The keto-alcohol **20** (500 mg) is dissolved in pyridine (20 ml) and phosphorus oxychloride (2.07 ml) is added with vigorous stirring at room temperature. The mixture is then warmed at 57° for 46 h before cooling and pouring into ice water. After chloroform extraction (and removal of the pyridine by shaking several times with dilute hydrochloric acid, washing and drying) the unsaturated ketone **16c** (352 mg, 77%) is obtained as an oil; ν_{KBr} 3210, 3080, 3020, 1713, and 1640 cm^{-1}; δ_{CDCl_3} *gem*-dimethyl two s 1.03 and 1.09, $HC{\equiv}C$ t(2.7) 2.01, $-CH{=}CH_2$ m 5.6 and m 5.04, $-CH{=}CH-$ ABq (J_{AB} = 9.8 Hz) broadened by W coupling) 5.68.

Semicarbazone, m.p. 164–165° (dec.).

Anal. Calcd. for $C_{15}H_{21}N_3O$: C, 69.5; H, 8.2; N, 16.2. Found: C, 69.6; H, 8.2; N, 16.4.

8-Allyl-5,5-dimethylhydrinda-3,6-dien-2-one (17d) via 16d

The triple bond in **19c** is hydrated as described for **10a** affording the diketone **16d** in yields exceeding 90%; ν_{CHCl_3} 3080, 3005, 1720, 1710, 1360 cm^{-1}; δ_{CDCl_3} (90 MHz) *gem*-dimethyl two s 1.11 and 1.13, $CH_3COCH_2{-}$ s 2.07 and ABq (J_{AB} = 17.0 Hz) 2.44, $CH_2CH{=}CH_2$ d(7.1) 2.28, m 5.55 and m 5.0, ring CH_2CO ABq 2.41, $-CH{=}CH-$ ABq (J_{AB} = 10.0 Hz) 5.65; *m/e* 220 (M+), 205, 178, 177, 163, 162, 147, 138, 137 (base). This product (**16d**) was unstable and was normally cyclized immediately. The diketone **16d** (1.2 g) is refluxed for 15 h in a solution of potassium hydroxide (1.8 g) in water (36 ml) and methanol (10 ml). The clear liquid obtained (1.15 g) is purified by evaporative distillation (76–77° at 0.09 mm); λ_{max} 233 (14 200) nm; ν_{CHCl_3} 3080, 3010, 1705, 1670, and 1625 cm^{-1}; δ_{CDCl_3} (90MHz) *gem*-dimethyl 0.94 and 1.20, $-CH_2CO-$ ABq (J_{AB} = 18.0 Hz) 2.32, $-CH_2CH{=}CH_2$ d(7.0) 2.34, m 5.4 and m 5.0, $-CH_2-C(=CH-CO)$ s(broad, sharpens on irradiation at 5.90) 2.53 and s(broad) 5.90, $-CH{=}CH-$ ABq (J_{AB} = 10.0 Hz) 5.50; *m/e* 202 (M+), 162, 161 (base), 133, 118, 117, and 105.

Anal. Calcd. for $C_{14}H_{18}O$: C, 82.1; H, 9.0. Found: C, 82.4; H, 8.9.

2-Propargyl-2-carboethoxycyclohexanone (23a)

Potassium (4.12 g) is dissolved in *t*-butyl alcohol (150 ml) and to the refluxing solution under nitrogen is added 2-carboethoxycyclohexanone (17 g) and 30 min later propargyl bromide (13.1 g). After 30 min of reflux, the cooled solution is decomposed in ice water and ether extracted. Vacuum distillation gave the alkylated product **23a** (16 g, 77%), b.p. 74–77° at 0.1 mm; ν_{film} 3295 ($C{\equiv}C-H$), 2128 ($C{\equiv}C$), 1740, and 1710 (ester and ketone) cm^{-1}; δ_{CCl_4} CH_3CH_2O- t(7.2) 1.26 and q(7.2) 4.22, $H-C{\equiv}C-CH_2-$ t(2.7) 2.08 and ABq (J_{AB} = 17.3 Hz, split by $\equiv CH$, 2.7) 2.58. *Semicarbazone*, m.p. 152–153° (lit. (4) 152.7–153.5°).

Anal. Calcd. for $C_{13}H_{19}O_3N_3$: C, 58.9; H, 7.2; N, 15.8. Found: C, 59.2; H, 7.3; N, 15.5.

2-Propargyl-2-carboethoxy-4-methylcyclohexanone (23b)

Prepared from α-carboethoxy-4-methylcyclohexanone in 81% yield as described above, b.p. 72–74° at 0.1 mm; ν_{film} 3290, 2128, 1730, 1710, 1210 cm^{-1}; δ_{CCl_4} CH_3CH d(4.9) 1.05, CH_3CH_2O- t(7.2) 1.23 and q(7.2) 4.19, $H-C{\equiv}C-CH_2-$ t(2.5) 2.09 and ABq (J_{AB} = 17.3 Hz, split by $\equiv CH$, 2.5) 2.67.

2-Propargyl-2-carbomethoxy-4-methylcyclohexanone (23c)

The α-carbomethoxy-4-methylcyclohexanone (prepared using dimethylcarbonate (10)) was alkylated as described above affording the product **23c** in 86% yield after distillation, b.p. 94–98° at 0.5 mm; ν_{film} 3295, 2130, 1745, 1720, 1225 cm^{-1}; δ_{CCl_4} CH_3CH d(5.6) 1.07, $H-C{\equiv}C-CH_2-$ t(2.5) 2.04 and ABq (centered at) 2.78, CH_3O- s 3.75.

2-Acetonyl-2-carboethoxycyclohexanone (24a)

To the carboethoxypropargylcyclohexanone **23a** (16.0 g) in methanol (50 ml) is added water (1.5 ml) and concentrated sulfuric acid (0.05 ml). Dowex 50 W-X4 resin, previously treated with mercuric ions (8) (500 mg), is introduced and after warming for a few minutes the mixture is stirred overnight. The filtered solution is neutralized with ammonium hydroxide, dried over sulfate, evaporated, and filtered through a short silica gel column in benzene solution. After distillation (85–90° at 0.1 mm) the yield of methyl-ketone **24a** was 95% (16.5 g); ν_{film} 1733, 1708 cm^{-1}; δ_{CCl_4} CH_3CH_2O- t(7.2) 1.21 and q(7.2) 4.15, CH_3COCH_2- s 2.10 and s 2.79. *Bis-semicarbazone*, m.p. 220–221° (lit. 12) 214° (dec.).

Anal. Calcd. for $C_{14}H_{24}O_4N_6$: C, 49.4; H, 7.1; N, 24.7. Found: C, 49.7; H, 7.3; N, 24.5.

2-Acetonyl-2-carboethoxy-4-methylcyclohexanone (24b)

Prepared in 53% yield using Dowex resin (as above) or in 85% yield following the boron trifluoride – trichloroacetic acid procedure (see **24c** below), b.p. 92–96° at 0.1 mm, on standing the product **24b** finally crystallized, m.p. 64–66° (from pentane); ν_{KBr} 1735, 1708, 1238 cm^{-1}; δ_{CCl_4} CH_3CH d(4.8) 1.00, CH_3CH_2O- t(7.3) 1.21, and q(7.3) 4.12, CH_3COCH_2- s 2.12 and s 2.96.

Anal. Calcd. for $C_{13}H_{20}O_4$: C, 65.0; H, 8.4. Found: C, 65.1; H, 8.4.

2-Acetonyl-2-carbomethoxy-4-methylcyclohexanone (24c)

To red mercuric oxide (7.8 g), anhydrous methanol (16 ml), boron trifluoride etherate (3.1 ml), and trichloro-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

acetic acid (156 mg) is added the propargyl-keto ester **23c** (114 g) in methanol (250 ml) at a rate to ensure a mild reflux. The mixture is stirred for 2.5 h before pouring into water (1 l) and acidifying with sulfuric acid. The yellow oil obtained by extraction gave the crystalline product **24c** on standing (109 g, 88%), m.p. 102–103° (from methylene chloride – petroleum ether); ν_{KBr} 1745, 1715 cm^{-1}; δ_{CDCl_3} CH_3CH d(5.0) 1.06, CH_3COCH_2— s 2.23 and s 3.05, CH_3O— s 3.87.

Anal. Calcd. for $C_{12}H_{18}O_4$: C, 63.7; H, 8.0. Found: C, 63.6; H, 8.2.

9-Carboethoxyhydrind-1(8)-en-2-one (22c)

Prepared as described for **22d** in yields up to 70%. After silica gel chromatography: ν_{film} 1740–1700 (ester and ketone), 1625 (conjugated double bond), 850 (double bond) cm^{-1}; δ_{CCl_4} CH_3CH_2O— t(7.0) 1.22 and q(7.0) 4.19, CH_2COCH ABq centered at 2.36 and s 5.93. *Semicarbazone*, m.p. 216–217° (dec.).

Anal. Calcd. for $C_{13}H_{19}O_3N_3$: C, 58.8; H, 7.2; N, 15.8. Found: C, 58.7; H, 7.4; N, 15.4.

5-Methyl-9-carbomethoxyhydrind-1(8)-en-2-one (22d)

To a solution prepared by dissolving potassium (15.6 g) in *t*-butyl alcohol (600 ml) is added at room temperature, the solid powdered diketo ester **4c** (84.6 g) in several portions during 20 min. After stirring for 45 min the mixture is poured into ice water and acidified (p*H* 4) with concentrated hydrochloric acid. Extraction gave a neutral fraction, the enone **22d** (43.9 g) and an acid (24.2 g) arising from ring fission. The enone was distilled, b.p. 98–103° at 0.05 mm; λ_{max} (EtOH) 232 (13 600) nm; ν_{film} 1740–1710 (ester and ketone), 1630 (conjugated double bond) cm^{-1}; δ_{CCl_4} CH_3CH d(7.0) 1.00 (mixture of stereoisomers), CH_3O s 3.72, =CH— s 5.91. *Semicarbazone*, m.p. 205–206° (dec.).

Anal. Calcd. for $C_{13}H_{19}N_3O_3$: C, 58.8; H, 7.2; N, 15.8. Found: C, 58.7; H, 7.3; N, 15.2.

5-Methylhydrind-1(8)-en-2-one (22b)

Cyclization of the diketo ester **23b** (4.8 g) by refluxing with 5% aqueous sodium hydroxide (50 ml) for 6 h under nitrogen affords the unsaturated ketone **22b** (2.6 g, 87%) after extraction and chromatography (silica gel); λ_{max} (EtOH) 231 (16 400) nm; ν_{film} 1709, 1623, and 838 cm^{-1}; δ_{CCl_4} CH_3CH d(7.0) 1.00, =CH— s 5.81. *Semicarbazone*, m.p. 220–221°.

Anal. Calcd. for $C_{11}H_{17}N_3O$: C, 63.7; H, 8.3; N, 20.3. Found: C, 63.5; H, 8.5; N, 19.9.

8-Vinylhydrindan-2-one (5)

To tetrakis[iodo(tri-*n*-butylphosphine)copper(I)] (15.7 g, prepared by the method of Kauffmann (11)) dissolved in tetrahydrofuran (50 ml) and cooled to −78° is added vinyl lithium (0.08 mol) in tetrahydrofuran. After 10 min the enone **22a** (2.72 g) is added in tetrahydrofuran (15 ml) and the temperature allowed to rise to 0°. Stirring is continued for 1 h and the mixture is poured into saturated ammonium chloride solution, ether extracted, and carefully chromatographed (silica gel) to afford the vinylhydrindanone **25** (1.1 g, 34%); ν_{film} 3095 (vinyl), 1740, 1633, 993, and 911 cm^{-1}; δ_{CCl_4} CH_2=CH— d of d(1.5 and 17.3) 5.05, d of d (1.5 and 11.3) 5.10, and d of d(18.5 and 10.0) 5.98. *Semicarbazone*, m.p. 214–215°.

Anal. Calcd. for $C_{12}H_{19}N_3O$: C, 65.1; H, 8.6; N, 19.0. Found: C, 65.4; H, 8.6; N, 18.5.

Cyclohexa-1,2-dione-1-ethyleneketal (27a)

α-Ethylidenecyclohexanone (85 g, lit. (12)), ethylene glycol (80 g), and *p*-toluene sulfonic acid (1.5 g) are dissolved in benzene (400 ml) and refluxed 12 h in a Dean–Stark apparatus. The spiro-ketal **26a** is isolated in the usual manner (92 g, 80%), b.p. 39–42° at 0.1 mm; ν_{film} 1670 cm^{-1}; δ_{CCl_4} CH_3CH= d(7.2) 1.61 and q of t(7.2 and 1.8) 5.65, —OCH_2CH_2O— s 3.88.

The spiro-ketal **26a** (30 g) in pyridine (68 ml) and methylene chloride (136 ml) is cooled to −78° and ozone (~5% in oxygen) is bubbled into the solution until a blue coloration persists. The solution is allowed to warm to ambient and the solvents removed in vacuum. Distillation affords the keto-ketal **27a** (16.1 g), b.p. 45–50° at 0.1 mm; ν_{film} 1735 cm^{-1}; δ_{CDCl_3} —OCH_2CH_2O— s 3.97. *2,4-Dinitrophenylhydrazone*, m.p. 169–170° (lit. (13) 171°).

Anal. Calcd. for $C_{14}H_{16}N_4O_6$: C, 50.0; H, 4.8; N 16.7. Found: C, 49.8; H, 4.9; N, 16.3.

3,3-Dipropargylcyclohexa-1,2-dione-1-ethyleneketal (28a)

To sodium hydride (1.8 g) in benzene (50 ml) is rapidly added the ketal-ketone **27a** (6.24 g) and the mixture refluxed 1 h. After cooling to room temperature, propargyl bromide (4.8 g) is added dropwise and the reaction is allowed to stand overnight. After pouring into ice water and extracting, the mixture (seen by t.l.c.) is chromatographed over alumina III affording the dipropargyl compound **28a** (2.3 g) which eventually crystallized, m.p. 87–88°; ν_{film} 3280, 3270, 2120, 1718, 1200, 1108, and 1092 cm^{-1}; δ_{CCl_4} —CH_2—C≡CH ABq (J_{AB} = 17.0 Hz, split by ≡CH, 2.7) 2.66 and —OCH_2CH_2O— s 4.0.

Anal. Calcd. for $C_{14}H_{16}O_3$: C, 72.4; H, 6.9. Found: C, 72.7; H, 6.9.

Further elution gave mixtures of dipropargyl, monopropargyl, and starting material (600 mg).

Hydrogenation of the dipropargyl derivative **28a** over 10% palladium-on-carbon gave the *3,3-di-n-propylcyclohexa-1,2-dione-1-ethyleneketal* **28b** as a liquid after chromatography: ν_{film} 1715, 1200, 1109, and 1040 cm^{-1}; δ_{CCl_4} CH_3CH_2 m 0.94 (6H) and —OCH_2CH_2O— s 3.96 (4H).

3-Hydroxymethylenecyclohexa-1,2-dione-1-ethyleneketal (28c)

Very dry sodium methoxide (from sodium (16 g) is taken up in benzene (300 ml) and methyl formate (75 ml) is added. The mixture is stirred for 30 min and the addition of more benzene (300 ml) precedes the addition of the ketal-ketone **27a** (41.6 g). After 20 h the mixture is decomposed in ice water and hydroxymethylene **28c** is extracted into iced 2% potassium hydroxide in the usual manner. The distilled product (20.3 g, 41%; b.p. 73–74° at 0.2 mm) crystallized from pentane, m.p. 40–41°; ν_{film} 1715, 1643, 1585 cm^{-1}; δ_{CCl_4} —OCH_2CH_2O— m 4.13, =CHOH s 8.84 and s 13.78 (disappears on adding D_2O).

3-Propargylcyclohexa-1,2-dione-1-ethyleneketal (28e)

The hydroxymethylene **28c** (2.6 g) is added to potas-

For personal use only.

sium *t*-butoxide (from potassium (0.55 g) in *t*-butyl alcohol (30 ml)) and after 10 min stirring, propargyl bromide (1.67 g) is added dropwise. The mixture is refluxed 1 h and then cooled, poured into ice cold dilute hydrochloric acid, and ether extracted. The crude product (1.65 g) is chromatographed over alumina III and the fraction eluted with carbon tetrachloride is the product **28***e* (1.01 g, 37%), m.p. 63–64°; ν_{KBr} 3270, 2120, 1725, and 1185, 1085, 1040 cm^{-1}; δ_{CCl_4} —CH—C=O m 2.79 and —OCH_2CH_2O m 3.99.

Anal. Calcd. for $C_{11}H_{14}O_3$: C, 68.0; H, 7.3. Found: C, 68.1; H, 7.4.

3-Acetonylcyclohexa-1,2-dione-1-ethyleneketal (28g)

The propargyl derivative **28***e* (2.5 g) is hydrated using the Dowex resin method (see **4***a*) to give the liquid acetonyl-ketone **28***g* (1.5 g, 52%); ν_{film} 1730, 1714, 1195, 1113, and 1040 cm^{-1}; δ_{CCl_4} CH_3CO s 2.13 and —OCH_2-CH_2O— m 3.94. *Bis-semicarbazone*, m.p. 208–209° (dec.).

Anal. Calcd. for $C_{13}H_{22}N_6O_4$: C, 47.8; H, 6.8; N, 25.7. Found: C, 48.1; H, 6.9; N, 25.8.

2-Benzylidene-5-methylcyclohexanone

3-Methylcyclohexanone (13.4 g) and benzaldehyde (10.6 g) are added to a solution of sodium hydroxide (4.0 g) in water. The mixture is refluxed for 3 h and is allowed to stand at room temperature overnight. Extraction with methylene chloride which is washed, dried, and evaporated gives a viscous oil affording the benzylidene derivative (17.9 g, 89%) by distillation (b.p. 108–110° at 0.04 mm). The product crystallizes slowly, m.p. 41–42°; λ_{max} (EtOH) 290 (13 100) nm; ν_{KBr} 3060, 3040, 1685, and 1600 cm^{-1}; δ_{CDCl_3} CH_3CH d(7.2) 0.97, aromatic s (5H) 7.38 and =CH— s 7.50.

Anal. Calcd. for $C_{14}H_{16}O$: C, 84.0; H, 8.1. Found: 83.9; H, 8.1.

The residue from the distillation is taken up in methanol and on cooling affords a small quantity (0.49 g) of the *2,6-bisbenzylidene-3-methylcyclohexanone*, m.p. 118–119°; λ_{max} 316 (11 500) nm; ν_{KBr} 3100, 3020, 1668, 1610, 705, and 695 cm^{-1}; δ_{CDCl_3} CH_3CH d(7.2) 1.28, aromatic s 7.48, =CH— two s 7.70 and 7.83.

Anal. Calcd. for $C_{21}H_{20}O$: C, 87.5; H, 7.0. Found: C, 87.6; H, 7.0.

4-Methylcyclohexa-1,2-dione-2-ethyleneketal (27b)

The benzylidene (from above, 89.5 g) is converted to the spiro-ketal **26***b* (79 g, 72% as described for **26***a*, m.p. 52–53°; λ_{max} 242 (14 250) nm; ν_{KBr} 3040, 1605, 1580, 1200, 1050, and 710 cm^{-1}; δ_{CDCl_3} CH_3CH d(7.2) 0.93, —OCH_2CH_2O— M 4.08, =CH— s 6.78 and aromatic s 7.34.

The benzylidene spiro-ketal **26***b* (24.4 g) in pyridine (100 ml) and methylene chloride (200 ml) is cooled in a Dry Ice – acetone bath and ozone (5% in oxygen) bubbled through the solution until the blue coloration persists (*ca.* 3 h). The solution is allowed to warm to room temperature, washed with 2% hydrochloric acid, sodium bicarbonate, and saturated sodium chloride, and evaporated. Distillation affords the ketal-ketone **27***b* (15.9 g, 93%), b.p. 71–72° at 0.35 mm; n_D^{23} 1.4651; ν_{film} 1735, 1200, 1050 cm^{-1}; δ_{CDCl_3} CH_3CH d(7.2) 1.05 and —OCH_2-CH_2O— m 4.00. The product was characterized as the semicarbazone but the spiro-ketal is also hydrolyzed under these conditions to give: *4-Methylcyclohexa-1,2-dionebis-semicarbazone*, m.p. 251–252°.

Anal. Calcd. for $C_9H_{16}N_6O_2$: C, 45.0; H, 6.7; N, 35.0. Found: C, 44.9; h, 6.8; N, 34.3.

3-Propargyl-5-methylcyclohexa-1,2-dione-1-ethylene-ketal (28f)

The hydroxymethylene **28***d* is prepared as described above (for **28***c*) in 81% yield. The product is normally used directly for the alkylation but a redistilled portion (b.p. 72–74° at 0.15 mm) was characterized: n_D^{27} 1.5095; λ_{max} 282 (8200) nm; ν_{1720}, 1660 and 1595 cm^{-1}; δ_{CDCl_3} CH_3CH d(7.2) 1.07, —OCH_2CH_2O— m 4.13, =CH—OH s 7.31 and s 8.92.

The crude hydroxymethylene **28***d* (46.4 g) is propargylated (as described for **28***c*) affording the alkylated product **28***f* (31.4 g, 76%) by distillation b.p. 85–86° at 0.13 mm, n_D^{24} 1.4879. Cooling affords a solid which is recrystallized from hexane with difficulty, m.p. 42–43°; ν_{KBr} 3300, 2130, 1735, 1200, and 1040 cm^{-1}; δ_{CDCl_3} CH_3CH d(7.2) 1.03, —OCH_2CH_2O— s 3.98.

3-Acetonyl-5-methylcyclohexa-1,2-dione-1-ethylene-ketal (28h)

The propargyl derivative **28***f* (5.2 g) is hydrated as described above for **23***a*. The reaction mixture is poured into ice – 2% sulfuric acid and extracted immediately. The crude product is chromatographed over alumina III to give the acetonyl compound **28***h* (5.2 g, 92%), m.p. 73–74°; ν_{KBr} 1735 (ketone adjacent to ketal), 1720, 1200, 1030 cm^{-1}; δ_{CDCl_3} CH_3CH d(7.2) 1.03, CH_3CO s 2.16, —OCH_2CH_2O— m 3.97.

Anal. Calcd. for $C_{12}H_{18}O_4$: C, 63.7; H, 8.0. Found: C, 63.9; H, 8.1.

6-Methylhydrind-3(9)-en-2,4-dione-4-ethyleneketal (29)

The diketo-ketal **28***h* (8.8 g) in *t*-butyl alcohol (50 ml) is added at room temperature to the solution resulting from dissolving potassium (1.72 g) in *t*-butyl alcohol (75 ml). After stirring for 1 h the reaction mixture is poured into ice water and extracted in the usual manner affording neutral (7.7 g) and acidic products (1.1 g). Chromatography of the former affords the pure enone **29** (4.3 g, 53%), m.p. 53–55°; λ_{max} 234 (13 200) nm; ν_{KBr} 1705, 1630, 1180, 1040 cm^{-1}; δ_{CCl_4} CH_3CH d(7.2) 1.06, —OCH_2CH_2O— s 3.92 and =CH— s 5.75. *Semicarbazone*, m.p. 207–208° (dec.).

Anal. Calcd. for $C_{13}H_{19}N_3O_3$: C, 58.8; H, 7.2; N, 15.8. Found: C, 58.7; H, 7.2; N, 15.9.

Hydrolysis of the ketal was tried using hydrochloric acid in tetrahydrofuran, a trace of perchloric acid in the same solvent, magnesium sulfate in benzene–water, and exchange with acetone catalyzed by *p*-toluene sulfonic acid. The last method afforded starting material and other methods gave no tractable products. Dilute aqueous hydrochloric acid gave the diketo-ketal **28***h* in almost quantitative yield (by hydration and retroaldolization presumably).

3-Allyl-5-methylcyclohexa-1,2-dione-1-ethyleneketal (28i)

The hydroxymethylene **28***d* (9.9 g) is alkylated with allyl bromide (7.5 g) in *t*-butyl alcohol containing potassium *t*-butoxide (as described in the propargylation to give **23***a*). The alkyl-ketone **28***i* (4.9 g, 47%) is obtained

by distillation, 72–76° at 0.04 mm; n_D^{23} 1.4790; ν_{film} 3080, 1645, 895 (=CH_2) and 1735, 1200, 1040 cm^{-1}; δ_{CCl_4} CH_3CH d(7.2) 1.00, —OCH_2CH_2O— m 3.98, CH_2=CH— complex 4.9 to 6.0.

This same compound resulted by hydrogenation of the propargyl derivative **28***f* (5.63 g) in acetone (50 ml) over Lindlar catalyst (800 mg) in the presence of quinoline (100 mg). Distillation gave the allyl compound **28***i* (5.01 g, 88%).

*3(2-Hydroxy-n-propyl)5-methyl-2-hydroxycyclohexanoneethyleneketal (**30**)*

Mercuric acetate (5.35 g) in water (17 ml) is diluted with tetrahydrofuran (17 ml). The allyl ketone **28***i* (3.5 g) is added and the coloration disappears in 15 s. After 5 min stirring, a solution (17 ml) of 0.5 *M* sodium borohydride in 3 *M* aqueous sodium hydroxide is added. The mixture is saturated with sodium chloride and benzene extracted. Evaporation affords the solid diol **30** (3.92 g, 93%), m.p. 131–132° (from acetone – petroleum ether); ν_{KBr} 3340, 1170, 1045 cm^{-1}; ν_{CCl_4} CH_3CH d(7.2) 0.93, CH_3CHOH— d(7.3) 1.24 and s 3.27, —CHOH— s 3.43, O*H* (2H) s 3.12 disappears on adding D_2O), OCH_2CH_2O m 4.10.

Anal. Calcd. for $C_{12}H_{22}O_4$: C, 62.6; H, 9.6. Found: C, 62.4; H, 9.5.

Sodium borohydride reduction of the diketone **28***h* affords this same diol **30** in 98% yield.

*Oxidation of Diol **30***

The ketal-diol **30** (10.7 g) dissolved in pyridine (100 ml) is oxidized with chromium trioxide (18.8 g) in pyridine (200 ml). The mixture is allowed to stand for 24 h and the dione **28***h* (8.4 g, 79%) isolated in the normal manner (identical with **28***h* prepared earlier).

Structure of Nickel Orthophosphate

CRISPIN CALVO AND ROMOLO FAGGIANI

Institute for Materials Research, McMaster University, Hamilton, Ontario L8S 4M1

Received October 18, 1974

CRISPIN CALVO and ROMOLO FAGGIANI. Can. J. Chem. **53**, 1516 (1975).

$Ni_3P_2O_8$ crystallizes in the monoclinic system with space group $P2_1/c$ with $a = 5.830(2)$, $b = 4.700(2)$, $c = 10.107(4)$ Å, $\beta = 91.22(2)°$, and $Z = 2$. The structure was refined by full-matrix least squares methods to a final R value of 0.035 using 986 symmetry independent reflections. The structure is isotypic with that of sarcopside, which in turn is related to that of olivine with vacant cation sites ordered. The Ni ions are octahedrally coordinated in two types of sites with average Ni—O bond lengths of 2.081 and 2.067 Å. The mean P—O bond length is 1.547 Å although the tetrahedron shows some unusually large distortions with bond lengths ranging from 1.521 to 1.595 Å.

CRISPIN CALVO et ROMOLO FAGGIANI. Can. J. Chem. **53**, 1516 (1975).

Le $Ni_3P_2O_8$ cristallise dans le système monoclinique avec un groupe d'espace $P2_1/c$ avec $a = 5.830(2)$, $b = 4.700(2)$, $c = 10.107(4)$ Å, $\beta = 91.22(2)°$ et $Z = 2$. On a affiné la structure par la méthode des moindres carrés (matrice complète) jusqu'à une valeur finale de R de 0.035 utilisant 986 réflexions non-équivalentes. La structure est isostructurale avec celle de la sarcopside qui est à son tour reliée à celle de l'olivine avec des sites cationiques vacants ordonnés. Les ions Ni sont coordonnés d'une façon tétraédrique dans deux types de site avec des longueurs de liaison moyenne Ni—O de 2.081 et de 2.067 Å. La longueur moyenne de la liaison P—O est 1.547 Å même si le tétraèdre montre des distorsions particulièrement grandes alors que les longueurs de liaison s'étalent entre 1.521 et 1.595 Å. [Traduit par le journal]

Introduction

A large number of distinct structural types are known for compounds represented as $M_3P_2O_8$. Amongst these only the sarcopside structure (1) is based upon a close-packed array of oxygen atoms. This structure is in fact olivinelike (2) with vacant cation site ordered and results in a change from an orthorhombic to a monoclinic cell. Joubert *et al.* (3) have shown that a metastable sarcopsidelike structure can be formed by the reaction of olivinelike $Li_2M_2P_2O_8$ plus MSO_4, with M = Mg or Co at reaction temperatures of 660 and 680 °C respectively. Approximate atomic positions, obtained from a powder pattern, are available for these forms of $Mg_3P_2O_8$ and $Co_3P_2O_8$ (3). These compounds transform to the stable "γ" $Zn_3P_2O_8$ structure type (4) at 820 and 870 °C for M = Mg and Co respectively (3). The structure of this form of $Mg_3P_2O_8$ was refined from single crystal data (5) while that of $Co_3P_2O_8$ was refined from powder data (6). The cation coordination numbers in this structure are six for the site at the center of symmetry and four or five for the cation site in the general position, depending upon the specific cation.

Moore (1) has refined the structure of sarcopside, whose composition was $(Fe_{0.78}Mn_{0.21}Mg_{0.01})_3P_2O_8$, but no attempt was made to investigate the cationic partitioning. In nature sarcopside does not occur as a primary phase but is found with graftonite or triphylite (7). The stabilization of graftonite has been attributed to cations of large radii (8) although as with the γ-$Zn_3P_2O_8$ structural type the cationic coordination numbers are variable. It is possible that ions of small radii play a role in stabilizing the sarcopside structure. However, $Fe_3P_2O_8$ has been prepared isotypic with both graftonite (9–11) and sarcopside (10). One form of $Mn_3P_2O_8$ is isotypic with graftonite and the other is not sarcopsidelike (12). Moore has suggested that sarcopside might be an exsolution from triphylite, which has the olivine structure, following a reaction formally much like that proposed by Joubert *et al.* (3). *A priori* ionic radii considerations suggest that $Ni_3P_2O_8$ should behave like $Co_3P_2O_8$ and therefore the fact that the sarcopside structure is the stable form of $Ni_3P_2O_8$ is curious.

Experimental

Crystals were grown from a stoichiometric mixture of NiO_2 and P_2O_5 in a platinum crucible heated in an induction furnace. The melt was cooled slowly across the solidification temperature (1350 °C (13)). Crystals whose size were a few millimeters across were obtained.

One of these crystals, ground to a sphere with 0.15 mm as its diameter, was used to collect the X-ray data. Accurate parameters were derived by a least squares fit to the 2θ values of 15 high angle reflections measured with a Syntex PĪ diffractometer, using graphite monochromatized MoK$_\alpha$ (λ_α = 0.71069 Å) radiation. The crystal data, measured at 21 °C, are as follows:

$Ni_3P_2O_8$ f.w. = 365.88

monoclinic, a = 5.830(2), b = 4.700(2), c = 10.107(4) Å, β = 90.22(2)°, V = 276.9 Å^3, Z = 2, ρ_m = 4.38 g/cm^3, ρ_x = 4.38 g/cm^3, space group $P2_1/c$.

The intensities of 1398 reflections within a quadrant up to 2θ = 65° were measured. Reflections were scanned at a rate dependent upon the peak intensity. A total of 986 were symmetry independent and of positive measure after correcting for background. The background was the average of the values measured at either side and one degree removed, in 2θ, from the peak. Reflections whose intensity measure were greater than 3σ, with σ determined from the counting statistics, were considered observed. Absorption corrections were made.

The structure was refined using the positional coordinates of the atoms reported for sarcopside (1), with the unit cell converted to the present designation. A parameter correcting for secondary extinction was varied. Atomic scattering factors, dispersion corrected, were obtained from Cromer and Waber (14) and Cromer (15). The structure was refined by full-matrix least squares refinement, using a program[1] where weights were chosen as

$$\omega = [0.435 + 0.0093F_o + 0.00085F_o^2]^{-1}$$

At convergence, when all the calculated shifts were less than $\frac{1}{3}$ of the standard errors, R = 0.035 and $R_\omega = \{(\Sigma\omega|F_o - F_c|^2)/\Sigma\omega F_o^2\}^{1/2}$ was 0.047. The final structural parameters are in Table 1. The observed and calculated structure factors have been placed in the Depository of Unpublished Data.[2]

Description of the Structure

The structure of $Ni_3P_2O_8$ consists of hexagonally close packed layers of oxygen atoms along (100). The cations are in two types of octahedrally coordinated sites and the phosphorus atom in tetrahedral interstices (Fig. 1). The mean NiO bond length for the cation on the center of symmetry is 2.081 Å and the Ni(2)—O bond lengths average to 2.067 Å. Similarly in sarcopside (1) the average M—O bond length for the cation at the center of symmetry is the larger. Individual bond lengths and angles are in Table 2.

Both NiO_6 octohedra are distorted significantly with edges shared with the PO_4 group, O(2)—O(4) for Ni(1) and O(3)—O(4) for Ni(2),

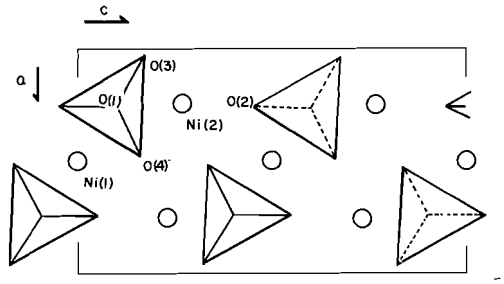

FIG. 1. The (010) projection of sarcopside. The PO_4 tetrahedra are indicated and the Ni(1) and Ni(2) sites are shown as circles.

contracted so as to subtend angles of 71.8 and 69.1° at Ni(1) and Ni(2) respectively. The Ni(1)O_6 group share O(1)—O(4) edges with two Ni(2)O_6 groups. In addition O(2) is shared between Ni(2) and the Ni(1)O_6 group generated by the glide plane. In turn the Ni(2)O_6 group shares four oxygen atoms, two of each of type O(3) and O(4), one each with four Ni(2)O_6 related to each other by $\pm a$, $\pm b$ (Fig. 2).

The average P—O bond length is 1.547 Å, a value higher than the grand mean reported by Baur (16). As in sarcopside, the overbonded O(3) shows the longest bond in the tetrahedron and P—O(1) the shortest. The edges shared with the NiO_6 are substantially contracted below the ideal tetrahedral value.

Discussion

The present structure poses a number of problems. One concerns the stability of the sarcopside structure relative to an olivinelike structure with disordered cation vacancies. Further, the stability of a sarcopside form of $Ni_3P_2O_8$ con-

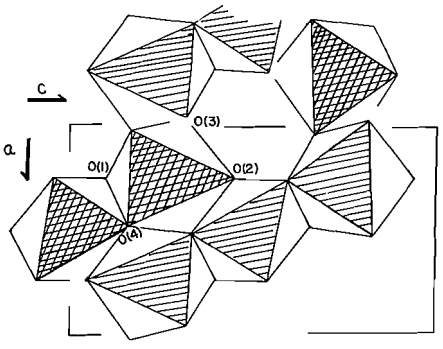

FIG. 2. The edge shared octahedral sites of sarcopside. Oxygen atoms lie at the corners of the octahedra. The ruled octahedra are filled with cations. Those octahedra with cross hatching contain cations at or near y = 0 and the remainder lie at or near $y = \frac{1}{2}$.

‡Reference 3.

trasted with the metastability of analogous forms of $Mg_3P_2O_8$ and $Co_3P_2O_8$ is unexpected. Finally it should be possible to relate the deviation of the β from 90° in sarcopside to the composition.

Olivine, A_2BO_4, is a structure based upon an hexagonal closest packing of oxygen atoms with each oxygen atom bonded to one B and three A type cations. The structure is orthorhombic with B tetrahedrally coordinated to oxygen atoms and lying on a crystallographic mirror plane. The 2(*a*) type sites, corresponding to the centers of symmetries at 0,0,0 and $0,\frac{1}{2},\frac{1}{2}$ of the sarcopside cell are filled with A type cations in the olivine structure. A disordered olivine structure for $Ni_3P_2O_8$ would lead to variations in P—O bond lengths of 0.06 Å (1.595–1.53 Å) since the cationic site vacancies would lead to oxygen atoms with 2 or 3 neighbors. Such disorder should be unlikely if an alternate structure is available. However, in $Co_3V_2O_8$ a spinel structure with disordered vacancy has been found (3) although V—O bond length variations up to 0.11 Å are expected (17).

At present those subtle contributions to the free energy which stabilize the sarcopside form of $Ni_3P_2O_8$ rather than the γ-$Zn_3P_2O_8$ form characteristic of $Co_3P_2O_8$ and $Mg_3P_2O_8$ are unknown. Accurate calculated structural energies and refinement of the metastable forms of the latter might provide some clues however.

The variation of the β angle seems to be related to the size and shape of the octahedral hole available for M(2). As seen in Fig. 2 this structure contains rows of MO_6 groups running along $(10\bar{1})$ and alternately at levels of $y = 0$ and $\frac{1}{2}$. Every 4th octahedral site in a row is unfilled. In olivine the additional cations lie adjacent to these empty sites and they share oxygen atoms with six separate rows. Thus in sarcopside this source of lateral stability is lost and adjacent rows slide relative to each other as the phosphate groups rotate. These rotations distort the octahedral site particularly through O(3) and O(4). This distortion should be largest for the smaller cation, a trend qualitatively in agreement with the results

For personal use only.

shown in Table 3. The cationic distribution in $(Fe, Zn)_3P_2O_8$ (18) would be of interest with regards to this question.

The long P—O(4) bond is not explained by either the Baur relationship (16) between bond length and Pauling bond strength at the oxygen atoms nor by the Brown and Shannon bond strength sums (19). The former would suggest a P—O(4) bond length that is too short by 0.03 Å and the latter that one or more of the bonds to O(4) are too short. The O(3)—O(4) and O(2)—O(4) edges are shared with Ni(2) and Ni(1) respectively and the angles subtended by these edges at the phosphorus atom are near 102°. This would suggest that the O—O repulsion might be in part responsible for the weakening of this P—O(4) bond.

Radiolysis of Liquid Nitrous Oxide: Alcohol and Carbonyl Additives[1]

TERANCE E. M. SAMBROOK AND GORDON R. FREEMAN
Chemistry Department, University of Alberta, Edmonton, Alberta T6G 2E1
Received November 22, 1974

TERANCE E. M. SAMBROOK and GORDON R. FREEMAN. Can. J. Chem. **53**, 1521 (1975).

Methanol, ethanol, acetaldehyde, and acetone were added separately over wide concentration ranges to liquid nitrous oxide at 183 K. The oxygen and nitrogen dioxide yields were reduced from their G values of 2.7 and 5.6, respectively, to 0 by <8 mol% organic solute. The nitrogen yield decreased from 13.1 to about 11 over the same concentration region, but continued to decrease as the nitrous oxide was progressively diluted by the solute. The results are consistent with the previous mechanism II. The nitrogen yields from dilute solutions of nitrous oxide in the carbonyl compounds are smaller than those from similar solutions in the alcohols. The smaller yields are attributed to electron scavenging by the carbonyl compounds in competition with the nitrous oxide.

TERANCE E. M. SAMBROOK et GORDON R. FREEMAN. Can. J. Chem. **53**, 1521 (1975).

Du méthanol, de l'éthanol, de l'aldéhyde acétique et de l'acétone furent ajoutés tour à tour, à des concentrations très différentes à l'oxyde azoteux liquide à 183 K. Les rendements en oxygène et en bioxyde d'azote sont réduits de leur valeur initiale, de 2.7 et 5.6 respectivement, à 0 par une quantité inférieure à 8 mol% en soluté organique. Le rendement en azote décroit de 13.1 à 11 pour le même domaine de concentration et décroit encore au fur et à mesure que l'oxyde azoteux est dilué par le soluté. Les résultats sont en accord avec le mécanisme II précédent. Les rendements d'azote, pour les solutions diluées en oxyde azoteux, dans les composés carbonyles, sont inférieurs aux rendements dans les alcools. Ces rendements inférieurs sont attribués à la capture des électrons par les composés carbonyles en compétition avec l'oxyde azoteux.

Introduction

The present article is a continuation of a study of the radiolysis of liquid nitrous oxide (1, 2). The purpose is twofold: (*i*) to increase the small amount of information available about the radiolysis of inorganic liquids; (*ii*) to help elucidate the radiolysis mechanisms in organic liquids to which nitrous oxide has been added as an electron scavenger.

Experimental

The methods of sample preparation, irradiation, and analysis were the same as those reported earlier (1, 2).

Anhydrous ethanol (U.S. Industrial Chemicals Co.) and spectral grade acetone (Baker Chemical Co.) were used as supplied. Acetaldehyde obtained from Fisher Scientific Co. was vacuum distilled before use and the middle fraction retained. Methanol supplied by Baker Chemical Co. was refluxed with 1.5 g of 2,4-dinitrophenylhydrazine and 1 ml of concentrated sulfuric acid per litre of methanol, and then distilled.

The irradiation dose rate, using appropriate corrections for the electron densities, was 3×10^{17} eV/(g min) and the dose was 3×10^{18} eV/g. The irradiation temperature was 183 K, maintained with a methanol slush bath.

[1]Assisted by the National Research Council of Canada.

Results

Nitrogen Yields

Values of $G(N_2)$ are plotted against the electron fraction ε_s of organic solutes in Figs. 1 and 2. The presence of an alcohol or carbonyl compound decreases the nitrogen yield from the radiolysis of nitrous oxide. In the absence of additive $G(N_2) = 13.1$. Each yield curve contains an inflection (Figs. 1 and 2), which indicates a change of reaction mechanism.

Yields of Oxygen and Nitrogen Dioxide

The addition of <8 mol% of an alcohol or carbonyl compound reduces the yields of oxygen and nitrogen dioxide to 0 (Fig. 3). The relative rate of reduction of the latter is about double that of the former.

Products from the Organic Liquids

The yields of gaseous products from the organic liquids at 183 K are listed in Table 1. The hydrogen yields from the methanol and ethanol are somewhat lower than those reported earlier for similar temperatures and doses (3, 4). One can deduce from the earlier work that the present alcohols contained $\sim 10^{-5}$ M of an

electron scavenging impurity. This small quantity of impurity would not affect the nitrous oxide results.

Addition of nitrous oxide to the alcohols decreased the hydrogen yields in the manner reported earlier (3, 4).

The formation of hydrogen, methane, and carbon monoxide from acetaldehyde and acetone were unaffected by the addition of nitrous oxide. This was demonstrated (5) by basing the hydrogen, etc., yields solely upon the energy initially absorbed by the carbonyl compound, *e.g.*,

$$[1] \qquad g(H_2) = G(H_2)/\varepsilon_{carb}$$

where ε_{carb} is the electron fraction of carbonyl compound in the solution. It was found that $g(H_2)$, $g(CH_4)$, and $g(CO)$ were independent of

nitrous oxide concentration up to 40 mol%, within experimental error (±0.1 units).

Discussion

Nitrogen Yields

A plot of $G(N_2)$ against ε_s has an approximately linear central portion (2). Extrapolation of this portion to the left axis gives the yield of nitrogen from the direct radiolysis of nitrous oxide that cannot be reduced by the solute. The phenomenological name given to this yield was the "plateau" value $g(N_2)^{plat}_{N_2O}$ (2). Extrapolation of the linear portion of the plot to the right axis gives $g(N_2)_s$, the yield of nitrogen obtained from the reaction of nitrous oxide with electrons generated by radiolysis of the solute (2).

Values of these quantities obtained from Figs. 1 and 2 are listed in Table 2. The solutes methanol, ethanol, and acetaldehyde gave $g(N_2)^{plat}_{N_2O} = 10.6 \pm 0.5$, the same as the value obtained with many hydrocarbons (2).

The results are compatible with the earlier mechanism II (2).

Addition of an organic solute RH apparently reduces the nitrogen yield by way of [2] (2)

[2] $$N_2O^+ + RH \rightarrow N_2O + RH^+$$

The ionization potentials of the organic solutes (6 ,7) are lower than that of nitrous oxide (Table 2), so the charge transfer [2] is exothermic. The fact that 20–30% of organic solute is required to reach the linear portions of the curves in Figs. 1 and 2 is consistent with the relative difficulty of scavenging positive charges in spurs (2). The free ion yield is expected to be small because the dielectric constant of the liquid is low (1.97 at 183 K), so [2] would have to occur mainly in the spurs.

The large value of $g(N_2)^{plat}_{N_2O} \geqslant 10$ (Table 2) indicates that the organic oxy compounds do not inhibit the decomposition of N_2O^*.

[3] $$N_2O^* \rightarrow N_2 + O$$

The same behavior was true of hydrocarbon solutes (2).

The value $g(N_2)^{plat}_{N_2O} = 11.9$ obtained with acetone was relatively high (Table 2), and similar to the value 11.6 obtained with propyne and toluene (2). These compounds cause a smaller than normal decrease in nitrogen yield, for reasons unknown.

Oxygen and Nitrogen Dioxide Yields

The variations of the O_2 and NO_2 yields with alcohol or carbonyl compound concentration (Fig. 3) are similar to those obtained with hydrocarbons (2). In particular, the concentration dependences of the yields are nearly the same as those obtained with olefins and the same mechanism (2) appears to apply.

$G(N_2)_s$

Electrons are generated by radiolysis of the solute as well as of the nitrous oxide.

[4] $$RH \rightsquigarrow RH^+ + e^-$$

These electrons can undergo [5], provided that enough nitrous oxide is present. Extrapolation

[5] $$e^- + N_2O \rightarrow N_2O^- \rightarrow N_2 + O^-$$

of the linear portion of the curves in Figs. 1 and 2 to the right axis reveals the maximum yield of nitrogen obtained through electrons generated in [4]. This yield is designated $g(N_2)_s$.

The values $g(N_2)_s = 4.5$ and 4.9 obtained for methanol and ethanol solutes, respectively (Table 2), are similar to the value 4.6 reported earlier for methanol (3) and 5 ± 1 deduced for many saturated and unsaturated hydrocarbons (2).

For the saturated compounds $g(N_2)_s$ appears to be approximately equal to the yield of [4], *i.e.* to the ionization yield in the liquid. However, there is no apparent reason why the ionization yield in acetaldehyde or acetone should be much smaller than those in the alcohols, yet the values of $g(N_2)_s$ for the carbonyl compounds are much lower than those for the alcohols (Table 2). The carbonyl compounds are themselves electron scavengers, so [6] competes with [5] and provides a smaller value of $g(N_2)_s$.

[6] $$R_2CO + e^- \rightarrow R_2CO^-$$

TABLE 2. Values of extrapolated nitrogen yields from nitrous oxide solutions at 183 K, and ionization potentials

Solute	Ionization potential* (eV)	$g(N_2)^{plat}_{N_2O}$†	$g(N_2)_s$‡
CH_3OH	10.85	10.6	4.5
C_2H_5OH	10.48	11.0	4.9
CH_3CHO	10.25	10.1	2.0
CH_3COCH_3	9.75	11.9	3.2

*Gas phase ionization potential, i.p. (N_2O) = 12.89 eV. Refs. 6 and 7.
†Estimated error is ±0.5 units.
‡Estimated error is ±0.3 units.

In the earlier work (2) butadiene-1,3 was the only efficient electron scavenger used as a solute, and it was the only hydrocarbon that gave a low value of $g(N_2)_s$, 1.9. Thus, electron scavenging by the solvent, *e.g.* [6], offers a plausible interpretation of low values of $g(N_2)_s$.

The Question of σ Participation in the Bonding of Fluorosubstituted Arenes to Chromium Tricarbonyl. A ^{19}F Nuclear Magnetic Resonance Investigation

JOHN L. FLETCHER AND MICHAEL J. MCGLINCHEY

Department of Chemistry, McMaster University, Hamilton, Ontario L8S 4M1

Received October 16, 1974

JOHN L. FLETCHER and MICHAEL J. MCGLINCHEY. Can. J. Chem. 53, 1525 (1975).

^{19}F n.m.r. chemical shifts of free fluoroarenes have been correlated with the Swain–Lupton field and resonance parameters. Comparison of these data with the corresponding $Cr(CO)_3$ complexes shows little change in the transmission of mesomeric effects by *para*-substituents. *Meta*-substituents which interact primarily by a field effect have very little influence on the fluorine chemical shift in the complexes suggesting that the σ framework of the ring interacts with the chromium.

JOHN L. FLETCHER et MICHAEL J. MCGLINCHEY. Can. J. Chem. 53, 1525 (1975).

On a établi une corrélation entre les déplacements chimiques en r.m.n. du ^{19}F de fluoroarènes libres avec les paramètres de résonance et de champ de Swain–Lupton. La comparaison de ces données avec celles des complexes $Cr(CO)_3$ correspondants montre peu de changements dans la transmission des effets mésomériques par les substituants *para*. Les substituants *méta* qui interagissent principalement par un effet de champ ont très peu d'influence sur le déplacement chimique du fluor dans les complexes; ceci suggère que les électrons σ du cycle interagissent avec le chrome. [Traduit par le journal]

Introduction

The bonding of arenes to the chromium tricarbonyl moiety has provoked much speculation over the past few years. There is much compelling evidence from reactivity data (1–7), dipole moment measurements (8), molecular orbital calculations (9), and n.m.r. chemical shifts (10–13) to suggest that the $Cr(CO)_3$ group is strongly electron-withdrawing, perhaps comparable to a *para*-nitro group. On the other hand, the transmission of π-substituent effects in complexed arenes has been shown to be largely unchanged from that in the free arenes (14–17). This apparent dichotomy has only recently been explored by Bodner and Todd (18) who proposed a model in which there is "a net withdrawal of electron density from the σ-framework of the arene ring with little or no concomitant reduction in π-electron density". This prompts us to publish the results of our own investigation into this problem.

It has long been thought that changes in ^{19}F n.m.r. chemical shifts of *para*-substituted fluorobenzenes reflect changes in the π-electron density at the C_4 position (19), and attempts have been made to separate such chemical shift data into inductive and resonance components via empirical correlations with inductive and resonance constants derived from reactivity considerations (20). The original observations of Taft (20) have been extended to include correlations of ^{1}H (21), ^{11}B (21), and ^{13}C (18) n.m.r. shift data with the field and resonance parameters devised by Swain and Lupton (22).

We have now utilized these empirical correlations of ^{19}F n.m.r. chemical shifts of a series of substituted fluorobenzene chromium tricarbonyls with the Swain–Lupton field and resonance parameters to probe the models of ring–metal bonding in arene chromium tricarbonyls.

Experimental

^{19}F nuclear magnetic resonance spectra were recorded on a Varian DP-60 spectrometer and ^{13}C spectra on a Bruker WH-90 spectrometer; mass spectra were recorded on a C.E.C. 21-110-B spectrometer. Infrared spectra were recorded as Nujol mulls.

All complexes were prepared by heating the appropriate fluoroarene under reflux with chromium hexacarbonyl following the procedure of Strohmeier (23) and purified by repeated sublimations.

The complexes were characterized by a combination of infrared, n.m.r., and mass spectrometry together with comparisons of literature melting points where available (1, 11, 23, 24). Relevant data are presented in Tables 1 and 2.

Results and Discussion

^{19}F and ^{13}C Nuclear Magnetic Resonance Data

Swain and Lupton (22) proposed that an empirical relationship exists between ^{19}F n.m.r. chemical shifts in *meta*- or *para*-substituted fluorobenzenes and field and resonance para-

meters and follows an equation of the form

$$[1] \qquad \Delta^F = f\mathcal{F} + r\mathcal{R}$$

where $\mathcal{F}$ and $\mathcal{R}$ are respectively the field and resonance constants characteristic of particular substituents and f and r are weighting factors determined by optimizing the difference between experimental and calculated data using a standard linear regression program to maximize the linear correlation coefficient.

The originally quoted values (22) of f and r for *para*-substituted fluorobenzenes are 35% and 65% respectively, which we calculate to have a low linear correlation coefficient using the substituents H, F, Cl, CH_3, CH_3O, NH_2, and CF_3. We find a better fit (correlation coefficient, $\bar{r}$, of 98.8%) for $f = 9\%$ and $r = 91\%$. Application of the same technique to the ^{19}F n.m.r. chemical shifts of the corresponding *para*-substituted fluorobenzene chromium tricarbonyl complexes

yields f and r values of 6% and 94%, $\bar{r}$ = 99.4% (see Fig. 1). This remarkable constancy of the dominance of the resonance parameter in the transmission of substituent effects is most gratifying especially as a recent ^{13}C n.m.r. study showed exactly comparable behavior (18). The correlation between the ^{19}F chemical shifts in *para*-substituted fluorobenzenes and the ^{13}C chemical shift of the C_4 carbon in the corresponding monosubstituted arenes is well established (25), and this relationship still holds in most cases when the arenes are complexed (see Fig. 2).

In contrast to the *para* isomers, *meta*-substituted fluorobenzenes show a greater than 95% dependence of the ^{19}F chemical shift on $\mathscr{F}$, the field parameter, (or as Taft (20) showed, Δ_m^F is directly proportional to σ_I). Upon complexation, however, a dramatic change occurs in that the ^{19}F chemical shifts of a wide variety of *meta*-substituted fluoroarenes (including ones of vastly differing electronic characteristics, such as CF_3 or NH_2) are almost all the same. The chemical shifts all fall within a narrow range of rather less than 2 p.p.m. (see Table 2), and show no obvious correlation with the electronic properties of the *meta*-substituent, whereas the free arenes cover a range almost five times as large as this (20).

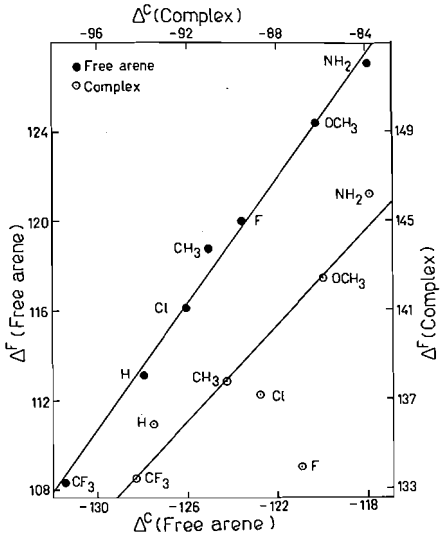

FIG. 2. Plot of ^{13}C chemical shifts of C_4 in monosubstituted benzenes and chromium tricarbonyl analogs against ^{19}F chemical shifts of *para*-substituted fluorobenzenes and tricarbonyl analogs. ^{19}F chemical shifts are in p.p.m. to high field of $CFCl_3$ and ^{13}C chemical shifts are in p.p.m. to low field of TMS.

Thus, the fluorine atom in the complex seems hardly able to distinguish any other *meta*-substituent from hydrogen, and is completely different to the *para* isomers where substituent dependence is very pronounced.

A fundamental change has clearly occurred in the arene ring upon complexation and, making the usual assumptions that mesomeric effects are transmitted predominantly via the π system while inductive effects primarily concern the σ framework, we are left with the following conclusions.

The chemical shifts of the fluorine atoms in the complexes reveal an indifference to the identity of the *meta*-substituent; thus it would seem that since this effect is transmitted almost entirely via the σ system, then the σ system itself must have been drastically modified. Indeed this would suggest participation by the σ framework of the ring in the arene–metal bond formation such as has been suggested by Drago and co-worker (26) from molecular orbital calculations. The observed upfield shift of about 20–25 p.p.m. relative to the uncomplexed arenes has been attributed to a partial sp^2–sp^3 rehybridization (27) which seems reasonable in light of the above evidence.

Since the transmission of substituent effects from the *para* position is scarcely changed upon complexation, and we have further shown this effect to be transmitted predominantly by a resonance effect, then, if this goes entirely via the π system of the ring, the π system must be essentially unperturbed by complexation. Conversely, if one could consider that the chromium atom were involved in the mechanism of transmission of the substituent effect, then it is not necessary to assume that the π-electron density remains unchanged. Furthermore, any modification of the π system would certainly affect the aromatic ring current and work to elucidate this point is currently being undertaken.

So it is clear that, upon complexation, there still remains an effective pathway by which a *para*-substituent can deliver its mesomeric effect while the net withdrawal of electron density from the σ framework seriously curtails the ability of a *meta*-substituent to bring about its inductive effect.

Infrared Data

The infrared spectra of the *meta*- and *para*-substituted fluorobenzene chromium tricarbonyl complexes reveal, as one might have anticipated

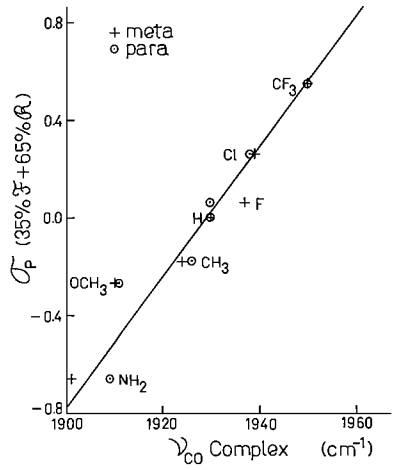

FIG. 3. Plot of carbonyl stretching frequencies (*E* mode) for *meta* and *para*-substituted fluorobenzene chromium tricarbonyls against Hammett's σ_p values (30) or 35%$\mathcal{F}$ + 65%$\mathcal{R}$ (22).

from the work of Brown *et al.* (15–17) and Reeves and co-workers (14), a good correlation between corresponding ν_{CO} stretching vibrations and a measure of the overall electron-accepting or -donating capability of a substituent whether it be *meta* or *para* to the fluorine. Thus a plot of ν_{CO} (*E* mode) against Hammett's σ_p, or against (35%$\mathcal{F}$ + 65%$\mathcal{R}$) using Swain's parameters, shows a linear correlation of 96.3% (see Fig. 3). Furthermore, as previously noted by Brown and co-worker (17), substituent effects are approximately additive, thus a plot of corresponding carbonyl stretching frequencies in the fluorinated and nonfluorinated complexes is linear with a slope very close to unity and an intercept of $\sim$10 cm^{-1}. That is, the additional fluoro substituent raises the carbonyl frequency by an approximately constant amount and is thus behaving as an acceptor of electron density in these systems.

Despite repeated syntheses of the *p*-difluorobenzene chromium tricarbonyl complex, an anomalous ^{19}F chemical shift was obtained (see Figs. 1 and 2) while its infrared and mass spectra were quite normal. The *para*-fluoro substituent would only fall on the line of Fig. 1 if one assumed an ($f\mathcal{F}$ + $r\mathcal{R}$) value of +0.13, *i.e.*, fluoro would need to be a much stronger electron-withdrawing substituent in these systems than implied by both Taft and Swain–Lupton values. As mentioned above, the carbonyl infrared data support the contention of fluorine as a relatively strong electron-withdrawing group in these instances. It is also worth noting that the ^{19}F chemical shift of the *para*-fluoro substituent in the bis(arene)chromium system was anomalously low (28).

The electronic environment in the complexed ring of arene chromium tricarbonyls appears to be considerably different from that in the corresponding bis(arene)chromium complexes. In the latter case there is a marked dependency of fluorine chemical shifts on both *meta*- and *para*-substituents (28) and this is presumably a reflection of the lack of carbonyl groups which act as an electron buffer (29). Thus, in the chromium tricarbonyl complexes an electron-donating substituent makes the ring electron rich and so electron density is siphoned off via the chromium into the π^* orbitals of the carbonyl ligands leading to a decrease in ν_{CO}; vice versa, electron-withdrawing groups produce an increase in ν_{CO}. This self-compensating mechanism is not available in symmetrically substituted bis(arene)-chromium complexes (28) and thus the arene ring itself must accommodate the relative excess or deficit of electron density; this in turn is reflected in the n.m.r. chemical shifts of nuclei such as ^{13}C or ^{19}F in the ring.

Interestingly, in the bis(arene)chromium systems, the ^{19}F n.m.r. spectra of CF_3 groups directly bonded to complexed arene rings exhibit downfield shifts of 4–6 p.p.m. relative to those of the uncomplexed arenes (28). In the $Cr(CO)_3$ analogs[1] this trend is also observed but the downfield shifts are approximately one-third the magnitude (see Tables 1 and 2).

Conclusions

^{19}F n.m.r. studies of *meta*- and *para*-substituted fluoroarene chromium tricarbonyl complexes indicate that transmission of resonance effects within the ring differs little from the free arenes but inductive effects are greatly diminished. This is rationalizable on the basis of withdrawal of σ-electron density from the ring with either little change in π-electron density of the ring or diminution of π-electron density in the ring if one invokes the concept of participation by the chromium atom in transmission of substituent effects between *para* positions.

[1] $(CF_3 \cdot C_6H_5)Cr(CO)_3$ shows ^{19}F absorption at 61.7 p.p.m. and ν_{CO} at 1908, 1940, and 1980 cm^{-1}.

Five-coordinate Bromobis(dialkyldithiocarbamate) Complexes of Arsenic, Antimony, and Bismuth

GEORGE E. MANOUSSAKIS, CONSTANTINOS A. TSIPIS, AND CHRISTOS C. HADJIKOSTAS
Laboratory of Inorganic Chemistry, University of Thessaloniki, Thessaloniki, Greece
Received October 8, 1974

GEORGE E. MANOUSSAKIS, CONSTANTINOS A. TSIPIS, and CHRISTOS C. HADJIKOSTAS. Can. J. Chem. **53**, 1530 (1975).

Fifteen bromobis(dialkyldithiocarbamate) complexes of arsenic, antimony, and bismuth have been prepared by reacting the corresponding tris(dialkyldithiocarbamates) with bromine. The structure of these compounds is studied by i.r., n.m.r., and electronic spectra. From the interpretation of the spectroscopic data it is deduced that each dithiocarbamate group acts as a bidentate ligand. The spectral data are discussed and compared to those of the corresponding tris(dialkyldithiocarbamate) complexes.

GEORGE E. MANOUSSAKIS, CONSTANTINOS A. TSIPIS et CHRISTOS C. HADJIKOSTAS. Can. J. Chem. **53**, 1530 (1975).

On a préparé 15 complexes bromobis(dialkyldithiocarbamate) de l'arsenic, de l'antimoine et du bismuth en faisant réagir les tris(dialkyldithiocarbamate) correspondants avec le brome. On a étudié la structure de ces composés par i.r., r.m.n. et spectroscopie électronique. A partir de l'interprétation des données spectroscopiques, on peut déduire que chaque groupe dithiocarbamate agit comme un ligand bidentate. On discute des données spectrales et on les compare avec celles des complexes tris(dialkyldithiocarbamate) correspondants.
[Traduit par le journal]

Introduction

In recent years a number of papers have been published on the reactions between dithiocarbamate complexes (both transition and non-transition elements) and halogens (1–12). The products of these reactions are usually halogenodithiocarbamate complexes, in which the central atom has an unusual oxidation number. From our point of view the paper of Willemse and Steggerda (12) on the oxidation of dithiocarbamate ligands is particularly interesting. According to these authors, halogenation of diethyldithiocarbamate complexes of iron(III), cobalt(III), antimony(III), and copper(II) gives compounds in which the dithiocarbamate ligand is oxidized to a positive ion, presumably with an S-tetrathian ring, and the metals are present as halogenated negative ions, for instance $SbCl_6^-$. After the above mentioned observations, the study of halogenation of the dialkyldithiocarbamate complexes of arsenic, antimony, and bismuth, which were prepared in this laboratory (13–14), was considered of interest.

In particular this paper deals with the preparation and study of fifteen bromobis(dialkyldithiocarbamate) complexes of arsenic, antimony, and bismuth of the general formula $BrM(R_2dtc)_2$ (where in the dithiocarbamato group, R_2dtc, R = Et, *i*-Bu, or Bz, $R_2 = (CH_2)_4$ or $(CH_2)_5$ abbreviated as Pyrr and Pip respectively, and M = As, Sb, or Bi).

As far as we know the above mentioned compounds are new compounds, except the bromobis(diethyldithiocarbamato)arsine, which has already been prepared and studied (15). The characterization and study of the prepared compounds were done by elemental analysis, molecular weight determination, and by i.r., n.m.r., and electronic spectroscopy.

Experimental

Measurements

Infrared spectra were recorded in the region 4000–650 cm^{-1} with a Perkin–Elmer 257 spectrophotometer. The complexes were studied as KBr disks and, in some cases, as chloroform solutions. No significant differences between solid-state and solution spectra were noted. Proton n.m.r. spectra were recorded on a Varian A 60A (60 MHz) instrument in $CDCl_3$ and C_6H_6 solutions using TMS as an internal standard. Electronic spectra were measured on a Zeiss PMQ II spectrophotometer with freshly prepared $CHCl_3$ solutions at about 30 °C. Molecular weights were determined using a Perkin–Elmer molecular weight apparatus Model 115 at a concentration range 3×10^{-3} to 6×10^{-4} *m* in $CHCl_3$ solution.

Preparation

The tris(dialkyldithiocarbamate) complexes of arsenic, antimony, and bismuth were prepared according to the published method (13).

The bromobis(dialkyldithiocarbamate) complexes were prepared as follows:

Bromobisdiethyl-, Bromobisdiisobutyl-, and Bromobisdibenzyldithiocarbamate Complexes of Arsenic, Antimony, and Bismuth

To a solution of the tris(dialkyldithiocarbamate) complex (5 mmol) in 100 ml CCl_4, or, for the compounds $Bi(Et_2dtc)_3$ and $As(Bz_2dtc)_3$, in a mixture of 150 ml CCl_4 and 50 ml $CHCl_3$, a solution of bromine (2.5 mmol) in 15 ml CCl_4 was added dropwise, while stirring constantly. After the addition of the bromine solution, the mixture was stirred at room temperature for 4–5 h. The mixture was then concentrated to about 30 ml and after addition of methanol the bromobis(dialkyldithiocarbamate) complexes were precipitated. Purified precipitates were obtained by dissolving them in a small amount of benzene and then precipitating with methanol or petroleum ether (b.p. 40–60 °C). The pure materials were dried under vacuum at room temperature. In the course of reprecipitating the bromobis(dibenzyldithiocarbamate) complexes by addition of methanol or petroleum ether to the benzene solution, viscous oils were obtained which were solidified on drying under vacuum. The prepared complexes are soluble in chloroform, methylene chloride, benzene, carbon tetrachloride, and acetone and insoluble in methanol, ethanol, ether, petroleum ether, and water.

Bromobipyrrolidyl-, and Bromobipiperidyldithiocarbamate Complexes of Arsenic, Antimony, and Bismuth

To a solution of the corresponding tris(dialkyldithiocarbamate) complex (5 mmol) in 100 ml $CHCl_3$ a solution of bromine (2.5 mmol) in 25 ml $CHCl_3$ was added dropwise, while stirring constantly. After the addition of the bromine solution the mixture was stirred at room temperature for 4–5 h. The mixture was then filtered and the precipitate washed with methanol and recrystallized from a mixture of dimethylformamide and methanol. The bromobis(dialkyldithiocarbamate) complexes obtained are insoluble in common organic solvents and water, but are soluble in dimethylformamide and dimethylsulfoxide, and slightly soluble in chloroform and methylene chloride.

The analytical data of the compounds studied are given in Table 1.

Results and Discussion

When the tris(dialkyldithiocarbamate) complexes of arsenic, antimony, or bismuth in carbon tetrachloride or chloroform solution are reacted with 1 equiv. of bromine, one of the three dithiocarbamate groups is displaced by a bromine atom.

Although, in some cases, bromine was used in excess (twofold of the required quantity), dibromodialkyldithiocarbamates were not isolated. This may be attributed to the easier detachment of one of the three dithiocarbamate groups, due to the stereochemically active lone pair of electrons of the central atom (13, 16, 17), while the presence of a bromine atom in the molecule of the bromoderivatives, because of its $-I$ inductive effect, strengthens the binding between the central atom and the remaining two dithiocarbamate ligands.

Conductance measurements in nitrobenzene solution indicate that the compounds studied are nonelectrolytes.

Infrared Spectra

In Table 2 are listed the relevant i.r. data for our new compounds with their assignments.

The most characteristic bands of the compounds studied are the "thioureide" bands near 1500 cm^{-1}, which indicate considerable double bond character in the C⋯N bond.

In bromobis(dialkyldithiocarbamate) complexes the stretching frequencies of the C⋯N bonds are higher than those of the corresponding tris(dialkyldithiocarbamate) complexes. This may be due to the $-I$ inductive effect of bromine atom, as well as to their different stereochemical structures. The observed shifting of the C⋯N bands to higher frequencies in the studied bromoderivatives relative to the corresponding trisdithiocarbamates follows the sequence As > Sb > Bi. Taking into consideration that the presence of the bromine atom reduces the electron density on bismuth atom more than on antimony and arsenic ones the observed sequence is abnormal. This discrepancy may be attributed to the more pronounced π-back donation in bismuth compounds than in those of antimony and arsenic. The π-back donation also seems to be more pronounced in bromoderivatives than the corresponding trisdithiocarbamates. Considering that the π-back donation is, generally, favored by the square pyramidal structure (18) and the fact that this structure was already established for the bromobis(diethyldithiocarbamato)arsine (15), we can accept the same structure for all the compounds studied.

Certain bands in the 800–1000 cm^{-1} region (Table 2) are attributed to the stretching vibration of C⋯S bonds (19, 20). The single band around 1000 cm^{-1} in the spectra of all the compounds studied (except dibenzylderivatives of arsenic and antimony) is evidence of bidentate linking of dithiocarbamato groups (21–23).

The existence of splitting in the C⋯N bands in some of the compounds studied, especially in those of arsenic, may be considered as evidence of inequivalent bonding of the dithiocarbamato groups or vibration mixings. Similar splittings have been observed by other authors (21, 23–25).

Proton Nuclear Magnetic Resonance Spectra

The signals of the proton n.m.r. spectra of the compounds studied are listed in Table 3. The absence of splitting in n.m.r. signals does not directly imply that the two dithiocarbamate ligands are bonded equivalently. This can be assigned to the isolation of the alkyl groups from the metal–sulfur bonds (26). The signals of the more distant protons are shifted less to lower fields in comparison to the signals of the corresponding tris(dithiocarbamates). This is something which can be expected, for the bromine atom in the dithiocarbamate molecules withdraws more of the electron density from the alkyl groups towards the central atom. This means that the deshielding effect is more pro-

*sh = shoulder.

nounced for the more distant protons of the bromoderivatives.

Paradoxically the behavior of the less distant protons (methylene) is the opposite. The signals of methylene protons are shifted to a higher field region (more shielding). This discrepancy may be assigned to the different location of these protons in the shielding cone of the C⋯N bond.

The proton signals of the compounds studied are subjected to benzene induced solvent shifts (Table 3). This effect is attributed to the formation of van der Waals complexes between benzene molecules (solvent) and the bromobis(dialkyldithiocarbamates) (solute) (14). The observed values of the solvent shifts increase as the stretching frequencies of the C⋯N bonds increase.

Electronic Spectra

The electronic spectra of the arsenic and antimony compounds show two absorption bands in the ultraviolet region. In the spectra of bismuth compounds there is a third maximum near the visible region (Table 4).

The high intensity band (Band I) at 38–40 kK is assigned to an intraligand $\pi \rightarrow \pi^*$ transition (27). The position of band I is not much affected by the presence of the central atom. The sequence in the bromoderivatives studied is Bi ≥ As ≥ Sb; in the corresponding tris(dialkyldithiocarbamate) complexes it is As > Sb > Bi. This discrepancy is perhaps a further indication for the more pronounced π-back donation in the case of bismuth derivatives in agreement with i.r. data. The position of band I in bromoderivatives is shifted to higher frequencies relative to tris(dithiocarbamate) complexes. Band I depends also on the electron releasing ability of the $-NR_2$ group. The increase of the basic character of the amine group leads to blue shifts.

Band II (inflection point) is attributed to another $\pi \rightarrow \pi^*$ transition (28). This inflection is more pronounced in arsenic than in antimony compounds and it almost disappears in bismuth ones. This band is evidence of inequivalent linking of dithiocarbamate ligands (27).

Molecular Weights

The compounds studied are monomeric in $CHCl_3$ solution at the concentration range 10^{-3}–10^{-4} *m*, except the bismuth compounds which show a tendency for dimerization. This tendency decreases with increasing basicity of amine group. This may be due again to π-back donation, which has as a result the decrease of electron density on bismuth atom. Therefore weak interaction forces exist between bismuth of one molecule and a bromine atom of another molecule.

Reaction of 4,4′-Bis(dimethylamino)triphenylmethyl Tetrafluoroborate with Alkoxide Ions. I. Determination of Ion-pair Dissociation Constant for Sodium Alkoxides

KENNETH T. LEFFEK AND ANDREJ SUSZKA[1]

Department of Chemistry, Dalhousie University, Halifax, Nova Scotia B3H 4H6

Received November 6, 1974

KENNETH T. LEFFEK and ANDREJ SUSZKA. Can. J. Chem. **53**, 1537 (1975).

The second-order rate constants have been determined for the reaction of 4,4′-bis(dimethylamino)triphenylmethyl tetrafluoroborate carbonium ion with sodium methoxide in methanol and sodium ethoxide in ethanol. The results have been used to evaluate the ion-pair dissociation constants for the two alkoxides. The activation parameters for the two reactions with the free alkoxide ions are also reported.

KENNETH T. LEFFEK et ANDREJ SUSZKA. Can. J. Chem. **53**, 1537 (1975).

On a déterminé les constantes de vitesse du deuxième ordre des réactions du carbocation du tétrafluoroborate de bis(diméthylamino)-4,4′ triphénylméthyle avec le méthylate de sodium dans le méthanol et avec l'éthylate de sodium dans l'éthanol. On a utilisé les résultats obtenus pour évaluer les constantes de dissociation des paires d'ions des deux alcoolates. On rapporte aussi les paramètres d'activation des deux réactions avec les ions alcoolates libres.

[Traduit par le journal]

Introduction

It has been pointed out recently (1) that despite the fact that ion association of alkali metal alkoxides must play an important part in the kinetics of their reactions in alcohol solution, few investigations have been made directly of this phenomenon by measurement of reaction rates. In the present study, the kinetics of the reaction of sodium methoxide and ethoxide, in the corresponding alcohol solvents, with 4,4′-bis(dimethylamino)triphenylmethyl tetrafluoroborate (malachite green) have been investigated and the ion-pair dissociation constants of the alkoxides have been calculated from the rate constant measurements.

