **2***a–c* par le méthylate de sodium dans le méthanol conduit aux dihydro-3,4 (2*H*)-diazépines-1,2 (**15***a–c*). L'acétylation de **15***a* conduit à **16***a*, acétylé en position 2; ce dérivé peut aussi être préparé par la déacétylation, à l'aide du méthylate de sodium, soit de **3***a* ou de **9**. On obtient la tosyl-2 dihydro-3,4 (2*H*) diazépine-1,2 (**18**) en soumettant **2***a* à une réaction de tosylation puis une réaction de déacétylation. Quand ont soumet soit **2***a* soit **3***a* à l'action du méthylate de sodium dans le méthanol-*O-d*, il y a production respectivement de **15***A* et de **16***a* dans lesquels il y a (d'après l'analyse par r.m.n.) une forte incorporation de deutérium en C_4 et en C_6. La photolyse des dihydro-2,3 (1*H*)-diazépines-1,2 (**2***a*, **3***a*, **8** et **9**) ainsi que celle de la dihydro-3,4 (2*H*)-diazépine-1,2 (**16***a*) fournit d'une part les diaza-2,3 bicyclo[3.2.0] heptènes-6 (**23***a*, **23***b*, **25***a* et **25***b*) qui sont instables et d'autre part le diaza-1,2 bicyclo[3.2.0] heptène-6 (**27**). Le traitement soit de **25***a* ou de **25***b* avec le méthylate de sodium conduit à une N_2 déacylation conduisant au composé **26**.

[Traduit par le journal]

As part of our continuing investigation of the organic (1) and organometallic (2) chemistry of 1,2(1*H*)-diazepines, we have studied the sodium borohydride reduction of the 1-acetyl- and 1-carbethoxy-1,2(1*H*)-diazepines (**1***a–e* and **7**) and the corresponding iron tricarbonyl derivatives (**4***a–b*). This reaction has provided the 2,3-dihydro-1,2(1*H*)-diazepines (**2***a–e*, **5**, and **8**) (Scheme 1), some of which by base treatment have given rise to 3,4-dihydro-1,2(2*H*)-diazepine derivatives (**15***a–c*) (Scheme 3). These results together with the photochemical (Scheme 4) and Diels–Alder (Scheme 2) reactivity of several

[1]On leave of absence from The School of Pharmaceutical Sciences, Showa University, Tokyo, Japan.



SCHEME 1

examples of both dihydro series constitute the present report.[2] Previous work has dealt with acid- (4, 5) and base- (4, 6) catalyzed, thermolytic (1*b*, 4, 6, 7), photochemical (1*b*, 6), and cycloaddition (5, 8, 9) reactions of simple and aryl substituted 1,2(1*H*)-diazepine derivatives. In comparison to the extensive studies on the 1,2-diazepin-4-one system by Moore and coworkers (10), the chemistry of the 1,2(1*H*)-diazepines is in the initial stages of exploration.

Sodium Borohydride Reduction

Sodium borohydride reduction of 1-acetyl-1,2(1*H*)-diazepine (**1***a*) in methanol solution gave, after chromatography, a single compound (75–80%) whose analytical and spectral data are consistent with 2,3-dihydro-1,2(1*H*)-diazepine formulation **2***a* (Scheme 1). The i.r. spectrum showed absorption at 3300 (NH) and 1660 (C=O) cm^{-1} while the 90 MHz n.m.r. spectrum exhibited signals as indicated aside the structural formula below. Assignments were made by reference to the n.m.r. spectrum of *1a* (11) and coupling constants were confirmed by decoupling experiments. The n.m.r. information in particular speaks against the alternate dihydro structures **10** (R = H) and **11** (R = H) in which coupling of the low field signal (C_3—H in both strucutes) with NH would have been expected. Due to some uncertainty of this spectral analysis, it was necessary to obtain chemical evidence in order to eliminate the alternate structures from further consideration. Towards this end, the methyl substituted 1,2(1*H*)-diazepines **1***b* and *c* were analogously reduced to give single products in high yields which showed, *inter alia*, methyl resonances at τ 1.21 (d, 3H, J = 7 Hz) and τ 1.87 (s, 3H), respectively. These data are consistent with the assignment of structures **2***b* and *c*, respectively, for the two products and not with alternate respective formulations, **10** (R = Me) and **11**

[2]During the preparation of the manuscript, a report appeared on the diborane and diisobutylaluminum hydride reduction of 1,2(1*H*)-diazepine derivatives (3). Our results, although partially complementary, are more extensive and overlap only in the obtainment of two compounds (**8** and **23***b*).

11

(R = Me). Additional data for compounds **2***b* and *c* as well as complete analytical, physical, and spectral information on the borohydride reduction products **2***d*, **2***e*, and **8** are collected in Table 1.[3] Spectral data for **8** are in good agreement with those reported by Streith and Willig for this compound obtained by diborane reduction of **7** (3).

Thus the 1-acyl-1,2(1*H*)-diazepine ring system (**1**) shows normal reactivity towards sodium borohydride in that the C=N function is reduced. The remaining *N*-acyl dienamine moiety in the product (**2**) is not susceptible to further reduction under the mild conditions of the reaction.

Reduction of the iron tricarbonyl 1,2(1*H*)-diazepine complexes **4***a* (2*a*) and **4***b* (4) provided the dihydro derivatives **5***a* (45%) and **5***b*, respectively (Scheme 1). In agreement with the structural assignment, compound **5***a* showed i.r. absorption at 3420 (NH), 2040, 1970, and 1950 (C≡O), 1655 (C=O), and 1635 and 1600 (C=C) cm^{-1} and n.m.r. parameters indicated aside the structural formula below. The $Fe(CO)_3$ complexes **5***a* and *b* could also be obtained from the reaction of compounds **2***a* and **8** with nonacarbonyldiiron(0). The instability of **5***b* precluded its characterization; therefore, it was immediately converted into its stable acetyl derivative (**6***b*) (65%). Complete analytical, physical, and spectral data for **5***a*, **6***a*, and **6***b* are recorded in Table 2.[3]

In fact, most of the other dihydro 1,2(1*H*)-diazepine derivatives (**2***a–c*, **5***a*, **8**) were found to be somewhat unstable under ordinary laboratory conditions. Therefore these compounds were also transformed into their stable acetyl derivatives (**3***a–c*, **6***a*, and **9**) (Scheme 1). Analytical and spectral data are summarized in Tables 1 and 2.[3] It is of interest to compare the n.m.r. spectra of compounds **3***a* and **6***a* with their corresponding

immediate precursors, **2***a* and **5***a*, respectively (see structures above). Whereas the C_3-methylene protons in **2***a* and **5***a* appeared as broad singlets at τ 6.30 and 6.6–7.1, respectively, these protons in the corresponding acetyl derivatives **3***a* and **6***a* were observed at chemical shift separations Δ p.p.m. $\approx$1.6 and 1.85, respectively. The behavior of **3***a* and **6***a* is reminiscent of 3,5,7-triphenyl-1,2(4*H*)-diazepines (**12**) and their corresponding diazepinium salts in which similar large chemical shift differences could be attributed to anisotropic effects on the methylene protons (H_a and H_b in **12**) (1*a*, 12). Similar behavior has been noted in some closely related 1,2-diazepin-4-one derivatives (13).[4] In the case of **3***a*, n.m.r. parameters for the C_3-methylene protons argue in favor of representation **13** for the predominant conformation. In this conformation, the anisotropic effects of the quasiequatorial N_2—Ac function are clearly more pronounced on H_b than on H_a in agreement with the assignments labelled on the structure. However, the n.m.r. spectrum of **3***a* at room temperature also shows the presence of a minor contributing conformational isomer (<5%). Thus these assignments are tentative pending a detailed temperature variable n.m.r. spectral (including line shape) analysis.[5] Another point of interest is the complicated N—Ac methyl absorptions in the n.m.r. spectra of **3***a* as well as the other acyl derivatives **3***b* and **3***c*. In sharp contrast to the corresponding NH systems (**2***a–c*), compounds **3***a–c* showed at least three N—Ac methyl signals at ambient temperature. For example, **3***a* shows two major singlets at τ 7.89 and 8.04 and a minor peak at τ 7.98. Most probably, these observations indicate the occurrence of N—Ac hindered rotation and/or inversion phenomena (13, 14) which, as a result of their apparent complexity, require a more detailed analysis.[5]

Several of the 2,3-dihydro-1,2(1*H*)-diazepines (**2***a*, **3***a*, **8**, and **9**) were converted into the (4 + 2)π cycloaddition products **14***a–d* with 4-phenyl-1,2,4-triazoline-3,5-dione (Scheme 2). Sasaki and his co-workers have previously shown that 1,2(1*H*)-diazepines exhibit this type of behavior with this reactive dienophile as well as with tetracyanoethylene (TCNE) (8). Furthermore, Streith and Willig have obtained some [4 + 2]π cycloadducts from the reaction of 2,3-dihydro-1,2(1*H*)-diazepines with TCNE and have offered a possible explanation for the much higher reactivity of the dihydrodiazepines in comparison to their fully unsaturated counterparts (3). The adducts **14***a–d* were also obtained in high yield under mild conditions. The collected analytical, physical, and spectral data (Table 3)[3] are in agreement with the normal Diels–Alder formulations **14***a–d* for the structures of these products. The n.m.r. spectral assignments (*e.g.* for **14***a* and *b* below) were derived by comparison with those of similar adducts of 1,2-diazepine (8) and dihydro-1,2-diazepine (3) systems and by effecting appropriate decoupling experiments. Contrary to the 1,2(1*H*)-diazepine–TCNE and -triazoline–dione adducts which undergo predominant mass spectral fragmentation by a retro-Diels–Alder reaction (8), the adducts **14***a–d* show a major common peak at *m/e* 227 corresponding to the loss of the —N_2—N_3—C_4— bridge. Common fragments are also observed at *m/e* 119 and 80 which may correspond to PhNCO and pyridazine, respectively, and may be derived

from the *m/e* 227 fragment. Minor H_2 loss from **14*a*** and *c* and major CH_2CO loss from **14*b*** and *d* are also evident.

Base-catalyzed Deacylation

Treatment of 1-acetyl-2-3-dihydro-1,2(1*H*)-diazepine (**2*a***) with an excess of sodium methoxide in methanol at room temperature gave the unstable 3,4-dihydro-1,2(2*H*)-diazepine (**15*a***) (Scheme 3). Of the three mechanistically reasonable dihydro-diazepines which may have been formed, the spectral data are consistent only with structure **15*a***. The available data also eliminate less plausible diazabicyclo[3.2.0]heptane derivatives which require *a priori* consideration in view of the past history of diverse ring contractions and rearrangements in the related 1,2-diazepin-4-one series (10). Compound **15*a*** shows i.r. absorption at 3300 (NH) and 1660 (C=N) cm^{-1} and u.v. (max) at 238 (3600) and 303 (3330) nm, the latter indicating extended conjugation. Its n.m.r. spectrum (indicated on structural formula **15*a***) also provides strong evidence for the structural assignment. As a consequence of its instability, **15*a*** was converted to the N_2—Ac derivative **16*a*** which could also be obtained by deacetylation of **3*a*** or decarbethoxylation of **9** under basic conditions. The transformation **9** → **16*a*** as well as the deacetylation of the N_2—Ts derivative **17** (obtained from **2*a*** by treatment with tosyl chloride and pyridine) to **18** offers clear evidence that N_2 is the common site of base-catalyzed deacylation.[6] The i.r. spectrum of **16*a*** shows absorption at 1670 (C=O) cm^{-1} and its u.v. and n.m.r. spectra (u.v. (max) 237 (3150) and 299 (4150) nm; n.m.r. indicated in structural formula **16*a*** below) are, as expected, very similar to those of **15*a***. Moreover, the close similarity of the n.m.r. spectrum of **15*a*** with that observed for the analogous compound, 2-benzoyl-7-phenyl-3,4-dihydro-1,2(2*H*)- diazepine may be noted (15).

The transformation **15*a*** → **16*a*** is of some interest in connection with the similar reaction of the 2,3-dihydro-1,2-diazepin-4-one **19** which, depending on conditions, gives either seven-membered ring (**20**) or bicyclic (**21**) tosyl or acyl derivatives (16, 17). The end result appears to depend on whether or not the N_2-anion of **19** is generated under the conditions of the tosylation or acylation reactions. Attempts to determine if similar behavior would be observed for compound **15*a*** have not been fruitful. Thus using Moore's experiments as a basis (16, 17), tosylation (TsCl, pyridine or NaH, TsCl, glyme) and acylation (MeCOCl, $PhNMe_2$, pyridine, or Et_3N) at a variety of temperatures were carried out to give reaction mixtures which underwent decomposition to red polymeric material upon attempted work-up.[7] In the case of **19**, it is possible that the course of the reaction and stability of the products are strongly influenced by the presence of the carbonyl function.

Compounds **2*b*** and **2*c*** were similarly deacetylated to give **15*b*** and **15*c***, respectively (Scheme 3). The spectral data (Table 4)[3] of **15*b*** and **15*c*** as well as of the N_2—Ac derivative (**16*c***) of the latter are also consistent with the 3,4-dihydro-1,2(2*H*)-diazepine representation and provide firm evidence against 1,2-diazabicyclo[3.2.0]heptane formulations for these products. The reaction undoubtedly involves the intermediacy of the N_1-

[6]Attempts to directly decarbethoxylate **8** with sodium methoxide gave mainly the corresponding carbomethoxy derivative by ester exchange together with a small amount of **15*a*** (see Experimental).

[7]We thank D. J. Harris for these experimental results.

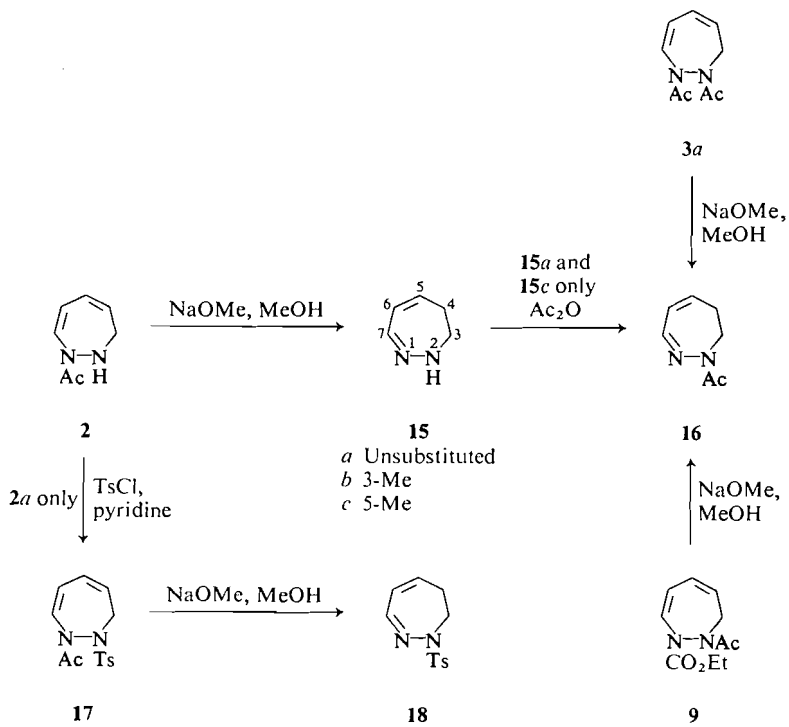
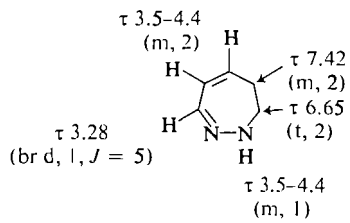
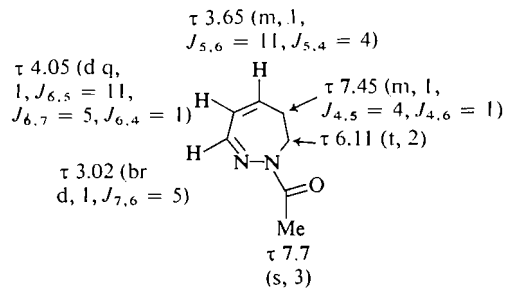


SCHEME 3

anion **22** since deacetylation of **2***a* and **3***a* using sodium methoxide in methanol-*O*-*d* gave, respectively, compounds **15***a* and **16***a* deuterated at C_4 and C_6 as evidenced by n.m.r. analysis (see Experimental). Protonation of the anion **22** then occurs at C_4 rather than at N_1 to generate the



15*a*



16*a*

thermodynamically more stable ene-hydrazine **15***a* or **16***a* as has been well established in other systems (18).

Photocyclization

Photolysis of the 2,3-dihydro-1,2(1*H*)-diazepines **2***a*, **3***a*, **8**, and **9** gave the 2,3-diazabicyclo-[3.2.0]hept-6-ene derivatives **23***a–b* and **25***a–b* whereas irradiation of the 3,4-dihydro-1,2(2*H*)-diazepine **16***a*[8] yielded the 1,2-diazabicyclo-[3.2.0]hept-6-ene **27** (Scheme 4). Unsaturated and more highly substituted derivatives of both bicyclic systems have been previously obtained by photolysis (1*b*, 6, 19). The NH compounds **23***a* and *b* were highly unstable but they were readily converted into the N—Ac derivatives **25***a* and *b* which were found to be identical with the photoproducts obtained directly from **3***a* and **9**, respectively. An N—Ts derivative **24** was also prepared for additional characterization purposes.

The structures of the bicyclic compounds **23–25** and **27** rest on their analytical and spectral data (Table 5).[3] Comparison of their n.m.r.

[8]Irradiation of the corresponding deacetyl compound **15***a* led only to decomposition.

R = Ts or COR′

22

R = H or Ac

spectra with those reported previously for other derivatives of these ring systems (6, 19) was helpful in the proton assignments. Nuclear magnetic resonance parameters for selected examples (**23***a*, **25***a*, and **27**) are given in the structural formulae below. Compound **23***b* was likewise obtained by Streith and Willig (3); our spectral data and theirs show close correspondence. *Cis* ring juncture stereochemistry is assigned to all compounds on the basis of the expected disrotatory mode of the photochemical electrocyclic reaction.

Finally, treatment of **25***a* or *b* with sodium methoxide in refluxing methanol cleanly gave compound **26**. Presumably the steric compression between the N_2-acetyl function and the C_1-hydrogen is responsible for the preferential N_2-deacetylation leading to the anion **28**. The interesting possibility that stabilization by homoconjugation with the C_6—C_7 double bond in **28** is in part responsible for the exclusive N_2-deacetylation was tested by subjecting compound **25***a* to the conditions of sodium methoxide in methanol-*O*-*d*. No incorporation of deuterium at C_6 was found (n.m.r. analysis) thus excluding this possibility.

The chemistry of a number of the dihydro-1,2-diazepine derivatives described in the present report is being explored.

Experimental

Melting points were determined on a Fisher-Johns apparatus and are uncorrected. Analyses were performed by A. B. Gygli, Toronto, Ontario and by Microanalytical Laboratories, Showa University, Tokyo, Japan. The i.r. spectra were recorded on Beckman IR-5A and -10 instruments in chloroform solution unless otherwise

noted. The u.v. spectra were measured on a Beckman DB-G spectrophotometer in ethanol solution. The n.m.r. spectra were recorded on Varian T-60 and HA-100 and Perkin Elmer-Hitachi 90 MHz spectrometers in deuteriochloroform solution using TMS as internal standard. In spectral tabulations, abbreviations for multiplicity are given as follows: br = broad, s = singlet, d = doublet, t = triplet, q = quartet, and m = multiplet. Mass spectra were determined with Hitachi-Perkin Elmer RMU-6E and AE1 MS-30 spectrometers. Thin-layer, preparative-thick-layer, and column chromatography were performed with silica gel specified for these purposes and obtained from Brinkmann (Canada) Ltd. Photolyses were carried out in a Rayonet Type RS Photochemical Reactor equipped with 3500-Å lamps using a Pyrex vessel cooled internally to 10–20° by a cold finger.

1-Acetyl-1,21(*H*)-diazepines (**1***a–e*, and **7**) and the irontricarbonyl complexes (**4***a* and *b*) were prepared by previously described methods (2*b*, 6, 11).

*Preparation of 2,3-Dihydro-1,2(1H)-diazepines (**2***a–e* **5***a–b*, **8**) (General Procedure)*

To a solution of the 1-acyl-1,2(1*H*)-diazepine (**1***a–e* and **7**) (0.2–0.3 g) in absolute methanol (30–40 ml) was added solid sodium borohydride (0.2–0.3 g) in small portions with stirring at room temperature. The solution was stirred further at room temperature for 5–6 h and then was evaporated to dryness *in vacuo* below 30°. The residue was cooled in an ice bath and treated with ice-water (10–15 ml). The resulting aqueous mixture was extracted with methylene chloride (2 × 50 ml). The organic extract was dried ($MgSO_4$) and evaporated to dryness to yield a yellow oil which, upon column chromatography (C_6H_6–CH_2Cl_2, 1:1 or CH_2Cl_2 eluents) gave the 2,3-dihydro-1,2(1*H*)-diazepines **2***a–e* and **8**.

The reduction of the irontricarbonyl complexes (**4***a–b*) to yield the corresponding dihydro complexes **5***a–b* was carried out similarly except that the reactions were effected under nitrogen and ethyl acetate was used as the eluent in chromatography.

The yields as well as full analytical, physical, and spectral data for compounds **2***a–e*, **5***a–b*, and **8** are collected in Table 1.[3]

*Formation of 2-Acetyl-2,3-dihydro-1,2(1H)-diazepines (**3***a–c*, **6***a–b*, and **9**) (General Procedure)*

A solution of the 2,3-dihydro-1,2(1*H*)-diazepine (**2***a–c*, **5***a–b*, and **8**) (*ca.* 100 mg) in acetic anhydride (4–5 ml) was allowed to stand at room temperature for 12–16 h. Excess acetic anhydride was evaporated *in vacuo* and the resulting residue was subjected to column chromatography (eluent: for **3***a–c* and **9**: C_6H_6–CH_2Cl_2, 1:1; for **6***a–b*: C_6H_6–EtOAc) to yield the pure compounds.

The yields as well as analytical, physical, and spectral data are presented in Table 1.[3]

*Reaction of 2,3-Dihydro-1,2(1H)-diazepines (**2***a*, **3***a*, **8**, and **9**) with $Fe_2(CO)_9$. Formation of $Fe(CO)_3$ Complexes (**5***a–b*, **6***a–b*) (General Procedure)*

To a solution of the ligand (**2***a*, **3***a*, **8**, and **9**) (0.2 g) in dry, degassed benzene (50 ml) was added an excess of $Fe_2(CO)_9$ (0.6 g) and the mixture was stirred in the dark at room temperature under nitrogen for 2 days. Solid material was removed by filtration and the filtrate was evaporated to dryness *in vacuo*. The resulting residue was dissolved in a small amount of benzene and subjected to column chromatography. Elution with C_6H_6–EtOAc (1:1) gave the yellow crystalline $Fe(CO)_3$ complex (**5***a*, **6***a–b*).

Complex **5***a*, obtained by the above method, was shown to be identical with the product of sodium borohydride reduction of **4***a* by m.p. and mixture m.p. determination. Likewise, complex **6***a* was shown to be identical with the acetylation product of **5***a*. Complex **5***b* could not be obtained in pure form due to extreme instability; it was therefore immediately acetylated (acetic anhydride, room temperature, overnight) to give complex **6***b*. Complex **6***b* thus obtained was found to be identical with the product of reaction between **9** and $Fe_2(CO)_9$ by m.p. and mixture m.p. determination.

Complete data for compounds **5***a* and **6***a–b* are given in Table 2.[3]

[4 + 2]π Cycloaddition Reaction of Compounds **2a**, **3a**, **8**, *and* **9** *with 4-Phenyl-1,2,4-triazoline-3,5-dione. Formation of Adducts* **14a–d** *(General Procedure)*

To a solution of the 2,3-dihydro-1,2(1*H*)-diazepine (**2a**, **3a**, **8**, and **9**) (100–200 mg) in dry acetone (5–10 ml) was added slowly with stirring at room temperature a solution of 4-phenyl-1,2,4-triazoline-3,5-dione (1.1 equiv.) in dry acetone (5 ml). The deep red color of the added reagent was discharged instantaneously. The solution was allowed to stand at room temperature for 2–3 h and was then evaporated to dryness *in vacuo*. The resulting residue was triturated with methanol to yield a solid which was collected by filtration and recrystallized from benzene or acetone to give colorless crystals of adducts (**14a–d**) (80–90%) whose analytical, physical, and spectral data are given in Table 3.[3]

Reaction of 1-Acyl-2-3-dihydro-1,2(1H)-diazepines **2a–c**, **3a**, **9**, *and* **17** *with Sodium Methoxide. Formation of 3,4-Dihydro-1,2(2H)-diazepines* **15a–c**, **16a**, *and* **18** *(General Procedure)*

To a solution of the 1-acyl-2,3-dihydro-1,2(1*H*)-diazepines (**2a–c**, **3a**, **9**, and **17**) (0.2–0.3 g) in methanol (30–40 ml) was added excess sodium methoxide (0.3 g) and the reaction was allowed to proceed at room temperature for the following duration depending on compound: **2a–c** (8–12 h), **3a** (32 h or 6–7 h at reflux), **9** (48 h), **17** (21 h). The pale yellow solution was evaporated to dryness *in vacuo* and the resulting residue was extracted with methylene chloride (2 × 50 ml). Column chromatography (CH_2Cl_2–MeOH, 95:5 eluent) gave the 3,4-dihydro-1,2(2*H*)-diazepines (**15a–c** (40–60%), **16a** (80%), and **18** (70%)). With the exception of **18**, all compounds were unstable yellow oils. Method of purification and complete data are presented in Table 4.[3]

Formation of 1-Carbomethoxy-2,3-dihydro-1,2(1H)-diazepine (Compound **i**, *Table 1)*[3] *from Compound* **8**

To a solution of **8** (0.28 g) in methanol (40 ml) was added sodium methoxide (0.3 g) and the mixture was stirred at room temperature for 24 h. Work-up followed by chromatography as described in the general procedure above gave 170 mg (65%) of 1-carbomethoxy-2,3-dihydro-1,2(1*H*)-diazepine (eluted with CH_2Cl_2) and 25 mg (15%) of compound **15a** (eluted with CH_2Cl_2–MeOH, 95:5). The former compound was characterized by analytical and spectral data (Table 1)[3] while the latter (**15a**) was found to be identical (t.l.c., i.r., n.m.r.) with the sample obtained by deacetylation of **2a**.

Reaction of Compounds **2a** *and* **3a** *with Sodium Methoxide in Methanol-O-d*

Treatment of compounds **2a** and **3a** with sodium methoxide in methanol-*O*-*d* under conditions described for the deacetylation reaction above (general procedure) gave after chromatography deuterated **15a** and **16a** respectively as yellow oils. The relative integrated intensities of the appropriate peaks in the n.m.r. spectra showed the following amounts (±10%) of deuterium incorporation: **15a**: C_5—H (35%), C_4—H_2 (40%); **16a**: C_5—H (80%), C_4—H_2 (70%), N_2—$COCH_3$ (70%). The mass spectrum of deuterated **16a** showed (*m/e*, % relative intensity): 144 (M^+ for $C_7H_4D_6N_2O$, 22), 143 (17), 100 (53), 99 (37), 98 (22), 72 (36), 71 (33), 70 (100), 69 (35).

*1-Acetyl-2-(p-toluenesulfonyl)-2,3-dihydro-1,2(1H)-diazepine (***17***)*

A mixture of **2a** (250 mg), tosyl chloride (350 mg) and dry pyridine (5 ml) was allowed to stand at room temperature overnight. The reaction mixture was evaporated to dryness *in vacuo* and the residue was dissolved in a small amount of benzene and chromatographed. Elution with methylene chloride gave yellow crystals of **17** whose analytical, physical, and spectral properties are given in Table 1.[3]

Photolysis Experiments

*Formation of 2,3-Diazabicyclo[3.2.0]hept-6-enes (***23a–b**, **25a–b***) (General Procedure)*

A solution of the 2,3-dihydro-1,2(1*H*)-diazepine (**2a**, **3a**, **8**, and **9**) (150–200 mg) in dry benzene (100 ml) was irradiated for 12–15 h under a nitrogen atmosphere. The solvent was removed *in vacuo* and the resulting residue was chromatographed (C_6H_6–CH_2Cl_2, 1:1 eluent) to give the bicyclic compound (**23a–b** and **25a–b**) as an unstable yellow oil in 70–80% yield. Analytical, physical, and spectral data are summarized in Table 5.[3]

Treatment of **23a** and *b* with a large excess of acetic anhydride at room temperature overnight followed by evaporation *in vacuo* and chromatography (CH_2Cl_2 eluent) gave compounds **25a** and *b* in 80–85% yields which were shown to be identical (i.r., n.m.r.) with the products obtained by photolysis of **3a** and **9** respectively.

*Formation of 2-Acetyl-1,2-diazabicyclo[3.2.0]hept-6-ene (***27***)*

A solution of **16a** (200 mg) in dry benzene (100 ml) was photolyzed for 12 h under nitrogen. Evaporation of solvent *in vacuo* followed by chromatography (C_6H_6–CH_2Cl_2, 1:2 eluent) gave 130 mg (65%) of compound **27** as a pale yellow oil for which complete data are given in Table 5.[3]

*2-Acetyl-3-(p-toluenesulfonyl)-2,3-diazabicyclo[3.2.0]hept-6-ene (***24***)*

A solution of **23a** (50 mg) and tosyl chloride (60 mg) in dry pyridine (5 ml) was allowed to react overnight at room temperature. Evaporation to dryness *in vacuo* followed by chromatography (CH_2Cl_2 eluent) afforded 73 mg (69%) of **24** as pale yellow crystals for which complete data are given in Table 5.[3]

*Formation of 3-Acetyl-2,3-diaza[3.2.0]bicyclohept-6-ene (***26***) from Either Compound* **25a** *or* **25b**

To a solution of the diacyl bicyclic derivative (**25a** or *b*) (90–100 mg) in absolute methanol (30 ml) was added excess sodium methoxide (200 mg) and the mixture was stirred at room temperature for 2 days or refluxed for 8 h. The reaction mixture was evaporated to dryness and the resulting residue was extracted with methylene chloride. The organic extract was dried ($MgSO_4$) and evaporated to dryness to yield a dark oil which upon chromatography (CH_2Cl_2 eluent) gave the same compound **26** (yellow oil, ~80% from either **25a** or **25b**) as shown by i.r. and n.m.r. spectral comparison. Analytical, physical, and spectral data are collected in Table 5.[3]

When the diacetyl derivative **25a** was treated with sodium methoxide in methanol-*O*-*d* under comparable conditions there was obtained, after chromatography,

compound **26** whose n.m.r. spectrum showed that deuterium incorporation had occurred only at the N_2–$COCH_3$ function (~75% by relative integrated intensity) during the deacetylation reaction.

We are grateful to the National Research Council of Canada and Bristol Laboratories for financial support of this work. We thank Dr. J. M. Miller, Brock University for fast and efficient mass spectral service under contract by our department. Professor D. Mackay kindly provided a large sample of 1-phenyl-1,2,4-triazoline-3,5-dione. Generous samples of pyridine derivatives were made available by the Reilly Tar and Chemical Corp.

Electrochemical Oxidation of Trifluoroacetic Acid in an Organic Substrate. III. In the Presence of Substituted Malonic Acid Half Esters and Unsaturated Carboxylic Acid Esters[1,2]

ROGER N. RENAUD AND PHILIPPE J. CHAMPAGNE[3]

Division of Chemistry, National Research Council of Canada, Ottawa, Canada K1A 0R6

Received September 26, 1974

ROGER N. RENAUD and PHILIPPE J. CHAMPAGNE. Can. J. Chem. **53**, 529 (1975).

The electrochemical oxidation of substituted malonic acid half-esters was studied in the presence of trifluoroacetic acid. Some 'crossed' Kolbe products were obtained together with some unsaturated carboalkoxy compounds, trifluoromethylated adducts to the double bond, and trifluoromethylated dimers.

The electrolysis of trifluoroacetic acid in the presence of olefinic carboalkoxy compounds was also studied.

ROGER N. RENAUD et PHILIPPE J. CHAMPAGNE. Can. J. Chem. **53**, 529 (1975).

On a étudié, en présence d'acide trifluoroacétique, l'oxydation électrochimique de monoester d'acides maloniques substitués. On a obtenu avec des produits de Kolbe croisés, quelques composés alkoxycarbonylés, des produits provenant de l'addition de groupe trifluorométhyles sur une double liaison de même que des dimères trifluorométhylés.

On a aussi étudié l'électrolyse de l'acide trifluoroacétique en présence de composés alkoxycarbonylés oléfiniques. [Traduit par le journal]

Introduction

The electrochemical oxidation of trifluoroacetic acid (TFA) has been shown to be a good source of trifluoromethyl radicals (1, 2) which, under appropriate conditions can be made to react with organic substrates to form new trifluoromethylated compounds. It is reported in a previous communication (2) that no 'crossed' Kolbe product was formed during the electrolysis of propionic acid in the presence of trifluoroacetic acid. This was due to the fact that an ethyl radical decomposes to ethylene at a faster rate than its condensation with a CF_3 radical. The aim of this work (part III of the series) was to study the effect of a carboalkoxy group on the formation of 'crossed' Kolbe products from the electrolysis of a mixture of substituted malonic acid half-ester and trifluoroacetic acid.

Since relatively important quantities of products deriving from unsaturated carboalkoxy intermediates were formed when the substituent on the malonic acid ester was a methyl group, the electrolysis of TFA in the presence of unsaturated carboxylic acid esters is also included in this study.[4]

Experimental

All starting materials were commercially available (or easily accessible) and were used without further purification. All melting points and boiling points are uncorrected. The electrolytic apparatus has been described elsewhere (1, 2).

Gas–liquid chromatographic analyses and separations were performed on an Aerograph Autoprep Model A-700 using the following columns: column A, 20 ft × 3/8 in., 20% Carbowax 20 M on 45–80 mesh Chromosorb P; column B, 20 ft × 3/8 in., 10% diethyleneglycol succinate on 45–60 mesh Chromosorb G (AW-DMCS).

The general pattern of the mass spectra is nearly the same for all the trifluoromethylated compounds obtained in this work. Therefore, only one spectrum will be shown (Fig. 1) and will serve as a typical model for the other compounds.

Electrolysis of Malonic Acid Monoester in the Presence of TFA

A solution of trifluoroacetic acid (3.4 g, 30 mmol) in water (6 ml) was added at a rate of 1 drop/10 s to an electrolyzed solution of malonic acid monoethyl ester (30 ml) and potassium hydroxide (2.2 g, 40 mmol) in water (40 ml). The electrolysis was carried out at a current density of 0.7 A/cm^2 at 20 °C and was continued for 1 h after the addition of TFA.

The cell was then attached to a vacuum manifold and

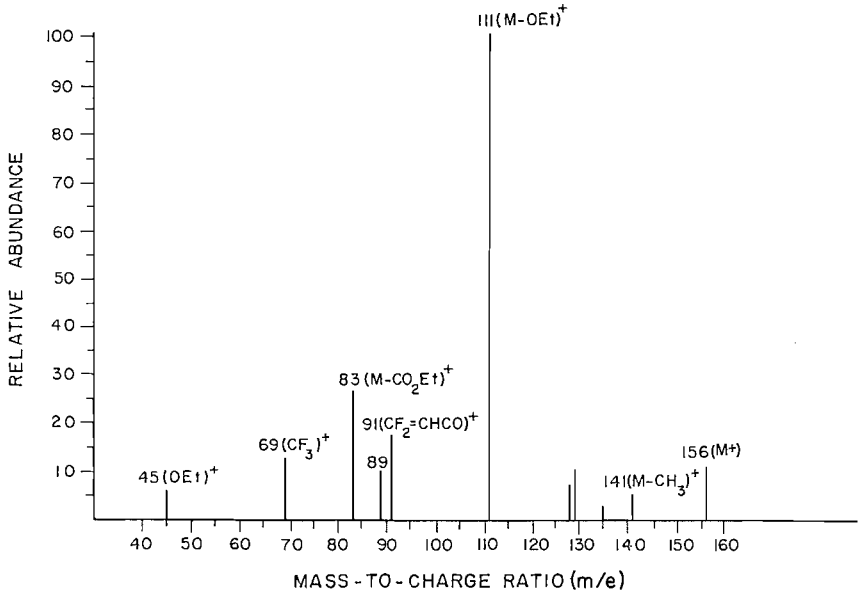

FIG. 1. Mass spectrum of methyl trifluoromethylacrylate (run 1) at 70 eV.

the organic material was collected together with some water in a cold trap (≈10 ml). The heavy oil (2 g, 46%) which separated from the water was nearly pure ethyl trifluoromethylacetate. Further purification can be made by fractional distillation at atmospheric pressure using a semimicro distilling apparatus. The main fraction, boiling at 107 °C (lit. (4) 50 °C/12 mm), showed only one triplet in the ^{19}F n.m.r. spectrum. The mass spectrum is shown in Fig. 1.

Anal. Calcd. for $C_5H_7O_2F_3$: C, 38.46; H, 4.49. Found: C, 38.10; H, 4.49.

Electrolysis of Methyl- and Dimethylmalonic Acid Monoester in the Presence of TFA

Using the same procedure as described above, methyl- and dimethylmalonic acid monoesters were electrolyzed in methanol due to the low solubility of the esters in water. The reaction mixture was poured into water (1l). The heavy oil that separated was washed with a solution of Na_2CO_3 (5%) and distilled in a vacuum manifold. The high vapor pressure (h.v.p.) fraction (>0.1 mm pressure) was collected in a cold trap and the low vapor pressure (l.v.p.) fraction was distilled in a Späth bulb. Both fractions were fractionated separately by preparative g.l.c. and each fraction analyzed by mass spectrometry and ^{19}F n.m.r. spectroscopy. The results are shown in Scheme 1 and Table 1.

Electrolysis of TFA in the Presence of Unsaturated Carboxylic Acid Esters

A solution of the ester (0.04 mol), sodium acetate (or sodium methoxide) (0.03 mol), and TFA (19 g) in acetic acid (or in methanol) (50 ml) was electrolyzed at a current density of 0.07–0.14 A/cm² until a 50% excess of current was used. The solution was then poured into water (1 l). The heavy oil that separated from the water was treated as described above. The results are reported in Table 2 and Scheme 2.

Results and Discussion

The electrochemical oxidation of malonic acid monoethyl ester in the presence of TFA gave ethyl trifluoromethylacetate in 46% yield (Table 1). The compound was easily obtained pure by only a vacuum line distillation. The synthesis of this compound has been described in the literature (4) in a yield of 40% by the Arrnt–Eistert reaction from trifluoroacetic acid. However, the best yields obtained by us by this method were ≈10%. The electrolysis of methyl- and dimethylmalonic monoester in presence of TFA gave some mixed Kolbe product **2** (Scheme 1). However, probably because of the low concentration of trifluoromethyl radicals in the medium, the possibility of the ethyl propionate radical **1** losing a hydrogen radical[5] to form the olefinic compound **3** must be relatively high. Therefore, the formation of compounds **4**, **5**, and **7** can be explained by the addition of two CF_3 radicals across the double bond of compound **3**, by the addition of two CF_3 radicals followed by a hydrogen abstraction, and by the crossed condensation of ethyl β-trifluoromethyl-

[5]By disproportionation or any other mechanisms.

propionate radical **6** and ethyl propionate radical **1**, respectively. It is worth noticing that the radical **1** is always present in relatively large quantity in the medium. In addition, a small quantity of the dimer of radical **6** was also formed.

The results obtained from the electrooxidation of substituted malonic acid monoesters prompted us to examine the electrolysis of trifluoroacetic acid in the presence of unsaturated carboalkoxy compounds. The reaction was carried out in either acetic acid or methanol. The advantage of the acetic acid solvent, aside from its ability to dissolve the esters, is that the medium is kept acidic: an important condition in the electrolysis of fluorinated acids, since a basic solution favors the formation of fluoride ions which can ruin the cell. As the pK value for acetic acid is much higher than the value for TFA, only a small concentration of acetate anions is present in the medium. Furthermore, a methanolic solution decreases the overall yield of products and favors the formation of some dark polymeric solids.

The result observed for the electrolysis of TFA in the presence of methyl acrylate is

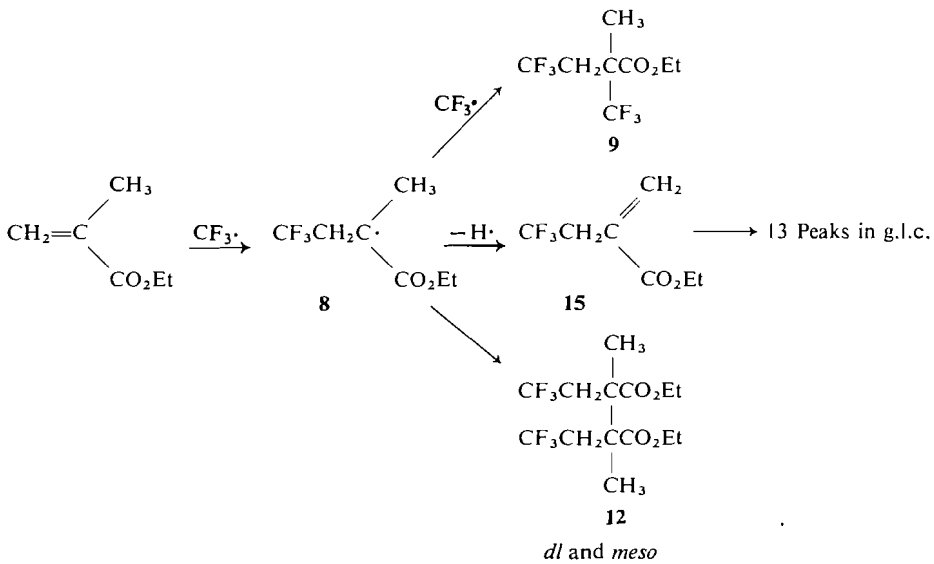
SCHEME 2



SCHEME 3

shown in Scheme 2 and in Table 2, run 4. The addition of two CF_3 radicals across the double bond to give **9** is the main product in the h.v.p. fraction. Some proton abstraction product (**10**) and proton loss product (**11**) were also observed. The dimerization of radical **8** is also important in this reaction. The dimer **12** was separated into the *dl* and *meso* forms in a ratio of $\approx 1:1$. The structure determination of **12** is based on its mass spectrum and on the fact that the ^{19}F n.m.r. spectrum of **12** showed only one triplet. Isomers **13** and **14** would show either a doublet or a doublet and a triplet respectively. Therefore, the attack of the first CF_3 radical occurs mainly, if not exclusively, on the β-carbon of the α,β-unsaturated carboalkoxy molecule.

Essentially the same result was observed for ethyl crotonate (run 5) as for methyl acrylate (run 4). However, the addition of a methyl group to the α-carbon of methyl acrylate (run 6) leads to a much more complicated reaction mixture than when the methyl group is on the β-position (run 5). In the case of substitution at the α-carbon, the radical **8** (Scheme 3), formed after the first addition of a CF_3 radical on the β-carbon, can condense with another CF_3 radical to give **9**, lose a hydrogen radical to form **15**, or dimerize to **12**. The increased complexity of the reaction mixture (besides the compounds mentioned, 13 other peaks were obtained in the g.l.c. in the h.v.p. fraction and 2 other unidentified peaks in the l.v.p. fraction) is due to the fact that the radicals **8** and CF_3 are in the presence of the starting material and compound **15**.

An electrolysis of TFA was also done in the presence of ethyl vinylacetate in order to study

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

the mechanism of the reaction on a non-conjugated system. Five compounds of the h.v.p. fraction were isolated by g.l.c. but only two were identified (compounds **9** and **11** in Table 2, run 7). The main fraction was that due to the addition of two CF_3 radicals across the double bond. The g.l.c. showed that the l.v.p. fraction contained five compounds. The elemental analysis and the mass spectrum of the crude mixture showed that these were all isomers of **12**. The ^{19}F n.m.r. of the main fraction indicates that the compound is most likely diethyl 3,4-bis(β-trifluoroethyl)adipate. Therefore, the attack of the CF_3 radical seems to favor the terminal carbon.

It can be concluded from this work that the electrochemical oxidation of malonic acid ester in the presence of TFA to give the 'crossed' Kolbe product has some limitation. The reaction becomes very complex for α-methylated malonic acid monoesters due to the formation of unsaturated intermediates. However, the addition of CF_3 radicals across a double bond of unsaturated carboalkoxy substrate can be useful for the synthesis of bistrifluoromethylated compounds which could be difficult to synthesize otherwise. Also, because of the fact that the attack of the first CF_3 radical occurs almost exclusively on the terminal carbon, the products of dimerization are limited to only few compounds; otherwise the reaction mixture would have been very complex.

A study was made on controlled concentrations of either the CF_3 radical or the methyl acrylate substrate in order to improve the formation of either the monomeric or the dimeric products, but no significant improvements resulted.

We wish to acknowledge Messrs. H. Séguin and R. Pilon for the elemental analyses and the mass spectral determinations and Dr. S. Brownstein and Mr. J. Bornais for the ^{19}F n.m.r. spectra.

Substituent Effects in the Thermal Isomerization of 1,2-Dicarbonyl Derivatives of 3,6-Bridged 1,2,3,6-Tetrahydropyridazines

JOHN A. CAMPBELL, IAN HARRIS, DONALD MACKAY, AND TIMOTHY D. SAUER

Department of Chemistry, University of Waterloo, Waterloo, Ontario N2L 3G1

Received Agust 12, 1974

JOHN A. CAMPBELL, IAN HARRIS, DONALD MACKAY, and TIMOTHY D. SAUER. Can. J. Chem. **53**, 535 (1975).

The Diels–Alder adducts of cyclopentadiene and azodiacyls or azodiaroyls isomerize to 1,3,4-oxadiazines at rates which show a trend qualitatively related to the rotation rates of the corresponding *N,N*-dimethylamides. The isomerizations probably occur by a cyclic concerted mechanism.

The ring substituents in the adducts of 1,4-dimethyl-2,3-diphenylcyclopentadiene and azodibenzoyl or azodiacetyl accelerate the isomerization; the kinetic evidence supports a cyclic intermediate in the reaction in isooctane as solvent but is more consistent with a dipolar intermediate in aqueous ethanol.

Some generalizations about the effect of substituents on the isomerization are presented on the basis of these and earlier experiments.

JOHN A. CAMPBELL, IAN HARRIS, DONALD MACKAY et TIMOTHY D. SAUER. Can. J. Chem. **53**, 535 (1975).

Les produits d'addition de Diels–Alder entre le cyclopentadiène et les azodiacyles et les azodiaroyles s'isomérisent en oxadiazines-1,3,4 à des vitesses qui indiquent une tendance reliée qualitativement aux vitesses de rotation des *N,N*-diméthylamides correspondantes. Les isomérisations se produisent probablement par un mécanisme cyclique concerté.

Les substituants sur les cycles dans les produits d'addition du diméthyl-1,4 diphényl-2,3 cyclopentadiène avec l'azodibenzoyle ou l'azodiacétyle ont comme effet d'accélérer la vitesse d'isomérisation. Les données cinétiques sont en accord avec un intermédiaire cyclique lorsque la réaction est effectuée dans l'isooctane alors qu'en milieu éthanol aqueux, le mécanisme impliquerait probablement un intermédiaire dipolaire. On présente quelques généralisations sur l'effet des substituants sur de telles isomérisations en se basant sur ces expériences et d'autres rapportées antérieurement. [Traduit par le journal]

Introduction

For some time we have been studying the generalized isomerization of the bridged pyridazine **1** to the *cis*-fused 1,3,4-oxadiazine system **2** and have shown that its rate is highly dependent on the nature of X, R, R_1, and R_2. Our experiments have concentrated on the [2.2.1] system with a one-carbon bridge, in particular the azodicarbonyl adducts **3** of cyclopentadiene (1, 2) and those, **5**, of 2,5-dimethyl-3,4-diphenylcyclopentadienone (3).

In the series **3** → **4** the participation of acyl groups in the isomerization showed a marked steric acceleration, with a rate order of R = CMe_3 > Ph > Me, and, in the phenyl case at least (1), appeared to involve a concerted cyclic mechanism (transition state **7**). Ester groups however, *e.g.* in **3** (R = OEt), did not participate.

The cyclone-derived substituents in the adducts **5** had a powerful accelerating effect. Thus the azodibenzoyl adduct **5***a* could only be transiently detected, the isomeric 1,3,4-oxadiazine **6***a* being the isolated product, whereas adducts of azo esters, *e.g.* **5***c*, though stable enough for isolation, could be isomerized readily and reversibly to **6***c* (3).[1] Detailed kinetic studies were not carried out but the mechanism for the isomerization of **5***c* was most reasonably interpreted as involving the doubly ambident dipolar intermediate **8**.

We wish now to discuss in more detail the effect of the group R in **3**, especially in the substituted phenyl series **3***d–h*, and of ring substituents in the presence of a methylene rather than a keto bridge, *viz.* the adducts **9** in contrast with **5**. We also present in summary some

[1]Both **5***c* and **6***c* isomerized irreversibly to the isomeric 1,2-diazetidine which was thus the end product (3). The mode of fusion of the oxadiazine ring in compounds **6** (oxygen to benzylic carbon) and the stereochemistry follow by mechanistic analogy with the formation of **4**, from their spectra (3), and, in the case of **6***c*, by its chemical reactions (4).

generalizations about the influence of X, R, R_1, and R_2 on the isomerization **1** → **2**.

Results and Discussion

All the substituted benzoyl derivatives in the series **3** → **4** have been described earlier (1, 2) except **3***g* and *h* and **4***g* and *h*. Compounds **9***a* and *b* and **10***a* and *b* have been used before in unrelated work (5) but their synthesis and properties are described here for the first time.

Azodi-*m*-nitrobenzoyl, m.p. 159–161°, rapidly gave labile crystalline **3***g* with cyclopentadiene. The hindered azodi-*o*-methoxybenzoyl was too unstable for isolation; it reacted slowly with cyclopentadiene to give the stable but amorphous **3***h*, purified by silica gel chromatography. The very labile (1) **9***a* was prepared in benzene at room temperature and purified by precipitation with pentane. The adduct **9***b*, obtained similarly, was more stable except in hydroxylic solvents. The melting points of **9***a* and *b* depended on the rate and time of exposure to heating. The oxadiazines related to these adducts were obtained by heating the latter in inert solvents at suitable temperatures. Their identities followed unequivocally from their spectra.

Kinetic analyses of the isomerizations were carried out by u.v. spectrophotometry as described before (1, 2, 6).

The first-order rate constants for the isomerization of **3***a–f* at 77° in 71% aqueous ethanol have been given earlier but, except for **3***b*, have now been determined for all of them over a range of temperatures. The Arrhenius activation energy and the entropy of activation are given in Table 1, along with the rate constants at 77°. The rate constants for **3***g* and *h* were determined only at 77° and are also given in Table 1.

From the similarity of the activation parameters to those of **3***a* it seems reasonable that all the isomerizations **3***b–f* go through a concerted cyclic transition state.

The isomerizations of the *p*-substituted benzoyl adducts, **3***d–f*, are clearly not subject to any simple linear free energy correlation (unlike the mechanistically related *ortho*-Claisen rearrangement where the rate data correlated well with σ_p^* constants (7, 8)) since all substituents are rate enhancing, though the effect is small except for the nitro group.

A rationalization of the substituent trends

TABLE 1. Rate constants at 77 °C and activation parameters for isomerization of adducts 3 in 71% aqueous ethanol

Compound	R	$10^4 k$ (s^{-1})	E_a (kcal mol^{-1})	No. of runs (range, °C)	$\Delta S^{\ddagger}$ at 77 °C (cal deg^{-1})	$\Delta G^{\ddagger}$, $RCONMe_2$ rotation[d] (kcal mol^{-1}) (temperature, °C)
3*a*	Ph	2.42	23.3±1.2	6 (69–84)	−5.5±1.8	15.3 (3–17)[e]; 15.0 (77)[f]
3*b*	Me	0.21[a]				18.1 (70–83)[e]; 17.5 (77)[f]
3*c*	CMe_3	74.5	21.3±0.8[b]	7 (61–79)	−5.0±1.2	11–13[g]
3*d*	*p*-BrC_6H_4	6.77	20.1±1.7	5 (69–80)	−9.0±2.5	
3*e*	*p*-$NO_2C_6H_4$	17.5	20.5±0.6	4 (66–78)	−7.6±0.9	
3*f*	*p*-$MeOC_6H_4$	2.64	23.1±0.6	7 (67–79)	−5.6±0.9	
3*g*	*m*-$NO_2C_6H_4$	30.2	[c]			16 (16)[h]
3*h*	*o*-$MeOC_6H_4$	0.21	[c]			19 (87)[h]

[a]From the value at 79.5 °C and an assumed E_a of 22 kcal mol^{-1}.
[b]Only one run in aqueous ethanol; activation data refer to runs in isooctane.
[c]Only one run.
[d]Data from refs. 9*a* and *b*.
[e]Average of values listed in ref. 9*a*, in the temperature range shown.
[f]Highly reliable values calculated from data of ref. 9*b*.
[g]Estimate at unspecified temperature by authors of ref. 9*a*.
[h]Notable inhibitory *ortho* effect (9*a*): $\Delta G^{\ddagger}$ for *o*-nitro compound, 20 kcal mol^{-1} (102°); for *m*-methoxy compound 15 kcal mol^{-1} (1°).

must explain both the most notable trend, the sensitivity to steric assistance shown in the sequence CMe_3 > aryl > Me, and, within the aryl series, the retarding effect of an *ortho* group (surprising in view of the steric effect of CMe_3) and the slight accelerating effect of a *meta* one.

The transition state for isomerization (*e.g.* 7), in which oxygen to carbon bond formation occurs, requires a well developed pyramidal geometry at nitrogen. A large portion of the free energy of activation must involve the energy difference between the planar amide (with sp^2 nitrogen) in the ground state adduct and the nonplanar amide (with sp^3 nitrogen) in the transition state.[2] This difference is simply the conformational energy barrier for amide rotation. A correlation might thus be expected between the latter and the activation energies for isomerization. The barrier heights ($\Delta G_{rot}^{\ddagger}$) for some of the related *N*,*N*-dimethylamides are also given in Table 1. They correspond to rotation rate constants which show, qualitatively at least, the trend found for the isomerization rates.[3]

The interpretation of the effect of R on the isomerization is thus probably the one applicable to amide rotation (9*a*). Bulky alkyl groups (*e.g.* R = CMe_3) are rate enhancing since they destabilize the ground state more than the transition state and aryl groups (phenyl, *m*- or *p*-substituted phenyl) are more effective than simple alkyl groups (*e.g.* R = Me) since ring resonance competes against amide ground state resonance. *o*-Substituted groups, however, create a retardation, ring twisting inhibiting this competing resonance and steric interaction being less severe in the ground state than in the transition state (9*a*). Thus the *o*-methoxy compound 3*h* reacts more slowly than the *p*-isomer 3*f*.

[2]The other contributions to the activation energy of the isomerization, involving changes in bonding type over the six centers, may be much less sensitive to the nature of R. Changes in bonding type, however, must be the dominant factor when R is an alkoxy group, since the cyclopentadiene adducts of azo esters are extremely stable, even though the rotational energy barriers in urethanes are 2–3 kcal mol^{-1} *lower* than in the corresponding amides (9*a*).

[3]Only the value for 3*g* is seriously out of line. Many early data on rotation barriers, however, are of limited reliability (*cf.* ref. 9*b*).

In each of the adducts 3 the group R has an identical neighbor at the adjacent amide link. A more accurate correlation might be observed if there was a common but nonparticipating neighbor throughout the series, as, for example, in the adducts of $RCON{=}NCO_2Et$.

The substituent effect is electronic to some extent as shown by the rate constants for 3*d*–*f*, in which steric effects are presumably negligible. Not enough reliable data are available on the rotational energy barriers of *p*-substituted benzamides to say whether they too are subject to the same electronic effects.

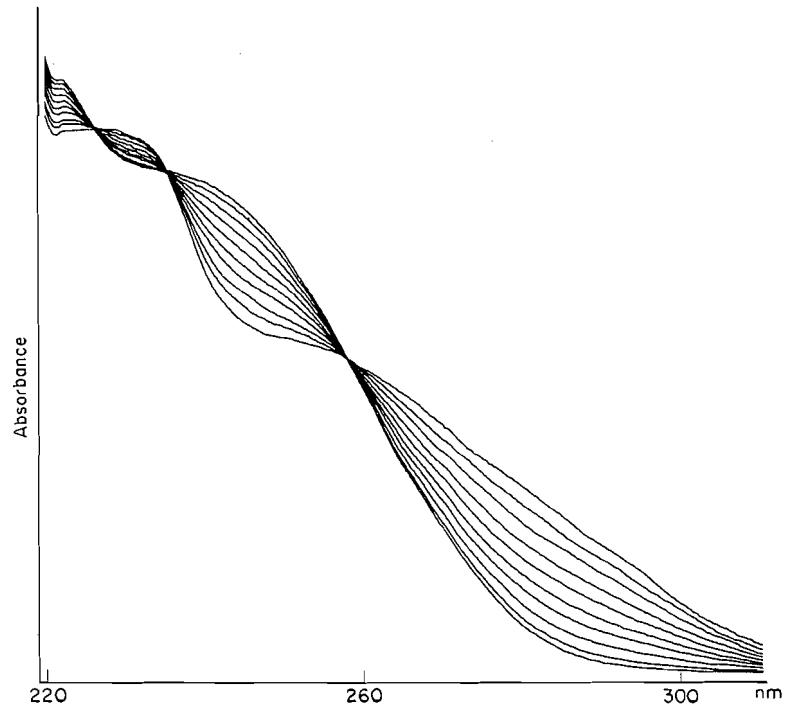

FIG. 1. Isomerization of **9***b* in isooctane at 79.5°. The absorbance decreases with time above 260 nm.

The slightly greater reactivity of **3***g* than **3***e* suggests that the nitro group sterically assists the reaction without causing significant ring twisting. An alternative explanation is that the rate enhancing ring resonance which must put positive charge at *ortho* and *para* carbon atoms would be more effective with the electronegative nitro group in the *meta* rather than the *para* position.

Known values of other amide rotation barriers (9*a*) permit the prediction that, for example, **3** (R = trichloromethyl) would isomerize very rapidly but **3** (R = 2,4,6-trimethylphenyl) would be very stable.

Isomerization studies on the adducts **9***a* and *b*, in which the degree of ring substitution is intermediate between that in the series **3** and **5**, were done in both isooctane and 71% aqueous ethanol. Clean first-order kinetics (see *e.g.* Fig. 1) were obtained in every case. The rates at 69.5° and the activation parameters are given in Table 2, together with the related data for the unsubstituted counterparts **3***a* and *b*. A remarkable solvent effect is observed.

The ring substituents in **9***a* and *b* are strongly rate enhancing in isooctane though the effect (compared with **3***a* and *b*[4]) is less pronounced for the benzoyl (37-fold) than the acetyl (220-fold) case. The rate ratio of $k_{9a}/k_{9b} = 35$ is again indicative of the greater conformational stability of the *N*-acetyl linkage.

In aqueous ethanol both **9***a* and *b* isomerize extremely rapidly at 69.5° (half lives < 30 s) and *at almost the same rate* in contrast with the 35-fold rate factor in isooctane. The high rates[5] and the levelling effect of the solvent suggest a mechanistic difference in the two solvent systems with the intervention of an intermediate whose formation is not dependent on activation to pyramidal

[4]The rate constant for **3***b* was obtained by extrapolation from the value in refluxing isooctane (99°) using an assumed Arrhenius activation energy of 24 kcal mol^{-1} (*cf.* other E_a values in isooctane from Table 2). It is probably a reasonable estimate.

[5]The ring substituent effect in aqueous ethanol is especially striking for the azodiacetyl adducts with $k_{9b}/k_{3b} = 2500$. Large rate factors with solvent change are not in themselves proof of a change in mechanism. Thus the linear plot of $\Delta H^{\ddagger}$ *vs.* $\Delta S^{\ddagger}$ (isokinetic relationship) in the *ortho*-Claisen reaction of allyl *p*-tolyl ether in a wide range of solvents is indicative of a common mechanism in all of them despite a very large rate spread (10).

TABLE 2. Solvent effect on rate constants at 69.5 °C and activation parameters for isomerization of *3a* and *b* and **9***a* and *b*

Compound	Solvent	$10^4 k$ (s^{-1})	E_a (kcal mol^{-1})	No. of runs (range, °C)	$\Delta S^{\ddagger}$ at 69.5 °C (cal deg^{-1})
3*a*	Isooctane	0.75	26.7±1.0	4 (69–84)	−0.8±1.5
	Aqueous ethanol	1.17	23.3±1.2	6 (69–84)	−5.6±1.8
3*b*	Isooctane	0.0036[a]			
	Aqueous ethanol	0.10[b]			
9*a*	Isooctane	27.4	23.3±0.4	7 (55–69)	−4.5±1.3
	Aqueous ethanol	267	19.1±0.5	9 (40–70)	−12.2±1.6
9*b*	Isooctane	0.79	25.5±0.8	6 (72–86)	−5.2±2.2
	Aqueous ethanol	253	17.9±0.3	7 (40–67)	−16.0±0.8

[a]Estimated from the value at the b.p. (99 °C) and an assumed E_a of 24 kcal mol^{-1}.
[b]See Table 1, footnote [a].

nitrogen. A plausible species is the dipole **11**, with a rigid (tight ion pair) rather than a freely rotating (about C—N) structure, a requirement implied by the negative entropy of activation[6] and the exclusive formation of a diasteromerically pure oxadiazine in the reaction. Stabilization of **11** would be provided by the substituents in the allylic cation portion, especially the electron releasing methyl group, and by the solvent polarity.

In our earlier work with the keto bridged compounds **5** we failed to isolate **5***a* from the reaction of azodibenzoyl and the cyclone, though its intermediacy in the formation of **6***a* in benzene solution could be detected by n.m.r. spectroscopy. We repeated the reaction with azodiacetyl in the hope that we might isolate **5***b*, provided the stabilizing effect of the acetyl group in nonpolar solvents still persisted in the presence of the keto bridge. However our efforts were vitiated by our inability to obtain a sufficiently concentrated solution of the azo compound (2) and the rather high temperature necessary to generate the cyclone from its dimer, factors which prevented the bimolecular formation of the adduct from being competitive with its unimolecular isomerization. Though there was evidence (n.m.r. spectroscopy) for the presence of **5***b* in small amounts during the reaction only the oxadiazine **10***b* (5) could be finally isolated.

[6]A negative contribution to $\Delta S^{\ddagger}$ could also come from a highly ordered solvation of the dipole. Other interpretations of the value of $\Delta S^{\ddagger}$ cannot be discounted. The transition state may be cyclic and have highly polarized bonding (positive in diene, negative in azodicarbonyl portion) without C—N rupture.

To conclude, the results in this and previous papers have established that the effectiveness of X, R, R_1, and R_2 in promoting the isomerization **1** → **2** decreases according to the following rules, other substituent variables being kept constant in each case:

(*i*) for R = alkyl or aryl rates appear to decrease roughly in the order of the rotation rates of the NCOR groups;

(*ii*) R = alkyl or aryl > R = alkoxy or aryloxy;

(*iii*) for $X = (CH_2)_n$, $n = 1 > n = 2 > n = 3 > n = 4$ (11);

(*iv*) X = CO, R_1 = Ph, R_2 = Me > X = CH_2, R_1 = Ph, R_2 = Me > X = CH_2, $R_1 = R_2$ = H.

Experimental

The following spectrometers were used: for i.r. a Beckman IR 10; for n.m.r. a Varian T60; for mass spectrometry an AE 1 MS 30; for u.v. a Coleman EPS-3T Hitachi. Details for the use of the latter in the variable temperature kinetic analyses have been given earlier (2, 6).

The isomerization of **3***h* was followed by the repeated scan technique as was that of **9***b* in isooctane at 79.5° (Fig. 1); others were followed by continuous external recording (Beckman Ten-Inch Linear Recorder) of the increase or decrease in absorbance at a suitable fixed wavelength: **3***g* at 305 nm (increase); **9***a* at 295 nm (increase); and **9***b* at 285 nm (decrease). The isomerization of **3***b* → **4***b* provides no suitable chromophore for u.v. analysis and was followed by refluxing solutions of **3***b* in isooctane (99°) or in 71% aqueous ethanol (79.5°) and by evaporating aliquots at intervals for analysis by n.m.r. spectrometry.

In the variable temperature experiments rate constants were determined at several temperatures over a convenient range (see Tables 1 and 2) and the Arrhenius activation energy calculated from a least-squares plot. The temperature range was limited at the lower end by the impracticality of very long reaction times, during which recorder drift or other instrumental variation might become significant. An upper limit was imposed by the risk of

damage to the u.v. cells by maintaining them at temperatures too close to the solvent boiling point.

The isooctane used was of spectrophotometric grade and was dried over sodium. The 71% aqueous ethanol was made by diluting 95% ethanol with one third of its volume of water. Anhydrous magnesium sulfate was used for drying organic solutions. Melting points are uncorrected.

*2,3-Di-m-nitrobenzoyl-2,3-diazabicyclo[2.2.1]hept-5-ene (**3g**)*

1,2-Di-*m*-nitrobenzoylhydrazine, m.p. 246–247° (lit. (12) m.p. 240–242°), was converted into its mercury(II) salt and reacted with bromine in methylene chloride as described for previous azo compounds. Concentration of the filtered solution and addition of carbon tetrachloride gave crude product (60%) which was recrystallized from methylene chloride – carbon tetrachloride (1:2) as orange crystals, m.p. 159–161°; ν (Nujol) 1743 cm^{-1} (C=O); λ_{max} ($CHCl_3$) 485 nm (ε 14).

Addition of cyclopentadiene (20 ml) to a solution of the azo compound (1.0 g, 3.05 mmol) in benzene (120 ml) caused the amber color to fade to pale yellow in 5 min. Evaporation and addition of pentane to the yellow residue gave a colorless precipitate which crystallized as prisms (50%), m.p. 196–198°, from benzene–cyclohexane; ν (Nujol) 1695, 1638 cm^{-1} (C=O); λ_{max} (EtOH) 268 nm; τ ($CDCl_3$) 1.1–2.7 (8 phenyl H, complex multiplet), 3.28 (2 vinyl H, closely spaced triplet), 4.56 (2 tertiary H, closely spaced triplet) 7.78, 8.02 p.p.m. (2 methylene H, AB quartet, J = 9.5 Hz).

Anal. Calcd. for $C_{19}H_{14}N_4O_6$: C, 57.87; H, 3.58; N, 14.21. Found: C, 57.74; H, 3.86; N, 14.26.

*cis-4-m-Nitrobenzoyl-4,4a,5,7a-tetrahydro-2-m-nitrophenylcyclopenta-1,3,4-oxadiazine (**4g**)*

Refluxing a solution of **3g** in chloroform for 6 h gave the oxadiazine quantitatively; it was crystallized from methanol as needles, m.p. 206–208°; ν (Nujol) 1650, 1620 cm^{-1} (C=O, C=N); λ_{max} (EtOH) 265 (ε 22 000), sh 295 nm (ε 16 000); τ ($CDCl_3$) 0.7–2.7 (8 phenyl H, complex multiplet), 3.54 (2 vinyl H), 4.5–5.0 (2 tertiary H), 6.72, 7.48 p.p.m. (2 methylene H, AB quartet with further splittings, J_{AB} = 18 Hz).

Anal. Calcd. for $C_{19}H_{14}N_4O_6$: C, 57.87; H, 3.58; N, 14.21. Found: C, 57.64; H, 3.67; N, 13.98.

*2,3-Di-o-methoxybenzoyl-2,3-diazabicyclo[2.2.1]hept-5-ene (**3h**)*

Lead tetraacetate oxidation of 1,2-di-*o*-methoxybenzoyl hydrazine, m.p. 197–199° (lit. (13) m.p. 202–203°), gave more consistent results than reaction of the mercury(II) salt with bromine.

To a stirred suspension of the hydrazide (1.5 g, 5.0 mmol) in methylene chloride (50 ml) at 0° was added, in portions, lead tetraacetate (2.5 g, 5.6 mmol) followed by cyclopentadiene (20 ml). The initial orange-red color faded over 1 h and the mixture was then kept at 5° for 12 h and filtered. The solution was washed in turn with water and aqueous sodium bicarbonate, and then dried and evaporated to a residue (2.4 g) whose n.m.r. spectrum showed the presence of the expected adduct as well as many methoxy containing impurities. The crude material was treated with cold benzene (10 ml), a small amount of insoluble hydrazide was filtered off, and the solution was chromatographed on silica gel. The use of increasing amounts of ether caused the elution of some of the impurities and then with 20% ether the adduct **3h** (1.35 g, 75%) as a glassy solid. It was purified from chloroform solution (5 ml) by adding hexane (75 ml) with stirring and chilling. The colorless adduct had ν (film) 1660–1700 cm^{-1}, broad (C=O); λ_{max} (EtOH) 284 nm (ε 6100); τ (CCl_4) 2.5–3.4 (8 phenyl H), 3.61 (2 vinyl H), 5.00 (2 tertiary H), 6.22 (6 methoxy methyl, sharp singlet), 7.98, 8.40 p.p.m. (2 methylene H, AB quartet, J_{AB} = 8 Hz); *m/e* 364 (P^+, 17%), 135 (o-$CH_3OC_6H_4CO^+$, 100%).

*cis-4-o-Methoxybenzoyl-4,4a,5,7a-tetrahydro-2-o-methoxyphenylcyclopenta-1,3,4-oxadiazine (**4h**)*

A solution of **3h** (1.0 g) was refluxed in tetrachloroethylene (20 ml) for 2 h and evaporated. The slightly brown residue was twice crystallized from benzene–cyclohexane to give dense colorless prisms of **4h**, a metastable polymorph which softened between 90 and 100°, resolidified, and then had m.p. 148–149° (its i.r. spectrum in Nujol showed minor differences from that of the high melting form). Heating at 100° for 3 h gave stable crystals, m.p. 148.5–149.5°; ν (Nujol) 1653, shs 1647, 1636 cm^{-1} (C=O, C=N); λ_{max} (EtOH) sh 278, 284 nm (ε 9900); τ ($CDCl_3$) 2.3–3.3 (8 phenyl H), 3.71 (2 vinyl H), 4.6–5.2 (2 tertiary H), 6.15 (3 methoxy methyl, sharp singlet), 6.33 (3 methoxy methyl, sharp singlet), 6.82, 7.44 p.p.m. (2 methylene H, AB quartet with further splittings, J_{AB} = 16 Hz).

Anal. Calcd. for $C_{21}H_{20}N_2O_4$: C, 69.22; H, 5.53; N, 7.69. Found: C, 68.93; H, 5.37; N, 7.44.

*2,3-Dibenzoyl-1,4-dimethyl-5,6-diphenyl-2,3-diazabicyclo[2.2.1]hept-5-ene (**9a**)*

A solution of azodibenzoyl (238 mg, 1 mmol) and 1,4-dimethyl-2,3-diphenylcyclopentadiene (246 mg, 1 mmol) in benzene (2 ml) at room temperature slowly faded in color and deposited crystals. After 40 min pentane (10 ml) was added slowly and the colorless product (400 mg, 82%) collected and washed with pentane (a longer reaction time led to some isomerization). Crystallization was effected by dissolving it in benzene – methylene chloride, evaporating till crystallization just began (20 ml), and adding pentane–cyclohexane (1:1, 50 ml) with stirring. The crystalline powder had a m.p. dependent on the rate and time of exposure to heating, *e.g.* 109–111° if raised from room temperature in 15 min (if heating was continued slowly above the m.p. the melt solidified and remelted at 162–163°, the m.p. of the pure isomer); ν (Nujol) 1680, 1629 cm^{-1} (C=O); λ_{max} (EtOH) 233, 270 nm; τ ($CDCl_3$) 2.2–3.1 (20 phenyl H), 7.56, 7.83 (2 methylene H, AB quartet, J_{AB} = 9.2 Hz), 8.32 p.p.m. (6 methyl H, sharp singlet).

*cis-4-Benzoyl-4,4a,5,7a-tetrahydryo-4a,6-dimethyl-2,7,7a-triphenylcyclopenta-1,3,4-oxadiazine (**10a**)*

Heating **9a** above its m.p. as described above, or for 10 min in refluxing benzene, gave the oxadiazine quantitatively. It formed fine prisms from 95% ethanol, m.p. 162.5–163.5°; ν (Nujol) 1655, 1640 cm^{-1} (C=O, C=N); λ_{max} (EtOH) 295 nm (12 100); τ ($CDCl_3$) 2.0–3.2 (20 phenyl H) 6.07, 7.40 (2 methylene H, AX quartet, J = 17 Hz), 8.01 (3 vinyl methyl H, sharp singlet), 8.60 p.p.m. (3 tertiary methyl H, sharp singlet).

Anal. Calcd. for $C_{33}H_{28}N_2O_2$: C, 81.79; H, 5.82; N, 5.78. Found: C, 81.55; H, 6.05; N, 5.75.

*2,3-Diacetyl-1,4-dimethyl-5,6-diphenyl-2,3-diazabicyclo-[2.2.1]hept-5-ene (**9b**)*

Azodiacetyl was prepared in benzene and the solution evaporated, as described earlier (2), to a concentration of 0.27 *M* (determined by n.m.r. spectrometry against the methyl peak in methyl benzoate as standard). To 15 ml of this solution was added 1,4-dimethyl-2,3-diphenylcyclopentadiene (1.00 g, 1.00 equiv.), and after 2 h at room temperature the yellow solution was evaporated to near dryness and pentane (30 ml) added with trituration and chilling. The colorless product (1.2 g, 82%) was recrystallized by dissolving it in cold benzene and adding a 1:1 solution of cyclohexane–pentane with stirring to give colorless prisms, m.p. 115–116°, if inserted at 110° at a heating rate of 2°/min; ν (Nujol) 1693, 1645 cm^{-1} (C=O); λ_{max} (EtOH) 235 (ε 17 600), 252 nm (ε 14 800); τ ($CDCl_3$—CCl_4) 2.5–3.2 (10 phenyl H), 7.6–8.3 (14 H, including slightly broadened 6 acetyl methyl H at 7.94 and 6 sharp tertiary methyl H at 8.04 p.p.m.).

Anal. Calcd. for $C_{23}H_{24}N_2O_2$: C, 76.64; H, 6.71; N, 7.77. Found: C, 76.33; H, 6.75; N, 7.95.

*cis-4-Acetyl-4,4a,5,7a-tetrahydro-2,4a,6-trimethyl-7,7a-diphenylcyclopenta-1,3,4-oxadiazine (**10b**)*

A sample of **9b** (300 mg) was kept at room temperature overnight in methanol (20 ml). Evaporation followed by two crystallizations of the residue from aqueous methanol gave the oxadiazine as large prisms, m.p. 160–161°; ν (Nujol) 1686, 1655 cm^{-1} (C=O, C=N); λ_{max} (EtOH) 243 nm (ε 21 000); τ ($CDCl_3$—CCl_4) 2.3–3.2 (10 phenyl H), 6.27, 7.60 (2 methylene H, AX quartet, J = 17 Hz), 7.70 (3 acetimidoyl methyl H, sharp singlet), 8.03 (3 acetyl methyl H, slightly broadened singlet), 8.48 (3 vinyl methyl H, sharp singlet), 8.80 p.p.m. (3 tertiary methyl H, sharp singlet).

Anal. Calcd. for $C_{23}H_{24}N_2O_2$: C, 76.64; H, 6.71; N, 7.77. Found: C, 76.86, H, 6.68; N, 8.08.

*cis-4-Acetyl-4,4a,5,7a-tetrahydro-2,4a,6-trimethyl-7,7a-diphenylcyclopenta-1,3,4-oxadiazin-5-one (**6b**)*

A solution of the dimer of 2,5-dimethyl-3,4-diphenylcyclopentadienone (1.30 g, 5 mmol cyclone monomer) in tetrachloroethylene (64 ml) containing azodiacetyl (6.7 mmol) failed to react on standing at room temperature for 20 h. When the temperature was raised to 40° n.m.r. spectrometry showed in the methyl region the four peaks of the dimer and the four peaks (two coincident) of the oxadiazine **6b** but also two other singlets at 7.80 and 7.98 τ, attributable to the adduct **5b**. After 3 days the estimated percentage composition was **5b**:**6b**:cyclone = 13:25:62, the proportion of **5b** not being exceeded thereafter.

At 85° reaction was complete in 12 h. Evaporation of the solvent and trituration of the residue with pentane gave the oxadiazine (1.77 g, 94%) which formed prisms from cyclohexane, m.p. 168–169°; ν (Nujol) 1730, 1678, 1664 cm^{-1} (keto and amide C=O, C=N); λ_{max} (EtOH) 242 (ε 15 600), 283 nm (ε 12 600); τ (CCl_4) 2.5–3.1 (10 phenyl H), 7.87 (3 acetimidoyl and 3 acetyl H, coincident, sharp singlet), 8.23 (3 vinyl methyl H, sharp singlet), 9.03 p.p.m. (3 tertiary methyl H, sharp singlet), but all four methyl peaks separated in benzene at 7.76, 7.96, 8.49, and 8.81 p.p.m. (assignments in order as before).

Anal. Calcd. for $C_{23}H_{22}N_2O_3$: C, 73.78; H, 5.92; N, 7.48. Found: C, 73.55; H, 5.90; N, 7.69.

Water-soluble Lysine-containing Polypeptides. II. The Interaction of Several Sequential Lysine–Glycine Polypeptides with DNA. A Circular Dichroism Study of DNA Conformation in Annealed Complexes[1]

ROSS E. WILLIAMS[2] and SANDRA L. KIELLAND

Division of Biological Sciences, National Research Council of Canada, Ottawa, Canada K1A 0R6

Received August 6, 1974

ROSS E. WILLIAMS and SANDRA L. KIELLAND. Can. J. Chem. **53**, 542 (1975).

To serve as models of protein–nucleic acid complexes, annealed complexes of several sequential lysine–glycine polypeptides with DNA have been formed. Circular dichroic spectra of the DNA contained in the complexes indicates that several discrete conformations of DNA can exist when complexed.

ROSS E. WILLIAMS et SANDRA L. KIELLAND. Can. J. Chem. **53**, 542 (1975).

Comme modèles des complexes entre les protéines et les acides nucléiques, nous avons préparé plusieurs complexes entre quelques polypeptides lysine–glycine de séquence régulière et l'ADN par une méthode de rassemblement spécifique. A partir d'une étude des spectres de dichroisme circulaire, nous avons observé quelques conformations différentes de l'ADN dans ces complexes.

Protein – nucleic acid interactions play an important role in maintaining the structural integrity of such complex biological structure as ribosomes, gene repressor–operator complexes, and nuclei in eukaryotic cells. Simplification of the structure of the individual components of these complex structures has been one of the experimental tools adopted in order to reduce the number of variables normally found in experiments on the native systems. This reduction has eased, to a certain extent, the interpretation of experiments designed to determine what factors are influential in determining the three-dimensional structure and stability of such complexes. Amongst these factors hydrophobic and electrostatic forces play an important role. Investigation of the role played by electrostatic forces has led to simplification of the protein portion of such complexes and the use of poly-(L-lysine) (**I**) as a model of the proteins involved in the complexes (see refs. 1–8 for leading references to previous work). Although many studies have investigated the interaction of poly-(L-lysine) with deoxyribonucleic acids (DNA) little work has been done on determining the importance of several of the factors controlling the structure and stability of poly-(L-lysine)–DNA complexes. Little work, for example, has been done to investigate the effect which the sequence of lysines within the polypeptide chain might have upon the structure of the complex as a whole and, more specifically, upon the structure of the deoxyribonucleic acid within complex.

Recently several sequential polypeptides containing lysine (lys) and glycine (gly), **II**, **III**, and **IV**, have been synthesized (9) so that studies can be made of the influence of sequence on the structure of DNA in complexes.

poly-(L-lysgly)$_n$ (**II**) = *lys*-gly-*lys*-gly-*lys*-gly

poly-(L-lysglygly)$_n$ (**III**) = *lys*-gly-gly-*lys*-gly-gly

poly-(gly-L-lysglygly)$_n$ (**IV**) = *lys*-gly-gly-gly-*lys*-gly

In this communication the results of a study of the conformation of DNA in annealed complexes of these polypeptides and calf thymus DNA are presented.

Experimental

Reagent-grade chemicals used for buffer preparation were purchased from commercial sources and used without further preparation. Cacodylic acid (dimethyl arsenate) was obtained from Fisher Scientific (Canada).

Dialysis tubing (Spectrapor 3), with nominal cut-off molecular weight 3500, was obtained from Science Essentials, Anaheim, California. This tubing was pre-

[1]NRCC No. 14381.

pared for use as directed (sodium sulfide and dilute sulfuric acid treatments). Leakage from and absorption by sacs prepared from this tubing was checked by amino acid hydrolysis of an aliquot of the polypeptide solution before and after 12 h dialysis against at least 50 vol of 0.15 *M* sodium chloride, sodium cacodylate, p*H* 7.0, and losses were found to be less that 3%. Similarly, DNA losses were found to be negligible as assayed by losses in u.v. absorption at 260 nm.

Polypeptides were prepared and characterized as previously described (9). Stock solutions of polypeptides (approximately 4×10^{-3} *M* lysine) were prepared in sodium cacodylate buffer 0.01 *M*, p*H* 7.0. An aliquot was analyzed for lysine concentration by hydrolysis in 6 *N* HCl and amino acid analysis (Beckman model 120C).

Highly polymerized DNA (Worthington Biochemicals, Freehold, N.J.) was treated as previously described (A260/A230 = 2.20) (10). Stock solutions of DNA (3×10^{-3} *M* phosphate) were prepared by dialysis against 0.01 *M* sodium cacodylate p*H* 7.0 overnight at 4 °C and dilution to the appropriate concentration. DNA-phosphate concentration was determined by absorbance at 260 nm (DNA-phosphate, ε_{260} 6600 (11)).

Circular dichroic spectra were taken in quartz cells (1 cm path) at 26 ± 1 °C on a Cary spectropolarimeter, model 61. No correction for sample turbidity was made. The spectropolarimeter was calibrated with purified, anhydrous *d*-10-camphorsulfonic acid (using $\varepsilon_L - \varepsilon_R$ (290 nm) = 2.36 (12)), $[\alpha]_D$ +21.6° (*c* 4.3, H_2O) (lit. (13) $[\alpha]_D$ +22.1° (*c* 1.0, H_2O)), m.p. (dec.) 198–199 °C (uncorr.).

Anal. Calcd. for $C_{10}H_{16}O_4S$: C, 51.7; H, 6.94. Found: C, 51.5; H, 7.08.

Ultraviolet absortion spectra were taken in quartz cells (1 cm path) at 22 ± 2 °C on a Cary spectrophotometer, model 14. Turbidity of each sample was measured and expressed as $dA^{400} = A_{com}{}^{400} - A_0{}^{400}$ where A_{com} is the absorbance at 400 nm of the complexed DNA solution and $A_0{}^{400}$ is the absorbance at 400 nm of the equivalent uncomplexed DNA solution.

Back Dialysis Experiments

A series of solutions were prepared as follows: 200 µl of DNA stock solution (3×10^{-3} *M* phosphate) was added to a 3.0 ml solution of sodium chloride, 1.5 *M*, sodium cacodylate, 0.001 *M*, p*H* 7.0. The solutions were mixed and an aliquot of polypeptide stock solution ($0 \rightarrow 200$ µl) was added to each in order to provide separate solutions with increasing lysine/DNA-phosphate ratios. The solutions were mixed again and transferred to separate dialysis sacs. Each of the sacs was placed in a 500-ml solution of sodium chloride, 1.5 *M*, sodium cacodylate, 0.001 *M*, p*H* 7.0, and back dialyzed at 4 °C to sodium chloride, 0.15 *M*, sodium cacodylate, 0.001 *M*, p*H* 7.0, according to the previously published procedure (14). The solutions were finally dialyzed against a fresh solution of the final buffer for 2 h at 4 °C before measurement of the c.d. spectra. For calculating the lysine/DNA-phosphate ratios, DNA-phosphate concentration was determined using a sample containing no polypeptide which had been back dialyzed under conditions identical to those used to prepare the complexes. Lysine concentration was taken as the input concentration since bag losses were negligible.

Although absorption readings at 260 nm on complexes with lysine/phosphate ratios around 0.5 indicated no changes in the DNA concentration through specific absorption of complexes by the dialysis sacs used, samples were taken from dialysis sacs containing DNA-poly-(L-lysine) complexes with lysine/phosphate ratios between 0.5 and 1.0. They were then resolubilized in 2 *M* sodium chloride (18). In all cases readings at 260 were taken relative to a DNA sample which had the same initial concentration before complex formation and which was dialyzed under the same conditions used to form the complexes. Only minor losses of DNA (less than 5%) were detected.

Results

Circular dichroic (c.d.) spectra have been proven to be quite useful in the investigation of changes in the conformation of DNA and other polynucleotides (15). Spectra have been taken on the native molecules, not only in solution, but also when they are complexed with various natural and synthetic polypeptides (16, 17). Circular dichroic spectra of the DNA complexed with the polypeptides **II–IV** should provide useful information on the effect the polypeptides have on the conformation of DNA.

Recently, annealed complexes between poly-L-lysine (**I**) and DNA were formed under physiological conditions (0.15 *M* NaCl, p*H* 7.0) by the back dialysis in a linear sodium chloride gradient of complexes formed at high salt concentrations (18). It was reported that the resulting c.d. spectra were reproducible as to type and amount of DNA distortion observed (18). Repetition of the experimental conditions necessary to form this type of complex with poly-L-lysine (**I**) (M_w 10 250 (9)) gave the c.d. spectra of DNA in Fig. 1. The spectra are similar to those previously reported. In general, at lysine/DNA-phosphate ratios less than 0.2 it was readily apparent that spectral alterations in the normal solution spectrum of DNA were occurring. Further increases in the lysine/DNA-phosphate ratio resulted in progressive loss of ellipticity at 275 nm and the formation of a single broad negative band at 280 nm. As the lysine/DNA-phosphate ratio passed above 0.8 apparent loss of distortion occurred, *i.e.* the intensity at 275 nm became less. Above this ratio however turbidity problems were acute as assayed by u.v. absorption spectra ($dA^{400} > 0.3$) and precipitation was occurring. These results are qualitatively similar to those found previously with the same system (18). The differences in the intensity of the ellipticity noted could be the result of

For personal use only.

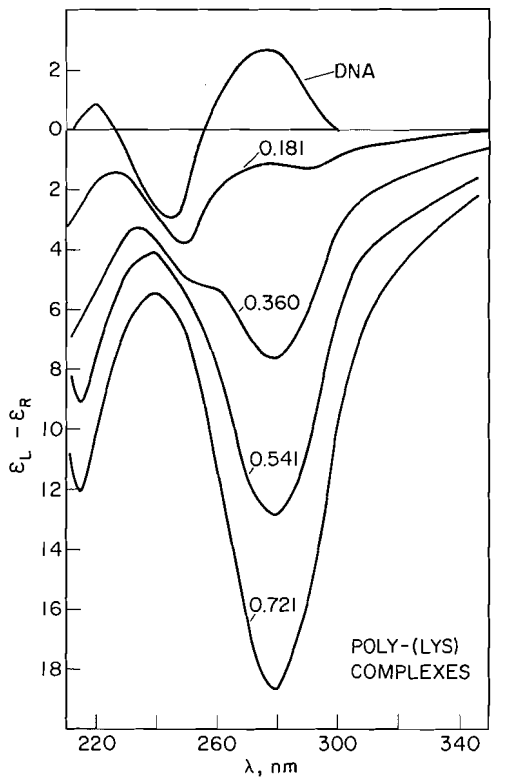

FIG. 1. Circular dichroic spectra of poly-L-lysine–DNA complexes. Variation of spectra with increasing lysine/DNA-phosphate ratios (given as fractional values). Ellipticity calculations were based on the nucleotide phosphate concentration. Repetition of experiments in triplicate indicated that errors in ellipticity values amounted to approximately 5% of the measured value. Turbidity, in all cases, as measured by dA^{400} was less than 0.28. No corrections for sample turbidity have been made. Experimental conditions: DNA-phosphate concentration 1.76×10^{-4} *M*; sodium chloride, 0.15 *M*, sodium cacodylate, 0.001 *M*, p*H* 7.0.

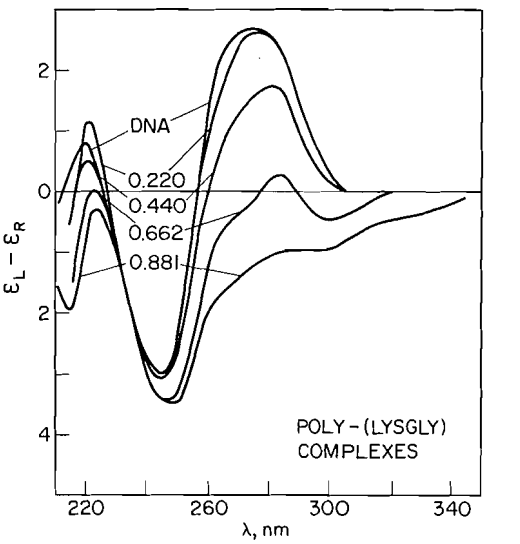

FIG. 2. Circular dichroic spectra of poly-(L-lysylglycine)–DNA complexes. Variation of spectra with increasing lysine/DNA-phosphate ratios. Other details as for Fig. 1. Experimental conditions: DNA-phosphate concentration 1.76×10^{-4} *M*; sodium chloride, 0.15 *M*, sodium phosphate, 0.001 *M*, p*H* 7.0.

differences in the molecular weight of the polylysine samples used. An estimate of the reproducibility of the experimental results was obtained from three repetitions of the complex formation and indicated that spectral intensities were reproducible to within ±5%.

Using the same experimental conditions complexes were formed between the sequential lysine-glycine polypeptides **II**, **III**, and **IV**. The c.d. spectra of the accessible u.v. region of the spectrum are presented in Figs. 2–4.

Several general observations can be made. At lysine/DNA-phosphate ratios less than 0.2 smaller alterations of the normal DNA spectrum occurred than were observed in the polylysine complexes, and within the group, variable amounts of distortion were noted. For example, poly-(L-lysylglycylglycine), **III**, (Fig. 3) seemed to be causing more distortion of the DNA spectrum than either of the other lysine–glycine polypeptides.

At lysine/DNA-phosphate ratios of approximately 0.5 it was noted that in each case the DNA portion of the spectrum was reminiscent of spectra seen in chromatin isolated from various sources (19–29). That is, the single band at 275 nm in the spectrum of the native DNA shifted over to a smaller positive band at approximately 282 nm upon complex formation with polymers **III** and **IV** (Figs. 3 and 4). The origin of this 282 nm band might be connected with the more rapid loss of one of the two bands recently suggested to be present in this spectral region of the calf thymus DNA c.d. spectrum (30). Poly-(L-lysylglycine) (**II**) (Fig. 2) complexes at this ratio (0.5), on the other hand, were reminiscent of spectra taken of DNA in C-type conformation (31). In addition to these changes in the DNA portion of the spectrum little or no increase in ellipticity below 246 nm occurred and seemed to indicate that little long-range ordering, *e.g.* helix formation in the polypeptide, was resulting from complex formation.

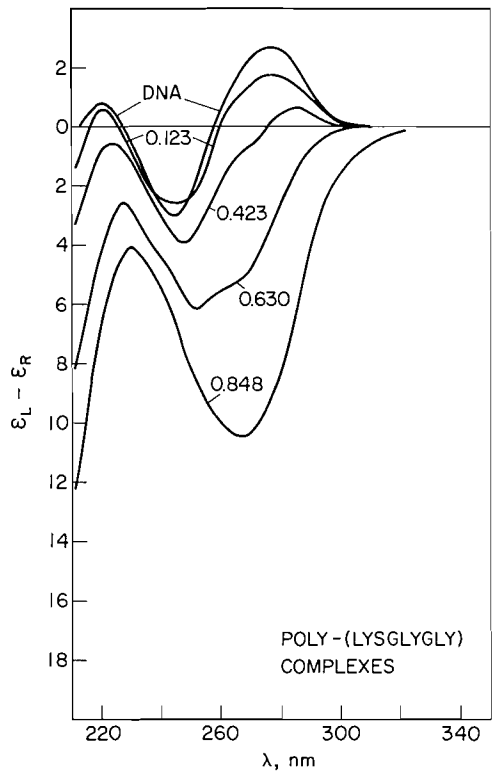

FIG. 3. Circular dichroic spectra of poly-(L-lysyl-glycylglycine)–DNA complexes. Variation of spectra with increasing lysine – DNA-phosphate ratios. Other details as for Fig. 1. Experimental conditions: DNA-phosphate concentration 1.76×10^{-4} *M*; sodium chloride, 0.15 *M*, sodium cacodylate, 0.001 *M*, p*H* 7.0.

Above lysine/DNA-phosphate ratios of 0.5 major differences in complex formation amongst the polylysine–glycine polypeptides became readily apparent. Polypeptides **III** and **IV** (Figs. 3 and 4) caused the formation of distorted c.d. spectra similar to those seen with polylysine (**I**) (Fig. 1), albeit of slightly reduced intensity at similar lysine/DNA-phosphate ratios. In appearance these spectra were like those seen in unoriented dehydrated films of DNA (31), in complexes formed between DNA and poly-(L-alanyl-L-lysyl-L-proline) (32), in complexes formed between calf thymus DNA and the lysine-rich histone f-1 (33–37) and in complexes of polyethylene oxide or sodium polyacrylate and DNA (38). Poly-(L-lysylglycine) (**II**) (Fig. 2) caused the formation of only slightly more distorted spectra than those observed at lower lysine/phosphate ratios; the resulting spectra being very similar to those of c.d. spectra of DNA in high salt concentrations (39–41).

The similarities and differences amongst annealed complexes formed between the polypeptides and DNA are further illustrated in Fig. 5 where changes in ellipticity at 275 nm with changes of lysine/DNA-phosphate ratio are plotted. From this plot it is readily apparent that in the case of polylysine complexes maximal distortion of the DNA spectrum occurred at lysine/DNA-phosphate ratios around 0.7 whereas in the case of the lysine–glycine polypeptide maximal distortion occurred at lysine/DNA-phosphate ratios around 1.5. Finally, within the group of lysine–glycine polypeptides, poly-(L-lysylglycine) (**II**) seemed to cause the least amount of distortion to the DNA spectrum at all lysine/DNA-phosphate ratios.

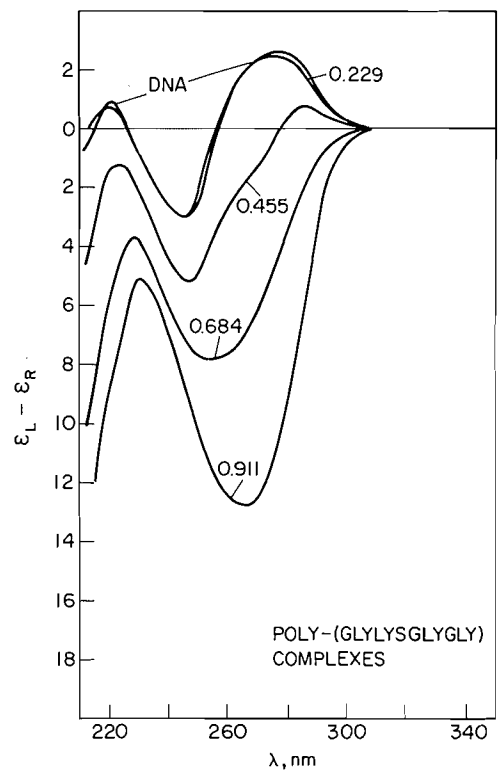

FIG. 4. Circular dichroic spectra of poly-(glycyl-L-lysylglycylglycine)–DNA complexes. Variation of spectra with increasing lysine/DNA-phosphate ratios. Other details as for Fig. 1. Experimental conditions: DNA-phosphate concentration 1.76×10^{-4} *M*; sodium chloride, 0.15 *M*, sodium cacodylate, 0.001 *M*, p*H* 7.0.

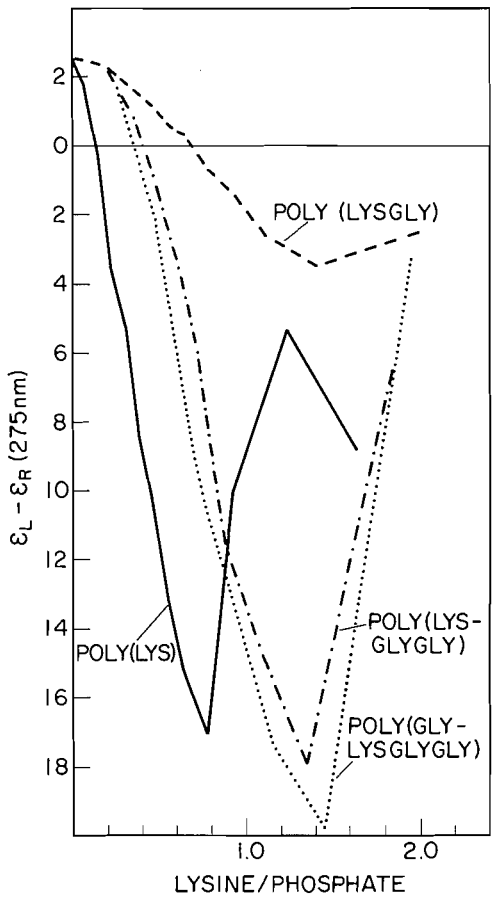

FIG. 5. Variation of molar ellipticity ($\varepsilon_L - \varepsilon_R$) at 275 nm with lysine/DNA-phosphate ratio in complexes between the lysine and lysine/glycine polypeptides and DNA. No corrections for sample turbidity have been made. Experimental conditions: DNA-phosphate concentration: 1.48×10^{-4} *M*; sodium chloride, 0.15 *M*, sodium cacodylate, 0.001 *M*, p*H* 7.0.

Discussion

The results indicate that, in the case of each of the polypeptides, changes in the original solution c.d. spectrum of DNA occur upon increasing the lysine/phosphate (L/P) ratio. These changes, as manifest in changes in the ellipticity at 275 nm (Fig. 5), seem to be of either large or small magnitude relative to the original c.d. spectrum of DNA. Large magnitude changes in the c.d. spectrum, for example those seen in Figs. 1, 3, and 4 at L/P ratios above 0.5, have been suggested to be the result of at least three different, but not unrelated, causes: (*i*) long-range order has been introduced into the DNA (18, 33, 37); (*ii*) solvent surrounding the DNA has been excluded (18, 33, 37); (*iii*) an increase in interhelix interactions caused by aggregation of the DNA has taken place (33, 37, 38). Small magnitude changes in the c.d. spectra, for example, those seen in Figs. 3 and 4 at L/P ratios below 0.5 and in Fig. 2 at all L/P ratios, could be the result, again, of at least three different, but not unrelated, causes: (*i*) the conformation of DNA has changed from that of the B-type to that of the C-type (31, 33); (*ii*) the charge shielding of the DNA sugar–phosphate backbone has been altered (39–41); (*iii*) the interhelix interactions in the aggregated state of the DNA have been reduced (33, 38).

The results also indicate that, even though the observed c.d. spectra are a mix of the spectra of complexed and uncomplexed DNA, differences in the abilities of the polypeptides to cause large or small magnitude changes in the DNA c.d. spectrum exist. These differences are unlikely to be caused by differences in the molecular weight of the polypeptides since each has very similar molecular weights and distributions of molecular weights (9).

The differences noted in the L/P ratio where maximal distortion of the DNA c.d. spectrum occurs (Fig. 5) could be attributed to either one of two different, but not unrelated, causes: (*i*) the poly-(L-lysine) and the lysine–glycine polypeptides adopt different conformations in the final complex; (*ii*) the state of aggregation of the DNA in the two types of complexes differs.

The differences might be related to differences in the abilities of the polypeptides to adopt discrete conformations. This, thereby, would influence the type of conformation the polypeptide could adopt in the final complex. The differences in conformational flexibility might be related to the fact that the polypeptides seem to possess different abilities to adopt several discrete conformations in solution. Poly-(L-lysine), as assessed by changes in its solution optical rotatory dispersion (o.r.d.) and c.d. spectrum, has been shown to have the ability to adopt several discrete conformations, dependent upon conditions of p*H*, ionic strength, and temperature (42–49). In contrast, the constancy of the c.d. spectrum of the lysine–glycine polypeptides upon changes in p*H* and ionic strength (9) as well as the presence of the helix-breaking amino acid, glycine (50), strongly suggest that they are unable to adopt radically different conformations in solution.

On the other hand, the differences might be related to differences in the state of aggregation of the DNA in the complexes. The presence or absence of an uncharged amino acid in the polypeptide, in this instance, glycine might be expected to influence DNA interhelix interactions through changes in the balance between electrostatic and hydrophobic forces in the complex. These changes in interhelix interactions might lead to changes in the compacting of the polypeptide–DNA structure and thus, to differences in the ordering of the DNA (18, 37, 38).

At present, the information is insufficient for a choice to be made between these two possible causes and further work in this area will be required before such a choice can be made.

The differences noted in the type of DNA c.d. spectrum seen at L/P ratios where maximal distortion of the c.d. spectrum occurs (Figs. 1–4) could be related to either one of two different, but not unrelated, causes: (*i*) the polypeptides possess different primary sequences; (*ii*) different states of interhelix interactions occur because of different states of DNA aggregation.

Differences in the polypeptide sequences might result in differences in the juxtaposition of charged groups within the complexes. Based on the predominance of simple electrostatic interactions between the polypeptides and the DNA it was recently suggested (9), after modification of a previous proposal (51), that juxtaposition of the positively-charged side chain of the lysine-containing peptides and the negatively-charged phosphates of one strand of the DNA would account for the differences observed in the abilities of the polypeptides to precipitate DNA from solution (9).

Where direct juxtaposition of charged groups would result, the polypeptide would be expected to have little influence on the overall DNA structure, save that of diminishing the electrostatic charges of the phosphate groups. This would offer a plausible explanation of the observations made on the poly-(L-lysylglycine)–DNA complexes (Fig. 2).

Where direct juxtaposition of charged groups would not be possible, thwarted either by primary sequence dictates or by polypeptide chain flexibility, much more extensive influence on the overall DNA structure might be expected. Primary sequence dictates would offer a plausible explanation of the observations made on the poly-(L-lysine)- –and poly-(L-lysylglycylglycine)–DNA complexes (Figs. 1 and 3, respectively). Polypeptide chain flexibility and a resulting lack of cooperativity in aligning charges would offer a plausible explanation of the observations made on the poly-(glycyl-L-lysylglycylglycine)–DNA complexes (Fig. 4).

Differences in type of c.d. spectra might also be related to the states of interhelix interactions which might result from differences in the states of aggregation caused by the polypeptides. This would require that the complexes formed by poly-(L-lysylglycine) and DNA (Fig. 2) be quite different from those of the others (Figs. 1, 3, and 4). The reason for this unique difference is not absolutely clear at present although it could be related simply to the presence of a series of positive charges along the polypeptide backbone which are in phase with the negatively charged phosphates of the DNA. Obviously more structural information would be required to ascertain if, indeed, the complexes of poly-(L-lysylglycine) and DNA did differ fundamentally from those of the others.

The authors wish to thank M. Hector Séguin for elemental analyses, M. A. E. Castagne for amino acid analyses.

Allowed and Forbidden Reaction Paths for the $H_2 + D_2$ Exchange Reaction

JAMES S. WRIGHT

Department of Chemistry, Carleton University, Ottawa, Canada K1S 5B6

JAMES S. WRIGHT. Can J. Chem. **53**, 549 (1975).

Symmetry arguments and *ab initio* s.c.f. calculations (double-zeta basis set) are used to show that the exchange reaction $H_2 + D_2 \rightarrow 2HD$ could proceed in a concerted fashion through a six-center transition state. The computed barrier height of 90 kcal/mol for this process lies below the experimental dissociation energy of H_2 (but above the computed dissociation energy) and also below the energy required for exchange through a four-center transition state. Either the termolecular (2+2+2) or bimolecular (4+2) cycloadditions are thermally allowed. The presence of a transition metal would allow the reaction to proceed through a four-center geometry, leading to the formation of a possibly stable metal-H_4 complex.

JAMES S. WRIGHT. Can. J. Chem. **53**, 549 (1975).

On utilise des arguments de symétrie et des calculs *ab initio* s.c.f. (ensemble double zeta) pour démontrer que la réaction d'échange $H_2+D_2 \rightarrow 2HD$ peut se produire d'une façon concertée par l'intermédiaire d'un état de transition à 6 centres. La barrière d'énergie calculée, 90 kcal/mol, pour ce processus est de beaucoup plus basse que l'énergie de dissociation déterminée expérimentalement pour H_2 (mais toutefois au dessus de la valeur calculée pour cette énergie de dissociation) et aussi plus basse que l'énergie requise pour un état de transition impliquant 4 centres. Les cycloadditions thermoléculaires (2+2+2) ou bimoléculaire (4+2) sont thermiquement permises. La présence d'un métal de transition permettrait à la réaction de se produire par l'intermédiaire d'une géométrie à 4 centres conduisant à la formation possible d'un complexe stable métal-H_4. [Traduit par le journal]

Introduction

The mechanism of the simplest bimolecular reaction, $H_2 + D_2 \rightarrow 2HD$ is of continuing interest because of the apparent disagreement between theory and experiment. In the original experiment of Bauer and Ossa (1), H_2, D_2, and argon were heated to temperatures between 1060–1420 °K in a shock tube. HD was observed as a product, and the following kinetic parameters were obtained: overall order = 2.04 ± 0.05; order with respect to H_2 = 0.38 ± 0.02; order with respect to D_2 = 0.66 ± 0.02; order with respect to argon = 0.98 ± 0.03; activation energy = 42 kcal/mol. In order to explain the argon dependence, the asymmetry in the H_2–D_2 dependence, and the low activation energy, a vibrational excitation mechanism was proposed (1). According to this mechanism, preexcitation of H_2 (D_2) to a critical level is necessary before exchange can occur, which then proceeds via a four-center transition state. Other shock tube studies by Burcat and Lifshitz (2) and Kern and Nika (3) gave similar kinetic results.

The importance of vibrational energy in reactants was proven in a subsequent study by Bauer and co-workers (4), where vibrationally hot but translationally cold molecules were shown to be reactive at room temperature. The possibility of an atomic exchange mechanism, *i.e.* $H_2 \rightarrow 2H$ followed by $H + D_2 \rightarrow HD + H$ has been considered to be ruled out (1) both because of the observed low activation energy and on kinetic grounds; the expected amounts of atoms present were far too low to account for the amount of HD produced.

These experiments have stimulated theoretical searches for low-lying four-center transition states through which exchange could occur. These studies, which have increased both in number and in sophistication, are summarized in the recent extensive *ab initio* search of Silver and Stevens (5). These authors use a double-zeta basis set with full configuration interaction, and are in agreement with the results of previous studies in their failure to find any four-center transition state below the dissociation energy of H_2, 109 kcal/mol (classical limit). To avoid searching the full six-dimensional hyperspace of four atoms these studies have of necessity been restricted to configurations possessing a certain amount of symmetry; however, it appears increasingly unlikely that a low activation energy four-center transition state will be found (5, 6).

This apparent conflict between theory and experiment led the author to propose the possibility of a six-center exchange pathway and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

to demonstrate the low energy of a hexagonal transition state (7). In the present paper we consider the orbital symmetry requirements along various possible paths leading to exchange, and supplement the discussion with *ab initio* calculations where appropriate.

Four-center Reaction Paths

It was shown by Hoffmann (8), using arguments based on the conservation of orbital symmetry (9), that the coplanar path proceeding through a square transition state is thermally forbidden. An approximate energy barrier for the process is that amount of energy necessary to raise two electrons from the bonding σ_g orbital in H_2 up to a non-bonding hydrogen 1s level, or 119 kcal/mole.[1] This very crude estimate is in reasonable agreement with the figure 142 kcal/mol obtained from quantum-mechanical calculations (10, 5).

Approaches other than coplanar may also be studied, and this has been done by several authors (5, 6, 10, 11, 20, 21). Two paths are particularly interesting: the orthogonal approach passing through a tetrahedron, and the linear approach (6). A correlation diagram for the orthogonal approach is shown in Fig. 1. Reactants pass through a tetrahedral transition state and the path is again thermally forbidden. The tetrahedral H_4 is a high-energy species (5, 6). Thus a resemblance to the allowed (2s + 2a) orthogonal path discussed by Woodward and Hoffman (9) for hydrocarbons is only superficial, due to the absence in this case of p-orbitals with their characteristic nodal properties.

A reaction path of particular interest to this study is the linear approach. A correlation diagram for this approach (also discussed by Gimarc (11)) is shown in Fig. 2. The occupied orbitals of $H_2 + H_2$ correlate directly with those of linear H_4 so the approach is thermally allowed. Indeed, linear equidistant H_4 has been shown to have the very low energy of about 45 kcal/mol relative to $H_2 + H_2$ (5, 12). However, as has been pointed out repeatedly, linear H_4 cannot serve as a transition state for exchange without bond breaking, as in

$$H—H + D—D \rightarrow H \ldots H \ldots D \ldots D \rightarrow H + HD + D$$

and subsequent high energy cost. Other paths have been considered, including the kite, Y, trapezoid, and rhombus geometries (6) and an allowed path suggested by Gimarc (11) passing

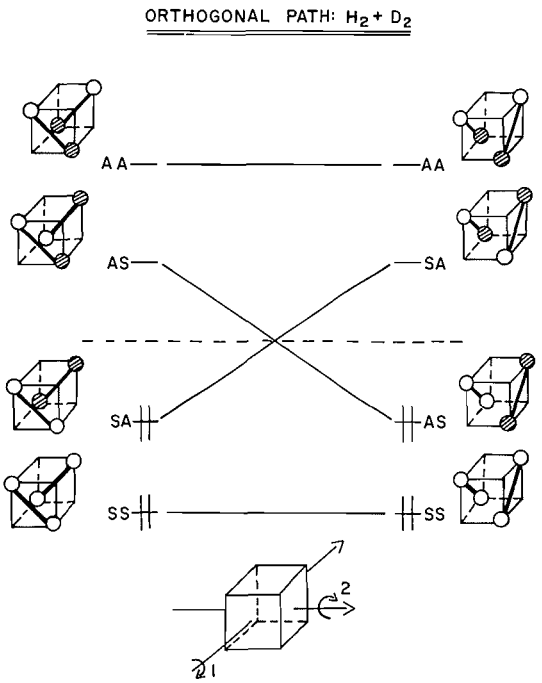

FIG. 1. Orthogonal four-center correlation diagram (thermally forbidden).

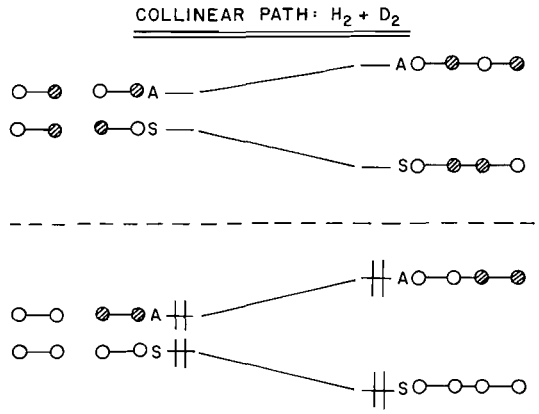

FIG. 2. Linear four-center correlation diagram (thermally allowed).

[1]A double-zeta calculation for H_2 at $r = 1.40$ bohr, $\xi_1 = 1.20$, $\xi_2 = 0.90$ gives -0.595 hartree as the energy of the σ_g orbital. The energy of the 1s orbital in the H atom is taken to be its exact value, -0.500 hartree. Since two electrons are raised to the non-bonding level, the total change is 119 kcal/mol.

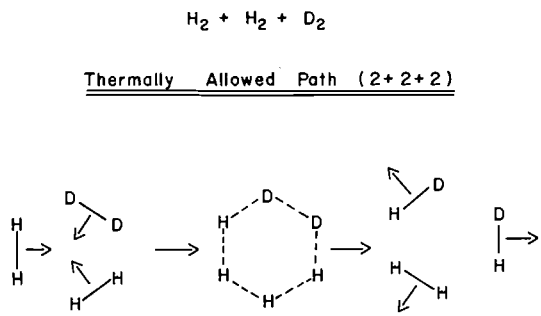

FIG. 3. The (2+2+2) termolecular cycloaddition, proceeding through a hexagonal transition state.

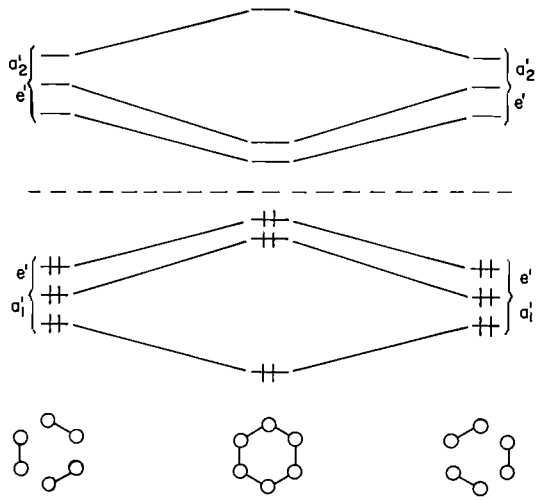

FIG. 4. Correlation diagram for termolecular exchange (thermally allowed).

through T- and Y-shaped transition states; however, it appears that these also are unfavorable energetically (5).

Application of the orbital phase continuity principle (21) has led to the prediction that *no* four-center pathway is of low energy. Thus, the theoretical attempts to find a low-lying four-center reaction path have not been successful, and we must consider alternative mechanisms.

Six-center Reaction Paths

Since (2+2+2) cycloadditions are in general thermally allowed (9), consider first a termolecular reaction, shown in Fig. 3. Along this path a three-fold axis of symmetry is preserved. Because of the C_3 axis and the resulting orbital degeneracy the S,A notation of Woodward and Hoffmann (9) breaks down, and it is necessary to return to group-theoretical notation and treat the conservation of molecular orbital configuration (13).[2] The symmetry combinations and their D_{3h} notation are shown in Fig. 4, which gives an orbital correlation diagram for the reaction passing through a hexagonal transition state. The occupied orbitals of like symmetry correlate directly, and the reaction is seen to be thermally allowed. The "aromatic" character of hexagonal H_6 should contribute to its stabilization (14), and a double-zeta s.c.f. calculation (7) showed hexagonal H_6 to lie only 90 kcal/mol above the energy of three molecules of H_2, *which is below the* (experimental) *energy required to dissociate* H_2. For comparison, the energy of $2H_2 + 2H$ obtained from the double-zeta calculation, and using the exact value of -0.500 hartree for the H atom (obtainable from a single basis orbital) would give an energy of $+80.5$ kcal/mol relative to $3H_2$. However, the fact that an exact result is obtained for H but not for H_2 skews this result, so that it is probably more meaningful to invoke the experimental dissociation energy of H_2 when comparing the energy of H_6, $3H_2$ and $2H_2 + 2H$. Assuming no additional barrier to be surmounted in the formation and decomposition of H_6 (as will be demonstrated), and neglecting zero point energy, an estimated activation energy for the formation of HD is 90 kcal/mol.

To establish whether hexagonal H_6 is a transition state or a potential minimum, a double-zeta calculation with the same exponents was used. The optimum hexagon at $r = 1.87$ bohr was allowed to distort along various possible paths, as shown in Fig. 5. The H_6 energy was studied as a function of increasing distortion. Figure 5*a* shows a "straight pull" path, where the optimum hexagonal distance was maintained at the internuclear distance of the separating H_2 molecules. After an initial flat region (energy constant to 0.001 hartree), the energy smoothly lowered toward that of three molecules of H_2 (at 1.87 bohr). H_6 thus is a transition state for this path, which is downhill toward product H_2. The B_{2u} normal mode for distortion is shown in Fig. 5*b*. Not surprisingly, the path from H_6 is more abruptly downhill, since H_2 can quickly ap-

[2]Alternative approaches include the generalized Woodward–Hoffman rules (9), or orbital phase continuity principle (21).

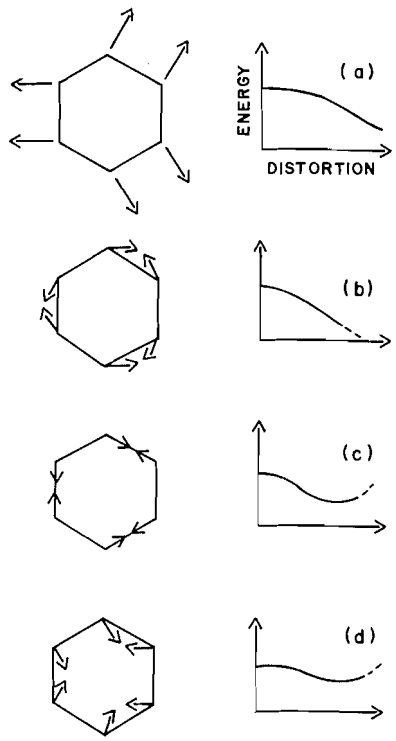

FIG. 5. Decomposition paths for hexagonal H_6. (*a*) Straight pull path. (*b*) B_{2u} distortion path. (*c*) Bond alternation path. (*d*) Implosion path.

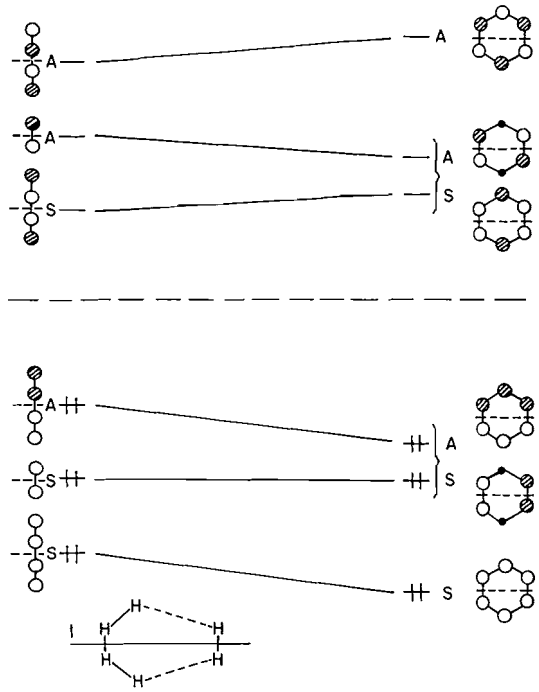

FIG. 6. Correlation diagram for the bimolecular (4+2) cycloaddition (thermally allowed).

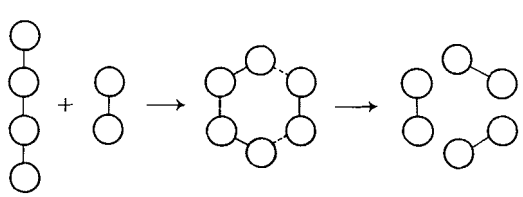
proach its preferred distance. Figure 5*c* shows that the hexagon is unstable with respect to bond alternation, again apparently due to the driving force toward formation of H_2 at its optimum bond length. The hexagon is even unstable towards "implosion", as shown in Fig. 5*d*. H_6 is thus far from aromatic in any ordinary sense, although it certainly owes whatever stability it possesses to its benzene-like pattern and occupancy of molecular orbitals (14).

A Symmetry-allowed Biomolecular Path

A straightforward extension of the Woodward–Hoffmann rules to hydrogen systems suggest that a 4+2 cycloaddition, involving 6 electrons, is thermally allowed. As proposed earlier (7), we



imagine a linear H_4 approached by D_2 in the manner shown below, collapse to the hexagon, and subsequent formation of $2HD + H_2$. The decomposition of the hexagon occurs with no additional activation energy, as already shown. Since the formation of linear H_4 has been shown to be thermally allowed, we need consider only the formation of hexagonal H_6 from linear $H_4 + H_2$. Figure 6 shows that the bonding orbitals of $H_4 + H_2$ do correlate directly with those of H_6. The reaction is allowed, but finding the activation energy for this approach is difficult, due to the number of geometric degrees of freedom available.

Geometric variables defining the (4+2) approach are shown in Fig. 7. Here R_1 is the distance of the approaching H_2, R_2 the (unique) distance in linear equidistant H_4, D the separation between opposite sides of the (incipient) hexagon, and α the bending angle in H_4. Starting from the optimum hexagon at 1.87 bohr, and using the geometric variables defined in Fig. 7, the results of a DZ calculation for the (4+2) decomposition are shown in Table 1. The important result is that there is *no* barrier

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

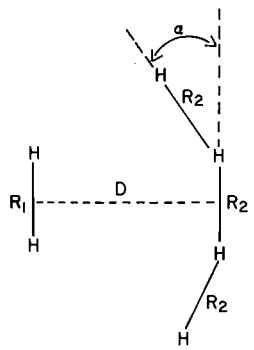

FIG. 7. Geometric variables used to define the (4+2) reaction path.

to be overcome along this path, which is smoothly downhill toward linear equidistant H_4 and H_2, the products of this reaction path. Further, it is seen that at large separation ($D = 4.00$) the energy of the H_6 system is correctly converging toward that of the separated products. The allowed nature of the reaction, and the closed-shell character of H_2, H_4, and H_6 makes this possible in a single determinant calculation.

Although the (4+2) path has the advantage of being a two-step process which is bimolecular at each step, there remains a serious objection to this mechanism. From the work of Silver and Stevens (5), it appears that linear H_4 does not represent a metastable state, even though it is of low energy. This makes it less likely that such a species could participate in a subsequent step, interaction with H_2 to form the hexagon. On the other hand, the only objection to the (2+2+2) path is the termolecular nature of the reaction. As will be discussed, related reactions now show that this sort of process can in fact occur.

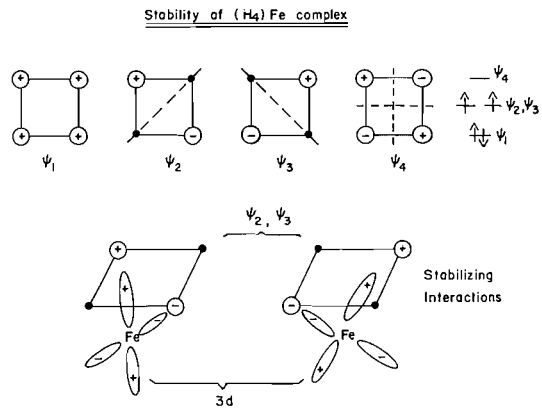

FIG. 8. Stabilizing interactions between non-bonding H_4 orbitals and metal d-orbitals.

Metal Catalysis

As shown by Mango and Schachtschneider (15), reactions which are symmetry forbidden can become allowed by interaction with the d-orbitals of a transition metal. These authors have discussed in detail the case of the addition of two ethylene molecules to give cyclobutane (16). The argument proceeds in a similar fashion for the $H_2 + D_2$ exchange reaction. As in (16), assume a degenerate pair of metal d-orbitals (d_{xy},d_{yz}) having AS and SA symmetry, respectively, and containing a total of 2 electrons. These orbitals can interact with the "ligand" $H_2 + D_2$ orbitals of the same symmetry. Since the non-bonding H_{1s} level at −0.5 hartree lies somewhat below the orbital energy of the metal d-orbital, the AS ligand orbital lies close to the d-orbital energy, and thus experiences a greater interaction with the AS d-orbital. Figure 8 shows these interactions depicted for square planar H_4 interacting with the metal. The net result is that non-bonding orbitals in H_4 and metal have become bonding, with a potentially significant lowering of the activation energy. A correlation diagram for the entire process is shown in Fig. 9 where it is to be understood that the metal orbitals lie underneath H_4 in such a way as to have the required overlap (*i.e.* the d-orbitals are shown in top view). SS and AA ligand orbitals are not included in the correlation diagram since their interaction with the metal is expected to be less significant. The reaction has become thermally allowed, since reactants correlate directly with products. The magnitude of the remaining activation energy is difficult to

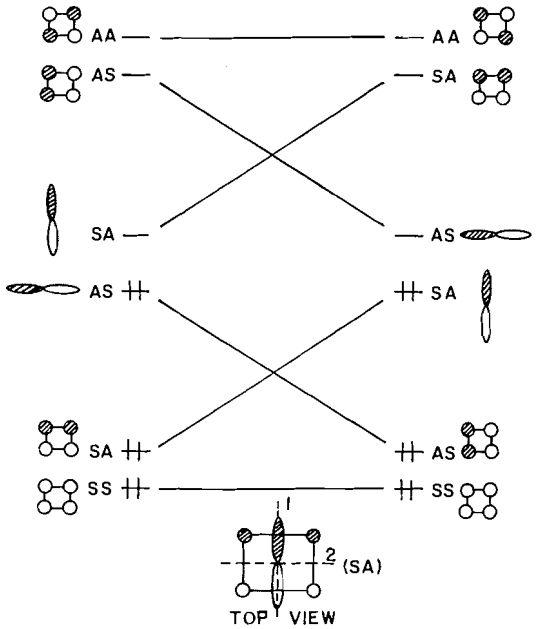

FIG. 9. Correlation diagram for the metal catalyzed 4-center reaction path (thermally allowed).

estimate, since it depends on the strength of the metal–ligand interaction in the region of the transition state. It is not difficult to imagine a stabilization in excess of 30 kcal/mol, which is the amount necessary to bring the energy of H_4 below that of $H_2 + 2H$.

We have so far assumed that the metal–H_4 complex would be a low-lying transition state along the exchange pathway. However, the formal similarity of the orbital energy pattern of square planar H_4 to that of the π-system in square planar cyclobutadiene (14) suggests that a *metastable* H_4–metal species might be isolable. The system iron–cyclobutadiene was predicted to be stable by Longuet-Higgins and Orgel (17) on theoretical grounds, and subsequently synthesized by Pettit and co-workers (18). The same theoretical argument applies to H_4: the degenerate non-bonding orbital containing two electrons can interact in a stabilizing way with the partially occupied metal d-orbitals, as shown previously in Fig. 8. The synthesis of a structure of type $H_4Fe(X)_3$, where X is a two-electron donor and H_4 is situated as described, would of course be of considerable interest.

Discussion

All the four-center reaction paths calculated to date, using *ab initio* techniques, are of unacceptably high activation energy to explain the mechanism of the $H_2 + D_2$ exchange reaction. It is therefore of interest to reexamine the experimental data to see whether, for example, the six-center path can be definitely ruled out.[3] Questions of mechanism have also been reviewed by Bauer and co-workers (4).

The possibility of a molecular exchange reaction proceeding through a six-center transition state has recently been proposed by King *et al.* (19). They studied the halogen exchange reactions $Cl_2 + Br_2$ and $Cl_2 + HI$ in crossed molecular beams. Analysis of the scattering data led to the conclusion that the reaction leading to formation of BrCl was termolecular and six-center. The same was true for the production of ICl. The authors stress the general nature of such a scheme. One reactant which is easily produced under their experimental conditions is a dimer of chlorine, $(Cl_2)_2$, considered to be a weakly bound "van der Waals molecule". By analogy $(H_2)_2$ would have a small van der Waals minimum, which would help to make the linear H_4 complex somewhat more "sticky".

In support of the four-center exchange mechanism the observed partial orders with respect to argon, H_2 and D_2 play a dominant role. As pointed out previously, the overall order is second, argon is strongly involved, and there is an asymmetry in the order between H_2 and D_2. These data have been successfully reconciled in the four-center mechanism with vibrational excitation (1). From the point of view of potential surface calculations, however, the resolution of a four-center transition state proceeds rather independently from these kinetic results. Argon is obviously not involved in the transition state, and the asymmetry in H_2, D_2 dependence seems best ascribed to dynamic effects. One is left with the question of how these results could be interpreted, even given a four-center potential surface of reasonable activation energy. It is the low experimental activation energy which has been the principal target of previous theoretical searches, and in this respect the exchange reaction proceeding through a six-center transition state is certainly promising. The inclusion of configuration interaction in the computation as well as correction for zero-point energy should lead to a lowering

[3]The author is grateful to Professor S. H. Bauer for a critical evaluation of the six-center mechanism from an experimental viewpoint.

of the energy of H_6 relative to $3H_2$. Such calculations are currently in progress (22).

The author would like to thank S. H. Bauer, D. R. Herschbach, and K. J. Laidler for helpful discussions, and the National Research Council of Canada for financial support.

Synthèse et propriétés des *tert*-butyl-5 triméthyl-2,3,3 cyclohexanols[1]

JEAN-CLAUDE RICHER ET CLAUDE LAMARRE[2]

Département de Chimie, Université de Montréal, B.P. 6210, Montréal, Québec H3C 3V1

Reçu le 26 juillet 1974

JEAN-CLAUDE RICHER et CLAUDE LAMARRE. Can. J. Chem. **53**, 556 (1975).

On rapporte la synthèse des quatre *tert*-butyl-5 triméthyl-2,3,3 cyclohexanols. On compare les propriétés de ces alcools secondaires avec celles des alcools tertiaires obtenus précédemment lors de la réduction des époxydes dérivés du *tert*-butyl-5 triméthyl-2,3,3 cyclohexène; on peut confirmer que lors de la réduction de ces époxydes il ne se forme pas d'alcools secondaires. On discute de la stéréochimie de la réduction, par $LiAlH_4$, des *tert*-butyl-5 triméthyl-2,3,3 cyclohexanones.

JEAN-CLAUDE RICHER and CLAUDE LAMARRE. Can. J. Chem. **53**, 556 (1975).

The synthesis of the four 5-*tert*-butyl-2,3,3-trimethylcyclohexanols is reported and the properties of these secondary alcohols are compared with those of the tertiary alcohols obtained earlier from the reduction of 5-*tert*-butyl-2,3,3-trimethylcyclohexene epoxides. It is confirmed that secondary alcohols are not formed during the reduction of these epoxides. The stereochemistry of the $LiAlH_4$ reduction of the 5-*tert*-butyl-2,3,3-trimethylcyclohexanones is discussed.

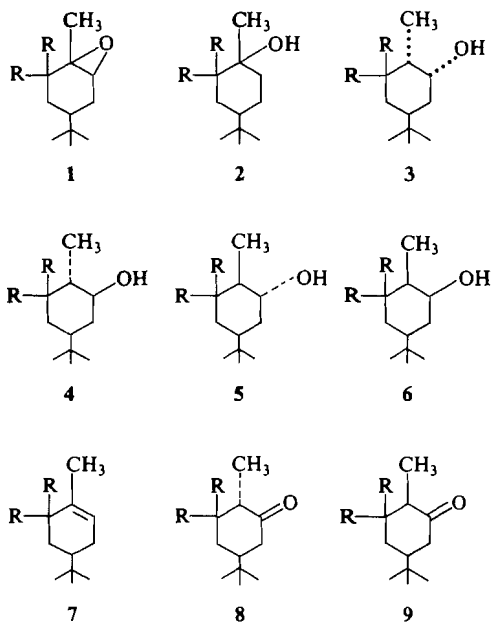
[Journal translation]

Introduction

Nous avons rapporté (1) que la réduction des époxydes **1***a* conduit uniquement aux alcools tertiaires du type **2***a*; par ailleurs la réduction de **1***b* trans[3] conduit selon LeBel et Ecke (2*a*) ainsi que Murphy *et al.* (2*b*) à un mélange contenant seulement *ca.* 31% de l'alcool tertiaire **2***b trans* avec environ 62% d'alcool secondaire **3***b* et 7% d'alcool secondaire **4***b*. La publication de nos résultats a inquiété un certain nombre de collègues et soulevé des questions de la part d'un arbitre. Afin de lever toutes ambiguités concernant nos données, nous avons synthétisé et caractérisé les quatres *tert*-butyl-5 triméthyl-2,3,3 cyclohexanols **3***a*, **4***a*, **5***a* et **6***a* pouvant être formés lors de l'ouverture "anormale" des époxydes **1***a*. Ce sont les résultats stéréochimiques obtenus au cours de cette étude qui font l'objet de la présente note.

Résultats et discussion

L'hydroboration de l'alcène **7***a* effectuée dans le tétrahydrofuranne suivant la technique décrite par Brown et Zweifel (3) conduit, après oxydation des organoboranes intermédiaires par l'eau oxygénée alcaline, à un mélange 83:17 des alcools **4***a* et **5***a*. La chromatographie d'adsorption sur alumine et en phase gazeuse préparative permet d'isoler les deux alcools **4***a* et **5***a* à l'état pur. Leurs propriétés physiques sont résumées dans le tableau 1.



Série *a* R = CH_3; *b* R = H

§Point d'ébullion 105 °C/9 mm Hg; $n_D^{23.5}$ 1.4680.

L'oxydation de ce mélange par une solution d'acide chromique dans l'éther (4) conduit, avec un rendement de 50%, à un mélange des cétones **8***a* et **9***a*. Sous l'influence de l'hydrure de lithium et d'aluminium, ces cétones fournissent un mélange de quatre alcools **3***a*, **4***a*, **5***a* et **6***a* dans les proportions 82.4:8.0:6.8:2.8. La chromatographie en phase gazeuse préparative permet d'isoler **3***a* à l'état pur; ses propriétés sont consignées dans le tableau 1.

La réduction du mélange des cétones **8***a* et **9***a* par le sodium dans l'éthanol conduit aux alcools **4***a* et **6***a* dans un rapport de 89.8:10.2; les propriétés de l'alcool **6***a* sont rapportées au tableau 1.

Il découle d'un examen du tableau 1, dans lequel les propriétés des alcools **2***a cis* et *trans* ont été aussi ajoutées pour fins de comparaison, que les temps de rétention des divers alcools secondaires **3***a* à **6***a* sont très différents de ceux des alcools tertiaires épimères **2***a* et que l'on peut maintenant affirmer d'une façon catégorique que la réduction de l'époxyde **1***a trans*, par opposition à l'époxyde **1***b trans*, conduit uniquement à l'alcool tertiaire **2***a trans* sans traces d'alcools secondaires **3***a* et **4***a*.

Ces résultats signifient qu'une attaque de l'hydrure sur le carbone tertiaire de l'epoxyde **1***a trans* est défavorisée en partie par l'effet du méthyle en position 1 et principalement par le passage par un état de transition chaise déstabilisée par l'interaction 1,3 diaxiale entre le volumineux substituant oxyaluminate et le groupe méthyle; en effet ce processus impliquerait une énergie d'activation tellement élevée qu'il favoriserait plutôt l'attaque de l'hydrure sur le carbone secondaire de l'époxyde **1***a trans* conduisant ainsi à un état de transition ayant une conformation sous la forme croisée et ensuite, après hydrolyse, à l'alcool tertiaire **2***a trans*. (Voir schéma 1.)

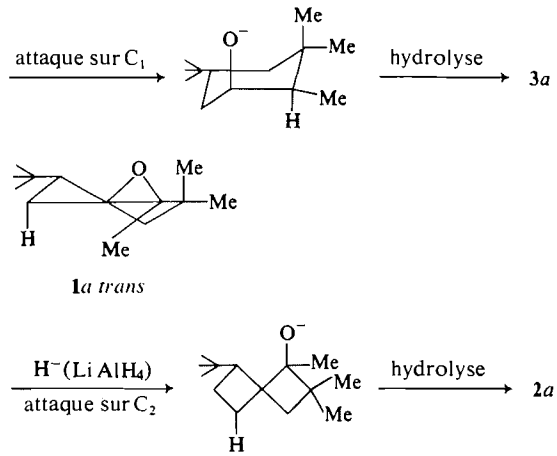

SCHÉMA 1

Les quantités importantes d'alcools axiaux par rapport aux alcools équatoriaux 82.4:8.0 et 6.8:2.8, obtenus lors de la réduction des cétones **8***a* et **9***a* par $LiAlH_4$, indiquent que la stéréochimie de ces réductions est affectée principalement par la présence d'un groupe méthyle axial en position 3 par rapport au groupement carbonyle.

Les pourcentages normalisés d'alcools équatoriaux **4***a* et **6***a* formés lors de la réduction par $LiAlH_4$ des cétones **8***a* et **9***a* sont respectivement de 9 et 30%. Ces résultats montrent d'une façon non ambigüe l'influence du groupe méthyle axial en position 2 de la cétone **9***a* qui contrebalance l'influence du groupe méthyle axial en position 3. Ces résultats tendent à supporter

l'hypothèse complètement stérique proposée (5) pour expliquer la stéreochimie des additions d'hydrure sur les cétones.

Partie expérimentale

Les spectres i.r. ont été pris sur un spectrophotomètre Beckman modèle IR-8 à double réseau. Les spectres de masse ont été enregistrés sur un spectromètre de masse Hitachi Perkin Elmer modèle RMU6-D et l'énergie du faisceau d'électrons ionisants était de 70 eV. Les spectres r.m.n. ont été déterminés sur un spectromètre modèle C-60 H de la Compagnie JeolCo. Le tétraméthylsilane est utilisé comme référence interne. Les points de fusion ont été pris sur un "hot stage apparatus" de la Compagnie Reichert et ne sont pas corrigés. Les indices de réfraction ont été déterminés à l'aide d'un réfractomètre de type Abbe de la Compagnie Karl Zeiss. Les analyses par chromatographie en phase gazeuse ont été effectuées à l'aide d'un appareil à détection thermique Microtek utilisant une colonne de 10 pieds par 1/4 de pouce contenant du chromosorb P 30–60 sur lequel 15% d'hyprose a été déposé. Les séparations par chromatographie en phase gazeuse préparative ont été effectuées sur un appareil Varian modèle 705 dans les conditions suivantes: colonne en aluminium de 20 pieds sur 3/8 de pouce de diamètre remplie de chromosorb P 30–60 sur lequel 20% d'hyprose a été déposé. Température de la colonne 160°, du collecteur 135°, du détecteur 255°, de l'injection 225°; le gaz porteur est l'azote et son débit est de 165 ml par min.

Hydroboration du tert-*butyl-4 triméthyl-1,6,6 cyclohexène* **7***a*

Le borane est préparé par addition, sur une période de 1½ h, de 3.6 g d'éthérate de trifluorure de bore fraîchement distillé à une solution de 1.3 g d'hydrure de bore et de sodium dans 50 ml de tétrahydrofuranne porté à reflux. Le borane ainsi formé est entraîné par un courant d'azote dans un ballon refroidi à 0 °C contenant 3.6 g d'alcène **7***a* en solution dans 25 ml de tétrahydrofuranne. Le traitement à la manière habituelle conduit à 3.9 g (rendement brut de 98%) d'un solide blanc qui par analyse en phase gazeuse sur hyprose à 160 °C, débit d'hélium de 75 ml/min, indique la présence de deux pics dans les proportions relatives suivantes: 17% de *tert*-butyl-5 triméthyl-2,3,3 cyclohexanol-1 (*trans* **5***a*), temps de retention 21 min, et 83% de *tert*-butyl-5 triméthyl-2,3,3 cyclohexanol-1 (*cis* **4***a*), temps de retention 24 min. La chromatographie de 6.6 g de ce mélange sur 700 g d'alumine Woelm neutre activité 1 permet d'isoler 5.6 g d'un mélange des deux alcools et 1 g de l'alcool **4***a* à l'état pur. La chromatographie en phase gazeuse préparative de 5.6 g de mélange permet d'isoler 100 mg de l'alcool secondaire **5***a* à l'état pur. Les caractéristiques de ces alcools sont décrites dans le Tableau 1.

Oxydation des alcools secondaires **4***a et* **5***a en cétones* **8***a et* **9***a*

L'oxydation de 9.5 g du mélange des alcools secondaires par 46 g de bichromate de sodium, selon la méthode de Brown et Garg (4), conduit après les extractions à la manière habituelle à 4.7 g (50% de rendement) du mélange des cétones de **8***a* et **9***a* qui n'ont pas pu être obtenues stéréochimiquement pures. Ces cétones ont un point d'ébullition de 114–118/12 mm Hg et présentent une bande à 1700 cm^{-1} dans l'infrarouge; l'indice de réfraction à 24 °C est 1.4609 et leur spectre de masse montre un ion moléculaire à *m/e* de 196.

Réduction des cétones **8***a et* **9***a par l'hydrure de lithium et d'aluminium*

La réduction de 2 g des cétones **8***a* et **9***a* par 1 g d'hydrure de lithium et d'aluminium dans l'éther anhydre conduit avec un rendement quantitatif au mélange des quatre alcools **3***a*, **4***a*, **5***a* et **6***a*; ce mélange peut être analysé par chromatographie en phase gazeuse sur hyprose à 160 °C avec un débit d'hélium de 75 ml/min. La chromatographie en phase gazeuse préparative sur hyprose de 2 g des alcools en solution dans 20 ml de méthanol permet d'obtenir 641 mg de l'alcool **3***a* à l'état pur. Les propriétés de cet alcool sont rapportées dans le Tableau 1.

La réduction par le sodium dans l'éthanol des cétones **8***a et* **9***a*

La réduction de 330 mg des cétones **8***a* et **9***a* par 5.5 g de sodium dans 55 ml d'éthanol absolu conduit à 287 mg (87% de rendement) d'un mélange des alcools **4***a* et **6***a* qui peuvent être séparés par chromatographie en phase gazeuse sur hyprose à 160 °C, débit d'hélium de 75 ml/min.

Les auteurs remercient vivement le Conseil national de recherche du Canada et le Ministère de l'Education de la Province de Québec pour l'aide financière apportée sous forme d'octroi de recherches (CNR A-1295) et de bourse de perfectionnement (C.L. 1966–1969).

The Reaction of Hydroperoxides with Triphenylarsine and Triphenylstibine

R. HIATT, CHRISTINE MCCOLEMAN, AND G. R. HOWE

Department of Chemistry, Brock University, St. Catharines, Ontario L2S 3A1

Received September 3, 1974

R. HIATT, CHRISTINE MCCOLEMAN, and G. R. HOWE. Can. J. Chem. **53**, 559 (1975).

Triphenylstibine reduced t-BuO_2H to t-BuOH almost as fast as Ph_3P does, while triphenylarsine reacts only 1/60 as fast. Both reductions are first-order in each component; in ethanol k_2 for Ph_3Sb and Ph_3As are $10^{6.7}e^{-9.7/RT}$ and $10^{9.1}e^{-15.7/RT}$, respectively. The reductions are not very sensitive to choice of solvent, but are strongly catalyzed by compounds of molybdenum and vanadium.

The relative rate order $PH_3P \geq Ph_3Sb > Ph_3As$ is ascribed to two conflicting trends, availability of d-orbitals for π-bonding with peroxidic oxygen, and the Group VB to oxygen bond strength.

R. HIATT, CHRISTINE MCCOLEMAN et G. R. HOWE. Can. J. Chem. **53**, 559 (1975).

La triphénylstibine réduit le t-BuO_2H en t-BuOH presqu'aussi rapidement que le fait Ph_3P; par ailleurs la triphénylarsine réagit environ 60 fois moins rapidement. Chacune des réductions est du premier ordre en chacun des réactifs; dans l'éthanol, les valeurs de k_2 pour Ph_3Sb et Ph_3As sont respectivement de $10^{6.7}e^{-9.7/RT}$ et $10^{9.1}e^{-15.7/RT}$. Les réductions ne sont pas sensibles au choix du solvant mais sont fortement catalysées par des composés du molybdène et du vanadium.

L'ordre relatif des vitesses $Ph_3P \geq Ph_3Sb > Ph_3As$ est attribué à deux tendances contradictoires soit la disponibilité d'orbitales pour former des liens π avec l'oxygène du peroxyde et la force de la liaison de l'oxygène avec les éléments du groupe VB. [Traduit par le journal]

Introduction

Not long ago we reported (1, 2) a kinetic study of the reduction of hydroperoxides by triphenylphosphine. This facile reaction, chiefly useful as an analytical tool (3, 4), was found to obey a simple relationship (1)

$$[1] \qquad \text{Rate} = k[RO_2H][Ph_3P]$$

and more importantly, although very rapid itself, to be catalyzed by compounds of vanadium and molybdenum (2). Thus the phosphines were placed squarely in the family of nucleophiles whose other members include olefins (5), organic sulfides, sulfoxides (6), and amines (7, 8) which stoichiometrically reduce hydroperoxides under the influence of these catalysts.

$$[2] \qquad RO_2H + N: \xrightarrow{\text{V or Mo}} ROH + N{\rightarrow}O$$

Phosphorous is unique, however, in giving clean reduction in the absence of catalyst, and may be contrasted particularly with nitrogen; amines take the alternate route of one electron reduction, free radical formation, and chain reaction unless catalyzed.

Accordingly it seemed desirable to investigate the other members of Group VA, arsenic, antimony, and bismuth. Horner and Jürgens had found earlier (3) that triphenylarsine reduced hydroperoxides (as well as acyl peroxides and peroxy acids) stoichiometrically and quantitatively, but did not comment on the rate of the reaction. The reduction of hydroperoxides by triphenylstibine has also been noted (8).

We here describe studies of the reactions of t-BuO_2H with Ph_3As and Ph_3Sb. Preliminary experiments on the reactions between Ph_3Bi and t-BuO_2H indicated a complexity which relegated that investigation to the area of future work.

Experimental

Triphenylarsine (Aldrich) and triphenylstibine (Eastman) were recrystallized from ethanol. t-Butyl hydroperoxide (*i.e.*, Lucidol) was generally used as received, as a 90% aqueous solution. Solvents were reagent grade, generally used without further purification.

To discover whether small amounts of water had any effect, some kinetic experiments were carried out with peroxide purified to greater than 99.5% by vacuum distillation and ethanol dried by distillation from magnesium. Also traces of water equal to that already present were added to reactions of unpurified hydroperoxide in undried ethanol. None of these measures had a noticeable effect on rates.

Rates of reaction were determined by monitoring the disappearance of the u.v. absorption characteristic of Ph_3M: Ph_3As, $\lambda_{max} = 240$ nm; Ph_3Sb, $\lambda_{max} = 255$ nm. Typically, a solution of each reactant in the solvent of choice was freshly prepared, aliquots were mixed and

For personal use only.

rapidly decanted into a 1 cc thermostated u.v. cell. Concentrations were chosen to give at very least a 25-fold excess of t-BuO_2H over Ph_3M so that peroxide concentration was approximately constant over the course of any run.

For both Ph_3As and Ph_3Sb plots of log $[Ph_3M]$ *vs.* time gave good straight lines. For the Ph_3As runs, pseudo-first-order rate constants were determined using the Newton–Raphson method (9) applied to the equation $A_t - A_\infty = \exp(C + k_1 t)$, where the symbols have their usual meaning and both k_1 and A_∞ are treated as unknowns. A full description and a copy of the Fortran 4 subroutine have been deposited with the International Quantum Chemistry Program Exchange, Dept. of Chemistry, Indiana University, Bloomington, Indiana. For subsequent work with Ph_3Sb a less sophisticated but probably more accurate method was adopted. A large number of runs under identical conditions might differ by as much as 5%, but second order rate constants based on 9 or more determinations seemed reasonably reliable.

Results and Discussion

Products

Reactions on a preparative scale, *i.e.* ~0.1 *M* reactants, between t-BuO_2H and Ph_3As in ethanol confirmed the finding of Horner and Jürgens (3) that the reduction was stoichiometric, yielding only t-BuOH and Ph_3AsO. Crystalline Ph_3AsO was isolated and shown by mass spectrometric analysis to be identical to the product obtained from permanganate oxidation of Ph_3As (10).

Similarly reduction of t-BuO_2H with Ph_3Sb gave only t-BuOH and a crystalline antimony product having the same characteristics as that produced by oxidation of Ph_3Sb by H_2O_2 (11). This has been shown to be a polymeric material (12) and not the monomeric Ph_3SbO prepared by McEwen *et al.* (13).

Kinetics

In ethanol solvent both Ph_3As and Ph_3Sb exhibited first order disappearance in the presence of a large excess of t-BuO_2H, with pseudo first-order rate constants independent of $[Ph_3M]_0$, (Tables 1 and 2). These k_1 were directly proportional to $[t\text{-}BuO_2H]_0$, (varied by a factor of 4 for Ph_3As and a factor of 10 for Ph_3Sb). Dividing k_1 by $[t\text{-}BuO_2H]_0$ gave the second order rate constants (Tables 1 and 2).

$$[3] \qquad \text{Rate} = k_2[Ph_3M][t\text{-}BuO_2H]$$

Qualitatively both reactions are fast, but Ph_3Sb reacts about 60 times faster than Ph_3As and almost as fast as Ph_3P. Table 3 which compares the three reagents shows that the relative slowness of the Ph_3As–t-BuO_2H reaction is due to a higher activation energy.

Reactions in Other Solvents

Both Ph_3Sb and Ph_3As exhibited moderately faster reactions in ethanol–water mixtures than in ethanol (Table 4) and both reacted faster in hexane than in ethanol. This rate increase both when the solvent is made more polar and when it is made less polar, also found with Ph_3P (2) probably has a simple explanation. More acidic solvents facilitate the required proton transfer (2). However, both RO_2H and Ph_3M are dipoles

and it is not unreasonable to expect that the transition state would permit a wider distribution of partial charge.

Catalysis by Metal Ions

Most of the molybdenum and vanadium catalysts at our disposal exhibited too great an absorption in the 240–260 nm region to be used in conjunction with the analytical method. However, trace quantities of vanadium naphthenate or $Mo(CO)_6$ could be used and their strong catalytic effect is shown in Table 5.

Plots of k_2 *vs.* $[V_{naphth}]$ intercepted nicely at k_2 measured in the absence of catalyst, leading to the equation

[5] Rate = $[Ph_3M][t\text{-}BuO_2H](k_2 + k_3[V_{naphth}])$

A similar plot for $Mo(CO)_6$ did not intercept at the uncatalyzed rate; this may have been due to the formation of $Mo(CO)_5SbPh_3$ and $Mo(CO)_4(SbPh_3)_2$ during the course of the reaction.

Relative Reactivities

The order of reactivity with t-BuO_2H (Table 3); $PhNH_2 \ll Ph_3As < Ph_3Sb \leq Ph_3P$, is surprising in two respects; the transposition of As

§MeO^-.

and Sb, and the virtual equality of Sb and P. That is, a series of nucleophilic attacks on a soft electrophile is expected to follow $N \ll Sb < As < P$ (14, 15) and this order has been found in rate studies of ligand substitution reactions (15, 16) (Table 6). It is also the order of the M to oxygen bond strength (14).

[6] $TX_lY_m + MPh_3 \rightarrow TX_lY_{m-1}(MPh_3) + Y$

where T is a transition metal and X and Y are the original ligands.

But as Pearson *et al.* have warned (15) it is fruitless to make too close correlations between apparently similar nucleophilic substitutions. To point out some anomalies, Table 6 compares displacements on peroxidic O—O (17) with those on $Pt(py)_2Cl_2$ and on CH_3I; values for H_2O_2 with MPh_3 are not available, but those from Table 3 for t-BuO_2H can be transposed with some confidence that orders of magnitude errors are not involved (17). While it is evident that reactivities of Ph_3M with O—O do not parallel their reactivities with $Pt(py)_2Cl$ or with methyl iodide, it is equally true that CN^- and OH^- do not parallel I^-. The low nucleophilicity of OH^- and CN^- for  , as compared to  has been explained in terms of nonbonded electron pair repulsions in the transition state. Conversely nucleophiles having low-energy unoccupied orbitals may minimize this repulsion through back-bonding (17, 18).

If the availability of the d orbitals for π-bonding increases monotonically in $Ph_3P \rightarrow Ph_3Sb$, for which there is some evidence (19), the nucleophilicity for oxygen should increase similarly if this were the only important effect. However, the strength of the M-to-oxygen bond being formed must be considered as well. Both As—O and Sb—O bonds are weak while the P—O bond is very strong (19). The combination of these factors satisfactorily accounts for the trend we have observed.

Finally, the relative rates for the vanadium-catalyzed reduction (Table 3), Sb > P > As, fit this hypothesis nicely. Catalysis as well as lowering the activation energy and exerting a general leveling effect would tend to move the transition state forward on the reaction coordinate, making

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

it less product-like. The effect of P—O bond strength is diminished, and Ph_3Sb reacts faster than Ph_3P.

A New Method for Determining Individual Rate Constants for Specific Non-chromophoric Substrates of Proteolytic Enzymes

LEWIS J. BRUBACHER

Department of Chemistry, University of Waterloo, Waterloo, Ontario N2L 3G1

Received July 9, 1973[1]

LEWIS J. BRUBACHER. Can. J. Chem. **53**, 564 (1975).

Equations are developed for the pre-steady state kinetics of the proteolytic enzyme-catalyzed hydrolysis of a substrate A in the presence of a monitoring substrate (or covalent inhibitor) S of known properties. A two-intermediate acyl–enzyme mechanism is assumed in which the first intermediate is in instantaneous equilibrium with enzyme and substrate. The appearance of the first product of substrate S is characterized by two relaxation rate constants. From these constants it is possible to determine the dissociation constant and the acylation and deacylation rate constants of substrate A. Criteria are also developed for using the steady state rate parameters of A to establish conditions for which the slower relaxation process is equivalent to the deacylation rate constant of A. The technique of premixing enzyme with substrate A has certain advantages in this approach.

LEWIS J. BRUBACHER. Can. J. Chem. **53**, 564 (1975).

On a développé des équations pour calculer la cinétique intervenant avant l'état stationnaire lors de l'hydrolyse protéolitique, catalisée par les enzymes, d'un substrat A en présence d'un substrat de contrôle (ou un inhibiteur covalent) S de propriétés connues. On fait l'hypothèse qu'un mécanisme à deux intermédiaires acyle–enzyme prévaut et que le premier intermédiaire est un équilibre instantané entre l'enzyme et le substrat. L'apparution du premier produit provenant du substrat S est caractérisé par deux constantes de vitesse de relaxation. A partir de ces données il est possible de déterminer la constante de dissociation et les constantes de vitesse d'acylation et de déacylation du substrat A. On a aussi développé des critères pour l'utilisation des paramètres de vitesse de l'état stationnaire A afin d'établir les conditions dans lesquelles le processus de relaxation le plus lent est équivalent à la constante de vitesse de déacylation de A. La technique de mélange préalable de l'enzyme avec le substrat A a certains avantages dans cette approche. [Traduit par le journal]

Introduction

It is generally accepted (1) that reaction 1 is the minimal mechanism of action of the serine proteinases and cysteine proteinases. The steady state rate equation and rate parameters are given in eqs. 2–5, where K_a is the substrate constant.

$$[1] \qquad E + A \rightleftharpoons EA \overset{k_2}{\rightarrow} EA' \overset{k_3}{\rightarrow} E + Q_2 + Q_1$$

$$[2] \qquad v = k_{cat,a}[E][A]/([A] + K_m)$$

$$[3] \qquad k_{cat,a} = k_2k_3/(k_2 + k_3)$$

$$[4] \qquad K_{m,a} = k_3K_a/(k_2 + k_3)$$

$$[5] \qquad K_a = (k_{-1} + k_2)/k_1$$

Measurement of the acylation and deacylation rate constants, k_2 and k_3, respectively, is important to the study of the nature of the catalysis associated with each step. Pre-steady state kinetic studies provide such information (2, 3), but many good substrates do not have convenient physical properties for rapidly determining their concentrations. Consequently, many indirect methods have been used. One such approach is the argument that the deacylation step is rate-determining if a series of derivatives of the same amino acid have the same value of $k_{cat,a}$. It is claimed that this approach is sometimes misleading (4).

This paper describes a general method, which is well adapted to spectrophotometric fast reaction techniques, by which k_2, k_3, and K_a may be determined for non-chromophoric substrates. A very good substrate with convenient spectrophotometric properties is used as a monitoring substrate in a manner similar to an approach described earlier (5) and used in a variety of ways (6, 7). This paper lays the mathematical basis for an extension of that approach to the case where the acyl–enzyme is too labile to be isolated.

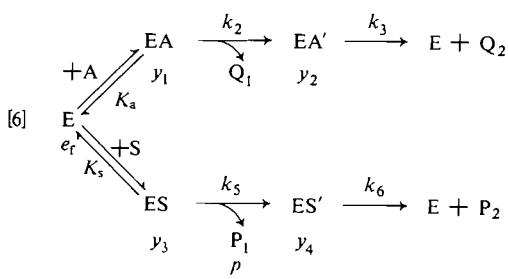
Theory

Two experimental procedures will be considered. In Type I experiments, substrate A and enzyme are pre-mixed. After the steady state is attained, a second substrate, S, is added at time zero at a sufficiently high concentration that in the new steady state, most of the enzyme is involved in catalyzing the hydrolysis of S. The kinetics of the approach to this new steady state are followed. In the second case, the enzyme is added to a solution containing both A and S. The derivation of the rate of appearance of P_1 is common to both procedures. The only difference is in the initial conditions which are needed to evaluate certain constants of integration.

The mechanism is given in reaction 6.



Three assumptions are made about the complete system. (*1*) The species EA, E, and ES are in instantaneous equilibrium with each other through the substrate dissociation constants K_a ($=k_{-1}/k_1$) and K_s ($=k_{-4}/k_4$), *i.e.*, $k_{-1} \gg k_2$ and $k_{-4} \gg k_5$. (*2*) The two substrates, A and S, are maintained at constant concentrations a_0 and s_0, respectively, during the interval of time in which the appearance of P_1 is observed. (*3*) The enzyme concentration, e_0, is much less than a_0 and s_0. The molar concentrations of E, EA, EA′, ES, ES′, and P_1 are defined as e_f, y_1, y_2, y_3, y_4, and p, respectively.

Integrated Rate Equation for P_1

From the definitions for the substrate dissociation constants we may write $e_f + y_1 + y_3 = by_3K_s/s_0$ where b is defined in eq. 7. The differential rate equation for the sum of the

$$[7] \qquad b = 1 + \frac{a_0}{K_a} + \frac{s_0}{K_s}$$

concentrations of E, EA, and ES is $\dot{y}_3 = (k_3y_2 + k_6y_4 - k_2y_1 - k_5y_3)s_0/bK_s$. Eliminating y_4 by use of the enzyme conservation equation, $e_0 = e_f + y_1 + y_2 + y_3 + y_4$, leads to

$$[8] \qquad \dot{y}_3 = \frac{k_6e_0s_0}{bK_s} + \frac{s_0}{bK_s}(k_3 - k_6)y_2 - (k_2' + k_5' + k_6)y_3$$

where

$$[9] \qquad k_2' = k_2a_0/bK_a$$

$$[10] \qquad k_5' = k_5s_0/bK_s$$

Also, from reaction 6

$$[11] \qquad \dot{y}_2 = -k_3y_2 + (k_2a_0K_s/s_0K_a)y_3$$

Combining eqs. 8 and 11, utilizing the operator method (8), gives

$$[12] \qquad \ddot{y}_3 + P\dot{y}_3 + Qy_3 = k_3k_6e_0s_0/bK_s$$

where

$$[13] \qquad P = k_2' + k_3 + k_5' + k_6$$

$$[14] \qquad Q = k_2'k_6 + k_3k_5' + k_3k_6$$

Following standard methods (8), eq. 12 may be solved to give

$$[15] \qquad y_3 = (e_0s_0/bmK_s)(1 + Me^{-Ft} + Ne^{-Gt})$$

where M and N are constants of integration, and

$$[16] \qquad F = (P - \sqrt{P^2 - 4Q})/2$$

$$[17] \qquad G = (P + \sqrt{P^2 - 4Q})/2$$

$$[18] \qquad m = 1 + k_2'/k_3 + k_5'/k_6$$

The parameter m is a convenient composite function of acylation and deacylation rate constant ratios for both substrates. Substituting eq. 15 into $\dot{p} = k_5y_3$ (from reaction 6) and integrating, taking $p = 0$ at $t = 0$, gives

$$[19] \qquad \frac{p}{e_0} = \frac{s_0k_{cat,s}}{s_0 + K_m}\left(t + \frac{M}{F}(1 - e^{-Ft}) + \frac{N}{G}(1 - e^{-Gt})\right)$$

where

$$[20] \qquad k_{cat,s} = k_5k_6/(k_5 + k_6)$$

$$[21] \qquad K_m = K_{m,s}(1 + a_0/K_{m,a})$$

$$[22] \qquad K_{m,s} = k_5K_s/(k_5 + k_6)$$

The first term on the right hand side in eq. 19 represents the steady state hydrolysis of substrate S in the presence of species A acting as a competitive inhibitor.

Evaluation of M and N

Expressions are needed for y_3 and $\dot{y}_3$ at time

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

zero, *i.e.*, $y_{3,0}$, and $\dot{y}_{3,0}$. These expressions depend on the order of mixing E, A, and S.

Type I (Premixed E and A)

Experimentally, two solutions are mixed at the defined zero time: solution 1 contains enzyme and substrate A already reacting under steady state conditions; solution 2 contains only substrate S. Equal volumes of both solutions are mixed at time zero to give solution 3. (This is the most convenient mixing ratio if a stopped-flow apparatus is used. Obviously, for slow reactions the solutions may be mixed manually. Other mixing ratios are considered in the Discussion.) Thus, in solution 1 the concentrations of total enzyme and substrate are defined as $2e_0$ and $2a_0$, respectively, and the enzyme conservation equation is $2e_0 = e_{f,ss} + y_{1,ss} + y_{2,ss}$. (The subscript ss denotes steady state concentrations.) Applying the steady state approximation to the upper pathway of reaction 6 leads to an expression for $y_{2,ss}$. Upon mixing the two solutions, the concentration of EA′ in solution 3 at $t = 0$ is

$$[23] \quad y_{2,0} = y_{2,ss}/2 = e_0 \Big/ \left(1 + \frac{k_3}{k_2} + \frac{k_3 K_a}{2k_2 a_0}\right)$$

Also at $t = 0$, that portion of the enzyme which was previously in the form of E and EA in solution 1 is instantaneously re-equilibrated in solution 3 to yield some ES as well. Since $y_{4,0} = 0$ in solution 3, substituting eq. 23 into the enzyme conservation equation at $t = 0$ leads to

$$[24] \quad y_{3,0} = e_0 s_0 (\tfrac{1}{2} + a_0/K_a)/[bK_s(\tfrac{1}{2} + a_0/K_{m,a})]$$

At $t = 0$, eq. 8, along with eqs. 23 and 24, becomes

$$[25] \quad \dot{y}_{3,0} = \frac{e_0 s_0 \left[k_2' \left(\frac{1}{2} + \frac{s_0}{K_s}\right) - k_5' \left(\frac{1}{2} + \frac{a_0}{K_a}\right)\right]}{[bK_s(\tfrac{1}{2} + a_0/K_{m,a})]}$$

When the boundary conditions of eqs. 23 to 25 are applied to eq. 15, the solutions for M and N are

$$[26] \quad M = \frac{\left[k_2' \left(\frac{1}{2} + \frac{s_0}{K_s}\right)\left(m - \frac{G}{k_3}\right) - k_5' \left(\frac{1}{2} + \frac{a_0}{K_a}\right)\left(m - \frac{G}{k_6}\right)\right]}{\left[(G - F)\left(\frac{1}{2} + \frac{a_0}{K_{m,a}}\right)\right]}$$

$$[27] \quad N = \frac{\left[-k_2' \left(\frac{1}{2} + \frac{s_0}{K_s}\right)\left(m - \frac{F}{k_3}\right) + k_5' \left(\frac{1}{2} + \frac{a_0}{K_a}\right)\left(m - \frac{F}{k_6}\right)\right]}{\left[(G - F)\left(\frac{1}{2} + \frac{a_0}{K_{m,a}}\right)\right]}$$

Type II (Premixed A and S)

In this procedure solution 1 contains enzyme only, solution 2, the two substrates. When these two solutions are mixed at $t = 0$ to give solution 3, there is no pre-existing EA′ as there was in the Type I procedure, *i.e.*, $y_{2,0} = y_{4,0} = 0$. From the enzyme conservation equation it follows that $y_{3,0} = e_0 s_0/bK_s$, and from eq. 8, $\dot{y}_{3,0} = -(k_2' + k_5')e_0 s_0/bK_s$. When these boundary conditions are applied to eq. 15, the solutions for M and N are

$$[28] \quad M = [k_2'(G/k_3 - m) + k_5'(G/k_6 - m)]/(G - F)$$

$$[29] \quad N = [k_2'(m - F/k_3) + k_5'(m - F/k_6)]/(G - F)$$

Special Case when $k_6 = 0$

When ES′ does not deacylate, S is a monitoring covalent inhibitor which releases a species P_1.[2] In this case the derivation is analogous to the previous case except that the terms containing k_6 in eqs. 8, 12, 13, and 14 vanish. The resulting expression for p/e_0 is given in Table 1. For both Type I and Type II experiments, the boundary conditions are the same as in the previous case. They lead to the expressions for M and N given in Table 1.

Discussion

The case for S as a substrate (*i.e.*, $k_6 > 0$) is considered first.

[2]Hijazi and Laidler (9) have considered the case of a competitive inhibitor, *i.e.*, $k_5 = 0$ in reaction 6.

TABLE 1. Equation and parameters for the case of a monitoring covalent inhibitor

$$\frac{p}{e_0} = \frac{k_5'M}{F}(1 - e^{-Ft}) + \frac{k_5'N}{G}(1 - e^{-Gt})$$

$$F = (P - \sqrt{P^2 - 4Q})/2$$

$$G = (P + \sqrt{P^2 - 4Q})/2$$

$$P = k_2' + k_3 + k_5'$$

$$Q = k_3k_5'$$

Type I

$$M = \frac{k_2a_0/K_a + (k_3 - F)(\frac{1}{2} + a_0/K_a)}{(G - F)(\frac{1}{2} + a_0/K_{m,a})}$$

$$N = \frac{-k_2a_0/K_a + (G - k_3)(\frac{1}{2} + a_0/K_a)}{(G - F)(\frac{1}{2} + a_0/K_{m,a})}$$

Type II

$$M = (k_3 - F)/(G - F)$$

$$N = (G - k_3)/(G - F)$$

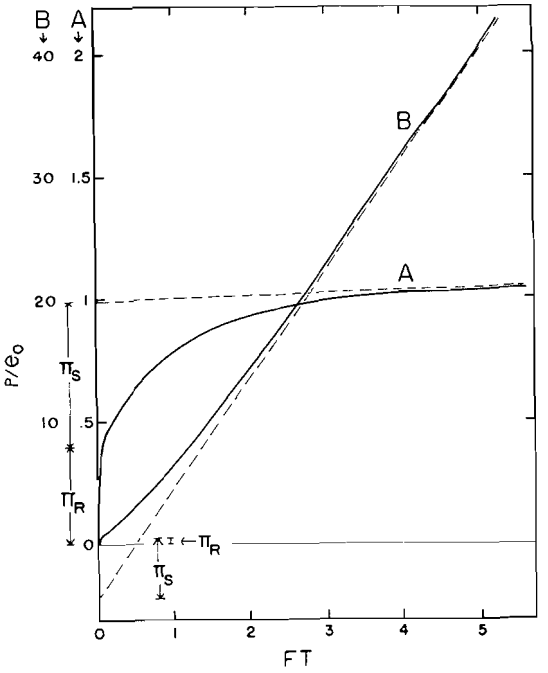

FIG. 1. Normalized plot for the production of P_1 as a function of time according to eq. 19. For both curves, $k_2 = 110$, $k_3 = 11$, $k_5 = 10{,}000$, $s_0/K_s = 10$, $a_0/K_{m,a} = 1$. Curve *A*, $k_6 = 0.1$; curve *B*, $k_6 = 100$. At $Ft = 5$, $e^{-Ft} < 0.01$, and the steady state has been attained.

General Analysis[3]

In Fig. 1 are plotted the general forms of eq. 19 for a Type I experiment. Curve A occurs for $k_3 > k_6$, curve B for $k_6 > k_3$. The rate parameters G and F may be evaluated from such curves by standard methods, either graphically (9, 10) or by data-fitting to an equation having the form of eq. 19. Since the sum and product of G and F are P and Q, respectively (9, 11), combining eqs. 9, 10, 16, and 17, along with the relationship $h = (1 + s_0/K_s)$, leads to

$$[30]\quad G + F = k_3 + k_6 + \frac{k_5s_0}{s_0 + K_s} + \left(k_2 - \frac{k_5s_0}{s_0 + K_s}\right)\left(\frac{a_0}{a_0 + hK_a}\right)$$

$$[31]\quad G \times F = k_3\left(k_6 + \frac{k_5s_0}{s_0 + K_s}\right) + \left(k_2k_6 - \frac{k_3k_5s_0}{s_0 + K_s}\right)\left(\frac{a_0}{a_0 + hK_a}\right)$$

In principle, the constants k_5, k_6, and K_s are independently available from pre-steady state studies on S alone (2, 3). Thus, experimental data obtained at constant s_0 and varying a_0 may be fitted to either eq. 30 or 31 to obtain k_2, k_3, and K_a. Alternatively, if the maximum a_0 is much smaller than $hK_{m,a}$ ($\leqslant hK_a$), eqs. 30 and 31 become linear in a_0, and k_3 may be determined from the intercept of data plotted according to either equation. (Another method for determining k_3 is discussed below.) Once k_3 is known, a plot of $1/[G + F - k_3 - k_6 - k_5s_0/(s_0 + K_s)]$ *vs.* $1/a_0$ according to the rearranged form of eq. 30 (or the analogous form derived from eq. 31) yields slope and intercept values from which k_2 and K_a may be determined.

The ability to observe the two relaxation processes depends upon the magnitude of the rapid and slow bursts (see Fig. 1), which are given by $\pi_r = k_{cat,s}s_0N/[G(s_0 + K_m)]$ and $\pi_s = k_{cat,s}s_0M/[F(s_0 + K_m)]$, respectively. Since the expressions for M and N contain unknown quantities, it is impossible to state general criteria which guarantee that π_r and π_s would be large enough to be observable in either Type I or Type II experiments. However, it is advisable to choose S such that k_6 is quite different from k_3. When k_6 equals k_3 (and one or both of k_2' and k_5' is greater than k_6), M vanishes for both types

[3]While this manuscript was under revision, an extensive series of papers on related topics has been published by Laidler's group (9, 16, 22–25). The revised paper reflects the influence of this series in the inclusion of a general analysis section, and the consideration of Type II experiments. The latter point was also suggested by a referee.

of experiment. Since k_3 is not known in advance, the safest choice is $k_6 < k_{cat,a}$.

Deacylation Monitoring, a Special Case

The preceding analysis may not always be applicable. The parameter G may be too large to measure. Decreasing G to bring it into the measurable range, by adjusting substrate concentrations, may make it difficult to separate G and F with sufficient precision. Thus, it is useful to consider conditions for which a knowledge of the smaller constant, F, and the steady state rate parameters, $k_{cat,a}$ and $K_{m,a}$, is sufficient to determine k_3 and in some cases k_2 and K_a as well.

The key to this analysis lies in the recognition that if k_5' is much greater than all of the terms k_6, k_2', k_6k_2'/k_3, and k_3, then F equals k_3 (see the exact expression for F in eq. 32).

$$[32] \quad F = \frac{Q}{P - F} = k_3\left(\frac{k_5' + k_6 + k_6k_2'/k_3}{k_5' + k_6 + k_2' + k_3 - F}\right)$$

From eqs. 3, 4, and 9 it follows that $k_2' = k_{cat,a}a_0/bK_{m,a}$, and $k_6k_2'/k_3 \ll k_6a_0/bK_{m,a}$. It will be demonstrated below that there is no advantage in having $a_0/K_{m,a}$ much larger than unity. Thus, the first three inequalities are met if the monitoring substrate S is chosen such that k_5s_0/K_s is much greater than k_6 and $k_{cat,a}$, and a_0 is made approximately equal to $K_{m,a}$. The latter restriction, along with $s_0 \geqslant K_s$, ensures that k_5' approaches its maximum value of k_5. The k_5'/k_3 ratio is not known in advance, but can be decided after the fact. If an experimentally determined value of F is much smaller than k_5 ($\simeq k_5'$), then it equals k_3 according to eq. 32, *i.e.*, $k_5'/k_3 \gg 1$, as required. On the other hand, if the experimental value of F is comparable to k_5, a monitoring substrate with a larger k_5 needs to be used.

The above conditions also ensure that $G \simeq k_5' \gg F$, and hence F may be measured readily from the experimental trace.

In Table 2 are compiled values of G and F which were calculated from the defining equations for Type I experiments using arbitrary values for k_5, k_6, and $k_{cat,a}$. Two pairs of k_2 and k_3 values are considered for each of two values of k_6, one pair having $k_2 \gg k_3$, the other, $k_2 \ll k_3$. The agreement between F and k_3 is generally excellent for a wide range of s_0/K_s and $a_0/K_{m,a}$ values, except when $s_0 \ll K_s$ and $a_0 \gg K_{m,a}$, in accord with the previous discussion.

Once k_3 (*i.e.*, F) is known, both k_2 and K_a can be evaluated from the steady state parameters $k_{cat,a}$ and $K_{m,a}$, provided $k_{cat,a}$ is not dominated by k_3. In effect this approach is limited to cases for which $k_2/k_3 \gtrsim 1$. Even if k_2 and K_a cannot be determined, a firm value of k_3 is always valuable information.

Under the same conditions for which F equals k_3 it may be shown that $k_2'(m - G/k_3) \simeq -k_5'(m - G/k_6) \simeq k_2'k_5'(k_3 - k_6)/k_3k_6$. For Type I experiments, substitution of eq. 26 into the definition for the slow burst, π_s (see above), gives

$$[33] \quad \pi_s \simeq \frac{k_2(k_3 - k_6)}{(k_2 + k_3)k_3} \cdot \frac{s_0}{s_0 + K_m} \cdot \frac{a_0}{K_{m,a}/2 + a_0}$$

Values of π_s given by eq. 33 agree well with the exact values in Tables 2 and 3, except when $s_0 \ll K_s$ and $a_0 \gg K_{m,a}$. Type II experiments are ruled out since $M \simeq 0$ in this case (see eq. 28). The relative slow burst, $\pi_{s,rel}$, is arbitrarily defined as

$$[34] \quad \pi_{s,rel} = |\pi_s|/[(p/e_0)_{5/F} - \pi_r]$$

where $(p/e_0)_{5/F}$ is the amount of P_1 produced (as a multiple of e_0) at a time ($t = 5/F$) when the term e^{-Ft} has decayed to less than 0.01. In Fig. 1, $\pi_{s,rel}$ is 93.6% for curve *A* and 12.1% for curve *B*.

In general π_s and $\pi_{s,rel}$ should be as large as possible so the curvature due to the decay of e^{-Ft} is observable in the P_1 trace. Tables 2 and 3 present exact values of F, G, π_s, and $\pi_{s,rel}$ for selected pairs of values of k_2 and k_3 consistent with $k_{cat,a} = 10$. These data illustrate the following criteria for maximizing π_s, which can be derived from eq. 33: $s_0 \gg K_m$; $a_0 \gg K_{m,a}$; and $k_6 \gg k_3$ or $k_6 \ll k_3$. In view of the previous restriction on a_0 ($\gtrsim K_{m,a}$), a compromise of $a_0 \simeq 2K_{m,a}$ is satisfactory. The k_3/k_6 ratio affects π_s and $\pi_{s,rel}$ in several ways. When $k_3 > k_6$, π_s is positive and cannot exceed $k_2/(k_2 + k_3)$. This case has three advantages over the reverse inequality: it can be confidently attained by choosing a substrate S with $k_6 < k_{cat,a}$; the P_1 *vs.* t curve shape (Fig. 1, curve *A*) permits a more precise determination of F; and $\pi_{s,rel}$ is essentially independent of the k_2/k_3 ratio (see Table 3). The major advantage of choosing $k_6 > k_3$ is that π_s can attain values considerably greater than unity (see Tables 2*A* and 3*A*). This multiplying effect may be useful if other factors demand that e_0 be small. Since k_3 is not known, the only guideline in this case is to choose S such that $k_6 > k_{cat,a}$. Such a choice, which may be dictated

by the need to have $k_5 \gg k_{cat,a}$ (see above), could result in a coincidental equality of k_3 and k_6 (see Table 3*A*). If no burst is observed, a second monitoring substrate with a quite different k_6 value should be used.

It should be noted that the *p*-nitrophenyl ester derivatives of specific amino acid or peptide substrates will generally satisfy the criteria established for substrate S, both for deacylation monitoring and for the general approach.

The Monitoring Covalent Inhibitor Case

When k_6 equals zero, the relationships for the rate of appearance of P_1 are summarized in Table 1. The two relaxations predicted are characterized by rate constants G and F whose sum and product may be expressed as

$$[35]\quad G + F = k_3 + \frac{k_5 s_0}{s_0 + K_s} + \left(k_2 - \frac{k_5 s_0}{s_0 + K_s}\right)\left(\frac{a_0}{a_0 + hK_a}\right)$$

$$[36]\quad G \times F = \frac{k_3 k_5 s_0}{s_0 + K_s} - \frac{k_3 k_5 s_0}{s_0 + K_s}\left(\frac{a_0}{a_0 + hK_a}\right)$$

where $h = (1 + s_0/K_s)$. As discussed above, data obtained at constant s_0 and varying a_0 may be used to determine k_2, k_3, and K_a.

For many covalent inhibitors, it is likely that $K_s \gg s_0$, *i.e.*, no saturation occurs. In this case h is unity and $k_5 s_0/(s_0 + K_s)$ reduces to $k_5 s_0/K_s$, which may be defined as k_i, the pseudo first-order rate constant for inhibition of the enzyme. Also, k_5' becomes $k_i a_0/(a_0 + K_a)$.

By much the same arguments as before, the parameter F reduces to k_3 when $k_5' \gg k_2', k_3$. The first requirement is safely assured when $k_i \gg k_{cat,a} a_0/K_{m,a}$; the latter is demonstrated experimentally if F is found to be much smaller than k_5'. For these same conditions, the slow burst ($\pi_s = k_5' M/F$, see Table 1) is zero for Type II experiments, but is given by $k_2 a_0/[(k_2 + k_3)(K_{m,a}/2 + a_0)]$ for Type I experiments. In the

latter case, the condition, $a_0 \gtrsim K_{m,a}$, ensures that the slow burst is close to maximal. Since there is no steady state reaction, the relative slow burst is equivalent to π_s.

The method of using a monitoring covalent inhibitor is most likely to be useful with enzymes such as the sulfhydryl proteases which have an essential catalytic group that is highly reactive.

Choice of e_0

The enzyme concentration has to be chosen as a compromise between the need to have an observable slow burst (large e_0), and the need to maintain s_0 constant[4] and to avoid too rapid hydrolysis of A in solution 1 of Type I experiments (small e_0). The latter problem may be minimized by using a three-syringe mixing device.

Mixing Ratio

In Type I experiments it was previously assumed that equal volumes of solutions 1 and 2 were mixed at $t = 0$. For any volumes, V_1 of solution 1 and V_2 of solution 2, it may be shown that the factor of $\frac{1}{2}$, which appears in three places in each of eq. 26 (for M) and eq. 27 (for N), should be replaced by $V_2/(V_1 + V_2)$ in the first numerator term, and by $V_1/(V_1 + V_2)$ in the denominator and second numerator terms. The latter replacement also applies to the denominator of eq. 33 (for π_s), and to both terms in the Type I values of M and N in Table 1. Possible advantages in using $V_1 < V_2$ are that, as V_1/V_2 is decreased, π_s increases for a given a_0 value, and temperature control of solution 1 is less critical.

Adequacy of the Mechanism

The steady state definitions of the substrate constants for A and S are $K_a = (k_{-1} + k_2)/k_1$ and $K_s = (k_{-4} + k_5)/k_4$. In this paper it has been assumed that $k_{-1} \gg k_2$ and $k_{-4} \gg k_5$. Although this approximation is not valid in some cases, *e.g.*, the peroxidases (12), it seems appropriate for the common amide, ester, and peptide substrates of the proteolytic enzymes. Association rate constants of 2×10^7 and 1×10^8 M^{-1} s^{-1} (which are typical of many enzyme:ligand associations (13)) have been measured for the

[4]In the deacylation monitoring approach, the only term of eq. 15 which depends significantly on s_0 is s_0/bmK_s $(=s_0k_{cat,s}/[k_5(s_0 + K_m)])$. Thus, a varying s_0 can be accommodated to a good approximation by replacing s_0 in this term with $(s_0 - p)$ before performing the integration of $p = k_5y_3$.

reaction between papain and a competitive peptide inhibitor (26) and between α-chymotrypsin and proflavin (11), respectively. Since substrate constants of 10^{-3} to 10^{-2} M are typical for the proteolytic enzymes (14), it follows that $(k_{-1} + k_2)$ is of the order of 10^5 s^{-1}, which is nearly 10-fold greater than the largest recorded k_2 value of α-chymotrpysin (15). It is possible to analyze the mechanism of reaction 1 without making the equilibrium assumption, in which case four relaxation processes are predicted (16). However, since the equations are exceedingly complex, it is useful to have available the simpler equations given in this paper.

It has been suggested (17, 18) that the mechanism of reaction 1 needs to be expanded to include an additional intermediate in the productive pathway. If that is so, in spite of the reported failure (19) to confirm one of these claims, the basic approach reported in this paper is still applicable. The integrated equation corresponding to eq. 19 would then contain an additional exponential term and somewhat more complex coefficients. Indeed the observation of more than two relaxation processes would constitute evidence for additional intermediate species on the reaction pathway (20), provided the equilibrium assumption is valid. As the number of intermediate species increases, it becomes less likely that a single rate constant in the mechanism could be identified with a particular relaxation process. However, a careful analysis of individual cases might prove fruitful.

The existence of additional enzyme:substrate complexes, such as nonproductive complexes (21), which are in rapid equilibrium with free enzyme, would not affect the form of eq. 19. Only the meaning of k_2, K_a, k_5, and K_s would be changed (27).

It has been observed (6) that *N*-acetyl-L-tyrosine ethyl ester causes a five-fold acceleration of the deacylation of acetyl-α-chymotrypsin. This was attributed to an interaction between the specific substrate and the acyl-enzyme where the acyl group (acetyl) was derived from an "incomplete" substrate. When A is a specific substrate, such an effect is less likely. To check this point an experiment may be performed with $s_0 < K_s$, a condition for which S is not likely to bind to EA′ since it does not bind significantly to E. If these results agree with those using $s_0 > K_s$, one may conclude that S does not bind to EA′. Table 3*E* illustrates that with proper choice of S and a_0, there is good separation of G and F, F equals k_3, and the relative slow burst is adequate for the case of $s_0 < K_s$.

Complexes of the Early Transition Metals with *o*-Mercaptophenol and 1,2-Dihydroxybenzene

JOEL L. MARTIN AND JOSEF TAKATS

The Department of Chemistry, University of Alberta, Edmonton, Alberta T6G 2E1

Received June 4, 1974

JOEL L. MARTIN and JOSEF TAKATS. Can. J. Chem. **53**, 572 (1975).

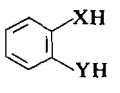
A novel synthetic approach, based on the reactivity of amido derivatives of the transition metals, $M(NR_2)_x$, towards protic reagents, for the synthesis of complexes of Ti, Zr, Hf, Nb, and Ta with *o*-mercaptophenol and 1,2-dihydroxybenzene is reported. The complexes, isolated as their tetraalkylammonium and tetraphenylarsonium salts, are moderately air stable, well behaved 2:1 (Ti, Zr, Hf) and 1:1 (Nb, Ta) electrolytes. The u.v.–visible spectra of the complexes, which are somewhat reminiscent of the corresponding benzene-1,2-dithiolates, are dominated by ligand-to-metal charge transfer bands. The band positions change in the expected manner, hypsochromic shifts in the order $C_6H_4S_2^{2-} < C_6H_4SO^{2-} < C_6H_4O_2^{2-}$ for a given metal and Ti < Zr ~ Hf, Nb < Ta, Nb < Zr for a given ligand. It is argued that these spectral resemblances could be a possible indication of variations in coordination geometry of the reported complexes similar to the ones found in compounds of benzene-1,2-dithiol.

JOEL L. MARTIN et JOSEF TAKATS. Can. J. Chem. **53**, 572 (1975).

On décrit une nouvelle synthèse pour la préparation des composés du Ti, Zr, Hf, Nb et Ta avec l'*o*-mercaptophénol et le benzène dihydroxy-1,2. La synthèse utilize la réactivité des amidures des métaux de transition, $M(NR_2)_x$, vis à vis les ligands contenant des protons acidiques. Les composés, obtenus sous forme de sels d'ammonium et d'arsonium quarternaires, sont modérément stable à l'air et se comportent en solution commes des électrolytes 2:1 (Ti, Zr, Hf) et 1:1 (Nb, Ta). Les spectres u.v.–visibles, qui sont dominés par des bandes de transfert de charge, ressemblent à ceux des composés correspondants avec le benzène-1,2-dithiolene. La position des bandes change d'une manière prévisible; les déplacements hyposochromes sont dans l'ordre $C_6H_4S_2^{2-} < C_6H_4OS^{2-} < C_6H_4O_2^{2-}$ pour un metal donné et dans l'ordre Ti < Zr ~ Hf, Nb < Ta et Nb < Zr pour un ligand donné. On discute la possibilité que les ressemblances spectrales indiquent une variation dans la géometrie de coordination similaire à celle trouvée dans le cas des composés avec le benzène dithiol-1,2.

Introduction

In the course of our investigation on the chemistry of benzene-1,2- and toluene-3,4-dithiol complexes of the early transition metals we have devised a convenient new synthetic procedure for the preparation of such complexes (ref. 1 and refs. therein). The method involved the reaction of a metal amide, $M(NR_2)_x$, with a mixture of the dithiol and its sodium salt in tetrahydrofuran and subsequent replacement of the sodium ions by a bulky organic cation. The application of our method to the synthesis of other complexes with ligands of type **1**, where



1

X and Y are S,O and O,O, was a logical extension of our previous study. Thus, we report here the preparation and characterization of the following complexes: $[R_4E]_{6-x}[M(XYC_6H_4)_3]$ where M = Ti, Zr, and Hf, $x = 4$, $R_4E = (C_2H_5)_4N$, X = O, and Y = S (also for Ti and Hf X = Y = O); where M = Nb and Ta, $x = 5$, $R_4E = (C_6H_5)_4As$, X = O, and Y = S.

The impetus to extend our studies to these complexes was twofold. First, the complexes are related to the corresponding transition metal benzene-1,2-dithiolates and as such might provide additional information to our understanding of the unusual chemical properties (facile one-electron transfer reactions, trigonal prismatic coordination geometry) of this class of compounds. Second, only a few reports of transition metal complexes where X = O and Y = S have appeared in the chemical literature (2–4) and

4

only in the case of Nb, Ta, and W were well behaved tris-*o*-mercaptophenolates isolated (4). Furthermore, with the exception of W, all the tris complexes contain ionizable hydrogens, present as SH or OH groups on the ligands (5–11), *i.e.* structures **2** (M = Ti, Zr) and **3** (M = Nb, Ta). The effect of ionizable hydrogens on the structure of this type of complexes produced a mild controversy. It was argued that for complexes of Si(IV), containing water of crystallization, instead of the simple tris-chelated octahedral geometry, a structure like **4** would be observed (12). However a recent single crystal X-ray structure determination of the anhydrous $(C_5H_6N)_2[Si(O_2C_6H_4)_3]$ (C_5H_6N = pyridinium) complex (13) disproved the above postulate and established the occurrence of the tris-chelated octahedral geometry, a similar result was also obtained for a P(V) complex, $[(C_2H_5)_3NH][P(O_2C_6H_4)_3]$ ($(C_2H_5)_3NH$ = triethylammonium) (14). Whether the implications of these studies can be applied to complexes of the transition metals is not yet known since there is a total absence of structural work in this area. Nevertheless the present synthetic method provides a way of avoiding this potential problem when necessary.[1]

Experimental

All operations were carried out under nitrogen atmosphere in Schlenk type apparatus using dry solvents as previously described (1). Metal amides were prepared by known procedures (15–18) and sodium cyclopentadienide was prepared by standard methods. 1,2-Dihydroxybenzene was obtained commercially and sublimed before use. *o*-Mercaptophenol was prepared according to U.S. patent 3,468,961 by permission of Hooker Chemical Corp., which was found to be a much more convenient method for the preparation of this ligand than the previously preferred method (19). Tetraethylammonium chloride was purchased as a monohydrate and dehydrated at 80–90° and 0.05 mm Hg. The anhydrous salt was then dissolved in CH_3CN and stored under nitrogen in a buret with a large reservoir attached to it. The CH_3CN solution was standardized by precipitation of Cl^- as AgCl. Analyses were performed by the analytical services of the University of Alberta.

Preparation of the Compounds

$[(C_2H_5)_4N]_2[Ti(OSC_6H_4)_3]$

Sodium cyclopentadienide, 0.330 g (0.00375 mol), in 20 ml of THF was added to 0.00563 mol of *o*-mercaptophenol in 20 ml of THF. Next 0.00188 mol of $Ti[N(C_2H_5)_2]_4$ in 20 ml of THF was added and after stirring 48 h, 13.8 ml of 0.272 *M* tetraethylammonium chloride in CH_3CN was added. This mixture was stirred for 2 h and then the solvent was removed under vacuum and replaced by 50 ml of CH_3CN. After stirring overnight the solution was filtered to remove NaCl. Addition of 55 ml of ether with vigorous stirring, followed by allowing the solution to stand, produced large black crystals. The reaction mixture was cooled in a freezer for 24 h and the black crystals were filtered off.

All other compounds were prepared in a similar manner with the following modifications.

$[(C_6H_5)_4As][Nb(OSC_6H_4)_3]$

This complex was isolated by adding solid tetraphenyl arsonium chloride to the THF reaction mixture. The THF was removed under vacuum after 2 h and replaced by 50 ml of CH_2Cl_2 and after 2 h the solution was filtered. Addition of ether and cooling produced black crystals in 60% yield which gave poor analysis. The product was recrystallized from hot CH_3CN.

$[(C_2H_5)_4N]_2[Ti(O_2C_6H_4)_3]$

This compound was prepared in the same manner as the corresponding *o*-mercaptophenol complex except that diglyme was used as solvent instead of THF. After several recrystallizations from CH_3CN and ether mixtures orange crystals of suitable purity were obtained.

$[(C_6H_5)_4As][Nb(OC_6H_4(SH))_2Cl_4]$

To 0.840 g (0.00665 mol) of *o*-mercaptophenol in 50 ml of THF was added 0.00229 mol of sodium cyclopentadienide in 12 ml of THF. Solid $NbCl_5$ was then added and the reaction mixture immediately turned dark brown. The reaction mixture was stirred for 96 h after which 0.96 g of tetraphenyl arsonium chloride was added. After stirring for 1 h the solvent was removed under vacuum and was replaced by 50 ml of CH_2Cl_2. After stirring 1 h the mixture was filtered and 20 ml of ether was added resulting in the formation of a dark brown oil. The supernatant was decanted off and the oil was dried under vacuum but could not be characterized. An additional 20 ml of ether was added to the supernatant causing more of the oil to form. This time the reaction mixture was allowed to stand for 1 week at room temperature and the oil disappeared leaving black crystals. The i.r. of the product was very similar to $[(C_6H_5)_4As][Nb(OSC_6H_4)_3]$ except for an additional peak at 800 cm^{-1} and loss of a peak at 270 cm^{-1}. The physical properties and analytical results of the synthesized complexes can be found in Table 1.

[1]It is worth pointing out that the previous synthesis (4) of $H_2[M(OSC_6H_4)_3]$, M = Ti and Zr, produced polymeric, insoluble, materials, clearly undesirable from the synthetic point of view and not too appealing for structural work either.

Physical Measurements

Infrared spectra were recorded as KBr pellets in the region 4000–250 cm^{-1} on a Perkin–Elmer 457. Visible and u.v. spectra were obtained in the region of 10 000–40 000 cm^{-1} on a Cary 14 using various path lengths and solutions which were 10^{-4} *M* in CH_3CN. Polarographic measurements were made as previously described (1). ^1H n.m.r. spectra were recorded on a Varian Associates A 60 and conductivity measurements were made using a Philips PR9500 conductivity bridge and a cell designed for measurements under an inert atmosphere.

Results and Discussion

Sodium salts of the desired complexes can be prepared as THF solutions according to the following equation.

$$M(NR_2)_x + (6 - x)NaXC_6H_4(YH) + (x - 3)(HX)C_6H_4(YH) \rightarrow Na_{(6-x)}M(XYC_6H_4)_3$$

where $x = 4$ for Ti, Zr, and Hf and $x = 5$ for Nb and Ta. In our previous report on the synthesis of complexes of benzene-1,2-dithiol, we isolated the complexes as tetraphenylarsonium or tetraalkylammonium salts by exchange with the appropriate halide salt in CH_3CN or CH_2Cl_2. We have found that, in the synthesis of complexes of *o*-mercaptophenol and 1,2-dihydroxybenzene, one must use a chloride and not a bromide or iodide. It seems that in the latter two cases, exchange of cations is never complete due to the higher solubility of NaBr and NaI. This does not cause a problem in the case of benzene-1,2-dithiol complexes which have lower solubility than the *o*-mercaptophenol and 1,2-dihydroxybenzene complexes. These latter complexes require more drastic conditions to effect precipitation and as a result of this tetraalkylammonium bromide or iodide also precipitates. Therefore, we recommend the use of chlorides in order to avoid such problems. Although most tetraalkylammonium chlorides are hygroscopic, we have found that they may be easily dehydrated under vacuum and subsequently used as standardized CH_3CN solutions.

Alternatively, we have attempted direct synthesis of the sodium salt of the Nb complex with *o*-mercaptophenol by reacting $NbCl_5$ with a mixture of *o*-mercaptophenol and its sodium salt in refluxing THF for 44 h. Under these conditions no characterizable compounds could be isolated but by doing the same reaction at room temperature for 96 h, black crystals were finally obtained from the work-up which appear to be a mixed complex of *o*-mercaptophenol and chloride ions of the formula

$$[(C_6H_5)_4As]Nb[OC_6H_4(SH)]_2Cl_4.$$

With the exception of the *o*-mercaptophenol complexes of Zr and Hf, the complexes reported here appear to be air stable, and all have reasonable solubility in polar solvents such as CH_3CN and CH_2Cl_2.

The u.v. and visible spectra of the synthesized complexes have been recorded in acetonitrile at 10^{-4} *M* concentration. The band positions with the corresponding extinction coefficients are shown in Table 2. Table 2 also lists the molar conductivities of the complexes. The values are consistent with the proposed formulations.

Since all the complexes contain transition metal ions in the d^0 electronic configuration the observed bands must be due to charge–transfer and (or) internal ligand type electronic transitions. The low energy bands observed in the Ti (24 300 cm^{-1}) and Nb (23 900 and 27 800 cm^{-1}) complexes are clearly inconsistent with ligand transitions since they occur at substantially lower energy than the bands observed in the

ligand themselves,[2] therefore they are assigned to charge–transfer transitions. The high energy bands which most assuredly contain ligand based transitions, must also have some charge–transfer character since their positions are shifting when changes are made in the central transition metal ions. Although the exact make-up and assignment of the bands cannot be made, it is nevertheless interesting to note that similar charge–transfer bands played an important role in the spectra of the corresponding benzene-1,2-dithiolate complexes (1). Furthermore the hypsochromic shifts in the band positions are also the same as those previously observed (1) in the dithiol complexes, *i.e.* Ti < Zr < Hf, Nb < Ta, and W < Ta < Hf. This order is consistent with the order of increasing metal d orbital energies[3] (see ref. 21 for the most recent tabulation of ionization potentials of the elements) and hence identifies the nature of the charge–transfer bands as being ligand-to-metal. Consistent with the above idea is the ligand dependence of the band positions. The anticipated trend of hypsochromic shift with increased stability of ligand orbitals is exactly met by the observed order $S_2C_6H_4^{2-} < OSC_6H_4^{2-} < O_2C_6H_4^{2-}$ (3).