The reaction of malachite green with methoxide, which is a clean formation of the methyl ether by combination of the methoxide ion with the carbonium ion was previously studied by Ritchie *et al.* (2, 3). Their experiments were made at 25 °C using tertiary amine solutions in methanol, buffered by strong organic acids, as a source of methoxide ions. Later sodium methoxide in methanol was used and the rate measurements carried out with a stopped-flow spectrophotometer. An ion-pair dissociation constant of $1.03 \times 10^{-2}\ M^{-1}$ was assumed for sodium methoxide and the second-order rate constant for malachite green was found to be $1250\ M^{-1}\ s^{-1}$ at 25 °C. The reaction of methanol itself with the carbonium ion was found to be negligible and our observations confirm this.

Results and Discussion

Two series of kinetic measurements have been made at a number of different temperatures be-

tween 0 and 35° at various concentrations of sodium methoxide in methanol and sodium ethoxide in ethanol. The substrate concentration was 3×10^{-6} *M* and the alkoxide concentrations were always in large excess, between 3×10^{-4} and 1×10^{-2} *M*. The pseudo first-order rate constants, k_1, calculated by the Guggenheim method and plotted against the alkoxide concentration, gave straight lines over the lower range of alkoxide concentration but at higher concentrations the rate constants fell on a curve below the line as shown in Fig. 1 for the methoxide reaction. The pseudo first-order rate constants and the corresponding second-order rate constants, calculated by the method of least squares applied to the seven lower concentrations, for both the methoxide and ethoxide reactions are shown in Table 1. The second-order rate constant for methoxide ion reaction at 25 °C is about 18% lower than the value recorded by Ritchie *et al.* (3).

The curvature of the plots in Fig. 1 is no doubt due to metal alkoxide ion-pair formation in the solutions at higher concentration, as suggested by Ritchie *et al.* (3). The dissociation constant of the ion-pair is given by

$$[1] \qquad K = \frac{[Na^+][\bar{O}Alk]}{[Na^+\bar{O}Alk]}$$

If the total methoxide concentration, as free ion and ion-pair, is denoted c then

$$[2] \qquad K = \frac{[\bar{O}Alk]^2}{c - [\bar{O}Alk]}$$

and

$$[3] \qquad [\bar{O}Alk] = \tfrac{1}{2}(-K \pm \sqrt{K^2 + 4Kc})$$

The relation between k_{obs} and the second-order rate constants for a reversible equilibrium is

$$[4] \qquad k_{obs} = k_2[\bar{O}Alk] + k_{-2}$$

where k_2 and k_{-2} are the second-order rate constants for the forward and backward reactions respectively. It can be seen from Fig. 1 that k_{-2} is very small compared to $k_2[\bar{O}CH_3]$ and, therefore, it may be omitted. Combination of eqs. 3 and 4 gives

$$[5] \qquad k_{obs} = k_2\left\{\frac{-K \pm \sqrt{K^2 + 4Kc}}{2}\right\}$$

which may be transformed into

$$[6] \qquad k_{obs}\left(\frac{1}{k_2{}^2K}\right) + \frac{1}{k_2} = \frac{c}{k_{obs}}$$

Equation 6 represents a straight line relation between k_{obs} and c/k_{obs} with an intercept equal to $1/k_2$ and a slope equal to $1/k_2{}^2K$.

The slopes and intercepts were calculated by the least squares method applied to the six higher concentrations in Table 1 for the methoxide and ethoxide reactions. The intercepts yielded values of k_2 which agreed reasonably well with those of Table 1, but the k_2 values of Table 1 are more precise, so these were combined with the slopes to give the dissociation constants shown in Table 2.

The above treatment assumes that the reactivity of the ion-pair is very much less than the free alkoxide ion. There is, of course, no absolute proof for this, but there is circumstantial evidence that the nucleophilic power of anion reagents is seen only when the anion exists in solution as a free ion. In 1956, Bevan and Monk (4) showed that the differences in the second-order rate constants for the reaction of sodium, potassium, magnesium, calcium, and strontium thiosulfates with *n*-propyl bromide in

a mixed ethanol–water solvent could be eliminated completely if the rate constant was calculated with respect to the free thiosulfate ion. They assumed that ion-pairs in solution made no contribution to the reaction velocity and the rate constants for the free thiosulfate ion were found not only to be independent of the cation present but also independent of the ionic strengths of the solution (4).

Cram *et al.* (5) investigated the rates of racemization and exchange of 1-phenylmethoxyethane-1-*d* in dimethyl sulfoxide – potassium *tert*-butoxide. The order of the reaction in potassium *tert*-butoxide and other kinetic observations led them to conclude that potassium *tert*-butoxide in DMSO is largely in the form of ion-pairs, but that only the dissociated *tert*-butoxide ion is chemically active with the reactivity of the ion-pairs vanishingly small in comparison.

In the present investigation, the validity of the assumption that the ion-pairs are very unreactive may be judged by making a comparison between our kinetically derived dissociation constants and the literature values calculated from conductance measurements. The values of the dissociation constants in Table 2 are not of high precision and it is not possible to distinguish a clear change with temperature for the sodium ethoxide. Nevertheless, the result $K = 1 \times 10^{-2}\ M^{-1}$ at 25 °C for sodium ethoxide is of the same order of magnitude but lower than the value of $2.0 \times 10^{-2}\ M^{-1}$ from conductance measurements (6). For sodium methoxide, the only value in the literature is the assumed one from the kinetic study by Ritchie *et al.* (3) of 1.03×10^{-2}

M^{-1} which is somewhat less than our 2.6×10^{-2} M^{-1} at 25 °C. Potassium methoxide has been reported (1, 7) as 1 to 2×10^{-2} M^{-1}, calculated from conductance measurements.

The derivation of the ion-pair dissociation constants ignores salt effects due to activity coefficients. The justification of this is that Ritchie *et al.* (3) found no such salt effect in the reaction of malachite green with hydroxide ion in water up to a concentration of added salt of 10^{-2} M and also reported (3) that Taft had found a salt effect of only 10% for added salt concentrations between 0.05 and 1 M for the same reaction. For our alkoxide reactions, there is clearly no ionic strength effect on the second-order rate constants up to alkoxide concentrations of 2×10^{-3} M, as can be seen from Fig. 1. The changes in k_2 values between 2×10^{-3} M and 1×10^{-2} M fit the ion-pair theory very well within the precision of the rate measurements, thus it is assumed that activity coefficient effects must be much smaller than the ion-pairing effect.

The relative sizes of the methoxide and ethoxide ion-pair dissociation constants is reasonable, since not much difference between them would be expected, but from qualitative studies, the ethoxide, if anything, should be the smaller since the free ethoxide ion will not be as strongly stabilized by solvation as the free methoxide ion.

The second-order rate constants of Table 1 allow the evaluation of the activation parameters for the two reactions. These activation parameters are given in Table 3.

The enthalpy of activation of the ethoxide reaction is slightly larger than that for methoxide which is opposite to what would be predicted from the greater solvation stability of the methoxide ion. The importance of solvent reorganization as a major or even the dominant factor in the activation process was pointed out in 1935 by Ogg and Polanyi (8) and later by Moelwyn-Hughes and Glew (9) for nucleophilic substitution reaction. Caldin and co-worker (10, 11) and recently we (12) have made similar arguments for proton transfer from organic acids to alkoxides, and Ritchie *et al.* (3) have published such arguments for the reactions of this study. Despite this, we do not find the activation enthalpy higher for the methoxide reaction than for the ethoxide reaction as would be expected if solvent reorganization were the only factor. However, the 8 to 9 kcal mol^{-1} observed for these reactions is very similar to the 7 to 11 kcal mol^{-1} found for proton transfers (10, 12–14) and the entropies of activation bear a similar general equivalence. Therefore, the activation parameters are consistent with the presence of a major solvent reorientation factor, although this cannot be controlling the activation process entirely.

TABLE 3. Activation parameters for the reaction of 4,4′-bis(dimethylamino)triphenylmethyl fluoroborate with methoxide and ethoxide

Parameter	Methoxide	Ethoxide
$\Delta H^{\ddagger}$ (kcal mol^{-1})	7.9±0.1	9.0±0.3
$\Delta S^{\ddagger}$ (cal deg^{-1} mol^{-1})	−18.1±0.5	−12.8±0.9

Experimental

Materials

Commercial methanol was fractionally distilled, passed through a 60 × 2.5 cm column filled with Linde molecular sieve 3A, then through a 20 × 2.5 cm column filled with Dowex 50WX8, and finally distilled again. The Dowex resin was dried *in vacuo* at 90 °C for several hours before packing the column.

Anhydrous ethanol was prepared by drying commercial absolute ethanol with Mg turnings. The traces of basic material were removed by fractional distillation from anhydrous sulfanilic acid.

Sodium alkoxide solutions were prepared by dissolving clean sodium metal in alcohol in flasks protected from moisture and carbon dioxide. All solutions were prepared in a glove bag containing dry nitrogen and stored in flasks sealed with rubber serum caps. The concentrations of the alkoxides were determined by titration with standard HCl solution using methyl red as the indicator.

4,4′-Bis(dimethylamino)triphenylmethyl tetrafluoroborate was prepared by adding a slightly acidic solution of sodium tetrafluoroborate to an aqueous solution of malachite green hydrochloride. The precipitated malachite green tetrafluoroborate was recrystallized from water and dried over P_2O_5.

Kinetic Measurements

The reaction rates were measured using a stopped-flow spectrophotometer according to the standard procedure described previously (12, 15). For each set of reagent conditions, two or three trial runs were made and observed on the oscilloscope in the nonstorage mode. If these appeared satisfactory and reproducible, the oscilloscope was switched to the storage mode and between four and six runs were made in rapid succession and superimposed on the oscilloscope screen. These runs nearly always superimposed exactly giving one very slightly broadened trace. The first-order rate constant was calculated from a photograph of the composite trace. The low initial concentration of the substrate dye gave a transmittance at the beginning of a run of about 90%. The quality of the runs was about as good as it is possible to get with a stopped-flow spectrophotometer.

The authors are grateful for financial support by the National Research Council of Canada and also to the Killam Trust for a Killam Memorial Fellowship to Andrej Suszka.

Electrical Conductivity and Phase Transformation Studies on Pure and Doped (Mg^{2+}, Zn^{2+}, Cu^{2+}, and Mn^{2+}) Crystals of K_2SO_4

MAHADEVA NATARAJAN AND ETALO A. SECCO

Department of Chemistry, St. Francis Xavier University, Antigonish, Nova Scotia B0H 1C0

Received July 19, 1974[1]

MAHADEVA NATARAJAN and ETALO A. SECCO. Can. J. Chem. **53**, 1542 (1975).

Electrical conductivity measurements have been made on single crystals of undoped potassium sulfate and on single crystals of K_2SO_4 doped with divalent ions, *viz.* Mg^{2+}, Zn^{2+}, Cu^{2+}, and Mn^{2+}. The presence of the divalent ion increases the cation migration energy. The lower defect formation energy is attributed to the lower symmetry of K_2SO_4 relative to the high symmetry cubic systems previously studied.

The presence of the dopants and dopant concentration, *i.e.* Cu^{2+}, show varying effects on the magnitude and nature of the conductivity discontinuity at the orthorhombic–hexagonal phase transition temperature. The phenomenon of "pretransition", 350 to 425 °C, is observed in both pure and doped crystals. Preannealing the crystal contributes to interesting behavior on all the crystals studied. The σ–T behavior of K_2SO_4 crystal doped with radioactive ^{65}Zn, however, exhibits a simpler linear dependence and the absence of "pretransition" anomaly.

MAHADEVA NATARAJAN et ETALO A. SECCO. Can. J. Chem. **53**, 1542 (1975).

On a fait des mesures de conductivité électrique sur des monocristaux de sulfate de potassium pur et sur des monocristaux de K_2SO_4 dopés avec des ions divalents comme Mg^{2+}, Zn^{2+}, Cu^{2+}, et Mn^{2+}. La présence d'ions divalents augmente l'énergie de migration du cation. On explique l'énergie plus faible de formation de défaut par la symétrie moindre de K_2SO_4 relativement aux systèmes de symétrie cubique qui ont été étudiés antérieurement.

Les impuretés, ainsi que leur concentration, *i.e.* Cu^{2+}, ont des effets variables sur l'amplitude et la nature de la discontinuité de la conductivité à la température de la transition orthorhombique–hexagonale. On observe le phénomène de "prétransition," 350 à 425 °C, dans les cristaux purs et dans les cristaux dopés. Le recuit des cristaux donne lieu à un comportement intéressant. La relation σ–T du cristal de K_2SO_4 dopé avec du ^{65}Zn radioactif est toutefois linéaire et on note dans ce cristal l'absence d'une anomalie de prétransition. [Traduit par le journal]

Introduction

Electrical conductivity measurements (1–4) on alkali halides have provided a simple and useful model for the transport mechanism in these solids involving point defects. However, such measurements have largely been restricted to crystals like KCl, KBr, CsCl, etc., which belong to a high symmetry crystal system. The existing data on defect energies in low symmetry crystals are inadequate and cannot provide a clear picture of the transport mechanism in such solids. Recently, reports on low symmetry crystals have appeared in the literature (5–8) indicating some very interesting features in the transport properties which may be linked to different conduction mechanism(s).

We have recently investigated the electrical properties in single crystals of potassium sulfate, both pure and doped with Mg^{2+}, Zn^{2+}, Cu^{2+}, and Mn^{2+}. In the case of Cu^{2+} dopant attention was also focussed on the effects of different levels of doping on the conductivity behavior of K_2SO_4. These cations show varying effects, not only on the conductivity features of the low temperature orthorhombic form but also on the magnitude of the conductivity discontinuity at the crystallographic transformation to the hexagonal form and on the conductivity of the hexagonal phase. It was also of interest to examine the recently reported (9) phenomenon of "pretransition" in K_2SO_4 monocrystals by the conductivity technique.

The source of K_2SO_4 was Fisher Certified grade (99.98%) which was further purified by crystallization. Single crystals of K_2SO_4 were prepared by slow evaporation of the aqueous solution. Seed crystals were washed and allowed to grow in saturated solution; crystals grew to $\sim$10 mm $\times$ 5 mm. The phase change in K_2SO_4 precludes growth from the melt since the crystal ruptures on cooling.

Doped K_2SO_4 crystals were similarly grown

from aqueous solutions containing 2 mol% of the respective divalent cation. Cu^{2+} doped K_2SO_4 crystals were grown from solutions containing 5.0, 3.0, 2.0, 1.0, 0.5, 0.1, and 0.05 mol% Cu^{2+}. Iodimetric titrations of the Cu^{2+} doped crystals, however, indicated ~20% of the original solution Cu^{2+} was incorporated in the K_2SO_4 crystal as shown in Table 1. The crystal Cu^{2+} shows a linear dependence on solution Cu^{2+} concentration. K_2SO_4 crystals grown in 1.0–5.0% solutions were clear and transparent while the lower concentration crystals displayed an opaque or milky appearance.

Radioactive ^{65}Zn metal (AECL Catalog No. Zn 65 S-1) was dissolved in H_2SO_4 to obtain ^{65}Zn doped K_2SO_4 crystals with specific activity ~1 count min^{-1} mg^{-1}. ^{65}Zn, $t_{1/2}$ ~ 245 d, emits γ (1.14 MeV) and β^+ (0.32 meV) radiations. The growth rate of single crystals was observed to occur in decreasing order as follows: $Cu^{2+} \approx Zn^{2+} > Mn^{2+} > Mg^{2+}$. All crystals showed a strong tendency to form contact twins and gave hexagonal bipyramids on full growth along the *c*-axis; the crystallographic axes *a* and *b* formed the basal plane.

Goniometric measurements confirmed all crystals to be orthorhombic and that the crystals grew along the *a* axis in the form of prisms terminated by the pyramidal planes.

Electrical conductivity measurements were made on crystals polished to sizes *ca.* 5 mm × 5 mm ⊥ to (100), ⊥ to (011) planes, and also ⊥ to the pyramidal planes; the experimental procedure for these measurements as described earlier (10, 11), maintained the crystal by a spring-loaded support between stainless steel leads using polished platinum discs as electrodes. The cell was heated at <25 °C per hour in a cylindrical well-type furnace. Temperature was measured by using standardized chromel–alumel thermocouples with a L & N potentiometer. The crystal conductivity was measured on a GR 1608-A bridge; the temperature was stabilized to ±1 °C prior to each measurement. The reproducibility of the conductivity values on heating–cooling cycle was excellent in the intrinsic region but was lacking in the temperature region prior to the pretransition effect.

TABLE 1. Dependence of Cu^{2+} incorporated in crystal relative to initial solution

Cu^{2+} (mol %)

Results and Discussion

Undoped K_2SO_4 Crystals

The plot of the logarithm of electrical conductivity, σ, *vs.* the reciprocal of temperature, $1000/T$ K, for pure K_2SO_4 is presented in Fig. 1. The room temperature σ value is 2.1×10^{-8} $(\Omega\ cm)^{-1}$ ⊥ to the (100) plane and 0.79×10^{-8} $(\Omega\ cm)^{-1}$ ⊥ to the (011) plane. Earlier reports (6, 12), using single crystals of K_2SO_4, have indicated appreciable anisotropic conductivity behavior up to 350 °C, with the same temperature dependence for all three principal crystallographic directions, suggesting a common transport mechanism.

The conductivity ⊥ to (100) is higher than that ⊥ to (011) over the temperature range 200–625 °C. The low temperature conductivity follows a linear dependence corresponding to activation energies of 0.20 eV and 0.10 eV ⊥ to (100) and (011) faces, respectively. The conductivity ⊥ to (100) begins its rise at ~320 °C accompanied by an activation energy of 0.80 eV. This energy value refers to the cation migration energy in K_2SO_4; such high migration energies have re-

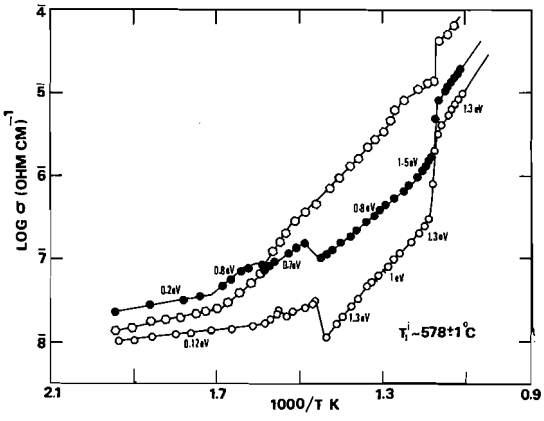

FIG. 1. Logarithm of electrical conductivity *vs.* $1000/T$ K for pure K_2SO_4 single crystal: ●, ⊥ to (100) face; ○, ⊥ to (011); ⬡, polycrystalline sample.

cently been reported for orthorhombic K_2SO_4 (6) and K_2CrO_4 (8).

The conductivity shows a sluggish increase up to ~356 °C, and an anomaly is observed at ~358 °C. Above this temperature the conductivity increases slowly with an activation energy ~0.70 eV up to ~418 °C where a sharp drop in conductivity occurred. The behavior of the sample in this region is comparable to the behavior observed for K_2CrO_4 (8) single crystals. Recently, Kolonotsova *et al.* (9) have reported a "pretransition" phenomenon in single crystals of potassium sulfate by diffuse X-ray scattering techniques. The "pretransition" is considered to be a preparatory stage that can extend over a wide temperature interval, caused by structural changes not associated with the formation of the new phase. Such changes could be described in general as an intermediate structural state between the low and high temperature modifications. According to Kolonotsova *et al.* (9) the most probable mechanism of such states is associated with cooperative atom shifts, caused by the appearance of point defects.

The anomalous conductivity behavior in the region above 375°C is also supported by the anomalous specific heat observed by Watanabe *et al.* (13), who attributed the excess specific heat to the onset of rotation of the sulfate radical. Thus, it is likely that the anomalous behavior in potassium chromate single crystals observed earlier (8) could also arise from pretransition effects and the onset of rotation by chromate radical.

Above 420 °C the (100) conductivity dependence is essentially linear with an activation energy of 0.80 eV. At 555 °C, the activation energy rises to 1.5 eV; it is not clear whether or not this represents the true intrinsic region in view of its lack of reproducibility; as evident later it varies in doped crystals. Thus, defect formation energy values are not reliable if deduced from these activation energy values. The conductivity shows a sharp discontinuity between 578 and 585 °C due to the orthorhombic–hexagonal phase transformation. Above 585 °C the conductivity with an activation energy of 1.30 eV refers to the hexagonal structure; the 1.30 eV value is in excellent agreement with that reported for Ag_2SO_4 (5).

The conductivity behavior $\perp$ to (011) face parallels the pattern observed for (100) face in the range 375–425 °C. The log $\sigma - 1/T$ dependence is essentially linear over the 425–580 °C range with a mean activation energy of 1.2 eV although we have identified segments of this temperature range with activation energies of 1.3, 1.0, and 1.30 eV. The higher activation energy of 1.2 eV, relative to 0.8 eV for (100) plane, after the "pretransition" phenomenon might incorporate the association enthalpy for the complex involving any impurity divalent ion and cation vacancies. The major transition is again evident by the abrupt rise in conductivity in the region 577–585 °C. The activation energy of 1.30 eV reappears for the hexagonal phase.

The polycrystalline σ–T data are situated between the (100) and (011) single crystal curves up to 350 °C. Above 350 °C the polycrystalline conductivity curve rises above the (100) curve and resembles the (011) single crystal slope, *viz.* 1.2 eV, with no evidence of "pretransition" phenomenon or anomalies. This crystalline behavior parallels that observed for polycrystalline potassium chromate (8). Although the activation energies below the major transition temperature are comparable in both K_2CrO_4 (8) and K_2SO_4, 1.0 and 1.2 eV, respectively, the hexagonal phase values differ appreciably from each other. This latter energy difference could arise from a more fluid-like nature of the K_2CrO_4 hexagonal phase relative to its sulfate counterpart.

Differential thermal analysis heating traces confirmed the "pretransition" effects for K_2SO_4 single crystals in the temperature range 375–425 °C and the absence of any such effect for the polycrystalline K_2SO_4 sample.

Doped (Mg^{2+}, Zn^{2+}) K_2SO_4 Crystals

Figure 2 shows the plot of logarithm of con-

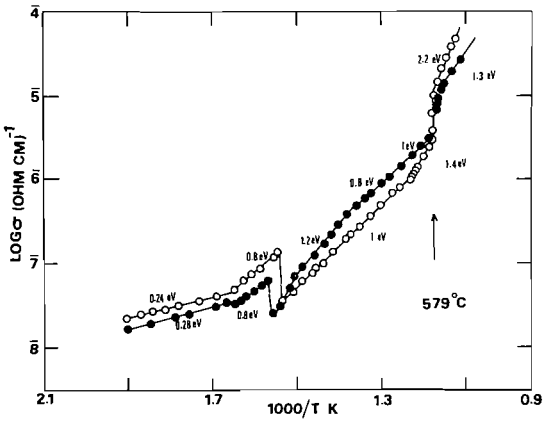

FIG. 2. Logarithm of electrical conductivity *vs.* 1000/T K for Mg^{2+} doped K_2SO_4 crystals: ○, and Zn^{2+} doped K_2SO_4 crystals; ●, measured $\perp$ to (011) face.

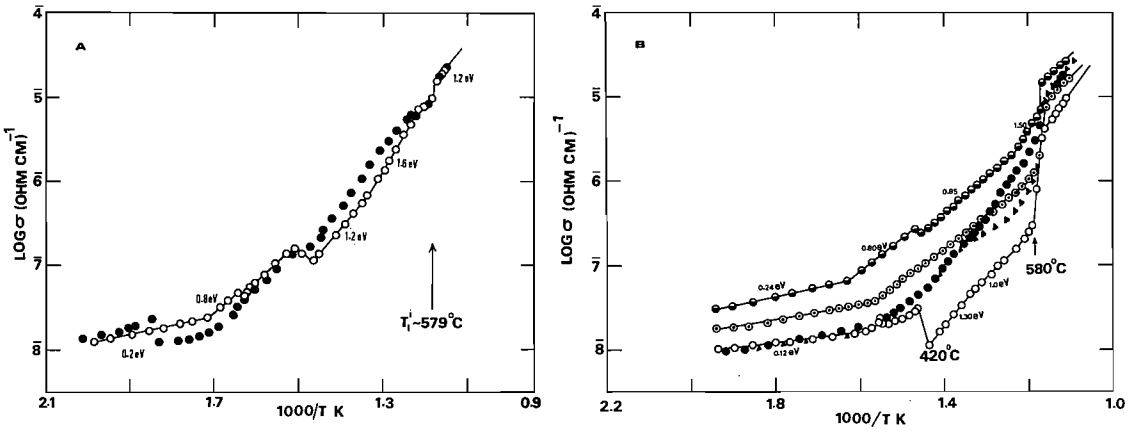

FIG. 3. (*A*) Logarithm of electrical conductivity *vs.* 1000/*T* K for Cu^{2+} doped K_2SO_4 crystals measured ⊥ to (011) face: ●, untreated crystals; ○, crystal preannealed at 330 °C for 15 min and cooled to 200 °C at ~2°/min. (*B*) Logarithm of electrical conductivity *vs.* 1000/*T* K for Cu^{2+} doped K_2SO_4 single crystals at different doping levels and pretreatment measured ⊥ to (011): ○, K_2SO_4 undoped; ▲, 0.1% Cu^{2+} grown K_2SO_4 preannealed for 30 min; ●, 0.1% Cu^{2+} grown K_2SO_4 preannealed for 60 min; ⊙, 0.5% Cu^{2+} grown K_2SO_4 preannealed for 60 min; ◒, 5% Cu^{2+} grown K_2SO_4 preannealed for 30 min.

ductivity σ *vs.* 1000/*T* K for K_2SO_4 crystals doped with Mg^{2+} (open circles) and Zn^{2+} (filled circles) measured ⊥ to (011) face. The initial slopes correspond to activation energies of 0.24 and 0.28 eV suggesting this to be due to physical defects, *e.g.* dislocations. This region is followed by an energy of 0.80 eV, in both samples, attributed to the cation migration energy. The initial higher conductivity of the Mg^{2+} doped K_2SO_4 relative to Zn^{2+} doped sample may be due to its smaller ionic radius, 0.66 Å compared to 0.74 Å, and the probability that Mg^{2+} is an interstitial impurity whereas Zn^{2+} may be present as a substitutional impurity.

The "pretransition" discontinuity appears at 370 °C for Zn^{2+} and 380 °C for Mg^{2+} doped crystals. The Mg^{2+} curve shows an activation energy of 1.0 eV after the "pretransition" effect and rising to 1.4 eV just prior to the major transition whereas the Zn^{2+} shows an activation energy of 1.2 eV and decreasing to 1.0 eV over the same temperature interval. The unusual energy trend for Zn^{2+} might incorporate the association enthalpy of divalent ion – cation vacancy complex which dissociates with increasing temperatures.

The magnitude of the jump in conductivity at the major transition, 579–585 °C, is less than that observed in the pure crystal. Above 585 °C, the conductivity of Mg^{2+} shows a higher temperature dependence than does Zn^{2+}, with activation energies of 2.2 and 1.3 eV, respectively.

Doped (Cu^{2+}) K_2SO_4 Crystals

The plot of logarithm of conductivity σ *vs.* 1000/*T* K for two crystals of K_2SO_4 containing Cu^{2+} measured ⊥ to (011) face is given in Fig. 3*A*; untreated crystal represented by filled circles and preannealed crystal, maintained at 330 °C for 15 min and cooled to 200 °C at rate of 2 °C/min, represented by open circles.

Preannealing the crystal lowers the conductivity and erases the anomaly observed at ~280 °C for the untreated crystal. The cation migration energy of 0.80 eV is reproduced here. A somewhat subdued "pretransition" effect, 350–420 °C, is followed by an activation energy of 1.20 eV. As the temperature increases the activation energy rises to 1.60 eV, reproducible to 0.10 eV for preannealed crystals, on its approach to the major transition temperature. Assuming this latter region to be the intrinsic region, the vacancy formation energy is calculated as 1.60 eV (Cu^{2+} enters the lattice substitutionally (14) giving rise to Schottky defects). Such a parallel increase in activation energy prior to the transition temperature occurred also in pure and Mg^{2+} doped K_2SO_4 crystals. The less exciting conductivity discontinuity at the transition temperature and the lower activation energy of 1.20 eV for the hexagonal phase conductivity relative to the pure crystal suggest that the Cu^{2+} doped K_2SO_4 crystal exists in highly comparable mobility configurations.

Figure 3*B* presents σ–T plots for K_2SO_4 crystals incorporating different levels of Cu^{2+} dopant and varying preanneal treatment. The σ–T curve for undoped K_2SO_4 (open circles) is included for comparison. It is evident that the conductivity of K_2SO_4 is enhanced by the level of Cu^{2+} concentration. The filled triangles represent measurements on 0.1% Cu^{2+} grown K_2SO_4 crystal preannealed for ~30 min beyond the pretransition temperature. The σ values are in excellent agreement with those of undoped K_2SO_4 up to 400 °C and the high sharp jump in σ near the phase transition ~580 °C is also evident. The filled circles refer to the same Cu^{2+} content crystal preannealed for ~60 min under identical conditions. These σ values fall on the established curve and the σ–T plot becomes linear but the discontinuity at ~580 °C is less well-defined.

The dotted circles represent 0.5% Cu^{2+} grown K_2SO_4 crystal preannealed for 60 min under identical conditions; well-defined linear slopes are observed. The half-filled circles represent a similarly preannealed 5% Cu^{2+} grown K_2SO_4 crystal. The data for 0.5% and 5% crystals were highly reproducible yielding an activation energy of 0.85 ± 0.05 eV for the cation migration and 1.4 ± 0.2 eV for the defect formation.

Doped (Mn^{2+}) K_2SO_4 Crystals

The logarithm of conductivity σ *vs.* 1000/T K for two crystals of K_2SO_4 doped with Mn^{2+} measured across the pyramidal faces is presented in Fig. 4; untreated crystal identified by filled circles and preannealed crystal, held at 425 °C for 15 min and slowly cooled to 200 °C, identified by open circles.

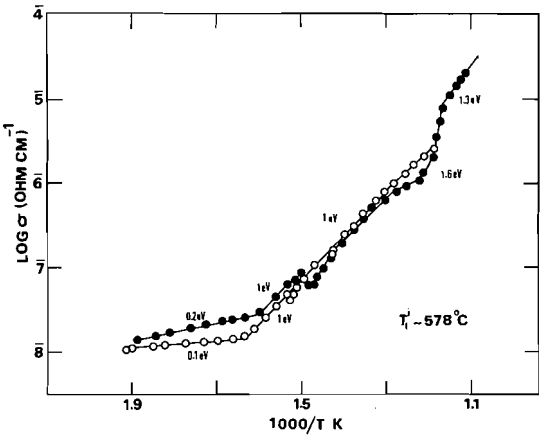

FIG. 4. Logarithm of electrical conductivity *vs.* 1000/T K for Mn^{2+} doped K_2SO_4 crystals measured across pyramidal face: ●, untreated crystal; ○, crystal preannealed at 425 °C for 15 min and slowly cooled to 200 °C.

Heat treatment lowers the initial activation energy to 0.10 eV relative to Cu^{2+} value of 0.20 eV. The cation migration energy of 1.0 eV is slightly higher than 0.80 eV recorded for the previous crystals. The "pretransition" effect is more prominent in the fresh crystal 379–406 °C, whereas the effect is barely discernible in the heated crystal. The fresh crystal shows an activation energy of 1.6 eV immediately following the "pretransition" effect and again prior to the major transition temperature while observing 1.0 eV between these two regions; the preannealed crystal, on the other hand, observes an activation energy of 1.0 eV throughout this temperature interval. The 1.6 eV region is not reproducible to 0.2 eV and therefore not reliable for defect formation energy evaluation; this latter energy value could be useful since Mn^{2+} is known to enter the K_2SO_4 lattice substitutionally (15) and expected to generate Schottky vacancies. The conductivity discontinuity at the orthorhombic–hexagonal transition lacks the sharpness observed in the undoped crystals.

Doped (Radioactive Zn^{2+}) K_2SO_4 Crystals

The σ–T data for preannealed Mn^{2+} doped K_2SO_4 crystal and Cu^{2+} doped K_2SO_4 crystal revealed (*i*) an appreciable lowering of the initial activation energy and (*ii*) the reduction in the intensity of the "pretransition" anomaly. The availability of radioactive ^{65}Zn prompted us to incorporate ^{65}Zn in the K_2SO_4 crystal to assess the effect, if any, of a constant internal energy source in the doped crystal.

The plot of the logarithm of conductivity σ *vs.* 1000/T K for two crystals of K_2SO_4 (one containing inactive Zn^{2+} and the other containing radioactive Zn^{2+}) measured ⊥ to (011) face is given in Fig. 5.

As expected the presence of the radioactive source raises the conductivity in the low temperature region with an appreciable lowering of the activation energy, 0.05 eV. The presence of ^{65}Zn also eliminates the anomaly and stabilizes the cation migration energy contribution, *i.e.* 0.85 ± 0.05 eV, prior to the major transition temperature of 579 °C. The effect of the radioactive ^{65}Zn dopant is interpreted to preclude secondary conductivity contributions arising from structural defects, ion-vacancy complex association, etc. to

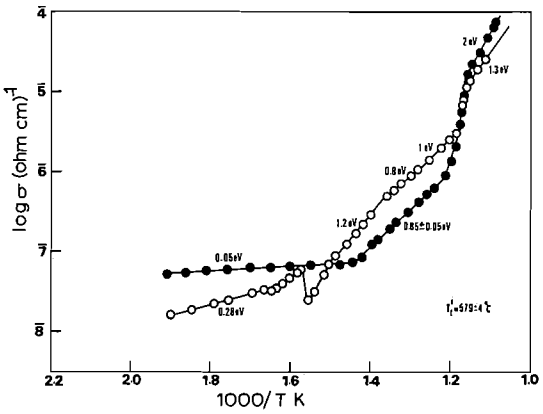

FIG. 5. Logarithm of electrical conductivity *vs.* $1000/T$ K for inactive Zn^{2+} doped K_2SO_4 crystal: ○, and radioactive Zn^{2+} doped K_2SO_4 crystal; ●, measured ⊥ to (011) face.

yield a less complex σ–T pattern of behavior; the exact interpretation must await more detailed studies.

Summary

The cation vacancy migration energy in K_2SO_4 is found to be 0.9 ± 0.1 eV. From the above conductivity measurements the defect formation energy is estimated to be 1.4 ± 0.2 eV. A decrease in lattice symmetry appears to favor Scottky defect formation and hence lower the defect formation energy; the case of CsCl supports this interpretation where defect formation energies of 1.40 eV and 2.20 eV are reported for the *Pm*3*m* (low symmetry) and *Fm*3*m* (high symmetry) phases (16, 17), respectively.

While ionic size might be the predominant factor contributing to the conductivity features of Mg^{2+} or Zn^{2+} doped K_2SO_4, the characteristic features of Mn^{2+} or Cu^{2+} doped crystals could be linked to d-electrons of the dopants, especially for a Jahn–Teller ion like Cu^{2+}. It would be worthwhile to obtain additional experimental results on crystals incorporating other transition metal ions to sort out these contributing factors.

The onset of the orthorhombic–hexagonal transformation, represented by T_t^i at $579° \pm 4$ °C as shown in the figures, is neither affected by the dopants nor by the crystallographic direction of measurement.

The phenomenon of "pretransition" is observed for all fresh crystals; the specific features of the phenomenon depend, however, on the crystallographic direction of measurement and the type of impurity ion. The persistence of this "pretransition" in preannealed crystals minimizes the confidence of any evaluation of defect formation energy or association enthalpy value. Furthermore, defect formation energies calculated from conductivity data on powder samples cannot be considered too reliable.

In conclusion, any interpretation contained above regarding defect energies should be taken only as suggestive of a trend for low symmetry crystal systems. The transport mechanism does involve defects as in the high symmetry alkali halides, but in the absence of comprehensive studies, theoretical and experimental, it is not possible at this time to describe a detailed model.

The authors are grateful to the National Research Council of Canada and the University Council for Research for financial support, and to Professor W. T. Foley for the goniometric measurements.

Studies of β-Diketone Complexes of Rhenium. VII. The Crystal and Molecular Structure of Oxodichloropentane-2,4-dionatotriphenylphosphinerhenium(V)

C. J. L. LOCK[1] AND CHE'NG WAN

Institute for Materials Research, McMaster University, Hamilton, Ontario L8S 4M1

Received September 17, 1974

C. J. L. LOCK and CHE'NG WAN. Can. J. Chem. **53**, 1548 (1975).

The crystal structure of oxodichloropentane-2,4-dionatotriphenylphosphinerhenium(V) has been studied by single crystal X-ray methods. The crystals are triclinic with lattice parameters $a = 11.023(8)$ Å, $b = 13.523(8)$ Å, $c = 9.360(7)$ Å, $\alpha = 90.2(1)°$, $\beta = 114.1(1)°$, $\gamma = 67.7(2)°$. The space group is $P\bar{1}$ and there are two formula weights per unit cell. A total of 2891 reflections, of which 2447 were observed, were examined, and the structure was refined by full matrix least squares to an R_2 value of 0.0782. The ligands are arranged around the rhenium atom such that the nearest six atoms are at the corners of a very distorted octahedron. Most of this distortion appears to be caused by nonbonding repulsive interactions. The short oxo–phosphine distance, 2.85(1) Å, suggests the possibility of a weak bonding interaction. Observed bond distances (Re—Cl, 2.35 Å av; Re—O(oxo), 1.69(1) Å; Re—O(diketone), 1.99(1), 2.10(1) Å; Re—P, 2.431(4) Å) are close to those observed previously in similar compounds.

C. J. L. LOCK et CHE'NG WAN. Can. J. Chem. **53**, 1548 (1975).

On a étudié la structure cristalline de l'oxodichloropentanedionato-2,4 triphénylphosphine-rhénium(V) à l'aide des méthodes de rayons-X de cristal unique. Les cristaux sont tricliniques avec des dimensions de mailles $a = 11.023(8)$ Å, $b = 13.523(8)$ Å, $c = 9.360(7)$ Å, $\alpha = 90.2(1)°$, $\beta = 114.1(1)°$, $\gamma = 67.7(2)°$. Le groupe d'espace est $P\bar{1}$ et il y a deux molécules par maille. On a examiné un total de 2891 réflections desquelles 2447 ont été observées; la structure a été raffinée par la méthode des moindres carrés (matrice complète) jusqu'à une valeur R_2 de 0.0782. Les ligands sont arrangés autours de l'atome de rhénium d'une façon telle que les 6 atomes les plus près sont dans les coins d'un octaèdre très tordu. Il semble que la plus grande partie de la distortion soit causée par des interactions répulsives non-liées. La courte distance oxo–phosphine, 2.85(1) Å, suggère la possibilité d'une interaction liante faible. Les valeurs observées pour les distances de liaison (Re—Cl, 2.35 Å moyen; Re—O(oxo), 1.69(1) Å; Re—O(dicétone), 1.99(1), 2.10(1) Å; Re—P, 2.431(4) Å) sont près des valeurs observées antérieurement pour des composés similaires. [Traduit par le journal]

Introduction

The reaction of acetylacetone with oxotrichlorobis(triphenylphosphine)rhenium(V) (**1**) or oxodichloroethoxobis(triphenylphosphine)rhenium(V) (**2**) yields a number of different products depending on the reaction conditions (1). It has been shown (2, 3) that the group *trans* to the oxo group in **1** and **2** is very susceptible to attack and the expected product of the above reaction is oxodichloropentane-2,4-dionatotriphenylphosphinerhenium(V) (**3**); initial attack of **1** or **2** would involve the replacement of the group *trans* to the oxo-oxygen by one end of the chelating ligand. A small amount of a compound of stoichiometry corresponding to **3** was obtained in some reactions, but only as a minor component. The title compound can exist in four geometric isomers, however, and a further three isomers have been isolated (4). It was of interest to see whether the structure of **3** was the one expected and whether the structure would give any clue to the low yields obtained in the reactions. We now report the structure of **3**.

Experiments

$ReOCl_2(acac)P(C_6H_5)_3$ was prepared from $ReOCl_2(OEt)[P(C_6H_5)_3]_2$.[2] A purple solution of $ReOCl_2(OEt)[P(C_6H_5)_3]_2$ (2 g) (5) and acetylacetone (2 ml) in benzene (50 ml) was boiled until it turned bright green (about 1 min) and then poured into light petroleum ether (b.p. 40–60°, 400 ml). The mixture was stirred vigorously and the precipitate allowed to settle. If the supernatant liquid was still appreciably green, it was decanted and set aside, green crystals of the compound separating; these were handpicked from some orange material.

Anal. Calcd. for $C_{23}H_{22}Cl_2O_3PRe$: C, 43.5; H, 3.5; P, 4.9; Cl, 11.2. Found: C, 43.1; H, 4.2; P, 5.0; Cl, 11.3.

Single crystals were obtained by crystallizing the compound from a mixture of methylene chloride and petroleum ether (80–100 °C). Crystals obtained from this solvent mixture at room temperature were usually twinned or fern-like with small crystals grouped around the main axis. If the temperature of crystallization was maintained constant at about 0 °C, nontwinned plate-like crystals were obtained suitable for X-ray diffraction purposes.

Crystallography

Two crystals were cut from a large crystal chosen because it had sharp extinctions and optical homogeneity when examined through a polarizing microscope. Crystal I, with dimensions 0.09 × 0.10 × 0.12 mm, and Crystal II, with dimensions 0.09 × 0.14 × 0.11 mm, were both mounted along their longest dimensions which were parallel to b^* and c^* respectively.

A series of Weissenberg and precession photographs showed the crystal was triclinic. Cell parameters were determined from $0kl$ and $hk0$ precession photographs which were calibrated with a diffraction pattern of TiO_2 (rutile: $a = 4.5929(5)$ and $c = 2.9591(3)$ Å (6)) and β was measured from the spindle reading. The density of a few crystals was determined in a tetrabromoethane – carbon tetrachloride mixture. The parameters were:

$C_{23}H_{22}Cl_2O_3PRe$ f.w. = 634.5

Triclinic, $a = 11.023(8)$, $b = 13.523(8)$, $c = 9.360(7)$ Å, $\alpha = 90.2(1)$, $\beta = 114.1(1)$, $\gamma = 67.7(2)°$, $V = 1158$ Å^3, $P\bar{1}$, (C_i^1, No. 2) $\rho_o = 1.76(4)$, $Z = 2$, $\rho_c = 1.82$ (22°, MoKα, $\lambda = 0.71069$ Å), $\mu = 58.6$.[3]

Photographs were taken of the layers nkl, $n = 0$–4 and hkm, $m = 0$–3 for crystal I and the first layer perpendicular to [110] for crystal II. All photographs were recorded on an integrating precession camera, using zirconium filtered MoKα radiation. The intensities of all reflections were measured with a Joyce–Loebl microdensitometer. The unobserved reflections were assigned an intensity equal to the minimum observed intensity in that region of reciprocal space. Standard errors, σ, were assigned by the method of Ibers (7) and Hughes (8) and weights, $w = 1/\sigma^2$, were used throughout the refinement. The measured intensities were corrected for Lorentz and polarization effects, but absorption corrections were not applied. The maximum error in F_o which could be introduced is 10%; the average error was much smaller.

Solution and Refinement

The Patterson functions projected on (100) and (001) gave the positions of the rhenium, chlorine, and phosphorus atoms. The magnitudes of the Re–Cl and Re–P peaks were consistent with $P\bar{1}$ symmetry and showed no splitting. All other nonhydrogen atoms were located by successive Fourier and electron difference syntheses. The phosphorus atom was distinguished from the chlorine atoms by its proximity to the carbon atoms of the phenyl groups. Refinement of the structure was by full matrix least squares treating the phenyl groups as rigid bodies (9, 10) but using individual isotropic temperature factors for each atom in the group (11). The program used was GROUPLS[4] for the CDC 6400 computer. At the beginning of the refinement, temperature factors, which had previously been isotropic for all atoms, were made anisotropic for the Re, P, Cl, and O atoms. Refinement was terminated when no parameter shifted by more than 1/20th of its estimated standard deviation at $R_1 = 0.0802$ and $R_2 = 0.0782$.[5] Of the 2891 measured reflections, 2447 were observed; 2558 reflections were given nonzero weight in the refinement. These included all observed reflections, except three which were of very doubtful accuracy because they were on the edge of the backstop shadow, and all unobserved reflections for which $F_c > F_{min}$ (114). F_{min} was the minimum observed intensity in that region of reciprocal space. For these unobserved reflections ($F_c > F_{min}$), the value of Δ, used in calculating the least squares matrix, was defined as $F_c - 0.6F_{min}$. The 2891 reflections represent about 43% of the reflections theoretically accessible with a precession angle of 30°.

The final electron difference map was essentially featureless, the only significant peaks being 2.2 e/Å^3 at 0.46, 0.81, 0.71, near the rhenium atom and between the rhenium and phosphorus atoms, and 2.1 e/Å^3 (0.29, 0.85, 0.69) between the rhenium atom and O2. The lowest valley was −1.2 e/Å^3 (0.33, 0.83, 0.02) close to O1. In all calculations, the atomic scattering factors given in the *International Tables for X-Ray Crystallography* were used for Cl, P, O, and C (12) and those of Cromer and Waber were used for Re (13). Anomalous dispersion corrections given by Cromer (14) were used for Re, Cl, and P. The calculated atom parameters are given in Table 1 and the values of F_o, F_c, and σ are given in Table 2.[6]

Results and Discussion

The principal intramolecular distances and angles for $ReOCl_2(acac)P(C_6H_5)_3$ are given in

[2]acac$^-$ is the anion of the ketoenolate form of acetylacetone, $C_5H_7O_2^-$; Et is ethyl, C_2H_5.

[3]The cell used in this work is the Niggli (30) reduced cell, as used in *Crystal Data* (31). It may be transformed into the Delaunay (32) reduced cell, $a = 13.829$, $b = 13.523$, $c = 11.174$ Å, $\alpha = 111.8$, $\beta = 98.7$, $\gamma = 132.5°$ by the transformation matrix (110/010/101).

[4]Program GROUPLS was written locally by J. S. Stephens.

[5] $R_1 = \dfrac{\Sigma||F_o| - |F_c||}{\Sigma|F_o|}$; $\quad R_2 = \left\{\dfrac{\Sigma\omega(|F_o| - |F_c|)^2}{\Sigma\omega F_o^2}\right\}^{1/2}$.

*Estimated standard deviations from the least squares programs are given in brackets. The atoms C11, C12, . . . C16; C21, C22 . . . C26; etc., were refined as three groups and the estimated standard deviations are derived from the group refinement.

†The temperature factor parameters U_{ij} were obtained from $\beta_{ij} = 2\pi^2 b_i b_j U_{ij}$ where β_{ij}'s appear as a temperature effect through $\exp[-(\beta_{11}h^2 + \ldots 2\beta_{12}hk + \ldots)]$ in the structure factor expression and b_i are the reciprocal lattice vectors.

Table 3 and the molecule is illustrated in Fig. 1.[7] The ligands are arranged around the rhenium atom such that the bound atoms are at the apices of a very rough octahedron. The structure is that of the expected isomer of $ReOCl(acac)P(C_6H_5)_3$ shown as **3**.

The Re—O(oxo) bond length (1.69(1) Å) agrees well, within the errors, with values of 1.60(5) to 1.73(6) Å found in other compounds containing the oxo-group (15–17), and the Re—P distance (2.431(4) Å) is in fair agreement with previous results (18, 19). The two Re—Cl distances in $ReOCl_2(acac)P(C_6H_5)_3$ (2.339(5) and 2.376(7) Å), while close to those observed in $Re(acac)_2Cl_2$ (20) and $Re(acac)Cl_2(P(C_6H_5)_3)_2$ (19), are shorter than those found in many compounds of Re(V) (18). Ibers and co-workers have

[7]Figures 1 and 2 were prepared with the aid of the program ORTEP written by Johnson (28).

TABLE 3. Selected intramolecular distances and angles in $ReOCl_2(C_5H_7O_2)P(C_6H_5)_3$

O2—Re—O3	108.6(5)	C24—P—C34	106.5(3)

opined (21) that the Re—Cl distances observed in most Re(V) compounds are unduly long because of steric effects. He suggests that a "normal" distance is that observed in $ReNCl_2(P(C_6H_5)_3)_2$ (2.377(2) Å) (22) which is very close to the distances observed for our compound. If the error limits derived from the inverse matrix are realistic, it appears that the Re—Cl distances in $ReOCl_2(acac)P(C_6H_5)_3$ are significantly different. This appears to be caused by interaction with the phosphine group, since, although the Cl—O distances do not vary markedly, the P—Cl1 and P—Cl2 distances differ by 0.27 Å. The longer Cl1—P and Cl—Re distances are probably caused by the interaction between Cl1 and a phenyl group since the calculated Cl1—H(C35) distance of 2.46 Å is considerably shorter than the van der Waals radius sum of 2.93 Å and the corresponding Cl2—H(C5) distance of 2.70 Å.

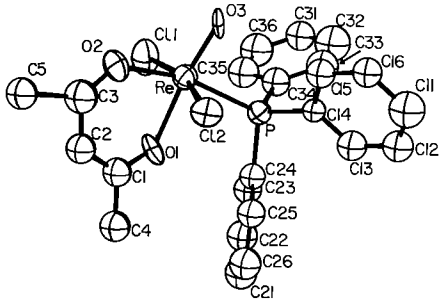

FIG. 1. The molecular structure of $ReOCl_2(C_5H_7O_2)P(C_6H_5)_3$. The numbering of the atoms is as in Table 1.

Distances within the β-ketoenolate group do not vary significantly from the average values reported by Lingafelter and Braun (23), and the

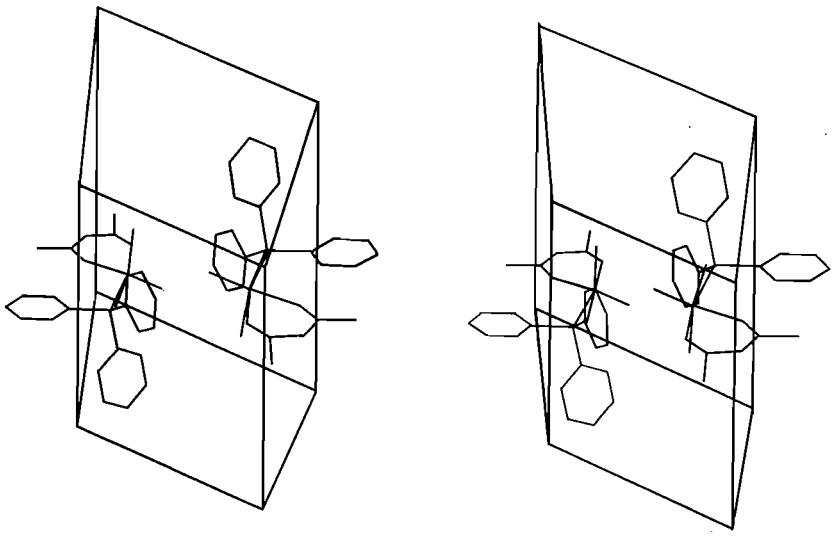

FIG. 2. Stereogram (stereoscopic pair of perspective projections) of two molecules of $ReOCl_2(acac)P(C_6H_5)_3$ in the unit cell viewed down the b^* axis. The c^* and a axes run roughly parallel to the top and side edges of the paper respectively.

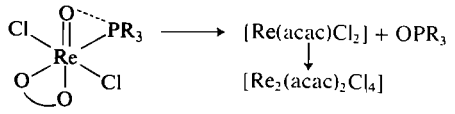
dihedral angle of 16° between the ReO1O2 and O1C1C2C3O2 fragments is within the range normally observed. However, the two rhenium–oxygen (ketone) distances (2.10(1) and 1.99(1) Å) appear to be significantly different. The lower value for the oxygen *cis* to the oxo-group is in fair agreement with values we have found previously for similar compounds (19, 20), but the Re–O distance for the oxygen atom *trans* to the oxo-group is longer than any of the others. Long bonds to atoms *trans* to multiply bonded oxo and nitrido ligands have been observed before (15–17, 21, 22, 24, 25). It has been postulated that strong π-bonding in Re=O groups weakens the bonding to the *trans* ligand (3), but Bright and Ibers (18) have put forward the more reasonable explanation that the effect is caused by steric repulsion of other ligands.

Certainly, the arrangement of the O1, O2, O3, P atoms suggests fairly strong steric interactions. Even though the O3–O1 distance is about 0.2 Å longer than the normal van der Waals (v.d.W.) radii sum (2.8 Å) (29),[8] the O2–O1 distance is shorter by about 0.15 Å than the v.d.W. radii sum, as are both the P–O1 and P–O3 distances (difference 0.2 and 0.45 Å respectively). Some shortening of "nonbonded" distances between ligand atoms is not unusual and the structure is slightly distorted in such a manner to relieve repulsive interactions. O1 and O3 are about 0.05 Å out of the least squares plane through O1O2O3P on one side and O2 and P by the same distance on the other. The rhenium atom is displaced 0.03 Å out of the plane on the same side as O1. Nevertheless, the P–O3 distance is unusually short. It is nearly 0.25 Å shorter than previously observed P–O distances in similar compounds (15, 19, 20) and 0.3 Å shorter than similar P–N distances (18). Since normal forms of the repulsion interaction are assumed to be $1/r^{12}$ or $\exp(-r)$, this extra shortening would require a large amount of energy which would be obtained from an increased attractive interaction. The Re—O3 and Re—P bonds are not unusually short so that it appears that the "bonding" interaction must be directly between O3 and the phosphine group.

Such an interaction is consistent with the observed thermal breakdown of $ReOCl_2(acac)P(C_6H_5)_3$ in the mass spectrometer. Peaks corresponding to $(C_6H_5)_3PO^+$ and $Re_2(acac)_2Cl_4^+$ are observed (4) which could arise from



The packing of the molecules within the unit cell is shown in Fig. 2. In the ***a*** direction we can

[8]Similar distances have been observed in vanadyl β-ketoenolates (26, 27).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

consider the packing as a double chain, the links being pairs of molecules related by the inversion center at $\frac{1}{2}, \frac{1}{2}, \frac{1}{2}$. Contact within this pair of molecules is such that the hydrogen atoms on the third phenyl ring of one molecule come close to O3 and Cl2 on the other molecule. Along the chain the intermolecular contact is between the first phenyl ring of one molecule and Cl1 and the β-ketoenolate ring on the next.

In the ***c*** direction each double chain contacts the next through C4 methyl groups and the third phenyl rings. In the ***b**** direction contact is between the C5 methyl groups and the first phenyl rings. All distances for the contacts mentioned above lie close to the values calculated from the sum of van der Waals radii. In addition further contact can occur between each phenyl ring and its centrosymmetrically related neighbor. Thus ring 3 lies 3.7 Å from the $\frac{1}{2}, \frac{1}{2}, \frac{1}{2}$ neighbor and ring 2 lies 3.5 Å from the $\frac{1}{2}, \frac{1}{2}, 0$ neighbor. In the case of ring 1 the related ring is obtained by inversion through $0, 0, \frac{1}{2}$, but in this case there is not substantial overlap of the rings, the shortest inter-ring C–C distance being 4.6 Å.

Received November 25, 1974

CLAUDIA A. BUSBY, ROBERT K. DINELLO, and DAVID DOLPHIN. Can. J. Chem. **53**, 1554 (1975).

The sulfonation of *meso*-tetraphenylporphyrin, in concentrated sulfuric acid followed by neutralization and dialysis, provides an efficient and convenient route to *meso*-tetra(4-sulfonatophenyl)porphyrin.

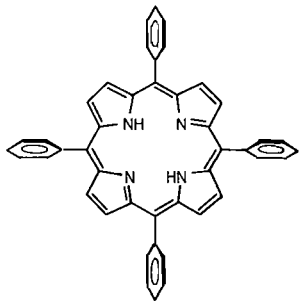
CLAUDIA A. BUSBY, ROBERT K. DINELLO et DAVID DOLPHIN. Can. J. Chem. **53**, 1554 (1975).

La sulfonation de la *meso*-tétraphénylporphyrine, dans l'acide sulfurique concentré, suivie par une neutralisation et une dialyse fournit une méthode efficace et facile d'obtenir la *meso*-tétra(sulfonato-4 phényl) porphyrine. [Traduit par le journal]

The initial studies by Winkelman (1) on the localization of *meso*-tetra(4-sulfonatophenyl)-porphyrin in tumors have been followed by an increasing interest in this water soluble porphyrin. This interest has been stimulated by the ready availability (2) of *meso*-tetraphenylporphyrin (TPP) **1** and its conversion into *meso*-tetra(4-sulfonatophenyl)porphyrin **2** by direct sulfonation.

Two methods for this sulfonation have recently been reported. Both methods bring about the sulfonation in hot sulfuric acid and differ only in the isolation and purification of the product. The method developed by Fleischer *et al.* (3) invokes preparation of the tetra-ammonium salt which is purified by six precipitations from methanol–acetone but, in our hands, a good recovery of the product always results in its contamination with ammonium sulfate. To remove the inorganic salts one must sacrifice large amounts of the product at each stage with a resultant poor yield.

The second method reported by Srivastava and Tsutsui (4) requires dilution of the reaction mixture and addition of lime to the resulting large volume of aqueous solution in order to remove the sulfuric acid as calcium sulfate. A number of time-consuming and cumbersome filtrations and concentrations are then required to isolate the product, which is always contaminated with inorganic salts unless careful precautions are taken, which again result in a lowering of the yield.



1

We wish to report here the preparation and simplified purification procedure which involves dialysis to remove inorganic contaminants and results in a 75% overall yield from TPP.

Experimental

Powdered TPP (2) (2 g) was suspended in concentrated sulfuric acid (50 ml) in a 250 ml round-bottomed flask equipped with a drying tube. The mixture was heated in a steam bath for 6 h and then left to stand overnight. At the beginning of the reaction the viscous mixture was occasionally swirled to dissolve the porphyrin. Water (150 ml) was then carefully added and the mixture was allowed to cool to room temperature. The green protonated porphyrin was collected by filtration and washed once with a little acetone. The porphyrin and Celite were suspended in water (150 ml) and neutralized with saturated sodium bicarbonate until the green solution turned purple. The mixture was filtered to remove Celite and unreacted TPP, and the filtrate was dialyzed four times to remove inorganic contaminants.

The dialyses were carried out using cellulose dialysis tubing with a pore diameter of 4.8 nm (Fisher), which had been previously boiled in distilled water for 15 min and then rinsed. Each dialysis was carried out for 3 h against a 40-fold excess of stirred distilled water. The solution was concentrated to 50 ml, filtered, and evaporated to dryness. Tetrasodium *meso*-tetra(4-sulfonatophenyl)porphyrin was recrystallized from methanol–ethanol and dried for 1 h at 110° to give 3 g of the dodecahydrated salt. The anhydrous product was prepared by heating *in vacuo* at 150° for 24 h.

Received November 13, 1974

LAWRENCE D. COLEBROOK, SIDDIK ICLI, and FRANK H. HUND. Can. J. Chem. **53**, 1556 (1975).

^1H and ^{13}C n.m.r. spectra have been determined for a number of 1- and 3-arylhydantoins in achiral and chiral solvents. These compounds, which have enantiomeric rotational isomers, show restricted internal rotation about the aryl C—N bond at normal probe temperatures. Chemical shifts between corresponding protons on the pairs of rotamers, induced by diastereomeric solute–solvent interactions in the chiral solvent, are strongly dependent on the location of the protons in the solute molecules. In conjunction with ^1H and ^{13}C chemical shifts, these data provide information on the geometry of the solvated species. No splitting of signals resulting from the presence of diastereomeric solvates was observable in the ^{13}C spectra. Activation parameters for hindered internal rotation, determined by complete p.m.r. line shape analysis using signals of the diastereotopic methyl groups in the 5-position, show some solvent dependence.

LAWRENCE D. COLEBROOK, SIDDIK ICLI et FRANK H. HUND. Can. J. Chem. **53**, 1556 (1975).

On a déterminé les spectres r.m.n. du ^1H et du ^{13}C d'un certain nombre d'hydantoines arylées en position 1 ou 3 dans des solvants achiraux et chiraux. Ces composés, qui ont des isomères de rotation énantiomères, montrent la présence d'une rotation interne empêchée autour du lien N—C aryle aux températures normales d'études. Les solvants chiraux provoquent des interactions diastéréoisomères soluté–solvant qui induisent des déplacements chimiques, entre les protons correspondants sur les paires de rotamères, dont l'amplitude dépend fortement sur la position des protons de ces molécules solutées. Si on utilise ces données en relation avec les déplacements chimiques des ^1H et ^{13}C, on peut déduire des informations sur la géométrie des espèces solvatées. Dans les spectres ^{13}C, on n'a pas pu observé de dédoublements de signaux qui résulteraient de la présence d'espèces solvatées diastéréoisomères. Les paramètres d'activation pour la rotation empêchée interne, tels que déterminés par une analyse complète de la forme des lignes des spectres r.m.p. et faisant appel aux signaux des groupes méthyles diastéréotopes en position 5, montrent une certaine dépendance sur le solvant.

[Traduit par le journal]

Following the initial demonstration by Pirkle (1), it has become well established that chemical species which are enantiomeric in achiral media, and hence exhibit identical properties, may be distinguished by their n.m.r. spectra in suitable optically active solvents. The distinction between the spectra of the *d* and the *l* forms of the solute is possible because of a chiral solvent induced diastereomeric relationship between the two forms, resulting from the formation of short lived solute–solvent associated species (1). For the spectra of the enantiomers to be rendered nonidentical it is necessary that the solute–solvent interactions be strong enough to produce closely associated solvates and for the solvent molecules to have a high degree of magnetic anisotropy so that the chemical shift differences between corresponding nuclei in the diastereomeric solvates will be large enough to be resolved. Pirkle and Beare (2) have found 2,2,2-trifluorophenylethanol (TFPE) to be a suitable optically active solvent for this purpose in many cases. This compound is capable of forming strong intermolecular hydrogen bonds to many types of solute molecules, thus forming sufficiently stable solvates, and has sufficient magnetic anisotropy associated with the phenyl group to produce adequate chemical shift differences in a number of instances.

We now report the n.m.r. spectral behavior

of some 1- and 3-arylhydantoins, which can exist in two enantiomeric forms as a result of restricted internal rotation about the aryl C—N bond (3–5), in the optically active solvent *S*-(+)-TFPE. Because of steric interaction between the *ortho* substituent on the aryl group and the substituents on the hetero ring adjacent to the point of attachment, the molecules are constrained to adopt conformations with large dihedral angles between the rings in the conformational ground states. Since the hetero rings should be approximately planar (5), and are symmetrically substituted with respect to the plane of the ring, the two rotational isomers are enantiomeric in the absence of chiral media.

The arylhydantoins studied in this project, or compounds of similar structure, had been shown previously (6) to have high barriers to internal rotation (free energies of activation within the range 17–21 kcal/mol) in conventional solvents and were expected to have sufficiently long lifetimes before interconversion of the rotational isomers at normal probe temperatures that isomeric integrity would be maintained over the time scale of the measurements.

The geminal dimethyl groups in the 5-position are diastereotopic and, in the compounds chosen for this study, are anisochronous at normal probe temperatures, giving rise to well resolved doublets with separations of 0.227–0.276 and 0.037–0.055 p.p.m. for the 1- and the 3-aryl series, respectively, in the ^1H spectrum. At elevated temperatures the 5-dimethyl doublet collapses to a singlet as the rate of rotamer interconversion increases and the environments of the methyl groups become averaged. The line shapes over an intermediate range of temperatures may be employed to measure rate constants for interconversion and hence to obtain activation parameters for the hindered rotation process (4).

Results and Discussion

Proton Magnetic Resonance Spectra

An examination of the ^1H n.m.r. spectra of the 1-aryl- and the 3-arylhydantoins in solution in the chiral solvent reveals characteristically different behavior for the two substitution patterns. This results from a very marked dependence of the extent of line doubling resulting from solute–solvent interactions on the location of the nuclei in the molecules. In the 3-arylhydantoins examined, only the *o*-methyl signal of **1***a* showed splitting. Although, in principle, the two signals resulting from the diastereotopic (in achiral media) 5-methyl groups should show further splitting in (+)-TFPE solution, no additional multiplicity or line broadening was observed. Thus, of the 3-arylhydantoins examined, only **1***a* shows evidence of line doubling in the chiral solvent.

In contrast, all of the 1-arylhydantoins examined exhibited spectral changes in the chiral solvent (Table 1). Although distinguishable doubling of the hetero ring methyl signals was not observed, the lines were broadened in all cases, indicating a small chemical shift difference between corresponding methyl groups in the diastereomeric solvates. Well resolved signals were exhibited by the nonequivalent *ortho* and *meta* aryl methyl groups of the two rotational isomers.

The magnitude of the chiral solvent induced chemical shift differences between corresponding aryl methyl groups in the rotamers is strongly dependent on the location of the methyl group, *i.e. ortho*, *meta*, or *para* to the hetero substituent. Chemical shift differences are listed in Table 2. The largest chemical shift difference between the aryl methyl groups of the diastereomeric solvates is exhibited by the *o*-methyl groups, 0.12–0.13 p.p.m. in the 1-arylhydantoin series (in the 3-arylhydantoin, **1***a*, the corresponding chemical shift difference is much smaller, 0.05 p.p.m.). A similar chemical shift difference (0.12 p.p.m.) is exhibited by the *m*-methyl groups of **2***c*, which has a 2,3-substitution pattern on the aromatic ring. In **2***d*, which has a 2,5-substitution pattern, the chemical shift difference between the *m*-methyl group signals is smaller, 0.06 p.p.m. In contrast to the other aryl methyl groups, the *p*-methyl protons of **2***c* (with a 2,4-substitution pattern) showed a single signal which did not change

its appearance at the lowest attainable temperature (about 0°).

On warming the samples, the magnitude of the chiral solvent induced splitting decreased until coalescence occurred at the temperature reported in Table 2. Loss of nonequivalence with increasing temperature could result from a shift towards the unassociated species in the equilibrium involving solute, solvent, and the diastereomeric solvates, from an increase in the rate of internal rotation in the solute molecules, or from a combination of these processes. The experimental evidence, based on the appearance of the spectra as a function of temperature, a comparison of coalescence temperatures, and measurements of free energies of activation, is not sufficient to establish the relative importance of these processes, but does suggest that both contribute to the temperature dependence of the spectra.

Carbon-13 Spectra

In principle, doubling of signals in the spectra of the enantiomeric mixture of rotational isomers when it is dissolved in the optically active solvent should occur in the ^{13}C as well as in the ^{1}H n.m.r. spectrum. If a major contribution to the shielding difference between ^{13}C nuclei in the two rotational isomers results from local magnetic anisotropy differences, as is the case for ^{1}H nuclei, the chemical shift difference (in p.p.m.) should be similar to that in the ^{1}H spectrum for ^{13}C nuclei in similar environments. On the basis of the observed ^{1}H chemical shift differences in the chiral solvent, the ^{13}C separation would be expected to be near the resolution limit of the instrument.

The ^{13}C spectra of **1***a* and **2***d* in the chiral solvent showed no additional splitting or definite line broadening resulting from diastereomeric solute–solvent interactions (Table 3). In addition to the small shift differences expected if anisotropy effects are important, the rather high temperature (*ca.* 55°) of the ^{13}C probe may have precluded observation of signal doubling by reducing the concentration of solute–solvent complex through a shift in the equilibrium and by reducing the lifetimes of the rotational isomers of the solute.

Although the ^{13}C spectra do not provide direct evidence for the existence of diastereomeric solute–solvent complexes, information is provided on the sites of bonding between solute and solvent molecules. A comparison of the ^{13}C spectra of **1***a* in DMSO and in the chiral solvent shows that the carbonyl carbon signals are shifted downfield about 2 p.p.m. in the hydrogen bonding chiral solvent with respect to the positions in the nonhydrogen bonding achiral solvent. Such shifts are typical of the carbon atoms of carbonyl groups subject to hydrogen bonding (7). With the exception of C-5, the chemical shifts of the remaining methyl and hetero ring carbon atoms are similar in the two solvents. The chemical shifts of **2***a* in the two hydrogen bonding solvents, morpholine and (+)-TFPE are similar, except for that of the C-5 carbon atom. Because of overlap with the aryl carbon signals from the chiral solvent, interpretation of the hydantoin aryl carbon spectrum was not attempted.

Proton Chemical Shifts

Comparison of the proton chemical shifts of the 1-arylhydantoins in achiral and chiral solvents (Table 1) provides further evidence for the existence of a strong association complex between the solute molecules and the chiral solvent and for its geometry. Use of the chiral solvent causes consistent upfield shifts for the C-5 methyl and the aromatic methyl protons, indicating that these protons lie in regions of shielding produced by the magnetic anisotropy of the solvent molecules. The greatest shielding effects in the 1-arylhydantoin series are experienced by the 5-methyl and the *o*-methyl protons, indicating that these groups are closest to the region of maximum shielding of the solvent phenyl groups. Models for the association complexes of the type which have previously been suggested by Pirkle *et al.* (8) may be based on the ^{1}H and the ^{13}C spectra of the arylhydantoins. One of the probable modes of association of a 1-arylhydantoin which is consistent with the experimental evidence and permits close association between solute and solvent molecules is depicted in Fig. 1 for one of the rotational isomers. The corresponding complex for the other isomer would have the solute aryl group rotated through approximately 180°. Complex formation results primarily from hydrogen bonding between the chiral alcohol and a carbonyl group of the hydantoin. Secondary attractive interactions between the π-electron systems of the solute and the solvent aryl groups appear to be responsible for deter-

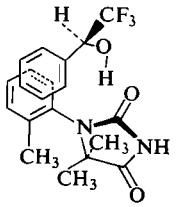

FIG. 1. Conformation of a solvate between *S*-(+)-2,2,2-trifluorophenylethanol (TFPE) and one of the rotational isomers of a 1-arylhydantoin.

mining the conformation of the complex. The greatest effects of the magnetic anisotropy of the solvent phenyl group would be exerted on those nuclei located in the immediate vicinity of the solute aryl group and the hetero substituent near the point of attachment, resulting in maximum sensitivity to differences in stereochemical environments in the two rotational isomers and in maximum overall shielding. The lack of sensitivity of a *p*-methyl substituent to the signal doubling effect of the chiral solvent is consistent with the similar environments of this group with respect to the solvated solvent molecules in the two solute isomers. The proposed model is consistent with the chemical shift evidence, which suggests that the solvent phenyl group is displaced towards the hydantoin moiety.

Barriers to Internal Rotation

Since the arylhydantoins are present in (+)-TFPE solution as strongly solvated species, it may be expected that the barriers to internal rotation about the aryl C—N bonds in the solute molecules will be influenced by the solvent. Activation parameters may be determined by complete line shape analysis of the 5-methyl signals as a function of temperature, for (+)-TFPE as well as for more traditional solvents. The only complication which is present in the spectra of (+)-TFPE solutions is the small amount of line broadening which is present at lower temperatures. Over the temperature range (84.5–110.5°, compound **2***a*) where collapse of the 5-methyl doublet occurs this broadening is small or absent because of the reduced concentration of the solvated species at high temperatures.

Complete line shape analyses of the 5-methyl group spectra were carried out, and the activation parameters calculated, for 1-(*o*-tolyl)-5,5-dimethylhydantoin (**2***a*) in pyridine, DMSO-d_6, and (+)-TFPE solutions (Table 4). Errors for the (+)-TFPE solution are somewhat higher than for the other solvents because of difficulty in estimating the correct natural linewidth for use in the line shape calculations.

TABLE 4. Activation parameters (100 °C) for 1-(2-methylphenyl)-5,5-dimethylhydantoin (**2***a*)*

Solvent	ΔH^* (kcal/mol)	ΔS^* (e.u.)	ΔG^* (kcal/mol)
Pyridine	13.1±0.7	−14±2	18.2±0.1
DMSO-d_6	15.2±0.5	−9±2	18.5±0.1
(+)-TFPE	15.4±1.1	−10±3	19.2±0.1

*Errors are 90% confidence limits.

The rotational barriers show a correlation with the expected solvating ability of the solvents. Thus, the free energy of activation is higher by 1.0 kcal/mol in (+)-TFPE than in pyridine, which is expected to solvate the solute molecules less efficiently. An intermediate position is occupied by DMSO-d_6.

Free energies of activation were also calculated at the coalescence temperatures of the 5-methyl doublets of **2***a–d* (Table 5). Because of the temperature dependence of the free energy function, these values are less useful than the data in Table 4, which are calculated at a common temperature, but they indicate higher barriers to internal rotation in (+)-TFPE, relative to the other solvents, in all cases. Free energies of activation are about 1.1 kcal/mol higher in (+)-TFPE than in pyridine solution. In most cases, coalescence temperatures are raised about 20°, from about 81° in pyridine to about 101° in (+)-TFPE. An exception is the 2,3-dimethylphenyl compound (**2***b*) which exhibits an increase of about 15° in its coalescence temperature in (+)-TFPE compared to 2-chloropyridine, possibly because a different achiral reference solvent was employed. The higher ΔG^* of **2***b* in all the solvents is attributed to buttressing between the *ortho* and the *meta* aryl methyl groups.

The feasibility of determining activation parameters for restricted internal rotation within solute molecules by employing the temperature dependence of the signals arising from corresponding protons in each association complex in a chiral solvent has recently been demonstrated (9). This method is applicable if the collapse of the signal doubling resulting from diastereomeric solute–solvent interactions

	DMSO-d_6	0.273	90.5	18.6
	(+)-TFPE	0.230	102.0	19.3

*Calculated from rate constants obtained by computer simulation of the line shapes in the coalescence region. Estimated errors are ±0.1 kcal/mol.

is a consequence of an increase in the rate of interconversion of the rotational isomers of the solute molecules with increasing temperature, rather than to a decrease in the concentration of the associated complexes. A similar analysis of the temperature dependence of the aryl methyl signals in the present series of compounds is probably not fully justified, since the coalescence temperatures were appreciably higher (68.5–117.0°) than those (26–30°) reported for (+)-TFPE solutions and, in consequence, the stability of the association complexes might be expected to be lower.

An indication that decreases in the stability of the association complex with increasing temperature are at least in part responsible for the disappearance of the signal doubling follows from the observation that the range of temperature dependence below the coalescence point was two to three times greater for the aryl methyl signals than for the 5-dimethyl signals, the spectra showing a decrease in chemical shift difference with increasing temperature. This temperature effect has been reported previously (9). Because of this complication, complete line analysis of the temperature dependent aryl methyl group spectra was not attempted. However, calculation of $\Delta G^{\ddagger}$ at the coalescence temperatures, using the chemical shift differences measured at normal temperatures, yielded values quite close to those obtained by analysis of the 5-dimethyl group spectra (Tables 2 and 5). Since the error involved in ignoring the temperature dependence of the chemical shift differences would have the effect of reducing the calculated values of $\Delta G^{\ddagger}$, this method provides lower limits for the free energies of activation. The reported values (Table 2) obtained by this method are all lower than those obtained from the 5,5-dimethyl group signals at coalescence (Table 5), consistent with this interpretation, but the usefulness of the comparison is limited by the different temperatures involved.