Polarographic studies on the W and Nb *o*-mercaptophenol complexes were made in CH_2Cl_2 and the Ti 1,2-dihydroxybenzene complex was studied in both CH_2Cl_2 and CH_3CN, but in no case was either oxidation or reduction observed. The absence of oxidation waves is not surprising considering that the ligand orbitals are more stable than in benzene-1,2-dithiol, and no oxidation waves were observed for complexes of this ligand and the early transition metals (1). Such reasoning assumes that the HOMO has substantial ligand character, as suggested by the visible spectra. However, if the LUMO has any ligand character, reduction of the complexes of *o*-mercaptophenol and 1,2-dihydroxybenzene should fall at more positive potentials than the corresponding benzene-1,2-dithiol complexes. The puzzling absence of any reduction waves for the former ligands remains unexplained at the present time.

Finally, we would like to comment on possible structural similarities between the reported complexes and those of the corresponding 1,2-benzenedithiols. It was shown previously (1) that, at least as far as the second and third row transition metals are concerned, the u.v. and visible spectra of the trisdithiolates can be successfully used to predict qualitatively the co-ordination geometry of the complexes in question. Indeed the prediction of trigonal prismatic geometry of the $Nb(S_2C_6H_4)_3^-$ and the distortion therefrom in the case of $Ta(S_2C_6H_4)_3^-$, were both verified by X-ray crystallographic work (22). It is then interesting to note that spectral similarities do exist between some of the reported complexes and the corresponding trisbenzendithiolates. As can be seen in Table 3 the spectrum of $W(OSC_6H_4)_3$ closely resembles that of $W(S_2C_6H_4)_3$ and there exists a good correlation between the spectra of $Nb(OSC_6H_4)_3^-$ and $Ta(S_2C_6H_4)_3^-$. Are these spectral similarities an indication of similar structures in the solid state? Based on the observation with trisdithiolates, it is tempting to say yes. However, more realistically, a definite answer to the question must await the results of structural studies on some of these complexes.

[2]Ligand spectrum in acetonitrile, maxima cm^{-1} (ε): *o*-mercaptophenol, 31 700(2000) and 35 300(9800); 1,2-dihydroxybenzene, 36 400(2900), this is in good agreement with the previously reported value of 36 000(2630) by Sandorfy and co-workers (20).

Dipole moments of a series of $\Delta^{8(14)}$ cholestenyl esters have been measured. These are isomeric with the cholesteryl alkanoates. There appears to be a limited correlation between crystal melting point and dipole moment. No correlation of dipole moment and mesomorphic tendency is observed.

On a mesuré les moments dipolaires d'une série d'esters du $\Delta^{8(14)}$ cholestényle. Ces composés sont des isomères des alkanoates de cholestéryle. Il semble y avoir une corrélation limitée entre le point de fusion du cristal et son moment dipolaire. On n'a observé aucune corrélation entre le moment dipolaire et la tendance mesomorphique. [Traduit par le journal]

Introduction

Odd–even effects of the number of carbon atoms in the alkyl chain of the ester group of cholesteryl esters have been reported (1–3) for a variety of physical properties. More recently Chadra and Bahadur (4) have shown these same effects with dipole moments and have noted that there is a correlation between the measured dipole moment and the crystal melting points of the materials.

Recently, one of us (5) has synthesized a series of esters based on $\Delta^{8(14)}$-*cholestenol*. These esters exhibit lower crystal melting points than their cholesteryl counterparts (10–40 °C) and many of them, in particular the C_8 through C_{13} series, exhibit large mesomorphic temperature ranges with low melting points.

It is the purpose of this study to see if a direct correlation exists between crystal melting and/or mesomorphic range and the measured dipole moments of these materials.

Experimental

Measurements

Dielectric and refractive index measurements were performed in reagent grade benzene (Baker) that was washed in succession with concentrated H_2SO_4, water, aqueous Na_2CO_3, and water, then dried over 5A molecular sieves, distilled, and stored in dark bottles over sodium. As no effect of nonpolar solvent was noted in measuring the dipole moments of other cholesteryl compounds (6), only benzene was used in these experiments (6).

Solution dielectric measurements (3 terminal method) were performed at 25.00 ± 0.02 °C with a General Radio 1615-A capacitance bridge at frequencies of 1 and 10 kHz, and within the limits of error, were constant for all solution concentrations. A constant temperature stainless steel cell through which regulated water from a Haake constant temperature bath circulated was fabricated for the measurement. Because of material scarcity, the continuous flow method of measurement was not used. The cell was repeatedly filled with fresh solution (at a given concentration) until three consecutive sets of data differing less than one part in 10^4 were obtained. The concentration range for all the systems studied was 1×10^{-6}–1×10^{-5} mol/l. The dielectric constant (ε) of the solution was measured by the substitution technique with an air reference. The cell gap was set by a Teflon^R spacer. A 1 in. diameter electrode was used in all experiments. Refractive indices (n) were measured with a Bausch and Lomb Precision Refractometer at 25.00 ± 0.02 °C.

The molecular dipole moments were obtained via the Guggenheim method (7) in which the quantity $(\varepsilon - n^2)/(\varepsilon + 2)(n^2 + 2)$ is plotted against concentration. The slope (S) of the best linear regression fit produces the dipole moment by the following equation

$$[1] \qquad \mu = [S(27/4)kT/\pi N]^{1/2}$$

where k = Boltzmann constant and N = Avogadro's number.

Plots of ε and n^2 against concentration were linear indicating that association does not occur in the concentration range considered.

Results and Discussion

Results of the dipole moment (μ) calculations as well as crystal melting points (T_m) (5) for the

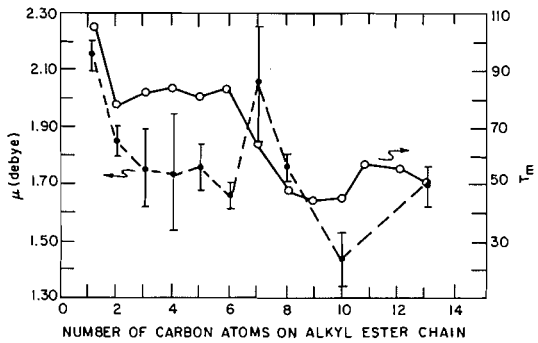

FIG. 1. Crystal melting point and molecular dipole moment (for $\Delta^{8(14)}$ cholestenyl esters) *vs.* cholestenyl ester chain length.

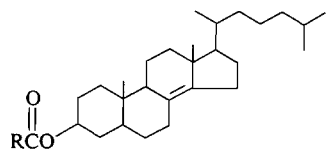
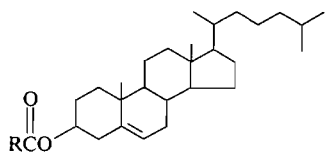
compounds are shown in Fig. 1. It is evident that a similarity exists between μ and T_m; however, a direct correlation is, at most, limited.

Structures for the esters of $\Delta^{8(14)}$ cholestenol (**1**) as well as the cholesteryl esters (**2**) are shown below



1

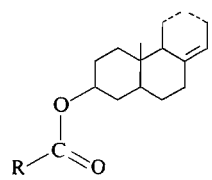


2

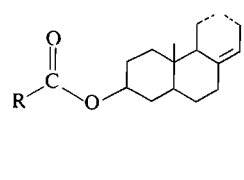
The compounds are isomeric and any changes in dipole moment must be due to differences in the electronic charge distribution in each system. Of importance is the fact that, in general, the $\Delta^{8(14)}$ compounds have lower dipole moments (especially those of C_{10} or lower) than their cholesteryl counterparts and exhibit much lower crystalline melting points. Because they are isomeric, this finding indicates that dipolar forces could be important in determining these materials melting points.

Another explanation exists, though; the differences in molecular conformations of the systems. The differences in isomeric series T_m as well as the data shown in Fig. 1 must be considered in light of this.

There is no reason to expect that molecular conformation in the solid and in solution would be identical. The cholesteryl moiety would probably not differ very much, but the ester conformation could change radically. At short ester chain lengths a direct correlation between T_m and μ might be expected, such as the large change in μ and T_m in going from C_1 to C_2. (See Fig. 1.) At longer chain lengths, the direct correlation would not be expected as the longer esters could assume different conformations. The C_2 through C_6 series exhibit an almost inverse relationship, but are only changing slightly. These subtle changes are probably more due to the ester conformation in the solid than the actual dipole moment. If any general conclusion were to be drawn in this region, it would be that solid state molecular conformation (rather than dipole moment) controls the relative melting temperature of this portion of the series. Between C_6 and C_7 of the ester chain, both T_m and μ exhibit large changes. These types of discontinuous changes have been observed in T_m of other liquid crystal systems and are not unique (8). Although all dipoles between C_7 and C_{13} in the series have not been measured, it appears that a general correlation exists in the data. The discontinuity could be an indication of a conformational change in the cholesteryl structure. For instance, a *cis–trans* isomerization of the type shown below may take place, or be the difference between solid and solution conformation.



cis



trans

In conclusion, we feel that a limited correlation is observed between the molecular dipole moment, as measured in solution, and the crystal melting point of the cholesteryl esters. For point dipoles, where intermolecular interaction forces might be proportional to the dipole moment, a direct correlation should exist. For true molecules the added complication of dipoles not being point charges, steric restraints (molecu-

For personal use only.

lar packing), conformation, and weak (Van der Walls) interactions should affect such a μ–T_m correlation. We feel steric constraints and variances in solution *vs.* solid state conformation are the most important of these and must conclude that the observed correlation is either fortuitous, or that solution and solid state conformation are similar enough to permit dipolar forces to control interaction energies in the solid state. Without experimental evidence on the molecular conformation a choice can not be made. Also, no correlation is observed between the mesomorphic temperature range, or mesophase, of the cholestenyl compounds, and the measured dipole moment.

^{13}C Nuclear Magnetic Resonance Studies. 45.[1] The ^{13}C Spectra of Some β,γ Unsaturated Polycyclic Ketones

J. B. STOTHERS, J. R. SWENSON, AND C. T. TAN
Department of Chemistry, University of Western Ontario, London, Ontario N6A 5B7

Received August 26, 1974

J. B. STOTHERS, J. R. SWENSON, and C. T. TAN. Can. J. Chem. **53**, 581 (1975).

The ^{13}C spectra of several β,γ unsaturated polycyclic ketones have been recorded to examine the shielding differences for all carbons relative to those for their saturated analogs and the parent olefins. The variations of the sp^2 carbon shieldings provide qualitative evidence for the existence of homoconjugative interactions between the olefinic and carbonyl groups in the ground state. Similar evidence of interaction between γ,δ double bonds and carbonyl groups was found from spectra for a few examples. A simple interpretation of the shielding trends entirely in terms of charge density variations arising from through space polarization is shown to be inadequate, thereby emphasizing the existence of other major shielding contributions.

J. B. STOTHERS, J. R. SWENSON et C. T. TAN. Can. J. Chem. **53**, 581 (1975).

On a enregistré les spectres r.m.n. du ^{13}C de plusieurs cétones polycycliques β,γ insaturées; ces expériences ont été réalisées afin de déterminer les différences de blindage de tous les carbones par rapport à ceux des analogues saturés et des oléfines apparentées. Les variations dans les blindages des carbones sp^2 fournissent une indication qualitative pour l'existence d'interactions homoconjugatives entre les doubles liaisons et les groupements carbonyles dans l'état fondamental. Des indications semblables pour des interactions entre les doubles liaisons γ,δ et les groupements carbonyles ont déjà été trouvées à partir des spectres de quelques exemples. On démontre qu'une interprétation simple des tendances dans les blindages qui dépendent entièrement des variations dans les densités de charge provenant d'une polarisation à travers l'espace est inadéquate et qu'il faut faire appel à d'autres contributions majeures de blindage.
[Traduit par le journal]

Introduction

Some years ago, the carbonyl carbon shieldings for a number of β,γ unsaturated bicyclic ketones were measured to investigate the possibility of detecting homoconjugative interactions between olefinic and carbonyl π systems (1). At that time instrumental limitations precluded definitive detection and assignments for the remaining carbon signals but the carbonyl data indicated an interaction between the β,γ double bond and carbonyl group since the carbonyl carbons were shielded relative to their absorption positions for the saturated analogs. Since it had been established (2) that conjugation significantly increases the shielding of carbonyl carbons, the shift in the β,γ unsaturated systems was ascribed to homoconjugation. The observed dependence of the magnitude of the shift on the relative orientation of the double bond and carbonyl group was also in agreement with this interpretation. Confirmatory evidence should be provided, however, by the variations in shieldings of the olefinic carbons and other closely neighboring centers. For this purpose the data for the β,γ unsaturated ketones were compared with those for the corresponding olefins and saturated ketones. In this report we wish to present these results which tend to support our original conclusions but only in a qualitative fashion. A detailed examination of the shielding variations clearly shows that factors in addition to charge density must make significant contributions to the observed shieldings. In addition the results for some ketones containing γ,δ double bonds were assessed in a similar fashion.

Experimental

Materials

The compounds employed in this study have been described in the literature and samples were prepared having essentially the same physical constants. Infrared and proton spectra were determined for each to ensure their identities. Compounds **1–10**, **23**, and **24** were available from earlier studies (1, 3, 4) whereas the remaining bicyclo[3.2.1]octane derivatives were obtained utilizing the reaction of dibromocarbene with **4** and with bicyclo-

heptadiene. The reaction with **4** gave 2,3-dibromobicyclo-[3.2.1]oct-3-ene (5), which upon reduction with $LiAlH_4$ gave **35** (5) and upon hydrolysis with $AgNO_3$ in aqueous acetone gave 3-bromobicyclo[3.2.1]oct-3-en-2-ol (6). Reduction of the latter with $Na–NH_3$ gave the unsaturated alcohol which was oxidized using CrO_3 in CH_2Cl_2–pyridine (7) to **13** (8) and subsequently reduced catalytically to **12**; compound **12** was also obtained by catalytic hydrogenation of the unsaturated alcohol over PtO_2 in ether followed by CrO_3 oxidation (7). Treatment of **35** with concentrated H_2SO_4 gave **19** (5) whereas reduction of **35** with $Na–NH_3$ gave **22** (5) from which **11** was obtained by catalytic hydrogenation (5). The reaction of dibromocarbene with bicyclo[2.2.1]heptadiene gave an epimeric mixture of 2,3-dibromobicyclo[3.2.1]octa-3,6-dienes (9) from which **29** was obtained by $LiAlH_4$ reduction (9) while hydrolysis with $AgNO_3$ – aqueous acetone (6) gave a mixture of **31** and **32**. Oxidation of this mixture with CrO_3 in CH_2Cl_2–pyridine furnished a sample of **30**. Reduction of **30** with $Na–NH_3$ (10) gave **16** which was converted to **17** by the Wolff–Kishner reduction (11). Treatment of **31** and **32** with $Na–NH_3$ gave a corresponding mixture of **33** and **34** which was oxidized (7) to **14**. Diene **15** was obtained from **29** by $Na–NH_3$ reduction (9). Formolysis (9, 12) of **29** led to the formation of *exo*-6-formyloxy-3-bromobicyclo[3.2.1]oct-3-ene which was converted to bicyclo[3.2.1]oct-3-en-6-ol by reduction with $Na–NH_3$ (12) and to bicyclo[3.2.1]octan-6-ol by catalytic hydrogenation over Pd–C in THF–NaOH (9). Oxidation of each of these alcohols afforded samples of **21** (12) and **20** (9), respectively. Ketone **18** was prepared following the method of LeBel and Maxwell (13) from *anti*-8-bromotricyclo[3.2.1.$0^{2,7}$]octan-3-one which was available from **29** (14). The preparation of **26** and **28** has been described by Haywood-Farmer *et al.* (15), who kindly provided us with samples of each of these ketones. Catalytic hydrogenation of these furnished samples of **25** and **27**, respectively.

Nuclear Magnetic Resonance Spectra

The ^{13}C spectra were obtained with a Varian XL-100-15 system operating in the Fourier transform mode. Samples were examined as 10–15% (w/v) solutions in deuteriochloroform using 5-mm sample tubes. Off-resonance decoupling experiments served to distinguish methylene from methine signals while selective decoupling experiments were employed to assign the olefinic carbons unequivocally. In these experiments the decoupler was operated in the low power mode (108–112 dB) and carefully adjusted to the resonance frequency of an individual olefinic proton to determine the specific olefinic carbon signal affected. To determine the appropriate proton resonance frequencies, spectra were obtained with a Varian HA-100 spectrometer and the individual proton assignments followed readily from the observed splitting patterns together with proton–proton spin decoupling experiments. In most cases the bridgehead proton signals were distinct and double irradiation at these positions uniquely defined the nearer of the two olefinic protons on a given double bond. Decoupling was not essential for the bicyclo[3.2.1]oct-3-ene derivatives since the vicinal coupling of H-4 with the bridgehead proton is relatively large, ~6.5 Hz, and therefore characteristic. In one case, bicyclo[3.2.1]oct-3-en-6-one (**21**) the olefinic protons are nearly equivalent giving rise to a deceptively simple pattern and consequently solutions containing the shift reagent, $Eu(fod)_3$, were employed to enhance their nonequivalence. In the presence of 0.185 equiv. of $Eu(fod)_3$, the olefinic protons differ by 0.56 p.p.m. and the coupling patterns readily identified each center. The ^{13}C shieldings have precisions of better than 0.1 p.p.m.

Results

The ^{13}C shielding data for the polycyclic ketones, olefins, and hydrocarbons are collected in Table 1; for comparison with the more extensive data now available, our earlier results (3, 4) for norbornen-2-one (**1–4**) and bicyclo[2.2.2]-octenone (**7–10**) derivatives have been included. In each case, the carbonyl signals were readily identified from their low field positions. Off-resonance decoupling experiments readily distinguished methylene and methine sp^3 carbons and the latter were easily assignable since, in the unsymmetrical cases, the methine carbon lying closer to the carbonyl group is the more deshielded of the pair in each spectrum. The methylene assignments for the 7-oxonorbornenes (**5** and **6**) as well as the 3-oxo- and Δ^6-bicyclo-[3.2.1]octanes (**17–19**) were straightforward from

the relative intensities and the strong deshielding effect exerted by the carbonyl group at the α carbons. The sp^3 assignments for bicyclo[3.2.1]-octa-3,6-dien-2-one (**14**) were also straightforward and led to the assignments for the corresponding diene. For most of the remaining [3.2.1] derivatives, however, the methylene assignments are not unequivocal but a consistent set was obtained by comparison within the series and with the results for the synthetic precursors **29–35** whose data are listed in Table 2.

The results for **14**, **15**, **29**, and **30** show that C-8 is only slightly affected by the 3-bromo group whereas C-2 in **29** is deshielded by *ca.* 10 p.p.m. relative to **15**. The data for **31–34** indicate that an *exo*-2-hydroxyl shields C-8 while its *endo* counterpart deshields C-8 relative to hydrocarbon **15** and its 3-bromo derivative **29**. The lone methylene signal in **30–34** renders this assignment unambiguous. The methylene shieldings of **22** and its 3-bromo derivative **35** together with the data for **15** and **29** indicated that the most deshielded methylene carbon is C-2; thus, C-8 was assigned the value near 35 p.p.m. for **22** and **35**. The two strong methylene signals for **11**, the parent hydrocarbon, were most appropriately assigned as 32.8 (C-2, -4) and 28.9 p.p.m. (C-6, -7) by comparison with the corresponding centers in **19**. From this it appeared that C-6 would be deshielded relative to C-7 in **22** and **35** because introduction of the double bond at C-3,-4 eliminates a steric interaction between the *endo* protons at C-4 and C-6 in hydrocarbon **11**. From these assignments for **11** and **22** the more intense CH_2 signals in **24** were assigned and those for the methylene signals of **23** followed on the same basis. From the data for **17** and the expected α effect of the carbonyl group, the methylene assignments for **16** were made. By comparison with **11**, the signal near 43.5 p.p.m. was assigned to C-7 in each of **20** and **21**, while

those near 30.5 p.p.m. for **20** were assigned to C-2 and C-4 and that at 32.0 p.p.m. for **21** was ascribed to C-2. These assignments for **20** agree with those made on the basis of the data for the 7-methyl and 7,7-dimethyl derivatives (16). The *exo*-3-methyl and 3,3-dimethyl derivatives of **12** were also available from another project (16) and the assignment in Table 1 was made by comparison with these data. Finally the methylene assignments listed for **13** appear to agree best with the trends found throughout the series. For ketones **25–28**, the assignments were essentially straightforward with the exception of those for C-7(-10) and C-8(-9) which were not unequivocally distinguished.

Individual assignments for the olefinic carbons in the unsymmetrical unsaturated compounds **13–16** and **21–23** were obtained by selectively irradiating each olefinic multiplet at its proton resonance frequency to determine the specific carbon associated therewith. The olefinic proton shieldings for these compounds and the symmetrical systems are listed in Table 3, from which it can be seen that the relatively large separations between nonequivalent protons in each case

rendered selective decoupling particularly easy. For **21**, however, the olefinic pattern was deceptively simple but with the addition of 0.185 equiv. of $Eu(fod)_3$ these protons were well separated and readily identified, whereupon selective decoupling readily distinguished the olefinic carbons bonded to each.

Some of the ketones were also examined in C_6D_6 solutions to investigate the solvent effect on these shieldings briefly. These data are included in Table 1.

Discussion

In our earlier study of homoconjugated bicyclic ketones (1), attention was focussed entirely on the carbonyl shieldings for which it was found that β,γ unsaturation tended to increase the carbonyl shielding relative to that observed for the saturated analog. The present data, summarized in Table 4, show that this trend is general and that **9** is not anomalous as originally concluded. Previously we had compared our value for **9** with that reported for **8** (17) but apparently the solvent difference masked the shift, now found to be −4.3 p.p.m. in $CDCl_3$. A brief examination of solvent effects for a few examples showed that the shieldings are lower in $CDCl_3$ than in C_6D_6 (Table 4) presumably because of hydrogen bonding in the former, a feature known to deshield carbonyl carbons (18). It is interesting that the $\Delta\delta_C$ values in Table 4 are somewhat less for C_6D_6 solutions. As found earlier, the magnitude of the shift caused by the β,γ double bond depends on the relative orientation of the olefinic and carbonyl bonds, ranging from −2.7 to −11.5 p.p.m. (in $CDCl_3$) for this series. The larger shifts for **5** and **21** are comparable to those found for conjugated systems (1), as illustrated by one bicyclic example, **13**, included in this series, for which $\Delta\delta_C = -10.8$ p.p.m. relative to **12**. Although the marked effect of the β,γ olefinic bond in **5** was well known (1, 17) it seemed somewhat surprising that **21** exhibited a shift of −9.0 p.p.m. since ketones **9**, **16**, and **23** show shifts near −4 p.p.m. although all four ketones appear to be very closely related in terms of the relative orientations of their olefinic and carbonyl bonds. On the basis of the carbonyl shifts for these homoconjugated ketones relative to their saturated analogs, the extent of homoconjugative interaction between the π systems appears to decrease in the order: **5** > **21** > **9** ≈ **23** ≈ **16** > **3**.

A comparison of **27** with **25** indicates that the homoconjugated diene system in **27** shields the carbonyl carbon by −5.6 p.p.m. It is also interesting that the carbonyl shift for **14** *vs.* **13**, −4.4 p.p.m., is comparable to that for **16** *vs.* **12**, −4.0 p.p.m. indicating that the 6,7 double bond is homoconjugated with the carbonyl group in each. The increased carbonyl shielding of **14** relative to **13** is analogous to that found for a number of cross-conjugated ketones (18). Additional evidence for a homoconjugative interaction in **14** is provided by the olefinic shieldings since C-6 is shifted 4.6 p.p.m. downfield from its

[c]β position on the conjugated double bond, *i.e.* C-4.

position in **15** and C-3 is essentially the same in both. The latter observation indicates a significant reduction in the α effect of the carbonyl group in **14** relative to that, for example, found for **13**.

A few ketones having γ,δ double bonds were included in this series and the results indicate that there is an interaction between the olefinic and carbonyl groups which is dependent on geometry. For **18** *vs.* **19** the carbonyl shift is −1.8 p.p.m. while for **26** *vs.* **25** the change is −3.3 p.p.m. In **18** and **26**, the relative orientations of the carbonyl and olefinic bonds must be similar since substitution of a tetramethylene chain between C-2 and C-4 in **18** gives **26**. The additional ring, however, must reduce the flexibility of **26** in the neighborhood of the carbonyl group and serve to hold the latter somewhat closer to the γ,δ double bond as the carbonyl shielding data indicate. Since $\Delta\delta_C$ for **28** *vs.* **27** is −2.9 p.p.m., which is comparable to that for **26** *vs.* **25**, the effect of the γ,δ olefinic bond appears to be approximately additive.

Homoconjugation between a double bond and a carbonyl group would be expected to alter the polarization of the olefinic carbons and, therefore, to be reflected in their ^{13}C shieldings relative to the values exhibited by the corresponding olefins. This appears to be the case and the appropriate data are collected in Table 5 including the proton shieldings. In each unsymmetrical β,γ unsaturated ketone the γ olefinic carbon absorbs downfield from its position in the olefin whereas the β carbons are generally shielded. A similar trend emerges for the β and γ olefinic protons. Thus the observed trends for the olefinic centers are qualitatively consistent with the carbonyl shifts but the relative magnitudes of the shielding changes would suggest a quite different order for the relative extents of homoconjugation throughout this series from that indicated by the carbonyl data, namely, **3** > **16** > **21** > **9** > **23**. Another trend could be anticipated to emerge from the shielding variations for the α carbons since homoconjugative interaction of an olefinic bond with a carbonyl group may be expected to reduce its inductive effect, thereby reducing the deshielding effect of the carbonyl carbon at the α positions. The appropriate data are listed in Table 5 to show that the expected trend is found for α-methylene carbons in the β,γ unsaturated cases but the opposite tendency is exhibited by the α-methine (bridgehead) carbons. Clearly, interpretation of the observed trends simply in terms of polarization changes arising from homoconjugative interactions is inadequate.

Recently, the shielding differences observed for

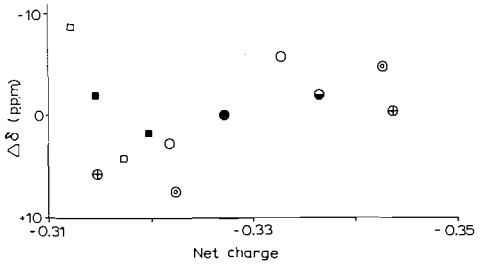

FIG. 1. A plot of the net charges on olefinic carbons as given by '4-31G' m.o. calculations for some β,γ unsaturated ketones *vs.* the observed shifts (Δδ) relative to the corresponding bicyclic olefins: **3** (⊙), **5** (○), **9** (○), **16** (⊗), **21** (□), **23** (■).

olefinic carbons in a series of acyclic unsaturated esters have been ascribed to through-space polarization arising from an electric field effect of the carbonyl group (19). As a test for this sort of contribution to the olefinic shieldings of the bicyclic β,γ unsaturated ketones some model '4–31G' *ab initio* molecular orbital calculations (20) were carried out. To simulate the bicyclic ketone system, the polarization of an ethylene double bond by an electric dipole field of a carbonyl group, defined by point charges 1.20 Å apart having the charges adjusted to simulate the dipole moment of a carbonyl group, was examined. Using the COORD program (21), the positions of the constituent atoms of a specific ketone were determined. With the point charges placed at the geometrical coordinates of the carbonyl C and O, the net charges at the olefinic carbons, represented by ethylene, were calculated using a carbonyl dipole moment of 2.84 D, the value for acetone. In this way the net charges on the olefinic carbons in **3**, **5**, **9**, **16**, **21**, and **23** were computed and the results are shown in Fig. 1. The calculated net charges are plotted against Δδ values representing the ^{13}C shielding difference for the olefinic carbons in the β,γ unsaturated ketone and the parent olefin. For those systems having the olefinic carbons in a two-carbon bridge there appears to be a rough linear trend having a slope of *ca.* 300 p.p.m./unit charge but the β carbons in the ketones having the olefinic bond in a three-carbon bridge, **21** and **23**, are significantly shielded relative to their counterparts in two-carbon bridges. Clearly the notion of a dominant shielding contribution arising from through space polarization by the carbonyl electric dipole field is inadequate to account for the observed trends. It may be noted that, for the present series, the separation between the olefinic bond and the carbonyl group is very much less than that in the acyclic esters for which the electric field effect contributions appeared to dominate the shielding variations.

The basic assumption inherent in an interpretation of the shielding differences in these unsaturated ketones in terms of homoconjugative interactions is that the observed shieldings are dominated by variations in electron density. While there seems little doubt that electron density is a major factor it is not the sole contributor, and it has been shown that variations in bonding parameters can make major contributions. These bicyclic systems undoubtedly differ in strain energy and therefore in the nature of the bonding parameters associated with the constituent carbons. Grant and his coworkers (22) have recently demonstrated for some simple systems that the bonding contribution to ^{13}C shieldings depends strongly on the σ and π character of the orbitals, their orientation, symmetry properties, and the energy gap between ground and excited states. From the variations observed in the present systems it would appear, therefore, that while the trends for the sp^2 carbons are qualitatively in accord with the existence of a homoconjugative polarization, interpretation solely in terms of charge density variations is a grossly simplified and inadequate view. These results underscore the dangers associated with such a simple interpretation and re-emphasize the fact that ^{13}C shieldings are dependent on additional factors. We conclude that homoconjugative interactions are observable by ^{13}C shielding variations but quantitative assessments of the relative extent of these interactions must await further theoretical developments.

We wish to thank the National Research Council of Canada for financial support of this work and we are especially grateful to Prof. N. C. Baird for discussions of the theoretical aspects. We wish to thank Prof. J. Haywood-Farmer for kindly providing generous samples of **26** and **28**.

^{13}C Nuclear Magnetic Resonance Studies. 47. ^{13}C Spectra of some *exo*-Methylenecycloalkanes and -norbornanes[1]

S. H. GROVER[2] AND J. B. STOTHERS

Department of Chemistry, University of Western Ontario, London, Ontario N6A 3K7

Received September 3, 1974

S. H. GROVER and J. B. STOTHERS. Can. J. Chem. **53**, 589 (1975).

The shielding effects of the *exo*-methylene group on neighboring carbons in several cycloalkanes, methylcyclohexanes, and in the norbornane ring system have been characterized by ^{13}C n.m.r. examination of 28 compounds. The results are compared with those for the carbonyl group and the utility of these data for structural elucidations is discussed. The more distinctive trends exhibited by the methyl carbons in these systems are compared with those for cyclohexanes, cyclohexanones, norbornanes, and norcamphors.

S. H. GROVER et J. B. STOTHERS. Can. J. Chem. **53**, 589 (1975).

On a caractérisé, en examinant les spectres r.m.n. du ^{13}C de 28 composés, les effets de blindage du groupe *exo*-méthylène sur les carbones voisins dans des cycloalkanes, des méthylcyclohexanes et des norbornanes. On compare ces résultats avec ceux obtenus pour le groupement carbonyle et on discute de l'utilité de ces données pour des élucidations de structure. On compare les tendances les plus caractéristiques des carbones des méthyles de ces systèmes avec ceux des cyclohexanes, cyclohexanones, norbornanes et norcamphres.

[Traduit par le journal]

Introduction

In ^{13}C n.m.r. spectra it is generally found that various substituents exert shielding effects which are additive within families of compounds. As a result, the positions of ^{13}C signals for closely related materials may often be predicted with good precision in a wide variety of systems (1). These trends are of special interest in "fixed" systems, as opposed to freely rotating cases, since the shielding effects of a variety of substituents exhibit marked geometrical dependencies (2). This sensitivity to stereochemistry can be useful both for signal assignments in complex spectra and for stereochemical assignments for groups within a molecule; several examples have been discussed in detail (2). Because of the relatively common appearance of the *exo*-methylene group in terpenes and other natural products, it was of interest to examine the variation of the shieldings of these olefinic carbons as a function of structure in some alicyclic model systems and to determine the substituent effects of this group on the neighboring carbons. Further, it has been known for some years that the shieldings of carbonyl carbons in alicyclic systems are remarkably dependent on ring size (1, 3) although an interpretation of the variation has been lacking. It seemed that the results for the corresponding carbon of the *exo*-methylene group in the series of methylenecycloalkanes could possibly aid our understanding of the trends exhibited in the ketone series. For these reasons we have prepared a series of *exo*-methylene substituted alicyclic compounds and recorded their ^{13}C n.m.r. spectra. The methylenecycloalkanes ranged from the 4- to the 12-membered ring examples. Series of methyl substituted cyclohexanes and norbornanes were also examined to compare the effects of methyl substitution in these ring systems with those established for the corresponding hydrocarbons (4) and ketones (5, 6).

Experimental

Materials

Apart from methylenecyclobutane and camphene, which were commercially available, the *exo*-methylene derivatives were prepared from the corresponding ketones using the Wittig reaction. For many cases the procedure described by Corey and co-workers (7) was quite satisfactory although with the hindered ketones and higher molecular weight cases, the procedure of Seyferth and Singh (8) gave better results. The samples were examined as 10–25% (v/v) solutions in dioxane, benzene, and/or deuteriochloroform.

Spectra

The ^{13}C spectra in dioxane and benzene solutions were obtained with a Varian HA-type instrument as previously

described (9) while the deuteriochloroform solutions were examined using a Varian XL-100-15 system operating in the Fourier transform mode. In the latter case, the solutions were contained in 10-mm tubes which were placed in a 12-mm sample tube containing D_2O, the signal of which was used as the lock. For the dioxane and benzene solutions, the proton decoupled solvent signal served as the lock.

All peak positions are reported relative to internal tetramethylsilane, a few drops of which were added to the $CDCl_3$ solutions; in benzene and dioxane the signal positions were measured relative to the solvent peak and then converted to the TMS scale with the factors 128.7 (C_6H_6) and 67.4 p.p.m. ($C_4H_8O_2$). The precision of these measurements is better than 0.1 p.p.m.

Results

The shielding data for the methylenecycloalkanes examined are listed in Table 1. For this series, the assignments for the methylene carbons more remote than one bond from the olefinic group are equivocal for the compounds with seven-membered or larger rings except for the unique methylene in the 8-, 10-, and 12-ring cases. The olefinic and α carbons, however, were readily assigned for this series. The shielding data for the methyl substituted *exo*-methylenecyclohexanes and norbornanes are collected in Tables 2 and 3. In the spectra of the cyclohexane derivatives, the olefinic, α-methylene, methyl, and methine carbons were readily identified by off-resonance decoupling and their line positions. The remaining methylene carbons were assigned from their relative intensities in the symmetrical cases and from the shielding effects of the methyl substituents at neighboring centers as shown by

the symmetrical examples. Assignments for the norbornane derivatives followed from the results of off-resonance decoupled spectra together with the expected trends for methyl substitution which had been characterized for the methylnorbornanes (11) and methylnorcamphors (5, 11). In this way, consistent assignments were accomplished for the norbornane series. The shieldings for some of the compounds were determined in more than one solvent, since two instruments with different locking capabilities were employed. For these cases, the data for different solvents are tabulated to illustrate the effect of solvent on the observed shieldings.

Discussion

Skeletal Carbons

From Table 1 it is apparent that the shieldings measured in dioxane and chloroform solutions are very similar, having differences <0.5 p.p.m. (average 0.3 p.p.m.) with those in $CDCl_3$ tending toward higher field. There seem to be no distinctive changes with ring size, in contrast to the results for the carbonyl carbons in the cycloalkanones (3, 12) although the *exo*-methylene carbon is somewhat more deshielded in the larger rings while the fully substituted olefinic carbon is slightly shielded. In contrast, carbonyl carbons in the eight-, and nine-, and, especially, the five-membered rings are significantly deshielded (5–10 p.p.m.) with respect to the others. To examine the substituent effects of the olefinic bond, the methylene shieldings may be compared with the results for the cycloalkanes (10) which are included in Table 1. Although definitive assignments are only available for the α-methylene and the most remote carbons in the even-membered rings for the larger systems, comparison with the effects of the carbonyl group indicates some interesting differences. In view of the difference in polarity of the carbonyl and *exo*-methylene bonds one would expect the α-methylene carbons to be less affected by the latter since the inductive effect of a substituent tends to dominate the α effect (1). The α effect in the cyclobutane derivatives is 8.9 and 23.6 p.p.m. for the olefin and ketone, respectively, whereas for the others the α effects are in the ranges 6.8–9.3 and 10.5–15.4 p.p.m., respectively. The much larger difference for the four-membered ring clearly indicates that factors other than the inductive effect are also important. It may be noted that the β carbon (C-3) in these derivatives is markedly shielded, -6.7 and -14.3 p.p.m., in the olefin and ketone, respectively, in contrast to the rest of the series for which the β effect in the

cycloalkanones is +0.3 to −4.2 p.p.m. (1, 12). The β effect in these olefins is only known with certainty for the five- and six-membered rings, 0.4 and 0.9 p.p.m., respectively, but in any event the β effects cannot exceed −1.3 p.p.m. for any of the examples. Thus, the β effect of the carbonyl group appears to be more shielding than that of the *exo*-cyclic double bond. It is interesting that both groups tend to shield the most remote methylene carbons in the even-membered rings and, again, the effect of the carbonyl group appears to be larger. This ω effect may have a conformational origin as has been suggested earlier (12) but a detailed interpretation of the trends cannot be presented. This difficulty is compounded by the findings for other olefinic systems. For example, the α effect of a double bond varies widely in different olefins. The effects in the methylene cycloalkanes are much larger than those in acyclic systems (1, 13) and those in cyclohexene, cycloheptene, and *cis*-cyclooctene (13) but the α effects in cyclobutene, cyclopentene, and *cis*-cyclododecene (13) are comparable to the corresponding 4-, 5-, and 12-membered methylenecycloalkanes. Presumably, small differences in the bonding parameters associated with the double bond have marked influences on the observed shieldings. It is also apparent from Table 1 that the shieldings for the olefinic *exo*-methylene carbons will be of limited utility for structural elucidations since the effect of ring size is not pronounced, although the methylene carbon in the derivatives having seven-membered or larger rings is deshielded by *ca.* 5 p.p.m. relative to those in the four-, five- and six-ring systems.

The series of methyl substituted methylenecyclohexanes was examined to compare the effects of the methyl substituents with those found for cyclohexane (4) and cyclohexanone (6). From Table 2 it is apparent that an α-methyl group alters the shieldings of the olefinic carbons in a distinctive, and expected, fashion whereas monomethyl substitution at C-3 and C-4 has little effect. Since the monomethyl derivatives exist predominantly in chair conformations with equatorial methyl groups, a set of substituent effects for the latter can be obtained by comparison of the observed shieldings for each carbon with those for the corresponding carbon in methylenecyclohexane. This sort of analysis is the same as that described for the methylcyclohexanones (6) and the data for the di-, tri-, and tetramethyl derivatives permit one to obtain substituent effects for axial methyl groups at C-2 and C-3 as described previously (6). To compare the results for cyclohexane (**1**), methylenecyclohexane (**2**), and cyclohexanone (**3**), the methyl substituent effects for the three systems are summarized in Table 4. From these data it is apparent that with a couple of exceptions the trends for the substituent effects of axial and

4

equatorial methyl groups are similar for the sp^3 carbons in the three systems. The most distinctive exception is the γ effect of the 3-equatorial methyl groups in the unsaturated cases. However, the conformational equilibrium for 3-methylmethylenecyclohexane (**4**) and the corresponding cyclohexanone is less heavily biased toward the equatorial conformer than 3-methylcyclohexane (**5**) because one *syn*-axial methyl–proton interaction has been eliminated. A recent determination of the equilibrium constant for **4** gave $K = 10$, an order of magnitude less than that for **5** (14). Thus, the 3-methyl group in **4** would be expected to shield the γ carbon through the well known γ *gauche* effect (1, 2). It is interesting, however, that the effect is as large as −1.5 p.p.m. since those found for axial 2- and 3-methyl groups are only −5 to −6 p.p.m. Clearly, the trend is qualitatively as anticipated but the quantitative discrepancy indicates the existence of additional contributing factors. The second notable exception is the magnitude of many of the δ effects which tend to be more pronounced in both unsaturated systems but an explanation is difficult. The β effects are moderately consistent for all cases with the somewhat smaller values for axial methyl groups attributable to the γ *gauche* interactions experienced by these substituents. It is established that all carbons in the fragment involved in a γ *gauche* interaction are shielded relative to the corresponding fragment lacking this interaction (2). This tendency can account also for the attenuated α effects of equatorial 2-methyl groups which are γ to the carbonyl oxygen or *exo*-methylene carbon. Supporting evidence for this interpretation seems to be given by the 2.5 p.p.m. upfield shift exhibited by the *exo*-methylene carbon but the remaining substituent effects on the olefinic centers show that this view may be oversimplified. Axial 2- and 3-methyl groups deshield the *exo*-methylene carbon and shield the fully substituted sp^2 carbon more than the equatorial groups, while the latter trend is reversed for the ketones. There are, however, important differences in the γ interactions of the α-methyl groups with these two substituents; the steric interaction of the methyl protons involves the lone pair on oxygen for the ketones and the nearer of the *exo*-methylene proton for the olefins. Furthermore the carbonyl bond is shorter than an olefinic bond so that the steric perturbation for an equatorial methyl group may be larger in the ketones. This will account for the observed trends if the γ interaction of the methyl with the carbonyl oxygen is greater than the *syn*-axial methyl–proton (in C-4 and C-6) interactions. The methyl shieldings, as discussed later, offer further support for this interpretation. Inspection of the shieldings for the *exo*-methylene carbons in the polymethyl substituted methylenecyclohexanes indicates that the substituent effects of the methyl groups at these centers (Table 4) are approximately additive. The same conclusion follows from a comparison of the monomethyl effects in the norbornane derivatives with those found for the di- and trimethyl substituted compounds. An interesting feature of these methyl substituent effects is the deshielding influence at the *exo*-methylene carbon produced by an axial 3-methyl group in the methylenecyclohexanes and the 7-methyl in the methylenenorbornanes. These can be regarded as δ effects and it has been found that methyl carbons lying close to δ carbons or δ oxygen functions experience significant deshielding (6, 15). In the present cases, the interaction must involve the methyl protons and the π cloud of the olefinic bond.

The sp^3 carbons of the methylenenorbornane derivatives are affected by methyl substitution in much the same way as the corresponding carbons in the norcamphor derivatives (6). The overall average deviations between the two cases is <1 p.p.m. for all cases with the greatest differences (2 p.p.m.) found for the 1,3,3-trimethyl derivatives. Perhaps this indicates slight differences in skeletal twist for the two compounds but in any event there are no major differences in the methyl substituent effects for the two systems.

Methyl Carbons

The methyl shieldings for the *exo*-methylene derivatives are collected in Table 5 together with the corresponding data for the cyclohexanes, cyclohexanones, norbornanes, and norcamphors. Without exception, the α-methyl carbons are more shielded in the ketones than in the *exo*-methylene derivatives and the latter are more shielded than those in the parent hydrocarbons. It is apparent, therefore, that an α-methyl group

in the ketones experiences a significant γ interaction with the carbonyl oxygen which is greater than that with an *exo*-methylene carbon. It is also interesting that an equatorial methyl at C-4 in the unsaturated cyclohexanes is slightly shielded relative to that of methylcyclohexane. This may arise from the flattening of the ring from a perfect chair conformation produced by the carbonyl and olefinic groups. The same trend for the 3-methyl group must arise partly from a significant contribution of the axial conformer because of the smaller equilibrium constant for **4** as discussed above. The somewhat greater deshielding of the isolated equatorial 5-methyl carbon in the 3,3,5-trimethyl derivatives is consistent with this notion. In contrast to the cyclohexanes, axial 2-methyl carbons in cyclohexanone and *exo*-methylenecyclohexane are deshielded relative to their equatorial counterparts; shieldings for the axial methyls can be estimated from the observed shieldings for the *trans*-2,6-dimethyl derivatives since these compounds exist as 1:1 mixtures of enantiomers each with one axial and one equatorial methyl group. In this way axial α-methyl shieldings are found to be 19.3 and 17.4 p.p.m. for the ketone and olefin derivatives, respectively, whereas an axial methyl on a cyclohexane ring absorbs at 18.9 p.p.m., from the results for the *trans*-1,3-dimethyl derivative. In all cases these axial methyls experience two *syn*-axial interactions with γ protons, γ *gauche* effects, but the enhanced shielding of the axial methyl for the ketone indicates that a γ interaction with the carbonyl oxygen also contributes while the corresponding effect in the olefin is negligible.

As noted earlier for the cyclohexanones (**6**), the averaged methyl shielding observed for each of the tetramethyl derivatives is at lower field than the values estimated by simply averaging the *gem*-dimethyl shieldings in the trimethyl derivatives. This is clear evidence for the deshielding *syn*-axial δ effect already noted in the cyclohexanones (**6**) and a variety of other systems (15). Since it is known that *both* methyl shieldings of a pair of geminal methyls are affected by the *syn*-axial interaction of one of them (15) it is not possible to estimate the axial and equatorial shieldings for the tetramethyl derivatives.

The α-methyl shieldings for the norbornane derivatives follow the same trends as those found for the cyclohexanes but the 7,7-dimethyl

systems show an interesting difference in that these methyl carbons appear to be equivalent in the *exo*-methylene and norcamphor derivatives. Although the assignments for the former were not established unambiguously as were those for the ketones (5), it appears that the *syn*-methyl is slightly deshielded by the unsaturated function, which can be regarded as a δ effect. As found for the corresponding ketones (5, 6), it seems that the methyl carbon shieldings undergo the most distinctive changes with molecular geometry and thus will probably be the more informative for structural elucidations in related systems.

We wish to thank the National Research Council of Canada for financial support of this study.

Nuclear Magnetic Resonance Chemical Shifts of some Monosubstituted Isothiazoles

RODERICK E. WASYLISHEN,[1] THOMAS R. CLEM, AND EDWIN D. BECKER
National Institutes of Health, Bethesda, Maryland 20014

Received September 13, 1974

RODERICK E. WASYLISHEN, THOMAS R. CLEM, and EDWIN D. BECKER. Can. J. Chem. **53**, 596 (1975).

Carbon-13 and proton chemical shifts have been measured for several monosubstituted isothiazoles. Substituent effects upon these chemical shifts are compared with those observed for monosubstituted benzenes, pyridines, and thiophenes. In general the observed substituent effects in the isothiazoles and thiophenes closely parallel one another. Correlations between the observed carbon-13 chemical shifts and CNDO/2 calculated charge densities are examined.

RODERICK E. WASYLISHEN, THOMAS R. CLEM et EDWIN D. BECKER. Can. J. Chem. **53**, 596 (1975).

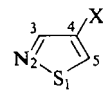
On a mesuré les déplacements chimiques du ^{13}C et du proton de plusieurs isothiazoles monosubstitués. On a comparé les effets des substituants sur ces déplacements chimiques avec ceux observés dans des dérivés monosubstitués du benzène, de la pyridine et du thiophène. D'une façon générale, les effets de substituants qui sont observés dans les isothiazoles et dans les thiophènes sont parallèles. On a examiné les corrélations qui existent entre les déplacements chimiques observés pour le ^{13}C et les calculs CNDO/2 pour les densités de charge.
[Traduit par le journal]

Introduction

Substituent effects on the carbon-13 n.m.r. chemical shifts of monosubstituted benzenes have been thoroughly investigated (1–3). The shielding effects induced by the substituents have been correlated with several different parameters which reflect the electronic nature of the substituent. For example, Levy *et al.* (3) have shown that carbon-13 chemical shifts at the *para* position are linearly related to the total calculated charge densities at this position and to the Hammett σ^* constants of the substituents.

There exist a few systematic studies of substituent effects on carbon-13 n.m.r. chemical shifts in aromatic systems containing one hetero atom. For example, substituent effects on the ring-carbon shielding in monosubstituted pyridines (4–8) have been compared with those observed for the corresponding benzenes. For a series of 3-substituted pyridines (6) substituent effects on the ring carbons usually lie within ± 1.3 p.p.m. of those found for the benzenes. The substituent effects in the 2-pyridine derivatives (7), where electronic interactions between the substituent and nitrogen are often significant, display differences from those in benzene derivatives that range up to 21 p.p.m. for the C_2 carbon in 2-fluoropyridine. The shielding effects in a number of 2- and 3-substituted thiophenes have been measured (9).

Here we report and discuss substituent effects on the carbon-13 and proton n.m.r. chemical shifts of several 4-substituted isothiazoles (**1**), aromatic systems containing two different hetero atoms.



1

Experimental

The ester of isothiazole-4-carboxylic acid was prepared by treatment of the acid with dimethyl sulfate – anhydrous potassium carbonate in dimethylformamide. All other compounds were obtained from Raylo Chemical Company, Edmonton, Alberta, and were used without further purification.

Carbon-13 Spectra

Natural abundance ^{13}C n.m.r. spectra were measured in 5-mm sample tubes with a homemade pulse spectrometer operating at 55.3 MHz. This spectrometer was used with the superconducting magnet of a Varian HR-220, and the data were accumulated and Fourier transformed with a Varian 620L computer. This computer is limited to 8K data points, which transform to 4K real points (10). We used spectral widths of 8–10 kHz; the resulting spectra consisted of data points at 2–2.5 Hz intervals,

[a]All chemical shifts are relative to TMS.

which at 55 MHz is adequate to insure that measurements of chemical shifts are accurate to 0.1 p.p.m. All measurements were made on approximately 3 *M* solutions of the isothiazoles in DMSO at 65 ± 5 °C. All carbon-13 chemical shifts were initially measured relative to DMSO ($^{13}CH_3SOCH_3$) and were then converted to the TMS scale by adding 40.48 p.p.m. (11) to the initial values. The 220 MHz circuitry of the HR-220 spectrometer was used to optimize magnetic field homogeneity with a strong proton resonance prior to each ^{13}C run. The HR-220 also served as the source of proton decoupling frequencies. A suitable homemade noise modulator and r.f. amplifier were used to obtain complete proton decoupling (or in some experiments off-resonance decoupling).

Proton Chemical Shifts

All proton chemical shifts were obtained for dilute solutions of the 4-substituted isothiazoles in carbon tetrachloride (approximately 10 mg/ml of CCl_4).[2] Measurements were made at 20 ± 1 °C on a Varian HR-220 spectrometer and a 620-L computer in the FT mode.

Results and Discussion

The general theory of chemical shifts is given in several texts (13–17). Following Saika and Slichter (18) the shielding constant for a nucleus A is usually divided into three components,

$$[1] \qquad \sigma^A = \sigma_d{}^A + \sigma_p{}^A + \sigma'$$

where $\sigma_d{}^A$ is the local diamagnetic contribution, $\sigma_p{}^A$ is the local paramagnetic term, and σ' is the contribution from other atoms. Variation in carbon-13 shieldings for a series of closely related molecules can usually be accounted for by consideration of the paramagnetic term alone (12, 19). The approximate expression for $\sigma_p{}^A$ given by Karplus and Pople (20) is

$$[2] \qquad \sigma_p{}^A = -\frac{e^2\hbar^2}{2mc^2}\langle r^{-3}\rangle_{2p}(\Delta E)^{-1}\sum Q$$

where $\langle r^{-3}\rangle_{2p}$ is the mean cube inverse distance of a 2p electron from the nucleus (there is no contribution from s electrons), ΔE represents a mean excitation energy, and $\sum Q$ is defined in terms of the elements of the charge-density and bond-order matrix. Increasing electron density in a 2p orbital of carbon atom A causes an expansion of the electron cloud, a decrease in $\langle r^{-3}\rangle_{2p}$ and an increase in shielding (high field shift). Since the ΔE and $\sum Q$ terms in eq. 2 are often taken as constants along a series of closely related molecules, one expects carbon-13 chemical shifts to be linearly related to 2p orbital electron densities.

In the discussion to follow, we compare the substituent effects on the carbon-13 shifts of the isothiazoles with those observed for benzenes (1–3, 21), pyridines (5–8), and thiophenes (9). In addition, we correlate variations in the carbon-13 shifts with electron densities obtained from all-valence-electron SCF molecular orbital calculations at the CNDO/2 level of approximation (22).

Carbon-13 Chemical Shifts of some 4-Substituted Isothiazoles

The carbon-13 chemical shifts for a series of 4-substituted isothiazoles are given in Table 1. Assignments were made on the basis of selective decoupling (23) and of off-resonance decoupling (24–37). First-order analysis of the proton coupled carbon-13 spectrum of the unsubstituted isothiazole gives the one-bond coupling constants $^1J(^{13}C,H_3) = 183.6$ Hz, $^1J(^{13}C,H_4) =$

[2]This concentration corresponds to less than 1 mol% for all of the substituted isothiazoles.

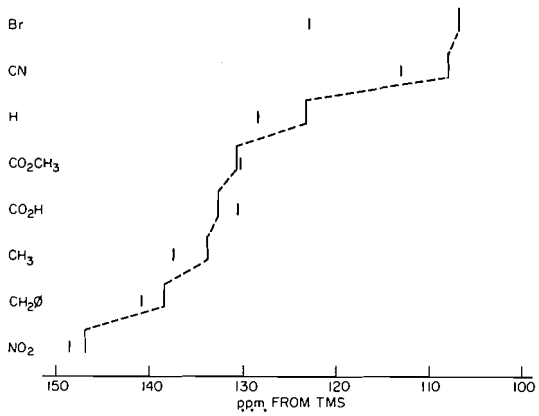

FIG. 1. Carbon-13 chemical shifts of C_4 in some 4-monosubstituted isothiazoles and C_1 in the corresponding monosubstituted benzenes. The dashed lines join vertical bars which indicate carbon-13 chemical shifts of C_4 in the substituted isothiazoles. Data for the benzenes (indicated by the smaller unconnected vertical bars) were taken from ref. 1, except for X = CO_2CH_3 (21) and X = $CH_2\phi$ (present study).

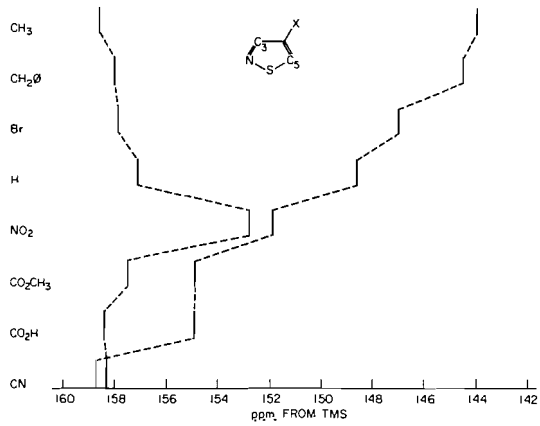

FIG. 2. Carbon-13 chemical shifts of C_3 and C_5 in some 4-monosubstituted isothiazoles; C_5 is to high field of C_3 in all cases except for X = CN.

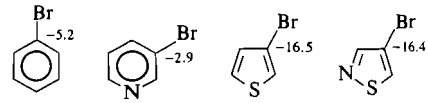
173.3 Hz, and $^1J(^{13}C,H_5)$ = 187.2 Hz. We have not determined the other $^{13}C,H$ couplings.

Chemical Shift of C_4

The shift of C_4 in isothiazole itself is 123.4 p.p.m., close to the shifts of the analogous carbons, C_3, in both pyridine (124.5 p.p.m.) and thiophene (127.2 p.p.m.). The relative carbon-13 chemical shifts for C_4 in the 4-substituted isothiazoles (**1**) roughly parallel those of C_1 in the monosubstituted benzenes (**2**) as illustrated in Fig. 1. The greatest departure is found for

2

X = Br, where C_4 in **1** lies 16 p.p.m. to high field of the corresponding value of C_1 in **2**. It is interesting to note that a similar large upfield shift is observed in 3-bromothiophene but not in 3-bromopyridine. The numbers give shifts relative to the parent molecules. The origin of this large upfield shift in the sulfur heterocyclics is not clear.



Chemical Shift of C_3 and C_5

The C_3 carbon of isothiazole resonates at 157.1 p.p.m., approximately 6.5 p.p.m. to low field of C_2 in pyridine, whereas the C_5 absorption is 13.2 p.p.m. to low field of the C_2 resonance in thiophene.

One of the striking features of the data in Table 1 is the relative sensitivity of the C_3 and C_5 chemical shifts to the various substituents at C_4. The shifts of C_5 vary over a range of 14.7 p.p.m. whereas those of C_3 vary over a range of only 5.8 p.p.m.; in fact, except for the NO_2 derivative they are virtually constant (see Fig. 2). A similar observation has been made for a series of 3-substituted thiophenes (**3**) where the ranges

3

for C_2 and C_4 were 40.4 and 16.0 p.p.m., respectively (9). However, in a series of 3-substituted pyridines (**4**) the range of shifts for C_2 and C_4 was not significantly different: 7.6 and 9.3 p.p.m., respectively (6).

*The geometry of the isothiazole ring was assumed unchanged for all substituted isothiazoles. Standard geometries (given on p. 110 of ref. 22) were used for the substituents.

we carried out CNDO/2 calculations. For related nitrogen and oxygen heterocyclics Bloor and Breen (28) found reasonably good correlations between total CNDO/2 charge densities and carbon-13 shifts. They found also that the CNDO/2 method predicted dipole moments in excellent agreement with experimental values. To assess the reliability of the CNDO/2 method for isothiazoles and related molecules we carried out calculations of charge densities and dipole moments for several five-membered nitrogen-sulfur heterocyclics. The calculated dipole moments, as indicated in Table 2, are in only fair quantitative agreement with experiment but their relative magnitudes correlate well with the observed order.[3]

The values of 2p and π electron densities, as obtained from CNDO/2 calculations, are given in Table 3, while the total charge densities are presented in Table 4. With the *assumption* that 2p orbital charge densities are linearly related to carbon-13 chemical shifts, the CNDO/2 cal-

[3]References to observed dipole moments and the geometries or coordinates used for these calculations are given in Table 2.

2p orbital densities (chemical shifts)

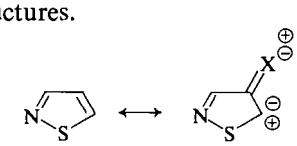
5

culations predict C_4 in isothiazole itself at highest field and C_3 at lowest field, in agreement with experiment. The calculations also predict the correct relative carbon-13 shifts in thiazole (**5**) (21, 35). It should be noted that π electron densities also predict the correct order of chemical shifts in isothiazole and thiazole but total electron densities (Table 4) are not in agreement with experiment.

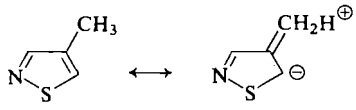
For the 4-substituted isothiazoles, there is no apparent correlation between observed chemical shifts at C_4 and the 2p orbital, π or total electron densities.[4]

On the other hand, all three measures of electron density do predict the greater range of chemical shifts observed for C_5 relative to C_3. The range of charge densities calculated for C_5 is approximately double the range calculated for C_3.[5] Also C_5 is calculated to be at highest field for $X = CH_3 > H > NO_2 > CO_2H$, in agreement with experiment.

The relative sensitivity to substituents of the observed shifts at C_5 and C_3 is also compatible with the importance of the following valence bond structures.



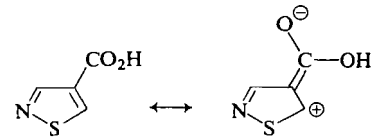
For example, when $X = CH_3$ the most important valence bond structures would be



[4]Corrections for substituents containing double and triple bonds, as suggested by Nelson *et al.* (1), for substituted benzenes, might be of some value but their use would be unwarranted with the limited number of data here.

[5]CNDO/2 calculations were also carried out for other 4-X-isothiazoles (X = F, Cl, OH, and NH_2). The total charge densities at C_3 varied over a range of 0.064 electrons while those at C_5 varied over 0.134 electrons.

with C_5 to high field of its value in the parent compound, in agreement with experiment.[6] By analogous argument one would expect low field shifts for C_5 in 4-isothiazole carboxylic acid:



Similar valence structures have been invoked to account for the relative sensitivity of proton (36) and carbon (9) chemical shifts at C_2 and C_4 in a series of 3-monosubstituted thiophenes (**3**).

Proton Chemical Shifts of the 4-Substituted Isothiazoles

The proton chemical shifts measured as dilute solutions in carbon tetrachloride are given in Table 5. All spectra were first order because $10\,J_{35} \ll (\nu_3 - \nu_5)$.

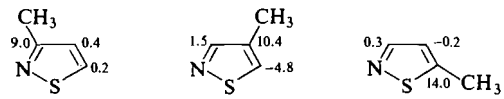
Table 6 gives the changes with substituent in the proton chemical shifts of several 3-substituted thiophenes (36) and 4-substituted isothiazoles. It is apparent that the shift of the proton adjacent to the sulfur atom (H_2 in the thiophenes and H_5 in the isothiazoles) varies over a much larger range than do H_4 of the 3-substituted thiophenes and H_3 of the 4-substituted isothiazoles. Gronowitz and Hoffman (36) have explained this behavior for the thiophenes in terms of inductive effects and simple resonance theory as discussed in the previous section.

Finally it is interesting to note that there is a correlation between the calculated proton charge densities (Table 4) and the substituent effects observed for the proton chemical shifts.

Carbon-13 Chemical Shifts of other Monosubstituted Isothiazoles

Methylisothiazoles

The carbon-13 chemical shifts of the three monomethylisothiazoles have been obtained. The chemical shifts, *relative* to isothiazole itself, are shown below.



[6]Here it is assumed that carbon-13 chemical shifts are directly related to charge densities.

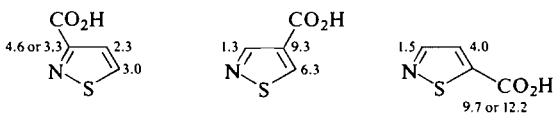
Br	8.33	8.57	—
CH_3	8.20	8.14	2.35 (CH_3)

*Measurements are accurate to ±0.01 p.p.m.
†Proton chemical shifts for three of these compounds have been reported elsewhere (37).

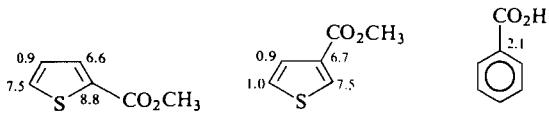
(A positive number refers to a shift to higher frequency, or lower field, upon substitution of the parent molecule.) In 3-methylisothiazole the 9.0 p.p.m. shift of C_3 is quite similar to that of the substituted carbon in toluene, 8.9 p.p.m. (1), and in 2-methylpyridine, 9.3 p.p.m. (7). For 4-methylisothiazole the shifts of 10.4 p.p.m. for C_4 and −4.8 p.p.m. for C_5 compare closely with those of 3-methylthiophene, 10.6 p.p.m. and −4.8 p.p.m. (9), and in 5-methylisothiazole the 14.0 p.p.m. shift of C_5 is almost identical with that of the analogous carbon in 2-methylthiophene, 13.9 p.p.m. (9, 38).

Isothiazole Carboxylic Acids

The carbon-13 chemical shifts of the three carboxylic acids of isothiazole have been obtained, and the observed substituent effects relative to isothiazole are shown below.

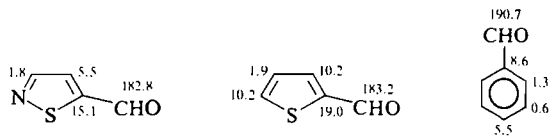


Carbon-13 chemical shift data are not available for carboxylic acids of thiophene and pyridine; however, data are available for 2- and 3-methoxycarboxyl derivatives of thiophene (9). Data are also available for benzoic acid (1) and methyl benzoate (21). The —COOH substituent effect on the carbon-13 chemical shifts for the 3-carboxylic acid is relatively small compared with that observed in the 4- and 5-carboxylic acids. The latter show substituent effects which are similar to those in the 2- and 3-methoxycarboxyl derivatives of thiophene (9):



5-Formylisothiazole

The substituent effects of the CHO group on the carbon-13 chemical shifts of isothiazole, thiophene (9), and the benzene ring (1) are compared below; in addition the chemical shifts of the carbonyl carbons are given relative to TMS.



Two points are apparent: (*i*) the carbon-13 chemical shift of the carbonyl carbon in 2-formylisothiazole and 2-formylthiophene appears to be shifted approximately 7 p.p.m. to high field of the values observed for benzaldehyde; (*ii*) the carbonyl group induces a much larger downfield shift of the directly-bonded ring carbon in the case of isothiazole and thiophene than in the case of benzene.

We have no explanation for these differences between the sulfur-containing heterocyclics and benzene at present. It may be important to note, however, that in the case of the sulfur-containing heterocyclics the conformation of the carbonyl group is *s-trans* (39–41).

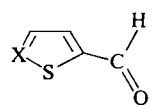


TABLE 6. Proton chemical shifts (p.p.m.) of 4-substituted isothiazoles and 3-substituted thiophenes (9) relative to the α-hydrogens in the parent compounds*

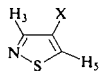

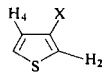

X	H_3	H_5	H_4	H_2
NO_2	0.53	0.79	0.60	0.95
CO_2CH_3	0.33	0.56	0.47	0.78
CN	0.22	0.54	0.20	0.63
H	0.00	0.00	0.00	0.00
Br	−0.14	−0.06	−0.08	−0.12
CH_3	−0.27	−0.49	−0.22	−0.45
Range	0.80	1.28	0.88	1.40

*A positive number refers to a shift to higher frequency, or lower field, with substitution.

To conclude, substituent effects on both proton and carbon-13 chemical shifts of the isothiazoles studied here are quite similar to those in the analogous thiophenes. CNDO/2 charge densities do not correlate well with carbon-13 shifts in general, but some trends are rather well reproduced. For example, the large variation with substituents in both proton and carbon-13 chemical shifts at the 5-position is paralleled by a large change in both total and 2p charge density.

The authors would like to thank Mr. Robert Bradley and Mrs. Val Wasylishen for technical assistance, Dr. Ken Rice for preparing 4-carbomethoxyisothiazole, and Drs. Ted Schaefer and Stan Sojka for helpful discussions.

R.W. is grateful to the National Research Council of Canada for the postdoctoral fellowship.

Etude par spectrométrie infrarouge de la complexation entre les *N,N*-diméthyl-*N'*-phénylformamidines et quelques donneurs de proton

J. VAES, F. FOUBERT ET TH. ZEEGERS-HUYSKENS

Département de Chimie, Université de Louvain K.U.L., Celestijnenlaan 200-F, 3030-Heverlee-Belgique

Reçu le 11 juillet 1974

J. VAES, F. FOUBERT et TH. ZEEGERS-HUYSKENS. Can. J. Chem. **53**, 604 (1975).

Les constantes de stabilité de complexes formés entre l'éthanol et des phénols avec quelques dérivés de la *N,N*-diméthyl-*N'*-phénylformamidine sont déterminées par spectrométrie i.r. L'application des relations de Hammett montre l'existence, outre des termes du premier degré dépendant de la somme des paramètres de substitution du donneur ($\sum\sigma_a$) et de l'accepteur de proton ($\sum\sigma_b$), d'un terme croisé dépendant du produit $\sum\sigma_a\sum\sigma_b$. Les différents paramètres sont discutés en fonction des propriétés acido–basiques des molécules. Les résultats suggèrent que la formation du pont d'hydrogène s'effectue sur l'atome imino de l'amidine. La constante de stabilité des complexes de stoechiométrie 2:1 est calculée; dans celui-ci, la deuxième molécule de phénol se fixe préférentiellement sur l'atome d'oxygène de la première plutôt que sur l'atome d'azote amino.

J. VAES, F. FOUBERT, and TH. ZEEGERS-HUYSKENS. Can. J. Chem. **53**, 604 (1975).

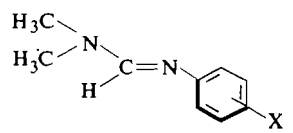
The stability constants of complexes formed between ethanol and phenols with some *N,N*-dimethyl-*N'*-phenylformamidine derivatives are determined by i.r. spectrometry. The application of the Hammett relation shows the existence, in addition to the first degree terms depending on the substitution parameters of the proton donor ($\sum\sigma_a$) and the proton acceptor ($\sum\sigma_b$), of a crossed term depending on the $\sum\sigma_a\sum\sigma_b$ product. The different parameters are discussed as a function of the acid–base properties of the molecules. The results suggest that the formation of the hydrogen bond takes place on the imino nitrogen atom. The stability constant of the complexes of 2:1 stoichiometry is calculated; in this complex the second molecule of phenol seems to be preferentially bonded to the oxygen atom of the first molecule rather than to the amino nitrogen atom.

Introduction

Les amidines sont des molécules caractérisées par la présence de deux centres basiques: l'atome d'azote amino N_1 et l'atome d'azote imino N_2 implantés sur le même atome de carbone, et subissant le phénomène de mésomérie suivant le schéma suivant:

Le caractère de double liaison du lien N_1—C est cependant moins accentué que dans les amides pour lesquels la barrière de rotation autour de ce lien vaut en moyenne 20 kcal par mole alors qu'elle se situe entre 13 à 16 kcal pour les amidines (1–5).

Dans le cadre de recherches effectuées sur la structure et la complexation de molécules organiques, l'on étudie dans ce travail la complexation par pont d'hydrogène de quelques donneurs de proton (éthanol et dérivés phénoliques) avec comme accepteurs de proton, des dérivés de la *N,N*-diméthyl-*N'*-phénylformamidine (DMPF) de formule



où X = 4-CH_3, H, 4-Cl, 3-Cl et 3,5-diCl.

Comme les benzamidines (6, 7), les amidines adoptent par rapport à la liaison C=N la configuration *trans*. Il est possible que les atomes C—N_1—C=N_2 soient localisés approximativement dans le même plan à cause de la forte conjugaison existant entre le doublet électronique de l'atome d'azote amino et les électrons π de la double liaison C=N (8). Par contre, le cycle aromatique adopterait une configuration non planaire par rapport au reste de la molécule; celle-ci proviendrait de la conjugaison existant entre les électrons non appariés de l'atome

For personal use only.

d'azote imino et les électrons π du noyau aromatique (9); la conjugaison serait cependant moins accentuée que dans l'aniline. Ces caractéristiques structurales ont été étudiées récemment par la méthode des moments dipolaires (10).

Partie expérimentale

Les amidines ont été synthétisées par la méthode de Bredereck *et al.* (11) à partir de diméthylformamide et d'aniline en présence d'oxychlorure de phosphore. La pureté de celles-ci a été vérifiée par leur spectre r.m.n. et par chromatographie.

Les phénols sont des produits commerciaux (Aldrich, Fluka) purifiés par cristallisation. Le cyclohexane (Fluka pour spectroscopie) a été sèché sur tamis moléculaire 4 Å.

Les spectres i.r. ont été enregistrés à l'aide du spectrophotomètre P.E. 325 dont l'épaisseur de fente spectrale est de 1.07 cm^{-1} à 3000 cm^{-1}. Les cellules munies de fenêtres en KBr sont étalonnées par la méthode des franges d'interférence.

La constante de complexation K est définie par le rapport

$$K = C_{ab}/C_aC_b$$

où C_{ab}, C_a et C_b représentent respectivement les concentrations en complexe, en donneur et en accepteur de proton libres. Cette constante est déterminée à partir de la mesure de l'absorbance de la vibration 1 ν_{OH} du dérivé hydroxylique libre située vers 3600 cm^{-1}; pour chacun de ces dérivés on a effectué une courbe d'étalonnage en fonction de la concentration; celle-ci varie de 0.010 à 0.020 mol dm^{-3}. Les concentrations en amidine sont de l'ordre de 0.010 à 0.030 mol dm^{-3}. Dans ce domaine limité de concentrations, la constante K calculée pour un complexe de stoechiométrie 1:1 reste stable.

Les mesures ont été effectuées dans le cyclohexane ou le tétrachlorure de carbone à la température de 30 ± 0.5 °C.

Résultats expérimentaux et discussion

A. Complexes de stoechiométrie 1:1

La figure 1 indique à titre d'exemple, le spectre i.r. de 3800 à 3000 cm^{-1} de l'éthanol libre et complexé à la DMPF dans lequel le large massif observé à 3383 cm^{-1} correspond au vibrateur $\nu_{OH...N}$. Le tableau 1 rassemble les valeurs de la constante de stabilité K et du glissement de fréquence $\Delta\nu_{OH...N}$ pour les complexes de l'éthanol et des DMPF substituées. Ce tableau reprend également les valeurs du pK_a déterminé dans l'eau à 25 °C par la méthode potentiométrique (10).

L'ensemble de ces résultats montre que les valeurs de K et $\Delta\nu_{OH}$ sont d'autant plus élevées que la basicité de l'amidine est plus accentuée. L'influence du substituant implanté sur le noyau aromatique peut se traduire par la relation de Hammett dans laquelle les valeurs du coefficient

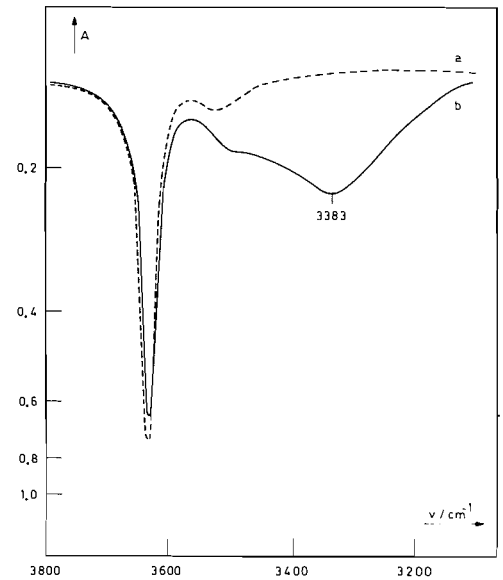

FIG. 1. Spectre i.r. (3800–3000 cm^{-1}); (*a*) éthanol (C = 0.08 mol dm^3); (*b*) éthanol (C = 0.08 mol dm^3) + DMPF (C = 0.12 mol dm^3); solvant = CCl_4.

ρ et de l'ordonnée à l'origine ont été calculées par la méthode des moindres carrés.

[1] $\log K = 0.74 - 0.48\sum\sigma \quad (r = 0.98)$

[2] $\Delta\nu_{OH} = 300 - 53.7\sum\sigma \quad (r = 0.96)$

La figure 2 indique la variation de $\Delta\nu_{OH}$ en fonction de la somme des paramètres de substitution de l'amidine.

Les valeurs de K obtenues pour les complexes de l'éthanol avec les DMPF sont du même ordre de grandeur que celle obtenue pour le même alcool complexé par la triéthylamine (K = 4.5 (12)) dont le caractère basique est cependant plus accentué (pK_a = 10.7). Cet effet peut s'expliquer par l'encombrement stérique important

TABLEAU 1. Valeurs de K (dm^3 mol^{-1}), $\Delta\nu_{OH}$(cm^{-1}) des complexes éthanol–DMPF (solvant = CCl_4, T^0 = 25 °C)

DMPF	K	$\Delta\nu_{OH}$*	pK_a
4-CH_3	6.4±0.3	308	8.45
4-OCH_3	6.5±0.3	316	—
H	6.1±0.3	293	8.15
4-Cl	3.7±0.2	286	7.54
3-Cl	3.6±0.2	276	7.10
3,4-diCl	2.7±0.3	271	6.60
3,5-diCl	2.5±0.2	261	5.13

*Précision sur la mesure = 2 cm^{-1}.

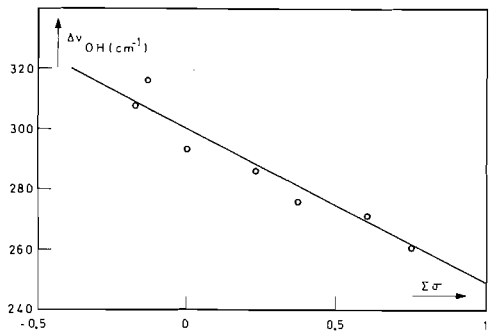

FIG. 2. $\Delta\nu_{OH}(cm^{-1})$ en fonction de $\Sigma\sigma$ pour les complexes éthanol–DMPF substituées.

provoqué par l'accumulation de trois groupements éthyles au niveau du centre réactionnel. Par contre la valeur de $\Delta\nu_{OH}$ reste sensiblement plus élevée pour les complexes des amines aliphatiques tertiaires ($\Delta\nu_{OH} = 427\ cm^{-1}$ pour le complexe éthanol–triéthylamine). En général, les effets stériques semblent influencer les valeurs des constantes de stabilité en diminuant le nombre de configurations favorables à la formation du pont d'hydrogène mais se répercutent moins sur les valeurs de $\Delta\nu_{OH}$ proportionnelles pour une même famille de complexes à l'enthalpie de complexation (17). Par contre, bien que les amidines soient caractérisées par un pK_a nettement plus élevé que la pyridine, les valeurs de K et de $\Delta\nu_{OH}$ sont très semblables (13); cet effet s'explique par la structure de la pyridine dans laquelle l'approche de l'atome d'azote endocyclique est peu limitée par des facteurs stériques.

Le tableau 2 indique les valeurs des constantes de stabilité relatives aux complexes formés de dérivés phénoliques et de DMPF substituées; dans le cas de ceux-ci, il n'est pas possible de déterminer avec précision la position de la vibration $\nu_{OH...N}$ qui se situe aux environs de $3000\ cm^{-1}$ et coïncide avec les vibrations ν_{CH}. Les résultats permettent de préciser l'influence d'un substituant implanté sur le donneur ou sur l'accepteur de proton vis-à-vis de l'équilibre de complexation. En effet, si l'on considère une amidine complexée par la série de dérivés phénoliques mentionnés, la relation de Hammett peut s'écrire:

$$[3] \qquad \log K = \log K^0 + \rho_a \Sigma\sigma_a$$

où K^0 représente la constante d'équilibre du complexe non substitué dans la famille considérée et $\Sigma\sigma_a$ la somme des paramètres de substitution du donneur de proton. L'ensemble de ces relations est illustré dans la fig. 3; par la méthode des moindres carrés, les valeurs suivantes ont été calculées.

DMPF	$\log K^0 + \rho_a \Sigma\sigma_a$
4-CH_3	$2.02+1.25\ \Sigma\sigma_a$
H	$1.96+1.18\ \Sigma\sigma_a$
4-Cl	$1.70+1.09\ \Sigma\sigma_a$
3,4-diCl	$1.52+0.79\ \Sigma\sigma_a$
3,5-diCl	$1.38+0.75\ \Sigma\sigma_a$

La valeur de la pente ρ_a est d'autant plus élevée que l'accepteur de proton est plus basique; la fig. 4 montre qu'il existe une relation approximativement linéaire entre celle-ci et la somme des paramètres de substitution de la base:

$$[4] \qquad \rho_a = \rho_a^0 + B\Sigma\sigma_b$$

De même, l'influence du substituant implanté sur l'amidine peut se traduire par la relation:

$$[5] \qquad \log K = \log K^0 + \rho_b \Sigma\sigma_b$$

dont on a calculé pour chaque dérivé phénolique les valeurs de la pente et de l'ordonnée à l'origine.

TABLEAU 2. Valeurs de K ($dm^3\ mol^{-1}$) pour les complexes des DMPF avec les phénols substitués (solvant = cyclohexane; $T^0 = 30\ °C$)

	Phénol				
DMPF	4-CH_3	H	4-Cl	3-Cl	3,5-diCl
4-CH_3	72 ± 3	98 ± 3	230 ± 5	330 ± 13	803 ± 23
H	58 ± 1	77 ± 2	199 ± 6	288 ± 11	595 ± 18
4-Cl	30 ± 1	56 ± 2	93 ± 2	121 ± 4	334 ± 9
3,4-diCl	24 ± 1	38 ± 1	44 ± 1	60 ± 2	137 ± 3
3,5-diCl	19 ± 1	25 ± 1	30 ± 2	42 ± 1	97 ± 2

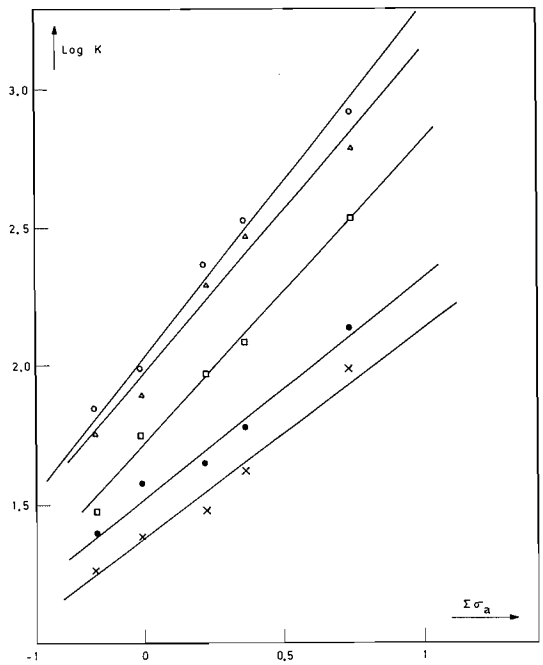

FIG. 3. Log K en fonction de $\Sigma\sigma_a$; ○, 4-CH_3 DMPF; △, DMPF; □, 4-Cl DMPF; ●, 3,4-diCl DMPF; ×, 3,5-diCl DMPF.

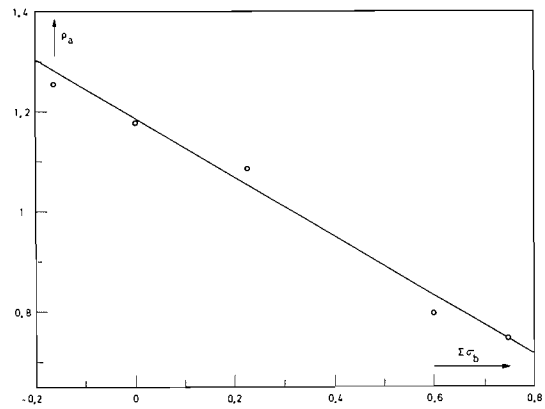

FIG. 4. Variation de ρ_a en fonction de $\Sigma\sigma_b$.

Phénol	$\log K^0 + \rho_b \Sigma\sigma_b$
4-CH_3	$1.71 - 0.64\,\Sigma\sigma_b$
H	$1.89 - 0.66\,\Sigma\sigma_b$
4-Cl	$2.23 - 0.99\,\Sigma\sigma_b$
3-Cl	$2.37 - 1.01\,\Sigma\sigma_b$
3,5-diCl	$2.74 - 1.03\,\Sigma\sigma_b$

La dépendance constatée entre ρ_b et l'acidité du phénol permet d'écrire:

$$[6] \qquad \rho_b = \rho_b^0 + B\Sigma\sigma_a$$

La comparaison des éqs. 3, 4, 5 et 6 fournit la relation:

$$[7] \quad \log K = \log K_o^0 + \rho_a^0\Sigma\sigma_a + \rho_b^0\Sigma\sigma_b + B\Sigma\sigma_a\Sigma\sigma_b$$

où K_o^0 représente la constante d'équilibre relative au complexe non substitué phénol–DMPF. Pour les complexes où la substitution porte à la fois sur le donneur et sur l'accepteur de proton, la constante K dépend donc, en plus des termes du premier degré, d'un terme croisé $B\Sigma\sigma_a\Sigma\sigma_b$ dans lequel la constante B peut être considérée comme une constante réactionnelle supplémentaire. Sa valeur négative (-0.6) montre qu'une augmentation d'acidité du phénol ($\Sigma\sigma_a > 0$) renforce les effets de substitution sur l'amidine. D'un point de vue moléculaire, ce terme croisé peut s'expliquer par une variation de la structure électronique provoquée par l'implantation d'un substituant de part et d'autre dans le complexe; ce changement de distance provoque une variation de l'interaction dipolaire et de l'énergie de polarisation effets qui sont d'autant plus importants que la liaison hydrogène se trouve condensée dans un espace plus réduit. L'existence de ce terme d'interaction peut être également lié aux effets de résonance existant dans le noyau aromatique, effets qui peuvent être perturbés par l'introduction de part et d'autre d'un substituant et qui entraînent une légère modification de l'hybridation de l'atome d'azote (14).

En remplacant dans l'éq. 7 les coefficients ρ et B par leurs valeurs numériques, on obtient l'expression:

$$[8] \quad \log K = 1.90 + 1.18\Sigma\sigma_a - 0.66\Sigma\sigma_b - 0.6\Sigma\sigma_a\Sigma\sigma_b$$

Celle-ci peut se comparer à l'équation obtenue pour les complexes phénol–aniline (15) dans le tétrachlorure de carbone dont la polarité diffère peu de celle du cyclohexane:

$$[9] \quad \log K = 0.61 + 0.67\Sigma\sigma_a - 0.70\Sigma\sigma_b - 1.30\Sigma\sigma_a\Sigma\sigma_b$$

et les complexes phénol–pyridine (16)

$$[10] \quad \log K = 1.76 + 1.08\Sigma\sigma_a - 1.30\Sigma\sigma_b - 0.6\Sigma\sigma_a\Sigma\sigma_b$$

La comparaison de ces expressions indique que les valeurs de K_o^0 et de ρ_a^0 sont d'autant plus

TABLEAU 3. Valeurs de K_2 (dm^3 mol^{-1}) pour quelques complexes phénol–DMF (solvant = cyclohexane; T^0 = 30 °C)

Complexe	K_2	Complexe	K_2
4-CH_3 Phénol – 4-CH_3 DMPF	13±2	Phénol–DMPF	15±2
4-CH_3 Phénol – DMPF	14±2	Phénol – 4-Cl DMPF	15±2
Phénol – 4 CH_3 DMPF	19±2	4-Cl Phénol – 4-Cl DMPF	13±2

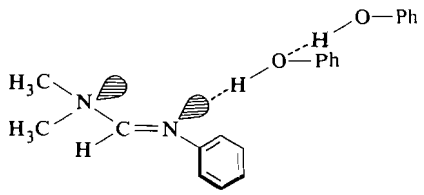
élevées que le caractère basique de l'accepteur de proton et l'enthalpie de complexation sont élevés. Celle-ci vaut en effet −5.10 (17), −6.5 (18) et −9 (10) kcal par mole.

Par contre la valeur de ρ_b^0 mesurant l'effet de substitution sur la molécule basique est nettement plus élevée pour la pyridine que pour l'aniline ou l'amidine; celle-ci dépend en général de la structure de la base et notamment du nombre de liaisons séparant le noyau aromatique du centre réactionnel. Cet effet se retrouve également pour l'ionisation de ces bases où le paramètre ρ_i mesurant l'effet de substitution sur l'équilibre d'ionisation dans l'eau est nettement plus élevé pour les pyridines ($\rho_i = -6.4$) (19) que pour les anilines ($\rho_i = -2.89$) (20) ou les amidines ($\rho_i = -2.66$) (10).

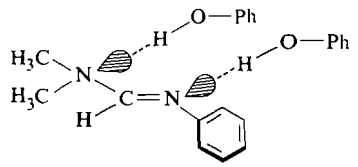
D'autre part, la valeur de ρ_b^0 est très proche pour les complexes des amidines et des anilines; cette similitude suggère que la formation du pont d'hydrogène s'effectue sur l'atome d'azote imino. La formation du complexe sur l'atome d'azote amino entraînerait des valeurs de ρ beaucoup plus faibles, les effets du substituant devant se transmettre à travers le squelette N—C=N—. L'étude des moments dipolaires des complexes phénols–formamidines permet d'arriver à une conclusion semblable (10). De même, la comparaison des valeurs de ρ_i des anilines et des amidines indique que la protonation s'effectue également sur la fonction imino; cette déduction est en accord avec les conclusions formulées à partir du spectre i.r. (21), u.v. (22) et de résonance magnétique nucléaire (5) de molécules semblables. De plus, l'étude théorique effectuée sur les aminoazirines caractérisées par un système N=C—N fortement conjugué, montre que la protonation s'effectue préférentiellement sur la paire électronique σ de l'atome d'azote endocyclique (23).

B. Complexes de stoechiométrie 2:1

Si les résultats précédents suggèrent que la formation d'un pont d'hydrogène s'effectue sur l'atome d'azote imino et non sur l'atome d'azote amino, dont le caractère basique semble fortement atténué par la délocalisation électronique, les complexes de stoechiométrie 2:1 formés de deux molécules de phénol et d'une molécule d'amidine peuvent être caractérisés par deux structures possibles: la deuxième molécule de phénol se fixe sur la première (structure **1**) ou forme un pont d'hydrogène avec l'atome d'azote-amino (structure **2**)



1



2

La constante de greffage K_2 d'une deuxième molécule de phénol sur le complexe 1:1 se définit par la relation

[11] $$K_2 = C_{a_2b}/C_{ab}C_a$$

dans laquelle C_{a_2b}, C_{ab} et C_a représentent respectivement les concentrations en complexe 2:1, en complexe 1:1 et en phénol libre. Cette constante a été déterminée par spectrométrie i.r. à partir de l'absorbance de la vibration ν_{OH} libre, par une méthode décrite précédemment (24, 25). Celle-ci se base sur la variation d'une constante apparente, K_{app}, calculée sur la base d'un complexe de stoechiométrie 1:1 en fonction de la concentration en phénol libre, C_a. On peut facilement montrer que

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

$$[12] \quad \frac{1}{2C_a + K_{app}C_a^2} = \frac{1}{K}\left(\frac{K_{app}}{2C_a + K_{app}C_a^2} - K_2\right)$$

Cette équation permet de calculer K et K_2 séparément. Pour chaque complexe étudié, les résultats énumérés dans le tableau 3 résultent d'une dizaine de points expérimentaux.

Ces résultats montrent qu'il n'existe pas de corrélation entre les propriétés acido–basiques de l'accepteur de proton et les valeurs de K_2. La même constatation s'applique aux constantes de dimérisation K_d des dérivés phénoliques dont la valeur oscille entre 4 à 5 $dm^3\ mol^{-1}$, quel que soit le substituant. Ce fait suggère que le complexe adopte préférentiellement la structure **1**; l'existence de la structure **2** entraînerait en effet une augmentation sensible de K_2 lorsque le phénol devient plus acide. La valeur plus élevée de K_2 vis-à-vis de K_d peut s'expliquer par le transfert de charge ayant lieu du doublet électronique libre de l'atome d'azote vers l'orbitale σ^*(O—H) de la première molécule de phénol; cet effet rend le caractère accepteur de proton de celle-ci vis-à-vis d'une deuxième molécule de phénol, plus élevé. Le spectre i.r. (fig. 1) confirme cet effet; le dimère du phénol absorbe vers 3520 cm^{-1} (vibration $\nu_{OH...O}$) tandis que dans le complexe de stoechiométrie 2:1, cette même vibration s'observe à des nombres d'onde de 20 à 30 cm^{-1} inférieurs. Les valeurs de K_2 relatives aux complexes des phénols substitués avec la triéthylamine où il n'existe qu'un seul centre basique, sont plus élevées (24). Ceci peut s'expliquer par le caractère basique nettement plus élevé de l'amine aliphatique; le transfert de charge dans la chaîne N...H—O...H—O doit par conséquent être plus important.

Les auteurs remercient le N.F.W.O. pour les subsides accordés au laboratoire ainsi que l'I.W.O.N.L. pour la bourse de spécialisation de deux d'entre eux (J.V. et F.F.).

The Structure of Isothiosemicarbazones

CHIJI YAMAZAKI

Department of Chemistry, School of Hygienic Sciences, Kitasato University, 1 Asamizodai, Sagamihara-shi, Japan

Received July 22, 1974

CHIJI YAMAZAKI. Can. J. Chem. **53**, 610 (1975).

Isothiosemicarbazones, except N^2-substituted ones, were found to exist exclusively in the amino structure by means of i.r. and n.m.r. spectroscopy. The *cis* configuration (N^1 *cis* to N^4 about the N^2=C bond) with intramolecular hydrogen bonding was proposed as the predominant structure for N^4-unsubstituted isothiosemicarbazones on the basis of the i.r. spectra from the partially deuterated compounds. The *trans* configuration (N^1 *trans* to N^4 about the N^2=C bond) was identified in all N^4-monsubstituted and in a few N^4-unsubstituted isothiosemicarbazones. The *cis*/*trans* ratios for the former varied depending on the solvent used.

CHIJI YAMAZAKI. Can. J. Chem. **53**, 610 (1975).

Utilisant la spectroscopie i.r. et la r.m.n., on a démontré que les isothiosemicarbazones, à l'exception de celles substituées sur N^2, existent exclusivement sous la forme amino. On propose, comme structure principale pour les isothiosemicarbazones non-substituées en position N^4, une configuration *cis* (N^1 *cis* par rapport à N^4 autour de la liaison N^2=C) impliquant une liaison hydrogène intramoléculaire; cette conclusion dérive des spectres infrarouges de quelques composés partiellement deutérés. On a identifié une configuration *trans* (N^1 *trans* par rapport à N^4 autour du lien N^2=C) dans toutes les isothiosemicarbazones mono-substituées en N^4 et dans quelques cas où il n'y a pas de substituant en N^4. Le rapport d'isomère *cis* à *trans* dans le premier cas varie suivant le solvant utilisé. [Traduit par le journal]

Introduction

Isothiosemicarbazones are potentially tautomeric systems and have long been depicted in either an amino form $>C{=}\overset{1}{N}{-}\overset{2}{N}{=}\overset{3}{C}(SR)\overset{4}{N}H_2$ or an imino form $>C{=}\overset{1}{N}{-}\overset{2}{N}H{-}\overset{3}{C}(SR){=}\overset{4}{N}H$. Shagidullin and co-workers (1) proposed an amino form for methylation products (R = Me) of certain thiosemicarbazones but detailed interpretations are not available as to tautomeric and configurational assignments. Partial deuteration technique in conjunction with n.m.r. spectroscopy now gives some information with respect to the structural classification as well as the conformational and configurational assignments.

Experimental

All melting points are uncorrected. The i.r. spectra were recorded on a Hitachi EPI-G2 grating spectrophotometer. Spectra of carbon tetrachloride solutions were obtained in 1- and 5-mm KRS-5 cells and those of solid samples taken using KBr discs. The frequencies reported in Tables 1–4 were determined by direct calibration against the standard frequencies of indene which were measured in a 0.1-mm KBr cell immediately after each compound was examined, whereas those from KBr discs were calibrated using the 3060 cm^{-1} band of polystyrene. The n.m.r. spectra were recorded at a probe temperature of 36° on a Nichiden-Varian T-60 spectrometer and a Hitachi R-24 spectrometer, both operating at 60 MHz. Chemical shifts were reported in parts per million downfield from internal tetramethylsilane (δ p.p.m.).

Partial deuteration was carried out as follows. A solution of the compound (5 mmol) to be investigated in methanol-d_1 (0.5 ml) was heated in a glass-stoppered flask at 80° for a few minutes and then evaporated *in vacuo*. The deuterated product thus obtained contained sufficient unchanged protium to give spectra as required.

Preparation of Acetophenone S-Methylisothiosemicarbazone (3)

A mixture of *S*-methylisothiosemicarbazide hydriodide (7.0 g, 0.03 mol), acetophenone (3.6 g, 0.03 mol), and 2-propanol (30 ml) was heated at 70° for 3 h. The crystals formed (9.15 g, 91%; m.p. 204.5°) were recrystallized from ethanol (80 ml) to give pure hydriodide (5.9 g) as white prisms, m.p. 206–207°. A portion of the hydriodide was converted to the free base which was then recrystallized twice from 2-propanol to give the product as colorless lustrous prisms, m.p. 94–95°.

Anal. Calcd. for $C_{10}H_{13}N_3S$: C, 57.96; H, 6.32; N, 20.28. Found: C, 58.18; H, 6.40; N, 20.07.

The following isothiosemicarbazones were prepared similarly.

Benzaldehyde S-Methylisothiosemicarbazone (1): colorless prisms (from hexane, and then isopropyl ether), m.p. 80–81° (lit. (2) m.p. 82°).

Benzaldehyde S-Benzylisothiosemicarbazone (2): faintly yellow plates (from 2-propanol), m.p. 113.5–114°. The hydrochloride melted at 191.5° (lit. (3) m.p. 190°).

Anisaldehyde S-Methylisothiosemicarbazone (5): white needles (from 2-propanol), m.p. 98–99° (lit. (2) m.p. 97°).

*p-Methoxyacetophenone S-Methylisothiosemicarbazone (**7**)*: colorless needles (from 2-propanol), m.p. 83–84°.

Anal. Calcd. for $C_{11}H_{15}N_3OS$: C, 55.68; H, 6.37; N, 17.71. Found: C, 56.00; H, 6.47; N, 17.75.

*p-Methoxyacetophenone S-Benzylisothiosemicarbazone (**8**)*: colorless flat needles (from ethanol), m.p. 125–126°.

Anal. Calcd. for $C_{17}H_{19}N_3OS$: C, 65.16; H, 6.11; N, 13.41. Found: C, 65.31; H, 6.24; N, 13.22.

*Preparation of Anisaldehyde S-Allylisothiosemicarbazone (**9**)*

A suspension of finely divided thiosemicarbazide (18.2 g, 0.2 mol) and 3-bromo-1-propene (24.2 g, 0.2 mol) in 2-propanol (80 ml) was stirred at 70° for 1 h, during which time all the solids dissolved. To this hot solution was added anisaldehyde (27.2 g, 0.2 mol) and the reaction mixture was refluxed for 2 h. The isothiosemicarbazone hydrobromide (57.4 g, 87%) crystallized out as yellow plates with m.p. 157–159° from the cooled reaction mixture. A portion of the hydrobromide was converted to the free base which was then purified by two recrystallizations from 2-propanol, yielding the desired product as faintly yellow prisms, m.p. 100–100.5°.

Anal. Calcd. for $C_{12}H_{15}N_3OS$: C, 57.82; H, 6.07; N, 16.86. Found: C, 57.89; H, 6.06; N, 17.04.

In the same manner as the preparation of **9**, but with some appropriate modifications, the following isothiosemicarbazones were prepared.

*Acetophenone S-Benzylisothiosemicarbazone (**4**)*: colorless needles (from hexane – isopropyl ether), m.p. 68–69°.

Anal. Calcd. for $C_{16}H_{17}N_3S$: C, 67.82; H, 6.05; N, 14.83. Found: C, 67.63; H, 6.13; N, 14.90.

*Anisaldehyde S-Benzylisothiosemicarbazone (**6**)*: almost colorless plates (from 2-propanol), m.p. 103–104°.

Anal. Calcd. for $C_{16}H_{17}N_3OS$: C, 64.20; H, 5.72; N, 14.04. Found: C, 64.31; H, 5.79; N, 13.91.

*Anisaldehyde S-Propylisothiosemicarbazone (**10**)*: white prisms (from hexane – isopropyl ether), m.p. 54–55°.

Anal. Calcd. for $C_{12}H_{17}N_3OS$: C, 57.35; H, 6.82; N, 16.72. Found: C, 57.54; H, 7.01; N, 16.52.

*Butyraldehyde S-Methylisothiosemicarbazone (**11**)*: white needles (from isopropyl ether), m.p. 67–68°.

Anal. Calcd. for $C_6H_{13}N_3S$: C, 45.27; H, 8.23; N, 26.40. Found: C, 45.52; H, 8.01; N, 26.38.

*Acetone S-Methylisothiosemicarbazone (**12**)*: faintly yellow plates (from hexane), m.p. 64.5–66°. The hydriodide melted at 182.5–183° (lit. (4) m.p. 178–180°).

*Cyclohexanone S-Methylisothiosemicarbazone (**13**)*: pale yellow prisms (from 2-propanol), m.p. 79.5–80.5°.

Anal. Calcd. for $C_8H_{15}N_3S$: C, 51.87; H, 8.16; N, 22.69. Found: C, 52.05; H, 8.08; N, 22.78.

*Acetone S-Benzylisothiosemicarbazone (**14**)*: white needles (from isopropyl ether), m.p. 72–73° (lit. (4) m.p. 72–73°).

*Benzaldehyde 4,S-Dimethylisothiosemicarbazone (**15**)*: pale yellow prisms (from ethyl ether – 2-propanol), m.p. 65.5–66.5° (lit. (5) m.p. 66°).

Anal. Calcd. for $C_{16}H_{17}N_3S$: C, 67.82; H, 6.05; N, 14.83. Found: C, 67.78; H, 6.06; N, 14.62.

*Acetophenone S-Benzyl-4-methylisothiosemicarbazone (**17**)*: pale yellow viscous oil. The hydrochloride monohydrate crystallized as faintly yellow needles from methanol and melted at 170–172° with loss of the water of crystallization at about 130°.

Anal. Calcd. for $C_{17}H_{22}ClN_3OS$: C, 58.03; H, 6.30; N, 11.94. Found: C, 58.29; H, 6.28; N, 12.10.

*Anisaldehyde 4,S-Dimethylisothiosemicarbazone (**18**)*: colorless needles (from 2-propanol), m.p. 84–85.5°.

Anal. Calcd. for $C_{11}H_{15}N_3OS$: C, 55.68; H, 6.37; N, 17.71. Found: C, 55.90; H, 6.38; N, 17.80.

*Cyclohexanone 4,S-Dimethylisothiosemicarbazone (**19**)*: colorless prisms (from isopropyl ether), m.p. 71–73°.

Anal. Calcd. for $C_9H_{17}N_3S$: C, 54.25; H, 8.60; N, 21.09. Found: C, 54.61; H, 8.70; N, 20.83.

*Preparation of Benzaldehyde 2,S-Dimethylisothiosemicarbazone (**20**)*

A solution of **1** (3.86 g, 0.02 mol) and methyl iodide (3.12 g, 0.022 mol) in 2-propanol (35 ml) was heated in a sealed glass tube at 80–86° for 10 h and the resulting solid (2.81 g, 42%) was crystallized from water to give the hydriodide as white needles, m.p. 187–188° (lit. (6) m.p. 187°). It was converted to the free base, m.p. 65–67°; n.m.r. ($CDCl_3$) δ 2.26 (s, 3H, SCH_3), 3.52 (s, 3H, NCH_3), 6.80 (br s, 1H, NH), 7.25–7.75 (m, 5H, C_6H_5), 7.52 (s, 1H, CH=N).

*Anisaldehyde 2,S-Dimethylisothiosemicarbazone (**21**)*

This was obtained similarly as pale yellow plates (from ethanol), m.p. 108–109.5°. The hydriodide melted at 199° (lit. (6) m.p. 195°); n.m.r. ($CDCl_3$) δ 2.26 (s, 3H, SCH_3), 3.49 (s, 3H, NCH_3), 3.82 (s, 3H, OCH_3), 5.75 (br s, 1H, NH), 6.87 (d, J = 9.0 Hz, 2H, ring protons), 7.58 (d, J = 9.0 Hz, 2H, ring protons), 7.50 (s, 1H, CH=N).

Anal. Calcd. for $C_{11}H_{15}N_3OS$: C, 55.68; H, 6.37; N, 17.71. Found: C, 55.81; H, 6.36; N, 17.45.

*Preparation of Benzaldehyde 4,4,S-Trimethylisothiosemicarbazone (**22**)*

A mixture of **25** (0.41 g, 2 mmol), methyl iodide (0.31 g, 2.2 mmol), and 2-propanol (4 ml) was heated at 60° for 2 h and the resulting hydriodide (0.63 g, 91.4%), m.p. 153.5–155°, was converted to the free base, a yellow glass; n.m.r. ($CDCl_3$) δ 2.50 (s, 3H, SCH_3), 3.12 (s, 6H, $N(CH_3)_2$), 7.22–7.83 (m, 5H, C_6H_5), 8.30 (s, 1H, CH=N).

Anal. Calcd. for $C_{11}H_{15}N_3S$: C, 59.71; H, 6.83; N, 18.99. Found: C, 60.00; H, 6.98; N, 18.82.

*Preparation of Acetophenone 4-Methylthiosemicarbazone (**24**)*

A mixture of acetophenone (0.6 g, 5 mmol), 4-methylthiosemicarbazide (0.53 g, 5 mmol), glacial acetic acid (0.5 ml), and ethanol (10 ml) was refluxed for 1 h. The

separated crystals (0.51 g, 53%) were recrystallized from ethanol to give the product as faintly yellow needles with m.p. 140–140.5° (lit. (7) m.p. 135°).

Anal. Calcd. for $C_{10}H_{13}N_3S$: C, 57.96; H, 6.32; N, 20.28. Found: C, 57.92; H, 6.29; N, 20.02.

Similarly, *p-decyloxyacetophenone 4-methylthiosemicarbazone* (**23**), m.p. 114–114.5°, and *benzaldehyde 4,4-dimethylthiosemicarbazone* (**25**), m.p. 167–168° (lit. (8) m.p. 161–162°), were prepared and gave satisfactory elemental analyses.

Results and Discussion

Infrared Spectra

The asymmetric and symmetric NH_2 stretching modes were observed in N^4-unsubstituted isothiosemicarbazones (**1–14**) as two sharp bands near 3500 and 3380 cm^{-1} in carbon tetrachloride at a concentration of 0.02 *M* (Table 1). In this concentration and even at 0.15–0.2 *M*, no bands due to associated species in the N—H stretching region were observed. If the N^4-unsubstituted isothiosemicarbazones were in the imino form, there would be a νN^4—H absorption near 3375 cm^{-1} as observed for the N^2-methyl compounds **20** and **21** and a νN^2—H absorption near 3380 cm^{-1} or lower as observed in the thiosemicarbazones **23–25** (Table 3). Consequently the much higher absorptions of 3501–3496 cm^{-1} exhibited by the compounds **1–14** could not be explained by an imino structure. The N^4-unsubstituted isothiosemicarbazones should thus exist predominantly in the amino structure in solution. With a few exceptions (**11–13**), they showed two to four bands in the N—H stretching region in the solid state of which at least one band appeared at frequencies higher than 3412 cm^{-1}. By analogy with the vibrational behavior of thiosemicarbazones (9), the N^4-unsubstituted isothiosemicarbazones also exist predominantly or exclusively in the amino structure in the solid state taking into account their sharp melting points. The absence of any band higher than 3345 cm^{-1} in **11–13** may be ascribed to strong intermolecular bonding rather than their existence in the imino form, in view of a general tendency (9*a*, 10) that the terminal NH_2 group of lower aliphatic thiosemicarbazones absorbs at relatively lower frequencies than those of aromatic series.

Two N—H bands (Table 4, columns 2 and 3) between the original bands (Table 4, columns 1 and 4) and four N—D bands were observed in the spectra of partially deuterated N^4-unsubstituted isothiosemicarbazones. If the original bands had been due to hydrogen attached to different nitrogen atoms, partial deuteration

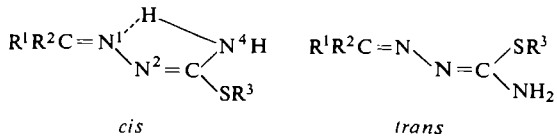

FIG. 1. *Cis* and *trans* isothiosemicarbazones.

would not give rise to such intermediate N—H bands (11). Thus the new N—H bands and the corresponding two N—D bands (Table 4, columns 7 and 8) could unambiguously be assigned to the NHD group. The remaining two N—D bands (Table 4, columns 6 and 9) increased in intensity at higher degrees of deuteration and were assigned to the vas and vs of ND_2 group, respectively. The two N—H bands arising from the NHD group indicate that the original amino group comprises nonequivalent N—H bonds, and from the magnitude of 48–62 cm^{-1} of the band separations ($\Delta\nu$) it may be deduced that the nonequivalency is ascribed to intramolecular hydrogen bonding (12). Thus the *cis* structure may be proposed for the predominant species of N^4-unsubstituted isothiosemicarbazones (Fig. 1). A *trans* form, which cannot hydrogen bond internally is expected to have equivalent N^4—H bonds and therefore a single absorption due to the NHD group at the mean of the vas and vs of the original NH_2 group. Such a band, however, was too weak to identify in the present spectra and in n.m.r. spectroscopy on the N^4-unsubstituted series, only **1**, **4**, and **7** showed two peaks of methylthio or methylenethio protons corresponding to the *cis* and *trans* structures in carbon tetrachloride (Table 5). In **11** and **13** the *trans* methyl peaks could not be identified because the region overlapped other proton resonances.

Proton Magnetic Resonance Spectra

4-Methyl isothiosemicarbazones **15–19** showed two sets of n.m.r. signals. The *N*-methyl protons appeared as two doublets at δ 2.39–2.53 (J = 5.2–5.6 Hz) and at 2.64–2.79 (J = 4.5–4.6 Hz) in benzene or at δ 2.86–2.92 (J = 5.4–5.8 Hz) and at 3.03–3.15 (J = 4.6–5.1 Hz) in pyridine while the methylthio or methylenethio protons appeared as two singlets corresponding to the *N*-methyl doublets in intensity ratio. Because each *N*-methyl doublet collapsed to a singlet on addition of deuterium oxide, the 4-methyl compounds exist essentially in the amino form and two molecular species having an $NHCH_3$ grouping should be present in solution. appearance of the α-methyl protons of **17** as a sharp singlet precludes the possibility of *syn–anti*[1] isomerism about the C=N[1] double bond in view of the fact that the two methyl groups of **12** and **14** appeared as two singlets separated by 2.0 Hz. The aldehydic protons (R^2 = H) of 4-methyl compounds were frequently found to be accompanied by a small peak about 1–3 Hz apart, which values are much smaller than those expected from *syn–anti* isomerism as in acetaldehyde semicarbazone and thiosemicarbazone (13). In carbon tetrachloride and chloroform-*d*, the differences in chemical shifts for the two peaks of methylthio or methylenethio protons are much larger than those[2] of the *N*-methyl protons (Table 5), suggesting that the isomerism will be about the N^2=C bond. In benzene, the methylthio or methylenethio proton resonances for a *trans* form exhibit a greater upfield shift than those for a *cis* form, whereas the upfield shift of the *N*-methyl proton signals is larger for the *cis* form (Table 5). As has been discussed by many investigators (14), these solvent shift effects may be explained by the structure of a collision complex in which the lone electron pair on the N^2 atom[3] is as far away from the center of the benzene ring as possible in both configurations about the N^2=C bond. Although the ^{13}C—H coupling constant (15) of 139 Hz obtained for the N—CH_3 protons of benzaldehyde 4,4,*S*-trimethylisothiosemicarbazone (**22**) could offer

[1]The terms *syn* and *anti* are used in this paper to designate the relationship between R^1 (or R^2) and N^2 about the C=N^1 double bond.

[2]In these solvents, the two doublets almost completely overlap to form an apparently single doublet, so that the differences in chemical shifts are equal to zero.

[3]The N^2 atom was believed to be most nucleophilic as shown by the preferential methylation of **1** and **5** with methyl iodide at this position to give **20** and **21**, respectively.

a possibility of observable hindered rotation about the C—N^4 bond, the protons gave rise to only a single resonance signal at the same probe temperature. This indicates rapid rotation about the C—N^4 bond at that temperature because the two conformationally different positions for the *N*-methyl groups should be magnetically non-equivalent. The preferred form of 4-methyl series, however, will predominantly involve a conformation stabilized by internal hydrogen bonding. Thus the *cis–trans* isomerism about the N^2=C double bond should account for the existence of two molecular species for isothiosemicarbazones and all the isothiosemicarbazones examined may probably exist in only one isomeric form in terms of *syn–anti* isomerism about the C=N^1 double bond.

Of the two signals from the methylthio or methylenethio protons observed in the n.m.r. spectra of compounds **1–18** (Table 5), the resonances at lower magnetic fields appeared at chemical shifts agreeing essentially with those of the corresponding N^4-unsubstituted compounds which exist substantially in the *cis* configuration, and therefore are reasonably assigned to those from the *cis* form while the signals at higher magnetic fields were assigned to the *trans* configuration. The assignment of the *N*-methyl signals is based on the peak intensity. Further strength for this assignment comes from observations that 4-methyl compounds absorb in the infrared at two different N—H stretching frequencies in a dilute carbon tetrachloride solution (Table 2) and that two NH proton resonances occurred at δ 6.20–6.50 and at δ 4.14–4.33 in chloroform-*d*, with respective peak intensities being approximately in accord with the relative intensity of the two methylthio or methylenethio proton peaks. The NH absorption at higher frequencies and the upfield resonance of the NH protons are unambiguously responsible for the unbonded NH group in the *trans* configuration, whereas the NH absorption at lower frequencies and the downfield resonance of the NH protons are responsible for the internally bonded NH group in the *cis* structure. The *cis*/*trans* ratio was strongly solvent dependent, with a ratio of 90:10 in carbon tetrachloride, 77:23 in chloroform-*d*, 49:51 in pyridine, or 30:70 in dimethylsulfoxide-d_6 being observed in compound **15**. In solution the equilibration is reached rapidly, with each peak intensity of a freshly prepared solution being identical to that of the solution after 24 h at ordinary temperature.

To conclude, the following information has been extracted from the i.r. and n.m.r. spectra of a number of aromatic and aliphatic isothiosemicarbazones. (*i*) Isothiosemicarbazones, except N^2-substituted ones, exist exclusively in the amino structure. (*ii*) N^4-Unsubstituted isothiosemicarbazones predominantly have the configuration in which N^1 lies *cis* to N^4 about the N^2=C double bond with intramolecular hydrogen bonding. (*iii*) N^4-Monosubstituted isothiosemicarbazones exist invariably in two configurations in which N^1 lies either *cis* or *trans* to N^4 about the N^2=C bond, with the *cis*/*trans* ratios varying in dependence of the solvent used.

Catalyzed Orientation Reversals in Diels–Alder Reactions

ŽARKO STOJANAC, ROBERT A. DICKINSON, NADA STOJANAC, RONALD J. WOZNOW, AND ZDENEK VALENTA

Department of Chemistry, University of New Brunswick, Fredericton, New Brunswick, E3B 5A3

Received November 29, 1974

ŽARKO STOJANAC, ROBERT A. DICKINSON, NADA STOJANAC, RONALD J. WOZNOW, and ZDENEK VALENTA. Can. J. Chem. **53**, 616 (1975).

Lewis acid catalysts cause an orientation reversal in the Diels–Alder additions of 2,6-dimethyl-1,4-quinone (**1**) and toluquinone (**12**) to 1-substituted 1,3-butadienes and to 1,2- and 1,3-dialkyl dienes. These results are explained by the preferential formation of one reactive quinone – Lewis acid salt.

ŽARKO STOJANAC, ROBERT A. DICKINSON, NADA STOJANAC, RONALD J. WOZNOW et ZDENEK VALENTA. Can. J. Chem. **53**, 616 (1975).

L'addition d'acides de Lewis comme catalyseurs cause un renversement de l'orientation lors des réactions d'addition de Diels–Alder entre d'une part la diméthyl-2,6 quinone-1,4 (**1**) et la toluquinone (**12**) et d'autre part des butadiènes-1,3 substitués en position 1 et des dialkyl-1,2 et -1,3 diènes. On explique ces résultats par la formation préférentielle d'un sel entre une quinone réactive et l'acide de Lewis. [Traduit par le journal]

We wish to report several cases of an efficient Lewis acid catalyzed (1, 2) orientation reversal in Diels–Alder reactions using alkylated 1,4-quinones as dienophiles. These results suggest that a closer attention to catalysis (or other substituent activation) will enlarge the synthetic utility of the Diels–Alder reaction (3–5) in certain cases; they are also relevant to the incompletely resolved question of the causes for preferred orientation (5–7).

Table 1 summarizes some of our most extreme cases. In all five additions listed, quinone (**1**) in the presence of Lewis acid (usually 1 mol/mol quinone) adds exclusively as indicated, while all five combinations of diene and dienophile give exclusively the expected 'normal' adducts of type **9** (4, 5) in a thermal addition in boiling benzene or toluene.[1] Thus, the catalyst achieves a complete orientation reversal in all five cases. The yields of pure products in these catalyzed additions are uniformly higher than 80%.[2]

Quinone (**1**) can thus be used for the preparation of adducts of either structural orientation. The simplest explanation of these results is the assumption that **1** complexes with the Lewis acid exclusively as indicated in **10** and that this activation then leads to the orientation shown.[3] In the thermal reactions, the generally observed dominance of the '*ortho*-rule' (4, 5) is followed and indicated in **11**. Thus, it is postulated that the cause of the reversal is simply a change of the dienophile to a more reactive

[1]Additional examples performed in this laboratory include a complete catalyzed reversal in addition of **1** to 2-methyl-1,3-pentadiene and a partial one in the total synthesis of ring-A aromatic steroids (8).

[2]In most cases lower temperatures than those listed can be used. Diene polymerization (with the exception of alkoxydienes) is slower than the addition under these conditions. Extraction of the acid with ice-water or ice-cold sodium bicarbonate does not epimerize the *cis* ring-juncture in the products. Configuration at C* of all products (*endo* addition) follows rigorously from synthetic studies in this laboratory.

[3]In frontier orbital reasoning (6, 7), it is plausible that, in combination (**10**), the bigger coefficient would be at * of the LU orbital of the complexed dienophile (7) and at * of the HO orbital of the diene (6).

TABLE 1. Catalyzed additions of 1,3-butadienes to 2,6-dimethyl-1,4-quinone

Diene	Dienophile	Catalyst	Temperature (°C)	Solvent	Product
	 **1**	$BF_3 \cdot Et_2O$	0	Ether	 **2** (b.p. 88–90°/ 0.35 mm Hg
	1	$BF_3 \cdot Et_2O$	10	C_6H_6	 **3** (m.p. 98–100°)
	1	$BF_3 \cdot Et_2O$	20	CH_2Cl_2	 **4** (m.p. 85–87°)
 **5**	**1**	$AlCl_3$	−78	CH_2Cl_2	 (ref. 8) **6** (m.p. 185–188°, 158–159°) (mixture of two diastereoisomers with A/B *trans* juncture)
 **7** (mixture of two diastereoisomers)	**1**	$BF_3 \cdot Et_2O$	20	Ether	 **8** (m.p. 123–126°, 155–156°) (mixture of two diastereoisomers)

TABLE 2. Reactions of toluquinone with *trans*-1,3-pentadiene

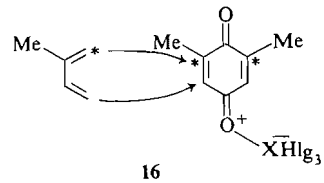
species (1, 2, 9) with a very different electronic distribution.

Synthetically, the above results are directly applicable only to the rather specialized 2,6-dialkylated quinones. Monoalkylated quinones obviously have wider applicability. It has been reported (10) that toluquinone (**12**) in dioxane reacts with *trans*-1,3-pentadiene to give two products, **13** and **14**, in an approximate 1:1 ratio.[4] Table 2 shows the results of our study of this addition. In toluene and acetone, **14** is the predominant thermal product, whereas **13** predominates on catalysis so that either adduct can be obtained in yields up to 60–70%.[5] Following the reasoning applied for additions in Table 1, it can be postulated that complex **15** is the predominant, but in this case not exclusive, reactive species. The result with toluquinone is thus in general accord with the results of Table 1 and indicates that improved yields of adducts of type **13** can be obtained by catalyzing additions of monoalkylated 1,4-quinones and 1-substituted butadienes.

The above results invite many extrapolations. It can, for example, be predicted that 2-substituted 1,3-butadienes will add to **1** (and similar quinones) giving '*meta*' adducts in a catalyzed reaction (see **16**); furthermore, replacement of the appropriate carbonyl group in an unsymmetrically substituted quinone by an imine



should lead to high regiospecificity in the desired direction in an acid-catalyzed reaction. Finally, it should be possible to use simple aliphatic dienophiles of type XCH=CHY and XCR=CHY, in which X and Y are conjugating and electron-withdrawing substituents, in a regioselective way by a drastic change in the electron demand of X or Y.

The support of this work by the National Research Council, Canada, in the form of an operating grant and a generous gift of a large quantity of **1** by the Hoffmann – La Roche Co., Nutley, N.J., are gratefully acknowledged. We thank Mr. M. S. Phang, a senior student at this University, for his experimental contribution to the toluquinone results.

[4]Unless the substituent is strongly electron withdrawing (11), monosubstituted quinones add exclusively at their unsubstituted side.

[5]The mixtures were analyzed by aromatizing the adducts, converting the resulting mixture of hydroquinones into disilyl ethers and analysing these by g.l.c. Pure **14** was also obtained by fractional crystallization (m.p. 98–99°) (10) and subjected separately to the aromatization sequence.

A Synthetic Approach to Quassin. Introduction of Functionality and Stereochemistry by a Diels–Alder Reaction

NADA STOJANAC, ASHWANI SOOD, ŽARKO STOJANAC, AND ZDENEK VALENTA
Department of Chemistry, University of New Brunswick, Fredericton, New Brunswick E3B 5A3

Received December 5, 1974

NADA STOJANAC, ASHWANI SOOD, ŽARKO STOJANAC, and ZDENEK VALENTA. Can. J. Chem. **53**, 619 (1975).

Using a Lewis acid catalyzed Diels–Alder reaction as the key step, the crystalline synthetic intermediate (**17**) has been prepared. Compound **17** contains all C-atoms of quassin (**1**) and stereochemistry and 0-functionality suitable for the conversion into **1**.

NADA STOJANAC, ASHWANI SOOD, ŽARKO STOJANAC et ZDENEK VALENTA. Can. J. Chem. **53**, 619 (1975).

On a préparé l'intermédiaire synthétique cristallin (**17**) en faisant appel dans l'étape déterminante à une réaction de Diels–Alder catalysée par un acide de Lewis. Le composé **17** contient tous les atomes de carbone de la quassine (**1**) de même qu'une stéréochimie et une fonctionnalisation sur l'oxygène susceptibles d'amener sa transformation en **1**.

[Traduit par le journal]

An efficient total synthesis of quassin (**1**) (1–3), the bitter principle of *Quassia amara*, should clearly involve a planned introduction of its oxygen functionality as well as a simple solution of its relatively complex stereochemistry. Of the seven chiral centers present, those marked * in formula **1** are particularly crucial synthetically. The remaining three, marked •, can be established in later stages of the synthesis since neoquassin (**2**) has been found to deuterate at these positions in base without epimerization (1, 2). We now wish to report a synthetic strategy which illustrates the use of a catalytic orientation reversal in Diels–Alder reactions (4), solves the stereochemistry at the four C*'s, and provides for the development of the desired oxygen functionality.

A reaction of diene (**3**)[1] with quinone (**4**) and boron trifluoride etherate (1:1:1) in ether at room temperature gives two crystalline compounds (**5**), m.p.'s 123–124° and 155–156°, respectively, in over 80% yield.[2] These are epimeric only at C—OAc, since acetate hydrolysis and oxidation of both of them gives the same methyl ketone. A rigorous proof of structure and stereochemistry of **5** is given below. It should be noted that the catalyst has directed the addition exclusively *against* the well-established "*ortho* and *para* rules" of diene addition (5, 6). Thermal reaction of **3** and **4** gives two different adducts in a very low yield (<10%) and no trace of **5**.

Reaction of **5** (m.p. 123–124°) with zinc in acetic acid reduces the conjugated double bond to give **6**, m.p. 138–152°.[3] Reduction of **6** with sodium borohydride in ethanol and water at 5° then gives ketoalcohol (**7**), m.p. 100–101°, which on continued reduction at room temperature yields diol (**8**). Without purification, **8** is con-

[1]Compound **3** is prepared by the addition of methyl vinyl ketone to 2-methylpenta-1,3-diene, epimerization in base, reduction with sodium borohydride, acetylation, bromination with Br_2, and dehydrobromination with collidine. The resulting diene is a mixture containing about 40% of the desired **3** (as a mixture of the two possible diastereoisomers) and 60% of dienes containing an exocyclic double bond (n.m.r. analysis). Separation proved impractical because of diene instability. Only cisoid diene (**3**) reacts in the Diels–Alder reaction; no adducts in addition to **5** are found on extensive chromatography.

[2]Yield is based on estimated content of **3** in the diene mixture. Compound **5** and all its transformation products reported here give the expected analytical and spectral data. All reported synthetic compounds are racemic.

[3]This and all subsequent reactions have been performed separately on the two epimers of **5** as well as on their mixture. For simplicity, only one (the major one), of the two epimeric series is given. It should be noted that the two series join at stage **12**.

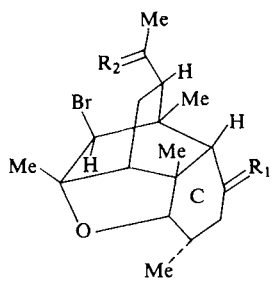
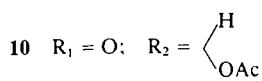
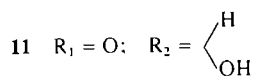
verted into cyclic ether (**9**) with *N*-bromosuccinimide in +-butanol and sulfuric acid. The three new chiral centers in ring C of **8** and **9** are formed stereospecifically and their configuration follows from n.m.r. analysis and subsequent reactions.[4] Oxidation of crude **9** with Collins' reagent (7) gives ketone (**10**), m.p. 157–158°,



9



10



11

12

which on prolonged treatment with hydrochloric acid in methanol yields alcohol (**11**), m.p. 138–139°. Oxidation of **11** with Collins' reagent (7) leads to the diketone (**12**), m.p. 120–122°, which is also obtained in the same way from the second epimer of **5** and which undergoes a quantitative epimerization to diketone (**13**), m.p. 136–138°, on treatment with potassium carbonate in methanol at room temperature. The overall yield of the seven steps leading from adduct (**5**) to diketone (**13**) is 30%.

Ethoxyethynyl magnesium bromide attacks the methyl ketone of **13** preferentially to give **14**, m.p. 150–152° (dec.), which rearranges on treatment with oxalic acid to the oily ester (**15**). Hydrogenation of **15** with platinum in ethanol then leads to the desired saturated ester **16**. Treatment of **16** with zinc powder in boiling methanol cleanly reforms the original double bond to give **17**, m.p. 96–97°.[5]

It should now be noted that **17** and its derivatives are related to compounds of type **18** by a simple double-bond cleavage[6] and that **18** contains all C-atoms of quassin, the correct stereochemistry at all four C*'s, as well as suitable functionality to complete the synthesis of **1**.

The following cyclization, retro-Michael reaction sequence rigorously establishes the structure of **5**. Treatment of ketone (**10**) (mixture

[4]On treatment of **9** with sodium hydride in benzene, for instance, a pentacyclic compound is formed by a displacement of bromine by the secondary hydroxyl group. Thus, both OH groups in **8** must be *endo* and the ether ring in **9** must be five membered.

[5]Both possible geometric isomers of **15** and C—CH_3 diastereoisomers of **16** are obtained, one in very small quantity. The minor epimer is removed in recrystallization of **17**.

[6]Preliminary study in this laboratory has shown that the ozonolysis of the isolated double bond in compounds related to **7** and **17** is very facile.

of epimers) with sodium hydroxide in aqueous methanol gives a high yield of cyclopropyl ketone (**19**), m.p. of one epimer 176–177°; i.r.$_{max}$ ($CHCl_3$) 1700 cm^{-1}; λ_{max} 212 nm (ε 2100); n.m.r. two low-field H's at τ 5.70 (1H, q), 6.37 (1H, unresolved d). Collins' oxidation of **19** yields diketone (**20**), m.p. 111–112°; λ_{max} 211 nm (ε 1950), which on treatment with potassium carbonate in hot methanol gives diketone (**21**), m.p. 123–124°; λ_{max} 258 nm (ε 6480); n.m.r. ($CDCl_3$) no olefinic H, signals at τ 6.25 (1H, d), 7.75 (3H, s), 8.02 (3H, narrow t), 8.65 (3H, s), 8.88 (3H, d), 8.95 (3H, s).

The geometry of ring C in **5** (*endo*-addition) follows from the formation of cyclic ethers **9–16** and from the fact that the expected cage cyclobutane is formed on exposure of **5** to u.v. light (8). The geometry of attachment of the acetoxyethyl side chain in **5** follows from n.m.r. data which show that the secondary methyl group is shielded by the isolated double bond and from the quantitative epimerization **12** → **13**.

Support of this work by the National Research Council of Canada, Ottawa, and a generous gift of quinone (**4**) by the Hoffmann-LaRoche Co., Nutley, N.J., are gratefully acknowledged.

A Kinetic Electron Spin Resonance Study of the Transfer of a Hydrogen Atom from α-Tetralin Hydroperoxide to a Tertiary Alkylperoxy Radical[1]

J. H. B. CHENIER AND J. A. HOWARD

Division of Chemistry, National Research Council Canada, Ottawa, Canada K1A 0R9

Received September 16, 1974

J. H. B. CHENIER and J. A. HOWARD. Can. J. Chem. **53**, 623 (1975).

A kinetic electron spin resonance spectroscopic study of the reaction of tertiary alkylperoxy radicals with α-tetralin hydroperoxide is reported. The absolute rate constants for this hydrogen atom transfer process (k_1) are given by the equation $\log (k_1/M^{-1}\,s^{-1}) = (6.0 \pm 0.5) - (4.5 \pm 0.5)/\theta$, where $\theta = 2.303\,RT$ kcal mol^{-1}.

A significant isotope effect is obtained when the hydroperoxidic hydrogen is replaced by deuterium, *e.g.* k_1^H/k_1^D at 21° = 9.

Other alkyl hydroperoxides, *e.g.* triphenylmethyl, *s*-butyl, and 9,10-dihydro-9-anthracyl have approximately the same reactivity to *t*-ROO· as α-$C_{10}H_{11}$ OOH.

J. H. B. CHENIER et J. A. HOWARD. Can. J. Chem. **53**, 623 (1975).

On rapporte une étude cinétique, effectuée par résonance paramagnétique électronique, de la réaction des radicaux alkylperoxy tertiaires avec l'hydroperoxyde de l'α-tétraline. Les constantes de vitesse absolues pour ce transfert d'atome d'hydrogène (k_1) sont représentées par l'équation $\log(k_1/M^{-1}\,s^{-1}) = (6.0 \pm 0.5) - (4.5 \pm 0.5)/\theta$, où $\theta = 2.303\,RT$ en kcal/mol^{-1}.

On obtient un effet isotopique important quand l'hydrogène de l'hydroperoxyde est remplacé par un deutérium; la valeur de k_1^H/k_1^D à 21° = 9.

D'autres hydroperoxydes en série alkylée, *e.g.* triphénylméthyle, *s*-butyle et dihydro-9,10 anthracyle-9 ont approximativement la même réactivité que l'α-$C_{10}H_{11}$ OOH vis à vis le radical *t*-ROO·.

[Traduit par le journal]

Introduction

Several investigations (1–8) have shown that the preexponential factors and activation energies for endothermic and thermoneutral H-atom transfer reactions between two oxyl radicals are significantly smaller[2] than the Arrhenius parameters that are usually associated with bimolecular reactions (10). A reaction of this class, for which there is little reliable kinetic data, is the nearly thermoneutral transfer of an H-atom from an alkyl hydroperoxide to an alkylperoxy radical. In order to rectify this situation we report in this paper the results of a kinetic electron spin resonance spectroscopic study of the reaction of α-tetralin hydroperoxide with tertiary alkylperoxy radicals, *t*-ROO·.

[1] *t*-ROO· +  $\xrightarrow{k_1}$ *t*-ROOH + 
[1]NRCC No. 14379.

[2]The only exception would appear to be the exchange reaction between di-*t*-butyliminoxy and di-*t*-butyloxime (9).

Experimental Section

Materials

α-Tetralin hydroperoxide (11) and 9,10-dihydro-9-hydroperoxyanthracene (12) were prepared by atmospheric autoxidation of tetralin and 9,10-dihydroanthracene and were purified by repeated recrystallization from hexane and toluene, respectively. *s*-Butyl hydroperoxide was prepared by the method of Williams and Mosher (13) and triphenylmethyl hydroperoxide by the method of Bissing *et al.* (14). All the hydroperoxides were close to 100% pure by iodometric titration.

Kinetic Procedure

t-Butylperoxy radicals were generated by photolysis of 2,2′-azoisobutane (0.02 *M*) in oxygen saturated isopentane and 2-ethyl-2-propylperoxy radicals were produced by photolysis of di-*t*-butyl peroxide (5%) in oxygen saturated isopentane. Photolyses were carried out in the presence of an alkyl hydroperoxide (0.0001–0.005 *M*) from −83 to +25 °C. The radical concentration was followed with respect to time, after the initiating light was shuttered, by kinetic electron spin resonance spectroscopy (15). In a few experiments at −80° the hydroperoxide was added after the radicals had been generated and the light switched off. In these cases radical decays were followed after complete mixing of the reactants had been achieved by bubbling oxygen through the solution. Stoichiometric factors, *n*, (*i.e.*, the number of radicals destroyed by each molecule of hydroperoxide) were determined by a similar technique except that a fraction (Δ[*t*-ROO·]) of a known concentration of *t*-alkylperoxy radicals was destroyed by a known concentration of hydroperoxide, [ROOH] ($n = \Delta$[*t*-ROO·]/[ROOH]).

Results and Discussion

The characteristic e.s.r. spectrum of an alkylperoxy radical was obtained when 2,2′-azoisobutane was photolyzed in the presence of α-tetralin hydroperoxide in an oxygen saturated solvent (usually isopentane or isopentane–trichlorofluoromethane 1:1 by volume) from −83 to +25 °C (broad singlet at $g = 2.015$). The steady state radical concentration ($[ROO\cdot]_{ss}$) was shown to be proportional to the first power of the intensity of the light (and consequently proportional to the first power of the rate of radical production, R_i,) and inversely proportional to the first power of the concentration of α-$C_{10}H_{10}OOH$, *i.e.*,

$$[ROO^{\cdot}]_{ss} \propto \frac{R_i}{[\alpha\text{-}C_{10}H_{11}OOH]}$$

This indicates that the alkylperoxy radical detected in this system was *t*-butylperoxy and not α-tetralylperoxy or a mixture of these two radicals. This is not unexpected as the termination rate constant for self-reaction of $(CH_3)_3COO^{\cdot}$ is $\sim 10^3$ times smaller than the rate constant for self-reaction of α-$C_{10}H_{11}OO^{\cdot}$ and the expected cross-termination rate constant for these two radicals (16).

Rates of disappearance of $(CH_3)_3COO^{\cdot}$ were exactly first-order with respect to the radical concentration and bimolecular rate constants were independent of the concentration of α-$C_{10}H_{11}OOH$. Two peroxy radicals were destroyed by each molecule of hydroperoxide.[3] The following rate law was, therefore, strictly obeyed.

$$[2] \quad \frac{-d[(CH_3)_3COO^{\cdot}]}{dt} = 2k_1[(CH_3)_3COO^{\cdot}][\alpha\text{-}C_{10}H_{11}OOH]$$

Rates of disappearance of the 2-ethyl-2-propylperoxy radical also obeyed eq. 2 and values of k_1 for this radical were identical to the values obtained for $(CH_3)_3COO^{\cdot}$.

Absolute values of the pseudo first-order rate constant k_ψ obtained at different hydroperoxide concentrations at −76 and +22 °C are listed in Table 1 while average values of the bimolecular rate constant k_1 obtained from −83 to +25 °C are summarized in Table 2. The plot of log $(k_1/M^{-1}\ s^{-1})$ against the reciprocal of the absolute temperature is shown in Fig. 1 and yielded the Arrhenius equation

$$[3] \quad \log (k_1/M^{-1}\ s^{-1}) = (6.0 \pm 0.5) - (4.5 \pm 0.5)/\theta$$

where $\theta = 2.303\ RT$ kcal mol^{-1}.[4]

It is conceivable that the reactivity of α-$C_{10}H_{11}OOH$ could be influenced by self-association, particularly at the lower temperatures; E_1 would then be overestimated. If it is assumed that the thermodynamic parameters for self-association of α-$C_{10}H_{11}OOH$ are similar to the values reported by Walling and Heaton (17) for $(CH_3)_3COOH$ ($-\Delta H^0 = 5.95$ kcal mol^{-1} and $-\Delta S^0 = 18.4$ e.u.), α-$C_{10}H_{11}OOH$ should be significantly self-associated at for example −76°. The invariance of k_1 from 0.0025 to 0.025 *M* hydroperoxide at this temperature implies, however, that our values of k_1 are not seriously affected by self-association of α-$C_{10}H_{11}OOH$.

[3]A stoichiometric factor of 2.0 indicates that the α-tetralylperoxy radical formed in reaction 1 is removed by reaction with a *t*-butylperoxy radical.

[4]Rate constants at any one temperature were reproducible to within a factor of 2 over a range of hydroperoxide concentrations. The maximum errors for the activation energy and preexponential factor are 0.5 kcal mol^{-1} and 0.5 log units, respectively.

Rate constants for reaction of *t*-ROO· with α-$C_{10}H_{11}$OOH at 30° (k_1 = 568 $M^{-1}\,s^{-1}$) and 56° (k_1 = 1025 $M^{-1}\,s^{-1}$) calculated from eq. 3 are in excellent agreement with the rate constants that have been reported (18) for reaction of the cumylperoxy radical (which is also a tertiary alkylperoxy radical) with α-$C_{10}H_{11}$ OOH at these temperatures (600 and 1100 $M^{-1}\,s^{-1}$).

The *A*-factor for reaction of *t*-ROO· with α-$C_{10}H_{11}$OOH is slightly smaller than the *A*-factors that have been reported for the almost thermoneutral abstractions of an H-atom from phenol, log ($A/M^{-1}\,s^{-1}$) = 7.2 (8) and toluene, log (A per active H/$M^{-1}\,s^{-1}$) = 6.1 (19) by *t*-ROO·. Furthermore, the activation energy E_1 is slightly smaller than the activation energy for abstraction of H-atom from phenol (ΔE = 0.7 kcal mol^{-1}) (8) and significantly smaller than the activation energy for abstraction of an H-atom from toluene[5] (ΔE = 6.5 kcal mol^{-1}) (19).

The low Arrhenius parameters for reaction of phenols with *t*-ROO· and the differences in the parameters between hindered and nonhindered phenols can be partially attributed to the involvement of a hydrogen bonded peroxy radical phenol complex in the transition state. A contribution to the low Arrhenius parameters for α-$C_{10}H_{11}$ OOH can also be attributed to this mechanism. This is because alkyl hydroperoxides can probably form an H-bonded complex with *t*-ROO· since they form an H-bonded complex with a Lewis base, such as tetrahydrofuran, with about the same heat of formation as phenol.[6]

[5]The *A*-factor per active hydrogen and the activation energy for reaction of *t*-ROO· with toluene have been assumed to be the same as the values for *p*-xylene (19).

[6]We find that K at 25° for the formation of an H-bond complex between an alkyl hydroperoxide and tetrahydrofuran = 3.0 M^{-1}, with no detectable enthalpy of activation. At this temperature K for phenol is 13.6 M^{-1} with $-\Delta S^0$ = 8.0 e.u. and $-\Delta H^0$ = 4.0 kcal mol^{-1} (20). If we assume that ΔS^0 for phenol and an alkyl hydroperoxide are of similar magnitude, $-\Delta H^0$ for an alkyl hydroperoxide should be about 3 kcal mol^{-1}.

TABLE 3. Absolute rate constants for reaction of t-ROO$^{\cdot}$ with deuterated α-tetralin hydroperoxide, α-$C_{10}H_{10}OOD$, in isopentane

Temperature (°C)	k_1^D (M^{-1} s^{-1})	k_1^H/k_1^D
21	70	9
−34	~20	~10
−83	~0.5	~20

TABLE 4. Rate constants for reaction of t-ROO$^{\cdot}$ with some alkyl hydroperoxides at 21°

Hydroperoxide	k (M^{-1} s^{-1})
9,10-Dihydro-9-anthracyl	740
s-Butyl	485
Triphenylmethyl	700

α-$C_{10}H_{10}OOD$

Rates of disappearance of tertiary alkylperoxy radicals were significantly slower in the presence of α-$C_{10}H_{10}OOD$ than in the presence of α-$C_{10}H_{11}$ OOH. Reaction 1, therefore, exhibits an isotope effect when the hydroperoxidic hydrogen is replaced by deuterium. Absolute values of k_1^D at the lowest, highest, and an intermediate temperature are summarized in Table 3 and the ratio of rate constants k_1^H/k_1^D at these temperatures are given in the last column. Unfortunately, these rate constants were not of sufficient accuracy to justify their presentation in the form of an Arrhenius equation.

We have previously reported (18) an isotope effect of approximately 30 for reaction of cumylperoxy radicals with α-$C_{10}H_{11}$ OOH at 30°. Based on the present results this rather indirectly determined isotope effect must have been overestimated.

Related Hydroperoxides

9,10-Dihydro-9-hydroperoxyanthracene, s-butyl hydroperoxide, and triphenylmethyl hydroperoxide react rapidly with t-ROO$^{\cdot}$ and rates of radical decay obeyed rate laws analogous to eq. 2. Absolute values of k_1 for these compounds are summarized in Table 4 and it would appear from these data that the nature of the alkyl moiety associated with the hydroperoxide has little influence on reactivity to an alkylperoxy radical.

Conclusions

The ease with which the hydroperoxidic hydrogen is transferred from an alkyl hydroperoxide to an alkylperoxy radical is the reason why the hydroperoxide method has proved to be so successful for determining absolute rate constants for reaction of alkylperoxy radicals with organic compounds (18, 19, 21–28). The facility of this reaction is the result of a low activation energy overshadowing a preexponential factor that is slightly smaller than the normal value for a bimolecular reaction. This H-atom transfer between two peroxy radicals is, therefore, analogous to most H-atom transfers between oxy radicals in that the activation energy falls in the range 0 to 5 kcal mol^{-1}. Both Mahoney (29) and Zavitsas (30) have suggested that BEBO and modified BEBO calculations predict these low activation energies; we eagerly await a full report of their work.

Mass Spectrometric Studies of the Ionization and Thermal Decomposition of Tungsten π-Cyclopentadienyl Tricarbonyl Dimer

J. R. KRAUSE[1] AND D. R. BIDINOSTI

Department of Chemistry, University of Western Ontario, London, Ontario N6A 3B7

Received September 6, 1974

J. R. KRAUSE and D. R. BIDINOSTI. Can. J. Chem. **53**, 628 (1975).

The ionization and thermal decomposition of tungsten π-cyclopentadienyl tricarbonyl dimer $[WC_5H_5(CO)_3]_2$ was investigated using a mass spectrometer fitted with single and double cell molecular flow inlet systems.

The electron impact mass spectrum and appearance potentials for the principle ions in the spectrum have been measured and recorded.

The enthalpy change for the dissociation

$$[WC_5H_5(CO)_3]_2 = 2WC_5H_5(CO)_3$$

obtained from van't Hoff plots of the temperature dependence of the equilibrium constant was found to be 234.4 ± 3.8 kJ/mol. This result was substantiated by an electron impact value of 221.0 ± 20.1 kJ/mol based on an ionization potential for $\cdot WC_5H_5(CO)_3$ of 7.66 ± 0.05 eV measured in the high temperature studies.

J. R. KRAUSE et D. R. BIDINOSTI. Can. J. Chem. **53**, 628 (1975).

On a examiné, en faisant appel à un spectromètre de masse adapté avec des systèmes d'introduction comportant des cellules simples et doubles d'écoulement moléculaire, l'ionisation et la décomposition thermique du dimère $[WC_5H_5(CO)_3]_2$. On a mesuré et enregistré le spectre de masse sous impact électronique et les potentiels d'apparition des principaux ions du spectre. Le changement d'enthalpie pour la dissociation

$$[WC_5H_5(CO)_3]_2 = 2WC_5H_5(CO)_3$$

obtenu à partir d'une courbe de van't Hoff pour la dépendance sur la température des constantes d'équilibre, est de 234.4 ± 3.8 kJ/mol. On a confirmé ce résultat par une valeur de 221.0 ± 20.1 kJ/mol provenant d'impact électronique en se basant sur un potentiel d'ionisation pour $\cdot WC_5H_5(CO)_3$ de 7.66 ± 0.05 eV tel que mesuré dans des études à haute température.

[Traduit par le journal]

Introduction

In the current investigation of tungsten π-cyclopentadienyl tricarbonyl dimer, $[WC_5H_5(CO)_3]_2$, the salient features of some previous Knudsen cell studies from this laboratory (1–4) have been combined and extended. As in the case of the binary metal carbonyls (1), the fragmentation pattern and appearance potentials of the major ions from $[WC_5H_5(CO_3]_2$ have been obtained from electron impact analysis of the molecular beam effusing from a single Knudsen cell adjacent to the ion source. High temperature pyrolysis studies, similar to those on cobalt octacarbonyl (2) and manganese carbonyl (3) were also carried out, but this time using a double Knudsen cell arrangement because of the lower volatility of the tungsten compound. In this way it was possible to study not only the ionization efficiency of thermally produced organotungsten free radicals, but also the enthalpy change accompanying the dissociation process occurring in the reactor chamber of the double oven inlet system.

Experimental

The mass spectrometer used in this work is a medium resolution, 38.2 cm radius, 90° magnetic sector instrument constructed in this laboratory. This new instrument is very similar to our other mass spectrometer (1) with the exception that the ion analyzer now lies in the horizontal plane.

For mass spectral and ion energetic investigations, an effusion cell – ion source arrangement similar to that shown in Fig. 2 ref. 1 has been retained. To minimize the filament temperature the emitter area of the rhenium filaments was covered with a thin layer of a mixture 99% LaB_6 – 1% $LaNO_3$ (5) so that under normal operating conditions (5 μA trap current) the resulting equilibrium ion chamber temperature was 100 ± 10 °C.

Thermal dissociation studies were carried out using the double oven arrangement shown in Fig. 1. The sample, contained in the lower of the two cells, was kept at the

[1]Present address: Abteilung Strahlenchemie, Max Planck Institute, Muehlheim (Ruhr), Federal Republic of Germany.

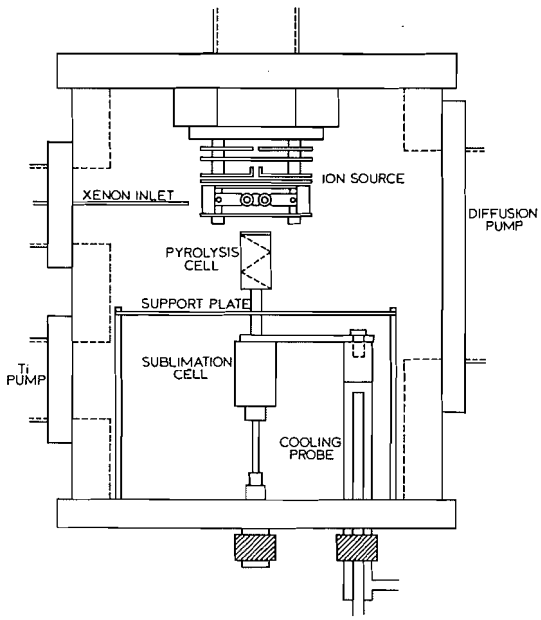

FIG. 1. Knudsen double oven diffusion cell arrangement.

constant temperature just needed to sublime the sample into the gas phase. The vapor so produced passed through a stainless steel connecting pipe into the top cell where it struck a stainless steel baffle. After obtaining thermal equilibrium through numerous collisions with the cell walls, the gas effused through a 0.076 cm orifice into the ion source where a fraction of the beam was ionized and mass analyzed.

During operation, the temperature of the lower cell was fixed by passing a known current from a regulated constant-current power supply through Thermocoax windings (not shown) wrapped around the cell (4). Concurrently, the temperature of the upper cell could be varied systematically by means of a separate regulated supply coupled to that cell's twenty-turn Thermocoax helical heater. Transfer of heat from the upper to the lower cell was effectively prevented by circulating either cold water or cold flowing nitrogen gas through the body of a cold probe connected through a copper bar to the top of the lower cell. The maximum upper cell temperature obtainable was 800 °C and regulation after thermal equilibration was ±2 °C. A sublimation cell temperature of approximately 110 °C gave a suitable pressure for both electron impact and thermal decomposition studies.

The volume about the effusion cells was evacuated by a titanium sublimation pump (1500 l max/s) and the ion source region was pumped by a liquid nitrogen trapped 600 l/s diffusion pump. A separate 150 l/s liquid nitrogen trapped diffusion pump was used to pump the analyzer tube and collector chamber.

Ion detection was with a 15-stage electron multiplier, followed by a Cary model 401 VRE operated in the integration mode.

The $[WC_5H_5(CO)_3]_2$ was prepared according to literature methods (6) and purified by vacuum sublimation before use in the mass spectrometer.

TABLE 1. Mass spectrum and appearance potentials for the ions from $[WC_5H_5(CO)_3]_2$

The relative abundances of "monoisotopic" species were calculated by standard procedures (7). All appearance and ionization potentials were measured relative to xenon (i.p. = 12.13 eV) (8) using Warren's method (9). Xenon was introduced into the ion source simultaneously with the effusing beam by means of an independent auxillary inlet system.

Results and Discussion

Single Effusion Cell Studies

The 50 eV mass spectrum and the appearance potentials of the major ions in the spectrum are given in Table 1.

In the mass spectrum, the molecular ion and ions of the type $W_2(C_5H_5)_2(CO)_n^+$ (n = 0–5) due to successive losses of carbon monoxide were found in high abundance. The remainder of the spectrum was composed of monometallic ions of the type $WC_5H_5(CO)_m^+$ (m = 0–3) together with ions formed by the loss of acetylene (C_2H_2) from π-cyclopentadienyl ligands. No ions due to the scission of carbon–oxygen bonds in the carbonyl ligands nor any rearrangement ions were observed.

From the energetics data, Table 1, it can be seen that the ionization potential of the molecular ion is much lower than the ionization potential of the carbonyl and π-cyclopentadienyl ligands (14.01 and 8.69 eV respectively) (8) and is closer to the ionization potential of the central tungsten atoms (7.98 eV) (8) suggesting that the primary ionization process involves removal of

1	1.65

an electron associated with an essentially nonbonding molecular orbital with prevailing metal character (10).

The energy required to break the first bond in the molecular ion is often different from the average metal–carbon bond energy since there is a variation in the energy necessary to break each successive bond (11). Using eq. 3 (1)

[1] Av. *ionic* metal–carbon bond energy =

$$1/6[\text{a.p.}(W_2(C_5H_5)_2^+) - \text{i.p.}(W_2(C_5H_5)_2(CO)_6)]$$

a value of 1.48 eV was calculated for the mean ionic tungsten–carbon bond dissociation energy. This can be compared with $\bar{D}(W^+—CO) = 2.09$ eV in $W(CO)_6$ (1). The ionic tungsten–carbon dissociation energies are given in Table 2.

The *ionic* tungsten–tungsten bond dissociation energy was calculated from eq. 2 using the appropriate ionization and appearance potentials from Table 1.

[2] $D((CO)_3C_5H_5W—WC_5H_5(CO)_3)$

$$= \text{a.p. } WC_5H_5(CO)_3^+ - \text{i.p. } W_2(C_5H_5)_2(CO)_6^+$$

$$= 10.05 - 6.65$$

$$= 3.40 \text{ eV} = 328 \text{ kJ/mol}$$

This value of the *ionic* tungsten–tungsten bond dissociation energy together with those of the average *ionic* metal–carbon bond dissociation energies help one to rationalize the mass spectrum observed. Since the average activation energy for the splitting of a carbon monoxide fragment from the molecular ion is much smaller than that for metal–metal bond breaking and since the A factors for both fragmentation processes should be similar, it is expected that the excited parent ion will decompose preferentially by carbon monoxide splitting. This in fact is what is observed in the mass spectrum of $[WC_5H_5(CO)_3]_2$.

Double Effusion Cell Studies

When the temperature of the upper cell of a double cell arrangement was the same as the lower cell, the ionic abundances recorded at 50 eV were those of the mass spectrum, Table 1. As the temperature of the upper cell was raised to approximately 460 °K, $WC_5H_5(CO)_3^+$ was observed at electron impact energies below the appearance potential of $WC_5H_5(CO)_3^+$ from $[WC_5H_5(CO)_3]_2$. In addition, with increasing upper cell temperature the relative intensities of ions containing a single tungsten atom remained constant whereas the ratio $I_{WC_5H_5(CO)_3^+}/I_{[WC_5H_5(CO)_3]_2^+}$ increased almost exponentially. This was taken as evidence for the production of $WC_5H_5(CO)_3$ from the dissociation process

[3] $$[WC_5H_5(CO)_3]_2 = 2 \cdot WC_5H_5(CO)_3$$

taking place in the upper cell.

Under conditions of molecular flow, the partial pressure P_i of a gaseous species i in a reactor cell is related to the observed ion current I_i^+ by

[4] $$P_i = C_i I_i^+ T$$

where T is the temperature of the gas in the reactor (13). The constant C_i contains a number of terms which depend on the geometry of both the reactor and ion source, the ion transmission characteristics of the mass spectrometer, the electron multiplier detection efficiency for the ion i^+, and the partial ionization cross section of the ith molecular species. Throughout each experiment, all the terms can be kept constant except the last which is assumed to be temperature independent.

The van't Hoff equation for the process [3] may be written in terms of ion intensities using eq. 4

[5] $$\log \frac{(I_{WC_5H_5(CO)_3^+})^2 T}{I_{[WC_5H_5(CO)_3]_2^+}} = \frac{\Delta H^0}{2.30RT} + C$$

where C is a temperature independent constant.

Van't Hoff plots of ion currents taken at 10 eV for three different reactor pressures are given in Fig. 2.

The least squares fitted analysis of the data (14) gives a value of

[6] $$\Delta H^\circ = 234.4 \pm 3.8 \text{ kJ/mol}$$

for the tungsten–tungsten bond dissociation process.

For personal use only.

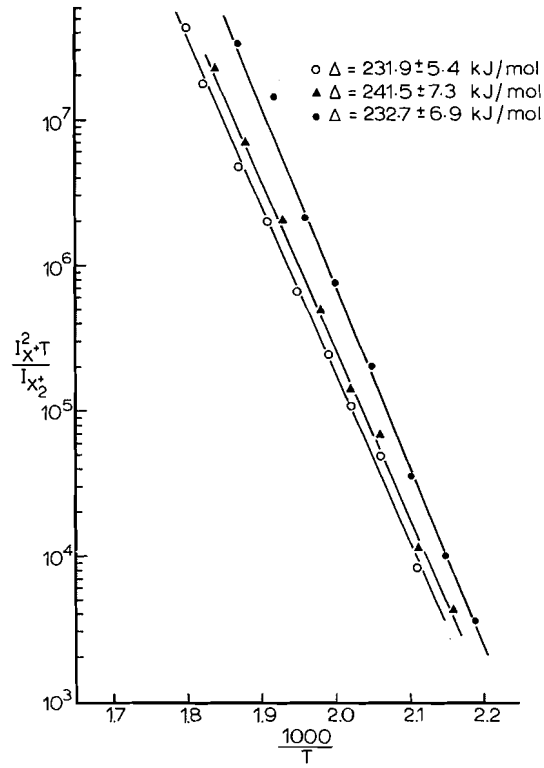

FIG. 2. Van't Hoff plots $[WC_5H_5(CO)_3]_2 = 2WC_5H_5(CO)_3$.

The ionization potential of the radical $WC_5H_5(CO)_3$ from

[7] $WC_5H_5(CO)_3 + e^- \rightarrow WC_5H_5(CO)_3^+ + 2e^-$

was found to be 7.66 ± 0.05 eV from six determinations taken at various times during the different high temperature runs.

From the appearance potential data of Table 1 the minimum energy for the process

[8] $[WC_5H_5(CO)_3]_2 + e^- \rightarrow WC_5H_5(CO)_3^+ + \cdot WC_5H_5(CO)_3 + 2e^-$

is 10.05 ± 0.2 eV.

If the ions produced in [8] and [7] are assumed to be energetically the same then the algebraic difference between them is just reaction 3 for which

[9] $D((CO)_3C_5H_5W—WC_5H_5(CO)_3)$
$= \text{a.p. } WC_5H_5(CO)_3^+ - \text{i.p. } \cdot WC_5H_5(CO)_3$
$= 10.05 - 7.66 \text{ eV}$
$= 2.39 \text{ eV}$
$= 221.0 \pm 20.1 \text{ kJ/mol}$

The agreement between this electron impact bond dissociation energy determination and that from the second-law studies [6] is excellent. It has been pointed out elsewhere (15) that measurements of bond dissociation energies based on the energetics of ions arising from complex organometallic molecules are very dependent on the temperature of the sample inlet system and on ion source temperatures. In this work gaseous samples entered the ion source as well defined molecular beams effusing from Knudsen cells whose temperatures were rigidly fixed and maintained. By using very thin rhenium ribbon cathodes treated with LaB_6 the temperature of the ion source itself was kept low and constant at about 100 °C. Moreover, the "open source" used in this work was designed in such a way that the molecular beam passed directly into the flux of ionizing electrons and any molecules not ionized were quickly pumped away before collisions with the walls led to appreciable decomposition products. It was felt that electron impact data and subsequent bond dissociation energies found under these conditions are more reproducible and dependable than those made using commercial instruments with undefined heated probe inlet and ion source temperatures. The results appear to substantiate these conclusions.

Two factors should be mentioned when viewing the results of the van't Hoff studies. First and foremost the method requires only a relative value of the equilibrium constants, K_i, determined at the various temperatures; absolute values, in contrast to third-law methods, are not necessary (13). With the van't Hoff equation written in the form

$$[10] \qquad \Delta H^0 = \frac{RT_1T_2}{T_1 - T_2} \ln (K_1/K_2)$$

it has been shown that, if $T_1 - T_2$ is 50 °K centered about 500 °K, then a 10% uncertainty in K_1 and K_2 each contribute ±4.2 kJ/mol to ΔH^0 for a total uncertainty given by their vector sum of ±5.9 kJ/mol (16). Secondly, errors in temperature measurement tend to become important when the relative error $2\,\delta T/\Delta T$, where δT is the error in temperature measurement and ΔT is the temperature interval covered, becomes large (13). At the limit, the relative error for temperature measurement in these experiments is at most 4%. Hence the experimental values of the bond dissociation energy determined by our second-law analysis, Fig. 2, are reasonably

defined and at the same time must be said to possess a high degree of precision considering their reproducibility at three different reactor pressures.

The tungsten–tungsten bond energy in tungsten π-cyclopentadienyl tricarbonyl dimer is thus best given as 234.4 ± 3.8 kJ/mol.

The Structure and Stability of Ni(II) Complexes of Thiourea and Related Ligands

D. R. EATON AND K. ZAW

Department of Chemistry, McMaster University, Hamilton, Ontario L8S 4M1

Received July 30, 1974

D. R. EATON and K. ZAW. Can. J. Chem. **53**, 633 (1975).

A number of Ni(II) complexes of thiourea, *N*-methylthiourea, *N,N'*-dimethylthiourea, *N*-naphthylthiourea, *N,N'*-diethylthiourea, and ethylene thiourea have been studied in acetone solution by proton magnetic resonance, magnetic susceptibility measurements, and conductivity measurements. In solution these complexes have tetrahedral, square planar, and octahedral geometries. In many cases equilibria between compounds with different geometries exist. Such equilibria have been studied as a function of temperature. The factors determining the relative stability of Ni(II) compounds with different geometries are discussed. In the present series of compounds it is concluded that the charge on the metal ion has the predominant influence in determining geometry. Some qualitative results on ligand exchange rates and mechanisms are also reported.

D. R. EATON et K. ZAW. Can. J. Chem. **53**, 633 (1975).

On a étudié, en solution dans l'acétone, par résonance magnétique nucléaire du proton, par des mesures de susceptibilité magnétique et par des mesures de conductivité, une série de complexes du Ni(II) avec la thiourée, la *N*-méthylthiourée, la *N,N'*-diméthylthiourée, la *N*-naphtylthiourée, la *N,N'*-diéthylthiourée et l'éthylène thiourée. En solution, ces complexes ont des géométries tétraédrique, plan carré et octaédrique. Dans plusieurs cas, des équilibres existent entre des composés ayant des géométries différentes. On a étudié de tels équilibres en fonction de la température. On discute des facteurs déterminant la stabilité relative de composés du Ni(II) avec différentes géométries. Dans la série de composés présentés dans cette communication, on conclut que la charge sur l'ion métallique a une influence prépondérante dans la détermination de la géométrie. On rapporte aussi quelques résultats qualitatifs sur les vitesses d'échanges des ligands et sur les mécanismes de ces échanges. [Traduit par le journal]

Thiourea and substituted thioureas form complexes with most of the transition metal ions in the first period (1). These complexes are generally labile in solution and often partly solvolyzed. They therefore constitute a suitable series for systematic study of the kinetics and mechanisms of rapid ligand exchange reactions. We have previously reported some solution studies of the Co(II) compounds (2). These latter complexes are uniformly tetrahedral in nonaqueous solution. The situation for the analogous Ni(II) compounds is more complicated. Octahedral, square planar, and tetrahedral geometries are all plausible and in the case of thiourea complexes all occur. In a preliminary communication (3) we suggested that the relative stabilities of Ni(II) thiourea complexes with different geometries were determined by electronic rather than steric factors. In the present paper we report the n.m.r. and magnetic susceptibility results that support this conclusion and will also discuss some aspects of the ligand exchange processes.

A substantial number of papers have been published on the synthesis and characterization of nickel thiourea complexes (1, 4–7). The majority of structural studies have concentrated on the solid complexes. The geometric information from these studies is not necessarily pertinent to the solution structures. It has however been concluded from infrared and crystallographic work that the thiourea is always bonded through the sulfur and this conclusion appears to hold in solution. Two papers contain information pertaining to the structure of Ni thiourea complexes in solution. Holt and Carlin (8) reported the magnetic susceptibilities, conductivities, and electronic spectra of a number of complexes involving ethylene thiourea, *N*-naphthylthiourea, and *N,N'*-diethylthiourea. Data on solutions in acetone and nitromethane at room temperature only were presented. They concluded that the compounds $Ni(nptu)_2Br_2$ and $Ni(nptu)_2I_2$ (nptu ≡ *N*-naphthylthiourea) are undissociated and tetrahedral in solution. $Ni(nptu)_4Cl_2$ loses thiourea ligands in solution to give a similar tetrahedral complex. The complexes $Ni(etu)_6$-

For personal use only.

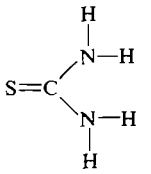
$(ClO_4)_2$ and $Ni(detu)_6(ClO_4)_2$ (etu ≡ ethylene thiourea, detu ≡ *N,N'*-diethylthiourea) are partly dissociated in solution to give equilibrium mixtures of octahedral and square planar complexes. $Ni(etu)_4(NO_3)_2$ loses thiourea ligands in solution but remains octahedral and is a nonelectrolyte. The NO_3^- ligands may be bidentate or solvent molecules may be involved in the first coordination sphere. They also concluded that $Ni(etu)_4X_2$ and $Ni(detu)_4X_2$ ($X = Cl^-, Br^-, I^-$) give tetrahedral species in solution. This information is supplemented by the work of Basso *et al.* (9). These authors examined the complexes $Ni(tu)_6X_2$ (tu ≡ thiourea, $X = NO_3^-$, ClO_4^-, and BF_4^-) in acetone and concluded that the nitrate was octahedral with coordinated anion but found the perchlorate and fluoroborates to be electrolytes and to show evidence of a square planar – octahedral equilibrium.

Our results agree with the conclusions of the above papers but we have been able to clarify the situation by combining n.m.r., magnetic susceptibility, and conductivity measurements and by studying the various equilibria over a range of temperatures.

Magnetic susceptibility measurements immediately distinguish square planar (diamagnetic) complexes from octahedral and tetrahedral (paramagnetic) compounds. In favorable circumstances they will also distinguish octahedral and tetrahedral compounds. Octahedral Ni^{2+} compounds have a nonorbitally degenerate ground state ($^3A_{2g}$) and they are therefore expected to have magnetic moments close to the spin only value. In practice a range of 2.8–3.3 B.M. is found. Tetrahedral compounds on the other hand have an orbitally degenerate ground state ($^3T_1$) and a moment of up to 4.1 B.M. can be anticipated. However, relatively modest distortions from T_d symmetry can remove the orbital degeneracy and produce a magnetic moment in the octahedral range. A high moment (> 3.4 B.M.) is therefore diagnostic for tetrahedral geometry but a low moment (< 3.4 B.M.) is inconclusive. In the latter case the electronic spectra provide a more useful probe.

The n.m.r. spectra of the paramagnetic complexes are expected to show large isotropic shifts from the usual diamagnetic positions of the resonances (10). In the case of a thiourea ligand (structure 1) restricted rotation about the C—N bond leads to separate resonances for the protons *cis* to the S ("outside") and those *trans* to the S



1

("inside") (2). There are analogous possibilities for substituted thioureas. Addition of free ligand immediately determines whether the ligand exchange is fast on the n.m.r. time scale (the spectrum shows a single resonance shifted towards the free ligand position) or slow on the n.m.r. time scale (the complexed ligand resonance is unshifted and a new line appears at the free ligand position). In the absence of equilibria between different geometric forms or of a transition from rapid to slow exchange the isotropic shifts of the complexed protons will approximately increase inversely with the temperature (Curie law). Equilibria between diamagnetic and paramagnetic forms are made apparent by pronounced curvature, often with a change in sign of the slope, of the $1/T$ plots. Transition from fast to slow exchange is manifested by broadening and disappearance of the resonance followed by the reappearance at a lower temperature of a complexed resonance in a different position. Thus the n.m.r. spectra provide information on both the geometric equilibria and the ligand exchange processes. If characteristically similar chemical shifts are observed for a series of compounds the n.m.r. can also be used to identify the geometries present.

$Ni(tu)_4Cl_2$

In the solid state this compound has been shown to have octahedral geometry (4). Acetone solutions show no conductivity at any temperature indicating no dissociation of chloride ion. Data in Table 1 show that the magnetic moment varies from 3.5 B.M. at 37 °C to 3.9 B.M. at −80 °C. The n.m.r. spectrum shows separate resonances for the "inside" and "outside" protons (Table 2). The solubility of this compound is rather low and addition of excess thiourea causes precipitation. At room temperature the two NH signals are of equal intensity. At −50 °C the low field signal becomes very broad but has become relatively sharp again at −84 °C. The high field line remains sharp throughout but

at −84 °C is approximately three times more intense than the low field line. The observed shift of this latter line at −84 °C is approximately one-third of that of the corresponding line of $Nitu_6Br_2$ (see below) for which there is slow exchange at this temperature. The temperature dependence of the low field line is shown in Fig. 1. There is no change in the color of the solution between room temperature and −90 °C.

The above observations are consistent with the complete dissociation of $Nitu_4Cl_2$ to give tetrahedral $Nitu_2Cl_2$ as suggested by Holt and Carlin on the basis of optical spectra for analogous substituted thiourea halide complexes. The high magnetic moment is strongly suggestive of this geometry. The rate of ligand exchange is such that the large shift (~ −4200 Hz) is frozen out at −50 °C but an average resonance is still observed for the smaller shifted complexed resonance (~ −600 Hz) and free ligand at −90 °C. There is no evidence for geometries other than tetrahedral.

$Nitu_6Br_2$

This compound is more soluble in acetone than the chloride. The magnetic moment of the

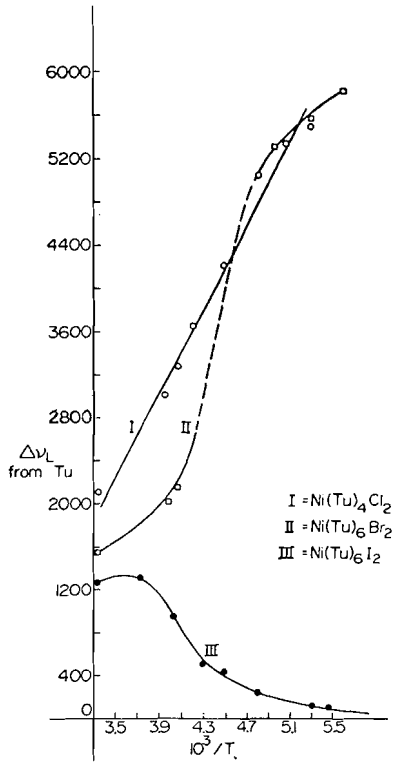

FIG. 1. Temperature dependence of the isotropic shifts of the low field NH resonances of nickel thiourea halides. Shifts in Hz from free ligands.

solution varies from 3.6 B.M. at 27 °C to 1.2 B.M. at −94 °C (Table 1). Acetone solutions give a small conductivity at room temperature which increases at low temperatures. At room temperature the n.m.r. spectrum is quite similar to that of the chloride. Addition of free ligand indicates rapid ligand exchange. A large excess of added thiourea leads to averaging of the inside and outside NH protons due to rapid rotation about the C—N bond in the free ligand. On cooling solutions of the complex the low field resonance commences to broaden at −25 °C and reappears as a complexed ligand resonance at −60 °C. At −93 °C the spectrum shows four resonances. Two at −6219 and −1138 Hz correspond to the frequencies found for the inside and outside protons of tetrahedral $Nitu_2Cl_2$ and a third is at the free ligand position and increases in intensity with the addition of excess free ligand. The fourth resonance comprises a doublet with 20 Hz splitting at −500 Hz and is assigned to a diamagnetic complex. The n.m.r. data is presented in Table 3 and the temperature dependence of the downfield

line illustrated in Fig. 1. Addition of tetramethyl ammonium bromide decreases the concentration of the diamagnetic complex relative to the paramagnetic complex.

In this case there is clearly an equilibrium between a paramagnetic and a diamagnetic complex. The high value of the magnetic moment at high temperature (3.7 B.M.) and the similarity of its chemical shifts at low temperature to those of $Nitu_2Cl_2$ suggest the paramagnetic species is tetrahedral $Nitu_2Br_2$. The diamagnetic compound must involve dissociation of bromide ion since its formation is repressed by the addition of tetramethyl ammonium bromide and the drop in susceptibility at low temperatures is paralleled by an increase in conductivity. It could therefore be square planar $Nitu_4^{2+}$ or $Nitu_3Br^+$. However studies of $Nitu_6(ClO_4)_2$ (see below) show that in the presence of 2 mol of excess thiourea at −90 °C $Nitu_4^{2+}$ is completely converted to octahedral $Nitu_6^{2+}$. We deduce therefore that the diamagnetic species in the present case is $Nitu_3Br^+$.

$Nitu_6I_2$

The magnetic moment of $Nitu_6I_2$ in acetone is 3.5 B.M. at 31 °C. The moment falls steadily with decreasing temperature and reaches a minimum of 0.6 B.M. at −80 °C but rises thereafter to 1.4 B.M. at −94 °C. This data is shown in Table 1. The conductivity of these solutions also increases with decreasing temperature and is greater than that of the bromide compound at all temperatures. The solution shows a color change from brown at room temperature to blue at −90 °C. At 27 °C the n.m.r. spectrum shows two lines, one shifted 1261 Hz downfield from the free ligand and the second shifted 95 Hz downfield from the free ligand. On cooling to −5 °C these resonances broaden and become unobservable. On further cooling they reappear and shift steadily upfield. At −90 °C the spectrum shows two lines, one at a position corresponding to free ligand and one at a position corresponding to a diamagnetic square planar complex. The n.m.r. data is given in Table 4 and the temperature dependence of the low field line is plotted in Fig. 1. No lines corresponding to a paramagnetic species are observed at −90 °C. Addition of tetramethyl ammonium iodide to solutions in the high temperature region shifts the lines to low field indicating that the equilibrium is disturbed with the formation of the paramagnetic species.

We infer from these results that at room temperature tetrahedral $Nitu_2I_2$ is the most important species. On cooling diamagnetic square planar $Nitu_3I^+$ is formed. At around −5 °C the equilibrium between square planar and tetrahedral forms becomes slow enough to cause line broadening. The ligand exchange reactions involving both forms remain fast but the proportion of tetrahedral diminishes with decreasing temperature. At −90 °C the square planar ligand exchange has been frozen out. The increase in magnetic moment at very low temperatures is attributed to further ionization to give the doubly charged cation which is stable as octahedral $Nitu_6^{2+}$ at these temperatures. Results with $Nitu_6(ClO_4)_2$ (see below) indicate that the n.m.r. resonances of $Nitu_6^{2+}$ are too broad to observe at −90 °C.

TABLE 4. Nuclear magnetic resonance data on nickel thiourea iodide solutions*

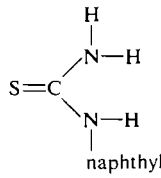
$Ni(nptu)_2Br_2$ and $Ni(nptu)_2I_2$

Both of these compounds were reported to have tetrahedral geometry in solution at room temperature by Holt and Carlin (8). The temperature dependence of the magnetic susceptibility of the bromide shows a constant value of 3.2–3.3 B.M. from 37 to −60 °C followed by a steady drop to 2.5 B.M. at −93 °C. The behavior of the iodide is similar except that the fall off in moment commences at a rather higher temperature (−40 °C) and reaches a value of 2.3 B.M. at −94 °C. The n.m.r. spectra show relatively small shifts for the aromatic protons of the naphthyl groups. At room temperature only two NH resonances appear but below zero three can be distinguished. Steric considerations will favor the configuration



for the ligand which gives three different N—H protons. The shifts are rather greater than those for the thiourea complexes, *e.g.* at −70 °C $Ni(nptu)_2Br_2$ has lines at −6081, −1743, and −1081 Hz compared to −5700 and −880 Hz for $Nitu_6Br_2$. The temperature dependence of the lines follows Curie law rather closely.

Although the magnetic moments of these compounds are rather lower than those of the thiourea complexes we see no reason to doubt the conclusion of Holt and Carlin that at room temperature they have tetrahedral geometry. This is confirmed by the similarity of the n.m.r. shifts to those of the compounds discussed above. The small drop in susceptibility at low temperature suggests some formation of square planar diamagnetic isomers.

Perchlorate and Tetrafluoroborate Complexes

Six complexes in this class have been examined. They all behave in a very similar fashion. Holt and Carlin (8) found the magnetic moment of $Ni(detu)_6(ClO_4)_2$ in acetone solution to be 2.0 B.M. at room temperature. It shows a strong band at 17 000 – 18 000 cm^{-1} which they attributed to a square planar species. Basso *et al.* (9) found similar electronic spectra for other perchlorate and borofluoride complexes. All the complexes are 2:1 electrolytes. On the basis of this evidence a square-planar octahedral equilibrium was suggested.

The variation of magnetic moment with temperature for the six complexes $Nitu_6(ClO_4)_2$, $Ni(dmtu)_6(ClO_4)_2$, $Ni(detu)_6(ClO_4)_2$, $Ni(etu)_6(ClO_4)_2$, $Ni(tu)_6(BF_4)_2$, and $Ni(detu)_6(BF_4)_2$ is shown in Table 5. This behavior is markedly different from the examples discussed above in that the moment *increases* with decreasing temperature. In each case the limiting value is 3.2–3.3 B.M. which is in excellent agreement with the value expected for an octahedral complex. A square planar – octahedral equilibrium is clearly indicated. It appears that the square planar form slightly increases in stability in the series tu < dmtu < detu. There is no significant difference between similar compounds with perchlorate or borofluoride anions.

At room temperature $Nitu_6(ClO_4)_2$ shows a single n.m.r. line at −880 Hz from TMS. At −30 °C there are two lines at −1552 and −394 Hz attributable to inside and outside NH protons. These broaden and disappear at lower temperatures presumably due to slowing of the ligand exchange reaction and no spectrum is observable at −90 °C. $Ni(dmtu)_6(ClO_4)_2$ shows a single NH and a single CH_3 resonance at room temperature. Two CH_3 resonances appear at −18 °C; exchange between the inside and outside positions is no longer fast. On further cooling the CH_3 broaden at around −30 °C and the NH at around −60 °C due to slowing of the ligand exchange process. At low temperature (−104 °C) two CH_3 resonances and one NH all shifted from the free ligand position are observed and this may be taken as the spectrum of the octahedral compound. Nuclear magnetic resonance spectra of $Ni(dmtu)_6(ClO_4)_2$ are shown in Fig. 2. Other alkyl thiourea complexes in this class behave very similarly. Some of the n.m.r. shifts are gathered together in Table 6.

Nitrate Complexes

$Nitu_6(NO_3)_2$ has been reported to be a non-electrolyte in acetone solution and to have octahedral geometry at room temperature. We have examined the magnetic susceptibilities of $Nitu_6(NO_3)_2$, $Ni(dmtu)_6(NO_3)_2$, and $Ni(detu)_6(NO_3)_2$ and find that in each case the moment is 2.8 B.M. at room temperature and increases slowly to 3.3 B.M. at −90 °C. These values are consistent with an octahedral species. The n.m.r. spectra are quite similar to those of the per-

chlorates and borofluorides except that the ligand exchange is significantly slower. Thus for $Nitu_6(NO_3)_2$ the NH resonance broadens at -30 °C and reappears as a complexed resonance at -45 °C. For $Ni(detu)_2(NO_3)_2$ the slow exchange limit has been reached at -15 °C. $Ni(dmtu)_6(NO_3)_2$ and $Ni(detu)_6(NO_3)_2$ both show several resonances at low temperature. For example at -100 °C $Ni(dmtu)_6(NO_3)_2$ shows NH lines at -5764, -5125, and -3819 Hz and CH_3 resonances at -1375, -1175, and -736 Hz as well as the free ligand resonances. Other NH lines are probably hidden by the CH_3 lines. This multiplicity of lines could arise from a combination of *cis* and *trans* isomers of $Ni(dmtu)_4(NO_3)_2$ and restricted rotation about the C—N bond. Addition of excess dmtu to this solution leads to a spectrum of $Ni(dmtu)_6^{2+}$ identical to that obtained from the perchlorate indicating replacement of complexed nitrate. It is apparent that these complexes are octahedral at all temperatures.

π-Allyl and π-Crotyl Complexes

We have examined the n.m.r. spectra of the following complexes: (π-allyl)$Ni(tu)_2Br$, (π-allyl)-$Ni(nptu)_2Br$, (π-allyl)$Ni(mtu)_2Br$, (π-crotyl)-$Nitu_2Br$, (π-allyl)$Ni(dmtu)_2Br$, (π-crotyl)-$Ni(dmtu)_2Br$. The thiourea compounds have been reported previously (11). They are reported to be diamagnetic and ionized in solution (11). A crystal structure has shown that the (π-allyl)-$Nitu_2^+$ ion has a planar geometry (12). They are also efficient catalysts for the synthesis of hexadienoic esters from allylic halides, acetylene, carbon monoxide, and alcohols (11). It is therefore of interest to compare the ligand exchange rates with those of noncatalytic thiourea complexes. All n.m.r. spectra were obtained in acetone-d_6 solution for comparison with other thiourea complexes. The π-allyl and π-crotyl resonances are very similar to those reported for analogous complexes (13, 14). Data on the thiourea resonances is given in Table 7. All the lines occur in positions corresponding to diamagnetic complexes. The chemical shifts are slightly temperature dependent and the lines are found 20–70 Hz to low field of the free ligand positions. At room temperature only a single NH resonance is observed but at lower temperatures there are separate lines for the inside and outside positions. The coalescence temperature for this exchange process increases in the series $RNitu_2Br$ (-35 °C) < $RNi(mtu)_2Br$ (-23 °C) < $RNi(dmtu)_2Br$ (-17 °C) < $RNi(nptu)_2Br$ (-10 °C). These temperatures are higher than those of the corresponding ligands. Addition of free ligand demonstrates that the ligand exchange remains fast on the n.m.r. time scale even down to -90 °C. There is no indication of any paramagnetic tetrahedral species in the nptu complex or of the formation of an octahedral species at low temperature on the addition of excess ligand

to the tu, mtu, or dmtu compounds. The compounds remain square planar and diamagnetic throughout.

Structural Equilibria

In cases where there is an equilibrium between a diamagnetic and a paramagnetic species it is possible to find the enthalpy and entropy change of the reaction either from the temperature dependence of the n.m.r. shifts or from the temperature dependence of the magnetic susceptibility. There are some difficulties associated with each of these methods. In the n.m.r. method it is necessary to know the shift of the fully paramagnetic species at each temperature. In these nickel complexes there is some displacement of thiourea by solvent acetone as was found for the analogous cobalt compounds (2). The extent of this solvolysis can be found from the concentration dependence of the n.m.r. chemical shifts. For $Nitu_2Cl_2$ equilibrium constants similar to those reported for $Cotu_2Cl_2$ are found. The analysis of the data becomes uncertain though when both solvolysis and a structural equilibrium occur and we have therefore preferred to use the magnetic susceptibility data to obtain equilibrium constants for the structural equilibria. To use this method it is necessary to estimate the moment of the fully paramagnetic species (μ_∞) and then find the fraction of this species at each temperature. There is some error in estimating μ_∞ and the measurement of susceptibility is inherently less accurate than the measurement of chemical shifts. Values of ΔH and ΔS obtained from the susceptibilities are given in Table 8. The quoted errors are from least squares fits of the data and do not include systematic errors arising from incorrect assignment of μ_∞.

For the tetrahedral – square planar equilibria ΔH varies from +2 to +6 kcal/mol and ΔS from +12 to +25 cal/deg mol. These values may be compared with those reported for the tetrahedral – square planar equilibrium in Ni aminotroponeimineates (15) (ΔH, +2 to +4 kcal/mol; ΔS, +8 to +12 cal/deg mol). In both cases the square planar species is favored by the enthalpy and the tetrahedral species by the entropy term. The rather higher values found for ΔS in the present case are consistent with greater solvation of the positively charged square planar form. For the octahedral – square planar equilibria we obtain ΔH −2 to −4 kcal/mol and ΔS −15 to −22 cal/deg mol. The negative signs are consistent with the formation of additional bonds. The magnitudes of ΔH and ΔS are comparable to those reported for octahedral – square planar equilibria in other Ni(II) systems (16).

Ligand Exchange Processes

The existence of equilibria between different geometric isomers of these nickel complexes limits the utility of n.m.r. in obtaining information on the kinetics and mechanism of the ligand exchange processes. Some qualitative information is however available. It is possible to distinguish between an associative and a dissociative mechanism for ligand exchange by examining the dependence of the line width of a complexed

For personal use only.

ligand resonance with the addition of free ligand in the slow exchange region (2). $Nitu_2Br_2$ and $Ni(dmtu)_6(ClO_4)_2$ give spectra suitable for this experiment. Not unexpectedly the former shows an associative process and the latter a dissociative process. We have also examined the line widths of mixtures of $Nitu_2Br_2$ and excess ligand in the fast exchange region (+27 to −8 °C) and using the standard approximations (17) for line widths in this region have analyzed the data to obtain $\Delta H^{\ddagger} = 4.6 \pm 0.6$ kcal/mol and $\Delta S^{\ddagger} = -15 \pm 3$ cal/mol. These results are not particularly reliable since the calculations do not take account of the square planar – tetrahedral equilibrium but it is noteworthy that the values of $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ are quite similar to those obtained for $Cotu_2Br_2$ ($\Delta H^{\ddagger} = 2.9 \pm 0.6$ kcal/mol, $\Delta S^{\ddagger} = -24 \pm 2$ cal/deg mol) (18). From data on $Ni(dmtu)_6^{2+}$ in the slow exchange region we obtain $\Delta H^{\ddagger} = 14 \pm 1$ kcal/mol and $\Delta S^{\ddagger} = +32 \pm 5$ cal/deg mol. The significant point here is the positive value of $\Delta S^{\ddagger}$ is indicative of a true dissociative mechanism.

For the remaining complexes we merely note some trends in ligand exchange rates deduced from coalescence temperatures. It is apparent that in the tetrahedral complexes the rates decrease in the order $Nitu_2Cl_2 > Nitu_2Br_2$. The iodide is apparently slower than the bromide but the presence of the square planar compound obscures the ligand exchange coalescence. This order is observed in the analogous cobalt complexes (2) and also in nickel triphenylphosphine halide complexes (19). For the square planar complexes although the difference is not great it appears that $Nitu_3I^+ > Nitu_3Br^+$. Thus separate lines can be observed for the bromide and excess ligand at −90 °C whereas under the same conditions a single line is observed for the iodide solutions. For the octahedral complexes the rates increase in the order $Ni(detu)_6^{2+} < Ni(dmtu)_6^{2+} < Nitu_6^{2+}$. This behavior also parallels that of cobalt thiourea perchlorate complexes (2). It is interesting to note that the catalytically active π-allyl complexes clearly undergo very rapid ligand exchange.

Discussion

The factors which determine the geometric preferences of Ni(II) complexes have been extensively discussed (20, 21) but not as yet clearly delineated. Thus Holt and Carlin (8) concluded from their study of the geometry of nickel thiourea complexes "we believe that this work on complexes of nickel with substituted thioureas has raised more questions than provided answers in this respect". In the present studies we have found cases where only the tetrahedral form occurs ($Nitu_2Cl_2$), where only the octahedral form occurs (nitrate complexes), where only the square planar form occurs (π-allyl complexes), where there is an equilibrium between tetrahedral and square planar forms ($Nitu_2Br_2$ and $Nitu_3Br^+$), and where there is an equilibrium between square planar and octahedral forms ($Nitu_4^{2+}$ and $Nitu_6^{2+}$). It therefore seems appropriate to ask whether these data throw any new light on the factors determining the relative stability of different geometries.

Thus far the possibility of five coordinate geometries has not been mentioned. Five coordination, although less common than four or six coordination, is well recognized in the chemistry of divalent nickel (22). The majority of examples involve multidentate ligands. With donor atoms such as sulfur they are nearly always diamagnetic. The most plausible possibility is therefore that the diamagnetic compounds which we have formulated as square planar $Nitu_4^{2+}$ and $Nitu_3X^+$ could be five coordinate $Nitu_5^{2+}$ or $Nitu_4X^+$. We do not favor this possibility. The electronic spectra obtained from perchlorate solutions have been satisfactorily assigned to square planar compounds. On lowering the temperature the magnetic susceptibility measurements indicate that a paramagnetic octahedral compound is formed rather than a diamagnetic five coordinate compound. No five coordination has been reported in solid state studies of nickel thiourea complexes. Finally, measurements of the relative intensities of the free ligand and diamagnetic complex lines at −90 °C are more consistent with the formulation $Nitu_3X^+$ than $Nitu_4X^+$. None of these arguments are unequivocal but nevertheless they incline to be against postulating five coordination.

The factors influencing the choice between tetrahedral, square planar, and octahedral geometries may be classified as either steric or electronic. Steric factors clearly operate to give diminishing stability in the order tetrahedral > square planar > octahedral. It would appear that steric factors are *not* dominant for the compounds under discussion. Thus for the compounds $Nitu_2X_2$ and $Nitu_3X^+$ the latter square planar

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

compound becomes increasingly more stable in the series Cl < Br < I. This is clearly the opposite of the order expected from the size of the halide ions. In the perchlorate series even the bulky detu ligand forms an octahedral complex but not a tetrahedral one. $Ni(nptu)_2Br_2$ is predominantly tetrahedral but $Ni(nptu)_2(\pi\ allyl)^+$ is square planar. The bulk of the naphthylthiourea ligand does not therefore seem to be the determining factor. We must therefore look to electronic factors to provide a rational interpretation of the observations.

Perhaps the most significant result is that under identical conditions of solvent (acetone) and temperature (−90 °C) the stable neutral molecule $Nitu_2X_2$ is tetrahedral, the stable singly charged species $Nitu_3X^+$ is square planar, and the stable doubly charged species $Nitu_6^{2+}$ is octahedral. This suggests that the geometry is determined primarily by the charge on the metal atom. A rationalization of this result is that the geometric preference depends on a competition between energy gained by bond formation and energy lost through interelectronic repulsion between bonding electrons. The greater the charge on the metal atom the greater will be the gain in bonding energy for either covalent or ionic bonding. Total bonding energy will increase in the series tetrahedral < square planar < octahedral. Total repulsion energy between the bonding electrons will increase in the same order. For a high positive charge on the metal the gain in bonding energy will outweigh the loss due to interelectronic repulsion and an octahedral complex will result. For a low positive charge on the metal the gain in bonding energy on passing from tetrahedral to octahedral will be insufficient to compensate for the increased interelectron repulsion between the bonding electrons and the tetrahedral geometry will be preferred. For intermediate charge on the metal atom an optimum balance is attained with square planar geometry. Competition between ligand field stabilization energy (which on the molecular orbital picture is closely related to bonding energy) and interelectron repulsion between d electrons is a dominant theme in ligand field theory. The role of interelectronic repulsion between bonding electrons and lone pairs in determining the geometry of nontransition metal compounds has long been advocated (23). Application of the idea of balancing bonding energy and interelectron repulsion energy to the problem of the geometries of transition metal complexes therefore seems quite reasonable.

Most of the observations reported above fit this pattern quite well. *N,N'*-diethylthiourea might be expected to be a slightly better donor than thiourea decreasing the positive charge on the metal and slightly favoring a square planar complex over an octahedral complex. The nitrate ion is a rather poor ligand forming essentially ionic bonds thus leaving a high positive charge on the metal favoring octahedral geometry. The π-allyl ligand is a much better π acceptor than a halide ion; hence the positive charge on the metal in the π-allyl complex is relatively high and it assumes a square planar geometry whereas $Nitu_2Br_2$ is tetrahedral. Other examples may be found in the literature. Thus *N,N'*-diphenylaminotroponeimineates of Ni(II) show equilibria between square planar and tetrahedral geometries (15). Electron withdrawing substituents on the phenyl ring, which would increase the positive charge on the metal, favor the square planar form whereas electron donating substituents favor the tetrahedral form.

Finally it should be noted that the above discussion is not intended to imply that electronic effects always dominate steric effects in determining the geometry of Ni(II) complexes. Thus Ni(II) *N,N*-dimethylaminotroponeimineate is predominantly square planar whereas the most stable form of Ni(II) *N,N'*-diethylaminotroponeimineate is tetrahedral. This must clearly be ascribed to the difference in size of a methyl and an ethyl group.

Experimental

Halide, perchlorate, borofluoride, and nitrate complexes of Ni(II) with thiourea and substituted thiourea were synthesized following methods described in the literature (1, 6, 8, 9). Typically mixtures of the appropriate nickel salt and thiourea in the correct stoichiometric proportions were dissolved in *n*-butanol and heated on a water bath until the presence of solid was noticeable. Products separated on cooling. They were then filtered, washed with ether, dried under vacuum, and recrystallized from the solvent used in the preparation. All compounds were characterized by melting points, visible and infrared spectra. All melting points agree to within 2 °C with literature values. The n.m.r. spectra provide a further check on purity since diamagnetic impurities are readily identified. These complexes are stable compounds and may be stored without decomposition. The perchlorates and borofluorides are somewhat deliquescent. All compounds were routinely dried over P_4O_{10} before obtaining spectral or magnetic data.

π-Allyl and π-crotyl complexes were prepared by reaction of the appropriate thiourea with π-allyl nickel

bromide dimer (11). The latter can be obtained by reaction of allyl bromide with nickel tetracarbonyl (24). Typically methanolic solutions of π-allyl nickel bromide dimer and thiourea in the ratio of 1 to 4 mol were mixed at −5 °C under nitrogen. On cooling to −78 °C the required complexes separated as orange red solids and were removed by filtration. All of these compounds are air sensitive materials and must be stored under nitrogen or argon. They were handled in a gas line. The n.m.r. spectra showed a small resonance assigned to benzene (used as a solvent in the synthesis) in addition to the lines due to the complex and to the solvent (acetone-d_5). These spectra served to identify the complex without ambiguity.

Conductivity measurements at 25 and −78 °C were made in a glass cell immersed in either an oil bath maintained at 25 °C or in Dry Ice – acetone mixture. The solvent used was dry acetone and the conductance of solutions was measured with a Wayne–Kerr bridge operating at 1000 Hz. Magnetic susceptibilities were measured in carefully dried acetone using the n.m.r. method suggested by Evans (25). Diamagnetic corrections were made using Pascals constants. It is known that acetone can complex to the metal ion. However, careful measurements revealed no appreciable shift of the solvent resonance relative to TMS in the presence of nickel thiourea complexes. Bulk susceptibility shifts of the solvent resonance can therefore be used to determine the magnetic susceptibility.

Nuclear magnetic resonance spectra were obtained with a Varian DP 60 spectrometer operating at 56.4 MHz. TMS was used as an internal reference throughout.

JAROSLAV RYBICKY. Can. J. Chem. **53**, 644 (1975).

The kinetics of the catalyzed reaction between two substrates is dealt with for the special case in which the product associated with the catalyst cannot be distinguished from the product dissociated from the catalyst. The rate equation in which the yield is a sum of products both associated with and dissociated from the catalyst is derived and its applicability is assessed with respect to the kinetic and concentration conditions. It was found that under steady-state conditions and fast preequilibrium condition a twenty-fold excess of the substrates over the catalyst is enough for the yield of reaction to be represented by the equation derived with less than 1% relative error, and even for a five-fold excess the equation remains a fairly good approximation. Under such conditions the rate equation can find practical utility.

JAROSLAV RYBICKY. Can. J. Chem. **53**, 644 (1975).

On traite la cinétique de la réaction catalysée impliquant deux substrats comme un cas spécial dans lequel le produit associé avec le catalyseur ne peut pas être distingué du produit dissocié du catalyseur. L'équation de vitesse dans laquelle le rendement est une somme de produits associés et dissociés du catalyseur est déduite et son champ d'application est évalué par rapport à la cinétique et aux conditions de concentration. On a trouvé que dans des conditions d'état d'équilibre et dans des conditions où il y a un prééquilibre rapide, un excès de 20 fois de substrat par rapport au catalyseur est suffisant pour que le rendement de la réaction puisse être représenté par l'équation dérivée avec moins de 1% d'erreur et même pour un excès de 5 fois, l'équation demeure une assez bonne approximation. Dans de telles conditions l'équation de vitesse peut avoir une utilité pratique.

[Traduit par le journal]

Introduction

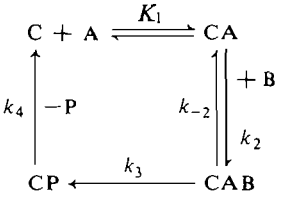
The yield of a catalyzed reaction is generally represented by the reaction product which has dissociated from the catalyst. The product of the reaction that is still associated with the catalyst is considered an intermediate in the overall reaction mechanism, and it does not form any part of the yield of the reaction (1). In a special case, however, it may be impossible or undesirable to discriminate between the ultimate and penultimate products of a reaction scheme. An example could be found in the polymerization of a ternary complex among a donor-monomer, an acceptor-monomer, and a complexing agent via a mechanism suggested by Gaylord (2). On precipitation the polymer comes out of the solution irrespective of the presence or absence of the catalyst on the macromolecule. For such cases it is necessary to employ kinetics which would consider the yield to be a sum of the products associated with and those dissociated from the catalyst. This paper derives and appraises a rate equation for cases of such nature.

The investigated reaction scheme is identical with the ordered ternary complex mechanism for enzyme systems. Recently, the rate equation for this system was derived (3) by use of the Laplace–Carson transformation and, consequently, the result is quite complex. It would be useful to have a simpler kinetic equation and the analysis of the conditions for which it is valid. This work employs the steady-state and equilibrium approximations to derive the combined transient-state and steady-state rate equation for the scheme.

Derivation of the Rate Equation

The derivation is based on the following scheme.

[1]



[1]Present address: 1255 Brydges Street, P.O. Box 2484, Terminal A, London, Ontario N5W 2C2.

In the foregoing reactions: C is a catalyst; A is a substrate able to complex with catalyst C; CA is a binary complex between catalyst C and substrate A; B is a substrate unable to complex with catalyst C, and able to complex with CA; CAB is a ternary complex among catalyst C, substrate A, and substrate B; CP is a product associated with catalyst C; P is a product dissociated from catalyst C; K_1 is an equilibrium constant; and k_i are rate constants for corresponding reactions. In the scheme, reaction 1 is a fast preequilibrium which controls the concentration of CA at any instant.

The yield of the reaction, Y, is defined by eq. 2.

$$[2] \qquad [Y] = [CP] + [P]$$

Two approximations had to be made in order to derive the rate equation. First, the steady-state treatment was applied to the concentration of the ternary complex, as is shown by eqs. 3 and 4.

$$[3] \quad d[CAB]/dt = k_2[CA][B] - (k_{-2} + k_3)[CAB] = 0$$

$$[4] \qquad [CAB] = k_2[CA][B]/(k_{-2} + k_3)$$

Second, the concentrations of the substrates, A and B, were treated as constants equal to the initial concentrations. In practice it means that the two components are in concentration excess over the catalyst.

$$[A]_0, [B]_0 \gg [C]_0$$

so that

$$[5] \qquad [A] \simeq [A]_0 \text{ and } [B] \simeq [B]_0$$

Both approximations are assessed in the following chapters and the kinetic and concentration conditions under which the final rate equation is valid are discussed.

The rate equation is derived as follows. Combining the conservation equation for the catalyst

$$[6] \quad [C]_0 = [C] + [CA] + [CAB] + [CP]$$

with the equilibrium constant K_1

$$[7] \qquad K_1 = [CA]/[C][A]$$

and eq. 4 (under condition 5), the instantaneous concentration of CAB can be expressed by the following form.

$$[8] \qquad [CAB] = R([C]_0 - [CP])$$

where

$$[9] \quad R = QK_1[A]_0/(1 + K_1[A]_0 + QK_1[A]_0)$$

and

$$[10] \qquad Q = [B]_0 k_2/(k_{-2} + k_3)$$

In order to find [CAB] as a function of time, [CP] must be expressed as a function of time.

$$[11] \qquad d[CP]/dt = k_3[CAB] - k_4[CP]$$

Substitution for [CAB] from eq. 8 into eq. 11 yields

$$[12] \quad d[CP]/dt = k_3R[C]_0 - (k_3R + k_4)[CP]$$

Equation 12 may be integrated to give

$$[13] \qquad [CP] = [1 - \exp(-G_2t)]G_1/G_2$$

where

$$[14] \qquad G_1 = k_3R[C]_0$$

$$[15] \qquad G_2 = k_3R + k_4$$

From eq. 2 it follows that

$$[16] \qquad d[Y]/dt = d[CP]/dt + d[P]/dt$$

and

$$[17] \qquad d[Y]/dt = k_3[CAB]$$

Combination of eqs. 8, 13, and 17 leads to

$$[18] \quad d[Y]/dt = k_3R[C]_0 - k_3RG_1/G_2 + k_3R\exp(-G_2t)G_1/G_2$$

This integrates to a rate equation

$$[19] \qquad [Y] = Et + F(1 - \exp(-G_2t))$$

where

$$[20] \qquad E = k_3R([C]_0 - G_1/G_2)$$

$$[21] \qquad F = k_3R\,G_1/G_2^2$$

It should be pointed out that eq. 19 has been derived for a low concentration of catalyst, for the first order conversion of CAB into CP, and that the steady-state approximation was applied.

Assessment of the Approximations in the Kinetics

The mathematical solution of the reaction scheme is based on the approximation of a steady-state concentration of CAB and the applicability of initial concentrations of the two substrates over a range of conversion. The limits imposed on the validity of the solution by the approximations will now be investigated.

A pair of yield/time curves was constructed

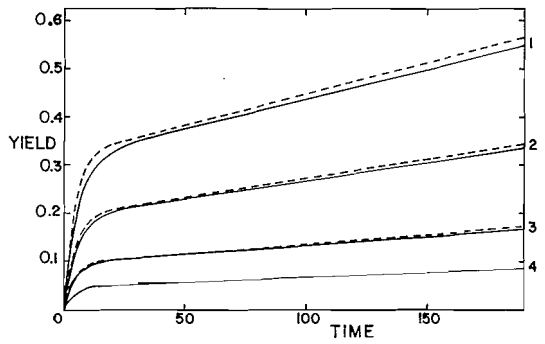

FIG. 1. Effect of conversion on applicability of eq. 19. (---) eq. 19; (—) exact solution: (1) $[C]_0/[A]_0 = 1/3$; (2) 1/5; (3) 1/10; (4) 1/20. Calculated for $[A]_0 = 1$, $[B]_0 = 1$, $k_1 = 8$, $k_{-1} = 4$; $k_2 = 0.4$, $k_{-2} = 0.4$, $k_3 = 4$, $k_4 = 0.004$.

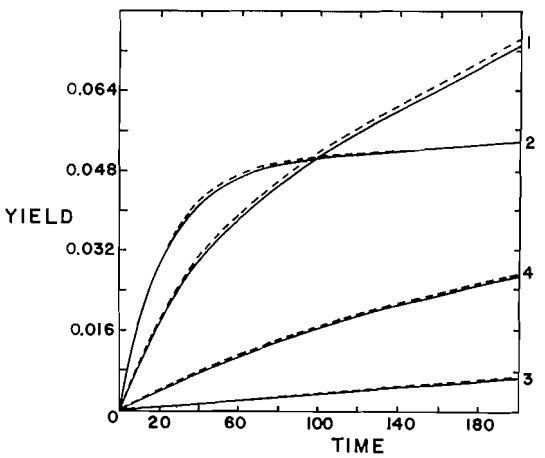

FIG. 2. Effect of relative magnitudes of k_2, k_{-2}, and k_3 on applicability of eq. 19. (---) eq. 19; (—) exact solution. See Table 1.

from a simulated set of concentration and rate parameters. One curve of the pair was calculated by means of eq. 19. The other curve was calculated by means of a fourth order Runge–Kutta numerical method (4) from a set of differential equations describing the reaction scheme and it does not involve any of the approximations.

The effect of the extent of conversion on the validity of results obtained by eq. 19 is demonstrated by Fig. 1. The reading from, *e.g.*, curve 4 shows a relative error of 7% at conversion of 2.3% B, and less than 1% error at conversion of 4.6% B.

Various ratios of the component concentrations were employed as these are also expected

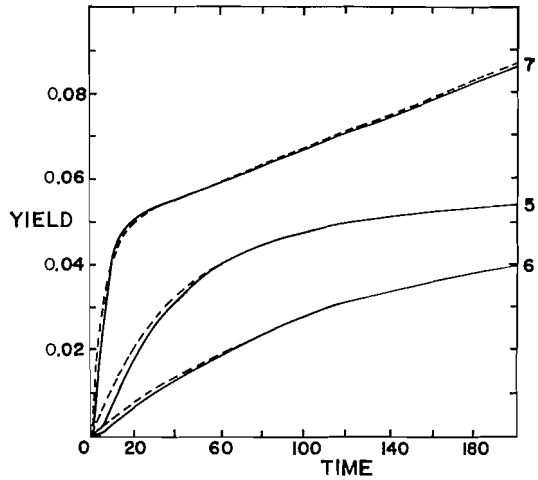

FIG. 3. Effect of relative magnitudes of k_2, k_{-2}, and k_3 on applicability of eq. 19. (---) eq. 19; (—) exact solution. See Table 1.

to affect the constancy of [A] and [B] during reaction. At conversion of 5% B, a ratio 1/3 of $[C]_0/[A]_0$ yields a relative error of 44.0%, 1/5 yields 24.2% error, 1/10 gives 8.1% error, and 1/20 yields 0.5% relative error. (The rate constants used in the simulation of the curves were chosen to satisfy the steady-state approximation and therefore eliminate any deviation due to the late attainment of a steady-state concentration of CAB. The constants also satisfied the assumed rapid attainment of equilibrium 1.)

The effect of the kinetic conditions on the validity of results is demonstrated in Figs. 2 and 3. The approximate and exact solutions were simulated for the following combinations of rate constants (L and S are large and small numbers, respectively; the ratio L/S is 100).

Combination	k_2	k_{-2}	k_3
1	S	L	L
2	S	S	L
3	S	L	S
4	L	L	S
5	S	S	S
6	L	S	S
7	L	S	L

Although other parameters may influence the rate of reaction, these three rate constants are sufficient to define the attainment of the steady state. The constants and concentrations employed

TABLE 1. Parameters used in the simulation*

Code	k_1	k_{-1}	k_2	k_{-2}	k_3	k_4
1	5	0.5	0.05	5	5	0.005
2	5	0.5	0.05	0.05	5	0.0005
3	8	0.8	0.08	8	0.08	0.0008
4	8	4	1	1	0.01	0.0001
5	8	0.8	0.08	0.08	0.08	0.0008
6	8	4	0.8	0.008	0.008	0.0008
7	8	4	0.4	0.004	0.4	0.004

*$[C]_0 = 0.05$; $[A]_0 = 1$; $[B]_0 = 1$.

for the simulation of the curves are summarized in Table 1. The number of the curve indicates an *L–S* combination for k_2, k_{-2}, and k_3, as listed above. Combinations 1, 2, and 3 (Fig. 2, lines 1, 2, and 3, respectively) satisfy the steady-state approximation and, as expected, the approximated and exact solutions are in good accord. Although the conversion region covered by line 3 is small, the calculations indicate good agreement as a non-steady state phenomenon would have been indicated at the beginning of the reaction. Similarly, a good fit is found for the fourth combination of rate constants, the fast pre-equilibrium condition (line 4). However, for the other three possible conditions, 5, 6, and 7 (Fig. 3, lines 5, 6, and 7) a discrepancy is evident at low conversion.

Conclusion

The reaction scheme for the special case of a catalyzed reaction in which the ultimate and penultimate products cannot be discriminated can be investigated kinetically best when the substrates are in a concentration excess over the catalyst. When the kinetic conditions are such that the steady-state approximation is justified, a twenty-fold excess of the substrates over the catalyst appears to be enough for the yield of reaction to be represented by eq. 19 with less than 1% relative error when the conversion of the substrates has attained 4.6%. However, even for $[C]_0/[A]_0$ ratios as large as 1/5 the kinetic equation derived remains a fairly good approximation.

I wish to thank Dr. B. L. Funt for his constructive and stimulating comments on this work. The helpful suggestions of one of the referees of this article also are gratefully acknowledged.

^{1}H, ^{13}C, ^{14}N, ^{19}F Nuclear Magnetic Resonance Contact Shifts and Electron Spin Distribution in Aniline and Fluoroanilines – Ni(II) Acetylacetonate Complexes

C. CHACHATY, A. FORCHIONI, AND J. VIRLET

Service de Chimie Physique, CEN de Saclay, B.P. n°2, 91190, Gif-sur-Yvette, France

Received July 4, 1974

C. CHACHATY, A. FORCHIONI, and J. VIRLET. Can. J. Chem. **53**, 648 (1975).

The contact shifts of ^{1}H, ^{13}C, ^{14}N, and ^{19}F in chloroform solutions of Ni(II) acetylacetonate – aniline and fluoraniline complexes have been studied by high resolution n.m.r. The unpaired electron spin distribution in these ligands is compared to that calculated by the INDO method for the corresponding aniline cation radicals. The ratio of the hyperfine coupling constants a_{NH}^{H}/a_{N} suggests that in these aniline complexes the $C_1—N\langle^{H}_{H}$ fragment is pyramidal with an angle of 13–15° between the perpendicular of the C—N bond and the axis of the p like orbital centered on nitrogen. The electron spin distribution between the NH_2 group and the phenyl ring may be partially accounted for by assuming an internal rotation about the C—N bond. The ^{13}C relaxation indicates a N—Ni distance of the order of 2 Å for aniline and 2 fluoraniline complexes and an electron spin–lattice relaxation time of $\sim 5 \times 10^{-10}$ s at 300 °K.

C. CHACHATY, A. FORCHIONI et J. VIRLET. Can. J. Chem. **53**, 648 (1975).

Les déplacements de contact de ^{1}H, ^{13}C, ^{14}N et ^{19}F dans les complexes d'acétylacétonate de nickel avec l'aniline et les fluoranilines en solution dans $CHCl_3$, ont été étudiés par r.m.n. haute résolution. La répartition de la densité de spin dans ces ligands est comparée à celle calculée par la méthode INDO pour les radicaux cations correspondants. Le rapport des constantes de couplage a_{NH}^{H}/a_{N} suggère que dans ces complexes d'anilines, le fragment $C_1—N\langle^{H}_{H}$ est pyramidal avec un angle de 13 à 15° entre la normale à la liaison C—N et l'axe de l'orbitale p centrée sur l'azote. La répartition de la densité de spin entre le groupe NH_2 et le cycle aromatique peut être expliquée en partie par une rotation interne autour de la liaison C—N. La relaxation des carbones 13 indique une distance azote–nickel de l'ordre de 2 Å pour l'aniline et la 2 fluoraniline ainsi qu'un temps de relaxation électronique voisin de 5×10^{-10} s à 300 °K.

Introduction

In some coordination complexes of paramagnetic transition ions, the delocalization of the unpaired spin into the ligand σ and π orbitals may be determined from n.m.r. contact shifts if the pseudocontact contribution is negligible (1, 2). It is generally assumed that this condition is fulfilled in the case of Ni(II) aminotroponeiminate (3, 4) and for Ni(II) acetylacetonate ($Ni(AA)_2$) complexes with pyridine like compounds (5–7) and aliphatic (7, 8) or aromatic (6, 8–10) amines. The $Ni(AA)_2$ aniline complex has been studied by proton (9, 10), ^{14}N (8) and ^{13}C (6) n.m.r. spectroscopy. It has been shown that the unpaired spin density is delocalized into the aniline π system and that its distribution on the phenyl ring is somewhat similar to that observed in the case of the benzyl radical, isoelectronic with the $C_6H_5—\dot{N}H_2^{+}$ cation radical (6). The similarity between the electronic structure of the ligand part of some coordination complexes and that of related free radicals which may be studied by electron spin resonance (e.s.r.) is interesting since subsidiary information may be provided by n.m.r., particularly the sign and magnitude of the hyperfine coupling parameters. The Fourier transform n.m.r. is also very convenient for the observation of ^{13}C in natural abundance and the study of its hyperfine coupling, which is difficult to determine by e.s.r., unless a well resolved spectrum is obtained with a high signal-to-noise ratio.

In this work we intend to study the correlation between the contact shifts of the different nuclei (^{13}C, ^{1}H, ^{14}N, ^{19}F) of aniline and its fluorinated homologs, complexed with Ni(II) acetylace-

For personal use only.

tonate in order to determine the spin density distribution in these ligands and to obtain some information about the hybridization state of nitrogen in the amino group. For that purpose, the experimental data will be compared to the theoretical ones calculated by the INDO method (11) for several possible configurations of the aniline radical cation chosen as a model. This work will be completed by a ^{13}C relaxation time study of the complex aniline and 2F-aniline with $Ni(AA)_2$ and the ligand-to-metal distance will be estimated.

Experimental

The ^1H n.m.r. measurements have been carried out at 250 MHz with a Cameca TSN 250 spectrometer, with some experiments at 60 MHz (Varian T60 or NV14). The ^{13}C and ^{19}F spectra were recorded with a Varian XL 100 12-WG spectrometer operating at 25.15 MHz (^{13}C in Fourier transform) or 94.1 MHz (^{19}F). The ^{13}C spin–lattice relaxation time was measured by the inversion recovery method using the pulse sequences . . . 90° ∞, $T \gg T_1$, 180°, t, 90° . . . (12). ^{14}N contact shift measurements were carried out with a pulsed n.m.r. spectrometer, operating at 4.35 MHz, designed by one of us (J.V.). Solutions of anilines in $CDCl_3$ (20 to 50% v/v) were dried on molecular sieve before addition of $Ni(AA)_2$. The contact shifts were measured for $[Ni(AA)_2]/[aniline]$ ratios of 0.001 to 0.01. In this range the shift variation is linear, indicating a complete complexation of $Ni(AA)_2$ by aniline.

The electron g value for $Ni(AA)_2$, $(aniline)_2$ complexes was determined from relative paramagnetic susceptibility measurements by n.m.r. The shift of the solvent peak ($CHCl_3$) in the presence of the complexes, with respect to TMS contained in a coaxial tube was compared to the shift observed with a known concentration of a reference paramagnetic compound such as diphenylpicrylhydrazyl ($g = 2.0036$, $S = \frac{1}{2}$) and copper diethylthiocarbamate ($g = 2.0486$, $S = \frac{1}{2}$). The g value of the complex was given by the ratio

$$[1] \qquad \frac{\vartheta - \vartheta_0}{\vartheta_{ref} - \vartheta_0} = \frac{C_{complex}}{C_{ref}} \frac{S'(S'+1)g_{complex}^2}{S(S+1)g_{ref}^2}$$

where ϑ and ϑ_{ref} are the shift observed in the presence of a paramagnetic solute, ϑ_0 the solvent shift, C the solute concentration, S' the total electron spin = 1 for the Ni(II) complexes in question.

Results and Discussion

Hyperfine Coupling Constants and Spin Densities

The relationship between the hyperfine coupling of a nucleus i and its contact shift is (13, 14)

$$[2] \qquad \frac{\Delta H}{H_0} = -a_i \frac{g_e^2 \beta_e^2 S(S+1)}{g_i \beta_n 3kT} pq$$

where a_i is expressed in G, g_e and g_i being the electron and nuclear g factor, β_e the Bohr magneton, and β_n the nuclear magneton. For $Ni(AA)_2$, $(aniline)_2$ complexes the total electron spin is $S = 1$ and $g_e = 2.2 \pm 0.1$. p is the ratio $[Ni(AA)_2]/[aniline]$ and q the number of coordinated anilines equal to 2. For all nuclei under study $g_i > 0$ and a downfield or upfield contact shift will be observed according to a_i being positive or negative.

Assuming that in the ligand the unpaired electron spin is delocalized through the π orbitals of the phenyl ring, the spin density on the carbon of a C—H fragment will be given by

$$[3] \qquad a_{CH}^H = \tfrac{1}{2} Q_{CH}^H \rho_C^\pi$$

with $Q_{CH}^H = -27$ G as in the case of benzyl type radicals. In this equation and the following ones, the factor $\frac{1}{2}$ corresponds to $S = 1$ (ref. 2, chapt. III, pp. 93 and 97).

The hyperfine coupling constants of atoms bearing a fraction of the π spin density, such as ^{13}C, ^{14}N, or ^{19}F are given by the general relation of Karplus and Fraenkel (15) which may be represented in the simplified form

$$[4] \qquad a_i^x = \tfrac{1}{2}\left(Q_1^x \rho_{x_i}^\pi + \sum_j Q_2^y \rho_{y_j}^\pi \right)$$

where y_j is a nucleus adjacent to x_i. The parameter Q_1^x may be dependent on the nature of y_j. For a C···C···C fragment (with H on the central C), the constants $Q_1^C = +35.6$ G and $Q_2^C = -13.9$ G given in ref. 15 are often used.

A great deal of work has been carried out on the problem of fluorine hyperfine coupling in π electron radicals and several values have been proposed for the relevant σ–π parameters (16) in eq. 4. It seems however that the ^{19}F hyperfine coupling constant may be given with sufficient accuracy by the simple equation (16*f*)

$$[5] \qquad a^F = \tfrac{1}{2} Q_{eff}^F \rho_C^\pi$$

which may be useful to determine the spin density on carbons in the case of highly fluorine substituted radicals or ligands. In the present work, Q_{eff}^F will be deduced from ρ_C^π values given by eq. 4. The hyperfine coupling constant of nitrogen depends on its hybridization state and is given by the relation (17, 18)

$$[6] \qquad a_N = \tfrac{1}{2}[Q_N^0 + 550 \times 2\mathrm{tg}^2 \varphi]\rho_N^\pi$$

where φ represents the angle between the perpendicular to the C_1—N bond and the axis of

TABLE 2. ^{13}C chemical shifts in fluorinated anilines (in p.p.m. from TMS, in $CDCl_3$ at 30 °C)

Compound	Chemical shift					
	C_1	C_2	C_3	C_4	C_5	C_6
2 fluoraniline	134.8	151.9	115.3	118.6	124.6	117.1
3 fluoraniline	148.7	101.8	163.8	104.6	130.4	110.7
4 fluoraniline	142.7	115.9	115.4	156.2	115.4	115.9
2-4-6 trifluoraniline	120.9	151.9	100.0	154.2	100.0	151.9
Pentafluoraniline	122.5	137.2	138.4	133.8	138.4	137.2

the p like orbital centered on nitrogen. Q_N^0 has been taken equal to +35 G in analogy with nitrogen containing cation radicals (19). The ratio a_{NH}^H/a_N depends linearly upon φ between 4 and 16° and is given in this range, by the relation

$$[7] \qquad a_{NH}^H/a_N = -1.32 + 0.072\,\varphi$$

This equation has been derived from INDO calculations on the aniline cation radical using the internuclear distances given in ref. 11. For the two limiting cases $\varphi = 0$ (sp^2 nitrogen) and $\varphi = 19.5°$ (sp^3 nitrogen) where eq. 7 is not valid, INDO calculations give respectively $a_{NH}^H/a_N = -1.14$ in good agreement with e.s.r. data (19) and $a_{NH}^H/a_N = -0.02$.

It will be shown that the spin density on carbon 1 is much smaller in absolute value than ρ_N^π so that its contribution by spin polarization to a_N (relation 4) and by hyperconjugation to a_{NH}^H may be neglected.

The hyperfine coupling constants measured from contact shifts are given in Table 1. The analysis of the proton magnetic resonance of 2, 3, and 4 fluoranilines, giving the chemical shifts of free ligands has been published elsewhere (20). The ^{13}C chemical shifts of fluoranilines under study are given in Table 2.

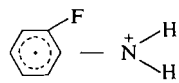
The ^{13}C hyperfine coupling parameters for complexed aniline and 2 fluoraniline, which include at least four successive —CH— fragments have been calculated from the system

$$[8] \qquad a_3^C = \tfrac{1}{2}[Q_1\,\rho_3 + Q_2\,(\rho_2 + \rho_4)]$$
$$a_4^C = \tfrac{1}{2}[Q_1\,\rho_4 + Q_2\,(\rho_3 + \rho_5)]$$

ρ_2 or ρ_6, ρ_3 or ρ_5, and ρ_4 being given by the corresponding value of a_{CH}^H (relation 3). Thus we get $Q_1 = 34.6$ G, $Q_2 = -12.0$ G for aniline, $Q_1 = 37.4$ G, $Q_2 = -12.8$ G for 2 fluoraniline, in close agreement with the values given in ref. 15, which will be used throughout this work for the calculations of spin densities from ^{13}C contact shifts. This result suggests that the delocalization of the electron spin occurs only through the ring π system and that the contribution of the ligand or metal centered pseudocontact shift is negligible for the ^{13}C.

The agreement between the spin densities calculated from several relations derived from eqs. 3 and 4 may be appraised on the example of the 2-fluoraniline complex (Table 3). It may be expected that relations 19 and 20 of table 3 providing a straightforward determination of ρ_C^π will give the most accurate results, but their use is restricted to a carbon bound to a proton or to a —CH=CH=CH— fragment.

The determination of ρ_1, may be done only by relation 21 since the value of the parameter Q_2^y of eq. 4 relative to the nitrogen is not accurately known. The discrepancy between the ρ_2 value deduced from eqs. 20′ and 21 may also be pointed out in Table 3. The value $\rho_2 = 0.0043$ seems the most likely since it is close to ρ_6 as expected from INDO calculation on the cation radical



The parameter Q_{eff}^F of eq. 5 has been estimated for the $Ni(AA)_2$ fluoraniline complexes, from the ratio $2a^F/\rho_C^\pi$, ρ_C^π being given by one of the relations of Table 3. It has been found that $Q_{eff}^F = 51 \pm 3$ G, in satisfactory agreement with the value previously determined by e.s.r. fluoroaromatic radicals which are in the range of 53 to 57 G (16*e*, *f*, *g*). It may be seen on the example of 2- and 3-fluoraniline complexes that the substitution of a proton by fluorine does not introduce a noticeable change in the spin density on the adjacent carbon (Table 4) and that $Q_{eff}^F \sim -2Q_{CH}^H$. On the other hand the total spin density on each aniline of the $Ni(AA)_2$-$(aniline)_2$ complex decreases almost linearly with

the number of fluorines showing an important effect of this substituent on the electron donor properties of aniline with respect to $Ni(AA)_2$ (Table 4). The Q_1 and Q_2 parameters of eq. 4, which have been given above for a C═CH═C fragment may be different for a C═CF═C fragment. Equation 8, together with $Q_{eff}^F = 51$ G, gives $Q_1 = 41.1$ G, $Q_2 = -10.1$ G for the penta fluoraniline complex, not so different therefore from the values determined for aniline and 2-fluoraniline in the case of a C═CH═C fragment ($Q_1 = 36$ G, $Q_2 = -12.4$ G).

The large downfield shifts observed for ^{14}N might be due in part to the pseudocontact effect arising from the vicinity of the metal ion or from the spin density in the nitrogen centered p like orbital (21). Such a contribution seems difficult to estimate without a precise knowledge of the geometry and electronic configuration of the whole complex. We shall therefore consider tentatively that the observed shifts result mainly from the Fermi contact interaction and verify the likelihood of this assumption.

The ratios a_{NH}^H/a_N of all the anilines under study (Table 1) fall between -0.2 and -0.3 and correspond therefore to an angle φ of the order of 14–16° (eq. 7).

It has been shown by microwave spectroscopy (22) (see also (23)) that for aniline, the angle φ is approximately equal to 13° in good agreement with our estimate from a_{NH}^H/a_N, suggesting that its configuration remains almost unchanged upon complexation. This conclusion may likely be extended to the fluoranilines under study. The differences between the values given in Table 4 for this angle are not very significant owing to the moderate accuracy of ^{14}N shift measurements ($\pm 10\%$).

The spin densities on nitrogen given in Table 4 have been calculated from eqs. 6 and 7 assuming only an isotropic contact shift. A contribution of the dipolar shift would lead to an overestimate of a_N and then to a smaller actual value of φ in the range of 0 to 15°. However, without knowing this angle, ρ_N^π may still be estimated from a_{NH}^H only, with a proportionality constant Q_{NH}^H between -32 and -42 G. These calculations show that 80–90% of the π spin density in complexed anilines is localized on nitrogen. The different experimental values obtained for ρ_N^π, ρ_{1C}^π and a_1^C indicate also that the parameter Q_2^N of eq. 3 (or Q_{NC}^C in the original notation (15) is equal to -3.5 ± 1.7 G).

On the other hand, INDO calculations, carried out on $C_6H_5\dot{N}H_2^+$ and its fluorinated homologs indicate that only 50–60% of the spin density is located on nitrogen in the sp^3 or sp^2 configuration, this last being energetically favorable. A recent e.s.r. work on $C_6H_5\dot{N}H_2^+$ (24) shows that this radical is actually planar with an almost equal distribution of the spin density between C_6H_5 and NH_2. The model of a radical anion, which could be alternatively considered (25), leads to a spin distribution completely inconsistent with our experimental data. The same is likely true for an hybrid of cation and anion radicals (26).

The contribution of metal orbitals (26), although difficult to estimate, could eventually account for the large difference observed between the spin densities localized on the two moities of the ligand. It may be pointed out however that the INDO calculations performed on the aniline cation radical, assuming the configuration of the amino group to be nearly the same as that in free aniline, gives a reasonable agreement with the experimental value of a_{NH}^H/a_N and with the spin distribution in the phenyl ring. We may therefore tentatively assume that the sharing of the spin density between the amino and phenyl groups results at least in part from an internal rotation about the C—N bond restricting the conjugation between these two fragments, as suggested by the example of the *p*-aminophenoxy radical reported by Stone and Carrington (27). The corresponding potential barrier calculated by INDO for $C_6H_5\dot{N}H_2^+$ is 17 kcal/mol against 6 kcal/mol for free aniline. Table 4 shows that in the complex, each aniline ligand bears less than 5% of the total spin density so that its configuration may be compared to free aniline rather than to the cation radical. This point is supported also by the estimate from eq. 7, of the configuration of the amino group in the complex, and the internal rotation about C—N seems therefore likely.

The influence of an internal rotation about C—N on the nitrogen and proton hyperfine couplings has been calculated by INDO for several values of the angle φ, on the example of C_6H_5—$\dot{N}H_2^+$. Figure 2 shows that the ratio a_{NH}^H/a_N is not very dependent upon the twist angle θ around this bond so that a_{NH}^H remains nearly proportional to ρ_N^π. It may be assumed likewise that $\sum a_{CH}^H$ is proportional to the total π spin density on the ring so that the ratio

For personal use only.

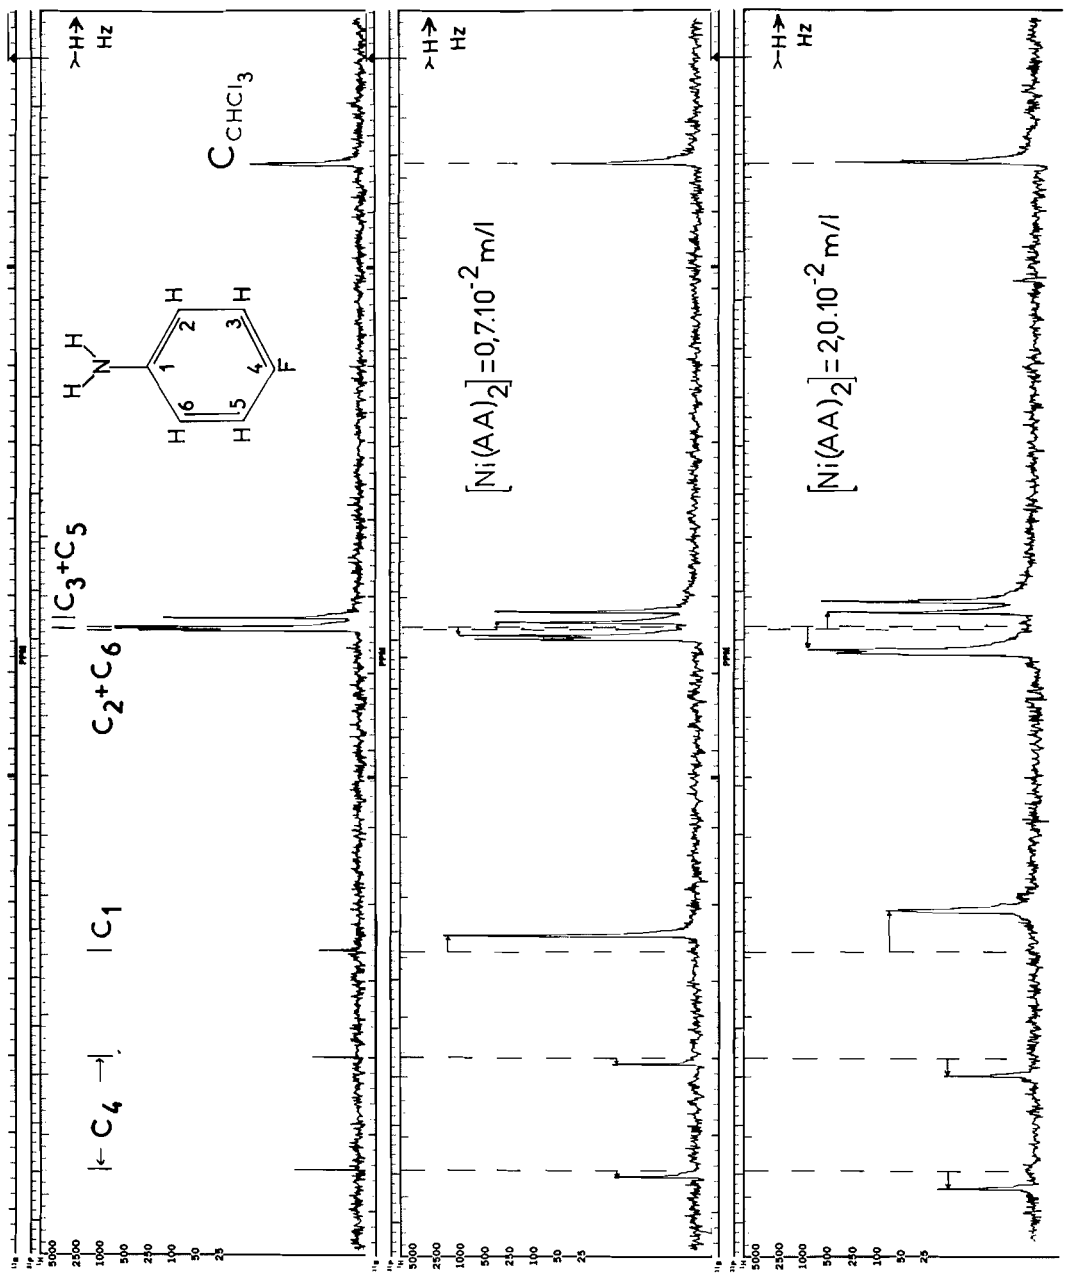

FIG. 1. Influence of the $Ni(AA)_2$ concentration upon the ^{13}C n.m.r. spectrum of a 30% chloroform solution of 4-fluoraniline.

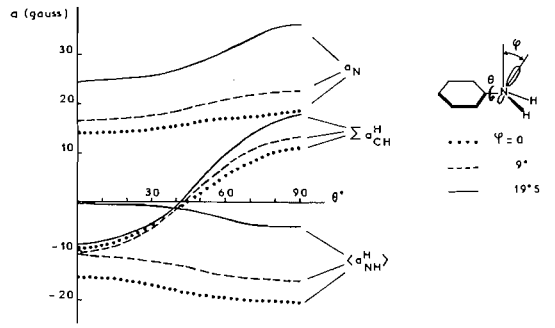

FIG. 2. Dependence of proton and nitrogen hyperfine coupling constants upon the twist angle θ around the C—N bond in the aniline cation radical, computed by INDO for different configuration of the amino group.

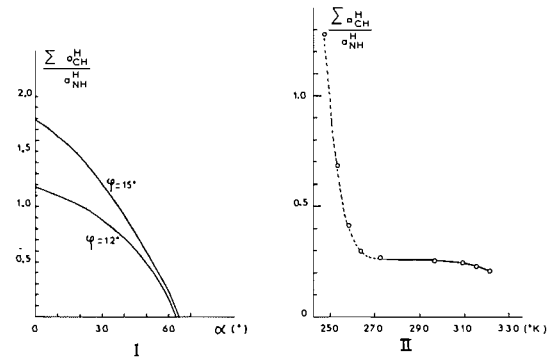

FIG. 3. (*I*) Computed dependence of $\Sigma a_{CH}{}^H/a_{NH}{}^H$ upon an internal harmonic oscillation of amplitude α, about the CN bond of $C_6H_5\dot{N}\overset{+}{H}_2$ for two possible configurations of the amino group. (*II*) Observed temperature dependence of this ratio in the case of the $Ni(AA)_2$, $(aniline)_2$ complex. The dotted line corresponds to the intermediate and slow exchange of the ligand.

$\Sigma a_{CH}{}^H/a_{NH}{}^H$ is a good criterion to estimate the spin density distribution between the ring and amino group in complexed anilines. The average of this ratio, calculated as a function of the amplitude α of an internal harmonic oscillation about $\theta = 0$ for the two boundary values expected for the angle φ (Fig. 3*I*) has been compared with the experimental data. In the temperature range of 275 to 320 °K the ratio $a_{NH}{}^H/a_N$ obtained with the aniline complex is consistent with an oscillation amplitude of 50–60° (Fig. 3*II*). Below 273 °K this ratio increases beyond the limits expected from INDO calculations. This apparent discrepancy may be attributed to a decrease of the exchange rate between the complex and the free ligand, since the contact shift of ring protons diminishes in turn below 240–250 °K to cancel out at ~230 °K (Fig. 4). The variation of $a_{NH}{}^H$ with temperature shows three characteristic domains according to the value of the exchange rate $1/\tau_h$ with respect to the difference $\Delta\omega_M$ in the resonance frequencies of the free ligand and the complex; above 280 °K, in the fast exchange region ($1/\tau_h \gg \Delta\omega_M$), the contact shifts varies as $1/T$. In the slow exchange region ($1/\tau_h \ll \Delta\omega_M$), below 240 °K, the resonance of the free ligand and that of the complex should be observed separately, but this last is undetectable on account of the low concentration of the complex and the line broadening. In the intermediate region (240 to 270 °K) $1/\tau_h$ becomes the same order of magnitude as $\Delta\omega_M$ and the linewidth passes through a maximum. Under these last conditions, the exchange rate may be calculated from eq. 9 (28):

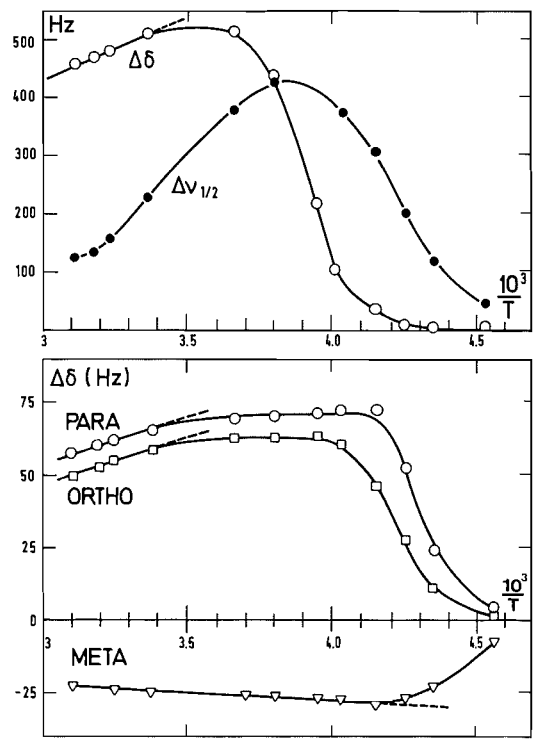

FIG. 4. Temperature dependence of the contact shift of NH_2 protons (upper diagram) and ring protons (lower diagram) for a ratio $[Ni(AA)_2]/[aniline]$ of $\sim 5 \times 10^{-3}$. $\Delta\nu_{1/2}$ is the linewidth of the resonance of NH_2 protons. The upfield shifts are counted positive on the vertical scale.

$$[9]\quad \Delta\omega = pq\frac{\Delta\omega_M}{\tau_h^2\left[\left(\frac{1}{T_{2M}}+\frac{1}{\tau_h}\right)^2+\Delta\omega_M^2\right]}$$

where $\Delta\omega$ is the observed shift and T_{2M} the nuclear transverse relaxation time in the complex, deduced from the linewidth ($1/T_{2M} = \pi\Delta\nu/pq$). $\Delta\omega_M$ is determined in the fast exchange region and introduced in eq. 9 after correction from Curie's law. In the temperature range of 240 to 320 °K, the exchange rate varies from 10^5 to 10^7 s^{-1} with an activation enthalpy $\Delta H^{\neq} = 12$ kcal/mol and an activation free energy $\Delta G^{\neq} = 9$ kcal/mol (Fig. 5).

^{13}C Relaxation

The T_1 and T_2 nuclear relaxation times in paramagnetic complexes are dependent upon the contact (29) and dipolar (30) hyperfine interactions. This last results from the local spin density and from the spin density localized on the metal giving therefore information on the internuclear distances. These two relaxation times are given by the relations (31):

$$[10a]\quad \frac{1}{T_{1M}} = \frac{2}{15}S(S+1)B^2\left(3\tau_c+\frac{7\tau_c}{1+\omega_e^2\tau_c^2}\right)+\frac{2}{3}S(S+1)A^2\frac{\tau_e}{1+\omega_e^2\tau_e^2}$$

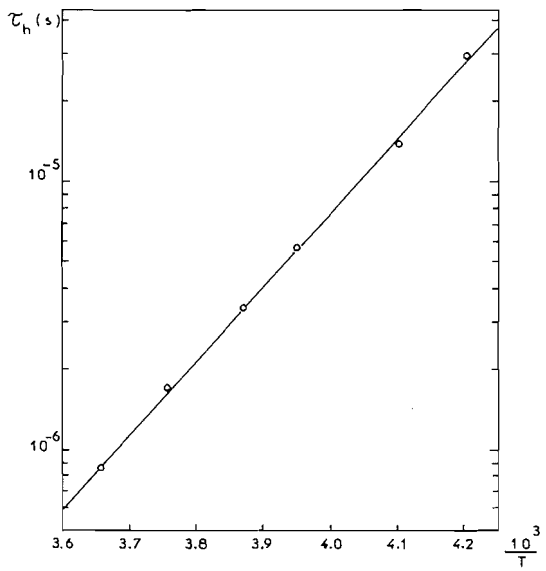

FIG. 5. Arrhenius plot of the residence time τ_h of aniline in the Ni(II) coordination sphere.

$$[10b]\quad \frac{1}{T_{2M}} = \frac{1}{15}S(S+1)B^2\left(7\tau_c+\frac{13\tau_c}{1+\omega_e^2\tau_c^2}\right)+\frac{1}{3}S(S+1)A^2\left(\tau_e+\frac{\tau_e}{1+\omega_e^2\tau_e^2}\right)$$

where T_{1M} and T_{2M} are the spin–lattice and spin–spin ^{13}C relaxation times in the complex, ω_e the Larmor frequency of the electron (4.54×10^{11} rad s^{-1} for a magnetic field of 23.5 kG and $g_e = 2.2$). A and B are the contact and dipolar hyperfine couplings in radians s^{-1}. T_{1M} and T_{2M} are deduced from the observed relaxation times by

$$[11]\quad \frac{1}{T_{1exp}} = (1-pq)\frac{1}{T_{1L}}+pq\frac{1}{T_{1M}}$$

or the similar expression for T_{2exp} which is given by the linewidth, T_{1L} or T_{2L} being the relaxation times of the free ligands. The second term of eq. 11 is predominant and we have actually observed a linear dependence of the relaxation rates on the ratio [Ni(AA)$_2$]/[aniline]. The correlation times τ_c and τ_e related respectively to the dipolar and scalar couplings are given by

$$[12]\quad \tau_c^{-1} = \tau_R^{-1}+\tau_h^{-1}+T_{1e}^{-1}$$

$$[13]\quad \tau_e^{-1} = \tau_h^{-1}+T_{1e}^{-1}$$

τ_R is the reorientation correlation time of the complex, τ_h the residence time of the ligand in the Ni(II) coordination sphere, of the order of 10^{-7} s at 300 °K as it has been shown above, and T_{1e} the electron spin lattice relaxation time. It may be assumed that $\tau_h \gg T_{1e}, \tau_c$, so that the contribution of exchange rate may be neglected in eqs. 12 and 13. If T_{1e} is not smaller than 10^{-11} s, we have $\omega_e^2\tau_c^2$ and $\omega_e^2\tau_e^2 \gg 1$, τ_R being likely of the order of 5×10^{-11} to 5×10^{-10} s. The large difference observed between experimental values of T_{1M}^{-1} and T_{2M}^{-1} suggests that the contact term is negligible compared to the dipolar term in eq. 10*a* but not in eq. 10*b*, so that we may use the simplified expressions

$$[14a]\quad 1/T_{1M} = (4/5)B^2\tau_c$$

$$[14b]\quad 1/T_{2M} = (14/15)B^2\tau_c+(2/3)A^2\tau_e$$

A^2 is given by the coupling constants of Table 2. B^2 is the sum of the contribution of the dipolar

coupling between the spin density localized on Ni(II) and a carbon i located at the distance r_i

$$[15] \qquad B_1^2 = \frac{g_e^2 \beta_e^2 g_n^2 \beta_n^2}{\hbar^2 r_i^6}$$

and the contribution of the π spin density localized on C_i which for $S = 1$

$$[16] \qquad B_2^2 = \frac{b^2}{4}(\rho_i^{\pi})^2$$

b being the ^{13}C dipolar coupling constant for $\rho_c^{\pi} = 1$ estimated to 4.1×10^8 rad s^{-1} (32). The ρ_i^{π} are given in Table 4. Knowing the geometry of the ligand, the carbon-to-metal distances r_i and r_j may be calculated from the ratio

$$[17] \qquad \frac{(B_1^2 + B_2^2)_i}{(B_1^2 + B_2^2)_j} = \frac{(T_{1M})_j}{(T_{1M})_i}$$

r_i and r_j being expressed as a function of d(N—Ni) which is adjusted in order to satisfy eq. 17.

A more simple way is to seek for nitrogen-to-metal distance which gives the minimum standard deviation between the values of τ_c derived from the spin–lattice relaxation times of the different carbons (eqs. 14*a* and 14*b*). These calculations have been carried out assuming (*i*) that the nickel ion occupies an average position in the ring plane, (*ii*) that it is located along the axis of the lone pair atomic orbital centered on nitrogen as expected for a σ bonding (10), the angle φ defined above being taken equal to 14.5°, (*iii*) the same as (*ii*) with an harmonic oscillation of amplitude 60° of the ring around the C_1—N bond.

The plot of $\Delta\tau_c/\bar{\tau}_c$ against d(N—Ni) shown in Fig. 6, indicates that assumption (*i*) is the most convenient, giving moreover nitrogen-to-metal distances of 2.0 and 2.3 Å for aniline and 2 for fluoraniline respectively, consistent with X-ray studies of nickel–amine complexes (see for instance refs. 33 and 34).

The electron spin relaxation time T_{1e} deduced from eqs. 14*a* and 14*b* is of the order of 2×10^{-10} to 5×10^{-10} s at 300 °K and the reorientation correlation time $\tau_R = (\tau_c^{-1} - T_{1e}^{-1})^{-1}$ is found to be $\sim 3 \times 10^{-11}$ s for both ligands (Table 5). For a rigid structure of the complex, τ_R may be estimated from the Stokes–Einstein relation

$$[18] \qquad \tau_R = \frac{4\pi\eta R^3}{3kT}$$

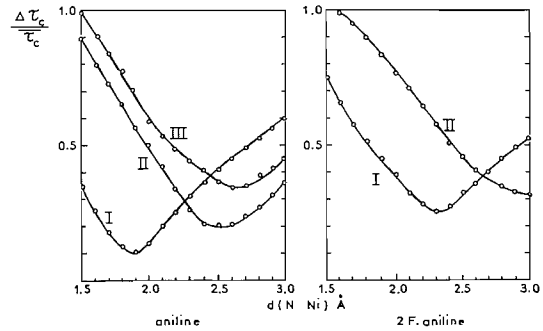

FIG. 6. Determination of the N—Ni distance from the relative deviation of τ_c deduced from the T_1 relaxation times of ring carbons curves *I*, *II*, and *III* correspond to the different assumption on the position of nickel relative to the phenyl ring.

which may be considered as valid for the complexes under study the molecular weights of which are nearly four times that of the solvent molecules (see for instance ref. 35).

For $\eta = 1.1 \times 10^{-2}$ P at 300 °K, a ratio aniline/chloroform of 1 v/v and a radius R of the equivalent sphere of the order of 5 Å, τ_R may be estimated to *ca.* 10^{-10} s. The much smaller experimental value of τ_R suggests that an additional motion of the ligand occurs in the nickel coordination sphere, which averages its position with respect to the ring plane, possibly the inversion of the C_1—N(H)(H) pyramid. A study in progress on other substituted anilines gives very similar results.

Conclusions

The hyperfine coupling parameters of ^{13}C and ^{19}F deduced from contact shift measurements an $Ni(AA)_2(aniline)_2$ complexes are found to be in close agreement with those provided by e.s.r., confirming that the delocalization of the unpaired spin on the phenyl ring may be safely compared to the case of aromatic π electron radicals. The measurement of the ratio of ^1H and ^{14}N hyperfine coupling constants in the amino group appears as a simple method to determine the hybridization state of nitrogen. This seems virtually unchanged upon complexation so that Ni(II) could provide valuable information on the conformation of other nitrogen containing molecules.

The study by Yonezawa *et al.* (36) of the ^1H

d(N—Ni)$_{II}$ (Å)	2.5	
d(N—Ni)$_{III}$ (Å)	2.6	

[a]Subscripts I, II, and III refer to the different assumption on the position of nickel relative to the ring plane.

pseudocontact shift in aniline – cobalt acetylacetonate complexes gave also a distance d(N—Co) ~ 2 Å and indicated a pyramidal conformation of the $C_1—N\begin{smallmatrix}H\\H\end{smallmatrix}$ in agreement with our study of ^{14}N and ^{1}H contact shifts in the amino group. The apparent discrepancy between the conclusions drawn from paramagnetic shift measurements and those derived from ^{13}C relaxation may be due to the fact that the former give information about the instantaneous metal and ligand relative positions whereas the latter gives the same information averaged over a long time interval, T_{1M} or T_{2M}, compared to the reorientation correlation time of the ligand in the coordination sphere. This interpretation is only tentative, ^{13}C relaxation measurements on aniline complexes with Gd $(DPM)_3$ are presently being carried out to verify this point.

The Application of a Simple Chemical Model of Natural Waters to Metal Fixation in Particulate Matter

ROBERT D. GUY, C. L. CHAKRABARTI,[1] AND LAURIER L. SCHRAMM

Department of Chemistry, Carleton University, Ottawa, Ontario K1S 5B6

Received August 15, 1974

ROBERT D. GUY, C. L. CHAKRABARTI, and LAURIER L. SCHRAMM. Can. J. Chem. **53**, 661 (1975).

A simple chemical model was used to investigate the mechanisms controlling the distribution of metals between soluble and particulate fractions in natural waters. The model particulates used were potassium bentonite, hydrous MnO_2, and solid humic acid. The soluble species in natural waters were modelled by soluble humic acid, tannic acid, and bicarbonate. The sorption curves for Cu(II), Cd(II), and Zn(II) onto humic acid and MnO_2 obeyed Langmuir adsorption isotherms whereas the sorption of the above ions onto bentonite followed a Freundlich isotherm. Chemical analysis of the total model using atomic absorption spectroscopy and differential pulse anodic stripping voltammetry indicated that copper distribution depends on the p*H* of the suspension: above p*H* 6.0, 50% of the copper is sorbed onto the particulates whereas the copper in solution is in a complexed form; between p*H* 6 and 3.8 the soluble copper is distributed between organic complexes and "free" copper ion; between p*H* 4.2 to 2.5 copper is being desorbed from the particulates; and below p*H* 2.5 all the copper is present in solution as "free" copper ion.

ROBERT D. GUY, C. L. CHAKRABARTI et LAURIER L. SCHRAMM. Can. J. Chem. **53**, 661 (1975).

On a utilisé un modèle chimique simple pour étudier les mécanismes contrôlant la distribution des métaux entre les fractions solubles et particulaires des eaux naturelles. On a utilisé le bentonite de potassium, le MnO_2 hydraté et l'acide humique solide comme modèles de particule. Les espèces solubles dans les eaux naturelles étaient représentées par l'acide humique soluble, l'acide tannique et le bicarbonate. Les courbes de sorption du Cu(II), Cd(II) et Zn(II) sur l'acide humique et le MnO_2 obéissent aux isothermes d'adsorption de Langmuir alors que la sorption des ions mentionnés plus haut sur la bentonite suit une isotherme de Freundlich. L'analyse chimique du modèle total, utilisant la spectroscopie d'absorption atomique et la redissolution anodique par impulsions différentielles indique que la distribution du cuivre dépend du p*H* de la suspension: au dessus d'un p*H* de 6.0, 50% du cuivre est absorbé par les particules alors que le cuivre en solution est sous forme complexée; entre les p*H* de 3.8 et de 6, le cuivre soluble se distribue entre les complexes organiques et des ions cuivre "libres"; entre des p*H* de 2.5 et de 4.2, le cuivre est désorbé des particules; aux p*H* plus bas que 2.5, tout le cuivre est présent en solution sous forme d'ions cuivre "libres". [Traduit par le journal]

Introduction

A natural water sample can be divided into several physico-chemical states, the most important being the particulate and soluble fractions. In the chemical analysis of water samples an operational definition has been employed for distinguishing between the suspended and soluble trace elements. An element is defined as soluble if it can pass through a 0.45 μ pore size membrane filter. Using this definition, several workers (1–3) have reported the analysis of fresh waters with specific reference to the distribution of trace metals between particulate and soluble fractions. Stiff (1), for example, found that the fraction of total copper in particulate form varied from 43 to 87% depending on the river water under study. The distribution ratio has been found to vary with the trace element (3); for example, 8, 21, and 79% of silver, selenium, and cobalt respectively were found in the particulate phase.

The variation in distribution ratio with both the trace element and water system prompted a study into the metal control processes prevalent in the aquatic environment. To date, most of the information on metal control processes has been derived from analysis of sediments and suspended material for major and minor metal content and, from the trends observed, various control mechanisms have been proposed. An example of this approach is a study by Leland *et al.* (4) on the factors controlling lead distribution in Lake Michigan sediments. Regression analysis on the sediment compositions indicated that trace elements were associated with the

organic and iron oxide components of the sediment. Studies by Rashid (5) indicate that humic acids can complex from 3.4 to 216.6 mg of metal per g of organic material and, since humic acids form colloids with clay minerals (6, 7), the organic matter associated with clays has been proposed as a possible mechanism in metal control. Jenne (8) has compared several possible metal control processes including metal chelation by organic matter, ion exchange reactions with clays, surface sorption or precipitation onto carbonates, and precipitation as the oxide or hydroxide. Jenne (8) proposed one additional control, metal sorption onto hydrous oxides of manganese and iron.

The dissolved components of natural waters can also act as metal control agents. Soluble species include inorganic anions such as bicarbonate, chloride, and sulfate as well as large organic molecules such as humic acids and amino acids (1). Studies by Matson (9), Chau (10), and Schindler *et al.* (11) indicate that the humic compounds can complex metal ions and keep them in solution. The organic compounds can solubilize metals by two possible mechanisms, they can form metal–ligand complexes with sorption characteristics different from those of the free metal ion or they could solubilize the iron and manganese oxides (12–14) thus releasing the sorbed trace elements.

In summary, the literature survey indicates the possible interactions responsible for metal control are as follows: (*1*) metal–clay colloid ion exchange reactions; (*2*) metal sorption onto hydrous oxides; (*3*) metal sorption onto humic acid – clay colloids; (*4*) metal – inorganic anion complexes such as soluble $CuCO_3^0$, $ZnSO_4^0$, and $CdCl^+$ (15); (*5*) metal – organic ligand complexes.

The above mechanisms were suggested from studies on complete natural water systems containing all possible components. Natural water samples are difficult to characterize fully, and in studies using them all the variables that may determine the metal distribution cannot be controlled. In order to obtain definitive conclusions about the metal control processes it is necessary to study simpler model systems that can be characterized more fully. Such a simpler model system was developed in this study, and was composed of: (*1*) potassium bentonite; (*2*) hydrous MnO_2; (*3*) solid humic acid (to represent humic colloids); (*4*) soluble humic acid and tannic acid to represent soluble organic molecules; (*5*) bicarbonate ion to represent inorganic anions. Each particulate was studied separately to determine its metal sorption characteristics as a function of p*H* and sorbing metal concentration. The components were then combined to simulate a natural water sample. This paper describes the behavior of the model system and, using the information obtained from this study, discusses the kind of information that is provided by the analytical techniques used to characterize natural waters.

Experimental

Apparatus

A Princeton Applied Research Polarographic Analyzer, Model 174 A equipped with a Metrohm, Microfeed hanging mercury drop electrode E410 and a magnetic stirrer (Model E405) was used for all anodic stripping voltammetry experiments. A Varian Techtron atomic absorption spectrophotometer, Model AA-4, equipped with an air–acetylene premix atomizer-burner was used for flame atomic absorption measurements, and a Perkin–Elmer atomic absorption spectrophotometer, Model 503, equipped with a Heated Graphite Atomizer 2000 was used for nonflame atomic absorption experiments.

Reagents

The hydrous MnO_2 was prepared *in situ* by adding a solution of $MnSO_4$ to a basic solution of $KMnO_4$ (16)

$$3Mn^{2+} + 2MnO_4^- + 2H_2O \rightarrow 5MnO_2 + 4H^+$$

The brown suspensions of MnO_2 were used in further studies after a 15 min stabilization period. Acid washed bentonite (Fisher Scientific Co.) was converted to the potassium form using the procedure of van Olphen (17). The potassium bentonite thus prepared has a cation exchange capacity of 0.59 meq/g of clay at a p*H* of 5.2 (this cation exchange capacity was measured by the ammonium acetate method). Solid humic acid (Aldrich Chemical Co.) was used after it had been leached with 0.01 *M* HNO_3 to remove metal impurities. Ultrapure water of resistivity 18.3 megohm cm was obtained from a Milli-Q2 system (Millipore Co.). All solutions of metals were prepared from pure metal (of 99.9% purity) by dissolving them in nitric acid. All other solutions were prepared from reagent-grade chemicals.

Procedure

The sorption of copper, cadmium, and zinc onto the separate particulates was studied by adding known weights of MnO_2, bentonite, or solid humic acid to metal ion solutions having initial metal concentrations of 0–15 μg/ml. The solutions were buffered to p*H* 5.0 with a potassium acetate buffer (1×10^{-3} *M*) and allowed to equilibrate for 18 h. The suspensions were filtered through a 0.45 μ pore size membrane filter (Millipore Co.) and the soluble metal concentration was determined by flame atomic absorption spectroscopy. The weight of metal sorbed onto the particulate equalled the difference between the initial and final metal concentrations.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

The effect of pH on the sorption of metal onto the particulates was studied by preparing suspensions of MnO_2, humic acid, or bentonite and 10 μg/ml in copper and allowing them to equilibrate for 18 h at different pH between 1 and 6 (set by HNO_3 or potassium acetate buffer). The suspensions were all 1×10^{-3} M in K^+. The suspensions were filtered and the equilibrium metal concentrations were determined by flame atomic absorption spectroscopy.

The soluble metal fraction of the model system was studied by differential pulse anodic stripping voltammetry (d.p.a.s.v.). The anodic stripping voltammetry (a.s.v.) technique involves two steps (18), the first a plating step in which metals are reduced to an amalgam. The second step is stripping the metal out of the amalgam back into the solution. In this study, the plating step was done at an applied potential of −0.800 V (*vs.* a Ag/AgCl (1 N KCl) reference electrode) into a hanging mercury drop electrode. The plating step was 90 s long. The metal was stripped out of the electrode at a rate of 2 mV/s. In all d.p.a.s.v. studies a 0.01 M potassium acetate electrolyte was used.

Model systems of 10 mg bentonite, 10 mg humic acid, 3.5 mg MnO_2, 5×10^{-5} M tannic acid, 1×10^{-3} M $NaHCO_3$, and 1×10^{-6} M in Cu^{2+} were prepared in 200 ml of ultrapure water and equilibrated for 18 h. The amount of soluble copper in the suspension as a function of pH was determined by both d.p.a.s.v. and nonflame atomic absorption spectroscopy.

Results and Discussion

The sorption of Cu(II), Zn(II), and Cd(II) onto the model particulates was studied with metal concentrations 10–100 times greater than those of natural water levels in order to permit their determination by flame atomic absorption spectroscopy and to study the limiting sorption characteristics of the model particulates. Figure 1 presents the sorption behavior of copper onto MnO_2 and humic acid. The curves are characteristic Langmuir isotherms

$$X = \frac{X_m C}{1 + bC}$$

where X is the amount of metal sorbed per unit weight of solvent, X_m the limiting value of X, C the equilibrium metal concentration in solution, and b is a constant. The sorption isotherm of copper onto potassium bentonite is presented in Fig. 2. Figure 2 shows that copper is preferentially sorbed over K^+ onto the clay. Metal sorption onto the potassium bentonite was found to obey Freundlich isotherms

$$X = kC^n$$

where X is the amount of metal sorbed per g of clay, C is the equilibrium concentration of metal in solution, and k and n are empirical constants.

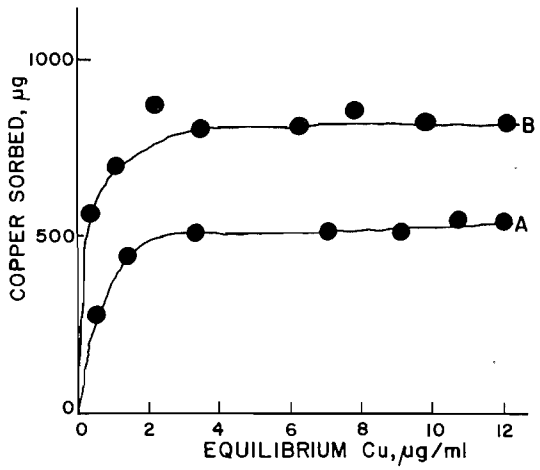

FIG. 1. Copper sorption isotherms at pH 7.5: (*A*) 10 mg humic acid; (*B*) 10 mg humic acid and 3 mg MnO_2.

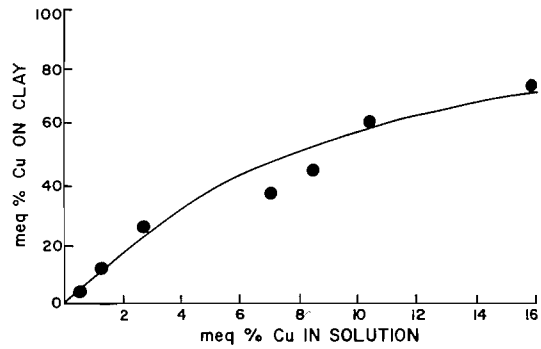

FIG. 2. Copper sorption isotherm onto potassium bentonite at pH 5.5.

TABLE 1. Freundlich isotherm constants for clay bentonite*

Metal ion	k	n
Cu^{2+}	2.96	0.65
Zn^{2+}	1.98	0.60
Cd^{2+}	2.25	0.64

*Determined at pH 5 in the presence of 1×10^{-3} M potassium acetate. Experimental uncertainties in k and n values are ± 10%. The constants are valid when X is in mg metal/g clay and C is in mg metal/ml solution.

Table 1 presents the values of k and n for copper, zinc, and cadmium sorption onto potassium bentonite.

Figure 3 presents the amount of copper sorbed onto the particulate as a function of pH. Each particulate has a characteristic pH below which copper is fully desorbed into solution: bentonite

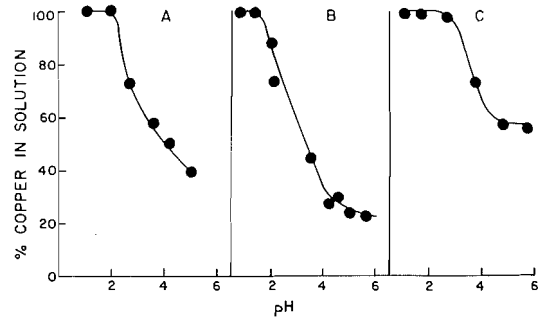

FIG. 3. Copper sorption as a function of pH: (A) potassium bentonite; (B) MnO_2; (C) humic acid.

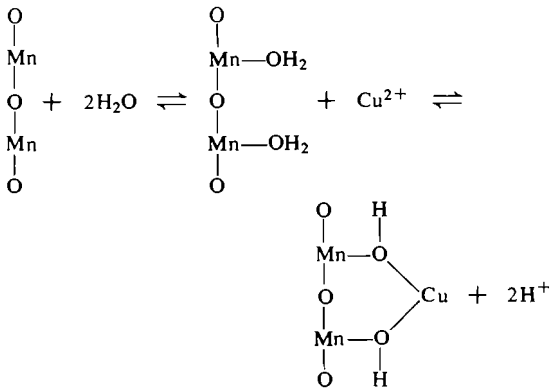

FIG. 4. Mechanism for sorption of copper onto MnO_2 surface.

pH < 1.8, MnO_2 pH < 1.5, and humic acid pH < 3.0.

The sorption characteristics of the metal ions onto the model particulates can be explained by examining the surface and complexing properties of the compounds.

MnO_2

Manganese dioxide crystals can interact with water at the solid–solution interface to form hydrous oxides (19). The polarized water molecule can then dissociate to form a negatively charged surface (16, 20). Metal ions can then interact with the negatively charged particle in two ways: (i) formation of a counter-ion layer. This occurs for both the alkali metal and heavy metal ions; (ii) specific sorption of ions onto the surface (as shown for copper in Fig. 4). The equilibrium responsible for formation of the surface charge

$$2H^+ + MO^- \rightleftharpoons MOH_2^+$$

(where MO^- and MOH_2^+ represent negative and positive surface sites respectively), indicates that H^+ ions are potential-determining. At a sufficiently low pH, the particulate surface would become positively charged and metal ions would be desorbed into solution. The above concept of the MnO_2 particulate leads to the following conclusions:

(i) The amount of metal sorbed will be proportional to the surface area of the particulate. The surface area of a dried, ground MnO_2 sample was 147 m^2/g (B.E.T. measurement using N_2 as the sorbing gas). The sorption of copper onto MnO_2 as a function of weight of MnO_2 prepared *in situ* is compared with a dried sample

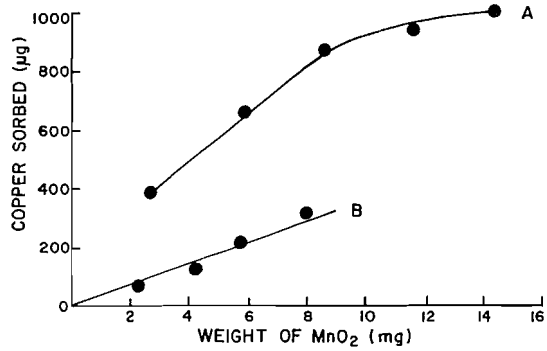

FIG. 5. Sorption of copper onto MnO_2 at pH 5.0 as a function of weight of MnO_2: (A) *in situ* MnO_2; (B) ground, dried MnO_2.

TABLE 2. Sorption characteristics* of humic acid, MnO_2, and bentonite

Metal	X_m (mmol metal / g MnO_2)	X_m (mmol metal / g humic acid)	Distribution coefficient for clay
Copper	1.95	0.42	9.0
Zinc	0.96	0.21	4.3
Cadmium	1.10	0.22	4.8

*These values were for pH 5.0 ± 0.1. The ionic strength was set with 1.0×10^{-3} M potassium acetate. The experimental uncertainties in X_m and the distribution coefficient for clay were ± 3% and ± 10%, respectively.

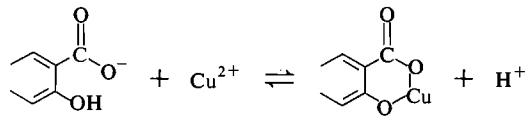

FIG. 6. Mechanism for sorption of copper onto humic acid particulate.

of MnO_2 in Fig. 5. It is evident that the surface area of MnO_2 generated *in situ* was much greater than that of the dried, finely ground sample.

(*ii*) The amount of metal sorbed will depend on the effective charge of the ion (ionic charge/hydrated ionic radius). Table 2 presents the sorption characteristics of humic acid, MnO_2, and potassium bentonite. The order of sorption (Cu > Zn ~ Cd) parallels the order of decreasing effective ionic charge.

Humic Acid

Schnitzer and Khan (7) propose that humic substances are phenolic and benzene carboxylic acids joined by hydrogen bonding to form large molecular structures. Humic acid particulates would have acidic functional groups at the water–solid interface which can chelate metal ions (Fig. 6). This sorption mechanism is consistent with the following conclusions: (*i*) the amount of metal sorbed would be proportional to the number of available complexing sites leading to a limiting sorption value; (*ii*) the relative affinity of different metal ions for humic acid will be a function of the ability of those ions to form metal chelates. The maximum sorption values, X_m, (Table 2) parallels the order of stability of metal humic acid complexes (7) ($Cu^{2+} > Zn^{2+} \sim Cd^{2+} > Ca^{2+}$); (*iii*) since conditional stability constants of the metal complex decrease in magnitude with p*H*, at low p*H* the complex is destabilized and the metal is desorbed into solution.

Clay Particulates

Clays are aluminum and magnesium silicates with layer-like structures. Isomorphous substitution of Al(III) for Si(IV) in the tetrahedral layers and of Fe(II), Zn(II), etc. for the Al(III) in the octahedral layers results in the crystals having a net negative charge. Counter-ions such as K^+ and Ca^{2+} can undergo ion-exchange with heavy metals in solution

$$2K\text{–clay} + Cu^{2+}(aq) \rightleftharpoons Cu\text{–clay}_2 + 2K^+(aq)$$

The exchange reaction can be characterized by a true equilibrium constant K_{eq} (21)

$$K_{eq} = \left[\frac{(C_{K^+})^2}{C_{Cu^{2+}}}\right]_{aq} \Big/ \left[\frac{(C_{K^+})^2}{C_{Cu^{2+}}}\right]_{clay}$$

or by a selectivity coefficient (22)

$$K_s = \frac{\text{meq\% } Cu^{2+} \text{ on clay} \times \text{meq\% } K^+ \text{ in solution}}{\text{meq\% } K^+ \text{ on clay} \times \text{meq\% } Cu^{2+} \text{ in solution}}$$

where

$$\text{meq\% } Cu^{2+} \text{ on clay} = \frac{\text{meq } Cu^{2+} \text{ on clay}}{\text{meq } Cu^{2+} \text{ on clay} + \text{meq } K^+ \text{ on clay}} \times 100$$

The selectivity coefficient is not a constant but is dependent on: (*i*) the size and charge of the exchangeable ions; (*ii*) the total concentration as well as the concentration ratio of existing ions. For the studies of sorption onto the potassium bentonite, the concentration of K^+ was 1×10^{-3} *M*. From inspection of the sorption isotherm (Fig. 2) it is evident that at low copper concentrations $K^+/Cu^{2+} > 50$ the plot is a straight line and the slope is equal to a distribution coefficient.

The distribution coefficient is defined as follows

$$\text{Distribution coefficient} = \frac{\text{meq\% } Cu^{2+} \text{ on clay}}{\text{meq\% } Cu^{2+} \text{ in solution}}$$

In general, the counter-ion concentration in natural waters is much greater than the heavy metal concentrations; therefore, distribution coefficients are reported instead of selectivity or equilibrium constants in Table 2.

The ion-exchange properties of the clays are consistent with the following conclusions: (*i*) the equilibrium constants (K_{eq}) are a function of the effective charge on the ion, the greater the effective charge on the heavy metal ion, the greater the equilibrium constant; (*ii*) the p*H* effects on clay sorption result from a mass action effect of the protons at low p*H*.

Table 2 summarizes the information obtained about the metal particulate interactions. Inspection of the table indicates that: (*1*) the order of sorption capacity of the particulates is MnO_2 > humic acid > clay (at the metal concentration equal to 8 μg/ml); (*2*) the order of metal sorption is $Cu^{2+} > Zn^{2+} \sim Cd^{2+} > K^+$.

As mentioned earlier, the three different partic-

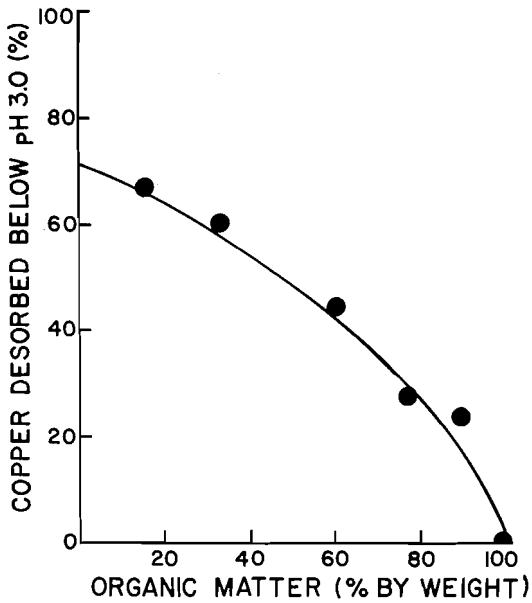

FIG. 7. Percentage of sorbed copper released below pH 3 as a function of humic acid content of suspension.

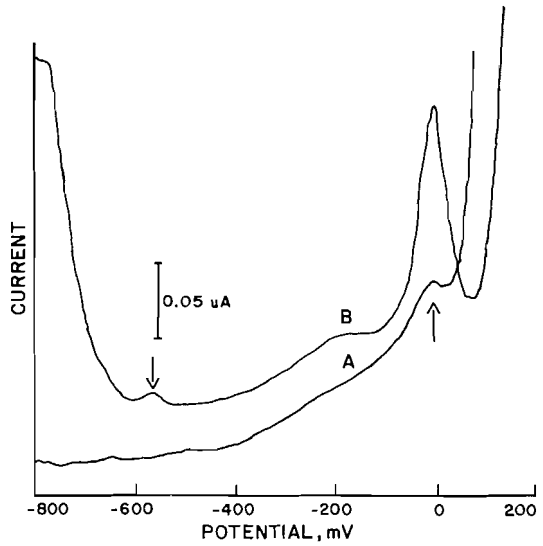

FIG. 8. Differential pulse anodic stripping voltammetry of natural waters in potassium acetate buffer: (*A*) pH 7.8; (*B*) pH 1.0.

ulates studied fully desorb copper at characteristic pH values. It is possible that, by comparing the amount of copper desorbed below pH 3 with the amount desorbed above pH 3, a qualitative differentiation between particulates can be made. The relationship between the amount of copper desorbed below pH 3.0 and the organic content of the suspension (Fig. 7) indicates that the percentage of copper desorbed below pH 3.0 decreases with increasing percentage organic content.

Studies on Soluble Metals

Figure 8 presents stripping voltammograms for a water sample from the Rideau River at two pH values. The stripping curve at pH 8 shows no significant stripping peaks whereas at pH 2 a lead stripping peak at -0.576 V and a copper stripping peak at -0.015 V are observed. Matson (9), Chau and co-worker (23), and Zirino and Healy (24) have observed similar pH-dependence of stripping curves for zinc, cadmium, lead, and copper in both fresh and saline waters. Both Matson (9) and Chau and coworker (23) have attributed this pH dependence to the lability of the metal–ligand complexes in natural water. Matson (9) has defined lability in terms of a relative cell constant; the cell constant, k_c, is related to the total amount of reduced species in the electrode, Q, the volume of the cell, v, the initial concentration of the species, C_0^0, and the time of electrolysis, t, by the equation

$$Q = nFvC_0^0tk_c$$

A metal complex Cu—L was termed nonlabile if k[CuL] $\ll k_c$, where k is the rate constant of the dissociation reaction

$$\text{Cu—L} \xrightarrow{k} \text{Cu}^{2+} + \text{L}$$

and [CuL] is molar concentration of the complex Cu—L.

Metal complexes are generally characterized by stability constants and rate constants of formation and dissociation. The relationship between these constants and the term nonlabile (as it applies to a.s.v. experiments) can be obtained by carefully considering the two steps of the a.s.v. procedure.

The first step is the reduction of metal ions in solution to form an amalgam. If the metal ion is present in the form of a complex and if the complex is not reducible then the plating step involves a chemical reaction before the metal is reduced at the electrode. Nicholson and Shain (25) have investigated the stationary-electrode polarography of kinetically controlled systems using fast, linear-sweep voltammetry. For a homogeneous first-order chemical reaction preceding a reversible charge transfer:

[1] $$Z \underset{k_b}{\overset{k_f}{\rightleftarrows}} O$$

$$K = [0]/[Z]$$

[2] $$O + ne^- \rightleftarrows R$$

where K is the equilibrium constant for reaction 1, it is found that when the scan rate exceeds the rate of conversion of $Z \rightarrow O$, the cathodic current is dependent on the equilibrium constant of reaction 1. If K is small then the current is determined by the equilibrium concentration of O denoted by C_0

$$C_0 = \frac{K}{K + 1} C^*$$

where C^* is the stoichiometric concentration of O. If the complex dissociation reaction is taken as a necessary step prior to metal reduction then the small stripping currents in natural water can be accounted for by assuming:

(*i*) That the natural water complexes are not reduced at the plating potential used in this study. If the complex is reducible, enough metal is reduced to give significant stripping peaks and the complex would be termed labile.

(*ii*) That the rate of dissociation of the metal complex is so slow that little metal is converted to an electroactive form in the time of the plating step (if longer plating times are employed more complex will dissociate and larger stripping currents will be observed, this condition is equivalent to Matson's (9) definition of nonlabile).

(*iii*) That the stability constant of the metal complex is large enough to reduce the equilibrium free metal concentration to a very low value. If one assumes a stability constant of 10^7 and [metal]/[ligand] = 10^{-1}, then for [ligand] = 10^{-6} M the equilibrium metal concentration would be 1×10^{-8} M. No appreciable copper stripping peak was observed at this copper concentration under the experimental conditions used in this study. The values for stability constants, metal/ligand ratio, and ligand concentration used in the above example are realistic values for natural waters (10, 23).

(*iv*) As the pH of a natural water sample is lowered, the conditional stability constants of the complexes would be lowered. Under these conditions, the equilibrium metal concentration increases and the stripping currents increase. If the example noted above is extended to include the equilibrium

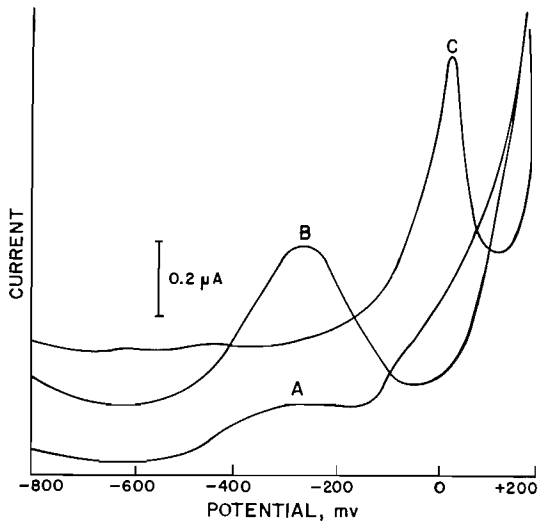

FIG. 9. Differential pulse anodic stripping voltammetry of humic acid – copper solutions as a function of pH: (*A*) pH 8.0; (*B*) pH 6.1; (*C*) pH 2.8.

$$LH \rightleftharpoons H^+ + L^-$$

$$K' = \frac{[H^+][L^-]}{[HL]}$$

and if K' is assumed to be 10^{-6}, then using conditional formation constants (26) one obtains that at pH 8, 9%; pH 4, 91%; and at pH 3, 100% of the total copper is present as uncomplexed copper.

Two model acids, tannic and humic acids, were used to simulate natural water organics. Stripping voltammograms of an 11.4 μg/ml humic acid and 1×10^{-6} M copper at pH 8, 6.1, and 2.0 are presented in Fig. 9. The voltammograms show a copper stripping peak cathodic to the normal copper stripping potential. Bradford (27) notes that such cathodic stripping peaks result from formation of metal–anion complexes only if the rate of formation of the complex is greater than the rate of oxidation of the metal out of the amalgam. The differences between the stripping curves of natural water and the model system arise from the appreciable dissociation of the model copper – humic acid complex during the time of the experiment and the rate of formation of complex being large enough to permit a cathodic stripping peak. The conditions under which a.s.v. will be valuable in distinguishing between soluble metal species is summarized as follows.

Case 1

The metal complexes are reduced at the elec-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

trode during the plating step or they dissociate to an appreciable extent during the time of the experiment. The complexes are called labile. Two different situations can be identified as follows: (*a*) If the rate of complex formation is faster than the rate of oxidation of the amalgam, the stripping peak occurs at a potential cathodic to the normal copper potential. Differentiation of species is possible. (*b*) If the stripping peak occurs at the normal copper potential, the metal complex can not be distinguished from the free copper.

Case 2

The rate of dissociation of metal complex is slow; therefore, the complexes are not dissociated during the time of the experiment. The complexes are called nonlabile. The following observations can be made. (*a*) The magnitude of stripping current is determined by the stability constant of the complex. (*b*) Lowering the solution p*H* to 1 permits the determination of the total concentration of the nonlabile complex.

Anodic stripping voltammetry was used to determine the distribution of copper between free metal and complexed metal for humic acid and tannic acid. The distribution curves are shown in Fig. 10. Complete dissociation of the metal complexes for tannic and humic acid occurs at p*H* 3.2 and 3.3, respectively.

The results of analysis of the total model system as a function of p*H* are presented in Fig. 11. Comparison of the atomic absorption spectroscopy and d.p.a.s.v. results indicated: (*1*) 50% of the total copper was found in the soluble form; (*2*) d.p.a.s.v. indicated that above p*H* 6 all of the soluble copper was in a complexed form and below p*H* 3.6 all soluble copper was in an uncomplexed form; (*3*) below p*H* 2.5 all the copper in the system was in a soluble form. Table 3 is a complete summary of the results.

The total model system indicated that most of the copper was desorbed above p*H* 3.0 which meant that most of the copper was sorbed onto the organic particulate (*cf.* Fig. 7). The filtered model system was light green in color whereas a 5×10^{-5} *M* tannic acid solution was normally colorless. Further studies indicated that the tannic acid can solubilize MnO_2. This agrees with the findings of Hem (13). It appears that the solubilization of MnO_2 by tannic acid can release copper into the solution. The mechanism

4.0	38	22	40
3.0	10	0	90
2.0	0	0	100

of the solubilization and its effect on metal distribution ratio is currently under study.

Conclusions

Studies on the interactions of metal ions with the model compounds bentonite, MnO_2, humic acid (solid and soluble), and tannic acid permitted metal distribution ratios to be explained in terms of coordination chemistry. The combination of the model compounds into a synthetic representation of a natural water sample indicated that the model was at least in qualitative agreement with the reported behavior of natural waters. Further studies using model systems may permit more definitive conclusions regarding the relative contributions of possible control mechanisms.

Anodic stripping voltammetry permits a more definitive characterization of a water sample than nonflame atomic absorption spectroscopy. Anodic stripping voltammetry permits the classification of the metal content of a water sample into several categories: (*1*) metal sorbed onto particulates; (*2*) soluble metal present in complexes and as free metal ion; (*3*) the p*H* titration (*cf.* Fig. 11) may be used as a possible "fingerprint" of natural waters (28).

Concerning the Problem of Stereospecific Glycosylation. Synthesis and Methanolysis of some 2-*O*-Benzylated D-Galactopyranosyl and D-Galactofuranosyl Halides[1]

JEAN M. J. FRÉCHET AND HANS H. BAER

Department of Chemistry, University of Ottawa, Ottawa, Canada K1N 6N5

Received October 7, 1974

JEAN M. J. FRÉCHET and HANS H. BAER. Can. J. Chem. **53**, 670 (1975).

Acetolysis of 1,6-anhydro-2,3,4-tri-*O*-benzyl-β-D-galactopyranose (**3**) followed by de-*O*-acetylation and *p*-nitrobenzoylation gave 2,3,4-tri-*O*-benzyl-1,6-di-*O*-*p*-nitrobenzoyl-β-D-galactopyranose (**4**) which was converted into 2,3,4-tri-*O*-benzyl-6-*O*-*p*-nitrobenzoyl-α-D-galactopyranosyl bromide (**5**). Benzylation of methyl 4,6-*O*-benzylidene-α-D-galactopyranoside (**6**) gave the 2,3-dibenzyl ether (**7**) which was hydrolyzed to 2,3-di-*O*-benzyl-D-galactose (**8**). *p*-Nitrobenzoylation of **8** furnished 2,3-di-*O*-benzyl-1,5,6-tri-*O*-*p*-nitrobenzoyl-β-D-galactofuranose (**9**) and an isomer, presumably a β-pyranose derivative (**10**). Compound **9** was converted into 2,3-di-*O*-benzyl-5,6-di-*O*-*p*-nitrobenzoyl-β-D-galactofuranosyl bromide (**11**) and chloride (**12**). The new halides **5**, **11**, and **12** as well as known 2,3,4,6-tetra-*O*-benzyl-α-D-galactopyranosyl bromide (**1**) and chloride (**2**) were subjected to methanolysis in dichloromethane solution in the presence of methanol alone and in the presence of tetrabutylammonium bromide, mercuric cyanide, and silver tetrafluoroborate, respectively, and the ratios of anomeric glycosides produced were examined by n.m.r. spectroscopy. Factors influencing stereoselectivity in these reactions are discussed. The new methyl α- and β-glycosides derived from **5** (**13** and **14**) and the methyl α-glycoside (**15**) produced from **11** and **12** were isolated, and methyl 2,3,5,6-tetra-*O*-benzyl-α-D-galactofuranoside (**16**) was prepared for the first time.

JEAN M. J. FRÉCHET et HANS H. BAER. Can. J. Chem. **53**, 670 (1975).

Par acétolyse du 1,6-anhydro-2,3,4-tri-*O*-benzyl-β-D-galactopyranose (**3**) suivie de désacétylation et de *p*-nitrobenzoylation, on a obtenu le 2,3,4-tri-*O*-benzyl-1,6-di-*O*-*p*-nitrobenzoyl-β-D-galactopyranose (**4**) qui est converti en bromure de 2,3,4-tri-*O*-benzyl-6-*O*-*p*-nitrobenzoyl-α-D-galactopyranosyle (**5**). La benzylation du méthyl 4,6-*O*-benzylidène-α-D-galactopyranoside (**6**) a donné l'éther 2,3-dibenzylique (**7**) qui, par hydrolyse, a produit le 2,3-di-*O*-benzyl-D-galactose (**8**). Par *p*-nitrobenzoylation de **8**, on a obtenu le 2,3-di-*O*-benzyl-1,5,6-tri-*O*-*p*-nitrobenzoyl-β-D-galactofuranose (**9**) et un isomère, sans doute le dérivé pyranosique (**10**). Le composé **9** a été transformé en bromure (**11**) et en chlorure (**12**) de 2,3-di-*O*-benzyl-5,6-di-*O*-*p*-nitrobenzoyl-β-D-galactofuranosyle. Ces nouveaux halogénures **5**, **11** et **12**, ainsi que le bromure de 2,3,4,6-tétra-*O*-benzyl-α-D-galactopyranosyle (**1**) et le chlorure correspondant (**2**) qui étaient déja connus, ont été soumis à des réactions de méthanolyse en solution dans le dichlorométhane en présence de méthanol seul, et en présence de bromure d'ammonium tétrabutylé, de cyanure de mercure et de tétrafluoroborate d'argent respectivement. Les quantités de glycosides anomères formées ont été analysées par spectroscopie de r.m.n. Les facteurs qui influencent la stéreosélectivité de ces réactions sont examinés. Les nouveaux méthyl α- et β-glycosides dérivés de **5** (**13** et **14**) et le méthyl α-glycoside (**15**) produit à partir de **11** et **12** ont été isolés; le méthyl 2,3,5,6-tétra-*O*-benzyl-α-D-galactofuranoside (**16**) a été préparé pour la première fois.

Introduction

As groundwork for a long-range project in glycoside and oligosaccharide synthesis we have commenced with the preparation of some new sugar derivatives which, it is hoped, may serve as suitable building stones in syntheses of certain compounds having biological significance, and we have undertaken some studies pertaining to the general problem of stereospecificity in glycoside formation. The present article deals with derivatives of D-galactose. This sugar occurs widely in nature in both α- and β-glycosidic linkage; it is one of the prominent structural units of such important natural products as, for example, gangliosides and other glycolipids, blood group determinants and related glycopeptides, human milk oligosaccharides, immunospecific bacterial polysaccharides, and a great variety of plant hemicelluloses, gums, and mucilages.

The methods most widely used and endowed

with broad generality for the synthesis of both simple glycosides and more complex oligosaccharides were, at least until recently, the classical Koenigs–Knorr condensation and its newer variants in which a blocked glycosyl halide is condensed with an alcoholic component. However, control of the anomeric configuration in the glycoside thus generated has long been a major problem and is remaining a current concern despite recent progress (1). Whereas the readily available per-*O*-acylated bromides and chlorides of galactose and other sugars having the same C-2 configuration (*e.g.*, glucose and xylose) normally give β-glycosides (1,2-*trans*) with a high degree of stereospecificity, the controlled synthesis of α-glycosides (1,2-*cis*) of these particular sugars is a far more complicated proposition and continues to draw much attention. With the notable exception of the novel, highly promising α-glycoside synthesis of Lemieux and co-workers (2) which in the key step involves addition of alcohol to an intermediate 2-nitrosoglycal, most approaches were aimed at influencing the stereochemical course of nucleophilic substitution at the anomeric center in glycosyl halides. Success in varying measure was achieved over the years by modifying the reaction conditions (such as solvent and choice of acid acceptor) in Koenigs–Knorr type reactions and by employing glycosyl halides that bear a nonparticipating group at C-2, frequently the benzyloxy function (1, 3). Of particular relevancy in this connection was the discovery by Lemieux and co-workers (4), that stable α-glycosyl halides anomerize by halide ion catalysis to give their more highly reactive β-anomers, albeit in low concentration, a phenomenon which can be utilized in α-glycoside synthesis (5–7). It was found, furthermore, that certain specific groups present in positions other than C-2 may influence reaction rates and have a directive effect which can be enlisted for making 1,2-*cis* glycosides (5, 8–14), and such glycosides have also been obtained from reactive glycosyl derivatives possessing an electropositive leaving group (15). Nevertheless, the scope of some of these approaches is still uncertain and a lack of predictability exists. For example, in our syntheses of several stereoisomeric disaccharides by mercuric cyanide-promoted condensation of per-*O*-benzyl-α-D-glucopyranosyl bromide, the type of linkage produced was found to depend strikingly upon the molecular configuration of the alcoholic monosaccharide component, a factor which apparently has received little attention hitherto (16). In extending their work (14, 17) on the stereoselective methanolysis of D-glucopyranosyl sulfonates, Schuerch and co-workers observed unexpected differences when analogous D-galactose derivatives were used (18).

In order to augment special knowledge in glycoside-forming reactions in the D-galactose series, we have now synthesized three new halides in addition to the previously-described 2,3,4,6-tetra-*O*-benzyl-α-D-galactopyranosyl bromide (**1**) (16) and the corresponding chloride **2** (19), namely, 2,3,4-tri-*O*-benzyl-6-*O*-*p*-nitrobenzoyl-β-D-galactopyranosyl bromide (**5**), 2,3-di-*O*-benzyl-5,6-di-*O*-*p*-nitrobenzyl-β-D-galactofuranosyl bromide (**11**), and 2,3-di-*O*-benzyl-5,6-di-*O*-*p*-nitrobenzoyl-β-D-galactofuranosyl chloride (**12**). With these five compounds we then made a comparative study of the steric course of glycoside formation with methanol under a variety of conditions.

Synthesis of Glycosyl Halides

The synthesis of the 6-*p*-nitrobenzoate **5** departed from 1,6-anhydro-2,3,4-tri-*O*-benzyl-β-D-galactopyranose (**3**) which, by acetolysis and subsequent de-*O*-acetylation and *p*-nitrobenzoylation of the product, was converted into 2,3,4-tri-*O*-benzyl-1,6-di-*O*-*p*-nitrobenzoyl-β-D-galactopyranose (**4**). The bromide **5** was then obtained from **4** by application of the elegant method, first recommended by Fletcher and co-workers (refs. 5 and 20; for further examples see refs. 11–14 and 16) which consists of a facile, quantitative displacement of the C-1 acyloxy function by means of anhydrous hydrogen bromide in dichloromethane solution. Although it seems plausible enough that a β-ester reacts with inversion to yield the stable α-bromide, we shall return to this point for further comment at the end of this section.

The blocked β-D-galactofuranosyl halides **11** and **12** were obtained as follows. Methyl 4,6-*O*-benzylidene-α-D-galactopyranoside (**6**) was benzylated to furnish its crystalline 2,3-dibenzyl ether (**7**). Acid hydrolysis of **7** gave 2,3-di-*O*-benzyl-D-galactose (**8**). This free sugar crystallized in a weakly dextrorotatory form ($[\alpha]_D$ +5.3° in chloroform) but the anomeric configuration and the ring structure of the crystalline material were not established, nor was it possible to assess the proportions of tautomeric forms present in solution. However, **8** must to a high degree exist in, or be especially prone to reaction through, a

furanose form as *p*-nitrobenzoylation afforded two isomeric triesters, each in 40% yield,[2] of which one showing $[\alpha]_D$ −5.5° was revealed to be 2,3-di-*O*-benzyl-1,5,6-tri-*O*-*p*-nitrobenzoyl-β-D-galactofuranose (**9**) (for proof see later). The other isomer also showed low levorotation ($[\alpha]_D$ −9.1°) and was on this basis tentatively judged to be the corresponding β-pyranose 1,4,6-tri-*p*-nitrobenzoate (**10**). It is known that acylation of galactose tends to give mixtures containing substantial amounts of furanose besides pyranose derivatives (21). Treatment of **9** with anhydrous hydrogen bromide and chloride, respectively, produced the substituted β-D-galactofuranosyl halides **11** and **12** as amorphous solids which exhibited strong levorotation but did not mutarotate. As is also the case with alkyl β-D-galactofuranosides (22), these β-halides are expected to be the thermodynamically more stable anomers because they are free from the unfavorable, 1,2-*cis* substituent interaction which exists in the α-anomers; therefore α-halides, if initially formed from **9**, would be liable to rapid anomerization during the reaction. The triester presumed to have structure **10** gave a dextrorotatory bromo sugar, but further examination of this product was postponed.[3]

We now wish to comment upon the isolation of compound **5**, a stable α-pyranosyl bromide, as the sole reaction product obtained from the β-ester **4**. Neither an n.m.r. spectrum nor the optical rotation, both taken prior to work-up as soon as the precipitation of *p*-nitrobenzoic acid was complete, gave any indication for transitory presence of the (expectedly labile) β-bromide. Similarly, 2,3,4,6-tetra-*O*-benzyl-1-*O*-*p*-nitrobenzoyl-β-D-galactopyranose had given (16) a stable α-bromide exclusively. In the absence of a participating group at C-2, such displacement with simple inversion leading directly to the stable halide would normally be no surprise. However, our findings stand in contrast to results of Ishikawa and Fletcher (5) who obtained crystalline β-bromides from the β-D-*gluco* isomer of **4** and from the corresponding 1,4,6-tri-*p*-nitrobenzoate. These and two other β-bromides (that arose, less surprisingly, from α-esters) all anomerized to their more stable α-anomers but seemed to differ in their tendencies to do so. Thus, the β-D-*gluco* isomer of **5** had a half-life of more than 2 h in dry dichloromethane solution, and stability in the series appeared to increase with the number of *p*-nitrobenzoyl groups present, a phenomenon which the authors (5) ascribed to a long-range effect of that functionality.[4] It might be argued that our β-D-galactopyranose esters may have formed intermediary β-bromides which went undetected owing to very fast anomerization.[5] However, this would still leave open the question by what mechanism labile bromides could arise, with retention of configuration. It has been speculated (5) that probably the steric requirement of the bulky bromide ion in its approach to the glucosyl carbonium ion is involved. An alternative possibility, namely participation by the 2-benzyloxy group, has been regarded both as unlikely (5) and as likely (6). Neither hypothesis readily accounts for the fact that Fréchet and Schuerch (11) obtained only α-bromides when they applied the same method to several 1,6-di-*O*-acyl-2,3,4-tri-*O*-benzyl-β-D-glucopyranosides wherein acyl was benzoyl and *p*-methoxy-, *p*-methyl-, *p*-cyano-, 3,5-dinitro-, and 2,4-dinitrobenzoyl.

Solvolysis of Glycosyl Halides

The halides **1**, **2**, **5**, **11**, and **12** were allowed to react with a 70–90 molar excess of methanol in dichloromethane solution at room temperature unless otherwise stated. The conditions were varied as follows: *A*, without any further addition; *B*, with addition of 4 mol-equiv. of tetrabutylammonium bromide; *C*, with addition of 1 mol-equiv. of mercuric cyanide; *D*, with addition of 1 mol-equiv. of silver tetrafluoroborate at −78°. Reactions according to *A* and *B* were followed polarimetrically and plots of optical rotation *vs.* time yielded first-order rate constants from the expression

[2]In addition, a di-*p*-nitrobenzoate resulting from incomplete acylation was isolated in 10% yield.

[3]Preliminary experiments of methanolysis led to mixtures of glycosides which were difficult to analyze and did not promise easy interpretation.

[4]Glaudemans and Fletcher suggested earlier (8) that the strongly electron-withdrawing character of the *p*-nitrobenzoyloxy group renders C-5 electron deficient so that destabilization of an incipient glucosyl carboxonium ion results in strengthening of the C-1—halogen bond. By the same token, β-D-glucopyranosyl halides are stabilized when a strongly electronegative substituent is present at C-2 (3*a*).

[5]In reactions implicating glycosyl carbonium ion intermediates, D-galactopyranose derivatives are generally more reactive than their D-*gluco* isomers. For example, the rates of acid hydrolysis of the pairs of methyl α- and β-pyranosides differ by factors of 5 and 4, respectively (3*b*). Larger factors could possibly apply to halide anomerizations.

TABLE 1. Methanolysis of 2,3,4,6-tetra-*O*-benzyl-α-D-galactopyranosyl bromide (**1**) and chloride (**2**)

Halide	Salt added	$t_{1/2}$ (min)	k (ln, s^{-1})	Ratio of methyl glycosides formed (α:β)
1	—	15	7.6×10^{-4}	35:65
1	*n*-Bu_4NBr	3.25	3.8×10^{-3}	75:25
1	$Hg(CN)_2$			2:98
1	$AgBF_4$ (−78°)			3:97
2	—	240	4.8×10^{-5}	37:63
2	$AgBF_4$ (−78°)			5:95

$$k = (1/t) \ln [(\alpha_0 - \alpha_\infty)/(\alpha_t - \alpha_\infty)]$$

Upon completion of the methanolyses, the anomeric composition of the mixture of methyl glycosides formed was determined by measuring the intensity ratio of the methoxyl proton peaks in n.m.r. spectra (11). In those cases where methoxyl peaks were superimposed on a background due to ring protons, adjustment was made by subtraction of the background intensity as obtained from the spectrum of a separate run that was performed with methanol-d_4.

The results obtained with the perbenzylated halides **1** and **2** are shown in Table 1. In line with expectations the bromide **1** was methanolyzed more rapidly than the chloride **2**. The preponderant product formed in both cases in the absence of an additive was the β-glycoside, which is due to direct displacement with inversion in the bulk of reactant. Halide ion liberated during the reaction catalyzes (4) a continuous anomerization of unreacted α-glycosyl halide to its more highly reactive β-anomer which is constantly and rapidly consumed by methanol, also with inversion. This accounts for the considerable proportion of α-glycoside produced. Increasing the halide ion concentration at the outset by addition of tetrabutylammonium bromide promotes anomerization of the glycosyl halide (4), and consequently the α-glycoside becomes the predominant product. The observed enhancement in the rate of methanolysis is consistent with this view. Thus far, the results parallel those obtained (5) with the D-*gluco* isomer of **1** and support the mechanistic picture which has evolved for this type of reaction (4–6, 11, 14, 23). It is important to note, though, that **1** solvolyzed more rapidly than its D-*gluco* isomer; with methanol alone, the rate was twice as large, and addition of bromide ion caused a fivefold increase in **1** and only a twofold increase in the isomer.[5]

The solvolyses performed in the presence of mercuric cyanide or silver tetrafluoroborate almost exclusively gave the β-glycoside. They proceeded extremely fast so that rates could not conveniently be measured. It is reasonable to assume that the rate increase is due to a 'push-pull' mechanism, a concerted process in which the halogen atom is attracted by the metal while the nucleophile attacks C-1 from the back (14, 24). The abstracted halide ion is bound by the metal and therefore unable to cause anomerization in any temporarily surviving glycosyl halide. The minor proportion of α-glycoside that arises nevertheless may perhaps originate from methanol attack on 'free' glycosyl carbonium ion, an event which could occur when from time to time a halide ion is abstracted without the benefit of simultaneous nucleophilic push.

The observations made on the 6-*O*-*p*-nitrobenzoylglycosyl bromide **5** (Table 2) were quite analogous although the ester group present at C-6 evidently caused the methanolyses with and without added tetrabutylammonium bromide to be slower than those of **1**. One experiment was conducted without additive at low temperature (−20°), with the result that the ratio of α-glycoside (**13**) to β-glycoside (**14**) was shifted slightly in favor of the latter, suggesting that temperature dependence of anomerization is somewhat greater than that of solvolysis. The reactions promoted by metal salts again exhibited a high degree of stereoselectivity, giving nearly exclusively the β-glycoside (**14**). Compounds **13** and **14**, which were previously unknown, were isolated in crystalline condition from runs containing tetrabutylammonium bromide and mercuric cyanide, respectively.

Comparison of Tables 1 and 2 shows that replacement of the 6-*O*-benzyl group by the *p*-nitrobenzoate function had a negligible influence upon the steric outcome of all the reactions here inves-

TABLE 2. Methanolysis of 2,3,4-tri-*O*-benzyl-6-*O*-*p*-nitrobenzoyl-α-D-galactopyranosyl bromide (**5**)

Salt added	$t_{1/2}$ (min)	k (ln, s^{-1})	Ratio of methyl glycosides formed (α:β)
—	42.5	2.4×10^{-4}	31:69
— (−20°)			24:76
n-Bu_4NBr	14	8.2×10^{-4}	70:30
$Hg(CN)_2$			3:97
$AgBF_4$			5:95

tigated. As far as the methanolyses with and without added bromide ion are concerned, this contrasts sharply with the behavior of the corresponding D-*gluco* derivatives where remarkable shifts in the anomeric product ratio were observed as the nature of the C-6 substituent was varied. Thus, the D-*gluco* isomer of **5** gave 90–96% α-glucoside (5, 11) whereas the corresponding 6-*p*-methoxybenzoate gave 93% β-glucoside (11); other C-6 substituents led to intermediate α/β ratios (11). In related studies, Schuerch and coworkers noted similar, wide ranges of stereoselectivity in diversely 6-substituted D-glucopyranosyl derivatives but at the same time, they observed directive effects of solvent (14, 17). In the D-*galacto* series, on the other hand, selectivity was greatly reduced and certain solvent effects were opposite (18). The results obtained in the D-*gluco* series have been rationalized in terms of a sensitive balance between two competing, key reactions whose rates are of similar order of magnitude but variable depending on the medium and the structure of the substrate; namely, the methanolysis of α-halide to give β-glycoside, and the anomerization of α-halide to form β-halide which subsequently reacts very rapidly to yield α-glycoside (14, 17).[6] Elaborating on this concept (4–6) with regard to the *galacto* series we suggest that both processes are affected, but not necessarily in equal manner, by inductive variation in the electron density at C-5, which should influence the stability and character of intermediary C-1 carbonium ion or ion-pair (*cf.* footnote 4), and also by the dipolar effect of axial O-4. The latter, probably, supplements the anomeric effect in opposing equatorial placement of electronegative groups at C-1, with halogen atoms being opposed more strongly than the methoxyl group. Thus α → β halide anomerization may be retarded and consequently, high proportions of α-pyranosides are less readily obtained in the *galacto* series than in the *gluco* series.

The results of methanolyses of the β-furanosyl halides **11** and **12** are given in Table 3. It is seen that the reactions both with methanol alone and with added tetrabutylammonium bromide were completely stereospecific as far as could be judged from n.m.r. spectra, the product being the methyl α-furanoside **15**. Evidently the methanolysis proceeds with inversion as in the preceding cases, but there is no prior anomerization in part of the glycosyl halide, not even in the presence of excess bromide ion which has no influence on the product composition and merely causes a slight increase in the reaction rate (probably a kinetic salt effect). Compared with its pyranoid counterparts **1** and **4**, the furanoid bromide **11** was considerably more reactive. The pair of chlorides **2** and **12** exhibited the same trend but their rate difference was relatively small. Two opposing factors appear to operate, namely, the generally recognized greater reactivity of furanosyl halides originating from conformational features, and inductive stabilization by the *p*-nitrobenzoyl groups (8). The first factor seems more important in the bromides, and the second factor, in the chlorides. Absence of halide anomerization in both **11** and **12** can be explained by assuming that, in generating the sterically unfavorable furanoid 1,2-*cis* arrangement, halide ions are at a serious disadvantage in competition with methanol molecules. An additional factor could possibly arise from hydrogen bonding of the ether oxygen atom at C-2 with the incoming methanol, assisting in its approach from the α-side of the ring, whereas a halogen ion on the same path would find no such assistance.

Also characterized by complete stereospecificity were the metal salt-assisted reactions of **12**, whereas selectivity was slightly lower in those of **11** (Table 3).

[6]Nonbonded interaction between the C-6 acyl carbonyl group and the anomeric center, as proposed earlier (11), does not satisfactorily explain the more recent findings.

12	$Hg(CN)_2$			100:0
12	$AgBF_4$ (−78°)			100:0

The methyl α-furanoside **15** was isolated in crystalline condition. Proof of structure was provided by its treatment with benzyl chloride and potassium hydroxide which replaced the *p*-nitrobenzoyl groups by benzyl groups to give methyl 2,3,5,6-tetra-*O*-benzyl-α-D-galactofuranoside (**16**). The n.m.r. spectrum of this new compound was superimposable on that of an identical product obtained by benzylation of authentic methyl α-D-galactofuranoside but differed clearly from the spectra of perbenzylated methyl β-D-galactofuranoside and methyl α- and β-D-galactopyranosides.

Experimental

Optical rotations were measured at approximately 25° in a Perkin-Elmer 141 automatic polarimeter. The n.m.r. data were obtained with a Varian HA 100 instrument using tetramethylsilane as internal standard.

Preparation of Fully Benzylated Methyl D-*Galactosides*

Samples of the fully benzylated methyl α- and -β-D-galactopyranosides and -furanosides were required as standards for identification of methanolysis products. They were prepared as follows.

Glycosidation of D-*Galactose*

D-Galactose was converted into a mixture of methyl glycosides and the (known) products were separated chromatographically by use of the procedure of Baddiley and co-workers (25), with minor modifications. A suspension of the sugar (5 g) in absolute methanol (40 ml) containing 0.4 ml sulfuric acid was refluxed for 2 h. The cooled solution was neutralized with calcium carbonate, filtered, and evaporated to give a syrup which, with a small amount of added water, was placed on a column containing approximately 200 g of anion exchange resin AG1-X2 (OH^-) of Bio-Rad Laboratories, Richmond, Calif. Elution was performed with carbon dioxide-free, distilled water and monitored by polarimetry of all fractions (8 ml). It yielded methyl α-D-galactopyranoside (fractions 16–20, 1.2 g), methyl β-D-galactopyranoside (fractions 24–32, ~0.1 g), methyl α-D-galactofuranoside (fractions 36–53, 0.66 g), and methyl β-D-galactofuranoside (fractions 85–180, 2.17 g). Intermediate, mixed fractions were discarded.

*Methyl 2,3,4,6-Tetra-O-benzyl-α- and -β-*D-*galactopyranosides*

Methyl α- and β-D-galactopyranoside, respectively, were benzylated with benzyl chloride and potassium hydroxide as described (19), or by use of the method (26) detailed in the next paragraph. The OCH_3 signal of the benzylated α-pyranoside was at δ 3.35, and that of the β-pyranoside at δ 3.51 (in $CDCl_3$).

*Methyl 2,3,5,6-Tetra-O-benzyl-α-*D-*galactofuranoside (16) and its β-Anomer*

To a solution of sodium hydride (0.55 g; oil dispersion, 55% pure) in dimethyl sulfoxide (3 ml) was added dropwise a solution of methyl α-D-galactofuranoside (0.45 g) in dimethyl sulfoxide (3 ml). The mixture was stirred for 30 min, after which benzyl chloride (3 ml) was added dropwise and stirring was continued for another 2.5 h. The reaction mixture was then poured into ice water (50 ml) which was extracted three times with chloroform. The dried ($MgSO_4$) extract was evaporated at 2 mm Hg, leaving an oil which was passed through a small column of silica gel (20 g) by means of benzene–ether (99:1). Compound **16** was obtained as a colorless oil (965 mg, 75%) showing $[\alpha]_D$ +20° (*c* 2, $CHCl_3$). The OCH_3 signal occurred at δ 3.29 (in $CDCl_3$).

Anal. Calcd. for $C_{35}H_{38}O_6$ (554.7): C, 75.79; H, 6.91. Found: C, 75.54; H, 7.01.

The same procedure applied to methyl β-D-galactofuranoside furnished the β-anomer of **16**, $[\alpha]_D$ −49° (*c* 2, $CHCl_3$), as reported (26). Its OCH_3 signal occurred at δ 3.33, and its pattern of ring proton signals was distinctively different from that of **16**.

*2,3,4,6-Tetra-O-benzyl-α-*D-*galactopyranosyl Bromide (1) and Chloride (2)*

Preparation of the bromide **1** via the corresponding 1-*p*-nitrobenzoate has been described (16). The chloride **2** was obtained in analogous fashion (11, 14, 20). Dry hydrogen chloride gas was passed through a solution of the 1-*p*-nitrobenzoate (1 g of crystalline β-anomer) in dry dichloromethane (50 ml), with exclusion of moisture and at room temperature. After 20 min, *p*-nitrobenzoic acid began to precipitate, the gas stream was stopped, and the tightly stoppered vessel was placed in a refrigerator for 3 days. The mixture was then filtered to remove *p*-nitrobenzoic acid (239 mg, 97%) and the filtrate was evaporated *in vacuo* at room temperature. Several portions of added dichloromethane were evaporated from the remaining, faintly yellow syrup of **2** which showed $[\alpha]_D$ +146.5°

(*c* 1.6, benzene). Reported (19) for **2** obtained from 2,3,4,6-tetra-*O*-benzyl-D-galactose and thionyl chloride, $[\alpha]_D$ +147° (*c* 2, benzene). The n.m.r. spectrum of **2** showed a doublet for H-1 at δ 6.14 ($J_{1,2}$ = 3.5 Hz).

2,3,4-Tri-O-benzyl-1,6-di-O-p-nitrobenzoyl-β-D-galactopyranose (4)

A solution of 10.3 g of 1,6-anhydro-2,3,4-tri-*O*-benzyl-β-D-galactopyranose (**3**) (27) in warm acetic anhydride (100 ml) was cooled in an ice water bath and mixed with a chilled solution of concentrated sulfuric acid (0.1 ml) in acetic anhydride (5 ml). After 3 min the mixture was poured into, and stirred with, ice water (600 ml) whereby the product of acetolysis separated as an oil. After 45 min the aqueous phase was decanted and replaced by fresh water (600 ml) which was removed after 24 h. The oily product was then dissolved in chloroform and washed with 5% sodium bicarbonate solution and water. After drying, the solvent was evaporated and the nearly colorless product (12 g) was deacetylated overnight, at room temperature, in methanol containing a small amount of sodium methoxide. The methanol was evaporated after neutralization with acetic acid and the product was dissolved in pyridine (100 ml) and allowed to react overnight at 25° with *p*-nitrobenzoyl chloride (15 g). The reaction mixture was treated with ice water and the precipitated product was taken up in chloroform. The solution was washed successively with water, sodium bicarbonate solution and water, then dried and evaporated to give a residue which was crystallized from ethyl acetate – petroleum ether (b.p. 30–60°). The yield was 8.2 g (49%) of **4**, m.p. 152–153°, $[\alpha]_D$ −6.6° (*c* 2, $CHCl_3$). The n.m.r. spectrum showed a doublet at δ 5.94 (H-1, $J_{1,2}$ = 7.5 Hz) indicative of the β-anomeric configuration.

Anal. Calcd. for $C_{41}H_{36}N_2O_{12}$ (748.9): C, 65.77; H, 4.85; N, 3.74. Found: C, 65.62; H, 4.85; N, 3.78.

2,3,4-Tri-O-benzyl-6-O-p-nitrobenzoyl-α-D-galactopyranosyl Bromide (5)

Compound **4** (1 g) was dissolved in dry dichloromethane (25 ml) saturated with hydrogen bromide gas, at room temperature. After 2 min, *p*-nitrobenzoic acid started to precipitate, and after 10 min it was collected by filtration (214 mg, 96%). The filtrate was evaporated to yield a nearly colorless heavy oil from which several portions of added dichloromethane were evaporated *in vacuo*. The product could not be crystallized. It had $[\alpha]_D$ +100° (*c* 2.6, CH_2Cl_2), and its n.m.r. spectrum showed a doublet at δ 6.53 (H-1, $J_{1,2}$ = 1.4 Hz).

Methyl 2,3-Di-O-benzyl-4,6-O-benzylidene-α-D-galactopyranoside (7)

A mixture of 11 g of methyl 4,6-*O*-benzylidene-α-D-galactopyranoside (**6**) (28), powdered potassium hydroxide (20 g), and benzyl chloride (120 ml) was stirred at 105° for 6 h. After cooling, the mixture was shaken with water (150 ml) and chloroform (150 ml). The organic phase was separated, washed with water, and dried over magnesium sulfate. Chloroform was evaporated and remnant benzyl chloride was removed partially by evaporation at 2 mm Hg and finally by steam distillation. The product **7** was then crystallized from ethanol as white plates, m.p. 174–175°, in a yield of 13.8 g (76%). Recrystallization from petroleum ether gave long needles; m.p. 176–177°, $[\alpha]_D$ +77° (*c* 2.4, $CHCl_3$).

Anal. Calcd. for $C_{28}H_{30}O_6$ (462.6): C, 72.71; H, 6.54. Found: C, 72.81; H, 6.63.

2,3-Di-O-benzyl-D-galactose (8)

A solution of 7 (12.5 g) in dioxane (300 ml) and 2 *N* sulfuric acid (90 ml) was refluxed for 3 days. The cooled solution was neutralized with barium carbonate, filtered, and evaporated to give a syrup which was extracted with petroleum ether for removal of benzaldehyde. The remaining material was chromatographed in a column of silica gel (250 g). Elution with benzene–ether (97:3) produced, first, several fractions containing incompletely hydrolyzed material (3.6 g), then a noncrystallizable oil (0.4 g) having $[\alpha]_D$ +43°, and finally, compound **8** (4.1 g, 42%) which crystallized from ether and showed m.p. 74–76°, $[\alpha]_D$ +5.3° (*c* 2, $CHCl_3$).

Anal. Calcd. for $C_{20}H_{24}O_6$ (360.4): C, 66.65; H, 6.71. Found: C, 66.50; H, 6.68.

2,3-Di-O-benzyl-1,5,6-tri-O-p-nitrobenzoyl-β-D-galactofuranose (9) and Isomer (10)

To compound **8** (3.95 g) in dry pyridine (40 ml) was added *p*-nitrobenzoyl chloride (8 g) at 0°. The reaction mixture was then stirred overnight at ambient temperature and processed with ice water (600 ml) in the usual manner. The solid product was washed thoroughly with water and then briefly with ice cold, 0.6 *N* hydrochloric acid. It was dissolved in dichloromethane, the solution was washed repeatedly with sodium bicarbonate solution and then with water, and after drying ($MgSO_4$) the solvent was removed again. The residue upon drying in high vacuum weighed 8.69 g, and t.l.c. revealed that it contained three products besides a small amount of *p*-nitrobenzoic acid. The crude material was passed through a column of silica gel (270 g) by means of benzene–ether (98:2). The fastest-moving component (**9**) was obtained as an amorphous powder (3.5 g, 40%) exhibiting $[\alpha]_D$ −5.5° (*c* 2, $CHCl_3$). It could not be crystallized but was homogeneous in t.l.c. (benzene–ether 7:1).

Anal. Calcd. for $C_{41}H_{33}N_3O_{15}$ (807.7): C, 60.97; H, 4.12; N, 5.20. Found: C, 61.02; H, 4.20 N, 5.19.

The second compound eluted from the column was also an amorphous, chromatographically homogeneous powder (3.5 g, 40%). It showed $[\alpha]_D$ −9.1° (*c* 2.5, $CHCl_3$) and was tentatively assumed to be 2,3-di-*O*-benzyl-1,4,6-tri-*O*-*p*-nitrobenzoyl-β-D-galactopyranose (**10**).

Anal. Calcd. for $C_{41}H_{33}N_3O_{15}$ (807.7): C, 60.97; H, 4.12; N, 5.20. Found: C, 60.80; H, 4.21; N, 5.27.

Finally, after a mixed fraction which was discarded, the most slowly moving component was eluted (952 mg); $[\alpha]_D$ −2° (*c* 1.5, $CHCl_3$). According to n.m.r. and i.r. spectra it contained a hydroxyl group and only two *p*-nitrobenzoyl groups.

2,3-Di-O-benzyl-5,6-di-O-p-nitrobenzoyl-β-D-galactofuranosyl Bromide (11)

Compound **9** (680 mg) was treated with anhydrous hydrogen bromide in dichloromethane as described above for the preparation of **5**. The *p*-nitrobenzoic acid collected weighed 133 mg (95%). The bromide **11** was obtained as a slightly colored, amorphous solid, $[\alpha]_D$ −59.4° (*c* 1.2, CH_2Cl_2).

Anal. Calcd. for $C_{34}H_{29}BrN_2O_{11}$ (721.5): C, 56.60; H, 4.05; Br, 11.08; N, 3.88. Found: C, 56.42; H, 4.17; Br, 10.87; N, 4.12.

2,3-Di-O-benzyl-5,6-di-O-p-nitrobenzoyl-β-D-galactofuranosyl Chloride (12)

Compound **9** (1.364 g) dissolved in a minimum amount of dichloromethane was added at room temperature to a saturated solution of anhydrous hydrogen chloride in dichloromethane (50 ml). Hydrogen chloride was passed through the solution continuously for 3 h and the closed vessel was then left standing for 36 h, after which t.l.c. indicated the reaction to be complete. By partial evaporation, the major part of *p*-nitrobenzoic acid precipitated (226 mg, 80%). The filtrate therefrom was rapidly washed with an ice cold sodium bicarbonate solution and with water. The dried ($MgSO_4$) solution was then treated with activated charcoal, filtered through Celite, and evaporated to furnish **12** (1.036 g, 90.6%) as an almost colorless solid; $[\alpha]_D$ −31.4° (*c* 2.3, CH_2Cl_2).

Methyl 2,3,4-Tri-O-benzyl-6-O-p-nitrobenzoyl-α-D-galactopyranoside (13)

The product obtained upon work-up of a methanolysis of **5** in the presence of tetrabutylammonium bromide (see a subsequent section) was crystallized from ethyl acetate – petroleum ether and recrystallized from anhydrous ether. It had m.p. 115–117° and $[\alpha]_D$ −3.5° (*c* 2, $CHCl_3$). The OCH_3 signal was at δ 3.34.

Anal. Calcd. for $C_{35}H_{35}NO_9$ (613.6): C, 68.50; H, 5.75; N, 2.28. Found: C, 68.62; H, 5.94; N, 2.36.

Methyl 2,3,4-Tri-O-benzyl-6-O-p-nitrobenzoyl-β-D-galactopyranoside (14)

The product obtained upon work-up of a methanolysis of **5** in the presence of mercuric cyanide was crystallized from ether and recrystallized from ethyl acetate – petroleum ether. It had m.p. 135–137° and $[\alpha]_D$ −33.5° (*c* 2.5, $CHCl_3$). The OCH_3 signal was at δ 3.53.

Anal. Calcd. for $C_{35}H_{35}NO_9$ (613.6): C, 68.50; H, 5.75; N, 2.28. Found: C, 68.61; H, 5.78; N, 2.47.

Methyl 2,3-Di-O-benzyl-5,6-di-O-p-nitrobenzoyl-α-D-galactofuranoside (15)

The product obtained by methanolysis of **11** in the presence of tetrabutylammonium bromide (see a subsequent section) was **15**. Recrystallized from ethyl acetate – petroleum ether it showed m.p. 116–118°, $[\alpha]_D$ +55.7° (*c* 2, $CHCl_3$).

Anal. Calcd. for $C_{35}H_{32}N_2O_{12}$ (672.6): C, 62.50; H, 4.80; N, 4.16. Found: C, 62.43; H, 4.72; N, 4.34.

A sample of **15** (350 mg) was treated with benzyl chloride (12 ml) and powdered potassium hydroxide (1 g) at 105° for 5 h. The reaction mixture was partitioned between chloroform and water. The dried chloroform phase was evaporated, eventually at 2 mm Hg to remove excess benzyl chloride. The oily residue was purified by passage through a silica gel column (30 g) with benzene containing 0.5% ether. There was obtained 167 mg (58%) of **16** whose n.m.r. spectrum was identical in every detail with that of **16** obtained from methyl α-D-galactofuranoside.

Methanolyses

(A) With Methanol Alone

A sample of glycosyl halide (approximately 100 mg, 0.14–0.18 mmol) was accurately weighed in a 5-ml volumetric flask and dissolved in dry dichloromethane (4.4 ml). Methanol (0.50 ml, 12.7 mmol) was added, and the volume was made up to 5 ml with dichloromethane. The change in optical rotation with time was recorded, a 1-dm tube being used. The first recording was usually made after 1 min. When the rotation had become constant, the solution was diluted with dichloromethane, washed once with aqueous sodium bicarbonate and once with water, dried over magnesium sulfate, and evaporated with eventual addition of several portions of carbon tetrachloride. The ratio of anomeric glycosides in the residue was then determined by integration of the OCH_3 signals of the n.m.r. spectrum in $CDCl_3$, at 250 Hz sweep width.

(B) In the Presence of Tetrabutylammonium Bromide

The procedure was the same as in *A* except that 200 mg of $(n\text{-}C_4H_9)_4NBr$ was added immediately prior to the addition of methanol and that, in work-up, two sodium bicarbonate and three water washings were included.

(C) In the Presence of Mercuric Cyanide

The procedure was the same as in *A* exeept that 40 mg (0.16 mmol) of $Hg(CN)_2$ was added prior to the addition of methanol. The reactions were too fast for polarimetric rate determination, and the runs were processed after one to several hours as convenient.

(D) In the Presence of Silver Tetrafluoroborate

In a typical experiment, a solution of glycosyl halide (160 mg) in dichloromethane (10 ml) was cooled to −78°, and approximately 95 mg of $AgBF_4$ was quickly introduced. (The reagent is very hygroscopic; rapid handling is more important than accurate weighing.) The mixture was first stirred in the dark for 10 min, methanol (0.5 ml) was then added, and stirring was continued for 1 h. The reaction mixture was filtered through Celite and then processed as in *A*.

GUY J. COLLIN et PIERRE AUSLOOS. Can. J. Chem. **53**, 680 (1975).

Les ions cy-$C_6H_{12}^+$ produits dans la photoionisation du cyclohexane (raies de résonance de l'argon: 11.6–11.8 eV) réagissent avec les composés insaturés et cycliques (C_3 et C_4) par transfert d'une molécule d'hydrogène. La réaction est quantitative avec le propène, l'isobutène, le butène-1, le pentène-1 et le butadiène-1,3. Avec les oléfines le transfert observé a lieu seulement si la double liaison est en bout de chaîne. Avec les petits cycles en C_3 et en C_4 il y a ouverture du cycle. Il y a également transfert d'un atome d'hydrogène entre l'ion cy-$C_6H_{12}^+$ et divers additifs et la structure du radical ainsi formé a été déterminée par analyse chimique. Avec le *cis*-butène-2 il y a seulement transfert de charge.

GUY J. COLLIN and PIERRE AUSLOOS. Can. J. Chem. **53**, 680 (1975).

The cy-$C_6H_{12}^+$ ions formed in the photoionization of cyclohexane (resonance lines of argon: 11.6–11.8 eV) react with cyclic (C_3 and C_4) and unsaturated hydrocarbons by H_2 transfer. This reaction is quantitative with propene, 1-butene, 1-pentene, 1,3-butadiene, and isobutene. This transfer is efficient only if there is a terminal double bond. There is ring opening with the C_3 and C_4 hydrocarbons. H atom transfer reactions are also observed between cy-$C_6H_{12}^+$ ions and several compounds and the structure of the radical formed in such a reaction is determined by chemical analysis. With *cis*-2-butene, there is only charge transfer reaction.

Introduction

Dans une étude récente, Ausloos et ses collaborateurs ont montré que les ions moléculaires cyclohexane (cy-$C_6H_{12}^+$) issus de la photoionisation du cyclohexane réagissent beaucoup plus vite avec le propène qu'avec le cyclohexane (1):

[1] $$cy\text{-}C_6H_{12}^+ + C_3H_6 \rightarrow C_3H_8 + C_6H_{10}^+$$

Lorsque la concentration de propène varie de 1 à 7%, le rendement en propane est pratiquement inaltéré. Dans le cas de la radiolyse, une variation de 1 à 87% n'affecte pas le rendement en propane (2): c'est dire que le cyclohexane est pratiquement inerte vis-à-vis des ions cy-$C_6H_{12}^+$, ou que s'il y a réaction, la constante de vitesse de celle-ci est très faible: $k \simeq 5 \times 10^{-14}$ cm^3 mol^{-1} s^{-1} (3). Il est donc intéressant d'utiliser ce système pour étudier certains aspects de la chimie des ions cy-$C_6H_{12}^+$. Il suffit, *à priori*, d'ajouter quelques pourcents d'un intercepteur convenablement choisi pour faire cette étude. Cette dernière s'inscrit dans notre programme d'études de la stabilité des hydrocarbures sous rayonnement et fait suite à d'autres travaux (4).

Nous ne démontrerons pas ici que globalement tout se passe comme s'il y avait un transfert d'une molécule d'hydrogène de l'ion cy-$C_6H_{12}^+$ vers l'additif, plus précisément de part et d'autre de la double liaison.

[2] $$cy\text{-}C_6H_{12}^+ + M \rightarrow C_6H_{10}^+ + MH_2$$

Nous mettrons plutôt l'accent vers les efficacités relatives de ce transfert et des réactions concurrentes possibles comme la réaction de transfert d'un atome d'hydrogène:

[3] $$cy\text{-}C_6H_{12}^+ + M \rightarrow cy\text{-}C_6H_{11}^+ + MH$$

Partie expérimentale

Le cyclohexane et les additifs sont le plus souvent des produits A.P.I. et sont employés sans autre purification. Les autres additifs sont le plus souvent purifiés par chromatographie en phase gazeuse. Les irradiations sont faites à l'aide d'une lampe à argon: 1066 Å (60%) –

[1]Une partie de ce travail a été subventionné par la U.S. Atomic Energy Commission et réalisé au Bureau National des Standards, Washington, D.C. L'autre partie a été réalisée grâce à l'aide reçue du Conseil national de recherches du Canada et de l'Université du Québec à Chicoutimi.

1048 Å (40%). Cette lampe a déjà été décrite ainsi que ses caractéristiques (5). La pression du cyclohexane est de 10 Torr (1330 N m^{-2}) sauf dans les cas indiqués. Les analyses ont été faites par introduction d'une fraction de l'échantillon irradié dans un chromatographe à gaz. Dans le cas du mélange cyclohexane:acétylène-d_2, l'éthylène formé est analysé par spectrométrie de masse (6). Chaque expérience est irradiée en présence de 5 ± 2% d'oxygène sauf dans les cas indiqués. Quelques expériences ont été réalisées dans un appareil de résonance cyclotronique ionique pulsé (i.c.r.). La durée de l'impulsion était de 5 ms; l'énergie des électrons était de 15 eV et la pression du cyclohexane était comprise entre 10^{-7} et 10^{-6} Torr.

Résultats

Ceux-ci sont consignés dans les tableaux accompagnant le texte. Les rendements sont indiqués comme étant le nombre de molécules produites (M) divisé par le nombre d'ions cyclohexane formés par le rayonnement (Ni). La quantification de ces rendements, M/Ni, est faite en utilisant la formation de l'éthylène (M/Ni = 0.95) ou le butadiène-1,3 (M/Ni = 0.33) dans la photolyse directe (1) du cyclohexane pourvu que la photolyse directe des additifs ne participe pas à la formation de produits mesurés, ce qui est le cas avec les faibles pourcentages de ceux-ci ajoutés (fig. 1).

La photolyse du cyclohexane pur produit des atomes d'hydrogène (1). En présence d'oléfine, ceux-ci conduisent aux radicaux alkyles susceptibles de former les produits MH et MH_2 par voie radicalaire. Afin d'éviter cette complication, on a ajouté de l'oxygène dans la majorité des systèmes étudiés. Par contre, il est connu que l'ion *cy*-$C_6H_{12}^+$ ne réagit pas avec l'oxygène (2).

Dans tous les cas, une variation de la proportion de l'additif entre 2 et 10% a peu d'effet sur le rendement des produits attribués à la réaction 2 (fig. 1). La variation de la pression totale dans le réacteur n'a pas non plus d'effet appréciable: (*i*) un accroissement de la pression totale de 5 à 20 Torr du système *cy*-C_6H_{12}:CH_3-*cy*-C_3H_5:O_2 (1.0:0.04:0.05) n'a pas d'effet sur le rendement en butane normal; (*ii*) l'addition de 500 Torr de xénon au mélange *cy*-C_6H_{12}:*cy*-C_3H_6:O_2 (1.0:0.04:0.05) n'a pas d'effet sur le rendement en propane; (*iii*) en outre, l'addition de 630 Torr de xénon au mélange *cy*-C_6H_{12}:C_4H_6-1,2:O_2 (10.0:0.3:0.5 Torr) ne change pas les rendements en *cis*- et *trans*-butène-2.

Le changement de l'éthylène-d_2 par l'éthylène-d_4 ne change pas le rendement en éthane. Enfin, aucun transfert du groupe H_2 n'a pu être mesuré avec l'isoprène, les pentadiènes-1,3 et -1,4, le pentène-2 et le méthyl-2-butène-2.

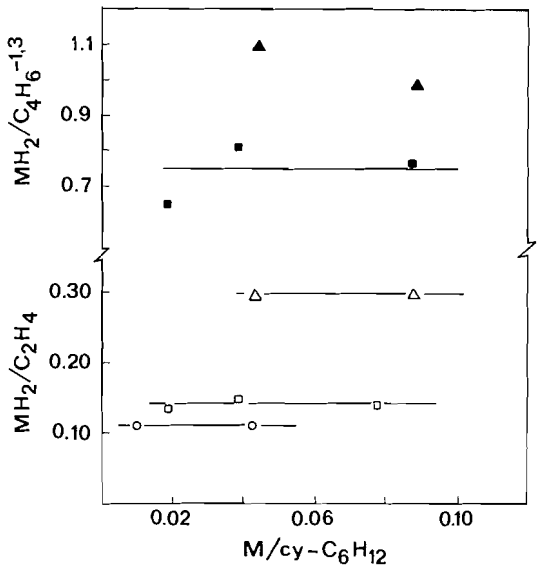

FIG. 1. Photolyse du cyclohexane (10.0 Torr) en présence d'additif M. Rendements relatifs MH_2/C_2H_4, points blancs; MH_2/C_4H_6-1,3, points noirs; ○: M = *cy*-C_3H_6; □, ■: M = *cy*-C_4H_8; △, ▲: M = CH_3-*cy*-C_3H_5.

Un certain nombre d'expériences ont été faites afin de déterminer la structure radical MH formé dans la réaction 3. A cette fin on a utilisé l'éthylène comme intercepteur radicalaire. L'addition des atomes d'hydrogène sur l'éthylène forment les radicaux éthyles. Une partie de ceux-ci se combinent aux autres radicaux présents dans le système pour former des produits caractéristiques. Les observations suivantes ont été notées: (*i*) l'addition de 4% de cyclopropane au mélange *cy*-C_6H_{12}:C_2D_4 (1.0:0.01) forme du *n*-$C_5D_4H_8$ (M/Ni = 0.19); on n'observe pas dans ce cas de formation d'isopentane (M/Ni < 0.01); (*ii*) l'addition de méthylcyclopropane produit du méthyl-3-pentane. On n'a pas observé de formation de *n*-hexane; (*iii*) l'addition de 4% de cyclobutane au mélange *cy*-C_6H_{12}:C_2D_4 (1.0:0.05) produit du *n*-$C_6D_4H_{10}$ tandis que l'on n'observe pas la formation d'hexanes ramifiés.

D'autres expériences utilisant des molécules partiellement ou complètement deutérées ont été faites afin d'obtenir la position dans la molécule de laquelle ou vers laquelle les atomes

d'hydrogène sont transférés: (*i*) au moins 90% du butane formé dans l'irradiation du mélange *cy*-C_6D_{12}:CH_3-*cy*-C_3H_6:O_2 (100:2:2) consiste de $CH_3CHDCH_2CH_2D$; (*ii*) la photoionisation du mélange méthyl-3-pentane-3-d_1:CH_3-*cy*-C_3H_5:O_2 (100:2:5) produit du *n*-butane dont 81 ± 5% sont constitués de $CH_3CH_2CH_2$-CH_2D, le reste étant formé de C_4H_{10} (5%), $CH_3CH_2CHDCH_3$ (7%) et de $C_4H_8D_2$ (7%); (*iii*) le *n*-butane analysé après l'irradiation du mélange *cy*-C_6H_{12}:*cy*-C_4H_8:CD_3-*cy*-C_5D_9:O_2 (100:5:2:2) consiste de C_4H_{10} (80%), CH_3CHD-$CHDCH_3$ (10%) et de C_4D_{10} (10%); (*iv*) environ 80% du *n*-butane formé dans l'irradiation des mélanges *cy*-C_6D_{12}:*cy*-C_4H_8:O_2 et *cy*-C_6H_{12}:*cy*-C_4D_8:O_2 (100:5:5) consistent en $CH_2DCH_2CH_2CH_2D$ et $CD_2HCD_2CD_2CD_2H$ respectivement.

Les irradiations faites dans l'appareil de résonance cyclotronique ionique des mélanges *cy*-C_6H_{12}:M (100:4) ont montré que l'ion *cy*-$C_6H_{12}^+$ transmet sa charge électrique très rapidement sur l'additif M lorsque celui-ci est soit le *cis*-butène-2, soit l'un des trois méthylbutènes. La constante de vitesse de ces réactions de transfert de charge a été déterminée comme étant voisine de 8×10^{-10} cm^3 mol^{-1} s^{-1}.

Discussion

Transfert de H_2

Il existe plusieurs possibilités de produire l'ion *cy*-$C_6H_{12}^+$. Une méthode simple consiste à photolyser le cyclohexane avec les raies de résonance de l'argon. Le potentiel d'ionisation du cyclohexane est de 9.88 eV et aux raies de résonance de l'argon (11.6–11.8 eV) le rendement quantique ionique est: $\eta = 0.49$ pour le cyclohexane et 0.50 pour le cyclohexane-d_{12}. Même si l'énergie disponible aux raies de résonance de l'argon est suffisante, l'ion parent ne se fragmente pas pourvu que la pression totale du système soit supérieure à 10 Torr (1, 3).

Les résultats indiqués dans le tableau 1 montrent la généralité de la réaction 2. Celle-ci a lieu avec les oléfines simples, conjuguées, les alcynes et les hydrocarbures cycliques en C_3 et en C_4. Thermodynamiquement toutes les réactions envisagées sont exothermiques par environ 1.5 ± 0.6 eV mol^{-1} dépendant de l'additif envisagé. Déjà la radiolyse du cyclohexane et du cyclopentane en phase gazeuse (2, 7) ont montré que la réaction 2 est en fait un exemple d'une réaction plus générale également observée en phase liquide (8).

[4] $\quad cy\text{-}C_nH_{2n}^+ + M \rightarrow C_nH_{2n-2}^+ + MH_2$

Cas des oléfines

Avec les oléfines simples, linéaires ayant la double liaison en bout de chaîne, le transfert d'un groupe H_2 est quantitatif sauf pour l'éthylène. La différence vient probablement du fait que l'éthylène a un potentiel d'ionisation supérieur à celui du cyclohexane. Récemment Lias et Ausloos ont discuté de la réaction de transfert d'un groupe H_2 (9). Tout d'abord, il y a déplacement de la charge électrique vers l'additif si son potentiel d'ionisation est plus bas que celui du cyclohexane. Concurremment il y a un accroissement de l'énergie interne du complexe réactionnel favorisant le transfert de particules de la partie cyclohexane vers la partie additif. Ce n'est pas le cas avec l'éthylène puisque son potentiel d'ionisation est plus élevé que celui du cyclohexane (10). Ensuite, le transfert des deux particules H, dont la première est chargée négativement (sauf dans

le cas de l'éthylène) se fait d'une façon successive. Le deuxième transfert n'est possible que si le temps de vie du complexe réactionnel est suffisamment long en regard de ce transfert. Dans le cas de l'éthylène l'énergie interne du complexe réactionnel étant moindre que celle des autres complexes, le transfert de la deuxième particule devient moins probable (tableau 2) (11).

[5] $cy\text{-}C_6H_{12}^+ + C_2H_4 \rightarrow (C_2H_5\text{-}cy\text{-}C_6H_{11})^+$

[5a] $(C_2H_5\text{-}cy\text{-}C_6H_{11})^+ \rightarrow C_2H_5 + cy\text{-}C_6H_{11}^+$

[5b] $(C_2H_5\text{-}cy\text{-}C_6H_{11})^+ \rightarrow C_2H_6 + cy\text{-}C_6H_{10}^+$

Lorsque la double liaison se trouve à l'intérieur de la chaîne, il y a d'abord transfert de la charge positive. Le transfert de la première particule, ici l'ion hydride H^-, n'est pas possible car la réaction est endothermique (9). Il s'ensuit qu'aucun transfert d'atome d'hydrogène n'est observable. C'est le cas du butène-2, pentène-2 et du méthyl-2-butène-2 (voir tableau 1).

[6] $cy\text{-}C_6H_{12}^+ + cis\text{-}C_4H_8\text{-}2 \rightarrow C_4H_8\text{-}2^+ + cy\text{-}C_6H_{12}$
$\Delta H = -0.7$ eV

[7] $C_4H_8\text{-}2^+ + cy\text{-}C_6H_{12} \rightarrow cy\text{-}C_6H_{11}^+ + s\text{-}C_4H_9$
$\Delta H = +0.2$ eV

La deuxième étape du transfert ne peut se réaliser bien que globalement le transfert d'un groupe H_2^- soit exothermique. L'absence

[8] $cy\text{-}C_6H_{12} + C_4H_8^+ \rightarrow cy\text{-}C_6H_{10}^+ + n\text{-}C_4H_{10}$
$\Delta H = -0.45$ eV

de transfert d'un atome d'hydrogène est mis en évidence dans l'irradiation du mélange $cy\text{-}C_6H_{12}$:$cis\text{-}C_4H_8$-2 (voir tableau 3). La formation des radicaux butyles secondaires est mis en évidence à travers la formation du *n*-butane

TABLEAU 3. Photoionisation du cyclohexane à 11.6–11.8 eV: mélange $cy\text{-}C_6H_{12}$:$cis\text{-}C_4H_8$-2 (10.0:0.35 Torr)

Produits	Rendements M/Ni
$trans\text{-}C_4H_8$-2	0.17 ± 0.03

iso-C_5H_{12}[a]	0.089
C_2H_6[a]	0.08

[a]En présence de 0.4 Torr d'oxygène, ces produits ne sont pas formés: M/Ni < 0.01.

et de l'isopentane (produits qui ne sont pas formés en présence d'oxygène). Cependant, l'analyse complète de ces résultats montre que ces radicaux sont formés en quantité juste suffisante pour expliquer la capture des atomes d'hydrogène libérés dans la photolyse directe du cyclohexane par le *cis*-butène-2. Le transfert de charge (réaction 6) est mis en évidence par la formation du *trans*-butène-2 même en présence d'oxygène (tableau 2). Il est connu que la photoionisation directe du *cis*-butène-2 conduit à la formation de ce produit à travers l'ion $cis\text{-}C_4H_8^+$ (12) avec un rendement M/Ni de l'ordre de 0.20. La réaction de transfert de charge (réaction 6) a été confirmée par les irradiations dans l'appareil i.c.r. (13). Ceci est enfin en accord avec le fait que l'ion $C_4H_8\text{-}2^+$ ne réagit pas, ou très lentement avec le cyclohexane (14, 15) contrairement aux ions $C_4H_8\text{-}1^+$ et iso-$C_4H_8^+$ (2).

Tout comme avec le *cis*-butène-2, on observe l'isomérisation de chacun des trois méthylbutènes (tableau 4). Récemment Collin et ses collaborateurs ont montré que la photoionisation de chacun des méthylbutènes conduit à cette isomérisation probablement par voie ionique (6, 16–18). L'explication la plus simple

serait d'admettre ici un transfert de charge entre l'ion cyclohexane et chacun des méthylbutènes, systèmes alors analogues à celui du *cis*-butène-2 (réactions confirmées par l'appareil i.c.r. (voir Résultats)). Cependant, l'isomérisation observée dans la photoionisation du méthyl-3-butène-1 est sensible à la pression contrairement à ce qui semble être observé ici. Ces observations sont pour l'instant mal comprises et d'autres travaux sont en cours pour essayer de clarifier ce point.

Cas des dioléfines

Alors que le transfert est quantitatif avec le butadiène-1,3, aucun transfert n'est observé avec les pentadiène-1,4 et -1,3 et l'isoprène. Par contre avec l'allène, le butadiène-1,2 et le pentadiène-1,2 un transfert est observé même s'il est très inférieur à l'unité. Il est remarquable que ce transfert a essentiellement lieu sur la double liaison terminale. La formation de pentène-1 (ou de pentyne-1) en présence de pentadiène-1,2 peut sembler être une exception à cette règle, bien que cette formation puisse être attribuable à d'autres processus réactionnels. Les rapports *cis*:*trans* des butènes-2 et des pentènes-2 formés en présence de butadiène-1,2 et de pentadiène-1,2, sont pour le moment incompris. Il faut noter que l'addition de xénon (voir Résultats) ne change pas ce rapport dans le cas du butadiène-1,2.

Cas des alcynes

L'efficacité du transfert de groupe H_2 augmente quand le potentiel d'ionisation de l'alcyne décroît conformément à l'observation déjà faite pour les oléfines linéaires. Il faut noter cependant que dans aucun des cas étudiés le rendement est quantitatif. D'autres réactions interviennent comme le transfert d'un atome d'hydrogène (tableau 2). On a même observé le transfert d'un groupe H_3 entre l'ion *cy*-$C_6H_{12}^+$ et l'acétylène (11). Dans le cas du butyne-2, on n'observe pas ou peu de transfert du groupe H_2.

Cas des cycles en C_3

Le transfert de groupe H_2 se fait avec ouverture du cycle, mais il n'est pas quantitatif. Avec le cyclopropane-d_6 il y a formation de $CD_2HCD_2CD_2H$ (7). L'irradiation du mélange *cy*-C_6H_{12}:*cy*-C_3H_6:C_2H_4 (tableau 5) dans lequel l'éthylène sert d'intercepteur radicalaire, il y a formation des *n*-butane, *n*-pentane et *n*-hexane. Il n'y a formation d'alkanes ramifiés. L'analyse complète de cette irradiation montre qu'il y a formation de radicaux *n*-propyles avec un rendement tel que M/Ni(n-$CH_3CH_2CH_2$) $\simeq 0.85 \pm 0.05$. Le rapport des efficacités des transferts des groupes H et H_2 est ainsi de l'ordre de 5.65 comparativement à 5 déterminé dans un spectromètre de masse (11). Avec le méthylcyclopropane (MCP), il a d'abord transfert de charge (11). L'ion MCP^+ ainsi formé semble réagir avec le cyclohexane pour former le propane (transfert d'un groupe H_2) ou un radical propyle (transfert d'un atome d'hydrogène) contrairement à l'observation faite dans le spectromètre de masse où il ne semble pas y avoir de réaction (11). Dans le présent système, la liaison C—C qui est brisée se trouve en position α du carbone substitué, c'est-à-dire là où la liaison est la plus fragile. Ainsi, la réaction de transfert du groupe D_2^- du cyclohexane vers l'ion MCP^+ se fait avec formation du $CH_3CHDCH_2CH_2D$ (voir Résultats).

[9] *cy*-C_6D_{12} + MCP^+ → *cy*-$C_6D_{10}^+$ + $CH_3CHDCH_2CH_2D$

Lorsque le transfert se limite à un ion hydrure, on observe la formation que du radical butyle secondaire. Ainsi, l'irradiation du mélange *cy*-C_6H_{12}:MCP:C_2H_4 (voir Résultats) conduit à la formation du méthyl-3-pentane et non de l'hexane normal. Le premier transfert de l'ion

[10] MCP^+ + *cy*-C_6H_{12} → $CH_3CHCH_2CH_3$ + *cy*-$C_6H_{11}^+$

[11] $CH_3CHCH_2CH_3 + C_2H_5 \rightarrow C_2H_5CH(CH_3)C_2H_5$

H^- a donc lieu vers le carbone terminal de la chaîne $CH_3CHCHC_2CH_2$ provenant de la

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

scission de la liaison C—C en position α dans le MCP. En d'autres termes, c'est le carbone situé en bout de chaîne qui attaque un atome d'hydrogène sur la molécule cyclohexane comme dans le cas des oléfines à double liaison terminale (9). Le mécanisme réactionnel est encore plus en évidence dans la photoionisation du mélange méthyl-3-pentane-d_1:MCP:O_2 (voir Résultats). Dans ce cas le *n*-butane formé est essentiellement constitué de $CH_3CH_2CH_2CH_2D$.

[12] 
Avec l'éthylpentane, il y a aussi formation de *n*-pentane et non d'isopentane. Là aussi la liaison qui se scinde est située en position α du carbone substitué. Avec le diméthyl-1,2-cyclopropane on n'observe pas de transfert de groupe H_2. La règle précédente voudrait que la liaison qui se scinde soit située entre les deux carbones substitués. Ainsi, cette molécule se comporte comme une oléfine avec la double liaison à l'intérieur de la chaîne.

Cas du cyclobutane

On observe aussi ici transfert d'un groupe H_2 avec ouverture du cycle. La formation du $CH_2DCH_2CH_2CH_2D$ (voir Résultats) en présence du cyclohexane perdeutéré donne une idée de ce que peut être la structure du complexe réactionnel. Ce résultat est cependant en opposition avec les résultats obtenus par spectrométrie de masse à basse pression (0–100 mTorr) (19). On y observe bien le transfert

[13] 
de charge. Cependant, cette réaction est endo-

[14] $cy\text{-}C_6H_{12}^+ + cy\text{-}C_4H_8 \rightarrow C_4H_8^+ + cy\text{-}C_6H_{12}$

thermique et l'endothermicité ne peut-être évitée que par l'ouverture simultanée du cycle. La structure de l'ion $C_4H_8^+$ ainsi formé ne peut-être identique aux ions $C_4H_8^+$ obtenus dans la photoionisation directe des butènes correspondants. L'ion C_4H_8-2^+ ne réagit pas (ou très lentement) avec le cyclohexane. Les ions C_4H_8-1^+ et iso-$C_4H_8^+$ forment le CH_2-$DCHDCH_2CH_3$ et l'isobutane respectivement avec le cyclohexane-d_{12} (2). D'autre part la photoionisation directe du cyclobutane produit des ions $C_4H_8^+$ dont la structure semble être C_4H_8-2^+ (80%) et iso-$C_4H_8^+$ (20%) (19, 20). Les ions $C_4H_8^+$ formés par transfert de charge du cyclohexane vers le cyclobutane semblent donc différents de ceux formés dans la photoionisation directe du cyclobutane. Ainsi, l'irradiation du mélange $cy\text{-}C_6H_{12}$:$cy\text{-}C_4H_8$:CD_3–$cy\text{-}C_5D_9$:O_2 (voir Résultats) forme du *n*-C_4H_{10} (80%) contrairement à celui formé dans l'irradiation du mélange $cy\text{-}C_4H_8$:CD_3 – cy-C_5D_9:O_2 (20.0:0.6:1.0 Torr) constitué de $CH_3CHDCHDCH_3$ (80%) et de CH_2DCD-$(CH_3)_2$ (20%) (19).

On observe également le transfert d'une particule H. L'usage de l'éthylène comme intercepteur radicalaire (voir Résultats) montre la formation de *n*-hexane. Il y aurait donc formation de radicaux *n*-butyles par transfert d'un

Photoreactions of Simple Halonaphthalenes in Solution

LUIS OCTAVIO RUZO, NIGEL J. BUNCE, AND S. SAFE
Department of Chemistry, University of Guelph, Guelph, Ontario N1G 2W1
Received August 22, 1974

LUIS OCTAVIO RUZO, NIGEL J. BUNCE, and S. SAFE. Can. J. Chem. **53**, 688 (1975).

The photolysis products and reaction quantum yields from a number of simple halonaphthalenes have been determined. Fluoronaphthalenes react from a singlet state to yield substitution products in nucleophilic solvents. Chloronaphthalenes and 1-bromonaphthalene afford mainly radical products (naphthalene and binaphthyls) through a triplet state, though some photonucleophilic substitution occurs with chloronaphthalene. Attempts at quenching lead to abnormal behavior, in that enhanced quantum yields for reaction are found with several potential triplet quenchers. Electron transfer processes are proposed to rationalize the observed products.

LUIS OCTAVIO RUZO, NIGEL J. BUNCE et S. SAFE. Can. J. Chem. **53**, 688 (1975).

On a déterminé les produits de photolyse et les rendements quantiques des réactions d'un certain nombre d'halonaphtalènes simples. Les fluoronaphtalènes réagissent à partir d'un état singulet pour conduire, dans les solvants nucléophiles, aux produits de substitutions. Les chloronaphtalènes et le bromo-1 naphtalène fournissent principalement des produits radicalaires (naphtalène et binaphtyls) par l'intermédiaire d'un état triplet; toutefois quelques produits de substitution photonucléophile se produisent avec le chloronaphtalène. Des essais de piégage ont conduit à des réactions anormales; en effet, on observe des rendements quantiques augmentés lorsque l'on utilise divers pièges d'états triplets. Afin de rationaliser la nature des produits obtenus, on fait appel à des transferts d'électrons. [Traduit par le journal]

In contrast with the photochemistry of halogenated benzenes, which has received considerable attention (1–4), little is known about the photochemical reactions of halonaphthalenes. Polychlorinated naphthalenes (Halowaxes, PCNs) are industrial compounds with properties and uses similar to polychlorinated biphenyls (PCBs) and in addition the former compounds have also been identified in commercial PCB preparations (5, 6). Polychlorinated naphthalenes are thus potential environmental pollutants so it is of interest to examine their photochemistry in considering their means of removal from the environment. Because the Halowaxes are complex mixtures, this paper examines the photoreactions of some simple halonaphthalenes with a view to establishing the main processes undergone by them, in terms of products and mechanisms.

Simple naphthalene derivatives exhibit moderate u.v. absorption near 300 nm due to a π–π^* transition. Interaction of the lone pair electrons of the halogen with the aromatic system leads to an excited state with some C—X antibonding character (7) so that bond fission might be expected for all but the fluoronaphthalenes where the C—F bond dissociation energy is greater than that of the incident radiation (8). Correspondingly, the only photoreaction previously observed in the fluoronaphthalene system has been reduction to a 1,4-dihydrofluoronaphthalene by a mechanism involving electron transfer (9).

Chloronaphthalenes have been found to undergo photochemical fragmentations. Chloride ion formation has been observed in the photolysis of 1-chloronaphthalene in ethanol (10); irradiation of the same compound in benzene afforded small amounts of 1-phenylnaphthalene (1). Kulis *et al.* (11) observed photoreduction of 1-chloronaphthalene to naphthalene in the presence of KOH–methanol, and found the quantum yield to be dependent on the concentration of base, suggesting an electron transfer mechanism. Similar photoreductions in the presence of bases have also been observed for 1-bromonaphthalene (12) and for bromoquinolines (13). Mamedov and Nasibov photolyzed the isomeric monochloronaphthalenes in hexane (14); they observed dechlorination but also claimed that there was photoisomerization of the α to the β isomer.

Results and Discussion

Irradiations were carried out at 300 nm, using as solvents methanol, cyclohexane, and aceto-

[d]Chlorination.
[e]The material balance on naphthyl residues was >95% in early stages of the reaction (6 h).

nitrile–water (4:1). The photoproducts are summarized in Table 1, and are seen to be a combination of dehalogenation, arylation, substitution of the halogen by solvent, and in the case of chloronaphthalenes, further chlorination.

Fluoronaphthalenes

Photolysis of each isomer in methanol gave only the corresponding methoxynaphthalenes. This suggests a photonucleophilic substitution, such as has been previously observed for fluorobenzene (15). The absence of quenching with oxygen and the failure of benzophenone to sensitize this reaction point to the involvement of a singlet excited state in the photosubstitution. Like fluorobenzene, both isomers also undergo substitution by diethylamine, affording *N,N*-diethylaminonaphthalenes, together with unstable neutral compounds, presumably dihydronaphthalene derivatives (9).

Chloronaphthalenes in Anhydrous Media

In cyclohexane solution, naphthalene and binaphthyl were the major products. Photolysis in methanol gave additional products of which methoxynaphthalene and dichloronaphthalene are the most notable, together with methoxy- and chlorobinaphthyls. However, we were unable to find any evidence for isomerisation of 1-chloronaphthalene to its isomer as previously claimed (14). The quantum yield for reaction was reduced by a factor of three in the presence of atmospheric amounts of oxygen, while in the presence of benzophenone approximately the same quantum yield was observed, suggesting that a triplet state is the principal precursor of both methoxylated and free radical products, as has been found in the chlorobiphenyl series (16). The predominance of the triplet-derived products is reasonable in view of the high phosphorescence/fluorescence ratio of 5.2 which has been observed in 1-chloronaphthalene (17), compared with 0.09 for the corresponding ratio in naphthalene itself. Such a pronounced heavy atom effect is not unusual for a π–π^* transition in an aromatic system of high symmetry (18).

Quantum yields for the reaction of both 1- and 2-chloronaphthalene are comparable, suggesting a similar lability for the chlorine atom in both environments. This is also true for 1,2-dichloronaphthalene, photolysis of which gave approximately equal yields of both monochloronaphthalenes and only small amounts of binaphthyls upon irradiation to low conversion in methanol.

The major organic products suggest that free radical intermediates are involved; however, simple homolytic fission according to eq. 1 seems unlikely because this reaction would be so endothermic. (Triplet energies of chloronaphthalenes are ~58 kcal/mol (17, 19) whereas

typical Ar—Cl bond dissociation energies are ~85 kcal/mol (20).)

[1] $$^3ArCl \rightarrow Ar\cdot + Cl\cdot$$

By analogy with previous observations on aryl halides (11–13, 21) some kind of electron-transfer process seems likely (eq. 2) and this postulate is supported by the observation that the quantum yield for disappearance of 1-chloronaphthalene increases eightfold in the presence of triethylamine, a known electron donor (9, 21; *cf. a* and *b* of ref. 22).

[2] $$^3ArCl + X \rightarrow Ar\cdot + X^{\cdot+} + Cl^-$$

Chloronaphthalenes in an Aqueous Medium

In aqueous acetonitrile, a solvent which can be considered a suitable model system for the environmental photochemistry, the main photoproducts from 1-chloronaphthalene were chlorobinaphthyl, 1-naphthol, and a hydroxylated dimer. In the presence of oxygen the dimers were largely suppressed. An additional product was detected in trace amounts showing *m/e* 104 by g.l.c. – mass spectrometry but could not be identified owing to its low yield and the difficulty of its separation from starting material. Polycyclic biaryls are thus formed but in the presence of oxygen 1-naphthol is the preponderant product; hydroxylated compounds are also known to arise from the metabolism of chloroaromatics (23). Photosubstitution to give the naphthol may be compared with similar observations by Crosby and Tutass (24) in the photolysis of the herbicide 2,4-dichlorophenoxyacetic acid.

1-Bromonaphthalene

The quantum yield for photolysis of this compound in methanol is considerably higher than those for the chloro compounds, presumably because of the lower C—X bond dissociation energy (65–70 kcal/mol). Naphthalene appears to be the major product; it is possible that HBr present in the solution upon photolysis acts as such a good source of hydrogen abstraction for the naphthyl radicals that arylation does not compete. That this may be the case is suggested by the observation that photolysis of 1-chloronaphthalene in the presence of small amounts of HBr also leads to an increase in the ratio of naphthalene to binaphthyls.

Quenching Experiments

An attempt was made to determine the triplet lifetimes of the isomeric chloronaphthalenes in methanol by quenching experiments (Table 2). 1,3-Cyclohexadiene was initially chosen for this purpose since its triplet energy ($E_T \sim 50$ kcal/mol) is considerably lower than those of the chloronaphthalenes ($E_T > 58$ kcal/mol). The most singular observation was made that the 'quencher' enhanced the rate of both disappearance of the chloronaphthalene and formation of naphthalene, though not to the same extent. Similar rate enhancements were observed when biacetyl ($E_T = 55$ kcal/mol) and *trans*-stilbene ($E_T = 50$ kcal/mol) were tried as quenchers, though as noted already, the reaction is quenched by oxygen. Some small amount of quenching was noted with 1-bromonaphthalene, but even here, the rate of naphthalene formation increased. These increases in the chemical yield of naphthelene apparently result from suppression of binaphthyls and higher arylation products. Either energy transfer does not occur in these systems, despite its energetic favorability, or it is in competition with some chemical pro-

cess by which the decomposition of the remaining unquenched molecules is enhanced. Certainly, energy transfer seems to be very inefficient, for the phosphorescence spectrum of 1-chloronaphthalene (5×10^{-2} *M*, EtOH, 77 °K) is quenched only 40% by piperylene concentrations as high as 0.12 *M*. A possible rate-enhancing reaction might be exciplex formation, followed by electron transfer (eq. 2, X = quencher). Whatever the mechanism behind the lack of quenching, its observation seems important because the quenching method is customarily used to determine triplet lifetimes in solution. Failure of the method may thus require reevaluation of the reliability of triplet lifetimes so determined, especially in reactions where ϕ_r is small, for example, other chloroaromatics (16, 25), since only a small intrusion from a rate enhancement process would be necessary to exert a significant effect in such cases.

Routes to Products from Monochloronaphthalenes

The photoreactions of the chloronaphthalenes are similar to those of other chlorinated aromatics. Reductive photodechlorination is well known (16, 26) and has been studied extensively for compounds of environmental importance (25, 27–29). Most of these investigations have been concerned exclusively with product identification; however, we may compare our results on the chloronaphthalenes with recent observations by Ruzo *et al.* (16) on the photolysis of the tetrachlorobiphenyls. Quantum yields for reaction (ϕ_r) for the tetrachlorobiphenyls are also low, in the 10^{-3} range for five of the six compounds studied. The phosphorescence lifetimes of chlorobiphenyls and chloronaphthalenes in rigid glasses are also comparable (1–10 s) (17, 19, 30).

The major products in our study, naphthalene and binaphthyls, clearly result from C—Cl fission, though as argued earlier, this is more likely to involve electron transfer than direct homolytic fission. Formation of the binaphthyl derivatives seems to result from arylation rather than radical coupling. This is apparent from the formation of chloro- and methoxy-substituted binaphthyls as well as the parent compound and by analogy with the production of 1-phenylnaphthalene on photolysis of 1-chloronaphthalene in benzene (1).

We have rationalized the products in the context of the reactions of Scheme 1, in which NpCl is chloronaphthalene, ArH is any naphthyl derivative (including NpCl) and Q is quencher.

[3] $\mathrm{NpCl^* + ArH \rightarrow Np^{\cdot} + Cl^- + ArH^{\cdot +}}$

[4] $\mathrm{Np^{\cdot} + RH \rightarrow NpH + R^{\cdot}}$

[5] $\mathrm{NpCl + Q \rightarrow Np^{\cdot} + Cl^- + Q^{\cdot +}}$

[6] $\mathrm{Np^{\cdot} + ArH \rightarrow \rightarrow Np{-}Ar}$

[7] $\mathrm{Ar^{\cdot +} + ArH \rightarrow \rightarrow Ar{-}Ar}$

[8] $\mathrm{Ar^{\cdot +} + CH_3OH \rightarrow \rightarrow Ar{-}OCH_3}$

SCHEME 1

Observations suggesting a role for chloronaphthalene and its derivatives as electron donors (eq. 3) are the suppression of biaryls in the presence of quencher, when presumably reaction 5 intervenes successfully. The electron transfer complex (exciplex) NpCl·ArH may correspond to the 'π-dimer' of chlorobenzene recently postulated by Fox *et al.* (31) in the photoreactions of chlorobenzene. Whether a monomeric π species corresponding to their π-chlorobenzene (a chlorinating agent) could account for the further chlorination of monochloronaphthalenes is unknown. We observed that photolysis of a solution of chlorine and 1-chloronaphthalene in methanol increased the rate of chlorination by 30% over the dark reaction, and in benzene the rate enhancement was 20-fold. It is possible that the chloronaphthalene undergoes attack by chlorine atoms whose selectivity has been increased by some kind of complexation. Other chloroaromatics have been observed to yield products of enhanced chlorine content upon photolysis (32).

Further experiments are currently in progress to try to substantiate these proposals. One interesting but unexplained observation is that the quantum yield for reaction of the monochloronaphthalenes is the same whether or not benzophenone is present, yet reactions conducted in the presence of benzophenone give substantially more binaphthyls and less naphthalene than those unsensitized, even though the conversion of chloronaphthalene is essentially unchanged. One possibility is that electron transfer is important here too, *e.g.* $\mathrm{NpCl + Ph_2CO^* \rightarrow NpCl^{+\cdot} + Ph_2CO^{-\cdot}}$ (*cf.* ref. 22) but to date we have no evidence to support such a proposal.

Experimental

Materials

Solvents were analytical grade materials that were

dried and distilled before use. Acetonitrile was purified by successive distillations from sodium hydride and phosphorus pentoxide (33). 1-Fluoronapthalene was obtained in 42% yield by the Schiemann reaction from 1-naphthylamine (34); 2-fluoronaphthalene (Columbia Organic Chemicals) was recrystallized from methanol. 1-Chloronaphthalene (Eastman) was distilled repeatedly until no impurities were present by g.l.c. 2-Chloronaphthalene (Eastman) was twice recrystallized from ethanol. 1,2-Dichloronaphthalene (Chemical Procurement Labs.), benzophenone, naphthalene, and 1-bromonaphthalene (all J. T. Baker) were used as supplied. 1,3-Cyclohexadiene and biacetyl for use as quenchers were Aldrich materials, distilled before use. 1,1′-Binaphthyl was prepared by copper coupling of 1-bromonaphthalene in dimethylformamide (35). All these compounds were authenticated by mass spectrometry and their purity checked by g.l.c. before use. The methoxynaphthalenes were prepared in solution by methylation of the appropriate naphthol with diazomethane but were not isolated.

Photochemical Procedures

Irradiations were conducted in a Rayonet Reactor equipped with RUL 3000 lamps having a maximum output at 300 nm. The chamber temperature was approximately 30°. Equal illumination of samples being photolysed simultaneously was assured by use of a 'merry-go-round' apparatus. Reactions in the presence of oxygen were carried out in screw cap vials; other irradiation mixtures were degassed by four freeze–pump–thaw cycles using liquid nitrogen and sealed *in vacuo*. For calculation of quantum yields, conversions were limited to $< 10\%$ to minimize light absorption and reaction of products. The light intensity was calculated using the modified ferrioxalate actinometer (36).

Analytical Procedures

The gas chromatograph was a Hewlett-Packard model 5710A equipped with a 6 ft × 1/8 in. i.d. glass column packed with 3% SE30 on 80–100 mesh Chromosorb W. This column was operated isothermally at 160° using helium (30 ml/min) as carrier gas. Detection of products was by flame ionization, with injector and detector maintained at 300°. This column separated all the necessary compounds except 1- and 2-chloronaphthalenes, which were partially resolved using a 25% 1,2,3-tris(cyanoethoxy)propane on Gas Chrom Q, 20 ft × 1/16 in. i.d., column operated isothermally at 90° and 30 ml/min helium flow. For product identification, retention times and mass spectra were compared with those of authentic samples. For mass spectrometric analysis a Varian Associates Model 1700 gas chromatograph was interfaced directly to a Varian MAT Model CH7 mass spectrometer operated at 70 eV ionizing voltage.

Irradiation of Simple Halonaphthalenes in Cyclohexane and Methanol

Irradiations of 10^{-2} *M* solutions were carried out from 20 to 60 h for degassed samples and up to 120 h for aerated ones. After photolysis the amount reacted was measured by g.l.c., solutions were then concentrated and analyzed for products.

Irradiation of 1-Chloronaphthalene in Acetonitrile–Water (4:1)

Solutions (10^{-2} *M*) were either degassed by nitrogen flushing or aerated. After 60-h photolysis the samples were evaporated and the residue extracted with ether until the aqueous layer showed no absorption at 250 nm, then concentrated and analyzed by g.l.c.–m.s. Sensitized reactions were 5×10^{-2} *M* in benzophenone and 2×10^{-3} *M* in chloronaphthalene. After photolysis the products were extracted as described.

Irradiation of 1- and 2-Fluoronaphthalenes with Diethylamine

These irradiations were carried out semipreparatively. The appropriate fluoronaphthalene (2.0 g) and diethylamine (100 ml) were irradiated with the unfiltered light of a 450 W medium pressure mercury arc for 7 h. After evaporation of the solvent, basic and neutral extracts were made. From the neutral extract were recovered starting material and unstable compounds presumed to be dihydronaphthalenes (9); chromatography of the basic material over silica gel afforded the isomeric *N,N*-diethylaminonaphthalenes, which were identical with samples prepared for comparison by the action of ethyl iodide on the naphthylamines. *N,N*-Diethyl-1-naphthylamine: oil (0.23 g); n.m.r. (CCl_4): δ 1.02 (triplet, J = 7 Hz, 6H), 3.16 (quartet, J = 7 Hz, 4H), 7.0–8.4 (multiplet, 7H).

The Reaction of Hydrogen Atoms with Palladium and its Alloys

W. A. OATES[1] AND TED B. FLANAGAN

Chemistry Department, University of Vermont, Burlington, Vermont 05401

Received September 16, 1974

W. A. OATES and TED B. FLANAGAN. Can. J. Chem. **53**, 694 (1975).

H atoms, which have been generated in the gas phase, have been allowed to interact with palladium metal and several of its substitutional f.c.c. alloys. It has been found that quite high concentrations of interstitial hydrogen can be introduced in this manner even in the absence of poisons such as H_2S. The kinetics of hydrogen uptake have been followed as a function of the hydrogen content of the palladium. The kinetics of the subsequent loss of hydrogen from the palladium have been investigated. Mechanisms for the surface reactions of hydrogen on palladium are discussed.

W. A. OATES et TED B. FLANAGAN. Can. J. Chem. **53**, 694 (1975).

On a permis à des atomes d'hydrogène qui ont été générés en phase vapeur d'interagir avec du palladium sous forme métallique et plusieurs de ses alliages f.c.c. On a trouvé qu'on peut introduire des concentrations importantes d'hydrogène interstitiel de cette manière, même en l'absence de poisons tel que H_2S. On a déterminé la cinétique de l'absorption d'hydrogène comme une fonction du contenu en hydrogène du palladium. On a examiné la cinétique de la perte subséquente d'hydrogène à partir du palladium. On discute des mécanismes des réactions de l'hydrogène sur le palladium. [Traduit par le journal]

Introduction

The attainment of large concentrations of interstitial hydrogen in palladium and its substitutional alloys is very desirable for several reasons. These systems become superconductive at high hydrogen contents; *e.g.*, pure palladium is a superconductor at H-to-Pd (atomic ratio) > 0.83 (1). Another reason is that values for limiting hydrogen contents are needed for theoretical models of these systems; *i.e.*, is the limiting hydrogen content in a f.c.c. substitutional alloy equal to the fraction of palladium or is it greater or less than this for a particular alloy system (2–4)? In palladium it is known that the hydrogen atoms occupy octahedral interstices about the palladium atoms (5). On geometric grounds, therefore, the limiting hydrogen content should be H-to-Pd (atom ratio) = 1. The attainment of this limiting ratio constitutes a scientific challenge.

Baranowski and colleagues in Poland (6) have pioneered in the use of high pressures of gaseous hydrogen for obtaining very high hydrogen contents in palladium. They have recently obtained hydrogen pressures as great as 30 000 atm (298 K) (6). One disadvantage of this direct high pressure technique has been that, so far, it has not been possible to determine the hydrogen contents of the samples *in situ*. For analysis of the hydrogen contents the high pressure apparatus has been cooled, the pressure released, and the samples have been subsequently analyzed. Hydrogen may escape during this process. For pure palladium they have obtained with this cooling procedure an H-to-Pd (atom ratio) of 0.96 (7). The high pressure method has the advantage that equilibrium is obtained and the hydrogen should be uniformly distributed throughout the sample; on the other hand, it has the drawback that it is experimentally very demanding.

The most commonly employed technique for introducing large hydrogen contents into palladium and its alloys has been electrolysis (8). In this method hydrogen atoms are produced at the surface of the metal by making it cathodic, generally in a poisoned electrolytic solution. The presence of the poison, *e.g.* H_2S, inhibits the desorption of hydrogen. With this technique in acidified methanol (195 K) an H-to-Pd ratio of 1.0 has been recently reported (9).

Using ion implantation at liquid helium temperatures Stritzer and Buckel (10) have succeeded in introducing very large concentrations of hydrogen (deuterium) in palladium and its alloys. They have reported a remarkably high superconductive temperature of 16 K for a deuterium-charged Ag/Pd alloy (11). Ion im-

plantation has the disadvantage that the hydrogen is not uniformly distributed throughout the sample. For the purpose of superconductivity experiments this is not a handicap because the superconductive current follows the path of lowest resistance, but non-uniform distributions of hydrogen may cause difficulties for other experiments.

In the method explored here, reaction of metals with gaseous hydrogen atoms, the equipment requirements are modest. Data relating to the introduction of hydrogen into transition metals by means of atomic hydrogen are scant and conflicting (12). The authors have reported in a brief note (13) that the method was a success for producing very high hydrogen contents in palladium. A value of H-to-Pd = 0.99 $\pm$ 0.01 was found and this was the closest value to the stoichiometric ratio of 1 where a direct and unambiguous method of analysis has been used. Other workers had reported values close to this, or even in excess of the stoichiometric ratio, but in all cases these reports had been based on indirect evidence. For example, arguing from the electrical resistance *vs.* fugacity relationships, Baranowski and co-workers (14) suggested that values in excess of unity may be formed. Suhrman and co-workers (15) reported an H-to-Pd ratio of 1.8 at 95 K on a palladium film but chemisorption could have been a factor. Buckel and Stritzer (16) have reported values in excess of 1 but the uncertain distribution of the implanted hydrogen could introduce sizable errors into their estimated ratios of H-to-Pd. It seems important to stress that the errors introduced into the analysis of the hydrogen contents must be carefully considered. Since our preliminary report (13), Harper has reported an H-to-Pd ratio of "about 1.0" (9) obtained by electrolysis and subsequently analyzed by weighing and by degassing. Values for the uncertainty in the ratio were not reported but it can be estimated for the 5 mm diameter, 25 μ palladium foil, which he employed, the expected error in the gravimetric determination, $\pm 2 \times 10^{-6}$ g, would lead to a minimum uncertainty in the atomic ratio of ± 0.025.

This paper reports the details of the absorption of hydrogen by palladium up to atom ratios near unity via the reaction of the metal with H atoms and additional experiments connected with the introduction of hydrogen into hydrogen-absorbing metals.

Experimental

Palladium metal (> 99.9% purity) was used in the form of thin wire (0.027 cm diameter). The samples were generally flame-annealed prior to insertion into the apparatus. The apparatus was a conventional high vacuum system employing stopcocks, mercury diffusion, and mechanical pumps. Gold-foil separated the sample vessel from mercury but no special precautions were taken to protect the samples from contamination by stopcock grease. Various types of reaction vessels were used depending upon the motive of the particular experiment and whether H-atoms were generated by an electrodeless discharge or by a hot-tungsten filament. For the latter method a tungsten filament from an incandescent light bulb (60 W) was heated (70 V) to approximately 2000 K. The reaction vessels were standard pyrex ones which were used without special pre-treatment. The use of H_3PO_4 to coat the walls of the vessel did not appear to help in the efficiency of loading the sample. (H_3PO_4 is believed to suppress the H–H recombination reaction (17).) After prolonged use, the efficiency of a bulb declined and it was either replaced or washed with HF and distilled water prior to re-use. Both static and flow systems were employed for H atoms generated either with a hot tungsten filament or with an electrodeless r.f. discharge.

In the static experiments the hydrogen absorbed by the sample was monitored by the pressure changes. The accuracy of pressure measurement is critical, especially during the final degassing analysis of the hydrogen content. The following gauges were available: a Pirani gauge (LKB), a McLeod gauge, a narrow-bore manometer (~0.4 cm). a diaphragm gauge (Data-metrics), and a wide-bore mercury manometer (> 1.0 cm). The wide-bore manometer, which was read with a cathetometer, was used to calibrate the diaphragm gauge and to make an independent measurement of the pressure of the evolved hydrogen in one experiment. The Pirani gauge was calibrated by the McLeod gauge.

The most effective procedure for the introduction of large interstitial hydrogen concentrations into palladium was a static one using a hot tungsten filament. The wire was flamed in air, weighed, and placed on the bottom of the reaction flask so as to maximize thermal contact. The wire (~1 g) was generally cut into 1 cm pieces, helping to insure thermal contact. About 1 mm Hg of hydrogen was introduced into the reaction vessel and a pressure change was not noted until the filament was turned-on. The pressure fall was then quite dramatic for an initially hydrogen-free sample and when the pressure fell to a low value, a further dose was introduced. This process was repeated until absorption became sluggish, *i.e.*, when H-to-Pd ~ 0.9. The sample vessel was then cooled to 195 K and the process repeated. The approximate H-to-Pd ratio could be monitored from the pressure changes. This was not very accurate because the temperature of the reaction vessel was not uniform. After absorption via H atoms had apparently stopped, the sample vessel was evacuated (195 K), and the sample gently heated by a flame on the outside of the reaction vessel. The evolved hydrogen was then measured whilst the measuring volume was at a uniform temperature. The Pyrex reaction flask had been repeatedly heated prior to the run at temperatures greater than the degassing temperature of the sample, and it was determined with blank

runs that negligible gas was evolved from the walls of the vessel during this heating. The temperature of the reaction flask during the degassing was only slightly above 500 K. Typical pressures evolved during the degassing of the samples were in the range 3 to 10 mm Hg.

In an attempt to introduce hydrogen more efficiently into palladium, the reaction vessel was cooled to 77 K after introducing hydrogen at 195 K. At 77 K water was produced whereas it was not at 195 K. The H–H recombination reaction is apparently very efficient on the pyrex walls at $\geqslant$195 K but at 77 K it is slow enough for the H atoms to linger on the walls and to react with oxygen atoms of the pyrex. Temperatures between 77 and 195 K were not attempted.

The Pirani gauge was used for the first series of runs and these indicated that large interstitial hydrogen contents were being formed. In order to insure that these results were indeed the case, a diaphragm gauge was installed and this confirmed the observation of values of H-to-Pd close to unity. The diaphragm gauge was then calibrated with a wide-bore mercury manometer. In the range between 3 and 10 mm Hg (the usual range of pressures found after evolution of the hydrogen) a standard deviation of $\pm$0.083 mm Hg was found between the readings of the manometer (corrected for the expansion of mercury) and the diaphragm gauge. The volume of the reaction vessel was determined by filling it with water and weighing. A typical volume for the reaction vessel-was 1225 cm^3. It was used to calibrate the remainder of the system into which the hydrogen evolved. The total volume for a representative reaction flask and the measuring system was 1885 $\pm$ 5 cm^3. The metal samples were weighed to $\pm$0.0001 g.

When H atoms were produced by the electrodeless discharge either a static or flow system was employed. A flow system was also tried for the hot tungsten filament generated H atoms. The pressure was maintained at approximately 1 mm Hg during the flow. The hydrogen was ultra-pure from a cylinder. The flow systems suffered from the disadvantage that the hydrogen contents of the samples could not be monitored by pressure changes. Electrical resistance measurements were used for this purpose.

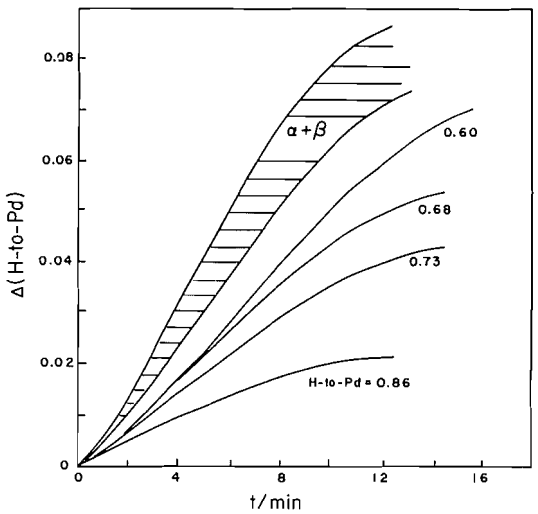

FIG. 2. Typical recording tracings of hydrogen uptake by palladium (273 K) via H-atoms generated by a hot tungsten filament.

Results

Kinetics for H atom Absorption and Subsequent Hydrogen Loss

A typical absorption run, where hydrogen was introduced via gaseous H atoms from a hot tungsten filament is shown in Fig. 1 (273 K). Hydrogen was admitted at 0.9 mm Hg and there were no pressure changes for as long as the pressure was monitored with a strip chart recorder. This finding is in accord with earlier observations; *i.e.*, hydrogen does not equilibrate with palladium in a conventional high vacuum system if possibilities exist for contamination by, for example, stopcock grease (18). On the other hand, equilibrium is fairly rapidly established between bulk palladium and hydrogen, although still controlled by surface steps, if a grease- and mercury-free system is employed (19, 20). When the filament was turned-on, the pressure dropped rapidly (Fig. 1). When it was turned-off again, the pressure did not change. The hydrogen rapidly enters the sample via H atoms and is retained. It has been shown elsewhere that hot tungsten filaments are effective H atom generators (21). It should be noted that the inhibition of the $H_2 \rightarrow 2[H]$ reaction, where [H] represents interstitially absorbed hydrogen, and its reverse, arises from traces of contaminants in the system and not from added poisons such as H_2S. Oxygen is not a poison because chemi-

For personal use only.

sorbed oxygen is rapidly removed by hydrogen (22). Further doses of hydrogen were added to the reaction vessel and the process repeated. A typical series of recording tracings during absorption (273 K) is shown in Fig. 2. It can be seen that in the two-phase region, the rate of hydrogen uptake is closely constant. Hydrogen-saturated palladium (α) and a non-stoichiometric hydride (β) phase coexist in the palladium/H_2 system at 273 K with the respective compositions H-to-Pd (atom ratio) = 0.009 (α) and 0.6 (β) (8). At ratios greater than 0.6, hydrogen dissolves in the non-stoichiometric hydride phase. Across the two-phase region, although the overall hydrogen content of the sample increases with the proportion of β to α, the surface composition is invariant and the rate of hydrogen uptake via H atoms is constant. At H-to-Pd ratios greater than 0.6, the rate of uptake gradually diminishes as the hydrogen content increases (Fig. 2). If a run was made with another sample, the absolute rates were found to be somewhat different but the general sequence of events is unaffected. When the rate of uptake became very slow at 273 K, the sample was cooled to 195 K, and the process repeated until no further hydrogen was absorbed. Generally at this point the sample vessel was evacuated (195 K) and the final hydrogen content of the sample was determined by degassing the sample *in situ* by gentle heating.

For the study of the kinetics of desorption of hydrogen from a palladium sample which had attained a high hydrogen content the reaction vessel was evacuated at 195 K and then gradually heated whilst monitoring the pressure as a function of temperature. A silicone oil bath was used to gradually heat the bottom of the reaction vessel. With a heating rate of 5° per min, the accumulated pressure against temperature relationship shown in Fig. 3 was obtained. This particular sample originally contained an H-to-Pd (atom ratio) of 0.99. It can be seen that hydrogen is slowly lost from the sample at ~393 K, and the rate of loss is greatest at 473 K where all of the hydrogen is lost. This same behavior was observed with other samples which were charged to ratios near unity and it agrees with the finding that absorption via molecular hydrogen is only established above about 393 K (18); *i.e.*, Everett and Nordon (18) observed that the forward reaction takes place only above about 393 K, and it was observed here that the reverse

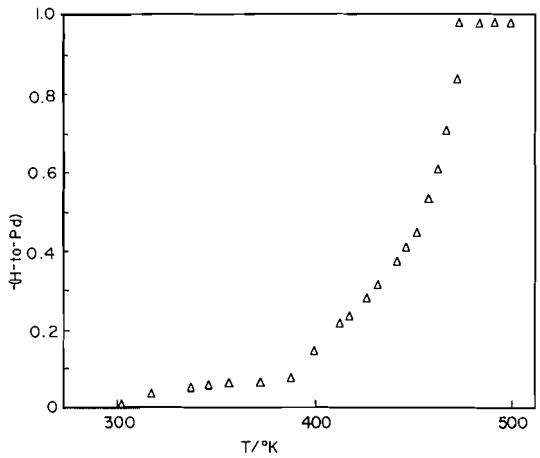

FIG. 3. Typical run showing hydrogen evolution from a palladium sample with an initial H-to-Pd ratio of 0.99. −(H-to-Pd) indicates loss of hydrogen from the sample expressed as the ratio.

reaction takes place at about the same temperature and, therefore, equilibrium cannot be established until the temperature is >393 K. This inhibition of the absorption and desorption of molecular hydrogen in a slightly contaminated system is, of course, a great convenience because it allowed the preparation and analysis of palladium containing large amounts of interstitial hydrogen.

Attainment of Interstitial Hydrogen Contents in Palladium Approaching Unity

Hydrogen to palladium ratios close to unity were obtained by progressive loading of the sample using H atoms generated from hot tungsten filaments in a static system first at 273 and then at 195 K. Typically 15 separate doses were required in order that the optimum pressure range could be employed for the hot tungsten-generated H atoms. The entire process required 4 to 5 h. Results are shown in Table 1. The probable error in the H-to-Pd ratios at large hydrogen contents, *i.e.* H-to-Pd > 0.9, can be estimated as ± 0.005 for the one sample whose evolved hydrogen was measured directly with the wide-bore mercury manometer and ± 0.01 for the majority of the samples which were measured with the diaphragm gauge. The errors in the ratios of the first series of samples run, whose hydrogen analyses were based on the Pirani gauge (calibrated with the McLeod gauge), are probably somewhat greater than ± 0.01. It is of interest that for a sample with a

16	Au (foil)	W-filament (static)	Diaphragm	0.00

lower hydrogen content (run No. 1), H-to-Pd = 0.90, a gravimetric determination of its hydrogen content agreed quite well with the subsequent degassing analysis via the Pirani gauge. (For this sample, at least, hydrogen was not lost upon exposure to air.) The hydrogen contents monitored during absorption of hydrogen were generally not as accurate as the final analysis by degassing; however, they generally agreed to within an uncertainty in the ratio of ± 0.02.

It should be emphasized that the reported ratios of H-to-Pd in Table 1 do not represent an experimental scatter about some maximum value but reflect rather the degree of success of the loading procedure. The more successful runs were performed after experience had been gained and these generally gave values for H-to-Pd = 0.99 ± 0.01, *e.g.*, runs 5 through 8. The report of H-to-Pd $\cong$ 1.0 via electrolysis (9) may certainly be correct but it would be more strongly supported if the errors in the analysis procedure had been fully reported.

The degree of agreement amongst the various analyses using different pressure gauges and the repeated attainment of H-to-Pd ratios of 0.99 ± 0.01 leaves no doubt that such ratios were indeed obtained via reaction of palladium with H atoms. There is still, however, a large degree of art connected with this method. The pre-treatment of the reaction vessel and metal surface and the geometry of the hot tungsten filament relative to the sample are all rather poorly understood variables.

Burch (4) has suggested that for Ag/Pd substitutional alloys the maximum hydrogen contents which can be achieved can be predicted from the relationship H-to-Pd (max) = $1 - CX_{Ag}/X_{Pd}$, where $C = 0.525$. He based this upon his analysis of pressure–composition–temperature data for the H/Ag/Pd system (3) which includes data up to $X_{Ag} = 0.4$. An attempt has been made to charge several Ag/Pd alloys up to their maximum hydrogen contents via H-atoms. For the Ag($X_{Ag} = 0.55$)/Pd a value of H-to-Pd = 0.53 (Table 1) has been found which is in excess of Burch's predicted value of 0.35.

In a recent investigation of the substitutional f.c.c. alloy system V/Pd it was found that only small amounts of substituted vanadium reduced the solubility of hydrogen at 1 atm (298 K) to very small values (23). For example, for an alloy with $X_V = 0.06$ the solubility of hydrogen was only H-to-metal = 0.06 (1 atm, 298 K). With the introduction of hydrogen via H atoms an H-to-metal ratio of 0.22 was found and an even greater ratio for the V($X_V = 0.1$)/Pd alloy (Table 1); this alloy absorbed negligible hydrogen at 1 atm. This suggests that the low one-atmosphere solubility in these alloys is due to energetic reasons and not because vanadium is excluding many adjacent interstitial sites.

Using the hot tungsten filament method for the generation of H-atoms it was found that hydrogen can be readily absorbed by nickel (Table 1). Ratajczykowa and Polczewska (24) have also reported that nickel hydride can be

prepared in this manner, in the presence of H_2S in their case. Nickel hydride can be prepared with gaseous H_2 at a pressure of approximately 7000 atm (298 K) (6). The low H-to-Ni ratio observed in this work (Table 1) may be due to the fact that nickel hydride has been observed to penetrate into the nickel substrate only to small depths (6).

There has been evidence presented in the literature that rhodium may form a hydride phase (25). This was based on the extrapolation of the behavior of Rh/Pd alloys to high pressure. The estimated conditions necessary for the formation of rhodium hydride are 35 000 atm (298 K). Attempts to prepare a rhodium hydride via the H atom method were unsuccessful. In one set of experiments a bright palladium layer was electroplated onto the surface of the rhodium but this was also unsuccessful.

The electrodeless discharge (r.f.) method of generating H-atoms also worked for the introduction of large interstitial hydrogen contents into palladium but was not employed as extensively as the simpler hot tungsten filament method. The electrodeless discharge technique was used for the determination of relationships between the relative electrical resistance of palladium (R/R_0, where R is the electrical resistance at any hydrogen content and R_0 is the hydrogen-free resistance) and its hydrogen content. In several experiments the increase of relative resistance with hydrogen content was followed up to a maximum value of 1.73 (273 K) and then past the maximum to values down to 1.2 at H-to-Pd = 0.9. We were not able to increase the hydrogen content so that the resistance fell to its hydrogen-free value and the method was not pursued. Relationships between R/R_0 and H-to-Pd have been obtained over a larger range of hydrogen contents using other methods for introduction of hydrogen (8). The heating effect from the recombination reaction on the electrical leads may have been a problem.

Discussion

Some conclusions may be drawn about the mechanism of hydrogen absorption and recombination on palladium (slightly poisoned surfaces) from these results. In their investigation of the reaction of H atoms with metallic sodium Anderson and Ritchie (26) found that the rate of reaction fell above 0.1 mm Hg; they attributed this to collisional deactivation of excited H_2 species which they suggest can react with the metal. By contrast, in the present study pressures near 1 mm Hg were the most effective for hydrogen uptake and for this reason we do not believe that excited H_2 species contribute. Hydrogen molecules are absorbed by palladium in two consecutive steps:

$$[1] \qquad \tfrac{1}{2}H_2 \rightarrow \underset{*}{H}$$

$$[2] \qquad \underset{*}{H} \rightarrow [H]$$

where $\underset{*}{H}$ and [H] represent chemisorbed and absorbed hydrogen, respectively. Step 1 is believed to be the slow step even for clean surfaces of palladium (bulk) (20). When absorption occurs via H atoms, the dissociation process is not needed and instead the following two steps obtain:

$$[1'] \qquad H\cdot \rightarrow \underset{*}{H}$$

$$[2] \qquad \underset{*}{H} \rightarrow [H]$$

Step 2 and its reverse are believed to be rapid enough for the equilibrium of chemisorbed and absorbed hydrogen (20). Step 1 is extremely slow on slightly poisoned samples as shown by the fact that it does not occur at 298 K or below (these studies) or 393 K (18) and the reverse process was not observed until the temperature was above 393 K (Fig. 3).

Palladium has a very high efficiency for the H–H recombination reaction (27). Approximately 1 out of every 5 atoms which collide with the surface undergo recombination. (The hydrogen content of the palladium was not noted during this study (27) and the efficiency may increase as the hydrogen content increases since the surface coverage increases with the bulk content.) Because of the rapid absorption which takes place via H atom generation it can be concluded that a significant fraction of the hydrogen atoms do not recombine but undergo the transition to the absorbed state.

Since it has been established here that the $2\underset{*}{H} \rightarrow H_2$ reaction is very slow at temperatures below 393 K, it is clear that recombination cannot proceed by this mechanism. The probable mechanism for the recombination reaction is $H\cdot + \underset{*}{H} \rightarrow H_2$. Bond (28) has also suggested this mechanism on the basis of the expected full

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

coverage by chemisorbed hydrogen on transition metals. Bond's argument may no longer be generally valid, however, because it has been shown, for example, that on platinum single crystals the coverage with hydrogen is not complete even at rather large pressures (29).

Absorption of hydrogen via H atoms probably occurs by collision with a favorable empty surface site; *i.e.*, a surface interstitial site followed by rapid transition to the absorbed state. The fall-off in the rate of hydrogen uptake (Fig. 2) occurs only at quite high hydrogen contents because only then does the surface coverage start to approach completion.

There are two research papers concerning the kinetics of hydrogen (H_2) absorption by palladium (20, 30). Wicke and Mayer (30) employed a palladium black surface whereas Auer and Grabke (20) used bright palladium. The latter research is, therefore, more relevant to the present situation. They have found that the dissociation of the hydrogen molecule is rate-determining, the reaction step occurs on only one site on the surface, and at least one of the atoms from the dissociation process is incorporated into the lattice.

The chemisorption → absorption equilibrium has been recently investigated (31) and it was proposed that there may be two different hydrogen-binding sites on palladium. On one site strong chemisorption occurs and on the other, which is postulated to be between the surface palladium atoms (a surface interstitial site), weak chemisorption takes place. The hydrogen chemisorbed on the latter site is in equilibrium with absorbed hydrogen. These sites were found to be only incompletely occupied at relatively high pressures, *e.g.*, 10 mm Hg, 298 K.

Auer and Grabke (20) have found an activation energy for the absorption of hydrogen by palladium of 28.6 kJ/mol H_2. It would be expected that the activation energy for the absorption via H atoms would be negligible. It is not clear why reaction step 1 is readily poisoned whereas step 1′ is not affected, if absorption proceeds at the same surface sites. If the atomic hydrogen removes the poison which blocked these sites, absorption could then occur readily through the surface interstitial sites. If this were the correct mechanism, then the poison would have to reblock these sites after cessation of the H atom production. On the other hand, it seems more likely that two adjacent surface interstitial sites are needed for step 1 but only one site for step 1′. If a poison occupied two adjacent surface sites, then there would be few free adjacent surface sites but some vacant single sites for step 1′.

This exploratory study of a complex phenomenon indicates that the interaction of those transition metals capable of absorbing large amounts of hydrogen with H atoms is both useful and mechanistically interesting.

Solvent Effects on Solvent Exchange Reactions at Nickel(II) Centers[1]

COOPER H. LANGFORD[2] AND JAMES P. K. TONG

AND
ANDRÉ MERBACH
Institut de Chimie Minérale et Analytique, Université de Lausanne, Lausanne, Suisse

Received June 26, 1974

COOPER H. LANGFORD, JAMES P. K. TONG, and ANDRÉ MERBACH. Can. J. Chem. **53**, 702 (1975).

Several recent correlations relating kinetics of Ni(II) complex formation and solvent exchange to solvent properties are examined after collection of literature and new experiments on solvent exchange kinetics at Ni(II) when *only the solvent* is varied (entering group, leaving group, and nonlabile ligands held constant). The results indicate solvent exchange is remarkably insensitive to bulk solvent. It is suggested that this implies that the interesting correlations of complex formation rates with solvents introduced by Bennetto and Caldin provide a means to study the solvent dependence of the encounter equilibria between a Ni(II) complex and a ligand L. The linear relationship between enthalpies and entropies of activation for reactions at Ni(II) in different media is attributed to the changes in the ligands bound to the Ni(II) center but not undergoing substitution in the reaction observed.

COOPER H. LANGFORD, JAMES P. K. TONG et ANDRÉ MERBACH. Can. J. Chem. **53**, 702 (1975).

On passe en revue plusieurs corrélations récentes reliant les propriétés des solvants avec la cinétique de formation des complexes du Ni(II) et la cinétique de leur échange avec les solvants. On compare les données compilées dans la littérature avec les résultats obtenus lors de nouvelles expériences sur des cinétiques d'échanges avec les solvants au niveau du Ni(II) quand *seule la nature du solvant varie* (on maintient constant le nucléophile, le nucléofuge et les ligands non labiles). Les résultats indiquent que l'échange du solvant est d'une façon remarquable insensible à la nature du solvant comme milieu réactionnel. On suggère que ces résultats impliquent que les corrélations intéressantes, introduites par Bennetto et Caldin, et reliant les vitesses de formation des complexes et les solvants fournissent un moyen d'étudier la dépendance sur le solvant de l'équilibre de formation de complexes externes entre un complexe de Ni(II) et un ligand L. La relation linéaire entre les enthalpies et les entropies de réaction pour la réaction du Ni(II) dans différents milieux est attribuée à des changements dans les ligands, liés au Ni(II) central, qui ne sont pas impliqués dans les réactions de substitutions des réactions observées.

[Traduit par le journal]

Introduction

The model currently accepted for ligand substitution (complex formation) at Ni(II) centers in water as solvent is an I_d path (1) usually called the Eigen–Wilkins (2) mechanism, and written as shown in reaction 1.[3]

$$[I]\quad NiS_6 + L \underset{\text{Encounter or outer sphere complex}}{\overset{K_E}{\rightleftharpoons} L,NiS_6} \overset{k_1}{\rightarrow} \underset{\text{Activated complex}}{L...NiS_5...S} \rightarrow NiLS_5 + S$$

K_E is the equilibrium constant for encounter between NiS_6 and L or, in other words, the constant for transfer of L from bulk solvent to the outer sphere of NiS_6 with a corresponding *reverse transfer of S*. The reaction is designated dissociative (d) because k_1 is insensitive to the specific nature of L and differs from the solvent exchange first order rate constant only by a statistical factor first identified by Langford and Muir (3). Under usual (low concentration) experimental conditions, an observed complex formation reaction is found to be second order, first order in NiS_6 and first order in L. Such a second order constant, k_L, has the interpretation under mechanism 1 that $k_L = K_E k_1$. Such K_E should depend primarily on charge type. The fact that k_L has been seen to vary 20-fold for neutral ligands reacting with $Ni(OH_2)_6^{2+}$ (4) (diamines excluded for the reason of the special

[2]To whom correspondence should be addressed.

[3]Charge notations are deliberately omitted for clarity. "S" and "L" stand for solvent and ligand molecules respectively.

mechanism discussed by Wilkins (2)) indicates that there are some problems for a simple account via an I_d mechanism and reaction 1. Caldin and Bennetto have developed a very interesting mechanistic picture which seeks to take solvent effects explicitly into account (4, 5). This picture is applied to reactions in nonaqueous solvents as well as water. A critical, but sympathetic, appraisal of the Caldin–Bennetto viewpoint has been given by Chattopadhyay and Coetzee (6) and the same viewpoint has been taken up for discussion of reactions at Mg(II) centers by Crea *et al.* (7). However, despite the active interest in the Caldin–Bennetto viewpoint, an alternative account of the factors which determine complex formation and solvent exchange (especially solvent exchange) reactivity when the solvent is changed has been developed (8, 9).

The Caldin–Bennetto Model and Reaction 1

The postulates underlying the Caldin–Bennetto model of solvent effects may be summarized as follows (4). (*1*) Solutions of metal ions in nonaqueous polar solvents can be represented by a model similar to the Frank and Wen (10) model for aqueous solutions. (*2*) The kinetics of complex formation are controlled partly by the energy required to dissociate the Ni—S bond and *partly by interaction of the leaving S* molecule with the *bulk solvent* into which it passes. The correlated movement of L or S out of the bulk solvent into the first coordination sphere seems to be less important. (*3*) The *structural* properties of the solvent are modified locally by the presence of L molecules, an effect related to solute–solvent intermolecular forces between L and S. The consequences of these postulates are worked out by consideration of the effects relating to transferring molecules from a "bulk solvent structure" region through a "disordered solvation region"[4] to the primary coordination shell of Ni^{2+} which is identified with the "ordered solvation shell" of Frank (4, 10). In particular, correlations of kinetic parameters with solvent *fluidity*, (viscosity/density) as defined by Bennetto and Caldin (4, 5), and *enthalpy of vaporization* of solvent are emphasized.

The object of the present paper is to consider the kinetics of reaction 1 and their implications for solvent effects. Reaction 1 implies in the case of Ni(II) complexes (where k_1 is of the order of $10^4\ s^{-1}$) that the distribution of L or S between the bulk solvent and the encounter sphere (second coordination sphere or outer sphere) of NiS_6 is governed by a pseudo *equilibrium* which adjusts *rapidly* to any changes in the primary coordination sphere. The effect of bulk solvent structure should then be found in the modification of K_E for L's that interact differently with solvent. Reaction 1 seems to imply the contrary of postulate 2 of Caldin and Bennetto in that the equation emphasized the role of bulk solvent in the transfer of L from bulk to the encounter region prior to any inner–outer sphere exchanges and *neglects* the interaction of the leaving S molecule "with the bulk solvent into which it passes". In the case of solvent exchange in the pure solvent, reaction 1 simplifies. The equilibrium for S between bulk and encounter sites is *trivial*. All sites of both types will be occupied by S at all times. As long as exchange between the two sites remains fast (diffusion is fast compared to k_1 as in all solvents studied except glycerol (11)), the rate of solvent exchange is *independent of bulk solvent structure*. This again sets interpretation according to reaction 1 in contrast with the second postulate above. Another way of looking at this contrast is to observe that solvent is always in encounter with NiS_6 and that solvent exchange is an *inherently* first order process and *not* a pseudo-first order "bimolecular" process (12).