The parallel increase in the coalescence temperatures of the aryl methyl (chiral solvent induced) and the 5,5-dimethyl doublets of the internally buttressed compound, **2***b*, compared to the less hindered compounds, even though the chemical shift differences are similar (Tables 2 and 5), is further evidence that internal rotation in the solute molecules contributes to the temperature dependence of the doublets resulting from the presence of diastereomeric solvates.

Experimental

Materials

The 1-arylhydantoins were prepared from the appropriate aniline derivative and *N*-(2-bromo-2-methylpropionyl)urea (obtained by reaction between 2-bromo-2-methylpropionyl bromide and urea (10)) by the method of Mazover (11).

The 3-arylhydantoins, **1***a* and *b*, were prepared from *o*-tolyl isocyanate and *o*-bromophenyl isocyanate, respectively, and 2-methylalanine by the method of Behr and Clarke (12)

These compounds were characterized through their

For personal use only.

p.m.r. and i.r. spectra and elemental analysis or mass spectra. Samples for ^1H and ^{13}C measurements were prepared in 2–3 *M* concentrations.

S-(+)-Trifluoromethylphenylethanol (TFPE) was obtained from Burdick and Jackson, Inc.

Magnetic Resonance Measurements

Proton magnetic resonance spectra were determined using a Varian HA-100 or a JEOL 4H-100 spectrometer equipped with standard variable temperature apparatus, and operating in the field sweep mode. For the variable temperature experiments, temperatures were determined immediately before or after each spectrum was taken by measuring the peak separation of a standard Varian ethylene glycol temperature reference sample, and they are believed to be accurate to $\pm 2°$. Adequate time was allowed for temperature equilibration to take place before spectra were measured.

Carbon-13 magnetic resonance spectra were determined at 25.12 MHz using a Varian HA-100 spectrometer equipped with an 8 mm spinning sample probe and a Varian V-3530 wide sweep accessory, and operating in the C.W. mode. Broad band proton decoupling was provided by a Varian V-3512-1 noise modulated heteronuclear spin decoupler. Spectra were accumulated (about 100 scans) in a C-1024 time averaging computer, using sweep widths of 100–200 Hz and scan times 10–25 s. The instrument was internally locked on a decoupled solvent line for the achiral solvents, and on an enriched (85%) methyl iodide sample contained in a capillary for the solutions in the chiral solvent.

The procedures used for complete line shape analysis of the temperature dependent proton spectra have been described earlier (4).

Horseradish Peroxidase. XVII. Reactions of Compounds I and II with *p*-Aminobenzoic Acid in Deuterium Oxide[1,2]

C. D. HUBBARD,[3] H. B. DUNFORD,[4] AND W. D. HEWSON

Department of Chemistry, University of Alberta, Edmonton, Alberta T6G 2E1

Received October 31, 1974

C. D. HUBBARD, H. B. DUNFORD, and W. D. HEWSON. Can. J. Chem. **53**, 1563 (1975).

The kinetics of reactions of horseradish peroxidase compounds I and II (HRP-I and HRP-II, respectively) with *p*-aminobenzoic acid have been studied in ordinary water and in deuterium oxide solution over a p*H* (p*D*) range 3–10, at 25° and at an ionic strength of 0.11. Under the conditions of the experiments the rate of reaction is first order both in substrate concentration and in enzyme concentration in both solvents. An analysis of the p*H* dependence of the second-order rate constant in H_2O confirms the presence of two acid dissociation groups on the enzyme with pK_a's of 8.6 and ~0 for HRP-II, whereas for HRP-I the data suggest a pK_a of 5.1 on the enzyme and reveal, as previously shown, the influence of the ionization of the substituted ammonium group of the substrate. In deuterium oxide the p*D* profiles are similar to those in water but significant shifts for both kinetic and acid dissociation constants are observed for both compounds.

The numerical values of the isotope effects taken together with previous results in general confirm that with labile substrates the group of pK_a 8.6 in H_2O on HRP-II is involved in general acid catalysis. *p*-Aminobenzoic acid is intermediate between labile and somewhat unreactive substrates and behaves similarly to the ferrocyanide ion in that both acid dissociation groups (pK_a's 8.6 and ~0) are influential in the catalysis of substrate oxidation by HRP-II. The kinetic isotope effect for the HRP-I reaction with *p*-aminobenzoic acid at high p*H* (p*D*) is consistent with a rate determining proton transfer but the group of pK_a 5.1 in H_2O remains unidentified.

C. D. HUBBARD, H. B. DUNFORD et W. D. HEWSON. Can. J. Chem. **53**, 1563 (1975).

On a étudié la cinétique de la réaction des composés I et II de la peroxydase du raifort (respectivement HRP-I et HRP-II) avec l'acide *p*-aminobenzoique; ces mesures ont été faites pour des solutions dans de l'eau ordinaire et de l'oxyde de deutérium à des p*H* (p*D*) allant de 3–10 à 25° et à une force ionique de 0.11. Dans les conditions des expériences, la vitesse de la réaction est du premier ordre en substrat et en concentration d'enzyme dans chacun des solvants. Une analyse de la dépendance sur le p*H* de la constante de vitesse du deuxième ordre dans l'eau confirme la présence de deux groupes de dissociation acide sur l'enzyme avec des pK_a de 8.6 et approximativement 0 pour HRP-II; pour HRP-I, les données suggèrent un pK_a de 5.1 sur l'enzyme et mettent en évidence, tel que démontré précédemment, l'influence de l'ionisation du groupe ammonium substitué du substrat. Dans l'oxyde de deutérium, les profils de p*D* sont similaires à ceux dans l'eau mais on observe pour chacun des composés des déplacements importants à la fois pour la cinétique et pour les constantes de dissociation des acides.

Les valeurs numériques des effets isotopiques, par comparaison avec les résultats antérieurs, confirment d'une façon générale qu'avec des substrats labiles le groupe de pK_a à 8.6 dans l'eau du HRP-II est impliqué dans une catalyse acide générale. La réactivité de l'acide *p*-aminobenzoique est intermédiaire entre celle d'un substrat labile et celle d'un substrat assez peu réactifs; cet acide réagit d'une façon similaire vis à vis l'ion ferrocyanure si l'on considère que les deux groupes de dissociation acide (pK_a de 8.6 et ~0) ont une influence dans la catalyse d'oxydation du substrat par HRP-II. Pour la réaction de HRP-I avec l'acide *p*-aminobenzoique, l'effet isotopique cinétique, à haut p*H* (p*D*) est en accord avec une étape déterminante indiquant un transfert de protons; le groupe de pK_a à 5.1 dans l'eau demeure non-identifié.

Introduction

Horseradish peroxidase (EC 1.11.1.7 donor – H_2O_2 oxidoreductase) has been shown for a large variety of reducing substrates AH_2, to follow the general mechanism (1–3)

[1] $$HRP + H_2O_2 \rightarrow HRP\text{-}I$$

[2] $HRP\text{-}I + AH_2 \rightarrow HRP\text{-}II + AH$

[3] $HRP\text{-}II + AH_2 \rightarrow HRP + AH$

where HRP refers to the native enzyme and HRP-I and HRP-II are compounds I and II containing two and one oxidizing equivalents, respectively, in excess to that of HRP. This mechanism was found to account for the major features of oxidation of the bacterial metabolite *p*-aminobenzoic acid (PABA) at any given p*H* (4). Some complications which occurred were (*i*) slow attack on the enzyme by free radical oxidation products, which became detectable when reaction 3 was studied at high p*H* where it occurs at a slow rate; (*ii*) formation of HRP-I–PABA and HRP-II–PABA complexes at low p*H* which react with an additional PABA molecule. These oxidation reactions of an enzyme–substrate complex with an additional substrate molecule occurred at a slower rate than the direct reaction of the enzyme with substrate. Since the substrate binding appears to be non-productive then reaction involving the enzyme substrate complex is not the major reaction pathway.

Several reducing substrates have been shown to exhibit marked p*H* dependences in their reactions with HRP-I and HRP-II (4–10) and in the case of the HRP-II reactions with iodide, ferrocyanide, and *p*-cresol, p*H* dependences were determined in both H_2O and D_2O in an attempt to elucidate further the mechanisms of the reactions (11).

The present study is concerned with the comparison of the p*H* dependences of the HRP-I and HRP-II reactions with PABA in light and heavy water under reaction conditions where the complications in mechanism, outlined above, are avoided.

Experimental

Materials

Horseradish peroxidase was purchased from Boehringer Mannheim GmbH as a salt suspension. All samples used were from batch Nos. 7403424 and 7024524, and were prepared for use by extensive dialysis against triply distilled water and subsequent Millipore filtration. Enzyme purity and concentration were determined from absorbance measurements at 280 and 403 nm.

Deuterium oxide, 99.7%, was purchased from Diaprep, Milwaukee, Wisconsin and used without further purification. Triply distilled water was used throughout. *p*-Aminobenzoic acid and buffering reagents were highest quality commercial products and used without further purification.

Spectra

Routine observations of the spectra of HRP and its compounds, and some slower kinetic runs were made on a Cary 14 spectrophotometer equipped with a jacketed cell holder through which temperature controlled water was circulated.

pH Measurements

The p*H* of both water and deuterium oxide solutions was measured on an Orion 801 p*H* meter using a Fisher combination electrode, No. 13-639-90, calibrated with standard buffers. The measured p*H* of deuterium oxide solutions was corrected to a value for the %atom fraction of deuterium (94% for HRP-II reactions and 92% for HRP-I reactions) assuming to a first approximation that the change in p*H* between 100% H_2O and 0% H_2O solutions is linear (11). Results used in interpreting the kinetic and equilibrium parameters as a function of solution acidity in the heavy water solutions are based upon measured p*H* + 0.38 for HRP-II reactions and measured p*H* + 0.37 for HRP-I reactions (12).

Kinetics

All kinetic experiments except for a few in the basic region where the reaction of HRP-II with PABA is quite slow, were carried out using a Gibson-Durrum stopped-flow spectrophotometer fitted with a 2 cm path length observation cuvette. The temperature for all reactions reported is 25.0 ± 0.2° and the ionic strength 0.11. The method of data collection has been described previously (5, 7). Since the observed signal change was very small compared with the total signal, signal amplitudes at various times are utilized directly in data analysis. All traces were single kinetic processes yielding excellent first-order plots, linear for several half-lives. A minor deviation occurs at the commencement of the HRP-II reaction traces and is perhaps worthy of further investigation but it does not interfere with the treatment of data obtained at 425 nm for the compound II reactions. The conversion of HRP-I to native enzyme was monitored at 411 nm.

Typical kinetic runs were carried out as follows. The substrate solution at appropriate p*H*, buffer concentration and ionic strength was introduced into the stopped-flow drive syringe and allowed to attain thermal equilibrium, while a solution containing native enzyme was thermally equilibrated in the reservoir of the stopped-flow instrument. An appropriate small volume of stock hydrogen peroxide solution for HRP-I reactions and additionally stock potassium ferrocyanide solution for HRP-II reactions was injected into the enzyme solution to convert ~90% of the native enzyme into the desired compound. The solution was then introduced rapidly into the other stopped-flow syringe and kinetic determinations commenced. All experiments were carried out under pseudo first-order conditions. For runs below about p*H* 6, the buffer required to achieve a buffer ionic strength of 0.01 in the mixed solution was contained in the substrate syringe to prevent interference before mixing from competing reactions brought about by acidic solution.

For the deuterium oxide runs the same stock buffers of ionic strength 0.2, made up in light water, were used. The other components contributing to the protium content were the enzyme itself, and the hydrogen peroxide and potassium ferrocyanide solutions. In most runs the stock

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

substrate solution was also made up in deuterium oxide and suitable adjustments made to retain a constant protium content. The final ionic strength was always 0.11 as in the light water experiments.

Enzyme solutions were of initial native enzyme concentrations in the range 0.8–0.9 μM for the compound II reactions and about 1.5 μM in the reactions of compound I. Small differences are attributable to different enzyme samples. Minor kinetic differences arising from different enzyme samples were normalized by comparing kinetic data measured under identical conditions with the different batches in the most convenient region of measurement (about pH 7 for compound II and pH 7–10 for compound I). Acetic acid – acetate ion or glycine buffers were used in the region of pH of 3.0 to 5.0. It was noticed that the reproducibility of the kinetic observations for HRP-II reactions was slightly reduced in acetate buffers particularly when the solutions were on the basic side of the pK_a of acetic acid, suggesting that the acetate ion may be involved in interfering with the reactions studied. Because the effects were small and the kinetic data fitted into the pattern obtained over the whole pH region, no corrections were made.

Substrate concentrations were chosen to yield conveniently measurable kinetics. In both reaction series a second molecule of substrate is involved in the reaction at higher substrate concentrations, an effect which is more pronounced at lower pH, and therefore in the pH range below 5, substrate concentrations were kept at a low level so as to circumvent the need for substrate concentration dependence plots and correction factors to the observed kinetic constants. However, at a few pH values checks of the substrate concentration dependence were made and good agreement with previous observations was obtained (4).

Results

The rate constants, $k_{2,app}$ and $k_{3,app}$ determined by dividing the pseudo first-order constants obtained from the stopped-flow traces by substrate concentrations in light water for the reactions of HRP-I and HRP-II with PABA confirm the results obtained earlier within experimental error (4) and provide the necessary references for comparing k^D/k^H ratios. These rate constant data are available from the authors upon request. Comparisons of the light and heavy water results for the reactions of HRP-I and HRP-II with PABA are shown in Figs. 1 and 2.

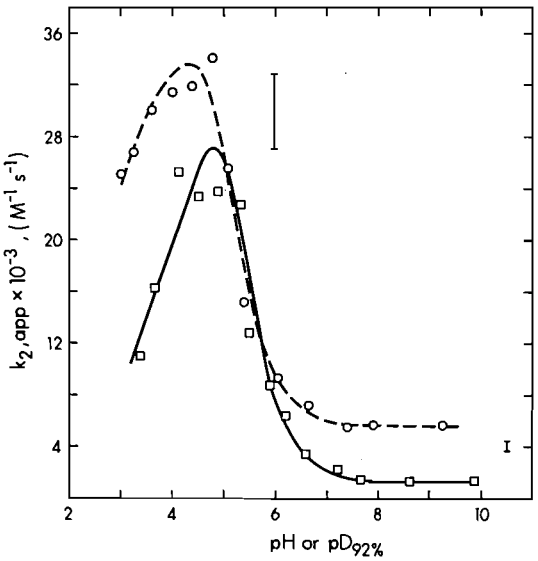

FIG. 1. Plot of the second-order rate constant, $k_{2,app}$, for the reaction of HRP-I with PABA *vs.* pH or pD in light water (dashed curve) and 92% D_2O (solid curve). $pD_{92\%} = pH_{reading} + 0.37$. The error bars show the magnitudes of $\pm 20\%$ error for two different values of k. The curves were computed by nonlinear least-squares analysis of eq. 7.

Discussion

The k^D/k^H ratios for HRP-II reactions with iodide ion, ferrocyanide ion, and *p*-cresol indicated that two reaction mechanisms were applicable (4). For the facile reactant, *p*-cresol, acid catalysis was observed which involved an acid group on HRP-II with a pK_a of 8.6. Since ionization of this group had no influence on the HRP-II spectrum, the group was assumed to be a distal group (7) and the ratio k^D/k^H of 0.45 indicated a rate-controlling proton transfer (11). For the less labile substrate, iodide ion, on the other hand, the log k *vs.* pH profile was linear with a slope of -1 over the pH range 2–9 which together with the consideration of the diffusion-controlled limit for a bimolecular reaction indicates an acid group with a pK_a of approximately 0 (5). A k^D/k^H value of 4.0 is consistent with a prior equilibrium between H_3O^+ (or D_3O^+) and the reactive acid form of HRP-II. Since this reactive form is present in vanishingly small amounts in pH ranges where the enzyme has stability, the absence of any detectable shifts in the HRP-II spectrum in moderately acidic solution does not rule out the possibility that the acid enzyme is protonated in a proximal position, either the fifth or sixth coordination position of the heme iron (11). A self-consistent explanation is that for the facile reactant *p*-cresol, catalysis by the distal group of pK_a 8.6 involves intramolecular general acid catalysis, in which the rate-controlling step is partial transfer of the proton to the proximal group in the fifth coordination position of the heme iron, believed to involve a nitrogen coordinated to iron (13) and to be the

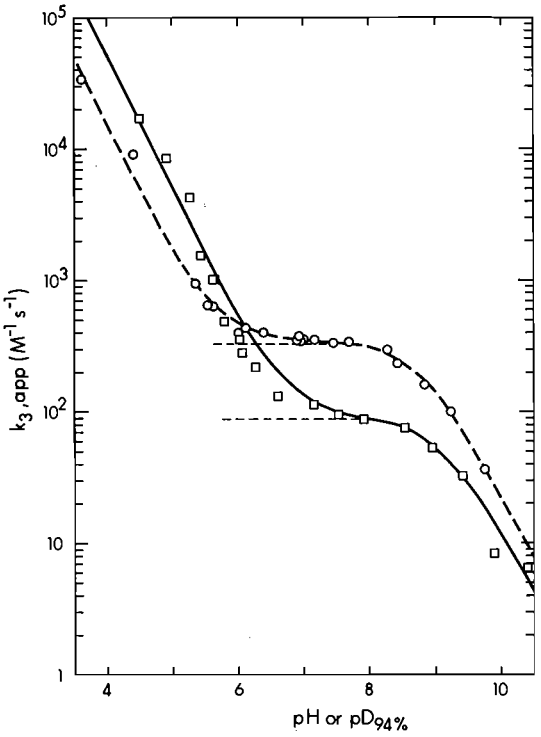

FIG. 2. Plot of log of the second-order rate constant, $k_{3,app}$ for the reaction of HRP-II with PABA *vs.* p*H* or p*D* in light water (dashed curve) and 94% D_2O (solid curve). $pD_{94\%} = pH_{reading} + 0.38$. The curves were computed by nonlinear least squares analysis of eq. 8. The horizontal portions of the curves indicate the values of k_1 (eq. 8).

imidazole ring of a histidine residue (14). Only a slight transfer of charge is required, so that the parameter which can be determined from the p*H*–rate profile is the pK_a of the distal group. For the difficult reactant, iodide ion, on the other hand, in accordance with the Hammond postulate (15, 16), total proton transfer is required and only H_3O^+ (or D_3O^+) is a strong enough acid to protonate the histidine residue, which because it is bound to Fe(IV) (17–19) has a pK_a of approximately 0. The latter catalytic mechanism is therefore specific acid catalysis (11). The ferrocyanide ion is an intermediate type of reactant in which the influence of both acid groups with pK_a's of 8.6 and 0 is felt. Intermediate k^D/k^H ratios were observed for the reaction of HRP-II with ferrocyanide ion: 2.6 ± 0.3 at high p*H* and 2.9 ± 0.6 at low p*H*. The ratio of $k^D/k^H > 1$ in basic solutions was somewhat surprising and was rationalized in terms of the relative bond distances in the transition state (11). However with the exception of the latter complication, the postulated explanation involving the two types of catalysis provided a simple and an overall self-consistent explanation of many rather diverse observations. An illustration of the two types of catalysis is given in Fig. 2 of ref. 10, which, however, should be revised in the following way. It would appear likely that if an imidazole group occupies the fifth coordination position of the heme iron, it would retain its proton. An analogy might be based upon the data of George *et al.* (20). Their data yield a value of

$$[4] \quad K = 1.5 \times 10^{-5} = \frac{[H^+][FeIm]}{[ImH^+][Fe^{III}H_2O]}$$

for the binding of imidazolium ion in the sixth coordination position of ferrimyoglobin

[5] 
This may be comparable to the equilibrium involving imidazole in the fifth coordination position of HRP-II (pK_a ~0) although at this stage there is no evidence as to whether the Fe(IV) in the acid form of HRP-II is five-coordinate or whether H_2O replaces imidazole in the fifth coordination position.

The reactions of HRP-II with ferrocyanide and PABA display a remarkably similar p*H* dependence (8). The k^D/k^H ratios for the reaction of HRP-II with PABA displayed in Fig. 2 are of interest in that $k^D/k^H < 1$ in basic solution and > 1 in acidic solution in accord with the explanations involving a rate-limiting partial proton transfer in basic solution and a prior equilibrium involving H_3O^+ (or D_3O^+) in acidic medium.

Reaction of HRP-I

For the p*H* (or p*D*) dependence of the reaction of HRP-I with PABA, the simplest empirical equation which fits the experimental data is

$$[6] \quad k_{2,app} = \frac{A_1'(1 + [H^+]/A_2')}{(1 + [H^+]/A_3')(1 + [H^+]/A_4')}$$

Best-fit parameters for this equation and the corresponding equation for D_2O are summarized in Table 1. The parameter A_1' is clearly the rate constant at high p*H* and $k^D/k^H = 0.21$ (±13%) in accord with a rate-controlling proton (or deuteron) transfer. (The above isotope effect and all

TABLE 1. Parameters obtained from analysis of the second-order rate constant $k_{2,app}$ *vs.* p*H* or p*D* for the reduction of HRP-I by PABA (eq. 6)

Parameter	H_2O results		Results in 92% D_2O

A_3'	7.7×10^{-6}	6.1×10^{-6} (±26%)	3.2×10^{-6} (±19%)
A_4'	2.0×10^{-3}	1.7×10^{-3} (±38%)	2.8×10^{-4} (±25%)

*Reference 4.
†All quoted errors are standard deviations obtained from the nonlinear least-squares fit to the experimental data.

subsequent isotope effects are extrapolated linearly to 100% D_2O.) This represents the first kinetic isotope measurement for a reaction of HRP-I. The parameter A_4' appears to correspond to the acid dissociation constant of the substituted ammonium group of PABA determined independently to be 3.5×10^{-3} *M* (4) but in the light of other evidence on the mechanism of HRP-I reactions, the interpretation of A_2' and A_3' is less straightforward. It appears that there is an acid group in the active site of HRP-I with a pK_a value (5.1 ± 0.2) identical within experimental error to that of the carboxylic acid group on PABA (10) which complicates the interpretation. There is no evidence for the role of a very acid group in the active site of HRP-I nor for an inverse isotope effect in acid solutions, as in the HRP-II reactions. It might be tempting to speculate that the distal group of pK_a 8.6 catalytically important in HRP-II reactions and the group of pK_a 5.1, also a distal group,[5] important in HRP-I reactions, are identical and the shift in the ionization constant is a reflection of changes in the electronic and/or steric environment between compounds I and II (10). Studies of HRP-I with *N*-substituted PABA will hopefully lead to a clearer interpretation of the p*H* dependence of the reaction.

Reaction of HRP-II

The p*H* dependence of the reaction of HRP-II with PABA can be accounted for using the empirical equation

$$[7] \qquad k_{3,app} = \frac{A_1[H^+](1 + [H^+]/A_2)}{(1 + [H^+]/A_3)}$$

in which the A_n represent adjustable parameters. A comparison of the present results with those obtained earlier (4) is shown in Table 2. For reactions studied in D_2O, with the p*H* meter readings adjusted by a constant factor as described above, the best fit to the equation analogous to [7] is also given in Table 2. A kinetic interpretation (4) based on eq. 7 is

$$[8] \qquad k_{3,app} = \frac{\frac{k_1[H^+]}{K_{1E}}\left(1 + \frac{k_2[H^+]}{k_1K_{2E}}\right)}{1 + \frac{[H^+]}{K_{1E}}}$$

so that the rate constant k_1, the acid dissociation constant K_{1E}, and the ratio K_{2E}/k_2 can be computed from the best-fit data obtained in both H_2O and D_2O, with results also shown in Table 2. The constants in eq. 8 and a list of the kinetic and equilibrium isotope effects extrapolated to 100% D_2O by assuming the parameters depend linearly upon deuterium content over the small range of the extrapolation are given in Table 3. The ratio K_{1E}^{D}/K_{1E}^{H} is 0.48 (±47%) and k_1^{D}/k_1^{H} is 0.25 (±81%). The value of k_1^{D}/k_1^{H} may also be estimated from the data in Fig. 2. Although a clearly defined region in which the rate is independent of p*H* does not exist, the slopes of the plots tend to approach 0 at intermediate p*H*; p*H* independent values of k_1^{D} and k_1^{H} are obtained where the second derivatives of the plots are equal to 0. The corresponding values of k_1^{D} and k_1^{H}, indicated in Fig. 2, are in agreement with the values obtained from the best-fit parameters in Table 2. An inspection of Fig. 2 reveals a slightly less satisfactory fit of eq. 7 to the experimental data for runs in 94% D_2O particularly on the slightly acidic side of the neutral point. This does give some cause for concern but at present there is neither any evidence of differences in mechanism in the two solvents, nor any precedent for this possibility which would be implied by use of different functions to fit the two sets of data.

[5]There is little or no effect of p*H* on the HRP-I spectrum in the Soret region. J. Stillman and H. B. Dunford, unpublished results.

TABLE 3. Summary of kinetic and equilibrium isotope effects for the reduction of HRP-II by PABA*

Parameter from eq. 8	Description	Isotopic ratio
k_1^D/k_1^H	Rate constant near neutral p*H*	0.25
k_2^D/k_2^H	Rate constant in acidic region	3.3
K_{1E}^D/K_{1E}^H	Group of $pK_a = 8.6$ in H_2O	0.48
pK_{2E}^D/pK_{2E}^H	Group of $pK_a \sim 0$	0.58

*Isotopic ratios corrected to 100% D_2O.

Consequently the very small deviation exhibited for the curve fit for the H_2O results is taken as assurance that the same functional equation is applicable for the results in heavy water. Some explanation may now be offered for the apparently anomalous value of k^D/k^H of 2.6 obtained in the basic region where the slopes of the plots of log k_1 *vs.* p*H* (or p*D*) are -1 in the reaction of HRP-II with ferrocyanide (11). The slopes are equal to k_1/K_{1E} so that any error in K_{1E} is reflected in the value of k_1. The value of K_{1E}^D/K_{1E}^H of 1.2 ± 0.4 for the HRP-II–ferrocyanide reaction was surprising and introduction of the result for the present study, 0.48, would reduce k_1^D/k_1^H close to unity for the HRP-II–ferrocyanide reaction, in better accord with the overall explanation of the trend in isotope effects. In this regard, it is of interest to note that both k_1^D/k_1^H and K_{1E}^D/K_{1E}^H are less than 1 for the reaction of *p*-cresol with bovine lactoperoxidase compound II.[6] There is a gross similarity in the behavior of compound II formed for both HRP and lactoperoxidase (21, 22).

The value of k_2^D/k_2^H for the HRP-II–PABA reaction may be determined in the acid region where the log $k_{3,app}$ *vs.* p*H* (or p*D*) plots have slopes of -1 (Fig. 2). The result is $k_2^D/k_2^H = 3.3$ in excellent agreement with the value of 2.9 obtained in the same p*H* region for the HRP-II–ferrocyanide reaction. It appears likely that both ferrocyanide and PABA are reacting at the diffusion-controlled limit with an acid form of HRP-II at low p*H* (4) whereas iodide does not.

The results for the reaction of the acid form of HRP-II with PABA and ferrocyanide in both light and heavy water can be correlated in an attempt to estimate $pK_{2E}^D - pK_{2E}^H$ for HRP-II. The cause of the k^D/k^H values being greater than 1 for the HRP-II reactions with ferrocyanide and PABA in acid solutions is mainly a concentration effect. Since acids in heavy water have smaller dissociation constants (23) the concentration of protonated HRP-II is larger in D_2O than in H_2O provided the p*D* is sufficiently greater than pK_{2E}^H as illustrated in Fig. 3. Therefore, the reactive acid form of HRP-II is present in higher concentration in D_2O than in H_2O in the region where the log $k_{3,app}$ *vs.* p*H* (or p*D*) plots have slopes of -1. If it were possible to study HRP-II reactions at a p*H* (or p*D*) of about -2, then the kinetic isotope effect should almost com-

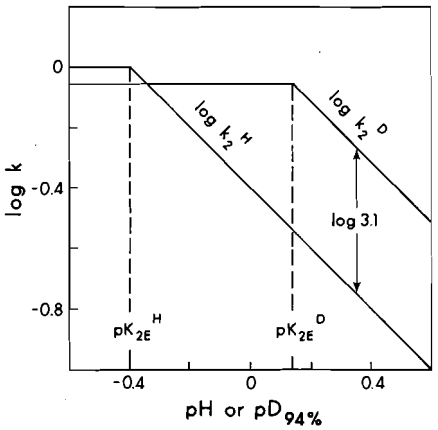

FIG. 3. Schematic representation of the pH– or pD-rate profile for a diffusion-controlled reaction if it could be studied in very acid solution. Rate constant data in the diagram, on a relative scale, are applicable to both the ferrocyanide and PABA reactions with the acid form of HRP-II. The small shift in the diffusion controlled rate when pH or pD < pK_{2E}^{H} is calculated on the basis of the viscosity ratios of light and heavy water at 25°. The mean difference in rate between the light and heavy water reactions of HRP-II with ferrocyanide and PABA where the slopes of the plots are −1 is 3.1 ± 0.2. The value of $pK_{2E}^{D} - pK_{2E}^{H}$ (extrapolated to 100% D_2O) can be estimated as 0.58 units from the plot.

pletely disappear since all of the HRP-II would be completely protonated (or deuterated) and every collision is effective for a diffusion-controlled reaction. However, one small isotope effect would remain in very acid solution and this would be attributable to the solvent isotope effect on the diffusion coefficients of reactants. Since diffusion coefficients of solutes are inversely proportional to the coefficient of viscosity, η, of solvent (25), there should be a k^D/k^H value of 0.81 as illustrated in Fig. 3 since η^D/η^H is 1.23 at 25° (24). The difference $\Delta pK = pK_{2E}^{D} - pK^{H}_{2E} = 0.58$ obtained by extrapolating the data of Fig. 3 to 100% D_2O may be compared to the prediction from an equation of Bell

$$[9] \qquad \Delta pK = 0.41 + 0.02pK^{H}$$

from which ΔpK should have a value of 0.41 (26).

Recently, a pH-dependent study of the cytochrome c peroxidase oxidation of ferrocyanide was interpreted in terms of total electrostatic charge of reactants using extended Debye–Hückel theory (27). Aside from the neglect of the charge in the active site of the enzyme (4, 28) this approach would fail to account for the kinetic and equilibrium hydrogen/deuterium isotope effects observed in the present and previous studies on HRP-II reactions (11) and to account for the pH dependences of all three classes of reactions with HRP-II, as typified by the substrates *p*-cresol, ferrocyanide ion or PABA, and iodide ion.

The authors are grateful to Dr. J. Stillman for experimental advice, to Prof. D. Dolman for helpful discussions concerning imidazole binding and to the National Research Council of Canada for financial support.

Nitration of 3,4-Dimethylacetophenone and 3,4-Dimethylbenzophenone. Formation and Rearomatization of Adducts

ALFRED FISCHER, COLIN CAMPBELL GREIG, AND ROLF RÖDERER
Department of Chemistry, University of Victoria, Victoria, British Columbia V8W 2Y2

Received November 15, 1974

ALFRED FISCHER, COLIN CAMPBELL GREIG, and ROLF RÖDERER. Can. J. Chem. **53**, 1570 (1975).

Nitration of 3,4-dimethylacetophenone in acetic anhydride gives a mixture of *cis*- and *trans*-2-acetyl-4,5-dimethyl-4-nitro-1,4-dihydrophenyl acetate as the main product, together with 3,4-dimethyl-2-, 3,4-dimethyl-5-, and 3,4-dimethyl-6-nitroacetophenone. Analogous products are obtained from 3,4-dimethylbenzophenone. Rearomatization of the adducts under mildly acidic conditions occurs via 1,4-elimination of nitrous acid to form 2-acetyl- and 2-benzoyl-4,5-dimethylphenyl acetate, respectively. In strongly acidic conditions elimination of acetic acid accompanied by 1,2- and 1,3-shifts of the nitro group occurs to form the 2- and 5-nitro derivatives of the parent ketones. The rearomatization to the nitro derivatives involves the intermediate formation of an *ipso*-cyclohexadienyl cation which may be trapped by anisole or mesitylene to form biphenyl derivatives.

ALFRED FISCHER, COLIN CAMPBELL GREIG et ROLF RÖDERER. Can. J. Chem. **53**, 1570 (1975).

La nitration de la diméthyl-3,4 acétophénone dans l'anhydride acétique donne un mélange d'acétates d'acétyl-2 diméthyl-4,5 nitro-4 dihydro-1,4 phényle *cis* et *trans*; aux côtés de ces produits principaux, il se forme aussi de la diméthyl-3,4 nitro-2, de la diméthyl-3,4 nitro-5 et de la diméthyl-3,4 nitro-6 acétophénone. On obtient des produits analogues à partir de la diméthyl-3,4 benzophénone. La réaromatisation des produits d'addition dans des conditions d'acidité faible, s'effectue par une élimination 1,4 d'acide nitreux conduisant, suivant les cas, à la formation d'acétates d'acétyl-2 et de benzoyl-2 diméthyl-4,5 phényle. Dans des conditions d'acidité forte, il y a une élimination d'acide acétique accompagnée par des réarrangements 1,2 et 1,3 du groupe nitro, pour conduire aux dérivés nitro-2 et nitro-5 de la cétone de départ. La réaromatisation des dérivés nitrés implique la formation intermédiaire d'un cation *ipso*-cyclohexadiényle qui peut être piégé par l'anisole ou le mésitylène pour conduire à des dérivés biphényles.
[Traduit par le journal]

Introduction

Ipso nitration of methylbenzenes and their derivatives in acetic anhydride gives diastereoisomeric adducts which are derivatives of 4-nitro-1,4-dihydro-*p*-tolyl acetate (1, 2). Such adducts readily undergo rearomatization reactions. Secondary acetate adducts (to which discussion is confined in this report) afford aryl acetates by elimination of nitrous acid (1*a–e*) and nitroarenes by elimination of acetic acid accompanied by migration of the nitro group. Elimination of acetyl nitrate and reversion to the original aromatic is also observed with some adducts. Thus, the *o*-xylene adduct exhibits a 1,2-shift of the nitro group to form 3-nitro-*o*-xylene (3) whereas those from 3-chloro- (1*e*) and 3- and 4-cyano-*o*-xylene (1*d*) exhibit 1,3-shifts of nitro as well as the elimination of acetyl nitrate. Formation and potential rearomatization reactions of methylbenzene adducts are depicted for toluene, the parent methylbenzene, in Scheme 1. It should be noted that not all of the rearomatization reactions have actually been observed for any one of the adducts previously studied and, in particular, the nitro rearrangement and acetyl nitrate elimination reactions have neither been looked for, nor observed, in the case of the toluene adduct itself.

The present study, which is concerned with the effect of the oxo group, is a continuation of our investigations of substituent effects on the formation and rearomatization reactions of adducts of substituted *o*-xylenes.

Results and Discussion

Nitration of 3,4-dimethylacetophenone in acetic anhydride formed a mixture of 68% diene adducts, 20% 3,4-dimethyl-6-nitroacetophenone, and small amounts of the 2-nitro and 5-nitro isomers. The diastereoisomeric acetoxynitro adducts **1***a* and *b* were isolated by chromatography. The relative yields of the products and the absence of adducts resulting from attack at the 4-(*ipso*) position are consistent with the combined directing effects of the acetyl and the two methyl

a NO_2, OAc *trans*
b NO_2, OAc *cis*

substituents. The *ortho* methyl groups should favor electrophilic attack in the positional order 3 = 4 > 6 > 5 = 2. The acetyl group, which is deactivating, would be expected to reduce the reactivity at the 4-(*para*) position to a greater extent than at the 2- and 6-(*ortho*) positions and least of all at the 3- and 5-(*meta*) positions. The observed order, 3 > 6 > 5 ~ 2 > 4, is in accord with these expectations.

Nitration of 3,4-dimethylacetophenone with mixed acid was carried out by Buu-Hoî *et al.* (4) who reported that 3,4-dimethyl-6-nitroacetophenone, m.p. 120° was obtained in 75% yield together with 3,4-dimethyl-5-nitroacetophenone. Brändström and Carlsson (5) repeated this reaction and they obtained a 2:1:1 mixture of 3,4-dimethyl-2-nitroacetophenone, m.p. 122°, 3,4-dimethyl-6-nitroacetophenone, m.p. 80°, and 3,4-dimethyl-5-nitroacetophenone. They concluded that Buu Hoî *et al.* (4) incorrectly identified the isomer of m.p. 120°. The n.m.r. spectra clearly identify each isomer (see Experimental) and our work confirms Brändström and Carlsson's observations that the isomer of m.p. 120° is the 2-nitro compound and that the isomer having m.p. 80° is 3,4-dimethyl-6-nitroacetophenone. However, the relative yields of substitution products that they found, in which the 2-nitro isomer predominates, is quite different from the

relative yields that we observed, where the 6-nitro isomer predominates. We suggest that under both sets of conditions the nitronium ion is the active electrophile and that its relative rate of attack at the nuclear positions is the same. Under the highly acidic conditions pertaining in sulfuric acid (Brändström and Carlsson's conditions) diene adducts are not stable and, if formed, will be readily converted back to the precursor cyclohexadienyl cation (5-Ac-2-Me-**4**)[1] which, by shift of the nitro group, followed by loss of a proton, will give the 2-nitro and 5-nitro substitution products of 3,4-dimethylacetophenone (*cf.* Scheme 1: **4** → **7** → **8** and **4** → **9** → **10**, see below). Thus the predominant attack by nitronium ion at the 3-(*ipso*) position will under their conditions lead to an increased yield of the 2-nitro and 5-nitro isomers. If the ratio of attack at the 2, 3, 5, and 6 positions that we observed, ~6, 68, ~6, and 20%, respectively, is assumed to be the same in sulfuric acid, and if the 68% of *ipso* attack leads to the 2-nitro and 5-nitro derivatives in the same ratio that we found for the rearrangements (3:1) then the observed yields of 2-, 5-, and 6-nitro derivatives would be 57, 23, and 20%, respectively. This is quite close to the 2:1:1 ratio found by Brändström and Carlsson. This provides a clear illustration of how *ipso* attack followed by rearrangement can complicate the interpretation of positional reactivity determined from the isomer distribution of the final substitution products (3, 6, 7).

Nitration of 3,4-dimethylbenzophenone gave the diastereoisomeric adducts **2***a* and *b*, in approximately 70% yield, the three 3,4-dimethylnitrobenzophenone isomers, and 3,5-dinitro-*o*-xylene. Because of the complexity of the spectrum of the reaction product it was not possible to measure the yields of the individual nitro substitution products. The formation of 3,5-dinitro-*o*-xylene is indicative of attack by the nitrating electrophile, assumed to be the nitronium ion, at the position *ipso* to benzoyl. The resulting 4-nitro-*o*-xylene would be expected to nitrate in the vacant *meta* position to form the 3,5-dinitro-*o*-xylene. However, study of the nitration of 4-nitro-*o*-xylene has shown that it is quite unreactive towards nitric acid in acetic anhydride under the conditions used for nitration of the dimethylbenzophenone.[2] The mode of formation of the dinitro-*o*-xylene is thus unexplained.

Rearomatization of **1** and **2** under aprotic, weakly acidic (acetic acid) and moderately acidic conditions (5% sulfuric acid in acetic acid, trifluoroacetic acid) gave the corresponding acetates, 2-acetyl-4,5-dimethylphenyl acetate and 2-benzoyl-4,5-dimethylphenyl acetate, by 1,4-elimination of nitrous acid. During the course of the slow elimination reaction of **1** in acetic acid, epimerization was evident. Under more strongly acidic conditions (50% sulfuric acid in acetic acid, 78% aqueous sulfuric acid) or in the presence of the Lewis acid boron trifluoride, a mixture of the 3,4-dimethylacetophenone (29%) and its 2-(53%) and 5-nitro (18%) derivatives, or 3,4-dimethylbenzophenone (37%) and its 2-(36%) and 5-nitro (27%) derivatives was obtained, respectively. The two distinct pathways for rearomatization reflect those observed for the *o*-xylene adduct 2-Me-**5** (3), and its derivatives 6-Cl-2-Me-**5** (1*e*), and 5-CN-2-Me-**5** (1*d*).

Clearly, the outcome of the competition between the two rearomatization pathways depends upon the acidity of the reaction medium and the results are explicable in terms of the previously proposed mechanisms (1*d*, *e*, 3). In the 1,4-elimination (E2) of nitrous acid (Scheme 1: **5** → **6**) a basic species (normally a solvent molecule) is required to abstract the proton. Under conditions of very high acidity the ability of the solvent to abstract the proton is markedly reduced and the 1,4-elimination pathway is disfavored with respect to the second rearomatization process. This involves the acid-catalyzed unimolecular loss of acetate to (re)form the *ipso*-cyclohexadienyl cation **4** which can in principle undergo (*i*) loss of the nitro group as a nitronium ion, to reform **3**; (*ii*) a 1,2-nitro shift to form **7**, which is in turn deprotonated to the 2-nitro derivative **8**; and (*iii*) a 1,3-nitro shift to form **9**, in turn deprotonated to the 3-nitro derivative **10**. The acidity at which the transition from the E2 to cation pathway occurs depends upon the substituents present in the adduct. Thus in the intermediate acidity range (5% sulfuric acid in acetic acid, or trifluoroacetic acid), where the less deactivated 6-Cl-2-Me-**5** has already exhibited the E2 to cation transition (1*e*), **1** and **2** still follow the E2 pathway. For **1** and **2** the transition is effected

[1]When reference is made to compounds as derivatives of those depicted in Scheme 1 the numbering system follows that of toluene itself *i.e.* the position to which the methyl substituent is attached is always taken as the 1-position.

[2]Unpublished work with B. Fowler.

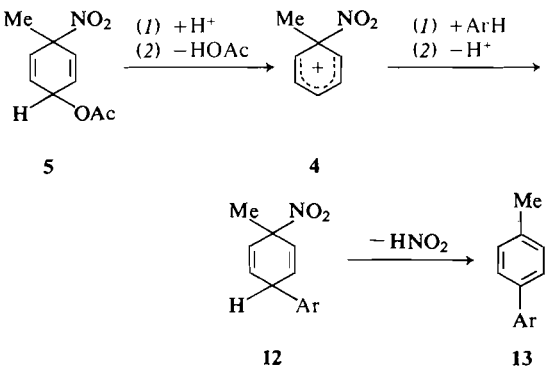
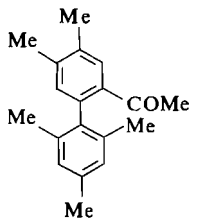
at higher acidities. The fact that epimerimization of **1***b* occurred in the course of the elimination reaction in acetic acid indicates that (reversible) cation formation does occur at low acidities. Presumably, the lifetime of the cation under these conditions is too short to allow the nitro shift processes (**4** → **3**, **7**, **9**) to occur.

The particular rearomatization processes which occur from the cation are determined by the substituents. For 2-Me-**4** only a 1,2-nitro shift, leading eventually to 3-nitro-*o*-xylene, is observed (*cf.* **4** → **7** → **8**). The other potential reactions of the *ipso*-cyclohexadienyl cation, *viz.* a 1,3-nitro shift followed by deprotonation to the isomeric nitro aromatic (*cf.* **4** → **9** → **10**), and the loss of the nitro group as nitronium ion, leading to parent aromatic (*cf.* **4** → **3**) but not the 1,2-nitro shift, are realized in the cases of 6-Cl-2-Me-**5**, (1*e*), 3-CN-2-Me-**5**, and 5-CN-2-Me-**5** (1*d*). In adducts **1** and **2**, which give rise to the cations 5-Ac-2-Me-**4** and 5-Bz-2-Me-**4**, respectively, all three processes are observed. The relative yields of the products indicate that in the case of 5-Ac-2-Me-**4** the 1,2-shift of the nitro group (**4** → **7**) is the most favored process; loss of the nitronium ion (**4** → **3**) occurs less readily and the 1,3-shift of the nitro group (**4** → **9**) occurs to the least extent. The data for **2** suggest that 1,2-shift of the nitro group in the cation is not so favored over the other processes as it is in the case of **1**. This may be attributed to the steric effect of the benzoyl substituent (larger than acetyl) which would be expected to inhibit the 1,2-nitro shift. For both **1** and **2** it is clear that the shift of the nitro group must be intramolecular. A dissociation–renitration process would give the 6-nitro derivative which is not observed; indeed in the case of **1**, 3,4-dimethyl-6-nitroacetophenone would be expected to be the major product, since the results of the nitration of 3,4-dimethylacetophenone show that of the unsubstituted positions the 6-position is the most activated. The fact that no 3,4-dimethyl-6-nitroacetophenone is obtained from the rearomatization of **1** (nor 3,4-dimethyl-6-nitrobenzophenone from **2**) although the precursor cyclohexadienyl cation (5-Ac-2-Me-**11**) is the most stable of the non-*ipso* cations also confirms the expectation that the direct 1,4-nitro shift is unlikely and shows that a non-*ipso* cation (5-Ac-2-Me-**9**) undergoes deprotonation (to 5-Ac-2-Me-**10**) much more rapidly than it rearranges to a more stable cation (*cf.* **9** → **11**). We suspect that this last is a general conclusion since no evidence for the rearrangement of a non-*ipso* nitrocyclohexadienyl cation has ever been adduced. Furthermore, the parallel observation that the only acetyl adducts which have ever been observed have the nitro group attached to an *ipso* position and the irreversibility of nitration, show that the *only* fate of a non-*ipso* nitrocyclohexadienyl cation is deprotonation.

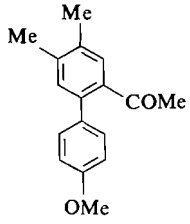
ipso-Cyclohexadienyl cations from tertiary acetate precursors (*e.g.* 4-Me-**4**) are trappable by nucleophiles other than acetic acid (*e.g.* methanol) to give other adducts (1*f*, *g*). The epimerization observed in the course of the rearomatization of **1***a* in acetic acid indicates that the secondary acetate adducts can undergo exchange reactions by formation of the cation and its subsequent combination with a nucleophile. The coupling reactions with aromatic substrates presumably follow this process, illustrated for the parent adduct **5** (Scheme 2). The cation substitutes in the aromatic to form as the immediate product the nitroaryl adduct **12** which readily undergoes elimination of nitrous acid to form the biphenyl derivative **13**. The biphenyl derivatives **14**, **15**, and **16** obtained by reaction of **1** with mesitylene and with anisole and by reaction of **2** with mesitylene, as well as that (**17**) previously reported from reaction of 6-Cl-2-Me-**5** with mesitylene, all have precisely the structures expected if they were formed by the pathway shown in Scheme 2. In the nitration of 1,2-dialkylbenzenes (*e.g.* *o*-xylene) and of hemimellitene with 90% nitric acid at low temperatures, coupling occurs to form polyalkylbiphenyls, which may be further nitrated (8). It is significant that such coupling takes place with substrates which when reacted with nitric acid in acetic anhydride are known to, or would be expected to, give good



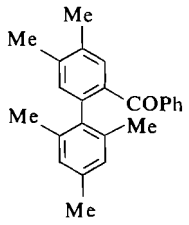
SCHEME 2



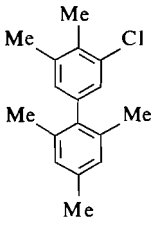
14



15



16



17

yields of secondary acetate adducts, and does not occur with substrates which do not form adducts (*e.g.* mesitylene) or which form only tertiary acetate adducts (*e.g. p*-xylene). It seems clear that the mechanism of this coupling reaction is just that shown in Scheme 2 except that the *ipso*-cyclohexadienyl cation **4** is generated by *ipso* attack of nitronium ion on the hydrocarbon. The susceptible hydrocarbons have a highly activated *ipso* position *para* to an unsubstituted position. Toluene itself was not observed to couple (8*a*) but since only a small amount of *ipso* attack occurs with toluene (1*c*) only a very small amount of coupling product would be expected. Cross coupling of two different arenes also occurs but only if one of the components is of the type required for successful self-coupling. Clearly the second component is merely filling the role of the aromatic which is substituted, not that which becomes the active electrophile. The high yields of biphenyl derivatives which are obtained from **1** and **2** indicate that the reaction has potential synthetic utility. The reaction is obviously related to the Scholl reaction of dehydrogenation condensation of aromatics (9) but has the important advantage over the latter that it provides a mixed biaryl product.

Reaction of **1** and **2** with sodium methoxide in methanol resulted in rearomatization by 1,4-elimination of nitrous acid accompanied by cleavage of the ester function.

Experimental

Nuclear magnetic resonance spectra at 220 MHz were determined on the Varian HR 200 spectrometer at the Ontario Research Foundation, Sheridan Park, Ontario. Microanalyses were by Dr. D. McGillivray. Nitric acid was purified by distilling the fuming acid (300 cm^3) at 100 Pa from urea (10 g) and sulfuric acid (500 cm^3). Alumina was deactivated with 3% of 10% acetic acid. Ether and pentane were dried by distillation from sodium and phosphorus pentoxide, respectively.

Nitration of 3,4-Dimethylacetophenone

A solution of freshly distilled nitric acid (10 cm^3, 0.24 mol) in acetic anhydride (40 cm^3) was added to 3,4-dimethylacetophenone (20 g, 0.14 mol) in acetic anhydride (60 cm^3) at $-40°$. The yellow reaction mixture was allowed to stand at 2° overnight after which time the n.m.r. spectrum indicated that approximately 70% of dienes had been formed. The mixture was worked up in the normal manner (10) to yield an oil consisting of (by n.m.r.) 68% dienes, 20% 3,4-dimethyl-6-nitroacetophenone, and lesser amounts of 3,4-dimethyl-2-nitroacetophenone and 3,4-dimethyl-5-nitroacetophenone. Chromatography on alumina at $-20°$ and elution with pentane and ether–pentane mixtures gave a mixture of 3,4-dimethylnitroacetophenones (1.2 g, 6 mmol) in the 50–70% ether fractions, *trans*-2-acetyl-4,5-dimethyl-4-nitro-1,4-dihydrophenyl acetate (**1***a*, 10.7 g, 42 mmol) in the second 70% ether fraction, a mixture of **1***a* and *b* (5.4 g, 21 mmol) in the first 100% ether fraction, and *cis*-2-acetyl-4,5-dimethyl-4-nitro-1,4-dihydrophenyl acetate (**1***b*, 1.0 g, 4 mmol) in the second 100% ether fraction.

Recrystallization of **1***a* from chloroform–pentane gave colorless crystals, m.p. 95.5–97°; u.v. (CH_3OH) 212.5 nm (ε 1130 $m^2\ mol^{-1}$); i.r. (Nujol) 1730 and 1245 ($OCOCH_3$), 1680 ($COCH_3$), 1545 and 1380 (NO_2), and 930 cm^{-1}; n.m.r. ($CDCl_3$) τ 3.08 (d, 1, 3-*H*) 3.83 (m, 1, 1-*H*), 4.00 (m, 1, 6-*H*), 7.62 (s, 3, $COCH_3$), 7.98 (s, 3, $OCOCH_3$), 8.09 (s, 3, 4-CH_3), 8.15 (t, 3, 3-CH_3), J_{13} = 0.90, J_{16} = 4.07, $J_{1,5-CH_3}$ = 1.26, $J_{6,5-CH_3}$ = 1.31 Hz; irradiation at 8.15 collapsed the multiplet at 3.83 to a doublet of doublets and that at 4.00 to a doublet, allowing the initial assignment of chemical shifts and coupling constants to be made to simulate the spectrum, the simulation then being refined to give the listed parameters.

Anal. Calcd. for $C_{12}H_{15}NO_5$: C, 56.91; H, 5.96; N, 5.53. Found: C, 56.61; H, 5.96; N, 5.45.

Recrystallization of **1***b* from chloroform–pentane gave colorless crystals, m.p. 120–120.5°; u.v. (CH_3OH) 213.5 nm (ε 1100 $m^2\ mol^{-1}$); i.r. (Nujol) 1730 and 1240 ($OCOCH_3$), 1680 ($COCH_3$), 1550 and 1380 (NO_2), 1020 and 940 cm^{-1}; n.m.r. ($CDCl_3$), τ 3.14 (d, 1, 3-*H*), 3.90 (m, 1, 1-*H*), 4.03 (m, 1, 6-*H*), 7.62 (s, 3, $COCH_3$) 7.95 (s, 3, $OCOCH_3$), 8.13 (t, 3, 5-CH_3). 8.17 (s, 3, 4-CH_3), J_{13} = 0.82, J_{16} = 3.83, $J_{1,5-CH_3}$ = 1.30, $J_{6,5-CH_3}$ = 1.28 Hz; irradiation at 8.08 collapsed the multiplet at 3.90 to a doublet of doublets and then at 4.30 to a doublet allowing the assignment of chemical shifts and coupling constants which were then refined as in the case of **1***a*.

Anal. Calcd. for $C_{12}H_{15}NO_5$ (M_r 253): C, 56.91; H, 5.96; N, 5.53. Found (249): C, 57.03; H, 5.93, N, 5.47.

Identical arguments to those adduced for the structure of the adduct from 3,4-dimethylbenzonitrile (**1***d*) can be made for the assignment of structure **1** to the 3,4-dimethylacetophenone adducts. The assignment is supported by the effect of the shift reagent tris-(1,1,1,2,2,3,3-heptafluoro-7,7-[$^2H_6$]dimethyl-4,6-[$^2H_3$]octanedionato)europium(III) {Eu([$^2H_9$]fod)$_3$} (Table 1). In both **1***a* and *b* the acetate methyl absorption moved downfield more rapidly

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

TABLE 1. Relative gradients (gradient 1-OAc = 1.00) of proton chemical shifts for diene adducts resulting from the addition of Eu([$^2H_9$]fod)$_3$

Compound	1-H	3-H	6-H	4-CH_3	5-CH_3	2-Ac	2′-H
1*a*	1.97	0.46	0.73	0.22	0.08	0.52	—
1*b*	1.94	0.40	0.73	0.08	0.09	0.51	—
2*a*	2.20	0.40	0.65	0.22	0.07	—	0.38
2*b*	2.40	0.40	0.66	0.04	0.08	—	0.42

than that of any of the other methyl groups, confirming the expectation of coordination of the reagent at the acetate function. The allylic hydrogen (1-H) peak moves downfield more rapidly than that of the adjacent vinyl hydrogen (6-H) which in turn moves more rapidly than that of the remote vinyl hydrogen (3-H), in accord with the increasing distance between the europium and the respective hydrogens. Similarly, in both **1***a* and *b*, the acetate methyl absorption moves more rapidly than that of the acetyl methyl which moves more rapidly than that of the 5-methyl, again in accord with the increasing distance between europium and the respective methyl groups. However, the 4-methyl peak in **1***a* moves more than twice as rapidly as the similar peak of **1***b* whereas the shift gradients for all other pairs of corresponding protons of **1***a* and *b* are not significantly different and on this basis the stereochemistry is assigned with 4-methyl and acetate *cis* in **1***a* and thus **1***a* as the *trans* adduct and the complementary assignment for **1***b*.

Nitro Compounds.

The residues from early column fractions containing the nitro compounds were combined and rechromatographed on alumina. 3,4-Dimethyl-6-nitro-acetophenone was eluted with 25% ether–pentane, m.p. 79–80° (lit. (5) m.p 80°); i.r. (Nujol) 1700 (C=O), 1545 and 1370 (NO_2); n.m.r. ($CDCl_3$), τ 2.15 (s, 1, 5-*H*), 2.72 (s, 1, 2-*H*), 7.50 (s, 3, $COCH_3$), 7.65 (s, 6, 3-CH_3 and 4-CH_3); mass spectrum (70 eV) *m/e* (relative intensity) 193 (32, M), 178 (100, *M* − CH_3), 151 (74), 103 (40), 91 (30), 43 (60). 3,4-Dimethyl-5-nitroacetophenone could not be obtained pure but was obtained in a mixture with the 6-nitro isomer: n.m.r. ($CDCl_3$), τ 1.85 (d, 1, *J* = 1.5 Hz, 6-*H*), 2.00 (d, 1, *J* = 1.5 Hz, 2-*H*), 7.40 (s, 3, $COCH_3$), 7.67 (s, 6, 3-CH_3 and 4-CH_3).

Anal. Calcd. for $C_{10}H_{11}NO_3$: C, 62.17; H, 5.74; N, 7.25. Found: C, 62.04; H, 5.60; H, 7.00.

3,4-Dimethyl-2-nitroacetophenone was isolated in a small amount from the 40% ether–pentane fraction on rechromatography of the nitro compounds. It was more readily obtained from the product of rearomatization of **1** using boron trifluoride (see below), m.p. 118° (lit. (5) m.p. 122°); i.r. 1700 (C=O), 1540 and 1350 cm^{-1} (NO_2); n.m.r. ($CDCl_3$) τ 2.45 (d, 1, *J* = 8 Hz, 6-*H*), 2.70 (d, 1, *J* = 8 Hz, 5-*H*), 7.48 (s, 3, $COCH_3$), 7.58 (s, 3, 3-CH_3), 7.80 (s, 3, 4-CH_3); mass spectrum (70 eV) *m/e* (relative intensity) 193 (6, M), 178 (100, *M* − CH_3), 151 (80), 103 (42), 91 (41), 43 (45), 42 (34).

Anal. Calcd. for $C_{10}H_{11}NO_3$: C, 62.17; H, 5.74; N, 7.25. Found: C, 62.00; H, 5.50; N, 7.48.

The three nitro substitution products have definitive n.m.r. spectra. 3,4-Dimethyl-2-nitroacetophenone has two *ortho* protons which give rise to a typical AB quartet with an 8 Hz coupling. Its 5-nitro isomer has *meta* protons and these give an AB quartet with a 1.5 Hz coupling. The 6-nitro isomer has *para* protons which appear as two singlets. None of the peaks overlap and this facilitates the detection of the individual isomers in mixtures.

2-Acetyl-4,5-dimethylphenol and 2-Acetyl-4,5-dimethylphenyl Acetate

Diene **1** (3 g) was added to a concentrated solution of sodium methoxide in methanol (5 cm^3). After neutralization with ammonium chloride and evaporation of excess methanol the residue was extracted with ether. Evaporation of the ether and recrystallization of the residue from petroleum ether gave 2-acetyl-4,5-dimethylphenol, m.p. 71.5–72.5° (lit. (11) m.p. 71°); i.r. (Nujol) 3300–3500 (OH), 1650 cm^{-1} ($COCH_3$); n.m.r. ($CDCl_3$) τ 2.50 (s, 1, 3-*H*), 3.20 (s, 1, 6-*H*), 7.45 (s, 1, $COCH_3$), 7.76 (s, 1, CH_3), 7.80 (s, 1, CH_3); mass spectrum (70 eV) *m/e* (relative intensity) 164 (36, M) (100, *M* − CH_3), 121 (5), 91 (12), 77 (14), 43 (15).

The phenol (278 mg) was dissolved in acetic anhydride (5 cm^3), 5 drops of sulfuric acid were added, and the mixture maintained at 35° for 30 min. The mixture was neutralized and extracted with ether. Removal of the ether gave 2-acetyl-4,5-dimethylphenyl acetate which was recrystallized from ethanol–water, m.p. 59–60°; i.r. (Nujol) 1780 ($OCOCH_3$) and 1700 cm^{-1} ($COCH_3$); n.m.r. ($CDCl_3$) τ 2.42 (s, 1, 3-*H*), 3.13 (s, 1, 6-*H*), 7.50 (s, 3, $COCH_3$), 7.69 (s, 3, CH_3), and 7.73 (s, 3, CH_3); mass spectrum (70 eV) *m/e* (relative intensity) 206 (6, M) 164 (62, *M* − CH_2CO), 149 (100), 91 (16), 43 (35).

Anal. Calcd. for $C_{12}H_{14}O_3$: C, 69.89; H, 6.84. Found: C, 69.78; H, 6.80.

*2-Acetyl-2′,4,4′,5,6′-pentamethylbiphenyl (**14**)*

Boron trifluoride etherate (1 cm^3) was diluted with ether (3 cm^3); the solution was added dropwise to a solution of diene **1** (2 g, 7.9 mmol) and mesitylene (5 cm^3) in methylene chloride (3 cm^3) and the mixture left to stand for 4 h. After work-up, chromatography on silica gel and elution with ether–pentane gave mesitylene in the 5% ether fraction, the biphenyl (1.47 g, 5.5 mmol) in the early 20% ether fractions and a mixture of 3,4-dimethyl-2- and 3,4-dimethyl-5-nitroacetophenone (300 mg, 1.6 mmol) in the later 20% ether fractions. After recrystallization from ethanol, 2-acetyl-2′,4,4′,5,6′-pentamethylbiphenyl had m.p. 74°; i.r. (Nujol) 1675 (C=O) 1610, 1275, 1220, 890, and 860 cm^{-1}; n.m.r. ($CDCl_3$) τ 2.44 (s, 1, 3-*H*), 3.11 (m, 3, 3′-*H*, 5′-*H*, and 6-*H*); 7.74 (s, 9, 4-CH_3, 4′-CH_3, and 5-CH_3) 8.10 (s, 9, 2′-CH_3, 6′-CH_3, and $COCH_3$); mass spectrum (70 eV) *m/e* (relative intensity) 266 (56, M) 251 (100, *M* − CH_3) 193 (78), 178 (43), 152 (54), 132 (47), 118 (100), 115 (49), 103 (55), 89 (67), 44 (71).

Anal. Calcd. for $C_{18}H_{22}O$: C, 85.67; H, 8.23. Found: C, 85.84; H, 8.23.

*2-Acetyl-4′-methoxy-4,5-dimethylbiphenyl (**15**)*

A solution of boron trifluoride etherate (1 cm^3) in ether

(5 cm^3) was added to a mixture of diene **1** (2 g, 7.9 mmol) and anisole (5 cm^3) at 0°. The mixture turned bright blue. After work-up and chromatography on silica gel, elution with 10% ether–pentane washed down excess anisole. Elution with 20% ether–pentane gave 2-acetyl-4′-methoxy-4,5-dimethylbiphenyl (230 mg, 0.9 mmol); n.m.r. ($CDCl_3$) τ 2.64 (s, 1, 3-*H*), 2.73 (d, 2, J = 8 Hz, 3′-*H* and 5′-*H*), 2.83 (s, 1, 6-*H*), 3.05 (d, 1, J = 8 Hz, 2′-*H* and 6′-*H*), 6.18 (s, 3, OCH_3), 7.68 (s, 6, 4-CH_3 and 5-CH_3), 8.00 (s, 3, $COCH_3$); mass spectrum (70 eV) *m/e* (relative intensity) 254.141 (19, M_r ($^{12}C_{17}{}^{1}H_{18}{}^{16}O_2$) 254.131), 149, (100), 132 (82), 104 (58), 83 (69), 77 (70), 43 (95.) Further elution with 20% ether–pentane gave 3,4-dimethyl-6-nitroacetophenone (700 mg, 3.6 mmol) and 3,4-dimethyl-2-nitroacetophenone (240 mg, 1.2 mmol).

Reaction of Diene 1 with Boron Trifluoride

Diene **1** (1.5 g, 5.0 mmol) was added to boron trifluoride etherate (1.5 cm^3). A vigorous reaction ensued. After work-up followed by chromatography on silica gel and elution with 20% ether–pentane there was obtained 3,4-dimethylacetophenone (245 mg, 1.7 mmol), 3,4-dimethyl-5-nitroacetophenone (245 mg, 1.3 mmol), and 3,4-dimethyl-2-nitroacetophenone (550 mg, 2.8 mmol). The identity of the products was confirmed by comparison of R_f values on thin-layer chromatography with those of authentic samples and by n.m.r.

Reaction of Diene 1 with 78% Sulfuric Acid

Diene **1** (500 mg) was stirred overnight with 78% (by weight) sulfuric acid. The n.m.r. of the product obtained after work-up showed 35% 3,4-dimethylacetophenone, 48% 3,4-dimethyl-2-nitroacetophenone, and 16% 3,4-dimethyl-5-nitroacetophenone. The identity of the components was confirmed by t.l.c.

Other Rearomatization Reactions of Diene 1

In each case diene **1** (100 mg) was reacted with the appropriate reagent in an n.m.r. tube and the products determined by n.m.r. and confirmed by t.l.c. Reaction with 50% sulfuric acid in acetic acid gave 23% 3,4-dimethylacetophenone, 61% of 3,4-dimethyl-2-nitro-, and 16% of 3,4-dimethyl-5-nitroacetophenone. Reaction with 5% sulfuric acid in acetic acid gave only 2-acetyl-4,5-dimethylphenyl acetate as did reaction with neat trifluoroacetic acid and reaction with neat acetic acid. Reaction with acetic acid was slow at ambient temperature ($t_{1/2} \sim 10$ days) and epimerization of the mixture in which **1*b*** predominated to a mixture in which **1*a*** was the major diastereoisomer occurred. At 120° elimination to the acetate was complete in 10 min. The rate of rearomatization was measured in 65% (by weight) trifluoroacetic acid – 35% [$^2H_4$]acetic acid mixture and at a probe temperature of 35°, by integrating over the upfield part of the diene region of the n.m.r. spectrum at measured time intervals. A plot of log(integral) against time was linear leading to a first-order rate constant of 4.0×10^{-4} s^{-1}.

Nitration of 3,4-Dimethylbenzophenone

A solution of nitric acid (8 cm^3, 0.2 mol) in acetic anhydride at −70° was added to a stirred solution of the ketone (20 g, 0.10 mol) in acetic anhydride (20 cm^3) also at −70°. The temperature of the reaction mixture was allowed to rise to 5° and held at this temperature overnight. Diene adduct **2** (9.7 g, 30 mmol) crystallized from the reaction mixture and was filtered off. The filtrate was worked up in the normal manner to yield a semicrystalline product from which more adduct **2** (4.3 g, 14 mmol) was filtered off after the addition of ether (50 cm^3). The residue (15.8 g) obtained after evaporation of the ether from the filtrate was chromatographed on deactivated alumina at −25°. Elution with ether–pentane gave 3,4-dimethylbenzophenone (0.5 g, 2 mmol) in the 20–30% ether fractions, 3,4-dimethyl-5-nitrobenzophenone (1 g, 4 mmol) in the 40–50% ether fractions, a mixture 3,4-dimethyl-2-nitro- and 3,4-dimethyl-6-nitrobenzophenone (2.5 g, 10 mmol) in the third 50% ether fraction, a mixture of 2- and 6-nitro isomers (0.7 g, 3 mmol) and diene adduct **2** (4.2 g, 13 mmol) in the 60–70% ether fractions from which the adduct **2** crystallized. In other nitration reactions 3,5-dinitro-*o*-xylene was isolated from early column fractions: n.m.r. ($CDCl_3$) τ 1.53 (d, 1, J = 2 Hz, 4-*H*), 1.75 (d, 1, J = 2 Hz, 6-*H*), 7.50 (s, 6, 1-CH_3 and 2-CH_3). Chromatography of the diene fractions at −45° gave the individual diastereoisomers **2*a*** and ***b***. *Trans* adduct **2*a*** was formed in larger amount (3:1) than *cis* adduct **2*b***. At higher temperatures adduct **2*a*** decomposed on the column and 2-benzoyl-4,5-dimethylphenyl acetate, eluted in the early column fractions, and 2-benzoyl-4,5-dimethylphenol, eluted with methanol, were formed. Adducts constituted 65–75% of the reaction product before work-up.

trans-2-Benzoyl-4,5-dimethyl-4-nitro-1,4-dihydrophenyl acetate (**2*a***) was recrystallized from chloroform–pentane, m.p. 118°; u.v. (CH_3OH) 255 nm (ε 1330 m^2 mol^{-1}); i.r. (Nujol) 1740 and 1250 ($OCOCH_3$), 1660 (C=O), 1560 (NO_2), 730 cm^{-1}; n.m.r. (220 MHz, $CDCl_3$) τ 2.22 (d, 2, J = 8 Hz, 2′-*H* and 6′-*H*), 2.38 (t, 1, J = 8 Hz, 4′-*H*), 2.51 (t, 2, J = 8 Hz, 3′-*H* and 5′-*H*), 3.46 (d, 1, 3-*H*), 3.60 (m, 1, 1-*H*), 3.90 (m, 1, 6-*H*), 8.01 (s, 3, $OCOCH_3$), 8.04 (s, 3, 4-CH_3), 8.10 (t, 3, 5-CH_3), J_{13} = 1.38, J_{16} = 3.60, $J_{1,5-CH_3}$ = 1.43, $J_{6,5-CH_3}$ = 1.43 Hz.

Anal. Calcd. for $C_{17}H_{17}NO_5$(M_r 315): C, 64.75; H, 5.43; N, 4.44. Found (307): C, 64.74; H, 5.29; N, 4.43.

cis-2-Benzoyl-4, 5-dimethyl-4-nitro-1,4-dihydrophenyl acetate (**2*b***) was recrystallized from chloroform–pentane, m.p. 128–130° (dec.); u.v. (CH_3OH) 252 nm (ε 1140 m^2 mol^{-1}); i.r. (Nujol) 1735 and 1250 ($OCOCH_3$), 1660 (C=O), 1560 (NO_2), 730 cm^{-1}; n.m.r. (220 MHz, $CDCl_3$) τ 2.11 (d, 2, J = 8 Hz, 2′-*H*, 6′-*H*), 2.37 (t, 1, J = 8 Hz, 4′-*H*), 2.50 (t, 2, J = 8 Hz, 3′-*H* and 5′-*H*), 3.54 (d, 1, 3-*H*), 3.68 (m, 1, 1-*H*), 3.93 (m, 1, 6-*H*), 7.99 (s, 3, $OCOCH_3$), 8.10 (t, 3, 5-CH_3), 8.26 (s, 3, 4-CH_3), J_{13} = 1.41, J_{16} = 3.21, $J_{1,5-CH_3}$ = 1.46, $J_{6,5-CH_3}$ = 1.43 Hz; in the 60 MHz spectrum irradiation of the methyl triplet collapsed the multiple t at 3.07 to a doublet of doublets and that at 3.95 to a doublet. The decoupled spectrum was simulated and refined to give coupling constants and chemical shifts for the hexadiene ring protons. These coupling constants together with the estimated coupling constants to the methyl group were then used to simulate the undecoupled 220 MHz spectrum and the simulation refined to give the listed coupling constants and chemical shifts.

Anal. Calcd. for $C_{17}H_{17}NO_5$ (M_r 315): C, 64.75; H, 5.43; N, 4.44. Found (306): C, 64.72; H, 5.16; N, 4.33.

The arguments for the structure of **2** are similar to those for the structure **1** and are likewise supported by the similar effects of shift reagent. The assignment of **2*a*** as the *trans* and **2*b*** as the *cis* adduct follows from the more rapid downfield shift of the 4-methyl peak in the former.

Nitro Compounds

The three nitro substitution products were obtained from the nitration mixture after chromatography and crystallization. The 2-nitro and 5-nitro isomers were also isolated from rearomatization reactions.

3,4-Dimethyl-2-nitrobenzophenone had m.p. 103–104°; i.r. (Nujol) 1680 (C=O), 1545 and 1375 cm^{-1} (NO_2); n.m.r. ($CDCl_3$) τ 2.20 (m, 2, 2′-*H* and 6′-*H*), 2.39 (m, 1, 4′-*H*), 2.53 (m, 2, 3′-*H* and 5′-*H*), 2.63 (d, 2, 6-*H*), 2.71 (d, 2, 5-*H*), 7.57 (s, 3, 3-CH_3), 7.69 (s, 3, 4-CH_3), J_{56} = 7.9, $J_{2'3'}$ = 8.1, $J_{2'4'}$ = 1.3, $J_{2'5'}$ = 0.6, $J_{2'6'}$ = 1.6, $J_{3'4'}$ = 7.5, $J_{3'5'}$ = 1.4 Hz; addition of the shift reagent to this isomer shifted the quartet of lines of the 2′-*H* and 6′-*H* down to τ 1.15 and the doublet (J = 8 Hz) of the 6-H to 1.65. Only three protons were moved substantially downfield confirming the identification as the 2-nitro isomer since there are only three protons *ortho* to the carbonyl group where the europium is expected to complex. Mass spectrum (70 eV) *m/e* (relative intensity) 255 (19, M), 238 (3, M − OH), 178 (23, M − C_6H_5), 165 (17), 162 (35), 149 (10), 132 (9), 105 (100), 77 (36).

3,4-Dimethyl-5-nitrobenzophenone had m.p. 64–69°; i.r. (Nujol) 1660 (C=O), 1540 and 1365 cm^{-1} (NO_2); n.m.r. ($CDCl_3$) 2.04 (d, 1, J = 2 Hz, 6-*H*), 2.19 (d, 1, J = 2 Hz, 2-*H*), 2.24 (q, 2, J = 2 Hz and J = 8 Hz, 2′-*H* and 6′*H*), 2.45 (m, 3, 3′-*H*, 4′-*H*, and 5′-*H*), 7.57 (s, 6, 3-CH_3 and 4-CH_3); addition of the shift reagent moved four aromatic protons to much lower field (τ 1.2). There are four protons *ortho* to the carbonyl group in the 5-nitro isomer and thus the identification of this isomer is confirmed. Mass spectrum (70 eV) *m/e* (relative intensity) 255 (80, M), 238 (80, M − OH), 105 (100), 77 (100).

Anal. Calcd. for $C_{15}H_{13}NO_3$: C, 70.58; H, 5.13; N, 5.49. Found: C, 70.31; H, 5.04; N, 5.29.

3,4-Dimethyl-6-nitrobenzophenone had m.p. 80°; i.r. (Nujol) 1680 (C=O), 1530 and 1360 cm^{-1} (NO_2); n.m.r. ($CDCl_3$) τ 2.02 (s, 1, 5-*H*), 2.26 (q, 2, J = 2 Hz and J = 8 Hz, 2′-*H* and 6′-*H*), 2.53 (m, 3, 3′-*H*, 4′-*H* and 5′-*H*), 2.79 (s, 1, 2-*H*), 7.60 (s, 3, CH_3), 7.64 (s, 3, CH_3); mass spectrum (70 eV) *m/e* (relative intensity) 255.083 (30, M_r ($^{12}C_{15}{}^{1}H_{13}{}^{14}N^{16}O_3$) 255.090), 178 (47, M − C_6H_5), 165 (23), 162 (100), 132 (25), 105 (94), 77 (50).

The structures of the three nitro substitution products are readily assigned from their n.m.r. spectra. In each case the aromatic region exhibits the complex multiplets from the protons of the benzoyl ring in addition to the peaks of the nitro-substituted ring, the patterns for which are similar to the dimethylnitroacetophenone analogs. 3,4-Dimethyl-2-nitrobenzophenone exhibits the AB quartet with an 8 Hz coupling of the two *ortho* protons of the substituted ring at higher field than the multiplets of the phenyl ring. The 5-nitro isomer exhibits for the *meta* protons of the substituted ring an AB quartet with a 2 Hz coupling of which the low field doublet (6-H) is at lower field than the phenyl ring multiplets, and the higher field doublet (2-H) overlaps the phenyl ring part of the spectrum. The 6-nitro isomer exhibits two singlets for the *para* protons of the substituted ring, one of which (5-H) lies at lower field and the other (2-H) at higher field than the phenyl ring multiplets.