Our purpose here will be to explore the evidence for the claim in postulate 2 of the Caldin–Bennetto model that "... interaction of the leaving S molecule with the bulk solvent into which it passes" is the important factor. We do this by exploring the effect on solvent exchange rates of modification of bulk solvent structure by introducing noncoordinating electrolytes or salts. Our reference point for this is the first approximation suggestion of reaction (1) that *solvent exchange rates are independent of bulk solvent structure* (and activity)!

Relevant Literature

We note that the work of Caldin and Bennetto, Chattopadhyay and Coetzee, and Crea,

[4]It may be noted that the implication that the secondary coordination sphere of a metal complex is "disordered" is valid if order is identified with bulk solvent order. However, various experimental techniques have suggested that the metal ion and primary coordination sphere impose order on the secondary coordination sphere. The degree of ordering in the secondary solvation shell is an unresolved issue.

[a]All rate constants are presented as first order exchange rates per coordination site at the metal ion. In some sources, ref. 13*a* for instance, rate constants are given as overall rates of solvent exchange at per molal metal ion, which then must be divided by a factor of 6 as was done by the same author in ref. 13*b*.
[b]Other experiments with added electrolytes revealed no effects on rates.

Lincoln, and West cited above involves change of more than bulk solvent. In those studies, when solvent is changed, so is the nature of the leaving group at the metal center and also the other five ligands attached to the metal center. Contemporaneously, a considerable amount of literature has accumulated in which the bulk solvent was the *only* variable. The main thrust of the present paper is to compare the two types of studies. We add in limited fashion to the experimental documentation by the new experiments reported. The literature we discuss has simply not yet compared the two types of studies. The reactions of the second type previously described are solvent exchange of $Ni(OH_2)_6^{2+}$ studied by $^{17}OH_2$ n.m.r. in water and $>6\,m$ $LiClO_4$ (13), study of solvent exchange of $Ni(NH_3)_6^{2+}$ with NH_3 in NH_3 and aqueous ammonia (14), the effect of the addition of CH_3NO_2 as an unreactive solvent component on the rate of dimethylsulfoxide (DMSO) exchange at $Ni(DMSO)_6^{2+}$ (15), and the addition of large mole fraction of inert solvent on the solvolytic replacement of DMSO by H_2O at $Co(NH_3)_5DMSO^{3+}$ (16). These results are collected in Table 1.

All these results tend to support the conclusion that solvent effects are small. Such changes in solvent exchange rates when the reactive solvent is "diluted" by a second solvent component or a salt are consistent with the idea that a few encounter sites have been denied to the reactive solvent molecules and that the rate is down somewhat for essentially statistical reasons. Even without specific data on viscosities or enthalpies of evaporation, it is clear that the examples represent cases of large change in bulk solvent structural parameters and yet fail to exhibit correspondingly significant changes in either k (which may be insensitive due to cancellation of $\Delta\Delta H^{\ddagger}$ and $\Delta\Delta S^{\ddagger}$) and/or $\Delta H^{\ddagger}$. The extreme is the first example. In water, bulk structure is important. In 6.5 *m* $LiClO_4$ an average of only 4.27 water molecules are associated with each ion. *There is no bulk*, and the co-sphere is also ill-defined. All water is in ion solvation shells. The effect is startlingly small viewed from the perspective of any model.

Results

In imitation of the first entry in Table 1, the present experiments concern the modification of the solvent by addition of salts. The first studies are dimethylformamide (DMF) exchange at $Ni(DMF)_6^{2+}$ in the presence of several concentrations of *n*-Bu_4NClO_4 and $LiClO_4$ studied with the ^1H n.m.r. T_2 of the formyl proton. The results are collected in Fig. 1 and Table 2. The second studies concerned water exchange at $Ni(OH_2)_6^{2+}$ studied by ^{17}O n.m.r. with the addition of tetra-*n*-butylammonium nitrate. The salt was chosen because it produces large changes in water viscosity. The viscosities of the solutions were measured. Temperature depen-

dence of observed rate parameters are shown in Fig. 2. Table 3 collects kinetic parameters and Table 4 reports the viscosities.

Discussion

Role of Solvent in Solvent Exchange Reactions

In the introduction, the concepts of effect of solvent structure on rate introduced by Caldin and Bennetto were outlined. These propositions were based on two kinds of *experimental* evidence. The first kind of evidence from experiments depended on correlation of bulk solvent properties with a parameter n based on eq. 2

$$[2] \qquad n = k_L/K_E k_{ex}$$

where k_L is the second order rate constant for complex formation by a ligand L in a solvent, K_E is the encounter equilibrium constant for that ligand with the solvocomplex and k_{ex} is the solvent exchange rate constant in the solvent. The correlation was between n and the solvent structure related parameters, or between $\Delta H_L^{\ddagger} - \Delta H_{ex}^{\ddagger}$ (where the subscripts L and ex assign the activation enthalpies to k_L and k_{ex} processes) and the solvent parameters. The second line of experimental evidence (5, 6) followed from interpretation of a correlation between enthalpy of activation and entropy of activation including both solvent exchange and complex formation reactions and common to several metal ion centers if correction for ligand field contributions to enthalpy were made.

The limits of the first line of evidence have already been tested by Chattopadhyay and Coetzee (6). Their work establishes that n (and $\Delta H_L^{\ddagger} - \Delta H_{ex}^{\ddagger}$) is a moderately sensitive function of the choice of L. Moreover, the ordering of solvents with respect to the magnitude of n is not constant as L varies. This points to n as a parameter of *ligand* solvent interaction. Such a conclusion accords with the view presented in this paper.

Postulate 2 of the Caldin–Bennetto model requires that change of the bulk solvent structure, dynamics, and activity should change the interaction of the leaving S with bulk solvent and hence the free energy of the transition state. Postulate 2 was introduced to account for variations of n over more than an order of magnitude and substantial changes in $\Delta H_L^{\ddagger} - \Delta H_{ex}^{\ddagger}$. Results in Tables 1 and 2 do not reveal any variations of corresponding magnitude. Most alterations of bulk solvent recorded there leave either

k_{ex} or $\Delta H_{ex}^{\ddagger}$ unaltered within experimental error.

The present paper also bears on the significance of the $\Delta H^{\ddagger}$–$\Delta S^{\ddagger}$ correlation and the role of the dynamic parameter, viscosity. If it is true that the correlation exists over a wide range of reactions in a wide range of solvents because it reflects solvent structure effects (5, 6), it should be possible to alter $\Delta H^{\ddagger}$, $\Delta S^{\ddagger}$, and perhaps k_{ex} by altering solvent structure. Table 1 collects literature data (not refuted by the new experiments) bearing on this question in a way different from the earlier correlations (6). Here the focus is on the effects of *altering solvent* and *solvent structure* while maintaining a *constant* reaction system. If the activation parameters for exchange of, say, DMSO between $Ni(DMSO)_6^{2+}$ and bulk DMSO are compared to those for exchange of water between $Ni(OH_2)_6^{2+}$ and bulk H_2O, at least the following relevant features have been varied: (*1*) the nature of the leaving group, (*2*) the nature of the other ligands bound to the reactive center, (*3*) the nature of the entering group, and (*4*) the solvent. Evidence exists that all of these factors may be important except (*3*).

If the $\Delta H^{\ddagger}$–$\Delta S^{\ddagger}$ correlation is to be interpreted, (*1*) and (*2*) must be considered as well as (*4*). One may begin with the observation that the fundamental significance of a $\Delta H^{\ddagger}$–$\Delta S^{\ddagger}$ correlation is that the reactions have a common mechanism (23). In terms of factor (*1*), the assumption of a dominantly dissociative mechanism suggests variations in $\Delta H^{\ddagger}$ with the enthalpy of the bond to be broken but only small variations in $\Delta S^{\ddagger}$. Factor (*1*) then implies a very large value of the isokinetic temperature in a $\Delta H^{\ddagger}$–$\Delta S^{\ddagger}$ correlation. This is not observed. In

terms of factor (*2*), the $\Delta H^{\ddagger}$–$\Delta S^{\ddagger}$ correlation requires a more negative $\Delta S^{\ddagger}$ as the five ligands which do not leave become more favorable to substitution. There are two points to note. First, the nonlabile ligands do change $\Delta H^{\ddagger}$ for water substitution at Ni(II) significantly (13). Second, a ligand which is strongly bound itself contributes to labilization of another (9). A dissociative transition state will be stabilized (lower $\Delta H^{\ddagger}$) if the five remaining ligands rearrange to bind more strongly to the center of reduced coordination number. This process puts restrictions on the five ligands which are expected to be reflected in lower $\Delta S^{\ddagger}$. It emerges that the $\Delta H^{\ddagger}$–$\Delta S^{\ddagger}$ correlation could be explained, at least in part, by factor (*2*) in a manner consistent with the observed isokinetic temperature. Of course, factor (*4*) can explain the correlation also.

The choice between emphasis on factor (*2*) and factor (*4*) as the major contributor to the $\Delta H^{\ddagger}$–$\Delta S^{\ddagger}$ correlation depends on examination of the behavior of $\Delta H^{\ddagger}$ (or $\Delta S^{\ddagger}$) when one of the factors (*2*) or (*4*) is changed and the other is held constant. The substantial changes in $\Delta H^{\ddagger}$ as nonlabile ligand is changed (factor (*2*)) with solvent (factor (*4*)) held constant, have been reviewed elsewhere in some detail (13). This paper concerns circumstances in which *factor (2) is invariant and factor (4) is varied.*

In aqueous solutions, we see that bulk solvent structure may be "destroyed" with little effect on $\Delta H^{\ddagger}$. A 6.5 *m* solution of $LiClO_4$ allows, on the modest estimate of 4 waters each as nearest neighbors of Li^+ and ClO_4^-, less than 7 mol of water to form secondary solvation shells intervening. Ionic co-spheres strongly overlap. The values of k_{ex} and $\Delta H_{ex}^{\ddagger}$ speak for themselves (Table 1). The impact of the more recent work on other salt containing media is consistent with this striking example. Adding salts to the lower dielectric constant solvent, DMF, resulted in $\Delta H^{\ddagger}$ parameters which could not be reliably distinguished in the presence or absence of salt (Table 2, Fig. 1). In this case, at maximum salt concentration, assumption of four solvent molecules each per cation and anion leaves ~6 mol of solvent outside contact layers. The average distance between two neighboring ions is ~2 solvent molecules. Ionic co-spheres do overlap. The new experiment in water bears on the emphasis on dynamic coupling in Bennetto and Caldin's postulate 2. In water dynamically altered by the significantly structure-making ion $(n\text{-but})_4N^+$ it was impossible to distinguish experimentally between the kinetic parameters in the presence or absence of the salt (Table 3, Fig. 2). The dynamic modification of water structure by the salt is attested by the increase in water viscosity by 40% (Table 4).

Similar results are seen for variation of factor (*4*) in the limited class of cases where solvent mixtures may be examined without alteration of the reactive systems. Frankel's results (15) for mixtures of DMSO with nitromethane, for example, were all represented on the same linewidth–temperature curve without regard to the nitromethane content. Liquid NH_3 and aqueous NH_3 are nearly equivalent and not experimentally distinguishable (14). The remaining examples are for rate constants only but the small variations suggest slight change in activation parameters.

The present critique of the solvent structure interpretation of the $\Delta H^{\ddagger}$–$\Delta S^{\ddagger}$ correlation also leads to the *conclusion that the I_d, Eigen–Wilkins, model has the advantage over the dynamic solvent coupling model of Caldin and Bennetto in that it is capable of explaining a lack of sensitivity of solvent exchange to bulk solvent modification.* In solvent exchange the encounter equilibria are trivial ($\Delta G^0 = 0$) and cannot be altered by alteration of the bulk alone. It remains to be shown that the I_d, Eigen–Wilkins, model can be adapted to the explanation of the solvent effects discovered by Caldin and Bennetto with respect to *complex formation* reactions.

Role of Solvent in Complex Formation Reactions

According to reaction 1, the I_d or Eigen–Wilkins model, the second order rate constant for complex formation, k_L, may be equated to $K_E k_1$ where $k_1 = sk_{ex}$ (*s* is a statistical factor). The role of the statistical factor can be seen in the new experiments in DMF (Table 2, Fig. 1). It can be seen that perchlorate ion can reduce the rate of solvent exchange without measurably changing the value of $\Delta H^{\ddagger}$. In light of the extensive pairing of $Ni(DMF)_6^{2+}$ with ClO_4^- expected in DMF, this is comprehensible. It is plausible to assume that the ClO_4^- ions occupy some outer sphere sites making them unavailable to participate as sites for solvent exchange. As a consequence, this may affect $\Delta S_{ex}^{\ddagger}$, and hence k_{ex}, but not to any significant extent $\Delta H_{ex}^{\ddagger}$.

The parameters for correlation with bulk solvent properties introduced by Caldin and Bennetto, ln *n* and $\Delta\Delta H$, can be interpreted

using the Eigen–Wilkins model. According to Bennetto and Caldin (4)

$$[3] \qquad n = k_L/0.1k_{ex}$$

and

$$[4] \qquad \Delta\Delta H^{\ddagger} = \Delta H_L{}^{\ddagger} - \Delta H_{ex}{}^{\ddagger}$$

In eq. 3, k_L is the observed second order rate constant; and 0.1 is the uniformly assigned value of K_E; refer to eq. 2 of Caldin and Bennetto (4, 5) in their critique of the Eigen–Wilkins model. Using the assumption that K_E is constant or may be calculated from the Fuoss–Eigen electrostatic equation (2, 8, 12) and making the substitution of the original formulation of k_L, due to the Eigen–Wilkins model, into eq. 3, one obtains

$$[5] \qquad n = \frac{K_E s k_{ex}}{0.1k_{ex}} = (s/0.1)K_E$$

It follows that the parameter, ln n, may be interpreted as

$$[6] \qquad \ln n = -\frac{\Delta H_E{}^0}{RT} + \left(\frac{\Delta S_E{}^0}{T} + \ln\frac{s}{0.1}\right)$$

where $\Delta H_E{}^0$ and $\Delta S_E{}^0$ are the free energy, enthalpy, and entropy of formation of the outer sphere complex, $NiS_6.L$. In eq. 4, $\Delta H_L{}^{\ddagger}$ is the observed enthalpy of activation for the ligand substitution process, and can be given as $(\Delta H_E{}^0 + \Delta H_{ex}{}^{\ddagger})$ according to the Eigen–Wilkins model. With this substitution for $\Delta H_L{}^{\ddagger}$, eq. 4 will then read

$$[7] \qquad \Delta\Delta H^{\ddagger} = (\Delta H_E{}^0 + \Delta H_{ex}{}^{\ddagger}) - \Delta H_{ex}{}^{\ddagger} = \Delta H_E{}^0$$

It is quite important to recognize that these parameters, $\Delta H_E{}^0$ and $\Delta S_E{}^0$ of the encounter equilibrium are solvent sensitive.

So far, only a few weak encounter equilibria have proved susceptible to direct experimental examination. Two recent n.m.r. studies are important (24, 25). They show that K_E values for neutral molecule neutral complex encounters vary over more than a factor of ten and are solvent sensitive. We believe that the Bennetto–Caldin parameters $\Delta\Delta H^{\ddagger}$ and n provide the widest ranging and most general method for exploration of the factors controlling K_E that is experimentally available.

Experimental

N,N-Dimethylformamide (DMF) line-broadening experiments were done on a Varian XL-100 n.m.r. spectrometer in 5 mm n.m.r. tubes. By locking on the methyl protons of DMF, the formyl proton absorption line was recorded. Linewidths at the half-height were measured. The probe temperature was calibrated by a copper–constantine thermocouple, and was kept constant to ±0.5 °C.

The ^{17}O n.m.r. line-broadening experiments for water were done on a Brüker HX-90 n.m.r. spectrometer in 8 mm n.m.r. tubes. The differential mode of the resonance signal was recorded. The peak-to-peak separations were measured. Modulation broadening was carefully avoided by minimizing the modulation amplitude and correcting for the residual (26). The sample temperatures were determined by direct insertion of a thermometer into the sample tube while it was still inside the probe.

Viscosity measurements were made by an Ostwald's viscometer which calibrated at 25.0 °C by four pure solvents, namely: water, acetone, methanol and ethanol, with reference to literature values (22).

Aldrich spectrograde DMF was dried over BaO and distilled under reduced pressure. 5% ^{17}O enriched water was obtained from YEDA Research and Development, Rehovoth, Israel,[5] which was then diluted to 2.5% enrichment.

$Ni(DMF)_6.(ClO_4)_2$ was prepared according to the procedure described by Babiec *et al.* (19). $Ni(H_2O)_6.(NO_3)_2$ was obtained from Merck as analytical grade reagent, and was used without further purification.

Tetrabutylammonium perchlorate (n-Bu_4NClO_4) was prepared by adding dilute perchloric acid to a dilute aqueous solution of tetrabutylammonium bromide (Eastman Kodak) solution. The precipitated n-Bu_4NClO_4 was recrystallized from methanol by adding ether. The crystals were dried under vacuum.

Tetrabutylammonium nitrate (n-Bu_4NNO_3) was prepared by mixing equimolar tetrabutylammonium bromide and silver nitrate solutions (with an extremely slight excess of $AgNO_3$) where the silver bromide precipitate was filtered off. The filtrate was used as the stock solution whose concentration was calculated through the reactant solution weights and molalities.

Treatment of Data

The treatment of data follows that reviewed by Stengle and Langford (27) utilizing the slow exchange region where

$$\tau_M{}^{-1} \simeq \frac{1}{P_M}\left(\frac{1}{T_2} - \frac{1}{T_{2A}}\right)$$

and

$$\tau_M{}^{-1} = \frac{kT}{h}\exp\left(-\frac{\Delta H^{\ddagger}}{RT} + \frac{\Delta S^{\ddagger}}{R}\right)$$

where the symbols carry their usual meanings (27). The spin–spin relaxation times, T_2, are related to the linewidths at half-height, $\Delta\nu_{1/2}$, by

$$\frac{1}{T_2} = \pi\Delta\nu_{1/2}$$

and to the peak-to-peak separation, Δ_p, of the differential mode of the absorption signal by

[5]We thank Dr. D. R. Wiles for providing this sample.

$$\frac{1}{T_2} = \sqrt{3}\pi\Delta_p$$

The activation parameters, $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$, are obtainable from the slope and intercept of a plot of $\ln(\tau_M^{-1}/T)$ *vs.* $(1/T)$ respectively.

Kinetic Studies of Copper(II)-exchange from L-Histidine to Human Serum Albumin and Diglycyl-L-histidine, a Peptide Mimicking the Copper(II)-transport Site of Albumin

SHOW-JY LAU AND BIBUDHENDRA SARKAR

Division of Biochemistry, The Research Institute, The Hospital for Sick Children, Toronto, Ontario M5G 1X8 and The Department of Biochemistry, University of Toronto, Toronto, Ontario M5S 1A8

Received May 1, 1974

SHOW-JY LAU and BIBUDHENDRA SARKAR. Can. J. Chem. **53**, 710 (1975).

The Cu(II)-exchange reactions of L-histidine with human serum albumin and diglycyl-L-histidine were studied at p*H* 7.53 in 0.1 *M* *N*-ethylmorpholine–HCl buffer. The exchange rates from L-histidine to albumin and peptide were determined as 0.67 and 0.42 s^{-1} respectively. Those from albumin and peptide to L-histidine were obtained as 0.04 and 0.07 s^{-1} respectively. This result is in accord with the earlier observations of the equilibrium study that the peptide has about half the Cu(II)-binding affinity as compared to albumin. The difference in the Cu(II)-exchange rates of albumin and peptide may reflect the influence of either the COOH-terminal free carboxyl group of the peptide or the side-chain residues of the Cu(II)-binding site in the native protein or both. An exchange mechanism is proposed in which the ternary complexes are shown to play the important role in the rate-determining step in the Cu(II)-exchange between a macromolecule and a small substance.

SHOW-JY LAU et BIBUDHENDRA SARKAR. Can. J. Chem. **53**, 710 (1975).

On a étudié les réactions d'échange du Cu(II) de la L-histidine avec l'albumine du sérum humain et la diglycyl L-histidine; ces études ont été effectuées à un p*H* de 7.53 dans un tampon de 0.1 *M* de *N*-éthylmorpholine sous forme chlorhydrate. Les taux d'échanges de la L-histidine à l'albumine et au peptide sont respectivement de 0.67 et 0.42 s^{-1}. Ceux de l'albumine et du peptide à la L-histidine sont respectivement de 0.04 et de 0.07 s^{-1}. Ce résultat concorde avec les observations faites antérieurement et selon lesquelles l'affinité du peptide pour le cuivre est environ la moitié de celle de l'albumine. La différence dans les taux d'échanges du Cu(II) de l'albumine et du peptide peut réfléter l'influence soit du groupe COOH terminal libre du peptide soit des résidus des chaines latérales du site fixant le Cu(II) dans la protéine libre ou les deux. On propose un mécanisme d'échange dans lequel on montre que les complexes ternaires jouent un rôle important dans l'étape déterminante dans l'échange du Cu(II) entre une macromolécule et une petite substance. [Traduit par le journal]

Introduction

It is known that metal ions may mediate the binding of small molecules to proteins. The formation of the intermediary ternary complexes has been suggested to play an important role in the exchange and transport of trace metals (1–3). In the case of serum Cu(II), it is the albumin- and the amino acid-bound fraction of Cu(II) which is in rapid equilibrium with Cu(II) in tissues (4–6). The ternary complex such as L-histidine–Cu(II)–albumin is considered to be essential in the exchange of Cu(II) between the macromolecule albumin and the low molecular weight amino acid L-histidine which, in turn, can readily be transported across the biological membrane (3). The tripeptide, diglycyl-L-histidine, which was designed to mimic the specific Cu(II)-transport site of human albumin has been shown to provide the same Cu(II)-binding geometry and specificity as that of albumin (7–10). The ligands involved in the binding are exactly identical to that found in albumin (11, 12) as being α-amino nitrogen, two intervening peptide nitrogens, and the imidazole nitrogen of the histidine in the third position. The four nitrogen atoms are arranged in a nearly square planar configuration around the Cu(II) ion. However, the Cu(II)-binding affinity of this peptide was found to be lower than that for albumin (10). In order to understand the nature of this functional deviation, that is, what effect the secondary and tertiary structures of the protein has on the complex, kinetic studies in regard to the Cu(II)-exchange of this tripeptide with L-histidine, as compared to albumin, were carried out. No such studies have previously been undertaken with either albumin or any histidine-containing peptides. The significance

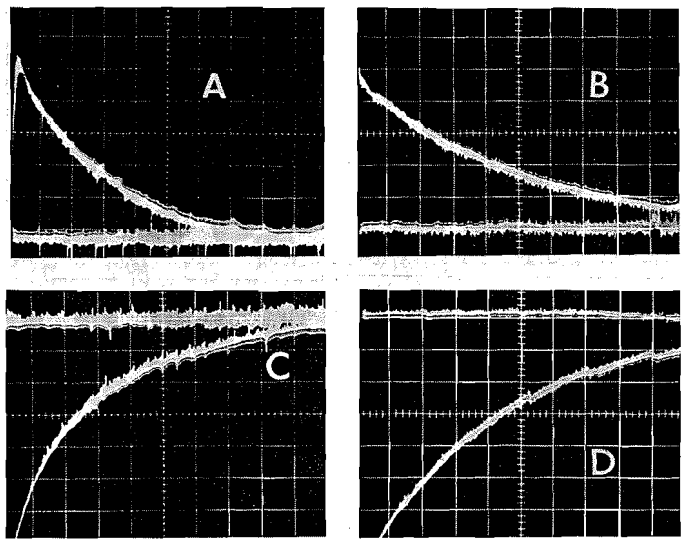

FIG. 1. Oscilloscope traces showing the reactions of Cu(II)-L-histidine$_2$ with albumin or peptide at 20° and p*H* 7.53, 0.1 *M* *N*-ethylmorpholine–HCl buffer. The traces indicate the changes of absorbance at 640 and 525 nm with time. The initial concentrations prior to mixing: Cu(II)-L-histidine$_2$, 2.90×10^{-3} *M*; albumin, 2.60×10^{-4} *M*, (*A*) and (*C*), 1 s per large division; and peptide, 2.54×10^{-4} *M*, (*B*) and (*D*), 2 s per large division.

of the observations as regard to molecular design (7–10) as well as the probable mechanism for the exchange reaction is discussed.

Experimental Section

Materials

Crystalline albumin was purchased from Hoechst Pharmaceutical Company, and further purified to obtain the Cu(II)-free monomeric form (10). Diglycyl-L-histidine was synthesized in our laboratory according to the procedure described elsewhere (10). The purity was checked by thin-layer chromatography and by electrophoresis at different p*H* values. The concentration of the peptide was established by titration and by quantitative analysis with Pauli's reagent. L-Histidine free base ($[\alpha]_D^{20}$ +39.9 ± 0.5°) was obtained from Nutritional Biochemicals. The purity was tested by chromatography. All other reagents were of analytical grade and the water was deionized.

Preparation of Solutions for Exchange Reactions

The $CuCl_2$ stock solution was prepared in 10^{-3} *M* HCl. The Cu(II)-L-histidine$_2$ solution was prepared just before the kinetic runs by mixing a microliter quantity of $CuCl_2$ with L-histidine solution in 0.1 *M* *N*-ethylmorpholine–HCl buffer at p*H* 7.53 and ionic strength 0.16 in a 1:2 molar ratio. The Cu(II)-albumin and Cu(II)-diglycyl-L-histidine solutions were prepared in the same manner except for the equimolar ratio.

Kinetic Experiments

The Cu(II)-exchange reactions were studied under pseudo-first-order conditions in the same buffer. The faster reaction, observed by mixing Cu(II)-L-histidine$_2$ and albumin or diglycyl-L-histidine solutions, was carried out on a Durrum–Gibson stopped-flow spectrophotometer at 20°. The slower reaction, observed by mixing Cu(II)-albumin or Cu(II)-diglycyl-L-histidine with L-histidine, was carried out on a Cary model 15 recording spectrophotometer at 25°. The changes of absorption were followed at both 640 nm, λ_{max} for Cu(II)-L-histidine$_2$ (13) and 525 nm, λ_{max} for Cu(II)-albumin (14) or Cu(II)-diglycyl-L-histidine (10) complexes. The pseudo-first-order rates were calculated accordingly.

Results and Discussion

Comparison of the Rates of Copper(II)-exchange from L-Histidine to Albumin and the Synthetic Site

The faster reaction, observed by mixing Cu(II)-L-histidine$_2$ with albumin or diglycyl-L-histidine solutions, was followed on a stopped-flow spectrophotometer with excess of Cu(II)-L-histidine$_2$. Typical oscilloscope traces, displayed in Fig. 1, show the changes of absorption at wavelengths 640 and 525 nm as the reaction proceeds. The slower reaction was observed from mixing Cu(II)-albumin or Cu(II)-diglycyl-L-histidine with excess of L-histidine solution and followed at both wavelengths. The initial first-order rates obtained at 640 nm corresponding to the change of Cu(II)-L-histidine$_2$ were found to be identical to that obtained at 525 nm for the change of Cu(II)-albumin or Cu(II)-diglycyl-L-histidine complexes for the reactions in both directions. The results of the observed Cu(II)-exchange rates of albumin and diglycyl-L-histi-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

dine with L-histidine are compared in Tables 1 and 2. Due to the relative low molar absorption of the Cu(II)-complexes, it was difficult to obtain reliable rates at the lower concentration regions of either Cu(II)-L-histidine$_2$ or L-histidine. However, in the reactions involving either albumin or the peptide, the rates increased as the Cu(II)-L-histidine$_2$ concentration was increased and began to approach maximum when it was about 30-fold excess. The saturation phenomenon was also observed in the exchange reaction between Cu(II)-albumin and excess L-histidine. In the reaction involving Cu(II)-diglycyl-L-histidine and L-histidine, the rates kept increasing as the concentration of L-histidine increased up to the solubility limit. These observations, together with the results obtained from potentiometric titration and spectral analyses (15), could be accounted for by assuming the pathways described in the following scheme:

$$\begin{array}{ccc} \text{Cu(II)-L-histidine}_2 + \text{albumin} & \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} & \text{L-histidine-Cu(II)-albumin} + \text{L-histidine} \\ & & \mathbf{1} \\ & & k_{ra} \uparrow\downarrow k_{-ra} \\ \text{Cu(II)-albumin} + \text{L-histidine} & \underset{k_2}{\overset{k_{-2}}{\rightleftarrows}} & \text{L-histidine-Cu(II)-albumin} \\ & & \mathbf{2} \end{array}$$

When mixing the solutions of Cu(II)-L-histidine$_2$ with albumin, there is the rapid formation of the intermediate **1**, followed by a rate-determining conversion to another intermediate **2** (presumably both **1** and **2** are identical to the thermodynamically stable ternary complexes L-histidine-Cu(II)-albumin (15)) through structural rearrangement which is then dissociated to the products, and *vice versa*. Due to the very similar spectral properties of Cu(II)-L-histidine$_2$ and **1**, Cu(II)-albumin and **2**, and also the Cu(II)-complexes of the peptide (3, 10, 14, 15), it is rather difficult to distinguish them in the reactions. Nonetheless, the experimentally determined initial rates are

$$[1]\quad v_f = -\frac{d[\text{albumin}]}{dt} = k_1[\text{Cu(II)-L-histidine}_2][\text{albumin}] - k_{-1}[\mathbf{1}][\text{L-histidine}] = k_{ra}[\mathbf{1}]$$

and

$$[2]\quad v_r = -\frac{d[\text{Cu(II)-albumin}]}{dt} = k_{-2}[\text{Cu(II)-albumin}][\text{L-histidine}] - k_2[\mathbf{2}] = k_{-ra}[\mathbf{2}]$$

By assuming steady-state concentrations of intermediate **1** for the forward direction and also of intermediate **2** for the reverse direction, the following equations may be derived.

$$[3]\quad v_f = k_{f,obs}[\text{albumin}]_0 = \frac{k_{ra}[\text{Cu(II)-L-histidine}_2][\text{albumin}]_0}{K_{Mf} + [\text{Cu(II)-L-histidine}_2]}$$

and

$$[4]\quad v_r = k_{r,obs}[\text{Cu(II)-albumin}]_0 = \frac{k_{-ra}[\text{L-histidine}][\text{Cu(II)-albumin}]_0}{K_{Mr} + [\text{L-histidine}]}$$

where

$$[5]\quad K_{Mf} = \frac{k_{-1}[\text{L-histidine}] + k_{ra}}{k_1}$$

and

$$[6]\quad K_{Mr} = \frac{k_2 + k_{-ra}}{k_{-2}}$$

TABLE 1. Comparison of the initial first-order rates for the reactions between excess Cu(II)-L-histidine$_2$ and albumin or peptide. The concentrations of albumin and peptide were constant throughout the studies. Conditions were the same as described in Fig. 1

*Conditions: pH 7.53 in 0.1 M N-ethylmorpholine–HCl buffer and 25°. Both the concentrations of Cu(II)-albumin and Cu(II)-peptide were 2.90×10^{-4} M.
†The numbers given are the average from three runs.

The double-reciprocal plots of k_{obs} *vs.* appropriate concentrations, as shown in Fig. 2*A* and *B*, yield straight lines. Obviously, during the initial part of the reaction, the term k_{-1}[L-histidine] is much smaller than k_{ra} as to be negligible, and K_{Mf} is thus reduced to k_{ra}/k_1 to become constant in eq. 3. Both kinetic parameters k_{ra}, k_{-ra} and K_{Mf}, K_{Mr} could be calculated from the slopes and intercepts of the reciprocal plots. The values of k_{ra} were obtained as 0.67 and 0.42 s^{-1}, and k_{-ra} were 0.04 and 0.07 s^{-1} for albumin and peptide respectively. The respective values of K_{Mf} were 1.38×10^{-3} and 3.47×10^{-3} M, and K_{Mr} were 2.11×10^{-3} and 6.74×10^{-3} M. The values of k_1 could also be obtained as 4.85×10^2 M^{-1} s^{-1} and 1.21×10^2 M^{-1} s^{-1} for albumin and peptide respectively. The higher values of k_{ra} than k_{-ra} are consistent with the equilibrium result that in the ternary system having equal molar concentration of Cu(II)-L-histidine$_2$ and albumin, the major amount of Cu(II) is in the form of Cu(II)-albumin (3), indicating the relatively higher affinity of Cu(II) for albumin over L-histidine. The ratio of the k_{ra} values for the exchange reactions involving albumin and diglycyl-L-histidine is about 1.7, just the reciprocal of the ratio of the k_{-ra} values. This is in accord with the observation of almost the double Cu(II)-binding strength of albumin over peptide, as a consequence of the kinetic effect (10). In addition, the equilibrium distribution of the quaternary system having Cu(II), L-histidine, albumin, and the peptide has shown the relatively higher binding affinity of the ternary complex L-histidine-Cu(II)-diglycyl-L-histidine than that of the other existing Cu(II)-complexes (10). This is also reflected from the kinetic observation of lacking saturation in the reverse reaction involving Cu(II)-diglycyl-L-histidine.

It is interesting to relate the difference in exchange rates to the different sequence of the peptide and the Cu(II)-binding site of albumin. The amino acid sequence at the native Cu(II)-binding site of human albumin is Asp-Ala-His. Obviously, the COOH-terminal carboxyl group of diglycyl-L-histidine has some influence on the exchange.[1] Also, the β-carboxyl group of the aspartyl residue in albumin could exert an inductive effect causing further change in the exchange rate. Interestingly enough, examination of the Kendrew model indicates that the β-carboxyl group of the aspartic acid residue can easily form an intramolecular hydrogen-bond with the imidazole moiety of the histidine residue. Due to this hydrogen-bond formation, the α-carbon of the NH_2-terminal aspartyl residue is rotated about 70° (ψ angle) and the α-amino nitrogen as a consequence is brought closer toward the plane for Cu(II) coordination.

Mechanism of Copper(II) Exchange

The physiological significance of the ternary complex L-histidine-Cu(II)–albumin in the biological transport of Cu(II) has previously been discussed (3). The present findings indeed demonstrate the rate-controlling role played by the ternary complex in the exchange of Cu(II) between albumin and L-histidine in order to maintain the equilibrium concentrations. A postulated scheme of the exchange pathways is illustrated in Fig. 3. It was derived taking into account both the known interaction of Cu(II) with several oligopeptides (16, 17) and the known structural features of several ternary complexes including those of L-histidine-Cu(II)-diglycyl-L-histidine (15, 18, 19). In the formation of the ternary complex C (involving either albumin or diglycyl-L-histidine) from Cu(II)-L-histidine$_2$ (A), the first step presumably involves the fast

[1]Both diglycyl-L-histamine and the N-methyl amide derivative of diglycyl-L-histidine have the same Cu(II)-exchange rate of 0.56 s^{-1} from L-histidine to the peptides under the same experimental conditions: 20°, pH 7.53 in 0.1 M N-ethylmorpholine–HCl buffer (21).

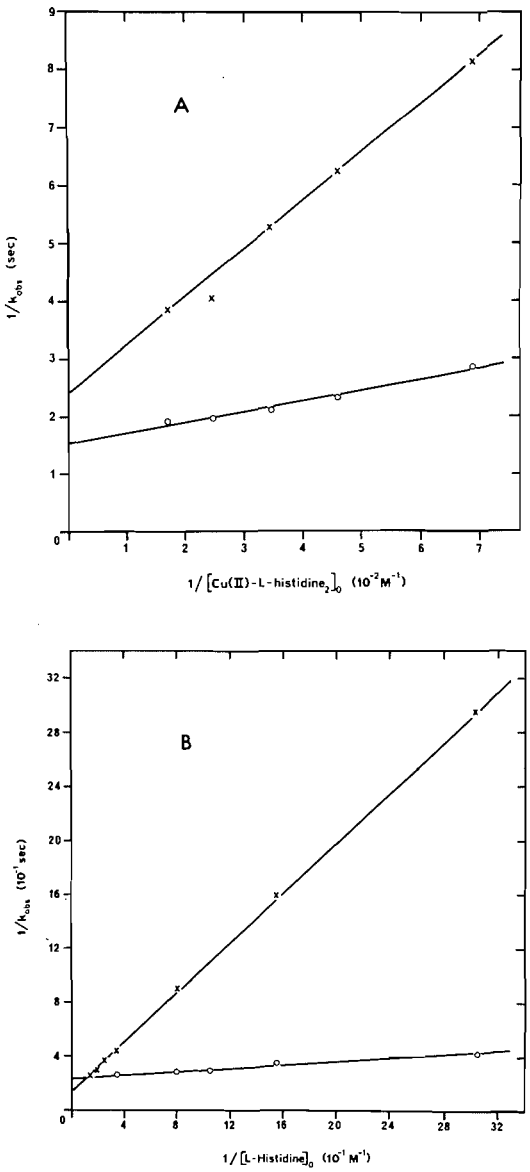

FIG. 2. The reciprocal plots of the initial first-order rates of the Cu(II)-exchange reactions as a function of concentration. The reactions are: (*A*) albumin (○) or peptide (×) with Cu(II)-L-histidine$_2$, (*B*) L-histidine with Cu(II)-albumin (○) or Cu(II)-peptide (×). Conditions are as described in Fig. 1 and Table 2.

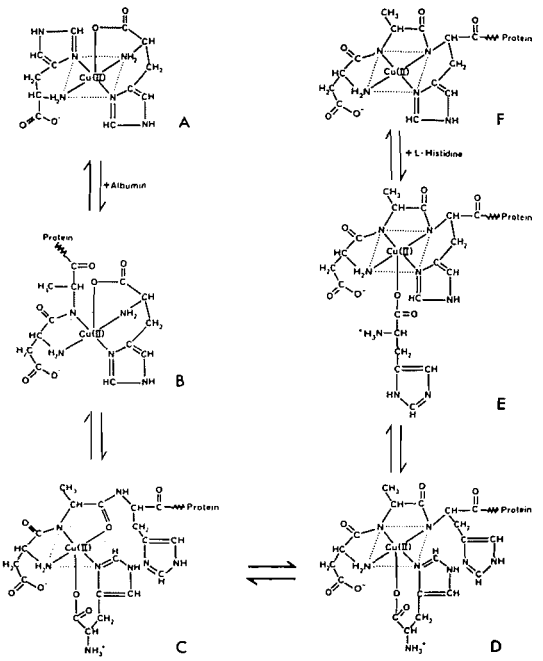

FIG. 3. The proposed reaction paths for the Cu(II)-exchange from L-histidine to albumin and peptide.

dissociation of one histidine molecule to form Cu(II)-L-histidine$^+$ (13), and allow the N-terminal amino nitrogen and the first peptide nitrogen of the protein or the peptide to enter as an anchoring point to form the intermediate B (16, 17). This is followed with the displacement of the amino nitrogen of the remaining histidine by the second carbonyl oxygen of the protein or the peptide to form the ternary complex C (18, 19), which is then converted to another ternary complex D through structural rearrangement. Since both ternary complexes C and D are thermodynamically favorable, this latter process would be expected to be rather sluggish. Once the ternary complex D is formed, three coordination sites of Cu(II) are occupied by the groups from the peptide or albumin, the displacement of the imidazole nitrogen of histidine by the imidazole nitrogen of the peptide or albumin from the histidine in the third position (E and F) would seem to be much more facilitated due to both the chelation and steric effects involved. In the reverse reaction, the same rationale is also implied. There is the facile attachment of the carboxyl group of L-histidine onto the Cu(II)-complex to start with, and followed exactly by the above-mentioned processes in the opposite direction to form the product. Because of the complexity caused by the different Cu(II)-binding species of the binary and ternary complexes as the p*H* varies (15, 20), the present data do not permit any rationale as far as the proton transfer is concerned.

The designed peptide diglycyl-L-histidine has been shown to possess the same Cu(II)-binding geometry and specificity and compete for Cu(II) with only about half the strength as that of albumin as a kinetic consequence. It is unlikely the conformation of the native protein exerts any effect on the Cu(II)-binding and exchange, although it remains to be solved. However, the present findings do indicate the possible significance of certain groups in the binding and exchange reactions which may shed light on further investigations to bring about the required specificity and affinity of the synthetic site analog. This approach of designing a small molecule to mimic certain functions of a macromolecule seems promising and may have important biomedical applications.

We are grateful to Dr. S. I. Kandel for use of the stopped-flow spectrophotometer. We also wish to thank Dr. J. T. Wong for helpful discussions on the exchange reactions. This work was supported by a grant from the Medical Research Council of Canada.

Thermodynamic Properties of Aqueous Organic Solutes in Relation to their Structure. Part II. Apparent Molal Volumes and Heat Capacities of *c*-Alkylamine Hydrobromides in Water[1]

CARMEL JOLICOEUR, JEANINE BOILEAU, SERGE BAZINET, AND PATRICK PICKER

Département de Chimie, Université de Sherbrooke, Sherbrooke, Québec J1K 2R1

Received September 9, 1974

CARMEL JOLICOEUR, JEANINE BOILEAU, SERGE BAZINET, and PATRICK PICKER. Can. J. Chem. **53**, 716 (1975).

The density and specific heat of aqueous solutions of various *c*-alkylamine hydrobromides, and of *n*-dodecylammonium bromide, have been measured at 25 °C. The limiting apparent molal volumes ϕ_v^0 and heat capacities ϕ_c^0, derived from these data, are compared to the corresponding quantities for *n*-alkylammonium and immonium salts. The methylene group contribution to ϕ_v^0 and ϕ_c^0 of the cyclic compounds is generally lower than that of the linear homologs; this group contribution is also found to depend markedly on ring size, in contrast to monotonous variations found in the series of the linear compounds. The difference is suggested to originate in solvation effects in which geometrical factors (solvent structure and solute geometry) play a significant role.

CARMEL JOLICOEUR, JEANINE BOILEAU, SERGE BAZINET et PATRICK PICKER. Can. J. Chem. **53**, 716 (1975).

Nous avons mesuré la densité et la chaleur spécifique de solutions aqueuses des bromhydrates de diverses *c*-alkylamines et de la *n*-dodecylamine à 25 °C. Les volumes, ϕ_v^0, et les capacités calorifiques, ϕ_c^0, molaires apparents obtenus de ces mesures sont comparés avec les valeurs correspondantes des bromhydrates d'imines et de *n*-alkylamines. Dans ces séries homologues, la contribution d'un groupe —CH_2— à ϕ_v^0 et à ϕ_c^0 est systématiquement plus élevée pour les dérivés linéaires que pour les dérivés cycliques. Pour ces derniers, les valeurs de $\Delta\phi_v^0(CH_2)$ et $\Delta\phi_c^0(CH_2)$ varient selon le nombre d'atomes compris dans le cycle, alors qu'elles atteignent une valeur constante dans la série des homologues linéaires. Nous interprétons ces effets en termes d'une solvatation spécifique, où les facteurs géométriques (structure du solvant et structure du soluté) jouent un rôle significatif.

Introduction

In the first part of this work (1), we reported measurements of the deuterium solvent isotope effect on the chemical potential of various hydrophobic ketones in water. The solutes differed mainly in the size and shape of their hydrocarbon group, and the $H_2O \rightarrow D_2O$ transfer functions were found to be rather sensitive to such differences. The main correlation which emerged from the data showed that linear hydrocarbon groups are more easily accommodated in D_2O than in H_2O, while the opposite seemed generally true for highly branched hydrocarbons. While the interpretation of solvent isotope effects rests on assumption which may be questionable, either from the remaining uncertainties as to the actual structural differences between water and heavy water (2), or from the results of simple calculations which consider both solvents as hard-sphere fluids (3), the previous data strongly suggested that liquid water exhibits preferences in the geometry or shape of the hydrocarbon solutes that it will dissolve.

In the hope of confirming the proposed concept of a relationship between the geometry of a hydrophobic solute and its thermodynamic properties in water, we have carried out other types of measurements which should give a different insight into the question. In this report, we present apparent molal volume and heat capacity data for a number of homologous *c*-alkylamine hydrobromides in water. Comparison with similar data available for the corresponding linear salts (4, 5) again suggests some specificity in the interaction of a hydrocarbon group with liquid water.

Experimental

The salts used in this study were prepared by reacting the amines with concentrated aqueous HBr in anhydrous ethanol; the products were recuperated upon evaporation

of the solvent and recrystallized in anhydrous ethanol – ether mixtures. The amines were purchased from Aldrich and distilled before use; their purity was found to be at least 99% from gas – liquid chromatographic runs carried out with a Hewlett–Packard (Model HP-5750) chromatograph using a Carbowax-20M on Chromosorb-W column. Conductometric analysis of the bromide content yielded results agreeing within less than 1% of the theoretical content. In the specific cases of the salts of c-pentyl, c-hexyl, and c-heptylamines, for which the analysis were carefully repeated, the deviations on the bromide content were respectively as follows: −0.2%, −0.5%, −0.3%. c-Heptylamine hydrobromide was also prepared from Fluka purum c-heptylamine; its bromide analysis showed −0.1% from the expected value, and the thermodynamic results obtained with this material were, within experimental error, identical to those obtained with previous preparations.

All solutions were prepared by weight using de-ionized water. The density measurements were performed on a flow digital densimeter reported previously (6) capable of 2 p.p.m. precision. The specific heats of the solutions were obtained with a differential flow microcalorimeter described recently by Picker *et al.* (7); the precision attainable on the specific heat increments was 0.3%, with a differential resolution limit of 2×10^{-5}. All measurements were carried out at a temperature of 25.00 ± 0.02 °C; the latter is the mean temperature in the case of specific heat measurement during which the temperature rise of the flowing liquids was 1.80 °C. The required temperature stability (±0.0005 °C) of the instruments was achieved with a closed-loop thermostat similar to the one described by Picker *et al.* (8).

Results

The apparent molal volumes ϕ_v were calculated from the solution densities d using the equation

$$[1] \qquad \phi_v = \frac{M}{d} + \frac{1000\,(d_0 - d)}{mdd_0}$$

where d_0 is the density of water at 25 °C (0.997047 g cm^{-3} (9)), M, the molecular weight of the solute, and m, its molal concentration. The molal concentrations were converted into molarities as required. The apparent molal heat capacities ϕ_c were computed from the measured volumetric specific heat σ ($J\ K^{-1}\ cm^{-3}$) of the solutions and the equation

$$[2] \qquad \phi_c = Mc_p + \frac{1000\,(c_p - c_p^0)}{m}$$

with

$$[3] \qquad \frac{c_p}{c_p^0} = \left(\frac{\sigma - \sigma_0}{\sigma_0}\right)\frac{d_0}{d}$$

In these equations, c_p is the weight specific heat ($J\ K^{-1}\ g^{-1}$) and the zero subscripts again refer to pure water; c_p^0 was taken as 4.1793 $J\ K^{-1}\ g^{-1}$ (10).

The derived quantities ϕ_v and ϕ_c were fitted by least-square methods to the following equations

$$[4] \qquad \phi_v = \phi_v^0 + 1.86c^{1/2} + B_v c$$

$$[5] \qquad \phi_c = \phi_c^0 + 28.99c^{1/2} + B_c c$$

The coefficients in $c^{1/2}$ represent the term given by the Debye–Hückel limiting law (11). The other coefficients ϕ^0 and B, for the systems studied, are collected in Table 1. The complete experimental data sets can be obtained elsewhere,[2] but we illustrate in Figs. 1 and 2 the concentration ranges investigated and the scattering found in the ϕ_v and ϕ_c values. It is obvious from these data that the results for the compounds containing dodecyl groups bear

[2]Values of d, c_p, ϕ_c, ϕ_v for various compounds have been lodged with the Depository of Unpublished Data, National Science Library, National Research Council of Canada, Ottawa, K1A 0S2. Photocopies may be obtained, upon request, at a nominal charge.

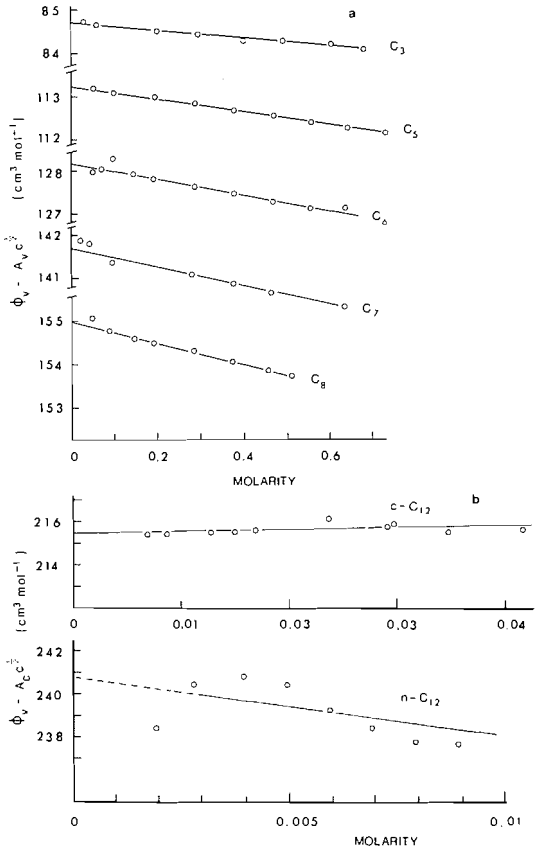

FIG. 1. Apparent molal volumes, corrected for the Debye–Hückel limiting law, of alkylammonium hydrobromides in water at 25 °C. (*a*) Data for *c*-RNH_3Br, R = C_3H_5, $C_5H_9 \rightarrow C_8H_{15}$; (*b*) data for *c*- and *n*-dodecylammonium bromides.

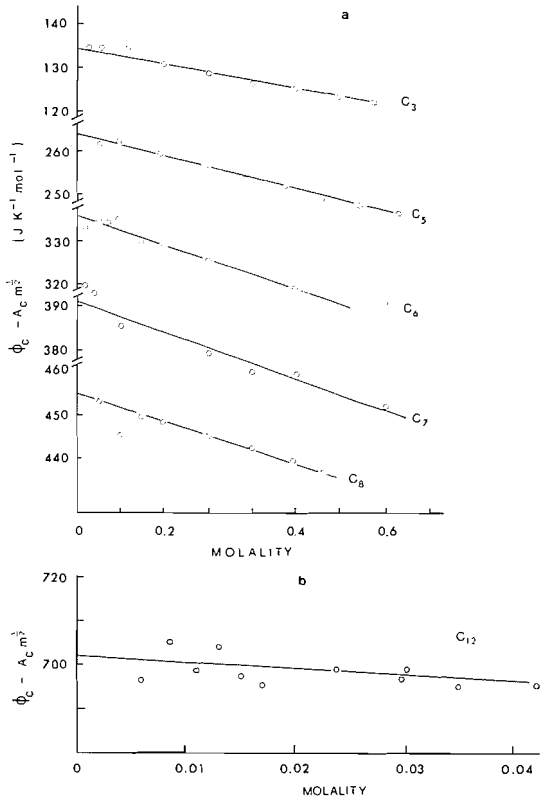

FIG. 2. Apparent molal heat capacities, corrected for the Debye–Hückel limiting law, of alkylammonium hydrobromides in water at 25 °C. (The results are shown here as a function of molality, but are given on the molarity scale in Table 1). (*a*) Data for *c*-RNH_3Br, R = C_3H_5, $C_5H_9 \rightarrow C_8H_{15}$, (*b*) data for *c*-dodecylammonium bromide.

large uncertainties. This is particularly so for *n*-dodecylamine hydrobromide, for which micelle formation limited the measurements to concentrations lower than 0.01 *m*. For the other compounds, the uncertainty on ϕ_v^0 and ϕ_c^0 is respectively ± 0.1 cm^3 mol^{-1} and ± 1.5 J K^{-1} mol^{-1}.

Discussion

(a) Limiting Apparent Molal Volumes and Heat Capacities

From the data in Table 1, it is readily seen that the limiting apparent molal volume and heat capacity of the homologous *c*-alkylamine salts increase in an approximately linear fashion with the number of carbon atoms in the alkyl substituents. The average increment in ϕ_v^0 per methylene group, $\Delta\phi_v^0(CH_2)$, is roughly 14 cm^3 mol^{-1}, compared to 15.9 cm^3 mol^{-1} for the corresponding contribution found within the homologous series bearing *n*-alkyl groups (4). This average difference has also been observed with various organic solutes by Cabani and coworkers (12–14), and it now appears quite general that $\Delta\phi_v^0(CH_2)$ is $\sim 10\%$ smaller for cyclic compounds than for linear compounds of analogous composition. This has been interpreted as resulting from a better packing of the cyclic alkyl group into the water hydrogen-bonded networks (12).

Effects similar to those mentioned above are also found in the ϕ_c^0 data for the linear and cyclic alkylamine salts. The methylene group contribution to ϕ_c^0 in the two homologous series is again quite different; the average $\Delta\phi_c^0(CH_2)$ is 88 ± 3 J K^{-1} mol^{-1} with the *n*-alkylamine

For personal use only.

hydrobromides (5), whereas the corresponding quantity in the cyclic homologs is in the range of 60–70 J K^{-1} mol^{-1}.

The lower $\Delta\phi_c^0(CH_2)$ for cyclic molecules reported recently by Cabani *et al.* (14) from data on amines, imines and their hydrochloride salts, has been attributed mainly to the larger hydrophobic surface area of the linear alkyl group, rather than to differences in the intrinsic heat capacity of the solute molecules.[3]

The available ϕ_v^0 and ϕ_c^0 data on the hydrochlorides of imines (12, 13, 15) can be converted to the same scale as the present data for the hydrobromides using the following differences

$$\phi_v^0(Br^-) - \phi_v^0(Cl^-) = 6.9 \text{ cm}^3 \text{ mol}^{-1} \quad (16)$$

and

$$\phi_c^0(Br^-) - \phi_c^0(Cl^-) = -4 \text{ J K}^{-1} \text{ mol}^{-1} \quad (17)$$

Comparison of the results then shows that the ϕ_v^0 of *c*-alkylammonium and immonium ions, having the same number of carbon atoms, are very nearly identical. Since it is generally expected (13, 18, 19) that the hydration of a charged nitrogen center depends upon the degree of alkyl substitution, and also in view of the specific effects discussed below, this similarity must be fortuitous. Within the limited values available for imine hydrochlorides, the ϕ_c^0 of immonium and *c*-alkylammonium ions of same carbon content differ by $\sim 10\%$.

(b) Variations of the Methylene Group Contributions to ϕ_v^0 and ϕ_c^0

To examine the variations in the methylene group contributions to ϕ_v^0 and ϕ_c^0, we plot in Figs. 3 and 4, the $\Delta\phi^0(CH_2)$ values calculated as

$$\Delta\phi^0(CH_2) = \frac{\phi^0(n_i) - \phi^0(n_j)}{n_i - n_j}$$

where n_i and n_j are the number of carbon atoms in the homologous pairs considered. In Fig. 3, we illustrate the $\Delta\phi_v^0(CH_2)$ obtained from the *n*-alkyl and *c*-alkylammonium and immonium salts as function of $(n_i + n_j)/2$. Within the *n*-alkyl homologs, the methylene group contribution levels-off for alkyl groups larger than C_4H_9 (4); in this series, it might be expected that $\Delta\phi_v^0(CH_2)$ will remain constant for all higher homologs, though coiling of long alkyl chains could provide deviations to this behavior. In the case of cyclic compounds, the $\Delta\phi_v^0(CH_2)$ shows marked variations, much larger than the experimental uncertainties. It is noteworthy that if we use the number of ring atoms rather than the number of carbon atoms, the two dotted curves shown in Fig. 3 would exhibit their extrema at the same position.[4] It is thus apparent that the ring size is a key factor in fitting these types of ions into the solvent water,

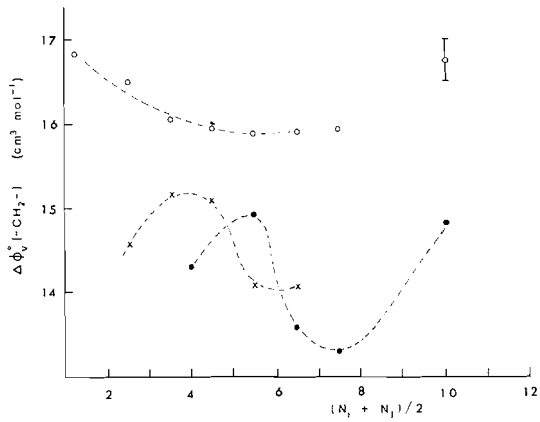

FIG. 3. Methylene group contribution to limiting apparent molal volumes from data on: ○, *n*-alkylamine hydrobromides; ●, *c*-alkylamine hydrobromides; ×, imine hydrochlorides.

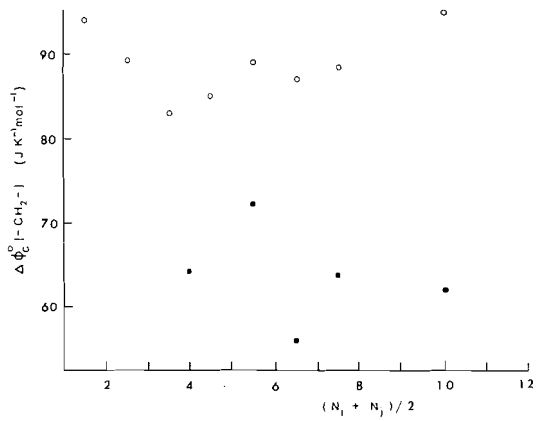

FIG. 4. Methylene group contribution to limiting apparent molal heat capacities from data on: ○, *n*-alkylamine hydrobromides; ●, *c*-alkylamine hydrobromides.

[3]We use here the terms imine and immonium to designate the 1-azacycloalkanes and their corresponding ammonium ions.

[4]A similar plot drawn for $\Delta\phi_v^0(CH_2)$ of imines (12) also exhibits a shallow minimum for the 6 and 7 membered-ring.

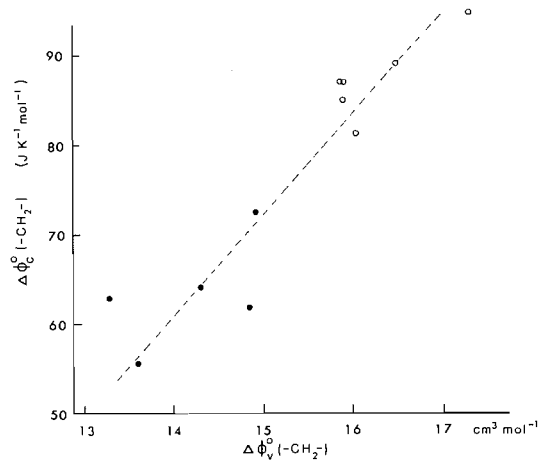

FIG. 5. Correlation plot of methylene group contributions to ϕ_v^0 and ϕ_c^0.

and the data indicate an optimum fit with 7- or 8-membered rings. Measurements on each cyclic homolog between C_8 and C_{12} may yield further details in the variation of $\Delta\phi_v^0(CH_2)$, though it seems probable that for very large rings, $\Delta\phi_v^0(CH_2)$ will be similar to that found with the linear homologs; the effect resulting from the addition of a $—CH_2—$ group to an infinitely long chain should be independent of whether or not the ends of the chain are tied.

The $\Delta\phi_c^0(CH_2)$ values plotted in Fig. 4 again exhibit a rather monotonous behavior in the *n*-alkylammonium homologs, while large variations are observed in the series of the *c*-alkyl compounds. In the latter, the extrema appear for the same ring sizes which were found to give maximum variations in $\Delta\phi_v^0(CH_2)$. In Fig. 5, we correlate the methylene group contributions to ϕ_v^0 and ϕ_c^0, as obtained from the homologous series of *n*- and *c*-alkylammonium salts; indeed we find that $\Delta\phi_c^0(CH_2)$ increases in a roughly linear fashion with $\Delta\phi_v^0(CH_2)$.

It may be pointed out immediately that, from the current views on solvent structural effects induced by hydrocarbon groups,[5] the correlation shown in Fig. 5 would have been expected with a negative slope, *i.e.*, the hydrocarbon group which exhibits the best packing in the solvent structure (minimum volume) would also exhibit the maximum heat capacity (after taking into account the intrinsic contributions of the solutes). In other words, for the data shown in Figs. 3 and 4, we would have anticipated that, corresponding to the minimum $\Delta\phi_v^0(CH_2)$ value, we would observe a maximum in $\Delta\phi_c^0(CH_2)$. Thus, explaining the variations in $\Delta\phi_v^0(CH_2)$ and $\Delta\phi_c^0(CH_2)$, as well as the relationship between these quantities, will require more details than a straightforward extension of the current interpretation of volume and heat capacity effects in the solvation of hydrocarbons. Amongst the various effects which could lead to specificity in the properties of the cyclic homologs studied here, we should first envisage those resulting from the intrinsic properties of the hydrocarbon groups.

While it is difficult to predict quantitatively how the addition of a $—CH_2—$ group will increase the intrinsic volume of a cyclic hydrocarbon, scale molecular models suggest that the $—CH_2—$ contribution to the effective volume should increase with ring size, for hydrocarbons between C_5 and C_{12}. For the latter molecules, the volume of the cavity in the ring center increases with ring size, while remaining excluded to the solvent molecules. Such an effect obviously could not account for the ring-size dependence shown in Fig. 3.

For the heat capacity, judging from earlier data on liquid *n*- and *c*-hydrocarbons, the intrinsic contribution for each methylene group, $\Delta C_{p,1}(CH_2)$, is lower for the cyclic homologs than for the linear ones by 10–20 J K^{-1} mol^{-1} (22). As pointed out by Cabani *et al.* (15) this only accounts for part of the difference in $\Delta\phi_c^0(CH_2)$ observed between the linear and cyclic homologs. Likewise, since $\Delta C_{p,1}(CH_2)$ for the cyclic hydrocarbons is ~30 J K^{-1} mol^{-1}, it seems improbable that variation in this quantity could account for the observed changes in the $\Delta\phi_c^0(CH_2)$ with ring size (see Addendum at the end of the article).

If it can be assumed that the contribution to ϕ_v^0 and ϕ_c^0 of the $—\overset{+}{N}H_3$ group, as well as solvation effects on this group, remain constant in the series of *c*-alkylammonium, we would have reasonable grounds for assigning the ring-size specificity in the $\Delta\phi_v^0(CH_2)$ and

[5]The dissolution of a hydrocarbon group in water is believed to occur with a stabilization of hydrogen-bonded structures in the solvent (20); the increase in volume expected from this effect (by analogy to freezing) would be more than compensated by the volume decrease when the hydrocarbon can be fitted in the structural cavities of water (4, 21). It is this water structure stabilization which is thought to be responsible for the large heat capacities of aqueous solutes containing significant hydrocarbon groups (20).

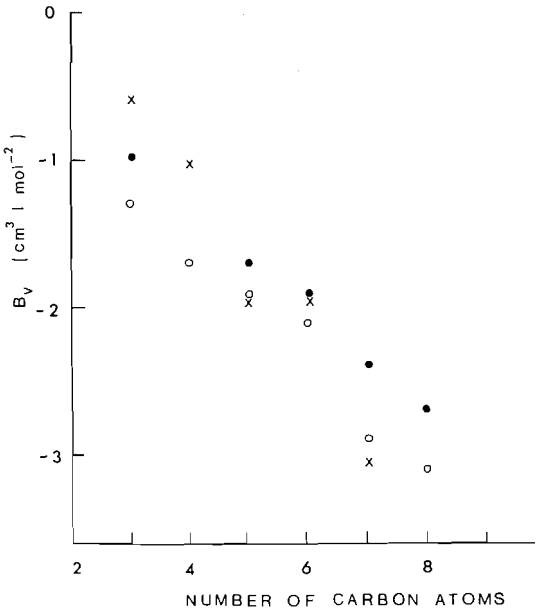

FIG. 6. B_v coefficients (eq. 5) for the various ammonium salts; the symbols are the same as those used in Fig. 3.

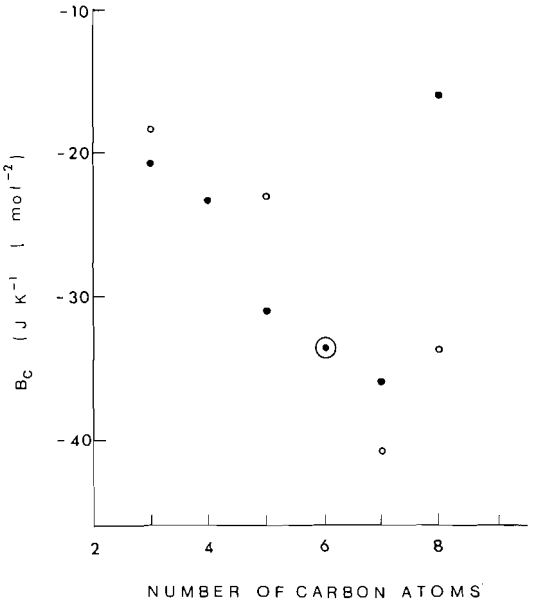

FIG. 7. B_c coefficients (eq. 6) for hydrobromides of *n*- and *c*-alkylamines; the symbols are the same as those in Fig. 4.

$\Delta\phi_c^0(CH_2)$ values to hydrocarbon–water interactions which depend on the structure of the solute. Until similar measurements are carried out in other solvents, however, it can only be suggested that this ring-size dependence is, in fact, a result of solvent structural effects which are responsive to the geometry of the solute.

(c) Excess Functions

We illustrate in Figs. 6 and 7, the deviations of ϕ_v and ϕ_c to the Debye–Hückel limiting law observed for the linear and cyclic ammonium salts. It is striking that the excess functions B_v and B_c, representing the effect of solute–solute interactions other than the limiting electrostatic contribution, appear rather insensitive to the nature of the hydrocarbon substituent on the cation. Except for the B_c coefficients of the *n*- and *c*-octylammonium salts, the other B_v and B_c coefficients are mostly a function of solute volume.[6] Thus any solvation specificity, which might be reflected in ϕ_v^0 and ϕ_c^0 of the homologous compounds, does not seem to play a major role in solute–solute interactions, in the concentration range investigated.

[6]Substantial variations in the magnitude of the B_c coefficients for large organic ions have been found in other systems and discussed elsewhere (23).

Conclusion

The investigation of the partial molal volumes and heat capacities of various homologous series of alkylammonium salts brings out some significant ring-size dependence in the limiting properties of the cyclic compounds. This we tentatively assign to geometrical aspects of the solvation, involving both the structure in the solvent and the structure of the hydrophobic solute. Further evidence will be required to assess the relationship between solute geometry and solvent structural effects, but additional work seems largely warranted if it may help to establish that part of the discriminating behavior observed in biochemical or biological systems, originate in such specific solvation effects.

Addendum

To evaluate the importance of changes in the intrinsic properties (volume and heat capacity) of the hydrocarbon group as function of ring-size, we have measured the density and specific heat of four cyclic hydrocarbons in the pure liquid state. The materials were purchased from Chemical Samples Co. and were quoted of the following purity: *c*-pentane, 99.9%; *c*-hexane, 99.9%; *c*-heptane, 99%; and *c*-octane, 99%. As the reference liquid, we chose *c*-hexane, for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

which molar volume and heat capacity are known as: $V_1^0 = 108.758$ cm^3 mol^{-1} and $C_{p,1}^0 = 156.2_0$ J K^{-1} mol^{-1} (25). The results including the data for *c*-hexane are tabulated below.

Compound	V_1^0 (cm^3 mol^{-1})	$\Delta V_1^0(CH_2)$ (cm^3 mol^{-1})	$C_{p,1}^0$ (J K^{-1} mol^{-1})	$\Delta C_{p,1}^0(CH_2)$ (J K^{-1} mol^{-1})
c-Pentane	97.72		127.28	
		14.04		28.9
c-Hexane	108.76		156.20	
		12.99		24.3
c-Heptane	121.75		180.4_7	
		13.13		33.8
c-Octane	134.88		214.2_4	

These results add a considerable amount of new information on this problem, illustrating that the methylene group contribution to V_1^0 is of the same order as $\Delta\phi_v^0(CH_2)$ observed in water with the *c*-alkylammonium ions; furthermore, it also exhibits a shallow minimum at the seven carbon homolog. Both of these observations were totally unexpected from packing effects, which ought to be rather different in the two situations compared here, *i.e.* pure liquid hydrocarbons and aqueous solutions. The methylene group contribution to $C_{p,1}^0$ is much lower than $\Delta\phi_c^0(CH_2)$ found in aqueous solutions of the cyclic organic ions, and though it also exhibits a minimum near the seven-membered ring, the amplitude of the variations are less than those observed in $\Delta\phi_c^0(CH_2)$.

Clearly, further work will be required to identify, in detail, the origin of the variations in methylene group contributions and the extent to which hydration effects may either enhance such variations or compensate for them.

Financial support of this work by the National Research Council of Canada is gratefully acknowledged.

Preparation of the Piperazine- and Triethylenediamine–Monoborane Adducts of BH_3, BH_2F, BHF_2, and BF_3

J. M. VANPAASSCHEN AND R. A. GEANANGEL

Department of Chemistry, University of Houston, Houston, Texas 77004

Received August 9, 1974

J. M. VANPAASSCHEN and R. A. GEANANGEL. Can. J. Chem. **53**, 723 (1975).

The new compounds, triethylenediamine–BH_2F, –BHF_2, –BF_3 and piperazine–BH_2F, –BHF_2, –BF_3 have been isolated and characterized from the base displacement reactions involving the diamine and the trimethylamine–fluoroboranes. By this method only the monoborane adducts of the difunctional amines are formed. The stability of these monoborane adducts is rationalized from a mechanistic point of view. The proton and boron-11 n.m.r. and i.r. spectra are presented with the analytical results.

J. M. VANPAASSCHEN et R. A. GEANANGEL. Can. J. Chem. **53**, 723 (1975).

On a isolé et caractérisé les nouveaux composés triéthylènediamine–BH_2F, –BHF_2, –BF_3, pipérazine–BH_2F, –BHF_2 et –BF_3; ces complexes sont obtenus en faisant réagir les diamines appropriées sur le complexe triméthylamine–fluoroborane. L'utilisation de cette méthode conduit uniquement aux adduits du monoborane sur les amines difonctionnelles. On rationnalise la stabilité de ces adduits de monoborane en se basant sur un point de vue mécanistique. En plus des données analytiques, on rapporte les spectres r.m.n. du proton et du bore 11 et les spectres i.r.

[Traduit par le journal]

Introduction

We have recently reported (1) the preparation of the new compounds $(CH_3)_3NBH_2F$ and $(CH_3)_3NBHF_2$ by the reaction of trimethylamine–borane with anhydrous hydrogen fluoride. The preparation of trimethylamine–difluoroborane by another method has been reported by other investigators (2). The synthesis of *t*-butylamine–fluoroboranes by the reaction of anhydrous hydrogen fluoride with *t*-butylamine–borane is reported elsewhere (3).

In this paper we wish to describe some new fluoroborane adducts of diamines which were prepared by base displacement reactions of the diamines on trimethylamine–borane and trimethylamine–fluoroboranes.

Experimental

Nuclear magnetic resonance spectra for boron (32.1 MHz) were obtained on a Varian HA-100 instrument. Chemical shifts are reported in p.p.m. relative to external trimethylborate. Proton n.m.r. spectra were taken on a Varian T-60 instrument. Chemical shifts are given in p.p.m. from internal tetramethylsilane. Infrared spectra were obtained as KBr pellets on a Perkin-Elmer Model 700 spectrophotometer. Melting points were obtained in sealed capillaries on a heated block and are uncorrected. Solvents (Matheson Co.) were dried (4) and stored under vacuum. The ethylenediamine, piperazine, and triethylenediamine (1,4-diazabicyclo[2.2.2]octane) were obtained from Eastman Organic Chemicals. The solids were sublimed and ethylenediamine was distilled before use. Analyses for boron and hydrolyzable hydrogen were carried out by standard methods. Carbon and hydrogen analyses were performed by Chemalytics, Inc., Tempe, Arizona.

Generally the monoborane adducts of the difunctional amines were prepared by displacement reactions starting with a diamine and the appropriate trimethylamine–borane adduct in equimolar quantities. In a typical reaction, 10 mmol of trimethylamine–borane (or –fluoroborane) and an equimolar amount of difunctional base were placed in a 50-ml round-bottom flask which was then evacuated. About 7 ml of dry benzene was condensed into the flask and the reaction was allowed to stir at room temperature for 48 h. The volatile components of the reaction were then fractionated and the quantity of trimethylamine measured. The trimethylamine was discarded and the benzene was condensed back into the reaction vessel. The reaction was then allowed to run for another 48 h after which time the volatile contents were again fractionated and the amount of trimethylamine measured. This procedure was continued until the evolution of trimethylamine had stopped. The benzene was vapor transferred from the reaction vessel. The nonvolatile portion of each reaction was removed from the vessel, purified, and analyzed. The yield at the first equilibration was calculated from the quantity of $(CH_3)_3N$ freed after the first 48 h, while the final yield was calculated from the amount of product isolated.

Triethylenediamine–monoborane, $N(CH_2CH_2)_3N:BH_3$, is a white crystalline sublimable solid which melts at 165–167 °C (lit. (5) 167–170 °C). The solid residue from the reaction between triethylenediamine and trimethylamine–borane was dissolved in a small amount of C_6H_6, then petroleum ether was added until precipitation occurred. The solid was filtered and held under dynamic

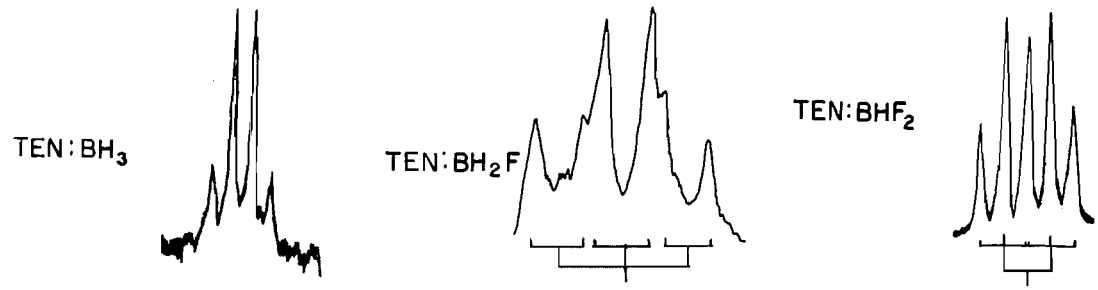

FIG. 1. Boron-11 n.m.r. spectra of triethylenediamine–monofluoroborane, –difluoroborane, and –borane.

vacuum for 24 h. The yield at the first equilibration was 87%, while the final yield was 89%. The resulting solid, which was soluble in C_6H_6, CH_2Cl_2, and CH_3CN, had an i.r. spectrum which matched that reported by Gatti and Wartik (5) for triethylenediamine–monoborane. The only observed proton resonance occurred at δ 2.86. The boron-11 resonance consisted of a 1:3:3:1 quartet (J_{BH} = 103 Hz) observed at +29.6 p.p.m. (Fig. 1).

Triethylenediamine–monofluoromonoborane, $N(CH_2CH_2)_3N:BH_2F$, is a white crystalline sublimable solid which melted in the range 162–164 °C. The solid residue from the reaction between triethylenediamine and $(CH_3)_3NBH_2F$ was dissolved in CH_2Cl_2, filtered, and the solvent removed from the filtrate by vacuum transfer. The crude solid was sublimed, giving a final yield of 83% and a first equilibration yield of 80%. The purified compound was found to be soluble in CH_2Cl_2 and CH_3CN and slightly soluble in C_6H_6. Its i.r. spectrum has bands at 3400(br), 2940(s), 2880(s), 2360(sh), 2310(s), 2260(s), 2190(m), 1460(s), 1445(s), 1305(s), 1270(w), 1205(s), 1180(s), 1150(s), 1110(s), 1040(s), 990(s), 950(s), 905(s), 840(sh), 830(s), and 780(m) cm^{-1}. The methylene proton resonance occurs at δ 2.90 and the ^{11}B resonance is observed at +14.0 p.p.m. (Fig. 1). The measured coupling constants are J_{BH} = 116 Hz and J_{BF} = 87 Hz.

Anal. Calcd. for $C_6H_{14}BFN_2$: B, 7.64; H(neg), 1.39; N, 19.45. Found: B, 7.55; H(neg), 1.43; N, 19.09.

Triethylenediamine–difluoromonoborane, $N(CH_2CH_2)_3N:BHF_2$, is a white crystalline solid which melts in the range 170–171 °C. The reaction between triethylenediamine and $(CH_3)_3NBHF_2$ gave essentially a 100% yield of trimethylamine at the first equilibration and a final yield of 95%. The solid did not sublime up to 130 °C. The solid was analyzed without further purification.

Anal. Calcd. for $C_6H_{13}BF_2N_2$: B, 6.79; H(neg), 0.62; N, 17.25. Found: B, 6.88; H(neg), 0.70; N, 17.33.

The compound has i.r. bands at 3400(br), 2950(m), 2890(m), 2330(m), 2275(m), 1450(m), 1315(m), 1210(s), 1190(s), 1170(s), 1120(s), 1060(s), 990(m), 960(m), 940(w), 910(s), 850(s), 840(s), and 780(vw) cm^{-1}. The methylene proton resonance consists of a doublet (J = 2 Hz) occurring at δ 2.93. The ^{11}B resonance is observed at +14.6 p.p.m. (Fig. 1) with coupling constants of 142 and 65 Hz for J_{BH} and J_{BF}, respectively.

Triethylenediamine–trifluoromonoborane, $N(CH_2CH_2)_3N:BF_3$, is a white crystalline solid with a melting ranging of 199–203 °C, isolated from the reaction of triethylenediamine and $(CH_3)_3NBF_3$, which gave a yield of essentially 100% of the theoretical amount of trimethylamine. The solid residue was washed with benzene and sublimed *in vacuo*, giving a final yield of 90%.

Anal. Calcd. for $C_6H_{12}BN_2F_3$: B, 6.11; N, 15.55. Found: B, 5.99; N, 15.64.

The i.r. spectrum (KBr pellet) contains bands at 3400(br), 2950(m), 2900(m), 1460(s), 1320(s), 1190(s), 1160(sh), 1120(s), 1050(s), 990(s), 930(s), 900(s), 840(s), and 790(m) cm^{-1}. The methylene proton resonance was observed at δ 2.97 and the boron-11 resonance was a singlet at +18.0 p.p.m.

Piperazine–monoborane is a white solid isolated from the reaction of piperazine and trimethylamineborane which yielded 77% of the possible trimethylamine when carried out as a batch reaction. The solid was purified by washing with CH_2Cl_2, after which the melting range was 171–172 °C.

Anal. Calcd. for $C_4H_{13}BN_2$: B, 10.8; H(neg), 3.0. Found: B, 11.0; H(neg), 3.2.

The solubility of piperazine–monoborane in C_6H_6, CH_2Cl_2, CH_3CN, and tetrahydrofuran was negligible; the solid dissolves readily in water with slow hydrolysis accompanied by gas evolution. The i.r. spectrum showed bands at 3400(br), 3300(m), 3075(m), 2900(s), 2850(s), 2325(vs), 2275(vs), 1450(m), 1370(w), 1350(w), 1310(w), 1270(m), 1180(vs), 1140(m), 1100(s), 1070(m), 1040(w), 940(m), 880(s), 840(s), and 740(vw) cm^{-1}. No n.m.r. spectra were obtained because of the low solubility of the solid product.

Piperazine–monofluoromonoborane and –difluoromonoborane are white solids which are insoluble in CH_2Cl_2, C_6H_6, CH_3CN, and THF. They were prepared by the reaction of piperazine with $(CH_3)_3NBH_2F$ and with $(CH_3)_3NBHF_2$ but no effective method was found to purify the solid products. This problem prevented a proper characterization of the adducts except by analogy with the other adducts reported here. When a sample of the solid believed to be piperazine–BHF_2 was heated until the evolution of hydrogen was complete, the ratio of moles of hydrogen to moles of compound was 0.9 to 1.0. This is in reasonable agreement with the amount of hydrogen elimination expected for aminoborane formation.

$$HN(CH_2CH_2)_2NH:BHF_2 \rightarrow HN(CH_2CH_2)_2NBF_2 + H_2$$

The compounds do not sublime and begin to decompose near their melting points (PIP:BH_2F, 106–107 °C; PIP:BHF_2, 133 °C). The yield of trimethylamine for the monofluoro adduct was 81% and for the difluoro adduct 72%. The final yields were not calculated due to the lack of purity in the products.

Piperazine–trifluoromonoborane, PIP:BF_3, is a white crystalline solid insoluble in CH_2Cl_2, CH_3CN and C_6H_6.

The reaction of piperazine with an equimolar quantity of trimethylamine–trifluoroborane yielded 66% of the possible trimethylamine and a white solid residue which, after being washed with CH_2Cl_2, melted in the range 142–145 °C.

The i.r. spectrum of the solid has bands at 3400(br, sh), 3310(w), 2625(m), 2500(w), 1450(m), 1410(m), 1370(w), 1320(vw), 1310(vw), 1260(w), 1180(s), 1140(s), 1100(s), 1040(s), 1020(w), 950(s), 880(m), 870(s), 830(m), and 740(w) cm^{-1}.

Anal. Calcd. for $C_4H_{10}BN_2F_3$: B, 7.14. Found: B, 7.39.

Ethylenediamine–boranes. Ethylenediamine displaces some trimethylamine from the trimethylamine-boranes in the formation of the ethylenediamine adducts, but p.m.r. indicates the products are mixtures. We were unable to separate and purify the components of these mixtures. The products were water- and air-sensitive oils similar to those described by Kelly and Edwards (6). The reaction involving $(CH_3)_3NBF_3$ gave a white solid which turned to an oil on exposure to air (7).

Results and Discussion

In principle a displacement reaction with a diamine acting upon an amine–borane (1:1 molar stoichiometry) could produce either a mono- or bisborane adduct of the diamine. One might expect the initial product of the displacement to be the monoborane adduct which could then react further or disproportionate to give the bis adduct with two acid molecules per diamine. There are relatively few reported cases of monoborane adducts of diamines which are stable towards disproportionation at room temperature (5).

Gatti and Wartik (5) reported that triethylenediamine–borane is stable at room temperature but disproportionates above its melting point (167–170 °C). They also found that the monoborane adduct of *N,N'*-dimethylpiperazine had disproportionated after 18 h at room temperature. Other monoborane adducts were even less stable; $(CH_3)_2NCH_2CH_2N(CH_3)_2{:}BH_3$ converted to the bisborane adduct after 1 h (8).

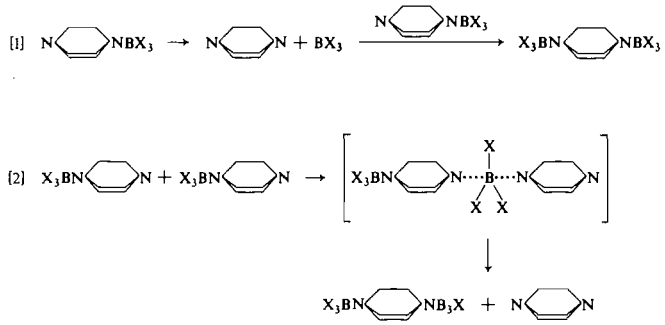
In this study ethylenediamine (EN), piperazine (PIP), and triethylenediamine (TEN) were reacted with $(CH_3)_3NBH_3$, $(CH_3)_3NBH_2F$, $(CH_3)_3NBHF_2$, and $(CH_3)_3NBF_3$. All the products which could be characterized were found to be monoborane adducts. The new monoborane adducts isolated and characterized in this work are $TEN{:}BH_2F$, $TEN{:}BHF_2$, and $TEN{:}BF_3$. These are solids which show no observable tendency to disproportionate at room temperature. They were characterized by elemental analysis and ^{11}B n.m.r. spectra (Fig. 1) which strongly resembled those of the corresponding trimethylamine adducts (1).

The piperazine adducts, $PIP{:}BH_3$, $PIP{:}BH_2F$, $PIP{:}BHF_2$, and $PIP{:}BF_3$, are less well characterized because of their low solubilities and decomposition above room temperature. Melting ranges were not especially good criteria of purity because of disproportionation. The elemental analysis obtained on these compounds suggests some impurity but is more consistent with monoborane adducts than bisborane adducts.

The products of the ethylenediamine displacement reactions were intractable oils which we were unable to purify and characterize. Kelly and Edwards (6) obtained an oil when attempting to prepare the monoborane adduct of ethylenediamine. Also an oil was obtained (7) when crude $H_2NCH_2CH_2NH_2{:}BF_3$ was exposed to air. Generally ethylenediamine displaced less trimethylamine than either of the other diamines, making isolation and purification of products more difficult.

The factors which determine the relative stabilities of monoadducts and diadducts of this type have not been rigorously investigated, but two effects have been discussed. Nöth (9) suggested that more efficient solid state packing of symmetrical bis adducts may favor their formation. Also, hydrolysis studies (7) of bis(trifluoroborane) adducts of ethylenediamine and hexamethylenediamine suggested that the former is more reactive (less stable adduct) because of the inductive effect transmitted through the shorter ethylene chain. The inductive effect tends to lower the base strength of the free amine group of the diamine and, in the absence of other factors, this should stabilize the monoborane with respect to the bisborane adduct. In reactions as carried out here with equimolar proportions of amine–borane and diamine, disproportion of the monoborane adduct to bisborane and free diamine is the most likely way that the bisborane adduct might be formed.

Two routes by which disproportionation might occur are [1] dissociative, where one mono adduct dissociates and the freed borane moiety bonds to another mono adduct giving one bisborane and one free diamine, and [2] by displacement, where the free amine end of one mono adduct attacks the borane portion of another displacing free diamine and leaving a bisborane adduct. The principal driving force for both (reversible) reactions is probably the



differences in coordinate (B—N) bond energies. Because of the inductive effect of one borane adduct on the other amine in a diamine we must suppose that the B—N bond energies would favor the monoborane adducts (of the diamines considered here) in the disproportionation. We would expect to see the bisborane adducts only when other factors, such as solvation energies or solid state effects which favored the more symmetrical adducts, are active.

Chemical and spectroscopic (u.v., i.r., ^1H and ^{13}C n.m.r., and mass) data are reported which suggest that cochliodinol is 2,5-dihydroxy-3,6-di(5′-(2″-methylbut-$\Delta^{2''}$-ene)-indolyl-3′)-cyclohexadiene-1,4-dione (**1***a*).

W. A. JERRAM, A. G. MCINNES, W. S. G. MAASS, D. G. SMITH, A. TAYLOR et J. A. WALTER. Can. J. Chem. **53**, 727 (1975).

On rapporte des données chimiques et spectroscopiques (u.v., i.r., r.m.n. du proton et du ^{13}C et spectrométrie de masse), qui suggèrent que le cochliodinol est la dihydroxy-2,5 di(méthyl-2″ butène-2″)-5′ indolyl-3′)-3,6 cyclohexadiène-dione-1,4 (**1***a*). [Traduit par le journal]

Introduction

The isolation of the purple antibiotic metabolite cochliodinol (**1***a*; λ_{max} 475 nm) from cultures of *Chaetomium globosum* and *C. cochliodes* has been reported previously (1, 2). The metabolite readily formed dimethyl (**1***d*; λ_{max} 475 nm) and diacetyl (**1***c*; λ_{max} 498 nm) derivatives. Of these compounds only **1***a* was acidic (pK_a 6.7); it gave stable green crystalline salts with strong bases (3). All three compounds (**1***a*, **1***d*, **1***c*) were highly colored, and were readily reduced with hydrogen sulfide in methanol to give colorless (λ_{max} 295 nm) crystalline phenols (**2***a*, **2***f*, **2***g*), which were easily oxidized by oxygen to yield the parent compounds. Such behavior is common among quinones in general and with vat dyestuffs in particular. The phenols were acetylated readily (**2***a* → **2***b*; **2***f* → **2***e*; **2***g* → **2***b*) and the i.r. spectra of the esters (*e.g.*, **2***e*, ν_{max} 1760 cm^{-1}) no longer contained the original carbonyl bands observed at 1640 cm^{-1} for **1***a* and **1***d*, or at 1660 cm^{-1} for **1***c*. Moreover, the phenolic esters (**2***b*, **2***e*) were colorless (λ_{max} 295 nm) and were readily reconverted (**2***b* → **1***a*; **2***e* → **1***d*) to cochliodinol or its dimethyl derivative on hydrolysis in acid or basic solution. These results imply that the products of hydrolysis, **2***a* and **2***f*, had been oxidized by air during the hydrolysis and/or isolation procedures. It is clear that the carbon skeleton of **1***a* and **1***d* remains intact during these interconversions.

Elemental and mass spectral analysis indicated that **2***b* had a molecular formula of $C_{40}H_{40}N_2O_8$ but the ^1H n.m.r. spectrum (see Table 1) only gave a ratio of 1:4:1:2:6:6 for NH, aromatic, olefinic, methylene, methyl (two which are chemically nonequivalent), and acetoxyl methyl (two which are chemically equivalent) hydrogens. All resonances of **2***b* therefore originate from a quartet (acetoxyl methyl) or pairs of chemically equivalent groups of hydrogen(s) due to symmetry in the molecule. This equivalence was unaffected by changing solvent polarity or the magnetic field (60, 100, 220 MHz). The above signals were also present

in the spectrum of **1***c* with a corresponding ratio of 1:4:1:2:6:3, whereas for **1***a*, which contained a broad hydroxyl resonance, but no acetoxyl signal, the same hydrogens bonded to nitrogen or carbon had a ratio of 1:4:1:2:6. Finally, a monoacetate **1***b* was obtained whose proton spectrum (see Experimental) contained the same types of hydrogens as in **2***b* and **1***c* in the ratio of 2:8:2:4:12:3. From the above observation it can be concluded that **1***a* and **1***c*, like **2***b*, are symmetrical molecules and contain double the number of hydrogens indicated by intensity measurements of their ^1H n.m.r. spectra. As **2***b* contains four acetoxyl groups it follows that the basic carbon skeleton of **1***a* has 32 carbons and its conversion to **1***c* implies that **1***a* has two hydroxyl groups. Thus, **1***a* probably has a molecular formula of $C_{32}H_{30}N_2O_4$ and **1***c* of $C_{36}H_{34}N_2O_6$. Similarly, **1***d* has a probable molecular formula of $C_{34}H_{34}N_2O_4$.

As previously reported (1) the ion of greatest mass in the mass spectrum of cochliodinyl diacetate (**1***c*) had *m/e* 592.2032, in agreement with the molecular formula $C_{36}H_{36}N_2O_6$, and similar precise mass measurements of the ions of greatest molecular weight in the spectra of **1***a* and **1***d* also indicated molecular formulae two mass units greater than the formulae deduced from the n.m.r. data, (the elemental analysis also fitted a H_{30} formula better than an H_{32}). When the mass spectrum of the diacetate was measured in the presence of deuterium (4) the ion of greatest mass had *m/e* 594 indicating exchange of two protons but in the presence of deuterium oxide the ion of greatest mass had *m/e* 596. Finally, the apparent molecular ion in the spectrum of the di(trideuterioacetyl) derivative had *m/e* 600. These results indicate that the mass spectra of cochliodinol and its derivatives are anomalous. It was shown recently (5) that the apparent molecular ion in the spectrum of

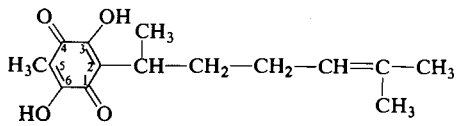
polyporyl diacetate (M = 376; $C_{22}H_{16}O_6$) had m/e 378 and in the presence of deuterium oxide m/e 380, whilst the di(trideuterioacetate) had m/e 386. These results are clearly analogous to those in the cochliodinol series and suggest that the latter compounds are also derivatives of 2,5-dihydroxy-1,4-benzoquinone.

Cochliodinol can be converted by chemical means (see below) to cochliodinone **3***a* ($C_{32}H_{28}N_2O_4$; λ_{max} 470 nm), an orange fluorescent metabolite reported previously (1). The ^1H and proton noise decoupled (p.n.d.) ^{13}C n.m.r. spectra of **3***a* only contained resonances for half the expected number of hydrogens and carbons (see Tables 1 and 2), and the proton resonances were the same as those observed for **1***a*, **1***c*, and **2***b* except for the absence of acetoxyl methyl and hydroxyl groups. Symmetry considerations therefore make it highly probable that all resonances for **3***a* arise from pairs of chemically equivalent groups of nuclei. The high resolution ^{13}C n.m.r. spectrum of **3***a* excluded the possibility of fortuitous chemical equivalence of resonances originating from quaternary carbons and carbons bonded to hydrogen, and the multiplicities of eight of the resonances accounted for half the expected number of hydrogens in accord with the above chemical equivalence and symmetry conclusions. Furthermore, eight carbon resonances had chemical shifts, $^1J_{CH}$ values, and multiplicities consistent with the presence of a 3,5-disubstituted indole residue, and five others indicated the presence of a 2-methyl-but-Δ^2-enyl substituent; symmetry considerations therefore require that **3***a* possess two residues of each type. The latter conclusions were supported by the ^1H n.m.r. data (see Table 1). The 13 resonances associated with these molecular fragments in **3***a* have their counterparts (similar chemical shifts, identical multiplicities) in the ^{13}C n.m.r. spectra of **1***a*, **1***c*, and **2***b*. It should be noted that the four acetoxyl groups in **2***b* and the two corresponding groups in **1***c* only give rise to two characteristic signals at about δ_C 20 (acetoxyl methyl carbon) and δ_C 167 (acetoxyl carbonyl carbon), thereby emphasizing molecular symmetry. This analysis accounts for 26 carbons; the remaining resonances in the pnd ^{13}C n.m.r. spectra of these compounds must arise from six carbons. It follows therefore that the three remaining signals of **1***c* (δ_C 180, 145, and 129) and **3***a* (δ_C 168, 152, and 99) are due to pairs of equivalent carbons, whereas in **1***a* (δ_C 168, 112) and **2***b* (δ_C 140, 124) one signal arises from four chemically equivalent carbons and the other from two. At this stage molecular formula considerations leave unaccounted the fragments $C_6H_2O_4$ for **1***a*, $C_{10}H_6O_6$ (two acetoxyls account for $C_4H_6O_4$) for **1***c*, $C_{14}H_{12}O_8$ (four acetoxyls account for $C_8H_{12}O_8$) for **2***b*, and C_6O_4 for **3***a*. The structural elucidation of **1***a*, **1***c*, **2***b*, and **3***a* therefore reduces to establishing the nature of the unknown fragments and how the three components in each molecule are bonded.

Treatment of **1***a* with dimethyl sulfoxide in the presence of acetic anhydride converted it to **3***a*. Under these conditions it is known that 2,5-dihydroxybenzoquinones undergo oxidative rearrangements to dilactones; *e.g.*, polyporic acid is converted in high yield to pulvinic acid dilactone (6). If a similar conversion has occurred in the reaction **1***a* → **3***a* characteristic signals for the dilactone moiety should be observed in the ^{13}C n.m.r. spectrum of **3***a*. For the reasons outlined above the relevant resonances are those occurring at δ_C 168.0, 151.9, and 98.6, and these are indeed very similar to those observed for the carbons of the dilactone moiety of *o*-methoxypulvinlactone (C-2, C-5, δ_C 167.7, 166.9; C-3a, C-6a, δ_C 159.3, 160.2; C-3, C-6, δ_C 99.8, 101.4: numbering system is the same as for the dilactone residue of **3***a*).

Acetylation of **3***a* gave a di-*N*-acetate **3***b* ($C_{36}H_{32}N_2O_6$), while catalytic reduction provided a tetrahydro derivative, **3***c*, having the same chromophore (λ_{max} 476 nm); no colorless intermediates were observed. All of these compounds were very sensitive to base. For example when **3***a* in methanol solution was treated with a trace of 0.02 *N* sodium hydroxide, the solution had λ_{max} 350 nm, whereas the solution on acidification had λ_{max} 408 nm. Such spectroscopic changes are consistent with the opening of a lactone ring. The i.r. spectrum of **3***b* also contained an absorption band at 1820 cm^{-1} in close agreement with that observed for pulvinic acid dilactone (ν_{max} 1825 cm^{-1}). Oxidation of **1***a* with manganese dioxide also gave a product $C_{31}H_{30}N_2O_3$ which was not a lactone and appeared to be analogous to the cyclopentadiene derivative **4***a* (7). These results provide convincing evidence that **3***a* is indeed an analog of pulvinic acid lactone and the reaction used for the interconversion **1***a* → **3***a* implies that **1***a* is a 2,5-dihydroxybenzoquinone. It is clear that the



5

carbons giving rise to the two resonances at δ_C 168.5 and 112.1 in **1***a* are the origin of the three pairs of equivalent carbons which appear at δ_C 168.0, 151.9, and 98.6 in the corresponding spectrum of **3***a* as all other spectral features are virtually identical. Moreover, of the above two signals in **1***a* the one at lowest field was a broad singlet whereas the one at highest field was a sharp singlet, and these two signals correspond to six carbons. This is reminiscent of the behavior of carbons in the 2,5-dihydroxyquinone ring system of hydroxyperezone **5** (8). In the pnd ^{13}C n.m.r. spectrum of this compound C-1, C-3, C-4, and C-6 appear as a broad resonance at δ_C 168.5, whereas the other quinone carbons bearing substituents resonate at δ_C 118.7 (C-2) and 111.2 (C-5). The almost complete chemical equivalence of the carbonyl carbons and carbons bearing hydroxyl substituents was attributed to the rapid interconversion of two equivalent tautomeric forms of the 2,5-dihydroxyquinone ring system, which results in the chemical shifts of the four carbons being averaged. If, as indicated by the above results, **1***a* is a symmetrically substituted 2,5-dihydroxybenzoquinone, acetylation to form **1***c* should eliminate chemical equivalences arising from tautomeric interconversions. Indeed in the spectrum of **1***c* the two resonances present at δ_C 168.5 and 112.1 are replaced by three resonances for three equivalent pairs of carbons at δ_C 180.5, 145.5, and 129.4, and are in close agreement with the chemical shifts observed for carbons bearing acetoxyl (δ_C 149.1), phenyl (δ_C 129.6), and carbonyl carbons (δ_C 180.1) in the p.n.d. ^{13}C n.m.r. spectrum of polyporic acid diacetate. The p.n.d. ^{13}C n.m.r. spectrum of **2***b* (which is formed from **1***a* by reduction followed by acetylation) does not possess any of the three characteristic signals of **1***c* given above but instead has two signals at δ_C 140.5 and 123.9. Clearly **2***b* contains a symmetrically substituted benzene ring containing four equivalent carbons bearing acetoxyl substituents (δ_C 140.5) and two others (δ_C 123.9) bearing substituents (ref. 9, p. 197). It can be concluded therefore that **1***a*, **1***c*, and **3***a* are analogs of polyporic acid, polyporic acid diacetate, and pulvinic acid dilactone, respectively, and that **2***b* is a symmetrically substituted 1,2,4,5-tetraacetoxy benzene.

The presence of 2-methyl-but-Δ^2-enyl substituents in **1***a*, **1***c*, **2***b*, and **3***a* was established by the following evidence. Abundant ions at m/e = 69.7040 were ubiquitously present in their mass spectra, as were metastable ions, indicating the loss of a neutral fragment of mass 69. In addition the ^1H n.m.r. spectra of these compounds (see Table 1) established that the two chemically equivalent olefinic hydrogens (H-11′) at δ 5.4 were allylic coupled to the hydrogens of the methyl groups at *ca.* δ 1.7 and vicinally coupled to the hydrogens of the chemically equivalent methylene groups (H-10′) at δ 3.4. Catalytic reduction of **1***a* and **1***c* resulted in the absorption of 3 mol of hydrogen per mole of compound to form hexahydrocochliodinol (**2***h*) and hexahydrocochliodinol diacetate (isolated as the tetraacetate, **2***j*) (**2***i*), respectively, whereas the di-*N*-acetyl derivative **2***c* formed by acetylation of **2***b*, reacted with only 2 mol of hydrogen to form di-*N*-acetyl hexahydrocochliodinol tetraacetate (**2***k*); in the case of **2***c* reduction occurred only under forcing conditions (70°; 100 atm; Pt; AcOH). The ^1H n.m.r. spectra of **2***j* and **2***k* (see Experimental) showed that the alkene substituents had been reduced to isopentyl residues. In addition, autoxidation or catalytic oxidation of hexahydrocochliodinol and hexahydrocochliodinol diacetate gave tetrahydrocochliodinol (**1***e*) ($C_{32}H_{34}N_2O_4$) and tetrahydrocochliodinol diacetate (**1***f*) ($C_{36}H_{38}N_2O_6$), respectively, and all four compounds had the same u.v. and visible absorption spectra. Hence the olefinic bonds in the alkene substituents were not conjugated with the chromopores giving rise to the absorption maxima 475 or 498 nm in **1***a* and **1***c*. The off-resonance decoupled spectrum of **2***b* contained signals with chemical shifts and multiplicities characteristic of methyl groups (δ_C 17.9 and 25.9), a methylene group (δ_C 35.2), a =CH group (δ_C 125.7), and a quaternary olefinic carbon at δ_C 131.0. The corresponding ^{13}C n.m.r. spectrum of hexahydrocochliodinol tetraacetate (**2***j*) was similar to that of **2***b* except that the five signals discussed above were absent and instead the spectrum contained a single methyl resonance (δ_C 22.9), two methylene resonances (δ_C 34.7, 42.6), and a methine resonance at δ_C 28.4. These observations are only consistent with the reduc-

TABLE 3. Radioactivity of cochliodinol (**1***a*) (and derivatives prepared therefrom) and cochliodinone (**3***a*), isolated from cultures of *C. globosum* fed ^{14}C-labelled precursors

	Metabolites				Derivatives		
	1*a*		**3***a*		**1***c*	**2***g*	**3***a*
Precursor	μCi/mmol	Yield (%)	μCi/mmol	Yield (%)	μCi/mmol	μCi/mmol	μCi/mmol
Bz-U-^{14}C-Tryptophan	15.9	3.6	16.1	0.05	15.8	17.1	16.1
2-^{14}C-Tryptophan	0.22	4.3	0.18	0.003	0.22		0.20
2-^{14}C-Tryptophan	0.56	2.9					
2-^{14}C-Mevalonolactone	0.09	0.15				0.08	

tion of 2-methyl-but-Δ^2-enyl substituents to isopentyl groups during the reduction of **2***b* to hexahydrocochliodinol tetraacetate. Supporting evidence for the nature of the alkene substituents was also obtained when **1***c* reacted smoothly with osmium tetroxide to give a black osmic ester which was readily reduced with hydrogen sulfide (10) to provide (after acetylation) a colorless product $C_{48}H_{52}N_2O_{16}$ whose i.r. spectrum had absorption bands at 1775 and 1740 cm^{-1} plausibly assigned to phenolic and alkyl acetate functions (suggested structure **2***l*). Finally, 2-^{14}C-mevalonolactone was incorporated into cochliodinol (see Table 3) by cultures of *C. globosum*, thus providing further evidence for the presence of such substituents.

An n.O.e. study on **2***b* gave the following results (irradiated protons in parentheses): H-4′ (H-10′) 17.1%; H-6′ (H-10′) 10.5%; H-7′ (H-10′) 0%; H-2′ (H-10′) 0%; H-11′ (H-10′) 12.4%; H-2′ (NH) 24.6%; H-7′ (NH) 13.4%; H-6′ (NH) 0%; H-4′ (NH) 0%; H-2′ (CH_3CO) 5.4%; H-4′ (CH_3CO) 8.5%; H-6′ (CH_3CO) 0%; H-7′ (CH_3CO) 0%. In addition the spin–spin coupling data in Table 1 indicates that the NH hydrogens are spin–spin coupled to H-2′ and that H-7′ is *ortho* coupled to H-6′ and *para* coupled to H-4′, while the latter is also coupled to H-6′. These results establish the relative positions of the NH and aromatic hydrogens in **2***b* (and therefore also in **1***a*, **1***c*, and **3***a*), and the enhancements observed for H-4′ and H-6′, but not H-2′, when H-4″ is irradiated require that the 2-methyl-but-Δ^2-enyl substituents be on C-5′. Moreover, in the ^{1}H n.m.r. spectra of di-*N*-acetyl derivatives **2***c* and **2***k* (see Experimental) H-7′ exhibits a downfield shift, a behavior characteristic of *N*-acyl indoles (11). The ^{1}H and ^{13}C n.m.r. spectra were also correlated by off-resonance decoupling experiments. Thus all signals for carbons bearing hydrogens were readily assigned. The $^1J_{CH}$ value obtained from high resolution spectra (**3***a* and **2***j*) or calculated from off-resonance decoupled spectra (**1***a*, **1***c*, and **2***b*) indicated that spin–spin coupling between C-2′ and H-2′ was greater than 180 Hz; the corresponding value for indole derivatives was 182 Hz. The four remaining quaternary aromatic carbons (at about δ_C 106, 128, 133, and 136) in all of the latter compounds have chemical shifts consistent with those expected for C-3, C-5, C-8, and C-9 of a 3,5-disubstituted indole (ref. 9, pp. 266 and 267); the shielding of C-3′ (δ_C 106) is greater than expected and is probably due to hydrogen bonding of the NH groups in all compounds with the oxygen of THF-d_8, thus increasing the electron density on nitrogen and the shielding of C-3′.

The u.v. spectrum of cochliodinol was similar to that reported (12) for 3,6-di-(2′methylindolyl-3′)-1,4-benzoquinone. The tetraacetate (**2***b*) did not give an Ehrlich compound with aldehydes but with ethyl orthoformate gave the di-*N*-formyl derivative (**2***d*). These observations are consistent with a linkage of two indole residues through a benzoquinone moiety. Finally, DL-tryptophan unspecifically labelled in the benzene ring with ^{14}C was incorporated by the fungus into cochliodinol in about 3% yield and in a similar experiment using DL-2-^{14}C-tryptophan the label was incorporated to about the same extent (Table 3).

The combined evidence therefore is consistent with structure **1***a* for cochliodinol and structure **3***a* for cochliodinone.

Experimental

A Perkin-Elmer 237 spectrophotometer was used to determine i.r. spectra. The u.v. spectra were measured on Cary 14 and Beckman DK-2 instruments. The n.m.r.

spectra were recorded on Varian A-60A (V-6058A spin decoupler), HA-100, and XL-100-15 spectrometers; the latter was equipped (VFT-100 data system) for Fourier transform operation. Chemical shifts are reported downfield using TMS as an internal standard. Mass spectra were obtained by direct introduction of samples into the source of a DuPont 110-B instrument at about 260°. Precise masses were measured by the peak matching method using an ion in the spectrum of perfluorokerosene as a standard. Radioactivity measurements were obtained using a Nuclear Chicago Mark I scintillation counter. Samples were dissolved in a solution (15 ml) of 2,5-diphenyloxazole (60 mg) in toluene. All fermentation experiments were carried out using *C. globosum* (HLX 707)[2] as described by Jerram and co-workers (1). Radioactive precursors were added aseptically to the cultures after 3.5 days growth. All cultures were harvested at 7 days and the antibiotics extracted from the lyophilized mycelium as previously described (1). Melting points are uncorrected.

*Cochliodinol (**1a**)*

(*a*) Cochliodinol diacetate (50 mg) in methanol (10 ml) was treated with hydrogen chloride at 25° and the solution kept for 18 h. The solution was evaporated, the residue absorbed from benzene on silica gel (30 g), and cochliodinol (40 mg, m.p. 206°) eluted with ether–benzene (1:9).

(*b*) The diacetate (50 mg) was dissolved in ethanol (10 ml) and treated with sodium hydroxide solution (2 *N*, 0.5 ml) and the green suspension immediately acidified, extracted with chloroform, and the cochliodinol (35 mg; m.p. 206°; λ_{max} (0.01 *N* NaOH) 295 nm (log ε 4.32); λ_{max} (after acidification) 278, 475 nm (log ε 4.38, 3.45)) purified as described.

*Cochliodinol Diacetate (**1c**)*

This compound was prepared as previously described (1); *m/e* 592.2573 (M + 2) ($C_{36}H_{36}N_2O_6$ requires 592.2573), 550 (*m** ≃ 511; 592 → 550 + 42), 534, 508 (*m** ≃ 470; 550 → 508 + 42), 492, 439 (m* ≃ 380; 508 → 439 + 69), 371.1043 ($C_{22}H_{15}N_2O_4$ requires 371.1032), 170, 154, 142, 130, 107, 101, 91, 69.0701 (C_5H_9 requires 69.0704); λ_{max} (MeOH) 278, 498 nm (log ε 4.48, 3.93); λ_{max} (0.01 *N* NaOH) 279, 400 nm (log ε 4.19, 3.61); ν_{max} (CCl_4) 3480, 3030, 2970, 2915, 2855, 1775, 1660, (KBr) 1660, 1600, 1520, 1430, 1280, 1190, 1150, 1030, 800, 730 cm^{-1}; n.m.r. Tables 1 and 2.

Cochliodinol Di(trideuterioacetate)

Cochliodinol (0.5 g) was treated with pyridine (0.2 ml) and trideuterioacetic anhydride (Merck, Sharpe and Dohme, 99.9 atom% [^{2}H]; 5 ml) and the solution kept at 4° for 18 h. The *ester* separated from benzene – light petroleum (b.p. 40–60°) as purple needles, m.p. 201°; 0.55 g.

Anal. Calcd. for $C_{36}[^2H]_6H_{28}N_2O_6$: C, 72.4; N, 4.7; O, 16.1. Found: C, 71.7; N, 4.75; O, 16.0.

*Cochliodinol Monoacetate (**1b**) (by-product of methylation reaction)*

Cochliodinol diacetate (0.5 g) in methanol (50 ml) was treated at room temperature with hydrogen sulfide until the solution was colorless (≃ 3 h). The solution was evaporated with a stream of carbon dioxide and potassium *t*-butoxide (0.5 g), methyl iodide (9 ml), and tetrahydrofuran (100 ml) were added to the residue while an atmosphere of carbon dioxide was maintained. The reaction mixture was stirred for 24 h, evaporated, the residue taken up in benzene, the solution washed with dilute hydrochloric acid and water, and dried (Na_2SO_4). The solution was concentrated to 10 ml, run onto a silica gel (30 g) column which was eluted with benzene (500 ml), and then ether–benzene (1:9). The first 200 ml of the ether–benzene eluate was discarded and the purple band collected in the next 400 ml gave *cochliodinol monoacetate* as almost black prisms from petroleum ether (b.p. 40–60°) – benzene (1:1), m.p. 183–184°; *m/e* 550, 548; λ_{max} (MeOH) 274, 480 nm (log ε 4.45, 3.69); ν_{max} (KBr) 1775, 1650, 1605 cm^{-1}; p.m.r. (60 MHz; $CDCl_3$) δ 8.57 (bs, 1H, exchanged with D_2O, NH), 8.43 (bs, 1H, exchanged with D_2O, NH), 7.45 (bs, 4H, H-2′ and -4′), 7.15 (AB, 4H, H-7′ and -6′, $\Delta\nu_{AB} \simeq 10.5$ Hz, $J_{AB} \simeq 8.5$ Hz, signals broadened by *meta* and *para* coupling of H-6′ and -7′ with H-4′), 5.42 (bt, 2H, H-11′, $J_{11',10'} \simeq 7.5$ Hz, broadened by allylic coupling with H-13′ and -14′), 3.45 (bd, 4H, H-10′), 2.12 (s, 3H, O_2CCH_3), 1.75 (bs, 12H, H-13′ and -14′, vinylic CH_3′s).

Anal. Calcd. for $C_{34}H_{32}N_2O_5$: C, 74.45; H, 5.8; N, 5.1; O, 14.6. Found: C, 74.5; H, 5.7; N, 5.1; O, 14.5.

*Dimethylcochliodinol (**1d**)*

Cochliodinol (2 g) in ether (500 ml) was stirred and treated at room temperature with a solution of diazomethane (0.8 g) in ether. When no further nitrogen was evolved the reaction mixture was evaporated and the residue, on recrystallization from methanol gave *dimethylcochliodinol* as purple needles, m.p. 208–210° (dec.); *m/e* 536.2666 (M + 2) ($C_{34}H_{36}N_2O_4$ requires 536.2675); λ_{max} (MeOH) 276, 475 nm (log ε 4.45, 3.66), (0.2 *N* NaOH) 278, 478 nm (log ε 4.43, 3.59); ν_{max} (KBr) 3350, 2980, 2920, 2850, 1640, 1585, 1575, 1300, 1145, 1060, 790 cm^{-1}; p.m.r. (60 MHz; acetone-d_6) δ 9.8 (bs, 2H, exchanged with D_2O, H-1′, NH), 7.65 (d, 2H, H-2′, coupled to NH, $J_{1',2'} = 2.8$ Hz), 7.37 (bs, 2H, H-4′), 7.20 (AB, 4H, H-7′ and -6′, $\Delta\nu_{AB} \simeq 22$ Hz, $J_{AB} \simeq 8.5$ Hz, $J_{4',6'} \simeq 1.5$, $J_{4',7'} \simeq 0.5$), 5.43 (bt, 2H, H-11′, $J_{11',10'} \simeq 7.5$ Hz, broadened by allylic coupling > 1 Hz with H-13′ and -14′), 3.87 (s, 6H, OCH_3), 3.45 (d, 4H, H-10′), 1.75 (bs, 12H, H-13′ and -14′, vinylic CH_3′s).

Anal. Calcd. for $C_{34}H_{34}N_2O_4$: C, 76.4; H, 6.4; N, 5.2; O, 12.0; OMe, 11.6. Found: C, 76.4; H, 6.5; N, 5.4; O, 11.9; OMe, 11.8.

*Tetrahydrocochliodinol (**1e**)*

(*a*) Cochliodinol (0.5 g) in acetic acid (100 ml) was shaken with hydrogen and platinum oxide (10 mg) until 70 ml of hydrogen had been taken up. The colorless precipitate (λ_{max} (MeOH) 295 nm (log ε 4.25)) was then shaken with oxygen and platinum (5 mg) when 25 ml were absorbed and a brown solution was obtained. The solution was filtered, the filtrate evaporated, and the residue absorbed from benzene on silica gel (30 g). A purple zone was eluted with ether–benzene (1:9) which

For personal use only.

after evaporation and recrystallization from methanol gave *tetrahydrocochliodinol*, m.p. 220–223°; *m/e* 512, 510, 496, 482, (m^* ~ 456; 510 → 482 + 28), 454 (m^* ~ 405; 510 → 454 + 56), 425, 325, 267, 130; λ_{max} (MeOH) 278, 471 nm (log ε 4.49, 3.55); ν_{max} (KBr) 3410, 3330, 2960, 2930, 2860, 1630, 1330, 985, 800 cm^{-1}; p.m.r. (60 MHz; acetone-d_6) δ 10.4 (bs, 2H, exchanged with D_2O, H-1′, NH), 7.63 (d, 2H, H-2′, coupled to NH, $J_{2',1'} = 2.8$ Hz), 7.48 (bs, 2H, H-4′), 7.18 (AB, 4H, H-7′ and -6′, $\Delta\nu_{AB}$ = 20.4 Hz, $J_{AB} = 8.4$ Hz, $J_{4',6'} = 1.6$, $J_{4',7'} \simeq 0.7$), 2.72 (m, 4H, H-10′), 1.2–1.9 (m, 6H, H-11′ (methylene) and -12′ (methine) coupled to signals at 2.72 and 0.96 (double resonance)), 0.96 (d, 12H, $J \simeq 5$ Hz, H-13′ and -14′, isopentyl CH_3's).

Anal. Calcd. for $C_{32}H_{34}N_2O_4$: C, 75.3; H, 6.7; N, 5.5. Found: C, 74.9; H, 6.5; N, 5.1.

(*b*) A solution of hexahydrocochliodinol tetraacetate (see below; 65 mg) in methanol (30 ml) under an atmosphere of argon, was saturated with hydrogen chloride. After 18 h the purple-brown solution (λ_{max} 471 nm) was evaporated, the residue absorbed from benzene on silica gel, and tetrahydrocochliodinol (45 mg, m.p. 220°) eluted from the column with ether–benzene (1:9). The ester (50 mg) was also hydrolyzed under alkaline conditions and gave *tetrahydrocochliodinol* (m.p. 220°; 35 mg).

Tetrahydrocochliodinol Diacetate (1f)

(*a*) Cochliodinol diacetate (0.3 g) in acetic acid (60 ml) was shaken with platinum oxide (5 mg) and hydrogen at room temperature and pressure until 90 ml was absorbed. The hydrogen was replaced when 20 ml of the gas were taken up in 30 min. The filtered solution was evaporated and the residue chromatographed as usual on silica gel. *Tetrahydrocochliodinol diacetate* separated from methanol as purple needles, m.p. 207–209° (dec.); λ_{max} (MeOH) 278, 498 nm (log ε 4.47, 3.93); ν_{max} (KBr) 3340, 2960, 2930, 2870, 1770, 1660, 1600, 1520, 1425, 1280, 1190, 1145, 1030, 800 cm^{-1}; *m/e* 596, 554, 538, 512, 496.

Anal. Calcd. for $C_{36}H_{38}N_2O_6$: C, 72.7; H, 6.4; N, 4.7; O, 16.2. Found: C, 72.9; H, 6.9; N, 4.1; O, 16.1.

(*b*) Tetrahydrocochliodinol (50 mg) in acetic anhydride (5 ml) was treated with pyridine (0.1 ml). The mixture was shaken until a distinct color change (brown-magenta) was noticed, when the solution was poured onto ice and the precipitated diacetate (50 mg; m.p. 207°) recrystallized from methanol.

Dihydrocochliodinol Tetraacetate (2b)

Cochliodinol (3 g) was dissolved in methanol (250 ml) and the solution treated with hydrogen sulfide as described above until a colorless solution was obtained. The solution was evaporated, the crystalline residue (λ_{max} (MeOH) 295 nm; ν_{max} 1780, 1760 cm^{-1}) was taken up in acetic anhydride (200 ml) and pyridine (3 ml) added. The almost colorless solution was kept for 24 h, methanol (1.5 l) added, and the solution heated under reflux for 1 h. The solution was concentrated to 50 ml, water (200 ml) added, and the colorless precipitate collected. *Dihydrocochliodinol tetraacetate* separated from ethanol as colorless needles, m.p. 225°; *m/e* 676.2778 (M) ($C_{40}H_{40}N_2O_8$ requires 676.2785), 371.1028 ($C_{22}H_{15}N_2O_4$ requires 371.1032); n.m.r. Tables 1 and 2.

Anal. Calcd. for $C_{40}H_{40}N_2O_8$: C, 71.0; H, 5.9; O, 18.9. Found: C, 70.4; H, 5.7; O, 18.8.

Di-N-acetyldihydrocochliodinol Tetraacetate (2c)

The tetra-*O*-acetate (1 g) was dissolved in acetic anhydride (50 ml) and anhydrous sodium acetate (4 g) added. The mixture was stirred and heated under reflux for 5 h, kept overnight, water (150 ml) added at 0°, and the mixture stirred until a colorless precipitate was obtained. *Di-N-acetyldihydrocochliodinol tetraacetate* separated from acetic acid as colorless prisms, m.p. 271°; *m/e* 760.2996 (M) ($C_{44}H_{44}N_2O_{10}$ requires 760.2996; $C_{42}H_{42}N_5O_9$ requires 760.2983); ν_{max} (KBr) 1780, 1720, 1350, 1230, 1125 cm^{-1}; p.m.r. (100 MHz; $CDCl_3$) δ 7.78 (AB, 4H, H-7′ and -6′, $\Delta\nu_{AB}$ = 113.0 Hz, $J_{AB} = 8.3$ Hz, $J_{4',6'} \simeq 1.5$, $J_{4',7'} < 0.5$), 7.47 (s, 2H, H-2′), 7.30 (bs, 2H, H-4′), 5.35 (bt, 2H, H-11′, $J_{11',10'} \simeq 7.0$ Hz, broadened by allylic coupling >1 Hz with H-13′ and -14′), 3.42 (d, 4H, H-10′), 2.61 (s, 6H, $NCOCH_3$), 1.88 (s, 12H, O_2CCH_3), 1.74 (bs, 12H, H-13′ and -14′, vinylic CH_3's).

Anal. Calcd. for $C_{44}H_{44}N_2O_{10}\cdot\frac{1}{2}H_2O$: C, 68.7; H, 5.85; N, 3.6; O, 21.8. Found: C, 68.6; H, 5.6; N, 3.8 ;O, 21.8.

Di-N-formyldihydrocochliodinol Tetraacetate (2d)

The tetra-*O*-acetate (150 mg) was suspended in acetic anhydride (10 ml) and ethyl orthoformate (4 ml) added. The colorless solution was heated under reflux for 18 h, diluted with methanol (100 ml), heated to boiling, and when the exothermic reaction ceased, concentrated to 5 ml. Water (10 ml) was added and the precipitate (160 mg) collected. The *diformyl* derivative separated from 1-ethoxy-2-hydroxyethane as prisms, m.p. 275–277°; *m/e* 732.2679 (M) ($C_{42}H_{40}N_2O_{10}$ requires 732.2683); ν_{max} (KBr) 1780, 1720, 740 cm^{-1}.

Anal. Calcd. for $C_{42}H_{40}N_2O_{10}\cdot\frac{1}{2}H_2O$: C, 68.0; H, 5.5; N, 3.8; O, 22.7. Found: C, 68.1; H, 5.6; N, 3.7; O, 22.4.

Dimethyldihydrocochliodinol Diacetate (2e)

Dimethylcochliodinol (0.4 g) was dissolved in methanol (100 ml) and was reduced with hydrogen sulfide as described for the diacetate. The colorless solution was evaporated and the residue (λ_{max} (MeOH) 293 nm) dissolved in a solution of pyridine (0.5 ml) in acetic anhydride (20 ml). The solution was kept for 24 h, was diluted with methanol (100 ml), heated under reflux for 1 h, and evaporated. Water (50 ml) was added and the colorless precipitate recrystallized from ethanol gave *dimethyldihydrocochliodinol diacetate* as parallelograms, m.p. 241°; *m/e* 620; λ_{max} (MeOH) 225, 290 nm (log ε 4.91, 4.39); ν_{max} (KBr) 3390, 1760, 1200, 790 cm^{-1}.

Anal. Calcd. for $C_{38}H_{40}N_2O_6\cdot\frac{1}{2}H_2O$: C, 72.7; H, 6.2; N, 4.5; O, 16.6. Found: C, 72.9; H, 6.6; N, 4.5; O, 15.8.

Hexahydrocochliodinol Tetraacetate (2j)

(*a*) Cochliodinol (1 g) in acetic acid (150 ml) was shaken with hydrogen and platinum (10 mg) in a flask fitted with a side arm equipped with a sintered disc, stopcock, and female ground-glass joint in this order, the disc being proximal to the flask. When the reaction mixture was colorless the flask was evacuated and a solution (30 ml) of pyridine (5 ml) in acetic anhydride was sucked into the reaction vessel through the stopcock and sintered disc. After 2 h the mixture was filtered, concentrated to 50 ml, and methanol (200 ml) added. The colorless solution was heated under reflux for 1 h, evaporated, the residue

triturated with water (100 ml), and the precipitate collected. The *tetraacetate* separated from ethanol (charcoal) as colorless needles, m.p. 258–260°; λ_{max} (MeOH) 220, 298 nm (log ε 4.85, 4.38); ν_{max} (CCl_4) 3390, 2955, 2925, 2860, 1770, 1750, (KBr) 1365, 1190, 1180, 1020, 990, 800 cm^{-1}; *m/e* 680.3079 (M) ($C_{40}H_{44}N_2O_8$ requires 680.3098), 638, (*m** ~ 602; 680 → 638 + 42), 596 (*m** ~ 557; 638 → 596 + 42), 554 (*m** ~ 517; 596 → 554 + 42), 512.2660 ($C_{32}H_{36}N_2O_4$ requires 512.2675; *m** ~ 473; 554 → 512 + 42), 69; p.m.r. (100 MHz; acetone-d_6) δ 10.42 (bs, 2H, exchanged with D_2O, NH), 7.37 (bs, 2H, H-4′), 7.35 (d, 2H, H-2′, coupled to NH, $J_{2',1'} \simeq$ 2.6 Hz), 7.20 (AB, 4H, H-7′ and -6′, $\Delta_{\nu_{AB}} = 33.6$ Hz, $J_{AB} = 8.4$ Hz, $J_{4',6'} = 1.6$, $J_{4',7'} = 0.6$), 2.70 (m, 4H, H-10′), 1.88 (s, 12H, O_2CCH_3), 1.2–1.9 (m, 6H, H-11′ (methylene) and -12′(methine) coupled to signals at 2.70 and 0.96 (double resonance)), 0.96 (d, 12H, coupled to H-12′, $J \simeq 5$ Hz, isopentyl CH_3's).

Anal. Calcd. for $C_{40}H_{44}N_2O_8$: C, 70.6; H, 6.5; N, 4.1; O, 18.8. Found: C, 70.7; H, 6.6; N, 4.1; O, 18.3.

(*b*) When cochliodinol diacetate (0.25 g) was treated as described above for cochliodinol, the tetraacetate (0.24 g; m.p. 258°) was obtained.

(*c*) Tetrahydrocochliodinol (50 mg) gave this tetraacetate (m.p. 258–260°; 35 mg) when reduced and acetylated as described in *a*.

(*d*) Similarly, tetrahydrocochliodinol diacetate (50 mg) gave the tetraacetate, (m.p. 258°; 35 mg) under the same reaction conditions.

Di-N-acetylhexahydrocochliodinol Tetraacetate (2k)

(*a*) Hexahydrocochliodinol tetraacetate (60 mg), acetic anhydride (15 ml), and anhydrous sodium acetate (0.5 g) were heated together under reflux for 5 h. The mixture was diluted with water at 0° and the colorless precipitate collected. *Di-N-acetylhexahydrocochliodinol tetraacetate* separated from *n*-butyl alcohol as colorless parallelograms, m.p. 276°; *m/e* 764.3317 (M) ($C_{44}H_{48}N_2O_{10}$ requires 764.3309); λ_{max} (MeOH) 235, 304 nm (log ε 4.16, 3.93); ν_{max} (KBr) 1760, 1715 cm^{-1}; p.m.r. (60 MHz, $CDCl_3$), δ 7.78 (AB, 4H, H-7′ and -6′, $\Delta_{\nu_{AB}} = 67.0$ Hz, $J_{AB} \simeq 8.2$ Hz, H-6′ and -7′ broadened by *meta* and *para* coupling with H-4′), 7.47 (s, 2H, H-2′), 7.30 (bs, 2H, H-4′), 2.70 (m, 4H, H-10′), 2.62 (s, 6H, $NCOCH_3$), 1.88 (s, 12H, O_2CCH_3), 1.2–1.9 (m, 6H, H-11′ (methylene) and -12′ (methine), irradiation of this multiplet causes signals at 2.70(m) and 0.94(d) to collapse to broad singlets), 0.94 (d, 12H, coupled to H-12′, $J \simeq 5$ Hz, H-13′ and -14′, isopentyl CH_3's).

Anal. Calcd. for $C_{44}H_{48}N_2O_{10}$: C, 69.1; H, 6.2; N, 3.7; O, 20.9. Found: C, 69.1; H, 6.2; N, 3.7; O, 21.2.

(*b*) Di-*N*-acetyldihydrocochliodinol tetraacetate (1 g) in acetic acid (400 ml) was stirred with platinum (50 mg) and hydrogen at 70°/100 atm for 48 h. The hot solution was filtered and the precipitate washed with ethyl acetate. The filtrate and washings were evaporated and the residue (1 g; m.p. 276°) recrystallized from *n*-butyl alcohol.

Hexahydrocochliodinol Octaacetate (2l)

Cochliodinol diacetate (0.58 g) in benzene (50 ml) was treated with a solution of osmium tetroxide (0.5 g) in benzene (50 ml). The mixture was stirred at room temperature for 48 h when the crystalline black osmic ester was collected, dissolved in methanol (200 ml), and the stirred mixture treated with hydrogen sulfide for 18 h. The osmic sulfide was collected and the filtrate evaporated. The residue was dissolved in acetic anhydride (100 ml) and pyridine (10 ml) added. The solution was kept at 4° for 48 h, when the colorless crystalline precipitate (0.5 g; m.p. 265–267°) was collected. *Hexahydrocochliodinol octaacetate* separated from 1-ethoxy-2-hydroxyethane as minute blunt colorless needles, m.p. 266°; *m/e* 912; ν_{max} (KBr) 3350, 1775, 1740, 1370 cm^{-1}.

Anal. Calcd. for $C_{48}H_{52}N_2O_{16}$: C, 63.2; H, 5.8; N, 3.1; O, 28.1. Found: C, 63.0; H, 5.9; N, 2.8; O, 28.2.

Oxidation of Cochliodinol with Manganese Dioxide and Silver Oxide

Cochliodinol (1 g) was dissolved in toluene (300 ml) and stirred with manganese dioxide (13) (0.3 g) and freshly prepared silver oxide (0.1 g). The stirred mixture was heated under reflux for 3 h when the hot solution was filtered and the metal oxides washed with boiling toluene until the washings were colorless. The combined filtrate and washings were concentrated to 50 ml and the hot solution applied to the top of a silica gel (30 × 4 cm) column. The column was eluted with toluene until the red-orange band was completely eluted. The fluorescent solution was concentrated to 50 ml and then kept at 4° for 24 h. *Cochliodinone* (*3a*) (0.2 g, 25% allowing for recovered cochliodinol; see below) separated from toluene as red-orange needles, m.p. 275–276° (depending on the rate of heating); *m/e* 504.2032 (M) ($C_{32}H_{28}N_2O_4$ requires 504.2049), 475, 462, 448.2150 ($C_{30}H_{28}N_2O_2$ requires 448.2151), 407, 393, 392, 337, 253, 196.1123 ($C_{14}H_{14}N$ requires 196.1126), 69.0706 (C_5H_9 requires 69.0704); λ_{max} (MeOH) 272, 293, 352, 470 nm (log ε 4.06, 4.05, 3.76, 4.35); λ_{max} (excitation) 470 nm (log ε 4.27); λ_{max} (emission, MeOH) 567 nm; λ_{max} (0.02 *N* NaOH) 281, 350 nm (log ε 4.16, 4.29); λ_{max} (after acidification) 272, 408 nm; ν_{max} (CCl_4) 3490, 1730, (KBr) 3430, 3415, 2960, 2850, 1785, 1760, 1660, 1500, 1420, 1100, 855 cm^{-1}; ^1H n.m.r. Table 1, ^{13}C n.m.r. Table 2.

Anal. Calcd. for $C_{32}H_{28}N_2O_4$: C, 76.2; H, 5.55; N, 5.55; O, 12.7. Found: C, 76.7; H, 5.6; N, 5.4; O, 12.3.

This compound was identical with the 'orange fluorescent pigment' previously described (1). Further elution of the column with toluene separated two purple bands and when these were completely separated (15 l) the band of greatest R_F was eluted with ether–toluene (1:19). That of lowest R_F was collected with ether–toluene (1:9) and gave cochliodinol (0.2 g, m.p. 204°) after evaporation. The band of greatest R_F was rechromatographed on a silica gel column (30 × 2 cm) made up with a solution (100 ml) of acetic acid (0.4 ml) in benzene. The column was washed with the same solvent (150 ml) and then the band of greatest R_F was applied to the top. The column was developed with 0.4% (v/v) acetic acid in benzene and the purple band of greatest R_F was collected, concentrated, and the precipitate gave a deoxocochliodinol *e.g.* (*4a*) (77 mg, 10% allowing for the recovered cochliodinol), as purple needles from benzene–petroleum ether (b.p. 40–60°), m.p. 215–220°; *M* (by measurement of depression of vapor pressure) 550; λ_{max} (MeOH) 263, 315 (sh), 475 nm (log ε 4.51, 4.18, 3.88); λ_{max} (0.02 *N* NaOH (MeOH–H_2O, 4:1)) 445 nm (log ε 3.81); λ_{max} (after acidification) 475 nm (log ε 3.88); ν_{max} (CS_2) 3465, 3440 (KBr) 1645, 1600, 1475, 1390, 1340, 1285, 1110, 800 cm^{-1}.

Anal. Calcd. for $C_{31}H_{30}N_2O_3 \cdot C_6H_6$: C, 79.9; H, 6.5; N, 5.0; O, 8.6. Found: C, 79.9; H, 6.0; N, 5.3; O, 8.8.

Oxidation of Cochliodinol with Dimethyl Sulfoxide

Cochliodinol (0.1 g) was dissolved in dimethyl sulfoxide (20 g) and acetic anhydride (10 g) added. The solution was heated on the steam bath for 30 min, kept overnight at room temperature, diluted with methanol (50 ml), and the solution heated under reflux for 1 h. The solution was evaporated, the residue absorbed from benzene on silica gel and the orange band eluted with benzene gave cochliodinone (m.p. 276°; 20 mg) after evaporation.

N-Acetylcochliodinone (3b)

Cochliodinone (0.1 g), acetic anhydride (20 ml), and anhydrous sodium acetate (0.5 g) were heated together under reflux. A complete solution was obtained from which orange needles were slowly precipitated. After 1.5 h the precipitate was collected. *N-Acetylcochliodinone* separated from acetic anhydride as yellow needles m.p. > 350°; ν_{max} (KBr) 1820, 1780, 1720, 1530, 1225, 1010 cm^{-1}.

Anal. Calcd. for $C_{36}H_{32}N_2O_6$: C, 73.5; H, 5.4; N, 4.8; O, 16.3. Found: C, 73.2; H, 5.2; N, 4.6; O, 16.8.

Tetrahydrocochliodinone (3c)

(*a*) Cochliodinone (0.3 g) in acetic acid (100 ml) was shaken with platinum (10 mg) and hydrogen at room temperature and pressure. A yellow precipitate separated slowly; at no time was a colorless solution obtained. After 30 ml (theory, 29.1 ml) had been absorbed, tetrahydrofuran (50 ml) was added until all the crystalline precipitate had dissolved when the mixture was filtered and evaporated. *Tetrahydrocochliodinone* separated from toluene as yellow needles, m.p. 310°; *m/e* 508.2351 (M) ($C_{32}H_{32}N_2O_4$ requires 508.2361); λ_{max} (MeOH) 230, 274, 298, 475 nm (log ε 4.77, 4.22, 4.22, 4.56); ν_{max} (KBr) 3410, 1795, 1770, 1675, 1510, 1430, 1105, 1040, 865, 805, 780 cm^{-1}.

Anal. Calcd. for $C_{32}H_{32}N_2O_4$: C, 75.6; H, 6.3; N, 5.5; O, 12.6. Found: C, 76.1; H, 6.3; N, 5.4; O, 12.2.

(*b*) Tetrahydrocochliodinol (30 mg) and manganese dioxide ((13), 10 mg) were stirred together in toluene (10 ml) and heated under reflux for 3 h. The mixture was filtered, the manganese salts washed with hot toluene until the washings were colorless, the filtrate and washings combined, concentrated, and absorbed on silica gel (30 × 2 cm). The red band, eluted with benzene, gave tetrahydrocochliodinone (m.p. 310°; 6 mg) on evaporation. The product was yellow in contact with benzene and orange-red when dry.

Di-N-acetyltetrahydrocochliodinone (3d)

Tetrahydrocochliodinone (20 mg), acetic anhydride (10 ml), and anhydrous sodium acetate (20 mg) were heated together under reflux for 1 h. Water (20 ml) was added and the yellow needles (22 mg; m.p. 305°) that separated were collected. *Di-N-acetyltetrahydrocochliodinone* separated from toluene as long yellow needles, m.p. 321°; *m/e* 592, 550 ($m^* \sim 511$; $592 \rightarrow 550 + 42$), 508 ($m^* \sim 469$; $550 \rightarrow 508 + 42$); λ_{max} (tetrahydrofuran) 300, 430 nm (log ε 4.21, 4.46).

Isomérisation d'époxydes d'acétates d'énols en série pinanique

YVONNE BESSIÈRE, MOHAMED MONCEF EL GAÏED ET GINETTE BOUSSAC

Laboratoire de Chimie de l'Ecole Normale Supérieure, 24, rue Lhomond, 75231 Paris Cédex 05, France[1]

Reçu le 7 décembre 1973[2]

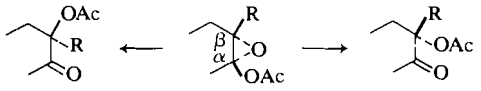
YVONNE BESSIÈRE, MOHAMED MONCEF EL GAÏED et GINETTE BOUSSAC. Can. J. Chem. **53**, **53**, 738 (1975)

L'isomérisation d'époxydes d'acétates d'énols par le bromure de zinc conduit à des cétoacétates avec rétention de configuration. L'isomérisation thermique conduit à un cétoacétate avec inversion de configuration (mécanisme concerté) lorsque l'oxiranne ne porte pas d'atome d'hydrogène. Dans le cas d'un oxiranne portant un atome d'hydrogène, le mécanisme concerté est fortement concurrencé par un mécanisme de type 'acide,' celui-ci conduisant au cétoacétate avec rétention de configuration. Cet isomère résultant de la rétention n'est pas le plus stable.

YVONNE BESSIÈRE, MOHAMED MONCEF EL GAÏED, and GINETTE BOUSSAC. Can. J. Chem. **53**, 738 (1975)

The isomerization of enol acetate epoxides by zinc bromide leads to ketoacetates with retention of configuration. Thermal isomerization yields a ketoacetate with inversion of the configuration by a concerted mechanism if the oxirane does not contain a hydrogen atom. In the case of an oxirane containing hydrogen, an 'acid' type mechanism competes favorably with the concerted mechanism; the former yields a ketoacetate with retention of configuration. The isomer in which the configuration is retained is not the most stable. [Journal translation]

Les époxydes d'acétates d'énols I s'isomérisent selon les cas en α-cétoacétates avec inversion, **II**, ou rétention de configuration, **III**, au niveau du carbone β.



II I III

Une interprétation de ces transpositions a été proposée par Leeds *et coll* (1): les mécanismes A ou B pourraient intervenir quelles que soient les conditions expérimentales. Par contre, d'après Williamson *et coll.* (2, 3), ces conditions détermineraient la formation de l'un ou l'autre des isomères, plusieurs mécanismes étant proposés pour la transposition directe de **I** en **III** en milieu acide, le mécanisme concerté agissant pour la transposition thermique **I** → **II**.

Les observations que nous avons faites sur deux acétates d'énols en série pinanique, doivent, par comparaison avec des résultats décrits dans la littérature, apporter des précisions pour l'élucidation de ces mécanismes.

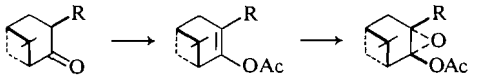
Résultats

La nopinone **1***a* et la *cis*-méthyl-3 nopinone[3] **1***b* traitées en milieu acide par l'acétate d'isopropényle conduisent aux acétates d'énols **2***a* (4) et **2***b*, oxydés en **3***a* et **3***b* par l'acide *p*-nitroper-

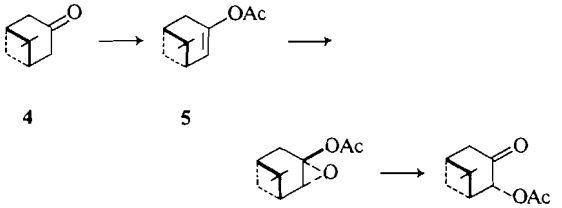


1 **2** **3**

a R = H
b R = CH_3

benzoïque (pour des raisons stériques connues en série pinanique, l'oxygène de l'oxiranne est *trans*). En vue de l'identification de produits secondaires, nous avons également préparé l'acétate d'énol **5** de l'isonopinone **4** puis son époxyde **6**. Il faut noter une difficulté spéciale pour obtenir **5** avec de bons rendements (voir partie expérimentale).

On étudie le comportement des époxyacétates **3***a* et **3***b* en présence de bromure de zinc et thermiquement. Les produits des réactions sont séparés par chromatographie en phase gazeuse (c.p.v.) sur colonne de DEGS.[4]



4 **5** **6** **8**

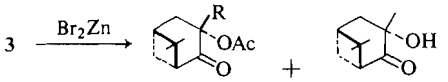
Action du bromure de zinc

Sous l'action du bromure de zinc, **3***a* donne principalement le cétoacétate **7***at* (85%) accompagné d'une petite quantité de **7***ac* (~10%) et d'un autre cétoacétate (d'après les spectres i.r. et r.m.n. du produit isolé en c.p.v.) identique au produit **8** obtenu par traitement de **6** dans les mêmes conditions (~5%).

Avec **3***b*, on obtient également de façon prépondérante le cétoacétate **7***bt* attendu. Cependant la c.p.v. indique la formation de produits légers (10% environ du total). Le composé **7***bt* constitue 70% du mélange des produits lourds; on identifie 5% du cétoacétate **7***bc* et 25% de cétol **9***bt*.

Traitement thermique

L'évolution thermique des époxyacétates est plus complexe. Mise à part la formation de 5%

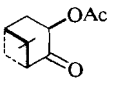


7*t* **9***bt*

c OH, OAc *cis*
t OH, OAc *trans*

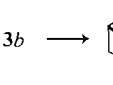
environ de produits légers et 2 à 3% de **8**, l'époxyde **3***a* donne un mélange des cétoacétates **7***a cis* et *trans*. A 190–195 °C, en 15 min, la transformation est complète; les proportions sont 25 et 75% respectivement. Si le chauffage est arrêté après 2 min, il reste (d'après la r.m.n.) la moitié d'époxyde non transformé, mais les deux cétoacétates sont présents dans le même rapport que lorsque la transformation est complète. A 255 °C par contre, en 15 min, les proportions sont inversées: on obtient 65% de **7***ac* et 35% de **7***at*.[5]

On observe par ailleurs une lente transformation thermique de **7***at*: le mélange 25% **7***ac* + 75% **7***at* obtenu précédemment donne 40–60 en 2 h à 200 °C; l'échantillon **7***at* (obtenu avec Br_2Zn) donne 30% de **7***ac* et 70% de **7***at* en 2 h à 185 °C, mais la transformation n'est pas sensible en 15 min à 195 °C. Notons enfin que, dans les conditions "acides" (Br_2Zn), un mélange **7***ac* + **7***at* n'est pas transformé.



7*ac*

+ **7***at* ⟵ **3***a*



7*bc*

3*b* ⟶ + **9***bt*

[3] *Cis* ou *trans* sont exprimés par rapport au pont *gem*-diméthylé.

[4] Les époxydes d'acétates d'énols, **3***a*, **3***b* et **6**, sont très fragiles en c.p.v. Si l'injecteur n'est pas nettoyé préalablement avec du diéthylaminoéthanol les époxydes s'isomérisent de la même façon qu'avec le bromure de zinc. Ils s'isomérisent de toute façon sur la colonne de DEGS. Les spectres de r.m.n. des mélanges réactionnels permettent de vérifier l'absence de produit de départ après le traitement d'isomérisation.

[5] A température plus élevée, le produit brunit trop et charbonne.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 84.22.46.98 on 09/08/12
For personal use only.

La transformation de **3***b* est également complète à 195 °C en 15 min. On observe la formation de produits légers (environ 5% du total). Le cétoacétate **7***bc* représente 82% des produits lourds. Il est accompagné de 3% de son isomère **7***bt* et de 15% de cétol **9***bt*. Dans les mêmes conditions, **7***bc* et **7***bt* sont stables.

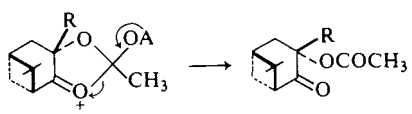
Si l'on chauffe l'époxyde **3***b* 30 min à 250 °C, il se forme beaucoup de produits légers (parmi lesquels, d'après la r.m.n. et la c.p.v., on identifie la méthylène-3 nopinone **15**), mais les quantités relatives de cétoacétate et de cétol sont les mêmes.

Interprétation des résultats

Nous traiterons d'abord les résultats essentiels, formation des cétoacétates **7**, puis des produits secondaires **8** et **9***bt*.

Action du bromure de zinc

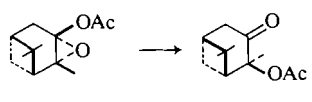
Les résultats essentiels obtenus dans l'action du bromure de zinc sont en accord avec le travail de Williamson *et coll.* (3); le mécanisme de type A (**I** → **II** → **III**) est ainsi exclu, dans le cas de **7***b* du moins où la forme énolique est impossible; il l'est aussi dans le cas de **7***a* puisque nous avons noté l'absence de transformation de **7***ac* dans les conditions "acides." Le mécanisme B intervient: la formation d'un cation tel que **IV** conduisant au cétoacétate, est ici favorisée par rapport à la transformation du squelette qui accompagne généralement la présence d'un carbocation sur le carbone 2.



IV 7*t*

Traitement thermique

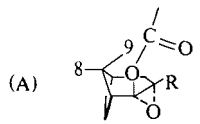
Dans l'isomérisation thermique, **7***bc* se forme par le mécanisme concerté A (**I** → **II**). Signalons que Carlson et Pierce (6) indiquent une isomérisation difficile pour **10**; ils obtiennent 45% de **11** à 265°, et invoquent des effets stériques pour expliquer cette difficulté.

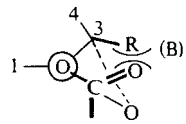


10 **11**

La transformation de **3***a* conduit aux isomères **7***ac* et **7***at* par deux voies différentes: en effet, dans la transformation incomplète, les deux cétoacétates sont présents dans les mêmes proportions que lorsque la transformation est complète (75% de **7***at*). (*a*) On peut exclure le passage **7***ac* → **7***at* (**II** → **III**) puisque le chauffage prolongé de **7***at* (obtenu par Br_2Zn) donne au contraire un mélange **7***ac* + **7***at*; dans le mélange d'isomérisation thermique de **3***a*, la proportion de **7***ac* croît si l'on prolonge le chauffage. (*b*) Pour une très grande part du moins, on peut exclure la formation de **7***ac* par **7***at* → **7***ac*, car la transformation de **7***at* est lente et peu sensible dans les conditions d'isomérisation de **3***a* (15 min à 190 °C). Même à 290 °C en 10 min, **7***at* ne s'isomérise pas. Le mécanisme concerté (type A) serait responsable de la formation de **7***ac* (inversion), d'autant plus que la température est plus élevée et **7***at* (rétention) serait formé par un mécanisme de "type acide" (type B).

Pourquoi l'époxyde **3***a* subit-il de préférence l'ouverture de "type acide" ? Si l'on examine les modèles moléculaires, on voit que pour **3***a* et **3***b* l'état de transition pour le mécanisme concerté (A) est gêné par le méthyle-9. Par contre, la conformation qui doit être adoptée dans un mécanisme de type B est nettement plus difficile à atteindre lorsque R = CH_3, **3***b*, que lorsque R = H, **3***a*. Ceci expliquerait donc que la transformation de type B soit relativement favorisée lorsque R = H, **3***a*, et que l'isomérisation de **3***b*, R = CH_3, soit plus lente en présence de bromure de zinc (il reste en effet 30% d'époxyde **3***b* non transformé après 3 h de reflux dans du benzène, alors que dans les mêmes conditions, la transformation de **3***a* est complète).





Cette interprétation est en accord avec l'examen des résultats décrits dans la littérature, pour l'isomérisation thermique d'époxyacétates ayant un atome d'hydrogène sur l'oxiranne. Lorsqu'il n'y a pas d'inversion (1), ou bien si l'inversion est partielle au niveau du carbone β (7) (formation de **III**), on observe des interactions stériques pour l'intervention du mécanisme concerté (A). En l'absence de ces interactions (2, 8) l'inversion est normalement observée.[6]

[6]Nous remercions tout particulièrement l'un des rapporteurs pour toutes les suggestions et discussions au sujet de ce paragraphe.

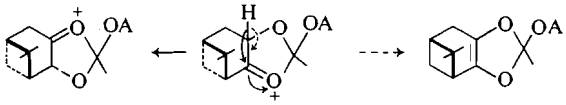
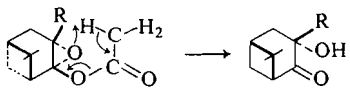
Produits secondaires

Avec **3***a*, la formation du produit secondaire **8** peut s'expliquer à partir du cation **IV**, par passage à une forme dérivée d'ène diol (5), ou même par simple isomérisation de l'époxyde.



IV

Quant à la formation du cétol **9***bt* dans tous les traitements de **3***b*, on l'explique par les difficultés rencontrées dans l'une et l'autre des transformations, par suite des contraintes stériques. On fait intervenir alors un troisième mécanisme, dans lequel l'oxygène de l'oxiranne attaque un proton de l'acétyle, avec élimination de cétène.[7]

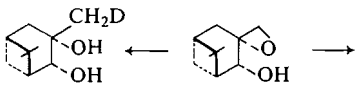


Détermination de la stéréochimie des produits obtenus

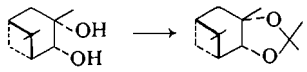
Série b

Les cétoacétates **7***b* sont réduits par l'aluminohydrure de lithium et les diols obtenus sont comparés avec des échantillons authentiques préparés comme suit.

L'époxyde **12** du méthylène-3 *trans*-nopinol (9) est réduit en diol **13***b* qui donne un dioxolanne **14***b*. Pour éliminer, dans le spectre r.m.n. de **13***b*, l'ambiguité dans l'attribution des signaux des méthyles 9 et 10, la réduction de **12** a également été effectuée avec $LiAlD_4$.

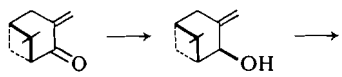


13′*b* **12**

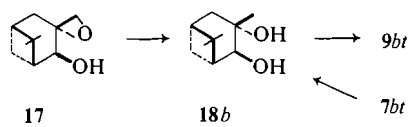


13*b* **14*b***

Le méthylène-3 *cis*-nopinol **16** peut être isolé à l'état cristallisé du mélange de réduction de la méthylène-3 nopinone **15** (10) par $LiAlH_4$. L'époxyde correspondant **17** est réduit en diol **18***b* dont l'oxydation (CrO_3–pyridine) fournit le cétol **9***bt*. Ce cétol ne peut être obtenu pur par oxydation de **13***b* car il y a en même temps rupture du cycle.

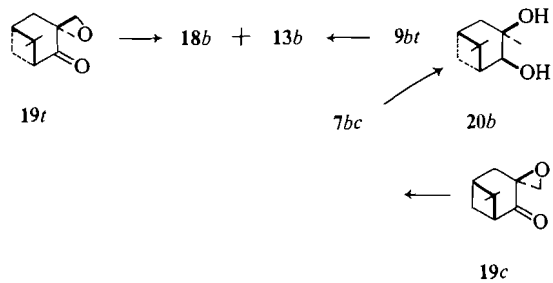


15 **16**



17 **18*b***

Enfin, du mélange **19***t* + **19***c* des époxydes de la méthylène-3 nopinone, on a séparé par c.p.v. l'époxyde *trans* **19***t* le plus abondant (11). Sa réduction par $LiAlH_4$ donne en quantités égales les diols **18***b* et **13***b*.



19*t* **7*bc*** **20*b***

19*c*

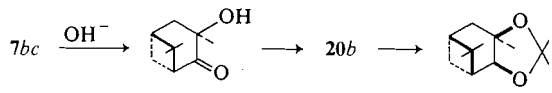
Un échantillon de **19***t* + **19***c* (2:1), donne les trois diols **18***b*, **13***b* et **20***b* dans des proportions pratiquement équivalentes.

On peut maintenant identifier à **18***b* le diol de réduction de **7***bt* et à **20***b* celui provenant de la réduction de **7***bc*. Ce dernier donne d'ailleurs un dioxolanne **21***b*, ce qui confirme la position *syn* des deux hydroxyles.

Si le cétoacétate **7***bc* est saponifié, on obtient le cétol **9***bc* dont le spectre r.m.n. possède les mêmes déplacements chimiques que celui du produit décrit dans (6). Sa réduction conduit au diol **20***b*, alors que la réduction du cétol **9***bt* est moins sélective (72% de **18***b* et 28% de **13***b*) que celle de l'acétate correspondant **7***bt*. Ces observations sont en accord avec celles de Carlson et Pierce d'une part (6), et Hirata d'autre part (12) sur la réduction de cétols et cétoacétates dans cette série.

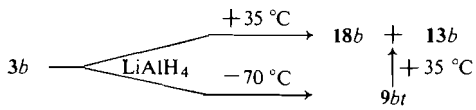
On pouvait également effectuer la réduction de l'époxyacétate **3***b* par $LiAlH_4$ pour préparer

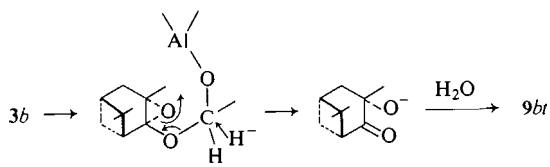
[7]A ce sujet, il faut noter un rapport M − 42/M beaucoup plus grand dans le spectre de masse de **3***b* que dans celui de **3***a*.



9*bc* 21*b*

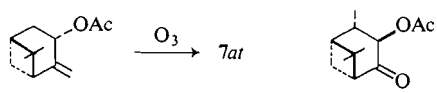
le diol **18***b*. La littérature indique en effet la formation d'un seul diol dans la réduction d'époxyacétates (1, 13). En fait, la sélectivité n'est pas totale: on obtient 87% de **18***b* et 13% de **13***b*, soit des proportions légèrement différentes de celles obtenues dans la réduction du cétol **9***bt* dans les mêmes conditions (72 et 28%). On constate, que si l'on effectue la réduction à basse température, avec une quantité limitée d'hydrure, on obtient, après hydrolyse, un mélange réactionnel très riche en cétol **9***bt* (composé de plus d'une petite quantité de produit de départ et de diols de réduction complète). La réduction de l'époxyacétate passe donc par un alcoolate intermédiaire dont l'hydrolyse donne le cétol **9***bt*.





Série a

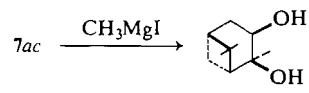
Le cétoacétate **7***at* a le même temps de rétention en c.p.v. et le même spectre r.m.n. que le produit que nous avons obtenu selon (6) par ozonolyse de l'acétate du *trans*-pinocarvéol **22**.



22 23

Le cétoacétate **7***ac* est obtenu pur par c.p.v. (DEGS) du mélange d'isomérisation thermique de **3***a*. En r.m.n., les déplacements chimiques pour les méthyles 9 et 8 (0.82 et 1.37) sont très proches de ceux (0.81 et 1.38) du cétoacétate **23**, pratiquement de même conformation (12).

Le composé **7***ac* est traité par l'iodure de méthylmagnésium. Le diol obtenu de façon prépondérante a les mêmes déplacements chimiques en r.m.n. que **24** décrit dans la littérature (6).



24

Par réduction avec $LiAlH_4$, le cétoacétate **7***at* donne un diol cristallisé pratiquement pur, auquel nous attribuons la structure **18***a* par comparaison avec la réduction de **7***bt* et par analogie des déplacements chimiques pour les méthyles 8 et 9 dans les spectres r.m.n. de **18***a* et **18***b*.

Dans cette série également, la réduction de l'époxyacétate **3***a*, qui aurait pu nous donner le diol **18***a*, n'est pas sélective. Par réduction complète, on obtient deux diols en quantités pratiquement équivalents, **18***a* et **13***a*, ce dernier formant un dioxolanne **14***a*. A basse température, par une réduction incomplète, on observe la formation du cétol **9***at*: dans les mêmes conditions que celles utilisées avec **3***b*, on obtient un mélange de 20% de produit de départ, 40% de cétol **9***at* et 20% de chacun des diols **18***a* et **13***a* (r.m.n.).

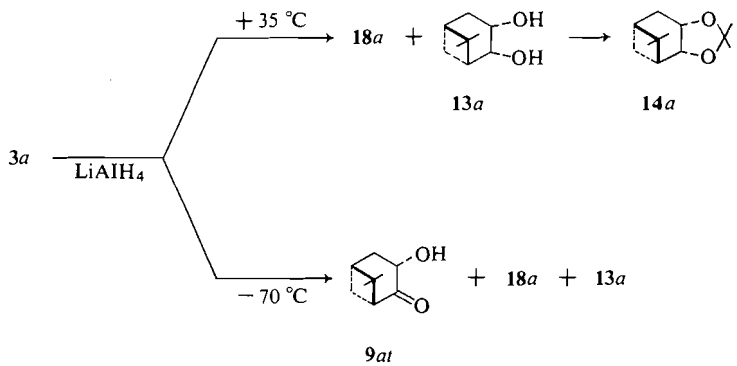
Résonance magnétique nucléaire

Il faut faire quelques remarques au sujet des spectres r.m.n. Il est connu que dans la série pinanique, les méthyles 8 et 9 ont des déplacements chimiques très distincts et que celui du méthyle 9 est très influencé par la présence de substituants oxygénés sur les carbones 2, 3 ou 4 (—OH, —OAc, —OTs, oxygène d'oxiranne) (14, 15, 16). Lorsque la fonction est *cis*, le signal est déplacé vers les champs faibles par rapport à l'isomère qui possède la même fonction en *trans*. Cette règle reste valable lorsque deux de ces fonctions sont présentes (6, 12 et, dans ce travail, comparer **13***a* et **18***a*, **13***b*, **18***b* et **20***b*).

Par contre lorsqu'il y a, en plus de la fonction oxygénée à liaison simple, une fonction carbonyle, cette règle n'est plus applicable sans restriction. S'il n'y a pas de différence notable de conformation entre les deux isomères (17), l'observation est la même (6, et ce travail: **7***bt* et **7***bc*, **9***bt* et **9***bc*). L'observation est différente lorsque la conformation varie d'un épimère à l'autre (12, et ce travail **7***at* et **7***ac*).

En conclusion, les époxydes d'acétates d'énols s'isomérisent selon deux schémas: l'isomérisation en milieu acide se fait régulièrement avec rétention de configuration; par action de la chaleur, l'isomérisation se fait avec inversion de configuration selon le mécanisme concerté, si

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 84.22.46.98 on 09/08/12
For personal use only.



l'oxiranne ne porte pas d'hydrogène; dans le cas contraire, si le mécanisme concerté est empêché stériquement, un mécanisme de "type acide" entre en concurrence. Dans le cas particulier d'un oxiranne entièrement substitué, pour lequel les deux mécanismes rencontrent des empêchements stériques, on observe, à côté de l'isomérisation en cétoacétate, un arrachement d'hydrogène, avec départ probable de cétène et formation de cétol.

Partie expérimentale

Sauf indications particulières, les pouvoirs rotatoires sont mesurés sur un appareil Perkin–Elmer 141, à 589 nm, à 21 °C, la concentration étant 5 g pour 100 cm³ dans le cyclohexane; les spectres de r.m.n. sont effectués sur les appareils Varian A 60 et Jeol C-60 H, dans le deutériochloroforme, le tétraméthylsilane servant de référence interne; les déplacements chimiques sont exprimés en unité δ (p.p.m.). Les spectres i.r. sont enregistrés sur un Perkin–Elmer 457 et effectués sans solvant pour les liquides, dans le Nujol pour les produits cristallisés. Le spectrographe de masse est un Varian MAT CH 7, 70 eV; on opère avec introduction directe sans chauffage pour les produits solides (dir), et vers 160 °C pour les liquides (160); les fragments sont exprimés en *m/e* (% du fragment le plus abondant), et l'absence d'ion parent est indiquée s'il y a lieu. Les chromatographies en phase gazeuse préparatives et analytiques sont effectuées à l'aide d'un Varian Aerograph Autoprep.

Modes opératoires

Les caractéristiques de tous les produits obtenus seront groupés dans un même paragraphe, à la suite des modes opératoires.

Acétates d'énols

Dans un ballon muni d'un réfrigérant, on met une solution de 0.06 mol de cétone dans 120 cm³ d'acétate d'isopropényle; on ajoute 10 cm³ d'acétate d'isopropényle contenant 0.2 cm³ d'acide sulfurique concentré. On laisse à reflux pendant 48 h, puis on concentre à la moitié du volume. La solution est refroidie et diluée avec de l'éther, lavée avec une solution de carbonate de sodium et à l'eau. On sèche et distille.

Acétate d'énol 2b: à partir de 9.2 g de *cis*-méthyl-3 nopinone **1***b*, on distille 9.5 g de **2***b* (82%).

Acétate d'énol 2a: à partir de 8.3 g de nopinone **1***a*, on distille 9.3 g de **2***a* (85%). Pour effectuer la mesure de $[\alpha]_D$, un échantillon est séparé par c.p.v. sur colonne de silicone SE 54 à 1% sur Chromosorb G, diamètre 1/4 po., longueur 3 m, à 110 °C.

Acétate d'énol 5: la mode opératoire est le même, mais il faut laisser le mélange réactionnel à reflux pendant une semaine. A partir de 4 g d'isonopinone **4**, on distille 4.5 g de **5** (85%).

Epoxydation des acétates d'énols

Une solution de 15 mmol d'acétate d'énol dans 20 cm³ d'éther anhydre est ajoutée goutte à goutte, à 0 °C, à une solution de 18 mmol d'acide *p*-nitroperbenzoïque dans 40 cm³ d'éther anhydre. On laisse avec agitation pendant 1 nuit à température ordinaire. L'acide *p*-nitrobenzoïque est essoré; la solution éthérée est lavée avec de la soude 1.5 *N*. Après séchage, on évapore le solvant et on distille.

Epoxyde 3b: 2.8 g d'acétate d'énol **2***b* (0.013 mol) donnent 2.55 g d'époxyde **3***b* cristallisé (80%).

Epoxyde 3a: 8.1 g d'acétate d'énol **2***a* (0.041 mol) donnent 8.5 g d'époxyde **3***a* cristallisé (95%).

Epoxyde 6: 2.5 g d'acétate d'énol **5** donnent 2.5 g d'époxyde **6** (90%).

Isomérisation des époxydes d'acétates d'énols par le bromure de zinc

A une suspension de 50 mg de bromure de zinc fraîchement fondu, dans 5 cm³ de benzène anhydre, on ajoute goutte à goutte une solution de 5.7 mmol d'époxyde dans 5 cm³ de benzène. On porte à reflux, on refroidit ensuite la solution et on lave à l'eau. Après séchage de la phase organique sur sulfate de sodium, on évapore le solvant et on distille (distillation moléculaire, bain vers 80 °C/ 0.05 mm Hg). Le produit est examiné en c.p.v. avant la distillation, sur colonne de DEGS, 15% sur Chromosorb P, diamètre ¼ po., longueur 3 m, à 145 °C. Les séparations par c.p.v. sont effectuées à l'aide d'une colonne de DEGS, 15% sur Chromosorb W NAW, diamètre 3/8 po., longueur 3 m, à 145 °C.

Isomérisation de 3b: une solution de 1.2 g de **3***b* (5.7 mmol) est laissée une nuit à reflux. Après les opérations décrites ci-dessus, on distille 1 g d'un mélange dans lequel on identifie après c.p.v. préparative (dans l'ordre d'élution): le cétol **9***bt* (25%), le cétoacétate **7***bt* (70%) et le cétoacétate **7***bc* (5%).

Isomérisation de 3a: une solution de 2 g (10.2 mmol) de **3***a* est laissé 3 h à reflux dans les conditions indiquées. En fin d'opération, on distille 1.7 g de produit (85%) dans lequel on identifie, après c.p.v. préparative (dans l'ordre d'élution): le *trans*-acétoxy-2 one-3 **8** (ci-dessous) (7%),

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 84.22.46.98 on 09/08/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 84.22.46.98 on 09/08/12
For personal use only.

le *trans*-acétoxy-3 one-2 **7***at* (80%) et le *cis*-acétoxy-3 one-2 **7***ac* (13%).

Isomérisation de **6**: la solution de 1 g (5 mmol) de **6** est laissée à reflux 5 h. On distille 850 mg de produit (85%) dans lequel le *trans*-acétoxy-2 one-3 **8** est le constituant principal.

Traitement thermique

Un ballon de 50 cm³ est chauffé à 195 °C sous un léger courant d'azote. On introduit 2 g d'époxyacétate en on chauffe à la même température pendant 15 min. Le ballon est choisi suffisamment grand par rapport à la masse de produit utilisée pour permettre une équilibration relativement rapide de la température au sein du liquide. Les conditions de c.p.v. sont les mêmes que pour l'isomérisation par le bromure de zinc.

Isomérisation de **3***b*: après le chauffage, on analyse le produit réactionnel par c.p.v.; outre quelques produits légers, on identifie 15% de cétol **9***bt*, 3% de cétoacétate **7***bt* et 82% de cétoacétate **7***bc*. A partir de 2 g de **3***b*, on distille 1.7 g de mélange (85%).

Isomérisation de **3***a*: à partir de 2 g de **3***a*, on distille 1.7 g de produit (85%) contenant essentiellement le *trans*-acétoxy-3 one-2 **7***at* et le *cis*-acétoxy-3 one-2 **7***ac*, dans le rapport 75/25, d'après les intégrations du spectre r.m.n. La c.p.v. préparative permet d'isoler les deux constituants purs.

Réduction des cétoacétates **7** *par l'aluminohydrure de lithium*

On ajoute, à 0 °C, le cétoacétate dissous dans l'éther anhydre, à la solution d'une quantité équimoléculaire de $LiAlH_4$ dans l'éther anhydre. On porte à reflux pendant 1 h après l'addition. Après refroidissement, on hydrolyse avec le minimum d'eau. On filtre et on évapore le solvant.

Réduction de **7***bt*: 840 mg de cétoacétate **7***bt* dissous dans 10 cm³ d'éther sont traités par 150 mg de $LiAlH_4$ dissous dans 10 cm³ d'éther. On obtient 650 mg de diol **18***b* (95%).

Réduction de **7***bc*: 1.35 g d'un échantillon contenant environ 15% de cétol **9***bt* (d'après la c.p.v. et la r.m.n.), dans 25 cm³ d'éther, sont traités avec 300 mg de $LiAlH_4$ dans 20 cm³ d'éther. On obtient 1 g (90%) de diols: 85% de **20***b* et 15% de **18***b* + **13***b* (3:1) provenant de la réduction du cétol **9***bt*. L'évaluation est faite d'après le spectre de r.m.n. et par comparaison avec le spectre du mélange de réduction de **9***bt* (voir plus loin).

Réduction de **7***at*: 200 mg de cétoacétate **7***at* dans 10 cm³ d'éther sont traités par 50 mg de $LiAlH_4$ dans 5 cm³ d'éther. On obtient presque quantitativement le diol **18***a* cristallisé.

Réduction de la méthylène-3 nopinone **15**

Lorsque la réduction de la méthylène-3 nopinone **15** est effectuée avec un excès d'aluminohydrure de lithium dans l'éther à reflux, ou de borohydrure de sodium dans le méthanol à température ordinaire, on obtient des mélanges contenant la *cis*-méthyl-3 nopinone **1***b*, le *cis*-méthyl-3 *cis*-nopinol et le méthylène-3 *cis*-nopinol **16** en quantités variables. Les deux alcools sont difficiles à séparer par c.p.v. Avec le mode opératoire suivant, le produit réactionnel contient uniquement la cétone **1***b* et l'alcool cherché **16**.

A une solution de 1.3 g de méthylène-3 nopinone **15** dans 25 cm³ d'éther anhydre, à 0 °C, on ajoute goutte à goutte assez rapidement, 50 cm³ d'une solution 0.39 *N* de $LiAlH_4$ dans l'éther anhydre (soit environ 2 équiv). On laisse revenir à température ambiante pendant 1/4 h. Puis on hydrolyse avec le minimum de glace, en refroidissant à nouveau le mélange réactionnel. On essore le précipité.

La c.p.v. préparative est effectuée sur une colonne de FFAP 20% sur Chromosorb A NAW, diamètre 3/8 po., longueur 3 m à 110 °C. Le mélange contient, par ordre d'élution, 65% de *cis*-méthyl-3 nopinone **1***b* et 35% de méthylène-3 *cis*-nopinol **16**.

Epoxydation des méthylène-3 nopinols cis et trans

Le mode opératoire est le même que pour l'époxydation des acétates d'énols.

Epoxyde du méthylène-3 cis-nopinol **17**: après réaction de 3.4 g (22 mmol) d'alcool **16** avec 4.6 g (24.5 mmol) d'acide *p*-nitroperbenzoïque, on distille 3 g d'époxyalcool **17** (80%).

Epoxyde du méthylène-3 trans-nopinol **12**: après réaction de 7.6 g (50 mmol) d'alcool avec 11 g (60 mmol) d'acide *p*-nitroperbenzoïque, on distille 6.9 g d'époxyalcool **12** (82%).

Réduction des époxyalcools

On ajoute, à 0 °C, l'époxyalcool dissous dans l'éther anhydre à la solution d'une quantité équimoléculaire de $LiAlH_4$ dans l'éther anhydre. On porte à reflux pendant 1 h après l'addition. Après refroidissement, on hydrolyse avec le minimum d'eau. On essore le précipité et on évapore le solvant.

Réduction de **17**: 840 mg (5 mmol) d'époxyalcool **17** dans 10 cm³ d'éther sont traités par 190 mg de $LiAlH_4$ (5 mmol) dissous dans 10 cm³ d'éther. On obtient 845 mg de produit brut cristallisé **18***b*.

Réduction de **12**: (*a*) avec $LiAlH_4$, 380 mg (10 mmol) dans 20 cm³ d'éther; la réduction de 1.69 g de **12** (10 mmol) dans 20 cm³ d'éther, donne 1.7 g de diol **13***b*; (*b*) avec $LiAlD_4$, 210 mg (5 mmol) dans 10 cm³ d'éther; la réduction de 840 mg de **12** (5 mmol) dans 10 cm³ d'éther conduit à 800 mg de **13***'b* (95%).

Réduction des époxycétones **19***c et* **19***t*

Le mode opératoire est le même que celui décrit ci-dessus pour les époxyalcools.

Réduction de **19***t*: 280 mg de **19***i* (1.68 mmol) dans 5 cm³ d'éther sont réduits par 60 mg de $LiAlH_4$ (1.6 mmol) dans 10 cm³ d'éther. On obtient 240 mg du mélange **18***b* + **13***b* dans des proportions pratiquement équivalentes d'après la r.m.n. Le composé **18***b* cristallise dans le mélange.

Réduction de **19***c* + **19***t* (1:2): 3.32 g (20 mmol) de cétones dans 25 cm³ d'éther sont traités par 0.760 g de $LiAlH_4$ (20 mmol) dans 50 cm³ d'éther. On obtient 3.3 g de trois diols en proportions pratiquement équivalentes (r.m.n. dans CCl_4 et pyridine): **20***b*, *cis*-OH-2 *cis*-OH-3 (réduction de l'époxyde **19***c*); **18***b*, *cis*-OH-2 *trans*-OH-3; et **13***b*, *trans*-OH-2 *trans*-OH-3 (réduction de l'époxyde **19***t*, voir ci-dessus). Le mélange réactionnel est dissous dans 10 cm³ de chloroforme: on laisse à 0 °C, on essore 1 g de **18***b*. La phase liquide contient alors essentiellement **13***b* et **20***b* en quantités équivalentes (spectres r.m.n. pris dans CCl_4 et dans la pyridine).

Préparation des cétols **9***bc et* **9***bt*

Composé **9***bc par saponification du cétoacétate* **7***bc*: dans un ballon de 50 cm³ muni d'un réfrigérant, on met

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 84.22.46.98 on 09/08/12
For personal use only.

la solution de 500 mg de **7***bc* dans 10 cm³ de méthanol; on ajoute la solution de 300 mg de potasse dans un minimum d'eau et 10 cm³ de méthanol. On laisse à reflux pendant 2 h. On évapore le méthanol sous pression réduite. On dilue avec 10 cm³ d'eau et on extrait plusieurs fois à l'éther. On sèche la solution éthérée, on évapore le solvant et distille (distillation moléculaire, bain vers 95 °C/0.05 mm Hg) 320 mg de cétol **9***bc* (80%).

*Composé **9***bt par oxydation du diol **18***b par le complexe anhydride chromique – pyridine*: 500 mg de diol **18***b* (réduction des époxycétones **19**) (3 mmol) dans 10 cm³ de pyridine anhydre sont ajoutés goutte à goutte au complexe formé par l'addition de 1.2 g d'anhydride chromique (12 mmol) à 20 cm³ de pyridine anhydre, à −20 °C. On laisse agiter une nuit à température ambiante. On ajoute 50 cm³ d'eau et on extrait à l'éther. La phase organique est lavée avec une solution diluée d'acide chlorhydrique, une solution de bicarbonate de sodium et à l'eau. On sèche et on évapore le solvant. On obtient 380 mg de cétol **9***bt* (80%).

Réduction des cétols

*Réduction de **9***bc*: on ajoute, à 0 °C, la solution de 300 mg de cétol **9***bc* (1.8 mmol) dans 5 cm³ d'éther anhydre, à la solution de 80 mg (2 mmol) de $LiAlH_4$ dans 10 cm³ d'éther anhydre. Après addition, on porte à reflux pendant 1 h. Après refroidissement, on hydrolyse avec le minimum d'eau, on essore le précipité et on évapore le solvant. On distille (distillation moléculaire, bain vers 110 °C/0.05 mm H) 260 mg de diol **20***b*, *cis*-OH-2 *cis*-OH-3 (87%).

*Réduction de **9***bt*: dans les mêmes conditions, on traite une solution de 360 mg de cétol **9***bt* dans 10 cm³ d'éther, par une solution de 120 mg de $LiAlH_4$ dans 20 cm³ d'éther. On recueille 350 mg de produit brut (95%) contenant les diols **18***b*, *cis*-OH-2 *trans*-OH-3, et **13***b*, *trans*-OH-2 *trans*-OH-3, dans le rapport 72/28 (évaluation faite d'après le spectre de r.m.n.).

Réduction complète des époxydes d'acétates d'énols

On opère dans les mêmes conditions que pour les cétols.

*Réduction de **3***b*: la solution de 1.05 g de **3***b* (20 mmol) dans 20 cm³ d'éther est traitée par la solution de 190 mg de $LiAlH_4$ dans 20 cm³ d'éther. On obtient 0.82 g (95%) de **18***b* + **13***b*, 87:13 d'après la r.m.n. (comparer avec les réductions de l'époxycétone **19***t*, du cétol **9***bt* et du cétatoacétate **7***bt*).

*Réduction de **3***a*: 100 mg de **3***a* (0.5 mmol) dissous dans 5 cm³ d'éther sont ajoutés à la solution de 95 mg de $LiAlH_4$ (2.5 mmol) dans 10 cm³ d'éther. On obtient 72 mg (92%) des diols **18***a* + **13***a* (45:55 d'après le spectre de r.m.n.).

Réduction incomplète des époxydes d'acétates d'énols

On porte à ébullition pendant 30 min la suspension de 420 mg de $LiAlH_4$ dans 40 cm³ d'éther anhydre. On laisse refroidir et décanter et on prélève 10 cm³ de la solution environ 1 *N* (2.5 mmol) que l'on ajoute lentement à la solution de 5 mmol d'époxyacétate dans 10 cm³ d'éther anhydre, refroidie à −70 °C. On laisse agiter pendant 30 min à cette température. Puis on hydrolyse toujours à −70 °C, successivement avec une solution de méthanol dans l'éther anhydre, du méthanol, de l'éther saturé d'eau; on ajoute enfin 10 cm³ d'eau. On essore le précipité, on extrait à l'éther, on sèche et distille.

*Réduction de **3***b*: 1.05 g de **3***b* (5 mmol) est traité par 10 cm³ de solution de $LiAlH_4$. On distille 0.80 g de produit (94%), contenant (d'après le spectre de r.m.n.) le cétol **9***bt* (70%), accompagné de produit de départ (10%) et de diols de réduction totale (20%).

*Réduction de **3***a*: on traite 0.50 g (2.5 mmol) par 5 cm³ de la solution de $LiAlH_4$. On obtient 0.4 g de produit contenant: 25% de produit de départ, 50% de cétol **9***at*, 25% de diol **18***a* et 25% de diol **13***a* (r.m.n.).

*Préparation du diol **24***

L'iodure de méthylmagnésium est préparé à partir de 0.22 g de magnésium (9 mmol) et de 1.3 g d'iodure de méthyle (9 mmol) dans 10 cm³ d'éther anhydre. On ajoute, à 0 °C, 300 mg de cétoacétate **7***ac* (séparé de **7***at* par c.p.v.) (1.5 mmol) dans 10 cm³ d'éther anhydre. On porte à reflux pendant 3 h. On hydrolyse avec une solution saturée de chlorure d'ammonium. On extrait plusieurs fois la phase aqueuse à l'éther. On sèche, on évapore le solvant et on obtient 260 mg de produit brut riche en diol **24** dont la r.m.n. correspond à ce qui est décrit dans (6).

Préparation des dioxolannes

Une portion (2.5 mmol) de diol est dissoutes dans 10 cm³ de diéthoxy-2,2 propane; on ajoute 1 à 2 mg d'acide *p*-toluène sulfonique et on laisse 3 h à température ambiante. On lave avec une solution de carbonate de sodium et à l'eau. On sèche et distille (distillation moléculaire, bain vers 80 °C/0.05 mm Hg).

*Dioxolanne **14***b*: 400 mg de diol **13***b* donnent 400 mg de **14***b* (80%).

*Dioxolanne **21***b*: 200 mg de diol **20***b* donnent 200 mg de **21***b* (80%).

*Dioxolanne **14***a*: à partir de 300 mg du mélange des diols **18***a* + **13***a*, (1:1, voir partie théorique), on distille 180 mg (90%) de dioxolanne **14***a*. Le résidu de la distillation est riche en **18***a*.

Caractéristiques des produits obtenus

Acétates d'énols

*De la cis-méthyl-3 nopinone **2***b*: p.é. 45 °C/0.05 mm Hg; $[\alpha]_D$ −21.5°; i.r.: 1760 (C=O) et 1700 cm⁻¹ (C=C); r.m.n.: 0.90 (CH_3-9), 1.30 (CH_3-8), 1.44 (d, J = 9 Hz, H-7α), 1.56 (CH_3—C=), 2.09 (CH_3—CO); spectre de masse (160): 194 (5), 152 (50), 137 (20), 119 (10), 109 (100), 108 (25), 97 (30), 83 (25), 55 (15), 43 (45).

Aril Azines. II.[1] Hydrogenation of *p*-Tolil Monoazine

PETER YATES AND E. M. LEVI

Lash Miller Chemical Laboratories, University of Toronto, Toronto, Ontario M5S 1A1

Received September 23, 1974

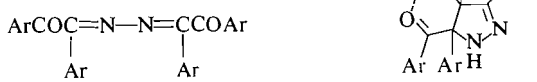
PETER YATES and E. M. LEVI. Can. J. Chem. **53**, 748 (1975).

Hydrogenation of *p*-tolil monoazine (**1***b*) over palladium-on-charcoal gives as the major product 4,5-dihydro-5-(*p*-toluyl)-3,4,5-tri-(*p*-tolyl)-1*H*-pyrazol-4-ol (**2***b*), which has previously been obtained by treatment of **1***b* with sodium methoxide. Several minor products are formed, which include *p*-tolualdehyde, *p*-toluic acid, and *p*-toluamide, *p*-tolunitrile, *p*-tolualazine, and 3,4,5-tri-(*p*-tolyl)-4*H*-pyrazol-4-ol (**9**). The structure of the last compound, which is also formed on reduction of **1***b* with sodium borohydride, was established by its independent synthesis from 1,2,3-tri-(*p*-tolyl)-1,3-propanedione by oxidation with lead tetraacetate followed by treatment with hydrazine. It is suggested that **2***b* arises via reduction of a C=N bond of **1***b* and aldol ring closure. The minor hydrogenation products are of interest in that their formation involves C—C hydrogenolysis; it is suggested that this is initiated by addition of a hydrogen atom to a carbonyl carbon atom of **1***b*.

PETER YATES et E. M. LEVI. Can. J. Chem. **53**, 748 (1975).

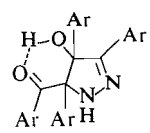
L'hydrogénation de la *p*-tolil monoazine (**1***b*) sur du palladium-sur-charbon conduit comme produit majeur au dihydro-4,5 *p*-toluyl-5 tri-*p*-tolyl-3,4,5 1*H*-pyrazolol-4 (**2***b*) qui avait été obtenu précédemment en traitant **1***b* par le méthylate de sodium. Plusieurs produits mineurs sont formés parmi lesquels on remarque la *p*-tolualdéhyde, l'acide *p*-toluique, la *p*-toluamide, la *p*-tolunitrile, la *p*-tolualazine et le tri-*p*-tolyl-3,4,5 4*H*-pyrazolol-4 (**9**). On a établi la structure du dernier composé, qui se forme aussi lors de la réduction de **1***b* par le borohydrure de sodium, par une synthèse non ambigue impliquant l'oxydation de la tri-*p*-tolyl-1,2,3 propanedione-1,3 par du tétraacétate de plomb et le traitement du produit obtenu avec l'hydrazine. On suggère que **2***b* provient de **1***b* par la réduction du lien C=N suivi d'une cyclisation aldolique. Les produits mineurs d'hydrogénation présentent de l'intérêt dû au fait qu'ils proviennent d'une hydrogénolyse d'un lien C—C; on suggère que cette réaction débute par l'addition d'un atome d'hydrogène sur l'atome de carbone du carbonyle de la molécule **1***b*. [Traduit par le journal]

Prolonged treatment of aril monoazines (**1**) with sodium methoxide has been shown to give phototropic products of type **2** (1). These products, which are dihydro derivatives of the azines, are formed in low yield (<25%). In order to obtain increased yields of these products we have investigated alternative methods of reduction of the azines. In preliminary experimentation it was found that benzil monoazine (**1***a*) is reduced to **2***a* by hydrogenation over palladium-on-charcoal.[2] We now report on an investigation of the hydrogenation of *p*-tolil monoazine (**1***b*).



1

a Ar = C_6H_5
b Ar = *p*-$CH_3C_6H_4$



2

a Ar = C_6H_5
b Ar = *p*-$CH_3C_6H_4$

Hydrogenation of **1***b* in benzene over 10% palladium-on-charcoal proceeded slowly with the uptake of *ca.* 4 molar-equiv. of hydrogen in *ca.* 30 h and gave as the major product the dihydro compound **2***b* in 56% yield.[3] This method is thus considerably more efficient and convenient than that involving treatment with sodium methoxide for the conversion of **1***b* to **2***b*.[4]

The hydrogenation of **2***b* also formed a number of other products in low yield. Several of these were compounds of known structure and were identified by direct comparison with authentic samples as *p*-tolualdehyde (**3**), *p*-toluic acid (**4**), *p*-toluamide (**5**), *p*-tolunitrile (**6**), and *p*-tolualazine (**7**). A crystalline product, m.p. 258–259°, isolated in too low a yield for full characterization is tentatively assigned structure

[1]For part I see ref. 1.

[2]We thank Dr. J. A. Weisbach for carrying out these experiments.

[3]The yield of this product was reduced if the hydrogenation was carried out for shorter periods.

[4]It has subsequently been found that the reduction of **1***b*–**2***b* is best effected by sodium in tetrahydrofuran (J. G. Smith and E. M. Levi, unpublished results).

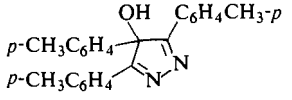
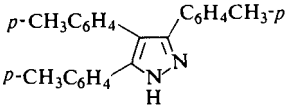
8

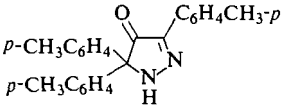
A pale green crystalline product, $C_{24}H_{22}N_2O$, isolated in 4% yield, is of particular interest since it is also formed by treatment of the pyrazoline **2***b* with sodium borohydride. Its i.r. spectrum shows a band at *ca.* 3.0 μ, but no band in the carbonyl-stretching region, and its u.v. spectrum has a maximum at 342 nm (log ε 4.35). Structure **9** is assigned to this compound on the basis of these data and the observation that it is reduced by zinc and acetic acid to 3,4,5-tri-(p-tolyl)pyrazole (**10**), a product that is formed in addition to **9** in the reduction of **2***b* with sodium borohydride. Treatment of **9** with hot methanolic hydrochloric acid gave an isomeric yellow crystalline product in high yield that is considered to be the pyrazolone **11** formed by migration of a p-tolyl group.



9



10



11

The structural assignment **9** was confirmed by an independent synthesis of this compound by the route shown in Scheme 1. Treatment of deoxy-p-toluoin (**12**) with sodium amide followed by p-toluyl chloride gave the 1,3-diketone **13** as the major product, accompanied by the *O*-acylation product **14** and the diacylation product **15**. Oxidation of **13** with lead tetraacetate in acetic acid gave the acetoxylation product **16**, which on treatment with hydrazine gave compounds **9** and **10**; the latter could arise via reduction of the former by hydrazine.

The catalytic hydrogenation of the azines of monocarbonyl compounds has been investigated extensively previously (2). Depending on the reaction conditions, reaction may involve saturation of one or both of the C=N bonds and hydrogenolysis of the N—N bond. In the present case the formation of the major product can be interpreted as proceeding via saturation of one of the C=N bonds of **1***b* to give **17** followed by an intramolecular aldol reaction to give **2***b* (Scheme 2, Ar = p-$CH_3C_6H_4$).

The minor products isolated from the hydrogenation reaction mixture are of interest in that their formation involves hydrogenolysis of one or more C—C single bonds. The formation of several of them can be rationalized in terms of a common radicaloid intermediate **18**, as shown in Scheme 3 (Ar = p-$CH_3C_6H_4$).[5] Others may arise via secondary reactions during work-up; *e.g.*, p-toluic acid (**4**) by air-oxidation of p-tolualdehyde and p-toluamide (**5**) by hydrolysis of p-tolunitrile.

The postulated hydrogenolysis of **1***b* to give the aldehyde **3** and the azines **19** and **7** finds some analogy in the C—C hydrogenolysis of β-diketones over Raney nickel to give aldehydes and ketones (3).

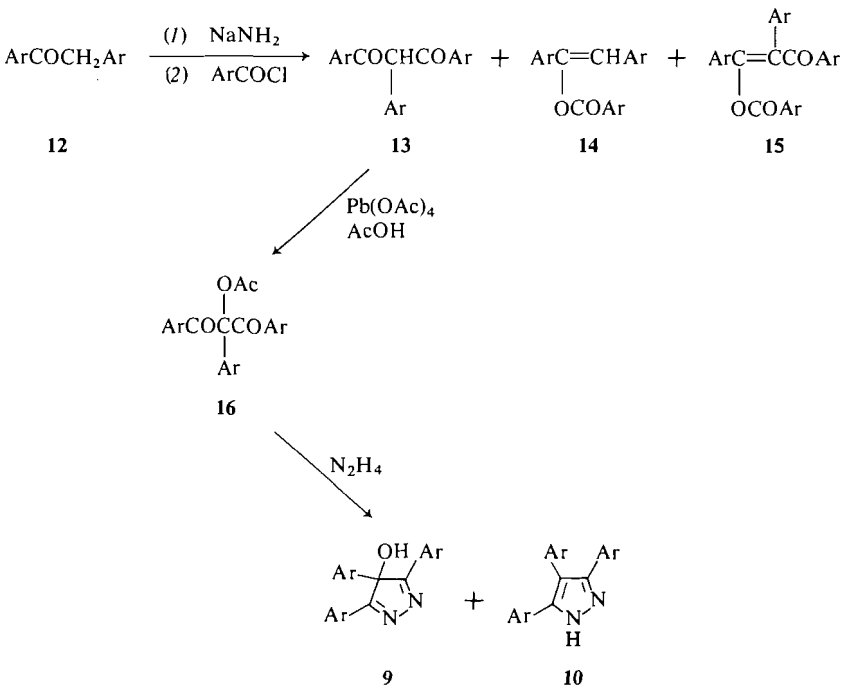
Experimental

Hydrogenation of p-Tolil Monoazine (1b)

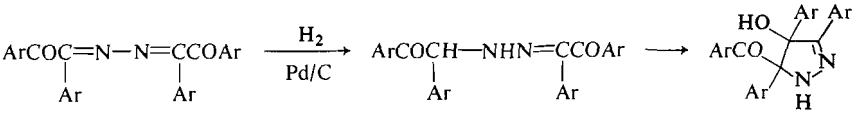
A solution of p-tolil monoazine (2.15 g) in hot dry benzene (thiophene free; 175 ml) was added to 10% palladium-on-charcoal (1.8 g) suspended in benzene (thiophene free; 20–40 ml) in an aluminum-foil-wrapped hydrogenation flask. Hydrogenation at atmospheric pressure led to the uptake of 500 ml (4.5 molar-equiv.) of hydrogen, which was complete in 34 h. The catalyst was removed at night under subdued light by filtration through sintered glass and the benzene solution was evaporated to give a red oil. This was taken up in ether (20 ml) and the solution was concentrated at room temperature to *ca.* 10 ml, giving crystalline compound **2***b*, m.p. 173–175° (dec.) (1.20 g; 56%), which was shown by i.r. and ^{1}H n.m.r. spectral comparison to be identical with the product obtained by treatment of **1***b* with sodium methoxide (1).

The residues (7.28 g) from four such hydrogenations of p-tolil monoazine (14.25 g) over 10% palladium-on-charcoal (12.41 g) with uptake of 3150 ml of hydrogen

[5]The radical species involved in this scheme are not considered to be free radicals but are viewed as remaining associated with the catalyst.



SCHEME 1



SCHEME 2

were combined after crystallization of compound **2b** (7.27 g) and chromatographed on silica gel (540 g).

Elution with benzene – petroleum ether mixtures gave fractions containing less than 30 mg of material. Elution with benzene gave a semisolid fraction (30 mg), whose i.r. spectrum, with a band at 4.47 μ, showed it to contain *p*-tolunitrile.

Elution with ether–benzene (0.5:99.5) gave *p*-tolil monoazine (330 mg), followed by fractions containing *p*-tolil monoazine and *p*-tolualdehyde (940 mg), identified by i.r. spectroscopy. The formation of *p*-tolualdehyde was confirmed by examination of a fresh hydrogenation residue by v.p.c. and comparison of this chromatogram with a chromatogram of a mixture of this residue with authentic *p*-tolualdehyde. Further elution with the above solvent mixture gave *p*-tolil monoazine (160 mg) and fractions containing *p*-tolil monoazine and *p*-tolualazine (110 mg).

Elution with ether–benzene (1:99 and 2:98) gave an oil (470 mg) from which *p*-tolualazine (220 mg), m.p. 154–155.5° (lit. (4) m.p. 157–158°), crystallized from ethanol, after filtration of some *p*-tolil monoazine. It had λ_{max} ($CHCl_3$) 6.17, 6.23 μ; δ ($CDCl_3$) 2.35 (s, 6H), 7.20 (d, J = 8 Hz, 4H), 7.72 (d, J = 8 Hz, 4H), 8.62 (s, 2H). A mixture m.p. with an authentic sample, m.p. 157–158°, was 157–158°; the spectra of the two samples were indistinguishable.

Elution with ether–benzene (1:24 and 2:23) gave an oil (720 mg), which crystallized from ethanol–benzene to give a white solid (57 mg), m.p. 258–259°; λ_{max} ($CHCl_3$) 2.92, 5.85, 6.03 μ; *m/e*(%) 357(1), 341(2), 238(54), 221(36), 119(100). This product is tentatively assigned structure **8**.

Elution with ether–benzene (3:7 and 1:1) gave a semi-solid mixture (1.52 g), which was triturated with benzene to give a greenish tinged solid (470 mg), m.p. 206–208° (dec.). Recrystallization from methanol gave material, m.p. 209–211° (dec.), which was shown to be 3,4,5-*tri*-(*p*-tolyl)-4*H*-pyrazol-4-ol (**9**) (*vide infra*) by mixture m.p. and i.r. spectral comparison. Extraction of the benzene solution with aqueous sodium bicarbonate followed by acidification of the aqueous solution and extraction gave *p*-toluic acid (510 mg).

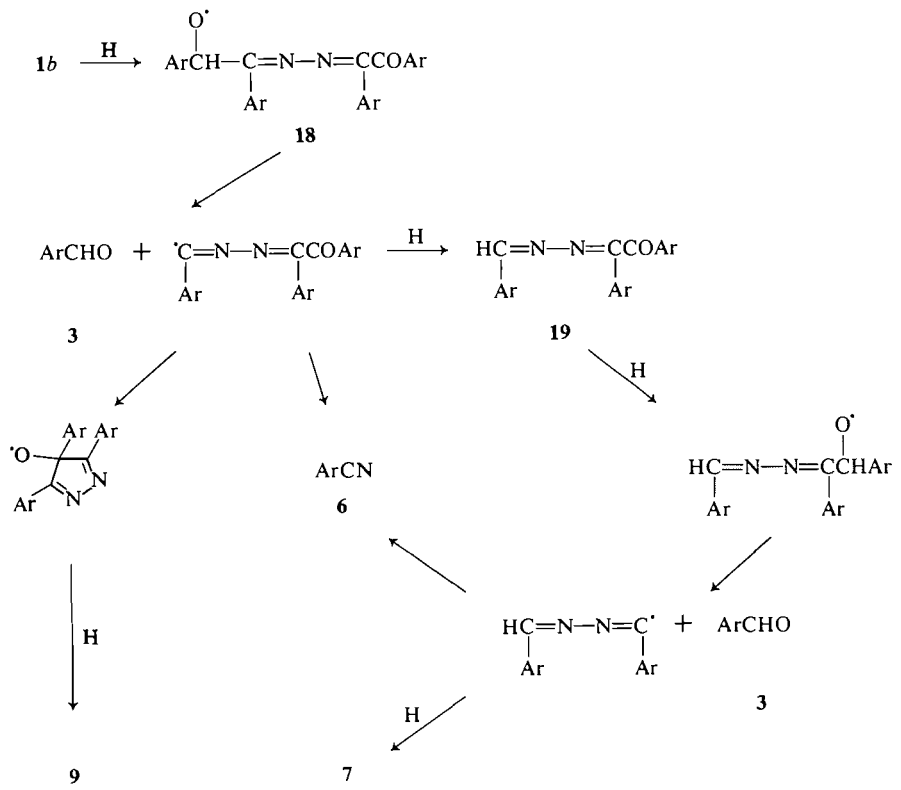

SCHEME 3

Elution with methanol–chloroform mixtures gave a white crystalline solid, m.p. 157–158°; λ_{max} ($CHCl_3$) 2.87, 2.98, 6.02 μ; *m/e*(%) 135(92), 119(100). This was identified as *p*-toluamide by mixture m.p. 158–160° with an authentic sample, m.p. 158.5–160°.

Reduction of **9** *with Zinc in Acetic Acid*

Compound **9** (20 mg) and zinc dust (148 mg) in acetic acid (30 ml) were heated under reflux with stirring until the original yellow color faded (3 h). The solution was filtered from unreacted zinc dust and the solvent was evaporated. The residue was taken up in hot methanol (*ca.* 3 ml), aqueous 10% sodium bicarbonate (4 drops) was added, and the solution was chilled to −20°. The crystalline product, m.p. 244–248°, had an i.r. spectrum indistinguishable from that of 3,4,5-tri-(*p*-tolyl)pyrazole (**10**) (1).

Acid-catalyzed Rearrangement of **9**

Compound **9** (104 mg) was added to a mixture of concentrated hydrochloric acid (3 ml) and methanol (50 ml) to give a dark yellow solution. This was heated under reflux for 1 day, cooled, and evaporated. The residue was taken up in chloroform and chromatographed on a silica gel t.l.c. plate (20 × 20 cm, 1 mm) developed with carbon tetrachloride. The major, deep yellow band (of seven) was extracted from the silica gel with chloroform. The residue obtained on evaporation of the extract was crystallized twice from aqueous methanol to give yellow needles, m.p. 151.5–153° (dec.); λ_{max} ($CHCl_3$) 2.98, 5.78, 5.87 μ; λ_{max} (EtOH) 250 nm (sh, log ε 4.10), 266 nm (log ε 4.16), 362 nm (sh, log ε 3.62), 393 nm (log ε 3.72); δ ($CDCl_3$) 2.27 (s, 6H), 2.33 (s, 3H), 7.0–7.2 (m, 10H), 7.45 (s, 1H, absent after D_2O treatment), 8.01 (d, J = 8 Hz, 2H); *m/e*(%) 354(3), 309(1), 219(50), 194(26), 140(62), 97(100).

Anal. Calcd. for $C_{24}H_{22}N_2O$: C, 81.32; H, 6.26; N, 7.90. Found C, 81.29; H, 6.55; N, 7.95.

*1,2,3-Tri-(p-tolyl)-1,3-propanedione (***13***)*

A crystal of ferric nitrate nonahydrate and sodium (4.4 g) were added to liquid ammonia (*ca.* 100 ml) in a three-necked flask, fitted with a Dry-Ice condenser, a double surface ether condenser, and a gas inlet tube. The solution was stirred for 30 min. Dry ether (100 ml) was added after removal of the Dry-Ice condenser and the flask was allowed to come to room temperature, the excess ammonia being removed by a stream of dry nitrogen. The ethereal suspension was heated under reflux for 5 min. A suspension of deoxy-*p*-toluoin (11.2 g) in dry ether (250 ml) was added and the mixture was heated under reflux for 6 h, cooled, and forced by nitrogen pressure into a pressure-equalized dropping funnel, whence it was added to a rapidly stirred solution of *p*-toluyl chloride (7.78 g) in dry ether (50 ml). The reaction mixture was stirred overnight and then treated with dilute hydrochloric acid (*ca.* 5%; 200 ml). The ethereal solution

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

was separated and the aqueous solution was extracted with fresh ether (200 ml). The ethereal solution was dried and evaporated. The residue was crystallized from absolute ethanol (500 ml) to give a white crystalline solid, m.p. 170–190°. This was treated with hot absolute ethanol to give a solution which upon cooling deposited a white crystalline solid (2.16 g), m.p. 168–170°. The residue (1.54 g) had m.p. 189–194°.

The solid, m.p. 168–170°, was recrystallized twice from absolute ethanol to give 1-(*p*-toluyloxy)-1,2-di-(*p*-tolyl)ethylene (**14**), m.p. 171–172°; λ_{max} ($CHCl_3$) 5.79, 6.06 μ (w); δ ($CDCl_3$) 2.24 (s, 3H), 2.30 (s, 3H), 2.40 (s, 3H), 6.72 (s, 1H), 7.0–7.6 (m, 10H), 8.12 (d, J = 8 Hz, 2H); *m/e*(%) 342(2), 341(7), 119(100).

Anal. Calcd. for $C_{24}H_{22}O_2$: C, 84.17; H, 6.47. Found: C, 84.08; H, 6.59.

The solid, m.p. 189–194°, was twice recrystallized from absolute ethanol to give 3-(*p*-toluyloxy)-1,2,3-tri-(*p*-tolyl)-2-propen-1-one (**15**), m.p. 194–195°; λ_{max} ($CHCl_3$) 5.79, 6.02 μ; δ ($CDCl_3$) 2.24 (s, 6H), 2.28 (s, 6H), 6.9–7.4 (m, 12H), 7.68 (d, J = 8 Hz, 2H), 7.97 (d, J = 8 Hz, 2H); *m/e*(%) 460(9), 341(1), 119(100).

Anal. Calcd. for $C_{32}H_{28}O_3$: C, 83.45; H, 6.13. Found: C, 83.36; H, 6.25.

The original ethanolic mother liquor was concentrated to 75 ml and cooled. A white crystalline product (7.38 g), m.p. 130–145°, was isolated. Seven crystallizations from ethanol gave 1,2,3-tri-(*p*-tolyl)-1,3-propanedione (**13**), m.p. 147–148°; λ_{max} ($CHCl_3$) 5.90, 5.99 μ; δ ($CDCl_3$) 2.27 (s, 3H), 2.32 (s, 6H), 6.54 (s, 1H), 7.0–7.6 (m, 8H), 7.90 (d, J = 8 Hz, 4H); *m/e*(%) 342(18), 119(100).

Anal. Calcd. for $C_{24}H_{22}O_2$: C, 84.17; H, 6.47. Found: C, 84.07; H, 6.32.

3,4,5-Tri-(p-tolyl)-4H-pyrazol-4-ol (9)

1,2,3-Tri-(*p*-tolyl)-1,3-propanedione (**13**; 2.06 g) and lead tetraacetate (9.5 g) were stirred in glacial acetic acid (80 ml) for 6 days. The reaction mixture was poured into water. The solid that precipitated was separated by filtration through sintered glass and washed well with water. The filter cake was extracted with chloroform and these extracts were dried, filtered, and evaporated. The product, a yellow oil (2.49 g), was taken up in benzene and the solution was chromatographed on silica gel (100 g). Elution with ether–benzene (1:99 and 3:97) gave 2-acetoxy-1,2,3-tri-(*p*-tolyl)-1,3-propanedione (**16**) as a yellow oil (1.24 g); λ_{max} (CCl_4) 5.76, 5.98, 8.1–8.2 μ; δ (CCl_4) 1.92 (s, 3H), 2.22 (s, 9H), 6.85–7.15 (m, 6H), 7.33 (d, J = 8 Hz, 2H), 7.63 (d, J = 8 Hz, 4H).

Compound **16** (830 mg), without further purification, and hydrazine (95+%; 300 mg) were stirred in benzene solution (50 ml), containing acetic acid (2 drops) at room temperature. After 3 h crystals appeared in the solution; stirring was continued for 3 days. The crystalline product (230 mg) was filtered; m.p. 198–200° (dec.). Two recrystallizations from methanol gave 3,4,5-tri-(*p*-tolyl)-4*H*-pyrazol-4-ol (**9**), m.p. 211.5–212° (dec.); λ_{max} (KBr) 3.0, 6.22, 6.62 μ; λ_{max} (EtOH) 342 nm (log ε 4.35); *m/e*(%) 354(13), 338(9), 326(4), 237(17), 194(14), 119(25), 118(100), 91(19).

Anal. Calcd. for $C_{24}H_{22}N_2O$: C, 81.52; H, 6.26; N, 7.90. Found: C, 81.05; H, 6.27; N, 8.30.

Evaporation of the benzene filtrate and crystallization of the residue from methanol gave 3,4,5-tri-(*p*-tolyl)pyrazole (**10**) (50 mg), m.p. 232–237°. Two recrystallizations from methanol gave material, m.p. 252–252.5°; mixture m.p. 252.5–253° with an authentic sample, m.p. 253.5–254° (1).

Reduction of 2b with Sodium Borohydride

Compound **2***b* (1.00 g) and sodium borohydride (196 mg) were stirred in tetrahydrofuran–water (9:1; 100 ml) for 12 h. The aqueous layer was separated and the organic layer was dried. Acetyl chloride (2 ml) was added, and the solution was stirred for a few minutes and then poured into water. The aqueous layer was separated and extracted with ether. The ethereal and tetrahydrofuran solutions were combined, dried, and evaporated to give a yellow oil (834 mg), which was taken up in benzene and chromatographed on silica gel (40 g).

Elution with benzene gave 3,4,5-tri-(*p*-tolyl)-4H-pyrazol-4-ol (**9**) (110 mg) as a green tinged solid; crystallization from methanol gave needles, m.p. 209–211° (dec.); mixture m.p. 211–212° (dec.) with an authentic sample, m.p. 211.5–212° (dec.) (*vide supra*).

Elution with ether–benzene (1:4) gave 3,4,5-tri-(*p*-tolyl)pyrazole (**10**) (50 mg), m.p. 243–249°, identified by i.r. spectral comparison.

We thank Mr. G. Koves for technical assistance and the National Research Council of Canada for financial support.

Crystals of 11*H*,22*H*-10,10,21,21-tetramethyl-3,5,14,16-tetra(*N*,*N*-dimethyl-2-aminoethyl)-1,12-dioxonia-3,5,7,10,14,16,18,21-octaazonia-2,4,6,11,13,15,17,22-octagallanata-nonacyclo-[13.7.0.0^{2,7}.0^{3,22}.0^{4,12}.0^{7,11}.0^{11,14}.0^{13,18}.0^{18,22}]docosane are triclinic, $a = 13.358(1)$, $b = 9.300(1)$, $c = 9.545(1)$ Å, $\alpha = 92.16(2)$, $\beta = 107.49(1)$, $\gamma = 89.23(2)°$, $Z = 1$, space group $P\bar{1}$. The structure was solved by Patterson and Fourier syntheses and was refined by full-matrix least-squares procedures to a final R of 0.038 for 3393 reflections with $I \geq 4\sigma(I)$. The bond lengths involving nonhydrogen atoms have been corrected for thermal motion. The molecular structure features a novel Ga, O, N cage structure which includes the first crystallographic examples of four-membered Ga_2NO and six-membered Ga_3N_2O rings. Three of the four crystallographically independent gallium atoms are tetrahedrally four-coordinate with bond lengths: Ga—O, 1.869 and 1.879(2), Ga—N, 1.945–2.001(3), and Ga—H, 1.40–1.52(4–5) Å. The remaining gallium atom is five-coordinate with distorted trigonal bipyramidal geometry (Ga—O(ax), 1.960(3), Ga—N(ax), 2.779(3), Ga—N(eq), 1.949 and 1.999(3), and Ga—H(eq), 1.49(5) Å). Other bond lengths in the molecule are: N—C, 1.449–1.493(4–10), C—C, 1.486–1.528(6–7), N—H, 0.85(5), and mean C—H, 1.03 Å. The errors quoted above are those arising from the least-squares analysis and do not reflect uncertainties introduced by the thermal analysis.

Les cristaux du 11*H*,22*H* tétraméthyl-10,10,21,21 tétra(*N*,*N*-diméthyl-amino-2 éthyle)-3,5,14,16 dioxonia-1,12 octaazonia-3,5,7,10,14,16,18,21 octagallanata-2,4,6,11,13,15,17,22 nonacyclo[13.7.0.0^{2,7}.0^{3,22}.0^{4,12}.0^{7,11}.0^{11,14}.0^{13,18}.0^{18,22}] docosane sont tricliniques, $a = 13.358(1)$, $b = 9.300(1)$, $c = 9.545(1)$ Å, $\alpha = 92.16(2)$, $\beta = 107.49(1)$, $\gamma = 89.23(2)°$, $Z = 1$, groupe d'espace $P\bar{1}$. On a résolu la structure par une synthèse de Patterson et Fourier et on l'a raffinée par la méthode des moindres carrés (matrice complète) jusqu'à une valeur finale R de 0.038 pour 3393 réflections avec $I \geq 4\sigma(I)$. On a corrigé les longueurs de liaison impliquant les atomes qui ne sont pas des hydrogènes pour les mouvements thermiques. La structure moléculaire implique une nouvelle structure en cage du Ga, O, N qui implique les premiers exemples cristallographiques de cycles à quatre membres du Ga_2NO et à six membres du Ga_3N_2O. Trois des quatres atomes de gallium, qui sont cristallographiquement indépendants, sont coordonnés d'une façon tétraédrique avec des longueurs de liaison de: Ga—O, 1.869 et 1.879(2), Ga—N, 1.945–2.001(3) et Ga—H, 1.40–1.52(4–5) Å. L'autre atome de gallium est penta-coordonné avec une géométrie bipyramide trigonale déformée (Ga—O(ax), 1.960(3), Ga—N(ax), 2.779(3), Ga—N(eq), 1.949 et 1.999(3) et Ga—H(eq), 1.49(5) Å). Les autres longueurs de liaison dans la molécule sont: N—C, 1.449–1.493(4–10), C—C, 1.486–1.528(6–7), N—H, 0.85(5), et la valeur moyenne du C—H est de 1.03 Å. Les erreurs mentionnées plus haut sont celles qui dérivent de l'analyse par la méthode de moindres carrés et ne sont pas un reflet des incertitudes introduits par l'analyse thermique. [Traduit par le journal]

Introduction

Two previous papers (1, 2) have presented crystallographic examples of five-coordinate gallium compounds which involve fused ring systems. In an attempt to extend our studies in this area the reaction of *N*,*N*-dimethylethylenediamine with trimethylamine-gallane has been investigated. The reaction predicted on the basis of previous results (3) was

$$Me_2NCH_2CH_2NH_2 + Me_3NGaH_3 \rightarrow Me_2NCH_2CH_2NHGaH_2 + Me_3N + H_2$$

It was then expected that the monomeric unit, $Me_2NCH_2CH_2NHGaH_2$, would either trimerize, $[—HN(CH_2CH_2NMe_2)GaH_2—]_3$, with non-involvement of the "Me_2N" groups, or that, more probably, these would become involved in the oligomerization process to yield another example of five-coordinate gallium atoms.

The novel Ga, O, N cage structure which is reported here was unexpected, and chance has played a large part in its discovery. The structure does provide a further crystallographic example of five-coordinate gallium atoms, but, more

importantly, presents the first example of an extensive cage structure involving Ga, N, and O atoms.

Experimental

The present compound was deposited as colorless crystals from a benzene solution of the products from the reaction

$$Me_2NCH_2CH_2NH_2 + Me_3NGaH_3 \rightarrow \text{products}$$

The crystals deposited from the solution over a period of years and it is presumed that the oxygen atoms incorporated into the cage structure entered the reaction sphere as water molecules, via the poor seal of the n.m.r. tube, and that these reacted with the initial product of the reaction to eliminate more hydrogen and incorporate the oxygen atoms into the structure. The small amount of crystalline material available did not enable chemical analyses to be obtained. The air-sensitive sample was positioned in a Lindemann glass capillary tube under nitrogen atmosphere and the tube was then flame-sealed. The instability of the compound precluded an experimental determination of the density.

The crystal chosen for study was mounted with b^* parallel to the goniostat axis and had dimensions of *ca.* 0.3 × 0.4 × 0.3 mm. Unit-cell and space group data were obtained from film and diffractometer measurements. The unit-cell parameters were refined by a least-squares treatment of $\sin^2\theta$ values for 18 reflections measured on a diffractometer with CuK_α radiation. Crystal data are:

$C_{24}H_{72}Ga_8N_{12}O_2$ f.w. = 1118.7

Triclinic, $a = 13.358(1)$, $b = 9.300(1)$, $c = 9.545(1)$ Å, $\alpha = 92.16(2)$, $\beta = 107.49(1)$, $\gamma = 89.23(2)°$, $V = 1130.1(3)$ Å^3, $Z = 1$, $\rho_c = 1.644(1)$ g cm^{-3}, $F(000) = 564$ (23 °C, CuK_α, $\lambda = 1.5418$ Å, $\mu = 60$ cm^{-1}). Space group $P\bar{1}$ (C_i^1, No. 2) from structure analysis. Intensities were measured on a Datex-automated General Electric XRD 6 diffractometer, with a scintillation counter, CuK_α (nickel filter and pulse height analyzer), and a θ–2θ scan at 2° min^{-1} over a range of $(1.80 + 0.86 \tan\theta)$ degrees in 2θ, with 10 s background counts being measured at each end of the scan. Data were measured to $2\theta = 145°$ (minimum interplanar spacing 0.81 Å). The intensity of the check reflection, measured every 40 reflections throughout the data collection, decreased slowly to a final value which was 0.87 times the initial value. Lorentz and polarization corrections and check reflection scaling were applied, and the structure amplitudes were derived. No absorption correction was made due to irregularity of the crystal surface. Of the 4474 independent reflections measured, 1019 had intensities less than $4\sigma(I)$ above background where $\sigma^2(I) = S + B + (0.06S)^2$ with S = scan count and B = time averaged background count. These reflections were given zero weight in the refinement but were included in the structure factor calculations. The criterion of 4σ, rather than $3\sigma(I)$, was used to limit the number of reflections to be included in the refinement and thereby reduce the computing costs. (There are 9.6 reflections included in the refinement for each variable for the 4σ cutoff.)

Structure Analysis

The positions of the gallium atoms were determined from the three-dimensional Patterson function, which indicated four instead of the three heavy atoms which were initially anticipated on the basis of two [—NH(CH_2-CH_2NMe_2)GaH_2—]$_3$ trimers per unit-cell. Two cycles of full-matrix least-squares refinement of the positional and isotropic thermal parameters of the gallium atoms gave $R = 0.24$. A difference map then revealed the positions of the C, N, and O atoms which were refined isotropically and the gallium atoms anisotropically for two cycles, reducing R to 0.082. The oxygen atom, which had been refined as a nitrogen atom up to this point, was characterized by an anomalously low isotropic temperature factor and by the Ga—O bond lengths which were too short to be Ga—N interactions. The nonhydrogen atoms were then refined anisotropically for two cycles giving $R = 0.070$. A difference map then gave positions for 32 of the 36 hydrogen atoms (those not located were associated with the C(11) and C(12) methyl groups). The remaining hydrogen atom positions were calculated and separate cycles of refinement of the nonhydrogen and then the hydrogen atoms reduced R to 0.043. The entire structure, including the hydrogen atoms with isotropic temperature factors (353 variables) was refined for three cycles giving a final R of 0.038 for 3393 reflections with $I \geq 4\sigma(I)$ (62 reflections which had $|F_o - F_c| > 3\sigma(F)$ were removed from the data set in the final stages of refinement due to suspected errors arising from absorption, instrument malfunction, and extinction).

The least-squares refinement was based on the minimization of $\Sigma w(F_o - F_c)^2$. The scattering factors of ref. 4 were used for the nonhydrogen atoms and those of ref. 5 for the hydrogen atoms. Anomalous scattering factors from ref. 6 were used for the nonhydrogen atoms. The anisotropic thermal parameters employed in the refinement are U_{ij} in the expression

$$f = f^0 \exp[-2\pi^2(U_{11}h^2a^{*2} + U_{22}k^2b^{*2} + U_{33}l^2c^{*2} + 2U_{12}hka^*b^* + 2U_{13}hla^*c^* + 2U_{23}klb^*c^*)]$$

where f^0 is the tabulated scattering factor and f is that corrected for thermal motion. The weighting scheme $w = 1/\sigma^2(F)$ where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$ gave uniform average values of $w(F_o - F_c)^2$ over ranges of $|F_o|$ and was employed in the final stages of refinement. The mean error in an observation of unit weight was 1.05. In the latter stages of refinement an extinction parameter, e (where $F_c = F_c^o/(1 + e \times I_u)$ with I_u the uncorrected intensity), was refined, the final value being 9.74×10^{-7}.

On the final cycle of refinement the mean parameter shift was 0.22σ; the largest shifts (up to 3σ) were associated with the C(11) and C(12) methyl group hydrogen atoms and presumably result from the large degree of thermal motion experienced by these groups. A final difference map showed maximum fluctuations of ±0.9 e Å^{-3} in the vicinity of the gallium atoms and ±0.2 e Å^{-3} elsewhere. The final positional and thermal parameters appear in Tables 1 and 2 respectively. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[1]

[1]The structure factor table is available, at a nominal charge, from the Depository of Unpublished Data, National Science Library, National Research Council of Canada, Ottawa, Canada K1A 0S2.

Thermal Motion and Correction of Molecular Geometry

The ellipsoids of thermal motion for the non-hydrogen atoms are shown in Fig. 1. The thermal motion has been analyzed in terms of the rigid-body modes of translation (**T**), libration (**L**), and screw (**S**) motion (7) using the computer program MGTLS. The r.m.s. standard deviation in the temperature factors U_{ij} is 0.0031 Å^2 indicating that the molecule as a whole (r.m.s. ΔU_{ij} = 0.0106 Å^2) is not a good rigid-body. The thermal motion of the 16 inner cage atoms (8Ga, 6N, 2O) is well described by the rigid-body thermal parameters given in Table 3 (r.m.s. ΔU_{ij} = 0.0025 Å^2). The **S** tensor is constrained to be identically equal to zero by the crystallographic center of symmetry. The indicated modes of motion are physically reasonable; the largest principal axis of libration being nearly coincident with the long axis of the molecule.

The appropriate bond distances and angles have been corrected for libration (8, 9), using shape parameters q^2 of 0.08 for all atoms involved. The corrected bond distances appear in Table 4. No bond angles changed by more than 0.04° so the corrected bond angles are not reported. Riding motion corrections based on the ΔU_{ij} (10, 11) have been applied to bonds outside the 16-atom molecular core.

Results and Discussion

Bond angles in the compound are given in Table 5 and intraannular dihedral angles in the polycyclic cage are listed in Table 6. Important intramolecular nonbonded contacts and details of the hydrogen-bonding scheme are given in Table 7. Ga—O, Ga—N, and Ga—H bond distances for several different structures are compared in Table 8.

A number of crystallographic examples of pentacoordinate gallium have been reported recently (1, 2, 12, 13). The present X-ray analysis provides an additional crystallographic example of this type of coordination and further information on Ga—H bond lengths. More importantly, the structure determination is the first one reported for this type of cage structure involving Ga, O, and N atoms. A similar, but less extensive, cage structure involving Al and N atoms has been recently reported (14) for the heptameric compound $[MeNAlMe]_7$, the structure being made up from four-membered, $(AlN)_2$, and six-membered, $(AlN)_3$, rings. The present framework

structure of Ga, O, and N atoms (see Fig. 1) is comprised of 8 six-membered rings with distorted "boat" conformations (six Ga_3N_2O rings and two Ga_3N_3 rings) and 2 four-membered Ga_2NO rings. In addition there are 2 five-membered GaNCCN rings in the centrosymmetric structure.

To produce the cage structure a total of 14 hydrogen molecules have been eliminated. Thus of the 24 hydrogen atoms originally associated with the 8 gallium atoms, 14 have been removed. This number is matched by the 10 hydrogen atoms lost from the 6 $Me_2NCH_2CH_2NH_2$ ligands plus the 4 hydrogen atoms lost from the two water molecules deemed to have entered the reaction sphere to provide the pair of oxygen atoms incorporated in the cage.

Each of the four crystallographically independent gallium atoms in the structure is unique. The bridgehead atom Ga(3) is five-coordinate with distorted trigonal bipyramidal geometry and is part of 3 six-membered rings, a five-membered ring, and a four-membered ring. The three remaining gallium atoms are each tetrahedrally four-coordinate. Two of these atoms, Ga(1) and Ga(2), are also bridgehead atoms, each coordinated to two nitrogen atoms, an oxygen atom, and a hydrogen atom. The difference

between Ga(1) and Ga(2) arises from the fact that Ga(2) is contained in three six-membered rings while Ga(1) is part of two six-membered rings and a four-membered ring. The other gallium atom, Ga(4), does not occupy a bridgehead position in the polycyclic cage and is coordinated to two nitrogen atoms and two hydrogen atoms.

The tetrahedral Ga—O distances, Ga(1)—O′, 1.879(2) and Ga(2)—O, 1.869(2) Å, are significantly different. This small but significant difference is not surprising since one of these bonds, Ga—O′, is part of a four-membered ring while the other is in a six-membered ring. These bond lengths are considerably shorter than the values of 1.94–1.99 Å in $[Me_2GaOH]_4$ (15). It should be noted that in $[Me_2GaOH]_4$ there are Ga—OH—Ga bridges while in the present structure we are dealing with a Ga—O(Ga)—Ga system. The mean bond angle about the three-coordinate O atom, 117.1°, indicates that there may be some d_π–p_π bonding taking place in this structure. A similar interaction appears to take place in the β-Ga_2O_3 structure (16), which contains two trigonally coordinated O atoms each bonded to three Ga atoms with mean valence angles of 116 and 119° and Ga—O distances ranging from 1.80–1.83 Å. The Ga_2O_3 structure also features a tetrahedrally coordinated O atom bonded to one tetrahedral Ga atom (Ga—O = 1.85 Å) and three octahedral gallium atoms. In light of this information the tetra-

*These bond lengths have been corrected for independent motion as well as libration (see text).

hedral Ga—O distances in this structure appear to be slightly long relative to the similar bonds in Ga_2O_3 while the axial Ga(3)—O bond, 1.960(3) Å, is correspondingly shorter than any other axial Ga—O bond yet observed (see Table 8).

The six unique tetrahedral Ga—N bond lengths range from 1.945(3) to 2.001(3) Å and have a mean value of 1.972 Å. The mean distance is shorter than the value of 1.982 Å for tetrahedral Ga—N bonds given in Table 8 but all of the individual distances in the present structure fall within the observed range of 1.930–2.009 Å. There are highly significant variations between the individual values. The two bonds involving the singly bridging nitrogen atom N(3) (Ga(2)—N(3), 1.980(3), and Ga(4)—N(3), 1.973(4) Å) are neither significantly different from each other nor from the mean value of 1.982 Å from Table 8. The four other tetrahedral Ga—N bonds involve the μ_3 nitrogen atoms N(1) and N(2). Three of these bonds are in the highly constrained six-membered Ga(1)—N(1)—Ga(2)—O—Ga(3)—N(2) ring and divide into two relatively short bonds (Ga(1)—N(2), 1.953(3), and Ga(2)—N(1), 1.945(3) Å) and one "normal" bond (Ga(4)—N(2), 1.982(3) Å), the latter differing from the two others in that it also is one side of a four-membered ring. The last tetrahedral Ga—N bond

(Ga(4)—N(2), 2.001(3) Å) is relatively long, but balances the two short Ga—N bonds involving N(2).

The bond lengths (Ga(3)—N(1)′, 1.999(3), and Ga(3)—N(2), 1.949(3) Å) are the first equatorial Ga—N distances reported. As expected, their mean value (1.974 Å) is shorter than the mean tetrahedral Ga—N distance of 1.982 Å. The longer of these bonds is in the four-membered Ga_2NO ring while the shorter one is in the same Ga_3N_2O ring which contains the short tetrahedral Ga—N bonds. The rather long axial Ga(3)—N(5) distance of 2.779(3) Å must be interpreted as a very weak interaction and further demonstrates the importance of steric forces (2) in the marked variation of axial Ga—N distances (see Table 8). The primary steric constraint in this case is the essentially fixed conformation of the five-membered Ga(3)—N(2)—C(5)—C(6)—N(5) ring, two of whose members are bridgehead atoms of the polycyclic cage. A shortening of the Ga(3)—N(5) bond would result

in an unfavorable increase in angular strain in the already strained system.

The four independent tetrahedral Ga—H distances range from 1.40 to 1.52 Å and have a mean value of 1.46 Å. There are no significant differences between the individual values. The equatorial Ga(3)—H(3) distance of 1.49(5) Å falls within the range of previously observed equatorial Ga—H bond lengths.

The distortion of the trigonal bipyramidal coordination group of Ga(3) occurs primarily as a lengthening of the axial Ga—N bond, a significant nonplanarity of the equatorial GaNNH group (which has H(3) displaced 0.37 Å from the

mean plane in the direction of N(5)), and distortions of the valence angles at Ga(3) between the axial and the equatorial substituents. Unlike the previous five-coordinate gallium structures (1, 2, 12, 13), in which the most notable distortion of the trigonal bipyramids is the deviation of the angles between the axial substituents (which range from 150.0 to 169.1°) from linearity, the angle in the present structure, N(5)—Ga(3)—O, is 175.9(1)°. Of the angles within the equatorial group, only N(1)′—Ga(3)—N(2), 121.5(1)°, differs significantly from the "ideal" value of 120°. The angles between the axial and equatorial substituents, ideally 90°, range from 78.5(1) for N(2)—Ga(3)—N(5) to 101(2)° for O—Ga(3)—H(3).

The range of bond angles at the tetrahedrally coordinated gallium atoms, from 88.4(1)° at Ga(1) in the four-membered ring to 121(2)° for the angle N(1)—Ga(2)—H(2), represents considerable distortion from ideal tetrahedral geometry. The mean valence angles are 108.9 at Ga(1), 109.0 at Ga(2), and 109.5° at the relatively strain-free Ga(4).

The four-membered Ga_2NO ring is the first such ring to be characterized by X-ray analysis. While the related Ga_2O_2 rings contain either two five-coordinate (1, 2) or two six-coordinate gallium atoms (17), the present Ga_2NO ring contains one four-coordinate, Ga(1), and one five-coordinate gallium atom, Ga(3)′. The nonplanar ring is folded with Ga(1) and Ga(3)′ displaced by −0.0046 and −0.0043 Å from the mean plane of the ring and O′ and N(1) by 0.197 and 0.140 Å. The mean intraannular dihedral angle in the ring has a magnitude of 10.1° (individual values are given in Table 6). As a result of the severe steric constraints inherent in the fused polycyclic system, the Ga_2NO ring, with angles ranging from 85.7(1)° at Ga(3)′ to 94.2(1)° at O′, is nearly square whereas the Ga_2O_2 rings were found to have angles between 74.7 and 76.0° at Ga and between 100.0 and 105.4° at O. The nonbonded Ga...Ga contacts across the Ga_2O_2 rings are near 3.2 Å while the Ga(1)...Ga(3)′ distance across the Ga_2NO ring is considerably reduced to 2.808(1) Å.

The mean valence angle in the five-membered

GaNCCN ring is 101.2° with individual values ranging from 78.5(1) at Ga(3) to 115.3(2)° at N(2). The conformation of the ring is quite different from those observed for the related GaOCCN rings (1, 2) (on the basis of the intraannular dihedral angles) and does not correspond to a minimum energy conformation (18). This indicates a high degree of strain in the ring and is consistent with the long Ga(3)—N(5) distance. The ring conformation may be described as a distorted "envelope" with the atoms N(5), Ga(3), N(2), and C(5) forming a rough plane with C(6) displaced from this plane.

Each of the unique six-membered rings in the polycyclic system has a distorted "boat" conformation. For each ring the dihedral angles (Table 6) may be split into a group of four large magnitudes and a group of two small magnitudes. The minimum-energy boat conformation is characterized by four dihedral angles with a magnitude of 54° and two of 0° and a mean valence angle of 111.7° (19). The presence of the five-coordinate atom Ga(3) in each of the three Ga_3N_2O rings introduces a source of strain in addition to that already imposed by the fused ring system alone. As for the five-membered ring, these conformations do not correspond to any of the simple minimum-energy arrangements calculated for free cyclopentane systems (18, 19). The observed conformation must correspond to a local energy minimum but represents a system which is strained relative to the free ring. The Ga(1)—N(2)—Ga(3)—N(1)′—Ga(2)′—O′ ring, which has an equatorial–equatorial angle at Ga(3), has a mean valence angle of 113.3° while the other two Ga_3N_2O rings (Ga(1)—N(1)—Ga(2)—O—Ga(3)—N(2) and Ga(4)—N(3)—Ga(2)—O—Ga(3)—N(2)), which have equatorial–axial angles at Ga(3), consequently have smaller mean valence angles (109.5 and 108.7° respectively). Individual angles in the six-membered rings range from 97.4(1)° for N(3)—Ga(2)—O to 131.1(1)° for Ga(1)′—O—Ga(2).

The mean N(quaternary)—C and N(pyramidal)—C bond lengths of 1.477 and 1.458 Å are as expected. The N—C bonds involving the cage nitrogen atoms are somewhat longer than the others. Those involving the bridgehead atoms, N(1)—C(1) and N(2)—C(5), are both 1.480 Å, while that involving the singly bridging nitrogen atom (N(3)—C(9), 1.493(5) Å) is significantly longer than the mean value. σ-hybridization effects have been calculated (20) and appear to be primarily responsible for the slight shortening of the $C(sp^3)$—$C(sp^3)$ bonds (1.487(7)–1.528(6) Å) from the usual value of 1.537 Å. The calculated single bond distances for these C—C bonds range from 1.508–1.524 Å.

The N—H distance of 0.85(5) Å does not differ significantly from the value expected for X-ray data. The mean C—H bond length is 1.03 Å and the individual values range from 0.88–1.22(4–8) Å. The R—N—H, R—C—H, and H—C—H angles have ranges of 97–124(4), 97–122(2–5), and 93–121(3–6)° and mean values of 105, 110, and 108° respectively. The unusually long C—H distances and the extreme angles associated with the ill-defined C(11) and C(12) methyl groups (Tables 4 and 5) have not been included in the above ranges and means in view of their apparent unreliability.

The two "free" nitrogen atoms, N(4) and N(6), are involved in an intramolecular bifurcated hydrogen-bonding arrangement with H(*n*). The N...N distances (N(3)...N(4), 3.128(5) and N(3)...N(6), 2.901(5) Å) are shorter than usual (21). This shortening may be partially due to the nonlinearity of the N—H...N interactions (see Table 7*c*) but both N—H...N interactions appear to be fairly strong for such a bifurcated system. The crystal structure consists of well separated molecules. There is only one intermolecular contact less than the sum of van der Waals radii, H(3*b*)[x, y, z]...H(3*b*)[$-x$, $1-y$, $1-z$], 1.9(1) Å.

Further work is in progress in an attempt to clarify the reaction sequence leading to the above cage structure, and also to produce further examples of extensive cage structures involving Ga and N atoms, and Ga, N, and O atoms.

We thank the National Research Council of Canada for financial support and the University of British Columbia Computing Centre for assistance.

Crystal and Molecular Structure of (±)-7,7-(2′,2′-Dimethyl)pentamethylene-1-methyl-norbornane-2-oxime

STEVEN J. RETTIG AND JAMES TROTTER

Department of Chemistry, University of British Columbia, Vancouver, British Columbia V6T 1W5

Received September 20, 1974

STEVEN J. RETTIG and JAMES TROTTER. Can. J. Chem. **53**, 765 (1975).

Crystals of (±)-7,7-(2′,2′-dimethyl)pentamethylene-1-methyl-norbornane-2-oxime are monoclinic, $a = 9.202(2)$, $b = 12.852(3)$, $c = 12.698(3)$ Å, $\beta = 110.83(2)°$, $Z = 4$, space group $P2_1/c$. The structure was solved by direct methods and was refined by full-matrix least-squares procedures to a final R of 0.048 for 1538 reflections with $I \geq 3\sigma(I)$. The crystal structure consists of pairs of molecules linked by N ... H—O hydrogen bonds (N ... O = 2.821(3) Å) to form centrosymmetric dimers. Bond distances are as follows: C—N = 1.266(3), N—O = 1.426(3), mean C(sp^3)—C(sp^3) = 1.540, and mean C(sp^3)—C(sp^2) = 1.511 Å.

STEVEN J. RETTIG et JAMES TROTTER. Can. J. Chem. **53**, 765 (1975).

Les cristaux de l'oxime de la (±)(diméthyl-2′,2′)pentaméthylène-7,7 méthyl-1 norbornanone-2 sont monocliniques $a = 9.202(2)$, $b = 12.852(3)$, $c = 12.698(3)$ Å, $\beta = 110.83(2)°$, $Z = 4$, groupe d'espace $P2_1/c$. On a résolu la structure par des méthodes directes et on l'a affinée par la méthode des moindres carrés (matrice complète) jusqu'à une valeur finale R de 0.048 pour 1538 réflections avec $I \geq 3\sigma(I)$. La structure cristalline consiste de paires de molécules liées par des ponts hydrogène N ... H—O (N ... O = 2.821(3) Å) formant des dimères centrosymétriques. Les longueurs de liaison sont les suivantes: C—N = 1.266(3), N—O = 1.426(3), valeur moyenne de C(sp^3)—C(sp^3) = 1.540, et la valeur moyenne C(sp^3)—C(sp^2) = 1.511 Å.

Introduction

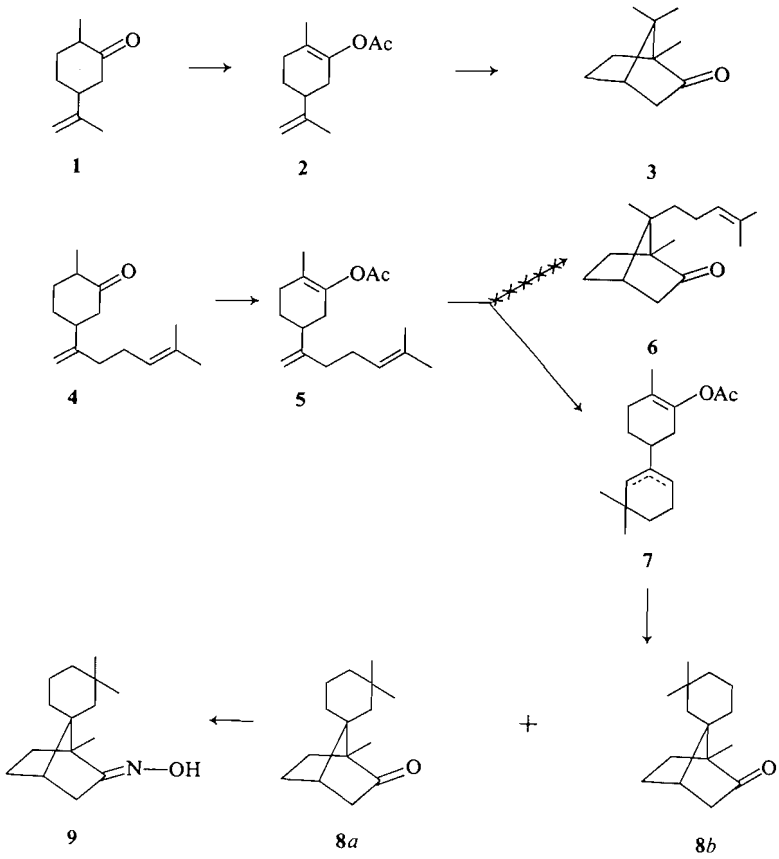
As part of a general approach (1, 2) to the synthesis of structurally related mono- and sesquiterpenes a simple synthetic route to camphor (**3**) based on biosynthetic ideas has been devised (3). This involves cyclization of the enol acetate (**2**) of dihydrocarvone (**1**) and the logical extension of this approach in the sesquiterpene area prompted synthesis of the enol acetate (**5**) of dihydrocryptomerion (**4**) and subjection of this to the same cyclization conditions. In this way it was hoped to achieve a simple synthesis of campherenone (**6**) which occupied a key position in the general synthetic strategy (1*b*). In the event, cyclization of the enol acetate (**5**) with boron trifluoride in wet methylene chloride provided a mixture of products from which the main components (A, B, and C) could be isolated by column chromatography (silica) and preparative g.l.c. (relative abundance of A, B, and C 5:8:1). Component A was assigned structure (**8***a*, *b*) on the basis of spectral characteristics: ν_{max}(neat) 1740 and 1410 cm^{-1}; *m/e* (relative intensity), 220 (22.5); $\tau(CCl_4)$ 9.21 (3H, s), 9.10, 9.05, 9.00, and 8.94 (6H, s). The formation of tricyclic ketones of this type was rationalized by invoking 1,5-diene cyclization of (**5**) to form an intermediate bicyclic enol acetate (**7**) which could cyclize further to yield (**8***a*, *b*). In terms of this rationalization the presence of both ketones (**8***a* and **8***b*) was expected and, although this could not be established by g.l.c., the n.m.r. supported this expectation. The separation of the suspected ketones was accomplished by conversion to the corresponding enol acetates which were separated easily by preparative g.l.c. The separated enol acetates were hydrolized to the corresponding ketones (**8***a* and **8***b*) and one of these (**8***a*) was converted to a crystalline oxime (**9**). A full X-ray crystallographic analysis of this oxime is now described, which establishes its structure (**9**) and, in addition, confirms the structural assignments indicated above. Additional evidence is required before a definitive statement can be made about the structure of components B and C in the cyclization reaction mixture.

Experimental

Full experimental details for the synthesis of compounds described in this paper have been published elsewhere (1*b*).

Recrystallization of (±)-7,7-(2′,2′-dimethyl)penta-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.



methylene-1-methyl-norbornane-2-oxime from benzene gave colorless crystals, m.p. 165–168 °C (1, 2). The crystal chosen for study was mounted with b parallel to the goniostat axis and had dimensions of *ca.* 0.5 × 0.5 × 0.7 mm. Unit-cell and space group data were obtained from film and diffractometer measurements. The unit-cell parameters were refined by a least-squares treatment of $\sin^2\theta$ values for 30 reflections measured on a diffractometer with CuK_α radiation. Crystal data are:

$C_{15}H_{25}NO$ f.w. = 235.4

Monoclinic, $a = 9.202(2)$, $b = 12.852(3)$, $c = 12.698(3)$ Å, $\beta = 110.83(2)°$, $V = 1403.6(6)$ Å^3, $Z = 4$, $\rho_c = 1.1138(5)$ g cm^{-3}, $F(000) = 520$ (20 °C, CuK_α, $\lambda = 1.5418$ Å, $\mu = 5.3$ cm^{-1}). Absent reflections: $0k0$, $k \neq 2n$ and $h0l$, $l \neq 2n$ define uniquely the space group $P2_1/c$ (C_{2h}^5, No. 14).

Intensities were measured on a Datex-automated General Electric XRD 6 diffractometer, with a scintillation counter, CuK_α (nickel filter and pulse height analyzer), and a θ–2θ scan at 2° min^{-1} over a range of (1.80 + 0.86 tan θ) degrees in 2θ, with 20 s background counts being measured at each end of the scan. Data were measured to $2\theta = 120°$ (minimum interplanar spacing 0.89 Å). The intensity of the check reflection, monitored every 40 reflections throughout the data collection, was 86% of its original intensity at the end of the data collection. Lorentz and polarization corrections and check reflection scaling were applied, and the structure amplitudes were derived. No absorption correction was made due to irregularity of the crystal surface. Of the 2061 independent reflections measured, 520 had intensities less than $3\sigma(I)$ above background where $\sigma^2(I) = S + B + (0.03S)^2$ with S = scan count and B = time averaged background count. These reflections were given zero weight in the refinement but were included in the structure factor calculations.

Structure Analysis

The structure was solved by direct methods. Sixteen sets of signs for 267 reflections with $|E| \geq 1.50$ were determined by a computer program which uses Sayre relationships in an iterative procedure (4). The starting set of reflections is given in Table 1. One set of signs was out-

standing in that it converged in 4 cycles to a set having the highest consistency index (4) (0.85) with 129 positive and 138 negative signs. An *E*-map was computed using the 267 signed values of *E* from this set. The 17 nonhydrogen atoms accounted for the 17 highest peaks on the map. Three cycles of full-matrix least-squares refinement of the positions and isotropic thermal parameters of the O, N, and C atoms gave *R* 0.160. The nonhydrogen atoms were then refined anisotropically for one cycle, reducing *R* to 0.122. A difference map at this point revealed possible locations for all 25 H atoms which were then refined isotropically for one cycle giving *R* 0.082. The entire structure was refined for one cycle resulting in *R* 0.059. At this point one of the hydrogen atoms, H(81), was clearly positioned incorrectly. A structure factor calculation omitting H(81) gave *R* 0.056. A difference map gave the correct coordinates. The entire structure was refined for two more cycles giving a final *R* of 0.048 for 1538 reflections with $I \geq 3\sigma(I)$ (3 reflections which had $|F_o - F_c| > 3\sigma(F)$ were removed from the data set in the final stages of refinement).

The least-squares refinement was based on the minimization of $\Sigma w(F_o - F_c)^2$. The scattering factors of ref. 5 were used for the nonhydrogen atoms and those of ref. 6 for the hydrogen atoms. The anisotropic thermal parameters employed in the refinement are U_{ij} in the expression

$$f = f^o\exp[-2\pi^2(U_{11}h^2a^{*2} + U_{22}k^2b^{*2} + U_{33}l^2c^{*2} + 2U_{12}hka^*b^* + 2U_{13}hla^*c^* + 2U_{23}klb^*c^*)]$$

where f^o is the tabulated scattering factor and f is that corrected for thermal motion. The weighting scheme: $w = 1$ if $|F_o| \leq 7$, $w = 7/|F_o|$ if $|F_o| > 7$ gave uniform average values of $w(F_o - F_c)^2$ over ranges of $|F_o|$ and was employed in the final stages of refinement.

On the final cycle of refinement, no parameter shift was greater than 0.33σ for the nonhydrogen atoms and 1.37σ for the hydrogen atoms; the mean parameter shift corresponded to 0.08σ. A final difference map showed maximum fluctuations of ± 0.12 e Å^{-3}. The final positional and thermal parameters appear in Tables 2 and 3. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[1]

Thermal Motion and Correction of Molecular Geometry

The ellipsoids of thermal motion for the nonhydrogen atoms are shown in Fig. 1. The thermal motion has been analyzed in terms of the rigid-body modes of translation (T), libration (L), and screw (S) motion (7) using the computer program MGTLS. The r.m.s. standard deviation in the temperature factors U_{ij} is 0.0014 Å^2 indicating that the thermal motion of the twelve ring carbon atoms, C(1)—C(12), is well described by the rigid-body thermal parameters given in Table 4 (r.m.s. $\Delta U_{ij} = 0.0022$ Å^2). The indicated modes of motion are physically reasonable; the translation tensor T is nearly isotropic while the libration tensor L is somewhat anisotropic. The location of the unique origin and the orientation of the principal axes of L indicates that the rigid-body libration of the monomer unit is constrained by the hydrogen-bonding. The origin lies near the center of gravity in *x* and *y*, but is displaced toward the hydrogen bond in *z*. The principal axes of L do not correspond to the principal moments of inertia but are oriented as follows: L_1 makes an angle of 18° with the C(7)—C(2) bond, L_2 makes an angle of 23° with the C(7)—C(12) bond, and L_3 is 19° away from the O—N bond.

The appropriate bond distances and angles have been corrected for libration (8, 9), using shape parameters q^2 of 0.08 for all atoms involved. The bonds O—N, N—C(1), C(2)—C(13), C(11)—C(14), and C(11)—C(15) have been corrected for independent motion using a riding model based on the ΔU_{ij} (10, 11). Corrected and uncorrected bond distances appear in Table 5. Bond angles (Table 6) changed by no more than 0.04°, thus corrected values will not be reported.

Results and Discussion

A general view of the molecule, with crystallographic numbering scheme, is shown in Fig. 1. Fig. 2 shows the structure viewed along *a*. Intraannular dihedral angles defining the conformations of the ring systems are given in Table 7 with e.s.d.'s calculated using the formula due to P. Huber (appendix to ref. 12). Weighted least-squares mean planes are given in Table 8. The structural parameters of (**9**) are compared with those of related compounds (13–20) and oximes (21–29) in Table 9. Important inter- and intramolecular nonbonded contacts and details of the hydrogen bonding scheme are given in Table 10.

The crystal structure consists of pairs of molecules linked by N...H—O hydrogen bonds (N...O = 2.821(3) Å) to form centrosymmetric dimers situated about the centers of symmetry at (0, 0, 0) and (0, $\frac{1}{2}$, $\frac{1}{2}$). The N...O distance is similar to those reported for other dimeric oximes: 2.84 Å in *syn-p*-chlorobenzaldoxime (23), 2.76 Å in dimethylglyoxime (25), and 2.87 Å

[1]The structure factor table is available, at a nominal charge, from the Depository of Unpublished Data, National Science Library, National Research Council of Canada, Ottawa, Canada K1A 0S2.

in 2-(*cis*-4-bromo-1-methylcyclohexyl)-3-(4-hydroxyimino-1-methylcyclohexyl)-*trans*-2-butene (29). The dimers are centered in the *bc* plane thus forming layers which repeat along *a* (see Fig. 2). This results in a staggering of layers which allows a compact stacking with a minimum of steric interference. All interdimer distances with the exception of H(91)...H(152), 2.23 Å, are greater than the sum of van der Waals radii (see Table 10).

The six-membered ring, C(1)—C(6), is in the boat conformation. The single atom bridge is responsible for significant deviations from the geometry expected for an unsubstituted boat. The magnitudes of the dihedral angles in the ring are considerably larger than those obtained from strain-energy minimization calculations (30). The mean bond angle in the ring, 104.9°, is significantly less than the predicted 111.7° (30). The C(2)...C(5) distance is significantly shortened from the 'ideal' 2.57 Å (30) to 2.270 Å, which is similar to corresponding distances in other norbornyl compounds (*eg.* 2.27 Å in tricyclo-[4.4.0.$0^{2,8}$]dec-3-ene-7,10-dione (13)). All atoms

in the ring undergo angular strain, the sp^2 carbon atom C(1) showing the highest strain with an angle of 108.1°. The angles at sp^3 carbon atoms range from 101.2 to 106.9°, all significantly less than the tetrahedral angle.

The bridge apex angle, C(2)—C(7)—C(5), is 92.5 and the boat to bridge angles range from 99.4 to 103.1 with a mean value of 101.6°. The two five-membered rings containing the apex atom C(7) have the envelope conformation. The dihedral angles in these rings (see Table 7) show a good relative agreement with those calculated for the low-energy conformation of cyclopentane with $\omega_1 = 0°$ (31). The mean angle in both rings is 100.9°, which is significantly less than the calculated value of 104.2° (31). It is the fact that the ring valence angles are smaller than the calculated values which accounts for the higher observed magnitudes of the dihedral angles in both five-membered rings and in the six-membered ring, C(1)—C(6), than those calculated from strain-energy minimization calculations. The steric constraints imposed by the bridging atom are responsible for these effects. Comparing the geometry of the norbornane skeleton with that observed in related compounds (see Table 9) one notes high consistency in the mean values of the various interior angles. This trend persists regardless of the nature of the compound, in particular with regard to the hybridization states at various carbon atoms. The 'ideal' mean angles in Table 9 are based on values of 109.5° at sp^3 carbons and 120° at sp^2 atoms. Introduction of sp^2 hybridized carbon atoms into the norbornyl skeleton does not significantly alter the mean interior angles but

serves to increase angular strain in the system. Table 9 shows that, unlike the interior angles, the bond lengths in the norbornyl skeleton vary significantly between the different compounds, particularly the boat to bridge distances which range from 1.51 to 1.58 Å.

The mean bond lengths for $C(sp^3)$—$C(sp^3)$ and $C(sp^3)$—$C(sp^2)$ bonds in the C(1)—C(6) ring are 1.543 and 1.511 Å respectively, both in good agreement with the accepted means (32). The individual $C(sp^3)$—$C(sp^3)$ distances range from 1.533(3) to 1.557(3) Å. This variation is a result of steric and electronic effects in the ring. The boat to bridge distances: C(2)—C(7), 1.587(3), and C(5)—C(7), 1.573(3) Å, are significantly longer, and the C(2)—C(13) bond, 1.507(3) Å, is significantly shorter than the normal $C(sp^3)$—$C(sp^3)$ bond. These effects result, to some degree, from hybridization changes at C(2), C(5), and C(7), arising from steric distortion of the tetrahedra. The weakening of the C(2)—C(7) bond is balanced by the slight strengthening of the C(2)—C(13) bond.

The oxime group is slightly, but significantly, nonplanar, with O and C(1) lying below the mean plane and N, C(2), and C(6) above. The grouping about trigonal C(1) is also significantly nonplanar (see Table 8). High angular strain at C(1) is probably responsible for this non-planarity. The hydroxyl hydrogen, H(0) is rotated 9° out of the oxime mean plane, the dihedral angle C(1)[N—O]H(0) being −171(2)°. The structural features of the oxime group are similar to those in related compounds listed in Table 9. The C—N distance of 1.266(3) Å is

shorter than most given in Table 9 and significantly shorter than the distance of 1.287 Å predicted for a C—N double bond (33). The N—O bond, 1.426(3) Å, is somewhat longer than those reported for the other oximes. The N—O and C—N distances suggest that the N—O bond may be slightly more polar in this structure than in most of the others given in Table 9. The O—H(0) bond, 1.07(3) Å, is unusually long for X-ray data. Some of the shortening of the C(1)—N bond is probably a result of effects. The mean R—C—N angle of 126° implies that the hybrid orbitals of C(1) involved in the C—N bond have more s character than usual, resulting in a slightly shorter bond (see *e.g.* ref. 34). The C—N—O and N—O—H angles are similar to those in related compounds (see Table 9).

The cyclohexane ring, C(7)—C(12), has the

*Superscripts refer to atoms at positions (*1*) 2 − x, −y, −z; (*2*) 1 − x, −y, −z; (*3*) 1 − x, y − ½, ½ −z; (*4*) x, ½ −y, ½ +z.

chair conformation. The experimental dihedral angles are in good agreement with those obtained from strain-energy minimization calculations (30) for free cyclohexane (see Table 7). This distortion from the ideal chair conformation occurs primarily as a result of the 1,3-diaxial interaction between C(5) and C(14). The mean bond angle in the ring is 111.9°, slightly larger than the predicted value of 111.1° (30). The angles at fully substituted C(7) and C(11), 108.0(2) and 108.5(2)°, are near the tetrahedral angle as expected. The 1,3-diaxial interaction opens the angle at C(12) to 117.7(2)° and an interaction between the C(13) methyl group and axial hydrogen atoms H(82) and H(122) may contribute to the slight opening of the angle at C(8), 112.9(2)°, as well as to that at C(12). The angles at C(9) and C(10) are generally as expected. The bond distances in the ring range from 1.521 to 1.542 Å, with a mean value of 1.532 Å, in excellent agreement with the mean of 1.533 Å for several cyclohexanes (30). The C(11)—C(14) and C(11)—C(15) bond lengths, 1.536(3) and 1.531(3) Å, are as expected.

Bond angles and distances involving the hydrogen atoms are generally as expected. The mean C—H distance is 1.01 Å, mean C—C—H, 111°, and mean H—C—H, 108°.

We thank Dr. T. Money and Dr. D. F. MacSweeney for suggesting the problem and providing the crystals, the National Research Council of Canada for financial support, and the University of British Columbia Computing Centre for assistance.

Crystal and Molecular Structure of 2,5-Bis(2′-hydroxyethylamino)-1,4-benzoquinone

STEVEN J. RETTIG AND JAMES TROTTER

Department of Chemistry, University of British Columbia, Vancouver, British Columbia V6T 1W5

Received October 17, 1974

STEVEN J. RETTIG and JAMES TROTTER. Can. J. Chem. **53**, 777 (1975).

Crystals of 2,5-bis(2′-hydroxyethylamino)-1,4-benzoquinone are monoclinic, a = 5.020(1), b = 19.238(3), c = 5.214(1) Å, β = 96.15(3)°, Z = 2, space group $P2_1/n$. The structure was solved by direct methods and was refined by full-matrix least-squares procedures to a final R of 0.045 for 646 reflections with $I \geq 3\sigma(I)$. The benzoquinone ring in the centrosymmetric molecule is slightly, but significantly, nonplanar. Bond distances in the compound (C—C, 1.247 (2) and 1.410 (3), C—N, 1.332 (3) and 1.457 (3), C—C, 1.384–1.514 (3), N—H, 0.89 (3), O—H, 1.07 (5), and C—H, 0.95–1.09 (3) Å) are similar to those in related compounds. The structure features an extensive network of N—H...O (N...O = 2.639 (3) and 3.033 (2) Å) and O—H...O (O...O = 2.757 (3) Å) hydrogen bonds.

STEVEN J. RETTIG et JAMES TROTTER. Can. J. Chem. **53**, 777 (1975).

Les cristaux du bishydroxy-2′méthylamino-2,5 benzoquinone-1,4 sont monocliniques, a = 5.020(1), b = 19.238(3), c = 5.214(1) Å, β = 96.15(3)°, Z = 2, groupe d'espace $P2_1/n$. On a résolu la structure par des méthodes directes et on l'a affinée par la méthode des moindres carrés (matrice complète) jusqu'à une valeur finale de R de 0.045 pour 646 réflections avec $I \geq 3\sigma(I)$. Le noyau benzoquinone dans la molécule centrosymétrique est légèrement mais toutefois pas d'une façon importante nonplanaire. Les distances de liaison dans le composé (C—C, 1.247(2) et 1.410(3), C—N, 1.332(3) et 1.457(3), C—C, 1.384–1.514(3), N—H, 0.89(3), O—H, 1.07(5) et C—H, 0.95–1.09(3) Å) sont semblables à celles trouvées dans des composés similaires. La structure comporte un réseau extensif de ponts hydrogène N—H ... O (N ... O = 2.639(3) et 3.033(2) Å) et O—H ... O(O ... O = 2.757(3) Å). [Traduit par le journal]

Introduction

An initially colorless solution of $(p\text{-}FC_6H_4)_2\text{-}\overline{BOCH_2CH_2NH_2}$ in ethanol turned deep red over a period of several months depositing a small amount of deep violet crystalline material. An X-ray crystallographic analysis of this material was undertaken in the hope that this sample would prove to be an interesting organoboron compound.

The results of the crystallographic analysis show that this material is 2,5-bis(2′-hydroxyethylamino)-1,4-benzoquinone, a compound whose structure is interesting in its own right and forms the main topic of this report. At present little is known about the reaction sequence leading to the formation of the benzoquinone. Some chemical tests are being carried out in order to solve this problem. Decomposition also occurs in other solvents (MeOH and acetone), but it is not yet known if the same product is formed. The reaction appears to be a photochemical one.

Experimental

A small quantity of 2,5-bis(2′-hydroxyethylamino)-1,4-benzoquinone was isolated as a decomposition product of *B,B*-bis(*p*-fluorophenyl)boroxazolidine, $(p\text{-}FC_6H_4)_2\text{-}\overline{BOCH_2CH_2NH_2}$, in ethanol. The dark violet crystals which were deposited from the solution were suitable for X-ray analysis after washing with cold ethanol.

The crystal chosen for study was mounted with b parallel to the goniostat axis and had dimensions of *ca.* 0.3 × 0.3 × 0.3 mm. Unit-cell and space group data were obtained from film and diffractometer measurements. The unit-cell parameters were refined by a least-squares treatment of $\sin^2\theta$ values for 20 reflections measured on a diffractometer with Cu K_α radiation. Crystal data are:

$C_{10}H_{14}N_2O_4$ f.w. = 226.2

Monoclinic, a = 5.020(1), b = 19.238(3), c = 5.214(1) Å, β = 96.15(3)°, V = 500.6(2) Å^3, ρ_m = 1.500 (flotation in aqueous KI), Z = 2, ρ_c = 1.501(1) g cm^{-3}, $F(000)$ = 240 (22 °C, Cu K_α, λ = 1.5418 Å, μ = 16.6 cm^{-1}). Absent reflections: $0k0$, $k \neq 2n$, and $h0l$, $h + l \neq 2n$ define uniquely the space group $P2_1/n$ (C_{2h}^5, No. 14).

Intensities were measured on a Datex-automated General Electric XRD 6 diffractometer, with a scintillation counter, Cu K_α (nickel filter and pulse height analyzer), and a θ–2θ scan at 2° min^{-1} over a range of

(1.80 + 0.86 tan θ) degrees in 2θ, with 20 s background counts being measured at each end of the scan. Data were measured to $2\theta = 145°$ (minimum interplanar spacing 0.81 Å). The intensity of the check reflection, measured every 40 reflections throughout the data collection, decreased slowly to a final value which was 0.90 times the original intensity. Lorentz and polarization corrections and check reflection scaling were applied, and the structure amplitudes were derived. No absorption correction was made in view of the low value of μ. Of the 1008 independent reflections measured, 357 had intensities less than $3\sigma(I)$ above background where $\sigma^2(I) = S + B + (0.05S)^2$ with S = scan count and B = time averaged background count. These reflections were given zero weight in the refinement but were included in the structure factor calculations.

Structure Analysis

The structure was solved by direct methods. Sixteen sets of signs for 139 reflections with $|E| \geq 1.50$ were determined by a computer program which uses Sayre relationships in an iterative procedure (1). The starting set of reflections is given in Table 1. One set of signs was outstanding in that it converged in one cycle to a set which had the highest consistency index (0.90) with 82 positive and 57 negative signs. The eight non-hydrogen atoms accounted for the 8 highest peaks on an E-map calculated from this set of phases. These eight atoms were refined first isotropically, then anisotropically as carbon atoms giving R 0.119. A difference map at this point revealed the positions of five of the seven hydrogen atoms, among them H(N). This information, along with bond distances and angles, and the magnitudes of the isotropic thermal parameters enabled us to identify unambiguously the nitrogen and two oxygen atoms. The remaining hydrogen atoms were located on a subsequent difference map. The entire structure (H atoms with isotropic thermal parameters) was refined for six cycles giving a final R of 0.045 for 646 reflections with $I \geq 3\sigma(I)$ (5 reflections which had $|F_o - F_c| > 3\sigma(F)$ were removed from the data set in the final stages of refinement).

The least-squares refinement was based on the minimization of $\Sigma w(F_o - F_c)^2$. The scattering factors of ref. 2 were used for the non-hydrogen atoms and those of ref. 3 for the hydrogen atoms. The anisotropic thermal parameters employed in the refinement are U_{ij} in the expression:

$$f = f^o \exp[-2\pi^2(U_{11}h^2a^{*2} + U_{22}k^2b^{*2} + U_{33}l^2c^{*2} + 2U_{12}hka^*b^* + 2U_{13}hla^*c^* + 2U_{23}klb^*c^*)]$$

where f^o is the tabulated scattering factor and f is that

corrected for thermal motion. The weighting scheme: $w = 1/\sigma^2(F)$ where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$ gave uniform average values of $w(F_o - F_c)^2$ over ranges of $|F_o|$ and was employed in the final stages of refinement.

On the final cycle of refinement, the largest parameter shift was 0.08 σ. A final difference map showed maximum fluctuations of ±0.19 e Å^{-3}, the maxima appearing at positions expected for the oxygen lone-pair and benzoquinone ring bonding electrons. The final positional and thermal parameters appear in Tables 2 and 3 respectively. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[1]

Thermal Motion and Correction of Molecular Geometry

The ellipsoids of thermal motion for the non-hydrogen atoms are shown in Fig. 1. The thermal motion has been analyzed in terms of the rigid-body modes of translation (T), libration (L), and screw (S) motion (4) using the computer program MGTLS. The r.m.s. standard deviation in the temperature factors U_{ij} is 0.0011 Å^2 indicating that the thermal motion of the entire molecule is satisfactorily described by the rigid-body thermal parameters given in Table 4 (r.m.s. $\Delta U_{ij} = 0.0032$ Å^2).

The appropriate bond distances and angles have been corrected for libration (5, 6), using shape parameters q^2 of 0.08 for all atoms involved. The corrected and uncorrected bond lengths appear in Table 5. Bond angles, given in Table 6, changed by no more than 0.05°, thus the corrected angles are not reported.

Results and Discussion

Figure 1 shows the atom numbering scheme and Fig. 2 the packing arrangement viewed down

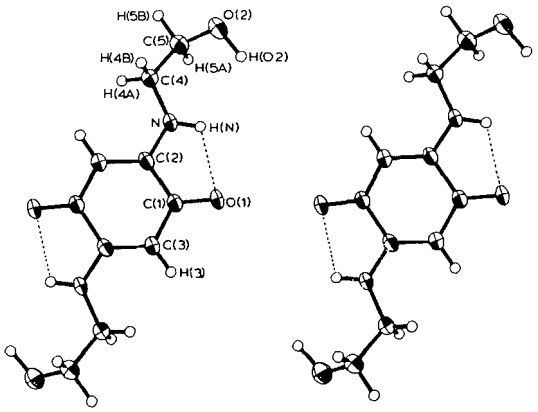

FIG. 1. Stereoscopic view of the 2,5-bis(2'-hydroxyethylamino)-1,4-benzoquinone molecule showing the atom numbering scheme and 50% probability thermal ellipsoids for the non-hydrogen atoms. Broken lines indicate hydrogen bonds.

*c**. The molecular geometry of 2,5-bis(2'-hydroxyethylamino)-1,4-benzoquinone is compared to that of related compounds in Table 7. Important inter- and intramolecular contacts and details of the hydrogen bonding arrangement are given in Table 8.

The benzoquinone ring in the centrosymmetric molecule is slightly, but significantly, nonplanar. The equation of the weighted least-squares mean plane through the six-membered ring is $-0.6787X + 0.2868Y - 0.6761Z = -0.3665$ (X, Y, and Z are orthogonal Å coordinates along a, b, and c*). Displacements of atoms from this plane are: C(1) −0.007(2), C(2) 0.007(2), C(3) 0.008(2), O(1) −0.022(2), N 0.028(3), H(3) 0.01(3), C(4) 0.069(3), and H(N) 0.05(3) Å, with symmetry related atoms displaced in the opposite direction. Nonplanarity of the benzoquinone ring has also been noted for other 2,5-diamino-1,4-benzoquinones (7–11). The intra-annular dihedral angles in the ring are alternately ±2.0°, thus the ring has adopted a slight chair conformation. The nonplanarity of the six-membered ring, the deviations of O(1) and N from the mean plane, and the small twist about the C(2)—N bond (C(3)'[C(2)—N]C(4) = 1.4(2)°) arise from steric repulsions (see Table 8(*a*)).[2]

The C(1)—O(1), C(2)—N, C(4)—N, and benzoquinone ring bond distances do not differ significantly from those in related 2,5-diamino-1,4-benzoquinones given in Table 7. The C(1)—O(1) bond, 1.247(2) Å, is significantly longer than a normal ketone double bond (*e.g.* 1.220 Å in both *p*-benzoquinone (12) and *o*-benzoquinone (13)). The C(2)—C(3)', C(1)—C(3), and N—C(2) bond lengths (1.384(3), 1.409(3), and 1.332(3) Å) are intermediate between single and double bond distances. The C(1)—C(2) bond, 1.511(3) Å, although slightly shorter than corresponding bonds in the other 2,5-diamino-1,4-benzoquinones, is significantly longer than the value of 1.485 Å expected for a

[2]Here and elsewhere in this paper primed atoms refer to those related to atoms in Table 2 by the molecular center of symmetry.

		C(5)—H(5*b*)	1.09(3)

C(sp^2)—C(sp^2) single bond. The N—C(4) bond (1.457(3) Å) is significantly longer than the expected value of 1.445 Å for an N(sp^2)—C(sp^3) single bond. The bonds O(2)—C(5), 1.410(3), and C(4)—C(5), 1.514(3) Å, are both significantly shorter than expected. This shortening is probably due to σ-hybridization effects (the angles N—C(4)—C(5) and C(4)—C(5)—O(2) are both significantly greater than the tetrahedral angle). The remaining bond distances in the molecule are normal.

The coordination groups of all trigonal atoms in the molecule (including N) are planar within experimental error. The bond angles in the central part of the molecule are again quite similar to those in related compounds (see Table 7). The small differences which do occur are probably a result of differences in the steric environments, including the intra- and intermolecular hydrogen bonding schemes. The angles N—C(4)—C(5), 113.0(2), and C(4)—C(5)—O(2), 113.9(2)°, are both significantly larger than the tetrahedral angle presumably as a result of the steric requirements imposed by the intermolecular O—H ... O hydrogen bond.

The geometry of the molecule is consistent with the resonance structures given by Kulpe (7, 8). The three most important contributors to the structure are **1**, **2**, and **3** giving the overall structure **4**.

4

The crystal structure consists of molecules each linked to two others by an extensive centrosymmetric network of N—H ... O and O—H ... O hydrogen bonds to form nearly planar "ribbons" of molecules extending along [1 0 −1] (see Fig. 2). H(N) is involved in a bifurcated hydrogen bonding scheme including an intramolecular, N ... O = 2.639(3) Å, and an intermolecular N—H ... O interaction, N ... O = 3.033(2) Å. This bifurcated arrangement involving H(N) is similar to that in 3,6-dichloro-2,5-bis(methylamino)-1,4-benzoquinone (8, 9) where the corresponding N ... O distances are 2.573(7) and 2.872(7) Å. The longer N ... O

1-Phenyl-2,2-dialkyl Vinyl Cation

SATORU MASAMUNE, MITSURU SAKAI, AND KAZUHIKO MORIO
Department of Chemistry, University of Alberta, Edmonton, Alberta T6G 2G2

Received November 4, 1974

SATORU MASAMUNE, MITSURU SAKAI, and KAZUHIKO MORIO. Can. J. Chem. **53**, 784 (1975).

1-Phenyl-2,2-dimethyl and 1-phenyl-2,2-diethyl vinyl cations have been generated. Their n.m.r. spectral data indicate (*i*) the presence of C_{2v} symmetry in these cations, (*ii*) the positive charge being mostly localized at the vinyl α-carbon (and the aromatic ring) but not at the β-position, and (*iii*) the bisected geometry for the aromatic ring of the system.

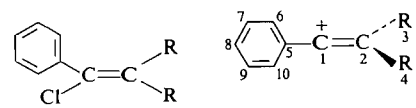
SATORU MASAMUNE, MITSURU SAKAI et KAZUHIKO MORIO. Can. J. Chem. **53**, 784 (1975).

On a généré les cations phényl-1 diméthyl-2,2 et phényl-1 diéthyl-2,2 vinyles. Leur spectre r.m.n. indique (*i*) la présence d'une symétrie C_{2v}, (*ii*) que la charge positive est localisée principalement sur le carbon α du groupe vinyle (et sur le cycle aromatique), mais pas en position β et (*iii*) que le système de cycle aromatique a une géométrie bisectée.

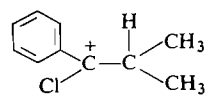
[Traduit par le journal]

The successful generation and direct observation of a vinyl cation has very recently been reported by Hanack and co-workers (1). This has prompted us to disclose the results of our investigation in this area (2). Our findings are mainly in accord with theirs but offer additional information, theoretically important and experimentally advantageous: (*i*) readily available vinyl chlorides rather than the corresponding fluorides serve equally well as precursors for the generation of vinyl cations, thus the latter halides that are synthetically less accessible are not required, (*ii*) the chemical shifts of both the α- and β-carbons of the vinyl cation are unambiguously determined, (*iii*) two different cations are generated to display (to the limit of the n.m.r. time scale) the linearity of the system, a feature that requires further confirmation of this unstable and elusive system, and finally (*iv*) our quenching experiments involve direct trapping of the cations rather than the isolation of secondary products.

We have chosen (1-chloro-2,2-dimethyleth-enyl)benzene(1)[1] and (1-chloro-2,2-diethyleth-enyl)benzene (**2**) (3) as precursors and have generated the corresponding carbocations in a manner similar to that previously described (4). Methylene chloride solutions of **1** and **2** were



1 R = CH_3 **1′** R = CH_3
2 R = C_2H_5 **2′** R = C_2H_5



3′

NOTE: The numbering of the cation is arbitrary.

separately mixed with a 1:5 mixture of SbF_5–SO_2ClF at −130°. The resulting dark orange lower layers contained the corresponding cations **1′** and **2′** and exhibited the spectra as shown below. The p.m.r. spectra of **1′** and **2′** in Fig. 1 clearly demonstrate the equivalence of the two methyl and ethyl groups, respectively. Furthermore, the chemical shifts of the aromatic protons suggest that the π system of the aromatic ring conjugates more effectively with the empty

[1]Proton magnetic resonance spectrum of **1** ($CDCl_3$): δ 1.73 (s.3H), 2.00 (s.3H), and 7.32 (br s 5H): c.m.r. ($CDCl_3$, TMS), δ 21.8, 22.1, 125.6, 127.8, 128.1, 129.3, 130.4, and 139.6.

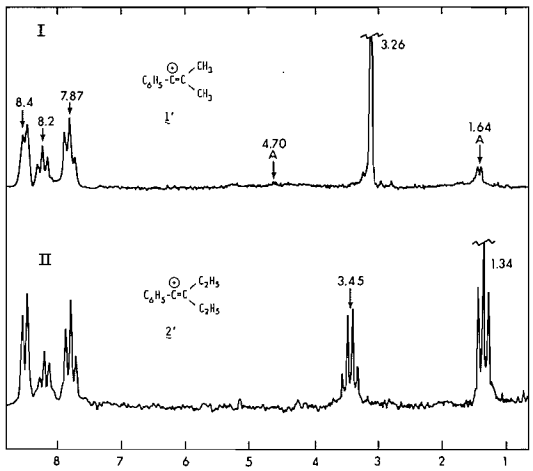

FIG. 1. Proton magnetic resonance (100 MHz) of **1′** and **2′** in SbF_5–SO_2ClF at −95°.

p-orbital of the vinyl cation rather than the double bond. This inference is in accord with the charge distribution calculated for 1-phenylvinyl cation by the MINDO/2–OPTMO program (5, 6).[2] Signals at δ 7.87, 8.2, and 8.4 are assigned to the *m*-, *p*-, and *o*-protons, respectively (5). The absorptions indicated by A have been confirmed by an independent preparation to be due to a tertiary cation **3′** contaminated in the sample.

Since off-resonance C-13 spectra did not permit unequivocal assignment of C-13 signals of **1′**, in particular, those of C(2) and C(5) of vital importance, compound **1** was labeled with C-13 either at C(1) or C(2), and also the aromatic ring was fully deuterated.[3] Figure 2 (7) shows proton-decoupled C-13 spectra of **1′** and these labeled cations. Comparison of spectra I and IV (C(1) labeled) and III (C(2) labeled) immediatedly leads to the assignment that signals A, D (overlapped with E), and G are ascribable to C(1), C(2), and C(3 and 4). Furthermore, spectrum II indicates that signal F is due to C(5) and B, C, and E are to the other aromatic carbons.[4] Another peak indicated by X appears

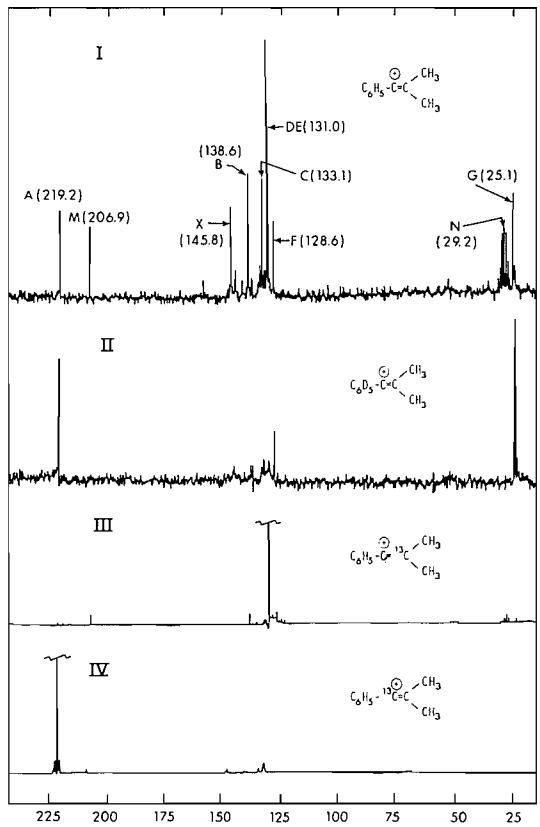

FIG. 2. Carbon-13 magnetic resonance (22.63 MHz) of **1′** and its labeled cations in SbF_5–SO_2ClF at —95°. External deuterioacetone (M and N) was used to lock the spectrometer and its signal taken as reference (N, δ 29.2).

irreproducibly in several experiments and are likely to arise from yet unidentified impurities contaminated in the superacid solution.

Thus, the equivalence of the two methyl (and ethyl) groups exhibited in both the p.m.r. and c.m.r. spectra point to the presence of C_{2v} symmetry in **1′**. The appearance of the C(2) signal in the normal olefinic region and that of the C(1) at low field clearly demonstrate that very little positive charge resides at the β-carbon of the cation even if two alkyl groups are attached to this carbon, and this aspect is being investigated further.[5] And as stated above, the chemical shifts of the aromatic protons suggest the bisected geometry for the aromatic ring of the system.

[2]The calculation also shows that this bisected geometry is *ca.* 6 kcal more stable than its geometrical isomer in which the phenyl ring and the two methyl groups are in one plane.

[3]These labeled compounds were prepared, using the corresponding C-13 benzoic acid, C-13 acetone, and deuterated toluene, respectively.

[4]The intensity of signal A, compared with those of B and C, appears to be anomously high but is not totally unexpected (8).

[5]Semi-empirical calculations (5, 9) indicate that alkyl substituents at the β-position significantly increase the positive charge density at this position.

Finally, quenching of solutions containing **1′** or **2′** with methanolic sodium methoxide at −80° provided the corresponding methoxystyrene derivatives in more that 50% yield and these experiments provide further evidence that **1′** and **2′** have indeed been generated.

Nuclear Magnetic Resonance Studies of the Solution Chemistry of Metal Complexes. XIII. The Lability of the Metal–Nitrogen Bonds in the Cadmium, Zinc, and Mercury Complexes of Selected Polyaminocarboxylic Acids

DALLAS L. RABENSTEIN, GEORGE BLAKNEY, AND BRYAN J. FUHR

Department of Chemistry, University of Alberta, Edmonton, Alberta T6G 2G2

Received February 21, 1974

DALLAS L. RABENSTEIN, GEORGE BLAKNEY, and BRYAN J. FUHR. Can. J. Chem. **53**, 787 (1975).

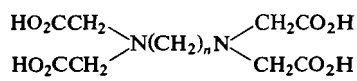
The lability of the metal–nitrogen bonds in the Cd(II), Zn(II), and Hg(II) complexes of $(HO_2CCH_2)_2N(CH_2)_nN(CH_2CO_2H)_2$ (n = 2, 3, 4) has been investigated by proton magnetic resonance spectroscopy. The acetate methylenic protons of each of the complexes give rise to AB multiplet patterns, indicating the metal–nitrogen bonds to be inert on the n.m.r. time scale. From the temperature dependence of the multiplet patterns, the relative lability of the metal–nitrogen bonds in each series of complexes has been established. In the Cd(II) and Zn(II) complexes, the metal–nitrogen bonds become more labile as the size of the internal chelate ring increases whereas it becomes more inert in the Hg(II) complexes. Also, the mercury–proton coupling constants increase as n is increased from two to four, which is interpreted as evidence that the increased kinetic stability results from structural changes to a more linear N—Hg—N arrangement. The metal–nitrogen bonds in the Cd(II) complexes having n = 3 and 4 is more labile than in the corresponding Zn(II) complexes. The thermodynamic stability patterns of the complexes are discussed in terms of their relative kinetic stabilities.

DALLAS L. RABENSTEIN, GEORGE BLAKNEY et BRYAN J. FUHR. Can. J. Chem. **53**, 787 (1975).

On a étudié, par r.m.p., la labilité des liens métaux-azote dans des complexes du Cd(II), Zn(II) et du Hg(II) avec $(HO_2CCH_2)_2N(CH_2)_nN(CH_2CO_2H)_2$ (n = 2, 3, 4). Les protons méthyléniques de l'acétate de chaque complexe donnent lieu à des patrons de type AB sous forme de multiplets, indiquant que les liens métaux-azote sont inertes à l'échelle de temps de la r.m.n. On a pu établir, grâce à la dépendance sur la température des patrons des multiplets, la labilité relative des liens métaux-azote dans chaque série des complexes. Dans les complexes Cd(II) et Zn(II), les liens métaux-azote deviennent plus labiles à mesure que la grandeur du cycle chélate interne augmente alors qu'ils deviennent plus inertes dans les complexes du Hg(II). De plus les constantes de couplage mercure–proton augmentent lorsque n augmente de 2 à 4; on interprète ces résultats comme signifiant que la stabilité cinétique accrue résulte de changements structuraux menant à des arrangements N—Hg—N plus linéaires. Les liens métaux-azote dans les complexes avec Cd(II) dans lesquels n = 3 et 4 sont plus labiles que dans les complexes Zn(II) correspondants. On discute des patrons de stabilité thermodynamique des complexes en terme de leur stabilité cinétique relative. [Traduit par le journal]

Introduction

In their pioneering studies of the solution chemistry of ethylenediaminetetraacetic acid (EDTA) and related ligands, Schwarzenbach, Anderegg, and co-workers (1–4) found that the formation constants of metal complexes of ligands of the type

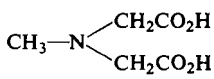


1

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

decrease as n is increased from two to eight, with the exception of the mercury complexes whose formation constants decrease as n is increased from two to three and then increase as n is increased from three to eight. Schwarzenbach and Anderegg proposed that larger chelate rings are favored in the Hg(II) complexes because of the tendency of Hg(II) to form linear N—Hg—N complexes. It also has been suggested that the decrease in formation constant as n is increased from two to three may indicate that some of the carboxylate groups coordinated in $Hg(EDTA)^{2-}$ are free in the Hg(II) complexes of the higher homologs (5).

Since the formation constant is determined by the ratio of the complex formation and dissociation rate constants, it seems likely that the changes in the formation constant may result from changes in the kinetic stability of the complex as the size of the internal chelate ring increases. If so, this should be reflected in the relative lability of the metal–nitrogen bonds of the different complexes, which can be determined from the complexity of the proton magnetic resonance (p.m.r.) spectra for their acetate methylenic protons (6, 7). To determine if the different stability trends do result from different changes in the kinetic stability as the size of the internal chelate ring increases, we have determined by p.m.r. the relative lability of the individual metal–nitrogen bonds in the Cd(II), Zn(II), and Hg(II) complexes of several homologs in the series represented by **1**. We have also studied the Zn(II) and Hg(II) complexes of the model ligand *N*-methyliminodiacetic acid (MIDA).



2

Experimental

1,4-Butylenediaminetetraacetic acid (1,4-BDTA) was synthesized by a method analogous to the synthesis of 1,3-propylenediaminetetraacetic acid (8). Cadmium nitrate (Fisher Certified Reagent), zinc nitrate, and mercuric nitrate (Baker Analyzed Reagents) and MIDA (K and K laboratories) were used as received.

pH measurements and 60 and 100 MHz p.m.r. measurements were made as described previously (7). 220 MHz p.m.r. measurements were made on a Varian HR-220 high resolution spectrometer at Sheridan Park, Ontario. Nuclear magnetic resonance measurements were made on samples in the pH range 6 to 8 to minimize contributions from reactions involving hydrogen or hydroxide ion (7).

Results and Discussion

Cadmium and Zinc Complexes

The 60 MHz p.m.r. spectrum of the acetate methylenic protons of $Zn(1,4\text{-}BDTA)^{2-}$ in H_2O is shown at several temperatures in Fig. 1. At 48 °C, the spectrum is a symmetrical AB pattern, the parameters for which are given in Table 1. The AB pattern indicates that, at this temperature, the zinc–nitrogen bonds are non-labile on the p.m.r. time scale (6, 7). At temperatures greater than 48 °C, the lability of the zinc–nitrogen bonds increases as evidenced by the partial collapse of the AB pattern; interchange of the protons between environments, and thus collapse of the AB pattern, can occur only by inversion of the nitrogen atom, which is possible only when the nitrogen is not metal coordinated. At temperatures less than 48 °C, the individual lines broaden at different rates, resulting in unsymmetrical AB patterns. Each half of the multiplet pattern is broadened further at 100 and 220 MHz, indicating that the broadening results from a second kinetic process, possibly a relatively slow exchange of the acetate dentates between the axial and equatorial sites. Such a process would yield an unsymmetrical

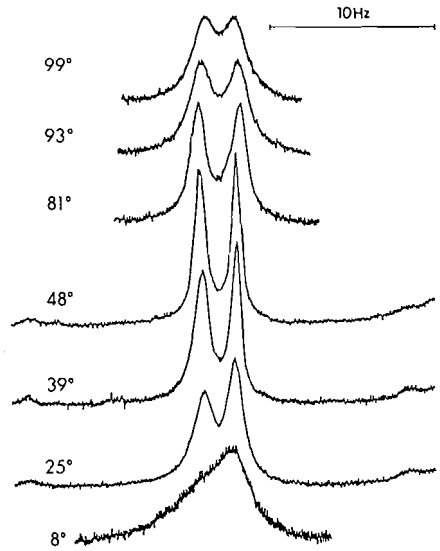


FIG. 1. Representative 60 MHz proton n.m.r. spectra of the acetate methylenic protons of $Zn(1,4\text{-}BDTA)^{2-}$ in H_2O. The pH of the solution was 8.4 at 25 °C.

pattern if J_{AB}, ν_A, and ν_B are different for the axial and equatorial acetate groups, as in the nonlabile cobalt(III) and rhodium(III) complexes of EDTA (6, 9–11), and if $\nu_{A(axial)} - \nu_{A(equatorial)}$ is different from $\nu_{B(axial)} - \nu_{B(equatorial)}$.

The average lifetime of the nonequivalent acetate methylenic protons of $Zn(1,4\text{-BDTA})^{2-}$ before interchange is given as a function of temperature in Table 2. The AB interchange rates were obtained by matching experimental p.m.r. spectra with theoretical spectra (7) which were calculated as a function of average lifetime before AB interchange using the density matrix formalism (12).

The average lifetimes of the nonequivalent acetate methylenic protons of the Zn(II) complex of 1,3-propylenediaminetetraacetic acid, $Zn(1,3\text{-PDTA})^{2-}$, have been reported as a function of temperature previously (7). The acetate methylenic protons of $Zn(EDTA)^{2-}$ also give an AB pattern at 220 MHz, although the spectral parameters have not been reported (13).

[a]pH = 7.78 at 25°. Determined by lineshape analysis of 60 MHz spectra; uncertainty is 5 to 10%.
[b]pH = 7.6 at 25°. Determined by lineshape analysis of 220 MHz spectra; uncertainty is ± 10% due to slight asymmetry of the multiplet pattern.

The p.m.r. spectrum for the acetate methylenic protons of $Cd(1,4\text{-BDTA})^{2-}$ is composed of the AB part of an ABX pattern superimposed on an AB pattern. The AB part of an ABX pattern is due to the complexes of the ^{111}Cd and ^{113}Cd isotopes, which have a natural abundance of 25% and a nuclear spin of 1/2, while the AB pattern is due to 1,4-BDTA complexes of the other cadmium isotopes. The spectral parameters obtained from the 220 MHz spectrum of $Cd(1,4\text{-BDTA})^{2-}$ are given in Table 1. At 70 °C, the multiplet pattern is A_2X, indicating that the ligand is not completely dissociating from the Cd(II) in the process which results in AB interchange.[1] Approximate values for the average lifetime of the nonequivalent acetate methylenic protons of $Cd(1,4\text{-BDTA})^{2-}$ before interchange are given as a function of temperature in Table 2.

The rates of AB interchange in the Cd(II) and Zn(II) complexes of ligands of the type represented by **1** are governed by their rates of partial dissociation to yield **4** (7).

[1]AB interchange can occur when the complex has partially dissociated to form **4** (7). However, the cadmium–proton coupling will collapse only if the complex completely dissociates (14); partial dissociation of the complex to **4** followed by reformation of the metal–nitrogen bond results in no change in the spin states of the coupled nuclei.

3 4

The metal–oxygen bonding in these complexes is labile at the temperatures at which the lifetimes were determined as indicated by a single AB pattern for the acetate methylenic protons. Thus, the rate determining step at these temperatures is dissociation of the metal–nitrogen bond.[2] The results in Table 2 indicate the metal–nitrogen bonding in the Cd(II) complex of 1,4-BDTA to be more labile than in the corresponding Zn(II) complex. Similar relative labilities were found for the Cd(II) and Zn(II) complexes of 1,3-PDTA (7). A comparison of the results in Table 2 with those for 1,3-PDTA (7) reveals that, for a given metal ion, the metal–nitrogen bonding in the 1,4-BDTA complexes is slightly more labile, in support of the idea that it is easier for a larger chelate ring to open (15 and references therein). Further support is derived from the AB pattern for the acetate methylenic protons of $Cd(EDTA)^{2-}$ which shows no evidence of line broadening due to AB interchange up to 100 °C (7).

Comparing the results in Table 2 with those for $Cd(1,3\text{-}PDTA)^{2-}$ and $Zn(1,3\text{-}PDTA)^{2-}$ (7), it is seen that the difference in the lability of $Cd(1,3\text{-}PDTA)^{2-}$ and $Cd(1,4\text{-}BDTA)^{2-}$ is larger than that of the corresponding Zn(II) complexes. The difference in the thermodynamic stability of the Cd(II) complexes is also larger (3), suggesting that the larger decrease in thermodynamic stability of the Cd(II) series is due, at least in part, to the decreased kinetic stability.

Opening the chelate ring involves a twisting of the aliphatic chain linking the two nitrogen atoms. To estimate an upper limit for the rate at which an iminodiacetate segment of these ligands would be expected to dissociate, the rate constant for dissociation of one MIDA ligand from $Zn(MIDA)_2^{2-}$ was determined.

$$[1]\quad Zn(MIDA)_2^{2-} \underset{k_f}{\overset{k_d}{\rightleftarrows}} Zn(MIDA) + MIDA^{2-}$$

From n.m.r. line-broadening measurements of the type described previously (16), $k_d = 40 \pm 5\ s^{-1}$ and $k_f = (1.2 \pm 0.2) \times 10^8\ M^{-1}\,s^{-1}$ at 25 °C. Taking the inverse of the lifetimes before AB interchange to be half the first order rate constants for partial dissociation to form **4** (7), the partial dissociation rate constant for $Zn(1,3\text{-}PDTA)^{2-}$ is $0.69\ s^{-1}$ at 25 °C. The difference between k_d and this value might provide an estimate of the energy barrier associated with the necessary twisting of the aliphatic chain in the formation of **4** from $Zn(1,3\text{-}PDTA)^{2-}$.

Mercury Complexes

The 220 MHz p.m.r. spectrum of $Hg(EDTA)^{2-}$ is shown as a function of temperature in Fig. 2. At 23 °C, the acetate methylenic protons give rise to a multiplet composed of the AB part of an ABX pattern superimposed on an AB pattern. The AB part of an ABX pattern is due to the EDTA complex of ^{199}Hg, which has a nuclear spin of 1/2 and a natural abundance of 16.9%, while the AB pattern is due to the EDTA complexes of the other isotopes of mercury. The ethylenic protons give rise to the A_4 part of an A_4X pattern. The spectral parameters are summarized in Table 1.

The mercury–nitrogen bonding in $Hg(EDTA)^{2-}$ is more labile than in $Cd(EDTA)^{2-}$ as evidenced by the collapse of the multiplet pattern for the acetate methylenic protons of $Hg(EDTA)^{2-}$ at higher temperatures. Indeed, collapse of the mercury–proton coupling at 70 °C indicates complete dissociation of the complex at this temperature.

The acetate methylenic protons of $Hg(1,3\text{-}PDTA)^{2-}$, $Hg(1,4\text{-}BDTA)^{2-}$, and $Hg(MIDA)_2^{2-}$ give rise to similar multiplet patterns whose spectral parameters are given in Table 1. The lines in the multiplet pattern for $Hg(1,3\text{-}PDTA)^{2-}$, however, are only very slightly broadened at 70 °C, including the satellite lines due to mercury–proton coupling, while there is no detectable broadening in the pattern for $Hg(1,4\text{-}BDTA)^{2-}$. These results indicate that, in contrast to the Cd(II) and Zn(II) complexes, the order of lability of the mercury–nitrogen bonds is $Hg(EDTA)^{2-} > Hg(1,3\text{-}PDTA)^{2-} >$

[2]Dissociation of complexes of multidentate ligands proceeds via the stepwise dissociation of the individual metal–ligand bonds. The rate of AB interchange will depend on the fraction of the complex in the different partially coordinated forms. The fraction of the complex in the various partially coordinated forms presumably is temperature dependent, which would give rise to non-linear Arrhenius plots of the type obtained with the data in Table 2 (7).

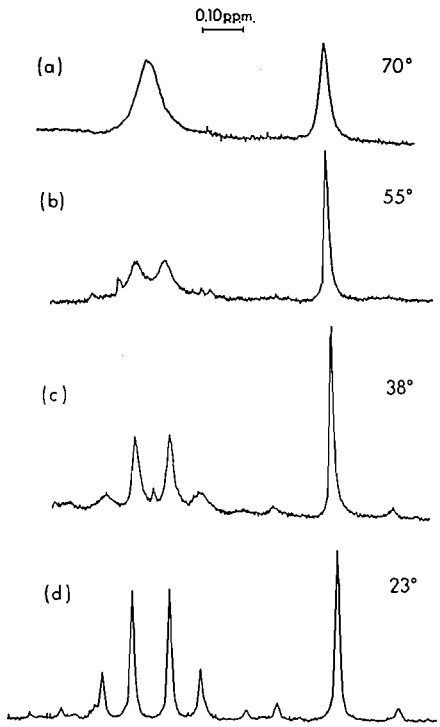

FIG. 2. Representative 220 MHz proton n.m.r. spectra of $Hg(EDTA)^{2-}$ in H_2O. The p*H* of the solution was 6.8 at 25 °C.

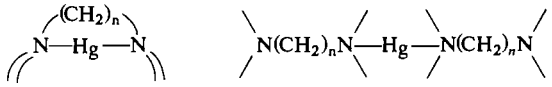
$Hg(1,4\text{-}BDTA)^{2-}$. Also, the coupling constants J_{AX} and J_{BX} for $Hg(1,3\text{-}PDTA)^{2-}$ and $Hg(1,4\text{-}BDTA)^{2-}$ are similar and somewhat larger than those for $Hg(EDTA)^{2-}$, suggesting that the structures of $Hg(1,3\text{-}PDTA)^{2-}$ and $Hg(1,4\text{-}BDTA)^{2-}$ are similar but different from that of $Hg(EDTA)^{2-}$. Specifically, the larger coupling in $Hg(1,3\text{-}PDTA)^{2-}$ and $Hg(1,4\text{-}BDTA)^{2-}$ indicates increased mercury s character in the mercury–nitrogen bonds which supports a more linear N—Hg—N arrangement as the size of the internal chelate ring increases (1). Two structures having the linear N—Hg—N arrangement are represented by **5** and **6**.



5 **6**

It is not possible to construct **5** from space filling molecular models, suggesting that coordination of Hg(II) to iminodiacetate segments of two ligands may be important in the mercury complexes of the higher homologs. An AB pattern for the acetate methylenic protons of $Hg(MIDA)_2^{2-}$, a model complex for **6**, indicates that the binding of an iminodiacetate segment by Hg(II) is sufficiently nonlabile to give the multiplet patterns observed for $Hg(1,3\text{-}PDTA)^{2-}$ and $Hg(1,4\text{-}BDTA)^{2-}$.

Summary

The decrease in the formation constants of the Cd(II) and Zn(II) complexes of **1** as the size of the internal chelate ring is increased from five membered to seven membered is accompanied by an increase in the lability of the metal–nitrogen bonds, suggesting that, in part at least, the smaller formation constants for the Cd(II) and Zn(II) complexes of the higher homologs of **1** are due to the decreased kinetic stability of these complexes. In contrast, the kinetic stability of the Hg(II) complexes of **1** increases as *n* is increased from two to three to four. Nuclear magnetic resonance coupling constant data suggests that this is accompanied by structural changes to more linear N—Hg—N bonding in the complexes of the higher homologs.

The Equivalent Conductivity of Aqueous Solutions of Salts of Carboxymethylcellulose: A Test of Manning's Limiting Law

JAN C. T. KWAK AND ALLAN J. JOHNSTON
Department of Chemistry, Dalhousie University, Halifax, Nova Scotia B3H 4J3
Received November 7, 1974

JAN C. T. KWAK and ALLAN J. JOHNSTON, Can. J. Chem. **53**, 792 (1975).

Measurements of the equivalent conductivity of aqueous solutions of lithium, sodium, potassium, and cesium salts of carboxymethylcellulose (CMC) at 25 °C are reported. The degree of substitution of the CMC used was 0.86, concentrations of the four salts were varied from 5×10^{-4} to 5×10^{-2} equiv l^{-1}. Results show a decrease of Λ with increasing concentration in each case. In the lower concentration range (up to 10^{-2} *N*) this decrease is in close agreement with a limiting law for conductivity recently developed by Manning. Above 10^{-2} *N* the decrease in Λ is less than the decrease predicted by the limiting law. The counterion dependence of Λ is accurately predicted by the theory, and a qualitative agreement is obtained when the theory is used to compare conductance data of polyelectrolytes with different charge densities.

JAN C. T. KWAK et ALLAN J. JOHNSTON. Can. J. Chem. **53**, 792 (1975).

On rapporte des mesures de la conductivité équivalente de solutions aqueuses de sels de lithium, de sodium, de potassium et de césium de carboxyméthylcellulose (CMC) à 25 °C. Le degré de substitution du CMC était de 0.86 et les concentrations des quatre sels variaient de 5×10^{-4} à 5×10^{-2} équiv par litre^{-1}. Dans chaque cas les résultats montrent qu'un abaissement de Λ se produit à mesure que la concentration augmente. Dans la zone de basse concentration (jusqu'à $10^{-2}N$), cet abaissement est en très bon accord avec une loi limite sur la conductivité récemment proposé par Manning. Au dessus de 10^{-2} *N*, l'abaissement de Λ est moindre que cellui prédit par cette loi. La relation de Λ avec l'ion antagoniste est bien prédite par la théorie et une relation qualitative est obtenue quand la théorie est utilisée pour comparer les données de conductivité de polyélectrolytes avec différentes densités de charge. [Traduit par le journal]

Introduction

The concentration dependence of the equivalent conductivity of polyelectrolyte solutions has been reported for polyacrylates and polymethacrylates (1, 2), polyvinylsulfonates (3), salts of carrageenan and of arabic acid (4, 5), sodium polystyrene sulfonate (6, 7), and for salts of quarternized polyvinylimidazole (8). In most cases Λ of polyelectrolyte salts decreases upon increasing the concentration, but some authors report Λ to be virtually independent of concentration (6), and in other cases a minimum in Λ is observed (4, 5, 7). The concentration dependence of Λ has normally been expressed by plotting $\Lambda - \Lambda^0$ as a function of $c^{1/2}$ and extrapolating to $c = 0$ to obtain Λ^0 of the polyelectrolyte, but in many cases this procedure led to ambiguities in the determination of Λ^0. Counterion condensation theory has shown that for polyelectrolytes with a charge density higher than a certain critical value some counterions are "condensed" on the polyion even at infinite dilution (9). Manning synthesized this counterion condensation effect and the electrostatic interactions of polyions and small ions to arrive at limiting laws for activity coefficients and osmotic coefficients (10–12). Manning's model assumes a rod-like polyion and point counterions, without interactions between different polyions or different segments of the same polyion. Application of this model to the conductance process in electrolyte solutions led to the following equation (11–13)

$$\Lambda = f(\lambda_c^0 + \lambda_p) \quad [1]$$

where f is related to the charge density parameter ξ (9, 10, 12) by

$$f = 0.87\,|z|^{-1}\,\xi^{-1} \quad [2]$$

z is the valency for the counterion, $\xi = e|\beta|/DkT$, $|\beta|$ is the charge in a unit-length of the polyelectrolyte cylinder, D the dielectric constant, k Bolzmann's constant, and T the temperature.

The appearance of λ_c^0 in eq. 1 expresses the fact that in this limiting law interactions between the uncondensed counterions are neglected. However, Debye–Hückel type interactions between the polyelectrolyte cylinder and the uncondensed counterions are taken into account,

which shows the inadequacy of treating f as the fraction of "free" ions. The conductance equation in the form of eq. 1 still contains the mobility of the polyion at finite concentration. In a recent paper, Manning (14) derived an expression for λ_p as a function of c, ξ, z, and λ_c^0. This expression allows us to calculate the complete concentration dependence of the equivalent conductivity of salt-free polyelectrolyte solutions, assuming the model on which the limiting laws are based is correct. Kwak and Hayes (15), and Scymczak, Holyk, and Ander (16) compared Manning's conductance equation to accurate data for a number of salts of polystyrenesulfonic acid. It was found that although the limiting law correctly predicted the counterion dependence when comparing polyelectrolyte salts with univalent counterions, the detailed concentration dependence in the low concentration range (below 0.01 N) was different for the two polymer samples studied. Above 0.01 N an increase in Λ was observed, whereas eq. 1 predicts a monotonous decrease in Λ with increasing concentration. These deviations from the limiting law were at least partially attributed to coiling of the polymer (15), causing the model on which the limiting law depends to break down.

It is the purpose of this investigation to compare data for the equivalent conductivity of salts of carboxymethylcellulose (CMC), a substituted polysugar with a less flexible polymer chain, to the limiting law values. The charge density of the CMC is much less than the charge density of the polystyrenesulfonates used in refs. 15 and 16, allowing for a check of the charge density dependence predicted by the limiting law. Although a report of the concentration dependence of Λ for salts of CMC has appeared (17), the values for Λ seem too high, in some cases well above 500 cm^2 ohm^{-1} $equiv^{-1}$! Rinaudo and Milas (18–20) report the equivalent conductivities of a number of salts of a high charge density CMC at one concentration (0.005 N) only. Conductance studies of salts of a few naturally occurring polysugars have been published (4, 5).

Experimental

Carboxymethylcellulose (Na-salt, Koch-Light Laboratories, Colnbrook, U.K.) was purified by repeated cation and anion exchange (Dowex 50W-X8 cation exchange resin and Dowex ANGA 542 anion exchange resin) and finally left in the H^+ form. The concentration of this stock solution was determined by titrating a weighed sample with NaOH. Weighed aliquots of HCMC were converted to the desired ionic form by adding the required amount of LiOH, NaOH, KOH, or CsOH, and finally adding the water needed to give a predetermined total weight of stock solution of each salt. This procedure is different from the one used for polystyrenesulfonates (15) and ensures that the concentrations of the different salt solutions are known relative to each other with a precision of $\pm 0.1\%$, even if the error in the actual concentration may be $\pm 1\%$. The pH of each stock solution was between 7 and 7.5. The equivalent weight of the CMC was determined by drying a weighed sample of known concentration under vacuum at 40 °C. The equivalent weight of HCMC was found to be 258 ± 2, of CsCMC 389 ± 3, corresponding to degrees of substitution of 0.85 and 0.86, respectively. In all calculations the value 0.86 will be used for the degree of substitution. Dilutions are made by weight using double distilled water ($\kappa = (1.0–1.1) \times 10^{-6}$ ohm^{-1} cm^{-1} at 25 °C). Densities of the more concentrated solutions were determined with a simple pycknometer (estimated accuracy ± 0.02%), and concentrations calculated from the known number of equiv/kg. Corrections were made for the conductance of the distilled water; for the lowest concentrations used this correction was less than 4%. No correction for hydrolysis was applied since the pH of each solution did not exceed 7.5. The conductance bridge, built around a Leeds and Northrup No. 1553 Campbell–Shackleton ratio box, and the constant temperature bath were the same as used in a previous investigation (15). Conductivity cells with cell constants 0.1527 ± 0.0001 cm^{-1} and 1.4492 ± 0.0004 cm^{-1} were used. Electrodes were lightly platinized, the reported conductivities were measured at 2000 cycles. The frequency dependence of the conductivity was determined for a few solutions. The measured conductivity increased less than 0.2% between 1 000 and 10 000 cycles.

Results and Discussion

The equivalent conductivities of Li, Na, K, and Cs carboxymethylcellulose (degree of substitution 0.86) at 25.0 °C as a function of the square root of the concentration are shown in Table 1. The results show the expected decrease in Λ over the complete concentration range studied (0.0006–0.05 N), and in this respect are markedly different from the polystyrenesulfonate salts. In Fig. 1 the experimental values for Λ (solid lines) are compared to the limiting law values for each salt, using eq. 1 (broken lines), with Manning's expression for λ_p (14). In calculating the theoretical curves, Robinson and Stokes' values for the limiting counterion mobility, λ_c^0, were used (21). Using a segment length of 5.15×10^{-8} cm (22), the charge density parameter ξ is calculated to be 1.20 (corresponding to 86% substitution per unit length of 5.15×10^{-8} cm) and $f = 0.73$. The theoretical value of λ_p, and thus of Λ, is depen-

dent on a, the radius of the polyelectrolyte cylinder. Obviously the assignment of a cylindrical radius to any polymer chain can only be a rough approximation at best, but fortunately λ_p is not strongly dependent on a, and the change in the concentration dependence of λ_p upon varying a between realistic values is small. A cylindrical radius of 7×10^{-8} cm was used in all cases. Typically, a variation of 2×10^{-8} cm in a causes a variation of about 5% in Λ, higher values of a leading to lower values of λ_p and Λ.

It can be seen that eq. 1, using Manning's expression for λ_p, gives an excellent representation of our data for different CMC salts. Qualitatively, the curves are in good agreement at all concentrations, and below 0.005 N the concentration dependence of calculated and experimental values are in quantitative agreement. It should be stressed that this agreement in both numerical value and slopes is obtained without the use of adjustable parameters. a is not an adjustable parameter, although a reasonable choice must be made for its actual value. The predicted variation of Λ upon changing the counterion is so close that if we choose a value of a to make the theoretical and experimental values for Λ of, *e.g.* NaCMC at a given concentration, coincide (*e.g.* $a = 8.5 \times 10^{-8}$ cm would do this at $c^{1/2} = 0.04$), eq. 1 would predict Λ of the three other salts within 1%. A similar good agreement for the counterion dependence was found in the case of polystyrenesulfonates.

In order to compare both the concentration dependence and the counterion dependence of experimental values for Λ to the limiting law, Manning (14) rearranged eq. 1 to give

$$[3] \qquad \bar{\Lambda} = -\log c + \text{constant}$$

where $\bar{\Lambda}$ is a function of ξ, Λ, λ_c^0, and c. An

Na-carboxymethylcellulose	1.20	0.005	7	68.3	66.8	This work

added advantage of this expression is that the cylindrical radius a of the polymer does not appear in $\bar{\Lambda}$. Equation 3 predicts that the $\bar{\Lambda}$'s calculated from the experimental values of Λ of different salts with the same valency counterion, when plotted against log c, should fall on a single straight line with unity slope. Although such a plot gives no information which is not already contained in Fig. 1, it does provide us with a convenient and indeed rather sensitive check of the limiting laws. Figure 2 shows this plot for the four CMC salts studied; the solid line indicates the theoretical slope only, the value of the constant in eq. 3 was not calculated. Again, we see that below 0.005 N the theoretical slope is closely obeyed. At higher concentrations the decrease in conductance is less than what is predicted by the limiting law, but the overlapping of points for the different salts shows again how closely the limiting law predicts the counterion dependence of Λ at all concentrations. In almost all cases the observed scatter in $\bar{\Lambda}$ for the four salts at the same concentration is within the limits of error of the experimental values. Deviations from the limiting slope in the case of polystyrenesulfonates (8) were attributed to coiling of this flexible vinylic polymer chain (15). The present results for the conductivity of a polyelectrolyte with a much more inflexible polymer backbone seem to support this contention. Deviations from the limiting law found at higher CMC concentrations may be due to a number of causes, including interactions between the uncondensed counterions, limited coiling of the polyion accompanied by a decrease in the degree of counterion condensation, and failing of the limiting law model of a freely draining cylinder.

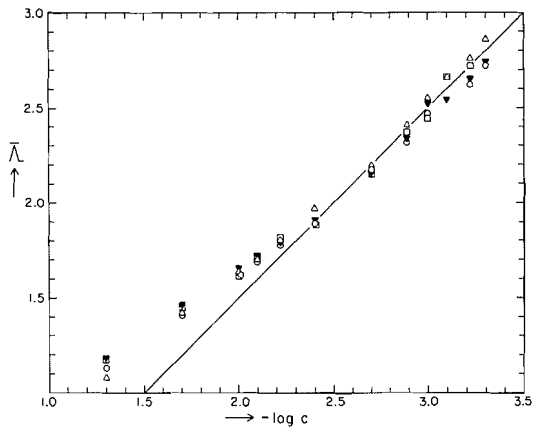

FIG. 2. $\bar{\Lambda}$ (eq. 3) *vs.* $-\log c$ for LiCMC (△), NaCMC (○), KCMC (□), and CsCMC (▼). Solid line: theoretical slope.

Equation 1 predicts the conductivity of any polyelectrolyte of finite concentration, with the charge density parameter, limiting counterion mobility, cylindrical radius, and concentration as the only variables. We have seen that this equation correctly describes both magnitude and concentration dependence of the four salts studied in this paper. The most important factor remaining is the dependence of Λ on the charge density parameter, ξ. In Table 2 we have listed calculated (eq. 1) and reported values of Λ for a number of polyelectrolytes selected to cover a range of ξ values. In discussing this table, it should be kept in mind that due to experimental conditions the uncertainty in the magnitude of Λ_{exp} in some cases may be as high as ± 2 units. Λ_{calc} is very sensitive to ξ, and therefore errors in the determination of the degree of substitution affect Λ_{calc} strongly. Also, the theory is meant to give a description of the concentration dependence of Λ rather than an *ab initio* prediction of its magnitude at a certain concentration. The qualitative agreement between Λ_{exp} and Λ_{calc} shown in Table 2 can largely be attributed to the calculation of the f parameter in eq. 1, and therefore is a qualitative confirma-

For personal use only.

tion of the calculated influence of counterion condensation on Λ. This justifies Manning's assumption of zero mobility for the condensed ions, and contradicts earlier theories in this respect (24).

Homogeneous Hydrogenation of Unsaturated Carboxylic Acids using Chlororhodate(I) Complexes and Rhodium(I) Diethylsulfide Complexes[1]

BRIAN R. JAMES AND FLORA T. T. NG[2]

Department of Chemistry, The University of British Columbia, Vancouver, British Columbia V6T 1W5

Received November 8, 1974

BRIAN R. JAMES and FLORA T. T. NG. Can. J. Chem. **53**, 797 (1975).

N,N-Dimethylacetamide solutions of the cyclooctene complex $[Rh(C_8H_{14})_2Cl]_2$, in the presence of excess chloride or diethylsulfide, are effective for the homogeneous hydrogenation of unsaturated carboxylic acids at *ca.* 80 °C and 1 atm H_2. Kinetic studies on the hydrogenation of maleic acid are consistent with a rate determining step involving oxidative addition of H_2 to square planar rhodium(I) olefin species. Rate constants and activation parameters agree with those determined previously from similar studies using corresponding rhodium(III) complexes and give confirmation that rhodium(I) catalysts are involved in the rhodium(III) systems. Discussion of the systems is limited by the somewhat uncertain nature of the catalysts; however, chlororhodate(I) species are involved in the chloride solutions, and bis(diethylsulfide) complexes appear likely in the sulfide systems.

BRIAN R. JAMES et FLORA T. T. NG. Can. J. Chem. **53**, 797 (1975).

Des solutions du complexe du cyclooctène, $[Rh(C_8H_{14})_2Cl]_2$, dans la *N,N*-diméthylacétamide, en présence d'excès d'ions chlorure ou de diéthylsulfure, sont efficaces pour l'hydrogénation homogène d'acides carboxyliques non-saturés à *ca.* 80 °C et 1 atm H_2. Les études cinétiques de l'hydrogénation de l'acide maléique sont en accord avec un mécanisme impliquant une étape déterminante de la réaction faisant appel à une addition oxydative de H_2 sur des espèces plan-carré de rhodium(I)-oléfines. Les constantes de vitesse et les paramètres d'activation sont en accord avec ceux déterminés auparavant lors d'études semblables utilisant les complexes correspondants du rhodium(III) et ces valeurs confirment que les catalyseurs au rhodium(I) sont impliqués dans les systèmes au rhodium(III). La discussion de ces systèmes est toutefois limitée due au fait que la nature de ces catalyseurs est un peu incertaine; toutefois des espèces de chlororhodate(I) doivent être impliquées dans les solutions contenant des ions chlorures et des complexes bis(diéthylsulfure) semblent probables dans le système au sulfure.

[Traduit par le journal]

Introduction

Earlier studies from this laboratory (1, 2) have reported on the homogeneous hydrogenation of olefinic substrates (especially unsaturated carboxylic acids) using *N,N*-dimethylacetamide (DMA) solutions of rhodium(III) chloride, and rhodium(III) sulfide complexes such as $RhCl_3(SR_2)_3$ (R = Et, CH_2Ph). Kinetic data in each case were interpreted in terms of a basic mechanism outlined in reactions 1–3.

$$[1] \qquad Rh^{III} + H_2 \xrightarrow{k_1} Rh^{I} + 2H^+$$

$$[2] \qquad Rh^{I} + \text{olefin} \xrightarrow{\text{fast}} Rh^{I}(\text{olefin})$$

$$[3] \qquad Rh^{I}(\text{olefin}) + H_2 \xrightarrow{k_2} [H_2Rh^{III}(\text{olefin})] \rightarrow Rh^{I} + \text{saturated product}$$

The systems were thought to involve initial hydrogen reduction to rhodium(I), which is stabilized by complexation to the olefin; subsequent reaction of the d^8 metal complex through oxidative addition of hydrogen leads to saturated product with regeneration of the rhodium(I) catalyst. Reactions 2 and 3 constitute a so-called and well-established "unsaturate route" for homogeneous catalytic systems involving square planar d^8 metal centers (ref. 3, p. 400).

Confirmation that rhodium(I) species are involved in the rhodium(III) systems has now been obtained by using rhodium(I) complexes directly (formed *in situ*), and comparing the kinetic data obtained with those for the rhodium(III) complexes. This paper reports on these studies; some of the work has been reported briefly elsewhere

(ref. 3, p. 275, ref. 4). Our failure to synthesize any rhodium(I)–R_2S complexes (R = alkyl or aryl) has limited our knowledge of the exact nature of the catalysts, but certain conclusions are drawn. In view of the well known poisoning of heterogeneous catalysts by sulfur compounds, the sulfur ligand systems are considered particularly interesting.

Experimental

Rhodium(III) trichloride was obtained as the trihydrate from Johnson Matthey Limited. The rhodium(I) cyclooctene dimer $[Rh(C_8H_{14})Cl]_2$, and the ethylene dimer $[Rh(C_2H_4)_2Cl]_2$, were prepared according to literature methods (5, 6).

Other materials used and the procedure used for following H_2 uptake at constant pressure have been described previously (1, 2).

Attempts to synthesize pure rhodium(I) complexes with R_2S type ligands (R = alkyl, phenyl, or benzyl) were unsuccessful, and such complexes do not appear to have been reported; procedures similar to those well-documented for synthesis of rhodium(I)–Group V ligand complexes were tried in various solvents (*e.g.* either from other labile Rh^I complexes, or from reaction of $RhCl_3 \cdot 3H_2O$ with the sulfide ligand in the absence or presence of added reducing agents). The rhodium(I) complexes were thus formed *in situ* by adding the appropriate ligand to DMA solutions of the labile dimeric rhodium(I) olefin complexes; the cyclooctene complex was especially useful since the ethylene complex decomposed slowly in the solid state (6). Addition of excess chloride or Et_2S to $[Rh(C_8H_{14})_2Cl]_2$ in DMA (Et_2S:Rh = 2) was shown by v.p.c. to liberate 2 mol of cyclooctene per mol of Rh. Such solutions were found effective for hydrogenation of maleic acid (MA) at 60–90 °C and 1 atm H_2.

Results

Spectral Studies

The $[Rh(C_8H_{14})_2Cl]_2$ dimer, **1**, is practically insoluble in DMA under vacuum or N_2 but it dissolves readily in the presence of excess chloride or Et_2S. For purposes of comparison with the previously studied rhodium(III) chloride system (1), a large excess of chloride (0.45 *M* LiCl) was used to form the *in situ* chlororhodate(I) species. An air-free solution of **1** ($\sim 10^{-3}$ *M*) in 0.45 *M* LiCl–DMA is red, and the visible spectrum is a continuum showing increasing intensity with decreasing wavelength ($\varepsilon = 230$ at 450 nm);[3] on adding a tenfold excess of MA, the spectrum slowly changed at room temperature, and a shoulder developed at 450 nm ($\varepsilon = 250$). Such spectral changes, accelerated at higher temperatures, are attributed to formation of a Rh^I(MA) complex; the complexing is "complete" at MA concentrations of 10^{-2} *M*, showing that the equilibrium constant for a reaction such as reaction 2 is $> 10^3\ M^{-1}$ at the hydrogenation conditions.

The DMA–LiCl solution of **1** in oxygen at 20 °C becomes brown due to formation of a 1:1 molecular oxygen complex (4) (Rh^IO_2;ν(0–0)895 cm^{-1}), and oxidation to higher valent rhodium species is slow. If H_2 is passed through the oxygenated solution at 80 °C for *ca.* 100 s, a red solution is obtained (longer reaction times produce some metal). The i.r. of this red solution shows a strong absorption at 1980 cm^{-1} and the disappearance of the 893 cm^{-1} band. No net gas uptake was observed, and reaction 4 is thought to occur

$$[4] \qquad Rh^IO_2 + H_2 \rightarrow Rh^{III}H_2 + O_2$$

The hydride solution was stable at 20 °C in air for several hours as evidenced from the i.r. spectra; we have been unable, however, to detect any proton signal by n.m.r. from 0–40τ. The same red hydride solution, which also showed a distinct shoulder at $\sim$475 nm (ε = 190) in the visible spectrum, could also be obtained on subjecting DMA–LiCl solutions of **1** to H_2 for a short time at 20 °C. In the presence of excess MA, however, the hydride solution was converted to the Rh^I(MA) solution; this change could be followed by visible spectroscopy at 20 °C and an isosbestic point was observed at 475 nm.

Finally, solutions of the Rh^IO_2 species under vacuum reacted with MA to again form the Rh^I(MA) species with liberation of O_2. Displacement by olefins of O_2 from d^8 molecular oxygen complexes has been noted by others (7).

During the conditions of catalytic hydrogenation (see below), the only species observed spectroscopically in solution was the Rh^I(MA) species, and this is consistent with the above findings. The Rh^I(MA) solutions reacted at 80 °C with O_2 to give finally orange solutions containing Rh^{III} chlorides with visible absorption maxima (1) at 440 nm (ε = 420) and 545 nm (ε = 125). The oxygen uptake corresponded to 0.5 mol O_2 per Rh, consistent with an oxidation of Rh^I to Rh^{III}.

Catalytic Hydrogenation

Stock solutions of **1** in 0.45 *M* LiCl–DMA

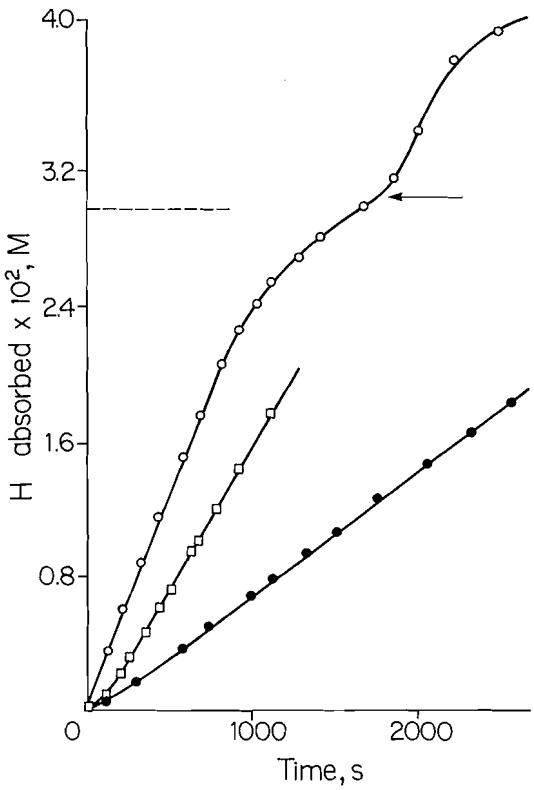

FIG. 1. Rate plots for catalytic hydrogenation of 0.03 *M* maleic acid in DMA at 80 °C, 725 mm Hg H_2 (2.32×10^{-3} *M*); ○, 5.0×10^{-3} *M* chlororhodate(I); ●, 1.8×10^{-3} *M* chlororhodate(I); □, 2.5×10^{-3} *M* rhodium(I) – diethyl sulfide; the dotted line shows the 1:1 stoichiometry for H_2:MA; the arrow marks the point of metal precipitation.

made up in air, were found to be efficient for the hydrogenation of MA at $\leq$ 1 atm H_2 around 80 °C. Typical H_2 uptake plots shown in Fig. 1 are essentially linear throughout, although the rate decreases in the regions where the ratio of H_2:MA approaches 1:1 and metal forms; a faster uptake followed metal production, and the stoichiometry for this faster reaction corresponds closely to that required for reduction of the cyclooctene. A short "autocatalytic" region was sometimes apparent at the start of the hydrogenations. In the absence of MA, metal was produced rapidly. The chlororhodate(I) solution did not hydrogenate cyclooctene homogeneously.

The kinetics for the chlororhodate(I) catalyzed hydrogenation of MA were obtained by measuring the long linear region of the uptake plots, and data are summarized in Table 1. The hydrogenation rate is seen to be first order in [Rh] and in $[H_2]$, and is independent of [MA] over the ranges of concentration used. The rate law is simply $k_2[\mathrm{Rh}][H_2]$, and the bimolecular rate constants (average = 2.1 M^{-1} s^{-1} at 80 °C) are also listed in Table 1. Data over the temperature range 70–80 °C give a good Arrhenius plot with activation parameters $\Delta H_2^{\ddagger} = 75.2 \pm 2.1$ kJ mol^{-1} and $\Delta S_2^{\ddagger} = -28.4 \pm 5.8$ J K^{-1} mol^{-1}.

The diethylsulfide catalyst was prepared *in situ* by adding Et_2S to **1** in DMA (Et_2S:Rh = 2; air was not excluded). The resulting orange-red solution was used to hydrogenate maleic, fumaric, and cinnamic acids following the same procedure used for the chlororhodate(I) solutions. Similar visible spectral changes were observed on adding MA to the catalyst solution although the initial Rh^I–Et_2S solution (ε = 460 at 450 nm) was more intensely colored than the chloride solution. The qualitative behavior of the H_2 uptake plots for MA hydrogenation (Fig. 1) was identical to that of the chloride solutions, and the kinetic dependences were found to be the same (Table 2). The average k_2 value at 80 °C is 2.85 M^{-1} s^{-1}, and the activation parameters are $\Delta H_2^{\ddagger} = 64.8 \pm 2.1$ kJ mol^{-1}, $\Delta S_2^{\ddagger} = -55.1 \pm 1.7$ J K^{-1} mol^{-1}. There was a small deuterium isotope effect ($k_2^H/k_2^D = 1.2$). Addition of (*a*), up to 0.05 *M* of the strong acid *p*-toluenesulfonic and (*b*), 0.05 *M* cyclooctene, or (*c*), a further mole of Et_2S, had little effect on the hydrogenation rate. Addition of LiCl significantly inhibited the catalysis; a constant k_2 value of 0.56 M^{-1} s^{-1} was obtained at 80 °C over a chloride concentration range of 0.01–0.125 *M*. In the absence of MA substrate, the Rh^I–Et_2S solutions were rapidly reduced by H_2 to the metal. The solutions were inactive for homogeneous hydrogenation of cyclooctene.

When a Rh^I–Et_2S solution was kept under N_2 at 80 °C for ~1 h, metal was formed, possibly through disproportionation (2). The molar conductances of stock catalyst solutions (0.2–5.0) $\times$ 10^{-3} *M* were about 1 ohm^{-1} cm^2 mol^{-1}; for 1:1 electrolytes in DMA, the values were 45–60 ohm^{-1} cm^2 mol^{-1}.

There was again evidence for formation of a molecular oxygen complex with the Rh^I–Et_2S system (8), but again under the hydrogenation conditions as for the chloride system, only a Rh^I–MA complex appeared to be present. It is of interest that the simple kinetics noted for the sulfide system were not observed for a series of

experiments in which the catalyst solutions were made up in the complete absence of oxygen. Under such conditions the rate plots for H_2 consumption analyzed for a first order dependence (*i.e.* on substrate), and the measured pseudo first order rate constants were approximately second order in [Rh] and between first and zero order in $[H_2]$.

Discussion

The k_2 values, activation parameters, and the isotope effects, are given in Table 3 with data for the Rh^{III} systems that we have studied previously. The activation parameters obtained for the Rh^{I}–Cl system are almost identical to those reported for the hydrogenation step in the $RhCl_3 \cdot 3H_2O$ catalyzed system in DMA–LiCl media, and offer convincing evidence for the same reactive Rh^{I} intermediates and the same rate determining step in both systems. The faster hydrogenation rates in the Rh^{I}–Et_2S system compared to the $RhCl_3(Et_2S)_3$ system is reflected in a lower $\Delta H_2^{\neq}$ value. However, different rhodium(I) species appear to be involved in these two systems since the ratio of Rh:Cl is different. On adding excess chloride (Cl:Rh $\geq$ 2) to the Rh^{I}–Et_2S system, which initially has one Cl per Rh, a lower limiting k_2 value of 0.56 M^{-1} s^{-1} is obtained and this is more comparable to the value of 0.33 M^{-1} s^{-1} for the $RhCl_3(Et_2S)_3$ system with three Cl per Rh. Studies on the $RhCl_3(Et_2S)_3$ system (2) showed that addition of chloride, or a strong acid, had no effect on the catalytic hydrogenation, again consistent with the present data.

The easy displacement of C_8H_{14} from $[Rh(C_8H_{14})_2Cl]_2$ has provided a general method for preparing other Rh^{I} complexes (5). The observed first order dependences on Rh give no evidence for a dimer $\rightleftharpoons$ monomer equilibrium, and indicate either that dimeric species are active or else the dimer dissociates completely to active monomer under the experimental conditions. There are a few examples of dimeric hydrogenation catalysts (ref. 3, p. 405, ref. 9), but monomeric catalysts seem highly likely in these DMA solutions with Et_2S or Cl^- cleaving the chloride bridges. Complexes such as $[Rh(CO)_2Cl]_2$ are readily cleaved by ligands, including the Cl^- ion (10), and the fact that the cyclooctene dimer is only slightly soluble in DMA but readily dissolves on addition of Cl^- or Et_2S supports monomer formation. The cyclooctene dissociates completely from the initial complex in solution, and hence Cl^-, Et_2S, or DMA will occupy the vacant coordination sites. Added cyclooctene did not interfere with the catalytic activity of such solutions. Wilkinson and coworkers (11) found that a benzene solution containing PPh_3 and $[Rh(C_8H_{14})_2Cl]_2$ (PPh_3:Rh = 3:1) gave the same kinetic results for olefin hydrogenation as using $RhCl(PPh_3)_3$ crystals in benzene.

As discussed for the previous studies using the rhodium(III) complexes (1, 2), the hydrogenations are thought to occur via the unsaturate route exemplified in reactions 2 and 3, rather than a hydride route which involves formation of a dihydride followed by reaction with olefin (ref. 3, p. 400). Indirect evidence for this is that in the absence of olefinic substrates the rhodium(I) complexes are rapidly reduced by H_2 to the metal: the sulfur ligands, for example, are weaker π-acceptors than triphenylphosphine and no stable hydrides are formed. An alternate scheme leading to the same overall kinetics is outlined in reactions 5 to 7.

$$[5] \qquad Rh^{I} + \text{olefin} \overset{K_1}{\rightleftharpoons} Rh^{I}(\text{olefin})$$

$$[6] \qquad Rh^{I} + H_2 \overset{K_2}{\rightleftharpoons} H_2Rh^{III}$$

$$[7] \qquad H_2Rh^{III} + \text{olefin} \overset{k}{\rightarrow} Rh^{I} + \text{products}$$

If K_1 is large, K_2 is small, and the Rh^{I}(olefin) complex is unreactive toward H_2, the rate law becomes $kK_2[H_2][Rh_{Total}]/K_1$. The factors governing metal precipitation, however, have not been studied, and whether the above scheme with undetectable but kinetically significant concentrations of Rh^{I} (or H_2Rh^{III}) would lead to metal production is not known with certainty. The hydride route has generally been favored for catalysis by the $RhCl(PPh_3)_3$ system which reduces *cis*-olefins faster than *trans*-olefins (maleate > fumarate), and this has been rationalized in terms of hindered approach of the substrate in a reaction such as [7] (12). The diethylsulfide system, however, reduces fumaric acid more effectively than maleic acid, and this is more readily interpreted in terms of reaction 3 involving a thermodynamically less stable Rh^{I}-

(fumaric acid) complex (8). The data in Table 3 are thus thought to refer to oxidative addition of H_2 to a square planar Rh^I–maleic acid complex.

The non-inhibition of rate on addition of one mole Et_2S to the Rh^I–Et_2S system is significant because this shows that a maximum of two sulfide ligands are coordinated per Rh. The previous work (2) had shown firstly that one Et_2S dissociated from $RhCl_3(Et_2S)_3$ prior to reduction of the complex to Rh^I, and secondly that addition of further excess sulfide had no effect on the subsequent catalytic hydrogenation. It is interesting to speculate on the nature of the various catalytic species. A likely species for reaction 3 in the Rh^I–Et_2S system is the neutral complex $RhCl(Et_2S)_2(MA)$, although we have been unable to isolate any pure Rh^I complexes from any of the catalytic systems; a maximum of one Cl per Rh can be involved, and the conductance measurements indicate no loss of chloride, at least in the absence of substrate. Several groups (13, 14) have shown that halide and not a diene ligand in complexes such as $[Rh(C_8H_{12})Cl]_2$ can be replaced in polar solvents by phosphine (L) to give solvated cationic species such as $[Rh(C_8H_{12})L_2]^+$; such species act as hydrogenation catalysts via initial dihydride formation (13). The diene ligand is presumably more strongly attached than the cyclooctene. The activation parameters for the Rh^I–Et_2S system are very similar to those reported for oxidative addition of H_2 to a number of neutral Vaska-type complexes $[IrCl(CO)L_2]$ in a range of solvents (ref. 3, p. 288), the negative activation entropy reflecting mainly the loss of translational entropy of the H_2 molecule upon coordination (15). The Rh^I–Et_2S system with added chloride could involve a less reactive $RhCl_2(Et_2S)(MA)^-$ complex, which could be the species formed *in situ* in the $RhCl_3(Et_2S)_3$ system, with addition of further chloride having little effect on reactivity as observed (2). The higher activation energy for this system is more comparable with those measured for the Rh^I–chloride systems, and these must involve anionic catalysts. These could be either $RhCl_3(MA)^{2-}$ or $RhCl_2(DMA)(MA)^-$ species. If the former, the data in Table 3 suggest decreasing reactivity toward H_2 in the trend $RhCl(Et_2S)_2(MA)$ > $RhCl_3(MA)^{2-}$ > $RhCl_2(Et_2S)(MA)^-$, which appears unlikely. The latter dichloro species thus appears more likely, and the resulting activity trend is then $RhCl(Et_2S)_2(MA)$ > $RhCl_2(DMA)(MA)^-$ > $RhCl_2(Et_2S)(MA)^-$. Oxidative addition reactions are known to be promoted by the presence of stronger σ-donors (15, 16), but in view of the limited knowledge of sulfide complexes (17) and the somewhat qualitative speculation concerning the nature of the catalytic species present, definite conclusions cannot be drawn. However, recent work from this laboratory (18) indicates that DMA is a more effective donor than chloride in some ruthenium(II) complexes (as regards reactivity toward H_2), and since chloride is a stronger donor than Et_2S (17) the relative reactivity order for the uni-negative anions seems reasonable.

The complex $RhCl_3(Et_3S)_3$ is inactive for hydrogenation in benzene solution because the initial hydrogen reduction process to Rh^I does not occur in the non-polar media (2). Wilkinson *et al.* (11) found that addition of Et_2S to $[Rh(C_8H_{14})_2Cl]_2$ in benzene (Et_2S:Rh = 2) gave inactive solutions for hydrogenation of cyclohexene, and during attempted hydrogenations the initially yellow solutions darkened during the exposure time. The results indicate that the stability and lability of the Rh^I(olefin)

complex are of paramount importance for activity of the system. Maleic acid is a better π-acceptor than cyclohexene and readily complexes with Rh^I, and the present work shows that maleic acid is hydrogenated homogeneously in preference to cyclooctene which fails to stabilize the Rh^I in DMA. Cyclooctene is similar to cyclohexene in its electronic properties and both are unlikely to stabilize Rh^I against reduction to the metal. Such reduction is almost certainly responsible for the darkening of the reaction solution noted in Wilkinson's paper. A corresponding diphenylsulfide system was said to exhibit some activity, before decomposition of the catalyst again occurred (11). If the Rh^I(olefin) complex is too stable, however, hydrogenation may not occur; this situation occurs in the case of attempted hydrogenation of tetracyanoethylene using Rh chlorides in DMA (1) and of tetrafluoroethylene using $RhCl(PPh_3)_3$ in benzene (12). An intimately related factor with these strong π-acid ligand systems is the increased electronic promotional energy necessary for the oxidative H_2 addition (12). The solvent also plays a critical role, since a maleic acid-stabilized chlororhodate(I) complex in aqueous 3 *M* HCl solution does not undergo reaction with H_2 according to reaction 3 (19). Factors for the promotion of this reaction in DMA are thought to be increased H_2 solubility, the donor power, and a possible lower dielectric constant for the non-aqueous media (1).

The short "autocatalytic" region sometimes observed at the start of the catalytic hydrogenations is attributed to some O_2 evolution from the oxygen complex (reaction 4) present in the stock catalyst solutions. The sulfide system, like the chloride system, does catalyze the oxidation of the amide solvent via an oxygen complex (4, 8), although the spectroscopic studies described for the chloride system were not carried out for the sulfide system. No autocatalytic region was observed in the hydrogenations when the catalyst solutions were made up in the absence of air, and this is consistent with O_2 having an initial deactivating effect by occupying a coordination site required for hydride or olefin. Hydrogenations catalyzed by square planar d^8 metal tertiary phosphine complexes may be markedly enhanced by the presence of traces of O_2 due to oxidation of the phosphine to non-coordinated phosphine oxide and the concomitant production of a vacant coordination site (20). Such an effect is not involved in the present Rh^I systems, as demonstrated by the good reproducibility of kinetic data, and the good agreement with data obtained from the Rh^{III} systems from which air was excluded entirely. The complex kinetic data obtained for the Rh^I–Et_2S system using the air-free catalyst solutions were therefore surprising, and are difficult to explain. The approximate second order dependence on Rh suggests that some monomer ⇌ dimer equilibrium might be involved; oxygen and a time factor could be important in promoting formation of monomeric species in the stock solutions. Some complex kinetics were observed in the $RhCl_3 \cdot 3H_2O$ catalyzed hydrogenation of MA in DMA in the absence of LiCl and these were interpreted in terms of dimeric Rh^I(MA) species.

The stoichiometric oxidation of the Rh^I(MA) complexes by O_2 at 80 °C to Rh^{III} suggests that such species will not be effective for catalytic oxygenation of olefinic substrates (21).

We thank the National Research Council of Canada and the University of British Columbia for financial support, Johnson Matthey Ltd., for loan of the rhodium, and a referee for helpful comments.

Photocyclization Reactions of Aryl Polyenes. IX.[1] The Photocyclization of Stilbenecarboxaldehydes and 1-Formylphenyl-4-phenyl-1,3-butadienes

CARL MANNING AND CLIFFORD C. LEZNOFF
Department of Chemistry, York University, Downsview, Ontario M3J 1P3

Received September 10, 1974

CARL MANNING and CLIFFORD C. LEZNOFF. Can. J. Chem. **53**, 805 (1975).

The photocyclization–oxidation reaction of 4-stilbenecarboxaldehyde gave 3-phenanthrenecarboxaldehyde. Similarly, irradiation of 3-stilbenecarboxaldehyde gave a mixture of 2- and 4-phenanthrenecarboxaldehyde. Irradiation of 1-(*p*-formylphenyl)-4-phenyl-1,3-butadiene gave a mixture of 1-(*p*-formylphenyl)naphthalene and 8-phenyl-2-naphthaldehyde. Photocyclization of 1-(*m*-formylphenyl)-4-phenyl-1,3-butadiene yielded 1-(*m*-formylphenyl)naphthalene, 5-phenyl-2-naphthaldehyde, and 8-phenyl-1-naphthaldehyde. The surprising nature of the photocyclization–oxidation reactions of stilbenes and 1,4-diphenyl-1,3-butadienes containing formyl substituents is discussed.

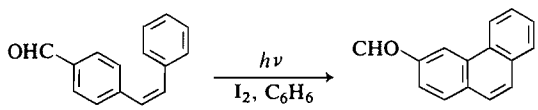
CARL MANNING et CLIFFORD C. LEZNOFF. Can. J. Chem. **53**, 805 (1975).

La photocyclisation oxydative du stilbènecarboxaldéhyde-4 donne le phénanthrènecarboxaldéhyde-3. De la même manière, l'irradiation du stilbènecarboxaldéhyde-3 donne un mélange de phénanthrènecarboxaldéhyde-2 et -4. L'irradiation du (*p*-formylphényl)-1 phényl-4 butadiène-1,3 donne un mélange de (*p*-formylphényl)-1 naphtalène et de phényl-8 naphtaldéhyde-2. La photocyclisation du (*m*-formylphényl)-1 phényl-4 butadiène-1,3 conduit au (*m*-formylphényl)-1 naphtalène, aux côtés du phényl-5 naphtaldéhyde-2 et du phényl-8 naphtaldéhyde-1. On discute de la nature surprenante des produits de photocyclisation oxydative des stilbènes et des diphényl-1,4 butadiènes-1,3 portant des substituants formyle. [Traduit par le journal]

Although the photocyclization-oxidation reaction of substituted stilbenes to substituted phenanthrenes is a well-known useful preparative procedure (1, 2), the reaction fails for *p*-acetylstilbene (3), nitrostilbenes (3), and the closely related 1-nitrophenyl-4-phenyl-1,3-butadienes (4). These latter failures have been rationalized in terms of the n–π* transitions of the carbonyl and nitro groups which interfere with the normal π–π* transitions responsible for the successful photocyclization reactions in other substituted stilbenes.

The related photocyclization–oxidation reactions of 1-substituted-phenyl-4-phenyl-1,3-butadienes to substituted 1-phenylnaphthalenes, where the substituents are methoxy, methyl, fluoro, chloro, and cyano, have also been reported (5) but in light of the previous failure of *p*-acetylstilbene to photocyclize, the photocyclization of the closely related stilbenecarboxaldehydes and 1-formylphenyl-4-phenyl-1,3-butadienes were not previously attempted. One isolated example of the surprisingly successful photocyclization–oxidation of 4,4′-stilbenedicarboxaldehyde has recently been reported from our laboratory (6) and has now been extended to cover a number of formylstilbenes and 1-formylphenyl-4-phenyl-1,3-butadienes.

Irradiation of 2.5×10^{-4} *M* solutions of 4-stilbenecarboxaldehyde (**1**), synthesized by our solid-phase method (7, 8), in dry benzene containing 5×10^{-4} *M* iodine gave, after 4 days, the known 3-phenanthrenecarboxaldehyde (**2**) (9) in 40% yield as shown in Scheme 1. Similarly,



1 **2**

SCHEME 1

irradiation of 3-stilbenecarboxaldehyde (**3**) (7) gave a mixture of 2-phenanthrenecarboxaldehyde (**4**) and 4-phenanthrenecarboxaldehyde (**5**) in 25% yields as shown in Scheme 2.

Fractional crystallization of the product mixture resulted in the isolation and separation of pure **4** and **5**, the former of which was compared with the known **4** prepared as previously des-

[1]For part VIII see ref. 6.

3 4 5

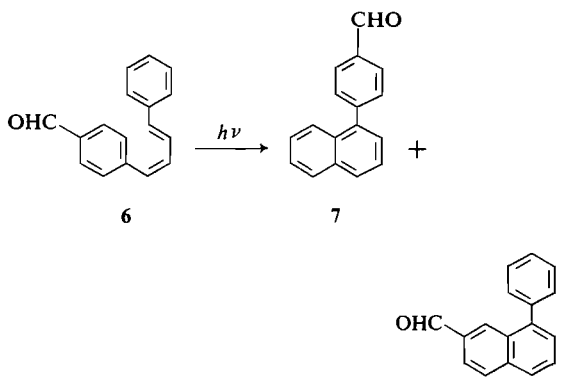
SCHEME 2

cribed (9) and the latter synthesized as described in the Experimental section. The ratio of **4** to **5** was approximately 10:1 based on the pure isolated compounds. Photocyclization of simple *m*-substituted stilbenes normally gives 2- and 4-substituted phenanthrenes in a 1:1 ratio (10), although photocyclization of *m*-hydroxystilbene yielded a 3:1 ratio of 2- to 4-hydroxyphenanthrenes (11).

In the photocyclization reactions of 1-substituted phenyl-4-phenyl-1,3-butadienes, there are two possible modes of cyclization, *i.e.* to the substituted or unsubstituted phenyl group. Although previous work (5) had established that the nature of the substituent had only minor influence (except for the fluoro substituent) on the direction of photocyclization, the reported failure of the photocyclization of the stilbene with an acetyl group led us to believe that the formyl group would either inhibit photocyclization or cause a dramatic influence on the direction of photocyclization.

Irradiation of 2×10^{-4} *M* solutions of 1-(*p*-formylphenyl)-4-phenyl-1,3-butadiene (**6**), prepared by our solid-phase method (7), in dry benzene containing 5×10^{-4} *M* iodine gave after 4 days a mixture of 1-(*p*-formylphenyl) naphthalene (**7**) and 8-phenyl-2-naphthaldehyde (**8**) in 35% yield as shown in Scheme 3.

Both **7** and **8** were synthesized by known procedures (9) from the appropriate methyl substituted aromatic compound. The n.m.r. spectrum of the synthesized **7** exhibited an absorption typical of an aldehydic proton at 10.00 p.p.m., whereas the aldehydic proton of synthesized **8** absorbed at 10.08 p.p.m. The n.m.r. spectrum of the mixture of **7** and **8** obtained by photocyclization of **6** exhibited appropriate absorption at 10.00 and 10.08 p.p.m., respectively, in an integrated ratio of 4:1, which strongly

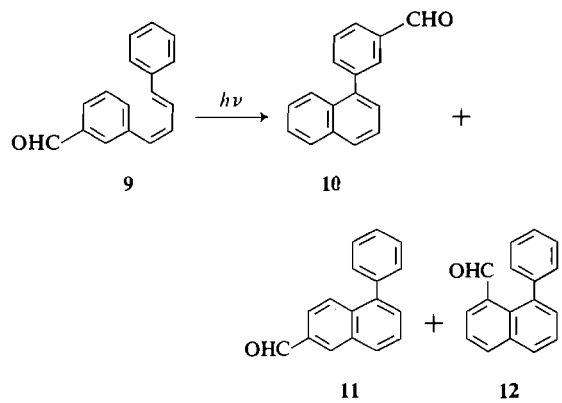


6 7 8

SCHEME 3

suggests that photocyclization occurs preferentially to the unsubstituted phenyl group of **6**.

Similarly, irradiation of 1-(*m*-formylphenyl)-4-phenyl-1,3-butadiene (**9**) (7) gave a mixture of 1-(*m*-formylphenyl)naphthalene (**10**), 5-phenyl-2-naphthaldehyde (**11**), and 8-phenyl-1-naphthaldehyde (**12**) in 40% yield as shown in Scheme 4.



9 10 11 12

SCHEME 4

The 220 MHz n.m.r. spectrum of the mixture of **10**, **11**, and **12** showed absorptions for aldehydic protons at 10.22, 10.42, and 10.02 p.p.m. The assignment of the absorption at 10.02 p.p.m. to the aldehydic proton of **12** is assured as only this aldehydic proton is shielded by the phenyl group at the 8 position of the naphthalene nucleus. In addition, it is expected that **12** would be formed in lowest yield as formation of **12** involves photocyclization to a hindered *ortho* position (5). An absolute assignment of the aldehydic absorptions at 10.22 and 10.42 p.p.m.

Compound	Yield (%)	Molecular formula	Analysis (%) Found C	Found H	Calculated C	Calculated H
5	3*	$C_{15}H_{10}O$	87.10	4.78	87.35	4.89
7	15	$C_{17}H_{12}O$	87.84	5.07	87.92	5.17
8	3	$C_{17}H_{12}O$	87.72	5.02	87.92	5.17

*The yield from photolysis of 3 was 2.5%.

must remain unresolved but together indicate the presence of **10** and **11**.[2]

The mass spectra of the photoproducts of **1** and **3**, *i.e.* **2** and **4** plus **5** respectively, all exhibited molecular ions at M^+ 206 and the expected fragmentation ions $M^+ - CHO$ at 177. The mass spectra of the mixtures of **7** plus **8** and **10** plus **11** plus **12** obtained from photocyclization of **6** and **9** respectively all exhibited parent ions at M^+ 232 and fragmentation ions $M^+ - CHO$ at 203, all consistent with the assigned structures.

Although the successful photocyclization–oxidation reactions of **1** and **3** to **2** and **4** plus **5**, respectively, are surprising, considering the fact that *p*-acetylstilbene did not photocyclize, several reports in the literature *do* suggest that aromatic aldehydes and ketones can react differently under photochemical conditions. The triplet state energies of acetophenone and benzaldehyde differ by ~2 kcal/mol (12, 13), the latter being lower. The lifetimes of the triplet states of benzaldehydes are shorter than the corresponding acetophenones (14).

Since it is highly likely that photocyclization occurs by way of an excited singlet state (15) and that the lifetimes of these states are comparable for the formyl and acetyl derivatives, the relative inefficiency of the acetyl derivatives to undergo photocyclization can be accounted for in terms of their long-lived triplet states. Thus the population of molecules in the triplet state is lower for the formyl derivatives than the acetyl derivatives. If all other effects are equal (intersystem crossing in aryl carbonyls occurs with unit efficiency), the relative population in the first excited singlet state of the formyl derivatives would be greater than acetyl derivatives.

Experimental

All m.p.'s were determined on a Kofler hot stage and are uncorrected. The i.r. spectra were recorded on a Unicam SP1000 spectrometer either as neat liquids or in a Nujol mull. The u.v. spectra were measured using a Unicam SP1800 spectrometer and cyclohexane as solvent. The n.m.r. spectra were measured on a Varian A60 spectrometer using tetramethyl silane as interval standard (δ = 0) and deuteriochloroform as solvent. The 220 MHz spectrum was recorded by the Ontario Research Foundation using a HR-220 Varian spectrometer. Mass spectra were measured on a Hitachi-Perkin-Elmer RMU-6 spectrometer. Both thin- and thick-layer chromatography were performed using silica gel as adsorbent and benzene as the eluant. All photochemical reactions were carried out in a Rayonet photochemical reactor using RPR-3500 Å lamps. Microanalyses were performed by Dr. C. Daesslé of Montreal.

[2]Several attempts were made to synthesize **10** and **11** unambiguously from 1-(*m*-tolyl)naphthalene and 6-methyl-1-phenylnaphthalene in the same way as **7** and **8** were prepared, but with no success. Other methods were also unsuccessful.

Irradiation of the Stilbenes and Butadienes

The irradiations of **1**, **3**, **6**, and **9** were carried out in a manner previously described (5). The mixtures of photoproducts were obtained as a single band on preparative thick-layer chromatography and the spectral data, given in Table 1, of these mixtures were obtained and compared with some of the products prepared by classical means.

4-Phenanthrenecarboxaldehyde (**5**), m.p. 88–91°, was separated from **4** by fractional crystallization from ether at 5° for 3 days. Synthetic **5**, m.p. 88–91°, did not show a depressed m.p. on admixture with **5** prepared by photolysis.

Synthesis of 4-Phenanthrenecarboxaldehyde (5), 1-(p-Formylphenyl)naphthalene (7), and 8-Phenyl-2-naphthaldehyde (8)

Compounds **5**, **7**, and **8** were synthesized from 4-methylphenanthrene (16), 1-(*p*-tolyl)naphthalene (17), and 7-methyl-1-phenylnaphthalene (18) by the known procedure of Cymerman–Craig *et al.* (9) and their spectral and analytical data are given in Tables 1 and 2, respectively.

The authors gratefully acknowledge the help of the Atkinson Charitable Foundation for a grant in aid of this research, the Ontario Research Foundation for running the 220 MHz n.m.r. spectrum, and Dr. E. Lee-Ruff and a referee for helpful suggestions.

Fluorinated Alkoxides. Part VIII. Mixed Ligand Complexes of Perfluoropinacol with Ni^{2+}, Pd^{2+}, Pt^{2+} and Cu^{2+}. Solvation Equilibria between 4- and 5-coordinate Ni^{2+}

W. Stafford Cripps and Christopher J. Willis

Department of Chemistry, University of Western Ontario, London, Ontario N6A 3K7

Received October 24, 1974

W. Stafford Cripps and Christopher J. Willis. Can. J. Chem. **53**, 809 (1975).

Perfluoropinacol, $(CF_3)_2C(OH)C(OH)(CF_3)_2$, ionizes by loss of two protons, and the resulting dinegative ion (PFP^{2-}) chelates to Ni^{2+}, Pd^{2+}, Pt^{2+}, and Cu^{2+}. A variety of stable neutral complexes may be isolated if the tetracoordination of the metal ion is completed with two monodentate or one bidentate nitrogen- or phosphorus-containing ligands; square-planar structures are invariably found. The structures of these complexes are contrasted with those of analogous halides, and it is concluded that electronic effects are predominant in determining them, although steric influences may sometimes be important. The ligand field strength of the perfluoropinacolato ion is approximately equal to that of the thiocyanate ion.

The nickel complexes $Ni(PFP)_2^{2-}$ and $(PFP)Ni(RNHCH_2CH_2NHR)$ react with donor solvents (water, methanol, pyridine, etc.) to give equilibria between four- and five-coordinate solvated species; six-coordinate species are not observed. This unusual behavior is attributed to the steric hindrance imposed by the bulk of the PFP^{2-} ligand.

W. Stafford Cripps et Christopher J. Willis. Can. J. Chem. **53**, 809 (1975).

Le perfluoropinacol, $(CF_3)_2C(OH)C(OH)(CF_3)_2$, s'ionise par perte de deux protons et l'ion dinégatif qui en résulte (PFP^{2-}) se chélate au Ni^{2+}, au Pd^{2+}, au Pt^{2+} et au Cu^{2+}. On peut isoler une variété de complexes neutres stables si la tétracoordination de l'ion métallique est complétée par deux ligands monodentates ou un ligand bidentate contenant de l'azote ou du phosphore; on trouve invariablement des structures plan-carré. Les structures de ces complexes sont en opposition avec celles des halogénures analogues et on en conclut que les effets électroniques sont prédominants dans leur détermination quoique des influences stériques peuvent quelquefois être importantes. La force du champ de ligand des ions perfluoropinacolato est approximativement égale à celle de l'ion thiocyanate.

Les complexes de nickel $Ni(PFP)_2^{2-}$ et $(PFP)Ni(RNHCH_2CH_2NHR)$ réagissent avec des solvants donneurs (eau, méthanol, pyridine etc.) pour conduire à des équilibres entre des espèces solvatées et tétra ou pentacoordonnées; on n'observe aucune espèce hexacoordonnée. On attribue cette attitude anormale à des facteurs stériques imposés par la grosseur du ligand PFP^{2-}.

[Traduit par le journal]

We have previously demonstrated the value of perfluoropinacol, $HOC(CF_3)_2C(CF_3)_2OH$ (H_2PFP),[1] as a ligand to first-row transition metals (*1*). Because of the acidity of the two protons, resulting from the fluorination of the molecule, perfluoropinacol coordinates to transition metal ions as the chelating dianion, $[OC(CF_3)_2C(CF_3)_2O]^{2-}$ (PFP^{2-}), and stable complexes of Al^{3+}, VO^{2+}, CrO^{3+}, Mn^{3+}, Fe^{3+}, Co^{2+}, Ni^{2+}, Cu^{2+}, and Zn^{2+} have been prepared by reaction in solution and isolated. An analogous chelate is the oxalate ion, and the complexes $[Fe(C_2O_4)_3]^{3-}$ and $[Fe(PFP)_3]^{3-}$ appear to be similar. However, the coordination of oxalate is complicated by the possible bidentate mode of attachment of each carboxylate group, so the PFP dianion offers a useful example of an unambiguously bidentate, dinegative ligand. The resemblance between a fluorinated ligand and a halide ion has been noted elsewhere (*2*) and we find many similarities between the complexes formed by PFP^{2-} and those formed by a pair of chloride ions. This approach, in fact, is probably more useful than the formalism of comparing PFP^{2-} derivatives with alkoxides, since the fluorination of the alcohol confers on H_2PFP properties quite different from those of an unfluorinated alcohol. Our aim has therefore been to prepare a number of metal complexes of PFP^{2-} and compare their properties with analogous halide derivatives.

Those complexes which we have previously reported have been anionic species containing two or three PFP^{2-} ions. In the present work, we describe some neutral mixed ligand complexes in which one PFP^{2-} chelate and one or more

[1]Throughout this paper, we abbreviate the name of this compound to H_2PFP and its dianion to PFP^{2-}.

neutral ligands are attached to a dipositive metal ion. Many of these are compounds of nickel, where the extensive known chemistry of analogous halide derivatives has shown the possibility of various geometries of coordination for this element. We have also studied some PFP^{2-} complexes of copper(II), palladium(II), and platinum(II).

Previous work on nickel(II) has demonstrated the existence of complexes with octahedral, square planar, and tetrahedral geometries. The last description has been generally applied to a class of nonplanar, four-coordinate, paramagnetic species, even when the structure departs from strictly tetrahedral symmetry; we shall follow that practice. The tetrahalo-ions $[NiX_4]^{2-}$ (X = Cl, Br, I) are tetrahedral, whereas the phosphine–halo complexes $(R_3P)_2NiX_2$ are generally *trans*-square planar for trialkylphosphines and tetrahedral for triarylphosphines. With mixed alkyl–aryl phosphines, *e.g.* $C_2H_5P(C_6H_5)_2$, either or both geometries may be found, depending on the halide used and the conditions of reaction. Bidentate phosphines give *cis*-square planar structures.

The different geometries of coordination found in these compounds may be rationalized on either steric or electronic grounds, noting that the ligands of higher ligand field strength favor the square planar configuration in a d^8 system, and most workers have concluded that the latter effect is dominant. Although the bulkier phosphine ligands produce the tetrahedral configurations, the structures suggest that the greater degree of steric interaction is between the two halide ions. In $[(C_6H_5)_3P]_2NiCl_2$, for example, the P—Ni—P angle is 117°, while the Cl—Ni—Cl angle is 123° (3); the corresponding angles in $[(C_6H_5)_3P]_2NiBr_2$ are 110 and 126° (4). PFP^{2-} is a bulky ligand overall, but it should take up less space in the immediate coordination sphere of nickel than does a pair of halide ions. The O—Ni—O angle in the chelate ring of the square planar complex $[Ni(PFP)_2]^{2-}$ has been found to be 91° (5), so one might expect, on steric grounds, that a square planar configuration would be more likely for a phosphine–PFP nickel complex than for a phosphine–halo complex, even though a *cis*-configuration is imposed on the phosphines in the former.

We have therefore prepared a series of phosphine–PFP complexes of nickel and examined their properties. Compounds isolated were $[(C_2H_5)_3P]_2Ni(PFP)$, $[(CH_3)_2P(C_6H_5)]_2Ni(PFP)$, $[CH_3P(C_6H_5)_2]_2Ni(PFP)$, $[(C_6H_5)_3P]_2Ni(PFP)$, and (diphos)Ni(PFP) (diphos = 1,2-bis(diphenylphosphino)ethane). All five of these complexes are yellow-orange and diamagnetic, from which we conclude that they all have a *cis*-square planar configuration. A comparison of their electronic spectra in the solid state and in solution (Table 1) shows essentially no difference between the two, indicating that there is no appreciable interaction between molecules in the solid state; the bulky nature of the ligands would, of course, be expected to preclude polymerization.

The availability of structurally similar complexes of halide ions and PFP^{2-} enables us to compare the ligand field strengths of these anions. For the square planar complexes $[(C_2H_5)_3P]_2NiX_2$, the first transition is found at

the following wavelengths: I^- at 610 nm, Br^- at 542 nm, Cl^- at 490 nm, SCN^- at 450–525 nm, and $PFP^{2-}/2$ at 460 nm.

We therefore place PFP^{2-} approximately equal to SCN^- in the spectrochemical series, with a greater ligand field strength than the halide ions, and observations on other PFP^{2-} derivatives are consistent with this assessment (6). The square planar geometry of the PFP^{2-} derivatives of nickel(II) is therefore entirely consistent with the greater ligand field strength, as compared with halide ions, so we cannot distinguish between steric and electronic effects in this series.

In an attempt to elucidate this point further, we have prepared nickel(II) complexes with PFP^{2-} and nitrogen donors. Unidentate bases such as pyridine or triethylamine were found to be unsuitable for the preparation of neutral complexes of the type $(R_3N)_2Ni(PFP)$, giving instead ionic salts $[R_3NH^+]_2[Ni(PFP)_2{}^{2-}]$. However, the use of tetra-*N*-alkyl substituted diamines such as tetramethylethylenediamine (TMED) or tetraethylethylenediamine (TEED) gave the desired complexes (TMED)Ni(PFP) and (TEED)Ni(PFP). As with the phosphine complexes, these were diamagnetic, and we therefore assume them to be *cis*-square planar, both in the solid and in solution.

In comparing these with the corresponding dihalide complexes, the position is more complicated than was the case for the phosphine complexes, since octahedral geometry occurs. $(TMED)NiCl_2$ contains octahedrally coordinated nickel in the solid state, presumably through bridging halide ions, and an octahedral–tetrahedral equilibrium exists in solution (7). The dibromide and di-iodide are exclusively tetrahedral, while the thiocyanate complex $(TMED)Ni(NCS)_2$ is insoluble and octahedral with bridging-NCS groups. It would seem likely that the occurrence of tetrahedral geometry in monomeric $(TMED)NiCl_2$ is the result of electronic, rather than steric, factors, since the metal readily increases its coordination to six by association of the complex, and the change to square planar coordination when PFP^{2-} replaces two Cl^- is consistent with the greater ligand field strength of the former. This view is confirmed by the persistence of square planar geometry in PFP^{2-} complexes when TMED is replaced by TEED or the even bulkier ligand $[C_6H_5CH_2(CH_3)NCH_2—]_2$.

The ligand 2,2′-bipyridyl (bipy) forms a series of complexes with nickel halides, with the nickel ion being uniformly six-coordinate. The compound $(bipy)_2NiCl_2$ is a monomeric nonelectrolyte (8), while $(bipy)NiCl_2$ is polymeric and octahedral through halide bridging (9); the corresponding bromides are similar (10). By contrast, we find the complex (bipy)Ni(PFP) to be monomeric and diamagnetic, and hence presumably square planar. It does not take up additional ligand to give $(bipy)_2Ni(PFP)$, nor does it form an octahedral dihydrate, as does $(bipy)NiCl_2$ (11). These results would be expected from the overall bulk of the PFP^{2-} ligand, which would tend to disfavor six-coordinate species. As for the configuration at the nickel atom in the four-coordinate complex, studies on many systems containing aromatic nitrogen donors and halide ions have shown a very fine balance between tetrahedral and square planar structures (12). Although the occurrence of the latter in (bipy)Ni(PFP) is entirely consistent with the greater ligand field strength of PFP^{2-}, the dominant effects here are probably the steric requirements of the chelating bipyridyl and PFP^{2-} rings.

Our general conclusion from a study of the nickel complexes formed by PFP^{2-} is that electronic effects make the more important contribution to determining whether 4-coordinate species adopt a tetrahedral or square-planar conformation. However, the bulk of the PFP^{2-} ligand effectively prevents the formation of a one-atom bridge between two metal ions (as commonly happens with halide ions), so the ready formation of complexes of six-coordinate nickel is prevented.

Solvation Effects and Five-coordinate Nickel

In the solid state, the nickel complexes of PFP^{2-} discussed above were invariably four-coordinate and square planar, but in several cases a change in the coordination number of the nickel through interaction with the solvent occurred in solution. For example, $K_2Ni(PFP)_2$, a purple solid, gave a yellow solution in water but purple solutions in dry methanol or ether; the latter became yellow on the addition of water. The visible spectra (Fig. 1) showed that the latter color was associated with the development of a strong absorption peak near 400 nm. By contrast, the red complex (TMED)Ni(PFP) showed no color change in a variety of solvents, suggest-

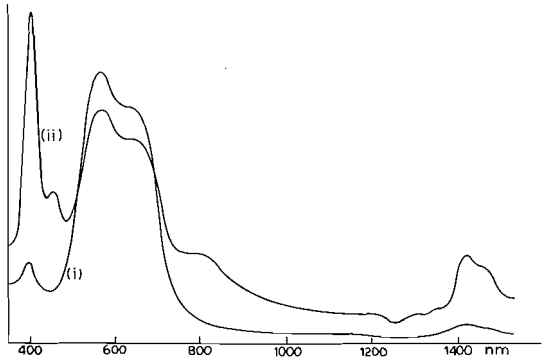

FIG. 1. Visible absorption spectrum of $K_2Ni(PFP)_2$ in (*i*) anhydrous ether, (*ii*) ether containing 1% water.

ing that the bulky tetra-*N*-alkylated ligand was preventing solvation.

Since the neutral diamine–PFP^{2-} complexes of nickel have favorable solubilities and are considerably more stable in solution than $Ni(PFP)_2^{2-}$ (which is decomposed by basic solvents), we prepared complexes using some *N*,*N*′-disubstituted diamines, in the hope that they would be less hindered and suitable for a study of solvation effects. The diamines *N*,*N*′-diethylethylenediamine (diethen) and *N*,*N*′-dibenzylethylenediamine (dibenzen) proved satisfactory, giving the complexes (diethen)Ni(PFP) and (dibenzen)Ni(PFP) as red diamagnetic solids giving red solutions in dichloromethane whose visible spectra showed a single absorption peak near 500 nm, very similar to those of the compounds (TMED)Ni(PFP) and (TEED)Ni(PFP). However, in the presence of coordinating solvents such as water, pyridine, or dimethylformamide (DMF), the solutions became green in color and the spectra changed, with the appearance of a peak at 370–390 nm. Spectra recorded in a range of solvent mixtures (Figs. 2 and 3) showed two isosbestic points, indicating that only two species were present. Pronounced thermochroic behavior was also shown, *e.g.*, the DMF solution of (dibenzen)Ni(PFP), reddish-brown at 25°, became bright green on cooling, while a methanolic solution, containing sufficient water to produce a green color at 25°, reverted to red on heating. A purple solution of $K_2Ni(PFP)_2$ in anhydrous methanol became yellow on cooling to −80°.

Although the majority of square planar nickel(II) complexes become six-coordinate if they undergo solvation, the appearance of these

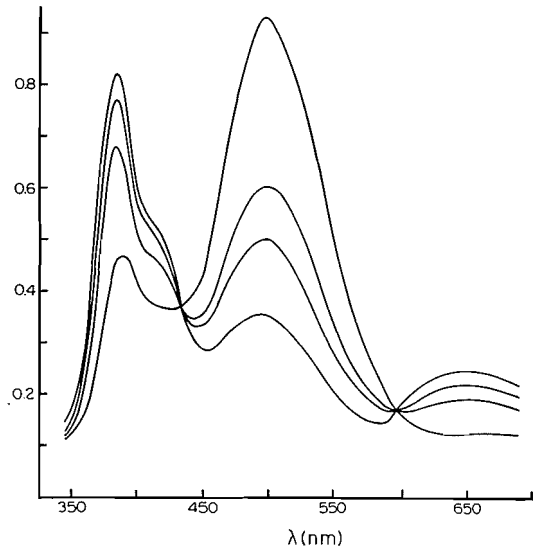

FIG. 2. Visible absorption spectra of (dibenzen)Ni(PFP) in water/methanol mixtures.

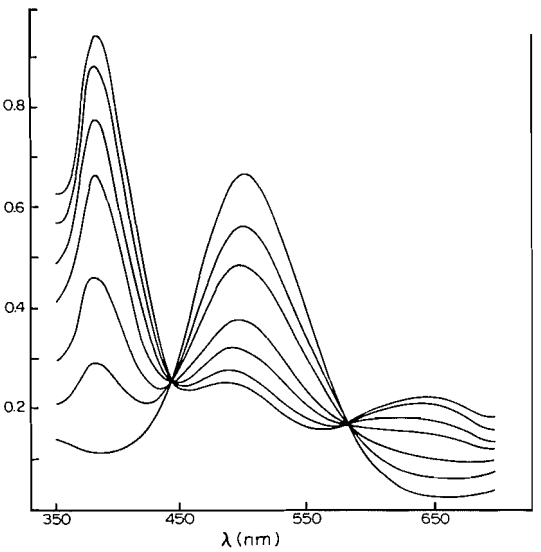

FIG. 3. Visible absorption spectra of (dibenzen)Ni(PFP) in pyridine/dichloromethane mixtures.

spectra suggested that, in this case, we were observing five-coordination. In support of this, we estimated the ratio of solvated to unsolvated species in mixed solvent from optical densities, and found this to be directly proportional to the concentration of donor solvent, as would be expected from an equilibrium of the type

$$\text{(dibenzen)Ni(PFP)} + \text{L} \rightleftharpoons \text{(dibenzen)NiL(PFP)}$$

The formation of the solvated complex is, in each case, favored by a decrease in temperature. As additional support for our suggestion that these solutions contain five-coordinate nickel, we prepared a neutral complex of Ni^{2+} with PFP^{2-} and the tridentate ligand diethylenetriamine, $NH_2CH_2CH_2NHCH_2CH_2NH_2$ (DETA). The product, (DETA)Ni(PFP), was a stable green solid, differing from the complexes prepared previously by being paramagnetic (μ_{eff} = 3.14 B.M.). It was a nonelectrolyte in methanol solution, eliminating the possibility that it could be the ionic compound $[Ni(DETA)_2]^{2+}[Ni(PFP)_2]^{2-}$, and its visible spectrum was very similar to those of our postulated five-coordinate solvates, and also to those of such well-characterized five-coordinate species as $ClNiN[CH_2CH_2N(CH_3)_2]_3 \cdot Cl$ (13). We therefore conclude that (DETA)Ni(PFP) is a monomeric species containing five-coordinate, highspin, nickel(II), whereas the analogous halide complexes (DETA)NiX_2 (X = Cl^-, Br^-), are dimeric through halide bridging and contain octahedral nickel (14).

The visible spectrum of (diethen)Ni(PFP) in dichloromethane solution containing benzylamine was very similar to that of (DETA)Ni(PFP), apart from a residual peak at 500 nm due to remaining four-coordinate species, supporting our suggestion that they are structurally alike.

The behavior of (diethen)Ni(PFP) and (dibenzen)Ni(PFP) in solution shows that they form five-coordinate 1:1 adducts with a wide variety of ligands. Ready addition occurs with good donors (water, pyridine, primary amines), which interact strongly even in low concentration, while poorer donors (methanol, ether, DMF) only give adducts in high concentrations or at low temperatures. Bulkier ligands (tertiary amines or phosphines) show no sign of interaction. Within the limitations imposed by its stability, the behavior of $Ni(PFP)_2{}^{2-}$ is similar. The restriction of solvation to a single molecule of ligand is clearly due to the bulk of the PFP^{2-} ion. Examination of molecular models shows that a distortion of the planar arrangement, which would be expected to accompany the attachment of one solvent molecule, produces a conformation of the PFP^{2-} ligand in which the CF_3 groups offer considerable hindrance to the sixth coordination site. However, it is surprising that there is insufficient room even for a second molecule of water, and this appears to be the first reported example of an equilibrium between square-planar and five-coordinate geometry for nickel associated with the addition of one water molecule.

In previous work, an equilibrium involving five coordination has been seen in the addition of pyridine to the square-planar bis(diethyldithiophosphato)nickel (15), but that system was also in equilibrium with the octahedral complex formed by the addition of a second pyridine molecule. In our studies so far, we have not seen any evidence for a six-coordinate species. It is hoped that additional information on these novel equilibria will be obtained from quantitative studies now in progress.

Copper Complexes

In the synthesis of neutral PFP^{2-} complexes of copper(II), we found *N*-alkyl substituted ethylenediamines to be the most useful co-ligands, and the complexes (TMED)Cu(PFP) and (TEED)Cu(PFP) were prepared. On the basis of their visible absorption spectra (Table 1), we suggest a square-planar configuration for these compounds. Both showed a single, broad, absorption near 550 nm with $\varepsilon \approx 60$. The spectrum did not alter when the solvent was changed from dichloromethane to methanol, showing that the latter was not coordinating to the metal.

The analogous halogen complexes (TMED)$CuCl_2$ and (TMED)$CuBr_2$ have similar absorption spectra with peaks at 700 nm (ε = 144) and 752 nm (265), respectively ($C_2H_4Cl_2$ solution) (16), which the authors consider to be consistent with an essentially planar structure, and the shift to higher energy in the position of the absorption with PFP^{2-} complexes is consistent with the greater ligand field strength of this ligand in a similar structure. However, this evidence is not strong enough to preclude some distortion from a planar configuration in the PFP^{2-} derivatives.

Palladium and Platinum Complexes

The PFP^{2-} ligand is obviously a "hard" base, in view of its structure and its ready coordination to such hard acids as Fe^{3+}, Al^{3+}, VO^{2+}, and CrO^{3+}. It would therefore be expected to show a lesser tendency to complex with the softer acids Pd^{2+} and Pt^{2+}, and our experiments have confirmed this. We were unable to prepare the anionic complexes $[Pd(PFP)_2]^{2-}$ or $[Pt(PFP)_2]^{2-}$ under conditions where Ni^{2+} readily reacted. However, the mixed ligand phosphine complexes

$[(CH_3)_2PC_6H_5]_2M(PFP)$ (M = Pt, Pd) were readily prepared from H_2PFP and the phosphino-dichlorides.

A number of analogous complexes of Pd^{2+} and Pt^{2+} have been reported, in fact the fluorinated derivatives of these metals are more numerous than their hydrocarbon analogs, where alkoxides are uncommon (17). Reaction of zerovalent metal complexes L_4M with hexafluoroacetone gives the 3-membered ring complexes $L_2\overline{MOC(CF_3)_2}$, which undergo further reaction in some cases (depending on the nature of L and M) with a second molecule of ketone to give $L_2\overline{MOC(CF_3)_2OC(CF_3)_2}$ (18, 19). The palladium(II) complex $[(C_2H_5)_3P]_2Pd(PFP)$ has been prepared by the reaction of $[(C_2H_5)_3P]_2Pd(CH_3)_2$ with H_2PFP (19), while platinum forms the unusual complex $[(C_6H_5)_3P]_2\overline{PtOC(CF_3)_2O}$, a derivative of hexafluoropropane-2,2-diol containing a four-membered chelate ring (20).

Our preparation of a stable PFP^{2-} complex of platinum demonstrates that this system is capable of existence. The fact that it is not formed in the reaction of low-valency metal complexes with hexafluoroacetone, whereas the reduction of the ketone with alkali metals (21), triethyl phosphite (22), or 2-propanol (23) leads readily to the formation of the C—C bond, has been rationalized by Stone (18) in terms of "head-to-tail" dimerization of two molecules of ketone coordinated to the same transition metal atom.

Experimental

General

Volatile compounds were handled in a conventional vacuum system. Infrared spectra were recorded on a Beckman IR-10 instrument; u.v.–visible spectra on Beckman DK or Cary 14 instruments. Microanalyses (Table 2) were performed by Alfred Bernhardt Laboratories, West Germany.

Perfluoropinacol

Caution: attention should be given to the toxic nature of this compound (23).

The most suitable method of preparation for large quantities of perfluoropinacol was found to be that based on triethylphosphite as a reducing agent (22). In a typical reaction, triethylphosphite (125 g, 0.75 mol) was cooled to 0 °C and gaseous hexafluoroacetone passed in with constant stirring, until the weight gain indicated uptake of the stoichiometric amount (1.50 mol), over a period of about 2 h.

To the resulting phosphorane was slowly added concentrated sulfuric acid (90 ml), followed by water (90 ml), stirring throughout. The solution was heated under reflux for 2 h to complete hydrolysis, then a further 50 ml of sulfuric acid added. The cooled mixture was repeatedly extracted with dichloromethane, the extract dried ($MgSO_4$), and fractionally distilled to yield crude perfluoropinacol, b.p. 110–130 °C. The product was redistilled from concentrated sulfuric acid to give anhydrous perfluoropinacol (215 g, 0.64 mol, 85% yield, b.p. 129–130 °C, m.p. 28–29 °C).

Nickel Complexes

The same general route was employed for the majority of the mixed-ligand Ni–PFP complexes. In a typical experiment, triethylphosphine (2.0 g, 17 mmol) was added slowly under nitrogen to a water–methanol solution of nickel nitrate hexahydrate (2.6 g, 8.9 mmol) and perfluoropinacol (2.8 g, 8.4 mmol). A solution of potassium hydroxide in methanol was then added dropwise with stirring to p*H* 8, and the resulting orange precipitate recrystallized from methanol/water to give bis(triethylphosphine)perfluoropinacolatonickel(II), m.p. 181°.

The same method gave:

$[(CH_3)_2P(C_6H_5)]_2Ni(PFP)$, orange, m.p. 132–133°, from methanol/water.

$[CH_3P(C_6H_5)_2]_2Ni(PFP)$, orange, m.p. 172–173°, from ethanol.

$[(C_6H_5)_2PCH_2—]_2Ni(PFP)$, golden, m.p. 228°, from methanol/water.

$[(C_6H_5)_3P]_2Ni(PFP)$. This preparation was carried out in *t*-butyl alcohol and the orange product recrystallized from chloroform/pentane, m.p. 208°.

$[(C_2H_5O)_3P]_2Ni(PFP)$. This complex could not be prepared directly, but was made by the reaction of excess triethyl phosphite with $K_2Ni(PFP)_2$ in aqueous ethanol, followed by reduction in volume and recrystallization of the precipitated product from dichloromethane/pentane.

(TMED)Ni(PFP), red, m.p. 232°, from methanol.

(TEED)Ni(PFP), magenta, m.p. 239–240° (decomp) from methanol.

(bipy)Ni(PFP), orange–brown, m.p. 280° (decomp) from ethanol/water.

The above nine complexes were diamagnetic and each showed a single peak in its ^{19}F n.m.r. spectrum in the range 70.6–71.3 p.p.m. from $CFCl_3$.

(DETA)Ni(PFP), green, m.p. 242–245° (decomp) from methanol. This complex was paramagnetic with μ_{eff} = 3.14 B.M. at 25°. It was a nonelectrolyte in methanol solution.

Palladium and Platinum Complexes

Dichlorobis(dimethylphenylphosphino)palladium(II) (0.30 g, 0.66 mmol) and H_2PFP (0.22 g, 0.66 mmol) were dissolved in methanol, and methanolic potassium hydroxide added to p*H* 8. The solution was evaporated to dryness and extracted with dichloromethane. Concentration of the extract gave $[(CH_3)_2P(C_6H_5)]_2Pd(PFP)$, off-white, m.p. 157° (decomp).

The platinum analog was similarly prepared; white, m.p. 174–175°.

Copper Complexes

TMED (1.20 g, 10.4 mmol) was slowly added to a solution of copper sulfate pentahydrate (2.0 g, 8.0 mmol) and H_2PFP (2.7 g, 8.1 mmol) in methanol/water, followed by methanolic potassium hydroxide to p*H* 8. The resulting purple precipitate was recrystallized from

acetone/water to give (TMED)Cu(PFP), m.p. 191–192° (decomp), μ_{eff} = 1.87 B.M./25°.

TEED similarly gave (TEED)Cu(PFP), purple, m.p. 195–197° (decomp), μ_{eff} = 1.87 B.M./25°.

Fluorinated Alkoxides. Part IX. The Resolution of Perfluoro(2,3-diphenylbutane-2,3-diol) and its use in preparing Optically Active Complexes of Ni^{2+} and Cu^{2+} [1]

W. Stafford Cripps and Christopher J. Willis

Department of Chemistry, University of Western Ontario, London, Ontario N6A 3K7

Received October 24, 1974

W. Stafford Cripps and Christopher J. Willis. Can. J. Chem. **53**, 817 (1975).

Perfluoro(2,3-diphenylbutane-2,3-diol), $CF_3(C_6F_5)C(OH)C(OH)(C_6F_5)CF_3$, prepared by the reductive dimerization of $C_6F_5COCF_3$, has been separated into *meso*- and DL-isomers and the latter resolved via its cinchonidine salt into optical enantiomers. The doubly ionized diol, $PDBD^{2-}$, acts as a dinegative, chelating, ligand, and neutral complexes of the form $(PDBD)ML_2$ may be isolated, where L is a neutral nitrogen- or phosphorus-containing ligand and $M = Ni^{2+}$ or Cu^{2+}. Use of the resolved diol enables optically active metal complexes to be prepared, and from their o.r.d./c.d. spectra we assign an absolute configuration to the diol. The partially fluorinated diols $CF_3(C_6H_5)C(OH)C(OH)(C_6H_5)CF_3$ and $CH_3(C_6F_5)C(OH)C(OH)(C_6F_5)CH_3$ have also been prepared from the appropriate ketones. The former, which appears to be exclusively the *meso*-isomer, has more limited chelating ability than the fully fluorinated analog, while the latter shows no ligand properties; these differences are ascribed to the reduced acidity resulting from the lower degree of fluorination.

Nuclear magnetic resonance studies suggest hindered rotation of the C_6F_5 groups through steric interaction with CF_3 groups in perfluoro(2,3-diphenylbutane-2,3-diol); an alternate explanation involving hydrogen bonding from the hydroxylic proton to aromatic fluorine atoms is considered less likely.

W. Stafford Cripps et Christopher J. Willis. Can. J. Chem. **53**, 817 (1975).

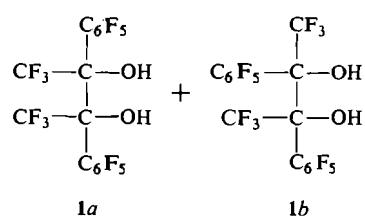
On a préparé les perfluoro (diphényl-2,3 butanediol-2,3), $CF_3(C_6F_5)C(OH)C(OH)(C_6F_5)CF_3$, par dimérisation réductrice de $C_6F_5COCF_3$; on a séparé les isomères *meso* et DL et ce dernier a été résolu en antipodes optiques par l'intermédiaire de son sel de cinchonidine. Le diol doublement ionisé, $PDBD^{2-}$ agit comme ligand dinégatif chélatant et on peut isoler des complexes neutres de la forme $(PDBD)ML_2$ dans lesquels L est un ligand neutre contenant de l'azote ou du phosphore et $M = Ni^{2+}$ ou Cu^{2+}. Si l'on utilise du diol résolu en antipodes optiques, on peut préparer des complexes métalliques optiquement actifs et en se basant sur les spectres o.r.d./c.d. on peut attribuer une configuration absolue au diol. On a aussi préparé, à partir des cétones appropriées, les diols partiellement fluorés $CF_3(C_6H_5)C(OH)C(OH)(C_6H_5)CF_3$ et $CH_3(C_6F_5)C(OH)C(OH)(C_6F_5)CH_3$. Le premier, qui semble être exclusivement l'isomère *méso*, a des propriétés chélatantes plus limitées que son analogue complètement fluoré alors que le dernier ne présente aucune propriété comme ligand; on attribue ces différences à une acidité réduite résultant du degré plus bas de fluoration.

Des études par résonance magnétique nucléaire suggèrent une rotation empêchée des groupes C_6F_5 due à des interactions stériques du groupe CF_3 dans le perfluoro diphényl-2,3 butanediol-2,3; on considère comme moins probable l'explication impliquant des liens hydrogène entre les protons hydroxyliques et les atomes de fluor du noyau aromatique.

[Traduit par le journal]

We have previously (1) reported the preparation of perfluoro(2,3-diphenylbutane-2,3-diol) (**1**) by the reductive dimerization of octafluoroacetophenone, and noted that the product appeared to contain more than one isomer. We now confirm this by the separation of the *meso*-isomer (**1***a*) and the DL-isomer (**1***b*), followed by

$$2\ C_6F_5COCF_3 \xrightarrow[h\nu]{2\text{-PrOH}}$$



1*a* **1***b*

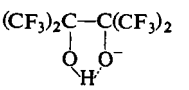
the resolution of the latter into optical enantiomers. The initial product of dimerization was separated by fractional crystallization into approximately equal amounts of two compounds; one melting at 119–120° and the other at 129–130°. Both had elementary compositions and molecular weights corresponding to the formula $C_{16}H_2F_{16}O_2$. Their infrared spectra, while not identical, were very similar, both showing strong absorption near 3630 cm^{-1} characteristic of free O—H stretching modes.

We therefore concluded that these two compounds were the *meso*- and DL-forms of the diol. In order to decide which fraction was which isomer, we studied their interaction with a variety of optically active organic bases. The usual method of separating optical enantiomers of diols is to make an ester, *e.g.*, the phthallate, to provide an acidic function from which salts may be prepared. In the present work, this was not necessary, because the fluorination of the molecule increases the acidity of the hydroxyl group to the point where a salt may be made directly, even though the aromatic diol (pK_a = 8.85 (1)) is a considerably weaker acid than perfluoropinacol (pK_a = 5.95 (2)).

Of various bases tried, L-strychnine gave a crystalline derivative with the lower m.p. diol isomer, but fractional crystallization, followed by regeneration of the diol on acidification, gave no indication of the separation of enantiomers. This suggests that this is the *meso*-isomer (**1***a*). With the higher m.p. isomer, strychnine gave no solid derivative, but L-cinchonidine readily formed crystals which were shown by analysis to be a 1:1 adduct. This dissociated in methanol to give a conducting solution and the infrared spectrum of the solid showed no O—H absorption peaks. We therefore formulate it as an ionic salt, although the possibility of solid-state interactions through hydrogen-bonding cannot be eliminated.

The cinchonidine salt was fractionally crystallized to constant optical rotation, and acidification of the less soluble fraction yielded resolved (+)-diol, m.p. 89–90°, $[\alpha]_{589}^{20} = 96.6°$. This separation shows unambiguously that the higher m.p. fraction from the dimerization product is the DL-isomer (**1***b*), and the fact that it has a m.p. 40° higher than that of the resolved enantiomer characterizes it as a racemic compound, rather than a mixture.

The pK_a values, measured in aqueous ethanol, are 8.7 for the *meso*-isomer and 9.1 for the DL-isomer. This difference, although slight, is surprising, since the acidic nature of fluorinated diols of this type was originally ascribed to intramolecular hydrogen-bonding in the anion (2):



Although the need for an explanation of this "enhanced" acidity of perfluoropinacol was removed by the subsequent revision of the accepted value of the pK_a of perfluoro(*t*-butanol) (3), there has been no reason to doubt the existence of intramolecular hydrogen-bonding, on which basis one would expect a greater acidity for **1***b*, the DL-isomer, since the steric interaction between the bulky pentafluorophenyl groups required to bring the two oxygen atoms into a *syn*-conformation would appear to be less than that in the *meso*-isomer, **1***a*. The greater acidity found in the latter would suggest that hydrogen-bonding, if present, is intermolecular to solvent molecules, rather than intramolecular.

Metal Complexes

The overall objective of this work is to study the formation of complexes between highly fluorinated molecules and metal ions, as we have previously done for perfluoropinacol (4, 5). We have therefore studied the reaction of **1** with Ni^{2+} and Cu^{2+}, but we find that the fluorinated aromatic diol does not form complexes as readily as does H_2PFP. Thus, we were unable to isolate anionic complexes of either **1***a* or **1***b* of the type $[M(PDBD)_2]^{2-}$ [where $PDBD^{2-}$ = dianion of perfluoro(2,3-diphenylbutane-2,3-diol)] under conditions where perfluoropinacol readily forms $[M(PFP)_2]^{2-}$ (4), and this can be ascribed in part to the reduced acidity of the aromatic diol. Using resolved (+)-diol in solutions containing Ni^{2+} in various concentration ratios, we varied the p*H* while monitoring the optical rotary dispersion (o.r.d.) of the solutions, but in no case was any evidence seen of interaction between the ligand and the metal ion, up to the point where decomposition of the ligand began.

However, the use of a neutral co-ligand enabled us to isolate a number of stable complexes of $PDBD^{2-}$ with Ni^{2+} and Cu^{2+}, similar to those formed by perfluoropinacol (6). Nickel complexes isolated were $[(C_2H_5)_3P]_2Ni(PDBD)$, $[(CH_3)_2PC_6H_5]_2Ni(PDBD)$, (TMED)Ni(PDBD) (TMED = tetramethylethylenediamine), and

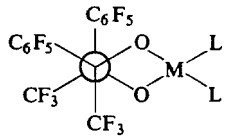
*Comparison with the data for the (+)-diol complex indicates about 93% optical purity.

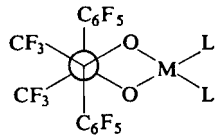
(TEED)Ni(PDBD) (TEED = tetraethylethylenediamine). These four complexes were diamagnetic and had visible absorption spectra similar to those of the analogous PFP^{2-} derivatives (6); they were therefore assumed to have a square-planar coordination of ligands around nickel. Bulkier phosphine ligands, such as triphenylphosphine, did not yield stable complexes. Copper (II) gave the complex (TMED)Cu(PDBD).

Several competitive reactions were examined in which more than one potential ligand was present in solution with the metal ion. Clearcut selective chelation occurred, and the order of complexing ability was found to be PFP^{2-} > DL-$PDBD^{2-}$ > *meso*-$PDBD^{2-}$. The preferential coordination of PFP^{2-} was expected, in view of the known properties of this compound, while the superiority of the DL-isomer of the aromatic diol, although contrary to the slight difference in acidity between the two isomers, is entirely consistent with steric requirements. Consideration of Newman projections along the C—C axes of the aromatic diols shows the relative steric interactions in the coordinated ligands:



2a

coordinated *meso*-diol



2b

coordinated DL-diol

Whereas the coordination of the *meso*-diol (**2a**) requires an axial-equatorial conformation of the C_6F_5 groups, the DL-diol may adopt a conformation in which they are *trans*-diaxial (**2b**), with reduced steric interaction.

Dissymmetric Complexes

The availability of resolved enantiomers of the aromatic diol enabled us to prepare optically active complexes of Ni^{2+} and Cu^{2+}. It is apparent from structure **2b** that the preferred conformation of the C_6F_5 groups will impose chirality on the chelate ring, and it is accepted (7) that chirality of this type is dominant over the vicinal effect of asymmetric centers in determining the optical rotatory power of a metal complex. Using the (+)-diol, dissymmetric complexes of the two metals were prepared, and essential features of the o.r.d. and c.d. (circular dichroism) spectra are shown in Table 1, while representative spectra are illustrated in Figs. 1 and 2.

These complexes represent an unusual example of a series of stable, isolable, compounds in which a chelate ring derived from a 2,3-diol contains two adjacent asymmetric carbon atoms. Although many other examples of interactions between metal ions and optically active diols are known, they mainly occur in solution without yielding solid products of established stoichiometry. It was of interest, therefore, to establish

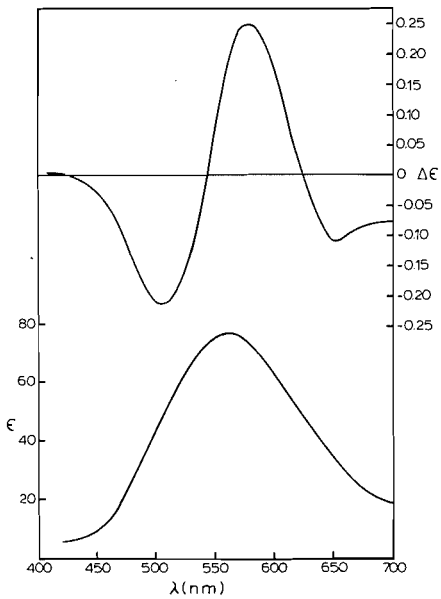

FIG. 1. Circular dichroism and visible spectra (methanol solution) of (TMED)Cu[(+)-PDBD].

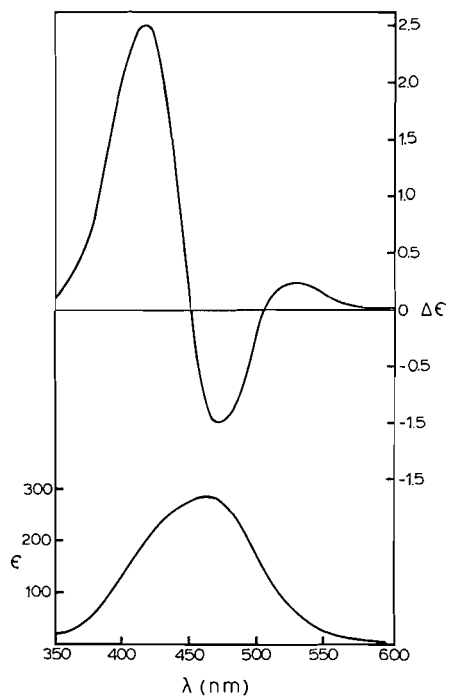

FIG. 2. Circular dichroism and visible spectra (methanol solution) of $[(CH_3)_2PC_6H_5]_2Ni[(+)\text{-PDBD}]$.

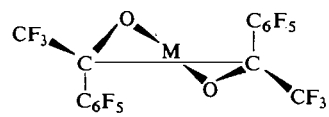
the absolute configuration of the chelate ring (and hence of the ligand itself) in the present complexes, and we have attempted to do this by a comparison of the o.r.d. spectra of the complexes with those of analogous systems of known absolute configuration.

It is convenient to refer to the conformations of the chelate rings as δ and λ

Reeves (8) investigated the configuration of a number of optically active ligands by their interaction with Cu^{2+} in ammoniacal solution ("cupra A"), where a 1:1 complex is formed, but not isolable. Using a conformationally rigid diol of known structure, subsequent workers (9) found that these solutions show a weak c.d. band at 580–600 nm and a more intense band of opposite sign near 280 nm, and established that a positive value of the former peak is associated with the δ-conformation of the chelate ring. The c.d. spectrum of our (+)-diol in cupra A shows a positive peak at 610 nm and a more intense negative peak below 300 nm, the reverse being shown by the (−)-diol. We therefore assign the δ-conformation to the coordinated (+)-isomer of $PDBD^{2-}$, *i.e.*



3

Additional evidence comes from studies on the conformations of a number of optically active Schiff base complexes of Ni^{2+} and Cu^{2+}. Downing and Urbach (10) found that a δ conformation in the ring of a copper complex led to a c.d. spectrum with a negative peak at 630–700 nm, a positive peak at 550–590 nm, and a further negative peak at 475–500 nm. The c.d. spectrum of (TMED)Cu[(+)-PDBD] (Table 1) is entirely consistent with this pattern, conforming our assignment of the δ-conformation to its chelated diol ring.

With the similar complexes of Ni^{2+}, several workers (11, 12) have drawn attention to the difficulty of assigning absolute configurations, so we do not feel justified in using data from the

c.d. spectra of the Ni^{2+} complexes of $PDBD^{2-}$ to support our arguments.

The extension from the assignment of a ring conformation to the assignment of an absolute configuration of each diol isomer depends on our assumption that the steric interaction between two vicinal C_6F_5 groups is greater than that between two CF_3 groups, so that the (+)-diol has the configuration illustrated in **3**. Since the difference in size between the two substituent groups is quite considerable, we consider that this assumption may be accepted with some confidence.

Partially Fluorinated Diols

In an attempt to extend the range of diols of the type RR'C(OH)C(OH)RR' which might form stable complexes with metal ions, we prepared the partially fluorinated compounds where $R = C_6F_5$, $R' = CH_3$ (**4**), and $R = C_6H_5$, $R' = CF_3$ (**5**) by reductive dimerization of the ketones $C_6F_5COCH_3$ and $C_6H_5COCF_3$ respectively.

Compound **5** had been prepared previously by Mosher and Heindel (13) who reported only one isomer, without identifying it as the *meso*- or DL-form. We also found evidence for only one isomer, which we attempted to separate into optical enantiomers as we had the fully fluorinated diol. Although strychnine gave a solid adduct with **5**, fractional crystallization showed no sign of resolution, from which we assumed it was the *meso*-form. Consistent with this, the singlet observed in the ^{19}F n.m.r. spectrum was not split when the compound was dissolved in an optically active solvent. After this work was completed, an alternate preparation of diol **5** was published (14) quoting a crystal structure on a derivative in which it was shown to have the *meso*-configuration.

Diol **5** was much less acidic than its fully fluorinated analog, having a pK_a of about 11.4. Nevertheless, it did form stable metal complexes such as $(TMED)\overline{NiOC(CF_3)(C_6H_5)C(CF_3)(C_6H_5)O}$. In competitive reactions, the fully fluorinated *meso*-diol (**1***a*) coordinated in preference to **5**, indicating that the effect of the greater acidity of the former predominated over the smaller degree of steric hindrance between the unfluorinated phenyl rings in the latter. However, diol **5** did form a complex with Ni^{2+} in the absence of any co-ligand when a solution of the diol and Ni^{2+} was made highly alkaline ($[OH^-] > 5\ M$). The resulting clear blue solution had a visible spectrum very similar to that of $Ni(PFP)_2^{2-}$ in noncoordinating solvent (6), and presumably contained a square-planar anionic complex of Ni^{2+} with diol **5**, although no solid compound could be isolated. The formation of a nickel complex under these conditions with diol **5**, but not with the other diols included in this study, may be attributed to the ligand's stability under highly basic conditions, where the diols containing pentafluorophenyl groups decomposed.

Diol **4** was produced in poor yield by the photolytic dimerization of $C_6F_5COCH_3$. As would be expected, it was less acidic than any of the other diols included in this study. It did not give an end-point on titration, nor could any evidence be found for the existence of isolable metal complexes. In the absence of salt formation with organic bases, no attempt was made to identify **4** as a *meso*- or DL-isomer.

The order of coordinating ability of the fluorinated diols covered in this study is therefore $[(CF_3)_2C(OH)—]_2 >$ DL-$[(C_6F_5)(CF_3)C(OH)—]_2 >$ *meso*-$[(C_6F_5)(CF_3)C(OH)—]_2 >$ *meso*-$[(C_6H_5)(CF_3)C(OH)—]_2 > [(C_6F_5)(CH_3)C(OH)—]_2$. With the exception of the slight difference between isomers **1***a* and **1***b*, this is the order of decreasing acidity of the diols.

^{19}F Nuclear Magnetic Resonance Spectra

We have previously (1) reported the ^{19}F n.m.r. spectra of a variety of fluorinated aromatic alcohols. The compound $C_6F_5C(CF_3)_2OH$ (**6**), for example, shows one peak associated with the CF_3 group and three others, with intensities in a 2:2:1 ratio, corresponding to the *ortho*-, *meta*-, and *para*-fluorine atoms of the aromatic ring (Table 2). By contrast, the spectra of the fully fluorinated aromatic diols studied in the present work contained the expected peak from the CF_3 groups and five equal-intensity peaks from the fluorine atoms of the aromatic rings, indicating that all five aromatic fluorine atoms were nonequivalent.

The following numbering scheme will be used to discuss these spectra; this diagram is not intended to show the conformation of the molecule.

The peak corresponding to each fluorine atom was split by fluorine–fluorine coupling and the

various peaks were identified by examination of the coupling pattern and use of standard decoupling techniques. The following ranges of coupling constants were found: $J(F^2–F^3) = J(F^3–F^4) = J(F^4–F^5) = J(F^5–F^6) = 21–23$ Hz; $J(F^2–F^4) = J(F^2–F^5) = J(F^3–F^6) = J(F^4–F^6) = 6–7$ Hz; $J(F^3–F^5) = 1$ Hz; $J(F^2–F^6)$ not resolved.

Coupling was also observed from the *ortho*-fluorine atoms to one of the CF_3 groups (F^1 or F^7), whose absorption peaks consisted of a complex multiplet. Irradiation of F^2 caused this to collapse to a broad singlet, while irradiation of F^6 produced a doublet ($J = 24$ Hz), indicating preferential coupling to each CF_3 group from one of the *ortho*-fluorine atoms.

The nonequivalence of the aromatic fluorine atoms indicates restricted rotation of the phenyl ring. Previous workers (15) have suggested the possibility of hydrogen-bonding from the hydroxyl group of an alcohol to an adjacent fluorine atom, but we may eliminate that in this case because the same pattern is observed in the coordinated ligand, where no hydroxyl group is present. We suggest, therefore, that the restricted rotation results from steric interaction between the *ortho*-fluorine atoms of the ring and those of one of the CF_3 groups (assuming that the diol adopts a conformation with the two phenyl rings too far apart to interact). Examination of molecular models shows that the greater degree of steric interaction is between the C_6F_5 group and the CF_3 in the vicinal position to it, rather than the *gem*-CF_3 group, and this is consistent with our observation that no such interaction is observed in **6** or in similar monohydric fluorinated alcohols. The coupling from F^2 to the CF_3 group may therefore be through-space coupling to F^7, rather than to F^1.

Additional evidence favoring our suggestion that steric interaction between C_6F_5 and CF_3 groups is dominant comes from the ^{19}F n.m.r. spectrum of the partially fluorinated diol $[C_6F_5C(CH_3)(OH)—]_2$. This shows a typical 2:2:1 set of peaks for *ortho*-, *meta*-, and *para*-fluorine atoms, indicating that the presence of the smaller CH_3 group allows free rotation of the phenyl ring.

Infrared Spectra

The infrared (i.r.) spectra of the diols **1***a* and **1***b* were very similar. The O—H stretching frequency appeared as a sharp absorption peak at 3640 cm^{-1} (**1***a*) and 3627 cm^{-1} (**1***b*) (mulls), showing the absence of hydrogen-bonding. A similar peak at 3630 ± 5 cm^{-1} has been noted previously (16) in a series of unfluorinated 1,2-diols.