2-Benzoyl-4,5-dimethylphenol and 2-Benzoyl-4,5-dimethylphenyl Acetate

Diene **2** was treated with a concentrated solution of sodium methoxide as described above for diene **1**. After work-up, 2-benzoyl-4,5-diemthylphenol was obtained, m.p. 112–113.5° (lit. (12) m.p. 111–112°); i.r. (Nujol) 1635 cm^{-1} (C=O); n.m.r. ($CDCl_3$) τ 2.44 (m, 5, C_6H_5), 2.72 (s, 1, 3-*H*), 3.15 (s, 1, 6-*H*), 7.75 (s, 3, 5-CH_3), 7.87 (s, 3, 4-CH_3); mass spectrum (70 eV) *m/e* (relative intensity) 226 (7, M), 225 (8, M − H), 149 (25, M − C_6H_5), 120 (10), 105 (30), 93 (14), 91 (50), 77 (100).

The phenol was acetylated with acetic anhydride containing sulfuric acid to give 2-benzoyl-4,5-dimethylphenyl acetate, m.p. 69–70°; i.r. (Nujol) 1720 ($OCOCH_3$), 1670 (C=O), 1285, 1210, 1180, 735, and 705 cm^{-1}; n.m.r. ($CDCl_3$) τ 2.2 (m, 2, 2′-*H* and 6′-*H*), 2.45 (m, 3, 3′-*H*, 4′-*H*, and 5′-*H*), 2.65 (s, 1, 3-*H*), 3.01 (s, 1, 6-*H*), 7.65 (s, 3, 5-CH_3), 7.71 (s, 3, 4-CH_3), 8.08 (s, 3, $OCOCH_3$); mass spectrum *m/e* 268 (M).

*2-Benzoyl-2′,4,4′,5,6′-pentamethylbiphenyl (**16**)*

A solution of diene **2** (2 g, 6.3 mmol) and mesitylene in methylene chloride was treated with boron trifluoride etherate as described for diene **1**. After work-up, chromatography on silica gel and elution with pentane and 15% ether–pentane gave mesitylene in the pentane fractions, the biphenyl (1.8 g, 5.5 mmol) in the early ether–pentane fractions followed by 3,4-dimethyl-2- and 3,4-dimethyl-5-nitrobenzophenone (90 mg, 0.4 mmol). After recrystallization from ethanol 2-benzoyl-2′,4,4′,5,6′-pentamethylbiphenyl had m.p. 98–99.5°; i.r. (Nujol) 1675 (C=O), 1265, 900 and 725 cm^{-1}; n.m.r. ($CDCl_3$) τ 2.7 (m, 5, C_6H_5), 2.72 (s, 1, 3-*H*), 3.02 (s, 1, 6-*H*), 3.26 (s, 2, 3′-*H* and 5′-*H*), 7.71 (s, 6, 4-CH_3 and 5-CH_3), 7.81 (s, 3, 4′-CH_3) 8.03 (s, 6, 2′-CH_3 and 6′-CH_3); mass spectrum (70 eV) *m/e* (relative intensity) 328 (20, M) 313 (58, M − CH_3), 251 (100, M − C_6H_5), 132 (100), 105 (60), 77 (50), 43 (78).

Anal. Calcd. for $C_{24}H_{24}O$: C, 87.76; H, 7.37. Found: C, 87.70; H, 7.23.

Reaction of Diene 2 with Trifluoroacetic Acid

Trifluoroacetic acid (2.5 cm^3) was added dropwise to a stirred solution of diene **2** (1 g) in chloroform (10 cm^3). Brown fumes of NO_2 were given off. After work-up, 2-benzoyl-4,5-dimethylphenyl acetate was obtained, identified by n.m.r. and t.l.c.

Reaction of Diene 2 with Acetic Acid

A solution of diene **2** (0.5 g) in acetic acid (5 cm^3) was heated under reflux for 30 min. Brown fumes of NO_2 were given off. After work-up, 2-benzoyl-4,5-dimethylphenyl acetate was obtained. When the reaction was carried out at ambient temperature it took 14 days to go to completion.

Thermolysis of Diene 2

A solution of diene **2** (0.5 g) in toluene (10 cm^3) was heated under reflux. Brown fumes of NO_2 were given off. The toluene was distilled off and the residue was characterized as 2-benzoyl-4,5-dimethylphenyl acetate by n.m.r. and t.l.c.

Reaction of Diene 2 with Boron Trifluoride Etherate

Diene **2** (3 g, 9.5 mmol) was added to boron trifluoride etherate (3 cm^3). A vigorous reaction ensued. After work-up and chromatography on silica gel and elution with 20% ether–pentane, 3,4-dimethylbenzophenone (640 mg, 3 mmol), 3,4-dimethyl-5-nitrobenzophenone (580 mg, 2.3 mmol), and 3,4-dimethyl-2-nitrobenzophenone (770 mg, 3.0 mmol) were obtained.

Reaction of Diene 2 with 78% Sulfuric Acid

Diene **2** (0.5 g, 1.6 mmol) was stirred with 78% sulfuric acid (2 cm^3) overnight. After work-up and chromatography on silica gel, 3,4-dimethylbenzophenone (112 mg, 0.5 mmol), 3,4-dimethyl-5-nitrobenzophenone (100 mg, 0.4 mmol), and 3,4-dimethyl-2-nitrobenzophenone (120 mg, 0.5 mmol) were obtained.

Reaction of Diene 2 with Mesitylene in Acetic Acid Containing Sulfuric Acid

A solution of sulfuric acid (1.35 cm^3) in acetic acid (2.5 cm^3) was added dropwise to a solution of diene **2** (2 g, 6.3 mmol) in mesitylene (10 cm^3). After stirring for 1.5 h the mixture was neutralized and worked-up. Chromatography on silica gel and elution with pentane removed the excess mesitylene. Elution with 20% ether–pentane gave 2-benzoyl-2′,4,4′,5,6′-pentamethylbiphenyl (810 mg, 2.5 mmol) and a mixture of 3,4-dimethyl-2-nitro- and 3,4-dimethyl-5-nitro-benzophenone (640 mg, 2.5 mmol).

Juvabione and its Analogs.[1] Juvabione and $\Delta^{4'}$-Dehydrojuvabione Isolated from the Whole Wood of *Abies balsamea*, have the *R,R* Stereoconfigurations, not the *R,S*

JOHN FIEVE MANVILLE

Department of the Environment, Canadian Forestry Service, Western Forest Products Laboratory, 6620 N.W. Marine Drive, Vancouver, British Columbia V6T 1X2

Received December 4, 1974

JOHN FIEVE MANVILLE. Can. J. Chem. **53**, 1579 (1975).

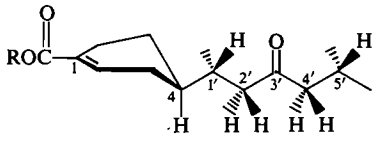
The petroleum ether soluble fractions from the whole wood meal of a number of native *Abies balsamea* (L.) Mill. var. *balsamea* and var. *phanerolepis* Fern. contain varying amounts of several juvabione analogs. These include the previously reported (+)-juvabione (**1***a*), atlantones (**2**), and lasiocarpenone (**3**). This paper describes the first isolation of (+)-$\Delta^{4'}$-dehydrojuvabione (*R,R*) (**5***a*) and proves the *R,R* stereoconfiguration for (+)-juvabione (**1***a*) isolated from native *Abies balsamea*. These results require that those samples previously isolated from a Slovak fir and which have the *R,S* stereoconfigurations, be renamed (+)-epijuvabione (**6**) and (+)-$\Delta^{4'}$-dehydroepijuvabione (**7**).

JOHN FIEVE MANVILLE. Can. J. Chem. **53**, 1579 (1975).

On a extrait des sciures entières de bois d'un certain nombre d'*Abies balsamea* (L.) Mill. var. *balsamea* et var. *phanerolepis* Fern. avec de l'éther de pétrole; les fractions solubles de ces variétés de notre pays contiennent des quantités variables de plusieurs analogues de juvabione. Ceux-ci incluent les produits rapportés précédemment à savoir la (+)-juvabione (**1***a*), les atlantones (**2**) et la lasiocarpénone (**3**). Dans ce travail, on décrit la (+)-$\Delta^{4'}$-déhydrojuvabione (*R,R*) (**5***a*) qui est isolée pour la première fois et l'on prouve la stéréoconfiguration *R,R* pour la (+)-juvabione (**1***a*) isolée d'*Abies balsamea*. Ces résultats impliquent que des échantillons isolés précédemment à partir d'un sapin Slovaque et qui ont des configurations *R,S* doivent être renommées (+)-épijuvabione (**6**) et (+)-$\Delta^{4'}$-dehydroépijuvabione (**7**). [Traduit par le journal]

Introduction

A number of continuing studies at the Western Forest Products Laboratory on the extractive composition of Canadian coniferous species (1–5) have shown that, in addition to (+)-juvabione (*R,R*) (**1***a*), several other related sesquiterpenes

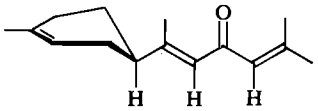


1

a R = CH_3

b R = H

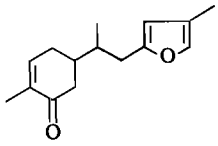
occur in many of the true firs (*Abies* sp.). These previously identified compounds include the atlantones (**2**) (4) and lasiocarpenone (**3**) (3).



2 (*Z* + *E* isomers)

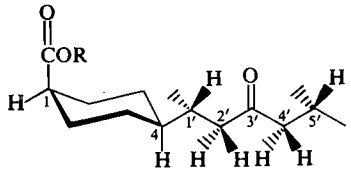
[1]Presented in part at the 167th National Meeting of the American Chemical Society, Los Angeles, California, April 1974.

Douglas fir (*Pseudotsuga menziessi* (Mirb.) Franco) also contains several juvabione analogs



3

(1, 6), including todomatuic acid (*R,R*) (**1***b*) and *cis*-dihydrotodomatuic acid (*R*) (**4***b*).



4

a R = CH_3

b R = H

The chemistry of the wood of balsam fir (*Abies balsamea* (L.) Miller) was largely ignored by extractive chemists until 1965, when Slama and Williams (7) discovered that paper towelling made from the wood of balsam fir contained an insect juvenile hormone analog (IJHA), which

For personal use only.

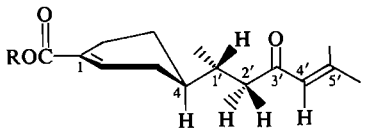
they first described as "the paper factor." Subsequently Bowers *et al.* (8) in 1966, isolated the only active component from native balsam fir and named this compound (+)-juvabione (**1***a*). Its structure was shown to be identical with the methyl ester of (+)-todomatuic acid (**1***b*) which had been first isolated (9) from bisulfite-treated pulp oil of a Japanese fir (*Abies sachalinensis* Schmidt).

In 1963, Nakazaki and Isoe had assigned (10) the *R,R* stereoconfigurations to (+)-todomatuic acid (**1***b*), after comparing the molecular rotations of **1***b* and its conversion products with a related series of natural compounds of known absolute stereochemistry. Thus (+)-juvabione (**1***a*) was described as (+)-4(*R*)-[1′(*R*)-5′-dimethyl-3′-oxohexyl]-1-cyclohexene-1-carboxylic acid methyl ester.

This paper will prove the stereochemistry of (+)-juvabione (**1***a*), isolated from the whole wood of *Abies balsamea* (L.) Mill. var. *balsamea* and var. *phanerolepis* Fern., to be *R,R* and will describe the first isolation and structural identification of (+)-$\Delta^{4'}$-dehydrojuvabione (*R,R*) (**5***a*).



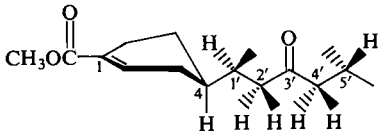
5

a R = CH_3
b R = H

The more recent literature, which "proves" a different stereochemistry for "natural (+)-juvabione" has, to this point, been purposely ignored so as to not unduly confuse the reader. A separate discussion of this *second* stereochemistry was considered necessary to establish clearly the correctness of *both* assignments.

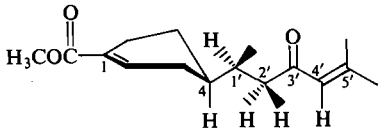
Clarification of Assignments of Stereochemistry to (+)-Juvabione

Following the initial discovery of "the paper factor" in North American balsam fir wood, Slama returned to Czechoslovakia in 1966 and with Cerny and co-workers (11) isolated two IJHA from a Slovak fir, which was purported to be a balsam fir, growing in the arboretum at Banska Stiavnica. Their study published in 1967 revealed the presence of, not only one compound (**6**) described as being (+)-juvabione but also a



6

second, slightly more active, IJHA (**7**) which they called dehydrojuvabione.



7

The next pertinent publications in this area were by Pawson *et al.* (12), in which the synthesis and absolute stereochemistry of all four diastereoisomers of juvabione were described. At this point, Pawson *et al.* (12) obtained a sample of the compound (**6**) isolated by Cerny *et al.* (11) and described by them as "natural (+)-juvabione" in order to assign the absolute stereoconfigurations to the natural product. At the same time, trivial names were given to the four diastereoisomers of juvabione.

Pawson *et al.* (12), not realizing the possibility that there could be two naturally occurring isomers of juvabione and believing that both isolations came from balsam fir trees, felt obliged to correct the original assignment of stereoconfiguration. They pointedly stated that the absolute stereochemistry of "natural (+)-juvabione" was *R,S*, not *R,R* as previously inferred by the study of Nakazaki and Isoe (10) on todomatuic acid (**1***b*). This *R,S* assignment was based on detailed optical rotatory dispersion (o.r.d.) and circular dichroism (c.d.) spectral comparisons between this natural product (**6**) and those of the four synthesized isomers of juvabione. Since an X-ray determination of structure for a key intermediate had been carried out (12*b*), there could be no question about the correctness of this assignment. Their *R,S* assignment for "natural (+)-juvabione" was widely accepted.

The stereospecific synthesis of *d,l*-juvabione as described in a recent paper (13), must in fact give (±)-epijuvabione. Also, the hydrolysis of this synthetic material gives (±)-epitodomatuic acid not (±)-todomatuic acid as was deduced by these authors who were guided by the literature.

Slama *et al.* (14) have just published a super-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

lative text titled "Insect Hormones and Bioanalogues" in which they unfortunately imply the original assignment by Nakazaki and Isoe (10) is erroneous and that (+)-juvabione has the *R,S* stereoconfigurations.

Nevertheless, this *R,S* assignment has not been universally accepted (1, 6). In fact, as this study will prove, natural (+)-juvabione (**1***a*) isolated from balsam fir has the *R,R* stereoconfigurations. At first, this statement seems to contradict an assignment of stereochemistry based on an absolute X-ray determination of structure but, as will be shown, the assignment of stereochemistry to that compound isolated by Cerny and coworkers (11) is not in question. The resolution of this seemingly contradictory statement lies in the previously unrealized facts that there must be *two* naturally occurring forms of (+)-juvabione (**1***a* and **6**) and that both assignments of stereochemistry are correct. However only one isomer is (+)-juvabione (**1***a*), the other is (+)-epijuvabione (**6**).

Since Bowers *et al.* (8) did not obtain either o.r.d. or c.d. curves for their isolated (+)-juvabione and original samples were no longer available, it was necessary to repeat their isolation (present study) to determine the absolute stereochemistry of (+)-juvabione. The study of Pawson *et al.* (12) indicated that comparisons of $[\alpha]_D$ values and melting points of the derived acids were basically unreliable in differentiating between the *R,S* and *R,R* isomers of (+)-juvabione.

Re-examination of the work of Cerny *et al.* (11) has provided an explanation for the fact that a *second* isomer of (+)-juvabione was actually isolated. Recent investigations indicate that this sampled tree, from the grove labeled as "*A. balsamea* L." in the arboretum at Banska Stiavnica, is not a balsam fir. This Slovak fir is now labeled as "*A. balsamea* – dubious – dying" but it is possibly a putative cross.[2]

This should be a lesson to all who work with biological materials. It indicates the need for all chemical and other investigations to be carried out only on authentic samples obtained from typical populations sampled and/or identified by experts. Arboretum samples should be avoided.

[2]Private communications with L. Greguss, Banska Stiavnica, Czechoslovakia; O. Sziklai and J. G. Worrall, Faculty of Forestry, University of British Columbia, Vancouver, B.C.; and E. von Rudloff, National Research Council of Canada, Saskatoon, Saskatchewan.

The sample (**6**) isolated by Cerny *et al.* (11) should be known as (+)-epijuvabione, since it was *not* isolated from the wood of *Abies balsamea* (L.) Mill. and it was *not* the first isolation of "natural (+)-juvabione."

Thus, it is now apparent that Pawson *et al.* (12*a*) using this *second* isolated "natural (+)-juvabione" ((+)-epijuvabione (*R,S*) (**6**)) from a "Slovak fir" and assuming it to be identical with (+)-juvabione [*R,R*] (**1***a*) isolated (8) from a native *A. balsamea*, named the wrong isomer (+)-juvabione, resulting in the ensuing confusion in the chemical literature (1, 6, 10, 11, 13, 14).

The correct names of the four diastereoisomers of juvabione will be (+)-juvabione (*R,R*), (+)-epijuvabione (*R,S*), (−)-juvabione (*S,S*), and (−)-epijuvabione (*S,R*).

Isolation

The petroleum ether soluble fractions from the ethanol extracts of the whole wood of balsam firs were pale yellow mobile oils. They were partially separated by ion exchange chromatography on DEAE-Sephadex A-25 (15), selecting only the neutrals fraction for study. Gas–liquid chromatographic (g.l.c.) analysis revealed (see Fig. 1) the presence of up to six major components which did not correspond to any of the common fatty

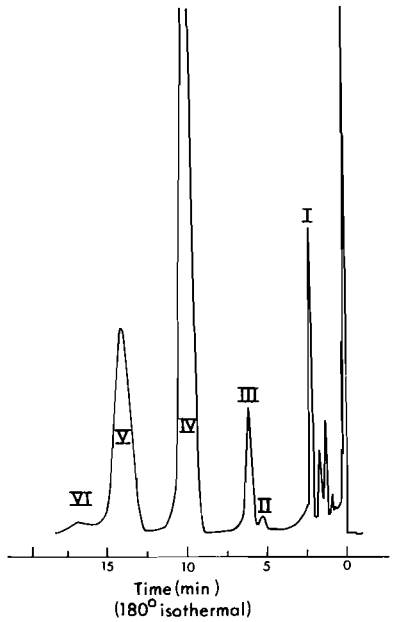


FIG. 1. Gas–liquid chromatogram of the petroleum ether solubles from the whole wood of *Abies balsamea* var. *phanerolepis* Fern.

For personal use only.

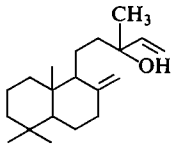
or resin acid methyl esters. Silicic acid column chromatography effected separation of some of the major components from the extractive mixture. Compounds **2**, **8**, and **3**, corresponding to peaks I, II, and III on the g.l.c. chromatogram, were separated from the rest by eluting with petroleum ether – ether (5:1); next were eluted (petroleum ether – ether, 4:1) two compounds (**2***a* and **5***a*) that gave rise to peaks IV and VI. Finally, a more polar component (peak V) was eluted. The identification of this unknown alcohol will be the subject of a forthcoming publication.

The last eluted (g.l.c.) component (**5***a*) (peak VI) was eventually separated from **1***a* by repeated column chromatography using Woelm silica gel-I and petroleum ether – ether (4:1) as developing solvent.

This sample of **5***a*, however, contained a mixture of C_{22} and C_{24} *n*-alcohols which crystallized from an acetone solution on standing in the freezer overnight.

Results

The first three major components were identified by g.l.c. retention times (r_t) (relative to internal (+)-juvabione), nuclear magnetic resonance (n.m.r.), and mass spectrometry (m.s.) relative to authentic materials isolated from *Abies lasiocarpa* and provided by Dr. E. P. Swan of this laboratory (2–4). They were the atlantones (**2**), r_t 0.25, manool (**8**), r_t 0.53, and lasiocarpenone (**3**) r_t 0.63. The latter compound, if present, causes a bright red-purple streak on the freshly exposed wood surface[3] and a red-purple spot on silicic acid t.l.c. plates to appear, when reacted with Ehrlich's reagent (5).



8

This study indicates a considerable degree of variation in the amounts of the various components in each wood sample (Table 1). Moreover, not all wood samples were found to contain manool (**8**) and/or, lasiocarpenone (**3**). Only one sample contained **3**; it was a balsam fir from Newfoundland (*A. balsamea* var. *phanerolepis* Fern.). The presence of **3** might serve as a means for chemotaxonomic differentiation between the varieties of *A. balsamea*. Further work on the occurrence of lasiocarpenone (**3**) is underway.

The fourth major component (peak IV) reported in this study had p.m.r., i.r., and mass spectra similar to those reported (1, 6, 8, 12) for (+)-juvabione (*R,R*) (**1***a*). The o.r.d. and c.d. curves were in accord with the published data (1, 12) for the *R,R* isomer of (+)-juvabione. The purity (g.l.c. 99.4%) of this isolated material was significantly improved over earlier isolations and had $[\alpha]_D^{25}$ +82.6°, which is much higher than earlier reported (1, 6, 12) and very close to the $[\alpha]_D^{25}$ of the saponified product **1***b* ($[\alpha]_D$ +85.6°, lit. (8) value +87°).

Compound **5***a*, corresponding to peak VI (g.l.c.), had the empirical formula $C_{16}H_{24}O_3$ as determined by high resolution mass spectrometry. The i.r. spectrum showed the compound to be an α,β-unsaturated ketone in *s-cis* conformation (1621, 1690 cm^{-1}) and an α,β-unsaturated carboxylic acid methyl ester (bands at 1441, 1654, and 1720 cm^{-1}). The p.m.r. and mass spectra were very similar to those reported (11) for (+)-dehydroepijuvabione (**7**). Whereas in general, the p.m.r. showed only slight random variations (±0.02 p.p.m.) between observed and quoted δ values (11), one of the C-5′ methyl groups resonated to higher field by 0.08 p.p.m. (δ 1.88 *vs.* 1.96) for **5***a* relative to the same group in **7**. Also the observed $[\alpha]_D^{23}$ of +57° was much lower than reported (11) for **7** ($[\alpha]_D$ +102°).

These spectroscopic similarities (i.r., m.s.) and differences (n.m.r., $[\alpha]_D$), together with the known fact that (+)-epijuvabione (**3***a*) isolated from a tree in an arboretum in Czechoslovakia was *R,S* (12), indicated that **5***a* was most likely to contain the *R,R* stereoconfigurations; whereas the Czechoslovakian sample (**7**) was undoubtedly, although never shown to be, the *R,S* isomer. Thus the "dehydrojuvabione" isolated by Cerny and co-workers (11) should be referred to as (+)-$\Delta^{4'}$-dehydroepijuvabione (**7**).

The *R* stereoconfiguration was assigned to C-4 based on the facts that the $[\alpha]_D$ was positive and the o.r.d. curve (Fig. 2) for **5***a* was similar to the o.r.d. curves of the *R,R* and *R,S* isomers of juvabione (12*a*) and clearly unlike either the *S,S*

[3]It is important to first remove the bark to eliminate any possible wood surface contamination from the bark constituents, which are known to contain varying amounts of other Ehrlich's positive compounds (indole acetic acid, its derivatives and catabolism products) and which can give rise to *false* positive indications of the occurrence of lasiocarpenone (**3**) in the heartwood.

*Site locations: (*1*) C.F.S. Research Forest, Petawawa, Ontario; (*2*) 10 miles outside St. John's, Newfoundland; (*3*) Fife Lake Road 4.7 miles north of main Gargantua Road and (*4*) Miron Lake Road 4.0 miles north of main Gargantua Road, both inside Lake Superior Provincial Park, Ontario.

†Bracted variety (var. *phanerolepis* Fer.), gave red-purple color with Ehrlichs' reagent.

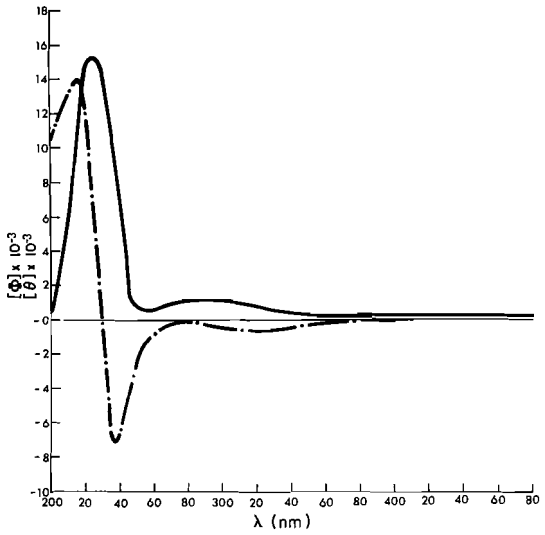

FIG. 2. The o.r.d. (———) and c.d. (—·—·) curves for $\Delta^{4'}$-dehydrojuvabione (**5***a*).

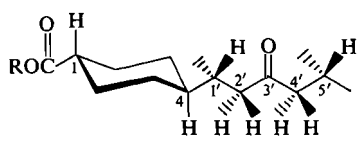
or *S,R* isomers; (Note: this center has always been shown (3, 7, 8) to be *R* for all naturally occurring samples). The remaining center (C-1′) could not be unambiguously assigned from either the o.r.d. or c.d. curves of **5***a* because of extra absorption bands present due to the conjugated double bond. However, this center was proven to be *R* by observing the o.r.d. curve of fully hydrogenated **5***a* (compounds **4***a* and **9**) (1).



9

In keeping with the nomenclature now established for the isomers of juvabione, this new compound (**5***a*), isolated from *A. balsamea* growing in North America and described as (+)-4(*R*)-[1′(*R*)-5′-dimethyl-3′-oxohex-4′-ene]cyclohex-1-ene-1-carboxylic acid methyl ester, should be known as (+)-$\Delta^{4'}$-dehydrojuvabione.

It is interesting to speculate on the fact that Bowers and co-workers (8) were not successful in finding (+)-$\Delta^{4'}$-dehydrojuvabione (**5***a*) in the whole wood extract of a North American grown balsam fir. One possibility is that **1***a* was not an IJHA under the screening conditions, whereas the *R,S* isomer (**7**) was an IJHA (11). Thus any fraction of the extract containing **5***a* but no **1***a* would not have been investigated due to the fact that they were only looking for the active component(s) of this extract. Another possibility is that **5***a* does not occur in sufficient amounts in all balsam fir trees to have been detected as a separate component by their separation and/or screening procedures.

This latter possibility is supported by the observation of a considerable degree of tree-to-tree variation in the relative amounts of the various extractives. In particular, the amounts of dehydrojuvabione (**5***a*) (see Table 1) range from a low of 4.1% of the petroleum ether soluble neutrals to a high of 66.5%, whilst juvabione (**1***a*) goes from 56.9 to 10.9% in the same tree. Undoubtedly, some of this variation is due to site differences; however, trees 5 and 6 which are from the same site show a considerable variation in the relative amounts of **5***a* and **1***a*. It is believed that such variations reflect the individualistic biochemical differences that exist between trees and that no two trees are identical.

In summary, this study has shown the atlantones (**2**), manool (**8**), lasiocarpenone (**3**), (+)-juvabione (*R,R*) (**2***a*), (+)-$\Delta^{4'}$-dehydrojuvabione (*R,R*) (**5***a*), together with an unknown alcohol (g.l.c. peak V), to be present in the whole wood of balsam fir.

Experimental

The general methods and spectral measurements followed the format outlined previously (1). All retention times (g.l.c. r_t) are relative to internal (+)-juvabione (**1***a*). Optical rotations were recorded on a Perkin Elmer-141-Polarimeter made available by the Chemistry Department, University of British Columbia. The o.r.d. and c.d. curves for compounds **5***a* and **1***a* were kindly provided by Dr. V. Toome of the Physical Chemistry Department, Hoffman-LaRoche Inc., Nutley, N.J.

Table 1 lists chemical constituents data for each individual tree studied in this investigation, together with its site location, age, and diameter. The *A. balsamea* (L.) Mill. tree No. 2 was the only sample of the bracted variety (var. *phanerolepis* Fern.) and was kindly provided by Dr. John Hudak, Canadian Forestry Service (C.F.S.), St. Johns, Newfoundland. Tree No. 1 came from the Petawawa Forest Experiment Station, Petawawa, Ontario. Trees numbered 3–6 were provided by Dr. R. Whitney of the Great Lakes Forest Research Centre, Sault Ste. Marie, Ontario.

Trees 1, 2 and 3 were studied in detail, including the isolation of individual components. Trees 4–6 were examined by g.l.c.

Isolation

In each case, debarked whole wood was air dried and ground in a Wiley mill to pass a 5-mm screen. The wood meal was then extracted over a 12-h period in an all-glass Soxhlet apparatus with ethanol. The recovered yellow oils were taken up in methanol–water (6:4) (100 ml/g of extract) and the petroleum ether (b.p. 65–70°) solubles were extracted. These extracts were then dried (Na_2SO_4) and the petroleum ether removed under reduced pressure. Yields and other details are listed in Table 1. These oils were redissolved in ether-methanol and chromatographed on a column of DEAE-Sephadex-A25 according to an established procedure (15). Elution with the starting solvent yielded a neutrals fraction (80% yield). The column was then stripped with 4% formic acid solution and the acids fraction was set aside for study at some future date. Analysis by g.l.c. of the neutrals fraction confirmed the presence of **1***a*, **2**, **3**, **8**, and **5***a* (see Fig. 1). Compounds **1***a* and **5***a* could be easily recovered as a pair by chromatographing the petroleum ether solubles on a column of Woelm – silica gel. Then by careful rechromatographing, using petroleum ether – diethyl ether (3:1) at lower loadings, it was possible to obtain samples of **1***a* and **5***a* which were free of each other. In this liquid chromatography, 20 ml fractions were collected and monitored by g.l.c. and t.l.c.: fractions 1–32 contained traces of **2**, **3**, and **8**; 33–40 contained **1***a*; 41–49 contained a mixture of **1***a* and **5***a*, and 50–60 contained **5***a*. The fractions containing **5***a* were dissolved in acetone and placed in the freezer (−10°) for 12 h during which time the C_{22} and C_{24} *n*-alcohols (identified by g.l.c. r_t values (0.99 and 1.84), m.s., and n.m.r.) crystallized out together and were filtered from solution.

Compound 1a ((+)-Juvabione)

Compound **1***a* was a colorless oil, which by g.l.c. was better than 99% pure; it had physical and spectral parameters in accord with those published (1, 8, 11) for (+)-juvabione (*R,R*), except for $[\alpha]_D^{25}$ (*c* 1.1, $CHCl_3$) +82.6°; (*c* 1.2, MeOH) +77.9° which are greater than those reported earlier (1, 8, 11). Compound **1***a* was saponified to todomatuic acid (**1***b*), m.p. 58.5–61° and $[\alpha]_D^{25}$ (*c* 0.5, EtOH) +85.6°, lit. (8) m.p. 57–59°, $[\alpha]_D$ +87°.

Compound 5a ((+)-$\Delta^{4'}$-Dehydrojuvabione)

Compound **5***a* was a colorless oil and had t.l.c. r_t 0.36 (silicic acid, petroleum ether – ether, 3:1), g.l.c. r_t 1.66, and $[\alpha]_D^{25}$ (*c* 0.68, CH_3OH) +49.0° or +57.4° (*c* 1.08, $CHCl_3$). The o.r.d. (*c* 0.322, C_2H_5OH; 23°) $[\Phi]_{700}$ +86°, $[\Phi]_{500}$ +197°, $[\Phi]_{411}$ +262° (peak), $[\Phi]_{365}$ +195° (trough), $[\Phi]_{284}$ +1157° (peak), $[\Phi]_{250}$ +717° (trough), $[\Phi]_{226}$ +15 372°, $[\Phi]_{200}$ 0°. The c.d. (0.012197 M, C_2H_5OH; 23°) $[\theta]_{388}$ 0°, $[\theta]_{325}$ −590°, $[\theta]_{274}$ −94°, $[\theta]_{237}$ −7175°, $[\theta]_{230}$ 0°, $[\theta]_{216}$ +13 530° $[\theta]_{200}$ +10 660°. The p.m.r. (100 MHz $CDCl_3$) δ 6.94_6 (1H, multiplet, H_2), 6.06_7 (1H, septet, J = 1.2 Hz, H_4'), 3.71_5 (3H, singlet, methyl ester), 2.14_1 (3H, doublet, J = 1.2 Hz, C-5′ *cis*-methyl), 1.88_3 (3H, doublet, J = 1.2 Hz, C-5′ *trans*-methyl), 0.90_5 (3 H, doublet, J = 6.5 Hz, C-1′ methyl), 2.7–1.0 (10 H). Mass spectrum (*m/e*): 264(0.6%) (M), 232(11.5) ($M-32$), 205(1.7), 204(4.1), 177(1.1), 167(3.8), 166(18.8) 164(1.3), 151(2.9), 139(2.0), 137(1.7), 134(33.4), 131(1), 126(1.5), 125(15), 123(1.4), 121(1.1), 107(11.02), 99(14), 98(24.3), *83*(100), 79(9.8), 59(4.3), and 55(25.4). Mol. wt. Calcd. for $C_{16}H_{24}O_3$: 264. 1724. Found (high resolution mass spectrometry): 264. 1757.

Hydrogenation of 5a

Compound **5***a* (183 mg) was dissolved in methanol (12 ml) containing palladium-on-charcoal (10% Pd, 200 mg). Hydrogenation was conducted at room temperature at 24 p.s.i. in a Parr bomb for 4 h. After removal of the catalyst by filtration, the product was recovered. Gas–liquid chromatography showed complete reaction with two products (g.l.c. r_t 0.40 and 0.55; **4***a* and **9** (3)) in a ratio of 1:2 with $[\alpha]_D^{25}$ (*c* 0.44, methanol) −6.7°. The o.r.d. curve of this mixture (*c* 0.443, methanol; 23°) $[\Phi]_{400}$ ≃0°, $[\Phi]_{350}$ −145°, $[\Phi]_{307}$ −871°, $[\Phi]_{292}$ 0°, $[\Phi]_{266}$ +1597°, molecular amplitude −24.7, was in agreement with that reported earlier (1).

The author wishes to thank Dr. V. Toome for providing the o.r.d. and c.d. curves of juvabione and $\Delta^{4'}$-dehydrojuvabione, and Drs. L. Greguss, O. Sziklai, E. von Rudloff, J. G. Worral, and Mr. S. Rowe for helpful discussions on the species identifications. Excellent technical assistance was provided by Mr. John Consiglio.

Combinatorial Entropy of Mixing Molecules that Differ in Size and Shape. A Simple Approximation for Binary and Multicomponent Mixtures

MARC D. DONOHUE AND JOHN M. PRAUSNITZ

Chemical Engineering Department, University of California, Berkeley, California 94720

Received October 1, 1974

MARC D. DONOHUE and JOHN M. PRAUSNITZ. Can. J. Chem. **53**, 1586 (1975).

For liquid solutions, the combinatorial entropy of mixing is commonly calculated using either (*a*) the ideal-solution model (suitable for mixtures of simple spherical molecules) or (*b*) the Flory lattice model (suitable for mixtures of chainlike molecules). Based on the lattice theories of Huggins, Staverman, Tompa, and Lichtenthaler for molecules of arbitrary size and shape, this work proposes an *ad hoc* generalization of Flory's formula for the combinatorial entropy of mixing in binary and multicomponent solutions. The generalized Flory model yields results that are always intermediate between those obtained from (*a*) and (*b*). Parameters required for the calculations are found from molecular structure data (bond angles and distances). Illustrative calculations are given for the system carbon tetrachloride – octamethylcyclotetrasiloxane.

MARC D. DONOHUE et JOHN M. PRAUSNITZ. Can. J. Chem. **53**, 1586 (1975).

Pour des solutions liquides, on calcule généralement l'entropie combinatoire de mélange en faisant appel soit (*a*) au modèle de la solution idéale (applicable pour des mélanges de molécules sphériques simples) ou (*b*) au modèle de réseau de Flory (applicable aux mélanges de molécules sous forme de chaines). En se basant sur les théories de réseau de Huggins, Staverman, Tompa et Lichtelthaler pour des molécules de grosseur et de forme arbitraire, ce travail propose une généralisation *ad hoc* de la formulation de Flory pour les entropies combinatoires de mélange dans des solutions binaires et à plusieurs constituants. La généralisation du modèle de Flory conduit à des résultats qui sont toujours intermédiaires entre ceux obtenus à partir de (*a*) ou de (*b*). On trouve les paramètres requis pour les calculs en se basant sur des données de structures moléculaires (angle de valence et distance). On donne des calculs illustrant la méthode pour le système tétrachlorure de carbone – octaméthylcyclotétrasiloxanne.

To interpret and correlate thermodynamic properties of liquid mixtures, it is customary to reduce experimental data by calculating residual properties, that is, properties in excess of those calculated from a model which serves as a reference. The values of the residual properties, in particular that of the residual entropy, depend on the reference model chosen. In this work we propose a reference model which is simple to use and which interpolates smoothly between the two common reference models.

Residual Properties

A residual property is defined as the observed change in that property upon mixing (at constant temperature and pressure) minus the calculated change in that property upon mixing (at the same temperature, pressure, and composition) where the calculation is determined by the choice of reference model. Two common reference models are the ideal solution introduced by Raoult nearly 100 years ago, and the athermal lattice due primarily to Flory (1) and to Huggins (2).

Residual Entropy

For a binary solution containing N_1 molecules of component 1 and N_2 molecules of component 2, the residual entropy is given by

$$[1] \qquad S^R = \Delta S(\text{observed}) - \Delta S^C$$

where superscript R stands for residual and superscript C stands for combinatorial; ΔS^C is determined by the choice of reference model.

Ideal solution

$$[2] \qquad \frac{\Delta S^C}{R} = -\left[N_1 \ln \frac{N_1}{N_1 + N_2} + N_2 \ln \frac{N_2}{N_1 + N_2}\right]$$

Flory lattice

$$[3] \qquad \frac{\Delta S^C}{R} = -\left[N_1 \ln \phi_1 + N_2 \ln \phi_2\right]$$

where R is the gas constant and ϕ is the site fraction

TABLE 1. Exponent in Generalized Flory Equation for combinatorial entropy of mixing

15									572
10									428

$$\phi_1 = \frac{N_1 r_1}{N_1 r_1 + N_2 r_2}$$

$$\phi_2 = \frac{N_2 r_2}{N_1 r_1 + N_2 r_2}$$

where r_i is the number of lattice sites occupied by molecule i.

Both eqs. 2 and 3 always give positive ΔS^C. When $r_1 = r_2$, eqs. 2 and 3 are identical. However, when r_1 and r_2 are not equal, eq. 3 always gives a combinatorial entropy larger than that given by eq. 2 at the same N_1 and N_2. Much discussion of these equations has led Hildebrand (3) to the conclusion that eq. 2 gives a lower limit to the combinatorial entropy of mixing and eq. 3 gives an upper limit; the "true" combinatorial entropy lies in between.

Equations 2 and 3 can be combined into a single expression by introducing one exponent p for each component

$$[4]\quad \frac{\Delta S^C}{R} = -\left[N_1 \ln \frac{N_1 (r_1)^{p_1}}{N_1 (r_1)^{p_1} + N_2 (r_2)^{p_2}} + N_2 \ln \frac{N_2 (r_2)^{p_2}}{N_1 (r_1)^{p_1} + N_2 (r_2)^{p_2}}\right]$$

When $p_1 = p_2 = 0$, eq. 4 reduces to eq. 2 and when $p_1 = p_2 = 1$, eq. 4 reduces to eq. 3. Hildebrand's conclusion, then, suggests that the exponent p_i lies somewhere between zero and unity.

Evaluation of Exponent p_i

Modifications of eq. 3 have been presented by several authors, including Huggins (2), Staverman (4), and Tompa (5) and most recently by Lichtenthaler *et al.* (6*a*, *b*).[1] The modifications introduced by Lichtenthaler, similar to those of Tompa, provide a reasonable method for calculating ΔS^C for mixtures of molecules differing in size as well as shape. Combinatorial entropies calculated from Lichtenthaler's expression lie in between those found from eqs. 2 and 3. However, Lichtenthaler's equation is cumbersome and cannot be generalized to mixtures containing more than two components. We propose here that eq. 4 be used to calculate combinatorial entropies of mixing with exponents p_i based on Lichtenthaler's work as discussed below.

The size of a molecule i is given by the parameter r_i and the external surface area of that molecule is given by the parameter q_i. When the lattice coordination number is designated by z, the product $q_i z$ gives the number of external lattice-site contacts available to molecule i for interaction with other, nearest-neighbor molecules. The ratio $(q/r)_i$ is a measure of the molecule's shape; for a monomer $q/r = 1$. As r becomes very large,

[1] Misprint in eq. 4 of ref. 6*a* corrected in eq. 9 of ref. 6*b*.

	Chloroethane	2.12	82.5

$q/r \to 2/3$ for a linear chain, and $q/r \to 0$ for a sphere (or cube). For a globular molecule the parameter q/r lies between zero and unity.

To use eq. 4, we postulate that for molecule i, p_i depends only on r_i and on $(q/r)_i$. We then calculate p_i by applying eq. 4 to the case where molecules i are mixed with monomers j ($r_j = q_j = 1$). The exponent p_i is found by obtaining the best possible agreement between ΔS^C as obtained from eq. 4 and ΔS^C as obtained from Lichtenthaler's model. (A more precise explanation of "best possible agreement" is given in the Appendix.) Results of these calculations are shown in Table 1 and in Fig. 1.

Evaluation of Parameters r and q

To obtain numerical values for r and q, we use bond angle and bond distance data as described by Bondi (7). Parameters r and q depend only on molecular size and structure; they are independent of temperature or density.

Table 2 gives parameters r and q for molecules of some common fluids. The parameters listed are relative to those for methane, *i.e.* in Table 2, $r = q = 1$ for methane.

Parameters r are found from van der Waals volumes v^* as calculated by Bondi's group-contribution method (7). For the results shown in Table 2

$$[5] \qquad r_i = v_i^*/v^*(\text{methane})$$

where $v^*(\text{methane}) = 17.1\ \text{cm}^3/\text{mol}$.

Parameters q are found by a procedure slightly different from Bondi's, as described by Lichtenthaler (6). Lichtenthaler's equation for ΔS^C is based on a simple cubic lattice with coordination number equal to 6; it follows that the surface area of a cube of volume v^* is given by $6(v^*)^{2/3}$. Following Lichtenthaler, we represent molecule i by a rectangular box with linear dimensions l_x, l_y, and l_z. The parameter q_i, as reported in Table 2, is calculated from

$$[6] \qquad q_i = \frac{2(l_x l_y + l_x l_z + l_y l_z)_i}{6(v^*)^{2/3}_{\text{methane}}}$$

Linear dimensions l_x, l_y, and l_z are found from molecular structure data.

Parameters r and q shown in Table 2 are arbitrarily normalized with respect to methane. Therefore if these parameters are used in eq. 4, the calculations are based on a monomer whose size is equal to that of methane. If we wish to use some

For personal use only.

other molecule as the monomer, a new set of parameters r and q can be calculated by simple scaling

[7] r_i(relative to monomer j) = $\dfrac{r_i(\text{relative to methane})}{r_j(\text{relative to methane})}$

[8] q_i(relative to monomer j) = $\dfrac{q_i(\text{relative to methane})}{q_j(\text{relative to methane})}$

In obtaining ΔS^C from eq. 4, one must decide on an appropriate choice for the monomer. This choice may well differ from one mixture to another.

To obtain numerical results with eq. 4, a monomer must be chosen to obtain numerical values for r and q/r. While these parameters in turn influence the value of p (Table 1), we must emphasize that the calculations leading to Table 1 and Fig. 1 are independent of the choice of monomer (see Appendix). In finding values of the exponent p which give best agreement between eq. 4 and Lichtenthaler's equation, it was *not* necessary to use a particular molecule (such as methane) for the monomer. Therefore while Table 2 gives numerical results based on a particular choice of monomer, the results shown in Table 1 and Fig. 1 are independent of that choice; they are not linked with the structural parameters given in Table 2.

Results

We refer to eq. 4 as the Generalized Flory Model. Its main advantage follows from its simplicity; molecular parameters r and q can be calculated from molecular structure data and parameters p can then easily be estimated from Table 1 or Fig. 1.

For binary mixtures of monomers with long linear chains, or for mixtures of linear chains differing markedly in length, parameter p_i is close to unity for both components and, as expected, there is little difference between eqs. 3 and 4. However, for mixtures containing either bulky molecules or short chains, combinatorial entropies calculated from eq. 4 are appreciably smaller than those found from eq. 3. To illustrate, it is convenient first to define an excess combinatorial entropy and second, to present a numerical example shown by Figs. 2 and 3.

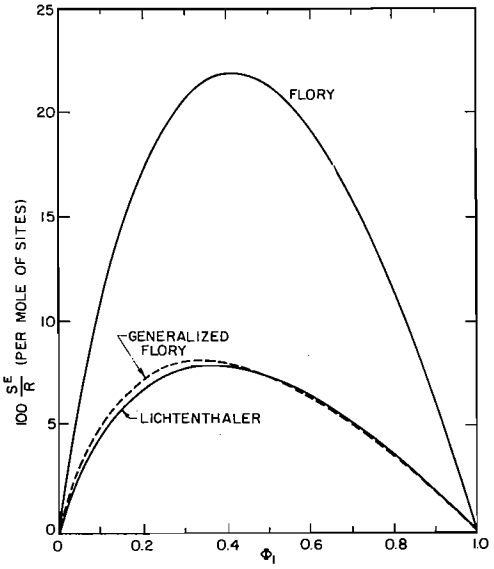

FIG. 2. Excess combinatorial entropy (per mol of sites) for binary mixture of monomers with cubes ($r = 10$, $q/r = 0.464$).

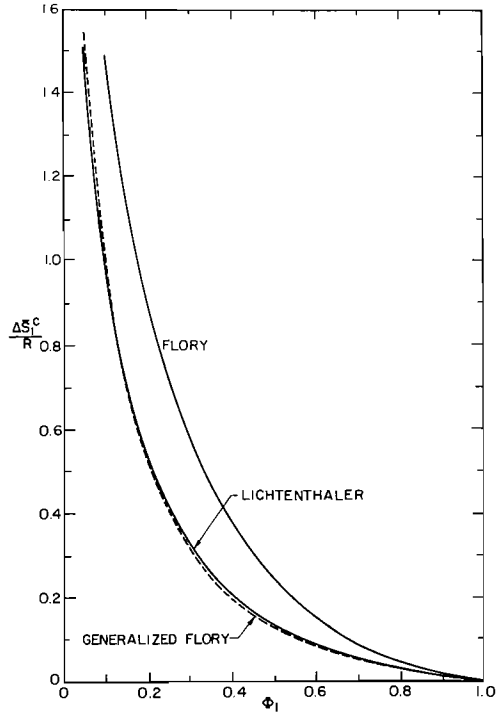

FIG. 3. Partial molar combinatorial entropy of monomers in a binary mixture with cubes ($r = 10$, $q/r = 0.464$).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

The excess combinatorial entropy per mole of sites, designated by S^E, is defined by

$$[9]\quad \frac{S^E}{R} = \left[\frac{\Delta S^C}{R}\left(\begin{matrix}\text{per mole}\\ \text{of mixture}\end{matrix}\right) + \left(\frac{N_1}{N_1+N_2}\right)\ln\frac{N_1}{N_1+N_2} + \left(\frac{N_2}{N_1+N_2}\right)\ln\frac{N_2}{N_1+N_2}\right] \times \left[\frac{N_1+N_2}{r_1N_1+r_2N_2}\right]$$

Figure 2 shows the excess combinatorial entropy of mixing for a solution containing monomers ($q_1 = r_1 = 1$) and large cubes ($r_2 = 10$, $(q/r)_2 = 0.464$). Calculations were performed, first, using the Flory Model ($p_1 = p_2 = 1$) and second, using the Generalized Flory Model ($p_1 = 1$, $p_2 = 0.646$). The corresponding partial molar combinatorial entropies for the monomer are shown in Fig. 3.

Similar calculations were performed for a solution containing monomers ($q_1 = r_1 = 1$) and very large cubes ($r_2 = 100$, $(q/r) = 0.215$); the results are qualitatively similar to those shown in Figs. 2 and 3 but now the difference between eqs. 3 and 4 is even more pronounced.

Evaluation of r and q. Effect of Monomer Size

To use eq. 4, it is necessary to specify for each component values of r and q/r which are relative to those of a chosen monomer size. In general, the choice of monomer size affects the numerical value of ΔS^C; only when all p_i are the same does the monomer size cancel. The need to specify the size of a monomer is not peculiar to the Generalized Flory Model; the same need arises if one wants to use the combinatorial-entropy formulas of Huggins (2), Staverman (4), Tompa (5), or Lichtenthaler (6). Specification of monomer size must be based on physical considerations, that is, on the dimensions and flexibility of the molecules present in a particular mixture. The higher the flexibility, the smaller the monomer size.

To illustrate the effect of monomer size, we consider a binary mixture of globular molecules differing appreciably in size, carbon tetrachloride – octamethylcyclotetrasiloxane (OMCTS). In the first calculation we consider carbon tetrachloride to be the monomer; thus $r_1 = q_1 = 1$ and $r_2 = 3.19$ and $(q/r)_2 = 0.680$. In the second calculation we consider carbon tetrachloride not as a monomer but as a globular molecule and we choose methane as the monomer. In this case $r_1 = 3.06, (q/r)_1 = 0.689$; for OMCTS $r_2 = 9.77$ and $(q/r)_2 = 0.468$. Calculated excess combinatorial entropies are shown in Fig. 4.

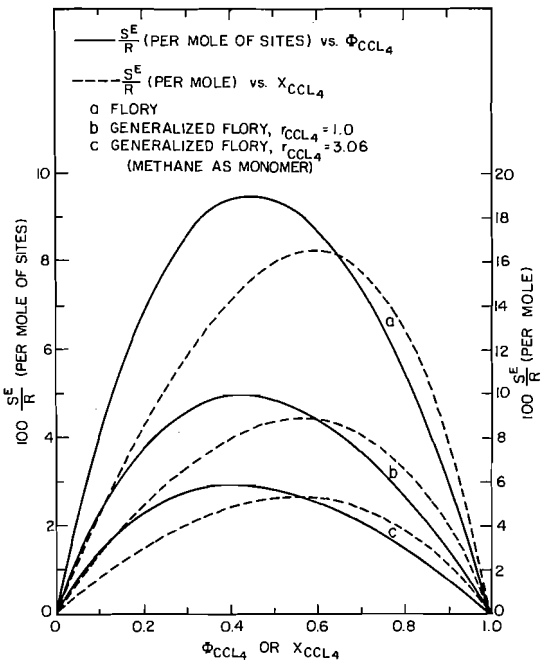

FIG. 4. Effect of monomer size on excess combinatorial entropy for mixtures of carbon tetrachloride with octamethylcyclotetrasiloxane.

Figure 4 shows that the choice of monomer size has an appreciable effect on the combinatorial entropy for this particular binary mixture; we have intentionally chosen this mixture of spherical molecules to dramatize the effect. As the shape of the larger molecule becomes less spherical and more chainlike, the effect of monomer size declines rapidly.

Experimental data of Marsh and Tomlins (8) were used to calculate residual entropies for carbon tetrachloride – OMCTS; results are shown in Fig. 5. In this case the residual entropy obtained from the data is strongly dependent on the expression used for the combinatorial entropy. The residual entropy is negative when the Flory combinatorial entropy is used but it is positive when the ideal-combinatorial entropy is used. Calculations based on the generalized Flory combinatorial entropy are in semiquantitative agreement with those obtained from hard-sphere calculations based on the Carnahan–Starling ver-

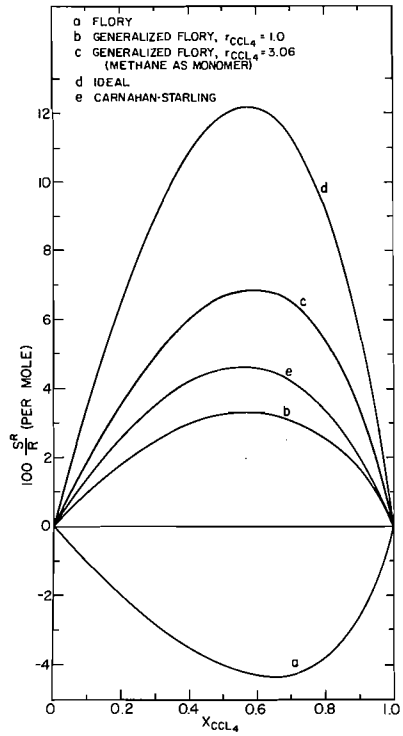

FIG. 5. Residual entropy per mol for mixtures of carbon tetrachloride and octamethylcyclotetrasiloxane at 25 °C.

sion of Percus–Yevick theory (9). In the latter calculations the hard-sphere diameters were obtained from pure-component entropy-of-vaporization data which yielded 5.25 Å for carbon tetrachloride and 8.12 Å for OMCTS. Volumetric data for the mixture were also obtained from Marsh and Tomlins (8).

The residual entropy of mixing for carbon tetrachloride – OMCTS can be calculated from an equation of state as discussed by Marsh (10). Using Marsh's calculations and observed entropies of mixing, we have used eq. 1 to find "empirical" combinatorial entropies of mixing; we then compared these "empirical" combinatorial entropies with those calculated from eq. 4. We hoped thereby to obtain information on which monomer size in eq. 4 gives the best results. However, no conclusion can be reached because, as shown by Marsh (10), the residual entropy of mixing is sensitive to the equation of state used. In other words, the uncertainty in the calculated residual entropy, caused by arbitrary choice of an equation of state, is as large as the uncertainty in eq. 4, caused by the arbitrary choice of monomer size.

Generalization to Multicomponent Mixtures

Equations 2 and 3 are readily extended to ternary (and higher) mixtures as discussed in many textbooks. By analogy (and without proof) we suggest that for a mixture of m components, the extension of eq. 4 is

Generalized Flory Model

$$[4a] \qquad \frac{\Delta S^C}{R} = -\sum_{i=1}^{m} N_i \ln \frac{N_i r_i^{p_i}}{\sum_{i=1}^{m} N_i r_i^{p_i}}$$

Conclusion

For most workers in the thermodynamics of liquid solutions, it is common practice to use *residual* functions for interpretation and correlation of experimental data. The residual functions are either expressed by empirical equations or by theoretical relations obtained from a partition function. While residual volumes and residual enthalpies of mixing are not affected, residual entropies and residual free energies are often sensitive to the choice of combinatorial entropy used for reducing the experimental data. This work presents a convenient method for calculating combinatorial entropies of mixing for mixtures of molecules differing in both size and shape.

While we cannot say with assurance what the "correct" combinatorial entropy is, the simple equation presented here (eq. 4) permits reduction of experimental data in a manner which interpolates rationally between the upper and lower limits as given by Flory's and Raoult's equations.

Appendix

Calculation of Exponent p

Exponents p_1 and p_2 in eq. 4 were first calculated by forcing agreement between ΔS^C as found from eq. 4 and ΔS^C as found from Lichtenthaler's equation (eq. 4 in ref. 6). In this calculation component 1 was chosen as the monomer; thus $r_1 = q_1 = p_1 = 1$. To use Lichtenthaler's equation, we varied the dimensions of molecule 2 and then, from simple geometry, calculated the corresponding r_2 and q_2. For various values of r_2 and q_2, parameter p_2 was found with results shown in Table 1 and Fig. 1.

The exponent p_2 was also determined by a second calculation in which we forced agreement between $\Delta \bar{S}_1{}^C$ as found from the Generalized Flory Model and $\Delta \bar{S}_1{}^C$ as found from Lichtenthaler's equation. Again, molecule 1 is the monomer with $r_1 = q_1 = p_1 = 1$.

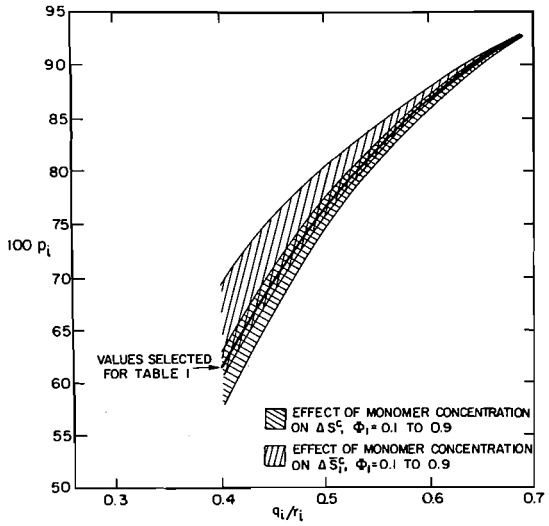

FIG. 6. Effect of monomer concentration on p_i for $r_i = 15$.

In both calculations, exponent p_2 is a weak function of segment fraction Φ, as illustrated in Fig. 6. As indicated by the dark line in Fig. 6, a representative value of p was chosen such as to give good agreement for both calculations (ΔS^C and $\Delta \bar{S}_1{}^C$). These representative values are given in Table 1 and Fig. 1.

Electron Spin Resonance Studies and Electronic Structure of *trans*-$[Ti(H_2O)_4F_2]^+$

PAVLE ILIJA PREMOVIĆ AND PAUL RONALD WEST
Department of Chemistry, University of Victoria, Victoria, British Columbia V8W 2Y2

Received July 25, 1974[1]

PAVLE ILIJA PREMOVIĆ and PAUL RONALD WEST. Can. J. Chem. **53**, 1593 (1975).

At p*H* 1.0–1.6 aqueous titanium(III) solutions containing added fluoride ion exhibit e.s.r. signals of *trans*-$[Ti(H_2O)_4F_2]^+$, $g = 1.9460 \pm 0.0005$, $a_{Ti} = 17.9 \pm 0.2$ G. The variation in the intensity of the optical and e.s.r. spectra with added fluoride ion indicate >90% conversion to the complex at [Ti]:[F] = 1:2. The *trans* geometry of the complex is established from the spectrum in D_2O, a 1:2:1 triplet with $a_F = 7.5 \pm 0.5$ G, and from the axial symmetry (D_{4h}) apparent in the frozen solution spectrum, $g_{\parallel} = 1.968$, $g_{\perp} = 1.932$.

The optical spectrum shows two bands assigned to the $^2B_{2g} \rightarrow {}^2B_{1g}$ (15 200 cm^{-1}) and $^2B_{2g} \rightarrow {}^2A_{1g}$ (23 300 cm^{-1}) transitions. Calculations based on the e.s.r. and optical spectra suggest covalent character in the in-plane π and σ bonding of the complex.

PAVLE ILIJA PREMOVIĆ et PAUL RONALD WEST. Can. J. Chem. **53**, 1593 (1975).

A des p*H* allant de 1.0 à 1.6, des solutions aqueuses de titane(III) contenant des ions fluorures ajoutés, montrent un signal r.p.e. du $[Ti(H_2O)_4F_2]^+$-*trans*, $g = 1.9460 \pm 0.0005$, $a_{Ti} = 17.9 \pm 0.2$ G. On note une variation de l'intensité des spectres optique et r.p.e. lorsqu'on ajoute des ions fluorures; cette variation indique que la conversion vers le complexe est plus grande que >90% lorsque la concentration de [Ti]:[F] = 1:2. On a établi que le complexe possède la géométrie *trans* en se basant sur le spectre dans le D_2O alors qu'on observe un triplet 1:2:1 avec $a_F = 7.5 \pm 0.5$ G et aussi sur l'existence d'une symétrie axiale (D_{4h}) observée pour le spectre de la solution congelée $g_{\parallel} = 1.968$, $g_{\perp} = 1.932$.

Le spectre optique montre deux bandes qui ont été assignées aux transitions $^2B_{2g} \rightarrow {}^2B_{1g}$ (15 200 cm^{-1}) et $^2B_{2g} \rightarrow {}^2A_{1g}$ (23 300 cm^{-1}). Des calculs basés sur les spectres r.p.e. et optique suggèrent un caractère covalent pour les liaisons π et σ dans le plan du complexe.

Introduction

Through analysis of the e.s.r. spectra of titanium(III) complexes considerable information concerning the nature of the bonding can be obtained. Provided that the orbital angular momentum is quenched sufficiently by the effects of the coordinating ligands, the $3d^1$ configuration of titanium(III) gives rise to an e.s.r. signal. Analogous systems are found in the VO^{2+} ion $3d^1$ and in the case of copper(II) where a "hole" in the d shell occurs. Detailed e.s.r. studies on complexes of the latter two species have been extensively reported. However, many fewer comprehensive examinations of titanium(III) complexes have been published (1–6).

Several accounts describing the spectrum of the $[Ti(H_2O)_4F_2]^+$ ion, **1**, have appeared. Garif'yanov and Semenova (1*b*) prepared green hydrated complexes $[Ti(H_2O)_{6-n}F_n]^{(3-n)}$ which exhibited an intense slightly assymetric resonance line ($g = 1.946 \pm 0.001$; linewidth 20 G) over the concentration range from 0.01 to 0.001 *M* titanium(III). Assignment of species as the complex **1** was made without any detailed optical or other experimental study. Waters and Maki (2) briefly referred to preparation of the paramagnetic complex, **1**, in aqueous solution, in conjunction with a report on ^{47}Ti and ^{49}Ti hyperfine structure in the $Ti(OCH_3)^{2+}$ spectrum. Of particular note are the references in both of these studies to a strong axial perturbation by the coordinating ligands. Such an axial perturbation creates a well-separated orbital singlet ground state and a long spin–lattice relaxation time. The result is a relatively narrow line and a much reduced **g**-tensor anisotropy in this complex. Glebov has reported calculation of the electronic energy levels of a series of titanium(III) complexes, and speculated on the assignment of the e.s.r. absorption in the aqueous titanium(III) solution containing added F^- ion as being $[Ti(H_2O)_5F]^{2+}$ (7).

In the present study, the structure of the paramagnetic complex in such solutions is firmly established as the *trans*-$[Ti(H_2O)_4F_2]^+$ ion on

the basis of detailed e.s.r. studies in H_2O and D_2O. A simple theory of the electronic structure of the complex is developed that is consistent with its observed physical properties.

Experimental

All spectra were recorded on a Varian E-6S X band e.s.r. spectrometer operating at 100 kHz modulation. Samples were contained in standard Varian E-248 aqueous solution cells.

Sample preparation was as previously described (19). The titanium(III) solutions were prepared by dissolving the metallic sponge (Fisher) with gentle heating in approximately 1 *N* HCl or H_2SO_4. An N_2 atmosphere was employed to minimize oxidation of titanium(III) ion. Alternatively Fisher Reagent titanium(III) chloride solution (20%) was used directly without qualitative change in any results. Titanium(III) solutions in aqueous acid containing fluoride or bromide as the anion were prepared by dissolving titanium(III) carbonate in the appropriate concentrated acid (HBr or HF) and diluting to the desired concentration. Titanium(III) carbonate was prepared by the method of Semenova (1*c*). In preparing solutions of the $[Ti(H_2O)_4F_2]^+$ complex by addition of NaF or KF, p*H* adjustment was made by addition of the appropriate concentrated acid. For study in heavy water, concentrated $TiCl_3$ solution was added to D_2O (Merck) such that the sample contained 98% D_2O.

The *g* factors are quoted relative to DPPH, $g = 2.0036$, employing a Varian E 232 dual cavity assembly in which the field shift between the cavities had been carefully determined. The integrated intensity of the 1st derivative signal was used to calculate the absolute concentration of the paramagnetic species by reference to standard samples of $Cu(H_2O)_6^{2+}$, $Cr(NH_3)_6^{3+}$, $Mn(H_2O)_6^{2+}$, and $VO(H_2O)_5^{2+}$. Approximate digital calculation was used to determine the integrated intensity of the signal (8). Frozen solutions were obtained by rapidly quenching the sample in liquid nitrogen, maintaining the sample in the Varian E-246 insert Dewar.

The u.v. and visible spectra were recorded on a Cary Model 17 instrument.

Results

By adding slightly more than 2 equiv. of fluoride ion (aqueous HF, KF, or NaF) to a violet solution of the $Ti(H_2O)_6^{3+}$ ion prepared from the sulfate, chloride, or bromide (0.1 *M*) we obtained a green solution that exhibited a rather broad e.s.r. absorption signal. One can discern the presence of unresolved hyperfine structure compatible with a triplet (1:2:1) splitting, Fig. 1*a*. When prepared in D_2O by the same route, the e.s.r. signal now showed a distinct triplet splitting through interaction with two equivalent ^{19}F nuclei, thus indicating the stoichiometry titanium(III):fluoride of 1:2, Fig. 1*b*. Spectral parameters for this complex are given in Table 1. At higher gain, the satellite

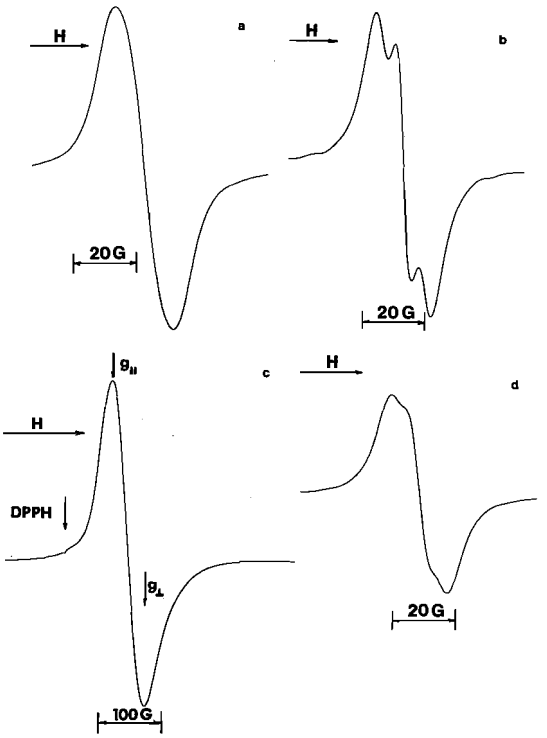

FIG. 1. Electron spin resonance spectra of TiF_2^+ ions in aqueous solution (p*H* 1.0): (*a*) $TiCl_3$ (0.02 *M*), NaF (0.06 *M*) in H_2O, 25 °C; (*b*) $TiCl_3$ (0.02 *M*), NaF (0.06 *M*) in D_2O, 25 °C; (*c*) $TiCl_3$ (0.01 *M*), NaF (0.03 *M*) in H_2O, frozen solution at 77 K; (*d*) $TiCl_3$ (0.06 *M*), NH_4F (0.06 *M*) in D_2O, 25 °C.

lines from ^{47}Ti and ^{49}Ti interaction were evident in both spectra, and revealed the same fluorine hyperfine splitting.

The p*H* dependence of the intensity of the e.s.r. absorption is shown in Fig. 2 for a 0.01 *M* solution derived from $TiCl_3$. From a constant maximum level under acidic conditions (p*H* 1.0–1.6) the signal steadily diminishes until it is no longer observed at p*H* 3.5.

TABLE 1. Electron spin resonance data for *trans*-$[Ti(H_2O)_4F_2]^+$

Parameter	Value
$g_{\parallel}$	1.968 ± 0.002
$g_{\perp}$	1.932 ± 0.002
g_0*	1.9460 ± 0.0005
a_{Ti}	17.9 ± 0.2 G
a_F†	7.5 ± 0.5 G
a_H	0.2 – 0.4

*g_0(calculated) = 1.944; by expression 13.
†Measured from $[Ti(D_2O)_4F_2]^+$.

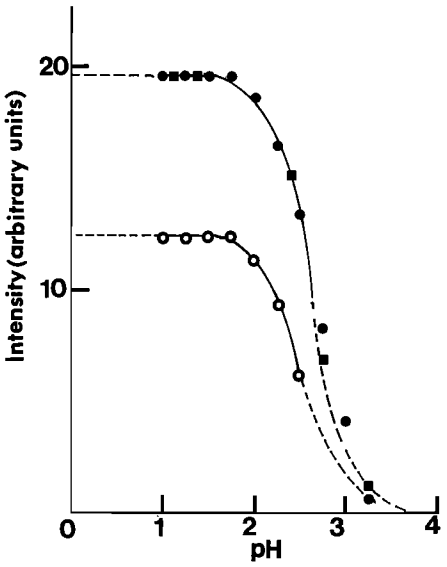

FIG. 2. p*H* dependance of proposed TiF_2^+ ion. Upper curve, e.s.r. signal intensity: ●, H_2O; ■, D_2O, relative to reading at p*H* 1.0. Lower curve, absorbance at 660 nm: ○, relative to reading at p*H* 1.0. $TiCl_3$ = 0.02 *M*, NaF = 0.06 *M*.

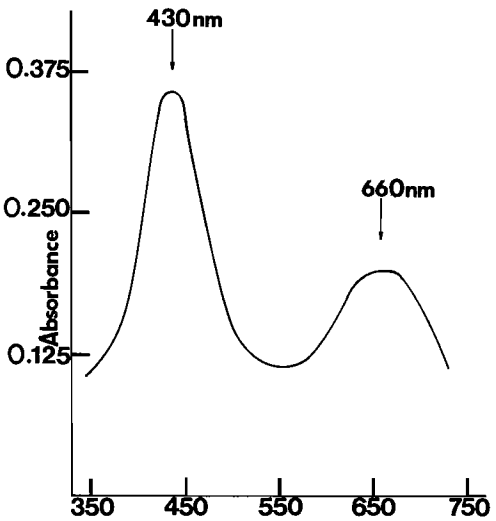

FIG. 3. Optical spectrum of TiF_2^+ in aqueous solution at p*H* 1.3; $TiCl_3$ (0.1 *M*), NaF (0.25 *M*).

In the p*H* range 1.0–2.5 the green aqueous solution derived from titanium fluoride, chloride, bromide, or sulfate exhibited the same optical spectrum in the presence of 2.5–4.0 equiv. of fluoride ion, with maxima at 430 nm ($\varepsilon \sim 3.4$) and 660 nm ($\varepsilon \sim 2$) (see Fig. 3). The decay in the intensity of these absorptions smoothly followed the decay of the e.s.r. signal to p*H* 2.5 (Fig. 2). Such behavior indicates an identity between the complex responsible for the green color and the paramagnetic species. Beyond p*H* 2.5, turbidity due to the onset of precipitation rendered optical readings unreliable. However the e.s.r. signal, though diminishing, persisted to p*H* 3.3 with sharp precipitation occurring at p*H* > 3.5. Note that in the presence of fluoride ion such samples no longer exhibited the $[Ti(H_2O)_4(OH)_2]^+$ e.s.r. signal normally observed in the p*H* region 1.0–3.5 (18). Therefore, it is likely that fluoride ion remained coordinated to titanium(III) ions undergoing hydrolysis, for example reaction 1.

[1] $[Ti(H_2O)_4F_2]^+ + OH^- \rightleftharpoons [Ti(H_2O)_3F_2(OH)]$

Qualitatively, precipitation produced a rose-white solid in contrast to the brown-black mass observed in the hydrolysis of $TiCl_3$ solution.

Variation of the e.s.r. signal intensity, Fig. 4*b*, indicated that $[Ti(H_2O)_4F_2]^+$ was one of the most stable complexes in solution. A relatively sharp breaking point was observed near a ratio of 1:2, and the depression of e.s.r. signal intensity with further increase in fluoride ion was gradual. Measurement of the integrated intensity of the maximum signal (see Experimental) indicated that 100 ± 10% of the titanium(III) was in the complex. Changes in absorbance at 430 and 660 nm, Fig. 4*a*, were compatible with the e.s.r. observations, though now loss of intense $Ti(H_2O)_6^{3+}$ bands was being monitored. At a mole ratio higher than 1:6 we observe a small shift of the 430 nm band to higher wavelength (450 nm) with 10% higher extinction coefficient. This observation is consistent with either significant population of higher complexes (1), or a second coordination shell effect of fluoride ion.

The evidence for $Ti(H_2O)F_2^+$ is in good agreement with the conclusions of other workers (1, 9, 10) and at variance with the experimental results of Glebov (7). The e.s.r. spectrum obtained from $TiCl_3$ in D_2O on addition of ammonium fluoride at a 1:1 mole ratio (Glebov's conditions for the supposed $[Ti(H_2O)_5F]^{2+}$ species in H_2O) again shows the symmetrical 1:2:1 triplet, Fig. 1*d*. Therefore the species present must actually be $[Ti(D_2O)_4F_2]^+$. Of some interest is the markedly lower resolution of the triplet splitting in the Ti^{3+}–NH_4F sys-

For personal use only.

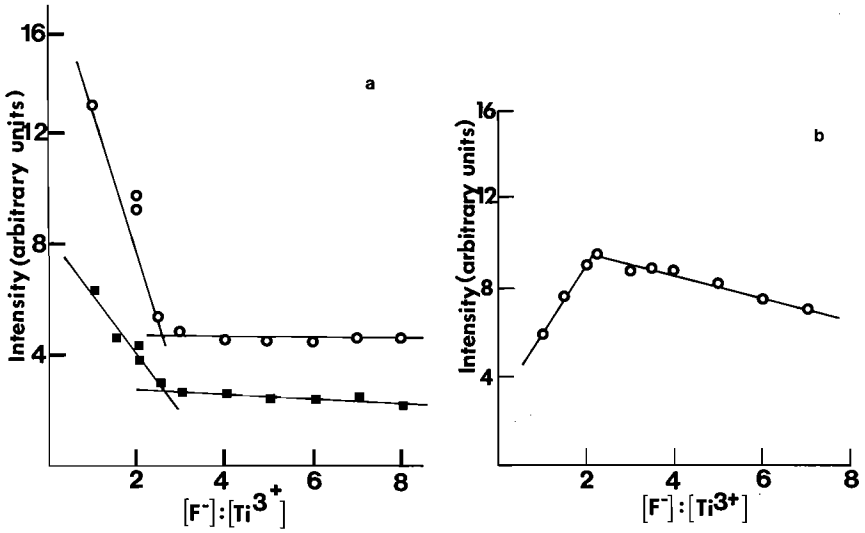

FIG. 4. Dependance of TiF_2^+ concentration on added fluoride ion. (*a*) Variation of absorbance of TiF_2^+ at: ○, 430 nm; ●, 660 nm; $TiCl_3$ (0.15 *M*) at p*H* 1.3; (*b*) Variation in e.s.r. signal intensity, $TiCl_3$ (0.01 *M*) at p*H* 1.1.

tem, relative to the higher resolution shown in Fig. 1*b* for a Ti^{3+}·NaF·D_2O sample. When titanium(III) concentration was varied from 0.01 to 0.1 *M* in the presence of NH_4F, the line broadening persisted, indicating the effect was not due to concentration dependent relaxation processes. Since spatially NH_4^+ exactly replaces an H_4O^{2+} unit in water structure (11), we tentatively ascribe the effect to association of ammonium ion with the complex in the second coordination sphere. Some delocalization of unpaired spin density to the second coordination sphere may provide additional hyperfine splitting.