Peaks associated with ring skeletal modes were seen at 1651 and 1534 cm^{-1} (**1***a*) and 1654 and 1535 cm^{-1} (**1***b*), and strong C—F stretching absorptions were present in the region 1100–1300 cm^{-1} in both compounds. The major difference in the i.r. spectra between the two isomers occurred near 1000 cm^{-1}. Whereas the *meso*-diol, **1***a*, had two sharp peaks at 995 and 945 cm^{-1}, the DL-diol had a broad, poorly resolved pair of peaks at 1010 and 990 cm^{-1}. The overall complexity of the spectra precluded any definite assignment of these peaks, but their presence provided a useful guide to the purity of the isomers.

The absence of any peaks corresponding to intramolecularly hydrogen-bonded O—H is in accord with previous work (17), which demonstrated that the fluorination of this type of molecule, while having little effect on the frequency of the O—H absorption, reduced the tendency towards hydrogen bonding.

Metal complexes of the diol isomers showed very similar i.r. spectra (the O—H peaks being, of course, absent) with the same difference in the appearance of the spectrum around 1000 cm^{-1} between complexes of **1***a* and **1***b*.

Experimental

General

Infrared spectra were recorded on a Beckman IR-10 instrument; u.v.–visible spectra on Beckman DK or Cary 14 instruments; o.r.d./c.d. spectra on a Durrum–Jasco ORD-UV-5 spectropolarimeter. Microanalyses (Table 3) were performed by Alfred Bernhardt Laboratories, West Germany.

Perfluoro(2,3-diphenylbutane-2,3-diol) (*1*).

The synthesis of the diol, as a mixture of isomers, has been described previously (1). The crude product was separated by fractional crystallization from light petroleum (b.p. 30–60°) into approximately equal amounts of two fractions; the less soluble *meso*-diol (**1***a*), m.p. 119–120°, and the more soluble DL-diol (**1***b*), m.p. 130–131°. Molecular weights (osmometric in benzene) were 535 and 543 respectively (calcd., 530).

Resolution of the DL-*diol*

Diol **1***b* (16 g, 30 mmol) and L-cinchonidine (9.0 g, 30 mmol) in a mixture of chloroform (150 ml) and hexane (20 ml) deposited a crystalline solid over a period of 3 days at 25°. Analysis showed this to be a 1:1 adduct. It had an equivalent conductance of 40 ohm^{-1} cm^2 in methanol and a molecular weight of 405 (calcd. for complete dissociation: 412) extrapolated to infinite dilution in methanol. The diol was regenerated by acidification with aqueous hydrochloric acid and extraction with dichloromethane; it had $[\alpha]_{589}^{20} = +62°$. The process was repeated to constant rotation to yield resolved (+)-diol, $[\alpha]_{589}^{20} = +96.6°$, m.p. 89–90°. Residues from the recrystallization gave an oil which yielded diol of specific rotation −42°, indicating about 45% concentration of the (−)-diol. This was used for the preparation of the metal complexes, described below, whose recrystallization provided a further degree of purification to give substantially pure (−)-diol derivatives.

Preparation of Nickel Complexes of $PDBD^{2-}$

(+)-Diol (0.30 g, 0.57 mmol) and nickel nitrate hexahydrate (0.17 g, 0.57 mmol) were dissolved in ethanol (15 ml) and TMED (0.15 g, 1.3 mmol) added slowly. Ethanolic potassium hydroxide was added dropwise to p*H* 8 and the resulting red solution filtered and evaporated to dryness. Recrystallization from ethanol gave (TMED)Ni[(+)-PDBD], red, m.p. 148° (decomp). The same procedure gave (TEED)Ni[(+)-PDBD], red.

The same procedure was used with partially resolved (−)-diol and the complex recrystallized from dichloromethane/hexane to constant rotation, yielding essentially pure (TMED)Ni[(−)-PDBD].

For both the DL-diol and the *meso*-diol, the following procedure was used. Equimolar amounts of diol and nickel nitrate were dissolved in aqueous methanol and a slight excess of TMED added. The solution was brought to p*H* 8 with methanolic potassium hydroxide and the resulting red precipitate removed by filtration, extracted with dichloromethane, and recrystallized from dichloromethane/hexane. Products were red, with m.p. 138–139° (DL-diol) and 130–131° (*meso*-diol).

The complex $[(C_2H_5)_3P]_2Ni[(+)\text{-PDBD}]$ was prepared by the slow addition of triethylphosphine (0.095 g, 0.80 mmol) under nitrogen atmosphere to a solution of (+)-diol (0.20 g, 0.38 mmol) and nickel nitrate hexahydrate (0.11 g, 0.38 mmol) in methanol, followed by the addition of methanolic potassium hydroxide to p*H* 8.5. The orange solution was evaporated to dryness and the residue extracted with dichloromethane and recrystallized from dichloromethane/hexane to yield $[(C_2H_5)_3P]_2Ni$-[(+)-PDBD], orange, m.p. 137–138°. The similar derivative of the *meso*-diol was prepared in the same way; orange, m.p. 124–125°.

The dimethylphenylphosphine complex was prepared by dissolving (+)-diol (0.30 g, 0.57 mmol) and nickel nitrate hexahydrate (0.17 g, 0.57 mmol) in ethanol under nitrogen, and slowly adding dimethylphenylphosphine (0.20 g, 1.5 mmol) followed by ethanolic potassium hydroxide to p*H* 8. The resulting solution was filtered and evaporated to dryness and the product recrystallized from 95% ethanol to give $[(CH_3)_2PC_6H_5]_2Ni[(+)$-PDBD], orange, m.p. 143°. The similar derivative of the *meso*-diol was prepared by the same route and recrystallized from dichloromethane/hexane; orange, m.p. 116°.

Preparation of (TMED)Cu[(+)-PDBD]

Copper sulfate pentahydrate (0.15 g, 0.60 mmol) and (+)-diol (0.30 g, 0.57 mmol) were dissolved in aqueous ethanol and TMED (0.20 g, 1.7 mmol) added, followed by aqueous potassium hydroxide to p*H* 8. The desired compound precipitated on concentrating the solution; it was recrystallized from ethanol to give (TMED)Cu[(+)-PDBD], purple, m.p. 88–90° (decomp).

2,3-Bis(pentafluorophenyl)butane-2,3-diol

Methyl pentafluorophenyl ketone was prepared by the Grignard reaction of acetyl chloride with pentafluorophenyl magnesium bromide (18). A solution of the ketone (5.1 g) in 2-propanol (25 ml) in a quartz tube was degassed and irradiated with ultraviolet light for 7 days. Removal of volatile material left a solid product which was recrystallized from dichloromethane/hexane to give 2,3-bis(pentafluorophenyl)butane-2,3-diol (2.1 g), m.p. 173–174°. The ^{19}F n.m.r. spectrum ($CHCl_3$ solution) showed three multiple peaks in a 2:1:2 ratio at 138.0, 154.7, and 162.3 p.p.m. from $CFCl_3$. Attempts to form nickel complexes of this diol, using methods successful with other diols, showed no evidence of interaction.

1,1,1,4,4,4-Hexafluoro-2,3-diphenylbutane-2,3-diol

Trifluoroacetophenone was prepared by the Grignard reaction of trifluoroacetic acid with phenylmagnesium bromide (19). The ketone (10 g) was dissolved in 2-propanol (22 ml) acidified with hydrochloric acid (0.2 ml) in a quartz tube, the mixture outgassed and irradiated with ultraviolet light for 8 days. Removal of solvent left a solid residue which was recrystallized from benzene/hexane to give 1,1,1,4,4,4-hexafluoro-2,3-diphenylbutane-2,3-diol (7.0 g), m.p. 154–155° (lit. m.p. (13), 155–156°). Fractional crystallization from a variety of solvents gave no evidence of the presence of more than one isomer. The ^{19}F n.m.r. spectrum showed a single peak both in chloroform (at 70.2 p.p.m. from TMS) and in (+)-α-phenethylamine (at 67.8 p.p.m.). Titration in a 1:1 ethanol/water solution gave a pK_a of about 11.4.

When equimolar quantities of this diol and L-strychnine were dissolved in a chloroform/hexane mixture, a crystalline precipitate formed. Its infrared spectrum showed the presence of both diol and strychnine, but no O—H stretching band. Fractional crystallization, followed by regeneration of the free diol by acidification and ether extraction, showed no evidence for the separation of an optically active form of the diol.

The complex (TMED)Ni$[CF_3(C_6H_5)CO—]_2$ was prepared similarly to (TMED)Ni[(+)-PDBD] and recrystallized from ethanol to give a red complex, m.p. 196–200° (decomp.).

Financial support of this work was provided by the National Research Council of Canada. We thank Dr. R. A. Haines for many helpful discussions.

Photolysis of Aqueous Solutions of 9,10-Anthraquinone-2-sulfonate. Part II. Dependence of Rates of Hydroxylation on Reaction Conditions

ARTHUR D. BROADBENT, HUGH B. MATHESON, AND RICHARD P. NEWTON

Department of Chemistry, Mount Allison University, Sackville, New Brunswick E0A 3C0

Received August 22, 1974

ARTHUR D. BROADBENT, HUGH B. MATHESON, and RICHARD P. NEWTON. Can. J. Chem. **53**, 826 (1975).

The rates of formation of hydroxy-9,10-anthraquinone-2-sulfonates, produced by irradiation of neutral and alkaline aqueous solutions of 9,10-anthraquinone-2-sulfonate (A) at 365 nm, have been measured for solutions with initial [A] ranging from 5×10^{-5} to 8×10^{-2} mol dm^{-3}, saturated with either O_2, air, or N_2. The rate of monohydroxylation was independent of the saturating gas and, for neutral solutions absorbing all the incident light, increased with increasing initial [A] reaching a constant maximum quantum yield of 0.08 above 2×10^{-2} mol dm^{-3}. In 0.1 mol dm^{-3} aqueous NaOH solution, the rate was about three times larger but had not attained a limiting value at the maximum [A] imposed by its solubility. Dihydroxy-9,10-anthraquinone sulfonates are proposed to arise from reaction of O_2 with an intermediate, rather than by further hydroxylation of monohydroxy products. The rate of dihydroxylation decreased on increasing [A] above 5×10^{-4} mol dm^{-3}, becoming essentially zero at high concentrations.

ARTHUR D. BROADBENT, HUGH B. MATHESON et RICHARD P. NEWTON. Can. J. Chem. **53**, 826 (1975).

On a mesuré à 365 nm, pour des solutions ayant des concentrations initiales de [A] allant de 5×10^{-5} à 8×10^{-2} mol dm^{-3}, saturées soit en O_2, en air ou en N_2, les vitesses de formation des hydroxyanthraquinone-9,10 sulfonates-2 produits par irradiation de solutions aqueuses, neutres ou alcalines d'anthraquinone-9,10 sulfonate-2 (A). Le taux de monohydroxylation est indépendant du gaz produisant la saturation et dans des solutions neutres absorbant toute la lumière incidente, la vitesse augmente avec l'augmentation de la vitesse initiale de [A] approchant un rendement quantique maximum constant de 0.08 au dessus de 2×10^{-2} mol dm^{-3}. Dans des solutions aqueuses de NaOH à 0.1 mol dm^{-3}, la vitesse est environ trois fois plus grande mais elle n'avait pas atteint une valeur limite à la concentration maximum de [A] imposée par sa solubilité. On propose que les dihydroxyanthraquinone-9,10 sulfonates se forment par réaction de O_2 avec un intermédiaire plutôt que par une hydroxylation ultérieure des produits monohydroxylés. Le taux de dihydroxylation diminue lorsque la concentration de [A] augmente au dessus de 5×10^{-4} mol dm^{-3} et cette vitesse devient pratiquement zéro à haute concentration.

[Traduit par le journal]

Introduction

When 9,10-anthraquinone-2-sulfonate (A) is irradiated in aqueous solution with near-ultraviolet light (λ = 300–425 nm), 1- and 2-hydroxy- (AOH) and dihydroxy-9,10-anthraquinone sulfonates ($A(OH)_2$) result, the actual product yields depending upon the photolysis conditions (1). There is evidence (2–6) that this photochemical reaction causes reduction of A and oxidation of H_2O or HO^- to $HO^\cdot$, which, in the absence of scavengers, reacts with A to produce hydroxy derivatives.

Two groups have recently established that the rate of formation of AOH (V_{AOH}) increases with increasing initial [A], even when all the incident light is absorbed. Phillips *et al.* (7) proposed the following reactions to account for this:

[1] $$A + h\nu \rightarrow A^*$$

[2] $$A^* \rightarrow A$$

[3] $$A^* + A \rightarrow A^{\cdot -} + A^{\cdot +}$$

[4] $$A^{\cdot +} + HO^- \rightarrow A + HO^\cdot$$

[5] $$A + HO^\cdot \rightarrow AOH^\cdot$$

[6] $$AOH^\cdot + O_2 \rightarrow \rightarrow AOH + HO_2^\cdot$$

A* represents the appropriate electronically excited state of A, $A^{\cdot -}$, and $A^{\cdot +}$ radical ions resulting from partial reduction and oxidation of A, respectively, and $AOH^\cdot$ the adduct from A and $HO^\cdot$.

Clark and Stonehill (8) modified and expanded this reaction scheme concluding that, if reaction 3 occurs, the initial product would be a radical ion-pair, $A^{\cdot -} \ldots A^{\cdot +}$, which either reverts to A or oxidizes H_2O or HO^-.

[7] $$A^* + A \rightarrow A^{\cdot -} \ldots A^{\cdot +}$$

[8] $$A^{\cdot -} \ldots A^{\cdot +} \rightarrow 2A$$

[9] $$A^{\cdot -} \ldots A^{\cdot +} + H_2O \rightarrow A^{\cdot -} + A + HO^\cdot + H^+$$

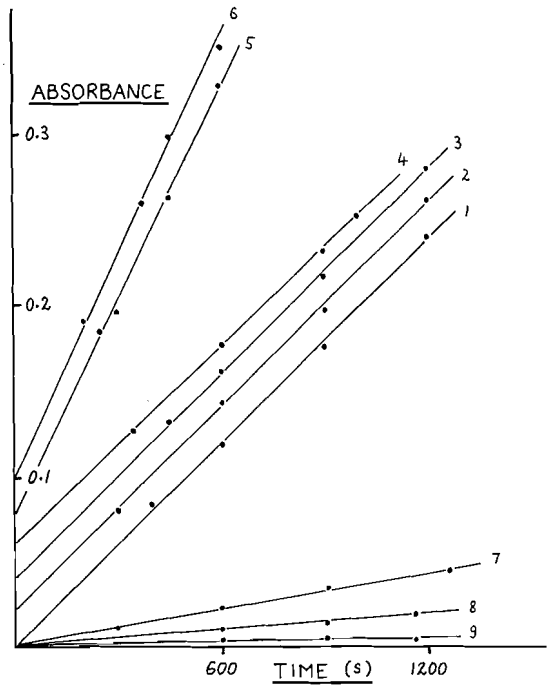

FIG. 1. Absorbance of AOH and $A(OH)_2$ as a function of time under various conditions.

Plot No.	Solvent	Salt	Gas	10^3 [A] (mol dm^{-3})	Product	λ_{max} (nm)
1	H_2O	Na^+	O_2	20	AOH	494
2	H_2O	Na^+	N_2	20	AOH	494
3	H_2O	NH_4^+	N_2	40	AOH	494
4	H_2O	NH_4^+	O_2	40	AOH	494
5	NaOH	Na^+	O_2	5	AOH	472
6	NaOH	NH_4^+	N_2	5	AOH	472
7	H_2O	Na^+	O_2	0.5	$A(OH)_2$	610
8	H_2O	Na^+	Air	0.5	$A(OH)_2$	610
9	H_2O	Na^+	N_2	0.5	$A(OH)_2$	610

Plots 1–6 successively displaced 0.02 absorbance units along the ordinate for clarity.

They also pointed out that their results were consistent with a primary process involving direct interaction of A* with H_2O or HO^-. However, the nature of AOH^-, the product of reaction 10, was not clearly identified, although several possible structures were discussed.

[10] $$A^* + H_2O \rightarrow AOH^- + H^+$$

[11] $$AOH^- \rightarrow A + HO^-$$

[12] $$AOH^- + A \rightarrow AOH^{\cdot} + A^{\cdot -}$$

In this paper, more detailed results on the effect of the initial [A] and $[O_2]$ on V_{AOH} and $V_{A(OH)_2}$ are reported. These results show that certain published observations and conclusions are erroneous.

Results

The time-independent V_{AOH} were measured over a wide range of [A] in H_2O and 0.10 mol dm^{-3} aqueous NaOH solutions of the Na^+ and the more soluble NH_4^+ salt, saturated with either O_2, air or N_2 (Figs. 1 and 2). Substitution of the Na^+ by the NH_4^+ salt had no effect on V_{AOH}, addition of excess NH_4NO_3 having no influence on V_{AOH} for the Na^+ salt in H_2O.

The maximum value for the quantum yield of AOH in H_2O solutions with [A] above 2×10^{-2} mol dm^{-3} was estimated to be $\Phi(AOH) = 0.08$, based upon the ε values in Table 1 and a value of 2.25 for the ratio of 1-$HOAQSO_3Na$ to 2-$HOAQSO_3Na$ photolysis products. Clark and Stonehill (8) have reported a maximum $\Phi(AOH)$

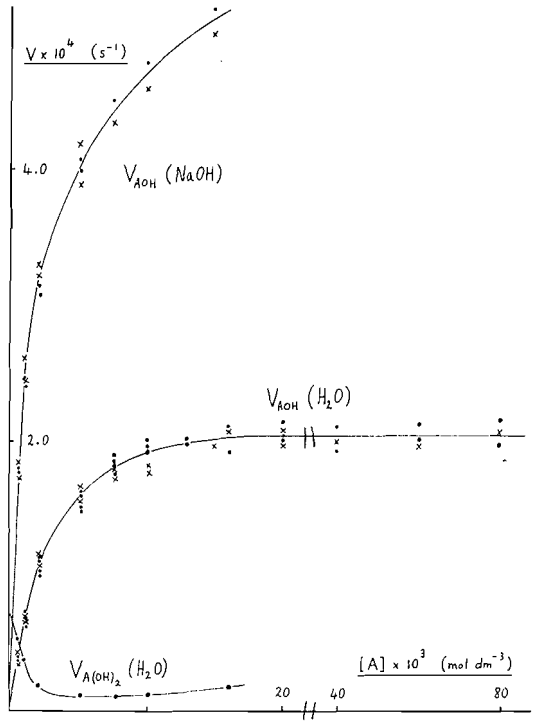

FIG. 2. Dependence of V_{AOH} and $V_{A(OH)_2}$ on [A] for solutions of the Na^+ and NH_4^+ salts saturated with O_2 or air (·) or N_2 (×).

= 0.067 in H_2O solution, based upon a value of 1.50 for the ratio of 1-$HOAQSO_3Na$ to 2-$HOAQSO_3Na$ photolysis products. Both the Φ(AOH) and the product ratio were based on low ε values (see Table 1). For solutions of A in 0.10 mol dm^{-3} aqueous NaOH only 2-$HOAQSO_3Na$ are formed and Φ(AOH) was 0.09 and 0.20 at [A] of 1.0×10^{-3} and 1.5×10^{-2} mol dm^{-3}, respectively. A limiting rate was not observed since the solubility of the Na^+ salt precludes [A] above 1.5×10^{-2} mol dm^{-3}. The higher Φ(AOH) = 0.26 in NaOH solution already published (8) was again based on erroneous ε values.

Previous studies (1) showed that photolysis of A in H_2O produces AOH and $A(OH)_2$, the latter exhibiting strong absorption at 610 nm in alkaline solution and being the major products at low [A] and high [O_2]. This absorbance at 610 nm was found to be directly proportional to the irradiation time (Fig. 1). For H_2O solutions, the derived $V_{A(OH)_2}$ decreased on increasing the [A] from 5×10^{-4} to 2×10^{-3} mol dm^{-3}, being negligible at higher [A], where the observed absorption at 610 nm is caused mainly by the

large excess of AOH produced. Oxygen is a necessary reaction partner for formation of $A(OH)_2$, since $V_{A(OH)_2}$ decreased on decreasing the [O_2] in solution becoming essentially zero in N_2-saturated solution (Fig. 1).

Discussion

Although Phillips *et al.* (7) claimed that a transient absorption observed on flash photolysis of A was caused by $A^{\cdot+}$, subsequent studies (10, 11) have revealed that the lifetime of A* (triplet state) is unaffected by large variations in [A]. Mechanisms including reactions 3 or 7 need not be considered.

Reactions 10–12 (8) could explain the present results. However, photolysis of A in O_2-free aqueous solution containing benzene gives not only phenol but also a larger yield of biphenyl for solutions of $pH < 7$ (12), while in alkaline solutions an enhanced yield of phenol is observed in agreement with Russian studies (4). These products can be readily detected at [A] as low as 1×10^{-4} mol dm^{-3}. These observations can only be in accord with reactions 10–12 if $AOH^{\cdot}$ or AOH^{-} is an efficient $HO^{\cdot}$ donor. The formation of biphenyl on photolysis of acidic solutions compares with the detection of this product after radiolysis of water containing benzene only when the solution was subsequently acidified (13), and is further evidence for the presence or availability of $HO^{\cdot}$ in photolyzed solutions of A.

Clark and Stonehill's reaction schemes were

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

introduced to explain the enhanced V_{AOH} in alkaline solution. Either of their schemes requires that the ratio of V_{AOH} in NaOH solution to V_{AOH} in H_2O should be independent of [A]. Both their data, and those reported here, show that this ratio decreases with increasing [A], indicating that reactions 10–12 are inadequate, since there is no evidence that any change in reaction mechanism occurs on increasing [A].

The same authors have also reported (14) that in anaerobic solution V_{AOH} is considerably lower than in the presence of O_2, although no actual data are given. This was rationalized in terms of reaction 6 and 13.

[13] $$AOH^{\cdot} + AOH^{\cdot} \rightarrow AOH + A + H_2O$$

In this study, V_{AOH} was independent of $[O_2]$ at all [A], and, in anaerobic solution, was certainly not half the value in aerobic solution, as required by reactions 6 and 13. In addition, these results indicate that $A(OH)_2$ are primary products of photolysis, requiring the involvement of O_2 in their formation, and that they do not arise by further hydroxylation of AOH.

The data reported here would also be consistent with a primary photochemical electron transfer reaction proposed by Russian workers (4–6, 15–17) for photolysis of aqueous solutions of anthraquinone sulfonates and also for other anthraquinone derivatives (18–20). However, some form of reverse reaction, such as reaction 15, must be considered to account for the effect of [A] on V_{AOH} and the low Φ(AOH).

[14] $$A^* + H_2O \rightarrow A^{\cdot -} + H_2O^{\cdot +} \; (A^{\cdot -} \ldots H_2O^{\cdot +})$$

[15] $$A^{\cdot -} + H_2O^{\cdot +} \; (A^{\cdot -} \ldots H_2O^{\cdot +}) \rightarrow A + H_2O$$

The enhanced V_{AOH} in alkaline solution would result partly from reduction of A* by HO^- rather than H_2O, and the maximum V_{AOH} would only be achieved at high [A] when the maximum available $HO^{\cdot}$ was captured by A.

The experimental results published to date are limited by the low selectivity of the spectrophotometric analysis, which will not clearly distinguish between the 1- and 2-hydroxy- and dihydroxyanthraquinone products, whose yields vary significantly on changing [A], $[O_2]$, and $[HO^-]$. Broadbent and Newton's product distribution data (1) and the rate data given here suggest that the product yields could be related to competitive reactions of some intermediate species such as $AOH^{\cdot}$ with A, O_2, or HO^-, in addition to any bimolecular reaction of $AOH^{\cdot}$ (reaction 13) (20).

Successful evaluation of the mechanism of the formation of AOH and $A(OH)_2$ will require more details of the precise nature of the involvement of $HO^{\cdot}$ in this reaction and clear distinction of the effect of the reaction conditions on both the primary photochemical process and on the secondary reactions leading to products.

Experimental

Sodium 9,10-anthraquinone-2-sulfonate monohydrate was purified as described previously (1). The anhydrous NH_4^+ salt was prepared by treating the barium salt with H_2SO_4, filtering off the $BaSO_4$ and neutralizing the free acid with NH_3.

Solutions of A were irradiated in a 5 cm optical cell while O_2, air, or N_2 was continuously bubbled through the solution using very narrow plastic tubing sealed into the end of the cell furthest from the stabilized Hanovia 679A 450W Hg lamp. The tubing did not interfere with the light beam and bubbling gave efficient mixing and saturation of the solution with the gas. The gas outlet was attached to a H_2O trap to ensure no air could enter the cell from outside. An almost parallel beam of light was passed through an Ealing-TFP interference filter to give radiation at 365 ± 5 nm, which then entered the solution cell.

For 0.10 mol dm^{-3} aqueous NaOH solutions, the absorbance of products at 472 nm could be measured directly as a function of time. Solutions in doubly distilled H_2O were irradiated for a given time, made strongly alkaline with one drop of concentrated NaOH solution and the absorbance of the products at 494 nm was measured. Formation of $A(OH)_2$ was detected by measurement of absorbance at 610 nm in alkaline solution. In all cases, the measured absorbance was directly proportional to the irradiation time showing that neither AOH, $A(OH)_2$, nor anthraquinone reduction products were effective internal light filters. V_{AOH} and $V_{A(OH)_2}$ were calculated in terms of the rate of increase of absorbance at the particular wavelength. Variations in V_{AOH} at fixed [A] were caused mainly by daily variations in incident light intensity. Because $A(OH)_2$ absorb light at 470–500 nm, the V_{AOH} values are more reliable at high [A] and low $[O_2]$. Similarly, slight absorption by AOH at 610 nm interferes with determination of $V_{A(OH)_2}$ at high [A].

Quantum yields were determined using potassium ferrioxalate solution as actinometer (21).

Molar absorptivities were calculated from the linear absorbance – concentration plots, for solutions of anthraquinones whose concentrations were established by potentiometric titration of the corresponding anthrahydroquinones with $K_3Fe(CN)_6$ solution. Spectra were recorded on freshly prepared alkaline solutions.

The ratio of 1-$HOAQSO_3Na$ to 2-$HOAQSO_3Na$ photolysis products and their respective ε values were determined by chromatographic separation of these products (1) and quantitative analysis of the resulting products by potentiometric titration.

The Structure of $(NO)_2[Ho(NO_3)_5]$, A 10-Coordinate Species

GERALD E. TOOGOOD AND CHUNG CHIEH

Department of Chemistry, University of Waterloo, Waterloo, Ontario N2L 3G1

Received August 2, 1974

GERALD E. TOOGOOD and CHUNG CHIEH. Can. J. Chem. **53**, 831 (1975).

Nitrosonium pentanitratoholmate(III), $(NO)_2Ho(NO_3)_5$, was prepared from holmium metal and dinitrogen tetroxide in anhydrous ethyl acetate. Its crystals are monoclinic with $a = 8.094$, $b = 11.979$, $c = 14.170$ Å and $\beta = 104.7°$, $Z = 4$, space group $P2_1/c$. The structure was solved by the heavy-atom method and refined by full matrix least-squares methods to an R value of 0.085 for 1514 observed reflections measured on the G.E. XRD-6 diffractometer. The structure consists of one $Ho(NO_3)_5^{2-}$ and two NO^+ ions. The holmium is 10-coordinated by five essentially symmetric bidentate nitrate groups which arrange themselves in a trigonal bipyramidal fashion around the metal with a mean Ho—O distance of 2.45 Å. The two NO^+ ions per metal occupy slightly different environments and give rise to two i.r. bands at 2250 and 2285 cm^{-1}, attributable to the (N, O^+) stretching vibration. The mean N—O distance within these ions is 1.00 Å.

GERALD E. TOOGOOD et CHUNG CHIEH. Can. J. Chem. **53**, 831 (1975).

Le pentanitratoholmate(III) de nitrosonium, $(NO)_2Ho(NO_3)_5$ a été préparé à partir de l'holmium métallique et du tétroxyde d'azote dans l'acétate d'éthyle anhydre. Les cristaux sont monocliniques avec $a = 8.094$, $b = 11.979$, $c = 14.170$ Å et $\beta = 104.7°$, $Z = 4$, groupe d'espace $P2_1/c$. On a résolu la structure par la méthode des atomes lourds et cette structure a été affinée par la méthode des moindres carrés (matrice complète) jusqu'à une valeur R de 0.085 pour 1514 réflexions observées à l'aide d'un diffractomètre G.E. XRD-6. La structure consiste d'un ion $Ho(NO_3)_5^{2-}$ et de deux ions NO^+. L'holmium est décacoordonnée par cinq groupes nitrates bidentates essentiellement symétriques qui s'arrangent d'une façon bipyramide trigonalle autour de l'atome d'holium avec une distance moyenne Ho–O de 2.45 Å. Les deux ions NO^+ occupent des environnements un peu différent et donnent lieu à deux bandes en infrarouge à 2250 et 2285 cm^{-1} attribuables à la vibration (N, O^+). La distance moyenne N—O dans ces ions est de 1.00 Å. [Traduit par le journal]

Introduction

Metal nitrates bound to one or more molecules of dinitrogen tetroxide have been prepared by various workers during the past twenty years (1–3). The nature of these compounds has been inferred from data obtained by spectroscopic and other physical methods but no definitive structural information was presented until the results of an X-ray diffraction study on $Fe(NO_3)_3 \cdot 1.5N_2O_4$ were reported by Addison and coworkers in 1973 (4). The authors of that report had realized previous to their X-ray work that this compound was unusual compared to other metal nitrate dinitrogen tetroxide adducts, particularly so far as its i.r. and Raman spectra were concerned. Their X-ray data revealed the presence of the previously unreported $N_4O_6^{2+}$ species. A more recent communication (5) which appeared during the course of our work has given preliminary data on $Cu(NO_3)_2N_2O_4$ showing that no molecular N_2O_4 exists in the structure and that bidentate nitrate groups bridge pairs of copper atoms.

In the course of our work with lanthanide metals we have prepared compounds of general formula $M(NO_3)_3 \cdot xN_2O_4$, where M = lanthanide, for all the lanthanides (except promethium). The value of x is 2 for the second half of the series but varies between 1 and 2 for the lighter elements. We formulated the compounds where $x = 2$ as $[NO]_2[M(NO_3)_5]$ (3) and this was supported by the presence of bands attributable to the N,O^+ stretching vibration in the 2280 cm^{-1} region of their i.r. spectra. In fact, two such bands were observed, separated by some 30 cm^{-1}, for each of the compounds from gadolinium to lutetium. This suggested the presence of two different environments for the NO^+ groups. To confirm this suggestion we have determined the crystal structure of $[NO]_2[Ho(NO_3)_5]$, nitrosonium pentanitratoholmate(III), using X-ray diffraction.

Experimental

Preparation of $Ho(NO_3)_3 \cdot 2N_2O_4$

The method employed was analogous to that first reported by Addison *et al.* for the copper nitrate adduct

except that extra care was taken to produce crystals of the compound suitable for X-ray work (6). Thus holmium metal was reacted with an approximately 1:1 by volume mixture of dinitrogen tetroxide and anhydrous ethyl acetate in a test tube guarded by phosphorus pentoxide against atmospheric moisture. The vigorous reaction was complete after 2 h at which stage some black residue, whose nature is unknown to us except that it is very inert, was filtered off. Addition of an appropriate excess of dinitrogen tetroxide to the filtrate will readily precipitate the desired product but not usually in a form suitable for single crystal X-ray diffraction. Since the adduct cannot be recrystallized, a "trial and error" method was employed in the step where the excess dinitrogen tetroxide was added to the initial filtrate. By varying the amount of ethyl acetate present at this stage, and controlling the rate of addition of dinitrogen tetroxide, suitable crystals were eventually obtained.

Analysis

The adduct was analyzed for holmium by thermal decomposition of the adduct to Ho_2O_3 which was collected and weighed by standard methods.

Anal. Calcd. for $Ho(NO_3)_3 \cdot 2N_2O_4$: Ho, 30.8. Found: 30.9.

X-Ray Diffraction

The crystals of $(NO)_2Ho(NO_3)_5$ are pale yellow prisms. A crystal of approximately cubic shape with edge of 0.2 mm was sealed in a capillary of 0.3 mm diameter. The crystal appeared to be stable during the course of data collection. The cell constants were established from various film data and refined by least-squares method based on 2θ values measured on the G.E. XRD-6 automatic diffractometer. The crystal data are summarized:

HoN_7O_{17} f.w. = 534.9

Monoclinic, $a = 8.094(5)$, $b = 11.979(6)$, $c = 14.170(7)$ Å, $\beta = 104.7(5)°$, $Z = 4$, $\rho_c = 2.673$, $V = 1328.9$ Å^3, F(000) = 1008, space group $P2_1/c$. $\mu_{Mo-K\alpha} = 63.0$ cm^{-1} ($\lambda_{Mo-K\alpha} = 0.7107$ Å).

The intensities of 3019 reflections ($2\theta \leq 40°$) were measured using Zr-filtered Mo–Kα radiation. Among them were four standard reflections which were measured after each 100 reflections. The intensities of the standard reflections were used as corrections (< 7%) for fluctuation over the course of data collections. The θ–2θ scan method was used and the scan range in 2θ was $\pm(0.9 + 0.3 \tan \theta)°$, with backgrounds measured at the beginning and end of each scan. The crystal was mounted with a^* along the φ axis of the goniostat. No absorption correction was made. Equivalent reflections were averaged to give 2615 independent reflections, of which 1514 had intensity I greater than the backgrounds by $3\sigma_I$ and were considered to be observed. Lorentz and polarization factors were applied to derive the structure amplitudes.

The structure was solved by heavy atom methods and refined using full-matrix least-squares methods. The revised version of least-squares program written by Doedens and Ibers was used. The atomic scattering factors for holmium are taken from Thomas–Fermi–Dirac statistical model and those of nitrogen and oxygen are from the self-consistent variational wave functions (7). Anomalous scattering corrections were made for holmium. The function minimized is $\Sigma w^2(F_o - F_c)^2$ where $w = (33.5 - 0.225F + 0.015F^2)^{-1}$, which was derived from consideration of given uniform error in each range of observed structure amplitudes. The unobserved reflections were given zero weight in the final analysis. Only the holmium atom was allowed to have anisotropic thermal parameters. The difference Fourier map showed two peaks of 3 e/Å^3 within 1 Å around the Ho atom. Other peaks are of the order of 1 e/Å^3. The final agreement index is 0.085 whereas the weighted R is 0.111. The final atomic parameters are given in Table 1.[1]

*Mean estimated standard deviations with respect to the last figure are 2, 1, 1 for Ho and 26, 18, 14 for atoms in the NO_3^- groups and 42, 27, 22 for the two NO^+ groups.

†Anisotropic temperature factor for Ho = $\exp\{-2\pi^2 \times 10^{-4}(461a^{*2}h^2 + 310b^{*2}k^2 + 321c^{*2}l^2 + 20a^*b^*hk + 144a^*c^*hl + 56b^*c^*kl)\}$ with an average e.s.d. of 6×10^{-4} for the U_{ij}'s.

Results and Discussion

The structure consists of one $[Ho(NO_3)_5]^{2-}$ and two NO^+ ions; there is no molecular N_2O_4 present.

The $[Ho(NO_3)_5]^{2-}$ Group

All the nitrate ions are coordinated to the holmium and at least four can be considered as symmetrically bounded to the metal (for a

[1]Photocopies of the table of structure factors may be obtained at a nominal charge, upon request, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Canada K1A 0S2.

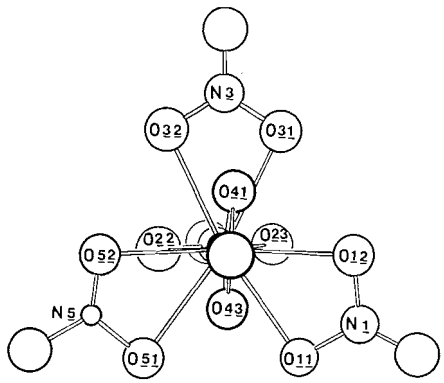

FIG. 1. The trigonal bipyramidal $Ho(NO_3)_5^{2-}$ complex looking down the axial direction.

discussion of "symmetrical" *vs.* "asymmetrical" and a general review of nitrate coordination see ref. 8). It is possible that the nitrate with its nitrogen labelled as N5 may be asymmetrically bound but it is difficult to see why this should be so. The bond distances and angles for this particular nitrate followed the same pattern throughout the refinement despite the use of different weighting schemes.

The coordination about holmium is most readily visualized in terms of the positions of the nitrogen of the five nitrate groups, that is, by considering each nitrate group as a unit)(9). These nitrogens occupy the apices of an essentially regular trigonal bipyramid which has holmium at its center as shown in Fig. 1. The planes of the two nitrate groups in the axial direction are almost perpendicular to each other, and the equatorial nitrate ions are not in the propeller fashion. An unweighted least-squares plane through Ho, N1, N3 and N5 gave the equation $0.7754X + 0.0682Y + 0.6278Z = 6.031$ referring to a, b, and c^* coordinates in Å, and the deviation of the atoms from this plane are:

Atom	Deviation	Atom	Deviation
Ho	0.05	Ce	0
N1	−0.02	N(1)	0
O11	0.39	O(2′)	0.34
O12	−0.45	O(2)	−0.34
N3	−0.02	N(2)	0
O31	−0.05	O(3)	−0.25
O32	0.06	O(4)	0.24
N5	−0.02	N(2′)	0
O51	0.42	O(3′)	0.25
O52	−0.31	O(4′)	−0.24

As a comparison the deviation of the corresponding atoms from a plane $-0.3027X - 0.9531Z = 5.44$ is also given above for the $Ce(NO_3)_5^{2-}$ ion in $(Et_3P)_2Ce(NO_3)_5$ (10). The pentanitratocerate(III) ion is situated at a special site which has C_2 symmetry and therefore the four atoms Ce, N(1), N(2), N(2′) are coplanar. A detailed examination of the two ions reveals that the arrangements of the nitrate ions are the same. The geometry of decacoordination has been discussed previously (9, 11) and it has been pointed out (9) that the highest point-symmetry achievable for these species is C_2. It is generally understood that molecules which possess certain symmetry might not be situated at crystallographic site with point symmetry corresponding to that of the molecule (12). If there were a C_2 axis for the pentanitratoholmate ion, it should be in the direction of Ho → N1. The fact that O31 and O32 are almost in the equatorial plane and O51 and O52 deviate from the plane by 0.4 and −0.3 Å indicates that the C_2 axis does not exist. The departure from C_2 symmetry may arise from the packing in the crystal and a free ion may still retain a C_2 symmetry.

The bond distances and angles with their estimated standard deviations calculated according to ref. 13 are given in Table 2. There is a slight variation in Ho—O distance but an average value of 2.45 Å compared with 2.57 (2) Å for Ce—O found in $Ce(NO_3)_5^{2-}$ (10) agrees with the contraction trend in the lanthanide series. Since no data concerning similar compounds of other elements in the series are available it is difficult to make a quantitative comparison here. The constraints imposed by the short bite of the nitrate ligand can be seen from the values found for O—Ho—O angles. In general, these can be divided into two groups, one in the range of 51–54° if both oxygen atoms are from the same nitrate and the other 68–81° if the oxygen atoms are from neighboring nitrates.

The NO^+ Groups

It is difficult to distinguish oxygen from nitrogen for the NO^+ group and the assignments of oxygen and nitrogen are based on the size of isotropic temperature factors in the initial state of structure analysis.

The bond lengths of 1.06 and 0.93 Å found for the NO^+ groups are not significantly different

and they agree with values found in literature (14). A recent report (15) showed that a compound $K_2Er(NO_3)_5$, prepared in a molten salt medium, is monoclinic with $a = 7.93$, $b = 11.92$, $c = 14.26$ Å, and $\beta = 102.8°$. These data are similar to those of $(NO)_2Ho(NO_3)_5$ and therefore indicate that the two compounds are isomorphous. A study currently being carried out (16) shows that $(NO)_2SnCl_6$ is isomorphous with K_2SnCl_6, K_2PtCl_6 etc with the NO^+ being situated at a site set corresponding to point symmetry of $\bar{4}3m$. This can be achieved through disorder of NO^+ group due to the approximate spherical shape of NO^+ ion. The disorder is also reflected in the high temperature factor for N01, O01, N02 and O02 of Table 1. The similarity between NO^+ and K^+ ions is evident. The two i.r. bands observed due to NO^+ presumably arise from the two different NO^+ environments. Both oxygen atoms in the two NO^+ ions have 6 to 7 neighboring oxygen

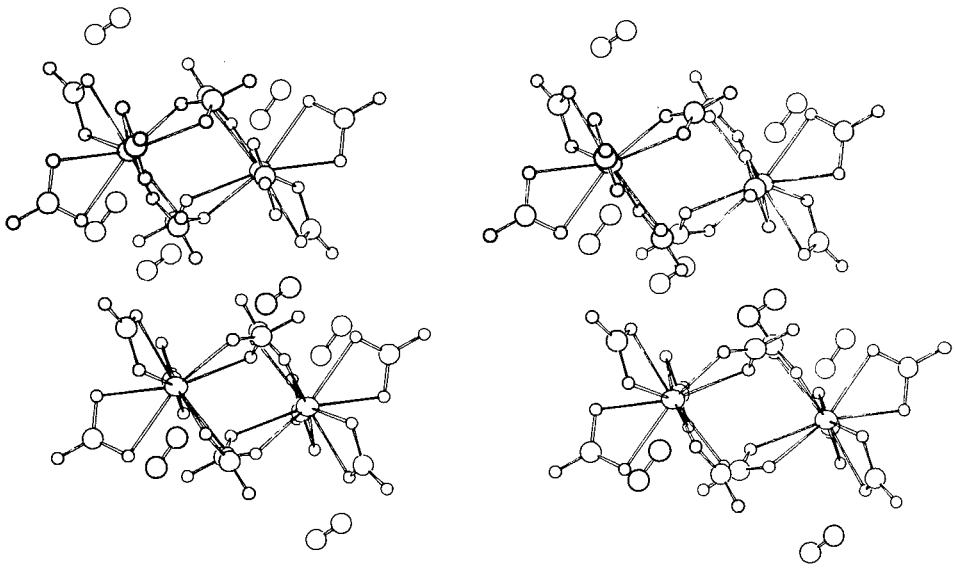

FIG. 2. A stereo-pair of the packing diagram.

at approximately the same distance but N01 has two very short contacts with other oxygen whereas N02 has four moderately close contacts with neighboring oxygen atoms. It is interesting to note that most atoms with which N01 or N02 have close contact are those involved in chelation to the metal. A stereo pair of the packing diagram is shown in Fig. 2, from which, the interionic relations are clear. In the present work, and presumably in all normal dinitrogen tetroxide – metal nitrate adducts, there is no nitrate group which is comparable to that found in the $N_4O_6^{2+}$ species in $Fe(NO_3)_3 \cdot 1.5N_2O_4$. However, in the holmium compound most of the distances between the NO^+ groups and their nearest neighboring oxygens are of comparable magnitude to those within the $N_4O_6^{2+}$ (between 2.4 and 2.7 Å) and hence it might be expected that the N,O^+ stretching vibrations would be similarly lowered. In fact the *two* i.r. bands in the spectrum of the holmium compound (2250 and 2285 cm^{-1}) are lower than, for example, in $Fe(NO_3)_3N_2O_4$ (2298 cm^{-1}), but not to the extent shown in $N_4O_6^{2+}$ (2235 cm^{-1}). It appears that the $O \ldots NO^+$ separations are not a very sensitive measure of the magnitude of the interactions between NO^+ and surrounding groups.

We are grateful to the National Research Council of Canada for financial support of this work. We thank Mr. Craig McDonald for assistance in the early stages of this work.

N. PLAVAC, I. W. J. STILL, M. S. CHAUHAN, and D. M. MCKINNON. Can. J. Chem. **53**, 836 (1975).

Carbon-13 chemical shift data have been obtained for a number of isothiazole, benzo[*c*]-isothiazole, 1,2-dithiole, and 1,3-dithiole derivatives. A number of these compounds are thiones and the chemical shifts of the C=S carbons are discussed in the light of recent attempts to predict such chemical shifts from those of the analogous carbonyl compounds. Comparisons of substituent chemical shift (s.c.s.) effects in these heterocyclic compounds with those in simpler aromatic or conjugated systems have been made and additivity correlations tested in a number of cases.

N. PLAVAC, I. W. J. STILL, M. S. CHAUHAN et D. M. MCKINNON. Can. J. Chem. **53**, 836 (1975).

On a obtenu des données concernant les déplacements chimiques du ^{13}C d'un certain nombre de dérivés d'isothiazoles, de benzo[*c*]isothiazoles, de dithiole-1,2 et de dithiole-1,3. Un certain nombre de ces composés sont des thiones et on discute des déplacements chimiques des carbones C=S à la lumière des essais récents qui ont été faits pour prédire les déplacements chimiques de tels carbones par comparaison avec ceux de composés carbonylés analogues. On a fait une comparaison des effets de déplacements chimiques dus aux substituants (s.c.s.) dans ces composés hétérocycliques avec d'autres dans des systèmes conjugués et aromatiques plus simples et on a vérifié, dans un certain nombre de cas, des corrélations d'additivité.

[Traduit par le journal]

Introduction

A growing volume of data on carbon-13 chemical shift parameters for organic sulfur compounds in general (1–3) and sulfur-containing heterocycles in particular (4–7) has appeared in recent publications. We wish to report our own observations on five series of heterocyclic compounds, three of which may be broadly categorized as isothiazole derivatives, the others comprising 1,2-dithiole and 1,3-dithiole derivatives, respectively. Many of these compounds contain the thione functional group and, in view of a recent claim (5) to have established a linear relationship between the chemical shifts of carbonyl and thiocarbonyl carbons in compounds of the type R(C=X)R′ and R—N=C=X, we were thus particularly interested in testing the predictive value of the correlation below discovered by Kalinowski and Kessler (5) in the wider context of the heterocyclic systems already referred to.

$$\delta_{C=S} = 1.45\delta_{C=O} - 46.5 \text{ p.p.m.}$$

We were also interested in applying some of the substituent chemical shift (s.c.s.) effects in alkenes and aromatic hydrocarbons, available from recent comprehensive reviews of the carbon-13 n.m.r. literature (8, 9) to the potentially more complex systems involved in our study and we will present our findings in this regard also.

Experimental

Natural abundance proton decoupled carbon-13 n.m.r. spectra were obtained on a Varian XL-100-15 spectrometer operating at 25.16 MHz in the pulsed Fourier transform mode. The temperature of the probe was 32 ± 3°. Spectral widths of 6000 Hz, acquisition times of 0.666 s, and pulse widths of 10 μs (90° pulse = 55 μs) were routinely used. In some cases, pulse delays of 1–5 s were used to intensify quaternary carbons, and in other cases, paramagnetic chromium trisacetylacetonate[2] was used for the same purpose. The spectra were transformed

using a Varian 16K-620i computer giving 4096 real points with an accuracy of ±0.1 p.p.m. Off-resonance proton decoupled spectra were obtained where deemed necessary. The deuterium of the solvent (chloroform-*d* or acetone-d_6) was used as lock and primary reference in all cases, and all chemical shifts are measured from TMS (5%) added as internal reference.

The sources of compounds used in this study, or the relevant literature references, are cited in the appropriate Table (1, 3, 4, 5, or 7). Procedures which have not been published previously appear below.

Preparation of Benzo[c]isothiazole

The procedure of Davis and White (14) gave a product contaminated with chlorinated product. It was therefore modified in that toluene was used as a solvent and the product was purified by recrystallization of its picrate.

Preparation of 4-Phenyl-1,2-dithiol-3-one

4-Phenyl-1,2-dithiole-3-thione (2.10 g, 10 mmol) (20) was added to a saturated solution of mercuric acetate in acetic acid (10 ml) and chloroform (40 ml) added. The mixture was stirred 16 h then diluted with water. Work-up afforded pale yellow needles which were recrystallized from petroleum ether (b.p. 60–80°), m.p. 81° (lit (24) m.p. 81°) (78%).

Preparation of 4,5-Diphenyl-1,2-dithiol-3-one

4,5-Diphenyl-1,2-dithiole-3-thione (2.86 g, 10 mmol) (23) was oxidized as above. Recrystallization from ethanol gave pale yellow needles, m.p. 116°, (lit. (24) m.p. 116°) (81%).

Preparation of Methyl 2-Thio-1,3-dithiole-4-carboxylate

2-Thio-1,3-dithiole-2-carboxylic acid (1.78 g, 10 mmol) (18) was added to a stirred solution of diazomethane (0.504 g, 12 mmol) in anhydrous ether (250 ml). The acid dissolved with effervescence. After 20 min the solution was filtered and evaporated to yield a yellow crystalline solid which was recrystallized from hexane as yellow flakes, m.p. 109° (98%); n.m.r. δ ($CDCl_3$) 4.12 (3H, s), 8.04 (1H, s) p.p.m.

Anal. Calcd. for $C_5H_4S_3O_2$: C, 31.41; H, 2.95; S, 50.00. Found: C, 31.46; H, 2.92; S, 50.15.

Results and Discussion

In Table 1 are gathered the chemical shift data for a series of simple isothiazole derivatives. In the case of the monomethyl derivatives these data are in good agreement with results obtained recently by Wasylishen and Becker.[3] Our data for 3-chloro-4-cyano-5-phenylisothiazole are also in good agreement with these authors' results for 4-cyanoisothiazole. In the parent compound, the C-4 carbon appears at 123.6 p.p.m., in accord with its α relationship to the polar C=N functionality. This carbon may also experience some shielding through electron release from the sulfur atom, although the examples of thiophene (in contrast to furan) (9) and our own earlier findings (3) indicate that this effect will be small. The chemical shift difference (Δδ) between C-4 and C-5 in isothiazole (24.4 p.p.m.) is, as expected, somewhat smaller than Δδ for the α- and β-carbon atoms in the presumably more polar cyclopentenone (31.3 p.p.m.) (9).

The α-, β-, and γ-shift effects for the monomethyl- and monophenylisothiazoles are collected in Table 2. It can be seen immediately from this table that these effects, especially the α- and β-effects, are quite variable and are clearly influenced by the location of the substituent and its ability to participate in conjugation with the unsaturated imine structural unit. Unfortunately, only one disubstituted compound, 4,5-diphenylisothiazole, was available and the use of the 4- and 5-phenyl s.c.s. effects gives calculated chemical shift values in only moderately good agreement with those observed. However, such departures from additivity have been noted previously even with simple *ortho*-disubstituted aromatic compounds (30, 31) and in the present case this is not at all surprising, considering the steric bulk of the phenyl substituents.

Data for a series of simple CH_3- and NO_2-substituted benzo[*c*]isothiazoles are collected in Table 3. Chemical shift data for the parent oxygen-containing analog, benzo[*c*]isoxazole, are also included for comparison. With the exception of the C-4 chemical shift in isothiazole itself, which is moved downfield (deshielded) by 11.1 p.p.m. (C-4a in the benzo-fused analog), the chemical shifts for the hetero-ring carbons are not affected very greatly by the extra fused ring. Substitution in the benzene ring does have an effect, however, on the C-3 carbon in benzo[*c*]isothiazole. For example, a methyl substituent at C-4 produces an upfield shift (γ-shielding effect) at C-3 of 1.8 p.p.m., whereas the introduction of a nitro group at C-5 or C-7 produces downfield shifts of 6.4 and 4.2 p.p.m., respectively. This latter effect can be rationalized in terms of the participation of structures such as the ones shown below.

TABLE 2. Substituent chemical shift (s.c.s.) effects* of CH_3 and C_6H_5 in isothiazoles

Derivative	α-effect	β-effect	γ-effect
3-Methyl	+9.7	+0.5	+0.3
4-Methyl	+10.8	+1.8(C-3) −4.2(C-5)	—
5-Methyl	+15.2	−0.1	+0.6
4-Phenyl	+16.5	−1.0(C-3) −5.2(C-5)	—
5-Phenyl	+19.5	−3.4	+1.1

*In p.p.m.; positive values indicate shifts to lower field.

When both a methyl group at C-4 and a nitro group at C-5 are present, the effects are additive at C-3 (+6.4 − 1.8 = +4.6, in agreement with the observed value).

The chemical shifts of the remaining heterocyclic ring carbons (C-4a, C-7a) show a much less clear-cut influence of substitution patterns in the benzenoid ring and indeed are markedly influenced (upfield shifts of the order of 8-10 p.p.m.) only if a nitro group is located on a neighboring carbon.

As far as the benzenoid carbons (C-4, C-5, C-6, C-7) are concerned we have used the simple additivity principle to calculate predicted chemical shifts (which appear in parentheses in Table 3), using recent literature values for the C-1, *ortho*, *meta*, and *para* s.c.s. effects of methyl (9) and nitro groups (31) in aromatic systems. Considering that the total range of shifts observed for the four carbon atoms involved is at least 25 p.p.m., and that we are ignoring any variable effects produced by the heterocyclic ring, the agreement between prediction and observation is quite good. For the two monomethyl derivatives, for example, the mean deviation is 0.6 p.p.m., whereas for the two mononitro derivatives the mean deviation is less good (1.3 p.p.m.). Extension of this approach to two benzo[*c*]isothiazoles substituted by both nitro and methyl groups, as expected, gives poorer agreement, with a mean deviation of 2.3 p.p.m., although no single value deviated by more than 4.5 p.p.m.

The final series of isothiazole derivatives studied were the isothiazolinethiones, for which chemical shift data are collected in Table 4. Since, with one exception, these compounds differ only in the nature of the substituent present on the nitrogen atom, the main interest in this table centers on the chemical shift of the thiocarbonyl carbon. In the 3-isothiazoline-5-thiones (**I**) the mean value for C=S is 193.4 p.p.m., compared with 187.0 p.p.m. in the 4-isothiazoline-3-thiones (**II**), where the thione group is attached to the more electronegative nitrogen atom. These values should be contrasted with an average value for C=S of 202.9 p.p.m. which we found earlier (3) for some α,β-unsaturated thio ketones. On the other hand, Radeglia and Scheithauer (2) found the chemical shift of C=S in dithio esters of the type RCH_2CSSEt to be around 225 p.p.m. and Kalinowski and Kessler (5) reported chemical shifts for C=S in thioamides in the range 179.6–207.2 p.p.m., so that it appears that it is likely that the range of chemical shifts observed for C=S will be at least as great as that for the more familiar C=O group. We will discuss this aspect further in connection with the data obtained for the 1,2- and 1,3-dithiole derivatives (Tables 5 and 7).

The introduction of the second phenyl substituent at C-4 in 4,5-diphenyl-4-isothiazoline-3-thione produces a β-effect (C-5) of −3.7 p.p.m. and a relatively small α-effect (C-4) of +9.1 p.p.m. The corresponding shifts observed for the introduction of a C-4 phenyl group in the somewhat analogous 5-phenyl-1,2-dithiole-3-thione system (Table 5) were −2.5(β) and +9.7(α) p.p.m., respectively. The β-effect of the extra phenyl substituent on the chemical shift of C-3 (C=S) in the isothiazolinethione is quite small (+0.6 p.p.m.). Data for two other derivatives in the 3-isothiazoline-5-thione series, the *N*-methyl and *N*-phenyl analogs, do not appear in Table 4 because they were too insoluble in the solvents chloroform-*d* and acetone-d_6 used throughout this study.

In Table 5 we have collected chemical shift data for a number of phenyl-substituted 1,2-dithiole-3-thiones and 1,2-dithiol-3-ones. Although a full range of comparisons is not available because we were unable to obtain the unsubstituted dithiolone to complete the series, some comparisons are possible. For example, the much greater difference in chemical shift (Δδ) between C_α and C_β of an unsaturated enone than the corresponding unsaturated thione, discussed in our earlier paper (3), is once again evident if one compares analogous compounds. For 4-phenyl-1,2-dithiole-3-thione the Δδ value is 4.9 whereas in 4-phenyl-1,2-dithiol-3-one the corresponding value is 18.3 and in the 5-phenyl substituted analogs the Δδ values are 36.8 and 52.5 p.p.m., respectively.

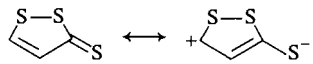
TABLE 6. Substituent chemical shift (s.c.s.) effects* of C_6H_5 in 1,2-dithiole-3-thiones†

Derivative	α-effect	β-effect	γ-effect
4-Phenyl	+9.0	−1.0(C-5) −2.9(C=S)	—
5-Phenyl	+17.7	−4.2	−1.1
5-*p*-Methoxyphenyl	+17.9	−5.8	−1.9

*In p.p.m.; positive values indicate shifts to lower field.
†Unfortunately, we have been unable to obtain the parent carbonyl compound to observe the s.c.s. effects of C_6H_5 in this series.

Substituent chemical shift (s.c.s.) effects for phenyl substitution in the thione series are collected in Table 6. The α-effect produced by 5-phenyl substitution (and in the very closely similar 5-*p*-methoxyphenyl analog) is approximately twice that produced by 4-phenyl substitution, presumably due to the greater contribution of phenyl in the former case to the charged resonance contributor shown below.



A similar doubling for the α-effects of methyl substitution at C_β *vs.* C_α in conjugated enones has already been reported by us (3). When the s.c.s. effects of phenyl were used to predict chemical shifts for C-3, C-4, and C-5 in 4,5-diphenyl-1,2-dithiole-3-thione, the agreement with the observed values was remarkably good, considering the steric bulk of the substituents and problems with the '*ortho*' effect already discussed for the isothiazole series.

For all compounds referred to in Table 5, the effects produced by the phenyl substitution on the chemical shifts of the C=S and C=O carbon atoms were rather small. The mean chemical shift observed for the C=O series of compounds is 193.5 p.p.m. and when this value is used in the empirical correlation of Kalinowski and Kessler (5) the predicted value obtained for the C=S chemical shift in this series is 234.1 p.p.m., in poor agreement with the mean value actually observed (Table 5) of 215.2 p.p.m. Similarly, as will be seen by the data in Table 7, the predicted value (using Kalinowski and Kessler's equation) of the C=S chemical shift of 1,3-dithiole-2-thione is 235.0 p.p.m., and the observed value is again approximately 20 p.p.m. to higher field at 213.3 p.p.m. We are presently unable to advance a reason for the poor correlation in this series, unlike the thioketone, thioamide, and isothiocyanate series reported by Kalinowski and Kessler. It may be worth noting that the observed chemical shift difference (C=O *vs.* C=S) for our two sets of carbonyl and thiocarbonyl compounds is approximately 20 p.p.m. in each case.

Chemical shift data on the final group of heterocyclic compounds are collected in Table 7. This group includes 1,3-dithiole-2-thione and the analogous carbonyl compound, as well as two mono- and two (symmetrically) disubstituted derivatives of the thiocarbonyl compound. It is interesting to note that the chemical shift of the C=S carbon remains essentially unaltered by being flanked by two bivalent sulfur atoms, rather than a sulfur atom and a carbon atom, as in the 1,2-dithiole analog (213.3 *vs.* 216.7 p.p.m.). If one compares a simple carboxylic acid ester with a dialkyl carbonate, for example, the Δδ for the respective carbonyl carbon atoms is approximately 15 p.p.m. (9), whereas for the case of amides and ureas (9), Δδ is slightly greater than 10 p.p.m. Thus it can be seen that the electronic effects on carbon-13 chemical shifts of oxygen, nitrogen, and sulfur run in the order O > N ≫ S. Comparing the parent thiocarbonyl compound with 1,3-dithiol-2-one, a pronounced upfield shift of the signal due to the ethylenic carbons can also be observed in the latter (118.5 *vs.* 129.4 p.p.m.).

In the mono-substituted derivatives of 1,3-dithiole-2-thione, introduction of a phenyl group produces an α-effect of +17.0 and a rather pronounced upfield shift at the β-carbon of −7.4 p.p.m. As in simple ethylene derivatives (9), introduction of a methoxycarbonyl group exerts a downfield shift on both the α- (+6.6) and the β- (+11.0) carbons, and the effect is more pronounced at the β-carbon.

In the disubstituted 1,3-dithiole derivatives, the ethylenic carbons (C-4 and C-5) are once more shifted downfield (+9.6 p.p.m.) in the dicarboxylic ester, although this is a much more pronounced shift than in dimethyl maleate (9) (+5.4 p.p.m.). It is noteworthy too that the chemical shift of the carboxylic ester carbons at 158.5 p.p.m. is at significantly higher field than that observed in diethyl maleate (9) (164.8 p.p.m.). In the 4,5-dicyano compound, the upfield shift (−6.5 p.p.m.) experienced by the ethylenic carbon atoms is again greater than that observed in maleonitrile (9) (−2.4 p.p.m.). The chemical shift observed for the CN group at

The Mechanism of the Microbial Hydroxylation of Steroids. Part 1. The C-21 Hydroxylation of Progesterone by *Aspergillus niger* ATCC 9142

HERBERT L. HOLLAND AND BARBARA J. AURET

Department of Chemistry, The Queen's University of Belfast, Belfast, Northern Ireland BT9 5AG

Received October 8, 1974

HERBERT L. HOLLAND and BARBARA J. AURET. Can. J. Chem. **53**, 845 (1975).

The mechanism of the C-21 hydroxylation of progesterone (**1***a*) by *Aspergillus niger* ATCC 9142 to give 11-deoxycorticosterone (**1***b*) has been studied by the use of progesterone derivatives and of C-21 deuterium labelled progesterones. The requirement of the C-21 hydroxylase system for a C-20 carbonyl group is demonstrated and the possiblity of the involvement of this group, in the C-20,21 enol form, in the C-21 hydroxylation reaction has been discussed. However, on the basis of the observed deuterium isotope effect ($K_H/K_D = 1.25$), a mechanism for the microbial C-21 hydroxylation reaction is proposed in which the rate-determining step is the direct insertion of oxygen into a C-21 carbon–hydrogen bond and not one involving enolization of the C-20 carbonyl.

In addition, C-11α and C-15β hydroxylation of both 20α- and 20β-hydroxypregn-4-ene-3-one (**2***a* and **2***b*) by *A. niger* has been observed.

HERBERT L. HOLLAND et BARBARA J. AURET. Can. J. Chem. **53**, 845 (1975).

On a étudié le mécanisme de l'hydroxylation (en position C-21) de la progestérone (**1***a*) par l'*Aspergillus niger* ATCC 9142 conduisant à la déoxy-11 corticostérone (**1***b*); cette étude a été effectuée à l'aide de dérivés de la progestérone et de progestérone marquée au deutérium en position C-21. On a démontré la nécessité d'un groupe carbonyle en C-20 pour rendre efficace le système d'hydroxylase en C-21; on discute aussi de la possibilité de l'implication du groupement carbonyle en position 20 sous forme d'énol C-20,21 lors de la réaction d'hydroxylation en C-21. Toutefois, sur la base de l'observation d'un effet isotopique ($K_H/K_D = 1.25$), on propose un mécanisme pour la réaction d'hydroxylation microbiologique en C-21 dans lequel l'étape déterminante est l'insertion directe de l'oxygène dans le lien carbone–hydrogène en C-21 et on suggère que cette réaction n'implique pas une énolisation du groupement carbonyle en position C-20.

De plus l'*Aspergillus niger* provoque l'hydroxylation en C-11α et en C-15β des hydroxy-20α et -20β pregène-4 one-3 (**2***a* et **2***b*). [Traduit par le journal]

In spite of the wide application of microbial steroid hydroxylation in both industry and research (1) and a thorough investigation of related biochemical processes (2), comparatively little is known about the chemistry of this reaction.

The proposal that microbial hydroxylation at saturated carbon proceeds by direct electrophilic insertion of oxygen into a C—H bond followed from the discovery of a relationship between microbial hydroxylation of steroids at C_n and microbial epoxidation of steroids unsaturated at C_n, demonstrating the electrophilic nature of microbial hydroxylation (3, 4) and the observation that microbial hydroxylation at saturated carbon proceeds with retention of configuration (5–7).

The question of enzymic substrate activation has received little consideration. For hydroxylation at saturated carbon, chemical analogy suggests that activation is unnecessary: oxidation of steroids at saturated carbon has been achieved under electrophilic conditions (8, 9). However, the problem of enzymic substrate activation during hydroxylation adjacent or vinylogous to carbonyl functions is potentially more complex. The substrates most commonly used (1) for microbial hydroxylations have been Δ^4-3-ketosteroids and it has been proposed (1) that, during their hydroxylation at C-2, -6, -17, or -21, activation occurs by enolization and that hydroxylation occurs by electrophilic attack of oxygen at the enol. This is shown for hydroxylation at C-21 of a C-20 ketosteroid in Scheme 1.

Precedent for such a mechanism is provided by

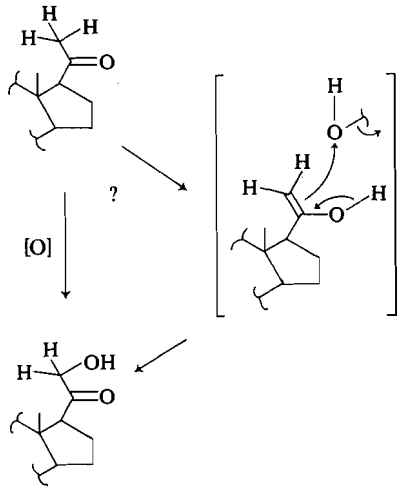

SCHEME 1. Alternative pathways for the C-21 hydroxylation of a C-20 ketosteroid.

the facile oxidation by electrophilic oxygen of steroidal enols to α-hydroperoxy or α-hydroxy ketones (10–14) and by enzymic enolization of ketosteroids (15). Further evidence, albeit circumstantial, is provided by the frequent occurrence of hydroxylations of Δ^4-3,20-diketosteroids at the axial 2β, 6β, 10β (in 19-norsteroids), and 17α positions, whereas microbial hydroxylations at 2α, 6α, 10α, and 17β are unknown (1): analogously, electrophilic attack on the corresponding enols gives exclusively axial substitution of the electrophile (11–13, 16).

To investigate activation by enzymic enolization, the C-21 hydroxylation of progesterone (pregn-4-ene-3,20-dione) (**1***a*) by *Aspergillus niger* ATCC 9142 to give 11-deoxycorticosterone (21-hydroxypregn-4-ene-3,20-dione) (**1***b*) has been examined. The absence of complicating factors such as rigid stereochemistry at C-21 and non-enzymic enolization of the C-20 carbonyl to C-21 (which does not occur under conditions of thermodynamic control (17, 18)) makes this system suitable for the present study.

Previous work (19) established that progesterone, 6β-, 11α-, 11β-, and 14α-hydroxyprogesterone, 11-ketoprogesterone, and 19-norprogesterone were hydroxylated at C-21 by *A. niger* but did not report the effect of variation of functionality at C-20: accordingly, 20α- and 20β-hydroxypregn-4-ene-3-one (**2***a* and **2***b*, respectively) were incubated with *A. niger*. In neither case was C-21 hydroxylation observed but C-15β hydroxylated (**2***c* and **2***e*) and C-11α,15β dihydroxylated (**2***d* and **2***f*) products were formed in minor amount. Their structures follow from the p.m.r. data presented in Table 1 and the Experimental section. Thus C-15β hydroxylation is characterized by a downfield shift of the signal of the C-18 methyl group, with respect to the unsubstituted (at C-15) steroid of *ca.* δ 0.3 p.p.m., and hydroxylation at C-11α produces a similar perturbation of the signal of the C-19 methyl group (20). The p.m.r. spectra of **2***c*–**2***f* accord with this and show signals due to methine protons geminal to hydroxyl of the expected multiplicity for, and in the region characteristic of, the proposed structures (20). The location of hydroxyl in **2***c*–**2***f* was confirmed by oxidation to the corresponding known ketones.

Removal of oxygen from C-20 led to a loss of hydroxylase activity in *A. niger*. Incubation of pregn-4-ene-3-one (**3***a*), the 20-methylene derivative **3***b*, and the 20-thiosteroid **3***c* produced no conversion products. The failure of *A. niger* to metabolize **3***c* is of interest in view of the facile thione–enethiol interconversion (21) and the metabolism of sulfur compounds by other strains of *A. niger* (22).

A C-20 carbonyl group is therefore essential for C-21 hydroxylation and activation of C-21 by enolization of this group has been investigated by the use of progesterone labelled with deuterium at C-21. The results are summarized in Table 2.

Progesterone fully substituted with deuterium at the enolizable carbons (**4***a*) gave, upon incubation with *A. niger*, 11-deoxycorticosterone (**5***a*) with loss of only one deuterium atom per molecule. This follows from mass spectral data (Table 2) and from the p.m.r. spectrum of **5***a*, which showed no absorption at δ 4.18 (*cf.* the spectrum of **1***a*, Table 1), and demonstrates that, if enolization is occurring during hydroxylation, it cannot be reversible with exchange of protium with the medium. It also establishes that no loss of label occurs from C-2, -4, -6, or -17 during hydroxylation. In this and subsequent incubations of labelled progesterones, starting material was recovered which showed no loss or scrambling of label.

Progesterone with one deuterium atom at C-21 (**4***b*) was prepared by hydrogenolysis of 21-iodoprogesterone with zinc and monodeuterioacetic acid, and the location of label confirmed by spectral analysis. Thus the p.m.r.

signal of the C-21 methyl at δ 2.11 corresponded to approximately two protons, while mass spectral analysis of **4***b* confirmed the presence of deuterium at C-21 (see Experimental).

Incubation of **4***b* with *A. niger* gave 11-deoxycorticosterone which consisted of unlabelled material **1***b* and the diastereomeric monodeuterioalcohols **5***b* and **5***c*. Mass spectral analysis showed all the label to be present at C-21: intense ions were observed at *m/e* 299 (M − CHDOH) and 271 (M − C_2HDO_2H) corresponding to the loss of C-21 and C-20 + C-21 and their substituents, respectively, whereas the ^{13}C corrected intensities of the corresponding ions at *m/e* 300 and 272, expected if label were located in the steroid nucleus, were zero. Analysis of the p.m.r. spectrum (C_6D_6 solution) of the mixture of **1***b*, **5***b*, and **5***c* showed **5***b* and **5***c* to be present in equimolar amounts. Two absorptions of equal area at δ 3.86 and 3.98, attributable to the C-21 hydrogens of **5***b* and **5***c*, were complicated by the presence of an AB quartet (J = 19 Hz) centered at δ 3.95 and assigned to the C-21 hydrogens of **1***b* but nevertheless their assignment to **5***b* and **5***c* is unambiguous. No attempt was made to assign these signals individually to **5***b* or **5***c*.

The formation of **5***b* and **5***c* in equimolar amounts shows that the two hydrogens originally present at C-21 may be lost with equal facility: by implication, the replacement of hydrogen by hydroxyl is nonstereospecific. The deuterium content of the product (**1***b* + **5***b* + **5***c*) thus enables the deuterium isotope effect of the C-21 hydroxylation to be calculated as $K_H/K_D = 1.3 \pm 0.1$.[1]

This was confirmed following synthesis of 2,2,4,6,6,17,21,21-d_8-progesterone (**4***c*) (Scheme 2) and incubation with *A. niger*. The synthesis involved loss of some deuterium during acid catalyzed hydrolysis of the intermediate 2,2,4,6,6,17,21,21-d_8-pregn-4-ene-3,20-dione 21-(2′-tetrahydropyranyl) ether but spectral analysis of **4***c* clearly indicated that deuterium content at C-21 was 2.0 atoms per molecule and that loss had taken place from C-2, -4, or -6. Thus the mass spectrum of **4***c* showed ions at *m/e* 126–129 from the fragment C-1-6 + C-19, a fragment appearing from unlabelled material **1***a* at *m/e* 124 (23) and observed in the mass spectrum of 2,2,4,6,6,17,21,21,21-d_9-progesterone (**4***a*) at *m/e* 129. The p.m.r. spectrum of **4***c* showed absorption in the region δ 2.0–2.6, essentially absent from the spectrum of **4***a* and attributable to protons adjacent or vinylogous to carbonyl; the signal of the C-21 methyl of **4***c* appeared as a singlet corresponding to approximately one proton at δ 2.11.

The 11-deoxycorticosterone formed from **4***c* consisted of the diastereomers **5***d* and **5***e*, analogous to **5***b* and **5***c*, in equimolar amount, together with **5***a* which contained a maximum

---

[1]If % d_1-progesterone is x and % d_0-progesterone is $(100 - x)$ then, in the absence of an isotope effect,

$(100 - x)d_0$-progesterone → $(100 - x)d_0$-11-DOC

and

xd_1-progesterone → $1/3xd_0$-11-DOC + $2/3xd_1$-11-DOC

In the presence of an isotope effect y, where $y = K_H/K_D$, then

$(100 - x)d_0$-progesterone → $(100 - x)d_0$-11-DOC

and

xd_1-progesterone → $(1/3)(x/y)d_0$-11-DOC + $(x - (1/3)(x/y))d_1$-11-DOC

Thus,

[1] final % d_1-11-DOC = $(x - (1/3)(x/y)) = z$

and

[2] final % d_0-11-DOC = $(100 - x) + (1/3)(x/y)$ = $(100 - z)$

Found

$x = 75.5 \pm 0.5$

$z = 58.0 \pm 0.5$

Therefore, from [1] or [2]

$y = 1.3 \pm 0.1$

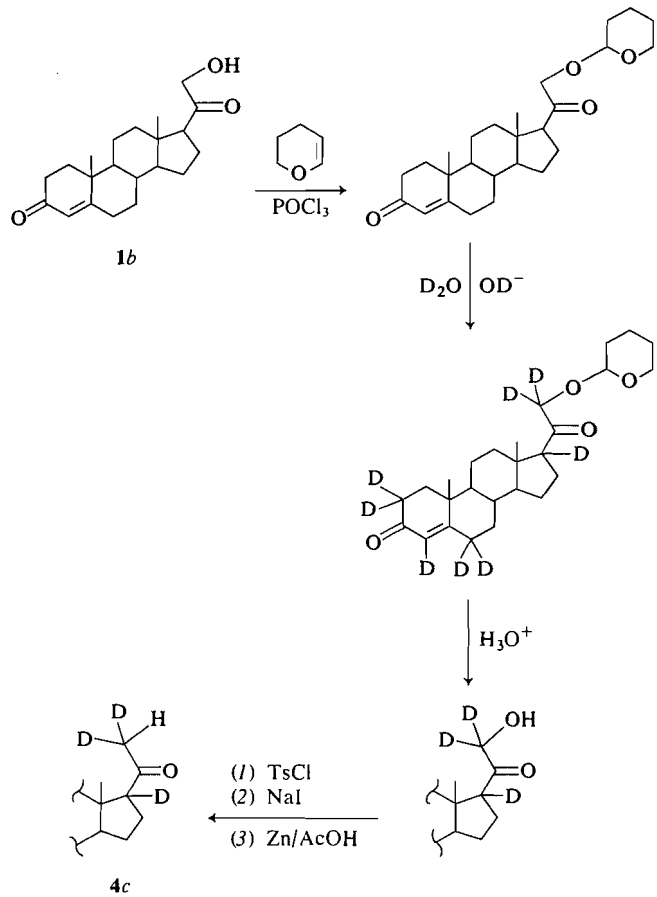

SCHEME 2. Synthesis of 2,2,4,6,6,17,21,21-d_8-progesterone (**4***c*).

of eight deuterium atoms per molecule. Proton magnetic resonance analysis was facilitated by the absence of material unlabelled at C-21 and confirmed the results of the incubation of **4***b*. Calculation of the deuterium isotope effect for the conversion of **4***c* to 11-deoxycorticosterone gave $K_H/K_D = 1.2 \pm 0.1$, in close agreement with the value obtained from the incubation of **4***b*.

The magnitude of this effect eliminates a mechanism of C-21 hydroxylation in which enolization of the C-20 carbonyl, with a rate determining loss of hydrogen from C-21, is the slow step. Primary deuterium isotope effects of between 5 and 10 for base (24–26) and acid (27) catalyzed enolizations of ketones, where the loss of α hydrogen is rate determining, have been reported. However, the effect is consistent with a mechanism of C-21 hydroxylation involving rate determining electrophilic insertion into a C—H or C—D bond. The observed value is similar to those of analogous chemical reactions such as the autoxidation of cholesterol at C-7α ($K_H/K_D = 1.8$) (28) and the insertion of a carbene into a C—H or C—D bond ($K_H/K_D = 1.8$) (29). The latter process has been the subject of calculations (30) which indicate a transition state with little C—H bond lengthening, consistent with an isotope effect of small magnitude (31). By analogy, the isotope effect of the C-21 hydroxylation may be the result of rate limiting electrophilic insertion of oxygen into a C—H or C—D bond, with little lengthening of that bond in the transition state.

This interpretation is supported by the isotope effects of enzymic hydroxylations of steroids

at nonenolizable positions. Hydroxylations at C-7β of estr-4-ene-3,17-dione (32), C-7α of cholesterol (28), C-6β of taurochenodeoxycholic acid (28), and C-11α of progesterone (6) all involve isotope effects close to unity.

This result does not, however, eliminate the C-20,21 enol from involvement in C-21 hydroxylation. Enolization may occur in which loss of hydrogen from C-21 is not rate limiting: Hine and co-workers (33, 34) have observed catalysis of the dedeuteration of α-deuteriocarbonyl compounds in which loss of deuterium is only partly rate controlling. Similar catalysis, in which the rate determining step may involve the carbonyl center (34), may occur in enzymic enolization of the C-20 carbonyl. In this event, the deuterium content of the product would depend on the relative rates of loss of protium or deuterium from C-21 and would therefore be subject to a primary isotope effect whose magnitude in this situation is unknown.[2] Exchange of deuterium at C-21 with protium from the medium does not occur during hydroxylation: the observed isotope effect is not therefore the result of an equilibration of protium and deuterium during reversible enolization.

The complexity of interpretation of the kinetic isotope effects of enzymic hydroxylations has been discussed fully (28, 32) and the isotope effect of the C-21 hydroxylation of progesterone is not open to unambiguous interpretation. It appears, however, that the effect is the result of a mechanism in which any of the C-21 C—H bonds may undergo direct insertion of oxygen, leading to the formation of 11-deoxycorticosterone directly. The microbial conversion of steroidal C-methyl groups into hydroxymethyl is well known (1) and is performed on androst-4-ene-3,17-dione by *A. niger* ATCC 9142 (35).

The C-21 hydroxylation of progesterone by *A. niger* ATCC 9142 is therefore a reaction directly analogous in mechanism to hydroxylation at saturated carbon not adjacent or vinylogous to carbonyl and not one in which the substrate is activated to electrophilic attack by enolization. The latter remains an attractive hypothesis however for axial hydroxylation at the enolizable positions of Δ^4-3-ketosteroids and will receive further consideration.

[2]J. Hine, private communication.

Experimental

Apparatus, Materials, and Methods

Melting points were determined on a Kofler heating stage and are uncorrected. Infrared spectra were recorded with a Perkin-Elmer 137, p.m.r. spectra with a Varian HA 100, using deuteriochloroform as solvent (unless otherwise stated) and TMS as internal standard, and mass spectra were obtained with an AEI MS902. Deuterium content was estimated by repeated scanning of the relevant ions and application of the appropriate corrections for ^{13}C. Accurate mass measurements were made by reference to the perfluorokerosene spectrum. Optical rotation data were obtained in chloroform solution with a Perkin-Elmer 141 polarimeter.

Column chromatography was performed on silica gel (Whatman's SG 31) and thin-layer chromatography on Merck silica $PF_{254+366}$.

Aspergillus niger ATCC 9142 was obtained from the American Type Culture Collection, Washington, D.C. and was maintained on 2% malt agar slopes.

Preparation of Substrates

Pregn-5-ene-3,20-dione Bis(ethylene acetal)

This was prepared by the method described (36) from progesterone (7.5 g). Recrystallization from acetone gave the title compound (6.8 g, 71%), m.p. 179–181° (lit. (36) m.p. 177–180°).

Pregn-5-ene-3,20-dione 3-(Ethylene Acetal)

This was prepared from pregn-5-ene-3,20-dione bis(ethylene acetal) (6 g) by the method described (37). Recrystallization from acetone gave the desired compound (3.8 g, 84%), m.p. 175–176° (lit. (37) m.p. 178–180°).

20α-Hydroxypregn-5-ene-3-one Ethylene Acetal

Sodium (9.3 g) was added portionwise to a refluxing solution of pregn-5-ene-3,20-dione 3-(ethylene acetal) (3.5 g) in 2-propanol (300 ml). When addition was complete refluxing was continued for 15 min. The solution was then poured onto ice-water (300 ml) and the precipitated solid collected by filtration, washed with water, and dried *in vacuo*. Recrystallization from ether gave the product (2.5 g, 71%), m.p. 177–179°, $[\alpha]_D^{21}$ −41.9° (*c*, 1.0) (lit. (38) m.p. 178–180°, $[\alpha]_D$ −43°).

20α-Hydroxypregn-4-ene-3-one (2a)

Sulfuric acid (8% v/v; 15 ml) was added to a solution of 20α-hydroxypregn-5-ene-3-one ethylene acetal (2.5 g) in methanol (50 ml). The solution was refluxed for 15 min, neutralized with 5% sodium bicarbonate, poured onto ice-water, and the precipitate collected by filtration and washed with water. Two crystallizations from ethyl acetate gave **2a** (1.9 *g*, 85%), m.p. 160–163°; $[\alpha]_D^{20}$ +95.4° (*c*, 1.0) (lit. (39) m.p. 161–162°, $[\alpha]_D^{22}$ +98.6°); p.m.r.: included signals at δ 0.72 (3H, s, C-18 methyl), 1.20 (3H, s, C-19 methyl), 1.26 (3H, d, J = 6 Hz, C-21 methyl), 3.70 (1H, quintet, J = 6,6,6,6 Hz, C-20 H), 5.75 (1H, d, J = 1 Hz, C-4 H).

20β-Hydroxypregn-4-ene-3-one (2b)

This was prepared from progesterone (5 g) by the method described (40). Recrystallization from aqueous methanol gave the product (3.1 g, 64% overall), m.p. 172–174°, $[\alpha]_D^{25}$ +85.2° (*c*, 1.0) (lit. (40) m.p. 174–175°, $[\alpha]_D^{20}$ +86°); p.m.r.: included signals at δ 0.78 (3H, s, C-18 methyl), 1.14 (3H, d, J = 6 Hz, C-21 methyl),

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

1.18 (3H, s, C-19 methyl), 3.70 (1H, m, C-20 H), 5.75 (1H, d, J = 1 Hz, C-4 H).

Pregn-4-ene-3-one (3a)

This was prepared from 3β-hydroxypregn-5-ene-20-one (3 g) by the route described (41). Recrystallization from methanol gave the product (1.4 g, 47% overall), m.p. 102–105°, $[\alpha]_D^{20}$ +124° (*c*, 0.9) (lit. (41) m.p. 102–104°, $[\alpha]_D$ +121°).

20-Methylpregna-4,20(21)-diene-3-one (3b)

This was prepared from 3β-hydroxypregn-5-ene-20-one (5 g) by the route described (42). The crude product (1.96 g) was purified by chromatography and crystallization from aqueous methanol to give the title compound (1.7 g, 34% overall), m.p. 153–156°, $[\alpha]_D^{18}$ +110° (*c*, 0.96) (lit. (42) m.p. 152–154°, $[\alpha]_D^{27}$ +112° (*c*, 1.35)).

20-Thiopregn-4-ene-3-one (3c)

This was prepared from 3β-hydroxypregn-5-ene-20-one (6 g) by the route described (43). Chromatography of the crude product on alumina gave the title compound (0.8 g, 11% overall), m.p. 112–115°.

2,2,4,6,6,17,21,21,21-d_9-Progesterone (4a)

Sodium (1 g) was added to a solution of progesterone (1 g) in dry dioxan (50 ml) and deuterium oxide (12 ml) added to this solution. The solution was refluxed for 7 days, cooled, neutralized to pH 8 with acetic acid, poured onto ice-water (150 ml), and rapidly extracted with ether. The ether extract was washed with water, dried, and evaporated to give a residue which, on crystallization from ether – light petroleum, gave the desired compound (0.64 g, 63%), m.p. 120–122°, $[\alpha]_D^{25}$ +165° (*c* 1.02, EtOH); p.m.r.: included signals at δ 0.67 (3H, s, C-18 methyl), 1.18 (3H, s, C-19 methyl), 2.0–2.6 (*ca.* 0.2H, m, protons adjacent or vinylogous to carbonyl); m.s.: *m/e* 323(100), 322(30), 321(5), 279(50), 278(10), 129(70), 128(21); analysis of ions at *m/e* 320–323 gave the following molecular isotopic composition: d_9, 78%; d_8, 19%; d_7, 3%; d_6, 0%.

21-d-Progesterone (4b)

Zinc dust (1.2 g) was added to a solution of 21-iodopregn-4-ene-3,20-dione (1.2 g) (44) in monodeuterioacetic acid (10 ml) and the mixture stirred for 10 min at room temperature. The solution was then filtered, water (100 ml) added to the filtrate, and this solution extracted with ether. The ethereal extract was washed with 2 M sodium bicarbonate, dried, and evaporated. The residue was chromatographed to give, after recrystallization from ether – light petroleum, the product (0.4 g, 46%), m.p. 120–122°; p.m.r.: included signals at δ 0.67 (3H, s, C-18 methyl), 1.18 (3H, s, C-19 methyl), 2.11 (*ca.* 2H, s, C-21 CH_2D), 5.76 (1H, broad s, C-4 H); m.s.: *m/e* 315(100), 314(30), 273(60), 272(20), 271(7), 125(30), 124(180); analysis of ions at *m/e* 314, 315 gave the following molecular isotopic composition: d_1, 77.5%; d_0, 22.5%.

Pregn-4-ene-3,20-dione 21-(2′-Tetrahydropyranyl) Ether

Phosphorous oxychloride (1 g) was added to a solution of 11-deoxycorticosterone (2.5 g) and 2,3-dihydropyran (0.64 g) in dichloromethane (50 ml) and the resulting solution stirred at 35° for 15 min. Ether (300 ml) was then added and the solution washed with 2 M sodium bicarbonate and water, dried, and evaporated to give a residue which, on crystallization from pentane, afforded the product (1.87 g, 62%), m.p. 110–113°, $[\alpha]_D^{18}$ +186° (*c*, 1.07) (lit. (45) m.p. 111–112°, $[\alpha]_D^{25}$ +183°).

2,2,4,6,6,17,21,21-d_8-Pregn-4-ene-3,20-dione 21-(2′-Tetrahydropyranyl) Ether

Sodium (1 g) was added to a solution of pregn-4-ene-3,20-dione 21-(2′-tetrahydropyranyl) ether (1.5 g) in dry dioxan (100 ml). Deuterium oxide (20 ml) was then added and the resulting solution treated as described in the preparation of 2,2,4,6,6,17,21,21,21-d_9-progesterone (**4a**). The title compound (1.36 g), after recrystallization from hexane, melted at 110–113°, $[\alpha]_D^{18}$ +181° (*c*, 0.94); m.s.: analysis of ions at *m/e* 414-422 gave the following molecular isotopic composition: d_8, 74%; d_7, 18%; d_6, 7%; d_5, 1%.

2,2,4,6,6,17,21,21-d_8-11-Deoxycorticosterone

Hydrochloric acid (37%, 5 drops) was added to a solution of 2,2,4,6,6,17,21,21-d_8-pregn-4-ene-3,20-dione 21-(2′-tetrahydropyranyl) ether (1.36 g) in hexane (100 ml) and methanol (100 ml). The mixture was stirred at room temperature for 2 h and evaporated to give a residue which was dissolved in ether, washed with 2 M sodium bicarbonate, dried, and evaporated. Recrystallization from aqueous methanol gave the product (1.0 g, 86%), m.p. 139–142°, $[\alpha]_D^{20}$ +181° (*c*, 1.0); m.s.: analysis of ions at *m/e* 330–338 gave the following molecular isotopic composition: d_8, 41%; d_7, 39%; d_6, 14%; d_5, 6%.

2,2,4,6,6,17,21,21-d_8-21-Iodopregn-4-ene-3,20-dione

This was prepared from 2,2,4,6,6,17,21,21-d_8-11-deoxycorticosterone (1 g) by the method described (44). The crude product (1.2 g) was used directly.

2,2,4,6,6,17,21,21-d_8-Progesterone (4c)

This was prepared from 2,2,4,6,6,17,21,21-d_8-21-iodopregn-4-ene-3,20-dione (1.2 g) by the procedure described for the preparation of 21-*d*-progesterone, using acetic acid in place of monodeuterioacetic acid. The product, after purification by chromatography and crystallization from aqueous methanol (0.48 g, 57%), melted at 120–121°; p.m.r.: included signals at δ 0.66 (3H, s, C-18 methyl), 1.18 (3H, s, C-19 methyl), 2.11 (*ca.* 1H, s, C-21 CHD_2), 2.0–2.6 (*ca.* 0.6H, m, protons adjacent or vinylogous to carbonyl); m.s.: *m/e* 322(80), 321(70), 320(25), 280(0.1), 279(2), 278(11), 277(37), 276(25), 275(11), 129(17), 128(60), 127(43), 126(37); analysis of ions at *m/e* 314–322 gave the following molecular isotopic composition: d_8, 40%; d_7, 40%; d_6, 13.6%; d_5, 6.4%.

Incubations with A. niger ATCC 9142

Incubations were performed in a 5-l fermentation vessel, mechanically stirred and aerated with air sterilized by passage through a Whatman Gamma 10 filter. Growth medium (2.5 l, containing Czapek Dox nutrient 33.4 g/l) was autoclaved in the fermentation vessel at 15 p.s.i. for 20 min, and then allowed to cool. A spore suspension obtained by shaking an agar slope of *A. niger* with sterile glass beads in water was then transferred to the vessel with a sterile syringe; this process was repeated so that two slopes were used to inoculate 2.5 l of medium. After 2 days growth at 28°, a solution of the substrate (1 g) in ethanol (50 ml) was added to the flask and growth allowed to continue for a further 4 days. The mycelium and medium were then separated by centrifugation, and both extracted with dichloro-

For personal use only.

methane. The extract was dried over sodium sulfate and evaporated. Incubations with smaller quantities of substrate were performed with proportionately smaller fermentation volumes.

Progesterone (1a)

One gram gave a crude extract (0.434 g) which was subjected to preparative t.l.c. (ether) and gave: progesterone (0.16 g from ether – light petroleum), R_f 0.87, identified by m.p. and spectral comparison with an authentic sample. And *11-deoxycorticosterone* (0.21 g from aqueous methanol), R_f 0.6, identified by m.p. and spectral comparison with an authentic sample; p.m.r.: included signals at δ 0.70 (3H, s, C-18 methyl), 1.20 (3H, s, C-19 methyl), 4.18 (2H, broad s, C-21 H), 5.73 (1H, broad s, C-4 H); p.m.r. (C_6D_6) included signals at δ 0.48 (3H, s, C-18 methyl), 0.70 (3H, s, C-19 methyl), 3.95 (2H, ABq, J = 19 Hz, C-21 H), 5.81 (1H, broad s, C-4 H).

20α-Hydroxypregn-4-ene-3-one (2a)

One gram gave a crude extract (0.537 g) which was subjected to preparative t.l.c. (ethyl acetate) and gave: 20α-hydroxypregn-4-ene-3-one (**2a**) (0.3 g from aqueous methanol), R_f 0.6, identified by m.p. and spectral comparison with an authentic sample. And *15β,20α-dihydroxypregn-4-ene-3-one (2c)* (0.028 g from ethyl acetate – light petroleum), R_f 0.43 (ethyl acetate), 0.16 (ether), 0.40 (chloroform–methanol–water 188:12:1), m.p. 210–212°, M^+ 332.2358 ($C_{21}H_{32}O_3$ requires M^+ 332.2351), $[\alpha]_D^{18}$ +60° (*c*, 0.4); i.r.: ν_{max} (KBr) 3470, 1670, 1620 cm^{-1}; p.m.r.: included signals at δ 1.03 (3H, s, C-18 methyl), 1.11 (3H, d, J = 6 Hz, C-21 methyl), 1.19 (3H, s, C-19 methyl), 3.80 (1H, quintet, J = 6,6,6,6 Hz, C-20 H), 4.30 (1H, t, J = 7,7 Hz, C-15 H), 5.75 (1H, d, J = 1 Hz, C-4 H).

Oxidation of **2c** was performed as follows: a solution of **2c** (0.015 g) in acetone (5 ml) was stirred at 25° during the addition of standard chromic acid reagent (46) until the reagent was present in excess. Water (15 ml) was then added and the mixture extracted with ether. The extract was washed with 2 M sodium bicarbonate, dried, and evaporated to give a residue (0.014 g) which on crystallization from aqueous methanol gave pregn-4-ene-3,15,20-trione (0.011 g), m.p. 154–156°, $[\alpha]_D^{24}$ +198° (lit. (47) m.p. 155–157°, $[\alpha]_D^{23}$ +200°). And *11α,15β,20α-trihydroxypregn-4-ene-3-one (2d)* (0.016 g from ethyl acetate – light petroleum), R_f 0.23 (ethyl acetate), 0.1 (ether), 0.25 (chloroform–methanol–water 188:12:1); M^+ 348.2298 ($C_{21}H_{32}O_4$ requires M^+ 348.2300); m.p. 230–232°, $[\alpha]_D^{18}$ +55° (*c*, 1.3); i.r.: ν_{max} (KBr) 3470, 1670, 1620 cm^{-1}; p.m.r.: included signals at δ 1.00 (3H, s, C-18 methyl), 1.25 (3H, d, J = 6 Hz, C-21 methyl), 1.35 (3H, s, C-19 methyl), 3.80 (1H, quintet, J = 6,6,6,6 Hz, C-20 H), 4.00 (1H, sextet, J = 10,10,6 Hz, C-11 H), 4.30 (1H, t, J = 7,7 Hz, C-15 H), 5.75 (1H, d, J = 1 Hz, C-4 H).

Oxidation by the method described above gave pregn-4-ene-3,11,15,20-tetraone (0.008 g), m.p. 214–216°, $[\alpha]_D^{20}$ +309° (*c*, 0.5) (lit. (48) m.p. 218–221°, $[\alpha]_D^{23}$ +325°).

20β-Hydroxypregn-4-ene-3-one (2b)

One gram gave a crude extract (0.4 g) which was subjected to preparative t.l.c. (ethyl acetate) and gave 20β-hydroxypregn-4-ene-3-one (0.246 g from aqueous methanol), identified by m.p. and spectral comparison with an authentic sample. And *15β,20β-dihydroxypregn-4-ene-3-one (2e)* (0.04 g from diisopropyl ether–hexane), R_f 0.35 (ethyl acetate), 0.32 (ether), 0.49 (chloroform–methanol–water 188:12:1); M^+ 332.2356 ($C_{21}H_{32}O_3$ requires M^+ 332.2351), m.p. 188–190°, $[\alpha]_D^{24}$ +44° (*c*, 0.8); i.r.: ν_{max} (KBr) 3470, 1670, 1620 cm^{-1}; p.m.r.: included signals at δ 1.10 (3H, s, C-18 methyl), 1.17 (3H, d, J = 6 Hz, C-21 methyl), 1.24 (3H, s, C-19 methyl), 3.90 (1H, m, C-20 H), 4.28 (1H, t, J = 7,7 Hz, C-15 H), 5.76 (1H, d, J = 1 Hz, C-4 H).

Oxidation by the method described above gave pregn-4-ene-3,15,20-trione, m.p. 153–156°, $[\alpha]_D^{23}$ +196° (*c*, 1.0). And *11α,15β,20β-trihydroxypregn-4-ene-3-one (2f)* (0.027 g from ether), R_f 0.22 (ethyl acetate), 0.15 (ether), 0.3 (chloroform–methanol–water 188:12:1); M^+ 348.2303 ($C_{21}H_{32}O_4$ requires M^+ 348.2300), m.p. 248–252° (dec.), $[\alpha]_D^{23}$ −24° (*c*, 1.0); i.r.: ν_{max} (KBr) 3470, 1670, 1620 cm^{-1}; p.m.r.: included signals at δ 1.10 (3H, s, C-18 methyl), 1.18 (3H, d, J = 6 Hz, C-21 methyl), 1.35 (3H, s, C-19 methyl), 3.90 (1H, m, C-20 H), 4.00 (1H, sextet, J = 10,10,5 Hz, C-11 H), 4.30 (1H, t, J = 7,7 Hz, C-15 H), 5.75 (1H, d, J = 1 Hz, C-4 H).

Oxidation by the method described above gave pregn-4-ene-3,11,15,20-tetraone, m.p. 216–219°, $[\alpha]_D^{20}$ +317° (*c*, 0.4).

Pregn-4-ene-3-one (3a)

One gram gave a crude extract (0.621 g). Analysis by t.l.c. indicated the presence of starting material (R_f 0.66, ether) only. Chromatography gave **3a** (0.508 g from methanol), identified by m.p. and spectral comparison with an authentic sample.

20-Methylpregna-4,20(21)-diene-3-one (3b)

A 0.2 g sample gave a crude extract (0.137 g), t.l.c. analysis of which indicated the presence of starting material (R_f 0.6, ether) only. Preparative t.l.c. gave **3b** (0.12 g from aqueous methanol), identified by m.p. and spectral comparison with an authentic sample.

20-Thiopregn-4-ene-3-one (3c)

A 0.24 g sample gave a crude extract (0.157 g). The only steroid detectable by t.l.c. analysis was **3c** (R_f 0.23, ether), which was recovered by chromatography on alumina.

2,2,4,6,6,17,21,21,21-d_9-Progesterone (4a)

One gram gave a crude extract (0.46 g) which was subjected to preparative t.l.c. (ether) and gave 2,2,4,6,6,-17,21,21,21-d_9-progesterone (0.11 g from ether – light petroleum), R_f 0.76, identified by m.p. and spectral comparison with an authentic sample; m.s.: analysis of ions at *m/e* 320–323 gave the following molecular isotopic composition: d_9, 77%; d_8, 20%; d_7, 3%; the mass spectrum was identical with that of authentic **4a**. And *2,2,4,6,6,17,21,21-d_8-11-deoxycorticosterone (5a)* (0.124 g from aqueous ethanol), R_f 0.4, identified by m.p. and spectral comparison with unlabelled material **1b**; p.m.r.: included signals at δ 0.70 (3H, s, C-18 methyl), 1.20 (3H, s, C-19 methyl) but no absorption in the region 4.18 (C-21 CH_2OH); m.s.: *m/e* 338(20), 337(5), 336(1), 335(0.05), 305(100) (M − CD_2OH), 277(50) (M − $C_2D_2O_2H$); analysis of ions at *m/e* 335–338

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

gave the following molecular isotopic composition: d_8, 77.2%; d_7, 18.8%; d_6, 4%.

21-d-Progesterone (4b)

A 0.35 g sample gave a crude extract which was subjected to preparative t.l.c. (ether) and gave 21-*d*-progesterone (0.062 g from ether – light petroleum), R_f 0.8, identified by m.p. and spectral comparison with an authentic sample; p.m.r.: included signals at δ 0.67 (3H, s, C-18 methyl), 1.18 (3H, s, C-19 methyl), 2.11 (*ca.* 2H, s, C-21 CH_2D), 5.76 (1H, broad s, C-4 H); m.s.: analysis of ions at *m/e* 314, 315 gave the molecular isotopic composition as d_1, 78%; d_0, 22%. The mass spectrum was identical with that of **4***b*. And *21-d-11-deoxycorticosterone (**1***b* + **5***b* + **5***c*)* (0.074 g from aqueous methanol), R_f 0.4, identified by m.p. and spectral comparison with an authentic sample of unlabelled material; p.m.r. (C_6D_6): included signals at δ 0.48 (3H, s, C-18 methyl), 0.70 (3H, s, C-19 methyl), 3.86 (*ca.* 0.3H, broad s, C-21 C*H*DOH), 3.95 (*ca.* 0.5H, ABq, J = 19 Hz, C-21 CH_2OH), 3.98 (*ca.* 0.3H, broad s, C-21 CD*H*OH), 5.82 (1H, broad s, C-4 H); m.s.: *m/e* 331(15), 330(9), 300(26), 299(100) (M − CHDOH), 272(12), 271(50), 270(1.1) (M − $C_2DO_2H_2$); analysis of ions at *m/e* 330,331 gave the following molecular isotopic composition: d_1, 58%; d_0, 42%.

2,2,4,6,6,17,21,21-d_8-Progesterone (4c)

One gram gave a crude extract (0.594 g) which afforded, after preparative t.l.c. (ether), 2,2,4,6,6,17,21,21-d_8-progesterone (0.214 g from aqueous methanol), R_f 0.8, identified by m.p. and spectral comparison with an authentic sample. And *2,2,4,6,6,17,21,21-d_8-11-deoxycorticosterone (**5***a* + **5***d* + **5***e*)* (0.092 g from aqueous methanol), R_f 0.4, identified by m.p. and spectral comparison with an authentic sample of unlabelled material; p.m.r. (C_6D_6): included signals at δ 0.48 (3H, s, C-18 methyl), 0.70 (3H, s, C-19 methyl), 3.86 (*ca.* 0.25H, broad s, C-21 CD*H*OH), 3.95 (*ca.* 0.25H, broad s, C-21 C*H*DOH); m.s.: *m/e* 338(10), 337(15), 336(10), 335(3), 334(2), 333(0.1), 305(100) (M − CD_2OH), 277(45), 276(40) (M − $C_2D_2O_2H$); analysis of ions at *m/e* 333–338 gave the following molecular isotopic composition: d_8, 16%; d_7, 40%; d_6, 29%; d_5, 9%; d_4, 6%.

The award of a demonstratorship (to H.L.H.) from the Queen's University of Belfast is gratefully acknowledged, as is the able technical assistance of Miss H. Reid with microbiological work.

Thanks are also due to Dr. D. B. MacLean of McMaster University, Hamilton, Ontario, for reading the manuscript, and to Dr. J. Hine of the Ohio State University, Columbus, Ohio, for helpful correspondence.

Reactions du phenyl-1 dimethyl-3,4 phosphole avec divers chlorures d'acides aromatiques

FRANÇOIS MATHEY, DANIEL THAVARD ET BERNARD BARTET
Institut National de Recherche Chimique Appliquée 91710 Vert-le-Petit, France

Reçu le 9 juillet 1974

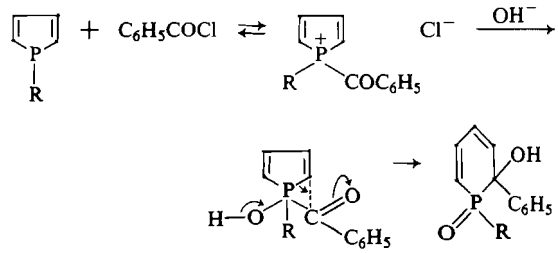
FRANÇOIS MATHEY, DANIEL THAVARD et BERNARD BARTET. Can. J. Chem. **53**, 855 (1975).

Le phényl-1 diméthyl-3,4 phosphole réagit en présence d'eau avec les chlorures de benzoyles substitués et les chlorures de 2- ou 3-thienyles pour fournir des hydroxy-2 dihydro-1,2 phosphorines. La réaction est particulièrement sensible aux effets stériques. Elle échoue avec les chlorures d'acides aliphatiques. Les résultats observés ne s'expliquent pas totalement par une compétition entre la réaction d'extension de cycle et l'hydrolyse des chlorures d'acides. Une explication complémentaire est proposée. Les hydroxy-2 dihydro-1,2 phosphorines se transforment à leur tour en oxa-1 phospha-2 cycloheptadiènes-4,6 en présence de traces de NaH. Cette nouvelle extension de cycle semble moins sensible aux effets stériques mais plus aux effets électroniques. Elle échoue avec les dérivés du thiophène. Les données r.m.n. de l'ensemble des produits préparés sont présentées et discutées. On note en particulier d'importants couplages P–C–OH dans les hydroxydihydrophosphorines.

FRANÇOIS MATHEY, DANIEL THAVARD, and BERNARD BARTET. Can. J. Chem. **53**, 855 (1975).

1-Phenyl-3,4-dimethylphosphole with water and substituted benzoyl chlorides or 2- and 3-thienyl chlorides is expanded into 2-hydroxy-1,2-dihydrophosphorines. This reaction is particularly affected by steric effects. It fails with aliphatic acid chlorides. These results are not fully explained by a competition between the expansion reaction and the hydrolysis of the chlorides. A complementary explanation is proposed. The 2-hydroxy-1,2-dihydrophosphorines are in turn expanded into 1-oxa-2-phosphacyclohepta-4,6 dienes with catalytic amounts of NaH. This other expansion reaction seems to be only weakly affected by steric but more strongly by electronic effects. It fails with thienyl derivatives. Nuclear magnetic resonance data are given and discussed for all the new products. Large P–C–OH couplings in hydroxydihydrophosphorines are noteworthy.

Dans un précédent travail (1) nous avons décrit la réaction de divers phospholes avec le chlorure de benzoyle en présence d'eau. Cette réaction conduit généralement à un oxyde de (phényl-2 hydroxy-2) dihydro-1,2 phosphorine. Ayant noté qu'à l'intérieur de la série des phényl-1 phospholes diversement substitués sur les carbones du cycle, les rendements de cette réaction décroissaient rapidement avec la nucléophilie du phosphore, nous avons admis que le premier stade de l'extension de cycle comprenait une attaque électrophile de l'ion acyle sur ce même phosphore. Dans l'hydroxy acyl phosphorane qui est le stade intermédiaire de l'hydrolyse du chlorure d'acyl phospholium ainsi obtenu, le noyau phosphole se trouve certainement en position apicale-équatoriale à cause de l'angle ∠CPC intracyclique qui reste voisin de 90° (2) quel que soit le degré de coordinance du phosphore par suite de la contrainte cyclique. Dans ces conditions, d'après les théories couramment admises sur l'hydrolyse des sels de phosphonium, c'est la liaison P—C apicale du cycle qui se rompt préférentiellement à la liaison P–acyle équatoriale. Il y a ensuite recyclisation par attaque de l'anion ainsi formé sur le carbonyle. Le schéma ci-dessous résume le mécanisme que nous proposons.



Si cette façon de voir est la bonne, on remarque que ce n'est pas l'"aromaticité" controversée des phospholes mais seulement leur contrainte cyclique qui est en jeu dans cette réaction. Ce fait vient d'être tout récemment confirmé par Smith et Smith (3) qui ont montré que l'on pouvait généraliser ce type d'extension de cycle aux phosphétanes (∠CPC ≃ 82° (4))

mais que, dès que l'on passait aux phospholènes ($\angle$CPC $\simeq$ 94° (5)) et aux phospholanes ($\angle$CPC $\simeq$ 96° (4)), la réaction prenait un cours différent et conduisait à l'oxyde de la phosphine utilisée et a l'aldéhyde benzoïque. Dans ces deux derniers cas, en effet, la contrainte cyclique n'est plus suffisante pour empêcher le groupement acyle très apicophile (6) de chasser le cycle de sa position apicale-équatoriale.

Cette réaction représentant le premier exemple général d'extension de cycle des phospholes (pour divers essais d'extension de cycle des

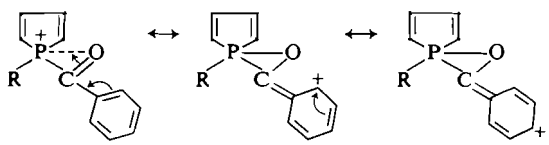
phospholes dans des cas particuliers voir réfs. 7–9) et étant, de plus, le premier cas connu d'insertion du motif d'un chlorure d'acide dans la liaison P—C d'une phosphine, nous avons voulu vérifier si d'autres chlorures d'acides pouvaient remplacer le chlorure de benzoyle dans cette transformation.

Les résultats de nos essais avec les chlorures d'acides aromatiques et le phényl-1 diméthyl-3,4 phosphole sont reproduits dans le tableau 1. Tous nos essais avec les chlorures d'acides aliphatiques (CH_3COCl, $(CH_3)_3CCOCl$, $C_6H_5CH_2$-COCl, ClCO COCl, C_2H_5OCO COCl) se sont par contre soldés par des échecs. Ce fait appelle un premier commentaire.

Comme la r.m.n. du proton d'un mélange de phényl-1 diméthyl-3,4 phosphole, de chlorure de benzoyle et de triéthylamine dans le deutériochloroforme ne permet pas de mettre en évidence le sel d'acyl phospholium, on peut admettre que l'équilibre de formation de ce sel est très fortement déplacé vers la gauche. Lorsqu'on ajoute de l'eau à un tel mélange, pour pouvoir observer la formation de l'hydroxy dihydrophosphorine, il faut donc que la vitesse de transformation du sel de phospholium en phosphorine soit beaucoup plus élevée que la vitesse d'hydrolyse du chlorure d'acide. Or, d'une manière générale, les chlorures d'acides aliphatiques s'hydrolysent beaucoup plus rapidement que les chlorures d'acides aromatiques. *A priori*, on a donc là une première raison pouvant expliquer les comportements différents des chlorures d'acides aliphatiques et aromatiques. Cette raison est cependant insuffisante pour rationaliser l'ensemble de nos résultats comme le montre le tableau 2. On remarquera en particulier le cas du chlorure de *p*-nitrobenzoyle.

Une déchlorhydratation du chlorure d'acide aliphatique par la base conduisant à un cétene étant exclue dans le cas du chlorure de l'acide pivalique, la solubilisation du produit final lors du remplacement d'un chlorure aromatique par un chlorure d'acide aliphatique ne pouvant expliquer une suppression totale de la réaction d'extension de cycle (des phosphorines solubles dans le milieu réactionnel ont été obtenues à partir des P alkyl phospholes(1)), il est donc nécessaire de postuler un mécanisme réactionnel faisant explicitement intervenir le noyau aromatique. Nous proposons une stabilisation du sel d'acyl phospholium intermédiaire par délocalisation de la charge positive sur le noyau aromatique du radical acyle. Dans le cadre de



I II III

cette hypothèse il est à remarquer que les formes limites **II** et **III** sont des phosphoranes dans lesquels la tension du noyau phosphole est supprimée en position apicale-équatoriale, ce qui est très favorable.

D'autre part, on constate que le transfert électronique du noyau aromatique vers le phosphore s'effectue au détriment des positions 2, 4 et 6. Un substituant en *para* sur le noyau aromatique n'affectant que très peu les densités électroniques sur ces positions, on rationalise

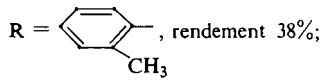
ainsi le résultat *a priori* surprenant suivant lequel le rendement de la réaction d'extension de cycle ne dépend que très légèrement de la nature du substituant greffé en position 4 (comparaison de **5** et **8** par exemple). Un substituant donneur en *méta* sur le noyau augmentant au contraire les densités électroniques sur les positions 2, 4 et 6, on comprend aussi pourquoi **3** se forme avec un meilleur rendement que **4**.

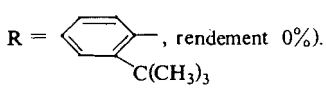
Dans le thiophene on sait que seules les liaisons C_2—C_3 et C_4—C_5 ont une multiplicité nettement supérieure à 1 (voir les données structurales (11)). L'influence d'un substituant en position 2 se fait donc sentir principalement sur la position 3 et inversement. D'autre part, on sait également que les doubles liaisons sont polarisées en direction du soufre

(le sens du moment dipolaire montre bien que le soufre joue un rôle globalement électroattracteur vis-à-vis du cycle (12)). Dans ces conditions la stabilisation du sel de 3-thienyl phospholium aux dépens de la position 2 riche en électrons est plus complète que celle du sel de 2-thienyl phospholium aux dépens de la position 3 pauvre en électrons. Il est donc logique d'observer pour **10** un rendement supérieur à celui de **9**.

Enfin l'azote en position 3 dans le chlorure de l'acide nicotinique appauvrissant fortement les positions 2, 4 et 6 par suite de sa forte électronégativité déstabilise sensiblement le sel de phospholium intermédiaire, ce qui permet d'expliquer l'échec de l'extension de cycle dans ce dernier cas. Nous voyons donc que le schéma de stabilisation proposé permet en gros de rendre compte correctement des résultats observés.

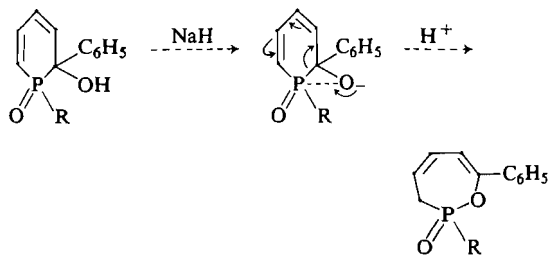
La lecture du tableau 1 appelle un second commentaire. Il apparaît immédiatement que les facteurs stériques jouent un rôle prépondérant (avec R = C_6H_5, rendement 87%):





Cet effet stérique est caractéristique des réactions nucléophiles du P^{III} et constitue un argument indirect supplémentaire en faveur du mécanisme proposé.

Dans notre précédent travail (1) nous avions également montré que les hydroxy-2 dihydro-1,2 phosphorines se réarrangeaient en présence de quantités catalytiques de NaH pour donner des oxa-1 phospha-2 cycloheptadiènes-4,6.



Disposant d'une gamme importante de phosphorines, nous avons voulu vérifier si leur extension en cycle heptagonal était une réaction générale. Sauf avec les dérivés thiophéniques **9** et **10**, nous avons réussi cette transformation. Le tableau 3 résume les résultats obtenus.

Nous ne ferons que deux commentaires sur cette réaction. Tout d'abord elle ne semble pas être sensible à la présence d'un substituant en *ortho* sur le noyau benzénique en position 2 (cas de la transformation **2** → **12**). Ensuite nous avons constaté que la présence d'un méthoxy ou d'un chlore en *para* sur le noyau aromatique en position 2 stabilisait la phosphorine et rendait nécessaire l'emploi de conditions plus dures pour effectuer sa conversion en cycle heptagonal (cas de **5** notamment). Nous avons alors, mais sans succès, tenté de piéger l'anion dérivé de **5** en l'alkylant par ICH_3.

Données de résonance magnétique nucléaire du proton des cycles à six et sept chainons

Ces données sont rassemblées dans les tableaux 4 et 5. La lecture du tableau 4 fait apparaître deux caractéristiques des hydroxydihydrophosphorines. (*a*) Dans de nombreux cas apparaît un important couplage P–C–O–H très sensible à la nature du solvant employé : environ 15 Hz dans le DMSO et compris entre 0 et 10 Hz dans le chloroforme. L'apparition de ces couplages traduit vraisemblablement l'existence d'un ralentissement des échanges entre OH dû à l'encombrement stérique régnant dans cette partie de la molécule. Rappelons à ce propos que fort peu de couplages P–C–O–H sont décrits dans la littérature (voir réf. 13). (*b*) Lorsque le groupement R comprend un noyau benzénique celui-ci apparaît comme un singulet élargi, sauf s'il comporte un substituant très électrodonneur

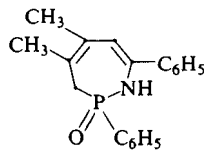
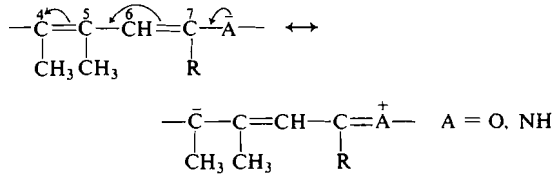
ou très électroattracteur qui provoque une différenciation des protons aromatiques. Ceci traduit sans doute la libre rotation du noyau benzénique autour de la liaison C(2)—R. Dans le cas de **2** cette libre rotation signifie qu'il n'y a pas d'intéraction entre le CH_3 en *ortho* et le OH ce qui est en accord avec les données i.r. qui ne montrent aucune anomalie dans la position de la bande OH. Cette absence d'intéraction explique pourquoi la réaction d'extension de cycle faisant passer de **2** à **12** se réalise aussi facilement qu'en l'absence de substituant en *ortho* comme nous l'avons noté précédemment.

A l'opposé le noyau benzénique du groupement R des cycles heptagonaux se présente toujours sous la forme d'un multiplet complexe très élargi et en moyenne plus déblindé que dans les cycles à six chaînons correspondants. Ce fait permet de soupçonner l'existence, d'ailleurs logique, d'une conjugaison entre le noyau aromatique et le système diènique du cycle bloquant la rotation du radical R autour de sa liaison avec C(7). Ce phénomène a été vérifié sur **19** homologue azoté de **11** par détermination de structure aux rayons X (14).



19

D'autre part, l'attribution des signaux CH_3-C(4) et $CH_3C(5)$ a été effectuée en admettant que leurs déplacements chimiques sont principalement affectés par la polarisation du système diènique induite par les doublets libres de l'oxygène ou de l'azote.



La présence d'une telle conjugaison a été mise en évidence indirectement par l'étude des propriétés chimiques de ces hétérocycles (pour A = NH on peut notamment substituer HC(6) par le brome (15)) et par l'étude de la structure de **19** (14) (la liaison N—C(7) est beaucoup plus courte qu'une liaison N—C normale). Dans ces conditions, nous attribuons le signal le plus blindé à $CH_3C(4)$. Cette conclusion est l'inverse de celle que l'on tirerait de l'étude des seuls couplages CH_3---P.

Pour finir, nous noterons le blindage anormal du proton HC(6) de **12** qui correspond d'ailleurs à une anomalie dans le spectre i.r. En effet, tous les cycles heptagonaux présentent trois bandes de doubles liaisons à environ 1640, 1610 et 1590 cm^{-1}. Pour **12** la deuxième bande, sans doute attribuable à la double liaison C(6)=C(7), est deplacée à 1630 cm^{-1}. Dans **12** existe donc vraisemblablement une intéraction entre cette double liaison et le méthyle en *ortho* sur R.

Partie expérimentale

Les spectres r.m.n. ont été réalisés par Mme R. Mankowski-Favelier sur des appareils Perkin-Elmer R12 à 60 MHz et Jeol PS 100 FT à 100 MHz. Pour la préparation du phényl-1 diméthyl-3,4 phosphole, voir réf. 16.

Synthèse des oxydes de phényl-1 hydroxy-2 diméthyl-4,5 dihydro-1,2 phosphorines

Dans un réacteur sous argon on place 3.8 g de phényl-1 diméthyl-3,4 phosphole (0.02 mol), 10 cm^3 de triéthylamine et 150 cm^3 d'éther sec. En agitant, on verse alors à température ambiante 0.04 mol de chlorure d'acide RCOCl. La triéthylamine neutralise les traces d'acide chlorhydrique toujours présentes dans le chlorure. Une fois la neutralisation terminée, on ajoute 200 cm^3 d'eau. On laisse réagir pendant 2 h. On filtre le précipité formé, on le lave à l'eau et à l'éther, puis on le sèche soigneusement. La phosphorine ainsi obtenue est simplement recristallisée. Pour les données analytiques, voir tableau 6.

Synthèse des oxydes de phényl-2 diméthyl-4,5 oxa-1 phospha-2 cycloheptadiénes-4,6 (cas général)

Dans un réacteur sous argon on place 0.01 mol d'hydroxydihydrophosphorine, 50 cm^3 de diméthylformamide anhydre et une pincée de NaH à 80% dans l'huile. On laisse agiter 4 h à température ambiante. On obtient ainsi une solution homogène légèrement colorée en jaune. On hydrolyse par 5 cm^3 d'eau, neutralise par HCl 2 *N* puis évapore à sec. On reprend le résidu par un mélange eau, chloroforme. La couche chloroformique est décantée, séchée et évaporée. Le produit ainsi obtenu est chromatographié sur colonne de silice 70–230 mesch Merck: éluant acétate d'éthyle. Le produit recherché élue avant la phosphorine (R_f 0.6). Pour les données analytiques, voir tableau 6.

*Cas particulier de **15** et **16***

Le mélange habituel est chauffé à 120 °C pendant 4 h. Le traitement est ensuite identique.

Les auteurs remercient vivement Mme. R. Mankowski-Favelier pour la réalisation des spectres r.m.n.

Identification of Phenyl Vinyl Ketone and Related Compounds as 2,4-Dinitrophenylhydrazones and Pyrazolines

C. F. H. ALLEN

Chemistry Department, Rochester Institute of Technology, Rochester, New York 14623

Received September 23, 1974

C. F. H. ALLEN. Can. J. Chem. **53**, 865 (1975).

The closely interrelated, titled compounds, which have similar physical properties and which form mixtures difficult to separate, are best characterized by instrumental methods.

All α,β-unsaturated aldehydes and methyl ketones gave open-chain dinitrophenylhydrazones directly, whereas the arylated ketones form pyrazolines, as is well known.

C. F. H. ALLEN. Can. J. Chem. **53**, 865 (1975).

La façon la plus simple de caractérisé les composés mentionnés dans le titre qui sont intimement reliés entre eux, qui ont des propriétés physiques similaires et qui forment des mélanges difficiles à séparer fait appel à des méthodes instrumentales.

Tous les aldéhydes et toutes les méthyles cétones non-saturés en position α,β donnent directement des dinitrophénylhydrazones en chaîne ouverte alors que les cétones portant un groupe aryle forment, comme il est bien connu, des pyrazolines. [Traduit par le journal]

During our earlier work (1) it was found that phenyl vinyl ketone (PVK, **1**) could be isolated in quantity by chloroform extraction of an alcoholic solution of 3-chloro- or 3-dimethylaminopropiophenone containing potassium acetate (1,2), thus avoiding the many tedious, recorded methods (3–13). The usual, characteristic solid derivative, now employed for identification of isolated PVK, is 1,3-diphenyl-2-pyrazoline **9** (2, 3, 15, 16, 20).

Because PVK is such a reactive substance, mixtures, difficult to separate, are formed in alcoholic and acidic solutions of 2,4-dinitrophenylhydrazine by all usual procedures. Furthermore, the solubilities, colors, and melting points of closely related compounds, including dinitrophenylhydrazine itself, are very similar, so they are not readily separated and identified; an example is the derivative of dinitrophenylhydrazone of 3-dimethylaminopropiophenone (**4**), probably the preferable source of PVK in solution, and 1-(2,4-dinitrophenyl)-3-phenylpyrazoline (**5**).

Anticipating that 3-chloropropiophenone-DNPH (**6**) could be dehydrohalogenated to PVK-DNPH (**2**), an alcoholic solution was treated with the reagent (14). The mixture formed consisted of a small amount of the desired derivative **6**, considerable 3-ethoxypropiophenone-DNPH (**3**), and, as the main product, the bis-DNPH of 2′,2′-di-(2-benzoylethyl)-2,4-dinitrophenyl-1-hydrazine (**7**); a propoxy derivative of the latter has been previously described (18).

When **6** was dissolved in warm pyridine it at once lost hydrogen chloride, with consequent formation of the known pyrazoline **5** (19). The formation of **3** suggests that there has been a partial dehydrohalogenation of 3-chloropropiophenone to give **1**, which preferentially adds alcohol (3).

Experimental

Preparation of Compounds

3-Dimethylaminopropiophenone-DNPH (4)

A mixture of the free base from 2.2 g of the hydrochloride (17) and 25 ml of alcohol was added to a hot, previously prepared dinitrophenylhydrazinium chloride solution (14). There was no visible change but small orange-yellow crystals began to separate in 3–4 min. After 1 h in the refrigerator, 1 g of the derivative was collected on a filter; successive crops made the yield practically quantitative. The same derivative (**4**) is directly obtainable from the hydrochloride. It is also formed on employing DMF as a solvent and evaporating all the latter in a current of air on the steam bath. The substance is very slightly soluble in alcohol, ethyl acetate, and chloroform, moderately soluble in hot acetic acid (unsuitable for recrystallization), but very soluble in hot pyridine, hot DMF, Diglyme, and DMSO.

When the usual procedure for preparing dinitrophenylhydrazones was employed with **1** the product was **3**. An attempted use of trifluoroacetic acid gave 2′-trifluoroacetyl-2,4-dinitrophenylhydrazine (**8**) almost instantly; off-white needles, m.p. 163–164°.

Because DNPH is moderately soluble in cold DMF, this solvent was examined. The deep red solution of 0.2 g of the hydrazine in 1.4 ml of DMF was unchanged after addition of 1 g of PVK but the color was at once lightened on adding 3 drops of concentrated hydrochloric acid. After removal of all the solvent in a current of air, on the steam bath, a gummy mixture remained; less than

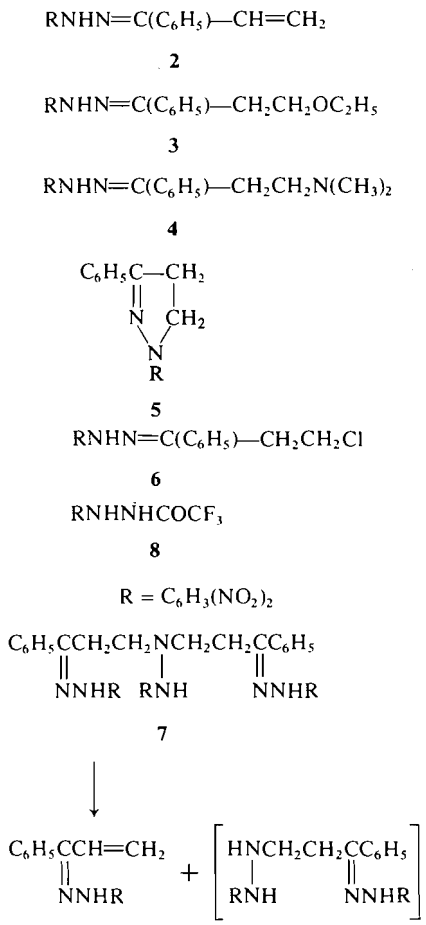
For personal use only.



1 mg of fine red material was isolated from two runs by triturating with ethyl acetate or formate, chloroform, or ether. It melted at 188–189° (lit. (9) m.p. 195–196°). It seems obvious that PVK-DNPH (**2**) is not a suitable reference compound.

3-Chloropropiophenone (6)

To a hot suspension of 0.8 g of dinitrophenylhydrazine in 25 ml of boiling alcohol, 4 ml of concentrated hydrochloric acid was added, followed by 0.8 g of the 3-chloro ketone in 15 ml of hot alcohol; shortly, a crystalline mixture began to separate. After 4 h it was collected on a filter. Separation of the mixture was tedious. The chloro derivative **6** was always formed in a very low yield. As it was more soluble in alcohol it could be separated from **3**; the latter crystallized well from ethyl acetate or propyl alcohol. Although it was difficult to remove traces of these low-melting components, the main product was always the bishydrazone **7**. The latter is sparingly soluble in the usual solvents but dissolves easily in warm pyridine, 1-methylpyrrolidone, Diglyme, and DMF. It is best purified by dissolving in a little hot pyridine and adding an equal volume of water. The pure product melts at 243–244°, with preliminary shrinking at about 225–226°.

Occasionally the crude chloro derivative (m.p. 139–140°), which contains considerable ethoxy-DNPH (**3**), separated in a few hours. Purification was then accomplished by suspending in hot alcohol and adding sufficient ethyl acetate to give a clear solution. After several recrystallizations the analytical sample had m.p. 131°. Small amounts were purified by chromatography (45 g of Al_2O_3 in 42 ml of hexane, using a 50 ml burette). A benzene suspension was added at the top and eluted with this solvent, collecting the deep orange-red effluent. The separation was discontinued when the color became yellow (due to **3**). The reddish product that separated on evaporation of the solvent was suitable for conversion to the dinitropyrazoline **5**. The crude, chlorinated hydrazone **6** dissolved readily in warm pyridine; upon the addition of water the known (19) pyrazoline **5** separated in shiny, yellow flakes, suggestive of 'gold dust.' This pyrazoline was also identified in the colored mixtures that resulted from the interaction of **1** and dinitrophenylhydrazinium chloride in methyl and ethyl alcohols; only the pyrazoline and unchanged DNPH could be isolated from the red tar that was formed in Diglyme (24).

1,3-Diphenylpyrazoline (9)

This compound (m.p. 151–152°) is obtainable reproducibly by mixing 3 drops each of isolated **1** and phenylhydrazine in 5 ml of alcohol, and adding a trace of acetic acid (3). More recently this pyrazoline has been obtained from the Mannich salt (16) and from 3-chloropropiophenone; the literature (15) gives no details but it "is easier to get than phenyl vinyl ketone." This pyrazoline and its benzene solution show a striking brilliant blue fluorescence in u.v. light; invisible spots that may get on the skin, not removable by washing, are readily detected in this way.

Physical Properties

The remainder of this section is concerned with the characterization of PVK and closely related compounds by instrumental methods. Although none of the latter is universally applicable, mass spectroscopy appears to be the most useful. In all but one instance **7** it gave the molecular ion and characteristic fragmentation pattern. These spectra were determined by the use of a Hitachi RMS-4.

Mass Spectroscopy

2,4-Dinitrophenylhydrazine has a molecular ion at *m/e* 198 (74% M) and fragment ions at *m/e* 180 (8.5), 122 (28), 92 (16), 79 (100), 76 (44), 75 (44), and 51 (89).

Phenyl vinyl ketone-DNPH (2) has a molecular ion at *m/e* 312 (70% M) and fragment ions at *m/e* 265 (41), 264 (13), 218 (15), 189 (14), 115 (74), 105 (100), and 77 (100).

3-Ethoxypropiophenone-DNPH (3) has a molecular ion at *m/e* 358 (84% M) and fragment ions at *m/e* 329 (6.3), 312 (27), 311 (16), 295 (16), 265 (46), 119 (65), 104 (41), 103 (100), 59 (70), and 29 (75). The fragmentation pattern is very similar to that of **5**.

3-Chloropropiophenone-DNPH (6) has a molecular ion at *m/e* 348 (13% M) and fragment ions at *m/e* 312 (50), 295 (5), 265 (40), 219 (24), 218 (33), 117 (25), 116 (25), 115 (65), 104 (37), 103 (30), and 77 (100). The fragmentation pattern is very similar to that of **5**.

3-Dimethylaminopropiophenone-DNPH (4) has a molecular ion at *m/e* 357 (12% M) and fragment ions at *m/e* 355 (2), 312 (0.8), 310 (0.1), 265 (2), 115 (4), 103 (22),

TABLE 1. Analyses

Compound No.	Empirical Formula	Molecular weight	Calculated (%) C	H	N	Found (%) C	H	N

*Calculated: Cl, 10.1. Found: 9.8.

77 (14), and 58 (100), the last attributed to $—CH_2N(CH_3)_2$.

3-Methoxypropiophenone-DNPH (26) has a molecular ion at *m/e* 344 and fragment ions comparable to the ethoxy homolog, as well as the significant one at 45 (100%) attributed to $—CH_2OCH_3$.

1,3-Diphenyl-2-pyrazoline (9) has a molecular ion at *m/e* 222 (100% M) and fragment ions at *m/e* 221 (27), 117 (8), with small amounts at 115, 111, 104, 103, 91, 75.

1-(2,4-Dinitrophenyl)-3-phenyl-2-pyrazoline (5) has a molecular ion at *m/e* 312 (100% M) and fragment ions at *m/e* 295 (23), 265 (91) plus smaller amounts at 220 (20), 219 (23), 218 (6), 165 (19), 117 (22), 116 (6), 103 (50), and 77 (36).

The pyrazoline from chalcone (25) has a molecular ion at *m/e* 388 (70% M), 386 (15), 371 (30), 356 (10), 353 (31), 340 (100), 294 (46), and small values down to 103 (13), and 77 (32).

The bishydrazone 7 decomposed in the mass spectrometer, leaving a brownish residue; because the peak intensity ratios changed during the analysis, thermal decomposition is suggested. Scale divisions (in parentheses) were measured. Found: *m/e* 329 (7), 328 (9), 325 (10), *312* (70), 298 (19), 279 (41), *265* (65), 264 (22), ***218*** (70), *217* (30), *183* (55), *115* (63), *105* (80), 104 (90), ***103*** (210), *77* (190). The values in italics are those characteristic of **2**. The value at 312 has the same *m/e* as **2** (70% M) and the isomeric dinitropyrazoline **5** (100% M); the latter also has values (bold face italic) *not found* in the above, at 295, 220, 219, 165, 117, 116, hence both **2** and **5** may be present. Although the peaks fit better for the PVK-DNPH, its presence is not unequivocally certain. However, on inspection of the structures involved it is seen that a cleavage of 7 to give this DNPH **2** is essentially a reverse Michael addition (21–23), consistent with and analogous to the formation of phenyl vinyl ketone from 3-dimethylaminopropiophenone (7). Its presence is a reasonable conclusion.

$$C_6H_5COCH_2CH_2N(CH_3)_2 \rightarrow C_6H_5COCH{=}CH_2 + HN(CH_3)_2$$

Nuclear Magnetic Resonance

These spectra were measured on a Varian A spectrometer. The chemical shifts are reported in ppm downfield from tetramethylsilane. The solvents were $CDCl_3$ and DMSO-d_6.

Compound 3: δ 1.15 (t, J = 7 Hz, 3H, O—C—CH_3), 3.20 (t, J = 5.5 Hz, 2H, N = C—CH_2), 3.85 (t, J = 5.5 Hz, N = C—C—CH_2—O—), 7.4 (m, 3H, ArH), 7.9 (m, 2H, ArH), 8.03 (d, $J_{AB} \simeq 9$ Hz, 1H, A of ABX of 2,4-DNP), 8.31 (dd, $J_{AB} \simeq 9$ Hz, $J_{BX} \simeq 2.5$ Hz, 1H, B of ABX), 9.13 (d, $J_{BX} \simeq 2.5$ Hz, 1H, X of ABX), 11.9 (broad s, 1H NH).

Compound 4: δ 2.85 (s, 6H, NMe_2), 3.3 (broad m, area uncertain since H_2O peak superimposed, =C—CH_2CH_2—N—), 7.5 (m, 3H, *m, p*-Hs of phenyl), 8.0 (m, 2H, *o*-Hs of phenyl), 8.05 (d, J_{AM} = 9 Hz, 1H, A of AMX of 2,4-DNP), 8.37 (dd, J_{AM} = 9 Hz, J_{MX} = 3 Hz, 1H, M of AMX), 8.83 (d, J_{MX} = 3 Hz, 1H, X of AMX), and 11.3 (broad s, 1H, NH).

Compound 6: ABX for dinitrophenyl at 9.12 (J = 2.5 Hz), 8.34 (J = 9 Hz, 2.5 Hz), the remaining H of this pattern is obscured by the other aromatic absorption: C_6H_5 at 7.76 (m, 2H) and 7.43 (m, 4H); AA′BB′ pattern at 3.42 (t, 2H) and 3.83 (t, 2H, NH at 11.7).

Compound 2: δ 5.86 (dd, J_{AM} = 2 Hz, J_{MX} = 17 Hz, 1H, =CH_2), 6.18 (dd, J_{AM} = 2 Hz, J_{AX} = 11 Hz, 1H, =CH_2), 6.75 (dd, J_{MX} = 1 Hz, J_{AX} = 11 Hz, 1H, =CH), 7.5 (m, 3H, *m*- and *p*-H of C_6H_5), 7.8 (m, 2H, *o*-H of C_6H_5), 8.14 (d, J_{AM} = 9 Hz, 1H, A of AMX of 2,4-DNP), 8.38 (dd, J_{AM} = 9 Hz, J_{MX} = 3 Hz, 1H, M of AMX of 2,4-DNP), 9.18 (d, J_{MX} = 3 Hz, 1H, X of AMX of 2,4-DNP), 13.0 (broad s, 1H, NH).

Compound 9: this showed a typical symmetrical AA′BB′ pattern, the two halves being centered at ~3.2 and 3.8 p.p.m. for the N—$CH_ACH_{A'}$—$CH_BCH_{B'}$—C= N moiety. The aromatic H appeared in a complex multiplet from 6.7–7.8 p.p.m.

Compound 5: ABX for DNP at 7.09 (J = 9 Hz), 8.27 (J = 9 Hz, 2.5 Hz), 8.45 (J = 2.5 Hz), phenyl at 7.44 (m, 3H), 7.67 (m, 2H), AA′BB′ at 3.43 (t, 2H) and 4.07 (t, 2H).

Ultraviolet Spectroscope

Ultraviolet absorption appears to be of less use for the identification of closely related 2,4-dinitrophenylhydrazones because, as will be noticed on inspection of the earlier literature (9), the wavelengths and extinctions of many of the derivatives are very close. This may be attributed to the fact that the major part of the molecule is the aromatic chromophore, $—C_6H_3(NO_2)_2$. In the data for the following compounds the first figure is wavelength and the second is log ε_{max}: 7, 368, 5.62; **3**, 380, 2.51; **6**, 372, 1.30; **4**, 368, 2.26; **2**, 383, 2.78 (9); **9**, 354, 1.87; **5**, 4.2, 4.52 (19); 2,4-dinitrophenylhydraz*ine*, 348, 4.12 (20), and 352, 4.17 (18).

Infrared Spectroscope

Examination of the i.r. absorption of the representative 2,4-dinitrophenylhydrazones of α,β-carbonyl compounds, $CH_2C{=}CHCHO$, $CH_2C{=}CHCOCH_3$, $C_6H_{13}CH{=}CHCOCH_3$, and $C_6H_5CH{=}CHCOCH_3$ revealed the presence of the typical NH band at 3.0–3.1 μ in each instance. The dinitrophenylhydrazone of chalcone (25) is now shown to be the lower melting isomer, m.p. 178°.

We are pleased to have had the invaluable assistance of Miss T. J. Davis for the i.r., D. Maier for the m.s., T. H. Regan for the n.m.r., D. Bush and D. Wall for the u.v. spectra, and D. Ketchum for the microanalyses, all of the Eastman Kodak Company Research Laboratory.

Neutral Solvolysis of Acyl Carbon and the Temperature Dependence of the Kinetic Solvent Isotope Effect

B. ROSSALL[1] AND R. E. ROBERTSON

Department of Chemistry, The University of Calgary, Calgary, Alberta T2N 1N4

Received September 17, 1974

B. ROSSALL and R. E. ROBERTSON. Can. J. Chem. **53**, 869 (1975).

The temperature dependence of the rate of hydrolysis of benzoic, phthalic, and succinic anhydrides have been determined in H_2O and D_2O under "neutral" conditions. Corresponding data have been obtained for methyl trifluoroacetate. While both series supposedly react by the same $B_{Ac}2$ mechanism, remarkable differences are made obvious by this investigation. Possible sources of such differences are proposed.

B. ROSSALL et R. E. ROBERTSON. Can. J. Chem. **53**, 869 (1975).

On a déterminé, dans H_2O et D_2O, dans des conditions neutres, l'influence de la température sur la vitesse d'hydrolyse des anhydrides benzoique, phtalique et succinique. On a obtenu les données correspondantes pour le trifluoroacétate de méthyle. Alors que l'on suppose que les deux séries réagissent par le même mécanisme $B_{Ac}2$, des différences importantes découlent de la présente étude. On propose diverses sources possibles pour de telles différences.

[Traduit par le journal]

Introduction

The unexpected changes in the kinetic solvent isotope effects (k.s.i.e.) with temperature found for the hydrolysis of acetic and propionic anhydrides (1) were without precedent (2–4) and did not appear to resemble the results published by Winter and Scott (5) for the methyl, ethyl, and isopropyl trifluoroacetates which, like the anhydrides and other haloacetates, are considered to react by a $B_{Ac}2$ mechanism (6). No satisfactory cause for such variation in k.s.i.e. with temperature was apparent for acetic and propionic anhydrides; hence in the hope of discovering some structural influence, the rates of hydrolysis for three other anhydrides with quite different structural features were determined in H_2O and D_2O. Rate measurements were made over a sufficient range of temperatures to permit a determination of the shape of the k.s.i.e. *vs.* T curve and to examine the temperature coefficient of $\Delta H^{\neq}$. Since Winter and Scott (5) had determined the k.s.i.e. for alkyl trifluoroacetate at three temperatures only, and had determined $\Delta C_p^{\neq}$ for ethyl trifluoroacetate, we undertook a more complete study of temperature effects on the rate of hydrolysis of methyl trifluoroacetate in both H_2O and D_2O.

[1]NRCC Postdoctoral Fellow, 1968–1970. Present address: Unilever Research, Port Sunlight Laboratory, Port Sunlight, Merseyside, U.K.

Experimental

Commercial samples of benzoic anhydride, succinic anhydride and phthalic anhydride were purified by recrystallization to constant melting point (Table 1).

Methyl trifluoroacetate was prepared by reaction of silver trifluoroacetate with methyl iodide in freshly distilled benzonitrile (8). The ester was isolated by distillation and purified by redistillation b.p. 40–41°, literature b.p. 43°.

Water and D_2O were purified by methods reported previously (1). In all D_2O experiments the %D exceeded 99.7% D.

First order rate constants for the reaction of each substrate in H_2O and D_2O were determined over the widest conveniently attainable temperature range by the conductance method used in the previous study (1) and treatment of the temperature dependence of these rates and derivation of pseudo-thermodynamic parameters followed previous formalism.

Results and Discussion

Rate determination for the solvolysis of organic substrates which produce weak electrolytes and the interpretation of the conductance–time data for these reactions present special problems which we solved previously (1). The observed pseudo first order rate constants were determined using the Guggenheim method (9) modified for weak electrolytes. The procedure may be summarized as follows: resistance readings were collected in pairs at a constant time interval, Δt apart. In addition the acid ionization constant, K_a, limiting equivalent ionic conductance, Λ_0, were required for application of the following

Methyl trifluoroacetate	126.02044	7466.7501	41.6549	$29_1{}^{18}$

TABLE 3. Empirical constants for the rate–temperature relation (2) for the solvolysis of acyl carbon in D_2O

Substrate	A_1	$-A_2$	$-A_3$	$n_{T_1}{}^{T_2}$
Benzoic anhydride	88.85618	6367.8447	28.8520	$22_{25}{}^{60}$
Succinic anhydride	2.29799	2642.6448	−1.4460	$23_5{}^{30}$
Phthalic anhydride	45.57871	4674.4670	13.0220	$17_4{}^{20}$
Methyl trifluoroacetate	122.53008	7415.0428	40.5306	$20_4{}^{28}$

equation. In (1) where C_0 = stoichiometric concentration of anhydride at time $t = 0$; C_t = concentration of acid at time t; $C_{t+\Delta}$ = concentration of acid at time $t + \Delta$; Δ = constant time interval, approximately $2t_{1/2}$, k^0 = observed first order rate constant, C_K = cell constant.

$$[1]\quad \log\left\{\frac{1}{R_{t+\Delta}}-\frac{1}{R_t}\right\} + \log\left[1+\frac{10^3 C_K}{\Lambda_0 K_a}\left(\frac{1}{R_{t+\Delta}}+\frac{1}{R_t}\right)\right] = \log\left[\frac{C_0\Lambda_0}{2\times 10^3 C_K}(1-e^{-k\Delta})\right]-\frac{k^0 t}{2.3026}$$

Least-squares fit to eq. 1 provided k^0, the observed rate constant, and its standard deviation. For derivation of eq. 1, see ref. 1.

K_a values used were for benzoic acid in H_2O (10), benzoic acid in D_2O (11), succinic acid in H_2O (12), succinic acid in D_2O (13), phthalic acid in H_2O (14), trifluoroacetic acid in H_2O (15). K_a for phthalic acid and trifluoroacetic acid in D_2O were not available, therefore values were estimated using Rule and LaMer's law (16) and the data of Bates *et al.* (13). In order to test the reliability of the assumptions, tests of variation in observed k^0 values with changes in K_a values were made. If K_a was estimated to within $\pm 10\%$, then the error introduced into k^0 was less than 0.1%. For the cyclic anhydrides which produced dicarboxylic acids the effective ionic concentration was estimated by using the K_a (1) values, hereto, tests indicated this approximation produced no significant error in k^0.

Calculated standard deviations in k^0 were usually $<\pm 0.25\%$ and the agreement between the four experimental values for each temperature were within $\pm 0.5\%$.

The observed rate constants were fitted to the following empirical equation ($k^0 = k_{\text{observed}}$):

$$[2]\quad \log k^0 = A_1 + A_2/T + A_3 \log T + A_4 T + \ldots$$

Using only a three parameter fit to eq. 2 the empirical constants A_1, A_2, and A_3, see Table 2 for H_2O and Table 3 for D_2O were calculated

for each reaction and could be used to recalculate smoothed curve values of k^0 at 5° intervals throughout the experimental temperature range. While a fourth term in T might seem to be desirable formally, the accuracy of the rate data did not justify such an extension. The kinetic solvent isotope effect, k.s.i.e. = $k_{H_2O}{}^0/k_{D_2O}{}^0$, was determined as a function of temperature, see Table 4.

An error estimate in k.s.i.e. values is provided by assuming that the error in each individual observed k^0 values was ±0.25%, then the same error was appropriate for the smoothed curve k^0 values. Consequently an error estimate on k.s.i.e. values would be ±0.5% or less.

A formal interpretation of the temperature effect on k^0 in terms of transition state assumptions permits the calculation of pseudo-thermodynamic quantities from the empirical constants A_1, A_2, and A_3 (17). The enthalpy, $\Delta H^{\ddagger}$, entropy, $\Delta S^{\ddagger}$, and heat capacity of activation, $\Delta C_p{}^{\ddagger}$, for each reaction is given in Table 5 for H_2O and in Table 6 for D_2O.

Discussion

Where comparisons are possible, our values of k.s.i.e. and of $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ for the hydrolysis of anhydrides agree with those published previously and lie in the range expected for a $B_{Ac}2$ mechanism (18–22). However, because we have examined the temperature dependence of the rate in both H_2O and D_2O, it is evident that these k.s.i.e. values, like those for acetic and propionic anhydrides (1), do not decrease smoothly with increasing temperature (see Fig. 1) as had been found in the hydrolysis of halides (2), sulfonyl chlorides (23), nitrates (24), and alkyl trifluoroacetates (5); the last presumably reacting by a $B_{Ac}2$ mechanism.

This departure from linearity was not uniform; the plot of log (k.s.i.e.) *vs.* $10^3/T$ for benzoic and acetic anhydrides passing through minima, while that for succinic and phthalic, like that for propionic anhydride, passed through flat maxima. Winter and Scott (5) had determined k.s.i.e. for methyl, ethyl, and isopropyl trifluoroacetate at three temperatures and had found an apparent linear decrease with temperature. We have determined the rate of hydrolysis for methyl trifluoroacetate over a wider range of temperatures in both H_2O and D_2O and found no evidence of departure from linearity of the above plot. The slope (0.88) being about the same as that found by the previous investigators.

Further empirical evidence of differences in the detailed mechanism of hydrolysis of the anhydrides and of the alkyl trifluoroacetates becomes apparent if we compare the nominal values of the temperature coefficient of the enthalpy of activation ($\Delta C_p{}^{\ddagger}$) for the two series

A comparison of $\delta_I\Delta H^{\ddagger}$ *vs.* $T\Delta S^{\ddagger}$ values for a series of anhydrides and methyl trifluoroacetate: (*1*) acetic anhydride, 25 °C; (*2*) propionic anhydride, 25 °C; (*3*) benzoic anhydride, 25 °C; (*4*) phthalic anhydride, 25 °C; (*5*) succinic anhydride, 25 °C; (*6*) methyl trifluoroacetate, 25 °C; (*7*) acetic anhydride, 15 °C; (*8*) propionic anhydride, 35 °C.

in light and heavy water. The values of $\delta_I\Delta C_p^{\ddagger}$ (Table 7) found for the anhydrides are seen to be large and variable while the corresponding term for the methyl trifluoroacetate is less than the combined experimental error. The latter condition is normal for the hydrolysis of alkyl halides (2) and is found also for the ionization of acetic acid $\Delta C_p^0 = -36.6$ cal deg^{-1} mol^{-1} in H_2O and -38.6 cal deg^{-1} mol^{-1} in D_2O (25). The difference for the autoprotolysis of water is somewhat larger, $\Delta C_p^0 = -47$ cal deg^{-1} mol^{-1} in H_2O and -55 cal deg^{-1} mol^{-1} in D_2O (26). These relatively small differences bear but accidental resemblance to those recorded in Table 7.

We could discern no relationship between the variation in $\delta_I\Delta H$, $\delta_I\Delta S^{\ddagger}$, or $\delta_I\Delta C_p^{\ddagger}$ and the pK_a of the derived acids. However, it was found that if $\delta_I\Delta H^{\ddagger}$ was plotted against $T\delta_I\Delta S^{\ddagger}$, (see Fig. 2), the values for benzoic and phthalic anhydride (the aromatic anhydrides) are separated from values for the saturated members along the usual linear plot and this in spite of the fact that k.s.i.e. for the benzoic anhydride is the highest and the k.s.i.e. for the phthalic anhydride is among the lower values. In the $\delta_I\Delta H^{\ddagger}$ *vs.* $T\delta_I\Delta S^{\ddagger}$ plot, the point for succinic anhydride, also cyclic, is found with the saturated anhydrides. The differences noted probably relate in some way to the effect of conjugation between the phenyl and carboxyl group and such factors as

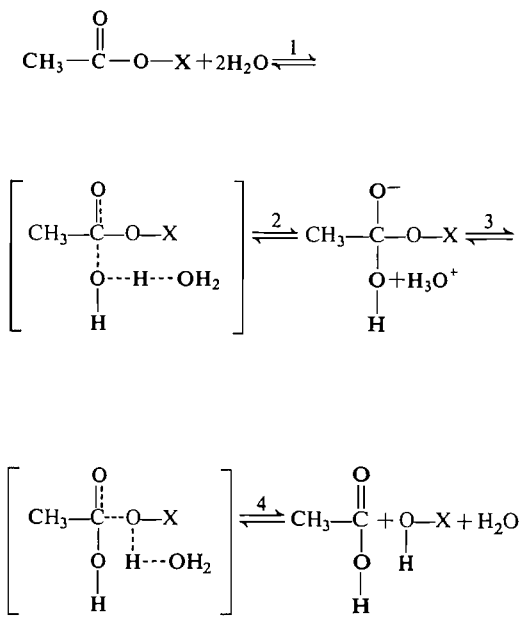
the approach of the nucleophilic water and solvation of the charged transition state but the exact relationship is not clear.[2]

One other observation, as yet unexplained, is that whereas k.s.i.e. decreases from 2.9 to 2.6 on passing from pure water to 40 vol% dioxane for acetic anhydride, and an even larger decrease occurs for methyl trifluoroacetate, benzoic anhydride shows a slight increase (20). While the decrease can be rationalized in terms of a decrease in water structure obviously the same argument will not apply for an increase. Since we are comparing results from various laboratories some allowance must be made for error, but the presence of a remarkable difference can hardly be doubted.

The changes in k.s.i.e. with T and in $\delta_I \Delta C_p^{\ddagger}$ may be related. If the $\Delta C_p^{\ddagger}$ is more negative in D_2O than in H_2O which might well be expected from a simple interpretation of the effect of temperature on the water structures, then k.s.i.e. would be expected to decrease as temperature increases. This in fact is found even though $\delta_I \Delta C_p^{\ddagger} \rightarrow 0$ under normal conditions *e.g.*, the case of the trifluoroacetates, Fig. 1. However, the decrease in k.s.i.e. with temperature for benzoic anhydride is far steeper than a $\delta_I \Delta H^{\ddagger}$ argument would require and points to an unusual influence. Moreover it should be noted that the extrema which characterize the log (k.s.i.e.) *vs.* $10^3/T$ plots for the anhydrides (Fig. 1) would not arise simply from the temperature effects on solvent structure. Some temperature dependent mechanistic change must occur which is dependent on the structure of the anhydride, the properties of D_2O and H_2O, and the wide range of mechanistic differences presently included under the definition of general acid base catalysis.

The relationship between structure and mechanism for general base catalyzed reactions has been investigated and discussed previously (21, 27–30) but not in terms of the distinction made evident in this paper. Here, a study of the temperature dependence of the k.s.i.e. and $\Delta H^{\ddagger}$ reveals characteristic differences attributable to differences in mechanism even though both series insofar as conventional tests go, hydrolyze by the same $B_{Ac}2$ mechanism (if we regard the mechanism for *t*-butyl trifluoroacetate and similar compounds as exceptional (5)).

One possible hypothesis would be the intrusion of various degrees of nucleophilic attack by OH^- or indeed the direct attack of H_2O in competition with general base catalyzed mechanism. Such a hypothesis is inconsistent with the fact that the reaction is p*H*-independent over the experimental range of temperature. Nor would a hypothesis based on the incursion of some degree of nucleophilic interaction appear to be satisfactory (31). Of course, competing reactions with different values of $\Delta H^{\ddagger}$ will give rise to changes in $\Delta C_p^{\ddagger}$ which may seem unusual (32, 33, 39). Winter and Scott (5) have shown that a change in mechanism from $B_{Ac}2$ to S_N1 probably does occur in the case of the alkyl trifluoroacetates, but this change is signalled by a dramatic change in the k.s.i.e. and in $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$. Such changes are not at all evident as between the anhydrides and the trifluoroacetates under investigation here. Rather we are faced by a more subtle temperature dependent distinction.



SCHEME 1. Generalized $B_{Ac}2$ mechanism for neutral hydrolysis (27).

[2]One referee drew attention to the possibility of differences arising from initial state differences as a possible contributing factor here. Such a possibility is difficult to disprove or to prove but we do not consider it a strong possibility. The major contribution to $\Delta C_p^{\ddagger}$ appears to arise in the vicinity of the anion and further appears to arise from solvation changes localized near the seat of reaction. For example, $\Delta C_p^{\ddagger}$ for the hydrolysis of both methanesulfonyl chloride and benzenesulfonyl chloride are the same (-55 cal deg^{-1} mol^{-1}).

If we accept Scheme 1 (27) as approximating the $B_{Ac}2$ mechanism then it might seem remarkable that complex temperature dependency was not observed in all cases and in fact the hydrolysis of the trifluoroacetates actually represent some kind of limiting case. We know that the latter (34–36) as well as the benzoic anhydride give evidence of ^{18}O exchange to a much greater degree than acetic anhydride, for example. However, if the rate of return k_{-1} and product formation, k_2, are fast compared to the rate at which the two oxygens become equivalent by proton transfer, significant ^{18}O exchange may not be observed. Support for such a possibility may be seen in the fact that the k.s.i.e. and the large negative values of $\Delta S^{\ddagger}$ are very similar for both series while significant differences in ^{18}O are observed. Bunton, Fuller, Perry and Shiner (21) proposed a pre-equilibrium involving a charged intermediate, as shown above, followed by partitioning between a pathway leading to a dihydroxy intermediate, admitting ^{18}O exchange, expulsion of the leaving group, and return to starting reactants. In attempting to account for the k.s.i.e. found for the spontaneous hydrolysis of acetic anhydride Bunton and Shiner (37, 38) show that differences in hydrogen bonding to such an intermediate so far exceed hydrogen bonding in bulk water as to account for observed k.s.i.e. values. It is an interesting fact that the same arguments applied to the prediction of the k.s.i.e. for methyl trifluoroacetate gave a value of 2.7, far closer to that obtained by Winter and Scott (5) and to our value for methyl trifluoroacetate, than the value which they used for comparison (21). While we regard their calculation as an oversimplification, we agree with the rather obvious principle on which it is formulated *i.e.*, that where electronic displacements develop centers of high local acidity or basicity, there will be an increase in the strength of the hydrogen bonds between these centers and the solvent water molecules.

These results point to questions which deserve further study. There is the remarkable difference in the temperature dependence of the k.s.i.e. found for the trifluoroacetates and for the anhydrides, both of which are considered to react by a $B_{Ac}2$ mechanism but which, on the basis of this evidence must differ in some significant manner. There is the difference in the temperature dependence of the same ratio among the various anhydrides as well as the existence of remarkable differences in the *apparent* $\Delta C_p^{\ddagger}$ values. There is the unprecedented difference in the *apparent* $\Delta C_p^{\ddagger}$ value for the various anhydrides in D_2O and H_2O, a fact which points to complexities in the mechanism of neutral solvolysis of the anhydrides not present in the hydrolysis of the alkyl trifluoroacetates.

The differences in $\Delta C_p^{\ddagger}$ values in H_2O and D_2O for the anhydride and trifluoroacetate series are not inconsistent with the important similarities which have led to both series being classed as reacting by general base catalysis (29). Whether this reaction is to be regarded as a single dominating concerted process (39, 40) or several stages involving pre-equilibria has been argued by several authors (27–29). We find no good reason to reject the formation of an intermediate of variable lifetime. That the trifluoroacetates are a better leaving group than the weak acid anions is accepted and this difference provides both for the difference in temperature dependency and in ^{18}O-exchange.

Scott and Robertson (41), in studying the effect of an intermediate on derived temperature coefficients for the hydrolysis of *t*-butyl chloride showed for the general mechanism

[4] $$\mathrm{A} \underset{k_2}{\overset{k_1}{\rightleftharpoons}} \mathrm{B} \underset{k_4}{\overset{k_3}{\rightleftharpoons}} \mathrm{C}, \quad \mathrm{B} \xrightarrow{2n} \mathrm{P}, \quad \mathrm{C} \xrightarrow{3n} \mathrm{P}$$

where

[5] $$k_{\text{obs}}^{\text{I}} = \frac{k_1}{1 + \dfrac{k_2}{k_3}} = \frac{k_1}{1 + \alpha}$$

that for the region I where $\alpha < 0.01$

[6] $$\Delta C_p^{\ddagger}{}_{\text{calc}} = \Delta C_{p_1}{}^{\ddagger}$$

and for region III where $\alpha > 100$

[7] $$\Delta C_p^{\ddagger}{}_{\text{calc}} = \Delta C_{p_1}{}^{\ddagger} - \Delta C_{p_2}{}^{\ddagger} + \Delta C_{p_3}{}^{\ddagger}$$

For the intermediate region II where $0.01 < \alpha < 100$ a much more complicated expression results *viz*

[8] $$\Delta C^{\ddagger}{}_{\text{calc}} = \Delta C_{p_1}{}^{\ddagger} + \frac{\alpha}{\alpha + 1}(\Delta C_{p_{2n}}{}^{\ddagger} - \Delta C_{p_2}{}^{\ddagger}) - \frac{\alpha}{(1 + \alpha)^2}\frac{(\Delta H_{2n}{}^{\ddagger} - \Delta H_2{}^{\ddagger})^2}{RT^2}$$

For personal use only.

The spurious heat capacity term on the r.h.s. will always be positive, hence will act to reduce $\Delta C_p^{\ddagger}{}_{calc}$ and $\Delta C_{p_3}{}^{\ddagger} - \Delta C_{p_2}{}^{\ddagger}$ will probably be positive. Further complications arise since α will be temperature dependent.

In principle such a scheme could provide the basis for understanding the differences in $\Delta C_p^{\ddagger}$ characteristics between the alkyl trifluoroacetates and the anhydrides, and the differences within these series. Queen (42) has used pre-equilibria and partitioning to account for the more extreme changes in $\Delta H^{\ddagger}$ with temperature found for the hydrolysis alkyl chloroformates some of which, like the above, display general characteristics of the $B_{Ac}2$ mechanism.

The above scheme provides for complex changes in $\Delta C_p^{\ddagger}$ depending on the solvent, and on the electronic nature of the reactants. As we have shown already, these can lead to differences in k.s.i.e. with changing temperature where $\delta_I C_p^{\ddagger}$ is large. In this connection there is a related factor which deserves comment. In an investigation of the hydrolysis of substituted benzenesulfonyl chlorides (43) it was found that the $\Delta C_p^{\ddagger}$ for the *p*-methoxy member was less negative than expected by comparison with other members of the series. This was attributed to a temperature dependent interaction of the water with the methoxy group, an effect which increased with increasing temperature as the equilibrium in cooperative water structure moved toward a greater number of unbonded water molecules (44). In support of this working hypothesis we noted that $\Delta C_p^{\ddagger}$ for the hydrolysis of 2-chloro-2-methoxymethylpropane was 18 cal mol^{-1} deg^{-1} more positive than the corresponding value for *t*-butyl chloride. The ΔC_p^{0} for the ionization of 4-methoxybenzoic acid was more negative than the value for other benzoic acids (45), the change in sign in the latter case being consistent with this hypothesis and the electronic requirements as applied to the benzoic acid system. Recently Koshy (20) found values of $\Delta C_p^{\ddagger}$ for the hydrolysis of 3-methoxybenzyl nitrate in accord with this hypothesis. This same temperature dependent solvation effect must surely be present in the general base catalyzed hydrolysis involving displacement from esters, anhydrides and acid chlorides where hydrogen bonding is important. In the trifluoroacetate system $\Delta C_p^{\ddagger}$ becomes less negative by 16 cal mol^{-1} deg^{-1} on changing from Me → Et and at isopropyl (for which no $\Delta C_p^{\ddagger}$ is available) the $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ values resemble those for $B_{Ac}2$ displacement, while at *t*-butyl, the reaction is S_N1 (5). These changes clearly follow changes in electron density on the ether oxygen with increasing solvation and decreased positive charge on the carbonyl carbon. A similar trend is apparent in the chloroformate series studied by Queen (42). Phenyl and methyl chloroformates appear to have an intermediate in which α lies outside the midrange while ethyl and propyl show large changes in $\Delta C_p^{\ddagger}$ with temperature. For isopropyl chloroformate mixed mechanism is suspected while for *t*-Bu—O—C(=O)—Cl the reaction is claimed to be S_N1. These changes in the alkyl group have a direct effect on the hydrogen bonding of the ether-oxygen and these effects are reflected in changes in $\Delta C_p^{\ddagger}$, $\Delta H^{\ddagger}$, and in mechanism. The changes noted above were in the leaving group and the consequences in terms of mechanism were marked. Similar changes adjacent to the carbonyl carbon can change the mechanism from $B_{Ac}2$ to S_N2 or S_N1 (4, 42). These too represent extremes.

The results reported here for the anhydrides do not show such wide variation in $\Delta H^{\ddagger}$, $\Delta S^{\ddagger}$ or in k.s.i.e. as reported by Scott and Winter and by Queen but rather, differences best explained in terms of changing solvation with temperature combined with related changes in partitioning. If the structure of acetic anhydride in solution is similar to that in the gas phase (46) the ether oxygen is exposed to potential hydrogen bonding before, and in the activated state. Models suggest similar comments apply to other anhydrides. The influence of potential hydrogen bonding on the leaving group is thus a factor which may vary with the degree of bond breaking at the transition state, and as between H_2O and D_2O.

Summarizing the above qualitative arguments, we attribute the unusual temperature dependence of the k.s.i.e. to temperature dependent solvation effects and to the related effect on partitioning both of which are made evident by surprising differences in the temperature coefficients of $\Delta H^{\ddagger}$ in H_2O and D_2O. The difference in the basicity of the leaving group probably contributes to an important degree to the rate of formation of the intermediate and breakup of same. Our results reveal an unexpected problem. We trust they may contribute to its solution.

RITCHIE MACLAREN MURRAY and ROBERT DONALD HEYDING. Can. J. Chem. **53**, 878 (1975).

Phase relationships in the copper/selenium system in the composition range 30–70 atomic % selenium have been studied at temperatures from 298 to 850 K and at pressures to 50 kbar. A revised atmospheric pressure phase diagram is given, as well as an outline of the phase diagram at 20 kbar.

αCu_2Se is monoclinic at 298 K with $a = 14.087$, $b = 20.481$, $c = 4.145$ Å, $\beta = 90° 23'$. The $\alpha \rightarrow \beta$ (f.c.c.) transformation is complex, and occurs over a 30 K interval centered on 396 K. The overall enthalpy change is 6.4 ± 2 kJ mol^{-1}. The maximum in the DTA signal for this transition decreases slowly with increasing pressure at <1 K kbar^{-1}. The signal disappears above 42 kbar, presumably due to the formation of a high pressure modification.

Variable composition in $Cu_{2-x}Se$ (*berzelianite*) extends from $Cu_{2.00}Se$ to $Cu_{1.75}Se$ in the range 402–523 K. $Cu_{1.80}Se$, with $a = 5.765$ Å at 298 K, is stable throughout the temperature and pressure ranges investigated.

Cu_3Se_2 (*umangite*) is stable at 298 K to at least 35 kbar. Dimensions of the tetragonal cell at 298 are $a = 6.385$, $c = 4.217$ Å. At atmospheric pressure it disproportionates to $Cu_{2-x}Se$ and βCuSe at 386 K with an enthalpy change of 10.0 ± 5 kJ mol^{-1}. The reverse reaction is very slow. Above *ca.* 5 kbar it disproportionates to $Cu_{2-x}Se$ and $CuSe_2$II at a temperature less than 413 K. The reverse reaction is fast.

αCuSe (*klockmannite*) is hexagonal with $a = 3.934$, $c = 17.217$ Å at 298 K. It transforms to βCuSe at 323 K under atmospheric pressure with an enthalpy change of 0.84 ± 5 kJ mol^{-1}. This modification is C end-centered orthorhombic with $a = 3.948$, $b = 6.958$, $c = 17.239$ Å at 324 K. With increasing temperature the orthorhombic a/b ratio increases rapidly until, at 393 K, the transition to γCuSe is complete. This modification is hexagonal with $a = 3.984$, $c = 17.288$ Å at 430 K. CuSe is unstable above 5 kbar at 298 K, decomposing to form Cu_3Se_2 and $CuSe_2$II.

Marcasite-type $CuSe_2$, with $a = 5.0046$, $b = 6.182_2$, $c = 3.739_7$ Å at 298 K, disproportionates to CuSe and Se at 605 K under atmospheric pressure with an enthalpy change of 9.6 ± 4 kJ mol^{-1}. It transforms at less than 5 kbar at 298 K to the cubic pyrite modification $CuSe_2$II, with $a = 6.116$ Å. $CuSe_2$II melts congruently at 818 K and 20 kbar. The melting point increases with increasing pressure at *ca.* 3 K kbar^{-1}.

RITCHIE MACLAREN MURRAY et ROBERT DONALD HEYDING. Can. J. Chem. **53**, 878 (1975).

On a étudié les relations de phase dans le système cuivre/sélénium à des compositions allant de 30–70 atomes % de sélénium; ces études ont été effectuées entre 298 et 850 K et à des pressions de 50 kbar. On donne un diagramme de phase à pression atmosphérique modifié de même qu'une ébauche d'un diagramme de phase à 20 kbar.

αCu_2Se est monoclinique à 298 K avec $a = 14.087$, $b = 20.481$, $c = 4.145$ Å, $\beta = 90° 23'$. La transformation $\alpha \rightarrow \beta$ (f.c.c.) est complexe et se produit sur un intervalle de 30 K centré autour de 396 K. Le changement global d'enthalpie est de 6.4 ± 2 kJ mol^{-1}. Le maximum dans le signal en DTA pour cette transition diminue lentement à mesure que la pression augmente à un taux moins de 1 K kbar^{-1}. Le signal disparait au-dessus de 42 kbar, probablement dû à la formation d'une modification à haute pression.

Des compositions variables en $Cu_{2-x}Se$ (*berzelianite*) existent entre $Cu_{2.00}Se$ jusqu'à $Cu_{1.75}Se$ entre les températures de 402–523 K. Le $Cu_{1.80}Se$ avec $a = 5.765$ Å à 298 K, est stable sur tout l'intervalle des températures et des pression étudiées.

Cu_3Se_2 (*umangite*) est stable à 298 K jusqu'à au moins 35 kbar. Les dimensions de la cellule tétragonale à 298 K sont $a = 6.385$, $c = 4.217$ Å. A pression atmosphérique, il se disproportionne pour donner du $Cu_{2-x}Se$ et du βCuSe à 386 K avec un changement d'enthalpie de 10.0 ± 5 kJ mol^{-1}. La réaction inverse est très lente. Au-dessus d'environ 5 kbar il se disproportionne en $Cu_{2-x}Se$ et en $CuSe_2$II à une température plus basse que 413 K. La réaction inverse est rapide.

L'αCuSe (*klockmannite*) est hexagonal avec $a = 3.934$, $c = 17.217$ Å à 298 K. Il se transforme en βCuSe à 323 K à pression atmosphérique avec un changement d'enthalpie de $0.84 \pm$

[1]Present address: Atlantic Industrial Research Institute, c/o Nova Scotia Technical College, Halifax, Nova Scotia.

5 kJ mol^{-1}. Cette modification est orthorhombique centre sur la face C avec $a = 3.948$, $b = 6.958$, $c = 17.239$ Å à 324 K. A mesure que la température augmente le rapport a/b du système orthorhombique augmente rapidement jusqu'à 393 K; à cette température la transformation en γCuSe est complète. Cette modification est hexagonale avec $a = 3.984$, $c = 17.288$ Å à 430 K. CuSe est instable au-dessus de 5 kbar à 298 K se décomposant en Cu_3Se_2 et $CuSe_2$II.

Du $CuSe_2$ du type marcasite avec $a = 5.0046$, $b = 6.182_2$, $c = 3.739_7$ Å à 298 K, se disproportionne en CuSe et Se à 605 K à pression atmosphérique avec un changement d'enthalpie de 9.6 ± 4 kJ mol^{-1}. Il se transforme à moins de 5 kbar à 298 K pour conduire à la modification cubique de pyrite $CuSe_2$II avec $a = 6.116$ Å. Le $CuSe_2$II fond d'une façon congruente à 818 K et 20 kbar. Le point de fusion augmente avec une augmentation de pression à *ca.* 3 K kbar^{-1}.

Introduction

An exhaustive review of the literature on the copper/selenium system was published recently (1). At least five compounds are formed: Cu_2Se, $Cu_{2-x}Se$, Cu_3Se_2, CuSe, and $CuSe_2$. Some of these, in one polymorphic form or another, exist as minerals. *Berzelianite*, *umangite*, and *klockmannite* correspond to $Cu_{2-x}Se$, Cu_3Se_2, and αCuSe, respectively. The mineral *krutaite* has the pyrite structure of $CuSe_2$II, but contains considerable quantities of cobalt and nickel. The mineral *athabaskaite* (Cu_5Se_4) has not been prepared synthetically.

There have been a number of reports on the properties of these compounds, particularly on the transport properties of the copper-rich phases. Often these reports do not include adequate identification of the compounds examined, and the structures must be inferred from the description of the procedures followed in their preparation.

This paper is a report on a reexamination of the copper/selenium system in the composition range 30–70 atomic % selenium, at temperatures from 298 to 850 K, and at pseudo-hydrostatic pressures to 50 kbar. A revised equilibrium phase diagram at atmospheric pressure is presented, as well as the outlines of the phase diagram at 20 kbar.

Experimental

Samples of various compositions were prepared by direct reaction of 69 grade copper and selenium (Asarco) in evacuated, sealed Pyrex or Vycor tubes in the usual way. Phases were identified by X-ray powder diffraction patterns using Philips 11.46 cm Debye–Scherrer cameras. In some instances diffraction patterns for accurate determination of unit cell dimensions were obtained in an Enraf–Nonius Guinier – de Wolff focusing camera using As_2O_3 as an internal standard.

"Kinetic" X-ray diffraction patterns above room temperature were obtained in an Enraf–Nonius Guinier – Lenne focusing camera. This camera was calibrated with respect to temperature by observing the transformations in KNO_3 (401 K) and $KClO_4$ (573 K) and the melting points of In (430 K), Sn (505 K) and Zn (573 K). In general sample heating rates were set at 5–10 K h^{-1} and film transport rates at 10 mm h^{-1} or less, using an exit slit of 1 mm and Kodak Type SB film. Specimens were prepared by painting an alcohol slurry of the selenide with high purity amorphous boron (as a binder) and silicon powder (as an internal standard) onto the platinum mesh sample holder. Above 470 K copper selenides containing more than 33 atomic % Se decomposed in the camera with the formation of $Cu_{2-x}Se$. Attempts to restrict the sublimation of selenium in such instances (for example, by sandwiching the selenide between thin graphite plates) were not successful.

A DuPont Instruments Model 990 Thermal Analyzer and DSC module were used for differential thermal analyses (DTA) in the temperature range between 223 and 673 K. The specimens were sealed in coated aluminum pans. The DSC module was calibrated with respect to temperature via the melting points of high purity Hg, In, Sn, Cd, and Bi. The same instrument was used to estimate the latent heats associated with phase transformations. For this purpose the enthalpy equivalent of the area of the DTA signal at a fixed heating rate was determined by observing the fusion of In (3.26 ± 4), Sn (7.07 ± 8), Cd (6.11 ± 8) and Zn (6.65 ± 40 kJ mol^{-1}).

The behavior of compounds in the system under high pressure was studied using devices constructed for that purpose. Exploratory "quench-and-look" experiments were conducted at room temperature between opposed anvils of supported tungsten carbide. Provision was made for rotation of one anvil with respect to the other to increase transformation rates. Samples were examined at nominal pressures to 60 kbar. In view of the large pressure gradients which are established in such uniaxial devices, no attempt was made at pressure calibration.

Differential thermal analyses were conducted at quasi-hydrostatic pressures to 50 kbar and temperatures to 850 K in a two-stage piston-cylinder apparatus.[2]

This device was used with a compound press, a 200 ton hydraulic ram serving to end load the cylinders, and a 100 ton ram to load the pistons. Details on the DTA cell

[2]Detailed drawings of the components of this device (the first and second stage pistons, the first and second stage compound cylinders, back-up plate and clamping plate) are available, at a nominal charge, from the Depository of Unpublished Data, National Research Council of Canada, Ottawa, Canada, K1A 0S2. Details on the design, construction, calibration and assembly of the high pressure DTA apparatus may be obtained from the authors.

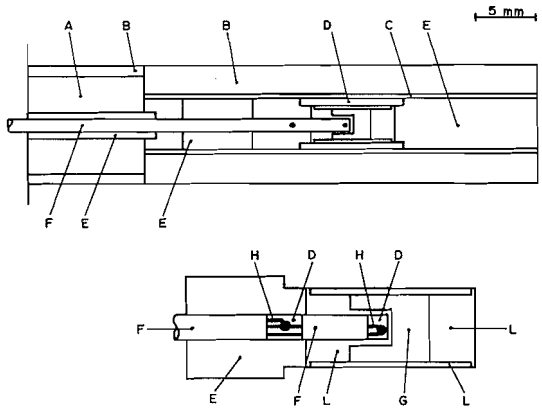

FIG. 1. High Pressure DTA Cell. The bottom drawing shows the sample capsule and thermocouple arrangement in detail. *A*, tool steel; *B*, AlSiMag; *C*, Graphite heater; *D*, boron nitride; *E*, pyrophyllite; *F*, three-hole Mullite thermocouple insulator; *G*, sample cavity; *H*, chromel/alumel thermocouples; *L*, stainless steel sample capsule.

used in the first stage cylinder (working volume 4.3 cm × 1.0 cm D) are shown in Fig. 1. The experimental procedure involved temperature sweeps at constant pressure. With the cell maintained at a temperature slightly below the transition under investigation, the pressure in the system was increased by finite intervals. At each interval, a small programmed increase and decrease in heater current carried the sample temperature through the transition in each direction. This procedure was followed through a cycle of increasing and decreasing pressure intervals. The signal from the differential thermocouple was amplified by a Keithley Model 148 Nanovoltmeter and displayed on a two pen chart recorder along with the sample thermocouple EMF. No corrections were made for the effect of pressure on thermocouple EMF.

Since the actual pressure in such a device is less than the load would indicate with increasing load (in-stroke) and greater than the load would indicate with decreasing load (out-stroke) due to internal friction, hysteresis in the transition temperature/load plots was observed. Here, in keeping with common practice, the "double value of friction" has been measured, and the equilibrium boundary in the *P–T* plane has been assumed to lie at the center of the hysteresis loop. The uncertainty invoked by this assumption is certainly greater than the probable error in apportioning the total load between the first and second stage pistons, but may well be less than the uncertainty inherent in the use of solids as pressure transmitting media. Nevertheless we estimate that the pressures observed are within 3 kbar of the true values.

The piston-cylinder apparatus was also employed in "quench-and-look" experiments using a less complicated cell than that depicted in Fig. 1. Both types of cell cooled from 773 K to room temperature in less than 5 s. In addition to powder diffraction analysis, several of these samples were sectioned, polished, and examined in an ARL electron microprobe and by optical microscopy.

Some samples were studied in a Materials Research Corporation Model XKB100 opposed diamond anvil X-ray diffraction camera at room temperature and nominal pressures to 50 kbar.

Results and Discussion

The atmospheric pressure phase diagram representing the result of this study is shown in Fig. 2. The general outlines of the phase diagram at 20 kbar are indicated in Fig. 3. In the following discussion, phase and structural relationships at each compound composition will be described in turn with reference to these figures.

Cu_2Se

Specimens of αCu_2Se (*i.e.*, the room temperature modification of Cu_2Se) at the copper rich limit of the field were prepared (*a*) by annealing samples of nominal composition *Cu_2Se* with high purity copper wire in evacuated sealed Vycor tubes at 673 K for some weeks; (*b*) by the sublimation of selenium from *Cu_2Se* at 913 K *in vacuo* (during which process long whiskers of copper are formed); and (*c*) by depositing thin films of selenium on copper foil at *ca.* 330 K and annealing at temperatures to 773 K.

Samples prepared by methods (*a*) and (*b*) gave identical well-resolved focusing camera patterns. Diffraction patterns of the product layers obtained by method (*c*), observed by X-ray transmission through the copper foil substrate in the focusing camera, were diffuse but clearly identical to those obtained in (*a*) and (*b*).

This pattern is significantly different from that given by Stevels and Jellinek (2) and much more complex than that described by Morimoto and Uchimizu (3). It can be indexed with reference to a monoclinic unit cell[3] with $a = 14.087$ Å, $b = 20.481$ Å, $c = 4.145$ Å, $\beta = 90° 23'$. This cell can be regarded as a simple monoclinic distortion of the orthorhombic unit cell ($a = 4.118$ Å, $b = 14.06$ Å, $c = 20.381$ Å) given by Stevels and Jellinek for powder specimens, and perhaps is not incompatible with the results of their single crystal studies.

Diffraction patterns of αCu_2Se at the selenium rich boundary were obtained by allowing *Cu_2Se* to undergo partial oxidation in air at 373 K.[4] These patterns were diffuse but of sufficient quality to establish that the interplanar spacings are larger than those of the same phase prepared in the presence of copper. The X-ray data are in close agreement with those observed by Stevels and Jellinek and by Heyding (4) for αCu_2Se in αCu_2Se–$Cu_{2-x}Se$ mixtures, and may be indicative of a narrow region of variable composition.

The transformations occurring in *Cu_2Se* in the temperature range 350–415 K are complex. Guinier–Lenne diffraction patterns indicate shifts in some interplanar spacings between 350 and 396 K which cannot be attributed to simple thermal expansion. There is an abrupt transition to the cubic $Cu_{2-x}Se$ ($x = 0$) phase at 396 ± 3 K. Above this temperature there are no obvious anomalies in the variation in interplanar spacings or relative intensities with increasing temperature. On the other hand, the long, asymmetric DTA signal begins at *ca.* 373 K, peaks at 409 ± 1 K, and returns to the baseline at *ca.* 415 K on heating cycles. On cooling the signal begins at 409 K and peaks at 407 K. Neither the form of the signal nor the temperature at the maximum are altered significantly by ten-fold changes in the heating rate. When the heating cycle is arrested for an annealing period within the interval below 409 K, the maximum in the signal develops in the usual way when the cycle is resumed; hence the phenomenon is not time dependent. Thus the abrupt crystallographic transformation occurs some 13 K below the maximum in a protracted DTA signal.

Comparison of these results with published data is complicated by uncertainty with respect to the composition of the various samples for which the data are given. Specimens slightly richer in selenium than *Cu_2Se* can be expected to exhibit anomalies over a protracted temperature range due to the change in composition of the $Cu_{2-x}Se$ component of the two phase mixture with increasing temperature. For example, in the data reported by Ogorelec and Celustka (5, 6) it is not clear what proportion of the anomaly in the conductivity of $Cu_{1.981}Se$ between 353 and 413 K is due to the transformation in αCu_2Se. Nevertheless our DTA results confirm the general observation that anomalies occur over a wide temperature interval. According to Routie *et al.* (7, 8) anomalies in the conductivity and thermoelectric EMF of *Cu_2Se* in the presence of copper begin at *ca.* 373 K and exhibit a maximum or discontinuity at 406 K. Similar behavior in the conductivity was observed by Okamoto (9) at slightly lower temperatures in specimens of uncertain composition. Kubaschewski and Nölting (10) have shown that the heat capacity of $Cu_{1.9975}Se$ (assumed) begins to increase abnormally at *ca.* 323 K, is very large in the interval 395–403 K, and is essentially constant above 403 K.

In his extensive study of the copper-rich selenides, Stevels (11) remarks that the temperature of 353 K observed for the $\alpha \rightarrow$ f.c.c. Cu_2Se transformation is somewhat low in comparison with DTA data giving temperatures between *ca.* 363 K ($Cu_{1.95}Se$) and 383 K ($Cu_{2.08}Se$). This latter sample apparently contained excess copper (2), and should therefore correspond to our specimens of αCu_2Se. Regardless of the rather large difference in crystallographic transition temperatures observed by Stevels and ourselves (353 K *vs.* 396 K), the occurrence of a polymor-

[3]Diffraction patterns of αCu_2Se. βCuSe, γCuSe and $CuSe_2$II have been submitted to the Joint Committee on Powder Diffraction Standards. Copies may be obtained from the authors, or, at nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Canada K1A 0S2. Diffraction patterns of the other compounds are in substantial agreement with those already included in the JCPDS File.

[4]Powders of *Cu_2Se* oxidize slowly in air at room temperature with the formation of Cu_2O and $Cu_{1.8}Se$. The $Cu_{2-x}Se$ phase is much less susceptible to oxidation under the same conditions.

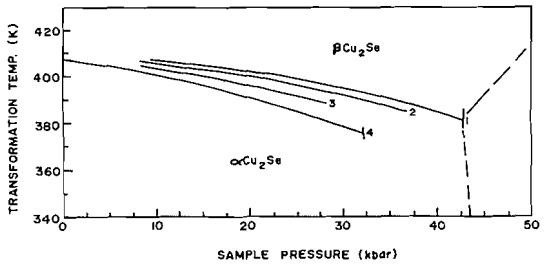

FIG. 4. Pressure dependence of the $\alpha \rightarrow \beta$ (f.c.c.) transformation temperature in Cu_2Se. Curve *1*: $Cu_{2.04}Se$, prepared by sublimation of Se from Cu_2Se. Curves *2*, *3*: Two samples of Cu_2Se prepared by direction reaction between the elements. Curve *4*: Data of Clark and Rapoport (12).

phic transition within a broad thermal effect is confirmed.

It may be significant that Stevels and Jellinek observed αCu_2Se at room temperature only in the presence of the cubic phase. The persistence of the cubic phase led to the suggestion that the f.c.c. $\rightarrow \alpha$ transformation is very slow; we did not find it to be so.

The overall enthalpy change according to our DTA data is 6.4 kJ mol^{-1}, and according to Kubaschewski and Nölting's calorimetric study (11) is 6.83 kJ mol^{-1}.

The temperature of the transformation decreases with increasing pressure as shown in Fig. 4. Here the transformation temperature has been taken as the average of the temperatures corresponding to the peak and the end of the differential signal. The T/P curves are therefore displaced to higher temperatures relative to the boundary reported by Clark and Rapoport (12) (curve 4, Fig. 4) who apparently observed well-defined peak onset temperatures and used those values. The onset of the DTA signal was not well defined in our experiments. In any case, the absolute transformation temperature *per se* is a difficult quantity to specify even at atmospheric pressure, and we would expect dT/dP to be essentially independent of the way in which T is defined.

The slope of the phase boundary observed for $Cu_{2.04}Se$ is significantly less in the 10–20 kbar range than for Cu_2Se (-0.4 K $kbar^{-1}$ *vs.* -0.8 K $kbar^{-1}$). This may be another indication of a narrow range of variable composition although, in that case, a slope of -0.8 K $kbar^{-1}$ would not have been expected from Clark and Rapoport's data since their samples were encapsulated in copper.

Assuming the enthalpy change is pressure independent, the Clausius–Clapeyron equation predicts a volume decrease during the transformation of *ca.* 0.06 cm^3 mol^{-1} ($dT/dP \simeq -0.4$ K $kbar^{-1}$; $T \simeq 400$ K; $\Delta H \simeq 6$ kJ mol^{-1}). The molar volume of αCu_2Se at 298 K, assuming the monoclinic cell proposed earlier and a cell content of 24 formula units, is 0.8% *less* than the molar volume of f.c.c. Cu_2Se at 394 K (a = 5.858 Å). A molar volume decrease could not occur during a direct transformation from the monoclinic to the cubic modification without an unrealistically high rate of thermal expansion in the monoclinic form. This is further evidence of the complexity of the transformations which occur in this phase between 343 and 409 K.

The DTA signal corresponding to the $\alpha \rightarrow \beta Cu_2Se$ transformation disappeared in Clark and Rapoport's experiments at 30 kbar. They attribute the disappearance to the formation of a high pressure Cu_2Se modification. The $\alpha \rightarrow \beta$ transformation was still evident in our experiments with Cu_2Se at 37 kbar, the highest pressure attained. However in a $Cu_{2.04}Se$ sample, the signal disappeared at about 42 kbar (curve 1, Fig. 4). This phenomenon was reversible, the signal being regained on decompression and lost again as the pressure was increased.

The boundary between the αCu_2Se and high pressure fields is assumed to be essentially vertical as shown in Fig. 4, since there was no indication of any transformation in differential thermal analyses at constant pressures close to 42 kbar. Specimens quenched from *ca.* 380 K at pressures above 42 kbar contained only αCu_2Se. Whether the high pressure field is a single phase field (Cu_2SeII) or a two phase field (*e.g.*, Cu + $CuSe_2II$) is not resolved, although of the two possibilities the former would seem to be the more likely.

Cubic βCu_2Se appears to be stable above the $\alpha \rightarrow \beta$ transformation temperature to at least 838 K. At 15 kbar no DTA signals were observed in this temperature range, and Cu_2Se samples were recovered unaltered.

$Cu_{2-x}Se$ (Berzelianite)

The compound $Cu_{2-x}Se$ occupies a field of variable composition in the phase diagram. With composition $Cu_{1.80}Se$, the cubic unit cell dimension is 5.765 Å at 298 K.[3] The space group is $F\bar{4}3m$, with Se in the face-centered sites and Cu

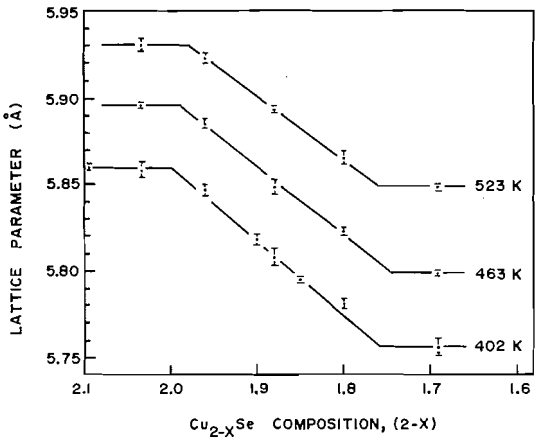

FIG. 5. The variation in the cubic lattice parameter of $Cu_{2-x}Se$ as a function of composition and of temperature. For clarity, the data at 463 and 523 K have been displaced along the ordinate by 0.03 and 0.06 Å respectively. The error bars indicate the standard deviations in *a*. The lines represent the least squares fit to the data.

distributed in non-random fashion on the octahedral, tetrahedral, and pseudo-trigonal sites in the Se sublattice (2, 13).

Compositions at the boundaries of this field at atmospheric pressure in the temperature range 402–523 K were estimated by determining the variation in unit cell dimension with nominal sample composition as indicated in Fig. 5. The field does not extend beyond Cu_2Se, and may, in fact, shift to slightly higher Se concentrations with increasing temperature. This is consistent with observations made by others (*e.g.*, Lorenz and Wagner (14), Celustka and Ogorelec (15)). The selenium-rich boundary is essentially vertical in the range 402–523 K. Much the same result was obtained by Bernardini *et al.* (16). Observations on nonequilibrated samples of composition Cu_3Se_2 suggest that the boundary may have slight positive slope from 273 to 385 K. The rather large shift to higher selenium concentrations suggested earlier (4) is not correct.

Evidence was sought for the transformation in $Cu_{1.8}Se$ at 338 K suggested by Stevels and Jellinek to account for an anomaly which they observed in the magnetic susceptibility at that temperature (2). Relative intensities of reflections in Guinier–Lenne diffraction patterns at 333, 376, and 465 K were measured and found to be identical within experimental error. Nor could this transformation be detected by DTA of $Cu_{1.8}Se$ at highest sensitivity.

Samples of nominal composition $Cu_{1.9}Se$ were examined in the high pressure DTA device. No transformations were observed. A sample of $Cu_{1.8}Se$ was annealed for 19 h at 348 K and 32 kbar, quenched, and examined by X-ray diffraction, optical microscopy, and electron probe analysis. It was unaltered. There is also evidence from experiments on other copper selenides indicating that the stability range of $Cu_{2-x}Se$ extends to the highest pressures and temperatures employed in this study.

This conclusion is in disagreement with the studies of Hinze and Neuhaus (17) which indicate that the high pressure pyrite modification of $CuSe_2$ ($CuSe_2$II) is the only copper selenide stable above 44 kbar at room temperature. These authors observed a series of pressure induced reactions in an opposed anvil device in which concentric rings of copper, $Cu_{2-x}Se$, Cu_3Se_2, $CuSe_2$, and $CuSe_2$II were formed. Copper appeared at the edge and $CuSe_2$II at the center of the anvil faces. From a knowledge of the pressure gradient in their device they ascribed a pressure stability range to each phase according to its position in the gradient.

We have observed reactions in uniaxial pressure devices very similar to those described by Hinze and Neuhaus. When samples of composition $Cu_{1.9}Se$ and $Cu_{1.8}Se$ were compressed with periodic rotation in opposed anvils at 298 K and nominal pressures of 10 kbar, mixtures of αCu_2Se, $Cu_{2-x}Se$, and Cu_3Se_2 were recovered after 1 h. Similar reactions in $Cu_{1.8}Se$ were observed in the MRC high pressure camera after several days at a nominal pressure of 27 kbar. At higher pressures, reflections due to $CuSe_2$II were observed. The mixture, containing $Cu_{1.8}Se$, αCu_2Se, Cu_3Se_2, and $CuSe_2$II, was retained on decompression. Copper was not observed as a product in these experiments.

These multiple disproportionations were not observed when other copper selenides were examined under uniaxial pressure loads. The phenomenon may be due to the abnormally high rate of diffusion of copper in $Cu_{2-x}Se$ (18, 19). In the large pressure gradients established in the specimen by the opposed anvils, mass transfer may occur not only by extrusion of the sample pellet, but also by diffusion of copper towards the edges of the anvil faces. Thus a concentration gradient may develop with copper-rich phases at the outer edge of the product lens and selenium rich phases in the center.

Cu_3Se_2 (Umangite)

The compound Cu_3Se_2 is tetragonal, space group $P\bar{4}2_1m$ (20). The unit cell dimensions obtained in this study[3] ($a = 6.385$ Å, $c = 4.271$ Å) are in good agreement with those reported earlier (4). The disproportionation to $Cu_{2-x}Se$ and CuSe is relatively slow. In DTA experiments at atmospheric pressure it occurs at 398 and 404 K for heating rates of 5 and 10 K min^{-1} respectively. In the Guinier–Lenne camera it was observed at 385 K with a heating rate of 8 K hr^{-1}. The unit cell dimension of the $Cu_{2-x}Se$ phase formed during the reaction corresponds to the selenium-rich limit of this phase as indicated in Fig. 5. The diffraction pattern of the other product of the disproportionation was ill-defined because at this temperature CuSe is involved in its own complicated $\beta \rightarrow \gamma$ transformation.

The enthalpy change associated with the disproportionation is 10.0 ± 5 kJ mol^{-1}.

The reaction of $Cu_{2-x}Se$ with CuSe to form Cu_3Se_2 below 385 K is extremely slow. Samples of *Cu_3Se_2* cooled from temperatures above 385 K contain only traces of *umangite*, and the reaction is not complete after several years at room temperature. The transformation is enhanced by pressure and shear, and may be brought essentially to completion by grinding for extended period with a mortar and pestle. Samples of *Cu_3Se_2* and of *CuSe* quenched from >673 K showed surprisingly large quantities of Cu_3Se_2, indicating that the reaction of $Cu_{2-x}Se$ with Se is more rapid than the reaction with CuSe. It was found that when mechanical mixtures of $Cu_{2-x}Se$ and $CuSe_2$II in stoichiometric proportions were ground lightly with mortar and pestle, conversion to Cu_3Se_2 was complete in less than 1 min.

It is this very rapid reaction between $CuSe_2$II and $Cu_{2-x}Se$ under shear stress which is responsible for the formation of Cu_3Se_2 in *Cu_3Se_2* mixtures in high pressure devices. The compound is formed in 1 h at room temperature between opposed anvils at 25 kbar, and at 10 kbar if the anvils are rotated.

Cu_3Se_2 is stable at room temperature to at least 35 kbar. At this pressure formation of Cu_3Se_2 from $Cu_{2-x}Se$–CuSe mixtures in the piston–cylinder synthesis cell was complete in *ca.* 12 h. The diffraction pattern of Cu_3Se_2 at 27 kbar in the high pressure camera contained no extraneous reflections.

Cu_3Se_2 was prepared *in situ* in the high pressure DTA cell. At 20 kbar no signals were observed between 273 and 865 K which might correspond to a disproportionation. However, the sample recovered contained $Cu_{2-x}Se$ and $CuSe_2$II, as well as Cu_3Se_2, indicating that some disproportionation had occurred. Apparently the disproportionation is too slow to be detected by DTA. Attempts were therefore made to determine the temperature stability limits at one pressure by a series of quench-and-look experiments.

In each experiment a sample of *Cu_3Se_2* was initially annealed at atmospheric pressure and 423 K for 1 h. Each sample could therefore be assumed to contain no Cu_3Se_2 prior to pressure increase. The pressure was raised to 18 kbar, and the temperature adjusted to the desired annealing temperature. After 1 h, the temperature and pressure were quenched simultaneously. The products contained $Cu_{2-x}Se$, Cu_3Se_2, and $CuSe_2$II in roughly the same proportions in each case. The quantity of Cu_3Se_2 recovered was no greater than that which would be formed by the reaction of $Cu_{2-x}Se$ and $CuSe_2$II either on quenching in the compacted sample or during preparation (grinding) of a specimen for powder diffraction.

These experiments indicate that the disproportionation of Cu_3Se_2 to $Cu_{2-x}Se$ and $CuSe_2$II at 18 kbar occurs at some temperature below 413 K (the lowest anneal temperature examined) and is relatively slow. Further evidence for this conclusion was obtained in quench-and-look experiments on αCuSe annealed at 18 kbar and 422 K. The product contained $Cu_{2-x}Se$ (as well as Cu_3Se_2 and $CuSe_2$II) which would not have formed were Cu_3Se_2 stable under those conditions.

CuSe

The low temperature atmospheric pressure modification of this compound, αCuSe, corresponds to the mineral *klockmannite*. Although there is some controversy in the literature as to the correct space group and structure of the mineral (21–23), the diffraction reflections can be indexed[3] with reference to a hexagonal cell with $a = 3.934$ Å and $c = 17.217$ Å in good agreement with Berry's analysis of *klockmannite* (21) and with other data on synthetic αCuSe (2, 4). The superlattice reflections observed by some authors (2, 22, 24) were not observed in samples

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

prepared for this study, although extra reflections have now appeared in αCuSe samples prepared in this laboratory seven years ago, indicating a slow ordering process.

αCuSe transforms abruptly to βCuSe at 324 K with an enthalpy change of 0.84 ± 5 kJ mol^{-1}. The β modification is C end-centered orthorhombic[3] with $a = 3.948$ Å, $b = 6.958$ Å, $c = 17.239$ Å at 324 K, in good agreement with the literature (2, 4).

As the temperature of the specimen is increased in the Guinier–Lenne camera, pairs of βCuSe reflections gradually coalesce (at 370 K, $a = 3.960$ Å, $b = 6.911$ Å, $c = 17.2$ Å) until, at 393 K, the transformation to γCuSe is complete. This remarkable transformation was first observed by Stevels and Jellinek (2). It cannot be detected by DTA. Both transformations are rapidly reversible.

The diffraction pattern of the γ modification can be indexed[3] with reference to a hexagonal cell, with $a = 3.984$ Å, $c = 17.288$ Å at 430 K. Although the Miller indices of the planes giving rise to diffraction are the same in αCuSe and γCuSe, and the relative intensities are remarkably similar, the rather large differences in interplanar spacings indicate that they are not isostructural.

Modifications in the αCuSe diffraction pattern are obtained when αCuSe is ground for 10 min in a mortar and pestle or compressed for short periods between opposed anvils at nominal pressures of less than 3 kbar. In this pattern the (107) reflection is unusually intense and a new reflection appears at $d = 1.64$ Å. This may indicate either a transformation or a disproportionation in CuSe at very low pressures. At slightly higher pressures (5 kbar) in the opposed anvil device with rotation, mixtures of this modification, Cu_3Se_2, and $CuSe_2$II are obtained.

At room temperature the disproportionation of αCuSe to Cu_3Se_2 and $CuSe_2$II occurred in the piston–cylinder apparatus at pressures below 10 kbar. The disproportionation is slow, and the pressure at which it occurs cannot be defined more accurately. This reaction occurs with a decrease in volume of 6.5%, assuming crystallographic densities and equal compressibilities in reactant and products.

The peritectic decomposition of CuSe was observed in the high pressure DTA cell at pressures close to atmospheric, and the decomposition temperature remained fairly constant (*ca.* 650 K) up to pressures of 5–6 kbar. At higher pressures no differential signal could be detected in the range 623–703 K. Samples quenched from this region contained $Cu_{2-x}Se$, $CuSe_2$II, and Cu_3Se_2, the latter formed by the $Cu_{2-x}Se$–$CuSe_2$II reaction on quenching.

At *ca.* 6 kbar DTA of *CuSe* exhibited a large reversible signal at 740 K. The pressure dependence of this transformation is shown in Fig. 6. Polished sections of a sample quenched from 787 K and 20 kbar were examined by optical microscopy and by electron probe. Considerable variation in composition was evident along the capsule axis. $Cu_{2-x}Se$ and $CuSe_2$II were identified, as well as Cu_3Se_2 and CuSe which formed during the quench. The identification of dendrites of $Cu_{2-x}Se$ indicates the growth of this phase from the melt, and suggests a $Cu_{2-x}Se$/$CuSe_2$II eutectic lying on the composition axis on the selenium rich side of *CuSe* as indicated in Fig. 3.

$CuSe_2$

The room temperature unit cell dimensions of orthorhombic, marcasite-type $CuSe_2$ obtained in this study[3] ($a = 5.004_6$ Å, $b = 6.182_2$ Å, $c = 3.739_7$ Å) are in good agreement with values reported in the literature (2, 4). The peritectic decomposition to $Cu_{2-x}Se$ and Se occurs at 605 K at atmospheric pressure, with a change in enthalpy of 9.6 ± 4 kJ mol^{-1}. The recombination reaction is slow.[5]

At room temperature the cubic pyrite modification, $CuSe_2$II, is formed at very low pressures (<5 kbar) although the rate of transformation is slow. "Pure" $CuSe_2$II can be prepared by

[5]An unusual feature of the disproportionation was observed during thermal analysis. As specimens were repeatedly cycled through the temperature range 548–623 K at 10 K min^{-1}, the DTA signal split into two endothermic peaks, one centered at 599 K, and the second at 609 K. On annealing for 1 h at 573 K, the original signal at 605 K was regained. When the DTA cycle was arrested at the maximum of the first peak (599 K) for 1 h, the second peak was not observed. In every case the DTA signals on cooling were identical. Samples quenched from 593 K after the double signal had been built up were mixtures of αCuSe, $CuSe_2$ and (presumably) amorphous Se, *i.e.* contained the same phases as specimens quenched from above or below the initial transition temperature. This behavior was observed in all samples known to contain $CuSe_2$. In all probability this phenomenon is a kinetic effect associated with the slow recombination of CuSe and Se, and as such should not be represented in the equilibrium phase diagram.

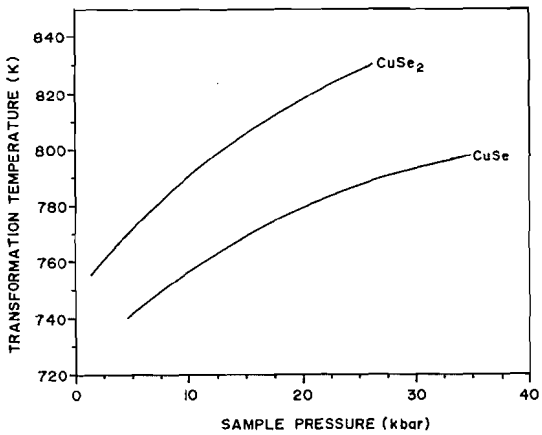

FIG. 6. The pressure dependence of the onset temperature of high pressure DTA signals in *CuSe* ($Cu_{2-x}Se$–$CuSe_2$II eutectic?) and in $CuSe_2$II (congruent melting point).

annealing $CuSe_2$ for 2 h at 12 kbar and 693 K. The unit cell dimension of the product prepared this way[3] ($a = 6.116$ Å) is in good agreement with the value reported by Bither *et al.* (25). Some $CuSe_2$II samples prepared under different conditions had a smaller unit cell with $a = 6.110$ Å. It is interesting that Bither originally reported a value of 6.123 Å (26). This range of values may be indicative of some variable composition in the pyrite structure.

Assuming crystallographic densities, the marcasite → pyrite transformation involves a 1.1% decrease in volume at atmospheric pressure.

The pyrite modification is remarkably stable at atmospheric pressure. It is stable for indefinite period at room temperature and is still present after annealing for 3 days at 483 K. In one experiment in which a mixture of the marcasite and pyrite modifications was annealed at atmospheric pressure for several hours at 623 K, decomposition of the $CuSe_2$ was observed but $CuSe_2$II was recovered unaltered.

The peritectic decomposition of $CuSe_2$ which occurs at 605 K at atmospheric pressure was observed in high pressure DTA experiments but only below 5 kbar. Above that pressure no thermal signals were observed to 723 K. Samples quenched from 5 kbar and 615 K were pure $CuSe_2$II. However, at pressures greater than 5 kbar a broad endothermic signal was observed at *ca.* 770 K. The pressure dependence of this signal is shown in Fig. 6. In some instances, liquid was extruded from the high pressure capsule during the transformation. This liquid penetrated cracks in the boron nitride sleeve, short circuiting the thermocouples and the heater. The material recovered from the sleeve was $CuSe_2$. Study of polished sections of capsules recovered intact following quenching from above the transformation temperature indicated that $CuSe_2$II is reformed completely during the quench. Electron probe analysis showed no variation in composition across the sections, and optical microscopy showed very large twinned grains with no obvious fine structure. This evidence leads to the conclusion that $CuSe_2$II melts congruently as indicated in Fig. 3.

We are indebted to Messrs. T. F. Blake, F. W. Everding, and F. F. Sziladi for assistance in the construction of our high pressure devices; to Mr. B. C. Forbes for technical assistance; and to Messrs. R. Armstrong, H. R. Holland, and D. E. Kempson for their assistance in the preparation and examination of polished sections. One of us (R.M.M.) gratefully acknowledges the award of an Alcan Postgraduate Fellowship, 1970–1973. This study was supported by operating grants from the National Research Council of Canada.

Spectrophotometric Studies on Sb(III) in Hydrochloric Acid Solutions

JOHN MILNE

Department of Chemistry, University of Ottawa, Ottawa, Canada K1N 6N5

Received September 17, 1974

JOHN MILNE. Can. J. Chem. **53**, 888 (1975).

Ultraviolet spectroscopy confirms the findings of solubility studies that Sb(III) in 3–12 *M* hydrochloric acid solutions is present as an equilibrium mixture of $SbCl_4^-$ and $SbCl_6^{3-}$ ions. In the presence of H_2SO_4 a further equilibrium with the $SbCl_3(HSO_4)^-$ ion is found. The spectrum of the $SbCl_6^{3-}$ ion in solution is unlike the diffuse reflectance spectrum of this anion in $Co(NH_3)_6SbCl_6$ but is similar to that in K_3SbCl_6. The Raman spectrum of 2 *M* $SbCl_3$ in 2.8 *M* hydrochloric acid is shown to be due to the $SbCl_4^-$ ion and the spectrum is assigned under C_{2v} symmetry. The Raman spectrum of the $SbCl_6^{3-}$ ion in solution is discussed.

JOHN MILNE. Can. J. Chem. **53**, 888 (1975).

Des études par spectroscopie ultraviolette confirment les résultats obtenus par l'intermédiaire d'études de solubilité et indiquant que Sb(III) dans des solutions d'acide chlorhydrique de 3 à 12 *M* est présent sous forme d'un mélange à l'équilibre d'ions $SbCl_4^-$ et $SbCl_6^{3-}$. En présence de H_2SO_4, on trouve un autre équilibre avec l'ion $SbCl_3(HSO_4)^-$. Le spectre de l'ion $SbCl_6^{3-}$ en solution n'est pas semblable au spectre de réflexion de cet anion dans $Co(NH_3)_6SbCl_6$; il est plutôt semblable à celui de K_3SbCl_6. On montre que le spectre Raman d'une solution de 2 *M* de $SbCl_3$ dans de l'acide chlorhydrique à 2.8 *M* est dû à l'ion $SbCl_4^-$ et le spectre est attribué à une symétrie C_{2v}. On discute du spectre Raman de l'ion $SbCl_6^{3-}$ en solution.

[Traduit par le journal]

Introduction

The nature of the chloroantimonate(III) species in aqueous solution has been studied by polarographic and solubility methods (1, 2), and by Raman spectroscopy (3, 4). These studies have indicated that the $SbCl_6^{3-}$ ion is present in equilibrium with $SbCl_4^-$. The u.v. spectrum of a solution of Sb(III) in concentrated hydrochloric acid has been shown to be constant over the range of HCl concentration 6 to 12 *F* (5) and this spectrum has been attributed to the $SbCl_6^{3-}$ ion (6). There are however, reasons to question an interpretation in terms of the $SbCl_6^{3-}$ ion. The absence, in the electronic spectrum of hydrochloric acid solutions of Sb(III), Sb(V) mixtures, of an Sb(III)–Sb(V) interaction band, which is observed in solid Cs_2SbCl_6, would seem to indicate that octahedral $SbCl_6^{3-}$ is not present (7) in solution. Furthermore, the symmetric stretching mode, ν_1, of the $SbCl_6^{3-}$ ion has been shown to occur at 269 cm^{-1} (8, 9) and this is inconsistent with the assignment of the strong polarized band at 329 cm^{-1} to the breathing mode of the $SbCl_6^{3-}$ ion (3, 4). On going from solid to solution state the change in ν_1 for octahedral hexachlorometallates is not of this order of magnitude and the frequency is higher in the solid than in solution (10, 11). The discrepancies between the solution and solid vibrational spectra for SbX_6^{3-} ions have been noted before (12) and attributed to departure from O_h symmetry in these species in solution. Because of the exceptional nature of the Sb(III) – hydrochloric acid system it was considered important to apply several physical methods to confirm the presence of $SbCl_6^{3-}$ in solution.

Experimental

Antimony trichloride (Fisher) was purified by sublimation. All chloroantimonates were prepared by literature methods; SbOCl (13); $pyHSbCl_4$ (14); $Co(NH_3)_6SbCl_6$ (15); $[(CH_3)_4N]_3Sb_2Cl_9$ (2), and their purity checked by analysis.

Solution electronic spectra were done at ambient temperature (30 ± 1 °C) on a Beckman DK-2 spectrophotometer. Variable path lengths were achieved by use of quartz spacers. Diffuse reflectance spectra were measured on a Beckman DU spectrophotometer with reflectance attachment; MgO was used as reference and diluent. Raman spectra were recorded using a Jarrell-Ash 300 with 4880 Å Ar^+ laser excitation. The samples were contained in 1 mm o.d. glass tubes. Solubility studies on $Co(NH_3)_6SbCl_6$ were carried out following procedures of Haight and Ellis (2). Solubility was determined by spectrophotometric analysis for $Co(NH_3)_6^{3+}$. The λ_{max} at 475 nm for solutions of $Co(NH_3)_6Cl_3$, used for standardization, obeyed Beer's Law closely up to 2×10^{-3} *M* both in distilled water and 4 *M* HCl.

Results and Discussion

Spectrophotometry

The spectrum of Sb(III) in 12 *M* HCl consists

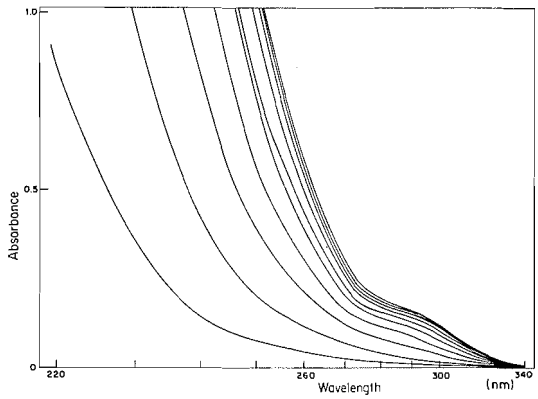

FIG. 1. Ultraviolet spectra of 10^{-3} M Sb(III) in 6.15 to 0.615 M HCl.

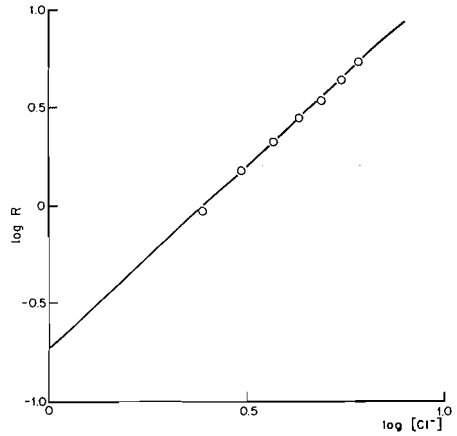

FIG. 2. Plot for the evaluation of n and K. (R = $[SbCl_{m+n}^{3-m-n}]/[SbCl_m^{3-m}]$).

of two maxima at 228 and 285 nm. Their intensities and positions at constant Sb(III) concentration remain unchanged over the HCl concentration range ~6.5 to 12 M as noted by Bonner and Goishi (5). Furthermore in 12 M HCl the spectrum obeys Beer's Law up to 0.02 M Sb(III). From these measurements the extinction coefficients at the maxima are found to be ε_{228} = 24 700 M^{-1} and ε_{285} = 2050 M^{-1}. In what follows the species giving these peaks is identified as A. As the HCl concentration is lowered from 6.5 M the peaks at 228 and 285 nm decrease and are replaced by an absorption which has a maximum below 200 nm. These changes are shown for the 285 nm peak of a 0.001 M Sb(III) solution in Fig. 1. The new species has no absorption at 285 nm and the concentration of A may be determined from the absorbance at 285 nm. Over the HCl range 6.15 to 3.07 M a single isosbestic point is observed at 224 nm indicating that two Sb(III) species are in equilibrium (A and B). Below 3.07 M HCl the short wavelength absorption shifts further below 200 nm indicating that at least one other species becomes involved. In the range where only two Sb(III) species are in equilibrium, the concentration of B may be calculated from stoichiometry

$$[B] = C_{Sb(III)} - [A]$$

where $C_{Sb(III)}$ represents total Sb(III) concentration. The equilibrium of interest is

$$SbCl_m^{(3-m)} + nCl^- \rightleftarrows SbCl_{m+n}^{3-m-n}$$

which is governed by the equilibrium constant

$$K = \frac{[SbCl_{m+n}^{3-m-n}]}{[SbCl_m^{3-m}][Cl^-]^n} \frac{f_{SbCl_{m+n}^{3-m-n}}}{f_{SbCl_m^{3-m}} f_{Cl^-}^n}$$

Ignoring the activity coefficient factor for the moment, a plot of log $[Cl^-]$ against log $\{[SbCl_{m+n}^{3-m-n}]/[SbCl_m^{3-m}]\}$ (=log R) should yield a straight line of slope n and intercept log K. Such a plot is given in Fig. 2 and from this n, is found to be 1.9 and K, 0.18 M^{-2}.

Such a plot can only be possible if there is a fortuitous cancelling of activity coefficients. Empirical equations describing the change in ionic activity coefficients, $f_\pm$, with ionic strength at moderate concentrations show an exponential dependence on ion charge (16, p. 231). One expression, introduced by Davies (17), is well known

$$\log f_\pm = -\frac{A|Z_1 Z_2|\sqrt{I}}{1+\sqrt{I}} + 0.1|Z_1 Z_2|I$$

where I represents ionic strength and A is a constant. Factoring out the ion charge part, we have

$$f_\pm = 10^{-|ZZ_2|F(I)}$$

where $F(I)$ represents the function of I. The activity coefficient of a multivalent ion, Y^{Z-}, can therefore be related to a reasonable approximation to that of a univalent ion, X^-, by the expression

$$f_{Y^{z-}} = f_{X^-}^{\,z}$$

Using this relation, it may be seen that the activity coefficient factor in the equilibrium expression with n = 2 would cancel for equilibria with m = 3 and 4, that is for

$$2Cl^- + SbCl_3 \rightleftarrows SbCl_5^{2-}$$

and

$$2Cl^- + SbCl_4^- \rightleftarrows SbCl_6^{3-}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

it may be assumed to a reasonable approximation that f_{SbCl_3} is unity. Cancellation of the activity coefficient factor arises with no other equilibrium with a $2Cl^-$ change and, for the cases where $m \neq 3$ or 4, introduction of the appropriate factor calculated from the molal activity coefficients for HCl (18) and known density data (19) leads to large curvature in the plot. Similarly equilibria involving other than a $2Cl^-$ change lead to curves and nonintegral slopes.

These spectrophotometric results cannot indicate whether A is $SbCl_5^{2-}$ or $SbCl_6^{3-}$ but studies on the solubility of chloroantimonate(III) compounds permit this distinction.

Solubility Studies

Haight and Ellis used the solubility of $[(CH_3)_4N]_3Sb_2Cl_9$ in H_2SO_4–HCl solutions to show that $SbCl_3$, $SbCl_4^-$, and $SbCl_6^{3-}$ are in equilibria in these solutions. The question arises as to whether Sb(III) may form sufficiently stable complexes with HSO_4^- or SO_4^{2-} to affect the solubility. Mixtures of $HClO_4$–HCl could not be used to check this possibility due to the low solubility of $(CH_3)_4NClO_4$. $Co(NH_3)_6SbCl_6$ is easily prepared and has a low solubility (15) which makes it an ideal compound for solubility studies (2). On the basis of the work of Haight and Ellis the following equilibria are expected

$$[1] \quad Co(NH_3)_6SbCl_6 \rightleftarrows Co(NH_3)_6^{3+} + SbCl_6^{3-}$$

$$[2] \quad SbCl_6^{3-} \rightleftarrows SbCl_4^- + 2Cl^-$$

$$[3] \quad SbCl_4^- \rightleftarrows SbCl_3 + Cl^-$$

According to these equilibria, as chloride concentration decreases the solubility should increase. Table 1 shows that the solubility in 4 *M* HCl–$HClO_4$ mixtures falls off sharply below 3 *M* HCl. Furthermore the insoluble material is flocculent below and crystalline above 3 *M* HCl.

TABLE 1. Solubility of $Co(NH_3)_6$ $SbCl_6$ in solutions of constant total acid molarity (4 *M*)

M_{HA}	10^3S (*M*)*
4 *M* HCl	0.12
3.6 *M* HCl–0.4 *M* $HClO_4$	0.10
2.8 *M* HCl–1.2 *M* $HClO_4$	0.08
2.4 *M* HCl–1.6 *M* $HClO_4$	0.03
4 *M* $HClO_4$	0.003
4 *M* H_2SO_4	0.57

*M = mol/l.

This suggests that the equilibria given by Haight and Ellis ([2] and [3]) may not describe precisely the solubilities in this system. It should, however, be pointed out that the increasing solubility with increasing chloride concentration may be a result of ion pair formation

$$Co(NH_3)_6^{3+} + Cl^- \rightleftharpoons Co(NH_3)_6Cl^+$$

in which case the equilibria 2–3 may still be valid, but their effect would be masked.[1] Such ion pairing has been shown to be not insignificant (20). Table 1 also gives the solubility of $Co(NH_3)_6SbCl_6$ in 4 *M* H_2SO_4 which is 1000-fold greater than in 4 *M* HCl. Moreover, $SbCl_3$ yields a flocculent precipitate on contact with 4 *M* $HClO_4$ but dissolves in 4 *M* H_2SO_4. These observations show that Sb(III) is complexed in solutions containing sulfuric acid and this should be considered in interpreting the $[(CH_3)_4N]_3Sb_2Cl_9$ solubility work in HCl–H_2SO_4 mixtures. The extrapolation used by Haight and Ellis at high chloride concentrations ($0.8\ M < [Cl^-] < 4.0\ M$) should be little affected by sulfate complexing and thus the solubility curve would be accounted for in this region by the equilibria

$$[(CH_3)_4N]_3Sb_2Cl_9 \overset{K_s}{\rightleftharpoons} 3(CH_3)_4N^+ + 2SbCl_4^- + Cl^-$$

$$SbCl_4^- + 2Cl^- \overset{K_5K_6}{\rightleftharpoons} SbCl_6^{3-}$$

In the region of high $[HSO_4^-]$ the solubility may be determined by

$$SbCl_4^- + HSO_4^- \overset{K_4'}{\rightleftharpoons} SbCl_3(HSO_4)^- + Cl^-$$

Solubility, $[Cl^-]$ and $[HSO_4^-]$ are related by the expression

$$S^{5/2}[Cl^-]^{1/2} = \frac{K_2^{1/2}}{10.4}\left\{1 + K_5K_6[Cl^-]^2 + \frac{[HSO_4^-]}{[Cl^-]}K_4'\right\}$$

where S represents the solubility of the salt. This expression is identical to that of Haight and Ellis at high $[Cl^-]$ values yielding $K_S = 1.8 \times 10^{-5}$ and $K_5K_6 = 0.17$. At the low $[Cl^-]$ end of the solubility curve, correction of $[Cl^-]$ and $[HSO_4^-]$ for the various equilibria involved could not be made due to the complexity of the system. However a plot of $S^{5/2}[Cl^-]^{1/2}$ *vs.* $[HSO_4^-]/[Cl^-]$ using uncorrected $[Cl^-]$ and $[HSO_4^-]$ values should lead to the same inter-

[1]We thank one of the referees for pointing this out.

cept as the first plot and give an estimate of K_4' from the slope. The value for K_4' found was 0.017. The equilibrium constants were now used in a computer program which calculated S at the stoichiometric concentrations. From the value of S and the equilibrium constants, improved $[HSO_4^-]$ and $[Cl^-]$ values were calculated and S redetermined. This procedure was repeated until S showed no significant change. Several sets of equilibrium constants were tested. The optimum fit to solubility data of Haight and Ellis was given by $K_S = 1.85 \times 10^{-5}$, $K_5K_6 = 0.16$, $K_4' = 0.016$. As in the original solubility work, HSO_4^- dissociation was considered negligible.

The agreement between the K, calculated from the spectrophotometric measurements and K_5K_6 is remarkably good, considering the assumptions made in the determination of K and confirms that the equilibrium involved in these solutions is between $SbCl_4^-$ and $SbCl_6^{3-}$. Furthermore the electronic spectrum at high $[Cl^-]$ is due to $SbCl_6^{3-}$. Attempts to fit an equilibrium between $SbCl_3$ and $SbCl_5^{2-}$ to the solubility data, using several possible equilibria with HSO_4^- lead to nonlinear extrapolations and the best computer fit to the solubility curve was given with $K_4K_5 = 3.3$, very different from the spectrophotometric value.

Reflectance Spectroscopy

An attempt was made to identify the Sb(III) complex present in concentrated HCl by analogy with the electronic spectral bands observed in the diffuse reflectance spectra of solids known to contain specific chloroantimonate(III) ions. The data are given in Table 2. No satisfactory correlation can be found between the solution spectrum and the spectra of any of the chloroantimonate species although the parallel between the K_3SbCl_6 spectrum with the 30 800 and 37 000 cm^{-1} peaks both contributing to the solution peak at 34 500 cm^{-1}, is closest. Normally there is little shift in the band maxima of an ion upon transfer from solid to solution. The behavior of the $Co(NH_3)_6^{3+}$ ion in this work is an example of this with solid maxima at 21 200 and 29 800 cm^{-1} and solution maxima at 21 000 and 29 500 cm^{-1} (21, p. 293). On this basis it would appear there is some difference between the $SbCl_6^{3-}$ ion in solution compared to the octahedral ion in $Co(NH_3)_6SbCl_6$ (22).

In the series of chloroantimonates studied, as the number of near-neighbor chloro-ligands increases, the strongest band which is the lowest energy band in $Sb_2Cl_9^{3-}$ and $SbCl_6^{3-}$ compounds, shifts to lower energy. The u.v. absorption of $d^{10}s^2$ species has been assigned to $s \rightarrow p$ transitions (6) and it has been noted that the $s - p$ energy difference decreases as the electronegativity of the ligands bonded to such a species decreases (21 p. 186). Since in a chloro-complex or compound "Sb^{3+}" would be more electronegative than chloride ion increasing the number of Cl^- ligands would increase the electronic charge on the antimony, which would produce the same effect as decreasing ligand electronegativity. If the bonding in these chloro-antimony(III) species is principally ionic, the decrease in s–p separation with increasing number of Cl^- ligands is probably a reflection of increasing ratio of electronic to nuclear charge.

Raman Spectroscopy

A solution of 0.5 *M* Sb(III) in concentrated HCl (12.3 *M*) gives the Raman spectrum shown in Fig. 3. As the concentration of Sb(III) is de-

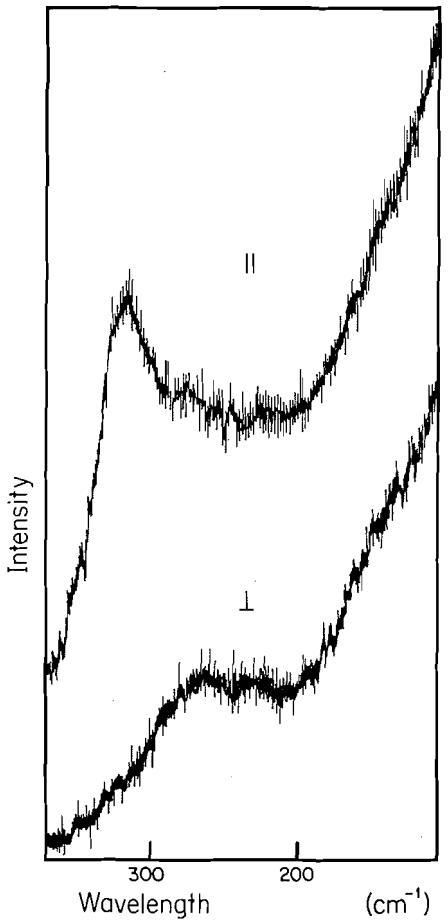

FIG. 3. Raman spectrum of $SbCl_6^{3-}$ ([Sb(III)] = 0.5 *M*).

creased the spectral profile shows virtually no change down to the limit of useful measurement at 0.02 *M* and the most intense peak remains at $325 \pm 2\ cm^{-1}$. Certainly there is no increase in relative intensity in the region of ν_1 for the octahedral $SbCl_6^{3-}$ ion in $Co(NH_3)_6SbCl_6$ at 266 cm^{-1} (8, 9, 15) as the concentration is decreased. Moreover the u.v. spectrum of the 0.02 *M* Sb(III) solution in 12.3 *M* HCl shows the typical $SbCl_6^{3-}$ spectrum. From the absorbance at 285 nm, $[SbCl_6^{3-}]$ is found to be 0.018 *M*, while using $K = 0.16$, $[SbCl_6^{3-}]$ is calculated to be 0.019 *M*. Therefore the Raman shift at 325 cm^{-1} definitely belongs to the $SbCl_6^{3-}$ ion and, as indicated above, there must be a considerable change in the nature of the $SbCl_6^{3-}$ in going from $Co(NH_3)_6SbCl_6$ to solution. In previous work

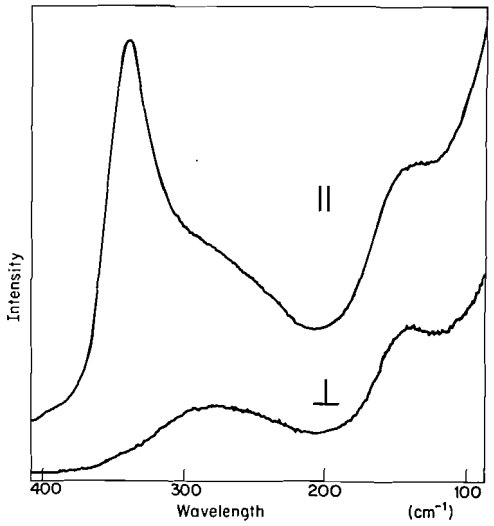

FIG. 4. Raman spectrum of $SbCl_4^-$ ([Sb(III)] = 2.0 *M*).

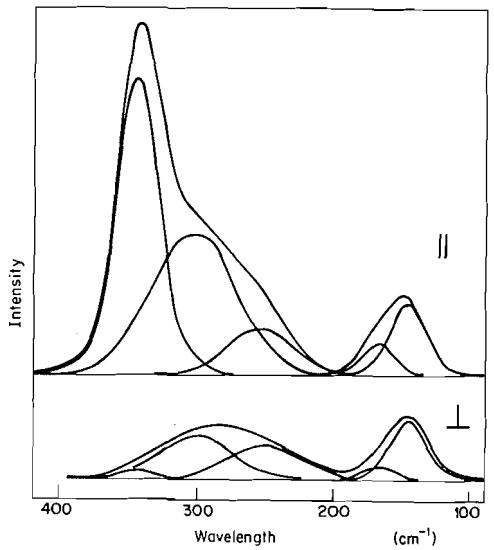

FIG. 5. Curve resolution of the Raman spectrum of $SbCl_4^-$.

TABLE 3. Assignment of the Raman spectrum of the $SbCl_4^-$ ion

Mode	Wave number	Approximate description of mode
ν_1 (A_1)	337 (10) p	ν_{sym} (eq. $SbCl_2$)
ν_2 (A_1)	300 (5) p	ν_{sym} (ax. $SbCl_2$)
ν_3 (A_1)	170 (1) p	δ_{sym} (eq. $SbCl_2$)
ν_6 (B_1)	252 (2)	ν_{asym} (eq. $SbCl_2$)
ν_7 (B_1)	146 (2)	δ_{asym} (eq. $SbCl_2$)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

(4, 12) these differences have not been clearly demonstrated since the relative contribution of $SbCl_4^-$ and $SbCl_6^{3-}$ to the Raman spectrum is concentration dependent. Calculation shows that at moderate $SbCl_3$ concentrations (2 *M*) only $\frac{2}{3}$ of the Sb(III) is present as $SbCl_6^{3-}$ and the Raman spectrum consists of shifts due to $SbCl_6^{3-}$ and $SbCl_4^-$. Calculation shows that for the solution used for Fig. 3, $[SbCl_6^{3-}] = 0.47$ *M*. This spectrum has been attributed to an octahedral ion (3, 4) but the breadth of the spectral bands, the high intensity ratio of ν_2 to ν_1 for O_h symmetry species and the relative weakness of the deformation modes, suggest that $SbCl_6^{3-}$ is not octahedral in solution. It is possible that the $SbCl_6^{3-}$ ion is like XeF_6 in the vapor phase (23) consisting of an equilibrium mixture of several stereo-chemical forms. An attempt was made to apply curve resolution to the spectrum but many solutions seemed possible and the results were not considered to be meaningful.

The spectrum of 2 *M* $SbCl_3$ in 2.8 *M* HCl is given in Fig. 4. This spectrum differs from that of $SbCl_6^{3-}$ in that the relative intensity of the deformation modes is greater and the broad band centered at 288 cm^{-1}, as well as that at 332 cm^{-1}, is polarized. Calculation shows $[SbCl_4^-] =$ 1.9 *M* and the spectrum shows a close parallel to that reported by Ahlijah and Goldstein for the C_{2v} $SbCl_4^-$ ion (24). Contrary to the findings of Petrov *et al.* (4), three polarized bands are observed. The curve resolved spectra are given in Fig. 5 and the assignment in Table 3. The observation of two polarized bands in the SbCl stretching region supports C_{2v} symmetry for this ion and rules out a tetrahedral ion (4). The assignment differs from that in ref. 24 in that ν_{sym} (eq. $SbCl_2$) rather than ν_{sym} (ax. $SbCl_2$) is assigned to the highest frequency polarized band. This parallels the assignment for the SbF_4^- ion and molecular TeF_4 (25) and agrees with the X-ray work which shows that the $SbCl_{eq}$ bond is stronger than $SbCl_{ax}$ ($SbCl_{eq}$, 2.38 Å; $SbCl_{ax}$, 2.64 Å) (14).

The author is grateful to Dr. A. R. Davis of Environment Canada for the use of his Raman equipment and the National Research Council of Canada for financial assistance.

Azole Chemistry. IX.[1] A New Synthesis of Fused Pyrimidines: Tetrahydropyrimido[1,2-*a*]benzimidazoles

HOWARD ALPER[2] AND LAWRENCE PEPPER[3]

Department of Chemistry, State University of New York at Binghamton, Binghamton, New York 13901

Received July 25, 1974

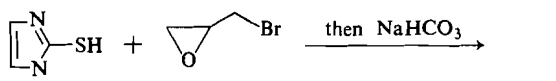
HOWARD ALPER and LAWRENCE PEPPER. Can. J. Chem. **53**, 894 (1975).

2-Aminobenzimidazole and 2-amino-5,6-dimethylbenzimidazole react with various epoxy bromides in hot 2-butanone to give, after basification, 3-hydroxy-1,2,3,4-tetrahydropyrimido-[1,2*a*]benzimidazoles. The spectral properties of these heterocycles are discussed.

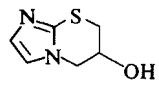
HOWARD ALPER et LAWRENCE PEPPER. Can. J. Chem. **53**, 894 (1975).

L'amino-2 benzimidazole et l'amino-2 diméthyl-5,6 benzimidazole réagissent avec divers bromures d'époxydes dans la butanone chaude pour conduire après basification aux hydroxy-3 tétrahydro-1,2,3,4 pyrimido-[1,2*a*] benzimidazoles. On discute des propriétés spectrales de ces hétérocycles. [Traduit par le journal]

The reaction of epoxy bromides with mercaptoazoles such as 2-mercaptoimidazole (1) and 5-mercapto-1-phenyl-1,2,3,4-tetrazole (2) represents a convenient synthetic approach to fused 1,3-thiazines (*e.g.*, **1** → **2**). A question arises as



1

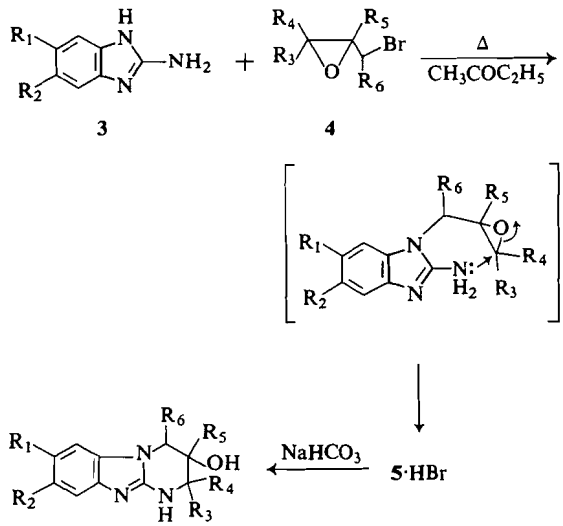


2

to whether amino azoles could also undergo this type of cyclization process and afford six-membered ring heterocycles containing two nitrogen atoms. Should such a transformation occur, it would provide a new and simple entry into fused, potentially pharmacologically active, pyrimidines. We now wish to report the synthesis of some tetrahydropyrimido[1,2-*a*]benzimidazoles, formed by treatment of 2-aminobenzimidazole and 2-amino-5,6-dimethylbenzimidazole with various epoxy bromides.

Results and Discussion

When an equimolar mixture of 2-aminobenzimidazole (**3**, $R_1 = R_2 = H$) or 2-amino-5,6-dimethylbenzimidazole (**3**, $R_1 = R_2 = CH_3$) and an epoxy halide (**4**) were refluxed in 2-butanone for 1–4 days, the hydrobromide salt of **5** was formed, either as an oil or as a solid. The salt was converted into its free base upon treatment with sodium bicarbonate. The reaction times, yields, and analytical data of the 3-hydroxy-1,2,3,4-tetrahydropyrimido[1,2-*a*]benzimidazoles (**5**) are listed in Table 1.



3 **4**

5·HBr

5

The initial step in the reaction process involves alkylation at a ring nitrogen to give the substituted 2,3-epoxypropane intermediate. Ogura and co-workers (3) have presented evidence for

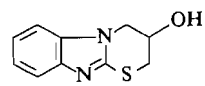
b	2550–3350	1159	1578	1627	—
c	2600–3350	1080	1580	1628	—
d	2600–3400	1098	1577	1632	—
e	2600–3400	1095 or 1115	1570	1620	233(3.69), 250(3.62), 299(3.67)
f	2600–3300	1078	1565	1628	231(3.61), 256(3.51), 302(3.57)

the occurrence of condensation at a ring nitrogen, rather than at the amino group nitrogen, of **3**, $R_1 = R_2 = H$, in the synthesis of the related imidazo[1,2-*a*]benzimidazole system. Annelation of the pyrimidine ring to the benzimidazole then occurs by ring opening of the intermediate epoxide.

The structures of the 3-hydroxy-1,2,3,4-tetrahydropyrimido-[1,2-*a*]benzimidazoles were assigned on the basis of analytical data and spectral results. Solid state i.r. spectra (Table 2) of **5** showed sharp, characteristic carbon–oxygen stretching vibrations between 1078 and 1159 cm^{-1} (1, 2). Broad bands were observed in the region of 3400–2500 cm^{-1} and were assigned to the hydrogen–bonded stretch of the hydroxyl and amino functions (carbon–hydrogen stretching absorptions overlap in the 3050–2825 cm^{-1} region). An intense absorption appeared at 1580–1565 cm^{-1} which is due to ν(N=C—N) of the benzimidazole portion of the molecule (4).

The heterocycles (**5**) were insufficiently soluble in solvents commonly used for n.m.r. purposes. The u.v. spectra for several of the tetrahydropyrimido[1,2-*a*]benzimidazoles were recorded (Table 2) and show three absorption maxima at 228–233, 250–256, and 291–302 nm. The latter maximum is probably due, at least in part, to an $n \rightarrow \pi^*$ transition.

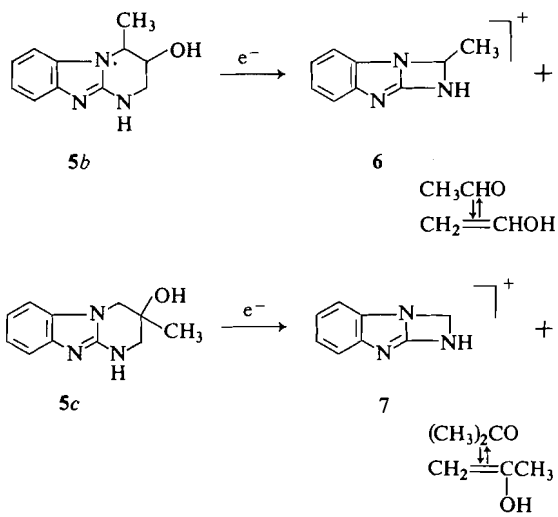
Electron impact mass spectra of two of the heterocycles provided important information regarding their structures. The isomeric compounds **5***b* and **5***c* each gave a parent molecular ion peak at *m/e* 203. A major fragmentation pathway of **5***b* was elimination of acetaldehyde to give an ion of *m/e* 159, possibly of structure **6**. The fused 1,3-thiazine **8**, also loses acetaldehyde



8

on fragmentation of the molecular ion (5). The tertiary alcohol **5***c* loses acetone on electron impact to afford a fragment of proposed structure **7** (*m/e* 145).

An oily by-product was formed in most of these reactions, easily separated from **5** by solubility differences. Nuclear magnetic resonance spectra of the oils lack signals due to aromatic protons. The oil is probably a polymer of the epoxy bromide.



Experimental

General

Melting points were determined on a Fisher–Johns apparatus and are uncorrected. Elemental analyses were determined by Hoffmann-LaRoche Microanalytical Laboratory and by Pascher Mikroanalytisches Laboratorium, Bonn, Germany. Infrared spectra were obtained on a Perkin-Elmer 457 spectrometer and u.v. spectra were recorded on a Perkin-Elmer 202 spectrometer. Mass spectra were determined using a Varian MS902 spectrometer.

Epoxy Bromides

Epibromohydrin was commercially available. 1-Bromo-2,3-epoxy-3-methylbutane was prepared by dehydrohalogenation of 1,2-dibromo-3-methyl-3-butanol (6). Dehydrohalogenation of 2,3-dibromobutan-1-ol yielded *threo*-3-bromo-1,2-epoxybutane (7). Halogenation of 2-methyl-2-propen-1-ol gave 1,2-dibromo-2-methyl-3-propanol (8), which was then dehydrohalogenated to yield 1-bromo-2,3-epoxy-2-methylpropane (9).

General Procedure for the Reaction of 2-Aminobenzimidazole or 2-Amino-5,6-dimethylbenzimidazole with Epoxy Bromides

Equimolar amounts of the heterocycle and epoxy halide (15.6 mmol) were refluxed with stirring in 2-butanone (125–225 ml) for 1–4 days, until either the color of the solution changed or a precipitate was formed, signifying that a reaction had occurred. The reaction mixture was allowed to cool to room temperature and work-up was then effected as follows for the individual cases:

(*a*) R_1—R_6=H: the hydrobromide salt of **5***a* precipitated out of solution. If was filtered and dried. Conversion to the free base was accomplished by dissolving the salt in hot water (~300 ml), adding a small amount (5 ml) of *N*,*N*-dimethylacetamide, and basifying the solution with 5% aqueous sodium bicarbonate (to a p*H* of 8). The solution was then continuously extracted with methylene chloride. Pentane was added to the residue obtained by flash evaporation of the methylene chloride extract in order to induce precipitation of pure **5***a*.

(*b*) R_1—R_4=R_6=H, R_5=CH_3: the reaction mixture was filtered and the filtrate was concentrated to a dark oil. The oil was dissolved in ethanol and basified as described in *a*. Continuous extraction with methylene chloride, followed by solvent evaporation, gave a semi-solid from which **5***b* was isolated by addition of ether and subsequent filtration. The heterocycle was washed well with acetone.

(*c*) R_1—R_5=H, R_6=CH_3: isolation of 5*c*·HBr and basification was effected as in *b*. A small quantity of an unidentified precipitate was filtered and the filtrate was extracted continuously with methylene chloride. Flash evaporation of the organic extract gave a yellow oil which, upon standing, deposited the fused azole. The heterocycle was filtered and washed with acetone. Evaporation of the filtrate gave an oil, possibly of polymeric composition (n.m.r. $(CD_3)_2CO$: δ 2.02s, 2.87s, 3.03s).

(*d*) R_1=R_2=R_5=R_6=H, R_3=R_4=CH_3: the work-up used was that of *b* up to the point of flash evaporation of the methylene chloride extract. The oil was dissolved in the minimum amount of tetrahydrofuran. Pentane was added and the reaction mixture was then allowed to stand overnight at room temperature. Decantation of the solution gave an orange oil from which **5***d* slowly crystallized on standing.

(*e*) R_1=R_2=CH_3, R_3—R_6=H: the reaction was worked up as described for **5***b*.

(*f*) R_1=R_2=R_6=CH_3, R_3=R_4=R_5=H: the reaction was worked up as described for **5***c*.

Carbonyl Addition Reactions: Factors Affecting the Hydrate–Hemiacetal and Hemiacetal–Acetal Equilibrium Constants

J. PETER GUTHRIE

Department of Chemistry, University of Western Ontario, London, Ontario N6A 3K7

Received August 19, 1974

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

J. PETER GUTHRIE. Can. J. Chem. **53**, 898 (1975).

Equilibrium constants for hydrate-hemiacetal interconversion in aqueous solution at 25° have been measured for four fluorinated carbonyl compounds: compound, alcohol, K_4 (M^{-1}): CF_3CHO, C_2H_5OH, 2.3; CF_3COCH_3, CH_3OH, 1.0; CF_3COPh, CH_3OH, 3.5; CF_3COCF_3, CH_3OH, 0.14. These values, combined with values from the literature, permit an examination of substituent effects upon the equilibrium constant for

$$-\overset{|}{\underset{|}{C}}-OH + ROH \rightleftarrows -\overset{|}{\underset{|}{C}}-OR + H_2O$$

The free energy change for this process, corrected for symmetry and steric effects, follows the equation

$$\Delta G_4'' = -0.54 + 0.63\ \Sigma\sigma^*$$

Thus electronic effects upon this equilibrium are generally small and in fact are often smaller than steric effects.

This analysis permits and justifies the calculation of free energies of formation of $-\overset{|}{\underset{|}{C}}-OH$ compounds from the (more generally measurable) free energies of formation of the analogous $-\overset{|}{\underset{|}{C}}-OR$ compounds.

J. PETER GUTHRIE. Can. J. Chem. **53**, 898 (1975).

On a mesuré, en solution aqueuse, à 25°, les constantes d'équilibre pour l'interconversion hydrate–hémiacétal de quatre composés carbonylés fluorés: le composé, l'alcool, K_4 (M^{-1}): CF_3CHO, C_2H_5OH, 2.3; CF_3COCH_3, CH_3OH, 1.0; CF_3COPh, CH_3OH, 3.5; CF_3COCF_3, CH_3OH, 0.14. Ces valeurs peuvent être combinées avec d'autres extraites de la littérature afin de permettre une évaluation de l'effet des substituants sur la constante d'équilibre

$$-\overset{|}{\underset{|}{C}}-OH + ROH \rightleftarrows -\overset{|}{\underset{|}{C}}-OR + H_2O$$

Le changement d'énergie libre au cours de cette réaction, corrigé pour la symétrie et les effets stériques, suit l'équation

$$\Delta G_4'' = -0.54 + 0.63\ \Sigma\sigma^*$$

On peut donc en déduire que les effets électroniques sur cet équilibre sont généralement petits et que de fait ils sont souvent plus petits que ceux des effets stériques.

Cette analyse permet et justifie le calcul d'énergies libres de formation de composés $-\overset{|}{\underset{|}{C}}-OH$, effectué à partir d'énergies libres de formation (généralement plus facilement mesurable) des composés $-\overset{|}{\underset{|}{C}}-OR$ qui leur sont analogues. Introduction

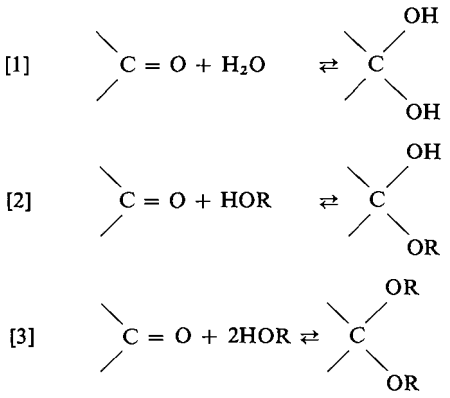
The three related equilibria 1–3 involved in hydrate (1–6), hemiacetal (1–7), and acetal (6–12) formation from carbonyl compounds have been



investigated in numerous laboratories. It has been found quite commonly that for a related series of compounds equilibrium constants for any one of these reactions can be correlated using the appropriate σ parameters (2, 3, 6, 12). Sander and Jencks (13) have shown that the equilibrium constants for hemiacetal and hydrate formation are often in constant proportion, depending only on the relative tendencies to add to carbonyl groups of the alcohol and water molecules. This tendency is expressed in terms of their γ parameters.

Recently it was shown (14) that a further generalization was possible in terms of the (sometimes hypothetical) reaction

since equilibrium constants for this reaction were close to unity and almost constant for a wide series of compounds and appeared to depend only upon the number of substituents on the central carbon.

This near constancy of the equilibrium constant for reaction 4 has great potential utility as a means for evaluating free energies of formation of the unobservable hydroxyl-bearing intermediates in acyl transfer reactions from the readily obtained free energies of formation of the stable methoxy or ethoxy analogs (14, 15). Accordingly it seemed essential to test the validity of this relationship for as wide a range of compounds as possible.

In the present paper are collected all available equilibrium constants from the literature, as well as some additional values determined in this laboratory. In agreement with the original generalization (14), the equilibrium constants for process 4 are close to unity for all but the most extreme cases. Inclusion of data for hemiacetals and hydrates of fluorinated aldehydes and ketones reveals that there is a small electronic effect on the equilibrium constant for reaction 4.

Results and Discussion

Equilibrium Constants for Addition to Fluorinated Aldehydes and Ketones

Fluorinated aldehydes and ketones have several advantages for the study of carbonyl addition reactions: (*a*) the trifluoromethyl group is one of the most powerful electron withdrawing groups, yet is relatively unreactive, so that electronic effects can be studied without interference; (*b*) the fluorine n.m.r. will have only signals from the trifluoromethyl group, without the massive interfering signals from solvent and other reagents which often plague the use of proton n.m.r.; (*c*) ^{19}F chemical shifts are very sensitive to substituents so that signals from hydrate and hemiacetal are well separated.

Trifluoroacetaldehyde, trifluoroacetone, trifluoroacetophenone, and hexafluoroacetone were studied in aqueous solution with varying amounts of methanol or ethanol. For all but trifluoroacetone, the free carbonyl compound is present only at unobservably low concentrations but the equilibrium between hydrate and hemiacetal is readily observed. No signals attributable to acetal were ever seen; estimation of the rate of acetal formation from the known linear free energy relation for rates of hydrolysis (16) suggests that acetal formation from these compounds would be *extremely* slow. The data are recorded in the Experimental; the final results are included in Tables 1 and 2.

Equilibrium Constants for Reaction 4

In Table 1 are collected the available data on equilibria for addition of water and methanol or ethanol to carbonyl compounds. There are numerous additional cases where only hydration or acetal equilibrium constants are available but these were not included, since equilibrium constants for reaction 4 could not be calculated without recourse to linear free energy relations to estimate the missing values. In the cases of

trifluoroacetaldehyde and hexafluoroacetone the equilibrium constants for hydration are unknown and could not be measured by the n.m.r. method employed in the present work; for purposes of comparison values were estimated using the linear free energy relation of Greenzaid *et al.* (2). In the case of trifluoroacetaldehyde, this is equivalent to assuming that the equilibrium constant is the same as for trichloroacetaldehyde. In any case, since the hydrate–hemiacetal equilibrium constant is directly measurable for these compounds, subsequent calculations in this paper are independent of the values of the equilibrium constants for hydration.

[f]Ratio of equilibrium constants for acetal formation and hemiacetal formation from Table 1.
[g]Pyridine-4-carboxaldehyde.
[h]For reaction at the carbonyl adjacent to the trifluoromethyl group.

In several cases free energies of formation for acetals and the corresponding carbonyl compounds can be calculated from values in the literature. These permit calculation of equilibrium constants for acetal formation. This was done (see Appendix) for the dimethyl and diethylacetals of formaldehyde, for which no direct measurements appear to have been reported.

In Table 2 are found the equilibrium constants for two cases of reaction 4, *i.e.* carbonyl hydrate to hemiacetal and hemiacetal to acetal. In order to make comparisons on a per hydroxyl basis, these equilibrium constants must be corrected for symmetry effects (17): the net result is that the numerical magnitude of the hemiacetal to acetal equilibrium constant is four times larger after this correction is made. Then the equilibria must be corrected for steric interactions introduced as the alkoxy group replaces a hydroxy. This was done following an approach used quite successfully in an additivity scheme for heats of formation of acetals (18); the least crowded conformation was drawn and the number of unfavorable interactions counted. The difference in these interactions is used to correct the free energy change for reaction 4.

The interactions which were considered were: the fifth-neighbour H–H interaction of the gauche butane type; the analogous fifth neighbour hydrogen – lone pair interaction, for which the values recommended by Pihlaja (18) were used, 0.77 and 0.15 kcal mol^{-1}, respectively; and the fifth neighbour H–F interaction, for which

half the axial–equatorial free energy difference for trifluoromethylcyclohexane (19) was used, *i.e.* 1.05 kcal mol^{-1}. It was assumed that the free energy change resulting from steric crowding is essentially all determined by the enthalpy change, so that enthalpies and free energies for these steric interactions are equal.[1] For the interaction between H and phenyl which would be encountered in methyl or ethyl hemiacetals or acetals of aralkyl and diaryl ketones or arylaldehydes no literature values could be found. Examination of space filling models showed that the interaction is likely to be very small. For lack of a better value this H–Ph interaction is assumed to be zero.

After these two corrections have been made to the observed free energy changes for reaction 4, the values obtained are symbolized $\Delta G_4''$ and are found in Table 2.

In order to determine whether compounds with one oxygen atom behave analogously to compounds with two oxygens, the standard free energy changes for the hypothetical reactions leading to the formation of methyl and ethyl ethers were calculated for those cases where sufficient free energy of formation data were available. The ΔG_4^0 and $\Delta G_4''$ values so obtained are found in Table 3. These values are necessarily less precise than those obtained from equilibrium studies. The $\Delta G_4''$ are corrected for symmetry and steric effects in a manner analogous to that employed for Table 2.

Figure 1 shows the dependence of ΔG_4^0, $\Delta G_4'$, and $\Delta G_4''$ upon $\sum\sigma^*$; although there is clearly a trend to the ΔG_4^0 plot, there is a great deal of scatter; the scatter is appreciably lessened by correcting for symmetry to give $\Delta G_4'$; the final values of $\Delta G_4''$, corrected for both symmetry and steric effects, show a regular linear dependence upon $\sum\sigma^*$, the sum of the σ^* values for the three substituents on the hydroxyl or alkoxyl bearing carbon. The values are fitted by the line[2]

$$[5]\quad \Delta G_4'' = (-0.66 \pm 0.12) + (0.48 \pm 0.04)\sum\sigma^*$$

determined by the method of least squares which is equivalent to

$$[6]\quad \log K_4'' = +0.48 - 0.34\sum\sigma^*$$

The only points which deviate seriously are those obtained using thermochemical calculations rather than directly evaluated equilibrium constants, and even these deviate by less than their probable errors.

The values of $\Delta G_4''$ clearly are influenced by electron withdrawal by the substituents on the central carbon, so that the initial generalization (14), that $\Delta G_4''$ was constant, is not correct. However the variation is clearly very small and only becomes appreciable for powerfully elec-

[a]In aqueous solution at 25°: the standard state for solutes is an ideal 1 *M* solution with an infinitely dilute reference state: the standard state for water is the pure liquid. Units are kcal mol^{-1}.
[b]Calculated from values in ref. 14, with ΔG_f^0(g) for diethyl ether from ref. 24 and ΔG_t calculated from data in ref. 17*a*.

[1]This is not strictly true but entropic effects are likely to be small. Symmetry effects are explicitly taken care of in this paper leaving as the major contributions entropy of mixing effects and restrictions in the rotational freedom of a methyl (*or* trifluoromethyl) group due to steric interference (cogwheeling), (19*b*). The entropy of mixing effect results from the shift in relative population of the three conformers arising from rotation about a C—OCH_3 bond as the spread in energy levels increases with increased crowding. Estimates of this effect suggest that it amounts at most to about 0.2 kcal mol^{-1} in free energy. Entropy effects due to "cogwheeling" are difficult to estimate: where they have been invoked they amount to about 0.2 kcal mol^{-1} in free energy (19*b*). If such entropic effects were mainly responsible for the residual scatter observed in Fig. 1*c*, one would expect systematic deviations for, say, aldehyde hemiacetals relative to ketone hemiacetals, since the aldehyde hemiacetals would be less subject to steric restriction of rotation. However both sets of data show what appears to be random scatter about the least squares line. Therefore the assumption that entropy effects may be neglected appears to be valid.

[2]The correlation coefficients for these graphs are: Fig. 1*a*, 0.624; Fig. 1*b*, 0.803; Fig. 1*c*, 0.869. For Fig. 1*c*, the standard deviation of the points about the line is 0.31. The most serious deviations in Fig. 1*c* are for compounds where steric effects are expected to be large (the chloroacetones, isobutyraldehyde, and pivaldehyde). If all of the equilibria involving these compounds are deleted from the set of data, eq. 5 becomes

$$\Delta G_4'' = -0.70 + 0.49\ \Sigma\sigma^*$$

with a correlation coefficient of 0.96.

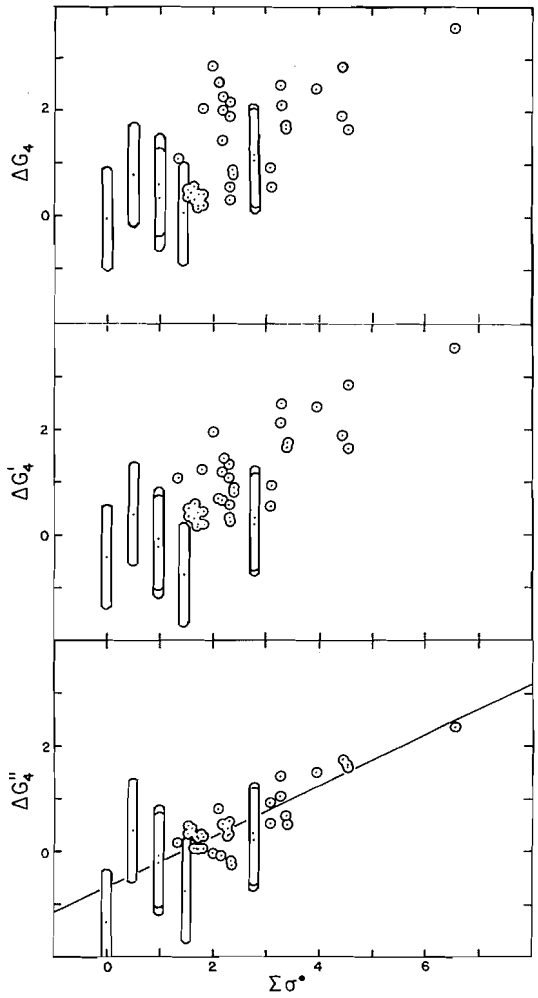

FIG. 1. Graphs of ΔG_4 (*a*), $\Delta G_4'$ (*b*), and $\Delta G_4''$ (*c*) *vs.* $\Sigma\sigma^*$, for the reaction $\gtrless$C—OH + HOR = $\gtrless$C—OR + H_2O. The elongated symbols are points based upon free energy of formation data. The line drawn in *c* was determined by weighted least squares.

tron withdrawing substituents. To keep the variation in perspective it should be noted that K_4'' varies by 300-fold, whereas $K_{\text{hydration}}$ varies by 10^9-fold. It should also be noted that the steric corrections can be as large as a factor of 28 in K_4''.

Sander and Jencks (13) have proposed the linear free energy relation

$$[7] \qquad \log K_{\text{add}} = A + \Delta\gamma$$

for addition of nucleophiles to carbonyl compounds. In this equation, A and Δ are constants for a given carbonyl compound and γ is a measure of the tendency of a nucleophile to add to carbonyl groups. γ is defined as the logarithm of the ratio of the equilibrium constants for the addition to pyridine-4-carboxaldehyde of the nucleophile and of methylamine. For the cases reported to date Δ is close to unity, although the observed dependence of $\Delta G_4''$ upon $\Sigma\sigma^*$ implies that this is a consequence of the limited set of carbonyl compounds which have been examined.

If eq. 7 is valid for all carbonyl compounds, then for the hydrate – methyl hemiacetal case of reaction 4, it would be predicted that

$$\log K = \Delta(\gamma_{CH_3OH} - \gamma_{H_2O})$$

Substituting the measured values for γ and making suitable corrections for the difference in standard state for water, this predicts that $\Delta G_4'' = +0.52\Delta$. Since $\Delta G_4''$ is dependent upon $\Sigma\sigma^*$ this implies that Δ is also dependent upon $\Sigma\sigma^*$. Since this dependence is small and since the cases examined to date have been for systems with $\Sigma\sigma^*$ in the range of 1.5–2.5, it is not surprising that Δ has appeared to be invarient. For compounds with $\Sigma\sigma^*$ in this range, examination of Fig. 1. shows that $\Delta G_4''$ is indeed close to +0.5. We are investigating other carbonyl addition reactions of aldehydes and ketones with electron withdrawing substituents to test the implications discussed above and will report on these studies later.

In view of the near constancy of the equilibrium constants for reaction 4 and of the readily analyzable nature of such variations as do occur, it seems reasonable to conclude that hydrate and hemiacetal formation constants which are not readily measurable can be obtained from the free energies of formation of the corresponding acetals. There are many cases where direct measurement of these equilibrium constants is well nigh impossible because of the extremely low magnitude of the constant or the excessive tendency of the free carbonyl compound to undergo competing side reactions. Free energies of formation for carbonyl compounds and their acetals can be calculated with adequate precision if the enthalpies of formation are available. Enthalpies of formation can in principle be measured for any compound which can be prepared in a pure state. Furthermore, methods for the estimation of enthalpies of formation either by additivity schemes (18, 20) or by semiempirical molecular orbital calculations (21) are avail-

For personal use only.

able and provide values of quite useful precision within their range of application, which is steadily expanding. Measurement (or estimation (22)) of solubilities and vapor pressures permits calculation of free energies of formation in aqueous solution. Finally the use of eq. 5 permits calculation of the equilibrium constants for reaction 4.

The procedure for calculating a standard free energy change for a particular case of reaction 4 is (*a*) from eq. 5 and the σ* values for all groups other than the reacting hydroxyl, calculate $\Delta G_4''$; (*b*) calculate the change in strain energy, considering the least hindered conformations of product and reactant; (*c*) calculate the symmetry correction after Benson; (*d*) combine these three values to give ΔG_4^0.

The analysis of structural effects on $\Delta G_4''$, presented above and in particular the small dependence upon electronic factors and the fact that compounds with one or two oxygen atoms fit the same correlation line, appears to justify the approach which has been proposed (14, 15) in this laboratory to evaluate the free energies of formation of tetrahedral intermediates in acyl transfer reactions. This approach involved the assumption that the behavior observed for molecules with one or two oxygen atoms on the central carbon could be extrapolated to molecules with three oxygen atoms (or two oxygens and a nitrogen). The values estimated when this approach was first devised (14, 15) require recalculation using the more detailed analysis presented in this paper. In Table 4 are presented values so calculated. The deviations from the initial estimates are most severe for the ortho acids and their monoesters (14), since here the difference between $\sum\sigma^*$ for the tetrahedral species and the reference compounds used is greatest; these deviations average around 1.5 kcal mol^{-1}. For the amide hydrates and hemiacetals, (15), the deviations are smaller (*ca.* 0.7 kcal mol^{-1}), since $\sum\sigma^*$ for these compounds is smaller.

Experimental

Hydration and Hemiacetal Formation from Fluorinated Aldehydes and Ketones

Trifluoroacetaldehyde ethyl hemiacetal, trifluoroacetone, trifluoroacetophenone, and hexafluoroacetone were reagent grade chemicals used without further purification. No extraneous signals were observed in the ^{19}F n.m.r. Weighed samples of the liquids were dissolved in water (or methanol for trifluoroacetophenone); hexafluoroacetone was bubbled into a weighed sample of water until a suitable increase in weight had occurred. From these stock solutions, samples with varying concentrations of alcohol were prepared.

The ^{19}F n.m.r. results and the equilibrium constants derived from them are recorded in Table 5. The values of K_4 appeared to vary with solvent composition, although this variation was relatively small. Graphs of K_4 *vs.* [Alcohol] were extrapolated to [Alcohol] = 0 to give values of K_4 in water as solvent.

Appendix

Equilibrium constants for acetal formation from formaldehyde and methanol or ethanol have not been reported but can readily be calculated from thermodynamic data in the literature. For methylal ΔG_f^0(g) = −54.03 kcal mol^{-1} can be calculated from the heat of formation (23) and the standard entropy (24). The free energy of transfer to aqueous solution can be calculated from the activity coefficient at infinite dilution (25) as ΔG_t = −1.04 kcal mol^{-1}. Then ΔG_f^0(aq) = −55.07 kcal mol^{-1}. For free (unhydrated) formaldehyde, ΔG_f^0(aq) = −24.91 kcal mol^{-1} can be calculated from the heat of formation (26) (gas phase), the standard entropy (24) (gas phase), the vapor pressure over aqueous solutions (27), and the equilibrium constant for covalent hydration (Table 1). For methanol ΔG_f^0(aq) = −56.69 kcal mol^{-1} (14). From these values, ΔG^0 for acetal formation is −3.09 kcal mol^{-1} and hence $K = 183\ M^{-2}$. For ethylal ΔH_f^0(g) = −99.13 kcal mol^{-1} (24). The standard entropy (gas phase) can be estimated after Stull (24) as S^0(g) = 99.75 e.u., so that ΔG_f^0(g) = −56.10 kcal mol^{-1}. The free energy of transfer to aqueous solution can be

[d] Extrapolated to pure water as solvent.

calculated from the vapor pressure of the pure liquid (28) and the solubility in water (28) as $\Delta G_t = -1.36$ kcal mol^{-1}. Thus ΔG_f^0(aq) = -57.76 kcal mol^{-1}. For ethanol, G_f^0(aq) = -43.31 kcal mol^{-1} (14). From these values, G^0 for acetal formation is -2.92 kcal mol^{-1} and hence $K = 140\ M^{-2}$.

Values of σ* were taken from the compilation in ref. 32 for all substituents except CH_3COCH_2—, for which σ* was estimated as 0.36 times σ* for CH_3CO— (32) and 4-pyridyl, for which σ* was estimated as follows. From pK_a values for the acids X—C_6H_4--CH_2COOH (33) and the defining equations given by Charton (34), σ* values for X—C_6H_4-- could be calculated. These were plotted *vs.* Hammet σ values for X, using values from the compilation in ref. 32, and gave a good line. Then from the σ suggested for the *para* heteroatom in 4-pyridyl (32), a value for σ* of 1.26 for 4-pyridyl could be estimated.

I thank the National Research Council of Canada for financial support of this work.

The Thermal Decomposition of Alkoxycarbonyl Thiocyanates and Isothiocyanates[1,2]

DENNIS LIOTTA AND ROBERT ENGEL

Department of Chemistry, Queens College of the City, University of New York, Flushing, New York 11367

Received July 30, 1974

DENNIS LIOTTA and ROBERT ENGEL. Can. J. Chem. **53**, 907 (1975).

Alkoxycarbonyl thiocyanates and isothiocyanates have been decomposed thermally under reduced pressure at temperatures of 240–375°. Primary systems yield primarily alkyl thiocyanates, whereas secondary and tertiary systems yield alkyl isothiocyanates. The viability of using this reaction in a conversion of primary alcohols to primary alkyl thiols and secondary and tertiary alcohols to tertiary alkyl amines is discussed.

DENNIS LIOTTA et ROBERT ENGEL. Can. J. Chem. **53**, 907 (1975).

Des thiocyanates et des isothiocyanates d'alkoxycarbonyle ont été décomposés thermiquement, sous pression réduite, à des températures allant de 240–375°. Les dérivés primaires conduisent principalement aux thiocyanates d'alkyle alors que les dérivés secondaires et tertiaires conduisent aux isothiocyanates d'alkyle. On discute de l'utilité de cette réaction pour transformer les alcools primaires en thiols primaires et les alcools secondaires et tertiaires en amines tertiaires.

[Traduit par le journal]

We have previously reported from this laboratory (1) the thermal decomposition of dialkyl phosphoroisothiocyanatidates **1** to yield the corresponding alkyl thiocyanates **2**. A logical

$$(RO)_2\overset{\overset{O}{\|}}{P}\text{—NCS} \xrightarrow{\Delta} \text{RSCN}$$

1 **2**

extension of this phosphorus containing system, which is of particular synthetic value for organic chemistry, is the thermal decomposition of the more readily available alkoxycarbonyl thiocyanates, **3**. We have now investigated the thermal decomposition of **3** and of alkoxycarbonyl isothiocyanates, **4**, over glass wool at

$$\text{ROC}\overset{\overset{O}{\|}}{\text{S}}\text{CN} \qquad \text{ROC}\overset{\overset{O}{\|}}{\text{N}}\text{CS}$$

3 **4**

temperatures of 240–375° under pressures of *ca.* 5 Torr.

Materials **3** and **4** can be considered to be compounds of the general type ROC(O)X. Others of this type have been decomposed thermally both in the liquid and vapor phases yielding RX and carbon dioxide. Investigations in which X = Cl (2, 3), SR(4), OAc(5), OC(O)R(6), and $NHS(O)_2Cl$(7) have been reported.

Although the pyrolysis conditions varied substantially in the several reports, all the previous studies resulted in proposals that the decompositions occur via ion pair intermediates. The various side reactions (predominantly elimination and Wagner–Meerwein rearrangements) which were observed in these studies were rationalized in terms of the degree of dissociation of the ion pair, as well as the basicity of X. For example, when alkyl chloroformates (X = Cl) were decomposed in the vapor phase at reduced pressure, the reaction proceeded with complete retention of configuration (3). Furthermore, no alkyl shifts were observed and the amount of olefin which was produced was small. These data have been interpreted in terms of an intimate ion pair intermediate. However, when the decomposition was accompanied via gas chromatography, substantial amounts of elimination and rearrangement products were obtained (8), presumably because of a greater degree of dissociation in the transition state.

When X = —S—C≡N (or —N=C=S), the decarboxylation reaction can, in principle, yield both an alkyl thiocyanate, R—SCN (**2**), and an alkyl isothiocyanate, R—NCS (**5**). If the decarboxylation reaction exhibits some selectivity for

one of the isomers, this may then provide a convenient route for the conversion of an alcohol into either a thiol or an amine as these latter are readily obtainable from the alkyl thiocyanate and alkyl isothiocyanate, respectively; such overall conversions are not generally convenient by other routes for several types of reaction systems because of rearrangement and elimination processes competing effectively (7, 9).

Results and Discussion

All the reported syntheses of alkoxycarbonyl thiocyanates and isothiocynates involve reaction of a thiocyanate salt (*e.g.* Pb^{2+}, NH_4^+, K^+) with an alkyl chloroformate. The latter are obtainable (usually in high yield) by treatment of an alcohol with phosgene (10). We prefer a modified version of the method reported by Takamizawa *et al.* (11) which involves the slow addition of an alkyl chloroformate to a heterogeneous mixture of anhydrous potassium thiocyanate in dry tetrahydrofuran under a nitrogen blanket. One obtains from this reaction a mixture of the alkoxycarbonyl thiocyanate and isothiocyanate in 45–80% yield. If one uses equimolar amounts of potassium thiocyanate and alkyl chloroformate, one obtains approximately equal amounts of both isomers; if a large excess of potassium thiocyanate is used, the alkoxycarbonyl isothiocyanate is obtained almost exclusively. Moreover, this work has shown that potassium thiocyanate catalyzes the isomerization of alkoxycarbonyl thiocyanates, **3**, to the alkoxycarbonyl isothiocyanates, **4**. Both isomers undergo thermal decarboxylation to yield a mixture of alkyl thiocyanate and alkyl isothiocyanate.

The effect of pressure on the decompositions of both **3** and **4** is found to be quite significant. For example, if these decompositions are studied via gas chromatography using a 20 ft × 3/8 in. SE-30 column at 350° only very small amounts (0.5–3.0%) of the expected alkyl thiocyanate and isothiocyanate are obtained. The major product is polymer although small amounts of the dialkyl carbonates are also isolated. Since these dialkyl carbonates must be the product of at least a bimolecular process, observation of these products in "low pressure" pyrolyses over glass wool constitutes an indication that either the pressure is too high or the rate of addition to the hot surface is too rapid.

When the decompositions are performed at reduced pressures significantly high yields of alkyl thiocyanates and isothiocyanates are obtained. An optimum yield of product may be obtained under conditions described below.

The method found to effect these decompositions most efficiently is to allow the vaporized compound, **3** or **4**, to pass through a 100 cm column packed with glass wool at a pressure of 5 Torr. The pressure drop across the glass wool causes the material to flow through the column with a contact time of 3–4 min; the pyrolysate is collected in a cold trap at −78°.

The results of the pyrolyses of five alkoxycarbonyl isothiocyanates and four alkoxycarbonyl thiocyanates are given in Table 1. The temperature at which the pyrolysis is listed as being performed is that temperature at which the maximum yield of either alkyl thiocyanate or alkyl isothiocyanate was obtained. For example, when **3***b* was pyrolyzed under reaction conditions identical to those in Table 1 at 325°, a 50% yield of **2***b* was obtained. The remainder was unreacted **3***b* and trace amounts of **5***b*. When **3***b* was pyrolyzed at 375°, **2***b* was produced in 25% yield and **5***b* in 50% yield. This change in product ratio is interesting and is discussed below. When **3***b* was pyrolyzed at 350° a 90% yield of **2***b* was obtained.

From the pyrolysis temperatures given in Table 1 it is apparent that as more alkyl substituents are added to the carbinolic carbon a decrease in the temperature at which alkyl thiocyanates or alkyl isothiocyanates are produced most effectively occurs. Furthermore, the fact that in all cases isomers **3** and **4** decompose to give essentially the same product ratios (at the same temperature) suggests a common intermediate. This also is consistent with other ROC(O)X systems.

From the results in Table 1 it is also seen that **3***a*, **3***b*, **4***a*, and **4***b* yield predominantly *S*-substituted products, **3***c*, **3***e*, and **4***c* predominantly *N*-substituted products, and **3***d* and **4***d* a mixture of *N*- and *S*-substituted products.

Several sets of experiments have been performed which allow an explanation of this phenomenon in terms of an initial formation of *S*-substituted product followed, in some cases, by isomerization. The first set of experiments involved the pyrolyses of the compounds **3** and **4** at a temperature *below* those giving optimum product yield. For example, when **3***c* was pyrolyzed at 230° under typical experimental conditions a 5% conversion to **2***c* could be

*These isolated yields are given as percentage of the theoretical yield. No rearrangement of the alkyl groups was observed.
†Ad = adamantyl.
‡No adamantyl thiocyanate was isolated.

detected in the n.m.r. spectrum of the pyrolysate; no **5***c* was observed. At 270° the pyrolysate was composed of **2***c*, 16%; **5***c*, 30%; and **3***c*, 54%. Thus it appears that **2***c* is formed initially but isomerizes readily to **5***c*.

Secondly, the product compounds themselves, *i.e.* **2**, were subjected to the same pyrolysis conditions as their precursors, **3** and **4**, with the exception of **2***e*, for which the compound is not available. In all cases, conversion to **5** occurred readily, along with some decomposition. For example, when **2***b* was subjected to the optimum pyrolysis conditions, as shown in Table 1 for **3***b* and **4***b*, a 19% conversion to **5***b* was found with the remainder being accounted for by decomposition to olefin (not isolated) and HSCN (isolated as the trimer); this rearrangement and attendant decomposition has been reported by Fava *et al.* (12). At lower temperatures (300°) a 57% conversion to **5***b* was observed with the remainder accounted for as decomposition. A mole balance of >97% was obtained for these investigations. With the secondary system, **2***c*, an even more complete conversion to **5***c* was observed.

These data serve as evidence for a mechanism partially proposed above, in which **3** and **4** decompose initially to yield **2** and carbon dioxide. This decomposition presumably occurs via a common intermediate. Negative evidence is available which argues against a preequilibrium of **3** and **4**; using pyrolysis temperatures below those listed in Table 1, where only partial conversion to products occurred and starting material could be reisolated, no conversion of **3** to **4** or **4** to **3** could ever be observed. Moreover, the formation of **5** is a secondary process, arising from rearrangement of **2**. The *amount* of **5** formed would appear to be a function of *rate* rather than *equilibrium position* as indicated by the above data.

While primary alkyl thiocyanates may be prepared more conveniently by other routes, this method does appear to be potentially important for the syntheses of secondary and tertiary alkyl isothiocyanates, not only because of the high overall yield, but also because of the lack of rearrangement and elimination products (7, 9, 13).

Furthermore, since alkyl isothiocyanates can be hydrolyzed to the corresponding amine (14) or reduced (catalytically or with lithium aluminum hydride) to the corresponding methyl amines in high yield (15), this process provides a general method for the conversion of a secondary or tertiary alcohol to the corresponding amine (or methyl amine) in 25–55% overall yield, based on normal yields in these reactions.

Experimental

Elemental analyses were performed by Schwarzkopf Microanalytical Laboratory, Woodside, New York. Nuclear magnetic resonance spectra were measured on a Varian A-60A spectrometer in CCl_4 solution using tetramethylsilane as an internal reference. Mass spectra were measured on a Varian MAT CH-7 spectrometer at 70 eV. Infrared spectra were measured on a Perkin-Elmer 237-B spectrophotometer. Phosgene (12.5% in benzene) was purchased from Matheson, Coleman, and Bell, Inc., and used without further purification. Tetrahydrofuran was dried over sodium ribbon and distilled before use. The potassium thiocyanate was dried either by fusing it and allowing it to cool in a desiccator or by allowing it to stir for 4 h over 2,2-dimethoxypropane followed by filtration and thorough washing with dry tetrahydrofuran.

General Synthesis of Alkyl Chloroformates

A typical procedure for the preparation of alkyl chloroformates is given for ethyl chloroformate. Ethanol,

*Compounds 3*d* and 4*d* gave analyses which were approximately 1.1 and 0.6% from the calculated % C and H, respectively. Although these compounds distill as clear, colorless liquids, they begin to yellow within 15 min after distillation, even in a nitrogen atmosphere in the dark. While the n.m.r. spectra of these compounds, taken immediately after distillation, indicate no detectable impurities, spectra of material which has been allowed to stand for 30 min shows a small but definite broadening in the peak widths. These results indicate that a small amount of decomposition occurs even under relatively innocuous conditions, and thus tends to make good analytical data unobtainable unless combustion analyses are performed immediately after distillation.

†Since isomers 3 and 4 yield the same products upon pyrolysis, mixtures of the two can be used for synthetic purposes. This is most convenient as separation of 3 and 4 is no longer necessary. Thus, the % yield of usable material is actually the sum of the yields of 3 and 4.

‡These absorptions are weak. All other i.r. spectra listed are strong.

§115 represents ($M^+ - 44$). No M^+ is observed. Apparently the molecular ion undergoes facile decarboxylation.

5.75 g (0.135 mol), was added dropwise to a stirred solution of phosgene in benzene (0.25 mol), cooled in an ice bath. The solution was stirred for 3 h after which the benzene and excess phosgene were removed by distillation at reduced pressure. From this was obtained 14.0 g of crude ethyl chloroformate (91%). All chloroformates were used without further purification. Adamantyl chloroformate was prepared by the method of Haas *et al.* (16).

General Synthesis of Alkoxycarbonyl Thiocyanates and Isothiocyanates

A typical procedure for the synthesis of alkoxycarbonyl thiocyanates and isothiocyanates is given below. Ethyl chloroformate, 14.0 g (0.122 mol), in 50 ml of dry tetrahydrofuran was added slowly to a suspension of 11.8 g of anhydrous potassium thiocyanate in 500 ml of dry tetrahydrofuran under a nitrogen atmosphere with vigorous stirring. The solution was allowed to stir for 6 h. The undissolved salt was removed by suction filtration and the solvent removed by distillation at reduced pressure. The resulting red oil was distilled at reduced pressure via a Vigreux column. From this was obtained 4.16 g (20%) of ethoxycarbonyl isothiocyanate, **3***b*, and 5.6 g (35%) of ethoxycarbonyl thiocyanate, **4***b*. Both of these compounds are clear, colorless liquids which yellow upon standing.

When 14 g of ethyl chloroformate (0.122 mol) was allowed to react with 36 g of anhydrous potassium thiocyanate in a procedure identical to that given above (*vide supra*), 10.40 g (65%) of ethoxycarbonyl isothiocyanate, **3***b*, was obtained.

Crude adamantyloxycarbonyl isothiocyanate, **3***e*, prepared in a similar fashion, was purified by dissolving it in a minimum amount of dichloromethane and reprecipitating it with a large volume of pentane.

Yields and pertinent physical and spectral data for all the alkoxycarbonyl thiocyanates and isothiocyanates studied are given in Table 2.

Pyrolysis Procedure

A Pyrex tube 100 cm × 2 cm was packed in the heated 85 cm portion with 65 g of Pyrex glass wool and placed in the tube oven. The pyrolysis temperature is measured by means of a thermocouple at the center of the oven. Although the pressure was maintained at 5 Torr in all cases, measured at the outlet of the collection trap, no significant differences were noted with small variations in the pressure (±2 Torr). The material to be pyrolyzed was dripped into the heated tube (250°, independently heated by a winding of Nichrome wire) at the entrance to the oven. In general, it was found that approximately 10 g of material could be pyrolyzed in a period of 1 h. Faster rates of addition usually resulted in the formation of small amounts (*ca.* 5%) of products resulting from bimolecular reactions. The contact time was estimated at 4–5 min by visual observation of condensate in the product trap after beginning of reactant addition.

Pyrolysis Results

The product mixtures were analyzed by gas–liquid chromatography (g.l.c.) using a 5 ft × 1/4 in. column of Apiezon L on Chromsorb W at temperatures of 100–150° (flow rate of He = 200 ml/min) or more conveniently with n.m.r. by measurement of the relative signal intensities of the protons adjacent to the —SCN or —NCS groups (17). The products were purified by distillation, with the exception of **5***e* which was recrystallized from a 1:1 mixture of benzene – petroleum ether. The identities of the materials were determined by comparison of their physical and spectral properties with those of authentic materials which were synthesized independently (18).

Independent Synthesis of Alkyl Thiocyanates and Isothiocyanates

Alkyl thiocyanates and isothiocyanates were prepared from the corresponding alcohols via their tosylates. The tosylates were prepared by the general method given by Fieser and Fieser (19). The tosylate was dissolved in acetone and added dropwise to a solution of excess potassium thiocyanate dissolved in acetone. The reaction was allowed to stir for 2–6 h after which it was filtered. The acetone was removed by distillation at reduced pressure and the remaining liquid (which sometimes needed further filtration) was distilled at atmospheric pressure at the appropriate temperatures given in Table 3. While the relative amounts of alkyl thiocyanate and isothiocyanate which were produced varied, significant quantities of both isomers could always be obtained.

The only compound not independently synthesized was **5***e* which is commercially available from the Aldrich Chemical Company, Inc.

Uses of Sydnones for Heterocyclic Syntheses

B. V. BADAMI AND G. S. PURANIK

Department of Chemistry, Karnatak University, Dharwar-580003, India

Received August 19, 1974

B. V. BADAMI and G. S. PURANIK. Can. J. Chem. **53**, 913 (1975).

N-(4-Bromo-3-chlorophenyl)sydnone is prepared and subjected to chlorination and bromination. 1,3-Dipolar addition of these sydnones with dimethyl acetylenedicarboxylate produces the substituted pyrazoles which could serve as intermediates.

B. V. BADAMI et G. S. PURANIK. Can. J. Chem. **53**, 913 (1975).

On prépare la *N*-(bromo-4 chloro-3 phényl) sydnone et on la soumet à des réactions de chloruration et de bromuration. Les réactions d'addition dipolaire-1,3 de ces sydnones avec l'acétylènedicarboxylate de méthyle conduisent à des pyrazoles substituées qui peuvent servir d'intermédiaire. [Traduit par le journal]

Sydnones unsubstituted at the 4-position undergo electrophilic substitution reactions (1). However, in view of the difficulties experienced in the synthesis of 4-halosydnones (2) an attempt was made to introduce a halogen atom at the *N*-arylglycine ethyl ester stage in the synthesis of sydnones and it resulted in the halogen entering the phenyl group rather than the side chain; this was proved by the elemental analysis and spectral data (Fig. 1) of the compound. *N*-(*m*-Chlorophenyl)glycine ethyl ester was taken as the starting material in the first instance, since there is a report that the chloro substituent in any position of the sydnone molecule enhances its biological activity (3). 3-Phenylsydnones undergo 1,3-dipolar addition with dimethyl acetylenedicarboxylate to produce the 3,4-disubstituted pyrazoles. 5-Halopyrazoles could easily be prepared by reaction of 4-halosydnones with dimethyl acetylenedicarboxylate. It is known that 1-phenylpyrazoles do not undergo halogenation in the 5-position easily (4, 5). The electrophilic attack may be initiated at the 4-position of the pyrazole ring or at the *para* position of the phenyl ring. This has been clearly interpreted by Lynch and co-workers (6) (Fig. 2).

The required *N*-(*m*-chlorophenyl)glycine ethyl ester was prepared from *m*-chloroaniline and

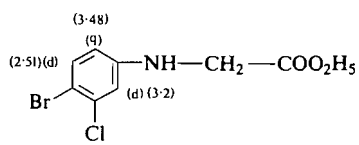

FIG. 1. Coupling constants for *N*-(4-bromo-3-chlorophenyl)glycine ethyl ester.

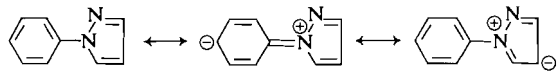

FIG. 2. Electrophilic attack on 1-phenylpyrazoles.

ethyl chloroacetate. The glycine ethyl ester was brominated in chloroform to yield *N*-(4-bromo-3-chlorophenyl)glycine ethyl ester. This was further hydrolyzed with 10% alkali and the resulting glycine subjected to nitrosation in alcoholic medium. The nitrosoglycine was heated with acetic anhydride to yield the sydnone. The sydnone was brominated in acetic acid medium to yield the 4-bromosydnone. Chlorination was effected with *N*-chlorosuccinimide to give 4-chlorosydnone. The sydnone and the 4-substituted sydnones were treated with dimethyl acetylenedicarboxylate in xylene to produce pyrazoles.

The i.r. spectrum of the sydnone carbonyl group is at 1750–1780 cm^{-1} (7). A band at *ca.* 3100 cm^{-1} is due to the sydnone C—H (7), whereas this is absent in the 4-halosydnones (8). The spectrum of pyrazoles shows absorptions at 1750 and 1740 cm^{-1} (CO_2CH_3).

Experimental

N-(m-Chlorophenyl)glycine Ethyl Ester

A mixture of ethyl chloroacetate (62.0 g), *m*-chloroaniline (64.0 g), ethanol (50 ml), and sodium acetate (60.0 g) was refluxed at 125° for 5 h in an oil bath. Water (200 ml) was then added and the precipitated ester collected and washed; recrystallized from ethanol, m.p. 105°; yield, 80.0 g.

Anal. Calcd. for $C_{10}H_{12}NO_2Cl$: C, 56.20; H, 5.62. Found: C, 55.80; H, 5.32.

N-(4-Bromo-3-chlorophenyl)glycine Ethyl Ester

N-(*m*-Chlorophenyl)glycine ethyl ester (40.0 g) was suspended in a mixture of chloroform (400 ml) and ether (200 ml), containing sodium bicarbonate (40.0 g). Bromine (5.4 ml) was added dropwise and the solution was stirred for 2 h at room temperature. The solution was filtered and the filtrate evaporated under reduced pressure. The resulting solid crystallized from petroleum ether, m.p. 85°; yield, 48.0 g.

Anal. Calcd. for $C_{10}H_{11}BrClNO_2$: C, 41.10; H, 3.76. Found: C, 40.8; H, 3.40.

Infrared (KBr) 1750 cm^{-1} (C=O); 3340 cm^{-1} (NH); n.m.r. ($CDCl_3$): 8.68 (3H, t, J_{CH_2,CH_3} = 7.5 Hz, CH_3 of $COOCH_2CH_3$), 6.08 (2H, d, $J_{CH_2,NH}$ = 6.0 Hz, CH_2 flanked between NH and ($COOCH_2CH_3$), 5.67 (2H, q, $J_{CH_2CH_3}$ = 7.5 Hz, CH_2 of ($COOCH_2CH_3$), 3.48 (1H, q, J_{ortho} = 8.0 Hz and J_{meta} = 2.5 Hz), 3.2 (1H, d, J_{meta} = 2.5 Hz), 2.51 (1H, d, J_{ortho} = 8.0 Hz).

N-(4-Bromo-3-chlorophenyl)glycine

N-(4-Bromo-3-chlorophenyl)glycine ethyl ester (40.0 g) was hydrolyzed with sodium hydroxide solution (10%, 95 ml) and ethanol (10 ml). The solution was refluxed for 1 h, then cooled and acidified. The glycine was filtered and crystallized from ethanol, m.p. 150°; yield, 30.0 g.

Anal. Calcd. for $C_8H_7BrClNO_2$: C, 36.29; H, 2.64. Found: C, 35.90; H, 3.14.

N-(4-Bromo-3-chlorophenyl)-N-nitrosoglycine

N-(4-Bromo-3-chlorophenyl)glycine (25.0 g) was suspended in a mixture of alcohol (100 ml) and water (250 ml). Sodium nitrite (8.0 g) in water (25 ml) was added at 0–5° with stirring. After 2 h of stirring the solution was acidified and the *N*-nitroso acid collected and crystallized from benzene, m.p. 125°; yield, 20.0 g.

Anal. Calcd. for $C_8H_6BrClN_2O_3$: C, 32.71; H, 2.04. Found: C, 32.34; H, 2.12.

N-(4-Bromo-3-chlorophenyl)sydnone

The above *N*-nitroso acid (20.0 g) was heated with acetic anhydride (100 ml) on a water bath for 2 h. Then it was poured into water and the solid filtered and crystallized from benzene – petroleum ether, m.p. 138°; yield, 12.5 g.

Anal. Calcd. for $C_8H_4BrClN_2O_2$: C, 34.85; H, 1.45. Found: C, 34.40; H, 1.3.

4-Bromo-N-(4-bromo-3-chlorophenyl)sydnone

N-(4-Bromo-3-chlorophenyl)sydnone (5.0 g) was dissolved in acetic acid (50 ml) containing sodium acetate (15.0 g) and cooled in ice. Bromine (1.1 ml) in acetic acid (5 ml) was added dropwise and the solution stirred for 2 h. Then it was diluted with water and the precipitated bromosydnone was crystallized from ethanol, m.p. 146°; yield, 4.0 g.

Anal. Calcd. for $C_8H_3Br_2ClN_2O_2$: C, 27.08; H, 0.84. Found: C, 26.69; H, 0.65.

4-Chloro-N-(4-bromo-3-chlorophenyl)sydnone

A solution of *N*-(4-bromo-3-chlorophenyl)sydnone (2.5 g) and *N*-chlorosuccinimide (1.6 g) in wet methanol (100 ml) was stirred for 5 min at room temperature. Evaporation of methanol furnished a slurry which was poured into water and extracted with chloroform. Evaporation of the chloroform extracts gave a residue which was crystallized from ethanol, m.p. 132°; yield, 1.8 g.

Anal. Calcd. for $C_8H_3BrCl_2N_2O_2$: C, 30.96; H, 0.96. Found: C, 31.20; H, 0.74.

Dimethyl 1-(4-Bromo-3-chloro)phenylpyrazole-3,4-dicarboxylate

N-(4-Bromo-3-chlorophenyl)sydnone (1.0 g) was dissolved in xylene (50.0 ml) and dimethyl acetylenedicarboxylate (1.0 ml) was added. The solution was refluxed until the evolution of carbon dioxide ceased. The solvent was removed under reduced pressure and the residue crystallized from petroleum ether, m.p. 142°; yield 1.2 g.

Anal. Calcd. for $C_{13}H_{10}BrClN_2O_4$: C, 41.77; H, 2.67. Found: C, 41.90; H, 3.40.

Dimethyl 1-(4-Bromo-3-chloro)phenyl-5-bromopyrazole-3,4-dicarboxylate

4-Bromo-*N*-(4-bromo-3-chlorophenyl)sydnone (1.0 g) was dissolved in dry xylene (50.0 ml) and dimethyl acetylenedicarboxylate (1.0 ml) added. On working up as in the earlier case, the compound obtained was crystallized from petroleum ether, m.p. 116°; yield, 0.9 g.

Anal. Calcd. for $C_{13}H_9Br_2ClN_2O_4$: C, 34.47; H, 1.98. Found: C, 34.07; H, 1.68.

Dimethyl 1-(4-Bromo-3-chloro)phenyl-5-chloropyrazole-3,4-dicarboxylate

4-Chloro-*N*-(4-bromo-3-chlorophenyl)sydnone (1.0 g) was dissolved in dry xylene (50.0 ml) and dimethyl acetylenedicarboxylate (1.0 ml) added. On working up as in the earlier case, the compound crystallized from petroleum ether, m.p. 104°; yield, 0.8 g.

Anal. Calcd. for $C_{13}H_9BrCl_2N_2O_4$: C, 38.23; H, 2.20. Found: C, 37.68; H, 1.88.

Adsorption of Polar Organic Molecules at Oil/Water and Air/Water Interfaces

ROBERT AVEYARD AND JOHN CHAPMAN
Department of Chemistry, The University, Hull HU6 7RX, England
Received October 17, 1974

ROBERT AVEYARD and JOHN CHAPMAN. Can. J. Chem. **53**, 916 (1975).

A study has been made of the adsorption of several esters of dicarboxylic acids both at the alkane/water and the air/water interface. The adsorption of *n*-butanol and *n*-heptanol at the air/water surface has also been investigated. The surface pressure (π) – surface area (A) isotherms are compared for the various films, and standard free energies of adsorption have been determined.

Attempts have been made to fit the π, A isotherms using surface equations of state based on the models of both a two-dimensional gas and a two-dimensional solution. The solution model has proved reasonably successful for fairly dilute films at the air/water surface. At higher coverages, an equation derived by Smith for liquid expanded monolayers gives a moderately good description of films of heptanol on water. A simple application of the solution model to adsorbed monolayers at the liquid/liquid interface met with little success. It is found however that two-dimensional gas equations describe such systems surprisingly well for fairly low surface concentrations.

As part of the study, the activity coefficients of methyl dodecanoate, and the diethyl esters of pentan-1,5-dicarboxylic acid and decan-1,10-dicarboxylic acid, all in dilute solution in *n*-octane at 30 °C, have been determined.

ROBERT AVEYARD et JOHN CHAPMAN. Can. J. Chem. **53**, 916 (1975).

On a fait une étude de l'adsorption de plusieurs esters d'acides dicarboxyliques aux interfaces d'alkane–eau et d'air–eau. On a aussi examiné l'adsorption du *n*-butanol et du *n*-heptanol à la surface air–eau. On compare les isothermes de pression de surface (π) et aire de surface (A) de divers films et on a déterminé les énergies libres standard d'adsorption.

On a fait des essais pour faire une corrélation des isothermes π et A utilisant des équations d'état de surface basées sur des modèles soit d'un gaz bi-dimensionnel ou d'un solution bi-dimensionnelle. Le modèle de solution s'avère raisonnablement correcte pour des films assez dilués à la surface air–eau. A des taux de recouvrement plus élevés, une équation dérivée par Smith pour des couches monomoléculaires liquides étendues donne une bonne description des films heptanol sur l'eau. Une application simple du modèle en solution à des couches monomoléculaires adsorbées à l'interface liquide–liquide n'a pas obtenu beaucoup de succès. On a trouvé toutefois que les équations d'un gaz bi-dimensionnel décrivent de tels systèmes d'une façon très correcte à des concentrations superficielles de surface relativement basses.

Dans le cadre de cette étude, on a mesuré, en solution diluée dans l'octane à 30 °C, les coefficients d'activité du dodécanoate de méthyle et des esters diéthyliques des acides pentandicarboxylique-1,5 et décanedicarboxylique-1,10. [Traduit par le journal]

Introduction

A rigorous theoretical treatment of the behavior of adsorbed films of simple amphipathic molecules at liquid surfaces has not yet been achieved. Some relatively simple and useful approaches have however been made, leading to equations of state for surface films which can be readily tested. Nevertheless, possibly as a result of the lack of sufficiently extensive and precise data, only a few thorough investigations into the applicability of these equations have been reported.

We have previously described studies of adsorbed films of 1-alkanols at alkane/water interfaces (1–3). It was shown that the Volmer equation of state, based on the model of a two-dimensional gas, and an equation based on the model of an ideal two-dimensional solution both fitted the experimental surface pressure (π), surface area (A) data reasonably well. However, there is no reliable independent check on the values of the constants of these equations (which are related to the effective sizes of molecules at the surface) required to give a fit of the data. This problem arises since it is not obvious what configurations the alkyl chains of the adsorbate, and the alkane molecules assume at the interface.

In the present paper we report studies of films

of some esters of dicarboxylic acids at the air/water and alkane/water interface, and of films of two *n*-alkanols at the air/water interface. In all these cases it is probable that the alkyl chains of the adsorbate molecules assume configurations which are essentially parallel to the interface, at least at low coverages. Thus, rough estimates of the effective areas can be made and compared with the values of the constants appearing in the various equations of state. We consider equations based both on the two-dimensional gas and two-dimensional solution models, and compare the levels of agreement the models give with the data obtained for the various systems.

Where necessary, activity coefficients of the solutes in dilute solution in alkane have been determined.

Experimental

Measurement of Surface and Interfacial Tensions

The drop-volume technique was used as described elsewhere (4). A stainless steel tip of circular cross section, radius 2.708 ± 0.002 mm, was used in conjunction with an "Agla" micrometer syringe of capacity 0.5 cm^3. The apparatus was immersed in a water thermostat, maintaining the temperature constant to within ±0.01 °C. All necessary densities were determined to within $\pm 2 \times 10^{-4}$ g cm^{-3} using a 25 cm^3 density bottle. Surface tensions were reproducible to ±0.1 mN m^{-1} and interfacial tensions to ±0.05 mN m^{-1}. The drop-volume method is not absolute but any small errors which might arise because of this are not likely to significantly affect values of π or A since these are obtained from differences in tensions (see later).

Determination of Activity Coefficients

Mole fraction activity coefficients f of the diethyl esters of pentan-1,5-dicarboxylic acid and decan-1,10-dicarboxylic acid, and of methyl dodecanoate in dilute solution in *n*-octane at 30 °C were determined using a Hitachi–Perkin Elmer Model 115 vapor pressure osmometer. The procedures involved have been described previously (3). It is difficult to assign precise errors to f. These largely arise from the graphical procedures used in the evaluation and are probably less than ±0.01.

Materials

n-Octane was supplied by Newton-Maine (England) and had a purity of ⩾ 99.5%. It was percolated through chromatographic alumina before use. Water was twice distilled using an all Pyrex glass still. The interfacial tension of the octane against the water at 30 °C was 50.80 ± 0.04 mN m^{-1} in excellent agreement with a previously recorded value (2) of 50.83 mN m^{-1}, indicating the probable absence of surface active impurities in either the water or the octane.

The following solutes were *puriss* samples obtained from Fluka: 1-heptanol (99.5%), methyl dodecanoate (99.4%), diethyl esters of methandicarboxylic acid (99.7%), pentan-1,5-dicarboxylic acid (99.4%), and dodecan-1,10-dicarboxylic acid (99.8%). The purities given in parentheses are estimates made by the use of g.l.c. in this laboratory. The 1-butanol sample (99.6%) was Hopkin and Williams (England) "Analar" grade, and the diethyl ester of butan-1,4-dicarboxylic acid used (99.7%) was a *puriss* sample from Koch-Light (England). All the esters were passed over alumina before being analyzed for purity and used.

Results

Activity Coefficients

The mole fraction activity coefficients, f, of methyl dodecanoate, and the diethyl esters of pentan-1,5- and dodecan-1,10-dicarboxylic acids (subsequently referred to as C_5 and C_{10} diesters respectively) at various mole fractions, x, in octane at 30 °C are given in Table 1. For a given value of x the monoester has a higher value of f (*i.e.* is more nearly ideal) than either of the diesters. Of the latter, the C_5 diester has the lower value of f for a given x. On the simple idea that the non-idealities arise primarily from the mixing of the polar groups with alkane, the results are, qualitatively, what would be expected.

Surface and Interfacial Tensions

The films at the alkane/water interface were formed by adsorption from the alkane phase, and in these cases x (and the mole fraction activity a) refer to concentrations in the alkane. For films

at the air/water interface, x refers to the mole fraction of solute in the aqueous phase. In the octane + water systems all the solutes, except the diethyl ester of butan-1,4-dicarboxylic acid (C_4 diester), distribute overwhelmingly in favor of the alkane phase. For the C_4 diester, the mole fraction distribution ratio was found to be 57 ± 17 in favor of octane. Prior to adsorption experiments therefore, a large mass of the octane phase was allowed to attain distribution equilibrium with a small mass of water. Using the distribution ratio, the equilibrium concentration of C_4 diester in octane could be calculated to within 1%.

The data have been fitted with the aid of a computer, by the least squares method using a simplex procedure (5), to cubic equations of the form

$$[1] \qquad a(\text{or } x) = c_1\gamma^3 + c_2\gamma^2 + c_3\gamma + c_4$$

where γ is the surface or interfacial tension and c's are constants. For adsorption of heptanol from water and the C_4 diester from octane x was used rather than a since only very dilute solutions were employed. In the case of butanol adsorption, activity coefficients relating to 0 °C (6) were used to obtain activities. The errors incurred in using these coefficients rather than those for 20 °C are unlikely to be serious. Values of the constants in [1] for the various systems are given in Tables 2 and 3. The coefficients lead to fits of the data which are well within the reproducibility of γ (*i.e.* to within 0.05 mN m^{-1}) in all cases. The fitting was made in overlapping regions of concentration since a single fit of a whole set of data was generally slightly less satisfactory.

Various workers have studied the adsorption of alcohols at the air/water interface but usually the results have not been presented in numerical form, so that comparisons with the present data are not possible. However, Clint *et al.* (7) give the slope of the linear π–x plot for butanol adsorption at the air/water interface at 20 °C in the region $0 < \pi < 5$ mN m^{-1}. Our results are in excellent agreement (see footnote 3, Table 4). This is particularly reassuring since Clint *et al.* used the pendant-drop technique, which is absolute, to measure γ.

Calculation of Areas per Molecule at the Surface

For systems such as those studied here, where strongly surface active solutes are being adsorbed from dilute solution, it is appropriate to use the simple form of the Gibbs adsorption equation

$$[2] \qquad A = -(kT/fx)(\partial fx/\partial\gamma)$$

to obtain the area, A, per molecule at the surface (1). In eq. 2 k is the Boltzmann constant and T the absolute temperature; fx ($= a$) is the mole fraction activity of the solute in the phase from which adsorption is being studied. Substitution in eq. 2 for fx using eq. 1 yields

$$[3] \qquad A = -kT(3c_1\gamma^2 + 2c_2\gamma + c_3)/a$$

Values of A (calculated by computer) were obtained only for experimentally used concentrations.

Discussion

Some General Observations

It has been noted elsewhere (2) that the π, A isotherms for films of different chain length 1-alkanols at oil/water interfaces (where the oil is a *n*-alkane) are virtually indistinguishable, suggesting that the alkanols have the same effective molecular areas at the surface. The isotherm for methyl dodecanoate is shifted to higher A values (for a given π) with respect to the alkanol curve (Fig. 1*a*), indicating a higher effective molecular area, due presumably to the larger head group. It is interesting however that for insoluble monolayers at air/water surfaces, the close-packed areas of *n*-alkanols and of esters of 1-alkanoic acids are very similar (8).

The isotherm for the C_{10} diester is shifted to considerably higher areas with respect to the curves for the monofunctional adsorbates (Fig. 1*a*). It is likely that the diester assumes orientations which are predominantly parallel to the surface, at least for higher values of A, which would result in the observed effect. Some of the quantitative aspects of the π, A curves are discussed later.

As shown in Fig. 1*b*, the π, A curves for 1-butanol and 1-heptanol adsorbed at the air/water interface differ substantially. They are both displaced to lower areas with respect to the (common) curve for 1-alkanols adsorbed at the oil/water interface. For a given value of A the difference in π for the film at the oil/water and

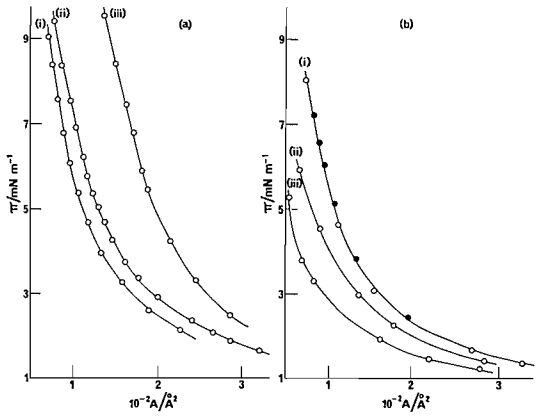

FIG. 1. π–A curves for (*a*):(*i*) dodecanol, (*ii*) methyl dodecanoate, and (*iii*) C_{10} diester (see text) at octane/water interface at 30 °C; and (*b*):(*i*) butanol, (●) and octanol (○) at dodecane/water interface, (*ii*) butanol at air/water interface, and (*iii*) heptanol at air/water interface all at 20 °C. (Results for dodecanol and octanol taken from refs. 1 and 2. Results for butanol at dodecane/water surface (20).

air/water interface is termed the "cohesive" pressure (9) since it is believed that there are interactions between adsorbate molecules at the air/water surface which are absent at the oil/water interface. However, the term "cohesive" may be misleading since different effective adsorbate areas (resulting from different orientations) for molecules at the two interface types would also contribute to a difference in π.

Standard Free Energies of Adsorption

We have determined standard free energies of adsorption, $\Delta_a\mu^0$, using the present data, and the values are consistent with the intuitive ideas con-

‡In excellent agreement with the value of 23.0 kJ mol^{-1} obtained by Clint *et al.* (7).

cerning the orientation of the various adsorbates at the surface. $\Delta_a\mu^0$ is given by the expression

$$[4] \qquad \Delta_a\mu^0 = -RT \ln (\pi/a)_0$$

The standard states are $a = 1$ for the solution and $\pi = 1$ mN m^{-1} for the surface (1, 7). The quantity $(\pi/a)_0$ is the initial slope (at $a = 0$) of the π, a curve and can be determined directly if an initial linear section exists, or by use of the constants given in Tables 2 and 3 since

$$[5] \quad (\pi/a)_0 = -(d\gamma/da)_{a=0} = -1/(3c_1\gamma_0^2 + 2c_2\gamma_0 + c_3)$$

where γ_0 is the tension of the interface for zero adsorption. Values of the free energies are given in Table 4.

We first note that $\Delta_a\mu^0$ for the adsorption of 1-dodecanol from octane to the octane/water interface is considerably more negative than the corresponding value for methyl dodecanoate. This is probably due to the —OH group having a greater tendency than the —COOMe group to enter into H-bonding with water at the interface.

As anticipated, the C_{10} diester adsorbs much more strongly from octane to the octane/water interface than does methyl dodecanoate. It is interesting that $\Delta_a\mu^0$ for the C_5 diester and the C_{10} diester are, within the errors, equal. It seems reasonable to suppose that for these latter solutes there will be some contact between the chain methylene groups and water at the interface. If this assumption is correct the free energy of interaction of a —CH_2— group with *interfacial* water is similar to the corresponding interaction with alkane. The suggestion was made elsewhere (2) (from a consideration of free energies of adsorption of gaseous alkanes to the air/water surface, and the surface tensions and free energies of vaporisation of alkanes) that this might be the case.

The average value of $\Delta_a\mu^0$ for the adsorption of the methylene group from dilute aqueous solution to the air/water interface, calculated from the difference in $\Delta_a\mu^0$ for the two alkanols, is -2.5 kJ mol^{-1}, in agreement with previously reported values (9). This is consistent with the alkyl chains having a flat orientation in dilute films. The free energy of adsorption of *n*-alkanes (pentane to octane) from vapor to the water/vapor interface is a linear function of the chain length (10), the —CH_2— increment being -1.76 kJ mol^{-1} at 15 °C. The linear dependence implies an essentially parallel orientation of the alkanes at the surface. Further, the free energy of hydration (*i.e.* transfer from dilute vapor to dilute aqueous solution) of the methylene group is 0.67 kJ mol^{-1} at 25 °C (11). Combination of these free energy changes, neglecting the temperature difference, gives a value of -2.43 kJ mol^{-1} for $\Delta_a\mu^0$ of the methylene group in chains parallel to the water surface. This is very close to the experimentally observed value of -2.5 kJ mol^{-1}.

The lower average value of $\Delta_a\mu^0$ (-2.1 kJ mol^{-1}) observed for the —CH_2— groups in the diesters may result from a modification of the hydration of these groups caused by the two terminal polar groups. Corkill *et al.* have discussed the way in which the hydration of nonpolar groups can be altered by the proximity of polar moieties (12).

Surface Equations of State

(a) Films at the Air/Water Interface

There are two basic approaches to the treatment of adsorbed monolayers at liquid surfaces.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

One is to suppose that solvent does not affect the film behavior so that the adsorbate molecules can be considered to behave as a two-dimensional gas. Alternatively, explicit account can be taken of the presence of solvent and the monolayer likened to a two-dimensional solution. The solution model is, in principle at least, the more attractive since it is more obviously in accord with reality (13*a*).

Saraga and Prigogine (14) have developed a statistical thermodynamic treatment for monolayers consisting of chain molecules (*r*-mers), disposed parallel to the surface, mixed with solvent molecules (monomers). The equation of state resulting from the model has remained almost untested for relatively simple systems such as those studied here. If the surface area of a monomer molecule is denoted σ_1, and that of an *r*-mer σ_2, the equation of state is written

$$[6]\quad \pi = -\frac{kT}{\sigma_1}\left\{\ln\left(1-\frac{\sigma_2}{A}\right)+\frac{\sigma_2-\sigma_1}{A}+\frac{\beta l}{kT}\left(\frac{\sigma_2}{A}\right)^2\right\}$$

β is an average heat of mixing per segment, and l is the fraction of nearest neighbor sites a site has within the same layer, the solution being considered to be made up of lattice planes parallel to the surface. In this work, we have followed Saraga and Prigogine and set $l = 0.5$, the value for close-packing.

Water (monomer) molecules are denoted a, the polar groups in the adsorbate (*i.e.* —OH or —COO—), b, and CH_2 and CH_3 groups (considered to be equivalent for present purposes), c. Then, β is given as (14)

$$[7]\quad \beta = \frac{n}{r}W_{ab}+\left(\frac{r-n}{r}\right)W_{ac}-\frac{n(r-n)}{r^2}W_{bc}$$

where n is the number of polar groups per *r*-mer and r is the total number of groups in the *r*-mer. The W's are heats of mixing of the various pairs of groups in the system.

Saraga and Prigogine applied eq. 6 to π, A data for insoluble films of esters of long chain carboxylic acids on water, and from the fitting of the data obtained the following values for the W

$$W_{ab} = 6.73 \times 10^{-20}\ \text{J segment}^{-1} \quad (\text{b} = \text{—COO—})$$

$$W_{ac} = 8.00 \times 10^{-21}\ \text{J segment}^{-1}$$

$$W_{bc} = 9.88 \times 10^{-20}\ \text{J segment}^{-1}$$

An independent value of $W_{ac} = 8.40 \times 10^{-21}$ J segment^{-1} was obtained from solubility data for esters in water.

Before applying eq. 6 to our own data we tested its validity for dilute monolayers of *n*-octane on water, since this system is an example of the simplest possible situation. We used the original data of Jones and Ottewill (10) and obtained values of A as described earlier. Equation 6 was rearranged to give

$$[8]\quad \frac{\pi\sigma_1}{kT}+\ln\left(\frac{A-\sigma_2}{A}\right)+\left(\frac{\sigma_2-\sigma_1}{A}\right) \doteq -\frac{\beta l}{kT}\left(\frac{\sigma_2}{A}\right)^2$$

If eq. 6 is to represent the data, a plot of the left hand side of eq. 8 against A^{-2} should be linear and pass through the origin; $\beta l/kT$ is obtained from the slope. In all our calculations we have used the value of σ_1 (6.5 Å^2) calculated by Saraga and Prigogine from the geometry of alkyl chains. The value of σ_2 ($= r\sigma_1$) for octane is thus 52 Å^2, in accord with the value obtained by the use of molecular models (Table 5). It is also noted that the molar volume of water is very similar to that of the CH_2 group. The plot of the data according to eq. 8 is shown in Fig. 2. The curve is rectilinear, passes through the origin and gives a value for $\beta l/kT = 0.84$. This corresponds to $W_{ac} = 6.7 \times 10^{-21}$ J segment^{-1}, in reasonable agreement with the value of 8.0×10^{-21} J segment^{-1} quoted by Saraga and Prigogine. Thus, eq. 6 represents the behavior of octane monolayers up to a surface coverage, θ, of about 0.3 ($A \sim 180$ Å^2) with reasonable values of the molecular parameters. For long chain esters ($C_{13}H_{27}CO_2Et$, $C_{14}H_{29}CO_2Et$, and $MeCO_2(CH_2)_{14}CO_2Me$) Saraga and Prigogine were able to obtain agreement between experiment and theory for areas per molecule down to about 400–500 Å^2, which corresponds to $\theta \sim 0.25$.

We consider now the shorter chain solutes used in the present study. Values of solute areas obtained by the use of Courtauld molecular models are compared with $\sigma_2 = r \times 6.5$ Å^2 in Table 5. The values are very similar, the largest difference (~20%) being for the C_1 diester; otherwise the values are within 5 or 6% of one another. In Fig. 3, the experimental π, A curves are compared with those given by eq. 6, using the $\beta l/kT$ given in Table 5. For the diesters, $\beta l/kT$ values are similar to those calculated from the W

values of Saraga and Prigogine. Agreement between the experiment and theory is quite satisfactory in all cases for surface coverages, θ, less than about 0.3. It is interesting to note that the data for butanol can be equally well represented by the ideal two-dimensional gas equation $\pi A = kT$ up to values of $\pi \sim 5$ mN m^{-1}.

One of the factors contributing to the breakdown of eq. 6 at lower areas is probably the reorientation of the solute molecules. It is likely that the alkanols in particular will tend progressively to a predominantly vertical orientation as the surface concentration of solute increases. Smith (15) has presented a theoretical equation of state for liquid expanded monolayers of fatty acids on water; this state frequently exists for areas per molecule between about 30 and 60 Å^2. The equation, which contains no adjustable parameters, was found to be reasonably successful for many saturated long chain monocarboxylic acids. We have therefore sought to apply the equation to the more concentrated adsorbed films of alcohols at the air/water surface.

The equation may be written

$$[9]\quad \left(\pi + \frac{m\varepsilon A_0}{2A^2}\right)\left[A\left(1-\frac{A_0}{2A}\right)^2\right] = kT$$

It is supposed that the solute molecule acts as a stack of disks (CH_2 groups) anchored to the water by the head group. The Lennard–Jones energy parameter ε, for the interaction of disks, is taken as that for methane (2.05×10^{-21} J) (16); m is the number of carbon atoms in the molecule.

The quantity A_0 is the solute co-area, and the term $A(1 - A_0/2A)^2$ replaces $(A - A_0)$ which appears in the familiar Volmer and two-dimensional van der Waals gas equations. It was obtained by the use of the two-dimensional analogue of the scaled particle theory for fluids, which is more appropriate than the imperfect gas theory for concentrated films. Smith suggests a value of 36 Å^2 for A_0. However, we have used 26 Å^2 for the following reasons. The co-area is twice the area defined by the distance, d, of closest approach, *i.e.* $A_0 = \pi d^2/2$ (13*b*). Recently,

Vochten and Petre (17) have reported saturation values of $A = 27$ Å^2 for adsorbed films of a series 1-alkanols at the air/water interface. If we suppose that at saturation the alkanols have a circular cross section and are hexagonally close-packed, the cross sectional area of all the alkanols studied (butanol to decanol) is 24.5 Å^2. From this, the "equilibrium" diameter, d_0, of the disks can be calculated. Using the approximate relationship $d_0 = 1.37\ d$ suggested by de Boer (18), a value of 26 Å^2 is then obtained for A_0.

It can be seen in Fig. 4 that the agreement between experiment and theory for heptanol is quite good using $A_0 = 26$ Å^2. For a given value of A in the region of 30 to 50 Å^2, the experimental and theoretical values of π do not differ by more than about 10%. However the theoretical line displays greater curvature than does the experimental π, A curve. If A_0 is set equal to 36 Å^2 the agreement is less satisfactory. We have also tested the data for butanol but in this case we do not have results extending to such low areas as for heptanol. Also, the shorter chain compound will presumably show less tendency to cohere. Again, $A_0 = 26$ Å^2 gives better absolute agreement between experiment and theory than does $A_0 = 36$ Å^2.

We have not investigated the application of eq. 9 to our data for the diesters since sufficiently high surface concentrations were not attained. In any event it would be difficult to select a suitable value of ε for the polar groups.

Finally in this section, we note that in some instances film behavior at air/water interfaces can be represented by a virial equation of state. In such cases however care has to be exercised in assigning physical significance to the coefficients. Consider the π, A data for octane for example. These results can be adequately represented, for $\theta < 0.2$, by

$$[10] \qquad \pi = kT\left(\frac{1}{A} + \frac{B^*}{A^2}\right)$$

with a value of -115 Å^2 for the second virial coefficient B^* (Fig. 5*b*). On the other hand, eq. 6 can be transformed to the virial type equation

$$[11] \quad \pi = kT\left[\frac{1}{A} + \left\{\frac{1}{2}\frac{\sigma_2^2}{\sigma_1}\left(1 - \frac{2\beta l}{kT}\right)\right\}\frac{1}{A^2} + \left\{\frac{1}{3}\frac{\sigma_2^3}{\sigma_1}\right\}\frac{1}{A^3} + \left\{\frac{1}{4}\frac{\sigma_2^4}{\sigma_1}\right\}\frac{1}{A^4} + \ldots\ldots\right]$$

Insertion of the appropriate values for $\beta l/kT$, σ_1 and σ_2 (see earlier) gives $B^* = -141$ Å^2, C^* (third virial coefficient, $\sigma_2^3/3\sigma_1$) $= 7.21 \times 10^3$ Å^4, and D^* (fourth virial coefficient, $\sigma_2^4/4\sigma_1$) $= 2.81 \times 10^5$ Å^6. The π, A curves obtained from eq. 11 by inclusion successively of B^*, C^*, and D^* terms are shown in Fig. 5*a*. Thus, although the data can be adequately fitted for $\theta < 0.2$ using only the second virial coefficient of -115 Å^2, if the solution model for the surface is accepted, the term involving the third and, at lower areas, the fourth virial coefficient should be included.

(b) Films at the Oil/Water Interface

Films of polar organic materials adsorbed at the liquid/liquid interface often behave as if they

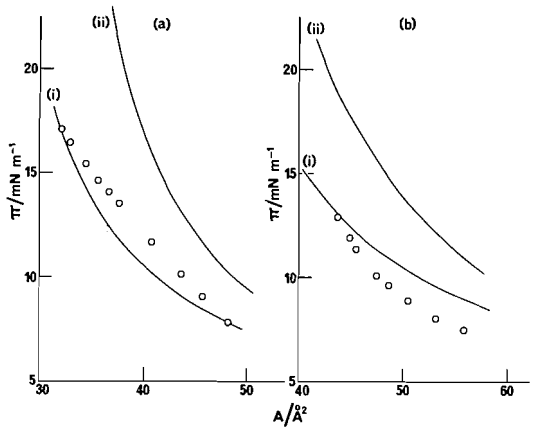

FIG. 4. π–A curves for (*a*) heptanol, (*b*) butanol at air/water interface at 20 °C. ○ are experimental points; full curves generated by eq. 9 with $A_0 = 26$ Å^2 (curves *i*) and 36 Å^2 (curves *ii*).

For personal use only.

were two-dimensional gases and the Volmer equation

$$[12] \qquad \pi(A - A_0) = kT$$

can be used to describe their behavior. Such films are normally considered to exhibit simpler behavior than corresponding films at the air/water interface since, if the gas model is employed to describe the data for the latter, allowances must be made for changes in lateral interactions between solute molecules as the surface concentration varies. In spite of the apparent success of the gas model, attempts have been made to fit data for films at the liquid/liquid interface using the solution model for the surface. Thus for example, the equation of state

$$[13] \qquad \pi = -\frac{kT}{\sigma_1} \ln\left(\frac{A - \sigma_2}{A - \sigma_2 + \sigma_1}\right)$$

for a two-dimensional ideal solution has been tested for alkanols at the alkane/water interface (2). The difficulty in treating such films however is that part of the adsorbate resides in the interfacial water, and part in the oil. The simplifying assumption was made in ref. 2, as elsewhere (19), that the whole of the adsorbed solute resides in the oil phase. Although data for the alkanols could be fitted by the use of eq. 13, unique values for σ_1 and σ_2 could not be obtained. The present data for methyl dodecanoate can be fitted in a similar manner. For example if σ_1 is set at 52 Å^2 corresponding to a flat orientation of octane at the interface, a reasonable fit of the data is obtained for $\sigma_2 = 73$ Å^2. However, it is not known with any certainty that the octane is parallel to the interface. Further, we find that the shape of the π, A curves for the diesters cannot be adequately represented by eq. 13. We conclude therefore that the use of eq. 13, even when a good fit of data can be obtained, does not lead to useful information about the physical reality in the system, although it can be very useful simply as a fitting equation. Similar remarks can be made about the use of eq. 6 with $\beta = 0$.

The Volmer equation describes the behavior of 1-alkanol films at oil/water interfaces very well, with $A_0 = 25$ Å^2 (2). It was previously suggested by one of us that the similarity between this value of A_0 and the close-packed areas of alkanols in insoluble monolayers might be fortuitous. However, the saturation adsorption of a series of 1-alkanols at the air/water surface reported subsequently by Vochten and Petre (see earlier discussion), provides further indication that this value of A_0 does mean that monofunctional alkyl chain compounds are oriented essentially normal to the alkane/water interface. It is very likely however that the diesters we have used in this study will be disposed parallel to the surface in films which are not very concentrated. In this case, if the Volmer model is adequate, much larger values of A_0 should be obtained. Indeed values of the order of, but greater than, the "static" geometrical areas would be expected. We find that for the C_4, C_5, and C_{10} diesters the Volmer equation fits the data for $A > 180$ Å^2 with A_0 values of, respectively, 90, 102, and 114 Å^2 (Fig. 6). The areas calculated from molecular models are respectively 68, 74, and 104 Å^2. For areas above about 300 Å^2 (not shown) the experimental π for the C_{10} diester fall about 0.2 mN m^{-1} above the Volmer curve.

For $A < 180$ Å^2, corresponding to a surface coverage of about 0.6, the experimental curves fall below those given by eq. 12 and, as can be seen in Fig. 6, approach one another. The curve for the C_4 diester (not included, for the sake of clarity, in Fig. 6) is indistinguishable from that for the C_5 diester for areas below about 120 Å^2. Taken together these observations are consistent

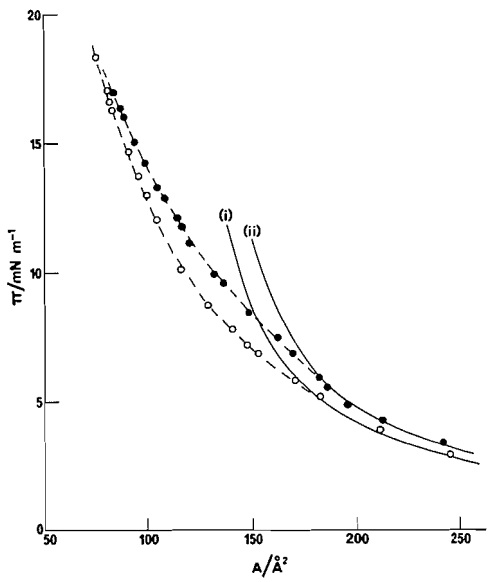

FIG. 6. π–A curves for C_5 diester (○) and C_{10} diester (●) at octane/water interface at 30 °C. Full lines generated by eq. 12 with (*i*) $A_0 = 102$ Å^2, (*ii*) $A_0 = 114$ Å^2.

with the diesters being parallel at the interface for coverages of less than 0.6, and tending towards a vertical orientation at higher coverages. The effective areas for all three diesters in a stretched vertical alignment would of course be the same.

It is perhaps surprising that an equation based on a two-dimensional gas model should be apparently more successful than one derived from a solution model, and we do not have a ready explanation for this observation. The apparent failure of the latter may be associated with the simplifying assumption that the solute resides totally in the oil at the interface. There are two circumstances, however, in which eq. 13 takes on the form of the Volmer equation. Expansion of the logarithmic term in the former gives

$$[14] \quad \pi = kT[1/(A - \sigma_2) - \sigma_1/2(A - \sigma_2)^2 + \sigma_1{}^2/3(A - \sigma_2)^3 + \ldots]$$

Equation 12 is obtained (with $A_0 = \sigma_2$) for $\sigma_1 = 0$. Alternatively, if $\sigma_1 = \sigma_2 = \sigma$, eq. 13 may be expressed

$$[15] \quad \pi = 2kT[1/(2A - \sigma) + \sigma^2/3(2A - \sigma)^3 + \ldots]$$

The second and higher terms in square brackets in eq. 15 will normally be very much smaller than the first so that to a good approximation

$$[16] \quad \pi(A - \sigma/2) = kT$$

Since in general $\sigma_1 \neq \sigma_2$, the films investigated here are behaving as if the solvent were absent ($\sigma_1 = 0$), *i.e.* as two-dimensional gases.

One of us (J.C.) is indebted to the Science Research Council for the provision of a maintenance grant.

The Kinetics and Mechanisms of Exchange in the Binary System Manganese(II) – Adenosine 5′-Triphosphate[1]

G. P. P. KUNTZ,[2] YIU-FAI LAM, AND GEORGE KOTOWYCZ
Department of Chemistry, University of Alberta, Edmonton, Alberta T6G 2G2

Received September 23, 1974

G. P. P. KUNTZ, YIU-FAI LAM, and GEORGE KOTOWYCZ. Can. J. Chem. **53**, 926 (1975).

^{31}P n.m.r. studies on the Mn(II) – adenosine 5′-triphosphate system indicate that two n.m.r. exchange mechanisms are present in solution; namely, the Eigen–Tamm mechanism and the direct ligand exchange mechanism. Their respective contributions to the observed n.m.r. linewidths and hence to the n.m.r. exchange rate depend upon the concentration of the ligand ATP. Equations are developed to prove what n.m.r. "sees" for the Eigen–Tamm mechanism and these equations are applied to this study.

G. P. P. KUNTZ, YIU-FAI LAM et GEORGE KOTOWYCZ. Can. J. Chem. **53**, 926 (1975).

Des études r.m.n. de ^{31}P sur le système Mn(II) – adénosine 5′-triphosphate indiquent que deux mécanismes d'échange en r.m.n. sont présents dans la solution, à savoir, le mécanisme Eigen–Tamm et le mécanisme d'échange direct du ligand. Leurs contributions respectives à la largeur observée pour les bandes en r.m.n., ainsi qu'au taux d'échange en r.m.n., dépendent de la concentration du ligand ATP. On a développé des équations pour démontrer ce que la r.m.n. "voit" pour le mécanisme Eigen–Tamm et on a appliqué ces équations à l'étude actuelle. [Traduit par le journal]

Introduction

The application of nuclear magnetic resonance (n.m.r.) in the area of biochemistry is constantly increasing as n.m.r. determines not only whether two substances interact but also, in many cases, the sites of interaction. Excellent reviews in this area have been written by Roberts and Jardetzky (1), Rowe *et al.* (2), Mildvan and Cohn (3), Mildvan (4), Cohn (5), and Kotowycz and Lemieux (6).

Researchers are also applying n.m.r. exchange rate studies to two or more interacting substances, *e.g.* a metal ion, substrate, and enzyme system. In these experiments the n.m.r. exchange rate is compared with the catalytic turnover number. Mildvan and co-workers have utilized the n.m.r. exchange rate to obtain kinetic information (7–9). The n.m.r. exchange mechanism must be known before the n.m.r. exchange rate can be compared with the catalytic turnover number. This paper explicitly points out how a substrate concentration dependence study of the n.m.r. exchange rate permits one to assign the n.m.r. exchange mechanism either as Eigen–Tamm (dissociation–association), M + L = ML, or direct ligand exchange, ML + L* = ML* + L.

The present study of the Mn–ATP system demonstrates that two exchange mechanisms are present and that their respective contributions to the observed n.m.r. linewidth depends upon the concentration of ATP.

Theoretical Introduction

In the study of metal ion–ligand interactions, Eigen and Tamm (10) showed that at least four species must be considered; namely, the solvated metal ion M(aq), the solvated ligand L(aq), and outer sphere metal ion – ligand complex M(aq)L and an inner sphere metal ion – ligand complex ML. Their mechanism may be written as

$$[1] \qquad \mathrm{M(aq) + L(aq)} \underset{k_{-os}}{\overset{k_{os}}{\rightleftharpoons}} \mathrm{M(aq)L} \underset{k_{-o}}{\overset{k_{o}}{\rightleftharpoons}} \mathrm{ML}$$

where k_{os}, k_{-os}, k_o, and k_{-o} are the forward and reverse rate constants of the outer and inner sphere complexes respectively. Eigen and Tamm (10), Stengle and Langford (11), Hewkin and Prince (12), Wilkins (13), Hunt (14) and many researchers cited in these papers have demonstrated that the first step is essentially diffusion controlled and the second step, the ligand penetration step, is the rate determining step for the

process. A relaxation technique such as temperature jump measures the over all rate (15)

$$[2] \qquad M(aq) + L(aq) \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} ML$$

where

$$k_1 = \frac{k_{os}}{k_{-os}} k_o = K_{os} k_o$$

$$k_{-1} = k_{-o}$$

and k_1 and k_{-1} are the forward and reverse rate constants, respectively. The K_{os} term is the outer sphere stability constant (10, 15). The overall stability constant is

$$K = k_1/k_{-1} = [ML]/[M][L]$$

To the best of the authors' knowledge, no one has proven what n.m.r. "sees" for the Eigen–Tamm mechanism. Labelling the three different species of L present in solution namely, L(aq), M(aq)L, and ML as a, b, and c, respectively, the three-site exchange theory previously presented (16, 17) may be applied to the present system. In the Appendix it is shown that the transverse relaxation rate due to the presence of the paramagnetic metal ion, T_{2p}^{-1}, is given by

$$[3] \qquad T_{2p}^{-1} = K_{os} k_o [M]$$

for the Eigen–Tamm mechanism when the rate of exchange from site a to b is rapid and the rate of exchange from site b to site c is in the chemical controlled region (16). Hence n.m.r. measurements also measure the process given in eq. 2. This has previously been assumed by Mildvan and co-workers (7–9).

If a ligand, L, is observed as it exchanges from one magnetic environment to another, then the lifetime of L, τ_L, is (18, 19)

$$[4] \qquad \tau_L^{-1} = k_L = \frac{\text{rate of decrease of L}}{\text{concentration of L}}$$

Hence n.m.r. experiments measure the pseudo-first order rate constant k_L. Equation 4 has been extensively applied to the interpretation of kinetics and mechanisms of exchange in inorganic chemistry (20, 21) and in studies of proton exchange kinetics (22, 23) to list but a few references.

The lifetime, τ_L, of L in state L(aq) for the exchange mechanism (eq. 2) is

$$[5] \qquad \tau_L^{-1} = k_1[M] = k_{-1} \frac{[ML]}{[L]}$$

and the lifetime, τ_M, of L in the complex ML is

$$[6] \qquad \tau_M^{-1} = k_{-1}$$

The lifetime τ_M is in general a quantity that cannot be directly measured as the bound signal is usually too broad or too weak in intensity to be observed. Therefore τ_M is calculated from the observable τ_L using

$$[7] \qquad \tau_M = \tau_L \frac{[ML]}{[L]}$$

Hence for the mechanism given by eq. 2, eq. 7 becomes

$$[8] \qquad \frac{\tau_M}{\tau_L} = \frac{k_1[M]}{k_{-1}}$$

[M], [ML], and [L] are the equilibrium concentrations of the free metal ion, the complex, and free ligand, respectively.

In addition to the above Eigen–Tamm mechanism, another common exchange mechanism may also be present. This mechanism is the direct ligand exchange and is written as[3]

$$[9] \qquad ML + L^* \underset{k_2}{\overset{k_2}{\rightleftharpoons}} ML^* + L$$

Then

$$[10] \qquad \tau_L^{-1} = k_2[ML]$$

and

$$[11] \qquad \tau_M^{-1} = k_2[L]$$

Finally, when both exchange mechanisms are simultaneously considered, then

$$[12] \qquad \tau_L^{-1} = k_1[M] + k_2[ML] = k_{-1} \frac{[ML]}{[L]} + k_2[ML]$$

$$[13] \qquad \tau_M^{-1} = k_{-1} + k_2[L]$$

The lifetime, τ_M, of L in the complex as well as τ_L, is no longer simple to interpret. Equation 13 is identical in form to eq. 4 in the paper by Pearson and Lanier (24). Pearson and Lanier (24) also point out that a plot of τ_M^{-1} *vs.* [L] must eventually flatten out in the high ligand concentration range. Therefore not detecting a ligand concentration dependence on τ_M^{-1} does not

[3]The ligand L* is the same as L. The * indicates that this ligand has just come off or on the metal ion. Reaction 9 is the overall exchange process. Intermediate steps which may also be present are too rapid to measure using n.m.r.

guarantee that the direct ligand exchange mechanism is absent if only a narrow ligand concentration range is studied. To show that the direct ligand exchange mechanism (mechanism 9) is absent, one must prove that $T_{2B}^{-1} \ll \tau_M^{-1}$ (24) where T_{2B}^{-1} is the transverse relaxation rate of the bound state. T_{2B}^{-1} can be estimated from the Solomon–Bloembergen equation (25)

$$[14] \quad T_{2B}^{-1} = \frac{2S(S+1)}{3}\frac{A^2}{\hbar^2}\tau_e + \frac{2}{5}\frac{S(S+1)}{r^6}\gamma_I^2\beta^2 g^2\tau_c$$

where the symbols have the usual meaning.

Experimental Procedure

Natural abundance ^{31}P n.m.r. spectra were obtained in the Fourier transform mode with proton noise decoupling on a Bruker HFX 90 NMR spectrometer (36.43 MHz) interfaced with a Nicolet computer. The deuterium resonance of the solvent D_2O was used as the lock signal. All measurements were carried out under controlled temperatures using the Bruker temperature control unit. Samples were in the probe for at least 15 min before the measurements were begun.

Transverse relaxation times were measured from the linewidths at half-height from the Fourier transformed spectra and calculated using

$$T_{2p}^{-1} = \pi[\Delta\nu_{1/2,obsd} - \Delta\nu_{1/2,o}] = \pi\Delta\nu_{1/2,p},$$

where $\Delta\nu_{1/2,obsd}$ is the observed linewidth at half-height of the ligand resonance for the metal ion solution, $\Delta\nu_{1/2,o}$ is the linewidth at half-height for the same resonance without metal ions and $\Delta\nu_{1/2,p}$ is the effective paramagnetic linewidth. Corrections were made for the $J(^{31}P—^{31}P)$ splitting of 19.5 Hz. Depending on the required resolution, the free induction decay signals were stored in either 8K or 4K data points corresponding to a frequency range of 3000 Hz. The transformed spectrum then yields 4K or 2K data points respectively.

ATP (disodium salt) of highest grade was obtained from Sigma Chemical Co. Samples were purified by passing an ATP solution through a Dowex 50 exchange resin. ATP solutions were then prepared in D_2O and adjusted to a pD of 8.2 (26) with sodium hydroxide. Stock solutions of Mn(II) were prepared from Fisher certified reagent $MnCl_2 \cdot 4H_2O$ crystals. The Mn(II) ion concentrations were calibrated against a Fisher certified atomic absorption Mn(II) standard solution by measuring the ^{31}P n.m.r. signals of 5′-AMP using both the stock and standard solutions. The ionic strength was maintained at one using tetramethylammonium chloride, TMA·Cl (Eastman Kodak Co.).

The ATP concentrations were determined by uv spectrometry ($\varepsilon_{max} = 1.54 \times 10^4$ at 260 mμ at pH 8). The metal solutions were added with calibrated H. E. Pedersen micropipets. After the addition of the metal ions, the solution pD was rechecked and was constant at 8.2 ± 0.1 in all cases.

Results and Discussion

Metal ion – ATP interactions have now been extensively studied (17, 27–39). However, the kinetics and exchange mechanisms have been difficult to study due to the high concentrations of ATP that are required. With the advent of pulse Fourier transform n.m.r. techniques, the ATP concentration range available for these studies has increased by a factor of ten. The inconsistencies in the interpretation of the previous metal ion – ATP kinetic study by n.m.r. (39) have been pointed out in previous papers (17, 35, 40, 41).

A plot of $\Delta\nu_{1/2,p}$ $(1/\pi T_{2p})$ as a function of the reciprocal of the absolute temperature for the ^{31}P resonance of ATP is shown in Fig. 1. The data for ATP concentrations of 0.1 and 0.01 M are shown in Fig. 1 whereas the results for 0.05 and 0.03 M solutions are tabulated in Table 3. Since T_{2p}^{-1} is in the chemical controlled region (16, 28, 33) it then equals the n.m.r. exchange rate τ_L^{-1}. It has previously been shown (17) that in the Mn(II) – ATP system, ATP exists in at

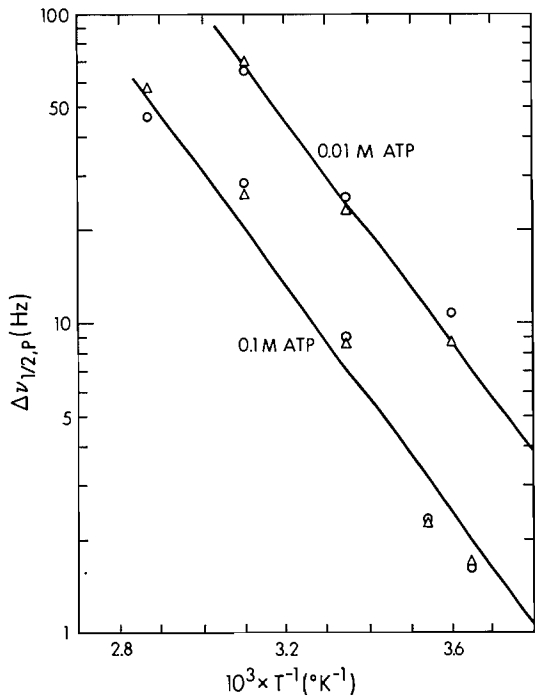

FIG. 1. Plot of $\Delta\nu_{1/2,p}$ *vs* T^{-1} ($°K^{-1}$). The γ phosphorus signal is labelled △ and the α phosphorus signal is labelled ○. The Mn(II) concentration is 1.0×10^{-5} M for all solutions. The ionic strength was maintained at one using tetramethylammonium chloride.

[b]$[ATP]_{total} \cong [ATP]$.

least three states in solution, namely free ATP (species a), metal ion – phosphate bound ATP (species b), and phosphate-metal ion-ring bound ATP (species c). In the chemical-controlled region, even if $T_{2b} = T_{2c}$ as may be true for the ^{31}P nuclei, n.m.r. sees only the a $\rightleftharpoons$ b exchange. Hence τ_L^{-1} (τ_{ab}^{-1}) is measured experimentally and τ_M^{-1} (τ_{ba}^{-1}) is calculated using eq. 7 written in the form $\tau_M^{-1} = [a]\tau_L^{-1}/[b]$. However, if the concentration of species b is not very well known, then τ_M is also not well known.

Since the stability constant for the Mn(II) – ATP complex for a solution with an ionic strength of one is not precisely known, in our calculations the present authors used $[b] \cong [Mn(II)]$ rather than $[b] = 0.8\ [Mn(II)]$ (17).

The analysis of the ATP concentration dependence on T_{2p}^{-1} is shown in Table 1. Since the ligand-to-metal ion ratio is very large, the free ATP concentration is essentially equal to the total ATP concentration in solution. The stability constant K for the Mn–ATP complex is very large and values have been reported ranging between 1×10^4 and 1.5×10^5 l mol^{-1} for an ionic strength of 0.1 (42, 43 and references therein). For the present discussion, values of the stability constant ranging from 1×10^4 to 5×10^4 l mol^{-1} have been chosen (ionic strength 1.0). The concentration of the Mn–ATP complex is very close to a constant and independent of the value of K or the ATP concentration (Table 1).

If only the exchange mechanism (mechanism 9) was present, the exchange rate would be independent of the ATP concentration over the ATP concentration range studied (eqs. 10 and 12). However, if the only mechanism present was the Eigen–Tamm mechanism (mechanism 2), then the exchange rate for 0.01 M ATP should be ten times that for 0.1 M ATP (eq. 5) as the concentration of Mn–ATP is constant (Table 1). Experimentally, from Fig. 1 it is seen that the exchange rate for 0.01 M ATP is about 3.3 times that at 0.1 M ATP.

Hence both exchange mechanisms must be simultaneously considered and the exchange rate is now governed by eq. 12. Therefore the forward rate constant, k_1, can easily be calculated based on the quantities in Table 1. The forward rate constant then ranges between $6 \times 10^8\ M^{-1}\ s^{-1}$ and $3 \times 10^9\ M^{-1}\ s^{-1}$ at 27 °C (Table 2). On the basis of temperature jump studies, Hammes and Levison (44) calculated k_1 to be $2 \times 10^9\ M^{-1}\ s^{-1}$ for the Mn–ATP system (ionic strength 0.1).

The exchange constant, k_2, for the direct ligand exchange mechanism is $1.8 \times 10^6\ M^{-1}\ s^{-1}$ (Table 2). Using these values of k_1 and k_2, the observed τ_L^{-1} for 0.05 M ATP and 0.03 M ATP are compared with the calculated values using eq. 12 (Table 3). The calculated exchange rates are compatible with the observed exchange rates. For 0.1 M ATP, the Eigen–Tamm mechanism contributes approximately 15% to the observed linewidth. The small concentration range that is feasible for this study (0.1 to 0.01 M) influenced us to analyze the data in this manner rather than by plotting $\Delta\nu_{1/2,p}$ *vs.* $[L]^{-1}$, the preferred approach. Hence our analysis of the data indicates that two n.m.r. exchange mechanisms

are required to explain the ATP concentration dependence in the binary system, Mn–ATP. The kinetic parameters thus obtained favorably compare with those obtained from other kinetic techniques as mentioned in the review article by Frey and Stuehr (40).

Summary

It has been shown that for the Eigen–Tamm exchange mechanism

$$M(aq) + L(aq) \overset{K_{os}}{\rightleftharpoons} MWL \overset{k_o}{\underset{k_{-o}}{\rightleftharpoons}} ML$$

nuclear magnetic resonance "sees" the exchange rate

$$\tau_L^{-1} = K_{os}k_o[M] = k_1[M]$$

We have also explicitly demonstrated the circumstances when a concentration dependence study is required to assign the exchange mechanisms. This understanding was then applied to the binary system Mn–ATP and it was thus seen that two exchange mechanisms are required to fit the n.m.r. lifetimes.

We wish to thank Dr. D. L. Rabenstein for valuable discussions and the National Research Council of Canada for financial support.

Appendix

The Eigen–Tamm exchange mechanism for a metal ion, M, and ligand, L, complex may be written as

$$[A1] \quad M(aq) + L(aq) \overset{k_{os}}{\underset{k_{-os}}{\rightleftharpoons}} M(aq)L \overset{k_o}{\underset{k_{-o}}{\rightleftharpoons}} ML$$

where k_{os}, k_{-os}, k_o, k_{-o} are the forward and reverse rate constants of the outer and inner sphere complexes respectively. The first step is diffusion controlled and the second step, the ligand penetration step, is the forward rate determining step. For n.m.r. exchange, mechanism A1 is rewritten as

$$[A2] \quad M(aq) + L(aq) \overset{k_{ab}}{\underset{k_{ba}}{\rightleftharpoons}} M(aq)L \overset{k_{bc}}{\underset{k_{cb}}{\rightleftharpoons}} ML$$

where $k_{ij} = \tau_{ij}^{-1}$ is the n.m.r. exchange rate of the ligand, L, going from site i to site j. From eq. 4, the above rate constants and n.m.r. exchange rates are related by the following

$$[A3] \quad \begin{aligned} k_{ab} &= k_{os}[M] \\ k_{ba} &= k_{-os} \\ k_{bc} &= k_o \\ k_{cb} &= k_{-o} \\ K_{os} &= \frac{k_{os}}{k_{-os}} \end{aligned}$$

The ligand sites are defined as free ligand, L(aq), outer sphere ligand, M(aq)L, and inner sphere ligand, ML, and are referred to as species a, b, and c respectively. The three site exchange theory that has previously been developed (16, 17) can now be applied to this system.

The change in the transverse relaxation caused by the paramagnetic metal ion in the consecutive three site exchange mechanism is

$$[A4] \quad \frac{1}{T_{2p}} = k_{ab} + k_x$$

where

$$k_x = \frac{-k_b(k_c^2 + \Delta\omega_c^2)k_{ab}k_{ba} + k_c k_{bc}k_{cb}k_{ab}k_{ba}}{[(k_b^2 + \Delta\omega_b^2)(k_c^2 + \Delta\omega_c^2) + 2(\Delta\omega_b\Delta\omega_c - k_b k_c)k_{bc}k_{cb} + k_{cb}^2 k_{bc}^2]}$$

$$k_b = T_{2b}^{-1} + k_{ba} + k_{bc}$$

$$k_c = T_{2c}^{-1} + k_{cb}$$

T_{2j} is the usual transverse relaxation time in the j environment and $\Delta\omega_j$ is the difference between the resonance frequency for site j and the actual frequency.

The outer sphere complex is usually in the fast exchange region while the inner sphere complex may be in either the fast or slow (chemical controlled) region in the n.m.r. time domain (45). In the present paper it is assumed that the inner sphere complex is in the chemical controlled region, a common occurrence for ^{31}P n.m.r. (28).

The rate of exchange of species b to species a is in the fast exchange limit. Assuming $K_{os} = 100$ for this ionic strength, then $k_{ba} = k_{-os} = k_{os}/K_{os}$ which is less than two orders of magnitude that is required for diffusion control. Hence

[A5] $$k_{ba} \gg T_{2b}^{-1}; \Delta\omega_b$$

The rate of exchange of species c to species b is in the chemical controlled region

[A6] $$\Delta\omega_c; T_{2c}^{-1} \gg k_{cb}$$

For a large stability constant (of the order of $10^4\ M^{-1}$)

[A7] $$k_{ba} \gg k_{bc} \gg k_{cb}$$

as k_{ba} is of the order of $10^9\ s^{-1}$, k_{bc} is of the order of $10^6\ s^{-1}$ or less for the first row transition metals and k_{cb} is of the order of $10^4\ s^{-1}$ (44).

In the case of manganese, the bound linewidth is always much greater than the shift so the shift terms are negligible. Hence

[A8] $$T_{2c}^{-1} \gg \Delta\omega_c$$

The inner sphere complex has a much greater linewidth than the outer sphere complex so that

[A9] $$T_{2c}^{-1} \gg T_{2b}^{-1} \gg \Delta\omega_b$$

Applying limits A5 to A9 to eq. A4, it is found that

[A10] $$\frac{1}{T_{2p}} = \frac{k_{ab}}{k_{ba}}(k_{bc} + T_{2b}^{-1})$$

Applying eq. A3, eq. A10 becomes

[A11] $$\frac{1}{T_{2p}} = K_{os}[M](k_o + T_{2b}^{-1})$$

The outer sphere bound transverse linewidth, T_{2b}^{-1}, is dipolar in nature. The distance between the metal ion and ligand is approximately 5.5 Å. T_{2b}^{-1} can be calculated from the Solomon equation (46).

[A12] $$T_{2b}^{-1} = \frac{2}{5}\frac{S(S+1)\gamma_I^2\beta^2 g^2}{R^6}\tau_c$$

T_{2b}^{-1} is of the order of 10^2 to $10^3\ s^{-1}$, much smaller than k_o ($10^6\ s^{-1}$ for Mn(II)). Equation A11 becomes

[A13] $$\frac{1}{T_{2p}} = K_{os}k_o[M]$$

When the bound shift is much greater than the bound linewidth as is true for Ni(II) and Co(II), the linewidth terms are negligible

[A14] $$\Delta\omega_c \gg T_{2c}^{-1}$$

The inner sphere complex has a greater shift than the outer sphere complex

[A15] $$\Delta\omega_c \gg \Delta\omega_b \gg T_{2b}^{-1}$$

Applying the limiting cases A5, A6, A7, A14 and A15 to eq. A4, T_{2p}^{-1} becomes

[A16] $$\frac{1}{T_{2p}} = \frac{k_{ab}}{k_{ba}}\frac{k_{bc}\Delta\omega_c^2}{(k_{cb}^2 + \Delta\omega_c^2)}$$

In the slow exchange limit (16)

[A17] $$\Delta\omega_c^2 \gg k_{cb}^2$$

and eq. A16 becomes

[A18] $$\frac{1}{T_{2p}} = \frac{k_{ab}}{k_{ba}}k_{bc} = K_{os}k_o[M]$$

which is equivalent to A13.

Therefore n.m.r. for both cases "sees" the Eigen–Tamm mechanism as a single step mechanism

[A19] $$M(aq) + L(aq) \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} ML$$

where

$$k_1 = K_{os}k_o$$

and

$$k_{-1} = k_{-o}$$

Energetics of the Ionization and Fragmentation of Phosphorus Trifluoride by Electron Impact

DAVID F. TORGERSON

Cyclotron Institute and Department of Chemistry, Texas A. & M. University, College Station, Texas 77843

AND

JOHN B. WESTMORE[1]

Department of Chemistry, University of Manitoba, Winnipeg, Manitoba R3T 2N2

Received September 5, 1974

DAVID F. TORGERSON and JOHN B. WESTMORE. Can. J. Chem. 53, 933 (1975).

Relative intensities and appearance potentials of several positive ions in the mass spectrum of PF_3 are reported as well as an ionization efficiency curve for F^-, the only negative ion of significant intensity. Probable ion fragmentation pathways are proposed, together with heats of formation of some positive ions, and ionization potentials for PF_3, PF_2·, and PF. The results are compared with available data for other Group V halides.

DAVID F. TORGERSON et JOHN B. WESTMORE. Can. J. Chem. 53, 933 (1975).

On rapporte les intensités relatives et les potentiels d'apparition de plusieurs ions positifs dans le spectre de masse de PF_3 de même que les courbes d'efficacité d'ionisation pour F^-, seul ion négatif d'intensité notable. On propose des chemins probables pour la fragmentation des ions, de même que les chaleurs de formation de quelques ions positifs et les potentiels d'ionisation de PF_3, PF_2. et PF. On compare ces résultats avec les données disponibles pour d'autres halogénures du groupe V. [Traduit par le journal]

There has been considerable interest in the ionization of the monomeric halides and hydrides of the main Group V elements, both from an experimental and a theoretical point of view. Photoelectron spectroscopy has been used to study PF_3 (1–5), other Group V halides (5–9), hydrides (3, 8–11) and PF_3-containing complexes of Ni and Pt (2, 12) and Cr, Fe, and Rh (13). Electron impact appearance potentials have been measured for NF_3 (14), PH_3 (15–20), PCl_3 (21–23), PBr_3 (24), PI_3 (25), $AsCl_3$ (7, 23, 26), $SbCl_3$ (23), AsH_3 (15, 26, 27), SbH_3, BiH_3 (15), and Ni and Co complexes containing PF_3 (28, 29). Photoionization studies have been reported for NF_3 (30) and PF_3, PCl_3, PH_3, AsH_3, and SbH_3 (31). Absorption spectra have been obtained for the hydrides and halides (32) and ionization and dissociation energies of hydrides and fluorides have been discussed (33). Molecular orbital calculations have been made for PH_3, PF_3, and $P(CH_3)_3$ (34) and for PF_3 and PF_2CN (35). In view of this extensive activity it is surprising that no electron impact studies have been published for PF_3. Consequently, we wish to report our results for this simple and important molecule.

[1]To whom correspondence should be addressed.

Results and Discussion

The positive ion mass spectrum of PF_3 at an electron energy of 70 V is shown in Table 1. Apart from background peaks due to air and water there were also small peaks of variable intensity observed at *m/e* 20, 35, 36, 37, 38, 81, 85, and 104 which could be assigned to HF^+, 20; Cl^+, 35, 37; HCl^+, 36, 38; SiF_3^+, 85; and SiF_4^+, 104. The source of HF and SiF_4 was thought to be from the reaction of PF_3 with background water, and the glass reservoir and inlet line respectively, while HCl was formed by the action of moisture on the SbF_3, PCl_3 mixture used to prepare PF_3. The peak at *m/e* 81 was tentatively assigned to P_2F^+ formed from P_2F_2 or P_2FCl as possible by-products of PF_3 preparation. For normal recording conditions no metastable peaks were observed, but at high sensitivity a metastable peak could just be detected at *m/e* 36.2, corresponding to the reaction $PF_2^+ \rightarrow PF^+ + F$ (36.23 calculated). The negative ion mass spectrum showed only F^-.

The appearance potential (a.p.) of PF_3^+ was determined from the experimental data by three procedures, namely, the "extrapolated voltage difference" (e.v.d.) method (36), the "semilogarithmic plot" (s.l.p.) method (37), and the

*Mean value = 11.65 ± 0.07 eV.
†Background CO_2 prevents determination.
‡Intensity too low for determination.

"energy distribution difference" (e.d.d.) method (38, 39), using krypton to calibrate the energy scale. Appearance potentials of fragment ions were determined by the s.l.p. method if the curves for fragment ion and Kr^+ were parallel, or nearly parallel, in the threshold region. When this was not true then the e.v.d. method was used. The results are given in Table 1 and represent the mean of several determinations.

PF_3^+

Values for the a.p. of this ion, determined by three procedures, are listed in Table 1. To some extent the values depend upon the method used for determination, the e.v.d. method giving a value slightly higher than the other methods while the s.l.p. method gave the most reproducible results. The mean value of 11.65 ± 0.07 eV is the statistically weighted average incorporating the overall standard deviation.

The i.p. of PF_3 has also been determined by photoelectron spectroscopy. The adiabatic i.p. has been reported as 11.66 eV (4) and the vertical i.p. as 12.28 eV (1), 12.3 eV (2, 3), 12.29 eV (4), and 12.27 eV (5). It is apparent that the i.p. determined by electron impact (especially as obtained by the s.l.p. and e.d.d. methods) is very close to the adiabatic value and that an earlier value of 9.71 eV obtained by photoionization (31) is incorrect.

Ionization by electron impact is a vertical ionization process and the probability of ionization to the ground vibrational state of the molecular ion will depend upon the relative shapes and positions of the potential energy surfaces of the neutral molecule and ground electronic state of the molecular ion. When the relative probability of producing the molecular ion in its lowest energy state is small the measured a.p. *may* be greater than the adiabatic i.p. of the molecule and will often be a function of the sensitivity of the ion detecting equipment. On the other hand, the measured a.p. will be smaller than the vertical i.p. (corresponding to the most probable ionizing transition) of the molecule, because of the still finite probabilities of ionization to lower vibrational states of the molecular ion. Generally, ionization potentials determined by electron impact are considered as upper limits to adiabatic ionization potentials.

Photoelectron spectroscopy shows that, for PF_3, the vertical i.p. lies some 0.6 eV above the adiabatic i.p. In spite of this, the sensitivity of the ion detecting system of the mass spectrometer is evidently high enough to detect formation of PF_3^+ in its ground state. To calculate ΔH_{f298}^0 for PF_3^+ the mean of −221.95 (40) and −219.6 kcal/mol (41) was used for ΔH_{f298}^0 (PF_3, gas).

PF_2^+

There are two plausible reactions which could lead to production of this ion

[1] $$PF_3 + e \rightarrow PF_2^+ + F + 2e$$

[2] $$PF_3 + e \rightarrow PF_2^+ + F^- + e$$

In order to distinguish between them the initial assumption was made that, at threshold, the excess energies associated with the reactions

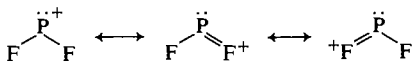
TABLE 2. Probable ion formation reactions and heats of formation of positive ions in the mass spectrum of PF_3

Ion	Reaction	ΔH_{f298}^0(kcal/mol)
PF_3^+	$PF_3 + e \rightarrow PF_3^+ + 2e$	48 ± 3
PF_2^+	$PF_3 + e \rightarrow PF_2^+ + F + 2e$	$\leqslant 117 \pm 6$
PF^+	$PF_3 + e \rightarrow PF^+ + F_2 + 2e$	$\leqslant 252 \pm 6$*

*Based on reaction 4. See text for possible uncertainties.

were small. By taking $D(PF_2—F) = 131 \pm 10$ kcal/mol (42), and the electron affinity of F as 3.45 eV (43, 44) values obtained for the i.p. of $PF_2\cdot$ were 9.8 ± 0.6 and 13.25 ± 0.6 eV for reactions 1 and 2 respectively. The i.p. of $PF_2\cdot$ is expected to be substantially lower than that of PF_3 because of the stabilization of positive charge in the even-electron PF_2^+ by delocalization over the three atoms as indicated by the canonical forms



The anticipated lowering is about 1–2 eV by comparison with other AX_3 and $AX_2\cdot$ species having similar valence shell electron configurations (see, for example, Table 3). A similar, but larger, lowering is observed between CF_4 (i.p. = 14.9 eV) and $CF_3\cdot$ (i.p. = 10.1 eV) (41) where the positive charge on CF_3^+ can be delocalized over four atoms rather than three as in AX_2^+. Thus, for reaction 2 to apply, an excess energy of at least 2.5 eV would be involved. In spite of the high bond energy in PF_3 this is considered unlikely because (*a*) in the threshold region the ionization efficiency curve for PF_2^+ was so similar to that of Kr^+ that the s.l.p. method could be used to determine the a.p. of PF_2^+, and (*b*) according to Stevenson's rule (45), as the i.p. of $PF_2\cdot$ is substantially less than that of F then the products of reaction 2 should be formed without excess energy. Consequently, reaction 1 is indicated. The value obtained for the i.p. of $PF_2\cdot$ is an upper limit, though according to Stevenson's rule, excess energy for this reaction should be small at threshold. Probably, the largest uncertainty in the value comes from $D(PF_2—F)$ which depends upon an estimated value, rather than an experimental value, for $\Delta H_f(PF_2\cdot)$. The calculated value for $\Delta H_{f298}^0(PF_2^+)$ in Table 1 is based on reaction 1, using $\Delta H_{f298}^0(F) = 19.0$ kcal/mol (41), and the value quoted earlier for PF_3.

PF^+

There are three plausible reactions which could lead to production of this ion

[3] $PF_3 + e \rightarrow PF^+ + 2F + 2e$

[4] $PF_3 + e \rightarrow PF^+ + F_2 + 2e$

[5] $PF_3 + e \rightarrow PF^+ + F + F^- + e$

Calculations for these reactions are based on $\Delta H_{f298}^0(PF) = 11 \pm 10$ kcal/mol, a value estimated from D(N—H) and the mean bond energies in NH_3 and PH_3 (ref. 42, p. 132). By assuming negligible excess energies at threshold the upper limits for the i.p. of PF are calculated to be 9.8 ± 0.6, 11.4 ± 0.6, and 13.2 ± 0.6 eV for reactions 3, 4, and 5 respectively. When compared with the i.p. of PF_3 the latter value is much too high (compare values in Table 3). Considerable excess energy is required for reaction 5 to apply, but the possibility is not definitely excluded. Because of the uncertainty in the i.p. values a choice between reactions 3 and 4 is more difficult though reaction 4 is to be preferred. The i.p. of PF should exceed that of $PF_2\cdot$ because there is less opportunity for positive charge delocalization in PF^+ compared to PF_2^+. Furthermore, the i.p. of PF should be greater than that of PCl (see below, and Table 3). For comparison, using tabulated data (41), the i.p. of the isoelectronic SO molecule is calculated to be 10.65 ± 0.35 eV. The calculated value of $\Delta H_{f298}^0(PF^+)$ in Table 2 is thus based on reaction 4.

P^+ and F^+

These ions are formed in reactions of considerable excess energy since the threshold energies for the highest energy reactions leading to their formation, namely

[6] $PF_3 + e \rightarrow P^+ + 3F + 2e$

[7] $PF_3 + e \rightarrow F^+ + P + 2F + 2e$

lead to a calculated a.p. for P^+ of 25.8 eV

compared with the experimental value of 32.3 eV, and to an a.p. for F^+ of 32.7 eV compared with the experimental value of 36 eV. (For these ions the ionization efficiency curves had low energy tails which were attributed to ionization of a background impurity amounting to ~5% at *m/e* 31 and ~1% at *m/e* 19. The threshold energies were much too low to arise from fragmentation of PF_3.)

Remaining Positive Ions

Since the reactions leading to formation of these ions cannot be definitely established, no further discussion is given.

F^-

The ionization efficiency curve for F^- is shown in Fig. 1. The energy scale was calibrated by comparison with curves for the formation of O^- from CO and O_2 (46). The dissociative electron capture reaction

$$[8] \qquad PF_3 + e \rightarrow PF_2 + F^-$$

is calculated to occur at 2.25 ± 0.4 eV which is below the low energy range of our instrument. Figure 1 may show the high energy tail of the capture peak. The remainder of the ionization efficiency curve shows much structure and processes corresponding to reactions such as [2] or [5] could not be identified. The onset occurring at ~6 eV is at much too low an energy to correspond to [2].

Comparisons with other Group V Halides

It is instructive to consider the i.p. of the Group V halide molecules and radicals given in Table 3. Most values are from electron impact work. Only a few of the photoelectron spectroscopic studies cite adiabatic i.p. In some cases values have been recalculated from the original data using thermochemical information from refs. 41 and 42. Some electron impact results for PCl_3, $AsCl_3$, and $SbCl_3$ (23, 26) are not included because of their low accuracy.

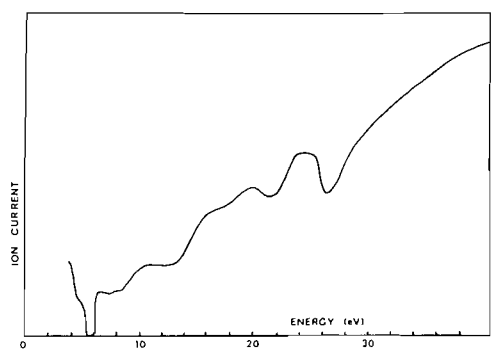

FIG. 1. Ionization efficiency curve for F^- from PF_3.

For each Group V halide in Table 3 the main fragmentation occurs according to

$$[1a] \qquad AX_3 + e \rightarrow AX_2^+ + X + 2e$$

Although Halmann and Klein (22) proposed a dissociative capture process for the formation of PCl_2^+ from PCl_3 their value of 11.8 ± 0.4 eV is clearly much too high for the i.p. of $PCl_2\cdot$. Their proposal was based on an interpretation of an ionization efficiency curve at least as complex as that of Fig. 1 and is extremely questionable. It appears that the energetically more favorable reactions analogous to [2] have very low ionization cross sections.

With the exception of PF_3 the formation of the AX^+ ion for all the other compounds in Table 3 is based on the reaction

$$[3a] \qquad AX_3 + e \rightarrow AX^+ + 2X + 2e$$

The reason for the difference is not obvious though the fragmentation may be sensitive to differences in potential energy surfaces for molecules and ion products. Other differences in behavior from PF_3 can be noted. For example, the formation of P^+ from PCl_3 occurs with little excess energy at threshold (21).

It is noteworthy that the i.p. of PCl is close to that of the isoelectronic S_2 molecule (9.9 ± 0.5 eV) (41).

It is apparent from the incomplete nature of Table 3 that further studies on the Group V halides are much needed.

Experimental

PF_3 was prepared in a vacuum rack by condensing PCl_3 onto SbF_3 using a liquid nitrogen trap. The first gases evolved on warming the sample were passed through several CO_2–acetone or CO_2–isopropanol traps to remove PCl_3, then stored in glass bulbs before use.

Mass spectra and appearance potentials were determined using a Hitachi Perkin–Elmer RMU-6D single focussing mass spectrometer, using an external potentiometer for potential measurements. For a.p. determinations ion current readings for a particular ion were taken at 0.100 V intervals upward from the ionization threshold and also at an electron energy of 50 V before and after these readings. Appearance potentials were determined relative to krypton (i.p. = 14.00 eV) and argon (i.p. = 15.76 eV) as standards.

Addendum

A referee has suggested the possibility that CF_4 might be present from the reaction of PF_3 with high vacuum grease or other organic

residues. Since CF_4 would give ions of the same nominal m/e values as PF_3 then a relatively small amount could affect the shape of some of the ionization efficiency curves. We cannot exclude this possibility but literature values (41) for a.p. of ions from CF_4, obtained by the s.l.p. method, are: CF_4^+, 14.9 ± 0.2 eV (derived value, since this ion is absent from the spectrum); CF_3^+, 16.0 ± 0.2 eV; CF_2^+, 20.3 ± 0.5 eV; CF^+, 22.6 ± 0.5 eV. Low amounts of an interfering ion are only likely to have a serious effect on the ionization efficiency curve of a more abundant ion if it has a lower a.p. than the more abundant ion. Thus CF_4^+ (which has a negligible intensity in any case) and CF_3^+ are unlikely to significantly influence the quoted a.p. for PF_3^+ and PF_2^+ respectively, while the a.p. of CF^+ is so far different from that of P^+ that a contribution to the ionization efficiency curve would be obvious. Only in the case of PF^+ could interference from CF_2^+ be troublesome.

We thank the National Research Council of Canada for financial support of this work.

Synthesis and Characterization of Some Dibasic Tridentate Schiff Base Ligands[1]

ELMER C. ALYEA AND ABDUL MALEK

Department of Chemistry, University of Guelph, Guelph, Ontario N1G 2W1

Received August 21, 1974

ELMER C. ALYEA and ABDUL MALEK. Can. J. Chem. **53**, 939 (1975).

The synthesis and characterisation of several dibasic tridentate Schiff base ligands (H_2SB) are described. Structural formulas for the isolated ligands are suggested on the basis of infrared, nuclear magnetic resonance, and mass spectral data.

ELMER C. ALYEA et ABDUL MALEK. Can. J. Chem. **53**, 939 (1975).

On décrit la synthèse et la caractérisation de plusieurs ligands (H_2SB) dibasiques tridentates et dérivés de bases de Schiff. On propose des formules structurales pour les ligands isolés en se basant sur les données infrarouges, r.m.n. et de masse. [Traduit par le journal]

Introduction

In continuing our studies of titanium(IV) compounds having uncommon coordination numbers for titanium (1, 2) we are presently engaged in investigations involving various Schiff base ligands, particularly dibasic tridentate ONO and ONS ligands. During the characterization of complexes of the types $Ti(SB)_2$ and $(RO)_2Ti(SB)$ it became necessary, in establishing physicochemical criteria for the coordinating behavior of the ligands, to isolate and characterize by spectral methods the free Schiff base ligands under study.[2]

In this paper we report the synthesis and characterization of several potentially tridentate ONO and ONS donor Schiff base ligands (H_2SB). Structural formulas for the following ligands, depicted in their Schiff base forms, are given in Fig. 1: salicylaldehyde-2-hydroxyanil (H_2SAP), salicylaldehyde-2-hydroxyethylimine (H_2SAE), salicylaldehyde-3-hydroxypropylimine (H_2SPA), acetylacetone-2-hydroxyanil (H_2AAP), and acetylacetone-2-mercaptoanil (H_2ASP). The characterization of salicylaldehyde-2-mercaptoanil (H_2SSP) was reported earlier (3).

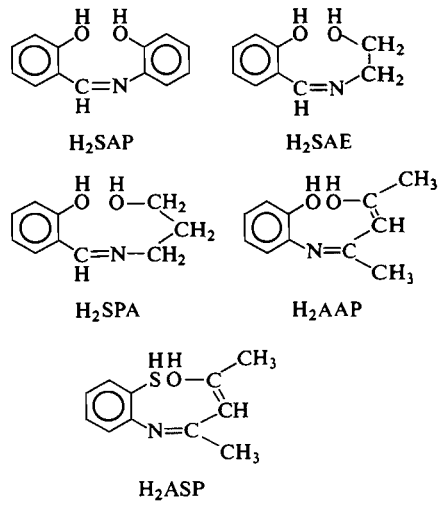

FIG. 1. Formulation of H_2SAP, H_2SAE, H_2SPA, H_2AAP, and H_2ASP.

Experimental

Chemicals

Salicylaldehyde was obtained from Fisher Scientific Company or J. T. Baker Chemical Company. The latter company also supplied acetylacetone, 3-amino-1-propanol, and 2-amino-1-ethanol. Eastman Organic Chemicals was the source of *o*-aminophenol, which was recrystallized from ethanol before use. *o*-Aminothiophenol was purchased from Matheson, Coleman and Bell. Solvents were purified and dried following standard procedures.

Physical Measurements

Elemental analyses were performed in this department by S. McKinnon and by M-H-W Laboratories, Garden City, Michigan. Infrared spectra were obtained in the region 4000–200 cm^{-1} using a Beckman IR-12 spectrophotometer. Mass spectra were recorded with a Varian Mat-7 mass spectrometer at an ionizing energy of 70 eV by L. MacDonald. Proton n.m.r. spectra were obtained with a Varian A-60A spectrometer at ambient temperatures with TMS as the internal standard.

[1]Presented in part at the 166th ACS National Meeting, Chicago, Illinois, August 26–31, 1973.

[2]For part I of a series concerning these complexes, see ref. 3.

Preparation of the Ligands

Previous preparative methods for H_2SAP (4), H_2SAE (5), H_2SPA (6), and H_2AAP (7) are only briefly described in the literature. Nevertheless, synthetic details are not described here since their preparation follows standard methods (8) and is similar to that described below. Acetylacetone-2-mercaptoanil (H_2ASP) was prepared by the following procedure: acetylacetone (5.0 g, 50 mmol) was dissolved in 100 ml ethanol and cooled in an ice bath. *o*-Aminothiophenol (6.25 g, 50 mmol) dissolved in 50 ml ethanol and also precooled was added to the acetylacetone solution. After stirring briefly the solution was allowed to stand at room temperature overnight. The large prismatic crystals which separated were collected by filtration, washed with chilled ethanol, and dried under vacuum over P_4O_{10}.[3]

[3]Cooling is essential to avoid formation of an orange oxidation product. Our preliminary findings indicate that the oxidized species is not the simple benzothiazole, as found for H_2SSP (3).

Some of the physical properties and the analyses of the free ligands are summarized in Table 1.

Results and Discussion

Structures of the Ligands

Even though earlier workers had isolated some of the Schiff base ligands used in this study (as compared to *in situ* preparation prior to adding a metal salt), the literature is sparse with respect to spectral characterization of their structures. We have previously demonstrated that the condensation product of salicylaldehyde and *o*-aminothiophenol exists in the benzothiazoline (cyclic) form in the free ligand but readily transforms to the chelating Schiff base form in reactions with titanium alkoxides (3). Accordingly, in order to employ changes in the infrared frequencies and n.m.r. chemical shifts as criteria

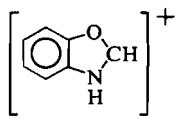
of tridentate behavior in a series of titanium(IV) complexes, it was necessary to obtain the characteristic spectral data for the ligands. This information for the free ligands is recorded in Tables 2 and 3. Broad multiplets assignable to phenyl protons were also observed in the range 6.4–7.5 δ for all of the Schiff base ligands.

The infrared spectrum of H_2SAP in dimethylsulfoxide shows several bands in the hydroxyl stretching frequency region (Table 2) and their weakening and shift to lower energy in the solid state (halocarbon mull) is compatible with even more extensive intramolecular H-bonding in the solid state. On the basis of observing frequencies at 3546 and 2730 cm^{-1} for a 0.01 *M* CCl_4 solution of H_2SAP, Baker and Shuligan (4) assigned the higher frequency to the hydroxyl of the salicylaldehyde residue (H-bonded to the azomethine nitrogen) and the lower frequency to the hydroxyl of the amine residue (H-bonded to the π-electron system of the —CH=N— bond). Our observation (Table 3) of resonance peaks at 13.75 δ and 9.64 δ which disappear with the addition of D_2O substantiates the infrared assignment of the presence of two intramolecularly-bonded hydroxyl- groups. The single proton giving a singlet at 8.95 δ in the n.m.r. spectrum of the dimethylsulfoxide-d_6 solution of H_2SAP does not exchange with D_2O and hence may be assigned to the azomethine proton (9). In monomeric $(CH_3)_2Sn(SAP)$, where distinct spin–spin coupling is observed between the tin nuclei and the azomethine proton via the N → Sn coordinate bond, the azomethine proton chemical shift has recently been reported to occur at 9.03 δ in dimethylsulfoxide-d_6 (10). Some of the strong infrared bands near 1600 cm^{-1} are doubtless associated with C=N stretching frequencies but any assignment (11) to uncoupled ν(C=N) is unwise in view of the recent exhaustive isotopic labelling study that indicates extensive vibrational coupling in Schiff bases derived from salicylaldehyde (9). The significant frequency shift of several bands in the 1700–1500 cm^{-1} region upon complexation of H_2SAP does indeed suggest vibrational coupling of the C=N and C=C stretching frequencies.

The mass spectrum of H_2SAP shows a base peak at *m/e* 213 corresponding to the parent molecular ion, $C_{13}H_{11}O_2N^+$. The high intensity is in accord with the stabilization of the molecule by strong intramolecular hydrogen-bonding. Similarly the high resistance of the ligand to hydrolysis reflects the stabilization of the azomethine bond by means of the hydrogen-bonded ring system. It is well established that chelate ring formation with metal ions allows stabilization of Schiff base —C=N— bonds (8). Additionally, it is worth noting that a very strong peak at *m/e* 120 can be assigned to the fragment



The formation of such stable heterocyclic species is characteristic of the mass spectra of *ortho*-substituted aromatic Schiff bases (12).

Schiff bases obtained from salicylaldehyde are expected to exist predominantly as the phenol-imine tautomer (8, 9). The spectral evidence obtained in this study and by previous workers (4, 11, 13) confirms that H_2SAP also can be

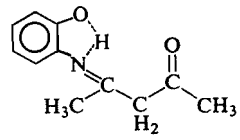
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

formulated in the Schiff base form (Fig. 1) in which intramolecular hydrogen-bonding occurs.

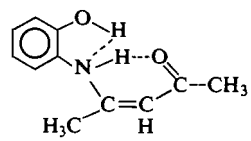
Salicylaldehyde condenses with 2-amino-1-ethanol and 3-amino-1-propanol to form amber oils (represented as H_2SAE and H_2SPA in this paper) which can be purified by distillation under reduced pressure. The infrared spectrum of each Schiff base is similar to that discussed above for H_2SAP, indicating their structure involves a —N=CH— linkage that is strongly hydrogen-bonded to the hydroxyl hydrogen atoms. It is reasonable to assume that the very intense bands at 1638 and 1635 cm^{-1} for H_2SAE and H_2SPA respectively have a strong ν(C=N) component because they shift to higher frequencies in dimethylsulfoxide, a solvent that is expected to weaken the intramolecular hydrogen bonds and thereby strengthen the —C=N— bond.

The single proton resonance in the n.m.r. spectra of H_2SAE and H_2SPA which occurs near 8.2 δ in $CDCl_3$ and 8.6 in DMSO-d_6 is assigned to the azomethine proton. The downfield shift in the more polar solvent is expected (10) and is of the same order of magnitude as the change in resonance position upon complexation to form titanium(IV) complexes. By integration of the phenyl resonance peaks before and after exchange with deuterium it was determined that the hydroxyl proton resonance signals are masked by the phenyl proton resonance peaks. This upfield shift of the hydroxyl proton chemical shifts for H_2SAE and H_2SPA as compared to H_2SAP can be attributed to the greater shielding of the hydroxyl protons by the more basic nitrogen atoms of the two compounds derived from aliphatic amines. In the mass spectra of H_2SAE and H_2SPA stepwise fragmentation of the aliphatic side-chain is quite evident and the parent ion is no longer the base peak as it was for H_2SAP. A metastable peak at *m/e* 85 for H_2SAE suggests the possibility that the two most intense peaks in the mass spectrum (*m/e* 106 and 133) may be related by the loss of HCN from the higher mass fragment. The spectral evidence thus supports formulation of both H_2SAE and H_2SPA in the (hydrogen-bonded) Schiff base forms shown in Fig. 1.

Although the structure of the mono-condensation product of acetylacetone with *o*-aminophenol is depicted in the Schiff base or enol-imine form in Fig. 1, H_2AAP might also be formulated in the keto-imine (**2***a*) or keto-amine (**2***b*) forms



2*a*



2*b*

shown above. Previous physico-chemical studies on related compounds (14, 15) gave no evidence for the keto-imine form, and in the case of condensation products of alkyl amines with acetylacetone the keto-amine form was predominant to the extent of >95 mol% in nonpolar solvents (15*a*). Our spectral evidence supports this formulation for H_2AAP, at least in $CDCl_3$ solution.

The n.m.r. spectrum of H_2AAP in $CDCl_3$ shows signals at 1.85 δ and 2.10 δ due to inequivalent methyl groups and a one-proton peak at 5.25 δ for the =CH— proton (Table 3). The broad signals at 8.10 δ and 12.08 δ are assigned to the N—H and O—H protons respectively because they disappear upon deuteration. In the halocarbon infrared spectrum (Table 2) the strong broad bands at *ca.* 3000 cm^{-1} may be assigned to the hydrogen-bonded N—H and O—H stretching frequencies expected for **2***b*. The absence of a free carbonyl stretching frequency and a methylene resonance peak in the n.m.r. spectrum clearly eliminates form **2***a* from consideration.

Significant changes occur in both the infrared and the n.m.r. spectrum of H_2AAP when DMSO-d_6 rather than $CDCl_3$ is the solvent. The strong bands attributable to ν(OH) and/or ν(NH) near 3500 and 3200 cm^{-1} might be interpreted as supporting either the keto-amine form **2***b* or the enol-imine form shown in Fig. 1. The more polar solvent might destroy any intramolecular hydrogen-bonding in particular, resulting in the observed increase in frequency. In DMSO-d_6, the methyl n.m.r. signal occurs as a singlet and the peak at 8.10 δ in $CDCl_3$ is now found at 9.90 δ; these changes may be followed by the addition of DMSO-d_6 dropwise to a $CDCl_3$ solution. Since one difference between form **2***b* and that shown in Fig. 1 for H_2AAP is a small displacement in the equilibrium position of the acidic proton, it is feasible that the signal at 9.90 δ in DMSO-d_6 is due to the hydroxyl proton (of the acetylacetone residue) of the enol-imine form. Support for this idea comes

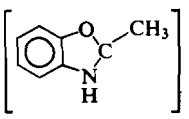
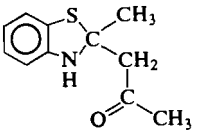
from the development of a yellow color as the proportion of the more polar solvent is increased (the yellow color is typical of the —N=C— chromophore in Schiff bases (8)) and the possibility, supported by molecular models, that conjugation in the enol-imine form would allow the methyl groups to become magnetically equivalent. Earlier workers had suggested the enol-imine form was of major importance in the condensation products of acetylacetone with substituted anilines by measuring their acid dissociation constants (15*b*). Nevertheless, it should be pointed out that methyl groups are known to become equivalent in some solutions even when the keto-amine form is predominant (15*a*) and also that the keto-amine form is found in the crystal structure of $[Cu(AAP)]_2$ (16). Molecular models do not allow us to favor one form over the other for H_2AAP but we interpret the above evidence as indicating a tautomeric equilibrium in DMSO-d_6 that shifts virtually completely to the keto-amine form in $CDCl_3$ solution and in the solid state (both are colorless).

The mass spectrum of H_2AAP provides no useful information in discriminating between the possible tautomeric forms. However, it is interesting that in addition to the parent ion peak at *m/e* 191 (77%), the mass spectrum shows the base peak at *m/e* 134. By analogy with the *m/e* peak observed for H_2SAP, this peak may be assigned to the fragment

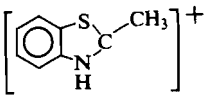


Although a dimeric nickel(II) chelate of H_2ASP has been reported (17) the isolation and characterization of the free ligand has not been discussed. Earlier work by one of us (13) and its extension in the present study indicates that the product obtained on the condensation of acetylacetone with *o*-aminothiophenol is not the Schiff base form shown in Fig. 1. Our results, summarized in Tables 2 and 3 and discussed below, indicate that H_2ASP is similar to salicylaldehyde-2-mercaptoanil (3) in having a heterocyclic benzothiazoline form, shown below. The sharpness of the bands in the solid state infrared spectrum attributable to ν(N—H) and ν(C=O) indicate that any intramolecular hydrogen-bonding must be quite weak.



The splitting of the ν(N—H) band in DMSO solution may arise from the competition of the solvent for the hydrogen-bond (14). The n.m.r. spectrum in $CDCl_3$ showed the N—H proton peak at 4.97 δ, identified by its ready exchange with D_2O. The methylene protons give rise to signals at 2.76, 3.05, 3.13, and 3.35 δ in $CDCl_3$ solution. The inequivalence of the methylene protons is due to their proximity to the asymmetric carbon atom of the heterocyclic ring. The observed coupling constant of 17.4 Hz is as expected for this type of AB system (18). In DMSO-d_6, however, the methylene peak becomes a singlet (two-proton) at 3.20 δ. Equivalence of the methylene protons may arise as a consequence of free rotation about the asymmetric carbon to methylene carbon bond by removal of the intramolecular hydrogen bond.

The mass spectrum of H_2ASP, which shows the parent peak at *m/e* 207, also shows a very strong peak at *m/e* 150 corresponding to the fragment



This peak is analogous to that found for H_2SSP at *m/e* 136 (3) and thus supports our formulation of H_2ASP as the benzothiazoline structure. Infrared and n.m.r. spectral evidence for tridentate ONO and ONS ligation of these dibasic tridentate Schiff base ligands in diamagnetic $Ti(SB)_2$ and $(RO)_2Ti(SB)$ complexes will be presented in a future paper.

This work was made possible by an operating grant from the National Research Council of Canada.

Received September 13, 1974

JERZY KRUSZEWSKI and TADEUSZ MAREK KRYGOWSKI. Can. J. Chem. **53**, 945 (1975).

A general rule of aromatic stability of non-alternant polycyclic conjugated hydrocarbons has been detailed and using aromatic stability indices, corroborated. The π-electron system is said to be relatively more stable if the difference between number of $4N + 3$-type rings minus number of $4N + 1$-type rings is 0 or divisible by 4. If not, the system is assumed to be relatively unstable. The presence of benzene rings does not affect the rule. A further extension for intramolecular H-bonded systems is also suggested. The rule suggested permits prediction of substituent effects on stability as well as the ionic form being most stable if the rule is not fulfilled.

JERZY KRUSZEWSKI et TADEUSZ MAREK KRYGOWSKI. Can. J. Chem. **53**, 945 (1975).

On a développé une règle générale permettant d'évaluer la stabilité aromatique des hydrocarbures polycycliques conjugués mais non alternants; cette règle a été corroborée en faisant appel aux indices de stabilité aromatique. On dit généralement que le système d'électrons π est relativement plus stable si la différence entre le nombre des cycles du type $4N + 3$ moins le nombre des cycles du type $4N + 1$ est 0 ou divisible par 4. Si tel n'est pas le cas, on fait l'hypothèse que le système est relativement instable. La présence de noyaux benzéniques n'affecte pas cette règle. On suggère aussi une autre extention pour les systèmes contenant des ponts hydrogène intramoléculaires. La règle suggérée permet aussi de prédire l'effet des substituants sur la stabilité de même que la forme ionique est la plus stable si la règle n'est pas suivie.

[Traduit par le journal]

The Hückel $4N + 2$ rule (1) is one of the best known and most useful rules for predicting the aromatic stability of monocyclic π-electron systems (2). An extension of this rule to polycyclic conjugated hydrocarbons has not been successfully developed. Some indirect applications, taking into account only peripheral π-bonds of these systems, led to rather good results (3), but most often in the case of alternant systems.

Recently a number of authors have reviewed the problem of aromatic stability (see *e.g.* refs. 4–8, 11–24, 35) and have suggested various quantitative measures of "aromaticity". The most advantageous seem to be those coming from quantum chemical calculations like the Hess–Schaad REPE (13) (Resonance Energy per Pi Electron) or other (7, 10, 11, 14) estimates of resonance energy. However, these calculations cannot always be carried out especially by those concerned with the practical aspects of organic chemistry such as synthesis; moreover, the quantum mechanical calculations are not always sufficiently reliable. It is clear that a simple rule as a qualitative guide to aromatic stability is needed in the area of non-alternant polycyclic conjugated hydrocarbon chemistry.

The main purpose of this paper is to present an attempt to extend the Hückel $4N + 2$ rule to polycyclic non-alternant conjugated hydrocarbons and to test it by using various indices of aromatic stability.

Indices of Aromatic Stability

The aromatic state of the molecule is most frequently associated with the following features (4, 5): (*i*) an increase of stability of the cyclic system in comparison with the polyene analogue (6, 7); (*ii*) an averaging of CC-bond lengths (8); (*iii*) an ability to sustain π-electron molecular ring current, when an external magnetic field is applied (4), and as the oldest criterion; (*iv*) a

TABLE 1. Normalized expressions for some indices of aromatic stability

Representative property	Method of estimation	Form of normalized index of aromatic stability A^{N*}
1. Empirical resonance energy E_R	Heats of atomization	$A^{N}_{pb,pe} = 0.167E_R(emp)_{pb,pe}$
2. Theoretical resonance energy E_R (ref. 7)	SCF–SPO (ref. 7)	$A^{N}_{pb,pe} = 4.552E_R(D\text{-}G)_{pb,pe}$
3. Theoretical resonance energy REPE (ref. 12)	HMO (ref. 13)	$A^{N}_{pb,pe} = 15.3848REPE$
4. Theoretical resonance energy SECC (ref. 9)	SCF–PPP (ref. 10)	$A^{N}_{pb} = 2.9265SECC$

*pe and pb stand for quantities calculated per one π-electron and per one π-electron bond of the π-electron system under consideration. This type of normalization permits comparison of the aromatic stability of various molecules when only one method is applied. Normalization in the scale (0, 1) for ethylene (Kekule structure of benzene) and benzene permit, to some extent, comparison of the various methods of estimation of aromatic stability indices.

tendency to react to form substitution products instead of addition, as is characteristic for the polyene analogues (9).

These quantitative rules permit classification of π-electron systems into aromatic, nonaromatic, and antiaromatic (5). According to Breslow (6) and Dewar (7) an aromatic system is a cyclic π-electron system which is more stable than its polyene analogue, whereas that which is less stable is said to be antiaromatic. Unfortunately, application of the above rules *i–iv* to a quantitative description is not too useful unless numerical measures of aromatic stability are introduced (7–17). On the other hand, the disadvantage of the varied approaches to this problem is that the studies of aromatic stability are not comparable to one another as a result of their different definitions. To rectify the situation a general definition of aromatic stability has been suggested (18) by which the stability index A is taken to be a linear function of some carefully chosen, representative property P (eq. 1)

$$A = a + bf(P) \qquad [1]$$

This index A is normalized so that $A = 1.0$ for the benzene molecule and $A = 0.0$ for its Kekule structure (with alternant double and single bonds) or for ethylene; a and b in eq. 1 are normalization factors, which are summarized for some popular indices in Table 1. The following rules have been suggested (16) as criteria of suitability in the selection of the more predictive aromatic stability indices: (*a*) a good aromatic stability index should be greatest for benzene and should decrease monotonically in the series of linear polyacenes, with increase in number of rings, and (*b*) a good index of aromatic stability should monotonically decrease for $(4N + 2)$-annulenes and monotonically increase for $(4N)$-annulenes, when the number of π-electrons increases.

Some indices of aromatic stability are discussed now in order to clarify further considerations. The most helpful index based on point (*i*) is the REPE as introduced by Hess and Schaad (13). Accordingly, the HMO-calculated resonance energy E_R divided by the number of π-electrons is used as a quantitative measure of aromatic stability. Hess and Schaad applied this quantity successfully to many molecules both carbo- and heterocyclic π-electron systems (13, 19–24). The main idea of their treatment of resonance energy is firstly to take into account non-zero contributions to the π-electron energy of the reference state with localized bonds coming from single C—C bonds in π-electron systems, and secondly to consider E_{CC}^{π} as a function of structural environment of this CC-bond. Owing to these improvements, the classical Hückel definition of resonance energy within the HMO approximation becomes as good as those calculated on the basis of more sophisticated quantum chemical methods (19). In Table 1, the expressions used to convert various resonance energy values, defined for various methods of calculation and estimation, into the normalized form described by eq. 1 are presented. Almost any of these indices fulfill at least one of the criteria of suitability (except SECC, which does not) but it seems to be most advantageous to use $REPE^N$-values, as these quantities are available for about 500 carbo- and heterocyclic π-electron systems. Moreover, $REPE^N$ is found analytically (16) to fulfill criterion (*b*) whereas criterion (*a*) is proved empirically for the first six members of the polyacene series (16).

Among the other aromatic stability indices resulting from the rules *i–iv*, that based on the criterion of bond length averaging is also quite helpful. The classical expression for this type of index comes from Julg and Francois (8) where

$$[2] \qquad A_j = 1 - \frac{225}{n}\sum_{r=1}^{n}\left(1 - \frac{d_r}{d}\right)^2$$

n is the number of peripheral CC-bonds, d_r is the length of a given CC-bond and d is an averaged value of CC-bond lengths calculated for all peripheral bonds. The disadvantage of this definition is, however, that only peripheral and only CC-bonds are taken into consideration and that the reference bond length to measure the degree of bond averaging is the average value of the bond length. As is known from the paper of Lo and Whitehead (10), for the polyacene series this quantity increases with increase in molecular size. A considerable improvement in predicting aromatic stability was achieved when the optimal value of the bond length d_{opt} was used as reference instead of the average bond length. These quantities can be easily calculated by use of the simple harmonic oscillator model (15–18).

$$[3] \qquad d_{opt} = \frac{s + wd}{1 + w}$$

where s and d in eq. 3 are bond lengths for "pure" single and double bonds, respectively (for CC, the bond lengths in ethane and ethylene have been chosen), whereas w is the force constant ratio for stretching modes of "pure" single and double bonds. Using experimental data for s, d, and w one obtains for a CC-bond the optimal length (15)

$$[4a] \qquad d_{opt}(CC) = 1.397 \text{ Å}$$

(*i.e.* just as in benzene), whereas for other bonds the magnitudes obtained are as follows (17)

$$[4b] \qquad d_{opt}(CN) = 1.338 \text{ Å}$$

$$[4c] \qquad d_{opt}(NN) = 1.308 \text{ Å}$$

$$[4d] \qquad d_{opt}(CO) = 1.300 \text{ Å}$$

Now, having a list of optimal bond lengths for the most popular bonds in π-electron systems, one can write a general expression for the index of aromatic stability called HOMAS (Harmonic Oscillator Model of Aromatic Stability),

$$[5] \quad \text{HOMAS} = 1 - \frac{98.89}{n}\left\{\sum_{r=1}^{n_{cc}}(d_{opt}^{cc} - d_r)^2 + \sum_{r=1}^{n_{cx}}(d_{opt}^{cx} - d_r)^2 + \sum_{r=1}^{n_{cy}}(d_{opt}^{cy} - d_r)^2 + \sum_{r=1}^{n_{xy}}(d_{opt}^{xy} - d_r)^2\right\}$$

where n_{cc}, n_{cx}, n_{cy}, n_{xy} are the numbers of CC, CX, CY, and XY bonds in the given π-electron system under consideration, and obviously $n_{cc} + n_{cx} + n_{cy} + n_{xy} = n =$ number of all π-electron bonds in the system. The HOMAS index fulfills both criteria of suitability on the basis of the experimental data taken from ref. 10, and by use of Dewar's (25) bond length calculated using the SCF method (26).

It should be mentioned, that detailed analysis (27) of various indices of aromaticity led to the statement that the most reliable index of aromatic stability to discuss molecular stability is REPE^N whereas HOMAS is most reliable when considering the local aromaticity of molecules. Thus, these two indices are used in the next section to present more clearly how the suggested rule-of-thumb operates in predicting the relative "aromaticity" of the systems under consideration. On applying the indices of aromatic stability one can find in a more qualitative form how this rule works and also find that non-alternant conjugated hydrocarbons form a wide spectrum ranging from aromatic to nonaromatic to antiaromatic. However, the rule suggested operates similarly to the original Hückel $4N + 2$ rule, *i.e.* it classifies π-systems into two classes: more stable, called frequently aromatic, and less stable identified also as nonaromatic and/or antiaromatic (5).

An Extension of the Hückel 4N + 2 Rule

The original Hückel $4N + 2$ rule states that a planar, monocyclic π-electron system containing $4N + 2$ π-electrons is more stable than the appropriate polyene analogue. These systems are often called aromatic (5) whereas those containing $4N$ π-electrons are less stable and are called antiaromatic. For annulenes this rule is completely equivalent to Craig's rules (28).

In polycyclic conjugated hydrocarbon molecules one can differentiate four types of rings: those containing $4N$, $4N + 1$, $4N + 2$, and $4N + 3$ centers giving π-electrons to the system. In general non-alternant systems chiefly contain

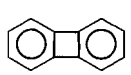
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

two types of odd rings: $4N + 1$, a five-membered ring; and $4N + 3$, a seven-membered ring. The number of rings of type $4N + 1$ is denoted by F and of type $4N + 3$ by S, respectively. Then, the proposed extension to the $4N + 2$ rule has the following form. Having defined a number R as follows

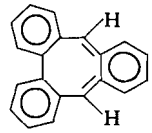
$$[6] \qquad R = S - F$$

then, if $R = 0$ or is divisible by 4, the non-alternant system is assumed to be relatively stable (aromatic), whereas if $R \neq 0$ and is not divisible by 4, it is assumed to be relatively less stable (non- or anti-aromatic). The presence of rings of $4N + 2$-type (*e.g.* benzene) does not influence the stability of the system. The presence of rings containing $4N$ π-centers does not influence stability of the system if these rings do not contain carbon atoms forming C—H bonds.

To clarify this last point let us consider two examples of alternant hydrocarbons. The biphenylene molecule **1** is stable and usually classified as aromatic and the $4N$ ring ($N = 1$) is supposed to be empty according to the terminology of Clar (38). On the other hand in bicyclo[6,2,0]decapentaene (**2**), the 8-member ring ($4N$ with $N = 2$) is not empty and does



1

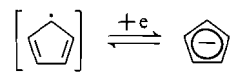


2

contain C—H bonds. Owing to its properties (35) this compound is not stable and can be classified as nonaromatic or perhaps even antiaromatic. In other words, the rule suggested may be used only for cases with empty $4N$ rings; otherwise these rings cause considerable decrease of stability.

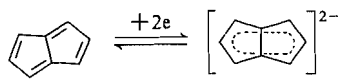
Additionally, the above presented extension of the Hückel-type rule cannot be applied to π-systems containing non-bonding orbitals.

The above mentioned rule can also be used to predict the most stable charged (ionic) form of a given non-alternant system. If $R = 1$ or -1 the system is more stable as a cation or anion, respectively. If $R = 2$ or -2 the di-cation or di-anion is the relatively most stable form respectively. To illustrate this idea let us consider the stability of cyclopentadiene radical **3** and its anion **4**.



3 **4**

From rule (6) one has $R = 0 - 1 = -1$ for the radical, and hence, the system should be unstable whereas its anion is assumed to be relatively stable; this is in agreement with experience (35) as well as with the Hückel $4N + 2$ rule. A more complex situation arises when a two-cyclic system such as pentalene (**5**) is considered. This molecule is known to be stable as the dianion (30) (**6**) or in a complex



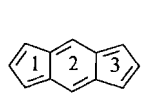
5 **6**

with Ni (31) in which it is also negatively charged. For pentalene (**5**) one has $R = 0 - 2 = -2$ and according to the rule proposed, the system is predicted to be unstable whereas its di-anion is supposed to be relatively stable. This agrees with experiment (35) and also with the low $REPE^N$ value for **5** (−0.275). Comparison of $REPE^N$ for **5** and **6** cannot be made, but for both of these species HOMAS-values have been calculated[2] as equal to 0.745 for **5** and 0.966 for **6**. Again the stability of the dianion relative to the parent molecule is evident.