The spectrum of a frozen solution of $TiCl_3$–NaF in H_2O is shown in Fig. 1*c* (Table 1). From the slight distortion of the linewidth, we conclude axial symmetry for the complex with much reduced **g**-tensor anisotropy and ^{19}F hyperfine tensor anisotropy. The values of $g_{\parallel}$ and $g_{\perp}$ (Fig. 1*c*) are assigned as the maximum limits of the anisotropy apparent in the nearly isotropic line that is observed (12). The calculated *g* factor is found to be in reasonable agreement with the isotropic *g* factor measured at room temperature.

Structure Assignment

The e.s.r. signal arises from the $[Ti(H_2O)_4F_2]^+$ complex ion, and this species is sufficiently stable to be the predominant form of titanium(III) in solution at $[Ti^{3+}]:[F^-] = 1:2$. The equivalence of the two fluorine ligands shown by the single h.f.s. constant, and the axial symmetry apparent from the frozen solution spectrum are only consistent with two axial fluoride ion ligands and four water molecules in the equatorial plane. The fluoride ion dependence of the e.s.r. spectrum (Fig. 4*b*) indicates that higher complexes of the type $[Ti(H_2O)_{6-n}F_n]^{(3-n)+}$ do not provide observable e.s.r. signals. The *trans* complex will have a well-separated orbital singlet resulting from a strong axial perturbation and leading to the requisite long spin–lattice relaxation time for the observation of the spectrum. Nonappearance of signals from the other possible ions $[Ti(H_2O)_{6-n}F_n]^{(3-n)+}$ is then direct confirmation of residency of the unpaired electron in ground states where the degeneracy is only slightly lifted by field distortions providing short spin–lattice relaxation times, and extremely broad resonance lines.

Discussion

The symmetry of the *trans*-$[Ti(H_2O)_4F_2]^+$ ion is D_{4h}. We propose that the ground electronic state is $^2B_{2g}$ (unpaired electron in b_{2g}* (d_{xy}) orbital). The e.s.r. spectrum provides direct confirmation of this assignment when the available alternative energy levels are considered.

If the electron were in an ^2E_g state (e_g*1 (d_{xz}) and e_g*2 (d_{yz}) orbitals), the degeneracy

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

probably only slightly split by field distortion would result in a short spin–lattice relaxation time and a broad resonance line. Note here the line width (D_2O) at 25 °C is only 5 G.

Next, for the $^2B_{1g}$ state (b_{1g}* ($d_{x^2-y^2}$) orbital) we would expect larger isotropic proton hyperfine splitting from the water ligands through σ bonding involving the b_{1g}* orbital and the a_1 (H_2O) orbitals. Also one might expect $g_\perp$ to be higher than the observed value (1.932), since the $^2B_{1g} \rightarrow {}^2E_g$ electronic transition would be relatively higher in energy compared to $^2B_{2g} \rightarrow {}^2E_g$.

In the $^2A_{1g}$ state (a_g*1 and a_g*2 orbitals; d_{z^2}, 4s) we would expect a higher isotropic h.f.s. constant for fluorine nuclei through the enhanced σ bonding. In addition the h.f.s. for titanium should be higher. In D_{4h} symmetry the d_{z^2} and 4s orbitals belong to the same irreducible representation and a direct contribution of spin density at the metal nucleus is allowed. For the $^2A_{1g}$ state, we would expect $g_\parallel$ to be very close to 2.0023 since the B_{1g} and B_{2g} states cannot mix with the ground state of A_{1g} symmetry under the perturbation of the angular momentum operator. The $g_\perp$ value would also be closer to 2.0023 since the $^2A_{1g} \rightarrow {}^2E_g$ transition will be expected to be high in energy.

Finally we consider the possibility of the unpaired electron being in any other metal orbital to be highly unlikely in view of the expected high energy of such states.

We now proceed to examine the assigned ground state $^2B_{2g}$ in more detail. Only states of B_{1g} and E_g symmetry can mix with this ground state under perturbation of the angular momentum operator. Therefore we need consider only molecular orbitals belonging to the representations b_{1g}*, b_{2g}*, and e_g*. The relevant antibonding MO's are

$$[2]\quad b_{1g}^* = \alpha_1 d_{xy} - \tfrac{1}{2}\alpha_1'[p_y^1 + p_x^2 - p_y^3 - p_x^4]$$

$$[3]\quad b_{2g}^* = \alpha_2 d_{x^2-y^2} - \tfrac{1}{2}\alpha_2'[-\sigma_x^1 + \sigma_y^2 + \sigma_x^3 - \sigma_y^4]$$

$$[4]\quad e_g^*1 = \varepsilon d_{xz} - \frac{1}{2^{1/2}}\varepsilon'[p_x^5 - p_x^6] - \frac{\varepsilon''}{2^{1/2}}[p_z^1 - p_z^3]$$

$$[5]\quad e_g^*2 = \varepsilon d_{yz} - \frac{1}{2^{1/2}}\varepsilon'[p_y^5 - p_y^6] - \frac{\varepsilon''}{2^{1/2}}[p_z^2 - p_z^4]$$

It is assumed that each of the oxygen ligand atoms has available 2s, $2p_x$, $2p_y$, and $2p_z$ orbitals and each fluorine $2p_x$, $2p_y$, and $2p_z$ for the formation of MO's with titanium 3d orbitals. The six ligands are placed on the $\pm x$, $\pm y$, and $\pm z$ axes and are labelled by superscripts starting with 1 on the $+x$ axis and proceeding counterclockwise with the 5th and 6th ligands (fluorine) placed on the $+z$ and $-z$ axes respectively. In the above states the σ^i are hybrid orbitals on oxygen given by expression 6 with a plus sign indicating the ligands on the positive x, y axes

$$[6]\qquad \sigma^i = np^i \pm (1 - n^2)^{1/2}s^i$$

and a minus sign those ligands on negative x, y axes. A value of n equal to $(\frac{2}{3})^{1/2}$ corresponds to sp^2 hybridization on the ligand atom.

The appropriate effective spin Hamiltonian for Ti^{3+} in a tetragonal field is given by expression 7

$$[7]\quad \mathcal{H} = \beta_e g_\parallel H_z S_z + \beta_e g_\perp (H_x S_x + H_y S_y) + A S_z I_z + \beta(S_x I_x + S_y I_y)$$

where

$$[8]\quad g_\parallel = 2.0023 - \frac{8\lambda\alpha_1^2\alpha_2^2}{\Delta E_{x^2-y^2}} \times \left[1 - \frac{1}{2}\frac{\alpha_1'\alpha_2'}{\alpha_1\alpha_2}T(n) - \left(\frac{\alpha_2'}{\alpha_2}\right)S - \left(\frac{\alpha_1'}{\alpha_1}\right)\Pi_1\right]$$

$$[9]\quad g_\perp = 2.0023 - \frac{2\lambda\alpha_1^2\varepsilon^2}{\Delta E_{xz}} \times \left[1 - \frac{1}{2^{1/2}}\left(\frac{\varepsilon'\alpha_1'}{\varepsilon\alpha_1}\right) - \left(\frac{\alpha_1'}{\alpha_1}\right)\Pi_1 - \frac{1}{2^{1/2}}\left(\frac{\varepsilon'}{\varepsilon}\right)\Pi_1\right]$$

The complete expression for $g_\perp$ contains an additional term within the square brackets namely

$$-\frac{1}{2^{1/2}}\left(\frac{\varepsilon''}{\varepsilon}\right)\Pi_2$$

that arises from out-of-plane π bonding with oxygen $2p_z$ orbitals. In view of the low energy of $2p_z$, the contribution of this term will be negligible and it is omitted from the final expression 9 for $g_\perp$.

$$[10]\quad A = P\left[-\alpha_1^2\left(\frac{4}{7} + K_0\right) - \frac{8\lambda\alpha_1^2\alpha_2^2}{\Delta E_{x^2-y^2}} - \frac{6\lambda\alpha_1^2\varepsilon^2}{\Delta E_{xz}}\right]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

$$[11] \quad B = P\left[\alpha_1^2\left(\frac{2}{7} - K_0\right) - \frac{11}{7}\cdot\frac{\lambda\alpha_1^2\varepsilon^2}{\Delta E_{xz}}\right]$$

The parameter $\lambda = 154\ \text{cm}^{-1}$ is the spin–orbit coupling constant for the free ion in the appropriate valence state, K_0 is the Fermi contact term for the titanium nucleus, and $\Delta E_{x^2-y^2}(\Delta E_{(^2B_{2g} \rightarrow {}^2B_{1g})})$ and $\Delta E_{xz}(\Delta E_{(^2B_{2g} \rightarrow {}^2E_g)})$ are the transition energies to the $^2B_{1g}$ and ^2E_g states respectively. The parameter $P = -25.7 \times 10^{-4}\ \text{cm}^{-1}$ for $^{47,49}Ti^{3+}$ was obtained by extrapolation (13, 14), as defined by expression 12 where r is average orbital radius.

$$[12] \quad P = g_e g_N \beta_e \beta_N \langle r^{-3} \rangle \text{ av}$$

In eqs. 8 and 9, the integral $T(n)$ is taken over all ligand functions and S, Π_1, and Π_2 are the group overlap integrals.

$$S = 2\langle d_{xy}|p_y{}^1\rangle$$
$$\Pi_1 = 2\langle d_{x^2-y^2}|\sigma^1\rangle$$
$$\Pi_2 = 2\langle d_{xz}|p_x{}^5\rangle$$

Expressions 10 and 11 can be written as follows after substituting from expressions 8 and 9 neglecting small contributions to A and B ($\leqslant 0.05$).

$$[13] \quad A = -KP - \frac{4}{7}\alpha_1^2 \cdot P + (g_\parallel - 2.0023)P + \frac{3}{7}(g_\perp - 2.0023)P$$

$$[14] \quad B = -KP + \frac{2}{7}\alpha_1^2 P + \frac{11}{14}(g_\perp - 2.0023)P$$

where $K = \alpha_1^2 K_0$

For the isotropic solution spectra

$$[15] \quad g_0 = \tfrac{1}{3}(g_\parallel + 2g_\perp)$$

and

$$[16] \quad a = \tfrac{1}{3}(A + 2B) = -KP - (g_0 - 2.0023)P$$

The spin density at the titanium nucleus may be given in terms of

$$[17] \quad \chi = \frac{4\pi}{S}\sum_{ns}(|\Psi_{ns}(0)\uparrow|^2 - |\Psi_{ns}(0)\downarrow|^2) = -\frac{3}{2}\frac{KP}{g_e g_N \beta_e \beta_N}$$

Electrons in d orbitals cannot contribute directly to χ, but finite values of this parameter result from polarization of the inner filled s orbitals by the unpaired electrons.

The expressions for $g_\parallel$ and $g_\perp$ are deficient in that they do not contain terms for the charge-transfer (c.t.) states. These c.t. terms are of the same general form as those for the d–d states. For the present complex, one predicts that these will be of minor importance since it is clear from the optical spectrum that c.t. transitions if present occur at fairly high energy ($>50\,000\ \text{cm}^{-1}$.)

It is worth noting that in the derivation of the above expressions several other approximations have been made including omission of spin–orbit coupling of the ligand atoms and ligand–ligand overlap.

Hyperfine Interactions

Titanium

The titanium isotopes ^{47}Ti (7.32% abundance; $I = 5/2$) and ^{49}Ti (5.46%; $I = 7/2$) have equivalent gyromagnetic ratio [$\gamma(^{49}\text{Ti})/(\gamma^{47}\text{Ti}) = 1.00026 \pm 0.00002$] and give rise to a familiar pattern of two overlapping spectra of six and eight lines respectively, appearing as satellites of the main intense central line (^{46}Ti, ^{48}Ti, ^{50}Ti).

The measured value of the isotropic h.f.s. constant a_{Ti} is 17.9 ± 0.2 G (Table 1). Through eqs. 16 and 17 using $P = -25.7 \times 10^{-14}\ \text{cm}^{-1}$ we calculate as a result that $\chi = -2.3$ a.u., in agreement with other titanium complexes (2, 3, 5).

However, calculation of the χ value using unrestricted Hartree–Fock methods (15) reveals that polarization of both 2s and 3s are important, with negative contributions from the 3s orbital. In these calculations covalency has been found to be important.

Fluorine

The fluorine 2s orbitals have no interaction with the orbitals (e_g and b_{2g}) derived from the cubic $^2T_{2g}$ state since the overlap integrals are zero, for example $\langle 2s|e_g\rangle = 0$. However, charge-transfer from the 2s orbital to vacant metal orbitals derived from the E_g cubic states, 4s and 4p orbitals is possible. The latter orbitals can accept ligand electrons of either spin orientation but exchange with the $^2B_{2g}$ state will increase the transfer probability for electrons of the same spin as the titanium(III) $3d^1$ unpaired electron.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Hence negative spin density is achieved in the fluorine 2s orbital.

In the present study we obtained an isotropic h.f.s. constant a_F for $[Ti(H_2O)_4F_2]^+$ as 7.5 $\pm$ 0.5 G (Table 1).

Spin density in the fluorine 2s orbital is given by eq. 18

$$[18] \qquad \rho_s = \frac{a_F}{A_{2s}}$$

where

$$[19] \qquad A_{2s} = \frac{8}{3}\pi g_e \beta_e g_N \beta_N |\Psi(0)_{2s}|^2$$

is the hyperfine interaction of a single unpaired 2s electron in a fluoride ion. Taking the value for $A_{2s} = 1.57\ cm^{-1}$ (16) we obtain $\rho_{2s} = -0.0011$ comparable in magnitude to values obtained for other transition metal fluorides (17). Similar ρ_s values are obtained for the TiF_2^+ species in a range of alcoholic solvents (2, 18) where nearly the same isotropic a_F value is observed for two equivalent fluorine nuclei. We infer the same geometry in all the TiF_2^+ species. Moreover, the magnitude of the hyperfine splitting is consistent with the axial (*trans*) geometry assumed from the frozen solution spectrum; since equatorial (*cis*) fluorine splitting should be enhanced by greater covalent interaction with the ligand

Hydrogen (Water Ligands)

Resolution of the fluorine h.f.s. in D_2O strongly indicates the existence of proton hyperfine structure from water ligands in the H_2O solution, Fig. 1*a*. Approximate calculation based on the improved resolution indicates a h.f.s. a_H for four water ligands (8H) of *ca.* 0.2 to 0.4 G.

Since the proton interaction is observed for the complex it is evident that $\alpha_1' > 0$ and that in-plane π bonding exists. Such bonding permits some spin density at hydrogen through spin–polarization as suggested previously for *trans*-$[Ti(H_2O)_4((CH_3)_3COH)X]$ (5) and for *trans*-$[Ti(H_2O)_4(OH)_2]^+$ (19).

For the *t*-butyl alcohol complex, the estimation of Johnson *et al.* (5) gave a total spin density of $\sim$0.22 on four equatorial water molecules with $a_H = 1.8$ G in their case. On this basis in *trans*-$[Ti(H_2O)_4F_2]^+$, the total spin density on the water ligands is in the range 0.03–0.06. However, the use of the Q_{OH}^H factor in the former study (5) is open to question in view of the determination through ^{17}O labelling that $Cu(II)(H_2O)_6$ has $p = 0.22$ on oxygens while no evidence of hydrogen hyperfine splitting is seen (20).

Optical Spectrum and g-Values

The expressions 8 and 9 can be rewritten in the form

$$[20] \qquad g_{\parallel} = 2.0023 - \frac{8\lambda}{\Delta E(^2B_{2g} \rightarrow {}^2B_{1g})} \cdot K_{\parallel}$$

$$[21] \qquad g_{\perp} = 2.0023 - \frac{2\lambda}{\Delta E(^2B_{2g} \rightarrow {}^2E_g)} \cdot K_{\perp}$$

where

$$[22] \qquad K_{\parallel} = \alpha_1^2\alpha_2^2\left[1 - \frac{1}{2}\frac{\alpha_1'\alpha_2'}{\alpha_1\alpha_2}T(n) - \left(\frac{\alpha_2'}{\alpha_2}\right)S - \left(\frac{\alpha_1'}{\alpha_1}\right)\Pi_1\right]$$

$$[23] \qquad K_{\perp} = \alpha_1^2\varepsilon^2\left[1 - \frac{1}{2^{1/2}}\left(\frac{\varepsilon'\alpha_1'}{\varepsilon\alpha_1}\right) - \left(\frac{\alpha_1'}{\alpha_1}\right)\Pi_1 - \frac{1}{2^{1/2}}\left(\frac{\varepsilon'}{\varepsilon}\right)\Pi_1\right]$$

The values of $K_{\parallel}$ and $K_{\perp}$ have been regarded as the "orbital-reduction factors" (21) and these parameters are usually employed to estimate covalency. It is clear from expressions 8 and 9 that $0 \leqslant K_{\parallel}, K_{\perp} \leqslant 1$, and that both factors tend to one as the corresponding bonding tends to be ionic and vice versa.

Since only the limiting ionic value for λ(154 cm^{-1}) is available for titanium(III) covalency might better be expressed by eq. 24.

$$[24] \quad \text{Covalency factor} = \left[K\frac{\lambda(\text{covalent})}{\lambda(\text{ionic})}\right] = \frac{\Delta g \cdot \Delta E}{n\lambda(\text{ionic})}$$

where n = symmetry dependent integer, $n = 8$ for D_{4h}; $\Delta g = 2.0023 - g_{\parallel}$ ($g_{\perp}$); ΔE = energy of appropriate electronic transition.

Clearly if λ(covalent) is actually lower than λ(ionic) calculated values of the "covalency factor" will be lower than K itself.

Since the optical spectrum shows two electronic bands at $\sim$15 200 cm^{-1} (660 nm) and 23 300 cm^{-1} (430 nm) either one might correspond to the $^2B_{2g} \rightarrow {}^2B_{1g}$ transition, expression 20. We find that expression 24 gives a value of 0.45 for the low energy (15 200 cm^{-1}) possibility and 0.68 for the high energy transition. Taking into consideration the high charge density (low effective ionic radius) of the axial fluoride ligands, simple crystal field theory would pre-

dict a tetragonally *compressed* octahedron (22). Accordingly, the 15 200 cm^{-1} band is then assigned to $^2B_{2g} \rightarrow {}^2B_{1g}$ and the higher energy band to the $^2B_{2g} \rightarrow {}^2A_{1g}$ transition. Since the covalency parameter is only 0.45 we conclude that both in-plane π bonding and σ bonding are relatively covalent. It is improbable that *only* one or other is highly covalent. Observation of hydrogen hyperfine splitting from H_2O ligands is clearly consistent with significant in-plane π bonding. We should stress that the actual value of $K_{\|}$ will be somewhat higher (*ca.* 0.60) if a reduction in λ due to covalency of 30% is assumed.

By first postulating an ideal ionic case *e.g.* $\lambda = 154$ cm^{-1} and $K_{\perp} = 1$ we can calculate the upper limit of the energy of the $^2B_{2g} \rightarrow {}^2E_g$ transition as 4300 cm^{-1}, eq. 21. However we note that fluoride ion is characterized by its π donor properties (23), suggesting that the overall covalency factor could be conservatively estimated as 0.6–0.8. Then $\Delta E(^2B_{2g} \rightarrow {}^2E_g)$ falls to 2500–3200 cm^{-1}. On the other hand the relatively low energy of the $^2B_{2g} \rightarrow {}^2A_{1g}$ transition (23 300 cm^{-1}) is consistent with the expected low covalent σ bonding between the metal ion and the axial fluorines. The marked stability of the *trans*-$[Ti(H_2O)_4F_2]^+$ ion is also consistent with substantial metal–fluorine π bonding.

The Hydrolysis of Cyclic Orthoesters. Stereoelectronic Control in the Cleavage of Hemiorthoester Tetrahedral Intermediates

PIERRE DESLONGCHAMPS,[1] ROBERT CHÊNEVERT, ROLAND J. TAILLEFER, CLAUDE MOREAU,[2] AND JOHN K. SAUNDERS

Laboratoire de synthèse organique, Département de chimie, Université de Sherbrooke, Sherbrooke, Québec J1K 2R1

Received November 1, 1974

PIERRE DESLONGCHAMPS, ROBERT CHÊNEVERT, ROLAND J. TAILLEFER, CLAUDE MOREAU, and JOHN K. SAUNDERS. Can. J. Chem. **53**, 1601 (1975).

The synthesis of several cyclic dialkoxy orthoesters is reported. Acid hydrolysis of these orthoesters under kinetically controlled conditions gives the corresponding hydroxy esters only. Conformationally rigid cyclic mixed orthoesters give a hydroxy ester by exclusive loss of the axial alkoxy group. A cyclic orthoester can have nine different *gauche* conformations. It is shown that they are hydrolyzed through only one *gauche* conformer. These results bring further experimental evidence that there is a stereoelectronic control in the cleavage of tetrahedral intermediates in the hydrolysis of esters.

PIERRE DESLONGCHAMPS, ROBERT CHÊNEVERT, ROLAND J. TAILLEFER, CLAUDE MOREAU et JOHN K. SAUNDERS. Can. J. Chem. **53**, 1601 (1975).

La synthèse de plusieurs dialkoxy orthoesters cycliques est rapportée. L'hydrolyse en milieu acide de ces orthoesters conduit aux hydroxy esters par contrôle cinétique. De plus, les orthoesters mixtes ayant une conformation rigide s'hydrolysent en éjectant le groupe alkoxy axial. Théoriquement, un orthoester cyclique peut prendre neuf conformations *gauches* différentes, cependant il est démontré qu'il préfère s'hydrolyser par un seul conformère. L'ensemble de ces résultats confirme qu'il y a un contrôle stéréoélectronique lors de la fragmentation d'un intermédiaire tétrahédrique durant l'hydrolyse des esters.

We have recently described a new stereoelectronic theory for the cleavage of the tetrahedral intermediate in the hydrolysis of esters (1) and amides (2). In this new theory (3), the precise conformation of the intermediate hemiorthoester or hemiorthoamide is very important. We have proposed that there is a direct relationship between the conformation of the tetrahedral intermediate and the nature of the products formed as a result of its breakdown. We have further postulated that the stereoselective decomposition of this intermediate is determined by the orientation of the lone pair orbitals on the heteroatoms; specific cleavage of a carbon–oxygen or a carbon–nitrogen bond being allowed only if the other two heteroatoms (oxygen or nitrogen) of the tetrahedral intermediate each have an orbital oriented antiperiplanar to the leaving *O*-alkyl or *N*-alkyl group.

This new theory originated from our study on the oxidation of acetals with ozone to give esters (4). We assumed that this reaction proceeds via the formation of a hemiorthoester tetrahedral intermediate or its equivalent. Product formation from this reaction was then explained by selective decomposition of this postulated intermediate according to the new stereoelectronic theory.

However, we could not use the results obtained from the oxidation of acetals to verify the new theory because it is experimentally difficult to demonstrate that a hemiorthoester intermediate is formed in the course of this reaction. Consequently, it became important to obtain direct independent experimental evidence for the selective cleavage of hemiorthoesters. These results were necessary to confirm the new stereoelectronic theory.[3]

Acid-catalyzed hydrolysis of orthoester doubtless proceeds through the formation of such a hemiorthoester intermediate as described in the following equation (6). Therefore, the preparation of several cyclic orthoesters was undertaken.

It was hoped that a study of the mild acidic hydrolysis of such orthoesters would give the experimental evidence needed to prove that the selective cleavage of hemiorthoesters does indeed take place. We wish to report in detail the result of this investigation.

Meerwein and his co-workers have described the reaction of triethyloxonium tetrafluoroborate with lactones (7); they have also reported that the resulting ethyl lactonium salts react with sodium ethoxide to yield the corresponding diethoxy cyclic orthoester. For example, γ-butyrolactone (**1**) gave the ethyl-γ-butyrolactonium salt **6** which was then converted into 1,1-diethoxytetrahydrofuran (**12**). We have utilized this two-step sequence for the preparation of the cyclic orthoesters **12–17**.[4]

The hydrolysis was carried out by stirring the orthoester in distilled water, at 0°, with a small amount of *p*-toluenesulfonic acid. The analysis of the product of the reaction was carried out after 20 min and then after 12 h. The corresponding hydroxyester or lactone are the two possible products of the reaction. For instance, the orthoester **12** can give the hydroxy ester **18** or the lactone **1**. The crude reaction mixture was treated directly with a large excess of pyridine and acetic anhydride. In this manner, the hydroxy ester was converted into the corresponding acetoxy ester (for example, **18** into **19**). The relative amount of acetoxy ester and lactone were measured by vapor phase chromatography and the results are described in Table 1.

We have verified that the hydrolysis of orthoester is a very fast reaction; when 1 drop of aqueous acid is added to a chloroform solution of an orthoester in a n.m.r. tube, proton nuclear magnetic resonance shows the instantaneous disappearance of starting material. For our study, we have allowed a period of 20 min for the hydrolysis; the reaction is highly selective, more than 94% of the acetoxy ester is produced. If the period allowed for the hydrolysis is much longer (12 h), the formation of a larger quantity of lactone is observed. This result shows that the hydroxy ester can give the lactone under the conditions of the hydrolysis but this is a relatively slow process. This means that the small percentage of lactone which appears to be present after 20 min, does not come from the lactonization of the hydroxy ester during the hydrolysis. The presence of minor amounts of lactone in these reactions can therefore be explained in two ways: (*a*) the hydrolysis of orthoesters is simply not specific; (*b*) the reaction is totally specific yielding only the hydroxy ester but this product would then be converted to a small extent into the corresponding lactone during the acetylation process. The second explanation was preferred because the acetylation of a secondary alcohol is not instant-

[4]We are grateful to Miss Madeleine Bélisle for her technical help in the preparation of these compounds.

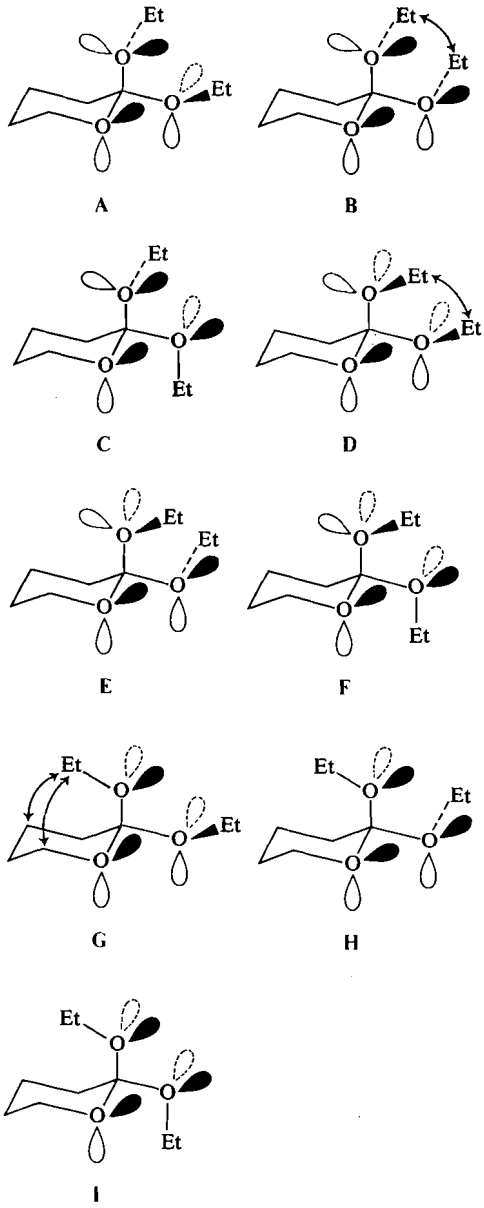
aneous under the conditions used and pyridine could easily catalyze the lactonization reaction.

We have, therefore, looked for a more direct method of analysis. There was a good possibility that carbon-13 n.m.r. spectroscopy could be utilized to analyze mixtures of hydroxy ester and lactone. This was found to be the case since each hydroxy ester gave a different carbon-13 spectrum than the corresponding lactone as can be seen in Table 2.[5] The hydrolysis of the orthoesters was repeated. The reaction was carried out in a n.m.r. tube by addition of aqueous acid to a chloroform solution of the orthoester. The reaction mixture was analyzed by carbon-13 n.m.r. After 10 min, the hydrolysis of the orthoesters was complete. The hydroxy ester was formed exclusively; no lactone product was detected at this time (1% of lactone would have been observed). After shaking for 30 min, lactone formation was observed.

The hydrolysis of orthoesters goes through the formation of a hemiorthoester intermediate. Consequently, the preceding results constitute rigorous experimental evidence that hemiorthoesters do indeed break down in a specific manner and these results can be used to support the stereoelectronic theory.

The exclusive formation of hydroxy ester from the mild acid hydrolysis of orthoesters can be explained in the following manner. The simple six-membered cyclic orthoester **13** can be taken as a good example because it is preferable to discuss precise conformation in a six rather than in a five-membered ring. Also, we can assume that no conformational change takes place during the hydrolysis, since the experimental results are the same for both rigid and conformationally labile cyclic orthoesters.

There are nine *gauche* conformers which are theoretically possible for the cyclic orthoester **13**. They are described in Scheme 1. The next task is to define which conformers of **13** should be taken into consideration. It is logical to assume that the hydrolysis of **13** will proceed through the most energetically favored conformers which have at the same time, proper orbital orientation to permit the cleavage of a carbon–oxygen bond. A detailed examination of each conformer shows that six of them (**B**, **C**, **D**, **G**, **H**, and **I**) are readily eliminated. There is a severe 1,3-synperiplanar interaction[6] between the two ethyl groups in conformers **B** and **D**; thus the population of these conformers



SCHEME I

[5]Proton nuclear magnetic resonance spectroscopy could not be used because of signal overlap. Also, vapor phase chromatography or any other type of chromatography could not be utilized because the hydroxy ester can be easily converted into the corresponding lactone either by heat, or by acid or base catalysis.

[6]A 1,3-synperiplanar interaction is equivalent to a 1,3-diaxial interaction in a six-membered ring.

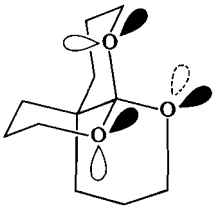
at equilibrium will be very small. Conformers **G**, **H**, and **I** can also be ruled out by utilizing a similar argument; the ethyl group of the axial ethoxy group in each conformer is in a 1,3-synperiplanar arrangement with two methylenes (C_3 and C_5) of the ring; thus there are two severe 1,3-synperiplanar steric interactions in **G**, **H**, and **I**. The population of these conformers will also be very small at equilibrium and they can therefore be neglected.

The remaining four conformers **A**, **C**, **E**, and **F** do not have strong steric interactions. The magnitude of the anomeric effect (8), which occurs whenever two lone pair orbitals are in a 1,3-synperiplanar arrangement is approximately the same in each conformer. Two of such orbital arrangements are present in conformers **A**, **E**, and **F**. Conformer **C** has three. Thus, these four must represent the real conformers of **13**.

Conformer **C** must be eliminated as a reactive conformer simply because it does not have proper orbital orientation on two oxygen atoms to permit the cleavage of the C—O bond of the third oxygen atom. We have prepared the tricyclic orthoester **30**[7] (9) which is a perfect rigid model for conformer **C**. When compound **30**

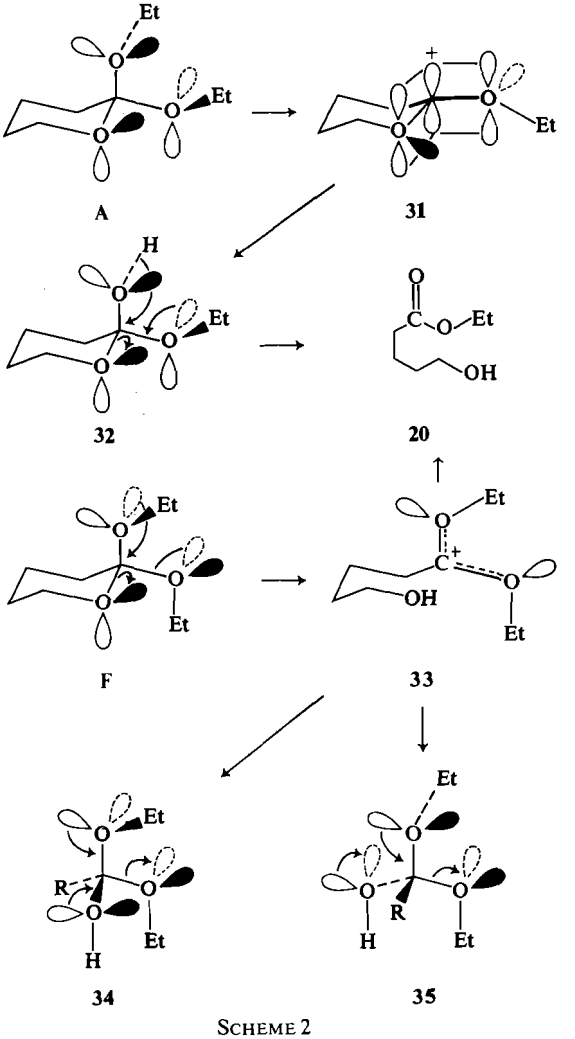


30

was submitted to the mild acidic conditions used for the hydrolysis of the preceding orthoesters, it was found to be completely stable after 24 h at room temperature. Consequently, we have obtained strong experimental support that conformer **C** is nonreactive. Indeed, it is a remarkably stable conformer and can therefore be eliminated.

The remaining conformers **A**, **E**, and **F** have each two oxygens with proper orbital orientation to cleave the C—O bond of the third oxygen atom. They will therefore be considered separately.

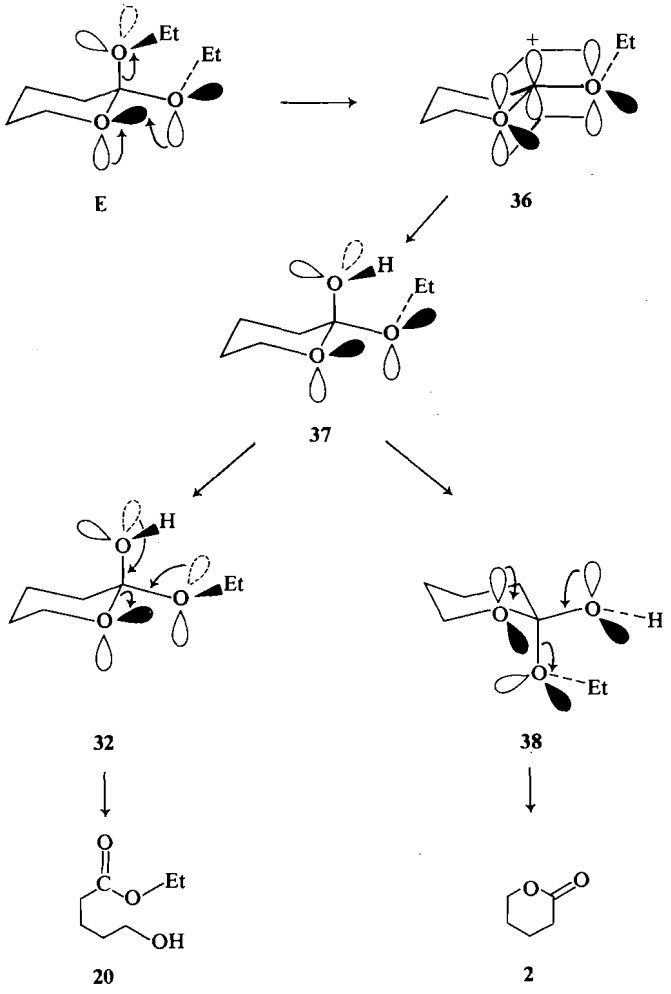
The cleavage of conformer **A** (Scheme 2) can



SCHEME 2

only give the dioxolenium ion **31** because of the orbital orientation (1). This ion **31** will then be attacked by water on the β face to form specifically the hemiorthoester **32** in which the ring oxygen and the OEt oxygen each have an orbital antiperiplanar to the C—OH bond which has just been formed. Attack by water on the α face of ion **31** would result in a hemiorthoester with a ring in a boat form. The hemiorthoester **32** can break down in the direction of the hydroxy ester **20** only; the OH and the OEt groups each have an orbital oriented antiperiplanar to the ring oxygen–C_2 bond. The conversion of **32** into δ-valerolactone (**2**) is a higher energy process because the ring oxygen atom does not have proper orbital orientation to assist the cleavage of the C—OEt bond.

[7]We are grateful to Messrs. Normand Beaulieu and Yvon Couture for their technical help in the preparation of this compound.



SCHEME 3

Conformer **F** (Scheme 2) should also yield the hydroxy ester **20** exclusively, since orbital orientation permits only the cleavage of the ring oxygen–carbon bond, yielding the dioxolenium ion **33**. Hydration of this ion **33** can be done in two ways giving the hemiorthoesters **34** and **35**. Nevertheless each hemiorthoester **34** and **35** can then break down to give only the hydroxy ester **20**.

Conformer **E** (Scheme 3) has proper orbital orientation to permit the cleavage of the axial ethoxy group; the ion **36** will thus be formed and hydration will then give the hemiorthoester **37**. The hemiorthoester **37** does not have proper orbital orientation to permit the cleavage of a carbon–oxygen bond. To break down, **37** will have to rotate one of its C—O bonds to obtain a reactive conformer.[8] For example, a rotation of the C—OEt bond will give **32** which will break down to give the hydroxy ester **20**. A chair inversion of **37** to **38** is also possible in a conformationally labile system; this new intermediate **38** should give δ-valerolactone (**2**). Thus, lactone formation could have been observed to some extent via conformer **E** if the orthoester is a conformationally labile system.

The preceding discussion on the manner by which conformers **A**, **E**, and **F** should break

[8]We have previously postulated (3) that a tetrahedral intermediate which does not have proper orbital orientation to break down, will prefer to undergo rotational changes to give new tetrahedral intermediates which may have orbitals properly aligned to undergo C—O bond cleavage.

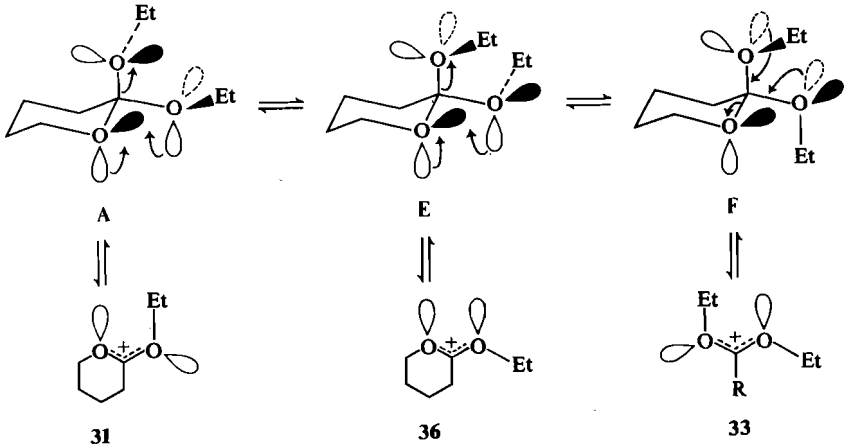


SCHEME 4

down indicates that each of them is, in principle, a reactive conformer. If the relative stability of the dioxolenium ions is taken into consideration, we believe conformer **E** can be eliminated. Conformers **A**, **E**, and **F** are going to form the dioxolenium ions **31**, **36**, and **33**, respectively (Scheme 4). The ions **31** and **33** are *trans* and the ion **36** is *cis*. It is known that *trans*-dioxolenium ions are more stable than *cis*-dioxolenium ions (10), just as *trans*-esters are more stable than *cis*-esters (11). If this difference in stability between **31**, **33**, and **36** is also operative in the transition states which are going to form these dioxolenium ions, the cleavage of conformer **E** should be a higher energy process. Conformer **E** could thus be eliminated on this basis.

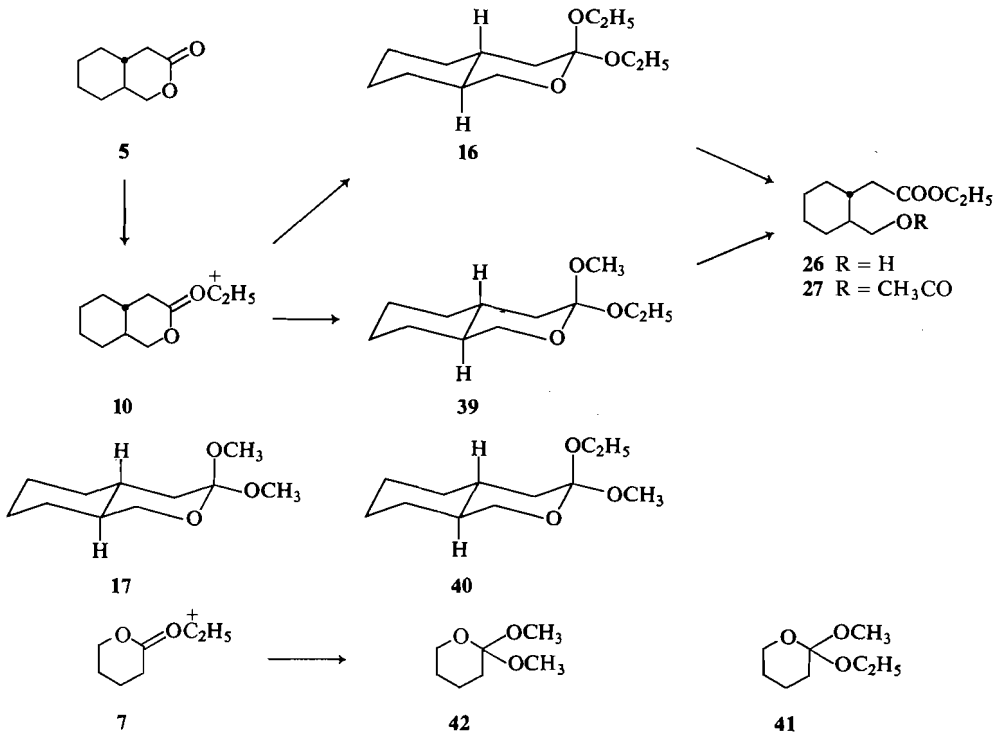
It is more difficult to find arguments to differentiate between conformer **A** and conformer **F**; however, the formation of the ion **31** from **A** should be an easier operation than formation of **33** from **F**. In principle, the formation of a cyclic dioxolenium ion (**31**) should be favored over an acyclic dioxolenium ion (**33**) when the starting orthoester is cyclic. Furthermore, cleavage of conformer **A** gives two molecules, the cyclic ion **31** and ethanol whereas conformer **F** gives only one molecule, the ion **33**. This entropy factor should favor conformer **A** over conformer **F** as the reactive species. Similarly, a kinetic argument can be used to favor conformer **A**. The k value for the reformation of **F** from the cyclization of **33** must be much greater than the corresponding k value for the reformation of **A** by reaction of **31** with ethanol which is diluted in the solvent. Conformer **A** is in rapid equilibrium with conformer **F** (also with conformers **C** and **E**) by bond rotation. If the barrier to give **31** from **A** is lower by more than 2.5 kcal/mol than the barrier to give **33** from **F** (or the barrier to give **36** from **E**), the orthoester **13** will prefer to be hydrolyzed via conformer **A** only.

It is possible, in principle, to devise a simple experiment to find out if conformer **F** is reactive when compared to conformer **A**. If the stereoelectronic theory is applied, it is interesting to note that conformer **A** will give the hydroxy ester **20** by the loss of its axial ethoxy group. Conformer **F** is predicted to form **20** by ejecting its equatorial ethoxy group. Scheme 2 describes these operations; with regard to **F**, both intermediates **34** and **35** will hydrolyze by ejecting the same ethoxy group, which is the equatorial one in conformer **F**. Thus, if the preparation of rigid cyclic orthoesters having two different alkoxy groups can be realized, it should be easy to differentiate between these two pathways.

We have already developed a method for the synthesis of such conformationally rigid cyclic orthoesters. For instance, lactone **5** was converted into the salt **10** which gave the cyclic orthoester **16**. This successful synthesis of a rigid cyclic orthoester by sequential introduction of the alkoxy groups is ideal for the synthesis of mixed orthoesters, if the last step is stereospecific. If the stereoelectronic theory is valid, the addition of alkoxide ion to a rigid lactonium salt, such as that of **10**, should indeed be completely stereospecific.

When the salt **10** was treated with sodium methoxide in a mixture of methanol and isopropyl alcohol, the mixed orthoester **39** was obtained with a small quantity ($\simeq 3\%$) of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.



SCHEME 5

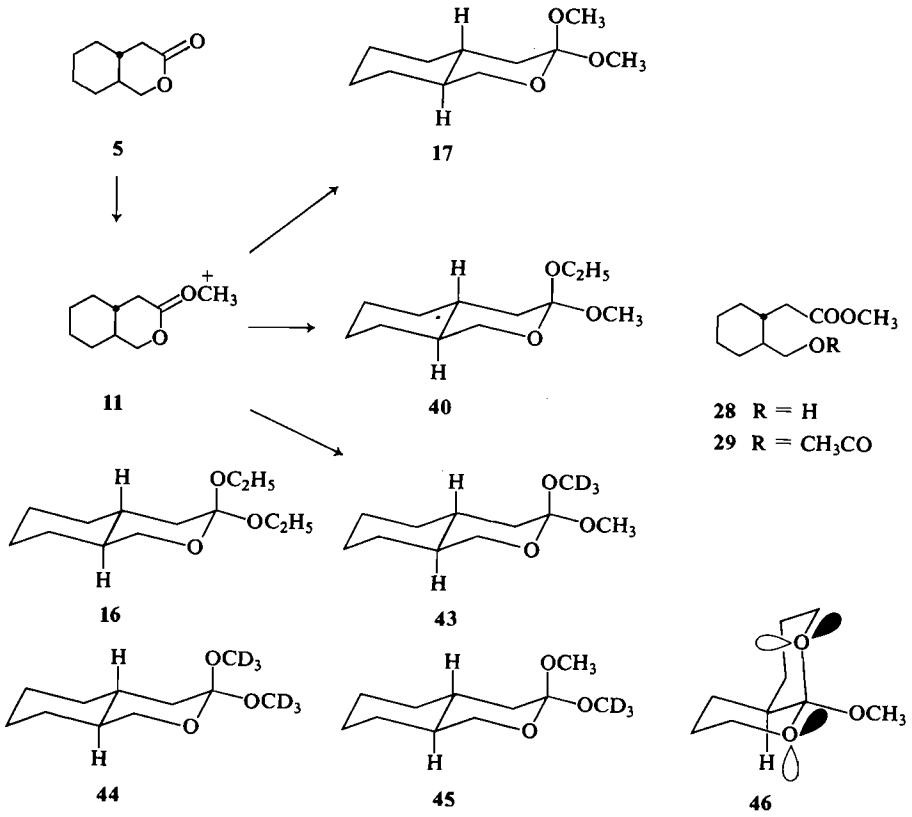
dimethoxy orthoester **17** (Scheme 5). None of the other possible mixed orthoester **40** was present. The addition of sodium methoxide to **10** is thus completely stereospecific. The stereoelectronic rule permits the formation of **40** from **10** but the attack of methoxide ion at the α face of the salt **10** would give **40** in a high energy conformation; the orthoester ring of **40** would be in a boat form. The α attack is therefore much less favored than the β attack which yields **39** directly in its more stable conformation. The small quantity of **17** must be formed by a secondary process. When the salt **10** was reacted with sodium methoxide in pure methanol, this secondary process became more important, since **17** was formed in 60% and **39** in 40% yield.[9]

[9]Under certain conditions, this unexpected reaction can become the major process! When the simple ethyl lactonium salt **7** was treated with sodium methoxide in methanol, none of the mixed orthoester **41** was isolated; the dimethoxy orthoester **42** was the only orthoester isolated. We have also shown that the diethoxy orthoester **13** is completely stable in presence of sodium methoxide in methanol. We think that this reaction occurs via the intermediate ketene acetal which can be formed by reaction of sodium methoxide with the lactonium salt. We are presently studying this new reaction.

The methyl lactonium salt **11** was prepared by reaction of lactone **5** with trimethyloxonium tetrafluoroborate (Scheme 6). An authentic sample of the dimethoxy ester **17** was prepared by reacting **11** with sodium methoxide in methanol. The methyl lactonium salt **11** was also reacted with sodium ethoxide in ethanol and a mixture of the mixed orthoester **40** (95%) and the diethoxy orthoester **16** (5%) was isolated. The lactonium salt **11** was also reacted with deuterated sodium methoxide and the mixed cyclic orthoester **43** was obtained with a small amount (10%) of the completely deuterated orthoester **44**; none of the isomeric orthoester **45** was formed.

The diethoxy orthoester **16** shows two distinct quadruplets for the methylenes of the two ethoxy groups in its n.m.r. spectrum. We have assigned the high-field quadruplet (3.55 δ) for the methylene of the axial ethoxy group and the low-field quadruplet (3.60 δ) for the methylene of the equatorial ethoxy group. Similarly, the cyclic dimethoxy orthoester **17** shows two different singlets at 3.18 and 3.28 δ which are, respectively, attributed to the axial and equatorial methoxy groups. This assignment is based on the chemical shift of α- and β-methyl glycopyranosides. It is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.



SCHEME 6

known that the axial methoxy group of α-glycoside always appears at a higher field than the equatorial methoxy group of β-glycoside (12). We have also prepared the bicyclic orthoester **46** (9) which is a good model for an orthoester having an equatorial methoxy group. The chemical shift of the methoxy group of **46** appears at 3.33 δ.

The stereochemistry of the mixed cyclic orthoesters **39**, **40**, and **43** was established by p.m.r. spectroscopy with the aid of compounds **16**, **17**, and **46** as models. The n.m.r. spectrum of the mixed orthoester **39** showed a singlet at 3.22 δ for the axial methoxy group and a quadruplet at 3.61 δ for the equatorial ethoxy group. The absence of a quadruplet at $\simeq$3.55 δ proves that **40** was not present with **39**. The mixed orthoester **40** displayed a quadruplet at 3.56 δ for the axial ethoxy group and a singlet at 3.32 δ for the equatorial methoxy group. Again, the reaction mixture of **40** did not show a singlet at $\simeq$3.22 δ which would have indicated the presence of the other mixed orthoester **39**. The mixed cyclic orthoester **43** showed a singlet at 3.32 δ for the equatorial methoxy group. No signal was observed at $\simeq$3.20 δ indicating that the other possible isomer **45**, was not formed with **43**. The relative proportions of **39**/**17**, **40**/**16**, and **43**/**44** were easily established by measuring the relative intensity of their respective molecular ions by mass spectrometry.

The orthoesters **39**, **40**, and **43** were hydrolyzed with water containing *p*-toluenesulfonic acid. The reaction mixture was then treated with pyridine and acetic anhydride and the resulting acetoxy esters were isolated. Compound **39** (containing $\simeq$3% of **17**) gave the acetoxy ethyl ester **27** containing a small quantity of **29** ($\simeq$3%). Compound **40** (containing $\simeq$5% of **16**) gave the acetoxy methyl ester **29** containing a small quantity of **27** ($\simeq$5%). The relative proportions of **27** and **29** were determined by vapor phase chromatography analysis. Finally, the hydrolysis of **43** (containing 10% of **44**) gave the acetoxy methyl ester **29**. Mass spectral analysis of **29** indicated the formation of a small amount (10%) of the deuterated acetoxy methyl ester (**29**, $CH_3 = CD_3$).

The above results show that the hydrolysis of cyclic orthoesters proceed by the loss of the axial methoxy group. Conformer **F** can be eliminated as a reactive conformer; consequently, the hydrolysis of cyclic dialkoxy orthoester takes place through the reaction of conformer **A**.

We would like to point out that the successful stereospecific synthesis of mixed cyclic orthoesters constitutes rigorous evidence for the direction of attack of the alkoxide on the cyclic dioxolenium ions. Also, the stereospecificity observed in the hydrolysis of these mixed cyclic orthoesters demonstrates that this reaction proceeds according to the same principle in the opposite direction.

The synthesis of more complex cyclic orthoesters is now in progress. The study of the hydrolysis of these substances should bring further results to support the new stereoelectronic theory.[10]

Experimental

The i.r. spectra were taken on a Perkin-Elmer 257 spectrophotometer; proton n.m.r. spectra (δ-value) were recorded on a Varian A-60 spectrometer in solvent indicated. Carbon-13 n.m.r. spectra were taken on a Bruker HX-90 spectrometer equipped with a Nicolet 1083 computer. All chemical shifts are recorded relative to internal TMS as standard. The vapor phase chromatographic analyses were done on a Varian 600-D chromatograph. Mass spectra were run in a Hitachi-Perkin Elmer RMU-6 spectrometer. Microanalyses were performed by Dr. C. Daesslé, Organic Microanalyses, Montreal.

Lactones 1, 2, 3, and 5

γ-Butyrolactone (**1**) and δ-valerolactone (**2**) are commercial products. They were distilled before use. Lactones **3** and **5** were obtained by Baeyer–Villiger oxidation (13) of commercial 5-methylcyclopentanone and *trans*-hydrindanone (14).

Lactone 4

2-Methyl-5-isopropylcyclohexen-2-one was treated by ozone in ethyl acetate at −78°; ozonides were destroyed by hydrogenation (platinum oxide) in the same solvent at 0°. The crude 3-isopropyl-4-formylbutanoic acid was reduced by sodium borohydride in basic aqueous medium at 0°. After acidification and extraction with ether, the crude lactone was treated with *p*-toluenesulfonic acid in refluxing benzene for 3 h. Distillation gave pure lactone **4**: b.p. 93–94°/0.8 mm, 84%; i.r.: ν_{max} (film) 1735, 1250, 1210, 1070 cm^{-1}; n.m.r.: δ($CDCl_3$) 0.93 (6H, doublet, J = 5.5 Hz, methyls), 1.2–2.2 (4H, multiplet, —*CH*$_2$—*CH*—*CH*(CH_3)$_2$), 2.2–3.0 (2H, multiplet, —CH_2—COO—), 4.0–4.7 (2H, multiplet, —COO—CH_2—).

O-Alkyl Lactonium Tetrafluoroborates (6–11)

General Method of Preparation

Lactone (10 mmol) and trialkyloxonium tetrafluoroborate (15) or trialkyloxonium antimony hexachloride ((16), 10 mmol) were dissolved in anhydrous dichloromethane (35 ml). The solution was magnetically stirred at room temperature during 3 h. Dry diethyl ether was added until turbid. The mixture was kept at 0° overnight. The crystals (white needles) were filtered and washed with ether–dichloromethane 5:1. The salts are extremely hygroscopic and any manipulation has to be done under controlled atmosphere.

Lactonium salt 6 (BF_4^-): m.p. 41–42° (*O*-tolunitrile) (lit. (7) m.p. 42° (same solvent)); i.r.: ν_{max} (CH_2Cl_2) 1550, 1000–1200 cm^{-1}; n.m.r.: δ(CD_2Cl_2) 1.53 (3H, triplet, J = 7.0 Hz, —CH_2—*CH*$_3$), 2.63 (2H, multiplet, methylene at C-4), 3.40 (2H, triplet, J = 7.5 Hz, methylene at C-3), 4.97 (2H, quartet, J = 7.0 Hz, —*CH*$_2$—CH_3), 5.33 (2H, triplet, J = 7.5 Hz, methylene at C-5).

Lactonium salt 7 (BF_4^-): m.p. 96–98° dec. (ether–CH_2Cl_2); i.r.: ν_{max} (CH_2Cl_2) 1550, 1000–1200 cm^{-1}; n.m.r.: δ(CD_2Cl_2) 1.48 (3H, triplet, J = 7.5 Hz, —CH_2—*CH*$_3$), 2.18 (4H, multiplet, methylenes at C-4 and C-5), 3.02 (2H, multiplet, methylene at C-3), 4.82 (2H, quartet, J = 7.5 Hz, —*CH*$_2$—CH_3), 5.16 (2H, multiplet, methylene at C-6).

Lactonium salt 8 ($SbCl_6^-$): m.p. 127–128° dec. (ether–CH_2Cl_2); i.r.: ν_{max} (CH_2Cl_2) 1500, 1000–1200 cm^{-1}; n.m.r.: δ(CD_2Cl_2), 1.43 (3H, doublet, J = 7.0 Hz, —CH—*CH*$_3$), 1.62 (3H, triplet, J = 7.5 Hz, —CH_2—*CH*$_3$), 2.10 (4H, multiplet, methylenes on C-4 and C-5), 3.03 (2H, multiplet, methylene on C-3), 4.80 (2H, quartet, —*CH*$_2$—CH_3), 5.42 (1H, multiplet, —O—*CH*—CH_3).

Lactonium salt 9 ($SbCl_6^-$): m.p. 131–132° dec. (ether–CH_2Cl_2); i.r.: ν_{max} (CH_2Cl_2) 1550, 1000–1200 cm^{-1}; n.m.r.: δ(CD_2Cl_2) 0.94 (6H, doublet, J = 5.5 Hz, —CH(CH_3)$_2$), 1.47 (3H, triplet, J = 7.0 Hz, —O—CH_2—*CH*$_3$), 2.03 (4H, multiplet, methylene on C-4, C-5 and —*CH*(CH_3)$_2$), 2.92 (2H, multiplet, methylene at C-3), 4.80 (2H, quartet, J = 7.0 Hz, —O—*CH*$_2$—CH_3), 5.17 (2H, multiplet, methylene on C-6).

Lactonium salt 10 ($SbCl_6^-$): m.p. 124–125° dec. (ether–CH_2Cl_2); i.r.: ν_{max} (CH_2Cl_2) 1550, 1000–1200 cm^{-1}; n.m.r.: δ(CD_2Cl_2) 1.50 (3H, triplet, J = 7.0 Hz, —O—CH_2—*CH*$_3$), 1.0–2.0 (10H, multiplet, ring hydrogens), 2.50–3.12 (2H, multiplet, methylene at C-3), 4.72–5.12 (2H, multiplet, methylene at C-6), 4.84 (2H, quartet, J = 7.0 Hz, —O—*CH*$_2$—CH_3).

Lactonium salt 11 ($SbCl_6^-$): m.p. 148–149° dec. (CH_2Cl_2–hexane); i.r.: ν_{max} (CH_2Cl_2) 1550, 850–1100 cm^{-1}; n.m.r.: δ(CD_2Cl_2) 1.0–2.3 (10H, multiplet, ring hydrogens), 2.9–3.4 (2H, multiplet, methylene at C-3), 4.56 (3H, singlet, —O—CH_3), 4.7–5.2 (2H, multiplet, methylene at C-6).

[10]One referee commented on the possibility that only one antiperiplanar lone pair might be sufficient to allow a specific cleavage. It is certainly possible to have a cleavage with the aid of only one lone pair. For instance, compound **30** can be hydrolyzed under more vigorous acidic conditions. However, we think that a specific cleavage with two lone pairs is a much easier process. Whenever it can occur, cleavage with the aid of one lone pair cannot compete.

*Orthoesters **12–17***

General Method of Preparation

A solution of *O*-alkyl lactonium tetrafluoroborate (10 mmol) in 35 ml of dichloromethane was prepared as described above. This solution was added dropwise and under dry nitrogen atmosphere to a solution of sodium alkoxide (30 mmol) in 35 ml of alcohol cooled to −78°. The reaction was magnetically stirred at this temperature for 1 h. The reaction mixture was then allowed to warm up to room temperature and ether was added. The organic phase was washed with an aqueous solution of sodium bicarbonate, dried over potassium carbonate, and evaporated to dryness yielding crude orthoester. Orthoesters were purified by distillation under vacuum.

*Orthoester **12**:* b.p. 72°/20 mm (lit. (7) b.p. 60–61.5°/10 mm); yield 85% (lit. (16) 83%); i.r.: ν_{max} (film) 1000–1200 cm^{-1}; n.m.r.: δ($CDCl_3$) 1.18 (6H, triplet, J = 7.0 Hz, —O—CH_2—CH_3), 1.8–2.5 (4H, multiplet, methylene at C-3 and C-4), 3.60 (4H, quartet, J = 7.0 Hz, —O—CH_2—CH_3), 4.0 (2H, multiplet, methylene at C-5); m.s.: *m/e* 160 (M^+), 102 ($M^+ - C_4H_{10}$), 87 ($M^+ - C_4H_9O$).

Anal. Calcd. for $C_8H_{16}O_3$: C, 59.98; H, 10.07. Found: C, 59.74; H, 10.09.

*Orthoester **13**:* b.p. 72–74°/20 mm (71%); i.r.: ν_{max} (film) 1000–1200 cm^{-1}; n.m.r.: δ($CDCl_3$) 1.18 (6H, triplet, J = 7.5 Hz, —O—CH_2—CH_3), 1.65 (6H, multiplet, methylenes at C-3, C-4, and C-5), 3.55 (4H, quartet, J = 7.5 Hz, —O—CH_2—CH_3), 3.70 (2H, multiplet, methylene at C-6); m.s.: *m/e* 174 (M^+), 129 ($M^+ - C_2H_5O$).

Anal. Calcd. for $C_9H_{18}O_3$: C, 62.04; H, 10.41. Found: C, 62.16; H, 10.22.

*Orthoester **14**:* b.p. 42°/0.8 mm (80%); i.r.: ν_{max} (film) 1000–1200 cm^{-1}; n.m.r.: δ($CDCl_3$) 1.18 (6H, triplet, J = 7.5 Hz, —O—CH_2—CH_3), 1.20 (3H, doublet, J = 6.5 Hz, —CH—CH_3), 1.66 (6H, multiplet, methylenes at C-3, C-4, and C-5), 3.55 and 3.61 (4H, two quartets, J = 7.5 Hz, —O—CH_2—CH_3), 3.60 (1H, multiplet, —CH—CH_3); m.s.: *m/e* 188 (M^+), 143 ($M^+ - C_2H_5$).

Anal. Calcd. for $C_{10}H_{20}O_3$: C, 63.80; H, 10.71. Found: C, 63.93; H, 10.42.

*Orthoester **15**:* b.p. 82–83°/1.7 mm (85%); i.r.: ν_{max} (film) 1000–1200 cm^{-1}; n.m.r.: δ($CDCl_3$) 0.90 (6H, doublet, J = 5.0 Hz, —CH—$(CH_3)_2$), 1.18 (6H, triplet, J = 7.0 Hz, —O—CH_2—CH_3), 1.47 (4H, multiplet, methylenes at C-3 and C-5), 2.05 (2H, multiplet, proton at C-4 and —$CH(CH_3)_2$), 3.58 (4H, two unresolved quartets, J = 7.0 Hz, —O—CH_2—CH_3), 3.80 (2H, multiplet, methylene at C-6); m.s.: *m/e* 216 (M^+), 171 ($M^+ - C_2H_5O$).

Anal. Calcd. for $C_{12}H_{24}O_3$: C, 66.63; H, 11.18. Found: C, 66.33; H, 11.12.

*Orthoester **16**:* b.p. 80–81°/0.4 mm (80%); i.r.: ν_{max} (film) 1000–1200 cm^{-1}; n.m.r.: δ($CDCl_3$) 1.18 (6H, triplet, J = 7.0 Hz, —O—CH_2—CH_3), 1.0–2.0 (12H, multiplet, ring hydrogens), 3.50 (2H, multiplet, methylene at C-6), 3.55 (2H, quartet, —O—CH_2—CH_3 axial), 3.60 (2H, quartet, —O—CH_2—CH_3 equatorial); m.s.: *m/e* 228 (M^+), 183 ($M^+ - C_2H_5O$).

Anal. Calcd. for $C_{13}H_{24}O_3$: C, 68.38; H, 10.59. Found: C, 68.55; H, 10.64.

*Orthoester **17**:* b.p. 84–86°/4.0 mm (74%); i.r.: ν_{max} (film) 1000–1200 cm^{-1}; n.m.r.: δ($CDCl_3$) 0.9–2.1 (2H, multiplet, ring hydrogens), 3.18 (3H, singlet, —O—CH_3 axial), 3.28 (3H, singlet, —O—CH_3 equatorial), 3.4–3.8 (2H, multiplet, —CH_2—O—); m.s.: *m/e* 200 (M^+), 169 ($M^+ - CH_3O$).

Anal. Calcd. for $C_{11}H_{20}O_3$: C, 65.97; H, 10.07. Found: C, 65.74; H, 10.03.

*Orthoester **39***

A solution of *O*-ethyl lactonium salt ***10*** (1.04 mmol) in 5 ml of dichloromethane was added dropwise and under dry nitrogen atmosphere to a solution of sodium methoxide (10.4 mmol) in methanol (3 ml) and isopropyl alcohol (10 ml) cooled to −78°. The reaction was magnetically stirred at this temperature for 1 h. The reaction mixture was allowed to warm up at room temperature and work-up as described in the general method furnished the crude orthoester **39**: yield 76%; i.r.: ν_{max} (film) 1000–1200 cm^{-1}; n.m.r.: δ($CDCl_3$) 0.8–2.2 (2H, multiplet, ring hydrogens), 1.22 (3H, triplet, J = 7.0 Hz, —CH_2—CH_3), 3.22 (3H, singlet, —O—CH_3 axial), 3.61 (2H, quartet, J = 7.0 Hz, —O—CH_2—CH_3, equatorial); m.s.: *m/e* 214 (M^+), 183 ($M^+ - CH_3O$), 169 ($M^+ - C_2H_5O$). A peak at *m/e* 200 indicated the presence of ≃3% of compound **17**.

*Orthoester **40***

A solution of *O*-methyl lactonium salt ***11*** (1.30 mmol) in 5 ml of dichloromethane was added dropwise and under dry nitrogen atmosphere to a solution of sodium ethoxide (13 mmol) in absolute ethanol (5 ml) and isopropanol (10 ml) cooled to −78°. The reaction was magnetically stirred at this temperature for 1 h. Work-up as described in general method gave crude orthoester **40**: yield 73%; i.r.: ν_{max} (film) 1000–1200 cm^{-1}; n.m.r.: δ($CDCl_3$) 0.8–2.2 (2H, multiplet, J = 7.0 Hz, ring hydrogens), 3.32 (3H, singlet, —O—CH_3, equatorial), 3.36 (2H, quartet, J = 7.0 Hz, —O—CH_2—CH_3, axial); m.s.: *m/e* 214 (M^+), 183 ($M^+ - CH_3O$), 169 ($M^+ - C_2H_5O$). A peak at *m/e* 228 indicated the presence of ≃5% of compound **16**.

*Orthoester **43***

A solution of *O*-methyl lactonium salt ***11*** (3.0 mmol) in 5 ml of dichloromethane was added dropwise and under dry nitrogen atmosphere to a solution of sodium methoxide (11.0 mmol) in deuterated methanol (3 ml) and isopropanol (5 ml) cooled to −78°. Usual work-up gave orthoester **45**: yield 79%; i.r.: ν_{max} (film) 1000–1200 cm^{-1}; n.m.r.: δ($CDCl_3$) 0.8–2.2 (2H, multiplet, ring hydrogens), 3.32 (3H, singlet, —O—CH_3, equatorial), 3.4–3.8 (2H, multiplet, —O—CH_2—); m.s.: *m/e* 203 (M^+), 172 ($M^+ - CH_3O$), 169 ($M^+ - CD_3O$). A peak at *m/e* 206 indicated the presence of ≃10% of compound **44**.

Orthoester Hydrolysis

General Procedure (Vapor Phase Chromatographic Analysis)

Orthoester (1 mmol) was dissolved in dichloromethane (1 ml) and poured on cold water (1 ml) containing a small amount of *p*-toluenesulfonic acid (10^{-3} *M*). A rigorous agitation was maintained at 0 °C for 20 min. Reaction mixture was dissolved in cooled pyridine (30 ml), excess acetic anhydride was added, and left overnight at room temperature. The excess acetic anhydride was destroyed by methanol with cooling. The solvents were removed

in vacuo and the crude product was analysed by v.p.c. (SE-30 10%, 5 ft × $\frac{1}{8}$ in. Chromasorb W, 100–200 mesh, 100° or specified).

Photoionization Cross Sections at 11.6–11.8 eV

JO ALLAN BERAN, ANIL KUMAR DHINGRA,[1] WU-SCHYONG LIU, AND DONALD FOSTER MULLICA

Department of Chemistry, Texas A & I University, Kingsville, Texas 78363

Received August 26, 1974

JO ALLAN BERAN, ANIL KUMAR DHINGRA, WU-SCHYONG LIU, and DONALD FOSTER MULLICA. Can. J. Chem. **53**, 1616 (1975).

The relative photoionization cross sections of a homologous series of alkanes, alkenes, alkyl chlorides, aldehydes, ethers, ketones, and alcohols have been determined at 11.6–11.8 eV using an argon resonance lamp. Correlations have been made between the photoionization cross sections and the molecular polarizability, the diamagnetic susceptibility, and the electron ionization cross sections of the molecules. No general correlation was found to exist but linear correlations were observed within each molecular class of compounds. These results are in general agreement with earlier studies on the electron ionization cross sections at 70 eV.

JO ALLAN BERAN, ANIL KUMAR DHINGRA, WU-SCHYONG LIU et DONALD FOSTER MULLICA. Can. J. Chem. **53**, 1616 (1975).

On a déterminé, à 11.6–11.8 eV utilisant une lampe à résonance d'argon, les sections efficaces relatives de photoionisation de séries analogues d'alcanes, d'alcènes, de chlorures d'alkyle, d'aldéhydes, d'éthers, de cétones et d'alcools. On a fait des corrélations entre les sections efficaces de photoionisation et la polarisabilité moléculaire, la susceptibilité diamagnétique et les sections efficaces d'ionisation électronique des molécules. On n'a trouvé aucune corrélation générale; toutefois on a observé des corrélations linéaires à l'intérieur de chaque classe moléculaire de composés. Ces résultats sont en accord général avec des études antérieures sur les sections efficaces d'ionisation électronique à 70 eV.

[Traduit par le journal]

Introduction

Theoretical and experimental electron ionization cross sections for a large number of atoms and molecules have been studied quite extensively at high energies (70 eV and above) over the past several years. These data have been used quite extensively for the evaluation of radiation chemical data and for the study of ion–molecule reactions.

The energy region for ion–molecule reactions has been extended more recently (1, 2) with the availability of intense monochromatic sources of light in the low energy region (<20 eV) (3), however, data on the experimental and theoretical photoionization cross sections at these energies have been minimal. Some studies have been reported on the photoionization cross sections of nitric oxide (4) and low molecular weight hydrocarbons (5) but no extensive body of data has been collected on photoionization cross sections as in the case with electron ionization cross sections.

Several investigators have made attempts to correlate electron ionization cross sections with some ground state molecular property of the molecule under study. Otvos and Stevenson (6) suggested that molecular ionization cross sections could be determined by the addition of constituent atomic cross sections; however, errors in their calculations invalidated the results. Lampe *et al.* (7) did an extensive study of ionization cross sections and found that the additivity postulate did not hold, but that a correlation with the polarizability of the molecule did exist. Later work has shown that a correlation with diamagnetic susceptibility is also probable (8).

Recently extensive studies and a review of earlier work on ionization cross sections have been reported by Harrison *et al.* (9) and Beran and Kevan (10) at 70 eV, in which they have reported that correlations do exist between the cross sections and the molecular polarizability and the diamagnetic susceptibility within a molecular class of compounds but that a general correlation for all molecules does not exist.

We have attempted to extend these studies into the low energy region by studying the rela-

tive photoionization cross sections at 11.6 to 11.8 eV, utilizing an argon resonance lamp as the energy source. We have attempted correlations between the photoionization cross sections and the molecular polarizability and the diamagnetic susceptibility of a system of molecules to see if such correlations are valid as they are at higher energies (70 eV). Our results at low energy show that such correlations do exist within a molecular class of compounds as had been reported earlier at 70 eV by Beran and Kevan (10). In addition a correlation has been drawn between the photoionization cross sections and electron ionization cross sections at 70 eV.

Experimental

All compounds were obtained commercially and used without further purification, but were degassed before use. In most cases the purities were quoted to be greater than 99% although some of the ketones were quoted at less than 99% pure. All the liquid samples used in this study were doubly distilled prior to use.

An argon resonance lamp was utilized for the photoionization studies. The lamp was filled on a mercury-free vacuum line capable of achieving pressures less than 1×10^{-6} Torr. A LiF window was used on the lamp. The detailed construction technique of the lamp and the operational characteristics of an argon resonance lamp, fitted with a LiF window, have been described in an article by Gorden *et al.* (11). The lamp was powered by a 2450 MHz Raytheon microwave generator. The discharge of the lamp was kept at least 15 cm removed from the window and was operated at low intensities ($\sim 10^{12}$ quanta/s) to reduce the formation of F centers in the LiF window. Under these conditions the fluctuation of intensity of the lamp during the course of an experimental run was minimal.

The irradiation of the sample was carried out by coupling the lamp to the photoreaction cell which contained two parallel-plate stainless steel electrodes, the window of the lamp being located at the edge of the two electrodes. The electrodes were insulated from the body of the cell. The total ion current generated from the photoionization of the sample was monitored by a Keithley 602 electrometer.

Since its photoionization quantum yield is well established at the argon resonance wavelength (12), nitric oxide was used as the reference gas in this study and all the results reported here are relative to its behavior. It also has a low absorption coefficient such that ions are uniformly distributed throughout the gas and meaningful saturation current values are obtained over a wide pressure range (13). The saturation ion current generated on irradiating NO was also used to determine the absolute intensity of the light entering the cell (11). This is given by

$$[1] \qquad {}^{q}a = 6.24 \times 10^{18}(i_{NO}/\eta_{NO})$$

where ${}^{q}a$ is the absolute intensity of the absorbed light in quanta s^{-1}, i_{NO} is the saturation current of NO in amperes, and η_{NO} is the ionization quantum yield (11) for NO. By adjusting the microwave power and the distance of the discharge from the window the intensity of the lamp was kept at $\sim 10^{12}$ quanta s^{-1}.

The photoionization cross section, Q, may be determined from the total ion current, I_t, by using the following relationship

$$[2] \qquad I_t = QLdN$$

where L is the intensity of the incident radiation, d is the ionization path length, and N is the number of molecules per cm^3 in the reaction cell. For a given set of experiments the intensity L and the ionization path length, d, were kept constant. Since N is proportional to the pressure, a plot of the total current I_t *vs.* pressure should be linear with a slope proportional to the photoionization cross section of the molecule.

All current *vs.* pressure plots in this study were linear. The slopes of the plots were determined by a computer least squares fit to the experimental points. The standard deviation of the fit was within 1%. Four or more pressure plots were determined in most cases for each molecule studied, the slope of the NO plot being used as the standard. The photoionization cross section of a molecule was obtained by taking the ratio of the slopes of the molecule to that of NO. The average deviation of these slopes was in most cases no more than 5%.

Results and Discussion

Relative Phototionization Cross Sections

The relative photoionization cross sections for various series of organic compounds were determined at the argon wavelength radiation and are reported in Table 1. These values are the average of four or more determinations. All the values reported in this work are relative to the cross section of nitric oxide, which was assigned a value of one. In addition Table 1 lists the standard deviation from the mean values of the cross section. In the case of liquid samples the upper limit of each series was determined by the volatility of the compound since the samples were run at room temperature. In some cases, *e.g.* methane, the ionization potential was higher than the energy emitted by the lamp (11.6–11.8 eV) and hence, their cross sections could not be determined.

The results in Table 1 show various examples of the effect of structural isomerism on the cross section of the molecule, *e.g.* butenes, pentenes, butyl alcohols, etc. It is observed from Table 1 that the cross sections for the various isomers are almost the same and that, within experimental error, the cross sections are independent of structure within a given class of compounds. However, if one compares the cross sections

*Average of different isomers.

of structural isomers belonging to different functional classes, as shown in Table 2, one does not observe the same values of cross sections. Similar behavior in the trend of cross sections at a higher energy (75 eV) was observed by Harrison *et al.* (9).

Table 1 also lists the molecular polarizability and the diamagnetic susceptibility values taken from the literature (14) and used for correlations in this study. In addition in Table 1, for comparison purposes, are listed the values of electron ionization cross sections at 70 eV. These values have been taken partly from the work of Beran and Kevan (10) and partly from Harrison *et al.* (9); however, for uniformity all these electron ionization cross sections are relative to the cross section of argon used by Beran and Kevan.

Correlation of Cross Sections with Molecular Parameters

The correlations of relative photoionization cross sections with molecular polarizability and diamagnetic susceptibility are shown in Figs. 1–3. The numbers in the figures refer to the numbers for the compounds in Table 1. The numerical values of the molecular polarizability and diamagnetic susceptibility used for these correlations are listed in Table 1 and are taken from the work of Beran and Kevan (14). These workers calculated the molecular polarizability using LeFevre's method of additivity of bond polarizabilities (15), and the diamagnetic susceptibility using the semi-empirical method of Haberditzl (16). In instances where the values of these two parameters were not available for certain molecules, they were calculated using LeFevre's method and Haberditzl's method, respectively. In addition to the correlations shown in Figs. 1–3, correlations can also be made with values of molecular polarizability and diamagnetic susceptibility calculated using other semi-empirical methods, *e.g.*, Lippincott–Stutman's δ-function model (17) for molecular polarizability and Baudet's method (18) for diamagnetic susceptibility. In each of these cases, however, the correlations obtained are similar to those reported in Figs. 1–3.

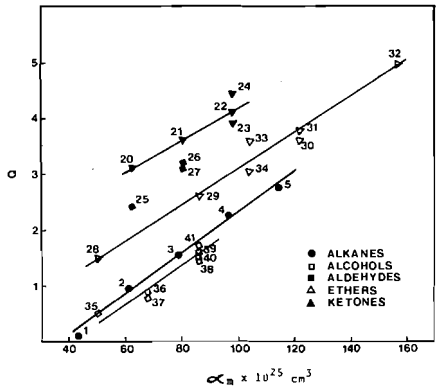

FIG. 1. Relative photoionization cross sections (Q) *vs.* molecular polarizabilities (α_m) for alkanes, alcohols, aldehydes, ethers, and ketones.

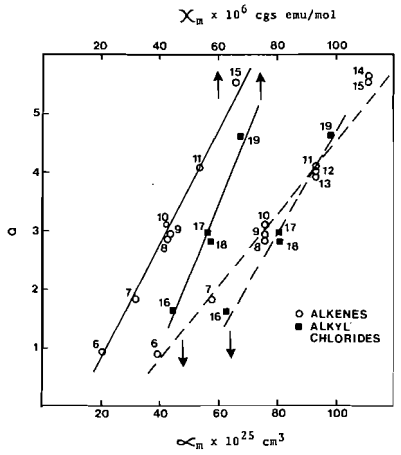

FIG. 2. Relative photoionization cross sections (Q) *vs.* molecular polarizabilities (α_m) and diamagnetic susceptibilities (χ_m) for alkenes and alkyl chlorides.

It is observed from the figures that a good linear correlation exists between the cross section and the molecular polarizability and diamagnetic susceptibility for each of the homologous series of compounds studied. These linear correlations are drawn from a least square fit. Although no linear correlation has been drawn for the aldehydes, their values are

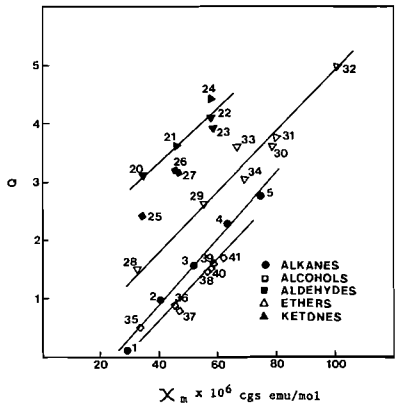

FIG. 3. Relative photoionization cross sections (Q) *vs.* diamagnetic susceptibilities (χ_m) for alkanes, alcohols, aldehydes, ethers, and ketones.

indicated on Figs. 1 and 3 to give a general idea for comparison with other series of compounds.

It is obvious from the figures that no general correlation exists for all the molecules for either the molecular polarizability or diamagnetic susceptibility; however, there is a linear correlation within a homologous series in each case. Thus a knowledge of either the molecular polarizability or the diamagnetic susceptibility of molecules should permit the estimation of cross sections for other members of the series.

In the case of molecular polarizability correlations, our conclusions are in complete accord with those at 70 eV by Harrison *et al.* (9) and Beran and Kevan (10). On studies conducted on the same series of compounds, as in this study, they observed that a correlation existed within each class of compounds but not overall. In addition a semi-empirical equation was derived by Beran and Kevan between molecular polarizability and cross section. A similar equation, which takes into account the slope and intercept of the correlations, can now be derived for low energies (11.6–11.8 eV) from our results. A look at Fig. 1 shows that the slopes of the various correlations (except for the alkenes and alkyl chlorides) are the same, within experimental error, and hence a semi-empirical equation can be written in which the slopes of all the correlations are adjusted to one slope. However, we feel that such an equation would be of limited value and that cross sections can be obtained readily by simple extrapolation.

In the case of diamagnetic susceptibility correlations, however, our conclusions are in distinct contrast to those reached at 70 eV by Beran and Kevan (10). They observed that a general correlation, as proposed earlier by Stevenson and Schissler (8) existed between the cross section and the diamagnetic susceptibility for the molecular classes: alkanes, alkenes, alkyl chlorides, ethers, ketones, and aldehydes. This general correlation, however, was not complete as the fluorine substituted compounds were found to deviate from it. From our results, as in the case of molecular polarizability correlation, we observe that a correlation exists only within each molecular class of compounds but not overall.

We observe from Fig. 3 that the slopes of the alkanes, alcohols, ethers, and ketone correlations are the same, within experimental error, hence it would again be possible for us to write a semi-empirical equation relating the cross section with the diamagnetic susceptibility.

Correlation of Photoionization Cross Sections with Electron Ionization Cross Sections

The correlation of relative photoionization cross sections at 11.6–11.8 eV with electron ionization cross sections at 70 eV is shown in Fig. 4. The values of the cross sections at 70 eV are taken from the literature and are listed for reference in Table 1. For the alcohol series, values of cross sections at 70 eV were not available.

From Fig. 4 it is observed that a good linear correlation is exhibited by molecules which are members of the same class of compounds. This shows that the photoionization cross sections can be predicted from the electron ionization cross sections or vice versa. This result seems significant in that a large body of data does exist for the electron ionization cross sections, since most of this data can be determined easily using mass spectrometric techniques. However, data on photoionization cross sections is very meager as the energy sources for such studies are relatively new. Hence such a correlation can be used for finding ionization cross sections at 11.6–11.8 eV. On the other hand we could also use this correlation to predict cross sections at 70 eV. For example, the electron ionization cross sections at 70 eV for the alcohols are not known except for ethyl alcohol. Using this cross section and assuming that the slope of the correlation is the same as for the alkanes, ketones, and ethers (this assumption would seem reasonable when one considers the fact

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

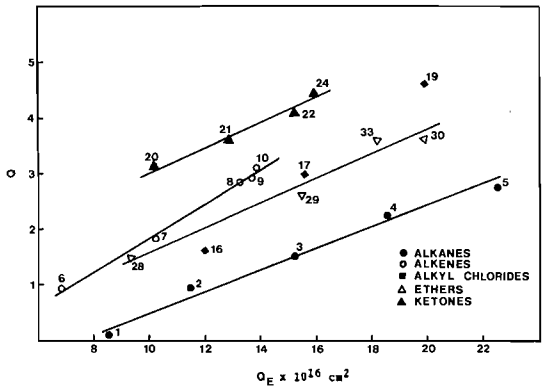

FIG. 4. Relative photoionization cross sections (Q) *vs.* electron ionization cross sections (Q_E) at 70 eV.

that the slopes for the alkanes, ketones, ethers, and alcohols are almost the same in all the other correlations studied in this work) one could draw a correlation for the alcohols in Fig. 4 and from it predict the electron ionization cross sections at 70 eV for the alcohol in question.

Conclusions

The relative photoionization cross sections of a number of molecules have been determined at 11.6–11.8 eV. Correlations have been made between the photoionization cross sections and the molecular polarizability and the diamagnetic susceptibility of the molecules to see if such correlations could be extended to the low energy region, as had been previously observed at the high energy region. From our results it is concluded that no apparent general correlation is valid but that each is valid within a given molecular class of compounds for both parameters used in the correlations. In addition a correlation is also observed with electron ionization cross sections at 70 eV. It should be mentioned here that a relation between the electron ionization cross section and the photoionization cross section was first shown by Bethe (19). The Bethe approximation has been applied successfully by Seaton (20) in determining the electron ionization cross sections from a knowledge of photoionization cross sections.

These correlations are similar to those observed at 70 eV except for the diamagnetic susceptibility case. Beran and Kevan (10) observed a general correlation when this parameter was used for the alkanes, alkenes, alkyl chlorides, ketones, ethers, and aldehydes; however, we find a correlation within each class only. This difference in observation can be attributed to the fact that photoionization and electron ionization are quite different phenomena. In photoionization only the outer electrons are ejected regardless of the photon energy while in the electron ionization process the inner shell electrons may also be ejected. Furthermore, in photoionization only one electron is ejected while in electron ionization more than one electron may be ejected leading to multiple ionization. In addition diamagnetic susceptibility is proportional to the square root of the polarizability times the square root of the number of electrons in the atom (21). Therefore, the observation at 11.6–11.8 eV that a correlation with diamagnetic susceptibility exists within each molecular class does not seem unfounded.

We wish to thank the Robert A. Welch Foundation for support of this work.

ABRAHAM CLEARFIELD, DAVID KEITH WARNER, CARLOS HERMAN SALDARRIAGA-MOLINA, RAMANATHAN ROPAL, and IVAN BERNAL. Can. J. Chem. **53**, 1622 (1975).

The crystal and molecular structure of bis(π-cyclopentadienyl)titanium dichloride, $(C_5H_5)_2TiCl_2$, has been determined from three dimensional X-ray data. The crystals are triclinic with $a = 7.882(5)$, $b = 19.478(10)$, $c = 12.156(9)$ Å, $\alpha = 90.46(2)$, $\beta = 102.58(2)$, $\gamma = 143.49(2)°$. Intensity data (3742 reflections above background) were collected by the θ–2θ scan method using an automated counter diffractometer. The structure was refined in space group $P\bar{1}$ by block-diagonal least squares methods to a conventional R of 0.032. Since $Z = 4$, there are two symmetry independent molecules per unit cell. However, these two molecules are almost identical structurally. The coordination about the titanium atom formed by the two chlorine atoms and the centroids of the cyclopentadiene rings is that of a distorted tetrahedron. The average Ti—Cl bond distance is 2.364(3) Å and Ti—Cp—(centroid) 2.058 Å. The C—C distances vary from 1.339(11) to 1.419(9) Å. The structural results are compared to those for similar type molecules.

ABRAHAM CLEARFIELD, DAVID KEITH WARNER, CARLOS HERMAN SALDARRIAGA-MOLINA, RAMANATHAN ROPAL et IVAN BERNAL. Can. J. Chem. **53**, 1622 (1975).

On a déterminé la structure cristalline et moléculaire du dichlorure de bis (π-cyclopentadiènyl) de titane, $(C_5H_5)_2TiCl_2$, à partir de mesures rayons-X tridimensionnelles. Les cristaux sont tricliniques, $a = 7.882(5)$, $b = 19.478(10)$, $c = 12.156(9)$ Å, $\alpha = 90.46(2)$, $\beta = 102.58(2)$, $\gamma = 143.49(2)°$. Les intensités ont été mesurées par la méthode de balayage θ–2θ avec un diffractomètre automatique (3742 reflexions ont une intensité supérieure au bruit de fond). On a affiné la structure dans le groupe d'espace $P\bar{1}$ par la méthode des moindres carrés (bloc diagonal) jusqu'à un facteur d'accord R de 0.032. Puisque $Z = 4$, il y a deux molécules indépendantes par unité asymétrique. Toutefois ces deux molécules ont des structures pratiquement identiques. La coordination de l'atome de titane, formée de deux atomes de chlore et des centres des cycles cyclopentadiènes est celle d'un tétraèdre déformé. La distance moyenne du lien Ti—Cl est de 2.364(3) Å et celle de Ti—Cp (centre) est de 2.058 Å. Les distances C—C varient de 1.339(11) à 1.419(9) Å. On compare ces résultats structuraux avec ceux de molécules de type semblable. [Traduit par le journal]

Introduction

Bis(π-cyclopentadienyl)titanium(IV) dichloride, hereafter referred to as either titanocene dichloride or Cp_2TiCl_2, was prepared in 1954 by Wilkinson and Birmingham (1), who suggested from infrared studies that the molecule contains π-bonds between the Ti and the two cyclopentadienyl moieties. In 1957, Natta *et al.* (2) isolated the adduct of titanocene dichloride with diethyl aluminum as part of their studies of the mechanism of Ziegler catalysis in the polymerization of ethylene. The isolation of this compound was an important achievement since Natta and his associates were attempting then to show that the Ziegler catalysts for the polymerization of ethylene are, in general, bimetallic compounds containing organometallic bonds.

In 1966, an electron diffraction study was reported (3) in which Cp_2TiCl_2 was described as a prismatic sandwich in which the Cp rings are inclined towards each other at an angle of 58.5°. The Ti—Cl and Cl—Ti—Cl parameters were listed as 2.24 Å and 100°, respectively.

[1]Portions of this paper are based on the M.S. Thesis of D. K. Warner, presented to the Chemistry Department, Ohio University, Athens, Ohio, March, 1969.

These results are significantly different from those obtained in single crystal, X-ray (4), and neutron (5) diffraction studies of closely related substances.

In the solid state, titanocene dichloride has been studied twice by single crystal X-ray diffraction methods (6, 7). In the first report (6) no positional parameters were given. The second one (7) gives positional parameters but the results are not very accurate. For example, the C—C distances range from 1.32(4) to 1.50(4) Å. Thus, for the purposes of more accurate comparisons (4, 5, 8–10) these results are not very useful. Since, at the same time, we were aware that there are serious twinning problems with *most* crystals of titanocene dichloride, we decided to continue with our study on a non-twinned crystal we had obtained earlier (see Experimental). The results of that study are given below.

Experimental

Titanocene dichloride (Arapahoe Chemical Co.) of unknown purity was recrystallized from a 1:1 xylene–chloroform mixture. The m.p. of the resulting crystals was 287–288 °C, compared with the value of 287 ± 2 °C given by Wilkinson and Birmingham (1). Titanium was determined by fuming a sample of the crystals with perchloric acid in order to destroy the organic matter, precipitating the hydrous oxide with ammonia, and igniting to TiO_2. Chloride was determined gravimetrically as AgCl and carbon and hydrogen by standard combustion analysis.

Anal. Calcd: Ti, 19.24; Cl, 28.48; C, 48.23; H, 4.05. Found: Ti, 19.44; Cl, 28.36; C, 48.26; H, 4.01.

Crystals used for the X-ray study were obtained from hot benzene. They were small, bright red prisms which appeared, from optical examinations,[2] to have a 2-fold axis of symmetry. Crystals grown from other solvents under a variety of conditions were invariably twinned. Even with those grown from hot benzene, only a few were untwinned. Survey photographs taken with both Weissenberg and precession cameras failed to show the presence of any symmetry axes higher than 1. A set of three noncoplanar axes was chosen from photographs of an untwinned crystal and subjected to a reduced cell calculation. The reduced cell dimensions were: $a = 7.89$, $b = 11.58$, $c = 12.17$ Å, $\alpha = 108.0$, $\beta = 102.7$, and $\gamma = 89°$. These values are in substantial agreement with those reported by Tkachev and Atovmyan (7).

Accurate unit cell dimensions were obtained with a CAD-4 four-circle diffractometer (Enraf-Nonius) at 24 ± 1 °C. Subroutines SEARCH, INDEX, AND DETCELL (11) were used to collect 25 reflections at high and moderate (2θ) angles. The reflections were scanned at both ±2θ by the θ–2θ scan technique using a graphite monochromated beam of MoKα radiation ($\lambda = 0.7107$ Å) at a take-off angle of 4°. The Bragg angles were accurately determined by program DETCELL which automatically centers reflections while compensating for wavelength dispersion. Then the cell dimensions were obtained from a least squares calculation using the θ_1 values and $\lambda K\alpha_1 = 0.70926$ Å. This cell is related to the previous one by the transformation

$$\begin{pmatrix} A \\ B \\ C \end{pmatrix}_R = \begin{pmatrix} 1 & 0 & 0 \\ 2 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} a \\ b \\ c \end{pmatrix}$$

where, A_R, B_R, and C_R are the reduced cell constants.

The transformed cell dimensions are given in Table 1 along with other crystallographic data of interest. The density of a crystal was determined by flotation in a solution of iodobenzene in carbon tetrachloride.

The crystal chosen for intensity data collection was almost cubic in shape and approximately 0.12 mm on an edge. The crystal to counter distance was 208 mm and the crystal to aperture distance 173 mm. Intensity data were collected by the θ–2θ scan method using a variable scan rate ranging from about 0.25°/min for the weakest reflections to about 10°/min for the strongest ones. The angular scan width was also variable and amounted to $3 \times (1.0 + 0.5 \tan\theta)°$. The right and left backgrounds were scanned for half the time required for the total peak scan. During data collection two standard reflections were recorded every time a set of 24 reflections was collected and those were used to place all the reflections on a common scale. The change in the intensities of the standards was small, random, and the maximum fluctuation about the mean was ±4%. A total of 13 508 reflections was scanned of which 3742 had intensities with $I \geq 3\sigma(I)$, where

$$\sigma(I) = (\text{Total counts} + \text{Background counts})^{1/2}$$

and were, thus, considered as observed.

The data were corrected for Lorentz and polarization effects but not for absorption or extinction. The absorption coefficient is small ($\mu R = 1.46$ cm^{-1}) (12) and the

[2]A description of some of the common crystal shapes encountered in the growth of crystals of Cp_2TiCl_2 is given in ref. 19. Most of them are shapes of twins.

crystal was quite uniform in shape so that we estimate, from previous experience with absorption corrections on compounds of this type (4), that the error introduced by this omission amounts to no more than 2%.

Solution and Refinement of the Structure

The intensity data set was collected and indexed using the diffractometer working cell rather than the reduced cell dimensions. We decided at this point to find out the correctness of the solution of the structure of titanocene dichloride by Tkachev and Atovmyan (7), by using their positional parameters as a starting point in our refinement. Their positional parameters were transformed into those required for the working cell, using the transformation

$$x = X + 2Y$$

$$y = Y$$

$$z = Z$$

where x, y, and z are the fractional coordinates in our working cell and X, Y, and Z are the coordinates reported by Tkachev and Atovmyan (7). After refinement of the scale and the individual isotropic thermal parameters we obtained an $R(F)$ factor of 0.12, where

$$R(F) = \frac{\sum ||F_o| - |F_c||}{\sum |F_o|}$$

Refinement was continued by allowing for anisotropic thermal motion of all the atoms in the asymmetric unit, which lowered the $R(F)$ factor to 0.045. At this point, the positions of the hydrogen atoms were added at idealized positions which assume (*a*) that the Cp ring is a perfect pentagon and (*b*) that the hydrogen atoms lie in the same plane as the carbon atoms. The second assumption is certainly reasonable on the basis of the results obtained by neutron diffraction (5) for the closely related $(CH_2)_3(C_5H_4)_2TiCl_2$. The calculation of the positional parameters for the hydrogen atoms was carried out using program HYDROGEN (13) (C—H = 0.91 Å; C—C—H = 126°). The hydrogen atoms were assigned isotropic thermal parameters one unit (Å^2) larger than that of the carbons to which they are attached. When the values of the positional parameters of the nonhydrogen atoms shifted by less than 0.1 of their standard deviations, refinement was considered to be complete (14). The final value of $R(F)$ was 0.032 and that of the weighted residual

$$wR(F) = \left[\frac{\sum w(|F_o| - |F_c|)^2}{\sum wF_o^2}\right]^{1/2}$$

was 0.023. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, with weights, w, given by

$$w = \frac{1}{\{1 + [(F_o - P_2)/P_1]^2\}}$$

where $P_1 = 30$ and $P_2 = 90$.

A final difference Fourier map was featureless, with residual density ranging from a maximum of 0.3 e/Å^3 to a minimum of -0.3 e/Å^3. The scattering factors for the nonhydrogen atoms were taken from the compilation by Hanson *et al.* (15) in the neutral atom form. A correction for anomalous dispersion (the real term only) was included also in the refinement. The hydrogen atom scattering factors were those given by Stewart *et al.* (16).

The final set of coordinates and isotropic temperature parameters for the nonhydrogen atoms is listed in Table 2, while the positional parameters of the hydrogen atoms are given in Table 3. The anisotropic thermal parameters for the nonhydrogen atoms are listed in Table 4 and a listing of the observed and calculated structure factors is available from the Depository of Unpublished Data.[3]

At this point a comment on the solution of the structure by Tkachev and Atovmyan (7) is in order. Although we found that their positional parameters led to a smooth refinement of our data, their wide range of C—C distances may be traceable to difficulties with the quality of their data crystal (*vide supra*) similar to those we have experienced in the solution and refinement of the structure of Cp_2ZrCl_2, which is isomorphous with titanocene dichloride. We found that one of the two molecules in the asymmetric unit ($P\bar{1}$, $z = 4$) is either disordered or has high amplitudes of thermal motion in the Cp rings. Furthermore, this has independently been confirmed by Prout (17),[4] who has described similar difficulties with Cp_2ZrCl_2. As a result, we have abandoned further work

on the structure of zirconocene dichloride using our current set of data.

Description of the Structure and Discussion

In spite of the fact that the substance crystallizes with two independent molecules in the asymmetric unit, they have almost identical molecular parameters. This is readily shown by consideration of the bond lengths and angles given in Table 5. The Ti—Cl and Ti—C distances in both molecules are the same within experimental error (approximately 0.002 Å for the former and 0.009 Å for the latter). Similarly, the corresponding Cl—Ti—Cl, Cl—Ti—(ring centroid, Cp) and Cp—Ti—Cp angles are essentially identical for the two of them. In fact, the only discernible difference is the slightly shorter (average) C—C distance in molecule 2. However, this difference can readily be traced to the larger librational motion of the rings of this molecule about the metal – (ring centroid) vector. This phenomenon has been observed

and discussed elsewhere (4, 5, 8–10, 17) for similar molecules.

Both molecules have the familiar, distorted-tetrahedral shape found in related molecules (4, 5, 8–10, 17, 18) in which the four ligands to the central metal ion are the centroids of the two Cp rings and the two X ligands (X = halides, S, O, etc.). The configuration of the two molecules, including the shapes of the ellipsoids of thermal motion are shown in Fig. 1, where the numbering scheme used in the tables is also given. The metal–chlorine and the metal–Cp distances are identical with those found in (1,1′-trimethylenedicyclopentadienyl) titanium dichloride, $(CH_2)_3(C_5H_4)_2TiCl_2$, which contains a $—(CH_2)_3—$ chain spanning the two Cp

rings. An interesting consequence of which is the fact that, whereas in titanocene dichloride the Cp rings are staggered, in the bridged compound the Cp rings are eclipsed. This difference in ring orientation has no effect on the C—C distances or on the Ti—Cl bond lengths. It influences the molecular geometry, nonetheless, since it causes changes in the Cp—Ti—Cp, Cp—TiCl, and the Cl—Ti—Cl angles. For the two compounds the values are (130.97, 106.40, and 94.53(6)°) and (132.64, 105.95, and 93.69(5)°), respectively, for titanocene dichloride and the $-(CH_2)_3-$ bridged derivative. Thus, the smaller the Cp—Ti—Cp angle, the greater the values of the other two, which implies that this is a very compact molecular system in

*Two molecules in the asymmetric unit ($P\bar{1}$). This is the one with lower thermal parameters for the Cp ring.
†Note the difference in these angles between the bridged and the nonbridged species. This change is probably due to the fact that the bridged compounds have eclipsed rings which are so oriented as a result of the constraints imposed on their geometry by the propylene chain. The rings in the nonbridged compounds are almost exactly staggered.
‡Note the lanthanide contraction effect. The result is the same for the metal–chlorine bond as for the metal – Cp ring distance.

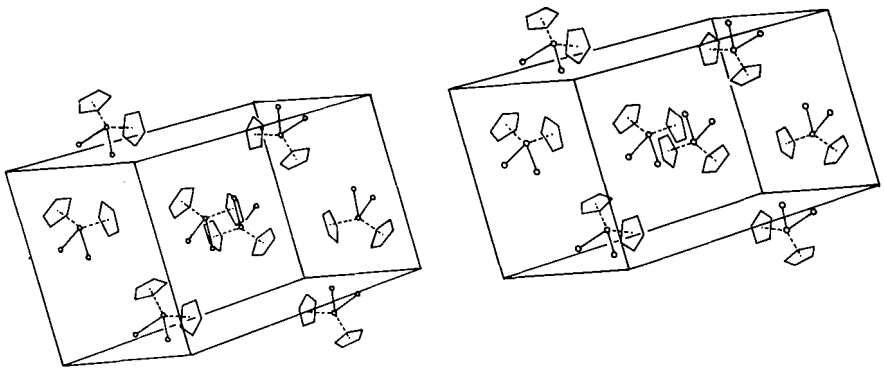

FIG. 2. This is a stereo packing diagram of the contents of the unit cell, also drawn using ORTEP.

which there is a fine balance between the Cp_2Ti and the $TiCl_2$ fragments that can readily be influenced by changes in either (*i.e.*, orientation of the rings as a result of constraints imposed by bridges, etc.).

The equations of the mean planes through the cyclopentadiene rings and the deviations of the carbon atoms from these planes are given in Table 6. In titanocene dichloride the deviations of the carbons from their mean plane are larger than those found in $(CH_2)_3(C_5H_4)_2MCl_2$, M = Ti, Zr, and Hf, as was to be expected in

view of the fact that the former exhibits larger freedom of librational motion of the Cp rings about the metal – (ring centroid) vector.

The distances of closest approach are listed in Table 7 and a packing diagram is shown in Fig. 2. Finally, a comparison of the molecular parameters (averaged values) for $(C_5H_5)_2TiCl_2$ and $(CH_2)_3(C_5H_4)_2MCl_2$ (M = Ti, Zr, and Hf) is presented in Table 8.

Electron Spin Resonance Studies on $Ti(H_2O)_6^{3+}$ in Frozen Aqueous Solutions of Titanium(III) Chloride, Bromide, Iodide, and Sulfate

PAVLE ILIJA PREMOVIĆ AND PAUL RONALD WEST

Department of Chemistry, University of Victoria, Victoria, British Columbia V8W 2Y2

Received November 14, 1974

PAVLE ILIJA PREMOVIĆ and PAUL RONALD WEST. Can. J. Chem. **53**, 1630 (1975).

Strongly acidic aqueous solutions of titanium(III) chloride, bromide, iodide, or sulfate (0.02 *M* metal ion) provide no detectable e.s.r. signal at room temperature. In the frozen solution (77 K) an identical spectrum is observed from each sample with $g_{\parallel} = 1.994 \pm 0.001$ and $g_{\perp} = 1.896 \pm 0.001$. A maximum signal is observed at 6–8 *M* added anion, indicating not all titanium(III) species are e.s.r. active. Analysis indicates that the local symmetry of the $Ti^{3+}(3d^1)$ ions providing the signal is D_3. It is proposed that these ions are $Ti(H_2O)_6^{3+}$ species located in sites in the ice structure subject to a strong asymmetric electric field from nearby counter ions. Since the spectrum is independent of anion, the counter ions are unlikely to be in the first or second coordination shell of the Ti^{3+}.

PAVLE ILIJA PREMOVIĆ et PAUL RONALD WEST. Can. J. Chem. **53**, 1630 (1975).

Lors de l'examen par r.p.e. à température de la pièce, de solutions fortement acides de chlorure, de bromure, d'iodure et de sulfate de titane(III) (0.02 *M* en ion métallique) on n'observe aucun signal. Dans des solutions congelées (77 K) on observe un spectre identique pour chaque échantillon avec $g_{\parallel} = 1.994 \pm 0.001$ et $g_{\perp} = 1.896 \pm 0.001$. On observe un signal maximum par addition de 6–8 *M* d'anions; ceci indique que toutes les espèces de titane(III) ne sont pas actives en r.p.e. Une analyse indique que la symétrie locale des ions $Ti^{3+}(3d^1)$ fournissant le signal est D_3. On propose que ces ions sont des espèces $Ti(H_2O)_6^{3+}$ situées dans des sites de la structure de la glace qui sont sujets à des champs électriques asymétriques très forts provenant des ions antagonistes voisins. Puisque le spectre est indépendant de l'anion, il semble improbable que les ions antagonistes soient dans la première ou dans la deuxième sphère de coordination du Ti^{3+}. [Traduit par le journal]

Introduction

The ground state of a d^1 ion such as Ti^{3+} is ^2D, separated in the free ion by a rather large energy, 80 378 cm^{-1} from the first excited state ^2S (the $3d^1 \rightarrow 4s^1$ transition) (1). An ideal octahedral ligand field (O_h symmetry) splits the ^2D state into a low lying $^2T_{2g}$ state and an upper $^2E_{2g}$ state. The acidic aqueous solutions of the titanium(III) halides, $TiCl_3$, $TiBr_3$, and TiI_3, have been studied both chemically and spectroscopically, and are believed to contain only octahedrally solvated titanium ions, $Ti(H_2O)_6^{3+}$ (2–4).

The broad weak band in the optical spectrum of the $Ti(H_2O)_6^{3+}$ ion is assigned to the $^2T_{2g} \rightarrow {}^2E_{2g}$ transition (5). One interesting feature of the spectrum is the asymmetric character of the visible absorption band. This band consists of a broad maximum at 21 000 cm^{-1} with a pronounced shoulder at $\sim$17 000 cm^{-1}. The splitting is considered to arise from a nuclear configurational instability in the excited state *i.e.* from the Jahn–Teller effect (6). The ideal octahedral ion $Ti(H_2O)_6^{3+}$ cannot be stable because of the threefold degeneracy of the $^2T_{2g}$ ground state, and a tetragonal distortion is required so that a nondegenerate ground state exists *i.e.* ($^2B_{2g}$). However the theoretical background of the Jahn–Teller effect gives no direct information concerning the magnitude of the deviation from octahedral symmetry, or a choice between a static distortion and a dynamic equilibrium between limiting structures. It is however expected that the splitting of the $^2T_{2g}$ ground state will be smaller than that of the excited $^2E_{2g}$ state.

No e.s.r. signals have been detected in solutions of $Ti(H_2O)_6^{3+}$ ions at room temperature since the residual angular momentum in the $^2T_{2g}$ ground state cancels the spin angular momentum. Eventual small axial or other distortion might possibly partially "quench" the orbital angular momentum, but the expected rather short T_1 (spin–lattice relaxation time) will render the e.s.r. signal undetectable.

We now report the appearance of identical

e.s.r. signals in frozen aqueous solutions of $TiCl_3$, $TiBr_3$, and TiI_3 at 77 K which we assign to $Ti(H_2O)_6^{3+}$ ions under the influence of a strong asymmetric electric field generated indirectly by the negative counter ions present.[1] A similar signal is observed from a frozen $Ti_2(SO_4)_3$ solution.

Experimental

All spectra were recorded on a Varian E-6S X Band e.s.r. spectrometer operating at 100 kHz modulation. Samples were contained in 5 mm cylindrical quartz cells and frozen by plunging into liquid nitrogen. Spectra were recorded while the sample was cooled in a Varian E-246 insert Dewar accessory.

The commercial 20% $TiCl^3$ solution (Fisher); or 15% $Ti_2(SO_4)_3$ solution (B.D.H., [Cl] < 0.02%) were used directly. The $TiBr_3$ and TiI_3 salts were prepared by the method of Semenova from the $Ti_2(CO_3^{2-})_3$ salt (8). The concentrations of anions were varied by either addition of the reagent grade salts (NaCl, KBr, KI, and Na_2SO_4) or concentrated acids (48%HBr, 37.5% HCl, 56%HI, and 98% H_2SO_4).

The g factors are quoted relative to DPPH $g = 2.0036$, measured by means of a dual cavity assembly.

Results

Strongly acidic solutions of titanium(III) chloride ($pH \leq 1.0$) provide no detectable e.s.r. signal at room temperature. However, a rapidly frozen solution of 0.02 M $TiCl_3$ in 2 M HCl provides the spectrum shown in Fig. 1, assigned to a species with axial symmetry with $g_{\parallel} = 1.994 \pm 0.001$ and $g_{\perp} = 1.896 \pm 0.001$. The result confirms the reported observation of Glebov (7).

We now report that a frozen solution of 0.03 M $Ti_2(SO_4)_3$ in 3.75 M H_2SO_4 provided an experimentally identical spectrum under conditions where chloride ion is totally absent. Moreover both a commercial $Ti_2(SO_4)_3$ solution (B.D.H.) and a solution prepared by dissolving Ti sponge in concentrated H_2SO_4 gave the same result. To further test the sensitivity of the observed spectrum to the nature of the anion we have prepared samples of both the iodide and the bromide salts of titanium(III) (8). The method involves precipitation of titanium(III) carbonate from a $TiCl_3$ solution and thorough water-washing until no further

[1]Recently Glebov reported the e.s.r. spectrum of a frozen hydrochloric acid solution of $TiCl_3$ with pronounced g factor anisotropy ($g_{\parallel} = 1.98$ and $g_{\perp} = 1.89$). However the assignment of the structure $Ti(H_2O)_5Cl^{2+}$ made without experimental or theoretical justification overlooks the true significance of the results (7).

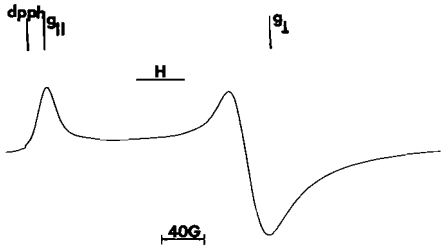

FIG. 1. Electron spin resonance spectrum of $Ti(H_2O)_6^{3+}$ in frozen aqueous solution: $Ti^{3+} = 0.02$ M, [HCl] = 6 N, 77 K.

chloride ion is detected. The $Ti_2(CO_3)_3$ is then dissolved in either aqueous HBr or HI to prepare solutions of titanous ion. Frozen solutions (77 K) prepared by this procedure [Ti] = 0.02 M, $[I^-]$ or $[Br^-] = 6$ M showed the *same spectrum* as recorded for the sulfate or chloride, Fig. 2. Even if a conservative estimate of say 10 mol% residual chloride is assigned to the solid carbonate, the ratio of $[Cl^-]$ to $[I^-]$ in the final solution would still be 10^4. It seems clear that the species providing the spectrum is independent of the anion selected, and hence does not contain anion in the first coordination shell.

A further convincing series of experiments relied upon the dependence of the signal intensity toward anion concentration. Employing 0.01 M titanium(III), a qualitatively identical spectrum was recorded at 2 M concentration of all the anions. In all cases the intensity gradually increased reaching a maximum at 4–8 M added anion. At elevated anion concentrations (> 10 M) further resonances due to additional species were apparent. Then the spectra were clearly different for Cl^-, Br^-, I^-, and SO_4^{2-}, showing a direct influence of the anion in the first coordination shell.

Of all the anions that were examined, sulfate

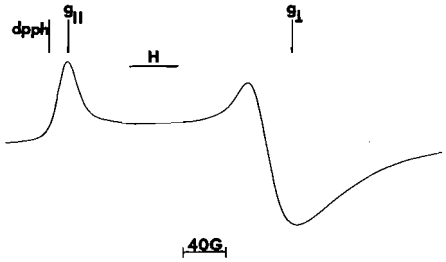

FIG. 2. Electron spin resonance spectrum of $Ti(H_2O)_6^{3+}$ in frozen aqueous solution: $Ti^{3+} = 0.02$ M, [HI] = 6.9 N, 77 K.

provided the weakest spectrum with a maximum intensity (7.5 *M* sulfate) that was only 40% of the strongest signal obtained with the halide ions. However addition of any one of NaCl, KBr, or KI to the sample caused an increase in intensity to the maximum observed with the halide ions alone, again with no change in the spectral parameters (line width or position). These experiments indicate that the studies with TiI_3 and $TiBr_3$ prepared via the carbonate route are indeed independent of chloride ion.

Our tentative assumption was that the species was $Ti(H_2O)_6^{3+}$ located in a site in the solid where a distortion of the local symmetry of the Ti^{3+} ions was created by nearby anionic species. As further tests of this hypothesis we have varied the Ti(III) concentration from 0.01 to 0.1 *M* with no appearance of resonances due to triplet Ti^{3+}---Ti^{3+} species over a wide-field sweep. Moreover we have observed that changing halide ion concentration by adding the salts (KI, KBr, or NaCl) gave the same effect as adding the corresponding concentration of the mineral acid. Therefore no specific effect of other cations (Na^+, K^+, H^+) on the e.s.r. active ions is indicated.

Discussion

The appearance of an e.s.r. signal in the frozen solutions of the titanous salts clearly indicates that a distortion of the pure octahedral O_h symmetry of the $Ti(H_2O)_6^{3+}$ species has occurred. Two lines of evidence can be used to identify the nature of the effect: (*i*) dependence of the signal on the chemical constitution of the sample, (*ii*) parameters of the observed spectrum.

There is no doubt that the signal is independent of the anion in the series Cl^-, Br^-, I^-, and SO_4^{2-}. Since dissolution of the pure metallic sponge in either concentrated reagent H_2SO_4 or in analyzed grade HCl gave samples with identical spectra, no systematic spurious impurity is suspected either. Since signal intensity increases with anion concentration, we conclude *not all* Ti^{3+} ions are located in the same environment. Clearly then we are not dealing with a (hypothetical) temperature dependent relaxation process of the $Ti(H_2O)_6^{3+}$ species that would render its spectrum observable at 77 K. Bearing in mind the uncertainty of even approximate concentration comparison in the frozen solution samples we estimate that less than 50% of the nominal Ti(III) concentration is e.s.r. active in the sample giving the most intense spectrum. In any event the fact that signal intensity *does increase* on addition of anion shows that 100% of the titanium(III) ions present do not contribute to the signal at low anion concentration.

The absence of specific effect of the anions on the spectrum leads us to suggest that while these counter ions are stabilized in water structures in the vicinity of the metal ion, they do not form a part of the first or second coordination shells. Although all four ions (Cl^-, Br^-, I^-, and SO_4^{2-}) are spherically symmetric their ionic radii and charge density are sufficiently different to project some spectral differences if neighboring (second shell) effects on the d^1 ions were primarily responsible for the distortion from octahedral symmetry. Hence, we favor the remaining alternative; that the ice structure requirements of closely situated anions and cations in turn cause a distortion of the local symmetry of the $Ti(H_2O)_6^{3+}$ unit located in that ice structure. Accordingly at low anion concentration fewer $Ti(H_2O)_6^{3+}$ would be at the required separation from a counter ion to be affected by its presence.

However the actual local symmetry of the Ti^{3+} ion in the structure is a rather complex question. In the following discussion we consider several important possibilities and compare the predicted spectrum with that actually observed.

D_{4h}

In D_{4h} symmetry, the five orbitals of a $3d^1$ configuration split into four energy states: $^2B_{2g}(d_{xy})$, doubly degenerate $^2E_{2g}(d_{xz}, d_{yz})$, $^2B_{1g}(d_{x^2-y^2})$, and $^2A_{1g}(d_{z^2})$. Consider that the Ti^{3+} ion is an octahedral ligand field of six water ligands with a small tetragonal distortion, *i.e.* D_{4h} symmetry with $^2B_{2g}$ as the ground state. The corresponding expression for $g_\parallel$ is

$$g_\parallel = 2.0023 - \frac{8\lambda}{\Delta E(^2B_{2g} \rightarrow {}^2B_{1g})} \cdot \phi_\parallel$$

where $\lambda = 154\ cm^{-1}$, ΔE refers to the electronic transition from the $^2B_{2g}$ to the $^2B_{1g}$ state, and $\phi_\parallel$ is a complex function employed to estimate covalency. The magnitude of ϕ is mainly determined by the appropriate molecular orbital coefficients. However the value of ϕ lies between 0 and 1 tending to unity as the σ and π bonding becomes more ionic, and conversely. Assuming

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

that we are dealing with a nearly purely ionic case *i.e.* $\phi_{\|} \rightarrow 1$ we can easily calculate (from $g_{\|}$ (exp) = 1.994 ± 0.001) that $\Delta E(^2B_{2g} \rightarrow {}^2B_{1g})$ would be as high as 154 000 cm^{-1}. Since we would expect the energy of this transition to be in the range 15 000–22 000 cm^{-1} (1–5) we must anticipate an unrealistically high covalency, *e.g.* $\phi_{\|} = 0.10$ to 0.15 to accommodate this possibility.

In an octahedral field with elongated tetragonal distortion (D_{4h} symmetry) the ground state might be expected in some cases to be $^2A_{2g}(d_{z^2})$ and corresponding expressions for the $g_{\|}$ and $g_{\perp}$ are

$$g_{\|} = 2.0023$$

$$g_{\perp} = 2.0023 - \frac{6\lambda}{\Delta E(^2A_{1g} \rightarrow {}^2E_{2g})} \cdot \phi_{\perp}$$

Now we expect $g_{\|}$ to be close to the free electron value, but $\Delta E(^2A_{1g} \rightarrow {}^2E_{2g})$ would have to be assigned an improbably *low* value ≤ 8700 cm^{-1}. Normally the transition lies between 25 000 and 45 000 cm^{-1}.

On the basis of the above discussion, we tentatively reject D_{4h} as the local point symmetry.

D_{2d}

Consideration of a $3d^1$ ion in a tetrahedral field with tetragonal distortion (D_{2d} symmetry) would involve nearly equivalent expressions and subsequent analysis would be qualitatively identical to D_{4h}.

D_{2h}

The d^1 ion in an octahedral field with a small rhombic distortion (D_{2h} symmetry) has five energy states: $^2B_{1g}$, $^2B_{2g}$, $^2B_{3g}$, and two ^2A_g states. Now the e.s.r. spectrum cannot exhibit true axial symmetry. The difference between g_x and g_y arises from the difference in energy between the $^2B_{2g}$ and $^3B_{3g}$ states.

$$g_z = g_{\|} = 2.0023 - \frac{8\lambda}{\Delta E(^2B_{1g} \rightarrow {}^2A_{1g})} \cdot \phi_z$$

$$g_x = 2.0023 - \frac{2\lambda}{\Delta E(^2B_{1g} \rightarrow {}^2B_{3g})} \cdot \phi_x$$

$$g_y = 2.0023 - \frac{2\lambda}{\Delta E(^2B_{1g} \rightarrow {}^2B_{2g})} \cdot \phi_y$$

Since our observed spectrum indicates that $g_x \simeq g_y$, then clearly the objection to D_{2h} becomes analogous to the arguments presented for D_{4h} (*vide supra*).

D_3

If the ligand field is determined primarily by the six oxygen atoms of the water ligands an approximately octahedral symmetry with a small axial trigonal distortion (D_3 symmetry) can also be considered.

In this symmetry the five orbitals are split into three energy states, one belonging to the A_1 representation and the other two to the E_1 representation. The appropriate combinations are

$$A_1 \qquad d_0$$

$$E_1 \quad \begin{cases} \sqrt{2/3}d_{-2} + \sqrt{1/3}d_1 \\ \sqrt{2/3}d_2 + \sqrt{1/3}d_{-1} \end{cases}$$

$$E_2 \quad \begin{cases} \sqrt{1/3}d_{-2} - \sqrt{2/3}d_1 \\ \sqrt{1/3}d_2 - \sqrt{2/3}d_{-1} \end{cases}$$

If pure octahedral symmetry exists, the energies of the A_1 and E_1 states are lowest and equal. A small axial distortion lifts the degeneracy and makes either A_1 or E_1 the ground state. If we are dealing with D_3 symmetry then our experimental g values are only consistent with A_1 as the ground state (if E_1 were the ground state both $g_{\|}$ and $g_{\perp}$ are predicted to be close to zero).

Consider A_1 as the ground state and assuming that we are dealing with a purely ionic case with $\Delta E(A_1 \rightarrow E_1) \gg \lambda$ we have

$$g_{\|} = 2.0023$$

$$g_{\perp} = 2.0023 - \frac{2\lambda}{\Delta E(A_1 \rightarrow E_1)} - \frac{4\lambda}{\Delta E(A_1 \rightarrow E_2)}$$

On the basis of this expression and assuming $\Delta E(A_1 \rightarrow E_2)$ is in the range 15 000–22 000 cm^{-1} (*i.e.* by analogy to $\Delta E(^2B_{2g} \rightarrow {}^2B_{1g})$ in D_{4h} symmetry) one calculates that $\Delta E(A_1 \rightarrow E_1) <$ 5600 cm^{-1}. Since the experimental value of $g_{\|}$ is rather lower than the free electron value, the assumption implicit in the above expression (*i.e.* $\Delta E(A_1 \rightarrow E_1) \gg \lambda$ for $\lambda = 154$ cm^{-1}) is not strictly valid, and $\Delta E(A_1 \rightarrow E_1)$ may be much lower than 5600 cm^{-1}.

Notwithstanding, the experimental g values are undoubtedly more consistent with D_3 local symmetry of the titanium(III) complex unit giving the spectrum than with the other possibilities that have been discussed.

On the basis of present data we are unable to make comment on the nature of the ice structure involved, for either anion or cation; or indeed whether the distortion of the field about the Ti(III) arises from the location of the ions near a phase boundary of two forms of ice structure.

The support of the National Research Council of Canada and of the University of Victoria in the form of operating grants is gratefully acknowledged. One of us (P.P) thanks the National Research Council for assistance through a National Research Council of Canada Fellowship.

Substituent Effects on the Ionization Equilibria of 9-Aryl-9-fluorenols and 10-Aryl-10-hydroxyanthracen-9-ones

TREVOR W. TOONE, EDWARD LEE-RUFF, AND ALAN C. HOPKINSON
Department of Chemistry, York University, Downsview, Ontario M3J 1P3

Received October 10, 1974

TREVOR W. TOONE, EDWARD LEE-RUFF, and ALAN C. HOPKINSON. Can. J. Chem. **53**, 1635 (1975).

The title compounds were prepared and their basicities measured. In both systems the major part of the molecule is held planar, while an aryl group is free to rotate. This may interact with the positive charge but steric hindrance to the *ortho* hydrogens may be expected to oppose planarity. In these systems no evidence was found for a reduction of the normal σ^+ value due to failure to achieve planarity. A formula is presented which gives the approximate degree of resemblance (α) of the transition state to the products and, in the case of the ionization of triarylmethanols, α is found to be linear with pK_R+. It is suggested that this could resolve the apparent contradiction between the Hammett equation and the Hammond postulate.

TREVOR W. TOONE, EDWARD LEE-RUFF et ALAN C. HOPKINSON. Can. J. Chem. **53**, 1635 (1975).

On a préparé les composés mentionnés dans le titre et on a mesuré leur basicité. Dans chacun des systèmes, la plus grande partie de la molécule est maintenue à l'état planaire alors que le groupe aryle est en rotation libre. Celui-ci peut interagir avec la charge positive mais on s'attend à ce que l'empêchement stérique des hydrogènes ortho s'oppose à la planarité. Dans ces systèmes, on n'a trouvé aucune preuve amenant une réduction de la valeur normale du σ^+ qui viendrait d'un empêchement à la planarité. On présente une formule qui donne un degré approximatif de ressemblance (α) de l'état de transition avec les produits et l'on trouve dans le cas de l'ionisation des triarylméthanols qu'α varie d'une façon linéaire avec le pK_R+. On suggère que ceci pourrait résoudre la contradiction apparente entre l'équation de Hammett et le postulat de Hammond. [Traduit par le journal]

The current controversy concerning the detection of unusual substrate ratios in some electrophilic aromatic substitution reactions (see ref. 1 for summaries of opposing arguments), claimed to be the result of very early transition states, may reopen an earlier controversy which surrounded the establishment of a discrete set of Hammett-type substituent constants for use in electrophilic aromatic substitution and similar reactions. Brown and Okamoto (2) established such a set of parameters in the face of opposition (3) which claimed that such a set would be valueless because of a variable resonance effect. Deno (4) justified their use in aryl carbonium ion – aryl alcohol equilibria claiming that it is not so important how much charge is delocalized in the substituent but that the amount should remain constant throughout the reaction series. Yukawa and Tsuno (5) have attempted to correlate rates and equilibria with a linear mixture of σ and σ^+, to allow for different degrees of development of positive charge in the transition state from one reaction series to another but their method has been criticized (6) for failing to show any correlation between ρ (reaction constant) and R (the fitting parameter); also, improved 'fit' may arise simply from inclusion of an extra parameter and may have no physical significance.

On the other hand, Hammond's postulate (7) requires that the more reactive the substrate, the more the transition state should be expected to resemble the reactants. In reactions in which a partial positive charge is generated in the transition state, such as the S_N1 solvolyses used to establish σ^+ (2), the reactivity is varied by changing the substituent on the phenyl group, and this in turn must change (perhaps only slightly) the position of the transition state along the reaction coordinate and the degree of positive charge generated in the transition state. Since Stock and Brown (8) have shown that σ^+ parameters do in fact correlate a large body of data, then it is likely that the movement of the transition state along the reaction coordinate is proportional from one series to another as the substituent varies. This proportionality must be included in the reaction constant, ρ, together with the usual terms measuring the suscepti-

bility of the system to electronic influences. The effect of the former will be to make ρ less negative for these reactions, since less charge is generated in the transition state in those reactions going via a more stable carbonium ion, and the $\sigma_{effective}$ for reactive compounds will lie closer to σ than σ^+, whereas for less reactive compounds $\sigma_{effective}$ will lie closer to σ^+ than to σ.

Unfortunately, studies of resonance effects in systems such as carbonium ions are frequently complicated by the twisting out-of-plane of aryl groups, as noted by Brown (8). A further complication could arise in cases such as the triaryl carbonium ion, in which it has been suggested (9) that two rings are twisted more than the third. Recently, however, this proposition has been contested (10). In the present study we examine the reduction of resonance through twisting of the aryl group in situations in which only one aryl group was free to rotate. We then compare our pK_{R+} values with the previously reported rate constants for the solvolysis of 9-phenylfluorenyl chlorides.

Experimental

Indicators

9-Aryl-9-fluorenols were prepared by the addition of an ethereal solution of 9-fluorenone to the required aryl magnesium bromide. The complex so formed was broken down by treatment with dilute acid and the crude product extracted with ether, followed by crystallization from a suitable solvent.

10-Aryl-10-hydroxyanthracen-9-ones were prepared by the dropwise addition of the required aryl magnesium bromide to a rapidly stirred suspension of anthraquinone in ether under reflux. Work-up was as for the fluorenol derivatives.

Physical data on the indicators are summarized in Table 1.

Measurements

Optical densities were measured at λ_{max} of the carbonium ion in 1 cm cells on a Unicam SP1800 spectrophotometer. Stock indicator solutions were made up in Analar methanol. Aliquots of these were transferred in a 5 µl syringe to 10 ml volumetric flasks and diluted with sulfuric acid solutions of the required strength. By weighing the flask before and after each addition it was possible to correct for small differences in indicator concentration and the changes in acid strength, by using the method of Katritzky and co-workers (11).

In the case of 10-(*m*-trifluoromethylphenyl)-10-hydroxyanthracen-9-one decomposition of the indicator occurred too rapidly for the above method to be used. Instead, solutions were made up by volume, by adding 0.05 ml of stock indicator solution to exactly 10 ml of acid solution. The resulting solution was shaken rapidly and quickly transferred to a cell, a time of about 15 s. The decrease in optical density with time was followed for a further 60–100 s and the plot extrapolated back to the time of mixing. The value so obtained was uncorrected for small differences in indicator concentration but an average correction of 0.2% was applied to the acid strength.

In all cases an acid solution of approximately the same strength as the test solution was used as reference in the spectrophotometer and care was taken to keep the temperature at 25° (±1), since the variation of pK_{R+}'s of carbinols with temperature is considerable (12).

Results and Discussion

Basicity measurements on the two series of compounds are summarized in Table 2. Both series of indicators give good linear plots of

[a]Numbering as in Table 1.
[b]Calculated from $pK_{R+} = mH_R + \log([R^+]/[ROH])$, following ref. 24.
[c]9-Aryl-9-fluorenyl cations exhibit a visible spectrum consisting of two peaks, a smaller peak centered around 470 nm and a larger peak usually close to 520 nm. The visible spectrum of the 9-aryl-9-anthraquinonyl cation consists of two peaks, a smaller usually close to 480 nm and a larger close to 530 nm.
[d]In 96% sulfuric acid unless otherwise stated.
[e]The spectrum of the carbonium ion shows a small increase in intensity with increasing acid concentration. The method of Katritzky (ref. 25) was used to calculate ionization ratios.
[f]In acetic acid – water – sulfuric acid $pK_{R+} = -10.27$ and log ε = 4.57 (ref. 26).
[g]Decomposes too quickly for measurement in sulfuric acid.
[h]In the spectrum of the carbonium ion, the shorter wavelength peak at λ = 461 nm is more intense, having log ε = 4.42.
[i]In 88% sulfuric acid, as decomposition occurs rapidly in more concentrated acid.
[j]In 84% sulfuric acid, for reasons as in [i].

pK_{R+} *vs.* σ^+, as shown in Fig. 1. Neither shows curvature attributable to reduced resonance through twisting of the aryl group. Since it is likely that steric hindrance to planarity of the aryl group is greatest in the 10-aryl-10-hydroxyanthracen-9-ones, it is unfortunate that 10-(*p*-methoxyphenyl)-10-hydroxyanthracen-9-one decomposes too rapidly in sulfuric acid for measurements to be taken, as this compound is the most likely to exhibit this effect. The reaction constants for the two series are −4.28 for the fluorenols and −2.71 for the 10-hydroxyanthracen-9-ones. The lower value in the latter case is consistent with a higher degree of solvation of these cations, which may be deduced (13) from their lower slopes of log ([R⁺]/[ROH]) *vs.* $-H_R$. It is likely that the reduced ability of substituents to delocalize the positive charge is compensated by increased interaction with the solvent.

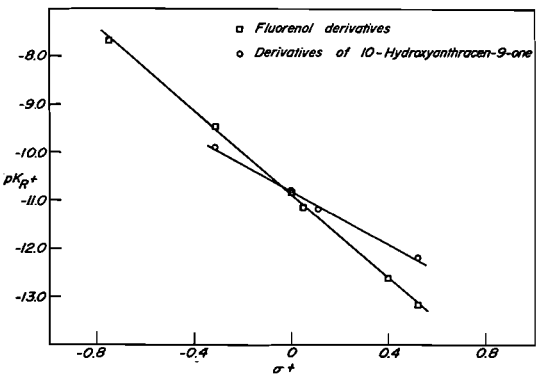

FIG. 1. Plot of pK_{R+} value against σ^+ constants.

If pK_{R+} values of 9-aryl-9-fluorenols are compared with those of similarly substituted aryldiphenyl carbinols (14) it may be seen that joining the phenyl rings in the *ortho* positions reduces the stability of the associated carbonium ion by a factor of 10^4. (The differences are 4.24 p*K* units for aryl = *p*-methoxyphenyl, 4.19 for *p*-methylphenyl, and 4.19 for phenyl.) This may be attributed to the introduction of 'antiaromaticity', since the joined system is effectively a dibenzocyclopentadienyl cation, a 12 π-electron system.

The solvolyses of 9-aryl-9-fluorenyl chlorides have been studied in 90% aqueous acetone at 25° (14) and the rates correlate well with σ^+ (correlation coefficient 0.995) with a reaction constant of −2.85. Similar correlation was found by Bolton *et al.* (15) for the solvolyses in 90:10 ethanol–acetone. Since both pK_{R+} values and

[d] Rate data from ref. 14.
[e] pK_{R+} values from ref. 27.
[f] Rate data from ref. 28.
[g] pK_{R+} values from ref. 9.
[h] Rate data from ref. 29.
[i] Rate data from ref. 30.
[j] Rate data from ref. 31.

logarithms of rate constants are linear with respect to σ^+, it follows that they will be linear with respect to each other. Values of the slopes of plots of log k (from the ionization of chlorides) *vs.* pK_{R+} (from the equilibrium with the carbinol) for three different series of compounds in a variety of solvents are given in Table 3.

It is reasonable to expect pK_{R+} values of closely related compounds to vary by a constant factor in going from solvent to solvent (16); therefore the slopes of log k (solvolysis in solvent s) *vs.* pK_{R+} (in sulfuric acid) are probably very close to log k (in s) *vs.* pK_{R+} (in s). The question then arises of the reason for the less than unit slope.

Pearson and Dillon (17) examined the correlation between rates and equilibria of carbon acid ionizations and found only a rough correlation between log k (ionization) and pK_a, with a slope of approximately 0.6; this was interpreted as the degree of proton transfer from acid to base in the transition state. It is pointed out, however, that on theoretical grounds even this rough correlation is unexpected, since, in accord with Hammond's postulate (7), the weaker acids would be expected to have a greater degree of proton transfer in the transition state than the stronger acids. These data have been reexamined by Jones (18) who incorporates recent, more accurate data and shows that the plot does show the expected curvature.

Taft and co-workers (19) have measured the rates of reaction of several triaryl carbonium ions with water and show that plots of log k (reaction) *vs.* pK_{R+} were linear but only for ions containing similar substituents.

It is likely, therefore, that the slopes of about 0.7 obtained for log k (solvolysis) *vs.* pK_{R+} correspond to the degree to which the transition state resembles the carbonium ion, i.e. in the transition state a charge of about +0.7 is developed. It should be remembered, however, that the charge in the transition state probably varies with reactivity of the substrate, although this change is probably small over the range of reactivities in this investigation.

In an attempt to put Hammond's postulate on a more quantitative basis, the normal energy profile for a simple reaction may be greatly simplified to that of Fig. 2. Since $\tan\theta = \Delta G^{\ddagger}/\alpha = (\Delta G^{\ddagger} - \Delta G^0)/(1 - \alpha)$, then α, which may vary between 0 and 1 and is a rough estimate of the distance the transition state lies between reactant and product along the reaction coordinate, may be calculated using eq. 1 for those reactions for which both $\Delta G^{\ddagger}$ and ΔG^0

$$[1] \qquad \alpha = \Delta G^{\ddagger}/(2\Delta G^{\ddagger} - \Delta G^0)$$

have been measured. One such reaction is the reaction of triaryl carbonium ions with water, for which data are collected in Table 4.

With the exception of the sesquixanthyl cation, which has an unusually low activation energy, the plot of α *vs.* pK_{R+} shows excellent

$(4\text{-MeO}\cdot C_6H_4)_2C_6H_5\cdot C^+$	−1.02(12)	14.9(19)	0.478
$(4\text{-MeO}\cdot C_6H_4)(C_6H_5)_2C^+$	−3.51(12)	13.5(33)	0.425

[a]Unpublished work by K. Sano and R. W. Taft, quoted from ref. 33.

linearity, with a correlation coefficient of 0.995 and slope of 0.020 (Fig. 3). $\Delta G^{\ddagger}$ does not show good linearity with ΔG^0 (correlation coefficient 0.971 excluding the sesquixanthyl cation). This is perhaps surprising in view of the success of the Hammett equation, which is frequently used to correlate free energies and activation energies of very different reactions.

Another reaction for which data on both $\Delta G^{\ddagger}$ and ΔG^0 are available is the rate of ionization of carbon acids, for which data are collected in Table 5.

In this case the treatment is a little less successful. A plot of α *vs.* pK_a has correlation coefficient 0.962. If the data on ethyl cyanoacetate, the pK_a of which is known only approximately, and 1-chloronitroethane, the pK_a of which was determined by a different method, are omitted, the correlation coefficient for the remaining three points is 1.000.

To extend the principle to incorporate our

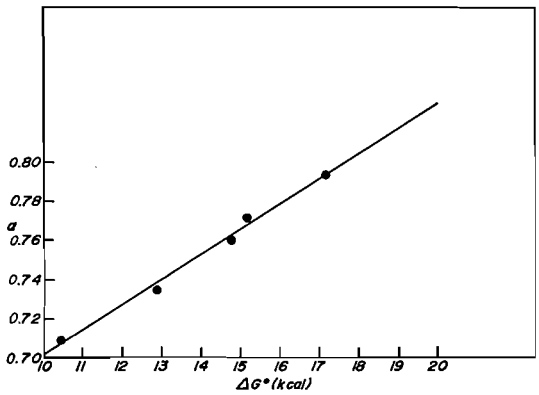

FIG. 4. Plot of α against ΔG^0 for the 9-aryl-9-fluorenyl cations.

results, we plotted α *vs.* ΔG^0 (Table 6 from the pK_{R+} values in Table 2) for the 9-arylfluorenols and obtained a linear plot (Fig. 4) with a correlation coefficient of 0.996. The $\Delta G^{\neq}$ values for the calculation of α were obtained from the kinetic data of Bolton *et al.* (15) and are referred to a different solvent system (9:1 ethanol–acetone). However, to calculate α for our solvent system, a constant difference in ΔG^0 would be involved and would not change the linearity of the plot.

While the parameter α is certainly an approximation, its linearity with pK (which must be limited as α approaches zero or unity) would seem to explain the success of the Hammett equation in the face of the apparently contradicting Hammond postulate. α also provides a simple method of converting equilibrium data into rate data, once the relationship between α and pK is established for a particular series.

The authors would like to thank the National Research Council of Canada for continued financial support.

Etude des spectres de vibration des dérivés monosubstitués en position 5 de l'isothiazole[1]

GILBERT MILLE,[2] JEAN-CLAUDE POITE,[3] JACQUES CHOUTEAU[2] ET JACQUES METZGER[3]

Faculté des Sciences de l'Université d'Aix-Marseille III, Avenue Henri Poincaré – 13397, Marseille, Cedex 4, France

Reçu le 16 septembre 1974

GILBERT MILLE, JEAN-CLAUDE POITE, JACQUES CHOUTEAU et JACQUES METZGER. Can. J. Chem. **53**, 1642 (1975).

Les spectres i.r. sous différents états et les spectres Raman en phases condensées d'une série de dérivés de l'isothiazole monosubstitués en position 5, C_3NSH_2Y (Y = CH_3, CD_3, Cl, Br, I) ont été analysés. Une attribution des modes fondamentaux de vibration de ces molécules est proposée.

GILBERT MILLE, JEAN-CLAUDE POITE, JACQUES CHOUTEAU, and JACQUES METZGER. Can. J. Chem. **53**, 1642 (1975).

The i.r. absorption spectra in different physical states and the Raman spectra in the liquid or solid state of 5-monosubstituted isothiazole derivatives, C_3NSH_2Y (Y = CH_3, CD_3, Cl, Br, I) have been analyzed. An assignment of the fundamental modes of vibration of these molecules is given.

Introduction

Dans la continuation du programme de recherches en série hétérocyclique et, plus particulièrement, isothiazolique (1, 2) nous avons examiné les spectres i.r. sous différents états (liquide, solution, vapeur) et Raman (liquide ou solide) d'une série de dérivés de l'isothiazole C_3NSH_2Y (Y = CH_3, CD_3, Cl, Br et I) monosubstitués en position 5. Récemment, dans une courte note (2), nous avons proposé une attribution partielle des modes normaux de vibration des monométhylisothiazoles, en indiquant que dans le méthyl-5 isothiazole il paraissait exister une interaction entre une vibration de squelette et l'oscillation de valence νC—C*.[4] C'est pour préciser les mouvements susceptibles de se coupler, lors d'une substitution en position 5, que nous avons entrepris l'étude i.r. et Raman de ces molécules.

Conditions expérimentales

Préparation des composés

Les dérivés substitués en position 5 de l'isothiazole ont été obtenus par la méthode classique de lithiation de l'isothiazole par le *n*-butyllithium à −80 °C (3).

Le bromo-5 isothiazole est obtenu en faisant réagir le brome à 0 °C sur une suspension d'isothiazolyl-5 lithium. Une température trop basse favorise, par un processus d'échange, la formation de bromo-4 et de dibromo-4,5 isothiazole (4).

Nous donnons ci-dessous les résultats et les caractéristiques des composés obtenus.

Y-5 isothiazole	Rendement (%)	Point d'ébullition (mm Hg) ou de fusion (°C)	Résonance magnétique nucléaire (δ/TMS dans CCl_4) 3	4	5	Ultraviolet (solvant, éthanol) λ_{max}	ε
CH_3 ou CD_3	40	142/760	8.24	6.92	2.56	243	(8960)
Cl	34	149/760	8.37	7.35	—	243	(6700)
Br	38	56/23	8.32	7.4	—	241	(7300)
I	45	70	8.25	7.4	—	245	(9400)

Spectres infrarouges

Les spectres i.r. ont été enregistrés sur spectrographes Perkin-Elmer, modèles 125 et 225. Pour l'étude à l'état gazeux nous avons utilisé une cellule chauffante Perkin-Elmer de 5 cm d'épaisseur, à fenêtre de KBr ou CsI. A l'état dissous, les concentrations étaient voisines de 0.2 mol/l. Le tétrachlorure de carbone a été employé dans les régions de 3000 et de 1500 à 1300 cm^{-1}, le tétrachlorure d'éthylène, le sulfure de carbone et le cyclohexane ont respectivement été utilisés entre 2000 et 1400 cm^{-1}, 1350 et 450 cm^{-1}, et entre 450 et 200 cm^{-1}. Les coefficients d'extinction molaire apparents ont été mesurés aux maximum des bandes d'absorption.

[1]Ce mémoire recouvre une partie de la Thèse de Doctorat ès Sciences Physiques devant être soutenue au cours de l'année scolaire 1974–1975 par G. M.

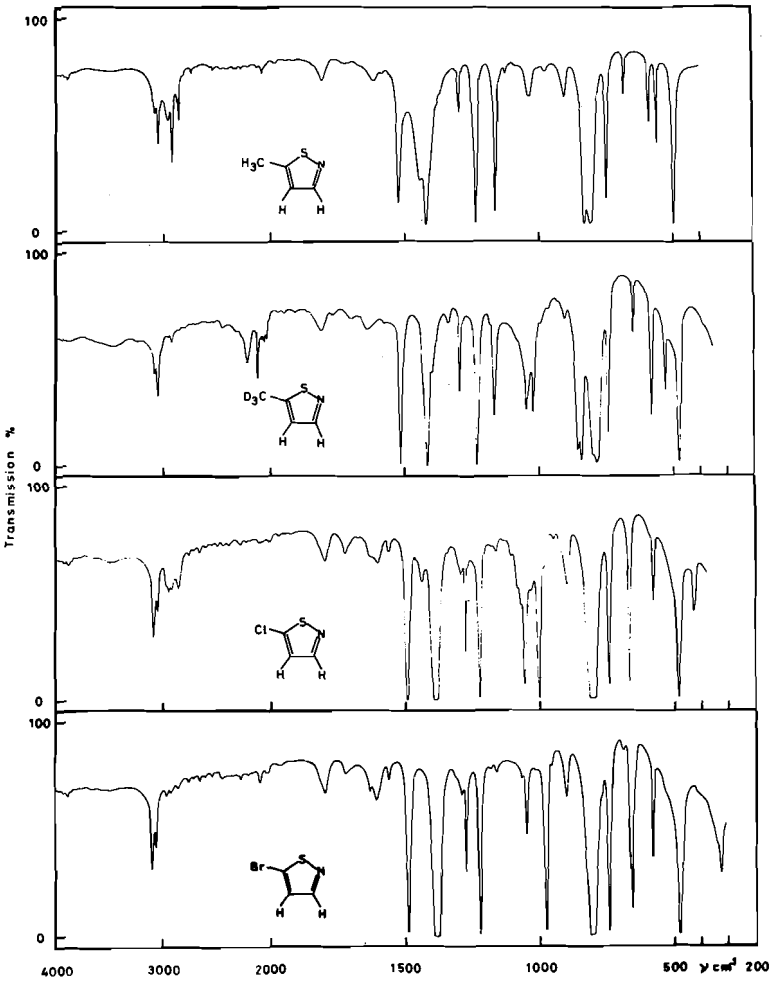

FIG. 1. Spectres des dérivés monosubstitués en position 5 de l'isothiazole.

Spectres Raman

Les échantillons à l'état liquide et solide ont été examinés dans des tubes capillaires, avec un spectrographe Raman Coderg, type PH 1 équipé d'un laser He–Ne de 100 mW émettant à 6328 Å. Les facteurs de dépolarisation ont été corrigés d'après la méthode décrite par Bribes et Gaufres (5). Les intensités ont été chiffrées de 0 à 10 par comparaison avec la raie la plus forte de chacun des spectres.

Résultats expérimentaux

Les spectres i.r. des méthyl-5, trideutériométhyl-5, chloro-5 et bromo-5 isothiazoles à l'état liquide sont reproduits dans la fig. 1. Le tableau 1 renferme sous forme de suites les fréquences i.r. et Raman des vibrations fondamentales et de quelques vibrations harmoniques ou de combinaison des hétérocycles C_3NSH_2Y. Dans le tableau 2 sont mentionnées les fréquences des vibrations propres au groupement trideutériométhyle.

Dans ces deux tableaux les fréquences infrarouges mesurées à l'état dissous sont suivies du coefficient d'extinction molaire (nombres en italiques) et lorsque les composés ont été examinés à l'état vapeur de la structure de vibration rotation (A, B ou C) des bandes. L'intensité des raies de diffusion, chiffrée de 0 à 10, et le facteur de dépolarisation succèdent aux fréquences Raman.

Analyse des spectres

Dans l'hypothèse d'une symétrie C_s (2) les 18 modes fondamentaux de l'hétérocycle C_3NSH_2X[5] actifs en i.r. et en Raman peuvent se

[5]X désigne les atomes Cl, Br, I ou C dans le cas où les substituants sont CH_3 et CD_3.

Infrarouge	~1040*e	1047	*25*		~1068*e			~765e	
Raman		1052	2	0.20					

NOTE: Les vibrations du groupement trideutériométhyle sont désignées par: ν_a, ν'_s, ν_s (valence); δ_a, δ'_s, δ_s (déformation) et $r_\perp$, $r_\parallel$ (balancement); e, épaulement.
*Fréquence relevée à l'état liquide.

décomposer en 13 mouvements A' (2ν(CH) + 2δ(CH) + δ(CX) + ν(CX) + 7ω)* et 5 vibrations A'' (2γ(CH) + γ(CX) + 2Γ)*. Nous examinerons successivement les oscillations des liaisons CH et du squelette C_3NSX, puis celles propres aux groupements méthyle et trideutériométhyle.

Vibrations des liaisons CH

Vibrations de valence ν(CH)

Les spectres i.r. de tous les dérivés monosubstitués en position 5 de l'isothiazole présentent vers 3093 ± 10 et 3056 ± 4 cm^{-1} (Tableau 1) deux absorptions auxquelles correspondent dans le spectre Raman des raies polarisées. Ces fréquences étant respectivement proches de celles des mouvements $\nu(C_4H)$[6] et $\nu(C_3H)$[7] des hétérocycles isothiazoliques (1, 2) peuvent être attribuées à des vibrations de valence des mêmes liaisons.

Vibrations de déformation δ(CH)

Par analogie avec les attributions proposées pour ces mouvements dans l'isothiazole (1) et ses dérivés (1, 2) les deux absorptions vers 1227 ± 7 et 1041 ± 19 cm^{-1} auxquelles correspondent en Raman des raies de diffusion polarisées, peuvent être rattachées à des vibrations δ(CH) dans les composés isothiazoliques monosubstitués en position 5.

Vibrations de déformation γ(CH)

Par analogie avec le méthyl-5 isothiazole (2), les mouvements γ(CH) des isothiazoles monosubstitués en 5 peuvent être situés à 901 ± 2 et 795 ± 10 cm^{-1}. Effectivement comme dans le spectre du méthyl-5 isothiazole (2) ces bandes ont une structure de type C dans le spectre du bromo-5 isothiazole à l'état vapeur (Tableau 1) et manquent dans les spectres Raman (Tableau 1).

Vibrations du squelette C_3NSX

Vibrations de symétrie A'

En raison de la structure de vibration–rotation de type A ou B des bandes i.r. d'une part, de l'intensité et de la polarisation des raies Raman correspondantes, d'autre part, six suites de fréquences vers 1502 ± 22, 1399 ± 22, 1284 ± 14, 831 ± 15, 750 ± 3, 670 ± 16 cm^{-1} doivent être rattachées à des vibrations de symétrie A'. Les absorptions classées dans les suites I, II, III, VI et VII peuvent être reliées à des oscillations comparables aux modes ω_1, ω_2, ω_3, ω_6 et ω_7 du méthyl-5 isothiazole (2). Par contre la suite de fréquences vers 831 cm^{-1} précédemment attribuée dans le méthyl-5 isothiazole à la vibration ω_4 (2) semble devoir l'être au mouvement ω_5. En effet, tandis que pour les alkyl-5 isothiazoles les fréquences classées dans les suites I, II et V ont des positions plus élevées que les oscillations ω_1, ω_2 et ω_5 de l'isothiazole (1) ces fréquences sont, pour les halogéno-5 isothiazoles, proches des vibrations correspondantes de l'isothiazole (1). Signalons que les absorptions de la suite VII ont des fréquences toujours plus élevées ($15 < \Delta\nu < 46$ cm^{-1}) que le mode ω_7 correspondant de l'isothiazole (1). Ceci est analogue aux observations faites pour le mouvement ω_7 des dérivés substitués en position-5 du thiazole (6).