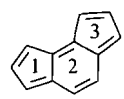
In the case when both neutral and ionic systems are taken into account the more general formula for R may be used[3]

$$[6a] \qquad R = S - F - \text{net charge}$$

In order to present rule [6] for uncharged polycyclic non-alternant systems let us consider the aromatic stability of s-**7** and as-**8** indacenes. In both cases $S = 0$, and $F = 2$ (rings Nos. 1, 3), hence $R = 0 + (-2) = -2$; thus, both these systems are said to be unstable. This



7



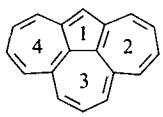
8

[2]Calculation of HOMAS values have been performed using bond lengths for **5** and **6** from Nakajima's SCF calculations (32).

[3]The authors are greatly indebted to the referee for this suggestion.

finding is in good agreement with predictions coming from the indices of aromatic stability; $REPE^N = 0.260$ and 0.362, respectively for **7** and **8**.

Another illustration of the rule is the azulene-[8, 8*a*, 1, 2-*de*]-heptalene molecule (**9**)



$F = 1$ (ring No. 1)
$S = 3$ (rings Nos. 2, 3, 4)

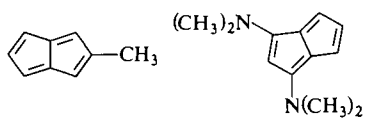
9

For this system $R = 3 - 1 = 2 \neq 0$ and thus, is not divisible by 4. This π-electron system is therefore assumed to be relatively unstable. This result is in excellent agreement with the $REPE^N$-prediction (0.138), as well as with magnetic and u.v.–spectral properties of this compound (29).

The rule presented above can be explained in a very qualitative fashion. When $R = 0$, it follows that $F = S$ and hence that each electron attracting ring of type $4N + 1$ may interact with the appropriate electron repelling ring of the $4N + 3$ type giving as a result a more convenient electron distribution in both rings. If $F \neq S$ such a pairing is not possible and the system cannot reach a more convenient charge distribution and thus, becomes less stable. This very simplified picture should be considered by use of more accurate quantum chemical calculations. To illustrate how rule [6] works values of R together with the appropriate $REPE^N$ values are given in Table 2 for representative compounds.

It is easily seen that compounds **9** and **10** do not fulfill the rule and that $REPE^N$ values are considerably lower than those for the remaining compounds **11** to **14**.

From rule [6] and its application described above one can also deduce that π-electron systems for which $R > 0$ or $R < 0$ should be stabilized by appropriate substituents: in the first case by electron-attracting substituents whereas in the second case by electron-withdrawing ones. To clarify this point let us consider penthalene **5** for which $R = -2$ and which is very unstable. Synthesis of 9-methyl-pentalene



15 **16**

(33) as well as 1,3-bis-[dimethylamino]-pentalene **14** (34) support these considerations, as both Me- and $N(Me)_2$-substituents are electron donating, and hence stabilize the π-electron system of pentalene.

TABLE 3. R-, REPE^N- and HOMAS-values for some fulvalene-type molecules

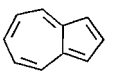
Molecule	R	REPE^N*	HOMAS†
Triafulvalene 	+2	−1.529	0.465
Calicene 	0	0.658	0.755
Fulvalene 	−2	−0.505	0.731
Sesquifulvalene 	6	0.336	0.852
Heptafulvalene 	+2	−0.214	0.782

*Calculated from the data taken from refs. 13, 19–24.
†Calculated according to eq. 5 using SCF–PPP bond lengths taken from ref. 32.

Other support of the rule proposed in this paper comes from the fulvalene-type compounds. Some data for these systems are collected in Table 3. In these cases rule [6] is still more clear as interactions between the various kinds of rings are "conducted" by only one double bond. Both calicene and sesquifulvalene are assumed to be much more stable than triafulvalene, fulvalene, and heptafulvalene on the basis of the values of R and also according to the relative values of REPE^N and HOMAS. The charge distribution in these compounds is in agreement with results from experimental measurements of dipole moments (39) as well as with those from theoretical calculations (39).

The extension of the Hückel $4N + 2$ rule presented above can also be successfully applied to the problems of stability of H-bond systems. As pointed out recently (36) stability of these systems is greater if the appropriate iso-π-electronic analogue is aromatic, and less if this analogue is antiaromatic. This analogy with hydrocarbons is as follows: aromatic and antiaromatic hydrocarbons can be easily transferred into iso-π- electronic quazi-aromatic and quaziantiaromatic systems,[4] if the fragment [C···C···C] is replaced by the iso-π-electronic = A···H—D group, where A is the proton acceptor and D—H the proton donor part of the molecule. Most frequently A is the oxygen atom in a carbonyl group or the nitrogen atom in an imine group whereas DH is usually an OH- or NH_2-group.

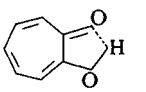
As an example let us consider azulene (**17**) and pentalene (**5**).



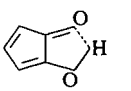
17
Azulene, $R = 1 - 1 = 0$
aromatic

5
Pentalene $R = 0 - 2 = -2$
antiaromatic

The respective quazi-aromatic and quazi-antiaromatic systems are as follows: tropolene (**18**) and (**19**).



18
Stable H-bond
stable molecule



19
Still not known

These examples illustrate rather clearly the advantage of extension of the rule presented to H-bond containing systems. The rule of increase in the stability if the iso-π-electronic analogue of H-bond system is aromatic and decrease if antiaromatic, has been proved (36) within the simple Dewar-PMO model (37).

Conclusions

It seems to be reasonable to conclude that the extension of the Hückel $4N + 2$ rule presented above gives a rather good prediction of aromatic stability. Also it seems to be advantageous to use normalized indices of aromatic stability to test this rule, as agreement between predictions of the rule and values of the aromatic stability indices is more distinct and more easily interpreted.

One of the authors (T.M.K.) would like to express his gratitude to Professors A. K. Colter and W. R. Fawcett for making possible his stay as visiting professor in 1974–1975 at the University of Guelph where this paper was written.

The Role of Hemicellulose in the Delignification of Wood[1]

A. J. KERR AND D. A. I. GORING

Pulp and Paper Research Institute of Canada and Department of Chemistry, McGill University, Montreal, Quebec H9R 3J9

Received November 4, 1974

A. J. KERR and D. A. I. GORING. Can. J. Chem. **53**, 952 (1975).

Hemicellulose was selectively removed from white birch by treatment with cold alkali. Untreated and alkali-treated samples were pulped to various stages of delignification by the acid chlorite process. The acid chlorite reagent was shown to be selective for lignin removal from both samples during the first 60% of delignification.

In alkali-treated white birch, the median pore width increased considerably as acid chlorite delignification proceeded. In contrast, in untreated white birch, this parameter remained relatively constant during the first 60% of delignification.

Alkali-treated white birch delignified at a much faster rate than untreated white birch. In addition, there was a topochemical preference for removal of lignin from the secondary wall of the fibers in the hemicellulose-deficient wood. Apparently, prior removal of hemicellulose caused larger pores to be produced in the fiber walls during pulping, thereby facilitating a more rapid removal of lignin.

A. J. KERR et D. A. I. GORING, Can. J. Chem. **53**, 952 (1975).

On a enlevé d'une façon sélective l'hémicellulose du bouleau blanc par le traitement avec de l'alcali à froid. On a transformé, divers échantillons de bois non traité et traité par les alcalis, en pâte à papier jusqu'à divers stages de délignification, utilisant le processus au chlorite en milieu acide. On a démontré que durant les premiers 60% de la délignification, ce réactif enlève sélectivement la lignine provenant des deux types d'échantillons.

Dans le cas du bouleau blanc traité par les alkalis, la largeur médiane des pores augmente considérablement à mesure que la délignification au chlorite se poursuit. Par opposition, lorsque le bouleau blanc n'est pas traité, ce paramètre demeure pratiquement constant durant les premiers 60% de la délignification.

Le bouleau blanc traité par les alcalis se délignifie à une vitesse beaucoup plus grande que le bouleau blanc non traité. De plus il y a une préférence topochimique pour l'enlèvement de la lignine provenant des cellules secondaires de la fibre dans le bois déficient en hémicellulose. Apparemment l'élimination préalable de l'hémicellulose amène la production de pores plus grandes dans la fibre au cours du processus de transformation en pâte facilitant ainsi l'élimination plus rapide de la lignine. [Traduit par le journal]

Introduction

Hemicelluloses are dissolved from wood along with lignin in the early stages of kraft and acid sulfite pulping but are retained during acid chlorite pulping (1). In all three pulping processes, the sizes of lignin macromolecules removed from the wood cells correspond closely to the sizes of the cell pores at various stages of delignification (2). In kraft and acid sulfite pulping, the pore sizes (3) and the sizes of the extracted lignin macromolecules (4, 5) increase during the pulping, whereas in acid chlorite pulping both remain almost constant throughout (2).

Thus, hemicellulose removal plays an important role in chemical pulping. When hemicelluloses are retained in the wood during pulping, the cell pores and the extracted lignin macromolecules remain small and delignification is characteristically slow. However, when hemicelluloses are removed in the early stages of pulping, the pores and lignin macromolecules increase in size and delignification is much more rapid.

To test whether the increase in pore size and the faster rate of delignification is really caused by hemicellulose removal, it would be instructive to compare a highly selective delignification of whole wood with an identical treatment of wood from which hemicelluloses have been removed. The hemicelluloses should be removed by a method that does not change the chemical properties of the lignin.

It is difficult to remove significant amounts of hemicelluloses from softwoods without chemical modification or simultaneous removal of lignin

(6). Hardwood hemicelluloses are more soluble, however, and it has been shown that large amounts can be removed from white birch by a cold alkali treatment (7). Accordingly, hemicelluloses were removed from white birch with alkali and the size of the pores in the cell wall and the rates of acid chlorite delignification of untreated and alkali-treated white birch were compared.

Dissolution of hemicellulose from wood also seems to affect the topochemistry of the delignification reaction. During kraft pulping of black spruce (8), there is an initial preferential removal of lignin from the tracheid secondary wall, followed at about 50% delignification by a rapid dissolution of lignin from the compound middle lamella. In contrast, during acid chlorite pulping of black spruce, lignin dissolution occurs at the same relative rate from the secondary wall and compound middle lamella regions of the tracheids (9). The topochemical preference for early lignin removal from the secondary wall, was found to be greatest in kraft pulping and decreased in the order

$$\underset{\text{kraft}}{\text{acid}} > \underset{\text{sulfite}}{\text{neutral}} > \underset{\text{sulfite}}{\text{acid}} > \text{chlorite}$$

In seeking an explanation for the above trend, Wood *et al.* (9) noted that the order of topochemical preference is the same as the order of the extent of hemicellulose dissolution from the wood in the early stages of pulping. Hemicellulose removal is rapid initially and occurs to decreasing degrees in kraft, acid sulfite, and neutral sulfite pulping (10, 11), whereas in acid chlorite pulping there is no hemicellulose removal until more than 60% of the lignin has been dissolved (1). This parallel behaviour led Wood *et al.* (9) to propose that the topochemical effect is associated with the removal of hemicelluloses from the wood.

The present investigation provided a good opportunity to test the hypothesis of Wood *et al.* (9). If the hypothesis is correct, the alkali-treated hemicellulose-deficient wood should show a topochemical effect whereas the untreated wood should not. Accordingly, the removal of lignin from the cell walls and middle lamellae by acid chlorite delignification of both the untreated and alkali-treated birch wood was analyzed by the techniques of ultraviolet microscopy recently developed in this laboratory (12).

Experimental

A sample of 20–40 mesh sawdust was prepared from the trunk of a 46 year old birch tree. Hemicelluloses were extracted by treatment with 3% NaOH for 24 h at 30 °C to produce a sample at 78% yield with 48.4% of hemicelluloses removed.

The acid chlorite pulping was carried out according to the procedure of Wise *et al.* (13) as adopted by Timell (14) and Ahlgren and Goring (1). The chemical charge was 0.3 g of sodium chlorite and 0.1 ml of acetic acid per gram of dry wood and the reaction temperature was 70 °C. A fresh charge of chemicals was added at hourly intervals without withdrawal of any liquor. The initial liquor-to-wood ratio was 13:1.

Tappi standard methods were employed for the determination of "Klason" lignin in the wood (15) and in the acid chlorite pulps (16). The acid-soluble lignin contents were calculated from the u.v. absorbances at 205 nm of the Klason hydrolysates, using an absorptivity of 113.4 $l\,g^{-1}\,cm^{-1}$. This figure was determined by Schöning and Johansson (17) on isolated samples of white birch acid-soluble lignin. Its application to acid chlorite pulps is justified as, for both spruce and beech, Campbell and McDonald (18) found little difference between the absorptivities of acid-soluble lignins prepared from wood and acid chlorite pulp. The total lignin content of each wood and pulp sample was obtained by adding the Klason and acid-soluble lignin contents.

The Tappi standard method was employed for the determination of α-cellulose (19). The hemicellulose content was calculated by difference, yield minus lignin and α-cellulose.

Cumulative volume distributions of pore size in water-swollen pulp samples were measured by the solute exclusion technique of Stone and Scallan (3, 20, 21). The technique measures the accessibility of the samples to a number of dissolved sugars and dextrans ranging in hydrodynamic diameter from 8 Å (glucose) to 560 Å (a dextran with a molecular weight of about two million). Further details of the method are given elsewhere (22).

For specimen preparation in u.v. microscopy, matchstick-size chips about 1 mm^2 × 5 mm were cut from the 44th annual ring of the tree and were alkali extracted and delignified together with the sawdust. At each stage of delignification, chips were solvent exchanged from the water-swollen state to absolute ethanol and then to propylene oxide prior to embedding in Epon 812. Ultrathin transverse sections (0.5–3.0 μm) were cut from the embedded samples with a diamond knife mounted on a Porter-Blum ultramicrotome and were photographed in a Leitz u.v. microscope. The microscopic methods used were essentially those of Scott *et al.* (12), although a lower wavelength of 240 nm was employed. Changes in the absorptivity of *in situ* lignin produced by the acid chlorite reagent were found to be smallest at this wavelength (22).

Results

Hemicellulose Removal

The results of the alkali treatment are summarized in Fig. 1. The data show that the alkali extracts mainly the hemicelluloses, although

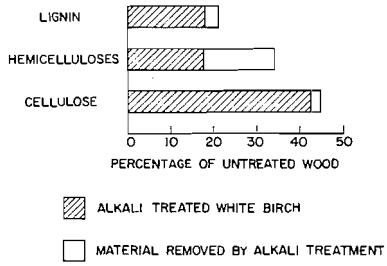

FIG. 1. Diagram illustrating the results of the cold alkali treatment of white birch.

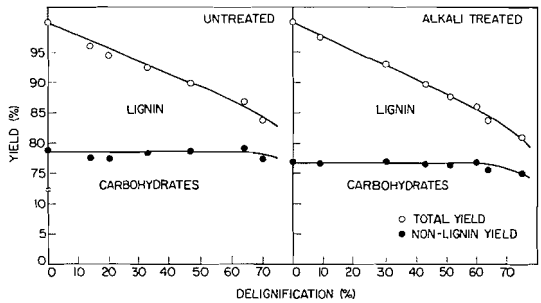

FIG. 2. Lignin and carbohydrate contents of untreated (left) and alkali-treated (right) white birch at various stages during acid chlorite delignification.

small amounts of lignin and cellulose are also removed from the wood.

To check if the lignin has been modified chemically during the alkali treatment, u.v. spectra were measured on fiber and vessel walls of untreated and alkali-treated white birch. For both morphological regions, the spectra of the untreated and alkali-treated wood were identical which indicated that the cold alkali caused no major chemical modification of the lignin.

Acid Chlorite Pulping

Yields, lignin contents, and percentage delignification are given in Table 1 and the selectivity of the delignification is illustrated in Fig. 2. The results show that only lignin is removed from both untreated and alkali-treated white birch during the first 60% of delignification. Ahlgren and Goring (1) previously observed similar behavior with black spruce. The present results, therefore, indicate that the acid chlorite reagent is selective for lignin removal not only from softwoods but also from hardwoods.

Pore Size

The cumulative pore size distribution curves for untreated and alkali-treated white birch at various stages of acid chlorite delignification are shown in Figs. 3 and 4, respectively. In all samples studied, the pore sizes were found to be distributed log normally to a good approximation (22). A similar distribution of pore sizes in various wood and pulp samples was reported previously by Ahlgren (23). The median pore

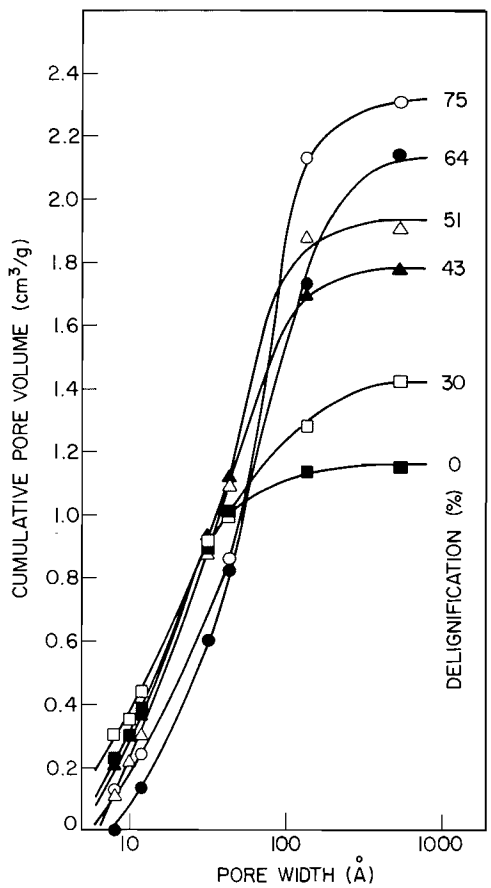

FIG. 4. Cumulative pore volume *vs.* pore width for alkali-treated white birch at various stages of acid chlorite delignification.

width, which is the pore width at one half the cell wall pore volume (or fiber saturation point) was conveniently determined for each sample from a straight line plot of the data on a log–probability diagram (22).

Median pore width is plotted against percentage delignification for both untreated and alkali-treated white birch in Fig. 5. The median pore width of alkali-treated white birch is 16.9 Å which is significantly higher than the value of 9.2 Å found for untreated white birch, indicating that hemicellulose removal causes the cell pores to increase in size.

The median pore width of untreated white birch remains fairly constant during the first 60% of acid chlorite delignification but increases slightly thereafter. A similar trend occurs in the median pore width of black spruce during acid chlorite delignification (2). In contrast to this, the median pore width of alkali-treated white birch increases throughout acid chlorite delignification (see Fig. 5). A rapid increase of the median pore width with the extent of lignin removal also occurs in kraft and acid sulfite pulping of black spruce (2, 3).

Rates of Pulping

Percentage delignification is plotted against pulping time in Fig. 6 for the acid chlorite pulps prepared from both untreated and alkali-treated white birch. It is clear that the rate of delignification of alkali-treated white birch is considerably greater than that of untreated white birch. Thus, the prior removal of hemicelluloses causes a marked increase in the rate of delignification.

This result is consistent with the findings of Procter (24) who compared the rate of delignification for western hemlock pretreated with H_2S with that for untreated wood. The H_2S pretreatment protected the hemicelluloses from dissolution during the kraft process and at the

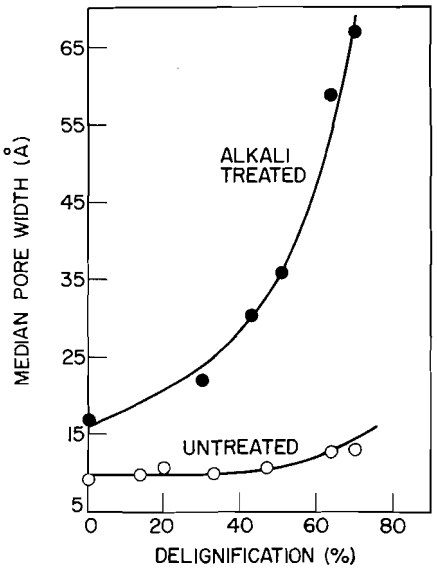

FIG. 5. Median pore width of untreated and alkali-treated white birch at various stages of acid chlorite delignification.

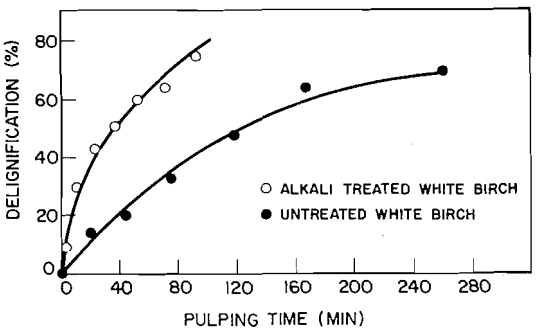

FIG. 6. Percentage delignification *vs.* pulping time for the acid chlorite pulps.

same time caused a reduction in the rate of delignification.

Topochemical Effects

The progress of acid chlorite delignification of untreated and alkali-treated white birch is illustrated for the fibers in the u.v. micrographs displayed in Fig. 7 and for the vessels in Fig. 8. As in previous studies of kraft, sulfite, and acid chlorite pulping (8, 9), no significant gradient of lignin concentration across the secondary walls of the cells can be detected at any stage of delignification.

The u.v. absorbances for the cell walls and middle lamellae of the fibers and vessels at

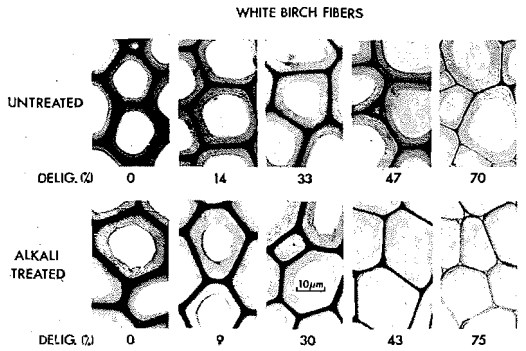

FIG. 7. Photomicrographs at 240 nm showing the progressive acid chlorite delignification of fibers in untreated and alkali-treated white birch. The photomicrographs are all of 1.0 μ sections.

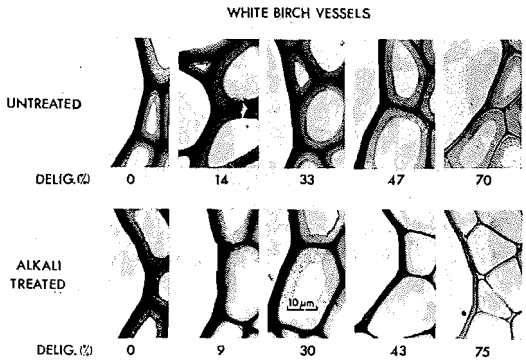

FIG. 8. Photomicrographs at 240 nm showing delignification of the vessels. The photomicrographs are all of 1.0 μ sections.

various stages of delignification are given in Table 2. The absorbances were measured at a wavelength of 240 nm and were corrected for changes in the dimensions of the morphological regions and the absorbtivity of the lignin which were produced by the chlorite treatment. Details of the correction procedures are given elsewhere (22).

The percentage of lignin removed from any morphological region of a sample at a particular stage of delignification, R_i, is given by

$$[1] \qquad R_i = 100\ A_i/A_0$$

in which A_i is the absorbance at any particular degree of delignification and A_0 is the absorbance in the original sample. The percentage of lignin removed from the secondary wall and compound middle lamella regions of the fibers and vessels

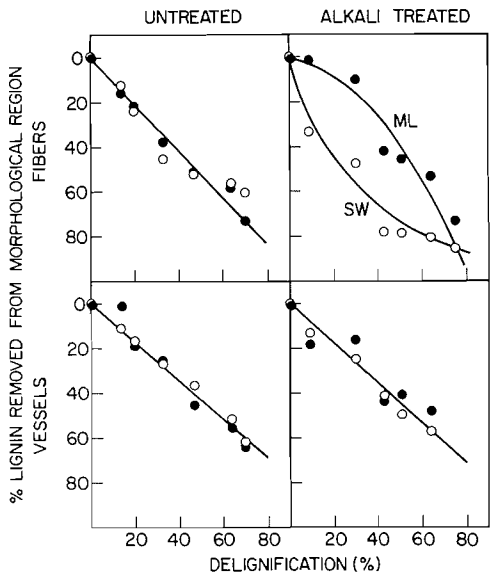

FIG. 9. Topochemistry of acid chlorite delignification of fibers and vessels of untreated and alkali-treated white birch: percentage of lignin removed from the middle lamella (ML, filled circles) and the secondary wall (SW, empty circles) *vs.* percentage of lignin removed from the whole sample (*i.e.* % delignification).

of untreated and alkali-treated white birch were calculated from the corrected u.v. absorbances using eq. 1 and are plotted against the percentage of lignin removed from the whole wood (*i.e.* percentage delignification) in Fig. 9.

No topochemical effect is apparent in either the fibers or vessels of untreated white birch. A marked topochemical effect occurs in the fibers of alkali-treated, hemicellulose-deficient white birch but not in the vessels. The results therefore indicate that hemicellulose removal produces a topochemical effect in the chlorite pulping of birch fibers.

Discussion

The results confirm that the removal of hemicellulose from birch wood (*i*) increases the average pore size in the cell wall during all stages of acid chlorite delignification; (*ii*) increases the overall rate of delignification; and (*iii*) increases the rate of delignification of the fiber wall with respect to that of the middle lamella.

What physicochemical mechanisms of delignification are indicated by the above trends?

Lignin in wood appears to be a polymeric material made up of rather short chains of phenyl propane units cross linked in a variety of ways to give a network structure. Between one third and one quarter of the lignin is found in the middle lamella region in a fairly pure form. Most of the remainder is in the secondary wall associated with the cellulose and hemicellulose moieties (25, 26).

When wood is pulped two things must happen. Firstly, the lignin network must be broken down to give macromolecules which are soluble in the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

pulping solvent. Secondly, the soluble lignin must diffuse out of the secondary wall into the lumen cavity. If the pores in the cell wall are small, then the lignin network must be broken down into small fragments to allow diffusion through the wall to the lumen. This will require sustained chemical action on the lignin and will tend to result in a slow rate of delignification. If the pore size is large, the chemical breakdown of the lignin network need not be excessive because large lignin macromolecules will be capable of diffusing through the wall to the lumen.

It should be noted that, regardless of diffusion constraints, there will be a limit to the size of lignin macromolecules which will be soluble in the pulping solvent. However, both kraft and acid sulfite pulping of isolated lignins were found to produce soluble lignins with molecular weights in excess of 10^6 (27, 28) which is considerably greater than the molecular weights of soluble lignins obtained by the usual methods of delignifying wood (4, 5). Thus the constraint to lignin removal from wood does not seem to be the solubility of the isolated lignin macromolecules but rather the porous structure of the cell wall.

What the present results confirm is that the hemicellulose governs the pore size in the cell wall and thus the rate of delignification. Removal of hemicellulose increases the pore size and therefore also increases the rate of delignification. Retention of hemicellulose imposes a constraint on the diffusion of soluble lignin molecules out of the wall and therefore slows up the delignification process.

The explanation of the enhancement of the topochemical effect by the removal of hemicellulose is not as straightforward. An obvious suggestion is that the S1 layer in the secondary wall acts as a diffusion barrier to the escape of lignin dissolved from the middle lamella. However a recent study of the kraft pulping of pressure refined spruce wood showed that even when the middle lamella lignin was exposed directly to the kraft pulping liquor, it dissolved more slowly than the secondary wall lignin (29). Thus it seems that the rate of dissolution of the lignin in the middle lamella is an intrinsic property of this morphological region and is not affected by the presence of the S1 layer.

Just as the dissolution of lignin from the cell wall is governed by the porous structure of the cell wall, the dissolution of the lignin in the middle lamella will be governed by the porous structure of the middle lamella. The true middle lamella is almost pure lignin and hence will contain less hemicellulose than the cell wall. Thus hemicellulose removal is likely to have a greater effect on the pore size of the cell wall than on the pore size of the middle lamella. This may be the cause of the enhancement of the topochemical effect produced by hemicellulose removal. It is also possible that the chemical structure (*e.g.* degree of cross linking) of middle lamella lignin differs from that of cell wall lignin and that such structural differences contribute to the topochemical effect.

It is interesting to observe in Fig. 9 that the vessels showed no topochemical effect even after removal of hemicellulose. The cold alkali extraction used in the present investigation would be expected to remove only the xylan (30). Perhaps the vessels are rich in glucomannan which is not extracted by cold alkali and the presence of which would be expected to reduce the topochemical preference for lignin removal from the cell walls.

Finally it should be noted that only one type of delignification (acid chlorite) and one type of wood (white birch) have been covered by the present investigation. However, previous results for the kraft, acid sulfite, neutral sulfite (8), and acid chlorite (2, 9) pulping of spruce wood and for the kraft and neutral sulfite pulping of birch wood (31) are all consistent with the results described herein. Therefore it seems likely that the trends noted and the principles elucidated in the present paper are of general applicability to the delignification of wood.

Studies Related to Antitumor Antibiotics. Part III.[1] Syntheses of 1,2,3,4,5,6-Hexahydro-2,3-benzazocin-5-ones as Possible Intermediates in the Biosynthesis of Mitomycins

J. WILLIAM LOWN AND TSUNEO ITOH[2]

Department of Chemistry, University of Alberta, Edmonton, Alberta T6G 2E1

Received August 29, 1974

J. WILLIAM LOWN and TSUNEO ITOH. Can. J. Chem. **53**, 960 (1975).

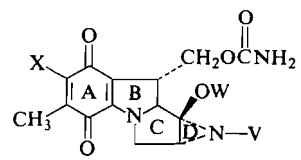
The synthesis of 8-methoxy-9-methyl-*N*-*p*-toluenesulfonyl-1,2,3,4,5,6-hexahydro-2,3-benzazocin-5-one (**23**) and its conversion via transannular interaction to the 2,3-dihydro-1*H*-pyrrolo-[1,2-*a*]indole ABC parent ring system of the antitumor antibiotic mitomycin C is described. The possible implication of this result in the biosynthesis of the mitosanes and the connection with the structurally and pharmacologically related pyrrolizidine alkaloids is discussed.

J. WILLIAM LOWN et TSUNEO ITOH. Can J. Chem. **53**, 960 (1975).

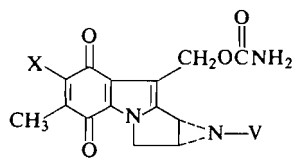
On décrit la synthèse de la méthoxy-8 méthyl-9 *N*-*p*-toluènesulfonylhexahydro-1,2,3,4,5,6 benzazocin-2,3 one-5 (**23**) et sa conversion, par l'intermédiaire d'une interaction transannulaire, en dihydro-2,3 1*H*-pyrrolo[1,2-*a*]indole qui comporte le système cyclique ABC du composé antitumoral et antibiotique mitomycin C. On discute de l'implication possible de ces résultats dans la biosynthèse des mitosanes et la relation avec les alkaloides pyrrolizidine qui leur sont reliés tant au point de vue de la structure que de la pharmacologie.

[Traduit par le journal]

The mitosane class of potent antitumor antibiotics (**1**), which contains several unique structural features including an aziridine group, has attracted considerable attention from synthetic chemists and pharmacologists (1, 2).



1



2

In part I of this series we explored some of the characteristics of the chiral aziridine moiety as they relate to the key alkylation role in the cytotoxic action of mitomycin C by irreversible cross linking of the complementary strands of DNA (3). Part II dealt with the spectroscopic evidence from c.m.r. and p.m.r. on the conjugative stabilization and conformation of the antibiotic (4). In the present paper we describe the synthesis of some 1,2,3,4,5,6-hexahydro-2,3-benzazocin-5-ones which pertain to a possible biosynthetic pathway to mitomycin C.

In early work on the biosynthesis the structural similarity of the mitosanes to indole-related compounds suggested a biosynthetic relationship of the antibiotic to tryptophan. However, several compounds structurally or biosynthetically related to the indole nucleus of mitomycin C failed to induce any increase in antibiotic yield (5, 6*a*). Neither labelled tyrosine nor tryptophan contributes label to mitomycin. Recent work by Hornemann and co-workers (6) employing radioactive labelling with ^{14}C and ^{15}N has established the involvement of D-glucose in the construction of ring A and of D-glucosamine in the formation of rings C and D (6). L-Methionine is implicated in the methylation of sites 7 and 9a (6*a*, 7) whereas citrulline is an intermediate in the insertion of the carbamoyl side chain of mitomycin (6*c*).

The introduction of the 9a bridgehead oxygen function in **1** poses considerable problems both biosynthetically and in attempted total synthesis.

[1]For part II see ref. 4.

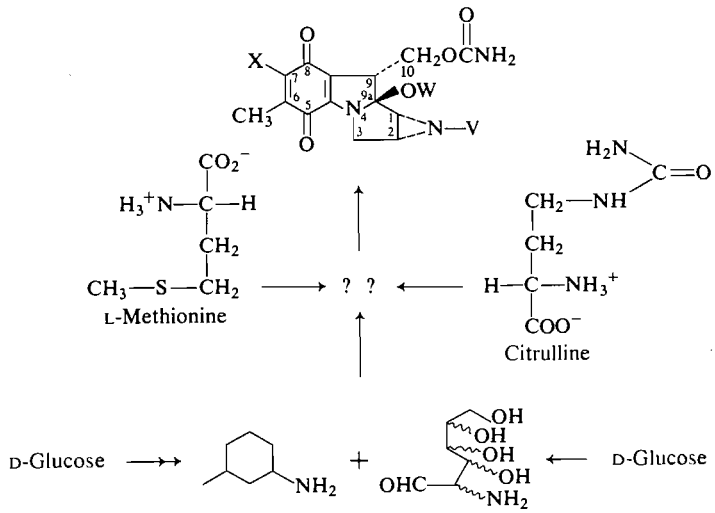
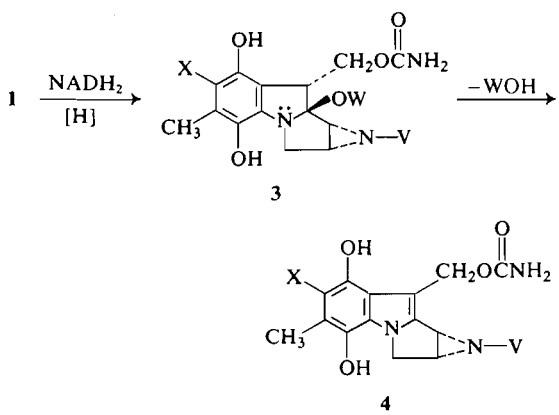


SCHEME 1

Previous synthetic explorations directed toward mitomycin have avoided the problem of introducing the 9a oxygen function and concentrated on the simpler aziridinomitosene structure, **2** (1*e*). The removal of the 9a group following enzymatic reduction of the mitosanes has been suggested as the primary mode of activation of mitomycin (2), *i.e.*



The reduced form of the aziridinomitosene (**4**) is then considered "activated", *i.e.*, capable of rapid bifunctional alkylation and hence covalent cross linking of DNA (2).

A possible clue to the origin of the 9a moiety and the biosynthetic formation of rings B and C in the mitosanes is provided by the pyrrolizidine alkaloids which they resemble in structure and function (Scheme 2) (2, 8–10). The comparison is even more striking between the pyrrole analogs of the alkaloids, *e.g.*, dehydrolasiocarpine and the activated form of mitomycin (8*b*). Compounds **6** and **4** are both bifunctional alkylating agents with similarly located linkage points. There is evidence that lasiocarpine brings about inhibition of DNA-dependent RNA-polymerase in rat liver suggesting covalent cross linking analogous to that of mitomycin C (11). Some pyrrolizidine alkaloids have mutagenic and tumor-inhibitory properties or cause chromosome breakage, and these conform to structure **6** (8*b*). The alkylating ability is for example associated with the possibility of alkyl–oxygen cleavage of the allylic ester grouping, analogous to the alkylating ability enhanced by indolic-conjugation found in **4**.

The relevant portion of the biosynthesis of the pyrrolizidine alkaloids (which proceeds from the amino acid ornithine) may be represented schematically (see Scheme 3) (12–16). An analogy for the transannular interaction envisaged in mitomycin biosynthesis is provided by the metabolic conversion of otosenine by rat liver microsomes to a pyrrole derivative considered to be dehydroretronecine (17).

Comparison of Schemes 1 and 3 suggests the intermediate formation of a hexahydrobenzazocinone followed by an analogous transannular interaction as the origin of the 9a oxygen function (see Scheme 4). Transannular interactions in cyclic aminoketones of eight or more atoms

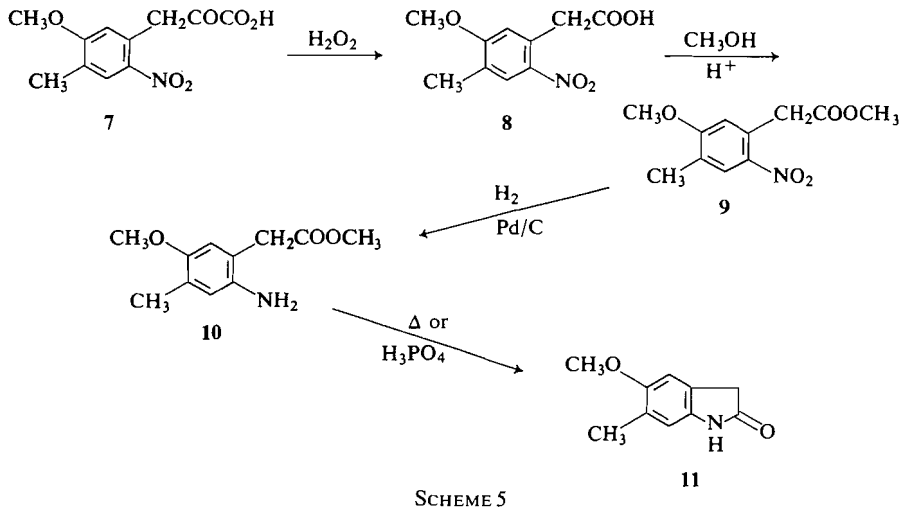

SCHEME 5

have been established by Leonard and coworkers (18*a–c*) and Johnson *et al.* (18*d*).

We considered that a comparable demonstration of the formation of rings A, B, and C from a suitably substituted hexahydrobenzazocinone would be valuable in pointing to its possible intermediacy in the biosynthesis. The interaction envisaged is different in type from that demonstrated by Leonard in that an aromatic amine is involved. However, successful ring closure of a benzazocinone might clarify the sequence of events in Scheme 4., *i.e.*, aromatization prior to transannular interaction or vice versa.

In our initial approach 5-methoxy-4-methyl-2-nitrophenylpyruvic acid (**7**) (19) was oxidatively decarbonylated to 5-methoxy-4-methyl-2-nitrophenylacetic acid (**8**) in 80% yield. Esterification of the latter followed by catalytic hydrogenation of the nitro group over palladium at atmospheric pressure afforded methyl 5-methoxy-4-methyl-2-amino-phenyl acetate (**10**) in 92.5% yield (Scheme 5).

The amino ester **10** was extremely labile and consequently, unless precautions were taken to cool the mixture during the catalytic hydrogenation, spontaneous ring closure to the indolinone **11** took place readily. This reaction

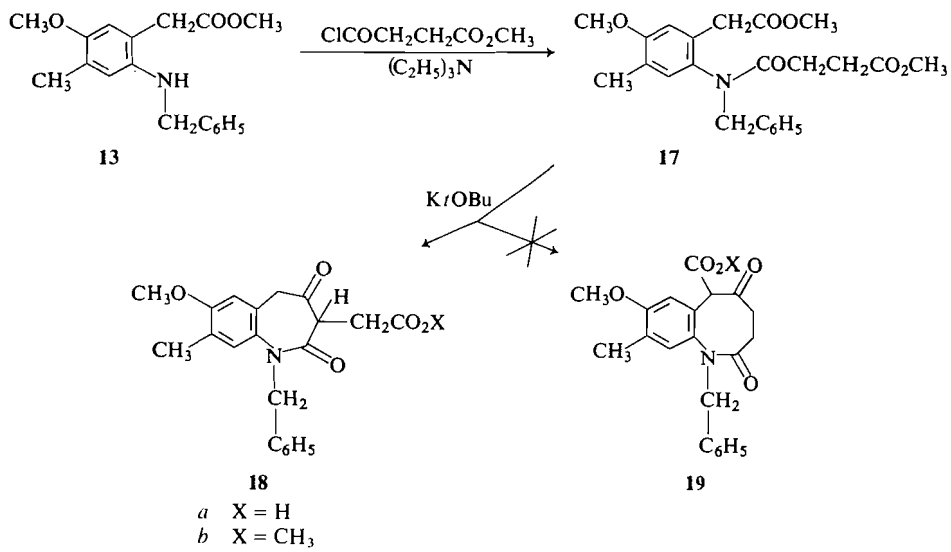


SCHEME 7

could also be accomplished quantitatively by brief warming of **10** with polyphosphoric acid. In view of its reactivity compound **10** was immediately converted into the anil **12**. Subsequent selective reduction of the imine function in the presence of the ester proved difficult; however the final method selected using sodium cyanoborohydride afforded the desired *N*-benzyl ester **13**. Careful chromatographic separation showed **13** to be accompanied by the two oxindoles **15** and **16**. The latter presumably arises from a Strecker-type addition (20) of the elements of hydrogen cyanide to **12** to form **14** which is unisolated but which would undergo rapid condensation to form **16**. Again these conclusions receive confirmation by the independent cyclization of **13** to **15** by warming with polyphosphoric acid (see Scheme 6).

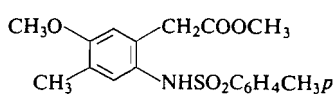
Compound **13** was acylated in 72.5% yield with 3-carbomethoxypropionyl chloride to give methyl 5-methoxy-5-methyl-2-[*N*-benzyl(3′-carbomethoxypropionamido)]phenyl acetate (**17**).

Base catalyzed cyclizations to form medium sized rings are well known to give variable yields (21). In this case treatment of **17** with potassium *tert*-butoxide gave the tetrahydrobenzazepin-2,4-dione-3-acetic acid derivative **18***a* in 63% yield by a Stobbe reaction, instead of the desired hexahydrobenzazocin-2,4-dione **19** (see Scheme 7).

Evidence in support of structure **18***a* rests on the molecular composition and on the n.m.r. spectrum which shows an ABC pattern to be expected for $COCH{\cdot}CH_2CO_2H$ and not an A_2B_2 pattern which is seen in **17** and which would be expected for structure **19**. The i.r. spectrum shows absorption for seven-membered ketone at 1720 and normal acid at 1700 cm^{-1} and no evidence of chelation which would be expected for **19**. Compound **19** would also be expected to undergo ready decarboxylation.

Treatment of **18***a* with diazomethane in ether gave the ester **18***b*, the n.m.r. spectrum of which is similar to **18***a* and whose i.r. shows normal ketone and ester absorption at 1725 and 1715 cm^{-1}, respectively. In order to prevent the Stobbe reaction and favor Dieckmann condensation, an alternative approach was made via an intermediate which is incapable of forming a carbanion β to the nitrogen.

Formation of the *N*-*p*-toluenesulfonyl derivative from compound **10** proceeded smoothly in 72% yield. The product compound **20** has the distinct advantage over derivatives of the type **13** in that direct *N*-alkylation is possible via the *N*-sulfonyl anion of **20**. For example treatment of **20** with ethyl γ-bromobutyrate in the presence of potassium carbonate gave the *N*-alkylated product **22** (see Scheme 8). Treatment of **22**



20

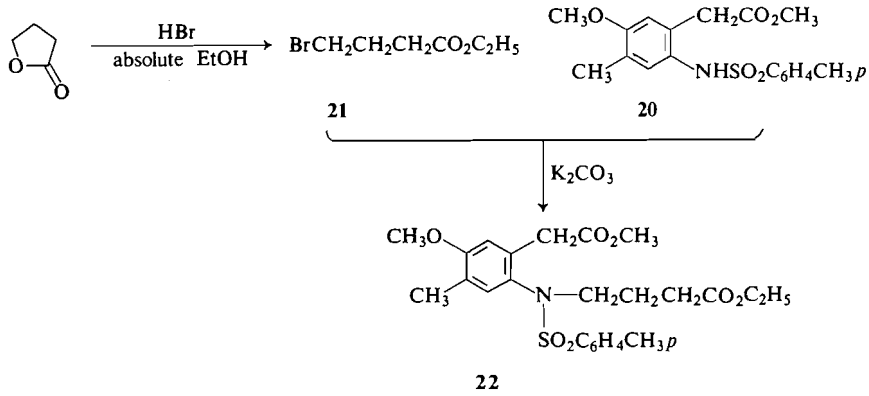

SCHEME 8

with potassium *tert*-butoxide in dry toluene afforded the desired 1,2,3,4,5,6-hexahydro-1,2-benzazocin-5-one **23** accompanied by small quantities of the analogs **24** and **25**. Compounds **24** and **25** were isolable as crystalline solids and characterized separately whereas **23** was obtained as an oil slightly contaminated with traces of **24** and **25** (Scheme 9). The spectral properties of all three compounds were consistent with their assigned structures (see Experimental).

Reductive cleavage of the N—S bond was accomplished with sodium in liquid ammonia; (this reagent has been used previously for the reductive cleavage of sulfur containing bonds (22)). The initial transannulated product **26** which was not isolated, eliminated water under these conditions to form the known compound **27** (19) in a reaction which is analogous to the conversion of **3** to **4** (Scheme 10). Compound **25** was accompanied by small amounts of **28** and **29** formed from the analogous ring closure of **24** and **25**, respectively. Compound **29** was isolated as a crystalline solid which could be characterized. The structure of **29** is given by its molecular composition and the n.m.r. spectrum which shows an ethyl ester and absence of vinylic absorptions and three groups of methylene absorptions (see Experimental).

The above experiments with model systems provide a chemical basis for the suggested intermediacy of a hexahydrobenzazacinone and its transannular interaction to form rings A, B, and C of mitomycin C during its biosynthesis. This sequence of reactions also may provide an alternative approach to the presently unsolved problem of a total synthesis of mitomycin C.

Experimental

Melting points were determined on a Fisher-Johns apparatus and are uncorrected. The i.r. spectra were recorded on a Perkin-Elmer model 421 spectrophotometer and only the principal, sharply defined peaks are reported. The n.m.r. spectra were recorded on Varian A-60 and A-100 analytical spectrometers. The spectra were measured on approximately 10–15% (w/v) solutions in $CDCl_3$, with tetramethylsilane as a standard. Line

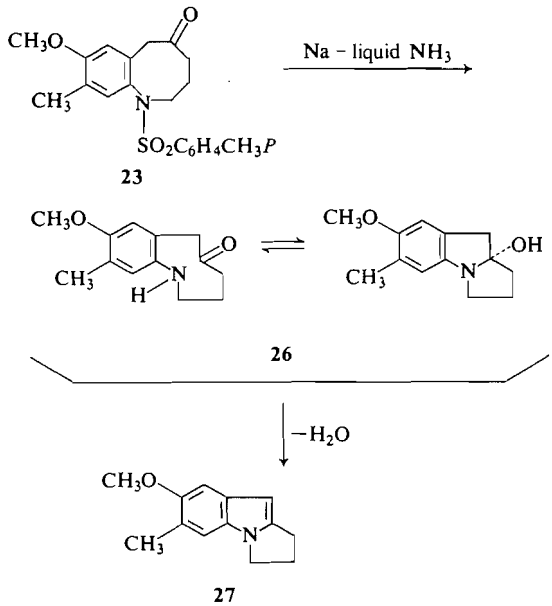
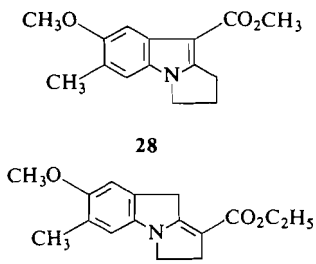


SCHEME 10



positions are reported in p.p.m. from the reference. Mass spectra were determined on an Associated Electrical Industries MS-9 double focusing high resolution mass spectrometer. The ionization energy, in general, was 70 eV. Peak measurements were made by comparison with perfluorotributylamine at a resolving power of 15000. Kieselgel DF-5 (Camag, Switzerland) and Eastman Kodak precoated sheets were used for thin layer chromatography. Microanalyses were carried out by Mrs. D. Mahlow of this department.

5-Methoxy-4-methyl-2-nitrophenylacetic Acid (8)

5-Methoxy-4-methyl-2-nitrophenylpyruvic acid 7 (25.321 g, 0.100 mol) (19) was dissolved in a solution of 40.0 g (1.0 mol) of sodium hydroxide in 130 ml of water. Ice (50 g) was added, followed by the slow addition of a solution of 27 g of 30% hydrogen peroxide in 75 ml of water with continuous stirring. The solution was set aside at room temperature for 5 h then cautiously acidified with concentrated hydrochloric acid. The resulting solid was collected and purified by recrystallization from methanol affording 18.0 g (80% yield) of compound **8**, m.p. 154°.

Anal. Calcd. for $C_{10}H_{11}O_5N$ (mol. wt. 225.0637): C, 53.33: H, 4.92; N, 6.22. Found (mass spectrum, 225.0630): C, 53.08; H, 4.80; N, 6.15.

The n.m.r. spectrum δ TMS ($CDCl_3$): 2.27 (s, 3H, CH_3), 3.97 (s, 3H, OCH_3), 4.07, (s, 2H, $—CH_2CO_2$), 6.71, 8.08 (s, 1H each, aryl). The i.r. ν_{max} ($CHCl_3$): 1710 (acid CO), 3500 cm^{-1} (acid OH).

Methyl 5-Methoxy-4-methyl-2-nitrophenylacetate (9)

A solution of 5.0 g (22 mmol) of 2-nitrophenylacetic acid **8** and 0.5 ml of concentrated sulfuric acid in 100 ml of methanol was heated under reflux for 3 h. The reaction mixture was concentrated *in vacuo* and the resulting solid collected and purified by recrystallization from methanol to give 4.0 g (76.5% yield) of compound **9** as white needles, m.p. 123–124°.

Anal. Calcd. for $C_{11}H_{13}O_5N$ (mol. wt. 239.0799): C, 55.23; H, 5.48; N, 5.86. Found (mass spectrum 239.0798): C, 55.12; H, 5.64; N, 5.78.

The n.m.r. spectrum δ TMS ($CDCl_3$): 2.26 (s, 3H, CH_3), 3.75 (s, 3H, $—CO_2CH_3$), 3.96 (s, 3H, OCH_3), 4.05 (s, 2H, $—CH_2CO_2R$), 6.75, 8.07 (s, 1H, each, aryl).

Methyl 5-Methoxy-4-methyl-2-aminophenylacetate (10)

A mixture of 7.17 g (30 mmol) of methyl 5-methoxy-4-methyl-2-nitrophenylacetate (**9**) and 1.0 g of 5% palladium-on-charcoal in 160 ml of ethyl acetate was subjected to hydrogenation at atmospheric pressure. The theoretical volume of hydrogen was absorbed in 6 h. Filtration and concentration of the solution gave a pale yellow oil which solidified on cooling. Crystallization from methanol gave 5.8 g (92.5% yield) of compound **10**, m.p. 158–160°. This material was extremely unstable and was immediately converted into the anil.

Anil of Methyl 5-Methoxy-4-methyl-2-aminophenylacetate (12)

To a solution of 4.180 g (20 mmol) of methyl 5-methoxy-4-methyl-2-aminophenylacetate **10** and 500 mg of *p*-toluenesulfonic acid in 30 ml of dry benzene was added a solution of 2.12 g (20 mmol) of benzaldehyde in 10 ml of dry benzene and the solution was stirred at ambient temperature overnight. The filtered solution was concentrated *in vacuo* to give 5.02 g (84.5% yield) of the Schiff base **12** as a yellow solid which was purified by recrystallization from methanol, m.p. 98°.

Anal. Calcd. for $C_{18}H_{19}O_3N$ (mol. wt. 297.1359): C, 72.70; H, 6.44; N, 4.71. Found (mass spectrum 297.1365): C, 72.54; H, 6.56; N, 4.68.

The n.m.r. spectrum δ TMS ($CDCl_3$): 2.22 (s, 3H, CH_3), 3.62 (s, 3H, $—CO_2CH_3$), 3.86 (s, 5H, CH_2CO_2R and OCH_3), 6.78, 6.96 (1H each, s, ring protons), 7.35–7.97 (aryl protons), 8.26 (s, 1H, $—N=CH—C_6H_5$). The i.r. spectrum ν_{max} ($CHCl_3$): 1730 cm^{-1} (C=O).

Methyl 2-Benzylamino-4-methyl-5-methoxyphenylacetate (13)

To a solution of 0.9 g of the Schiff base **12** in 5 ml of ethyl acetate was added a solution of 120 mg of sodium cyanoborohydride (23) in 3 ml of methanol, and the mixture stirred at room temperature for 6 h. The p*H*

of the solution was adjusted to 7.0 periodically by the addition of hydrochloric acid, the solution was filtered and concentrated *in vacuo*. The residual oil was treated with water and methylene chloride and the aqueous layer extracted several times with methylene chloride. Concentration of the dried extract gave 0.780 g of compound **13** as an oil.

The n.m.r. spectrum δ TMS ($CDCl_3$): 2.12 (s, 3H, CH_3), 3.54 (s, 2H, $CH_2CO_2CH_3$), 3.63 (s, 3H, CO_2CH_3), 3.73 (s, 3H, OCH_3), 4.86 (s, 2H, CH_2Ph), 6.54, 6.84, (s, 1H each, ring protons), 7.04–7.65 (m, 5H, aryl protons). The i.r. spectrum (film): 1695 (C=O), 3350 (NH) cm^{-1}.

Mol. Wt. Calcd. for $C_{18}H_{21}NO_3$: 299. Found (mass spectrum): 299.

Further elution with benzene gave 180 mg of 5-methoxy-6-methyl-*N*-1′-cyanobenzyl-2-indolinone (**16**) as a white crystalline solid, m.p. 152–153° (methanol).

Anal. Calcd. for $C_{18}H_{16}O_2N_2$ (mol. wt. 292.1212): C, 73.95; H, 5.52; N, 9.58. Found (mass spectrum 292.1213): C, 73.91; H, 5.48; N, 9.39.

The n.m.r. spectrum δ TMS ($CDCl_3$): 2.16 (s, 3H, CH_3), 3.76 (s, 2H, —CH_2); 3.89 (s, 3H, OCH_3), 6.74, (s, 1H, 4 or 7 proton), 7.06 (s, 2H, 4 or 7 proton and —N—C*H*(CN)Ph), 7.66 (s, 5H, phenyl group). Further elution with benzene gave *N*-benzyl-5-methyl-2-oxindole (**15**). The spectral and physical data on this compound were identical with those described in its synthesis below.

*5-Methoxy-6-methyl-2-indolinone (**11**)*

A mixture of 1.5 g (7.1 mmol) of the amine **10** and some polyphosphoric acid (prepared from 7.5 ml of orthophosphoric acid and 7.5 g of phosphorous pentoxide) was heated at 130–140° with stirring for 15 min. After cooling, the mixture was treated with excess of cold water and the precipitated product was collected and purified by recrystallization from methanol affording 950 mg (74.5% yield) of compound **11**, m.p. 162–164°.

Anal. Calcd. for $C_{10}H_{11}O_2N$ (mol. wt. 177.0790): C, 67.78; H, 6.26; N, 7.91. Found (mass spectrum, 177.0794): C, 67.69; H, 6.11; N, 8.02.

The n.m.r. spectrum δ TMS ($CDCl_3$): 2.23 (s, 3H, CH_3), 3.55 (s, 2H, CH_2), 3.87 (s, 3H, OCH_3), 6.87 (s, 1H), and 7.13 (s, 1H, aryl protons). The i.r. spectrum ν_{max} (film): 1655 (amide C=O), 3430 cm^{-1} (br, NH).

*N-Benzyl-5-methoxy-6-methyl-2-indolinone (**15**)*

A solution of 0.7 g (2.3 mmol) of methyl 2-benzylamino-4-methyl-5-methoxyphenyl acetate **13** in 15 ml of dry ether in a pressure bottle was warmed at 40–50° with stirring for 16 h. The solvent was removed *in vacuo* and crystallization of the residue from methanol gave 400 mg (65% yield) of *N*-benzyl-5-methoxy-5-methyl-2-indolinone (**15**), m.p. 103–104°.

Anal. Calcd. for $C_{17}H_{17}O_2N$ (mol. wt. 267.1259): C, 76.38; H, 6.41; N, 5.24. Found (mass spectrum 267.1256): C, 76.21; H, 6.51; N, 5.18.

The n.m.r. spectrum δ TMS ($CDCl_3$): 2.20 (s, 3H, CH_3), 3.67 (s, 2H, CH_2), 3.87 (s, 3H, OCH_3), 5.02 (s, 2H, NCH_2Ph), 6.78 (s, 1H), and 7.02 (s, 1H, oxindole ring protons), 7.47 (s, 5H, aryl). The i.r. spectrum ν_{max} ($CHCl_3$): 1675–1690 cm^{-1} (C=O).

*Methyl 2-[N-Benzyl-N-(3-carbomethoxypropionyl)]-amino-4-methyl-5-methoxyphenylacetate (**17**)*

To a solution of 5.3 g (17.4 mmol) of compound **13** and 1.92 g (18 mmol) of trimethylamine in 30 ml of dry benzene was added a solution of 2.61 g (17.4 mmol) of 3-carbomethoxypropionyl chloride in 10 ml of dry benzene. The mixture was stirred for 1 h then washed with water (3 × 20 ml) and the organic layer dried ($MgSO_4$). Evaporation of the solvent gave a yellow oil which was purified by chromatography on silica gel. Elution with 4.0 g (72.5% yield) of compound **17** as a yellow oil.

Anal. Calcd. for $C_{23}H_{27}O_6N$ (mol. wt. 413.1838): C, 66.81; H, 6.58; N, 3.39. Found (mass spectrum 413.1842): C, 66.61; H, 6.62; N, 3.35.

The n.m.r. spectrum δ TMS ($CDCl_3$): 2.14 (s, 3H, CH_3), 2.10–2.83 (br m, 4H, —$CH_2CH_2CO_2R$), 3.50 s, 2H, —CH_2CO_2R), 3.80 (s, 6H, CO_2CH_3), 3.96 (s, 3H, CH_3O), ABq centered at 4.52 and 5.35, J = 14 Hz (2H, —CH_2Ph), 6.79 (s, 1H), and 6.98 (s, 1H, aryl ring protons). The i.r. spectrum ν_{max} ($CDCl_3$): 1645 (amide CO), 1725 cm^{-1} (ester CO).

*1-Benzyl-7-methoxy-8-methyl-2,3,4,5-tetrahydrobenzazepin-2,4-dione-3-acetic Acid (**18a**)*

A mixture of 0.78 g (20 mmol) of potassium and 4.5 g (62 mmol) of *tert*-butyl alcohol was allowed to react in 60 ml of freshly distilled toluene in a three-necked flask purged with nitrogen. The mixture was stirred and heated below the boiling point of the alcohol–toluene azeotrope until all of the potassium had reacted. The excess of alcohol was then removed by distillation. Dry toluene was introduced to bring the total volume in the flask to 150 ml and 3.10 g (7.5 mmol) of the diester **17** in 60 ml of dry toluene was added dropwise over a period of 12 h to the reaction mixture with vigorous stirring and refluxing. After cooling, the resulting mixture was neutralized with dilute hydrochloric acid and the organic layer dried ($MgSO_4$). Removal of the solvent *in vacuo* from the filtered solution afforded 1.79 g (63% yield) of 1-benzyl-7-methoxy-8-methyl-2,3,4,5-tetrahydrobenzazepin-2,4-dione-3-acetic acid (**18a**) as an oil.

Anal. Calcd. for $C_{21}H_{21}NO_5$ (mol. wt. 367): C, 69.27; H, 6.08; N, 3.67. Found (mass spectrum 367): C, 69.53; H, 6.21; N, 3.44.

The n.m.r. spectrum δ TMS ($CDCl_3$): 2.22 (s, 3H, CH_3), 2.92–4.20 (3H, ABC COC*H*—CH_2CO_2H), 3.80 (s, 3H, CO_2CH_3), 3.90 (s, 2H, CH_2CO), ABq centered at 4.78 and 5.40, J = 14.5 Hz (CH_2Ph), 6.53 (s, 1H, ring proton), 6.9–7.5 (m, 6H, phenyl and ring protons).

The i.r. ν_{max} (KBr disc): 1645 ( ), 1700 (CO_2H), 1720 (seven-membered ring C=O) cm^{-1}.

*Methyl 1-Benzyl-7-methoxy-8-methyl-2,3,4,5-tetrahydrobenzazepin-2,4-dione-3-acetate (**18b**)*

To a solution of 1.00 g (2.7 mmol) of the tetrahydrobenzazepindioneacetic acid in 45 ml of dry ether was added by distillation, an ethereal solution of diazomethane (prepared from 1.5 g of nitrosomethylurea and 20% sodium hydroxide solution). The mixture was stirred at ambient temperature for 18 h and taken to dryness to give an oil which was purified by chromatog-

For personal use only.

raphy on neutral alumina giving 1.02 g (97% yield) of methyl 1-benzyl-7-methoxy-8-methyl-2,3,4,5-tetrahydrobenzazepin-2,4-dione-3-acetate (**18***b*).

Anal. Calcd. for $C_{22}H_{23}NO_5$ (mol. wt. 381.1576); C, 69.27; H, 6.08; N, 6.37. Found (mass spectrum, 381.1565): C, 69.53; H, 6.21; N, 3.42.

The n.m.r. spectrum δ TMS ($CDCl_3$): 2.20 (s, 3H, CH_3), 2.85–4.25 (ABC, 3H, $COCHCH_2CO_2H$), 3.64 (3,3H, CO_2CH_3), 3.78 (s, 3H, OCH_3), 3.89 (d, 2H, $—CH_2CO$), AB quartet centered at 4.72 and 5.44, J = 14.5 Hz, $—NHCH_2Ph$, 6.52 and 7.25 (s, 1H each, ring protons), 7.20 (s, 5H, phenyl group). The i.r. ν_{max} ($CHCl_3$): 1645 ($\diagdown$N—CO$\diagup$); 1715 (CO_2CH_3) and 1725 (seven-membered ketone) cm^{-1}.

*Methyl 5-Methoxy-4-methyl-2-toluenesulfonamidophenylacetate (**20**)*

To a solution of 4.18 g (20 mmol) of the *o*-aminophenylacetate **10** in 45 ml of dry pyridine was added 3.80 g (20 mmol) of *p*-toluenesulfonyl chloride. The solution was stirred for 3 h at room temperature then the pyridine was allowed to evaporate in the fume hood. The residue was shaken with chloroform and dilute hydrochloric acid and the organic layer was dried ($MgSO_4$). Concentration of the solution afforded 5.2 g (71.5% yield) of compound **20** as white crystals, m.p. 109–110°.

Anal. Calcd. for $C_{18}H_{21}O_5NS$ (mol. wt. 363.1140): C, 59.49; H, 5.83; N, 3.86. Found (mass spectrum 363.1136): C, 59.38; H, 5.85; N, 3.71.

The n.m.r. spectrum δ TMS ($CDCl_3$): 2.10, (s, 3H, CH_3), 2.38 (s, 3H, CH_3), 3.20 (s, 2H, $—CH_2CO_2R$), 3.65 (s, 3H, CO_2CH_3), 3.77 (s, 3H, OCH_3), 6.53 (s, 1H), 7.01 (s, 1H, phenyl ring protons), AB quartet centered at 7.20 and 7.58, J = 8.0 Hz (4H, toluenesulfonyl ring protons). The i.r. spectrum ν_{max} ($CHCl_3$): 1715 (ester C=O), 3350 cm^{-1} (sulfonamide NH).

*Methyl 5-Methoxy-4-methyl-2-[N-(3-carbomethoxypropyl)]-p-toluenesulfonamidophenyl Acetate (**22**)*

A mixture of 3.63 g (10 mmol) of methyl 5-methoxy-4-methyl-2-*p*-toluenesulfonamidophenylacetate **20**, 3.66 g (20 mmol) of ethyl γ-bromobutyrate, and 4.95 g (36 mmol) of anhydrous potassium carbonate in 60 ml of dry acetone was heated under reflux with stirring for 16 h. The reaction mixture was filtered and concentrated *in vacuo* and the oil was subjected to chromatography. Removal of the solvent afforded 4.5 g (94% yield) of **22** as an oil.

Anal. Calcd. for $C_{24}H_{31}O_7N^{32}S$ (mol. wt. 477.1822): C, 60.36; H, 6.54; N, 2.93. Found (mass spectrum 477.1833): C, 60.18; H, 6.63; N, 3.15.

The n.m.r. spectrum δ TMS ($CDCl_3$): 1.29 (t, 3H, $CH_3CH_2—$), 2.03 (s, 3H, $CH_3—$), 1.61–2.52 (m, 4H, $CH_3CH_2CH_2—$), 3.31–3.56 (m, 2H, CH_2CO_2R); 3.74 (s, 3H, CO_2CH_3), 3.87 (s, 3H, $CH_3O—$), 3.90–4.45 (m, 2H, $—CH_2CH_3$), 6.30 (s, 1H), 6.87 (s, 1H, phenyl ring protons), AB quartet centered at 7.28 and 7.55, J = 8.5 Hz (4H, aryl absorption). The i.r. spectrum ν_{max} ($CHCl_3$): 1725 cm^{-1} (C=O).

*Dieckmann Condensation of Methyl 5-Methoxy-4-methyl-2-[N-(3-carbomethoxypropyl)]-p-toluenesulfonamidophenylacetate (**22**)*

A solution of 4.77 g (10 mmol) of diester **22** in 60 ml of dry toluene was added over a period of 3 h with vigorous stirring and continuous refluxing under nitrogen to a suspension of 5.75 g (0.05 mol) of potassium *tert*-butoxide in 150 ml of dry toluene. The solution was concentrated to about half the volume *in vacuo* and after cooling the filtered solution was washed with (*i*) dilute hydrochloric acid (3 × 25 ml) and (*ii*) water (2 × 15 ml) then dried ($MgSO_4$). Removal of the solvent and chromatography of the residual oil on silica gel with chloroform as eluant gave (*a*) an oil and (*b*) crystals.

Fraction *a* the oil was 8-methoxy-9-methyl-*N*-*p*-toluenesulfonyl-1,2,3,4,5,6-hexahydro-2,3-benzazocin-5-one (**23**) 0.92 g (24.6% yield).

Anal. Calcd. for $C_{20}H_{23}NO_4S$ (mol. wt. 373.1348): N, 3.14. Found (mass spectrum 373.1337): N, 3.63.

The n.m.r. spectrum δ TMS ($CDCl_3$): 0.9–2.5 (m, 6H, CH_2), 2.02 (s, 3H, CH_3), 2.43 (s, 3H, CH_3), 3.30–4.2 (m, 2H, $ArCH_2CO$), 3.82 (s, 3H, OCH_3), 6.48, 6.66 (s, 1H, each phenyl ring proton), AB quartet centered at 7.30 and 7.67, J = 8.0 Hz (4H, $—C_6H_4CH_3$). The i.r. spectrum ν_{max} ($CHCl_3$): 1705 cm^{-1} (C=O).

Fraction *b* provided sufficient material (65 mg), m.p. 110–112° for an n.m.r. spectrum confirming the presence of both **24** and **25**.

The n.m.r. spectrum δ TMS ($CDCl_3$): 1.23 (t, 3H, $CH_3CH_2—$), 1.74–2.10 (br, *ca.* 6H, methylenes), 2.12, 2.14, (s, 3H each, ring CH_3), 3.66 (s, 3H, CO_2CH_3 of **24**), 3.79, 3.81 (s, 3H each, ring OCH_3), 4.02–4.38 (q, 2H, CH_2CH_3 for **25**), 6.70 and 6.76 (s, 1H each, phenyl ring protons), AB quartets centered at 7.18 and 7.56, J = 9.0 Hz (4H each, $SO_2C_6H_4CH_3$).

The i.r. spectrum ν_{max} (KBr disc): 1733 (eight-membered ring ketone), 1715 cm^{-1} (ester C=O). Fractional recrystallization of *b* from ether afforded pure methyl 8-methoxy-9-methyl-*N*-*p*-toluenesulfonyl-1,2,3,4,5,6-hexahydro-2,3-benzazocin-5-one-2-carboxylate (**24**, 11 mg), m.p. 173°.

Anal. Calcd. for $C_{22}H_{25}O_6N^{32}S$ (mol. wt. 431.1403): C, 61.24; H, 5.84; N, 3.25. Found (mass spectrum, 431.1391): C, 61.45; H, 5.98; N, 2.89.

Recrystallization of the residue from the mother liquor gave ethyl 8-methoxy-9-methyl-*N*-*p*-toluenesulfonyl-1,2,3,4,5,6-hexahydro-1,2-benzazocin-4-carboxylate (**25**, 8 mg), m.p. 121°.

Mol. Wt. Calcd. for $C_{23}H_{27}O_6N^{32}S$: 445.1566. Found (mass spectrum): 445.1559.

*Reductive Cleavage of the N-Tosylhexahydrobenzazocinone **23** and Ring Closure to 2,3-Dihydro-7-methoxy-6-methyl-1H-pyrrolo[1,2-a]indole (**27**)*

To a stirred suspension of 873 mg (2.72 mmol) of the hexahydrobenzazocinone **23** in *ca.* 30 ml of liquid ammonia was added 230 mg (10 mgatom) of sodium and after 10 min a blue color developed. Ammonium chloride was added when the solution became colorless, then the ammonia was allowed to evaporate and methanol then water and chloroform were added. The organic layer was washed with water and dried ($MgSO_4$).

Evaporation of the solvent afforded an oil which was chromatographed on silica gel. Elution with chloroform gave 230 mg (45% yield) of 2,3-dihydro-7-methoxy-6-methyl-1*H*-pyrrolo[1,2-*a*]indole (**27**), m.p. 112–113°, as needles crystallized from *n*-hexane. The m.p. was depressed (by admixture with traces of the corresponding pyrrolo[1,2-*a*]indoles **28** and **29**) compared with literature (19) value of 116–118°. The m.p. was undepressed upon admixture with an authentic sample of **27**.

Mol. Wt. Calcd. for $C_{13}H_{15}NO$: 201.1154. Found (mass spectrum): 201.1145.

The n.m.r. spectrum δ TMS ($CDCl_3$): 2.32 (s, 3H, 6-CH_3), 2.45–2.71 (m, 2H, —$CH_2CH_2CH_2$—), 2.97 (t, 2H, —$NCH_2CH_2CH_2$—), 3.86 (s, 3H, OCH_3), 3.96 (t, 2H, —N—CH_2—CH_2CH_2—), 6.04 (s, 1H, indole H), 6.96 (s, 1H), 6.98 (s, 1H, 5 and 9 ring protons).

Fractional crystallization of the mother liquor allowed the isolation of pure **29**, m.p. 118.9°.

Mol. Wt. Calcd. for $C_{16}H_{19}NO_3$: 273.1372. Found (mass spectrum): 273.1366.

The n.m.r. spectrum δ TMS ($CDCl_3$): 1.38 (t, 3H, CH_2CH_3), 2.21 (s, 3H, CH_3), 2.57 (quintet, 2H, —CH_2—), 3.19 (t, 2H, —CH_2—), 3.89 (s, 3H, OCH_3), 3.95 (q, 2H, —CH_2), 6.94, 7.55 (s, 1H each ring protons). The n.m.r. spectrum shows in addition an absorption due to **28**, a band 3.86 (s, 3H, —CO_2CH_3). The i.r. spectrum ν_{max} ($CHCl_3$): 1683 cm^{-1} (N—C=C—C=O). The mother liquor showed the presence of compound **28**.

Mol. Wt. Calcd. for $C_{15}H_{17}NO_3$: 259.1208. Found (mass spectrum): 259.1213.

This research was supported by grants to J. W. Lown from the National Research Council of Canada and from the National Cancer Institute of Canada and by the Chemistry Department, University of Alberta. We thank Dr. A. Hogg and Mr. R. Swindlehurst for the mass and n.m.r. spectra. We wish to thank Dr. M. J. Weiss, Lederle Laboratories, Pearl River, N.Y. for supplying an authentic sample of **27** for comparison.

Information on the Proton Affinity and Protolysis of Propane from Measurement of the Ion Cluster Equilibrium: $C_2H_5^+ + CH_4 = C_3H_9^+$

KENZO HIRAOKA AND PAUL KEBARLE

Chemistry Department, University of Alberta, Edmonton, Alberta T6G 2E1

Received December 23, 1974

KENZO HIRAOKA and PAUL KEBARLE. Can. J. Chem. **53**, 970 (1975).

The clustering equilibrium $C_2H_5^+ + CH_4 = C_3H_9^+$ [1] was measured between -60 and -110 °C in 0.5–8 Torr methane. A van't Hoff plot of K_1 leads to $\Delta H_1^0 = -6.6$ kcal/mol, $\Delta S_1^0 = -23.4$ e.u. (std. st. 1 atm), and ΔG_1^0 (300 K) $\approx +0.4$ kcal/mol. The $C_3H_9^+$ formed by [1] is probably the most stable structure of protonated propane which corresponds to a three center bond of the proton with the electrons of a C—C bond. This structure is also similar to an ethyl ion forming a three center bond with C—H in CH_4 *i.e.* the product of reaction 1. With this assumption $\Delta H_f(C_3H_9^+) = 194.5$ kcal/mol and p.a.$(C_3H_8) = 147$ kcal/mol are obtained. The pathways for the decomposition of $C_3H_9^+$ (protolysis of propane) are examined. The reaction to $C_3H_7^+ + H_2$ is shown to involve a 9 kcal/mol energy barrier compared to the decomposition to CH_4 and $C_2H_5^+$. The latter is favored at low temperature and low excitation of $C_3H_9^+$.

KENZO HIRAOKA et PAUL KEBARLE. Can. J. Chem. **53**, 970 (1975).

On a mesuré l'équilibre d'agrégation du $C_2H_5^+ + CH_4 = C_3H_9^+$ (1) à des températures allant de -60 à -110 °C et à des pressions de méthane allant de 0.5 à 8 Torr. Une courbe de van't Hoff de K_1 conduit à une valeur de $\Delta H_1^0 = -6.6$ kcal/mol, $\Delta S_1^0 = -23.4$ e.u. (std. st. 1 atm) et ΔG_1^0 (300 K) $\approx +0.4$ kcal/mol. Le $C_3H_9^+$ formé par la réaction 1 est probablement la structure la plus stable pour le propane protoné; elle correspond à un lien à trois centres impliquant le proton avec les électrons du lien C—C. Cette structure est aussi semblable à celle d'un ion éthyle formant un lien à trois centres avec le C—H dans le CH_4 *i.e.* le produit de la réaction 1. En faisant cette hypothèse on obtient $\Delta H_f(C_3H_9^+) = 194.5$ kcal/mol et p.a. de $(C_3H_8) = 147$ kcal/mol. On examine les différents chemins de décomposition du $C_3H_9^+$ (protolyse du propane). On démontre que la réaction de $C_3H_7^+ + H_2$ implique une barrière d'énergie de 9 kcal/mol si on la compare à la décomposition en CH_4 et $C_2H_5^+$. Cette dernière réaction est favorisée à basse température et pour des faibles excitations de $C_3H_9^+$.

[Traduit par le journal]

The proton affinities of alkanes apart from CH_4 have not been measured experimentally. CH_5^+ and $C_2H_7^+$ have been observed in many mass spectrometric ion molecule reaction studies. The higher compounds $C_nH_{2n+3}^+$ have been observed only rarely (1–4) and under conditions where their structure could not be deduced with certainty.

In an investigation of the ion molecule reactions in methane at pressures 0.5–8 Torr we observed the reaction equilibrium 1 in the tem-

[1] $$C_2H_5^+ + 2CH_4 = C_3H_9^+ + CH_4$$

perature range -60 to -110 °C. The next step in the clustering equilibrium could be observed at lower temperatures.

[2] $$C_3H_9^+ + 2CH_4 = C_4H_{13}^+ + CH_4$$

The measurements were obtained with a pulsed electron beam high ion source pressure mass spectrometer. The clustering reactions of the other major ion CH_5^+ and details on the experimental conditions and apparatus are given in a separate publication (5).

Van't Hoff plots for the equilibria 1 and 2 are shown in Fig. 1. The straight line obtained for [1] leads to $\Delta H_1^0 = -6.6$ kcal/mol and $\Delta S_1^0 = -23.4$ e.u. (standard state 1 atm). The error in the determinations is estimated to be about 10 to 20%. The temperature range for reaction 2 is too narrow to permit reliable determination of ΔH_2^0 and ΔS_2^0. It is evident from Fig. 1 that the second clustering interaction is much weaker. Figure 1 includes also results from an earlier measurement of equilibrium 1 by Field

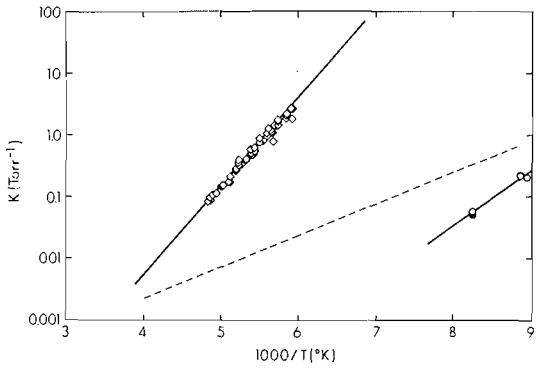

FIG. 1. Van't Hoff plots of equilibrium constant for clustering reactions: □, $C_2H_5^+ + CH_4 = C_3H_9^+$; ○, $C_3H_9^+ + CH_4 = C_4H_{13}^+$; results of Field and Beggs (6) for reaction 1 given by dashed line.

and Beggs (6). These results are in disagreement with the present work. Similar disagreements in other measurements were ascribed to inadequacies of the continuous ionization apparatus used by Field (5, 7).

Lathan *et al.* (8) have made theoretical studies of protonated ethane and found that structure **2** is some 11 kcal/mol more stable than structure **1** (Fig. 2). By analogy we assume that the lowest energy structure of protonated propane is **4**, which corresponds to a proton interacting with the σ electrons of one C—C bond. This structure is also akin to an ethyl ion, in its classical structure, interacting with the electrons of one C—H bond of methane. This suggests strongly that the $C_3H_9^+$ formed by [1] has this structure.

Using $\Delta H_f(C_2H_5^+) = 219$ kcal/mol (9) and the present $\Delta H_1 = -6.6$ kcal/mol one obtains $\Delta H_f(C_3H_9^+[1]) = 194.5$ kcal/mol and p.a.$(C_3H_8) = 146.8$ kcal/mol. This proton affinity appears of the right magnitude since

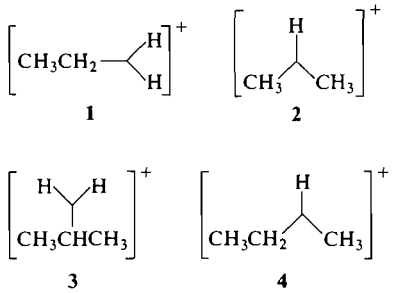

FIG. 2. Isomeric structures for protonated ethane and propane. **1** and **2** structures for ethane due to Pople and co-workers (8).

p.a.$(CH_4) = 127$ kcal/mol (10). Unfortunately the exact p.a.(C_2H_6) is not known but the limits $136 <$ p.a.$(C_2H_6) < 159$ have been set by Bohme *et al.* (11). The present p.a.$(C_3H_8) = 147$ kcal/mol predicts a difference of 20 kcal/mol between p.a.(C_3H_8) and p.a.(CH_4). Assuming that some 70% of this difference should appear between CH_4 and C_2H_6 one obtains a tentative p.a.$(C_2H_6) \approx 141$ kcal/mol.

It is interesting to note that the dissociation of $C_3H_9^+$ via [4] is more exothermic by 5 kcal ($\Delta H_f(s\text{-}C_3H_7^+) = 192$ kcal/mol (9)) than the dissociation by the reverse of reaction 1. Using the present $\Delta H_f(C_3H_9^+[1]) = 194.5$ kcal/mol one finds that [4] is exothermic by 2.5 kcal.

[4] (most stable) $C_3H_9^+ = s\text{-}C_3H_7^+ + H_2$

[-1] $= C_2H_5^+ + CH_4$

Obviously an energy barrier must exist for reaction 4. We assume that [4] must proceed via the isopropyl ion – H_2 type structure **3** shown in Fig. 2. The energy barrier between **3** and **4** may be expected to be similar but smaller than that between **1** and **2**. In agreement with this expectation it was observed (12) that at temperatures above −60 °C, $C_2H_5^+$ and CH_4 do not react according to [1] but according to [5]. An investigation (12) of the temperature dependence of [5] led to the determination of the activation energy $E_5 = 2.5$ kcal. This result predicts a difference of $E_5 + (-\Delta H_1) = 9.1$ kcal/mol between structures **3** and **4** which is close to the difference of the analogous ethane structures. This is additional evidence that the $C_3H_9^+$ formed by [1] corresponds to the stable form **4**.

[5] $C_2H_5^+ + CH_4 \rightleftarrows (C_3H_9^+) \rightarrow C_3H_7^+ + H_2$

On basis of the above energy values one can make some predictions regarding the outcome of proton transfer reactions 6 to propane.

[6] $RH^+ + C_3H_8 = R + C_3H_9^+ \xrightarrow{(3)} H_2 + C_3H_7^+(s)$; $\xrightarrow{(4)} CH_4 + C_2H_5^+$

For $146.8 <$ p.a.(R) $< 146.8 + 6.6$ stable $C_3H_9^+$ of structure **4** should be formed by the proton transfer reactions. When $146.8 + 6.6 <$ p.a.(R) $< 146.8 + 9$ dissociation of structure **4** via (*4*) is energetically possible and will probably occur. For p.a.(R) $> 146.8 + 9$ structures **3** and **4** could be formed. We expect structure **3** to dissociate via (*3*) and structure **4** largely but not exclusively via (*4*). This is in agreement with

For personal use only.

results of Ausloos and Lias (13) who showed by means of deuterium labelling that the methane product and not the $C_2H_5^+$ contains the proton transferred to propane.

It is important to note that even the stable structure **4** of protonated propane is unstable above room temperature and dissociates by [−1]. This follows from $\Delta G_1 \approx 0.4$ kcal/mol (300 K, standard state 1 atm) obtained by extrapolation of the plot in Fig. 1.

The production of higher C_nH_{2n+3} compounds by clustering reactions like [1] is possible and some such reactions have been reported (3, 4). It will be interesting and thermochemically rewarding if many of these species turn out to be the most stable protonated alkanes.

Independently of the present work, Ausloos (14) has come to the conclusion that the $C_3H_9^+$ formed via [1] is the most stable structure.

The Photoelectron Spectrum of Methyl Tri-*t*-butylcyclobutadienecarboxylate

R. S. Brown and S. Masamune[1]

Department of Chemistry, University of Alberta, Edmonton, Alberta T6G 2G2

Received November 5, 1974

R. S. Brown and S. Masamune. Can. J. Chem. **53**, 972 (1975).

The photoelectron spectrum of the title compound has been determined and found to contain a very low ionization potential. An interpretation of the spectrum and comparison with other cyclobutadienes are presented. The effect of the substituents on the ring and hence on the ionization potential of π_2 is discussed.

R. S. Brown et S. Masamune. Can. J. Chem. **53**, 972 (1975).

On a déterminé le spectre photo-électron du composé mentionné dans le titre et on a trouvé qu'il contient un potentiel d'ionisation très bas. On présente une interprétation du spectre et une comparaison avec ceux d'autres cyclobutadiènes. On discute de l'effet des substituants sur le cycle et en conséquence sur le potentiel d'ionisation de π_2. [Traduit par le journal]

The recent report (1) of the photoelectron spectrum of a cyclobutadiene derivative (**1**) has prompted us to reveal our results concerning the vertical ionization potential of methyl tri-*t*-butylcyclobutadiene carboxylate (**2**). Both compounds are crystalline and thermally stable, but differ in important ways. Unlike **1** the substitution pattern in **2** is such that the two bonds, $C_{(1)}$—$C_{(2)}$ and $C_{(1)}$—$C_{(4)}$ can attain equivalence if the π-electrons of the system are fully delocalized (ref. 3 and references therein). Thus the geometrical distortion of the cyclobutadiene system

(Bond lengths given in Å.)

ing to published procedure (2), and upon exposure to air quickly decomposed to a mixture of oxygenated materials presumably arising from an initial dioxetane formation. The photoelectron spectra [2] of **2**, **3**, and the final oxygenated material (**4**)[3] are displayed in Fig. 1.

The assignment of the ionizations in the cyclobutadiene systems rests primarily upon the validity of sophisticated computational methods. At present there is ambiguity about several important features of cyclobutadiene itself including the ground state geometry and multiplicity (3). Notwithstanding, the first vertical ionization potential (v.i.p.) of **2** is 6.90 eV and can be most certainly assigned to the removal of an electron from π_2 of the cyclobutadiene ring.[4] At first glance this value appears to correlate well with that reported for **1** (6.89 eV) but due to the presence of the inductively withdrawing methoxycarbonyl group which lies nearly perpendicular to the plane of the ring (4), one would have expected the value for **2** to be somewhat

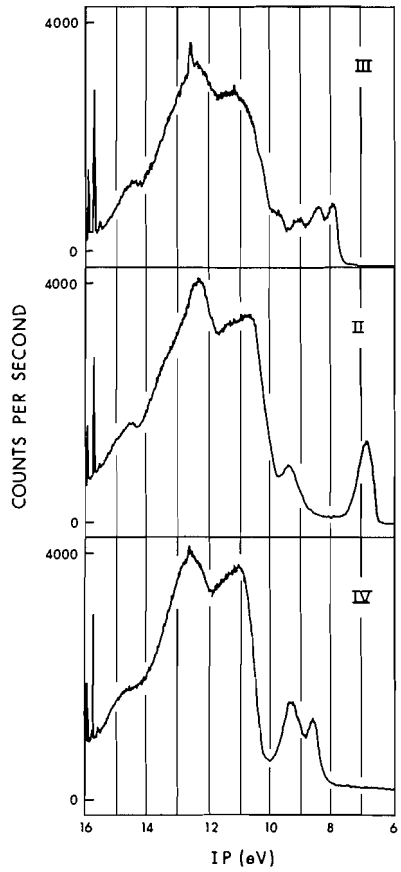

FIG. 1. Pholoelectron spectra of diazo-precursor (3), methyl tri-*t*-butylcyclobutadienecarboxylate (**2**), and the final oxygenated product (**4**).

higher than that of **1**. We feel that the constraint placed upon **1** by the two fused rings would restrict the geometry in such a way that the two double bonds will become more localized and interact less. Indeed, the single bond in **1** is found to be 1.60 Å (5), and hence the first v.i.p. assigned to π_2 in **1** should appear at somewhat higher energies than in unrestricted tetra-*t*-butylcyclobutadiene. In contrast **2** contains somewhat shorter single bonds of 1.506 and 1.547 Å (4). Apparently the presence of the methoxycarbonyl group in **2** counterbalances the effect of distortion in **1** and hence the v.i.p. are the same.

The value reported for the first v.i.p. of tri-*t*-butylcyclobutadiene of 6.83 eV (6) indicates a lower value in the absence of the methoxycarbonyl group in agreement with the above reasoning.

The ionization pertaining to the second band

[2]Spectra were determined at room temperature and 20 μ pressure using argon as an internal calibrating gas, on a MacPherson Model 36 Esca Spectrometer equipped with a He(I) excitation source. The resolution of the argon $^2P_{3/2}$–$^2P_{1/2}$ peaks was 32 meV.

[3]As yet the products of oxygenation have not been identified. The important point is that after exposure to oxygen, the cyclobutadiene ring is destroyed, and hence the low i.p. disappears.

[4]A linear combination of two molecular π orbitals (LCMO) gives a bonding orbital ($\pi_a + \pi_b$) and an antibonding orbital ($\pi_a - \pi_b$) both of which are occupied. In the text, the latter otbital is referred to as π_2.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

in the p.e. spectrum of **2** (9.45 eV) cannot be assigned with absolute certainty at this time. While we cannot rigorously exclude the possibility that this band is due to some impurity,[5] careful and repeated experiments have shown no diminution of band 2 with time. If one is allowed to use CNDO/2 calculations[6] as an aid, then this band can be assigned to removal of an electron from a σ-orbital located primarily on the cyclobutadiene ring. That the ionization occurs simply from the methoxycarbonyl group can be ruled out, since the values reported for methyl acetate are 10.45 eV (n_0) and 11.16 eV (π_0) (7).

The full width at half maximum intensity (f.w.h.m.) of the first band in the p.e.s. of **2** is 0.5 eV. This in addition to the extremely broad u.v. transition from 350 to 550 nm (λ_{max} pentane 425 nm) (2) for **2** suggests a marked difference in the ground and excited state geometries, and hence a wide Franck–Condon envelope.

While in principle it may be possible to use photoelectron spectroscopy to determine ground state multiplicities (1, 8), we believe that the large f.w.h.m. in both **1** (1) and **2** preclude such a distinction. However e.s.r. and n.m.r. data provide no evidence for a triplet nature of **2** (2), and no e.s.r. signals can be detected for cyclobutadiene itself generated in a low temperature matrix (2, 4, 9).

The above i.p. for π_2 in **2** is expected to be roughly 1.5 eV lower than that for cyclobutadiene due to the presence of the substituents (the effect of substituting a *t*-butyl group for a hydrogen in ethylene is to lower the observed i.p. from 10.51 to 9.7 eV (10)). The value reported by Hedeya *et al.* (11) of 8.2 eV based upon the appearance potential of the molecular ion stands as the best present value for the first i.p. of cyclobutadiene.

[5] We can be certain that this peak is *not* due to either the starting material (**3**) or the final oxygenated product (**4**) since the p.e. spectra of these two are quite different from that of (**2**) as shown in Fig. 1.

[6] Calculations were performed on methyl trimethylcyclobutadienecarboxylate since the number of basis functions required in **2** exceeded the limits of the program. Bond lengths were maintained from the X-ray data of **2** (4) but when the *t*-butyl groups were replaced by methyl groups, the C—H bond lengths were altered accordingly.

Dicarbonylcycloheptatrienylmolybdenum Derivatives of Silicon, Germanium, and Tin[1]

E. E. ISAACS AND W. A. G. GRAHAM

Department of Chemistry, University of Alberta, Edmonton, Alberta T6G 2E1

Received November 11, 1974

E. E. ISAACS and W. A. G. GRAHAM. Can. J. Chem. **53**, 975 (1975).

Convenient procedures are reported for the synthesis of the compounds $(\eta\text{-}C_7H_7)Mo(CO)_2MR_3$ (M = Si, R = Cl; M = Ge, R = Cl, F, Ph; M = Sn, R = Cl, Ph). The triphenyl derivatives were accessible through the anion $[(\eta\text{-}C_7H_7)Mo(CO)_2]^-$, while the MCl_3 derivatives were prepared from $(\eta\text{-}C_7H_7)Mo(CO)_2Cl$. Infrared, n.m.r., and mass spectrometric properties are reported.

E. E. ISAACS et W. A. G. GRAHAM. Can. J. Chem. **53**, 975 (1975).

On rapporte des méthodes simples pour la synthèse de composés $(\eta\text{-}C_7H_7)Mo(CO)_2MR_3$ (M = Si, R = Cl; M = Ge, R = Cl, F, Ph; M = Sn, R = Cl, Ph). On arrive aux dérivés triphénylés par l'intermédiaire de l'anion $[(\eta\text{-}C_7H_7)Mo(CO)_2]^-$ alors que l'on prépare les dérivés MCl_3 à partir de $(\eta\text{-}C_7H_7)Mo(CO)_2Cl$. On rapporte les spectres infrarouges, r.m.n. et de masse de ces composés. [Traduit par le journal]

Introduction

Although species of the type $(\eta\text{-}C_7H_7)Mo(CO)_2L$ (where L is a one-electron donor) satisfy the effective atomic number rule, few have actually been prepared. Among the known examples are $(\eta\text{-}C_7H_7)Mo(CO)_2I$ (1), $(\eta\text{-}C_7H_7)Mo(CO)_2Mn(CO)_5$ (2), $(\eta\text{-}C_7H_7)Mo(CO)_2(\sigma\text{-}C_6F_5)$ (3), and various tertiary phosphine and phosphite derivatives of the general formula $(\eta\text{-}C_7H_7)Mo(CO)(PR_3)I$ (4, 5).

We report in this paper the syntheses and properties of derivatives of the general formula $(\eta\text{-}C_7H_7)Mo(CO)_2MR_3$ (M = Si, R = Cl; M = Ge, R = Cl, F, Ph; M = Sn, R = Cl, Ph) which extend considerably the chemistry of cycloheptatrienyl systems. While this work was in progress, the preparation of several tin derivatives (6) and the crystal structures of two of them (7) were reported.

[1]Organometallic Compounds Having Metal–Metal Bonds, Part XXIV. For Part XXIII, see ref. 11.

Experimental

Melting points were determined using a Kofler hot-stage microscope. Analytical results (Table 1) were obtained by the Microanalytical Laboratory of this department. Infrared spectra of the carbonyl stretching region were measured by means of a Perkin–Elmer Model 337 spectrometer at a scanning rate of 39 cm^{-1} min^{-1}, and recorded in expanded form (1 cm of chart $\approx$ 10 cm^{-1}) on an external recorder. Spectra were calibrated with bands of gaseous CO and DBr, and are considered accurate to ± 1 cm^{-1}. Band positions quoted in Table 2 refer to the mid-point at half-height. Nuclear magnetic resonance spectra were obtained using a Varian A56-60a and results are included in Table 2. Mass spectra are given in Table 3, which lists major fragments and those common to two or more compounds.

Reactions were carried out and products recovered and purified under a nitrogen atmosphere, using Schlenk apparatus. Dichloromethane was distilled from P_4O_{10} and tetrahydrofuran from CaH_2 prior to use. In other cases, reagent grade solvents were used without purification.

Preparation of Dicarbonyl(chloro)(η-cycloheptatrienyl)-molybdenum, $(\eta\text{-}C_7H_7)Mo(CO)_2Cl$

The compound $[(\eta\text{-}C_7H_7)Mo(CO)_3][PF_6]$ (4.2 g, 10.1 mmol), prepared by the published method (8), was

TABLE 1. Analytical data, colors, melting points, and yields

stirred with a large excess of sodium chloride in 100 ml of reagent acetone to which 5 ml of water had been added. The solution turned deep green immediately with vigorous gas evolution. The reaction mixture was stirred for at least 4 h to ensure complete reaction. The solvent was then removed using a water aspirator vacuum. A black residue remained which was washed with water to remove sodium hexafluorophosphate and air dried. The residue was extracted with dichloromethane, filtered, and the solvent removed using a water aspirator. Deep green crystals remained, and these were washed on a filter with ether and pentane and sucked dry affording 2.3 g (82% yield) of the product.

Preparation of Dicarbonyl(η-cycloheptatrienyl)(trichlorosilyl)molybdenum, $(\eta\text{-}C_7H_7)Mo(CO)_2SiCl_3$

To a solution containing $(\eta\text{-}C_7H_7)Mo(CO)_2Cl$ (1.2 g, 4.3 mmol) and $HSiCl_3$ (2.5 g, 18.5 mmol) in 30 ml acetonitrile at room temperature triethylamine (3.0 g, 29.7 mmol) was added dropwise. The initial green color of the solution turned red after a few minutes and stirring was continued for 1 h. The solution was filtered through Celite (degassed just prior to use) and the solvent was removed under reduced pressure. After pumping in vacuum for 24 h the residue was extracted with 20 ml dichloromethane, filtered, and *n*-heptane was added dropwise until the solution became cloudy. This was cooled at −78° affording red-brown crystals (0.5 g, 35% yield) which darkened on exposure to air and/or light.

Preparation of Dicarbonyl(η-cycloheptatrienyl)(trichlorogermyl)molybdenum, $(\eta\text{-}C_7H_7)Mo(CO)_2GeCl_3$

Trichlorogermane (1.8 g, 10.0 mmol) was added to a magnetically stirred dichloromethane solution of $(\eta\text{-}C_7H_7)Mo(CO)_2Cl$ (2.0 g, 7.2 mmol). The solution turned deep red immediately and a red precipitate formed. After stirring for 20 min the reaction mixture was filtered, the precipitate washed with ether and sucked dry. The filtrate was cooled at −20° overnight, affording more of the red crystalline product. The two batches of product were combined and recrystallized from dichloromethane (yield 2.2 g, 72%).

Preparation of Dicarbonyl(η-cycloheptatrienyl)(trifluorogermyl)molybdenum, $(\eta\text{-}C_7H_7)Mo(CO)_2GeF_3$

Solid silver tetrafluoroborate (2.3 g, 12.0 mmol) was added to a solution of $(\eta\text{-}C_7H_7)Mo(CO)_2GeCl_3$ (1.5 g, 3.6 mmol) in 25 ml acetonitrile. A white precipitate of AgCl immediately formed, with no noticeable color change. After stirring for a short period, 15 ml of ether was added and the reaction mixture was filtered and concentrated under reduced pressure. Addition of more ether precipitated an orange-red solid which was recrystallized from dichloromethane–ether to yield 1.0 g (75%) of the analytical sample.

Preparation of Dicarbonyl(η-cycloheptatrienyl)(trichlorostannyl)molybdenum, $(\eta\text{-}C_7H_7)Mo(CO)_2SnCl_3$

Anhydrous $SnCl_2$ (2.3 g, 12.0 mmol) and $(\eta\text{-}C_7H_7)Mo(CO)_2Cl$ (2.8 g, 10.0 mmol) were refluxed in dichloromethane for 12 h. The reaction mixture turned brown and a brown precipitate was formed. This was filtered, washed with dichloromethane, and sucked dry. Recrystallization from hot acetonitrile gave red-brown plate-like crystals of product (3.2 g, 68% yield).

Preparation of Dicarbonyl(η-cycloheptatrienyl)(triphenylstannyl)molybdenum, $(\eta\text{-}C_7H_7)Mo(CO)_2SnPh_3$

The reaction was conducted in a 250-ml three-necked flask with a stopcock fused to the bottom. After filling with nitrogen, the flask was charged with 10 ml of mercury and 1.0 g of sodium metal was added in small portions with stirring. After all the sodium had reacted, $(\eta\text{-}C_7H_7)Mo(CO)_2Cl$ (2.0 g, 7.2 mmol) and 100 ml of tetrahydrofuran were added. The progress of the reaction was followed by i.r. spectroscopy, specifically by the disappearance of the bands at 2023 and 1974 cm^{-1} and appearance of bands at 1926 and 1857 cm^{-1}. When the formation of the anion was complete, excess amalgam was removed through the stopcock at the bottom. Then Ph_3SnCl (2.6 g, 7.7 mmol) in 50 ml tetrahydrofuran was added and the mixture stirred overnight. The solution was filtered through Celite and the solvent removed under reduced pressure leaving a muddy brown solid. This was extracted with dichloromethane, filtered, concentrated, and chromatographed on alumina, eluting as a single red band. Recrystallization from dichloromethane – petroleum ether (60–80°) afforded 1.3 g (30% yield).

The Ph_3Ge analogue was prepared in the same manner.

Results and Discussion

Synthesis

Group IV derivatives of the $(\eta\text{-}C_7H_7)Mo(CO)_2$ moiety have been prepared in this work from $(\eta\text{-}C_7H_7)Mo(CO)_2Cl$ by three routes: insertion into the Mo—Cl bond, displacement of chloride ion by a group IV nucleophile and by reduction to the $[(\eta\text{-}C_7H_7)Mo(CO)_2]^-$ anion followed by reaction with group IV halides.

[e]Phenyl region complex multiplet.
[f]$J(^{117,119}Sn—C_7H_7) = 5$ Hz.

The last of these routes is perhaps most interesting, since no previous successful synthetic use of the $[(\eta\text{-}C_7H_7)Mo(CO)_2]^-$ anion has been reported. Thus it has been reported that sodium amalgam reduction of $(\eta\text{-}C_7H_7)Mo(CO)_2I$ followed by reaction with methyl iodide afforded no $(\eta\text{-}C_7H_7)Mo(CO)_2CH_3$ (2). We observe strong infrared evidence for the formation of the anion by sodium amalgam reduction of the chloride in tetrahydrofuran, and find that the reduction product reacts with Ph_3GeCl and Ph_3SnCl forming the expected derivatives in yields of 30%.

$$(\eta\text{-}C_7H_7)Mo(CO)_2Cl \xrightarrow[THF]{Na/Hg} [(\eta\text{-}C_7H_7)Mo(CO)_2]^- \xrightarrow{Ph_3MCl\ (M = Ge, Sn)} (\eta\text{-}C_7H_7)Mo(CO)_2MPh_3$$

Surprisingly, no reaction was observed with Me_3SnCl or with Ph_3SiCl, and the reactivity of this anion merits further investigation. Recently, the synthesis of $(\eta\text{-}C_7H_7)Mo(CO)_2SnPh_3$ in 2% yield was reported by the reaction of $(\eta\text{-}C_7H_7)Mo(CO)_2Br$ with Ph_3SnLi (6); this low yield was due in part to the formation during workup of phenylchlorotin compounds.

Trichlorotin and trichlorogermanium derivatives were prepared by the insertion of $SnCl_2$ of $GeCl_2$ ($HGeCl_3$ is considered to be a source of the latter), as in the following reaction.

$$(\eta\text{-}C_7H_7)Mo(CO)_2Cl + HGeCl_3 \xrightarrow[CH_2Cl_2]{25°} (\eta\text{-}C_7H_7)Mo(CO)_2GeCl_3 + HCl$$

The trichlorogermanium compound was conveniently converted to the trifluoro derivative by means of $AgBF_4$, a reaction first applied in this area by Marks and Seyam (9). The insertion reaction of $SnCl_2$ or $SnBr_2$ with $(\eta\text{-}C_7H_7)Mo(CO)_2Br$ has been reported recently as a route to $SnCl_3$ or $SnBr_3$ derivatives respectively (6).

Trichlorosilane reacted in the following way with $(\eta\text{-}C_7H_7)Mo(CO)_2Cl$.

$$(\eta\text{-}C_7H_7)Mo(CO)_2Cl + HSiCl_3 + Et_3N \xrightarrow[CH_3CN]{25°} (\eta\text{-}C_7H_7)Mo(CO)_2SiCl_3 + Et_3NH^+Cl^-$$

Benkeser *et al.* (10) have shown that the trichlorosilyl anion, $SiCl_3^-$, is present in $HSiCl_3$–amine–CH_3CN systems, and this anion is no doubt the reactive species in the nucleophilic displacement of chloride ion.

Attempts to prepare $(\eta\text{-}C_7H_7)Mo(CO)_2Cl$ in analogy with the preparation of $(\eta\text{-}C_7H_7)Mo(CO)_2I$ (8) failed. It was discovered that only in the presence of small amounts of water does the reaction proceed to give the desired product. Thus treatment of $[(\eta\text{-}C_7H_7)Mo(CO)_3][PF_6]$ with sodium chloride or tetraethylammonium chloride in reagent acetone failed, whereas tetraphenylarsonium chloride, which contains water of hydration, reacted to give the chloride. We have included in the Experimental section a convenient preparation of $(\eta\text{-}C_7H_7)Mo(CO)_2Cl$ from sodium chloride in acetone with added water.

Physical and Spectroscopic Properties

The six derivatives prepared in this work range in color from brown to red. They are insoluble in hydrocarbon solvents and ether, and are only slightly soluble in benzene. With one exception, the compounds are very soluble in dichloromethane, acetonitrile, and acetone. The trichlorotin derivative is only sparingly soluble in

these solvents. The compounds can be handled in air for short periods but are gradually oxidized on long exposure.

All compounds were characterized by their infrared, n.m.r., and mass spectra. The infrared spectra showed the expected two bands in the carbonyl region and the ^1H n.m.r. spectra confirmed the presence of the heptahapto cycloheptatrienyl group.

The molecular formulae of the group IV compounds were confirmed by their mass spectra. Molecular ions were observed for all compounds except the trichlorotin derivative. The latter did not show a parent peak, but peaks due to loss of the two carbonyls, chlorine, dichlorotin, and tropylium from the parent were observed in low abundance.

Extraneous peaks, identified by computer fitting of the observed patterns, due to $C_{15}H_{14}O_2Cl_3Mo_2^+$ (*m/e* 525) and $C_{14}H_{14}Cl_3Mo_2^+$ (*m/e* 481) were observed in the mass spectra of both the trichlorogermanium and trichlorotin compounds but not for the trichlorosilicon derivative.[2] The pattern centered at *m/e* 481 was also observed in the mass spectrum of $C_7H_7Mo(CO)_2Cl$. It is not clear whether the extraneous peaks are due to the presence of an impurity in the starting material or are formed in the mass spectrometer, perhaps by decomposition of the solid sample during heating.

[2]These values refer to the nominal mass of the major peak in the observed isotope pattern for a particular fragment or that computed using all isotopes and their natural abundances.

Steric Crowding and the Reactivity of Substituted *tert*-Butyl Perbenzoates[1]

SIDDICK ICLI, KANDIL A. KANDIL, C. THANKACHAN, AND THOMAS T. TIDWELL
Department of Chemistry, University of Toronto, Scarborough College, West Hill, Ontario M1C 1A4

Received October 10, 1974

SIDDICK ICLI, KANDIL A. KANDIL, C. THANKACHAN, and THOMAS T. TIDWELL. Can. J. Chem. **53**, 979 (1975).

The relative rates of decomposition of peroxyesters in cumene at 100° and their activation parameters $\Delta H^{\ddagger}$ (kcal/mol) and $\Delta S^{\ddagger}$ (cal deg^{-1} mol^{-1}) were *tert*-butyl perbenzoate (**1**) 1.0, 34.0, 9.3; *tert*-butyl pertoluate (**7**) 1.3, 32.2, 4.8; *tert*-butyl permesitoate (**8**) 11, 31.9, 8.4; and *tert*-butyl 2,4,6-tri-*tert*-butylperbenzoate (**9**) 29, 32.9, 13.0. Each peroxyester yielded the corresponding acid as one of the products. The reactions are all interpreted as proceeding through a rate-determining scission of the O—O bond to yield a benzoyloxy radical, which then undergoes competitive decarboxylation and hydrogen abstraction from the solvent. The small rate acceleration due to a *para* substituent is interpreted as due to a polar factor and the larger rate enhancing effect of the *ortho* substituents is interpreted as due to destabilization of the ground state due to twisting of the carboxyl group out of conjugation with the ring.

SIDDICK ICLI, KANDIL A. KANDIL, C. THANKACHAN et THOMAS T. TIDWELL. Can. J. Chem. **53**, 979 (1975).

On a évalué, dans le cumène à 100°, les vitesses relatives de décomposition de peroxyesters ainsi que leurs paramètres d'activation $\Delta H^{\ddagger}$ (kcal/mol) et $\Delta S^{\ddagger}$ (cal deg^{-1} mol^{-1}); les valeurs sont pour le perbenzoate de *tert*-butyle (**1**) 1.0, 34.0, 9.3; pour le pertoluate de *tert*-butyle (**7**) 1.3, 32.2, 4.8; pour le permésitoate de *tert*-butyle (**8**) 11, 31.9, 8.4; et pour le tri-*tert*-butyl-2,4,6 perbenzoate de *tert*-butyle (**9**) 29, 32.9, 13.0. Chaque peroxyester conduit entre autre à l'acide correspondant. On interprète toutes les réactions en fonction d'une étape déterminante de la réaction qui impliquerait la scission du lien O—O conduisant au radical benzoyloxy qui subirait ensuite une décarboxylation ou enlèverait un hydrogène du solvant. On attribue la petite augmentation de vitesse due à un substituant en *para* à des facteurs polaires; par ailleurs l'augmentation importante observée lorsqu'il y a des substituants en position *ortho* implique une déstabilisation de l'état fondamental due à une rotation du groupement carboxyle hors du plan de conjugaison du cycle. [Traduit par le journal]

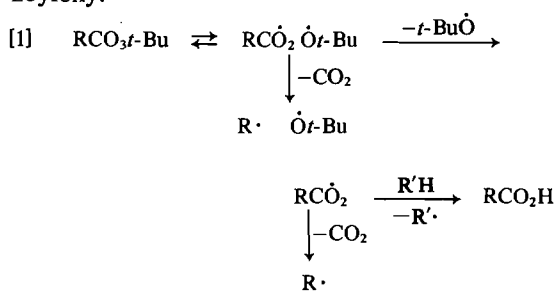
Introduction

Organic peresters are of widespread use as initiators of free-radical reactions. The utility of these materials justifies the intense interest in elucidating their mode of reactivity and many aspects of their chemistry are well understood (for recent reviews see ref. 1 and footnotes 3, 5, 18, and 19 of ref. 2).

Perhaps the most commonly used perester is *tert*-butyl perbenzoate (**1**), which is commercially available from several suppliers. However, several features of the chemistry of this material appear to deserve further examination.

1 **2**

Firstly, *tert*-butyl perbenzoate (**1**) decomposes faster than *tert*-butyl peracetate (**2**) by a factor of about 2 but whereas **1** gives an 82.9% yield of CO_2 on thermolysis in cumene, plus residual acid (3, 4), **2** gives a 96.5% measured yield of CO_2 in cumene and no detectable residual acid (5). Both of these reactions are commonly interpreted (1) as proceeding through an initial one-bond scission to give a carboxylate–*tert*-butoxy radical pair which reacts by decarboxylation both before and after diffusion of the radical pair (eq. 1). This scheme requires that the benzoyloxy radical be formed more rapidly than acetoxy, yet the acetoxy radical undergoes decarboxylation more efficiently than benzoyloxy.



[1]The research for this paper was supported by the Defence Research Board of Canada, Grant No. 9530-129.

For personal use only.

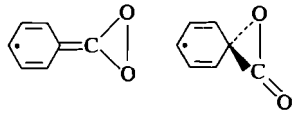
The cause of greater rate of reaction of the perbenzoate has occasioned much discussion, including the proposed interactions with the phenyl ring shown in **3** and **4** (6). Analogous



3 **4**

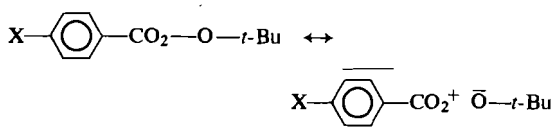
structures were proposed for the intermediate from naphthoyl peroxide (7). The results of CIDNP experiments with benzoyl peroxide have been interpreted in terms of the occurrence of a small amount of concerted decarboxylation on scission of the O—O bond, leading directly to phenyl radical, although this interpretation has been criticized (ref. 1*a*, p. 127).

Evidence that aliphatic acyloxy radicals decarboxylate more rapidly than aromatic ones includes the lower yields of CO_2 from the latter and the fact that the latter can be trapped by olefins to yield adducts which can be examined by electron spin resonance, whereas the former cannot (8).

The reported rate constant for decarboxylation of acetoxy is $1.6 \times 10^9\ s^{-1}$ at 60° (9), while the corresponding values reported for benzoyloxy are $1 \times 10^4\ s^{-1}$ (10*a*) at 80° and $7.4 \times 10^3\ s^{-1}$ (10*b*) at 60°.

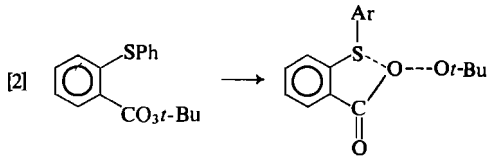
It is of interest that benzoyl peroxide has a lesser tendency to undergo isotopic scrambling between the carbonyl and peroxidic oxygens than does acetyl peroxide (11–13). This scrambling has been proposed to occur either by sigmatropic rearrangement (11, 13*a*) or by cage recombination of radical pairs (12, 13*b*). It has been suggested (ref. 1*d*, p. 238, and ref. 12) that the opposite propensity of scrambling would have been expected for the cage recombination route for scrambling but there have been no proposals as to which substrate would be expected to scramble more rapidly by sigmatropic rearrangement.

The effect of substituents on the rate of perbenzoate thermolysis reactions has also occasioned considerable comment. The decomposition of a series of *tert*-butyl *p*-substituted perbenzoates was correlated with σ values with $\rho = -0.68$ (14). The lower reactivity of the peresters substituted with more electron-withdrawing substituents was attributed (14) to a greater ground state bond strength due to enhanced resonance contributions of the ionic structure with an electron-deficient benzoyloxy group (**5**). *Ortho* substituents in aryl peresters (6, 15, 16) and diacyl peroxides (17)

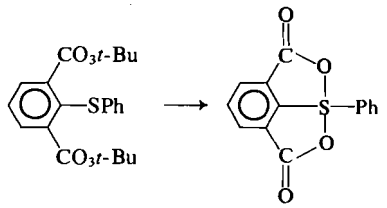


5

invariably cause enhanced reactivity, however, and these effects are as large as 10^6 for highly polarizable substituents such as iodine and sulfur. These latter effects were ascribed to direct anchimeric participation by the *ortho* substituent (6, 15) (eq. 2). The presence of



two such substituents, in the *o*,*o*′ positions, leads to no further rate increase, (16*a*) but when two percarboxy groups flank a single phenylthio group, a further rate acceleration by a factor of 81 is observed and the formation of the sulfurane **6** occurs (16*b*). This reaction was interpreted in



6

terms of simultaneous participation of the phenylthio group in cleavage of both perester functions (16*b*).

Alkyl groups, which are incapable of such participation, also cause modest rate enhancements in the *ortho* positions of peresters (6) and diacyl peroxides (17*a*), as does an *ortho*-phenyl group in peresters (18). Despite some proposals of a role for nonbonding steric interactions in these systems (6, 17*a*), these have been more commonly neglected or "ruled out" (ref. 1*b*, p. 497).

It appeared to us that a further investigation of steric effects in this series might result in

[a]Average of two runs at each temperature, reproducibility ±1 to ±6%.
[b]The rate calculated for 1 at 25° is 7.41×10^{-11} s^{-1} and the calculated relative rates for 1 and 7–9 are 1.0, 2.4, 23, and 43, respectively.
[c]Calculated from data at other temperatures.
[d]In *p*-chlorotoluene, calculated from data in ref. 22.

greater understanding of the reactivity of these species. We were especially impressed with the fact that the examination of the effect of bulky *ortho* substituents on benzoate ester hydrolysis (19) and solvolyses leading to substituted benzyl cations (20) had elucidated an interrelation of steric blocking of bimolecular attack, inhibition of resonance by twisting of the ring out of conjugation with the side chain, and steric repulsion of the departing group. Accordingly, we have investigated the reactivity of a series of substituted *tert*-butyl perbenzoates.

Results

The compounds chosen for study were *tert*-butyl perbenzoate (**1**), *tert*-butyl pertoluate (**7**), *tert*-butyl permesitoate (**8**), and *tert*-butyl 2,4,6-tri-*tert*-butylperbenzoate (**9**). Compound **1** was

7	Me	H
8	Me	Me
9	*t*-Bu	*t*-Bu

a commercial sample, and **7**–**9** were obtained from reaction of their known acid chlorides with sodium *tert*-butylhydroperoxide.

The rates of thermal decomposition of **1** and **7**–**9** in cumene were monitored by the i.r. technique (21). Rate constants and derived activation parameters are collected in Table 1, along with suitable literature data for comparison.

The data for **1** are in quite satisfactory agreement with results obtained with *p*-chlorotoluene solvent (22*a*) and an unpublished rate constant for **1** in cumene at 105°[2] of 1.82×10^{-5} s^{-1} is in close agreement with the value for that temperature calculated from our data (1.80×10^{-5} s^{-1}). There is also reasonable agreement with rates in *n*-undecane (22*b*).

The formation of acids during the decomposition of **1** and **7**–**9** to the extent of about 10% was monitored by i.r. spectroscopy. The identity of the tri-*tert*-butylbenzoic acid from **9** was confirmed by treatment of the reaction product with diazomethane and isolation of the methyl ester, which was compared to an authentic sample.

The formation of the tri-*tert*-butylphenyl radical (**10**) from photolysis of **9** in cyclopropane

was shown to occur by e.s.r. spectroscopy. The observed spectrum showed a main triplet with hyperfine coupling $a = 7.3$ G due to coupling with the 3,5-protons. The spectrum of 2-(3,5-di-*tert*-butylphenyl)-2,2-dimethylethyl radical could also be detected. This latter radical is derivable from **9** by an intramolecular hydrogen shift.

Radical **10** is the only phenyl radical which has been observed in solution. It was discovered recently by Barclay *et al.* (23) by bromine atom abstraction from 2,4,6-tri-*tert*-butylbromobenzene. Our e.s.r. spectra are in complete agreement with theirs and the formation of **10** from two different sources yields definitive confirmation of the structure assigned. Attempted observation of the 2,4,6-trimethylphenyl radical by photolysis of **8** was unsuccessful, however.

Discussion

The reported rates confirm the previous findings that *p*-alkyl substituents cause minimal rate enhancement of the decomposition of *tert*-butyl perbenzoates. Thus our value of 1.3 for the **7**/**1** rate ratio at 100° agrees well with the reported values of 1.1 (at 131°) and 1.4 (at 100°) (14). This enhancement is apparently due to a subtle electronic factor, in which the ground state is either destabilized by electron-donating substituents (this argument is given in ref. 14 and was mentioned in the Introduction) or the transition state is stabilized by the electron donating substituent.

The effect of the *ortho* substituents is much larger than that ascribable to the electronic factor. Further the effect is enhanced by the presence of two *ortho* substituents, as evidenced by the fact that the rate of *tert*-butyl perbenzoate decomposition is increased by a factor of 3.8 for an *ortho-tert*-butyl group at 60° (6) and 2.7 for an *ortho*-phenyl group at 110° (18) as compared to our factors of 11 for 2,4,6-trimethyl substituents and 29 for 2,4,6-tri-*tert*-butyl at 100°.

Bonding between the *ortho* substituents and the carboxy groups was invoked to explain the large rate enhancements due to *ortho*-iodo and -sulfur substituents (refs. 1*a*, p. 127, and 15). Such an effect does not seem reasonable for alkyl substituents without low-lying vacant orbitals or unshared electrons.

Direct steric compression of the alkyl groups by the carbonyl carbon and oxygens, if relieved in the transition state, would provide acceleration of these reactions. This relief of *F*-strain has been proposed as a major factor in certain ionic reactions (24, 25). However, the formation of acids in the present reactions shows that the bond between the phenyl ring and the carboxyl group is not broken in the rate-determining step of these reactions (eq. 3) so this effect cannot

$$[3] \qquad ArCO_3t\text{-}Bu \xrightarrow[r.d.]{slow} ArC\dot{O}_2 + t\text{-}Bu\dot{O}$$

be appreciable. Examination of molecular models suggests no steric interaction between the substituted aryl ring and the departing *tert*-butoxy group, so such a factor also presumably does not affect the rates.

Relief of *B*-strain has also been considered as a possible accelerating effect in free-radical reactions (26–29). However this effect depends on a rehybridization of the molecule on conversion to a free radical which reduces steric interactions. Since no rehybridization occurs on formation of the carboxy radical in the rate-determining step of these reactions this factor also can be excluded.

Apparently only conformational effects, which are significant in analogous ionic reactions (19) and on the physical properties of *ortho*-substituted benzenes (30), can explain the observed trends. The carboxyl group in the ground state for **8** and **9** would be twisted completely out of conjugation with the phenyl ring. For example, mesitoic acid has been calculated to have a twist angle of 65° (31), and similar effects have been observed in aryl ketones with *ortho* substituents (32), including *tert*-butyl groups (33). The ground state energy of these molecules will be raised by the amount of the resonance energy due to conjugation between the aryl ring and the carboxyl group. The magnitude of this interaction can be estimated from the rotational barrier of benzaldehyde of 7.9 kcal/mol (34). This value is consistent with earlier estimates of the resonance energy of this interaction as 4 kcal in benzoic acid (35*a*) and 5 kcal in benzoate esters (35*b* and *c*). Conjugation between the phenyl ring and the developing carboxy radical in the transition state will also be eliminated. However, there is reason to suspect that the magnitude of this interaction is not as large as it is in the ground state. In benzoate anions it has been proposed

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

that the strong delocalization of the negative charge inhibits cross-conjugation of the carboxyl group with the ring and that this difference in conjugation amounts to 0.7 kcal (ref. 35*b*, pp. 581 and 656). A similar phenomenon might well occur in the transition state leading to the radical, so that the net energy difference between the ground and transition states would be decreased by twisting the carboxyl group out of the plane.[3]

Quantitative estimates of the magnitude of this effect would depend on reliable data of the resonance energy in the benzoyloxy radical and these are not available. A simple molecular orbital treatment suggested that there was no extra resonance stabilization of the carboxyl radical relative to the carboxyl group (36*c*) but this appears unreasonable and the author pointed out that a more sophisticated treatment might give different results.

An alternative hypothesis to explain the observed rate trends is that entropy effects are responsible. In particular, the higher rate of **9** is due in part to the fact that this compound has the highest entropy of activation in this group and this favorable entropy of activation is plausible since the crowded ground state of the molecule must greatly restrict the freedom of the movement of the groups involved. On the basis of this argument the entropy of activation of **8** would be expected to be larger than was observed but this discrepancy could be due to experimental error because of the narrower range of temperatures of the rate constants of **8**.

Despite the fact that the explanation based on entropy effects accounts for the observed results, we prefer to attribute the results to ground state destabilization due to loss of resonance. Activation parameters are frequently used as a criterion of mechanism of perester reactions (21) but it has been emphasized (37) that such treatments ought to be applied with great caution due to the difficulty of obtaining reliable values. We agree with the statement of Pryor and Smith (37) that "It is probable that the rate constants, rather than the activation parameters, would be more reliable for use in classifying initiators."

The lower rate of decarboxylation of benzoyloxy radicals relative to alkyl carboxy radicals is probably due to a stronger C—C single bond between the ring and the carboxy group because of the sp^2 hybridization of the ring, as proposed by Traylor *et al.* (38).[4] This argument also suggests that rate enhancement due to formation of the α-lactone intermediate **4** does not occur, as this involves rehybridization.

Thus we believe that the major cause of the enhanced reactivity of *tert*-butyl perbenzoates with *ortho*-alkyl substituents is the increased energy of the ground states caused by the substituents forcing the carboxyl group into a conformation orthogonal to the π-system of the phenyl ring.

Experimental

Elemental analyses were performed by A. B. Gygli Microanalysis, Ltd., Toronto. Nuclear magnetic resonance spectra were measured using a Varian T-60 instrument with TMS as an internal standard. Vapour phase chromatography (v.p.c.) separations were carried out using a Varian-Aerograph 920 instrument. Kinetic measurements were carried out by i.r. (21) using Beckman IR 12 and Perkin Elmer 625 i.r. spectrophotometers and 0.06 *M* solutions of the peresters in cumene.

Cumene was purified by shaking with H_2SO_4 and then $NaHCO_3$, followed by distillation from sodium. Lucidol 90% *tert*-butylhydroperoxide was distilled using a helix packed column and aspirator pressure. The fraction boiling at 30–35° (15 Torr) was collected. Iodometric titration indicated a purity of 99%. *tert*-Butyl perbenzoate (**1**) from Aldrich or Lucidol was used as received, although one sample was purified by chromatography on Florisil using pentane–chloroform as the eluent. The kinetic behavior of the different samples was indistinguishable. *tert*-Butylbenzene was alkylated to 1,4-di-*tert*-butylbenzene (39) which was converted to tri-*tert*-butylbenzene (40) and brominated with bromine and silver nitrate (40, 41). The bromide was exchanged with *n*-butyllithium and carbonated with Dry Ice to give 2,4,6-tri-*tert*-butylbenzoic acid, (40, 41) which was converted to the acid chloride by treatment with thionyl chloride at 25° (42).

tert-Butyl 2,4,6-Tri-tert-butylperbenzoate (9)

This was prepared by the dropwise addition of the acid chloride (2.53 g, 0.0133 mol) in ether at 25° to a solution obtained from the addition of *tert*-butylhydroperoxide (6.33 g, 0.070 mol) to a pentane suspension of NaH (0.05 mol rinsed with pentane to remove oil). The mixture was stirred 24 h at 25° and was then poured into water and extracted four times with ether and the combined ether layers were washed first with water, then four times with 10% NaOH, and twice with

[3]The related 2-alkonyl radicals have been examined recently (36) and in support of our hypothesis the phenacyl radical has "little delocalization of the spin density into the aromatic ring" (36*a*).

[4]These authors also report a moderately greater tendency for decarboxylation of the *o,o'*-dimethylbenzoyloxy radical, indicating some stabilization of the benzoyloxy radical by conjugation involving the ring.

saturated NaCl solution. The solution was dried over Drierite and the solvent removed on the rotary evaporator at room temperature. Recrystallization of the solid product from pentane at 0° gave white crystals: m.p. 127–128° (with gas evolution); i.r. (cumene) 1765 cm^{-1} (C=O); n.m.r. (CCl_4) δ 1.28 (s, 9, *t*-BuO), 1.33 (s, 9, *p*-*t*-Bu), 1.40 (s, 18, *o*-*t*-Bu), and 7.35 (s, 2, Ar H).

Anal. Calcd. for $C_{23}H_{38}O_3$ (362.53): C, 76.20; H, 10.56. Found: C, 76.28; H, 10.59.

tert-Butyl Permesitoate (8)

This was prepared by a procedure analogous to that for **9** and was obtained as a colorless oil after chromatography on Florisil with pentane–chloroform: i.r. (CCl_4) 1770 cm^{-1} (C=O); n.m.r. (CCl_4) δ 1.32 (s, 9, *t*-BuO), 2.24 (s, 3, *p*-Me), 2.28 (s, 6, *o*-Me), and 6.76 (s, 2, Ar H).

Anal. Calcd. for $C_{14}H_{20}O_3$ (236.31): C, 71.16; H, 8.53. Found: C, 71.25; H, 8.55.

tert-Butyl Pertoluate (7) (14)

This was prepared by an analogous procedure.

Products of 9

A solution of **9** (0.36 g, 1 mmol) in 5 ml cumene was heated 24 h in a sealed tube at 140°. The mixture was treated with ethereal diazomethane. Volatile solvent was removed on the rotary evaporator and the residual oil separated by v.p.c. (10 ft × 0.375 in. 20% DEGS on 45–60 mesh AW Chromosorb W at 170°). One of the isolated peaks had the same retention time as methyl 2,4,6-tri-*tert*-butylbenzoate and the identity was confirmed by comparison of its n.m.r. and mass spectra with those of an authentic sample.

Stereospecific Spin–Spin Coupling between Hydroxyl Protons and ^{19}F Nuclei in *o*-, *m*- and *p*-Fluorophenol Derivatives. "Through-space" Interactions via the Hydrogen Bond

J. Brian Rowbotham,[1] Murray Smith, and Ted Schaefer
Department of Chemistry, University of Manitoba, Winnipeg, Manitoba R3T 2N2

J. Brian Rowbotham, Murray Smith, and Ted Schaefer. Can. J. Chem. **53**, 986 (1975).

Under conditions of slow intermolecular hydroxyl proton exchange $^6J_p^{OH,F} < 0$, $^5J_{trans}^{OH,F} > 0$, $^5J_{cis}^{OH,F} < 0$, $^4J_o^{OH,F} < 0$ in fluorophenol derivatives. $^5J_m^{OH,F}$ is remarkably insensitive to intrinsic substituent effects, yields accurate values of conformational populations of *m*-fluorophenol derivatives and can be used to demonstrate a buttressing effect on the strength of the relatively weak O—H···halogen hydrogen bond. $^4J_o^{OH,F}$ displays a stereospecific dependence opposite to that of other couplings from a side-chain proton to a ring fluorine nucleus, is apparently very sensitive to the distance between proton and fluorine nucleus and is cited as an example of a negative through-space coupling mechanism. Approximate molecular orbital calculations give some support to the last suggestion.

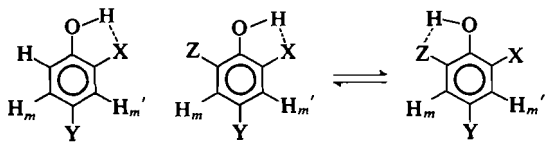
J. Brian Rowbotham, Murray Smith et Ted Schaefer. Can. J. Chem. **53**, 986 (1975).

Dans les dérivés du fluorophénol, dans des conditions où l'échange intermoléculaire du proton hydroxylique est lent, $^6J_p^{OH,F} < 0$, $^5J_{trans}^{OH,F} > 0$, $^5J_{cis}^{OH,F} < 0$, $^4J_o^{OH,F} < 0$. La valeur de $^5J_m^{OH,F}$ est, d'une façon remarquable, insensible aux effets intrinsèques des substituants et fournit des valeurs précises des populations conformationnelles dans les dérivés du *m*-fluorophénol; on peut aussi utiliser cette valeur pour démontrer l'influence d'un effet de répulsion sur la force de la liaison hydrogène O—H···halogène qui est relativement faible. Une dépendance stéréospécifique existe pour la valeur de $^4J_o^{OH,F}$; cette dépendance est toutefois opposée à celle des autres couplages provenant d'un proton sur une chaîne latérale avec le noyau de fluor sur le cycle. La valeur de $^4J_o^{OH,F}$ est apparemment très sensible à la distance entre le proton et le noyau de fluor et on peut la citer comme un exemple d'un mécanisme négatif de couplage à travers l'espace. Des calculs approchés d'orbitales moléculaires apportent quelques confirmations pour cette dernière suggestion. [Traduit par le journal]

Introduction

The signs and magnitudes of electron-coupled spin–spin coupling constants between nuclei in the side chain and in the benzene ring are known for toluene (1, 2) and many of its ring (3) or α-substituted derivatives (4), for benzaldehyde (5, 6), styrene (7), and aniline (8) derivatives. Their dependence on conformation has been explored in some detail, both experimentally and theoretically (7–9), and is of use in the deduction of the relative energies of conformations (4, 6) as well as in the measurement of large (10) and small (11, 12) barriers to conversion between conformers.

Accurate long-range coupling constants between hydroxyl protons and nuclei on the benzene ring until recently have been observed only for phenol derivatives (5, 13) in which the hydroxyl group is strongly hydrogen bonded to *ortho* nitro or carbonyl groups and is thereby prevented from undergoing relatively rapid intermolecular proton exchange. Under the right circumstances the preexchange lifetime of the hydroxyl protons in the halophenols is also large enough to allow the observation[2] of $^5J_m^{OH,H}$ in compounds of type *1* or *2*. The stereo-



1 **2a** **2b**

specificity of this coupling then yields the relative hydrogen bond strengths between the phenolic proton and the *ortho* halogen atoms (14). The accuracy of such determinations is limited by the intrinsic substituent effects on $^5J_m^{OH,H}$. Fortunately, these perturbations on the stereo-

[1]Research associate, 1973–1974.

[2]As shown in ref. 14 the line widths of the phenolic proton resonance peaks are just as narrow as those of the ring protons.

TABLE 1. Spin–spin coupling constants in Hz* between hydroxyl protons and ring protons or fluorine nuclei in fluorophenol derivatives in dilute CCl_4 solutions

	Compound	$^{4,5,6}J_{o,m,p}^{OH,F}$	$^{5}J_{m}^{OH,H_3}$	$^{5}J_{m}^{OH,H_5}$	% *cis*†
1	2-F-6-NO_2	−0.43	0.68	0.00	0
2	2-F-4,6-diCl	−2.44	0.40	0.20	33
3	2-F-4,6-diBr	−2.58	0.38	0.20	34
4	2-F-4,6-diI	−3.49	0.25	0.28	53
5	2-F-4-Br	−4.42	0.00	0.44	100
6	2,3,5,6-tetraF	−2.49(0.59 ± 0.03)‡	—	—	50
7	3-F-6-NO_2	1.56	—	0.00	0
8	3-F-4,6-diBr	1.53	—	0.00	0
9	3-F-2,4,6-triBr	1.02(1.03)§	—	0.18(0.20)§	32 ± 3‖
10	3-F-2-NO_2	−0.35	—	0.42	100
11	4-F-2-Cl	−0.23 ± 0.03	0.00	0.45	—
12	4-F-2,6-diBr	−0.27	0.26	0.26	—

*The accuracy is estimated at 0.01 Hz for simple spectra of compounds like 2–4, 9, 12; at 0.02 Hz for others, unless otherwise indicated. See ref. 14 for the quality of the spectra.
†The *cis* conformation has the O—H bond *cis* to the C—F bond.
‡The smaller coupling is that over five bonds.
§In dilute benzene-d_6 solution.
‖Assuming $^{5}J_{trans}^{OH,H}$ as 0.57 ± 0.04 Hz.

specificity of $^{5}J_{m}^{OH,H}$ depend more on the degree of substitution than on the position of the halogen atoms, at least for **1** and **2** (14).

In this paper the signs and magnitudes of $^{4}J_{o}^{OH,F}$, of $^{5}J_{m}^{OH,F}$, and of $^{6}J_{p}^{OH,F}$ are reported for some derivatives of the corresponding fluorophenols. Their conformational dependence is investigated. The unique behavior of $^{4}J_{o}^{OH,F}$ is discussed from the viewpoint of a "through-space" (15–25) or "fragment" (26, 27) coupling mechanism. Approximate molecular orbital calculations partially corroborate the experimental conclusions.

Experimental

The derivatives of *o*, *m*, and *p*-fluorophenols were obtained commercially or by standard preparative methods (14). Samples were prepared as previously described and were degassed at concentrations of less than 5 mol%. Not all samples displayed slow intermolecular exchange of the hydroxyl proton. For example, of nine samples of 2,3,5,6-tetrafluorophenol only one yielded the couplings to the fluorine nuclei.

Proton magnetic resonance spectra were calibrated on an HA100D spectrometer at sweep widths of 1 Hz/cm and sweep rates of 0.02 Hz/s. Double resonance experiments (28, 29) yielded the signs of coupling constants. Line widths of the hydroxyl proton resonance peaks were comparable to those of the ring protons. Sample temperatures were 32 °C.

Results and Discussion

Spectral Analyses

Analyses were performed with the aid of the computer program LAME (30, 31) yielding spectral parameters for which the r.m.s. errors were generally well below 0.01 Hz. The coupling constants between ring protons themselves, and between ring protons and fluorine nuclei, were unexceptional in their magnitudes and signs (32–35) and are not tabulated here. Table 1 presents the coupling constants involving the hydroxyl protons. These are of interest in the following discussion.

The Hydroxyl Proton–fluorine Couplings, $J^{OH,F}$

Stereospecificity of $^{5}J_{m}^{OH,F}$

The energy differences between **2***a* and **2***b*, (X, Y, Z = F, Cl, Br, I) are such that comparable $^{5}J_{m}^{OH,H}$ values were measured for both *meta* protons (14). When Z = H, as in **1**, no coupling to H_{m}' was observed, indicating the predominance of the intramolecular hydrogen bonded form in the equilibrium; this is in agreement with far infrared data which gave enthalpies of formation of the intramolecular hydrogen bond, O—H···X as lying between 1.44 and 1.62 kcal/mol (36).

For compounds **6–10** in Table 1 the values of $^{5}J_{m}^{OH,F}$ are also stereospecific. Thus, in **7** and **10** the strong intramolecular O—H···ONO hydrogen bond ensures that the measured couplings are $^{5}J_{trans}^{OH,F} \equiv {}^{5}J_{t}^{OH,F} = 1.56$ Hz and $^{5}J_{cis}^{OH,F} \equiv {}^{5}J_{c}^{OH,F} = -0.35$ Hz, respectively. These two members define the solid line in Fig. 1, where $^{5}J^{OH,F}$ is plotted *vs.* % *cis* conformation of the *m*-fluorophenol derivatives. The *cis* conformation has a *cis* arrangement of O—H and C—F bonds, as illustrated in Fig. 1.

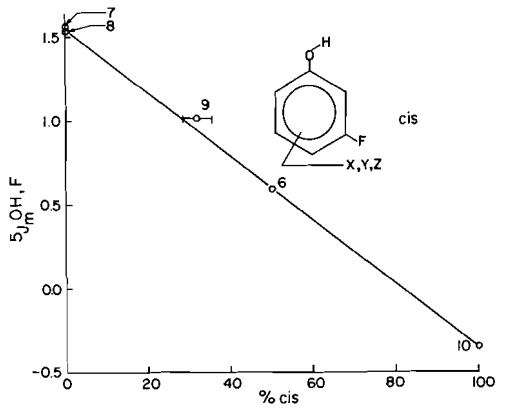

FIG. 1. The values of $^5J_m^{OH,F}$ in Hz in *m*-fluorophenol derivatives are plotted *vs.* the % *cis* conformation, in which the O—H bond lies *cis* to the C—F bond. The points are numbered in accordance with the compounds in Table 1. The point for compound **9** is plotted on the assumption that the population of the *cis* form is given by $^5J_m^{OH,H}$. See text for an elaboration of this procedure.

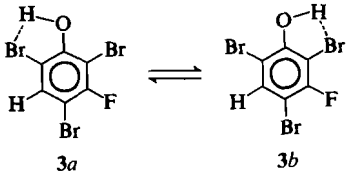
In compound **6** the *cis* and *trans* conformations must be equally abundant. $^5J_m^{OH,F}$ is observed to be 0.59 ± 0.03 Hz and falls on the line in Fig. 1, indicating that $^5J_m^{OH,F}$ is insensitive to intrinsic substituent effects on the electron distribution in the molecule. Furthermore, $^5J_m^{OH,F}$ is 1.53 Hz for 8, indicating 100% *trans*, and this indication is confirmed by the absence of coupling from the hydroxyl proton to the *meta* proton in the *cis* C—H bond.

In 3-fluoro-2,4,6-tribromophenol (compound **9**) $^5J_m^{OH,H}$ is 0.18 Hz. In 2,4,6-tribromophenol $^5J_c^{OH,H} + {}^5J_t^{OH,H} = 0.58$ Hz. Actually, in 10 2,4,6-trihalophenols (14) this sum varies between 0.53 and 0.61 Hz. On the assumption that $^5J_t^{OH,H}$ is 0.57 ± 0.04 Hz one has 32 ± 3% of the *cis* conformation **3***b*. This value is plotted in Fig. 1, together with the observed $^5J_m^{OH,F}$ of 1.02 Hz.



3*a* **3***b*

However, $^5J_m^{OH,F}$ may well be a better indicator of conformational populations than is $^5J_m^{OH,H}$ because it is larger in magnitude and is therefore measurable with a smaller percentage error. $^5J_m^{OH,F}$ also appears less sensitive to intrinsic substituent effects than does $^5J_m^{OH,H}$. Accordingly, using $^5J_m^{OH,F}$ and the calibration line in Fig. 1 gives 28% *cis*, *i.e.*, 28% of **3***b*.

Buttressing of the O—H···X Hydrogen Bond

Clearly, neither $^5J_m^{OH,H}$ nor $^5J_m^{OH,F}$ is compatible with equal abundances of **3***a* and **3***b*. The extra stability of **3***a* could arise for two reasons. First, the steric crowding of the three neighboring halogen atoms could cause an extra repulsion between the lone pairs of the oxygen and bromine atoms in **3***a*, forcing the O—H bond nearer the hydrogen bonded bromine atom and strengthening the interaction. Evidence for such a buttressing is adduced from i.r. spectra (37) on di-*ortho* substituted phenols. Buttressing is also consistent with the behavior of $^4J_o^{OH,F}$, to be discussed below.

Second, the dipole moment of **3***a* is larger than that of **3***b*, the dipole vectors of the O—H and C—F bonds lying more nearly parallel in the former. Classical solution theory (38) suggests the more polar isomer is favored in solvents of dielectric constant greater than unity. Experience (38) then dictates that benzene behaves[3] *as if* it had a dielectric constant of 7 to 9. Accordingly, the coupling parameters of 3-fluoro-2,4,6-tribromophenol were also measured in a dilute benzene-d_6 solution but no significant changes from the values in CCl_4 solution were found (see Table 1). More polar solvents cause intermolecular proton exchange, at least in our laboratory.

In our opinion, the likely explanation of the relative stabilities of **3***a* and **3***b*, the former being about 500 cal/mol more stable at 32 °C, involves the concept of steric crowding. The strength of the relatively weak "five-membered" O—H···X hydrogen bond in *o*-halophenols probably depends on a delicate balance between the effects of charge densities or distributions and O—H···X distances or angles and could well be altered appreciably by small changes in any of these parameters. A systematic variation of the ring substituents, combined with the advantages of $^5J_m^{OH,F}$ as an indicator of conformational populations, may lead to some interesting conclusions.

[3]That is, the relative stabilities of many conformational isomers can be predicted (38) if the dielectric constant is assumed to be larger than the observed one.

Stereospecificity of $^4J_o^{OH,F}$

Reasoning as before, one has $^4J_t^{OH,F}$ as -0.43 Hz and $^4J_c^{OH,F}$ as -4.42 Hz from the data for compounds **1** and **5** in Table 1. If these values are correct, $^4J_o^{OH,F}$ in compound **6** should be $-(4.42 + 0.43)/2 = -2.42$ Hz, comparing fairly well with the observed coupling of -2.49 Hz. The three numbers are plotted *vs.* % *cis* conformation in Fig. 2, where the end points define the solid line.

Compounds **2**, **3**, and **4** possess values of $^4J_o^{OH,F}$ which deviate considerably from the solid line in Fig. 2. A likely explanation once again calls on a small buttressing of the oxygen atom by the large *ortho* halogen atom, causing a small shift of the hydrogen atom towards fluorine. This shift need only be 0.03 Å or less in order to account for the observed deviation of $^4J_o^{OH,F}$ (see below). If the deviation of -0.07 Hz for **6** in Fig. 2 is taken as real, then the deviations are -0.07, -0.70, -0.80, and -0.95 Hz for F, Cl, Br, and I, respectively. In other words, an *ortho* fluorine substituent causes at most a very small buttressing in these phenols.

The proportions of the *cis* and *trans* forms of **2**, **3**, and **4** indicated in Fig. 2 are calculated from the $^5J_m^{OH,H}$ values in Table 1. The deviations from the line in Fig. 2 cannot arise from errors in conformational proportions. For example, for compound **4** there must occur almost 80% *cis* if the point shall fall on the line, implying $^5J_c^{H,OH} \gg {}^5J_t^{H,OH}$ and contradicting a wealth of experimental data concerning the stereospecificity of five-bond couplings to a ring nucleus in benzene derivatives. Furthermore, the internal consistency of the conclusions about the relative hydrogen bond strengths in halophenols (14) would disappear.

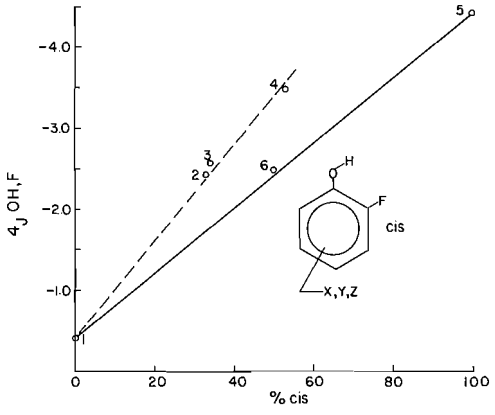

FIG. 2. A plot of $^4J_o^{OH,F}$ in Hz in some *o*-fluorophenol derivatives *vs.* the % *cis* confirmation, in which the O—H and C—F bonds are *cis* to one another. The numbering of the points conforms to that in Table 1.

The implied sensitivity of $^4J_c^{OH,F}$ to the H···F distance in the O—H···F hydrogen bond is discussed below from the viewpoint of spin–spin coupling mechanisms.

The Six-bond Coupling $^6J_p^{OH,F}$

The barrier to rotation of the hydroxyl group lies near 5 kcal/mol in a number of *o*-halophenols (39). The proportion of molecules in which the hydroxyl group lies in the plane of the ring in compounds **11** and **12** is therefore overwhelming at ambient temperatures. The measured values of -0.23 and -0.27 Hz for $^6J_p^{OH,F}$ in **11** and **12** can therefore be taken as those for a planar molecule. A similar situation holds for *p*-fluorobenzaldehyde for which $^6J_p^{F,CHO}$ is -0.44 Hz (6). If it is assumed that a coupling over six bonds in these molecules is transmitted via the π electron system of the ring (40, 41), then the hyperfine interaction constant Q_{OH}^H must be negative and small (32, 40, 41) because Q_{CF}^F is large and positive. Some e.s.r. data suggest Q_{OH}^H as -7 G (42) compared to a Q_{CF}^F of about +40 G (32, 43, 44).

$^4J_c^{OH,F}$ *as a "Through-space" Coupling*

$^4J_t^{OH,F}$ is -0.43 Hz and $^4J_c^{OH,F}$ is -4.42 Hz for the *o*-fluorophenol derivatives in Table 1. In contrast, $^4J_t^{F,CH}$ is -2.5 Hz and $^4J_c^{F,CHCl_2}$ is -0.3 Hz in derivatives of *o*-fluorobenzalchloride (4), whereas $^4J_t^{F,CHO}$ and $^4J_c^{F,CHO}$ are estimated at -1.6 and -0.2 Hz, respectively, in *o*-fluorobenzaldehyde (6). As all these couplings occur for a planar arrangement of the intervening bonds, it appears that the large negative value of $^4J_c^{OH,F}$ in *o*-fluorophenol may arise via an electron-coupled interaction which depends on the proximity of the proton and fluorine nucleus, *i.e.*, via a "through-space" or "fragment" coupling (15–27).

Such a coupling is distinct from other "direct" interactions which would involve only the O—H and C—F bonds (45) and not the other intervening bonds. Such direct interactions are important in coupling over two and three bonds.

In a hydrogen bond the proximity may be high enough so that a through-space interaction, involving overlap of the valence s orbitals on the hydrogen and fluorine atoms, may occur.

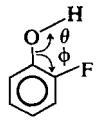
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Such interactions apparently occur when the distance, r_{AB}, between the nuclei is approximately equal to or less than the sum of the van der Waals radii of atoms A and B.

Indeed, one semi-empirical theory (46) makes the coupling proportional to the square of the overlap integral between the valence s orbitals of the two relevant atoms, implying a positive coupling constant, apparently true for ^{19}F, ^{19}F through-space interactions (25). Another semi-empirical theory (27) uses a sum-over-states perturbation method in conjunction with INDO molecular orbitals, predicting large negative $^{1}H,^{19}F$ couplings at small r_{HF} values. Both theories assume a Fermi contact mechanism. The signs of through-space $^{1}H,^{19}F$ couplings are apparently unknown. On the basis of $^{4}J_c^{OH,F}$ it is now suggested that these are negative, insofar as this coupling depends at least to some extent on such a mechanism.

CNDO/2 and INDO-MO-FPT Calculations of $^{4}J_c^{OH,F}$

A standard geometry (47) was assumed for **4** but the angles ϕ and θ were varied in steps of



4

2°, describing a grid defined by $116° \leq \phi \leq 124°$ and $104° \leq \theta \leq 112°$. The finite perturbation was applied to the s orbital of the hydroxyl hydrogen atom in the Fock matrices (48) and yielded 50 computed values of $^{4}J_c^{OH,F}$ over the grid, partitioned between the CNDO/2 and INDO approximations. The distance between the proton and fluorine nucleus lay between 2.05 and 2.42 Å, which may be compared to 2.55 Å as the sum of the van der Waals radii of the hydrogen and fluorine atoms.

The calculated values of $^{4}J_c^{OH,F}$ ranged from +0.64 Hz at 2.42 Å to −12.9 Hz at 2.05 Å. The INDO calculations yielded a $^{4}J^{OH,F}$ of −4.5 Hz at $\phi = 120°$, $\theta = 106°$, and $r_{HF} = 2.21$ Å, while CNDO/2 gave −4.5 Hz at $\phi = 118°$, $\theta = 109°$, and $r_{HF} = 2.18$ Å.

The steep dependence of $^{4}J_c^{OH,F}$ on r_{HF} is very similar to that proposed by Myhre *et al.* (17) for coupling between side-chain protons and ring fluorine nuclei in 2,4,6-trialkylhalobenzenes, attributed to a through-space coupling mechanism. In our calculations a change of 0.03 Å in r_{HF} produces a change of 1 Hz in the vicinity of −4.5 Hz and is therefore consistent with the buttressing effect on $^{4}J_o^{OH,F}$ proposed in connection with the data in Fig. 2.

Of course, the approximate nature of the semi-empirical MO-FPT treatment does not permit the statement that the r_{HF} values which reproduce the observed J values shall also represent the lowest energy of the molecule. In fact, the calculated energy minima occur at $r_{HF} = 2.30$ Å for the CNDO/2 and at 2.35 Å for the INDO calculations, emphasizing the approximate nature of the theory.

The computations agree with our suggestion that through-space $^{1}H,^{19}F$ couplings are negative, in negation of one theory (46) but in confirmation of the sum-over-states model (27). It is true that such couplings are thought to arise from repulsive overlap of nonbonding orbitals centered on the coupled nuclei, whereas the $^{4}J^{OH,F}$ values observed here arise in a weakly (hydrogen) bonding situation. However, the sum-over-states model accommodates this situation (see p. 37 of ref. 27) and predicts a negative coupling.

Other CNDO/2 and INDO-MO-FPT Calculations

For a standard geometry (47) but with $\phi = 123.5°$ and $\theta = 108° 50'$, conforming with microwave data (49), such calculations were performed for *p*- and *m*-fluorophenol. As expected, the INDO calculations of $^{5}J_m^{OH,H}$ and $^{5}J_m^{OH,F}$ reproduced the zigzag stereospecificity of these couplings but considerably over estimated their magnitude, in line with similar results found for the corresponding fluorobenzaldehydes (6), while CNDO/2 yielded values in better agreement with the data in Table 1. Neither approximation gave a negative value for $^{5}J_c^{OH,F}$.

On the other hand, $^{6}J_p^{OH,F}$ was given as −0.15 and 0.02 Hz by INDO and CNDO/2, respectively, but became 1.63 and 0.02 Hz when the O—H group lay in a plane perpendicular to the benzene ring. The INDO results emphasize the increased probability of a σ–π interaction where the O—H group rotates out of the node of the π electron system, so that such an occurrence could be followed by observing $^{6}J_p^{OH,F}$ in an appropriate compound.

For the θ and ϕ angles as given, the *cis* form of *o*-fluorophenol yielded $^{4}J_c^{OH,F} =$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

$-0.25(-0.23)$ Hz and ${}^4J_t^{OH,F} = -2.16(-0.80)$ Hz for the INDO (CNDO/2) methods, in agreement with the stereospecificity observed for the other molecules discussed above, and confirming the necessity of a close approach of H and F atoms if a large negative ${}^4J_c^{OH,F}$ value is to be observed. Hence at least part of ${}^4J_c^{OH,F}$ is probably contributed by a through-space interaction.

The observed torsion frequencies yield a twofold barrier of 2.96 kcal/mol for *p*-fluorophenol (39) whereas the calculations gave 3.17 (INDO) and 2.71 (CNDO/2) kcal/mol. Similarly, the INDO (CNDO/2) calculations predict hydrogen bond energy of 1.00 (0.97) kcal/mol but a barrier of only 3.77 (3.11) kcal/mol, as compared to a torsion barrier of 4.84 kcal/mol. Of course, an accurate calculation of barriers requires *ab inito* methods (50). The selected values quoted here perhaps indicate that the m.o. calculations in this paper have some degree of validity.

In conclusion the proportions of *cis* and *trans* isomers of halophenol derivatives can be determined fairly reliably from the stereospecific couplings over five bonds between the hydroxyl protons and ring protons or fluorine nuclei, the coupling to the latter being of relatively large magnitude and remarkably insensitive to intrinsic substituent effects. Buttressing effects on the strengths of OH···X hydrogen bonds (X = halogen) occur and are most dramatically indicated by ${}^4J_c^{OH,F}$ in *o*-fluorophenol derivatives. This coupling evidently has a large through-space component, which is very sensitive to distance between the hydroxyl proton and the fluorine nucleus. ${}^6J_p^{OH,F}$ is negative for planar *p*-fluorophenol derivatives but theory indicates substantial positive values when the hydroxyl group leaves the plane of the benzene ring.

Commentaire: Sur la sensibilité differente du vibrateur carbonyle d'acétophénones *méta* et *para* substituées aux facteurs σ_m^+ et σ_p^+

M. BERTHELOT ET C. LAURENCE

Laboratoire de Spectrochimie Moléculaire, U.E.R. de Chimie, B.P. 1044, 44037 Nantes Cédex, France

Reçu le 1 février 1974

M. BERTHELOT et C. LAURENCE. Can. J. Chem. **53**, 993 (1975).

Les conclusions de Laurence et Wojtkowiak sur la nécessité de traiter séparément les substituants *méta* et *para* dans les corrélations entre les fréquences ν_{CO} d'acétophénones *m*- et *p*-substituées et le facteur σ^+ sont confirmées. A partir d'un échantillonnage de substituants adapté au mieux au problème posé, les auteurs trouvent en effet une différence significative entre les coefficients ρ_p^+ et ρ_m^+ avec un pourcentage de confiance supérieur à 99.9%.

M. BERTHELOT and C. LAURENCE. Can. J. Chem. **53**, 993 (1975).

The conclusions of Laurence and Wojtkowiak concerning the need to treat separately *meta* and *para* substituents in correlations between the frequencies ν_{CO} for substituted acetophenones and the factors σ^+ are confirmed. From a sampling of substituents chosen to illustrate best the effect under consideration, we indeed find a significant difference between the coefficients ρ_p^+ and ρ_m^+ at a confidence level greater than 99.9%. [Journal translation]

Dans un travail récent Krueger (1) rapporte une corrélation linéaire entre la fréquence ν_{CO} de 27 acétophénones substituées sur le noyau et le facteur σ^+ (2) avec un coefficient de corrélation r de 0.988 et un écart-type s sur l'estimation de ν_{CO} par l'éq. 1 de 1.2 cm^{-1}

$$[1] \quad \nu_{CO}\,(cm^{-1}) = 11.53\sigma^+_{m\ et\ p} + 1691.5$$

Selon lui ces résultats contredisent les conclusions de Laurence et Wojtkowiak (3) sur la différence des coefficients ρ_m^+ et ρ_p^+ dans les éqs. 2 et 3 de la corrélation $\nu_{CO} = \rho^+\sigma^+ +$ constante

$$[2] \quad \nu_{CO}\,(cm^{-1}) = 14.86\sigma_m^+ + 1690.3$$
$$n = 8 \quad r = 0.969 \quad s = 1.2\ cm^{-1}$$

$$[3] \quad \nu_{CO}\,(cm^{-1}) = 10.48\sigma_p^+ + 1691.4$$
$$n = 10 \quad r = 0.983 \quad s = 1.3\ cm^{-1}$$

En effet, l'éq. 1 se rapporte à un plus grand nombre de composés et possède un coefficient de corrélation plus élevé.

A partir des coefficients ρ_p^+ et ρ_m^+ des éqs. 2 et 3 et de leurs écarts-type $s_{\rho_p^+}$ et $s_{\rho_m^+}$, si l'on teste la différence $\rho_p^+ - \rho_m^+$ en formant le rapport[1]

$$[4] \quad t = (\rho_p^+ - \rho_m^+)/s_{(\rho_p^+ - \rho_m^+)}$$

on trouve une valeur $t = 2.58$ qui correspond dans la table de distribution du t de Student (4) pour 14 degrés de liberté à une probabilité comprise entre 2 et 5% que la différence $\rho_p^+ - \rho_m^+$ soit due au hasard. Ce test ne nous paraissant pas décisif pour juger avec un grand pourcentage de confiance si $\rho_p^+ - \rho_m^+$ est significativement différent de zéro, nous avons complété l'échantillonnage de Laurence et Wojtkowiak avec 7 substituants *para* et 4 substituants *méta*. L'additivité des effets des substituants *méta* et *para* a également été étudiée sur 4 composés polysubstitués. Les fréquences ν_{CO} de 32 acétophénones sont ainsi reportées dans le tableau 1. Les résultats des corrélations correspondantes entre ces valeurs et σ^+ sont consignés dans le tableau 2.

Les valeurs ρ et s_ρ des éqs. 5 et 6 permettent de calculer une valeur $t = 4.12$ à partir de la formule 4. La table de t lue pour 25 degrés de liberté nous autorise alors à affirmer que $\rho_p^+ - \rho_m^+$ est différent de zéro avec un pourcentage de confiance supérieur à 99.9%. Les conclusions de Laurence et Wojtkowiak se trouvent ainsi confirmées sur un échantillonnage aussi nombreux que celui de Krueger. Cet échantillonnage nous paraît surtout mieux adapté au problème posé, pour les raisons suivantes:

(*a*) il ne nous paraît pas judicieux d'inclure des substituants *ortho* dans une étude voulant juger la sensibilité d'une propriété aux effets des substituants *méta* et *para*.

[1] $s_{(\rho_p^+ - \rho_m^+)}$ est l'écart-type de la différence $\rho_p^+ - \rho_m^+$. Il est égal à $\sqrt{s_{\rho_p^+}^2 + s_{\rho_m^+}^2}$.

TABLEAU 2. Corrélations entre fréquences ν_{CO} d'acétophenones *m*- et *p*-substituées et σ^+

Equation[a]	n[b]	r[c]	s[d]	s_ρ[e]
[5] $\nu = 15.50\sigma_m^+ + 1690.2$	12	0.974	1.3	1.13
[6] $\nu = 10.44\sigma_p^+ + 1691.5$	17	0.985	1.1	0.48
[7] $\nu = 10.99\sigma_{m,p}^+ + 1691.5$	28	0.975	1.3	0.49
[8] $\nu = 10.84\sigma_{m,p}^+ + 1691.6$	32	0.969	1.4	0.50

[a]Les éqs. 5 à 8 se rapportent dans l'ordre: aux composés *méta*, aux composés *para*, aux composés *méta* et *para* et enfin aux composés *méta*, *para* et polysubstitués en *méta* et *para*.
[b]Nombre de points.
[c]Coefficient de corrélation.
[d]Écart-type sur l'estimation de ν.
[e]Écart-type sur le coefficient de régression ρ.

TABLEAU 3. Comparaison des fréquences ν_{CO} expérimentales et des fréquences calculées en supposant l'additivité des effets de substituant

	Calcul de la fréquence ν_{CO}				
Substituants	ν_{CO} acétophénone	+	Incréments de substitution	= ν_{calc}	$\nu_{calc} - \nu_{expti}$
3,4,5-tri-OCH_3	1691.2		2(−1.6) − 8.1	1679.9	5
3.4-di-CH_3	1691.2		−3.9 − 0.5	1686.8	0
3.4-di-Cl	1691.2		4.5 + 0.4	1696.1	0.1
3-NO_2, 4-OCH_3	1691.2		10 − 8.1	1693.1	1.2

(*b*) de même les composés polysubstitués nous semblent à proscrire de l'échantillonnage du fait du caractère aléatoire de la loi d'additivité des effets de substituant mis en évidence dans le tableau 3 où l'on compare la fréquence ν_{CO} expérimentale des composés polysubstitués à la fréquence calculée en additionnant les incréments de substitution déterminés à partir des acétophénones monosubstituées. Ceci conduit dans l'éq. 8 à une diminution de la précision de la corrélation par rapport à l'éq. 7.

(*c*) le nombre de substituants *méta* nous semble insuffisant dans l'échantillonnage de Krueger; en tenant compte des remarques (*a*) et (*b*) il n'est que de 4 alors que notre étude porte sur 11 de ces substituants. Puisque σ_m^+ traduit l'effet de substitution avec une précision moindre que σ_p^+ (pour l'éq. 5 $r = 0.974$ et

pour l'éq. 6 $r = 0.985$), on explique ainsi en partie, le coefficient de corrélation supérieur trouvé par Krueger.

(*d*) l'étude de Krueger ne porte en réalité que sur une combinaison de 8 substituants différents (NH_2, OCH_3, CH_3, F, Cl, Br, I, NO_2) alors que notre échantillonnage contient 17 substituants très diversifiés (NH_2, $NHCOCH_3$, OCH_3, OH, SCH_3, CH_3, C_2H_5, $C(CH_3)_3$, C_6H_5, F, Cl, Br, I, COOH, CF_3, CN, NO_2). En particulier Krueger ne prend en considération qu'un seul substituant électroattracteur $\pi(NO_2)$ alors que nous étudions 4 substituants de ce type (COOH, CF_3, CN, NO_2) conformément aux recommandations de Taft *et al.* (5) sur l'importance de l'équilibre numérique à établir entre les diverses classes de substituant.

Partie expérimentale

Les composés utilisés sont des produits commerciaux purifiés par recristallisation fractionnée ou distillation sous pression réduite. Les mesures ont été effectuées en solution diluée dans du CCl_4 de qualité spectroscopique désséché sur tamis moléculaire 4 Å, à l'aide d'un appareil Beckman IR 9 étalonné avec la vapeur d'eau, purgé à 8 p.p.m. d'eau atmosphérique et dont la précision dans cette région est de 0.5 cm^{-1} et la reproductibilité de 0.1 cm^{-1}. Ces résultats, moyennes de trois mesures, sont en bon accord avec nos valeurs précédentes (3), sauf pour *p*-F, et avec les valeurs de Jones *et al.* (6) et Krueger (1).

Sorption of the Inert Gases (Ar, Kr, and Xe) in Type A Zeolites

RUSSELL IAN DERRAH[1] AND DOUGLAS MORRIS RUTHVEN

Department of Chemical Engineering, University of New Brunswick, Fredericton, New Brunswick E3B 5A3

Received November 12, 1974

RUSSELL IAN DERRAH and DOUGLAS MORRIS RUTHVEN. Can. J. Chem. **53**, 996 (1975).

Theoretical potential profiles for Ar, Kr, and Xe occluded in an idealized 5A zeolite are calculated and used to evaluate the Henry's law equilibrium constants for these species. Calculations were made using the three common formulae to estimate the dispersion constants (Kirkwood–Mueller, Slater–Kirkwood, and London) and the theoretical Henry constants are compared with the values obtained directly from experimental equilibrium isotherms. For both Kr and Xe the Slater–Kirkwood formula gives the best agreement with the experimental values while, for argon, the London formula is best. At higher concentrations the isotherms for Kr can be well represented by a simple Langmuir expression with eleven sites per cavity while for Xe there appears to be a transition from localized sorption at low temperatures to a mobile adsorbed phase at higher temperatures. These conclusions are qualitatively consistent with the results of the theoretical potential calculations.

RUSSELL IAN DERRAH et DOUGLAS MORRIS RUTHVEN. Can. J. Chem. **53**, 996 (1975).

On calcule les profils potentiels théoriques de Ar, Kr et Xe occlus dans une zéolithe 5A idéalisée; on utilise les valeurs ainsi calculées pour évaluer les constantes d'équilibre de la loi d'Henry pour ces espèces. On a fait des calculs utilisant les trois formules ordinaires pour estimer les contantes de dispersion (Kirkwood–Mueller, Slater–Kirkwood et London) et l'on compare les constantes théoriques d'Henry avec les valeurs obtenues directement à partir des isothermes expérimentales d'équilibre. Pour le Kr et le Xe, la formule de Slater–Kirkwood donne la meilleure relation avec les valeurs expérimentales alors que pour l'argon, la formule de London est la meilleure. A des concentrations plus hautes, les isothermes de Kr peuvent aussi être présentés par une expression simple de Langmuir avec onze sites par cavité alors que pour Xe il semble qu'il existe une transition passant d'une sorption localisée à basse température à une phase adsorbée mobile à plus haute température. Ces conclusions sont qualitativement en accord avec les résultats des calculs potentiels théoriques. [Traduit par le journal]

The monatomic nature of the rare gas molecules makes these species ideally suited to fundamental sorption studies since the equilibrium data are amenable to a more detailed theoretical analysis than is at present feasible for more complex molecules. An added incentive for such studies has arisen from the practical requirement for a suitable adsorbent for the removal of krypton and xenon which are formed in considerable quantities during the controlled fission of uranium fuels. The sorption of argon and krypton in chabazite (1–4) and faujasite (5, 6) have been investigated in some detail. More recently the results of several experimental studies of sorption in the type A zeolites have been reported and a semi-empirical correlation of the isotherms has been given by Lee and Basmadjian (7). Kiselev and co-workers have achieved some success in the theoretical calculation of Henry's law equilibrium constants from potential theory (8–10) but, as yet, the nature of the adsorbed species remains uncertain and the similarities and differences between the isotherms for the different gases have not been examined in detail.

In the present paper experimental equilibrium isotherms for the sorption of argon, krypton, and xenon in 4A and 5A zeolites are presented and discussed in relation to the published data of other authors. In particular the present data, which were obtained at subatmospheric pressures, are compared with the recently published high pressure isotherms of Barrer, Papadopoulos, and Ramsay (11), thus allowing the validity of model isotherms to be tested over a very wide range of conditions.

Experimental

Equilibrium isotherms were measured gravimetrically using a Cahn vacuum microbalance system. Prior to the experimental measurements the sample of zeolite (Linde 4A or 5A crystals) was degassed at 400 °C, 10^{-5} Torr for several hours. The isotherms obtained under these con-

[1]Present address: C.I.L., Central Research Laboratories, McMasterville, Quebec.

ditions were perfectly reversible and reproducible and show good agreement with the isotherms of other workers who used an equally severe degassing procedure. The isotherms for xenon reported by Kitani and Takada (12) are, under comparable conditions, appreciably lower than those obtained in the present study presumably as a result of an inadequate regeneration procedure (temperatures of only 200 °C were used).

Experimental Henry's Law Constants

At sufficiently low pressures the equilibrium isotherm reduces to a simple linear expression

$$[1] \qquad c = Kp$$

where c is the sorbate concentration at equilibrium pressure p. Under the conditions of the present study (temperatures 190–398 °K, pressures 0–400 Torr) the isotherms for argon and krypton were linear over a substantial pressure range so that the Henry constants (K) could be found directly. The low temperature isotherms for xenon, however, showed significant curvature and an extrapolation procedure was needed to determine the limiting slopes. Two methods were used: the Langmuir plot and plots of log (c/p) *vs.* c, as recommended by Barrer and Davies (4). The values found in these two ways showed good agreement.

The van't Hoff plot showing the temperature dependence of the Henry constants is given in Fig. 1 which includes also the values calculated from previously reported isotherms. The values of K_0 and q_0 defined by the equation

$$[2] \qquad K = K_0 e^{q_0/RT}$$

are given in Table 1. The Henry constants for 4A and 5A zeolites are very similar. There is no significant difference between the present 4A and 5A values for krypton and argon while the 4A values calculated from the data of Harper *et al.* (15), Springer (13), Ackley and Browning (16), and Lloyd and McNees (17) are about 80% of the present values for 5A. The sorption of xenon in the 4A sieve was too slow to allow reliable equilibrium data to be obtained and even for krypton fairly high temperatures are required, thus restricting the range of concentrations over which the isotherms could be measured.

Theoretical Calculation of Henry Constants

The Henry constant may be simply expressed as a ratio of partition functions

$$[3] \qquad K = f_z \exp[(u_g - u_z)/kT]/f_g' \, kT$$

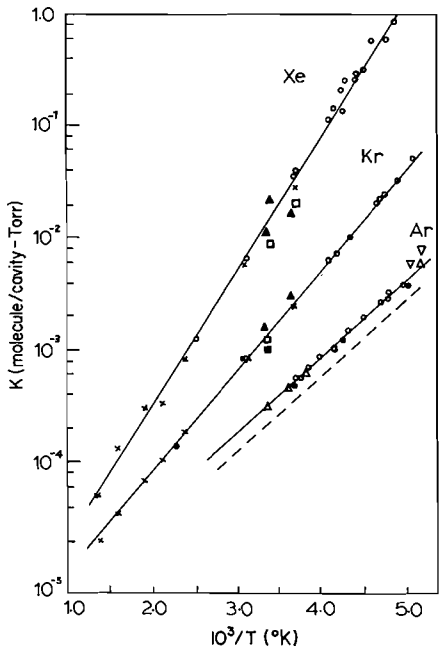

FIG. 1. Van't Hoff plot showing temperature dependence of Henry's law constants for sorption of inert gases in 4A and 5A zeolites: this work, ○, (5A); ●, (4A); △, Springer (13) (5A); ▽, Cook (14) (5A); Ackley and Browning (16), □, (5A); ■, (4A); ▲, Lloyd and McNees (17) (5A); ×, Barrer *et al.* (11); ---, data of refs. 13 and 15 for Ar-4A.

f_z is the partition function for an adsorbed molecule, f_g' is the partition function per unit volume for the gaseous molecule, $u_g - u_z$ is the difference in potential energy, and k is Boltzmann's constant. Since the rare gas molecules have no internal degrees of freedom the ratio of partition functions reduces simply to the configuration integral (Z) for a single molecule occluded within a cavity of the zeolite lattice

$$[4] \qquad K = Z/kT$$

where $Z = \int_v \exp(-u(\boldsymbol{r})/kT) \cdot d\boldsymbol{r}$ and $\boldsymbol{r}$ is the position vector.

In order to calculate the configuration integral detailed knowledge of the potential energy contours within the cavity is required. The interaction energy for an inert gas molecule, which has no permanent dipole or quadrupole moment, may be written simply as the sum of the contributions arising from dispersion (ϕ_D), repulsion (ϕ_R), and polarization (ϕ_P) energies:

$$[5] \qquad u(\boldsymbol{r}_i) = \phi_D + \phi_R + \phi_P$$

TABLE 1. Comparison of theoretical and experimental Henry constants for 5A zeolite correlated according to eq. 2

Gas	Method of calculation	Temperature range (°K)	$K_0 \times 10^6$ (molecule/cavity-Torr)	q_0 (kcal/mol)
Ar	Experimental	200–300	1.04	3.36
	Theory eq. 9	200–300	1.64	5.21
	Theory eq. 10	200–300	1.98	4.25
	Theory eq. 11	200–300	2.89	2.9
	ref. 26	80–90	—	3.0
Kr	Experimental	200–245	1.26	4.24
	Theory eq. 9	200–300	2.22	6.06
	Theory eq. 10	200–300	2.72	4.32
	Theory eq. 11	200–300	2.38	3.52
	ref. 11	273–723	—	4.66
	ref. 33	200–300	—	4.25
Xe	Experimental	200–400	1.29	5.38
	Theory eq. 9	200–350	1.21	7.78
	Theory eq. 10	200–350	1.65	5.05
	Theory eq. 11	200–350	2.15	3.62
	ref. 11	273–723	—	5.25

[6] $$\phi_D = \sum_j A_{ij}/r_{ij}^6$$

[7] $$\phi_R = \sum_j B_{ij}/r_{ij}^{12}$$

[8] $$\phi_P = -\frac{1}{2}\alpha_i \left\{\text{grad}\left(\sum_j \frac{e_j}{(r_i - r_j)}\right)\right\}^2$$

α_i is the polarizability of a sorbate molecule located at position vector r_i, r_j is the position vector of the jth ion of the zeolite lattice (charge e_j e.s.u.), and r_{ij} is the distance between probe molecule and lattice ion. The dispersion constant A_{ij} may be estimated by the Kirkwood–Mueller (18, 19), Slater–Kirkwood (20), or London (21) formulae

[9] $$(A_{ij})_{KM} = 6mc^2\alpha_i\alpha_j/(\alpha_i/\chi_i + \alpha_j/\chi_j)$$

[10] $$(A_{ij})_{SK} = 3eh\alpha_i\alpha_j/[4\pi\sqrt{m}(\sqrt{\alpha_i/n_i} + \sqrt{\alpha_j/n_j})]$$

[11] $$(A_{ij})_L = 1.5\alpha_i\alpha_j E_i E_j/(E_i + E_j)$$

m and e are respectively the mass and charge of an electron, c is the velocity of light, h is Planck's constant, χ is diamagnetic susceptibility, n is the number of electrons in the outermost shell, and E the ionization potential of species i or j. The repulsion constant B_{ij} is calculated by setting the equilibrium separation of an isolated molecule–ion pair (r_e) equal to the mean van der Waals radius (σ)

[12] $$\left\{\frac{\partial}{\partial r_{ij}}[u(r_{ij})]\right\}_{r_e} = 0$$

$$r_e = (\sigma_i + \sigma_j)/2$$

whence

[13] $$B_{ij} = \tfrac{1}{2}A_{ij}r_e^6(1 + \alpha_i e_j^2 r_e^2/3A_{ij})$$

Using eqs. 5–8, one of the eqs. 9–11, and eq. 13 the potential energy of a probe molecule at any point within the cavity may be calculated, provided that the positions of all ions in the crystal lattice are known.

In the present calculation the ionic positions given by Broussard and Shoemaker (22) were used and the small contribution arising from the Si and Al ions was neglected. An idealized A zeolite containing 4 Na^+ and 4 Ca^{2+} ions located symmetrically in the type I sites (near the centers of the 6-membered oxygen rings) was considered. Calculations were also performed assuming 8 hypothetical $NaCa^{+1.5}$ ions per cavity as suggested by Whitford (23). The resulting potential profiles agreed fairly well with those obtained using the symmetrical tetrahedral arrangement of Ca^{2+} and Na^+. A few calculations were performed using random arrangements of Ca^{2+} and Na^+. In all cases of random arrangement the polarization energy was unrealistically large as a result of the charge imbalance in the particular cavity considered.

*In cal cm^6 mol^{-1}.
†In cal cm^{12} mol^{-1}.

Since the Si and Al atoms were neglected in the calculations, the oxygen ions were each assigned a charge of $-e/4$ after Kiselev (8). The molecular constants used in the calculations are summarized in Table 2 and the corresponding values of the dispersion and repulsion constants are given in Table 3.

The dispersion and repulsion energies at each point were obtained by direct summation of the contributions arising from interaction between a probe molecule and each ion in a $5 \times 5 \times 5$ block of cells. The electric field was calculated from the vector sum of the individual ionic contributions and the polarization energy was then obtained directly from eq. 8. A few calculations were carried out using a $10 \times 10 \times 10$ block of cells but the calculated energies showed no significant difference from those obtained for the $5 \times 5 \times 5$ block indicating that the effect of ions outside the $5 \times 5 \times 5$ block of cells could be neglected.

Potential profiles across the cavity in several directions were calculated using dispersion constants given in Table 3. The profiles which are illustrated in Figs. 2–4, were then used to calculate the configuration integral Z. The integral by which Z is defined was replaced by a double summation over radial coordinate (r) and direction, with the weighting factor $f(j)$ chosen to be proportional to the fraction of the cavity surface taken up by ions (or windows) of a particular type

$$[14] \quad Z = \sum_{j=1}^{N} f(j) \sum_{r=0}^{R} 4\pi r^2 \times \exp\left[-u(r, j)/kT\right] \cdot \Delta r$$

where

$$\sum_{j=1}^{N} f(j) = 1$$

and $R = 6.16$ Å is the maximum radius of the cavity. Further details including the values assigned to $f(j)$ are given by Derrah (24).

By an exactly similar calculation the average energy of interaction for an adsorbed molecule $\boldsymbol{u}$ was obtained from the integral

$$[15] \quad \boldsymbol{u} = \int_v \frac{u(\boldsymbol{r}_i) \cdot \exp\left(-u(\boldsymbol{r}_i)/kT\right) \cdot d\boldsymbol{r}_i}{Z}$$

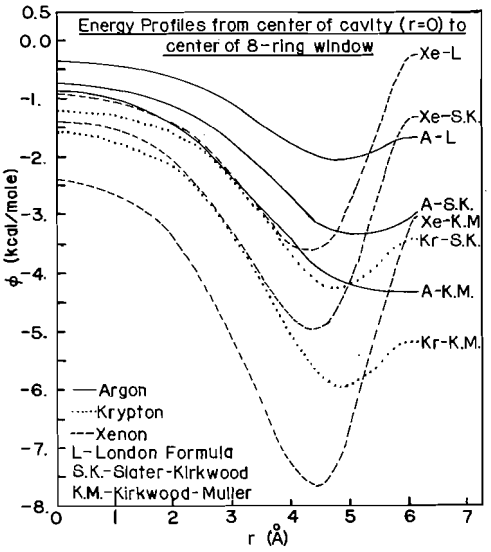

FIG. 2. Potential profiles from center of cavity to center of 8-membered oxygen window showing effect of choice of dispersion constant.

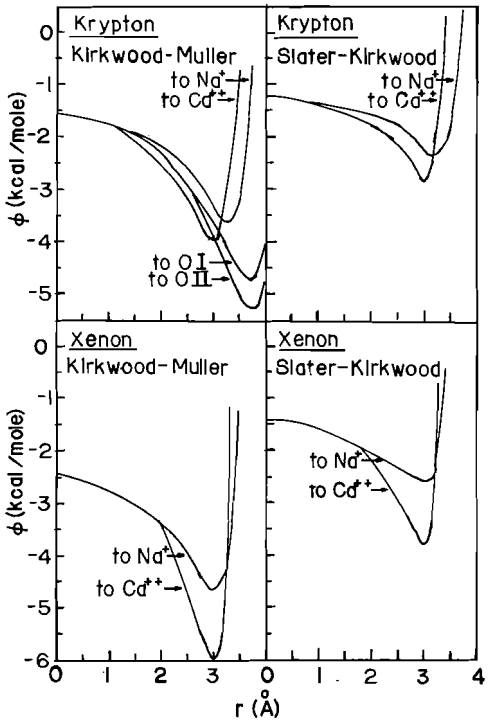

FIG. 3. Potential profiles from center of cavity to various ions showing effect of choice of dispersion constant. (The Na^+ and Ca^{2+} ions are located at the centers of the 6-membered oxygen rings. O_I denotes an oxygen shared between a 6 and 4-membered ring. O_{II} denotes an oxygen shared between an 8 and 6-membered ring.)

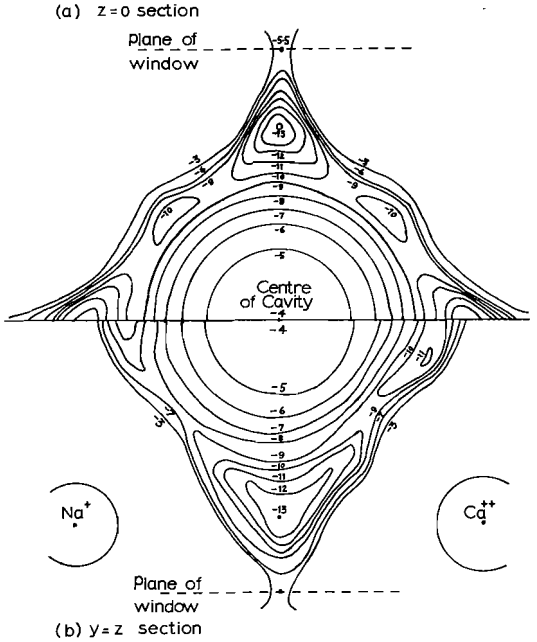

FIG. 4. Potential energy contours for a xenon atom in an idealized 5A zeolite cavity: (*a*) shows a section along a plane bisecting the unit cell through the centers of four 8-membered oxygen windows ($z = 0$ plane); (*b*) shows a section along a plane bisecting the unit cell on the diagonal ($y = z$ plane). Kirkwood–Mueller dispersion constants were used in the calculation of these contours. Potentials are given in units of 10^{-21} cal/molecule.

The theoretical values for the limiting heat of sorption q_0 were then obtained from the relation

$$[16] \qquad q_0 = -u + RT$$

It may be seen from Figs. 2 and 3 that the different methods of estimating the dispersion constants lead to significantly different potential profiles. Errors are also compounded by the addition of the terms in eq. 5 since small differences between relatively large quantities are involved. As a result of these uncertainties the potential energy profiles cannot be considered as quantitatively accurate although they give useful qualitative and semiquantitative information. It has been shown by Young and Crowell (25) that the constants in eqs. 9–11 do not exactly match the empirical potential profiles for the interaction of two inert gas molecules as obtained from crystal data although, of the three formulae, the Slater–Kirkwood expression was found to be the best approximation. This suggests that in interpreting the results of the

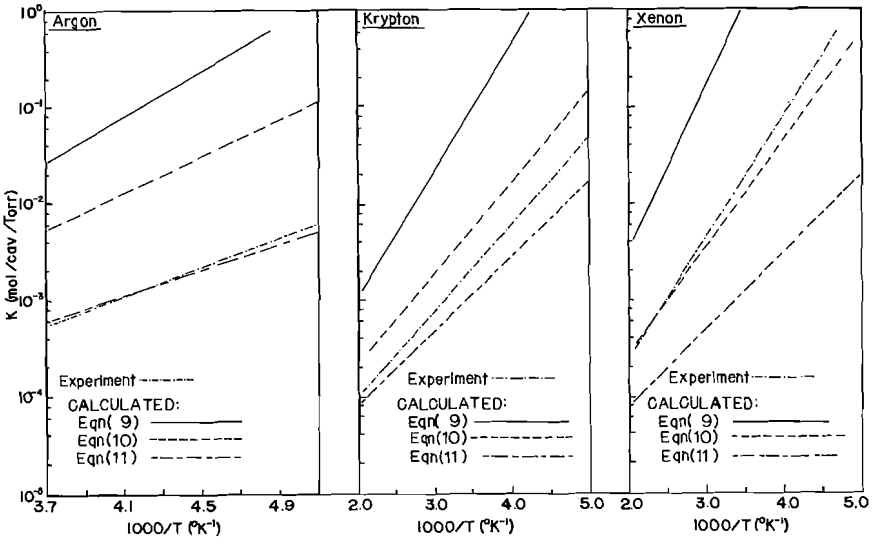

FIG. 5. Comparison of experimental Henry constants with theoretical values calculated from potential energy profiles using Kirkwood–Mueller, Slater–Kirkwood, and London dispersion constants.

present calculations one should probably consider the Slater–Kirkwood values to give the best representation of the actual energy profiles.

The Henry's law constants calculated by integration of the potential profiles are summarized in Table 1 and in Fig. 5 in which the experimental data are also shown. It may be seen that the Slater–Kirkwood expression does indeed give the best prediction of the Henry constant for both krypton and xenon and that the values for argon are correct within an order of magnitude. A somewhat better representation of the experimental data for argon is obtained from the London formula but this formula gives constants for krypton and xenon which are considerably smaller than the experimental values.

In view of the uncertainties involved in the calculation of the potential profiles, the agreement between the theoretical and experimental Henry constants may be considered satisfactory. However, it is apparent that, with the present state of knowledge, the theoretical prediction of Henry constants does not offer a viable alternative to direct experimental measurements, even for the rare gases. For more complex molecules the problems involved in the theoretical calculations are even more severe owing to the possibility of molecular rotation and the distribution of the centers of force.

Variation of Isosteric Heat with Sorbate Concentration

The concentration range covered by the argon isotherms was so low (0–1 molecule/cavity) that no significant variation in isosteric heat of sorption could be observed. The data for krypton and xenon covered a larger concentration range and in order to extend the range of temperatures over which the isosteres could be plotted, and so improve the accuracy of estimation of the isosteric heat, the present isotherms were taken in conjunction with the high pressure – high temperature isotherms of Barrer *et al.* (11).

Over the range 0–6 molecules per cavity the isosteric heat of krypton was essentially constant (~4.2 kcal/mol) while, for xenon, the isosteric heat showed a slight increase from about 5.4 to 6.0 kcal/mol. Similar near constant or slightly increasing values of isosteric heats have been observed for these gases in other zeolites (4, 6, 11) and in the case of krypton and argon in 5A zeolites the values have been confirmed by calorimetric measurements (27, 33).

Isotherm Models

Various theoretical models have been used to correlate the isotherms for sorption of inert gases in the type A zeolites. Mahajan and Walker (28), who reported isotherms for krypton in 5A

zeolite at 195, 273, and 298 °K, correlated their data in terms of the Polanyi potential theory. This theory does not really give an adequate representation of the data as different characteristic curves of W (volume sorbed) *vs.* ΔG (adsorption potential) are obtained below and above the critical temperature. Furthermore, the Polanyi theory suffers from the disadvantage that it does not reduce automatically to Henry's law in the low concentration limit. In order to obtain insight into the nature of the sorbed species a more detailed physical model is needed.

Lee and Basmadjian (7) attempted to develop a general correlation of equilibrium data for the rare gases in A type zeolites based on the theory of pore volume filling. The isotherm equation involves a relation between the effective volume of a sorbed molecule and the average free energy of adsorption. It was assumed that the average interaction energy of a mobile sorbed molecule is equal to the interaction energy (sum of the molecule–ion interactions) for a molecule in the center of the cavity. This is a poor assumption as may be seen from the potential energy profiles, illustrated in Figs. 2–4. This method of estimation gives too high a value (too near zero) for the interaction energy but the effect of this error is to some extent compensated for by calculating the polarization energy contribution from experimental data. A fairly good fit of the isotherm data is thus obtained using only a single empirical parameter.

The results of the theoretical potential calculations, which are discussed above, suggest considerable energetic heterogeneity within the zeolite cavity. One may therefore expect that single atom molecules, such as the rare gases, will be adsorbed at specific localized sites and that mobility within the cavities will be limited. It is in principle possible to distinguish between a localized and mobile adsorbed phase by analysis of the isotherms. This approach has been used in several previous studies.

Ideal localized adsorption on a set of discrete sites with no interaction between adsorbed molecules leads to the simple Langmuir expression

$$[17] \qquad bp = \theta/1-\theta)$$

where b is an equilibrium constant, $\theta = c/c_s$, and c_s is the number of sites per cavity. Weak interaction between neighboring adsorbed molecules leads to the modified expression

$$[18] \qquad bp = \{\theta/(1-\theta)\} \exp(2w\theta/RT)$$

in which allowance is made for the pair interaction energy $2w/z$ and the coordination number z is assumed to be constant for all sites. The case of ideal mobile adsorption leads to the Volmer equation

$$[19] \qquad bp = \{\theta/(1-\theta)\} \exp\{\theta/(1-\theta)\}$$

The isotherms for argon and krypton in H-chabazite (4) showed almost ideal Langmuir behavior (eq. 17) at least for $\theta < 0.65$ while the isotherms for krypton in Na-faujasite (6) were interpreted in terms of eq. 18, again suggesting localized adsorption but with some sorbate–sorbate interaction. By contrast, the isotherms for argon in both mordenite (29) and chabazite (2) have been found to obey Volmer's equation, suggesting a mobile adsorbed phase. The xenon isotherms could not however be adequately interpreted in terms of any simple model equation and this led Barrer and Davies (4) and later Barrer, Papadopoulos, and Ramsay (11) to use an empirical virial expression to correlate their data.

An alternative model isotherm has recently been developed for a system in which the sorbed molecules are confined within a particular cavity but are freely mobile within the cavity (30, 31). For such a system, simplified considerations of the reduction in free volume available to the sorbed molecules lead to the following expression for the isotherm

$$[20] \qquad c = \frac{Kp + (Kp)^2(1 - 2\beta/v)^2 + \ldots + \dfrac{(Kp)^m}{(m-1)!}(1 - m\beta/v)^m}{1 + Kp + \dfrac{1}{2!}(Kp)^2(1 - 2\beta/v)^2 + \ldots + \dfrac{(Kp)^m}{m!}(1 - m\beta/v)^m}$$

in which the small intermolecular attraction terms have been dropped. In this expression v is the cavity volume, β is the molecular volume of the sorbate molecule, and $m \leq v/\beta$ is the saturation limit, rounded to an integral number of molecules per cavity. This model has been found to provide a very satisfactory representation of the equilibrium isotherms for light hydrocarbons in type A zeolites (31) and also in H-chabazite (32). However the assumption of free molecular movement within a cavity is more likely to be correct for polyatomic molecules such as the hydrocarbons since the effect of molecular rotation will be to substantially reduce any energetic heterogeneity, thus favoring free mobility.

Argon

The range of concentration covered by the argon isotherms was insufficient to allow a reliable choice to be made between various isotherm equations. This is true also of the data of Springer (13), Cook (14), and Harper *et al.* (15) for sorption of argon in both 4A and 5A zeolites.

Krypton

The saturation capacity, as estimated from the quotient of the cavity volume of the A type zeolite and the van der Waals covolume of krypton, is about 11 molecules per cavity. The potential calculations show that there are, within the cavity, eight energetically favorable sites (type I) near the 6-membered oxygen rings and a further six favorable sites near the centers of the 8-membered oxygen windows (type II). Each type II site is in effect shared between two adjacent cavities since, although the potential minimum does not occur actually at the center of the window, it is sufficiently close to the window to prevent simultaneous occupation of the sites on either side of any particular window, while the energy barrier between the two minima on either side of a window is very small ($\sim$500 cal). (See Fig. 2.) Each window would therefore be expected to behave as a single site thus giving effectively three type II sites per cavity.

For krypton the distance between two adjacent sites (one of type I and one of type II) is about 4.09 Å which is close to the equilibrium distance between an isolated pair of krypton atoms, as estimated from the Lennard–Jones potential curve (4.04 Å). The results of the potential calculations thus suggest that with only very minor adjustments of position a cavity can accommodate eight krypton atoms in sites of type I and a further three atoms in sites of type II. Furthermore the energy difference between the type I and type II sites is not large ($\sim$1 kcal) and the distance between adjacent sites is sufficient to ensure that repulsive interactions are small. As a first approximation one may therefore expect that an idealized representation as a set of eleven equivalent noninteracting sites might be a fair approximation for this system.

Figure 6 shows the krypton equilibrium data plotted as $\ln [\theta/p(1 - \theta)]$ *vs.* θ, (c_s = 11 molecules/cavity). The data extend only up to about 50% of saturation but it is evident that, within this range, the equilibrium constant calculated according to eq. 18 is essentially constant, indicating that the ideal Langmuir model fits the data well. This was also found to be true of the data of Mahajan and Walker (28).

The adequacy of the simple Langmuir model is further illustrated in Fig. 7 in which the experimental isotherms are compared with the theoretical curves calculated according to eq. 17. Also shown are the high pressure, high temperature data of Barrer *et al.* (11) which are well represented by the theoretical curves, calculated according to eq. 17 with values of b ($=K/c_s$) estimated by extrapolation of the low temperature Henry constants according to eq. 2, with the experimental values of K_0 and q_0 given in Table 1.[2] The remarkable agreement, over such a wide range of conditions, between the experimental isotherms and the simple theoretical predictions based on an idealized Langmuir model provides strong evidence that the approximations on which the model is based are essentially correct.

Xenon

The quotient of the cavity volume and the van der Waals covolume of xenon gives a value of 9 molecules per cavity for the saturation concentration. The interpretation of the theoretical potential profiles is, however, less straightforward for xenon than for krypton. As with krypton

[2]At the higher pressures and lower temperatures the fugacity coefficient is significantly less than unity ($\sim$0.7) and Figs. 7 and 8 are therefore plotted in terms of fugacity rather than pressure.

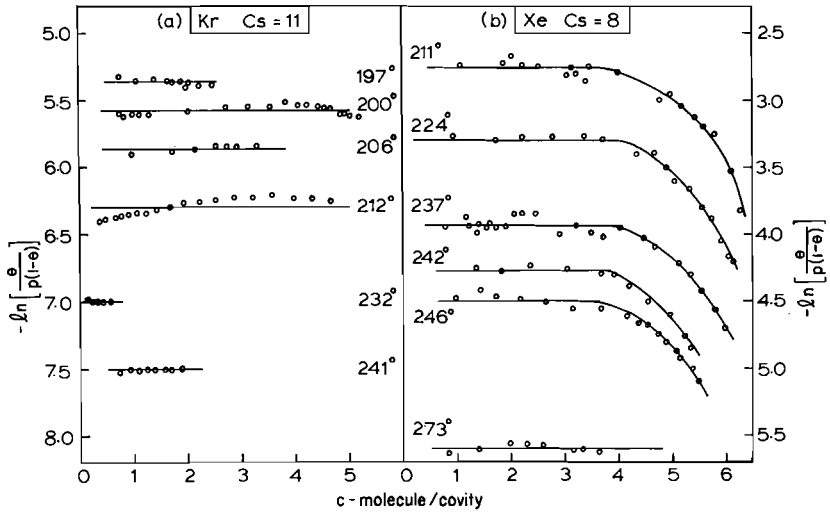

FIG. 6. Plot showing variation of equilibrium constant, calculated according to eq. 17, for Kr and Xe in 5A zeolite (temperatures in °K).

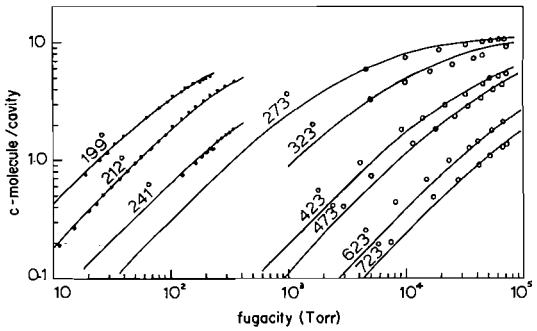

FIG. 7. Equilibrium isotherms for krypton in 5A zeolite: experimental data of Barrer *et al.* (11); ●, present experimental data; —, theoretical lines calculated according to eq. 17.

there are 8 favorable type I sites near the six-membered oxygen rings and effectively three further type II sites per cavity. The distance between adjacent sites of types I and II is, however, only 3.7 Å which is much smaller than the equilibrium separation between isolated xenon molecules (4.56 Å). It is therefore evident that the type I and type II sites cannot be simultaneously occupied.

As a first approximation we assume that the type I sites are preferentially occupied. The simplest representation of this system then becomes an idealized Langmuir model with eight equivalent noninteracting sites per cavity. Figure 6*b* shows the plot of $\ln [\theta/p(1-\theta)]$ *vs.* θ calculated from the experimental isotherms with $c_s = 8$. For $\theta < 0.5$ it is clear that the equilibrium constant calculated according to eq. 17 is indeed approximately constant so that the simplified Langmuir model is an adequate approximation. However, at higher sorbate concentrations deviations become pronounced as may be seen from Fig. 8, in which the experimental isotherms are compared with the theoretical curves calcu-

lated from eq. 17. Also shown in Fig. 8 are the high temperature, high pressure isotherms of Barrer *et al.* and it is clear that the extrapolated curves based on eq. 17 provide but a poor approximation to these isotherms.

The high temperature isotherms are however well represented by eq. 20 with the values of the Henry constant calculated by extrapolation, according to eq. 2, with the experimental values of K_0 and q_0 given in Table 1. However this equation does not fit the low temperature isotherms (or the isotherms for krypton).

The simplest interpretation of these results is that at low temperatures the molecules are adsorbed at localized sites and that there are approximately eight equivalent sites per cavity. At high temperatures and possibly also even at lower temperatures when the concentration is sufficiently high, the molecules become mobile thus occupying all the available space within the cavity. The distance between the potential minima of adjacent type I sites is 4.23 Å which is slightly smaller than the equilibrium separation between two xenon atoms (4.56 Å). The energy barriers between adjacent sites are not large ($\sim$1 kcal) and such barriers would be reduced by repulsion between neighboring adsorbed molecules. The suggestion of a transition from a predominantly localized adsorbed phase at low temperatures to a mobile adsorbed phase at high temperatures therefore seems physically reasonable but, in the absence of more direct evidence, any such conclusion is tentative. From the practical point of view the important result is that eq. 20 provides a useful method of extrapolation in the high temperature, high pressure region.

Conclusions

The Henry's law equilibrium constants and heats of sorption for the inert gases in the type A zeolites can be estimated theoretically from potential calculations and the resulting values are in satisfactory agreement with experiment. The practical limitations of this approach arise not from the difficulty of performing such calculations but rather from the present unsatisfactory state of knowledge of intermolecular forces. The use of dispersion constants calculated according to each of the three well known formulae (eq. 9–11) leads to significantly different values for the equilibrium constant. For both krypton and xenon the Slater–Kirkwood formula gives closest agreement with experiment while for argon, the London expression seems preferable.

At least up to about 50% saturation the isotherms for krypton fit a simple Langmuir model with eleven equivalent sites per cavity. The behavior of xenon is more complex and there appears to be a transition from localized adsorption to mobile adsorption at high temperatures and sorbate concentrations. Further direct evidence such as might be obtained from a calorimetric study would however be needed to substantiate such a conclusion.