Les spectres i.r. de l'isothiazole et des deutério isothiazoles (1) montrent deux maximums d'absorption ou raies de diffusion (7) attribuables à des mouvements de symétrie A' entre 950 et 815 cm^{-1} tandis que les spectres i.r. et Raman des

[6]La notation νC_iH correspond aux vibrations de valence des liaisons C_iH. "i" (3, 4, ou 5) désignant la position de l'atome de carbone dans le cycle isothiazolique.

[7]Les symboles ν, δ, γ, ω et Γ sont définis dans la réf. 2 et dans le tableau 1.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

halogéno-5 isothiazoles n'en présentent qu'un, assigné à l'oscillation ω_5. Tandis que la vibration de noyau ω_4 de l'isothiazole se manifeste par une bande infrarouge et Raman moyenne à 869 cm^{-1} aucune bande i.r. ou raie Raman de position voisine, susceptible d'appartenir à un mouvement de symétrie A' n'est observée dans les spectres des alkyl- et halogéno-5 isothiazoles. On note par contre l'existence de deux bandes i.r. et Raman classées dans les suites IV et VIII ayant des positions respectivement très voisines de deux absorptions attribuées, dans les dérivés homologues du thiazole substitués en position-5 au mode ω_5 et ν(CX) (6). On peut donc par analogie avec cette molécule envisager que les bandes des suites IV et VIII résultent du couplage du mouvement ω_4 avec la vibration ν(CX). Dans le spectre du deutério-5 isothiazole (1) où la vibration ν(CD) est située à une fréquence beaucoup plus élevée que le mode ω_4 on observe bien une bande à 922 cm^{-1} voisine de celle du mode ω_4 de l'isothiazole et une bande à 2320 cm^{-1} due à une oscillation ν(CD) pratiquement pure.

Nous avons attribué les modes δ(CX) par comparaison avec les dérivés du thiazole substitués sur le carbone 5 (6). La raie Raman correspondante est généralement polarisée.

Vibrations de symétrie A''

Deux suites de bandes vers 581 $\pm$ 8 et 491 $\pm$ 8 cm^{-1} proches des vibrations Γ_1 et Γ_2 de l'isothiazole (1) du deutério-5 isothiazole (1) et du méthyl-5 isothiazole (2) sont observées. Les enveloppes correspondantes sont de type C dans le spectre du bromo-5 à l'état vapeur (Tableau 1) et comme pour l'isothiazole (1) les raies de diffusion, lorsqu'elles apparaissent sont faibles et dépolarisées.

Par comparaison avec les dérivés homologues du thiazole (6) une raie Raman faible et dépolarisée peut être attribuée à l'oscillation γ(CX) sauf pour le bromo-5 isothiazole pour lequel elle n'a pas été observée.

Vibrations des substituants CH_3 et CD_3

Les attributions propres au groupement méthyle antérieurement proposées pour le méthyl-5 isothiazole (2) sont confirmées par l'examen de son homologue trideutériométhylé. Les vibrations du substituant CD_3 ont été assignées par analogie avec les trideutériométhylnaphtalènes (8) et sont consignées dans le tableau 2. L'ensemble de ces attributions se trouve justifié par la bonne concordance entre les valeurs des rapports isotopiques calculés à partir de nos données et celles calculées par Krimm (9) sur des bases théoriques et par Dizabo (8) sur des bases expérimentales.

Dans chaque classe de symétrie on peut remarquer aussi la bonne concordance entre le produit de Teller Redlich théorique et l'expérimental. Ces produits sont respectivement pour le trideutériométhyl-5 et le méthyl-5 isothiazole de 0.190 et 0.191 dans le cas des oscillations de symétrie A' et de 0.276 et 0.301 en ce qui concerne les modes A''.

ANN AUGUSTINE, GEORGE FERGUSON, and FRANK C. MARCH. Can. J. Chem. **53**, 1647 (1975).

The crystal structure of triphenylarsenic difluoride has been determined from three-dimensional X-ray diffractometer data. Crystals of Ph_3AsF_2 are orthorhombic, space group *Pbcn*, with four molecules of $C_{18}H_{15}AsF_2$ in a unit cell of dimensions $a = 6.270$, $b = 16.593$, $c = 14.519$ Å; molecular symmetry C_2 is required. The structure was solved by the heavy atom method and refined by full-matrix least-squares calculations to a final residual R of 0.054 for 979 intensities regarded as "observed" ($I > 3\sigma(I)$). The crystals contain well separated discrete molecules. The arsenic atom has near regular trigonal bipyramidal geometry with apical fluorine atoms (As—F 1.834(7) Å) and equatorial phenyl rings (mean As—C 1.925(5) Å). Idealized D_3 symmetry is not achieved because of unequal rotations of the phenyl rings about the As—C bonds.

ANN AUGUSTINE, GEORGE FERGUSON et FRANK C. MARCH. Can. J. Chem. **53**, 1647 (1975).

On a déterminé la structure cristalline du difluorure de triphénylarsenic à l'aide de données tri-dimensionnelles obtenues avec un diffractomètre à rayon-X. Les cristaux de Ph_3AsF_2 sont orthorhombiques, groupe d'espace *Pbcn*, avec quatre molécules de $C_{18}H_{15}AsF_2$ dans la cellule de base dont les dimensions sont $a = 6.270$, $b = 16.593$, $c = 14.519$ Å. Une symétrie moléculaire C_2 est requise. On a résolu la structure par la méthode des atomes lourds et on l'a affinée par la méthode des moindres carrés (matrice complète) jusqu'à une valeur résiduelle finale R de 0.054 pour 979 intensités considérées comme "observées" ($I > 3\sigma(I)$). Les cristaux contiennent des molécules bien séparées. L'atome d'arsenic a une géométrie pratiquement bipyramidale trigonale régulière avec des atomes de fluor aux sommets (As—F 1.834(7)Å) et des noyaux phényles en positions équatoriales (valeur moyenne de As—C 1.925(5)Å). La symétrie D_3 idéalisée n'est pas obtenue à cause de rotations inégales des noyaux phényles autour des liaisons As—C.
[Traduit par le journal]

Introduction

The series of compounds R_3MX_2 (R = alkyl or aryl; M = As, Sb, or Bi and X = halogen) are well known from spectroscopic studies (2, 3) to be generally 5-coordinate nonionic species with near regular trigonal bipyramidal geometry at the metal atom. Anomalies exist with the compounds $(CH_3)_3AsX_2$ where X = Br and I; these compounds apparently being more correctly formulated as $(CH_3)_3AsX^+,X^-$ with tetrahedral geometry at the As atom (3, 4). A number of the trigonal bipyramidal R_3MX_2 species have been subjected to crystallographic analysis *e.g.* $(CH_3)_3AsCl_2$ (4), $(CH_3)_3SbX_2$ (X = Cl, Br, I) (5), Ph_3SbCl_2 (6), and Ph_3BiCl_2 (7). No fluoride derivatives have been examined by X-ray methods and we report here the structure of Ph_3AsF_2.

Experimental

Crystal Data

$C_{18}H_{15}AsF_2$ f. w. = 334.2

Orthorhombic, $a = 6.270(1)$, $b = 16.593(3)$, $c = 14.519(2)$ Å, $U = 1510.5$ Å^3, $Z = 4$, molecular symmetry 2, $D_c = 1.470$, $F(000) = 696$, CuK_α($\lambda = 1.5418$ Å), $\mu = 34.7$ cm^{-1}, space group *Pbcn* (D_{2h}^{14}) from the systematic absences $hk0$, k = odd; $h0l$, $h + l$ = odd; $0kl$, l = odd.

Small lathe-shaped crystals were obtained from Dr. G. S. Harris.[3] The crystal chosen for the data collection was cut to the approximate dimensions 0.10 × 0.10 × 0.20 mm^3. The cell dimensions were obtained from a least-squares refinement of the setting angles of 12 high order reflexions measured on a Hilger and Watts Y290 diffractometer. The intensity data were collected using nickel filtered CuK_α X-radiation ($\lambda = 1.5418$ Å) by the $\theta/2\theta$ scan technique with a symmetric scan of 0.70°, consisting of 70 0.01° steps of 1 s duration. Stationary crystal-stationary counter background counts of 17.5 s duration were measured at each end of the integrated scan. Three reflexion intensities were monitored as

[a]Fractional coordinates $\times 10^5$ for As, $\times 10^4$ for C and F, $\times 10^3$ for H.
[b]Temperature factor = $\exp[-2\pi^2(U_{11}h^2a^{*2} + U_{22}k^2b^{*2} + \ldots + 2U_{23}klb^*c^*)]$.
[c]Values multiplied by 10^4 for As, by 10^3 for C and F. The estimated standard deviations range from 0.0006 to 0.0008 for As and from 0.002 to 0.006 for C and F.
[d]Numbering for H atoms is the same as the C atom to which they are bonded.

standards at regular intervals throughout the data collection, but did not vary significantly, indicating that both crystal and beam stability were good. Each intensity was corrected for background and the estimated standard deviation for each was given by $\sigma I = [S + 4(B_1 + B_2) + (0.05I)^2]^{1/2}$, where S, B_1, and B_2 are the scan, first background, and second background counts, respectively. A total of 1301 independent intensities were measured in the sphere $1.5° < \theta < 72°$, of which 979 were greater than three times their e.s.d.'s and were regarded as "observed." The data were corrected for Lorentz, polarization and absorption effects (8); minimum and maximum transmission coefficients were 0.62 and 0.73, respectively.

Structure Solution and Refinement

The space group *Pbcn* has three special sites of multiplicity 4, two with $\bar{1}$ symmetry, and one with 2-fold symmetry. Only the last is possible for Ph_3AsF_2 and this was confirmed by the three-dimensional Patterson function from which we deduced coordinates for the arsenic, fluorine, C(11), and C(14) atoms. One cycle of least-squares refinement of F, in which the scale factor and overall temperature factor were varied, yielded $R = \Sigma||F_o| - |F_c||/\Sigma|F_o| = 0.21$. A difference F_o synthesis was then calculated and yielded chemically sensible positions for the remaining nonhydrogen atoms. In all calculations of F_c the atomic scattering factors for As, C, and F were from ref. 9 and those for H were from ref. 10. Only the observed data were used in the refinement cycles and the function minimized was $\Sigma\omega(F_o - F_c)^2$. Absolute weights (based on $\sigma(F_o)$) were used throughout the refinement and anomalous dispersion corrections for As were included at later stages. The structure was refined by full matrix least-squares calculations, with all atoms allowed individual isotropic vibration parameters, to give $R = 0.10$. All nonhydrogen atoms were allowed anisotropic thermal motions and the refinement converged with $R = 0.056$. A final difference Fourier synthesis revealed peaks in positions corresponding to all the phenyl hydrogen atoms. The highest peak which did not correspond to a hydrogen atom was approximately 0.5 e/Å^3 and was close to the arsenic atom. Theoretical positions were calculated for the hydrogen atoms using C—H = 1.08 Å and two further cycles of refinement, with the hydrogen atoms included ($Uiso$ = 0.063 Å^2) but not refined, gave convergence with $R = 0.054$ and $R_\omega = [\Sigma\omega(F_o - F_c)^2/\Sigma\omega F_o^2]^{1/2} = 0.093$. The maximum shift in any parameter on the last cycle was 0.3 of its e.s.d.

The final atomic positional and thermal parameters are listed in Table 1. Bond lengths and angles are given in Table 2. Figure 1 is a stereoscopic view of the molecule, showing the atomic numbering scheme; the molecular packing is shown in Fig. 2. A table of measured and calculated structure factors has been placed in the Depository of Unpublished Data.[4]

Results and Discussion

As expected the molecules are nonionic 5-coordinate species, the arsenic atom having a near regular trigonal bipyramidal geometry with the fluorines in apical positions. The molecule possesses crystallographic C_2 symmetry, with

F···C(26)^{I}	3.321(6)	C(23)···C(23)^{III}	3.535(12)

[a]Distance corrected for thermal motion.
[b]The Roman numerals refer to the following equivalent positions: I $1-x, y, \frac{1}{2}-z$; II $x-\frac{1}{2}, \frac{1}{2}-y, -z$; III $-x, 1-y, -z$.

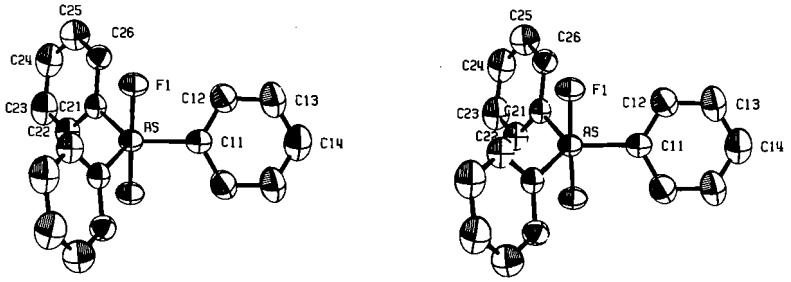

FIG. 1. Stereo view of Ph_3AsF_2. The thermal ellipsoids are drawn at the 50% level.

the As atom and two carbon atoms of one phenyl ring (C(11) and C(14)) lying on the two-fold axis; the small significant angular deviations from regular trigonal bipyramidal geometry at the As atom (∠F—As—F 177.9(2)° ∠F—As—C(11) 88.9(1)°) are doubtless caused by crystal packing effects. The molecule does not possess idealized D_3 symmetry mainly because the rotations of the phenyl groups about the As—C bonds are in opposite senses. (Table 3). The mean As—C bond distance (1.925(7) Å) is slightly longer than is generally observed for As—C(phenyl) bonds where the metal atom has tetrahedral geometry (normally in the range 1.89–1.91 Å *e.g.* ref. 11). The As—F distance, 1.834(3) Å, is slightly longer than that predicted from covalent radii data (12) and is much longer than As—F distances in hexafluorarsenate ions, *e.g.* 1.67 Å (13). There are no pentavalent As—F systems in the literature with which to compare the As—F distance found in Ph_3AsF_2.

The distances and angles in the phenyl rings vary within normal limits for structures of this kind with C—C(aromatic) = 1.390(7) Å; and ∠C—C—C 119.9(7)°. The As atom lies slightly off the planes of the two phenyl rings (Table 3),

The Ionization of Picric Acid in Ethanol–Sulfolane and *t*-Butyl Alcohol – Sulfolane Mixtures at 30 °C

MAURIZIO CASTAGNOLO, ANGELO DE GIGLIO, ANGELO DELL'ATTI, AND GIUSEPPE PETRELLA

Institute of Physical Chemistry, University of Bari, Via Amendola, 173 70126 Bari, Italy

Received November 25, 1974

MAURIZIO CASTAGNOLO, ANGELO DE GIGLIO, ANGELO DELL'ATTI, and GIUSEPPE PETRELLA. Can. J. Chem. **53**, 1651 (1975).

Dissociation constants at 30 °C of picric acid have been determined by a spectrophotometric method in ethanol–sulfolane and *t*-butyl alcohol – sulfolane mixtures over the entire solvent composition range. Picric acid behaves as a weak acid in all mixtures. In pure sulfolane, picric acid undergoes simple dissociation for $c < 0.08\ M$ ($pK_{HPi} = 7.6$). At concentrations higher than 0.08 *M* more complex equilibria have been observed and interpreted assuming $Pi(HPi)_2^-$ as the principal picrate species in solution. Complex behavior of dependence of association constant on solvent composition was observed; in both solvent mixtures association of picric acid decreases with decrease of dielectric constant. This behavior was discussed in terms of preferential solvation of picric acid by alcohols. the more basic components of the mixtures. A reaction mechanism of four alcohol molecules with one acid molecule accounts for the behavior observed.

MAURIZIO CASTAGNOLO, ANGELO DE GIGLIO, ANGELO DELL'ATTI et GIUSEPPE PETRELLA. Can. J. Chem. **53**, 1651 (1975).

On a déterminé à 30 °C, par une méthode spectrophotométrique, dans des mélanges éthanol–sulfolanne et alcool *t*-butylique – sulfolanne à toutes les compositions du solvant, les constantes de dissociation de l'acide picrique. L'acide picrique se comporte comme un acide faible dans tous les mélanges. Dans le sulfolanne pur, l'acide picrique subit une dissociation simple à $c < 0.08\ M$ ($pK_{HPi} = 7.6$). A des concentrations plus élevées que 0.08 *M*, on a observé des équilibres complexes qui ont été interprétés en faisant l'hypothèse que $Pi(HPi)_2^-$ est l'espèce principale du picrate dans la solution. On a observé un comportement complexe de la dépendance de la constante d'association sur la composition du solvant; dans les deux mélanges de solvant, l'association de l'acide picrique diminue lorsque la constante diélectrique diminue. On discute de ce comportement en terme d'une solvatation préférentielle de l'acide picrique par les alcools qui sont les composants les plus basiques des mélanges. On peut rationaliser les résultats à l'aide d'un mécanisme de réaction impliquant quatre molécules d'alcool pour une molécule d'acide. [Traduit par le journal]

Introduction

Previous results of conductivity measurements, performed in our laboratory, on some electrolytes in water–sulfolane and methanol–sulfolane mixtures have shown association behavior in contrast to the predictions of the electrostatic theory. In water–sulfolane, alkali chlorides (1–3) and hydrochloric acid (4) are associated to ion pairs despite the high value of the dielectric constants. The association constant of lithium chloride, very high in pure sulfolane ($K_A = 14\,595$), decreases on adding methanol even though the dielectric constant of the solvent mixtures decreases (5).

These findings show that, in these solvent mixtures, the influence of specific solute–solvent interactions on ionic equilibria is very important. In order to obtain more information about these effects, acidity constants of picric acid in ethanol–sulfolane and *t*-butyl alcohol – sulfolane mixtures have been determined at 30 °C by spectrophotometric measurements.

Experimental

Reagents

Commercial sulfolane (Shell Company) was purified as described by Desbarres *et al.* (6) and then vacuum distilled three times over sodium hydroxide pellets.

Ethanol and *t*-butyl alcohol (C. Erba RP) were purified by distillation, after refluxing for many hours over anhydrous calcium oxide. The distilled fractions were kept over molecular sieves.

Picric acid (C. Erba RP) was recrystallized three times from acetone and dried *in vacuo* for 3 h at 80 °C (m.p. 121 °C).

Apparatus

Spectrophotometric measurements were made using a Zeiss PMQ II spectrophotometer equipped with

temperature control accessories. Stoppered Ultrasil quartz cells of 1, 0.5, and 0.1 cm path length were used. The cells were thermostated at 30.0 ± 0.1 °C during experiments.

Procedure

Solvent mixtures were made up by weight. Stock solutions for each system were prepared by weighing picric acid and solvent, and working solutions were obtained by weight dilution. Spectrophotometric measurements were made at 420 nm, the wavelength at which picrate ion and picric acid molar absorptivities have their maximum difference. Molar absorptivities of picrate ion and picric acid were determined for each system by adding to a solution of picric acid concentrated solutions of 1,3-diphenylguanidine and $HSbCl_6$ respectively, in the same solvent.

Results

The properties of the solvent mixtures ethanol–sulfolane and *t*-butyl alcohol – sulfolane are listed in Table 1, where w_2 and x_2 are sulfolane weight per cent and mole fraction, ρ and ε are densities and dielectric constants at 30 °C, [ROH] are the concentrations in mol/l of alcohol in solvent mixture. Densities and dielectric constants were obtained by interpolation from literature data for ethanol–sulfolane mixtures (7) and by interpolation from unpublished data for *t*-butyl alcohol – sulfolane mixtures.[1]

Analytical concentrations of picric acid and total concentrations of picrate ion species, spectrophotometrically determined, are listed in Table 2. Identifying numbers are the same as the first column of Table 1.

[1]A. Sacco. Unpublished results from this laboratory.

Discussion

The ionization constant for a weak acid which dissociates according to reaction

[1] $$HA \rightleftharpoons H^+ + A^-$$

is

[2] $$K_{HA} = \frac{[A^-][H^+]f_{H^+} \cdot f_{A^-}}{[HA]f_{HA}}$$

Neglecting activity coefficients (at very low ionic strength) eq. 3 is obtained

[3] $$\log [A^-] = \tfrac{1}{2} \log K_{HA} + \tfrac{1}{2} \log [HA]$$

A plot of log $[A^-]$ *vs.* log [HA] should yield a straight line with a slope of 0.5 and intercept $\frac{1}{2} \log K_{HA}$. From the intercept, then, it is possible to calculate the K_{HA} value.

Our spectrophotometrical data were interpreted on the basis of eq. 3. Experimental values of log $[Pi^-]$ and log [HPi] for systems 1–6 and 8–13 were analyzed by a least squares method. Equation 3 holds good as may be seen by standard deviation values σ and by the slope values given in Table 3. In Table 3 dissociation constants of picric acid at 30 °C obtained from eq. 3 are reported.

In pure sulfolane (system 7) it was found that in solutions more dilute than 0.08 *M* the trend of log $[Pi^-]$ *vs.* log [HPi] was like that of the other systems studied. In solutions more concentrated than 0.08 *M* experimental data gave a straight line with a greater slope than 0.5.

This behavior may be interpreted in the light of recent theoretical work by Caruso and co-

workers (8). As suggested, our data have been plotted in the form of $-\log [Pi^-]$ *vs.* $-\log c$ (c = analytical HPi concentration). Such a plot is shown in Fig. 1. As may be seen there are two linear portions with slopes of 0.46 when $c < 0.08\ M$ and 1.56 when $c > 0.08\ M$.

According to Caruso's treatment, the slope of 0.46 when $c < 0.08\ M$ indicates that at low concentrations simple dissociation [1] mainly occurs in solution. By extrapolation of this linear portion of the curve to $-\log c = 0$, the value of $10^{-7.6}$ may be calculated for K_{HPi}.

The slope of the curve at higher concentrations indicates that more complex equilibria than simple dissociation [1] occur in solution. Previous data (9–11) suggest that in pure sulfolane, a typical dipolar aprotic solvent, anions are stabilized by conjugation, forming AHA^-, $A(HA)_2^-$, or more complex species.

Eller and Caruso (12), by conductometric measurements of picric acid in sulfolane at 30 °C, suggest that only polymer formation can explain the magnitude of the experimental slope ($d \log \Lambda / d \log c = -0.96$). $Pi(HPi)_2^-$ was proposed by Kolthoff *et al.* (13) as the predominant picrate species present in acetonitrile at concentration greater than 0.1 M on the basis

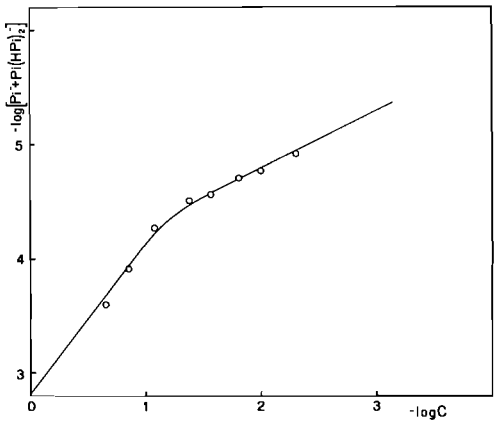

FIG. 1. Spectrophotometric data of picric acid in sulfolane. The line is the theoretical curve for equilibria 4–6 ($K_{HPi} = 10^{-7.6}$, $K_{(HPi)_2} = 10^{-1.9}$, and $K_{Pi(HPi)_2^-} = 10^4$).

of spectrophotometrical data. A graph of $-\log [Pi^-]$ *vs.* $-\log c$ shows very similar behavior, in shape and slopes (0.48 and 1.45), to our data.

Thus it is possible to suppose that in sulfolane also the mechanism of ionization of picric acid and the corresponding equilibrium constants are

[4] $$HPi \rightleftharpoons H^+ + Pi^-$$

$$K_{HPi} = \frac{[H^+][Pi^-]f^2}{[HPi]}$$

[5] $$2HPi \rightleftharpoons (HPi)_2$$

$$K_{(HPi)_2} = \frac{[(HPi)_2]}{[HPi]^2}$$

[6] $$Pi^- + (HPi)_2 \rightleftharpoons Pi(HPi)_2^-$$

$$K_{Pi(HPi)_2^-} = \frac{[Pi(HPi)_2^-]}{[Pi^-][(HPi)_2]}$$

Certainly it may be possible that the species Pi^- and $Pi(HPi)_2^-$ in these equilibria have different spectral properties; however photometric data were analyzed on the basis of identical molar absorptivities of picrate species at 420 nm. The identical assumption was made by Kolthoff *et al.* for the same anions in acetonitrile (13) and was suggested by Eller and Caruso (12).

In order to derive the values of the constants $K_{(HPi)_2}$ and $K_{Pi(HPi)_2^-}$, taking for K_{HPi} the value of $10^{-7.6}$ determined above, the procedure suggested by Caruso was used. As shown in the mathematical derivations in the microfilm edition of ref. 12, analytical picric acid concentration c is

[7] $$c = [HPi] + 2K_{(HPi)_2}[HPi]^2 + \frac{1}{f}B + \frac{1}{f}\frac{2K_{HPi}K_{(HPi)_2}K_{Pi(HPi)_2^-}[HPi]^3}{B}$$

where B is

[8] $$B = (K_{HPi}[HPi] + K_{HPi}K_{(HPi)_2} \times K_{Pi(HPi)_2^-}[HPi]^3)^{1/2}$$

and total concentration of picrate ion species is

[9] $$[Pi^-] + [Pi(HPi)_2^-] = \frac{1}{f}B$$

Neglecting activity coefficients, for an assumed set of equilibrium constants K_{HPi}, $K_{(HPi)_2}$, and $K_{Pi(HPi)_2^-}$, [HPi], and $([Pi^-] + [Pi(HPi)_2^-])$ values for different concentrations c may be respectively calculated by eqs. 7 and 9. Thus, for each set of equilibrium constants, a theoretical curve $-\log([Pi^-] + [Pi(HPi)_2^-])$ *vs.* $-\log c$ is obtained. This procedure was iterated using different values of $K_{(HPi)_2}$ and $K_{Pi(HPi)_2^-}$, in order to obtain the best agreement between theoretical and experimental data.

The theoretical curve obtained for $K_{HPi} = 10^{-7.6}$, $K_{(HPi)_2} = 10^{-1.9}$, and $K_{Pi(HPi)_2^-} = 10^4$, fits the experimental data very well, as may be seen in Fig. 1.

Let us now consider the association behavior of picric acid with solvent composition change. In Fig. 2 the curves of the logarithms of the

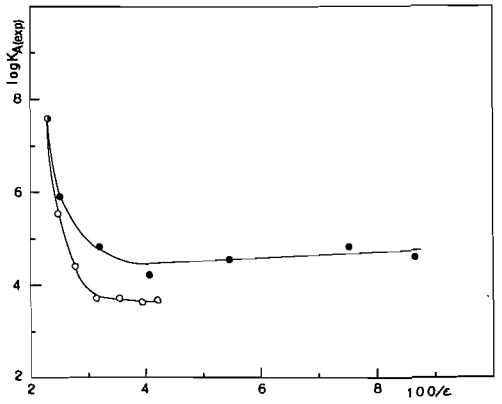

FIG. 2. Association constants of picric acid in ethanol–sulfolane (○) and *t*-butyl alcohol – sulfolane (●) mixtures.

association constants against the reciprocal of dielectric constant are shown.

If the association constant were controlled only by electrostatic forces, the Fuoss (14) equation would be valid

$$[10] \qquad \ln K_A = \ln \frac{4\pi N a^3}{3000} + \frac{e^2}{a\varepsilon kT}$$

where N is Avogadro's number, a the ion size, e the electron charge, ε the dielectric constant, k the Boltzmann constant, and T the absolute temperature. On the basis of eq. 10, the plot $\log K_A$ *vs.* $1/\varepsilon$ should be linear with positive slope.

On the contrary, for the two systems studied, the trends are not linear and association increases with increase of dielectric constant in spite of electrostatics. Clearly this behavior can only be explained by assuming that in our solvent mixtures solute–solvent interactions affect association phenomena much more than short range ion–ion interactions which depend only on the dielectric constant of the solvent.

In pure sulfolane, picric acid is weaker than in ethylic and *t*-butyl alcohols ($pK_{HPi} = 7.6$, 3.7, and 4.6 respectively). HPi reacts mainly with the alcohol which is the more basic component and sulfolane acts as an inert solvent. As suggested by Shedlowsky (15), the equilibria in solution and relevant constants should be

$$[11] \qquad HPi + n\text{ROH} \rightleftharpoons HPi\,.\,n\text{ROH}$$

$$K_1 = \frac{[HPi \cdot n\text{ROH}]}{[HPi][\text{ROH}]^n}$$

$$[12] \qquad HPi\,.\,n\text{ROH} \rightleftharpoons \text{ROH}_2^+.\text{ROH}_{(n-1)}\text{Pi}^-$$

$$K_2 = \frac{[\text{ROH}_2^+ \cdot \text{ROH}_{(n-1)}\text{Pi}^-]}{[HPi \cdot n\text{ROH}]}$$

$$[13] \qquad \text{ROH}_2^+\,.\,\text{ROH}_{(n-1)}\text{Pi}^- \rightleftharpoons \text{ROH}_2^+ + \text{ROH}_{(n-1)}\text{Pi}^-$$

$$K_3 = \frac{[\text{ROH}_2^+][\text{ROH}_{(n-1)}\text{Pi}^-]}{[\text{ROH}_2^+ \cdot \text{ROH}_{(n-1)}\text{Pi}^-]}$$

The three equations show that picric acid reacts with n molecules of alcohol, forming a complex which rearranges to an ion pair, which then dissociates. Under these conditions, eqs. 11 and 12 are controlled by specific solute–solvent interactions, while eq. 13 is controlled by electrostatics.

Then, according to eq. 10, $1/K_3 = K_A = K_0 \exp b$, where $K_0 = 4\pi N a^3/3000$ and $b = e^2/a\varepsilon kT$.

The overall constant for the equilibria 11–13 is

$$[14] \qquad K_1K_2K_3 = \frac{K_1K_2}{K_A} = \frac{[\text{ROH}_2^+][\text{ROH}_{(n-1)}\text{Pi}^-]}{[HPi][\text{ROH}]^n}$$

The experimental association constant $K_{A(exp)}$, neglecting activity coefficients, is

$$[15] \qquad K_{A(exp)} = \frac{[HPi]}{[\text{ROH}_2^+][\text{ROH}_{(n-1)}\text{Pi}^-]}$$

Evidently

$$[16] \qquad K_{A(exp)} = \frac{K_A}{[\text{ROH}]^n K_1K_2}$$

By taking logarithms, eq. 16 may be written

$$[17] \qquad \log K_{A(exp)} + n \log [\text{ROH}] = \log K_0 - \log K_1K_2 + \frac{0.434e^2}{100akT}\left(\frac{100}{\varepsilon}\right)$$

According to D'Aprano and Fuoss (16) it is possible that four alcohol molecules react with picric acid, one molecule forming ROH_2^+ species, and the other three solvating the three nitro-groups of picrate anion by hydrogen bonds. A plot of $\log K_{A(exp)} + 4 \log [\text{ROH}]$ *vs.* $100/\varepsilon$ should yield a straight line with slope $0.434e^2/100akT$ and intercept $\log K_0 - \log K_1K_2$.

Such plots for picric acid in ethanol–sulfolane and *t*-butyl alcohol – sulfolane mixtures are shown in Fig. 3. As can be seen, the graphs are reasonably linear. Higher deviation was observed in the case of pure *t*-butyl alcohol. The values of the ion size parameter a of picric acid, obtained from the slopes, are 4.7 and 2.2 Å

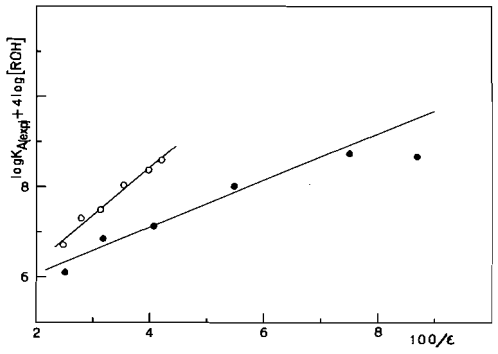

FIG. 3. Test of eq. 17 ($n = 4$) for ionization of picric acid in ethanol–sulfolane (○) and *t*-butyl alcohol – sulfolane (●) mixtures.

for *t*-butyl alcohol – sulfolane and ethanol–sulfolane mixtures respectively. Even if the last value is lower than might be expected, it is reasonable to expect lower values in ethanol than in *t*-butyl alcohol mixtures, keeping in mind the molecular size of the two alcohols studied.

From intercept values, which are 4.16 and 5.06 for ethanol–sulfolane and *t*-butyl alcohol – sulfolane mixtures respectively, it is possible to derive for the K_1K_2 products the values $10^{-5.6}$ and $10^{-5.7}$ respectively.

This result shows that, in the proposed reaction sequence [11]–[13], the interactions between hydroxyl group and picric acid are scarcely affected by different alkyl groups in the two alcohols.

Photoisomerization of Bicyclo[3.1.1]heptan-2-ones in Methanol: Chemical Transformations of 'Verbanones'[1]

ALEX G. FALLIS

Department of Chemistry, Memorial University of Newfoundland, St. John's, Newfoundland A1C 5S7

Received December 5, 1974

ALEX G. FALLIS. Can. J. Chem. **53**, 1657 (1975).

The products (predominantly unsaturated aldehydes) from photolysis in methanol of a series of 6,6-dimethylbicyclo[3.1.1]heptan-2-ones are reported. These results are rationalized on the basis of stereochemical interactions and the apparent preference for cleavage to occur adjacent to the less highly substituted α-carbon but more stable alkyl radical. It is concluded that the photochemical behavior of α-cyclobutyl ketones displays a closer parallel to the α-cyclopropyl ketones than previously recognized and that cleavage will occur preferentially on the side of the carbonyl group remote from the four-membered ring whenever possible. The synthetic steps involved in the preparation of the ketones from 'pinene' precursors are described.

ALEX G. FALLIS. Can. J. Chem. **53**, 1657 (1975).

On rapporte les produits (principalement des aldéhydes non-saturés) formés lors de la photolyse dans le méthanol d'une série de diméthyl-6,6 bicyclo[3.1.1]heptanones-2. On rationalise les résultats en se basant sur les interactions stéréochimiques et la préférence apparente pour que la coupure se produise dans la position adjacente à celle du carbone α moins substitué mais possédant le radical alkyle le plus stable. On en conclut que le comportement photochimique des α-cyclobutyl cétones montre un parallélisme plus près de celui des α-cyclopropyl cétones qu'il n'avait été reconnu auparavant; de plus, chaque fois que cette coupure sera possible, la coupure se produira préférentiellement sur le côté du groupement carbonyle éloigné du cycle à quatre membres. On décrit les étapes synthétiques impliquées dans la préparation des cétones à partir de précurseur du type 'pinène'. [Traduit par le journal]

Introduction

Interest in the photochemistry of cyclic ketones is widespread but in spite of considerable attention, some facets are still imperfectly understood. The use of simple, photoinduced cleavage reactions of cycloalkanones in organic synthesis has been less than might be anticipated due in part to difficulty in predicting product ratios accurately. In general, the major product upon photolysis of saturated cyclic ketones in solution results from preferential photoinduced cleavage adjacent to the more highly substituted α-carbon (1). At the outset of our work, only two exceptions to this generalization appeared to have been reported other than for cyclic α-cyclopropyl ketones, which are known (2) to form a special class and usually cleave on the side of the carbonyl function remote from the three-membered ring.

One such exception *cis*-verbanone (**1**) was reported (3) to give the unsaturated aldehyde **2** as the only significant product upon photolysis in methanol. The second example also involved an α-ketocyclobutane system. Irradiation of *trans*-5,5,7,7,8,8-hexamethylbicyclo[4.2.0]octan-2-one (**3**) gave rise to aldehyde **4**, a product derived from cleavage of the least substituted bond α to the carbonyl group (4).

We were intrigued by the reason for this 'abnormal' behavior particularly in the case of *cis*-verbanone since the p.m.r. data reported in support of **2** assigned the vinyl hydrogens of its semicarbazone derivative to a multiplet at δ

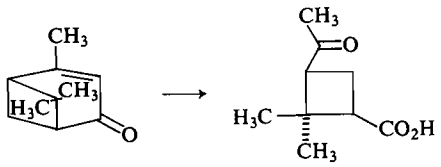
6.65 p.p.m., more nearly in accord with the range expected for cyclobutene olefinic protons. Thus, the structural assignment might have been in error and the photolytic behavior of the ketone unexceptional.

Results and Discussion

The photolysis of a methanol solution of *cis*-verbanone in a quartz tube was repeated but gave two unsaturated aldehydes in a ratio of 7:1. The important signals of the p.m.r. spectrum of the semicarbazone derivative of the major isomer are listed in Table 1 and are clearly consistent with the assigned structure **2** although they differ considerably from those reported by Matsui (3).[2] Significantly, the chemical shift and multiplicity of the vinyl hydrogen signals are as expected for geminal olefinic protons of the type found in **2** and the position of these signals is not compatible with a cyclobutene structure. In addition, the proton H_f appears as a distinct doublet (J = 5.7 Hz) whereas for the isomeric cyclobutene aldehyde (see **7**), it would appear as a triplet. The assignment of the cyclobutyl methyl signals has been reversed in accord with previous work on pinene derivatives (5) which indicates that the *trans*-methyl function lies in the deshielding zone of the unsaturated side chain. The assignment of the semicarbazone hydrogen signals was verified by D_2O exchange and comparison with model systems such as *n*-heptanal semicarbazone. (Although semicarbazones are not ideal derivatives for n.m.r. study, due to their low solubility, the signal due to the hydrogen on nitrogen (H_g) has occasionally been incorrectly assigned or missed entirely in related systems.) Additional support for the structural assignment is provided by the p.m.r. spectrum of **2** itself which displayed a doublet at δ 9.75 p.p.m. J = 1 Hz due to the aldehydic hydrogen, a broad singlet at δ 1.67 due to the vinyl methyl group and broad singlets at δ 4.71, $w_{\frac{1}{2}}$ = 4 Hz and δ 4.90, $w_{\frac{1}{2}}$ = 6 Hz for the vinyl hydrogens.



5 6

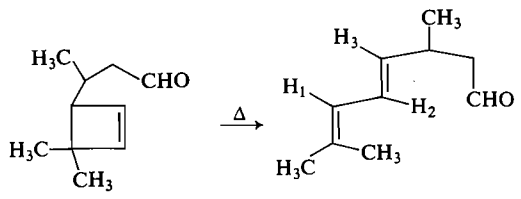
Ozonolysis of **2** followed by oxidation with Jones' reagent gave *cis*-pinononic acid (**6**) which was identical on the basis of spectral and mixture melting point comparison with an authentic sample. This sample was prepared from verbenone (**5**) by ozonolysis followed by oxidative work-up with 30% hydrogen peroxide and thus firmly established the structure of the major photolysis product as **2**.

The minor isomer is assigned the cyclobutene structure **7**. The i.r. spectrum indicates that the product is an aldehyde ν_{max} (CCl_4) 2810sh, 2710, 1730 cm^{-1}. This is supported by the p.m.r. spectrum which contained a triplet at δ 9.78, J = 2 Hz due to the aldehydic hydrogen and a multiplet at δ 6.09, representing two protons, as expected for the cyclobutene olefinic protons. The correctness of the structural assignment was further established by thermally induced ring opening to give the octadienal **8**, a situation that would not have pertained if the double bond were not in the four-membered ring. The p.m.r. spectrum of **8** displayed a doublet at δ 1.11, J = 6.5 Hz due to the saturated methyl substituent, the *gem*-dimethyl group appeared as a six-proton singlet at δ 1.73 and the aldehydic hydrogen as a triplet at δ 9.72, J = 2 Hz. The assignment of the vinyl hydrogen resonances (100 MHz) δ 6.21 (H_2, d of d, J = 10.5, 15 Hz), 5.70 (H_1, d of br s, J = 10.5 Hz), 5.40 (H_3,d of d, J = 6.5, 15 Hz) is consistent with related work on butadienes (6).

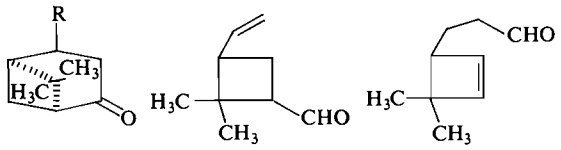


7 8

The preferential photolytic formation of **2** was previously rationalized on the basis of the efficient orbital overlap felt to be provided by the fixed geometry of this ring system and the suggestion that the β-hydrogen atom migration was probably concerted with ring cleavage to give the cyclobutane product directly (3, 7). However, in the light of evidence that diradicals are discrete intermediates for Norrish Type I reactions (8) this may be an oversimplification. More recently, in the case of related bridged-ring ketones such as camphor and bicyclo[3.2.1]-octan-2-one, the diradical intermediates formed upon photolysis have been observed directly by chemically induced dynamic nuclear spin polarization (CIDNP) (9).

Examination of molecular models (Dreiding, Prentice-Hall) suggested that steric interactions between the bridge and C_4 methyl groups may be partially responsible for the preferential formation of the cyclobutane aldehyde. If so, photolysis of suitable ketones with this interaction removed or reduced would be expected to give increased amounts of cyclobutene aldehydes resulting from bond rupture adjacent to the more highly substituted α-carbon.

A suitable model in which this interaction is absent is nopinone (**9**) which lacks the C_4 methyl substituent. Photolysis of nopinone in methanol gave rise to two major products **11** and **12** in a ratio of 4:1.[3] Thus, although **12** is a significant product and the relative amount of it has increased this aldehyde does not predominate and nonbonded interactions are not the only factor influencing the product distribution. By comparison, irradiation of *trans*-verbanone (**10**), whose behavior might be expected to parallel that of nopinone since the nonbonded interaction under consideration is also absent, gave predominately the cyclobutene aldehyde **7** in a 2:1 ratio (**7**:**2**).



9 R = H
10 R = CH_3

11 **12**

The structures assigned to **11** and **12**, which are analogous to the products from *cis*-verbanone, are supported by spectral data. The p.m.r. spectrum of the major isomer contained a doublet J = 2 Hz at δ 9.74 for the aldehydic hydrogen while the vinyl proton appeared as a multiplet at δ 5.5–5.9, one of the terminal methylene hydrogens as a singlet at δ 5.04, and the remaining one as a doublet of multiplets J = 6 Hz at δ 4.91. In addition, a synthesis of the *cis*- and *trans*-methyl ketones derived from **11** has been

[3]While this work was in progress, we learned of parallel studies on nopinone by Professor N. J. Turro, Columbia University, whom we thank for exchange of information and subsequently another report on nopinone has appeared (7).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

reported by Shaffer and co-workers (7) who have noted, as have we, that further irradiation gave rise to 4-isopropenyl-5-hexenal (**13**) a Norrish Type II product.

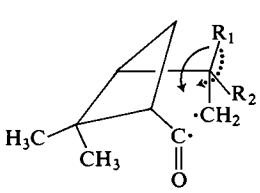
The spectrum of the minor isomer was consistent with structure **12**: the aldehydic hydrogen gave rise to a triplet at δ 9.78, $J = 2$ Hz, the olefinic protons appeared as a multiplet δ 6.10, and the saturated alcohol derived from **12** has been compared with an authentic sample by others (7).

The photochemical results clearly require a more detailed explanation and consideration of the relative stability of the alkyl portion of the diradicals involved is appropriate. Unfortunately, accurate figures for radical stability in solution do not appear to be available, however, values (see Table 2) based on bond dissociation energies of gaseous hydrocarbons (10) provide an approximate measure of relative stability whose order would not be expected to change appreciably in solution. Significantly, the primary radicals *n*-propyl and isobutyl are slightly more stable than the cyclobutyl radical. This implies that if other factors are equal photoinduced cleavage of α-cyclobutyl ketones adjacent to the least substituted α-carbon is slightly preferred in contrast to the earlier generalization (1). Consistent with this view, as was kindly pointed out by a referee, the hybridization of the four-membered ring is such that the adjacent single bond will have higher s-character resulting in a slightly stronger bond with a lower tendency to cleave as is observed for α-cyclopropyl ketones. Thus in the absence of other directing influences, the cyclobutene aldehyde(s) would be expected to be the minor photolysis product(s) as found for nopinone. The balance between the two competing pathways is undoubtedly delicate and steric effects will exert a strong influence.[4]

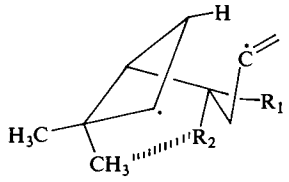
TABLE 2. Relative scale of radical stabilities (10)

Radical		$\Delta H^{\circ}_{298.2}$(kcal/mol)
tert-Butyl		91
Isopropyl Cyclohexyl		94
Cyclopentyl		95
n-Propyl Isobutyl		98
Cyclobutyl		99
Methyl	CH_3·	102
Cyclopropyl		103

In simple cyclohexanones, it has been found by Wagner (11), Agosta (12) and their respective co-workers that a β-substituent exerts a directing effect which increases the amount of product derived from cleavage on the side of the carbonyl function remote from the substituent. If this directing effect is operative in these bicyclic systems cleavage adjacent to the cyclobutane ring should be enhanced for the verbanones relative to nopinone but for *cis*-verbanone this was not the case. Thus, the product distributions can now be reconsidered in the light of the radical stability data as well as the steric interactions.



A $R_1 = R_2 = H$
B $R_1 = H; R_2 = CH_3$
C $R_1 = CH_3; R_2 = H$



D $R_1 = R_2 = H$
E $R_1 = H; R_2 = CH_3$
F $R_1 = CH_3; R_2 = H$
G $R_1 = R_2 = CH_3$

Photolysis of nopinone results in preferential cleavage on the side of the carbonyl group remote from the four-membered ring to form **A** which gives the major product. The minor isomer arises from **D** and, although there may be a slight nonbonded methyl–hydrogen interaction, this is not sufficient to inhibit the formation of significant amounts of cyclobutene aldehyde.

Cleavage of *cis*-verbanone in the preferred sense affords **B** which requires only a slight rotation (↻) to permit hydrogen abstraction to give the major product. In addition, as the requisite rotation occurs in this diradical inter-

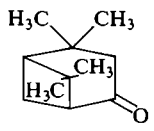
[4]It should be realized that the numerical difference in relative stabilities between primary and cyclobutyl radicals is of similar magnitude to the probable error in the measurement, nevertheless, the trend must be real.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

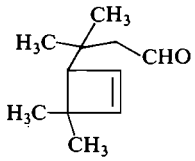
mediate, any nonbonded methyl–methyl interaction is relieved. In contrast, bond fission adjacent to the cyclobutane ring gives **E** which must adopt a conformation possessing nearly a 1,3-diaxial methyl–methyl interaction (3.7 kcal/mol) (13) for hydrogen abstraction to proceed. This is probably sufficient to permit reclosure to starting material to compete efficiently and to minimize the formation of cyclobutene aldehyde **7**.

The results for *trans*-verbanone are consistent with this interpretation. Intermediate **C** requires considerable rotation (↻) to achieve a conformation suitable for hydrogen abstraction to occur and in accord with 'the principle of least motion' one should expect the predominant path to be that which requires minimum energy in changing the positions of atoms in the reactant to their corresponding positions in the product (14). This rotation introduces an unfavorable steric interaction with the bridge methyl group such that ring closure may occur in preference. In contrast, the other pathway resulting in fission adjacent to the cyclobutane ring to give **F** does not suffer this restriction (compare **E**) and allows the reaction to funnel through to cyclobutene product even though this cleavage is slightly less preferable initially.

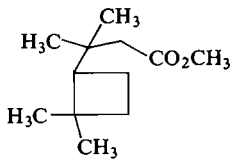
The validity of this explanation was tested as follows. In a molecule such as **14**, the path to the cyclobutane aldehyde is blocked and unless a more deep seated rearrangement occurs **15** should be the only aldehydic product. However, formation of **15** will be unfavorable, since it must arise via intermediate **G**, which contains the unfavorable diaxial interaction discussed previously. Consistent with this, the major photolysis product is the saturated ester **16**, the first ketene derived product encountered in the series. The formation of **16**, requires an intermediate of type **H** which must approach the geometry between that found in bicyclo[3.1.1]-heptanes and the more highly strained bicyclo[2.1.1]hexanes (15); thus, in the other cases aldehydes are produced in preference. The structure of the ester is established by its i.r. carbonyl absorption at 1733 cm^{-1} and C—H stretch due to the methoxyl function at 2820 cm^{-1}. The absence of signals below the methoxy methyl resonance at δ 3.60 in the p.m.r. spectrum clearly indicates that the four-membered ring is saturated. Attempts to isolate the cyclobutene aldehyde **15** or trap it as its acetal were unsuccessful



14



15

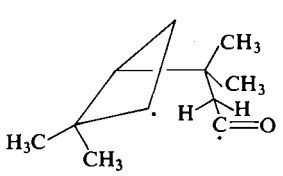


16

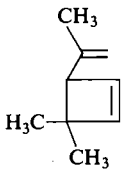
as it underwent a rapid Norrish Type II reaction to give cyclobutanol **18**. It appears that this γ-hydrogen abstraction is faster than the initial α-cleavage. This is consistent with the results of Lewis and co-workers (16) who found that γ-hydrogen abstraction from a secondary alkyl center is approximately 10 times more rapid than α-cleavage of *tert*-alkyl phenyl ketones. In the above case, although a primary center is involved, six equivalent hydrogens are available and the geometry is favorable. A small amount of the diene **17** may also be formed but it has not been positively identified. The ester:aldehyde ratio varied with time but an average value based on the cyclobutanol present at 65–70% conversion of starting material was 1.5:1 (**16**:**15**), compared with the value of 1:1.6 found by Coyle for cyclohexanone (17).

The i.r. spectrum of **18** contains hydroxyl bands at 3585 and 3300 (broad) cm^{-1} in addition to bands at 3020, 1625, and 860 cm^{-1} indicating the presence of a double bond. The cyclobutene nature of this double bond was established by the p.m.r. spectrum (100 MHz) which contained two separate doublets due to the olefinic protons, $J = 3$ Hz at δ 6.25 and 6.13. This is in reasonable agreement with related systems (18, 19) but in this case since the allylic couplings are apparently near zero, it is not possible to explicitly assign these signals. As anticipated for a cyclobutene system thermal ring opening on the gas chromatograph afforded a butadiene. The resonance for the proton on the carbon bearing the hydroxyl function appears as a 'quintet like' multiplet $J \sim 8.5$ Hz at δ 4.11 possessing unresolved fine structure. Both the

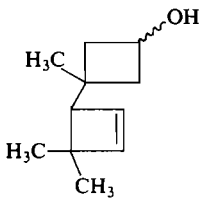
position and the appearance of this signal are similar to these reported for 3-isopropylcyclobutanols and amines (20). To ascertain with more certainty the environment of this hydrogen, the spectrum was recorded in the presence of a shift reagent [$Eu(fod)_3$]. This caused the signals due to the adjacent methylene hydrogens to shift downfield and improved the resolution so they appeared as a three-line multiplet (2H) $J = 8.5$ Hz and a distorted doublet of doublets $J = 2.5$, 6 Hz representing two protons. Coupling constants of cyclobutanes cover a wide



H



17



18

range due to the ability of the ring to adopt a number of conformations but generally the vicinal *cis*-coupling constant is larger than the *trans*-coupling constant (19). However, since the stereochemistry of the alcohol function is not established it is not possible to assign these signals with certainty at present. Although several reagents were examined conditions were not found by which the alcohol could be oxidized cleanly to a cyclobutanone.

Thus, it is suggested that the photolytic behavior of α-ketocyclobutane systems has more in common with α-cyclopropyl ketones than has previously been recognized. It is anticipated that upon photolysis in methanol α-ketocyclobutanes will generally display a slight preference to cleave on the side of the carbonyl group remote from the four-membered ring (*i.e.*, less substituted side) unless conformational preferences, geometric constraints, or radical stabilities dictate otherwise.[5]

Present literature examples can be rationalized on this basis in keeping with the generalization that the major photoproducts from cycloalkanones result from cleavage to form the most stable alkyl–acyl diradical whenever possible.

For example, the previous conclusion that "cleavage, next to a cyclobutane ring, is normal" (2) was primarily based on the photolysis of **19** and **21**. However, for the intermediate diradical which would result from fission remote from the four-membered ring, H_1 is geometrically inaccessible such that ring closure should compete efficiently and **20** is thus the aldehyde expected. For carvonecamphor (**21**), the ester arises from a *tert*-cyclobutyl radical in preference to a primary alkyl radical in accord with expectations. Similarly the spiro ketone **23** gives the anticipated product arising from a *tert*-cyclobutyl radical intermediate. The final example (**25**) appears initially to be an exception to the above suggestions but, in fact, gives the expected product when the geometric constraints in the system are considered since cleavage on the side of the carbonyl group remote from the ring gives an intermediate in which the abstraction of the requisite hydrogen (H_2) from the β-carbon appears difficult from models. In addition, **26** results from the favorable abstraction of a tertiary hydrogen.[6]

A referee has suggested our results can be equally well explained on the basis of a concerted mechanism. However, the original experimental evidence supporting a concerted process, based on the photolysis of 2-methylcyclohexanone, has been shown to be in error (8) and the photochemically generated diradical from 2-methylcyclohexanone has been detected by

[5]Generally, α-cleavage of cycloalkanones proceeds from a triplet excited state (21). The possibility that the product distributions for the bicycloheptanones are a consequence of different products from singlet and triplet excited states rather than resulting from the stability and conformations of the intermediate diradicals was rendered unlikely by quenching studies. Irradiation of *cis*- and *trans*-verbanone in the presence of 1,3-cyclohexadiene (1 and 5 *M*) caused a complete suppression of detectable aldehydic products.

[6]Since submission of this manuscript grandisol has been synthesized by photolysis of a substituted verbanone in methanol to give the cyclobutane aldehyde as the major product in accord with expectations (51).

CIDNP (9). An attempt to detect diradicals upon photolysis of *cis*-verbanone in the cavity of an e.s.r. spectrometer was unsuccessful[7] but the experimental evidence for related systems (8–11, 21) favors the biradical rather than the concerted mechanism for the photolysis of cyclic ketones in solution.[8] Once formed the biradical partitions itself between disproportionation to yield alkenal(s), disproportionation to yield ketene, and recoupling to yield ground state ketone. As indicated above the relative importance of recombination (ring closure) *vs.* hydrogen abstraction is influenced by radical stability and the ease of formation of the transition states required for hydrogen transfer. Thus substituents and conformational preferences exert a significant influence on the product distribution. When two or more pathways are involved the quantum yield is not an accurate reflection of the importance of recombination unless the recoupling rates from each intermediate are equal, which is unlikely. Thus, to clearly distinguish between the competition for recombination and hydrogen abstraction, data for both cyclobutene and cyclobutane aldehyde formation are required. Unfortunately a referee's suggestion that "quantum yields might be conclusive" is overly optimistic, although they are indicative. The quantum yields (Φ_{-K}) (7, 11) for nopinone (0.32) and *cis*-verbanone (0.40) are between those of cyclohexanone (0.20) and 2-methylcyclohexanone (0.50) suggesting that in each case some ring closure competes favorably with hydrogen abstraction; for although these figures indicate that the forward disproportionation reaction is facile the efficiency does not approach unity and steric effects on the competition are undoubtedly subtle. Barltrop and Coyle (8) have estimated that 33% of the biradical formed on photolysis of 2,3-dimethylcyclohexanone reverts to ketone rather than product. Thus these data support the conformational and radical stability arguments enunciated above to rationalize the product distributions in these bicyclo[3.1.1]heptan-2-ones.

Preparation of 'Verbanones'

The ketones used in this study have been prepared previously; nevertheless, they are not readily available especially in the case of *trans*-verbanone. During and after the completion of this work, several reports appeared concerning transformations in these systems. The pertinent portion of our own work in this area is outlined below.

Verbenone (**5**) was prepared from α-pinene by allylic oxidation in improved yield when the chromium trioxide – pyridine reagent was prepared and utilized *in situ* (26, 27). Catalytic hydrogenation of verbenone (Pd/C) in methanol containing pyridine afforded *cis*-verbanone (**1**) (28) uncontaminated with the saturated alcohol (29, 30).

Previously, the standard route to *trans*-verbanone (**10**) has been via *trans*-verbenol (**32**) followed by reduction and oxidation to give a mixture of *cis*- and *trans*-verbanones 55:45 (28). Since the more stable isomer frequently predominates when α,β-unsaturated ketones are reduced with lithium in liquid ammonia verbenone (**5**) was reduced to give a mixture in which the *cis*:*trans* ratio was reversed 45:55. (Similar reduction with sodium in hexamethyl-

[7]N. J. Gogan and C. K. Chu are thanked for conducting this experiment.

[8]The possibility that this is a special case involving a concerted pathway cannot be completely excluded but no 'proven' example for a photoinduced α-cleavage has been reported.

Collidine	Reflux	3 h	~2% plus **9** and **29**

NOTE: Attempted debrominations via the ketal, semicarbazone, and 2,4-dinitrophenylhydrazone derivatives were also unsuccessful.

phosphoramide gave a *cis*:*trans* ratio of 35:65.) In an attempt to improve the amount of *trans*-ketone produced the catalytic hydrogenation of *trans*-verbenol (**32**) was examined in *tert*-butyl alcohol and 50% aqueous methanol, since it is known (28) that the *cis*:*trans* ratio decreases in polar solvents but in each case the *cis*-isomer predominated. If a bulkier group is attached to the alcohol function hydrogenation of the double bond from the desired direction should be encouraged; however, hydrogenation of the acetate **33** in acetic acid gave a *cis*:*trans* ratio of 2:1 after hydrolysis and oxidation, whereas the trimethyl silyl derivative was reduced to only a slight extent at atmospheric pressure.

As separation was tedious attention was turned to a stereoselective synthesis of *trans*-verbanone (10) the essential step of which was the 1,4-conjugate addition of dimethyl copper lithium to apoverbenone (**30**). It was envisaged that the reagent would approach from the less hindered side of the molecule away from the dimethyl bridge to give the desired ketone. It is reported that apoverbenone can be prepared by dehydrobromination of 3-bromonopinone (**29**) in collidine (31). In our hands, this approach was unsuccessful and several other dehydrobromination procedures were examined as summarized in Table 3. New Zealand workers have experienced this same difficulty (32) and thus this approach to apoverbenone was abandoned. However, Grimshaw and co-workers have developed conditions for the preparation of apoverbenone in 77% yield by treating *cis*-bromonopinone[9] with lithium carbonate – lithium bromide in dimethyl sulfoxide at 150° for 60 h (33).

Selenium dioxide and dichlorodicyanobenzoquinone (DDQ) have been widely used in the steroid field to effect dehydrogenations (34). Reactions with DDQ were not encouraging and SeO_2 was investigated especially since it has been reported that verbenone can be prepared from verbanone using SeO_2 in ethanol although no yield is given (35). Several solvents were examined, dioxane, *tert*-butyl alcohol, ethanol, acetic acid, and while the reaction with nopinone (**9**) worked reasonably well on a modest scale (~1 g) yields dropped when it was scaled up. Thus, reactions were run in refluxing dioxane to approximately 70% completion to afford apoverbenone (**30**) in 40% yield. The selenium produced as a byproduct of the reaction causes ring fission and renders the reaction unsuitable for large scale preparation of apoverbenone. However, material was obtained to study the conjugate addition with dimethyl copper lithium which proceeded smoothly to give *trans*-verbanone in 80% yield uncontaminated with the *cis*-isomer. French workers have noted this also and have published a detailed study of the addition of dimethyl copper lithium and copper complexed methyl magnesium iodide to both verbenone and apoverbenone (36). These reactions thus constitute a stereoselective route to *trans*-verbanone. Jones and Webb have developed a different route to *trans*-verbanone starting with pinocamphone (*trans*-2,6,6-trimethylbicyclo[3.1.1]heptan-3-one) (37).[10]

An alternative preparation of apoverbenone involves allylic oxidation of apopinene (**28**) (31,

[9]The stereochemistry of substituted compounds in these series is frequently designated by α and β. However, different workers use different conventions (*cf.* ref. 33) and thus we prefer to designate the substituent as *cis*- or *trans*-relative to the *gem*-dimethyl bridge.

[10]These bicyclic systems may be named as pinane derivatives (IUPAC Rule A75-2); however, we favor the von Baeyer system (IUPAC Rule A31) due to its general applicability.

38). The standard route to apopinene (other than from natural sources) proceeds via catalytic decarbonylation of myrtenal but gave disappointing yields in our hands (39). An earlier report (40) outlined the preparation of apopinene by dehydration of nopinol (**31**) with potassium bisulfate and while apopinene is produced, there are additional components. Similarly, alkyl lithium treatment of nopinone tosylhydrazone gives a mixture of products (41).

Reduction of nopinone with $LiAlH_4$ gives a mixture of *cis*- and *trans*-alcohols in which the *cis*-isomer predominates (42). The use of a bulkier reagent such as 'Red-al' (sodium *bis*(2-methoxyethoxy)aluminum hydride) in refluxing benzene afforded better than 95% of the *cis*-isomer which crystallized directly upon work-up. Early attempts to form the brosylate of this alcohol resulted in a rearranged product (43) and thus a dehydration procedure must be conducted under nonacidic conditions to avoid rearrangement. Various combinations of alumina and Florisil with amines and thionyl chloride – pyridine were examined but in all cases, other products were formed in addition to the desired olefin. The procedure adopted utilized phosphorus oxychloride – pyridine at 0° and gave a 50% yield of apopinene which was oxidized to apoverbenone with chromium trioxide – pyridine in dichloromethane. The tetramethyl ketone **14** was prepared by conjugate addition of dimethyl copper lithium to verbenone.

Experimental

Melting points were determined in capillary tubes with a Thomas-Hoover Uni-Melt apparatus and are uncorrected. Microanalyses were performed by Alfred Bernhardt, West Germany.

Infrared spectra were recorded in carbon tetrachloride solution, unless otherwise indicated, on a Perkin-Elmer 237B grating spectrophotometer and were calibrated with the 2850 and 1601 cm^{-1} bands of polystyrene film. Ultraviolet spectra were recorded on a Perkin-Elmer 202 ultraviolet–visible spectrophotometer and were calibrated with the 279.4 nm band of a Holmium filter. Proton magnetic resonance spectra were measured using a Varian Model A-60, Varian Model EM-360, or Varian Model HA-100 spectrometer in carbon tetrachloride solutions, unless otherwise stated, containing tetramethylsilane as an internal standard. Band positions are reported in parts per million downfield from TMS (δ scale).

The g.l.c. analyses were conducted on a Varian Aerograph gas chromatograph Model 1720 with helium as carrier gas on an 8 ft × ¼ in., 13% SE-30 column supported on Chromosorb W (AW-DMCS) (70–80 mesh) or on an 8 ft × ¼ in., 20% Carbowax 20M column supported on Chromosorb W (AW-DMCS) (70–80 mesh).

Solutions in organic solvents were dried over anhydrous magnesium sulfate and stripped of solvent with a Büchi rotary evaporator connected to a water aspirator. Irradiations were conducted using a water cooled Hanovia 450 W medium pressure mercury arc source.

Verbenone (4,6,6-Trimethylbicyclo[3.1.1]hept-3-ene-2-one) (5)

Commercial (±)α-pinene (20 g, 0.147 mol, Aldrich) in dichloromethane (100 ml) was added dropwise to chromium trioxide – pyridine reagent prepared *in situ* in dichloromethane (1500 ml) from pyridine (240 g, 3 mol) and chromium trioxide (150 g, 1.5 mol, dried over P_2O_5 15 h/12 mm). The reaction was stirred mechanically for 48 h at room temperature after which time the bulk of the dichloromethane was removed by decantation and concentrated. The dark residue remaining in the reaction flask was extracted thoroughly with ether as was the residue resulting from the concentration of dichloromethane. The ether solutions were combined and washed successively with 10% aqueous $NaHCO_3$, 10% aqueous HCl until washings remained acidic, 10% aqueous $NaHCO_3$, water, and dried. Distillation of the residual oil which remained after removal of the solvent provided 12.1 g (55%) of verbenone (**5**); b.p. 108–110°/11 mm (lit. (44) b.p. 100–102°/5 mm); i.r. 1690 (C=O) cm^{-1}; p.m.r. δ 0.99 (3H, s), 1.50 (3H, s), 2.00 (3H, d, J = 1.5 Hz), 5.57 (1H, q, J = 1.5 Hz, CH=C) p.p.m.

cis-Verbanone (cis-4,6,6-Trimethylbicyclo[3.1.1.]heptan-2-one) (1)

A methanol solution (60 ml) of verbenone (**5**) (5.7 g, 0.038 mol) containing pyridine (0.6 ml, 0.006 mol) was stirred with 5% Pd/C (0.20 g) under hydrogen at atmospheric pressure until 1.05 molar-equiv. of hydrogen were absorbed. The mixture was filtered and g.l.c. analysis indicated a single product was present. The oil obtained after removal of solvent was dissolved in ether (50 ml) and the ether solution extracted with 10% aqueous HCl, water, and dried. The solution was filtered,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

concentrated, and distilled to give 5 g (87%) of the *cis*-ketone **1**; b.p. 91–92°/11 mm (lit. (44) b.p. 104–105°/15 mm); i.r. 1710(C=O) cm^{-1}; u.v. (CH_3OH) 275sh nm (ε 34); p.m.r. δ 0.99 (3H, s), 1.17 (3H, d, J = 6.5 Hz) 1.33 (3H, s) p.p.m.

Lithium–Ammonia Reduction of Verbenone: cis- and trans-Verbanone

Small pieces of lithium (1 g) were added to liquid ammonia (450 ml) contained in a three-necked 1-l round bottom flask equipped with a solid carbon dioxide condenser and a pressure equalizing dropping funnel. After all the lithium had reacted verbenone (3 g, 0.020 mol) in anhydrous petroleum ether (5 ml) was added. The solution was stirred for 1 h and solid ammonium chloride was added in small portions until the blue color dispersed. After the ammonia had evaporated water (100 ml) and ether (100 ml) were added, the aqueous layer further extracted with ether, and the combined extracts dried. To facilitate the analysis, the liquid product remaining after removal of the solvent was dissolved in acetone (20 ml) and treated with Jones' reagent (45). Analysis of the resulting ketone mixture by g.l.c. indicated the ketones were formed in a *trans*:*cis* ratio of 55:45. Repeated spinning band distillation (3) (b.p. 42–44°/0.3 mm) afforded a sample of *trans*-verbanone (**10**) containing 5% of the *cis* isomer **1**.

Ketone Photolysis

cis-Verbanone (1)

cis-Verbanone (0.200 g, 1.32 mmol) in dry methanol (15 ml, distilled from magnesium) to which sodium bicarbonate (~15 mg) had been added was flushed with nitrogen, stoppered, and irradiated in a quartz tube for 1–2 h. (Longer reaction times were required when Pyrex vessels were employed.) The methanol was removed, petroleum ether (20 ml) was added, the solution filtered, and concentrated. Gas–liquid chromatographic analysis at 85% conversion of starting material indicated the two aldehyde products were present in a ratio of 7:1 (**2**:**7**); (minor components ~4%, possibly oxetanes have not been examined). The products were purified by t.l.c. on silica gel (10% ether–hexane). Alternatively samples of **2** were collected from the gas chromatograph. The major component *cis*-1-formyl-2,2-dimethyl-3-isopropenylcyclobutane (**2**) had the following spectral properties; i.r. 2800 (CHO), 2705 (CHO), 1720 (C=O), 1640 (C=C) cm^{-1}; p.m.r. δ 0.87 (3H, s, CH_3), 1.36 (3H, s, CH_3), 1.67 (3H, br s, C=C—CH_3), 4.71 (1H, br s, $w_{\frac{1}{2}}$ = 4 Hz, C=C—H), 4.90 (1H, br s, $w_{\frac{1}{2}}$ = 6 Hz, C=C—H), 9.75 (1H, d, J = 1.7 Hz, CHO) p.p.m.

Aldehyde **2** was further characterized as its semicarbazone derivative prepared according to the method of Fieser (46), crystallized from MeOH–H_2O, m.p. 176–178°.

Anal. Calcd. for $C_{11}H_{19}N_3O$: C, 63.13; H, 9.15; N, 20.08. Found: C, 63.08; H, 9.04; N, 20.25.

The minor component 3-(2′,2′-dimethylcyclobutane-3′-enyl)butanal (**7**) had the following spectral properties; i.r. 2810 sh (CHO) 2710 (CHO), 1730 (C=O), 1640 (C=C) cm^{-1}; p.m.r. δ 0.97 (3H, d, J = 6 Hz, CH_3—CH), 1.18 (6H, s, CH_3, CH_3) 6.09 (2H, m, J = 3 Hz, CH=CH), 9.78 (1H, t, J = 2 Hz, CHO) p.p.m.

Aldehyde **7** was further characterized as its semicarbazone derivative prepared according to the method of Fieser (46), crystallized from MeOH–H_2O, m.p. 116–118°.

Anal. Calcd. for $C_{11}H_{19}N_3O$: C, 63.13; H, 9.15; N, 20.08. Found: C, 62.92; H, 8.91; N, 20.42.

trans-Verbanone (10)

Irradiation was conducted as described above for *cis*-verbanone. At 75% conversion of starting material the aldehyde ratio was 1:2 (**2**:**7**).

Nopinone (9)

Nopinone (0.450 g, 3.26 mmol) in dry methanol (40 ml, distilled from magnesium) to which sodium bicarbonate (~35 mg) had been added was flushed with nitrogen, stoppered, and irradiated in a quartz tube for 2–3 h. Work-up as above gave an oil which contained the two aldehydes **11** and **12** in a 4:1 ratio, established by integration of the methyl signals in the p.m.r. spectrum. The major isomer *cis*-1-formyl-2,2-dimethyl-3-vinylcyclobutane (**11**) was purified by preparative g.l.c.; i.r. 2810sh (CHO), 2700 (CHO) 1720 (C=O), 1635 (C=C) cm^{-1}; δ 0.94 (3H, s, CH_3), 1.29 (3H, s, CH_3), 4.91 (1H, d of m, J = 6, ~2.5 Hz, C=CH), 5.04 (1H, s, C=CH), 5.5–5.9 (1H, m, CH=C), 9.74 (1H, d, J = 2 Hz, CHO) p.p.m.

A sample enriched in the minor isomer 3-(2′,2′-dimethylcyclobut-3′-enyl)propanal (**12**) was prepared by t.l.c. on silica, (petroleum ether followed by 5% ether–hexane); i.r. 2810sh (CHO), 2700 (CHO), 1720 (C=O), 1635 (C=C) cm^{-1}; p.m.r. δ 1.10 (3H, s, CH_3), 1.17 (3H, s, CH_3), 6.10 (2H, m, CH=CH), 9.78 (1H, d, J = 2 Hz, CHO) p.p.m.

In some runs a small quantity of another aldehydic component 4-isopropenyl-5-hexenal (**13**) derived from photolysis of **11** was detected and isolated by g.l.c.; i.r. 2810 (CHO), 2715, (CHO), 1725 (C=O) cm^{-1}; p.m.r. δ 1.65 (3H, br s, C=CCH_3), 4.73 (2H, br s, C=CH_2), 5.10 (2H, br s, C=CH_2) 5.4–6.1 (1H, m, CH=C), 9.72 (1H, t, J = 1.5, CHO) p.p.m.

4,4,6,6-Tetramethylbicyclo[3.1.1]heptan-2-one (14)

A sample of the tetramethylketone **14** (0.030 g, 1.81 mmol) in dry methanol (20 ml, distilled from magnesium) to which sodium bicarbonate (~18 mg) had been added was flushed with nitrogen, stoppered, and irradiated in a quartz tube for 20–25 h. The methanol was removed, petroleum ether – diethyl ether (2:1) (30 ml) was added, the solution filtered, and concentrated. Gas–liquid chromatographic analysis indicated 65% of the starting material had been consumed and two new major components were present in a ratio of 1.5:1 (**16**:**18**). (The amount of **18** present decreased as photolysis time increased.) The major component **16** was identified as methyl 3-methyl-3-(2′,2′-dimethylcyclobutyl)butanoate and was purified by t.l.c. on silica gel (5% ether–hexane) or collected from the gas chromatograph; i.r. 2820(OCH_3) 1733 (C=O) cm^{-1}; p.m.r. δ 1.00 (6H, s, CH_3, CH_3), 1.11 (3H, s, CH_3), 1.17 (3H, s, CH_3), 2.17 (2H, s, CH_2CO), 3.60 (3H, s, OCH_3) p.p.m.

The second component 3-methyl-3-(2′,2′-dimethylcyclobut-3′-enyl)cyclobutan-1-ol (**18**) was purified by t.l.c. on silica gel (5% ether–hexane); i.r. 3585 (OH), 3450–3150 (OH), 1625 (C=C) cm^{-1}; p.m.r. δ 1.03 (3H, s, CH_3), 1.13 (6H, s, CH_3, CH_3), 3.6 (1H, br s, OH), 4.12 (1H, m, J ~ 8.5 Hz, CHOH), 6.23 (2H, 2d, J = 3 Hz, CH=CH) p.p.m.

For personal use only.

*cis-Pinononic Acid (cis-3-Acetyl-2,2-dimethylcyclobutane Carboxylic Acid (**6**)*

*From Verbenone (**5**)*

A sample of verbenone (1.5 g 0.01 mol) in dichloromethane (25 ml) was cooled to ~ −70° in a solid carbon dioxide – acetone bath and a stream of oxygen containing ~7% ozone passed through the solution until it retained a permanent blue color. A solution of 30% hydrogen peroxide (5 ml) was added to the cold solution, it was warmed to room temperature, and the mixture stirred vigorously for 12 h. Water (50 ml) was added, the aqueous solution extracted with dichloromethane, the dichloromethane extracts combined, dried, and concentrated. Carbon tetrachloride was added to the remaining solution from which the acid crystallized with scratching on cooling, 1.1 g (64%), m.p. 129–130° (lit. (47) m.p. 129°); i.r. 3200–2800 (CO_2H) 1760 sh (C=O), 1700 (C=O) cm^{-1}; p.m.r. δ 0.88 (3H, s, CH_3), 1.35 (3H, s, CH_3), 2.03 (3H, s, CH_3CO), 2.87 (1H, t, J = 8.5 Hz, CHCO), 11.58 (1H, s, CO_2H) p.p.m.

*From cis-1-Formyl-2,2-dimethyl-3-isopropenylcyclobutane (**2**)*

The aldehyde **2** (0.230 g, 1.51 mmol) was dissolved in dichloromethane (10 ml), cooled to ~ −70° in a solid carbon dioxide – acetone bath and a stream of oxygen containing ~7% ozone passed through the solution until it retained a permanent blue color. The solution was warmed to room temperature and the solvent removed under reduced pressure without external heat behind a safety shield. Acetone (10 ml) was added followed by Jones' reagent (45), dropwise as a titration, to the stirred solution until the characteristic orange color of the reagent persisted for approximately 20 min. Water (25 ml) was then added and the aqueous layer extracted with ether. The ether extracts were washed with water, dried, filtered, and the solvent removed. The semisolid residue which remained was crystallized from $CHCl_3$–CCl_4 to give fine prisms 0.18 g (70%), m.p. 129–130° (lit. (47) m.p. 129°), mixture m.p. with sample prepared above 129–130°.

*3,7-Dimethyl-4,6-octadienal (**8**)*

A sample of the cyclobutene aldehyde **7** (0.060 g, 0.39 mol) was dissolved in hexane (0.1 ml), injected in small portions into the gas chromatograph (injector temperature 210°; column temperature 140°, detector temperature 250°) and the peak corresponding to the ring opened material collected to give the butadiene **8** as an oil 0.035 g (58%); i.r. 2805 (CHO), 2705 (CHO), 1725 (C=O), 1655 (C=C) cm^{-1}; p.m.r. δ 1.11 (3H, d, J = 6.5 Hz, CH_3CH) 1.73 (6H, s, CH_3, CH_3), 9.72 (1H, t, J = 2 Hz, CHO), vinyl signals 100 MHz, 5.40 (1H, d of d, J = 6.5, 15 Hz), 5.70 (1 H, d of br s, J = 10.5 Hz), 6.21 (1H, d of d, J = 10.5, 15 Hz) p.p.m.

The butadiene aldehyde **8** was further characterized as its semicarbazone derivative m.p. 91–92° prepared according to the method of Fieser (46).

Anal. Calcd. for $C_{11}H_{19}NO_3$: C, 63.13; H, 9.15; N, 20.08. Found: C, 63.42; H, 9.03; N, 20.36.

*Nopinone (6,6-Dimethylbicyclo[3.1.1]heptan-2-one) (**9**)*

A sample of β-pinene (60g, 0.44 mol, Aldrich) was treated with ozone according to the procedure of Meinwald and Gassman (48) to give nopinone 35 g (57%), b.p. 96–97°/18 mm (lit. (48) b.p. 83–86°/12 mm); i.r. 1715 (C=O) cm^{-1}; u.v. (CH_3OH) 275 nm (ε 33); p.m.r. δ 0.85 (3H, s, CH_3), 1.35 (3H, s, CH_3) p.p.m.

*trans-Verbenyl Acetate (4,6,6-Trimethyl-2-acetoxybicyclo[3.1.1]heptan-3-one (**33**)*

trans-Verbenyl acetate was prepared by rearrangement of the product from lead tetraacetate oxidation of α-pinene according to the method of Whitham (49). The sample had b.p. 105–106°/12 mm (lit. (50) b.p. 97–98°/9 mm).

Reduction

(*a*) The acetate (1 g) in glacial acetic acid (20 ml) was stirred in a hydrogen atmosphere with 5% Pd/C, 50% water wet (0.30 g) until a molar quantity of hydrogen was utilized. The solution was filtered, concentrated, and stirred with alcoholic KOH for 1 h, water (100 ml) was added and the aqueous solution extracted with ether. The ether extracts were concentrated and oxidized with Jones' reagent to give a 2:1 mixture of *cis*:*trans* verbanone as determined by g.l.c. analysis.

(*b*) *trans*-Verbenol (0.10 g) (prepared by alkaline hydrolysis of the acetate) in *tert*-butyl alcohol (15 ml) was hydrogenated using a 5% Pd/C (0.050 g) catalyst. Filtration, removal of the *tert*-butyl alcohol and oxidation of the residual oil with Jones' reagent afforded a 3:1 mixture of *cis*:*trans* verbanone.

(*c*) Similar reduction of *trans*-verbenol using 50% aqueous methanol as the solvent gave a *cis*:*trans* ratio of 3:2.

*3-Bromonopinone (6,6-Dimethyl-3-bromobicyclo[3.1.1]heptan-2-one) (**29**)*

Bromine (~0.25 g) was added dropwise to a stirred solution of nopinone (0.20 g, 1.45 mmol) in carbon tetrachloride (15 ml) containing sodium carbonate 0.20 g) and boron trifluoride etherate (3 drops) until the color of the last drop of bromine was not dispersed by stirring for a further 5 min. Water (50 ml) was added and the solution was extracted with chloroform, the combined extracts washed with water, dried, filtered, and evaporated. The oil so obtained 0.285 g (90%) contained the two isomeric bromoketones in a ~3:1 ratio (*trans*:*cis*) by g.l.c. analysis. For the trial dehydrobrominations the mixture was used as obtained but when dissolved in hexane (7 ml) the *trans*-isomer could be isolated by fractional crystallization, m.p. 67–68° (lit. (32) m.p. 69.5–70°), i.r. 1725 (C=O) cm^{-1}; u.v. (CH_3OH) 301 nm (ε 104); p.m.r. δ 0.84 (3H, s, CH_3), 1.39 (3H, s, CH_3), 4.27 (1H, d of d, J = 3.5, 7.5 Hz, CHBr) p.p.m.

A sample of the *cis*-isomer was collected from the gas chromatograph, m.p. 109–110° (lit. (32) m.p. 109.5–110.5°); i.r. 1728 (C=O) cm^{-1}; u.v. (CH_3OH) 282 nm (ε 100); p.m.r. δ 0.87 (3H, s, CH_3), 1.39 (3H, s, CH_3), 4.68 (1H, d of d, J = 8, 10 Hz, CHBr) p.p.m.

Dehydrobrominations were carried out under standard literature conditions as indicated in Table 3.

*cis-Nopinol (cis-6,6-Dimethylbicyclo[3.1.1]heptan-2-ol) (**31**)*

Nopinone (0.675 g, 4.89 mmol) in benzene (10 ml) was added to 'Red-al' (2 ml) and the solution refluxed for 3 h. Moist benzene was added dropwise followed by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

dropwise addition of water and then careful addition of 10% aqueous HCl until the complex just dissolved. This solution was extracted with ether, dried and filtered to give a solid, m.p. 90–92°, upon removal of solvent. Gas–liquid chromatographic analysis indicated a single component. Recrystallization from methanol–water afforded the alcohol 0.60 g (88%) as fine needles, m.p. 100–101° (lit. (42) m.p. 101.5–102°); i.r. 3590 (OH), 3300–3460 (OH) cm^{-1}; p.m.r. δ 1.07 (3H, s, CH_3), 1.22 (3H, s, CH_3), 4.18 (1H, m, CHOH) p.p.m.

Apoverbenone (6,6-Dimethylbicyclo[3.1.1]hept-3-en-2-one) (30)

Dehydration of Nopinone

A sample of nopinone (1.38 g 0.01 mol) in dioxane (2 ml) was added to dioxane (80 ml) and the solution refluxed under nitrogen. Selenium dioxide (1.32 g, 0.012 mol sublimed from concentrated nitric acid) was added and reflux continued for 6.5 h. The reaction mixture was cooled at room temperature, a solution of 20% ether – petroleum ether (50 ml) added, and the mixture filtered. The solvent was removed and the product purified by distillation on a spinning band column, b.p. 60–62°/4 mm (lit. (33) b.p. 48.5–49°/1.9 mm) to give apoverbenone 0.55 g (40%).

Allylic Oxidation of Apopinene

The oxidation was conducted as described above for α-pinene. Apopinene (12 g, 0.098 mol) in dichloromethane (100 ml) was added dropwise to a dichloromethane solution containing the red oxidizing agent prepared by adding chromium trioxide (100 g, 1 mol) to a cold solution of dichloromethane (800 ml) containing pyridine (160 g, 2 mol). The reaction mixture was stirred for 48 h at room temperature and worked-up as above to give apoverbenone as an oil which was purified by distillation, b.p. 60–62°/4 mm (lit. (33) b.p. 48.5–49°/1.9 mm), 6.1 g (45%); i.r. 1690 (C=O) cm^{-1}; p.m.r. δ 1.02 (3H, s, CH_3), 1.51 (3H, s, CH_3), 5.85 (1H, d, J = 9 Hz, C=CH—C=O), 7.40 (1H, d of d, J = 9, 5.5 Hz, CH=C—C=O) p.p.m.

Apopinene (6,6-Dimethylbicyclo[3.1.1]hept-2-ene) (28)

cis-Nopinol (18 g, 0.128 mol) was dissolved in dry pyridine (100 ml) and cooled to 0° in an ice bath. To this solution was added with stirring $POCl_3$ (19.5 g, 0.128 mol) and stirring continued for 30 min. Gas–liquid chromatographic analysis indicated the presence of 75% olefin plus 23% of an unidentified component. A saturated solution of sodium carbonate was slowly added to the cold solution until it was basic and the aqueous solution was extracted with ether. The combined extracts were washed with water, a 10% aqueous solution of tartaric acid, dried, filtered, and the solution concentrated. Distillation of the residue at atmospheric pressure gave apopinene, b.p. 138–140°, 7.8 g (50%) (lit. (39) b.p. 140.5°); p.m.r. δ 0.87 (3H, s, CH_3), 1.23 (3H, s, CH_3), 5.48 (1H, d of m, J = 9 Hz, CH=C), 6.08 (1H, m, C=CH) p.p.m.

trans-Verbanone (trans-4,6,6-Trimethylbicyclo[3.1.1.]heptan-2-one (10)

Cuprous iodide (6.85 g, 0.036 mol) in anhydrous ether (100 ml), contained in a flask equipped with a condenser, serum cap, magnetic stirrer, and maintained under nitrogen, was cooled to −60° by means of a solid carbon dioxide – acetone bath and a molar-equiv. of methyl lithium in hexane (Alfa) added, causing a yellow precipitate to form. The temperature was then raised to 0° and a second equiv. of the methyl lithium solution added as a titration until the yellow precipitate just dissolved. The unsaturated ketone (2.5 g, 0.018 mol) was then added, the reaction stirred at 0° for 1 h and then quenched by the addition of a saturated aqueous solution of ammonium chloride. The product was isolated by extraction with ether, the extracts dried, and the *trans*-verbanone so obtained distilled on a spinning band column, b.p. 51–52°/4 mm (lit. (44) b.p., 104–105/20 mm) 2.3 g (83%). Gas-liquid chromatographic analysis did not reveal the presence of any *cis*-verbanone; i.r. 1712 cm^{-1}; u.v. (CH_3OH) 278 sh nm (ε 41); p.m.r. δ 0.81 (3H, s), 1.05 (3H, d, J = 6.5 Hz), 1.32 (3H, s) p.p.m.

4,4,6,6-Tetramethylbicyclo[3.1.1]heptan-2-one (14)

The procedure utilized was the same as outlined for the preparation of *trans*-verbanone above. A sample of verbenone (5 g, 0.33 mol) was added to 2 molar-equiv. of preformed dimethyl copper lithium at 0° and the reaction stirred at 0° for 1 h. The reaction was quenched by the dropwise addition of a saturated aqueous solution of ammonium chloride, the ether layer separated, the aqueous solution extracted with ether, and the combined extracts dried. Distillation of the product afforded the tetramethyl ketone, b.p. 60–62°/0.5 mm (lit. (36) b.p. 52–56°/0.05), 4.2 g (82%); i.r. 1715 (C=O) cm^{-1}; u.v. (CH_3OH) 278 sh nm (ε 40); δ 0.99 (3H, s, CH_3), 1.06 (3H, s, CH_3), 1.16 (3H, s, CH_3), 1.34 (3H, s, CH_3) p.p.m.

We are grateful to Memorial University of Newfoundland and the National Research Council of Canada for financial support of this research and to Professor P. Yates for his encouragement.

Dibenzo[*a*,*e*]fluoranthene is treated by osmium tetroxide, the nature, structure, and configuration of the compound obtained (a *trans* dihydro diol) are defined taking into account the chemical, theoretical, and physicochemical arguments.

P. JACQUIGNON, O. PERIN-ROUSSEL, F. PERIN, O. CHALVET, J. M. LHOSTE, A. MATHIEU, B. SAPERAS, P. VIALLET et F. ZAJDELA. Can. J. Chem. **53**, 1670 (1975).

On traite le dibenzo[*a*,*e*]fluoranthène par le tétroxyde d'osmium; on définit la nature, la structure et la configuration du composé obtenu (un dihydro diol *trans*) en tenant compte d'arguments chimiques, théoriques et physicochimiques. [Traduit par le journal]

Recently we presented a preliminary note (1) on the properties of dibenzo[*a*,l]pyrene (**1**) and dibenzo[*a*,*e*]fluoranthene (**2**). The fact that the hydrocarbon **2** is strongly cancerogenic has been confirmed by recent experiments (2) achieved with a product whose structure has no ambiguity.

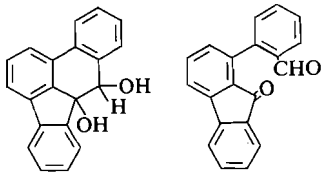
We must note that contrary to **1** this molecule does not seem to possess a geometric region corresponding to the definition of the "K zone" following the terminology of Pullman and Pullman (3). Consequently, it was interesting to submit it to the action of osmium tetroxide in order to determine the presence of a bond with a marked ethylenic character of the K zone type (4).

The first observation that we have made relates to the slowness of the reaction between **2** and osmic anhydride. In fact, contrary to the majority of the cases described in the literature for the series of benzo[*a*]anthracene (5) the time of contact to obtain an appreciable quantity of the complex had to be extended to 40 days. (Note: the action on the lower homolog **3** is not easier since in this case, the reaction must be continued for several months.) On the other hand, the oxidation of the isomer (**4**), or naphto[2,1-*b*]fluoranthene, which has been studied equally from the theoretical and spectroscopic points of view, occurs in a very short period of time.

These operations were carried out using the method of Criegee *et al.* (6) modified by Cook and Schoental (5). After dissociation of the complex, treatment, and chromatography, we have isolated a compound which is proved, as we expected, to be a dihydrodiol. This is confirmed by the mass spectrum, the microanalysis, and the infrared spectrum. For the position of the reactive bond, a chemical proof as well as the examination of the n.m.r. spectra allowed us to conclude that the two OH groups were situated on the carbons 5 and 5*a* and from this fact, that the diol corresponds to formula **5**. Indeed, from the chemical point of view, the oxidation by lead tetraacetate (7) breaking the 5–5*a* bond, leads to (formyl-2-phenyl)benzo[*c*]-fluorenone (**6**), the structure of which is defined without ambiguity by the resonance spectra of the protons, microanalysis, and fragmentation in mass spectrometry.

Confirmation of this structure was obtained by the complete analysis of the resonance spectrum of aromatic protons of both the diol and the parent hydrocarbon which confidently identifies all the protons of the molecules. Furthermore, the n.m.r. analysis provided information on the conformation of the diol obtained. Thus, it appears that the mechanism of reaction of osmium tetroxide with aromatic hydrocarbons parallels closely that established for reactions with aliphatic or cycloaliphatic compounds. Then, the diols formed by the action of osmium tetroxide should have a *cis* conformation (6) and only in the course of biochemical degradation could *trans* diols be formed directly from the hydrocarbons (8).

However, we have been somewhat surprised to be unable to obtain the cleavage of **5** in benzofluorenone (**6**) by sodium periodate, a specific reactive for the oxidation of *cis* glycols; and for this operation, to have to use lead tetraacetate with which the cleavage occurs very easily. Since the same phenomenon was observed for the oxidation into (formyl-2-phenyl)-1-fluorenone (**8**) of the diol **7** obtained from the lower homolog **3** of the hydrocarbon **2**, this observation suggested a *trans* conformation for these glycols.

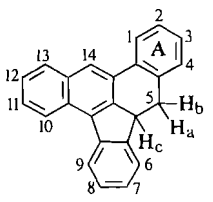


7 8

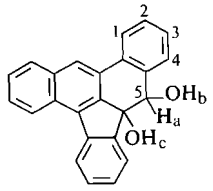
This assumption was further supported by a comparative examination of the spectra of diol **5** in the infrared taken in the solid state in KBr (bands OH, 3280 and 3370 cm^{-1}) and in solution in CS_2 (bands OH, 3550 and 3580 cm^{-1}). The shift of the characteristic bands, that we also find in the spectrum of diol **8** (KBr, 3300 cm^{-1}; CS_2, 3670 and 3550 cm^{-1}; $CHCl_3$, 3670 and 3550 cm^{-1}), does not appear consistent with the intramolecular hydrogen bond usually present in the *cis diols* (9). The variations observed suggest that the two OH groups are at a distance from each other, and thus situated on each side of the molecule midplane.

These indirect chemical and spectroscopic observations do not constitute unquestionable evidence of the *trans* type configuration. Direct evidence from the n.m.r. spectrum is not available since only one proton is directly bonded to the hydrocarbon framework and since no observable coupling between the hydroxylic protons is present.

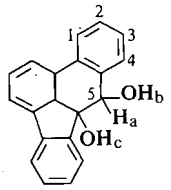
For this reason, dihydro-5,5*a*-dibenzo[*a*,*e*]-fluoranthene (**9**) was prepared by the method of Vingiello and Youssef (10) and its n.m.r.



9



5



7

spectrum was analyzed and compared with that of the two diols **5** and **7**.

The spectrum of the dihydrogenated compound **9** exhibits three aliphatic protons (designated as a, b, and c in the formula) characterized by their chemical shifts and their coupling constants (δ (p.p.m.): $H_a = 4.09$, $H_b = 2.67$, $H_c = 3.56$; $J_{ab} = 14.5$ Hz, $J_{bc} = 14.3$ Hz, $J_{ac} = 6$ Hz). Thus, the high field proton H_b should be geminal and strictly *trans* with respect to the two others. Indeed, a large vicinal coupling could arise only from a strict *cis* or *trans* configuration, but the former one with a zero dihedral angle is sterically impossible in a cyclohexane type structure. Finally, the smallest coupling corresponds to a vicinal *gauche* interaction.

The assignment of H_a and H_c is easily made by double resonance experiments because in the lower field one H_a exhibits a coupling of 0.8 Hz with the neighbor aromatic H_4 proton and even a smaller long distance coupling with H_2 (*ca.* 0.5 Hz). On the other hand, the H_c resonances are very little broadened, but still exhibit an unresolved coupling with the H_6 proton. On the contrary, the high field resonances of H_b exhibit only very little, if any, coupling with H_4.

In the diol compounds **5** and **7** the remaining proton appears at 4.925 and 4.920 p.p.m. respectively. The decoupling experiments confirmed that the corresponding lines had the same structure, due to long distance coupling to H_4 (0.9 Hz) and H_2 (0.5 Hz), as H_a. Consequently, H_b and H_c have been substituted by hydroxylic groups, in agreement with the assumed *trans* configuration.

The H_a proton exhibits a downfield shift of 0.83 p.p.m. upon diol substitution. This shift could appear small when compared to downfield shifts of about 2 p.p.m. of geminal protons in cyclohexanol, but it does not correspond to the simple effect of the geminal OH group. As a matter of fact, the H_a proton has a more marked equatorial character in the dihydrogenated compound **9** than in the diol, resulting in a lowfield shift due to steric repulsion with H_4. Indeed, the $J_{H_a-H_c}$ coupling, in compound **9**, is nearly a *gauche* coupling, but the $J_{H_a-OH_b}$ coupling (11.4 Hz) certainly corresponds to a more widely opened geminal angle. Thus, the H_a proton is probably displaced a little further from the molecular plane, resulting in less steric interaction with H_4.

Considering the importance of this conclusion of a *trans* diol configuration with respect to the assumed mechanism of the diol formation and to the problems of the metabolism and cancerogenic activity of these compounds, a systematic n.m.r. investigation of the configuration of the diols obtained by osmium tetroxide and *o*-quinone reduction from related hydrocarbons possessing a true "K zone", has been undertaken. These results, which will be reported in detail elsewhere (11), indicate that the behavior of dibenzofluoranthene (**2**) with respect to osmium tetroxide is not at all an exception due to some steric or electronic reasons but is a common rule. As a matter of fact, *trans* diols, which could often be assigned by n.m.r. much more easily because of high symmetry and vicinal HH couplings, have been found for any aromatic hydrocarbon treated by osmium tetroxide, in contrast with the diols obtained by reduction of quinone which correspond to a *trans* H structure. No direct evidence for *cis* diols has been yet found, contrary to the structure assumed until now. For example, the unsymmetrical diol **10** exhibits a vicinal coupling $J_{H_a-H_d}$ of 3.9 Hz corresponding to a *gauche* configuration, which could be attributed to a *cis* configuration, but could correspond as well to two equatorial protons as revealed by the detailed analysis of the n.m.r. spectrum of the whole molecule.

But, in spite of its importance, this question was not the purpose of this work and the

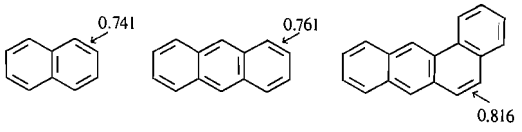
FIG. 1. Calculated bond orders for hydrocarbons **2** and **4**.

problem, presently under active investigation, will be reported and discussed later (11) from the point of view of the n.m.r. analysis as well as that of its chemical aspects with respect to previous assignments.

In regard to dibenzofluoranthene, chemical investigations, such as the possible diol conversion, are continuing in order to obtain a chemical proof of this structural assignment, more specific than the unsuccessful periodate oxidation. It is, however, worthwhile to mention that we were not able to obtain the corresponding epoxide until now.

In conjunction with these practical results, the prediction of the eventual reactive zone has been undertaken by the theoretical calculation of the bond indices of the hydrocarbons **2** and **4**.

We know that naphthalene (**11**), anthracene (**12**), and benzanthracene (**13**) react with osmium tetroxide uniquely on the bond possessing the strongest ethylenic character and therefore the greatest bond order, the reaction being faster the higher the bond order. Using the method of Pariser, Parr, and Pople (12) we obtain for these hydrocarbons the three values indicated in the formulas and which agree well with the experimental results.



11 12 13

For the hydrocarbons **2** and **4** and assuming all the bonds of equal length ($\beta = -2.39$ eV) an analogous calculation leads to the values indicated in Fig. 1.

The indices of 0.755 for **2** and 0.807 for **4** which are the highest for each molecule could thus appear satisfactory since they situate the attack at the position where it does occur.

Nevertheless, the chosen parameters for the two molecules do not allow us to obtain a correct description of the electronic absorption spectrum, the "theoretical" spectrum being displaced too much towards the visible.

Thus it appears necessary to make the preceding calculation more precise by taking the values of β (thus the bond length) different from the rest of the molecule for the bonds a and b of Fig. 1. This value of β has been deduced by interpolation of the values (Table 1) used by Mulliken and Parr (13) for butadiene and benzene.

TABLE 1. Values for β used for butadiene and benzene (13)

Bond	Length (Å)	β (eV)	Index p
C1—C2 butadiene	1.34	−2.92	0.977
C2—C3 butadiene	1.46	−1.68	0.212
Benzenic	1.39	−2.39	0.666

This leads to a mean value $\beta_a = \beta_b = -1.90$ eV and a bond index $p_a = p_b = 0.360$. With this new parameter we then obtain the values of *0.777* and *0.811* respectively for the bond orders C5—C5*a* of **2** and C5—C6 of **4** (Fig. 1) which thus preserve the strongest character of a double bond.

Likewise this same value of mean B obtains the best correlation between the theoretical and experimental spectra of the two hydrocarbons (Table 2).

The u.v. absorption spectra of the compounds **2** (Fig. 2) and **4** (Fig. 3) show strong analogies between them and yet are clearly distinguishable from that of benzanthracene (14) and from phenyl benzanthracene (Fig. 4). The latter presents all the characteristics of the tetraphenic series: band α forbidden, bands p, β, and β' permitted. On the other hand, the relative intensities of the various bands bring the hydrocarbons **2** and **4** nearer to the fluoranthenes for which the electronic spectra presents the

TABLE 2. Comparison of theoretical and experimental spectra for compounds **2** and **4**

Band	Spectrum	
	Theoretical	Experimental
Hydrocarbon **2**		
p	382.6	390
α	384	Band masked
β	320	330
Hydrocarbon **4**		
p	372.9	380
α	348.9	Band masked
β	325.5	325

following structure: band p permitted, band α forbidden, bands β and β′ permitted.

The absorption spectra confirm a convenient choice of parameters and consequently constitute a nonnegligible proof of the validity of theoretical calculation of the bond orders of dibenzo[*a*,*e*]fluoranthene. These calculations have been confirmed by the chemical results.

Thus the low relative value of 0.777 for the reactive bond order, possibly associated with the steric requirements, could explain the slowness of the attack by osmium tetroxide. This appears more correct especially as the same calculation applied to benzofluoranthene (**3**) leads to an index of 0.767, appreciably lower, for the bond involved in the reaction. Now we have effectively established that this hydrocarbon reacts even more slowly than its superior homolog.

When the biological results concerning the hydrocarbons **2** and **4**, their benzologs, and nitrogenous analogs are published, we propose to continue our investigations and to extend them to other cancerogenic hydrocarbons apparently lacking in the K zone that present the family of more condensed homologs of fluoranthene.

Experimental

The melting points were determined either in a capillary tube on a Buchi apparatus or on a metallic block heated electrically and with an electronic temperature detection (laboratory built apparatus).

The centesimal analyses were made by the Laboratoire de Microanalyse du C.N.R.S. at Gif-sur-Yvette.

The u.v. spectra in hexane have been read on a spectrophotometer Safas 1800 modified by the laboratory, and the i.r. spectra, on a KBr disk and in solution in CS_2, on a Perkin–Elmer 225 apparatus.

The n.m.r. spectra at 100 MHz, have been recorded at high resolution in a 10 mm diameter cell on a Varian XL 100 machine at 34 °C. The concentrations of solutions in $CDCl_3$ were from 1 to 3 × 10^{-2} *M*.

The protons were identified by selective decoupling, tickling, and INDOR. Using chloroform as internal reference, the values of chemical displacement (*d*) indicated in p.p.m. have been converted to TMS taking $d(CHCl_3) = 7.26$ p.p.m.

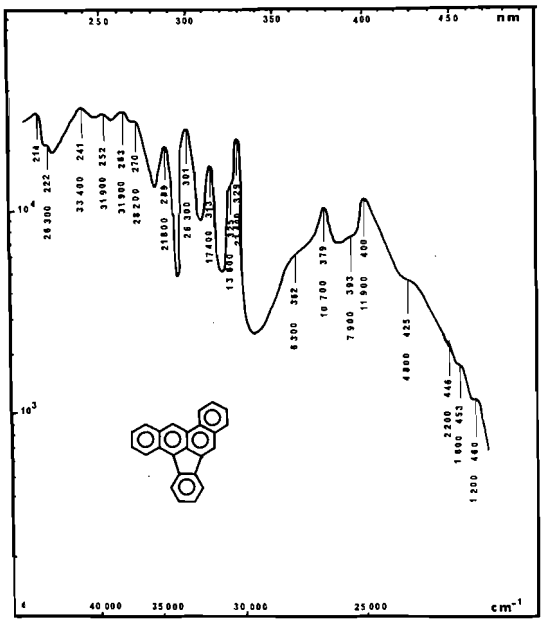

FIG. 2. Ultraviolet spectra of **2**.

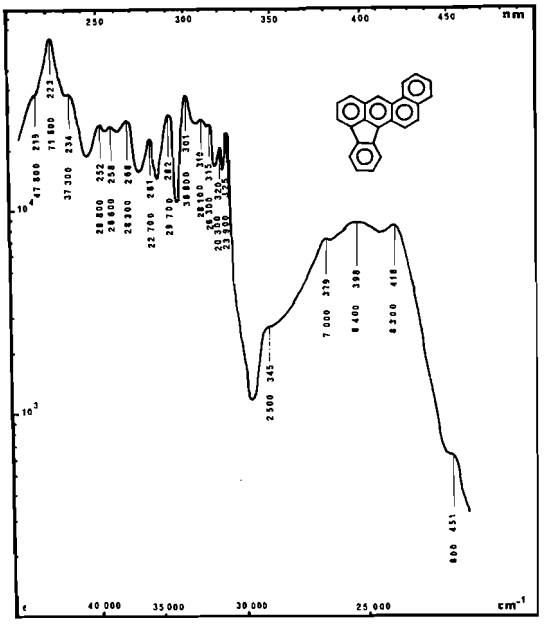

FIG. 3. Ultraviolet spectra of **4**.

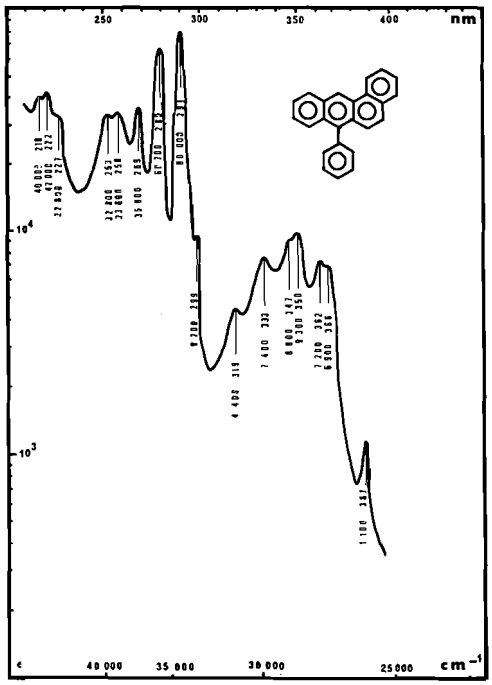

FIG. 4. Ultraviolet spectra of phenyl benzanthrene.

Oxidation by Osmium Tetroxide

The technique used for the three hydrocarbons **2**, **3**, and **4** is that designed by Cook and Schoental (5).

5,5a-Dihydroxy-5,5a-dihydrodibenzo[a,e]fluoranthene (5)

The solution of 1.2 g of dibenzofluoranthene (**2**), 1 g of osmium tetroxide, and 790 mg of pyridine in 120 ml of dry benzene is maintained at 30° for 3 to 4 weeks. Then the brown solution is decanted and the solid brown complex is dissolved in a minimum of methylene chloride. This solution is agitated and treated with an equivalent volume of an aqueous solution of potassium hydroxide (2%) and mannitol (10%). The operation is repeated several times until the aqueous phase is colorless. The organic phase is washed with water, dried with Na_2SO_4, and the solvent is evaporated under vacuum. The recrystallization in benzene of the solid obtained gives 540 mg of fine colorless needles, m.p. (inst.) 224–225° (slow decomposition from 195°); n.m.r.: δ p.p.m.: H_a = 4.925, H_b = 2.95, H_c = 2.23, H_1 = 8.21, H_2 and H_3 = 7.425 to 7.465, H_4 = 7.90, H_6, H_9, and H_{13} = 7.92 to 8.01, H_7 and H_8 = 7.425 to 7.465, H_{10} = 8.56, H_{11} and H_{12} = 7.575, H_{14} = 8.04; $J_{H_a-H_b}$ (H, OH) = 11.4 Hz; $J_{H_a-H_c} \simeq 0.5$ Hz, $J_{H_b-H_c} \simeq 0$.

Anal. Calcd. for $C_{24}H_{16}O_2$ (mol. wt. 336); C, 85.70; H, 4.80; O, 9.51. Found (336, mass spectrum): C, 84.55; H, 4.85; O, 9.21.

The treatment of the reactive benzene solution with mannitol and potassium hydroxide permits the recovery of 460 mg of the initial hydrocarbon.

A second test using double the quantity of osmium tetroxide under the same conditions yielded 730 mg of recrystallized dihydrodiol. The hydrocarbon–dihydrodiol mixture from the treatment of the mother liquors can be separated on an alumina column eluted with benzene for the hydrocarbon and then with chloroform for the diol.

5,5a-Dihydroxy-5,5a-dihydrobenzo[b]fluoranthene (7)

The above technique, with an equivalent of osmium tetroxide, starting with 500 mg of benzo[*b*]fluoranthene (**3**) and after a time of contact of 3 months, leads to the recovery of 250 mg of hydrocarbon and of 130 mg of dihydrodiol recrystallized in benzene into brilliant, colorless needles, m.p. (inst.) 242–243° (decomposition from 215°). n.m.r.: δ p.p.m.: H_a = 4.92, H_b = 2.90, H_c = 2.165; $J_{H_a-H_b}$ = 11.4 Hz, $J_{H_a-H_c}$ = 0.8 Hz, $J_{H_b-H_c} \simeq 0$. Very complex spectrum of aromatic protons, H_1 = 7.92, H_2, H_3, H_7, and $H_8 \simeq 7.42$, H_4 = 7.69, H_6 and H_9 = 7.72 and 7.84, H_{10}, H_{11}, and $H_{12} \simeq 7.52$.

Anal. Calcd. for $C_{20}H_{14}O_2$ (mol. wt. 286): C, 83.89; H, 4.93. Found: C, 83.59; H, 4.84.

5,6-Dihydroxy-5,6-dihydronaphtho[2,1-a]fluoranthene (10)

With the naphtho[2,1-*a*]fluoranthene (**4**) and an equimolar quantity of osmic anhydride, the reaction is completed after 48 h. The hydrocarbon (310 mg) gave 210 mg of fine colorless needles of diol (**10**) after recrystallization in benzene, m.p. (inst.) 194–195° (decomposition from 180°); n.m.r.: only the glycolic part of the spectrum has been analyzed; δ p.p.m.: H_a (H_5) = 5.02, H_b (OH_5) = 2.82, H_c (OH_6) = 1.98, H_d (H_6) = 5.77; $J_{H_a-H_b}$ = 10.3 Hz, $J_{H_c-H_d}$ = 7.0 Hz, $J_{H_a-H_d}$ = 3.9 Hz.

Anal. Calcd. for $C_{24}H_{16}O_2$ (mol. wt. 336): C, 85.70; H, 4.80. Found: C, 84.23; H, 4.96.

(Formyl-2-phenyl)-6-benzo[c]fluorenone (6)

All the attempts to produce oxidative cleavage of the diol **5** by metaperiodate by the described methods (15, 16) at different conditions of temperature and p*H*, have led only to the recovery of the initial product.

On the other hand, oxidation by lead tetraacetate using the technique of Boyland and Wolf (7) occurs very easily. The mixture of 350 mg of diol **5** and 1 g of lead tetraacetate in 100 ml of benzene is agitated at room temperature. After 3 h the chromatography of a sample on a thin layer of silica shows the disappearance of the initial product and the presence of a single compound (orange spot). The benzene solution is then filtered, washed successively with 1 *N* hydrochloric acid, with an aqueous solution of Na_2CO_3, then with water. After drying on Na_2SO_4 the solvent is evaporated under vacuum. The reddish residue is chromatographed on a silica column. The elution of a dark red ring by benzene, after evaporation of the solvent, gives fluorenone (**6**) the recrystallization of which in ethanol produces 290 mg of orange prismatic needles, m.p. 217–218°. Mass spectrum: molecular peak at 334, important peak at 305 by loss of —CHO; n.m.r. (The protons are numbered keeping the numbering of the diol or the hydrocarbon.): H_5(CHO) = 9.92 (coupling 0.7 Hz characteristic of the *ortho* substituted benzaldehydes), H_1, H_2, H_3, H_4 (phenyl) = 7.51 to 7.66, H_6 and H_9 = 8.075 and 8.12, H_7 and H_8 = 7.38, H_{10} = 8.61, H_{11} and H_{12} = 7.69, H_{13} = 7.895, H_{14} = 7.63.

Anal. Calcd. for $C_{24}H_{14}O_2$ (mol. wt. 334): C, 86.21; H, 4.23; O, 9.57. Found: C, 86.52; H, 4.50; O, 9.69.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

(Formyl-2-phenyl)-1-fluorenone (8)

Same technique as previously cited for diol **7**. Test with periodate negative. The product recrystallizes from the benzene – petroleum ether mixture in yellow crystals, m.p. 108–109°.

Anal. Calcd. for $C_{20}H_{12}O_2$ (mol. wt. 284): C, 84.48; H, 4.26. Found: C, 83.82; H, 4.39.

5,5a-Dihydrodibenzo(a–e)fluoranthene (9)

This hydrocarbon was prepared following the method of Vingiello and Youssef (11) with a view to its study in n.m.r. δ p.p.m.: $H_a = 4.09$, $H_b = 2.67$, $H_c = 3.56$; $J_{H_a-H_b} = 14.5$ Hz, $J_{H_a-H_c} = 6$ Hz, $J_{H_b-H_c} = 14.3$ Hz. $H_1 = 8.385$, H_2 and $H_3 = 7.40$ to 7.46, $H_4 = 7.742$, H_6, H_9, and $H_{13} = 8.04$ to 8.08, $H_{10} = 8.68$, H_{11} and $H_{12} = 7.58$, $H_{14} = 8.10$.

Reçu le 14 août 1974

ROBERT FAURE, JEAN-RICHARD LLINAS, EMILE-JEAN VINCENT et MICHEL RAJZMANN. Can. J. Chem. **53**, 1677 (1975).

Dans le cadre d'une étude générale par r.m.n. d'hétérocycles pentagonaux à deux hétéroatomes, nous avons déterminé en résonance du ^{13}C les déplacements chimiques, les couplages vicinaux $^1J_{^{13}C-H}$ et les couplages à longue distance d'une série d'isothiazoles diversement substitués. A cette occasion nous avons pu comparer les effets de divers substituants à l'effet du groupe d'hétéroatomes, et montrer l'influence prépondérante de sa dissymétrie sur la grandeur des paramètres observés. De plus la comparaison avec les résultats de calculs théoriques fondés sur le modèle CNDO a montré des insuffisances qui justifient la recherche d'une représentation mieux adaptée de l'atome de soufre par introduction des orbitales d; étude qui entre dans la paramétrisation en CNDO, des éléments de la troisième ligne que nous poursuivons par ailleurs.

ROBERT FAURE, JEAN-RICHARD LLINAS, EMILE-JEAN VINCENT, and MICHEL RAJZMANN. Can. J. Chem. **53**, 1677 (1975).

During a general n.m.r. study of five-membered heterocycles with two hetero-atoms, we measured the ^{13}C chemical shifts, the vicinal couplings $^1J_{^{13}C-H}$ and the long range couplings for a series of variously substituted isothiazoles. At that time we were able to compare the effects of the various substituents to the effect of the group of hetero-atoms and to demonstrate the predominant influence of dissymmetry of the latter on the values of the observed parameters. Moreover, a comparison with theoretical results based on a CNDO model showed deficiencies which justify the search for a representation better adapted, by the introduction of d orbitals, to the sulfur atom. Studies of CNDO parametrization for third row elements are being undertaken by other means. [Journal translation]

Introduction

Dans le cadre de l'étude des hétérocycles pentagonaux à caractère aromatique, nous avons entrepris l'analyse des spectres du carbone-13 de l'isothiazole **1** et de quelques uns de ses dérivés monosubstitués. Les déplacements chimiques et les constantes de couplage $^nJ_{CH}$ des différents carbones du cycle ont pu être attribués sans ambiguité grâce à l'examen des dérivés monométhylés. L'effet des substituants sur les déplacements chimiques a fait l'objet de nombreux travaux (1–10), et dans la série isothiazolique les résultats obtenus confirment généralement ces diverses études. En ce qui concerne les couplages J_{CH} à longue distance, ces effets de substituants sont relativement faibles devant l'effet de dissymétrie dû au groupement hétéroatomique S—N. Les grandeurs observées en r.m.n. peuvent être interprétées en fonction des modèles de la chimie quantique: nous avons pour cela utilisé les résultats obtenus dans le cadre de l'approximation CNDO. Toutefois les corrélations observées ne relèvent encore que du domaine qualitatif.

1

Partie expérimentale

Les spectres du carbone-13 ont été enregistrés sur un spectromètre Varian NV-14 opérant à la fréquence de 15.087 MHz et équipé d'un système à transformée de Fourier. Les déplacements chimiques sont rapportés au signal du TMS choisi comme référence interne, et sont obtenus sur les spectres découplés par bruit, avec une erreur inférieure à 0.1 p.p.m. pour une largeur spectrale

de 3500 Hz (accumulation sur 8192 points). Les constantes de couplage sont mesurées sur les spectres non découplés, avec une erreur absolue de 0.5 Hz. Pour bénéficier du gain de sensibilité provenant de l'effet nucléaire Overhauser, le système de spins a été irradié durant l'intervalle de temps compris entre deux impulsions successives, selon la technique du 'gate decoupling' (11). Les spectres ont été enregistrés à la température de 28° à partir de produits commerciaux, sans purification ultérieure, en solution à 60% en volume dans l'acétone deuteriée, excepté pour le dérivé cyané qui a été étudié en solution saturée dans le même solvant. L'analyse des spectres non découplés, en haute résolution a été effectuée au premier ordre; les spectres du proton ayant été eux-mêmes interprétés au 1er ordre (15, 16).

Résultats

Les déplacements chimiques et les constantes de couplage relatifs aux composés étudiés sont rassemblés dans les tableaux 1 et 2. L'attribution des déplacements chimiques des trois carbones de l'isothiazole dont le spectre totalement découplé se présente sous forme de trois pics d'intensité à peu près égale[1], a été réalisée sans

[1]Une étude de la relaxation spin–réseau a montré que les T1 des trois carbones de l'isothiazole sont sensiblement identiques (12).

ambiguité par l'étude comparative des spectres des dérivés monométhylés. La perturbation apportée par un groupement méthyle se traduit par un déblindage du carbone substitué d'une quantité de l'ordre de 10 p.p.m., tout en n'influençant que très peu les déplacements chimiques des autres carbones du cycle (tableau 3). Cette attribution est confirmée par les deux observations suivantes: tout d'abord, le carbone en position α de l'atome d'azote résonne à champ plus faible que l'atome de carbone adjacent au soufre comme cela avait déjà été observé pour la molécule de thiazole (13); d'autre part, le carbone C_4 en position β des deux hétéroatomes est moins déblindé que les précédents, et le couplage $^1J_{C_4H_4}$ associé, toujours inférieur aux couplages $^1J_{C_3H_3}$ et $^1J_{C_5H_5}$ (14).

Sur les spectres non découplés on a pu déterminer les couplages à longue distance $^2J_{CH}$ et $^3J_{CH}$ pour tous les carbones à l'exception de celui qui porte le substituant, pour lequel on observe un multiplet très mal résolu. L'attribution a été réalisée par analogie avec l'ensemble des dérivés monométhylés, la valeur de ces couplages étant très peu affectée par la substitution par un groupement méthyle (1). En ce qui concerne le formyl-5 et le cyano-4 isothiazole les déplacements chimiques sont attribués par analyse des spectres non découplés, plus simples que les précédents, et par comparaison des diverses constantes de couplage.

Discussion

Dans le tableau 3 se trouvent regroupées les variations de déplacements chimiques crées par les différentes substitutions opérées sur l'isothiazole. Les groupements méthyles provoquent sur le carbone en α un déblindage d'environ 10 p.p.m., une vériation de cet ordre ayant déjà été observée sur des hétérocycles pentagonaux analogues (2, 4, 5); cette perturbation est beaucoup plus importante (+15 p.p.m.) lorsque le substituant alcoyle est situé en α du soufre, comme dans le cas du méthyl-2 thiophène (10).

Les effets des substituants saturés sur les atomes de carbone en α sont très atténués sauf pour ceux qui sont également en α du soufre; dans ce cas, on observe pour le carbone 5 du méthyl-4 isothiazole une variation de déplacement chimique égale à −4.4 p.p.m.; ce phénomène est d'ailleurs comparable à ce que l'on observe pour les carbones occupant des positions identiques dans le méthyl-4 thiazole et le méthyl-3 thiophène, pour lesquels on a respectivement pour les carbones 5 et 2 des variations égales à −5.4 (13) et −4.3 p.p.m. (10). La présence du groupement cyano provoque en position 5 du cycle isothiazolique, un important effet de déblindage (+10.1 p.p.m.) que l'on n'observe pas pour des pyridines substituées par ce même groupement. L'ordre de grandeur des couplages $^nJ_{CH}$ ($n > 1$) est relativement élevé, ainsi qu'on a déjà pu le noter pour des cycles pentagonaux comportant un ou deux hétéroatomes, et particulièrement lorsqu'on passe des molécules de pyrrole ou de thiophène au cycle isothiazolique (4, 10).

A l'inverse des hétérocycles hexagonaux, les couplages $^2J_{CH}$ sont sensiblement supérieurs aux couplages $^3J_{CH}$ et, au sein de chacune de ces deux familles, la dissymétrie du cycle isothiazolique induit des variations très importantes contrairement aux cycles pentagonaux symétriques pour lesquels ces variations sont inexistantes: $^2J_{C_4H_3} \gg {}^2J_{C_4H_5}$ et $^3J_{C_3H_5} > {}^3J_{C_5H_3}$. On retrouve d'ailleurs un tel phénomène dans le cas de l'isoxazole, molécule dans laquelle le facteur de dissymétrie est le groupement O—N.

Les substitutions opérées sur le cycle isothiazolique par des groupements méthyles ont pour effet d'abaisser les valeurs des constantes de couplage J_{CH} et dans le cas particulier de la substitution en position 4 on a pu observer comme dans le cas de la méthyl-3 pyridine (6) que les couplages vicinaux à travers un carbone substitué par un méthyle étaient multipliés par un facteur de l'ordre de 0.9 par rapport aux valeurs déterminées sur le composé non perturbé.

*Valeurs moyennes.

Les substitutions, en position 4 et 5, par les groupements insaturés CN ou CHO, entrainent une augmentation des couplages $^1J_{CH}$ et une diminution sensible des couplages à longue distance.

Partie théorique

Les déplacements chimiques ont été calculés selon la méthode de Pople (17) et les constantes de couplage dans le cadre de la théorie des perturbations finies (18). Dans le cas des déplacements chimiques la fonction d'onde est déterminée dans l'approximation CNDO/S (19), dont l'un d'entre nous a montré qu'elle était le mieux adapté pour ce type de calcul (20). En ce qui concerne les constantes de couplage, faute de pouvoir utiliser, du fait de la présence de l'atome de soufre, la méthode INDO (21) nous avons mis en oeuvre la méthode CNDO/2 (22). A partir de cette fonction d'onde nous avons calculé le terme de contact de Fermi, nous limitant ainsi à l'évaluation des couplages entre atomes liés, car les couplages à longue distance font intervenir d'autres types d'interactions (23).

Les résultats sont montrés dans les tableaux 4 et 5 et la divergence évidente entre valeurs

expérimentales et valeurs théoriques est certainement due à une paramétrisation inadéquate de l'atome de soufre. La recherche d'une paramétrisation mieux adaptée doit être poursuivie par introduction des orbitales d, études que nous poursuivons par ailleurs.

Alkylation of 1-Methyl-2-piperidones[1]

PIERRE DESLONGCHAMPS, UKKEN O. CHERIYAN, AND DENNIS R. PATTERSON
Laboratoire de synthèse organique, Département de chimie, Université de Sherbrooke, Sherbrooke, Québec J1K 2R1
Received October 23, 1974

PIERRE DESLONGCHAMPS, UKKEN O. CHERIYAN, and DENNIS R. PATTERSON. Can. J. Chem. **53**, 1682 (1975).

The alkylation of 1-methyl- and 1,3-dimethyl-2-piperidone is reported in good yield.

PIERRE DESLONGCHAMPS, UKKEN O. CHERIYAN et DENNIS R. PATTERSON. Can. J. Chem. **53**, 1682 (1975).

L'alkylation de la méthyl-1 et de la diméthyl-1,3-pipéridone est rapportée avec un excellent rendement.

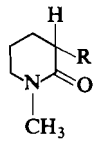
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

In the course of our investigation which led to the development of a new stereoelectronic theory for the hydrolysis of amides[1] it was necessary to prepare *N*-dialkylated imidate salts. Some of those salts can be easily produced from the appropriate 3-alkyl-1-methyl-2-piperidones. The direct alkylation of 1-methyl-2-piperidones was therefore considered.

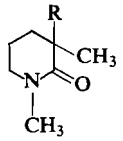
The α-alkylation of 1-methyl-2-pyrrolidone (3) and of *N*,*N*-dialkylamides (4) has been reported but the yields were moderate.[2] This is presumably due to the base used ($NaNH_2$) to produce the enolate salt of the amide function because when *n*-butyl lithium was used to generate the dilithioamide of secondary amide, high yield of α-alkylated secondary amides was obtained (6).

We would like to report the optimum experimental conditions that we have found for the alkylation reaction of *N*-methyl six-membered lactams.[3]

We have found that 1-methyl-2-piperidone (**1**) can be converted into **2** or **3** in high yield with the proper alkyl iodide. The lithium enolate of **1** was generated with lithium dimethylamide in benzene. A slight excess of the base and alkylating agent ensured complete alkylation. There were no detectable amounts of *O*-alkylated or bis-alkylated products. 1,3-Dimethyl-2-piperidone (**2**) could be further alkylated to give the bis-α-alkylated products **4** and **5** in excellent yield. Consequently, this method provides a convenient route to α-disubstituted-*N*-alkyl lactams.



1 R = H
2 R = CH_3
3 R = C_2H_5



4 R = CH_3
5 R = C_2H_5

We would like to point out that α-alkylation of an amide function has a great potential in organic synthesis. Generation of the lithium enolate with appropriate base seems easy. No side reactions occur presumably because the amide function does not react with its lithium enolate during its formation. Also, *O*-alkylation of the lithium enolate does not occur in normal conditions. The amide function is a versatile and fairly chemically stable functional group which is at the oxidation level of an acid. Still, it can be easily converted to the corresponding amine, acid, ester, and aldehyde function (10).

Experimental

The i.r. spectra were taken on a Perkin-Elmer 257 spectrophotometer; proton n.m.r. spectra were recorded on a Varian A-60 spectrometer. The chemical shifts are reported in δ-values relative to tetramethylsilane as internal standard. The vapor phase chromatographic (v.p.c.) analysis was done on a Varian aerograph model 90-P. Mass spectra were taken on a Hitachi-Perkin-Elmer RMU-6 mass spectrometer. Microanalyses were carried out by Mr. J. Tamas, Laboratoire de microanalyse, Université de Sherbrooke.

Reagents

The alkyl iodides were washed with aqueous sodium thiosulfate, dried over anhydrous calcium chloride, and distilled. *N*-Butyl lithium in hexane (2.2 *M*) supplied by Alpha Products was used in all experiments. Benzene was dried over sodium hydride and distilled. 1-Methyl-2-piperidone (Chemical Procurement Laboratories) was dried over molecular sieves (type 4A, Fisher Scientific) and distilled. Dimethylamine was used as a solution in benzene: a solution of the amine ($\simeq 1.2$ *M*) was prepared by bubbling the gas for 4 h through benzene and this solution was diluted with an equal amount of benzene and the concentration was determined by titration (11).

1,3-Dimethyl-2-piperidone (2)

A solution of dimethylamine in benzene (33 ml, 39.6 mmol) was added dropwise to a magnetically stirred cold (ice bath) solution of *n*-butyl lithium in hexane (15 ml, 33 mmol) under an atmosphere of argon. The white slushy precipitate formed was stirred (ice bath) for 0.5 h. Addition of 1-methyl-2-piperidone (**1**; 3.5 g, 31.5 mmol) to this mixture gave a pale yellow homogeneous solution. The solution was heated for 1 h at 50–60 °C under vacuum (15–20 mm) to remove excess dimethylamine. Methyl iodide (4.68 g, 33 mmol) in benzene (10 ml) was then added to the cold (ice bath) magnetically stirred reaction mixture. Stirring was continued for 2 h at room temperature. Water (10 ml) was then added and the benzene layer was separated. The aqueous phase was then extracted with dichloromethane. The combined extract was washed with a small quantity of water and dried over sodium sulfate. The solvent was removed by distillation and the resulting oil was filtered through a column of silica gel with dichloromethane to yield after removal of the solvent, a pale yellow liquid (3.75 g). Distillation gave 1,3-dimethyl-2-piperidone (**2**; 3.25 g, 83%) which was shown to be pure (> 98%) by v.p.c.; b.p. 92–94 °C/5 mm (lit. (12) b.p. 113–114 °C/18 mm); i.r.: ν_{max} ($CHCl_3$) 1625 cm^{-1}; n.m.r.: δ($CDCl_3$) 1.25 (3H, doublet, CH_3—CH), 1.52–2.2 (4H, multiplets), 2.3–2.6 (1H, multiplet), 2.98 (3H, singlet, N—CH_3), and 3.2–3.5 (2H, multiplets); m.s.: *m/e* 127 (M^+), 112 ($M^+ - CH_3$).

1-Methyl-3-ethyl-2-piperidone (3)

The lithium enolate was generated from 1-methyl-2-piperidone (**1**; 3.5 g, 31.5 mmol) in benzene by the method described above. Ethyl iodide (5.14 g, 33 mmol) in benzene (10 ml) was added dropwise. The stirring was continued for 8 h at room temperature. Work-up as described above gave 1-methyl-3-ethyl-2-piperidone (**3**; 3.7 g, 85%) which was shown to be pure (> 98%) by v.p.c.; b.p. 78–79 °C/1 mm (lit. (13) b.p. 87–90 °C/2 mm); i.r.: ν_{max} ($CHCl_3$) 1625 cm^{-1}; n.m.r.: δ($CDCl_3$) 0.96 (3H, triplet, $J = 6$ Hz, CH_2—CH_3), 1.2–2.5 (7H, multiplet), 2.98 (3H, singlet, N—CH_3), and 3.2–3.5 (2H, multiplet); m.s.: *m/e* 141 (M^+), 126 ($M^+ - CH_3$).

1,3,3-Trimethyl-2-piperidone (4)

1,3-Dimethyl-2-piperidone (**2**; 2.4 g, 18.2 mmol) was converted into its lithium enolate by lithium dimethylamide in benzene prepared from *n*-butyl lithium (9 ml, 19.8 mmol) and dimethylamine (20 ml, 24 mmol) solutions. Methyl iodide (2.85 g, 20 mmol) in benzene (10 ml) was added to the cold reaction mixture. Stirring was then continued for 15 h at room temperature. Work-up as described above gave 1,3,3-trimethyl-2-piperidone (**4**; 2.3 g, 86%) which was shown to be pure (> 98%) by v.p.c.; b.p. 72–74 °C/1 mm (lit. (12) b.p. 106–107 °C/18 mm); i.r.: ν_{max} ($CHCl_3$) 1620 cm^{-1}; n.m.r.: δ($CDCl_3$) 1.21 (6H, singlet, two CH_3), 1.7–2.0 (4H, multiplet), 3.00 (3H, singlet, N—CH_3), and 3.2–3.5 (2H, multiplet); m.s.: *m/e* 141 (M^+), 126 ($M^+ - CH_3$).

1,3-Dimethyl-3-ethyl-2-piperidone (5)

1,3-Dimethyl-2-piperidone (**2**; 2.47 g, 19.5 mmol) was converted into its lithium enolate by lithium dimethylamide in benzene prepared from *n*-butyl lithium (10 ml, 2.2 mmol) and dimethylamine (22 ml, 26.4 mmol) solutions. Ethyl iodide (3.5 g, 22 mmol) in benzene (10 ml) was added to the cold reaction mixture. Stirring was then continued for 24 h at room temperature. Work-up as described above gave 1,3-dimethyl-3-ethyl-2-piperidone (**5**; 2.38 g, 80%) which was shown to be pure (> 98%) by v.p.c.; b.p. 80–82 °C/20 mm; i.r.: ν_{max} ($CHCl_3$) 1620 cm^{-1}; n.m.r.: δ($CDCl_3$) 0.83 (3H, triplet, CH_2—CH_3), 1.18 (3H, singlet, C—CH_3), 1.4–2.0 (6H, multiplet), 2.98 (3H, singlet, N—CH_3), and 3.3–3.5 (2H, multiplet); m.s.: *m/e* 155 (M^+), 140 ($M^+ - CH_3$).

Polar Substituents in Pericyclic Reactions: Mechanistic Course of the $2\pi + 2\pi$ Photocycloaddition of Dimethyl 1,4-Dihydro-1,4-ethenonaphthalene-2,3-dicarboxylate

CHRISTOPHER OWEN BENDER AND DEE WINTON BROOKS

Department of Chemistry, University of Lethbridge, Lethbridge, Alberta T1K 3M4

Received November 7, 1974

CHRISTOPHER OWEN BENDER and DEE WINTON BROOKS. Can. J. Chem. **53**, 1684 (1975).

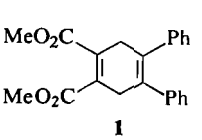
Deuterium labeling studies are consistent with the initial photochemical $2\pi + 2\pi$ closure of singlet excited dimethyl 1,4-dihydro-1,4-ethenonaphthalene-2,3-dicarboxylate (**4**) proceeding via bridging between the vinyl and vinyl diester moieties and not via the vinyl–benzo bridging mode favored by Grovenstein and by the Epiotis polar pericyclic theory. The possible involvement of the charge-transfer excited state of **4** in the reaction is discussed.

CHRISTOPHER OWEN BENDER et DEE WINTON BROOKS. Can. J. Chem. **53**, 1684 (1975).

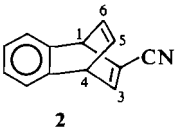
Des études de marquages au deuterium sont en accord avec une fermeture photochimique initiale $2\pi + 2\pi$ de l'état excité singulet du dihydro-1,4 éthéno-1,4 naphtalènedicarboxylate de diméthyle (**4**) se produisant par l'intermédiaire d'un pont entre les portion vinyle et vinyle diester et non pas par un intermédiaire du pont vinylbenzo favorisé par Grovenstein et aussi par la théorie péricyclique polaire d'Epiotis. On discute de l'implication possible d'un état de transfert de charge de **4** dans la réaction. [Traduit par le journal]

Introduction

Recent configuration-interaction calculations by Epiotis indicate that strongly polar substituents can in some cases reverse the usual Woodward–Hoffmann formulations for concerted pericyclic processes (1). In particular, Epiotis predicts that for polar $2\pi + 2\pi$ systems, photoadditions should occur in the s + a mode. An interesting situation pertains in the case of rigid polar molecules when the s + a mode of closure is precluded by geometry, and an illustrative case discussed by Epiotis is that of hexadiene **1**, which gives no intramolecular $2\pi + 2\pi$ photoaddition product (2).[1] In an attempt to test further the theory in a rigid system, we had examined (3) the photoformation of cyclooctatetraenes from 2-cyanobenzobarrelene (**2**), it being assumed that the initial step in the reaction involves a concerted $2\pi + 2\pi$ cycloaddition to give a quadricyclic intermediate (*e.g.*, see **5** and **7**, Scheme 1).



1



2

Of the three possible $2\pi + 2\pi$ modes of closure of **2** (between benzo–vinyl, vinyl–vinylcyano, or benzo–vinylcyano groups) the theory predicts that bonding to the polar vinylcyano bridge should be the least favored since steric prohibition prevents a concerted cyclization in the s + a mode. Nevertheless, the predicted benzo–vinyl cycloaddition, the preferred mode of closure in benzobarrelene itself (4), was not observed; only $2\pi + 2\pi$ cyclizations involving the vinylcyano bridge occurred, 65% to the vinyl and 35% to the benzo group.

A contentious point with regard to the study with **2** is that the single cyano group may not impart significant polar character to the barrelene, thus making it a poor test system.[2] To overcome this objection we have sought to examine a more potent polar species. Since the photoaddition of dimethyl maleate to cyclohexene gives the *trans*-cyclobutane **3**, a reaction cited by Epiotis as being a polar $2\pi + 2\pi$ process (1), we thought that the intramolecular photoadditions of 2,3-dicarbomethoxybenzobarrelene (**4**) would be an analogous and a pertinent polar system to investigate.

Interestingly, much of the photochemistry of **4** has been determined by Grovenstein *et al.* (5),

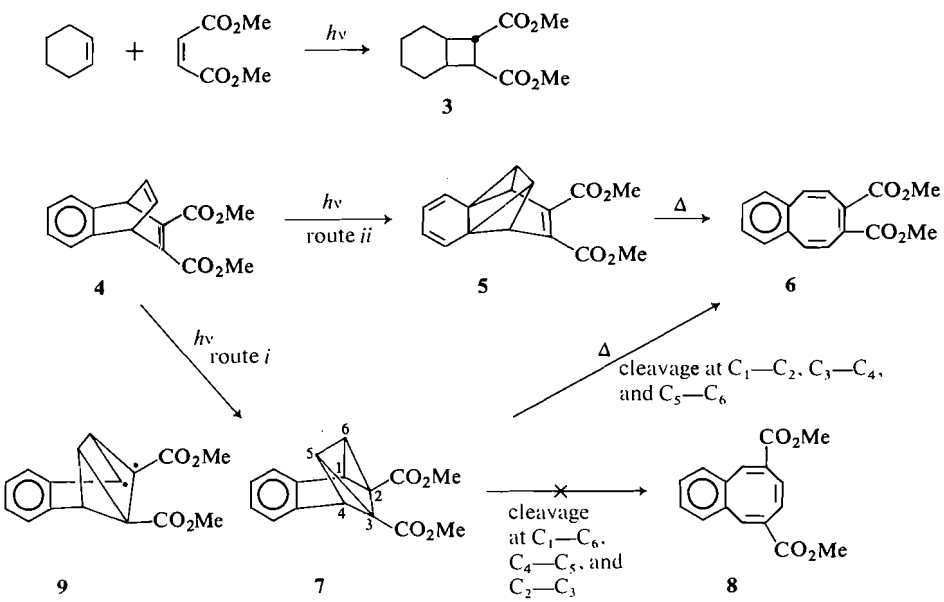

SCHEME I

who report that the direct irradiation of **4** yields 7,8-dicarbomethoxybenzocyclooctatetraene (**6**). However, the mechanism of formation of **6**, which could conceivably involve either of two initial $2\pi + 2\pi$ photoaddition pathways (route *i*, vinyl–vinyldiester bonding or route *ii*, benzo–vinyl bonding; see Scheme 1), was not elucidated, other than it being noted that route *ii* seemed to be more reasonable on the grounds that it would yield only one COT (**6**), whereas route *i* should give rise to two COT's (**6** and **8**). Route *ii* is also favored by the Epiotis polar theory.

We have now carried out deuterium labeling studies to determine the initial $2\pi + 2\pi$ bonding preference of barrelene **4**. Our results reveal that the vinyl–vinyldiester route (*i.e.*, route *i*) is solely utilized in the formation of COT **6**.

Results

To distinguish between the two possible $2\pi + 2\pi$ cycloaddition pathways which can lead to COT **6**, the mixture of deuterated barrelenes **10** and **11** was synthesized by cycloadding dimethylacetylene dicarboxylate to 2-deuterionaphthalene. It can be seen from inspection of Scheme 2 that although both routes *i* and *ii* can produce aromatically labeled COT (**17**), only route *i* can yield COT product **16** containing the label at C-6 whereas only route *ii* can yield COT product **18** containing the label at C-5.

The total deuterium content of the mixture of **10** and **11** was found to be 0.99 ± 0.08 but the relative amounts of **10** and **11** could not be ascertained directly from analysis of the n.m.r. spectrum of the mixture because of overlap of the barrelene vinyl and aromatic signals. The distribution was obtained, however, from inspection of the n.m.r. spectrum of the deuterated COT photoproducts (*vide infra*). The mixture of barrelenes **10** and **11** was irradiated directly in cyclohexane and in methanol solvent systems and runs at both low and high conversions were carried out to evaluate the possible isotope effects arising from the differing deuterium locations in the starting barrelene mixture. The resulting deuterated COT products were isolated by column chromatography and the deuterium distributions were analyzed by n.m.r. spectroscopy (see Table 1). The assignments of the protons in the undeuterated COT **6** follow from comparison of its spectrum with that of other benzo-COT's (see Table 2). The assignments were confirmed by examining the spectrum upon adding the lanthanide shift reagent tris(perfluorobutylpivaloylmethanato)europium, $Eu(fod)_3$. As shown in Fig. 1, the addition of increasing amounts of $Eu(fod)_3$ consistently moves the

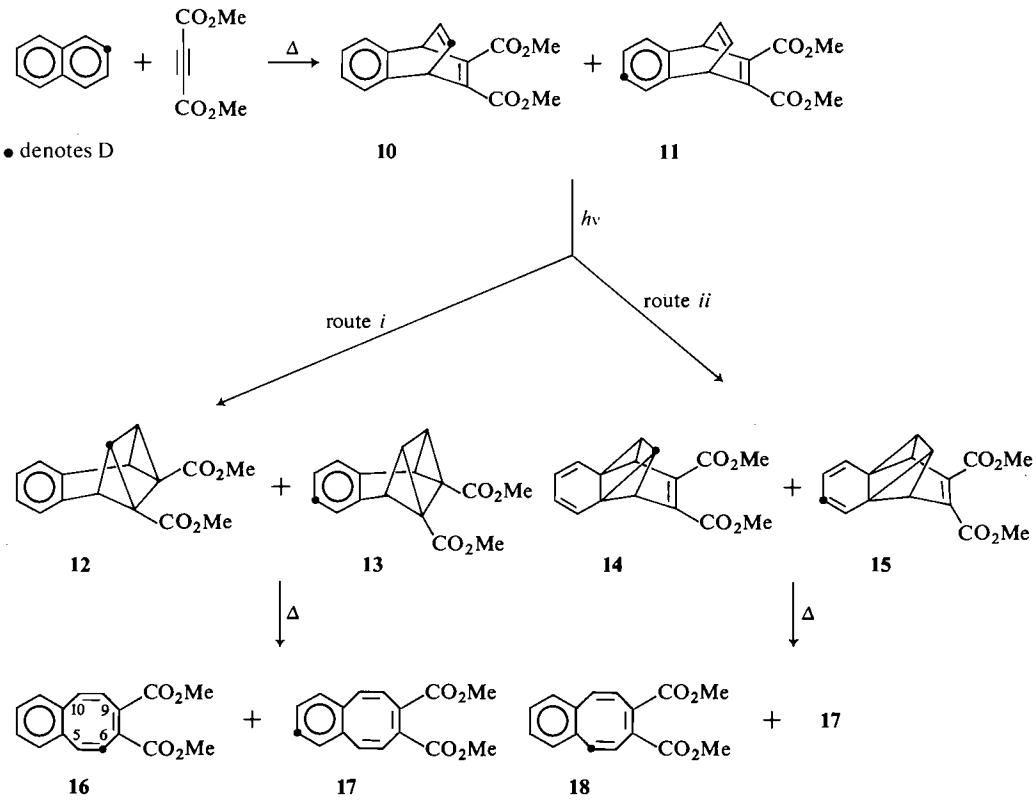

SCHEME 2

H-6(9) doublet further downfield than the H-5(10) doublet (at molar ratio 0.27 the two doublets converge to a singlet at τ 2.92), which accords with H-6(9) being closer than H-5(10) to the ester–lanthanide complexation centers.

In the case of the deuterated COT products, the n.m.r. spectra are essentially the same as that for **6**, except that there are now two types of signal for H-5. Besides the *doublet* centered at τ 3.34 (*A*B, J = 11.5 Hz) arising from coupling to H-6 (A*B*, J = 11.5 Hz) there is a *singlet* at τ 3.34 which results from the absence of coupling when C-6 is partially deuterated.

The quantum yields for the formation of COT **6** were also investigated to ascertain the relative efficiency of the reaction; in cyclohexane the appearance Φ is 0.16 ± 0.02 whereas in methanol it is 0.10 ± 0.01.

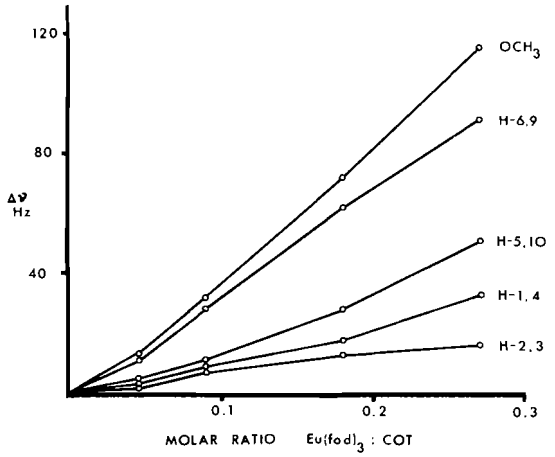

FIG. 1. Variation of chemical shift for the protons in COT **6** with increasing concentrations of the shift reagent $Eu(fod)_3$.

Discussion

It can be seen from Table 1 that irradiation of barrelene mixture **10** and **11** leads to COT product **16** containing the olefinic label uniquely at C-6 and thus the COT formation cannot proceed (within experimental error) via the benzo–vinyl bridging mechanism favored by Grovenstein and by the Epiotis polar theory. The observation that only **6** is formed from the proposed intermediate **7** can be attributed to the preferred rupture of the C_1—C_2 bond of **7**, since favorable stabilization from the carbomethoxy and benzo groups is afforded both radical centers in the ensuing species **9**. An alternative explanation is provided by the fact that in cyclopropanes electron withdrawing substituents strengthen the bond opposite, while weakening the bonds adjacent (6).

Also from Table 1, it can be seen that a comparison of the integrated area of the aromatic region with that of the well separated olefinic region of deuterated COT product provides a method of determining the relative amounts of **10** and **11** present in the original deuterated barrelene mixture. From each run, the two areas are of equal magnitude and it therefore seems reasonable to assume that the mixture is comprised of equal amounts of **10** and **11** and hence to conclude that no measurable isotope effect is observed either in the original preparation of the deuterated barrelenes, or in the subsequent photolysis of the mixture.

The reason for investigating the photolysis of barrelene mixture **10** and **11** in two solvent systems was to relate the photochemical studies of **2** and **4**, the former of which was studied in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

cyclohexane and the latter in methanol. Although the large increase in solvent polarity on going from cyclohexane to methanol does decrease the efficiency of the reaction by about 40%, the overall mechanism of formation of **6** appears to be unaffected (see Table 1). Thus COT formation from both **4** and vinylcyano-2,3-naphthobarrelene (7) occurs exclusively via initial $2\pi + 2\pi$ bonding between vinyl and polar vinyl groups, whereas COT formation from **2** occurs predominately via this route (3) and it is only in the cases of the unsubstituted benzobarrelene (4) and 1,2-naphthobarrelene (8) that initial aromatic–vinyl bridging has been observed. We therefore conclude that if the cyclization step is product controlling then the Epiotis polar theory seems unable to correctly predict the preferred modes of $2\pi + 2\pi$ photoclosure in polar barrelene systems.

With regard to the nature of the excited-state species involved in the formation of COT **6**, Grovenstein has shown that the acetone sensitized irradiation of **4** yields di-π-methane rearrangement product together with some unidentified material but COT **6** appears to be absent. The singlet excited state of **4** is therefore implicated in the COT formation. Interestingly, the u.v. spectrum of **4** shows a long wavelength band at 335 nm (ε 40) in cyclohexane (334 nm inflexion (ε 60) in methanol) and this may be due to a charge-transfer transition (*cf.* the long wavelength band of benzobarrelene at 277 nm (ε 710) in cyclohexane (4)). A similar red-shifted long wavelength band for 2,3-dicyanobenzobarrelene (313 nm (ε 760) in ethanol) has been attributed by Cookson and Dance to a charge-transfer transition (9). The effect of solvent polarity on the quantum efficiency of the formation of COT **6** is also in support of the reacting singlet excited state of **4** being the charge–transfer state. If we assume that the quantum yields measured here do in fact reflect the excited state reaction rates for the formation of **6**, then a minimum interpretation of the decrease in Φ on going to more polar solvent is that the activation energy for the rearrangement of excited **4** in methanol is increased relative to that in cyclohexane because in polar solvent the stabilization afforded the charge-transfer state of **4** is greater than that afforded the less polar (and more product-like) transition state leading to **6**. If the charge-transfer state of **4** is the reacting singlet excited-state species, then since the mechanism of formation of **6** proceeds via bonding between vinyl and vinyldiester groups, it is tempting to speculate that the charge-transfer arises from an intramolecular donation of an electron from the vinyl group to the vinyldiester acceptor. Recently, Bryce-Smith *et al.* (10) have pointed out that donor–acceptor properties of olefins are of critical importance in connection with their ability to undergo 1,2-photoadditions to benzene. Perhaps also, charge-transfer contributions are of similar importance in directing the initial mode of photochemical $2\pi + 2\pi$ bridging in barrelene systems.

Experimental

The n.m.r. spectra were recorded on a Varian HA-100 spectrometer. Cyclohexane solvent was prepared for photolyses by scrubbing with 10% of its volume of 30% fuming sulfuric acid, followed by washing with 10% aqueous sodium hydroxide, drying ($MgSO_4$), and finally distilling from calcium hydride. Methanol solvent was prepared for photolyses by refluxing with basic furfural, according to the method of Morton and Mark (11), followed by fractionation on a 6 ft column packed with 8 mm Raschig rings.

*Preparation of Deuterated Barrelene Mixture **10** and **11***

A solution of 10.0 g (0.0483 mol) of 2-bromonaphthalene in 50 ml of dry THF (CaH_2) was added dropwise over a period of 0.5 h to a stirred mixture of 1.2 g (0.0515 mol) of magnesium turnings in 20 ml of THF. The reaction was maintained at reflux throughout the addition and during a further 1 h period, by which time the magnesium was consumed. The mixture was cooled in an ice bath and 20 ml of 99%-d_1 CH_3OD was added dropwise with stirring. After stirring for an additional 0.5 h, 100 ml of a 20% aqueous solution of NH_4Cl was added, the mixture was extracted with 250 ml of ether, and the extract was washed (2 × 100 ml), dried ($MgSO_4$), and concentrated *in vacuo*. The residue was taken up in cyclohexane and chromatographed on a silicic acid column (CC7, 100–200 mesh; 3 × 35 cm) with cyclohexane as eluting agent. The first major band yielded, after crystallization from hexane, 4.6 g (74%) of 2-deuterionaphthalene, m.p. 80–81.5° (lit. 80°).

A mixture of 3.0 g (23.3 mmol) of 2-deuterionaphthalene and 1 ml (8.0 mmol) of dimethyl acetylenedicarboxylate was sealed in a 250 ml pressure bottle (Fisher) and heated on an oil bath at 155–160° with stirring for 72 h. After cooling, the reaction mixture was taken up in 10 ml of benzene and chromatographed on a silicic acid column (2 × 35 cm). Elution with 1 l of cyclohexane brought off the unreacted deuterionaphthalene; elution with 5% ether in cyclohexane gave 384 mg of an oil. The oil was rechromatographed on a 2.5 × 200 cm column of silicic acid with 5% ether in cyclohexane as eluting agent; 250 ml fractions were collected. Fractions 32–34 contained 30.2 mg of an unidentified oil; 38–45 gave 308.2 mg of an oil which upon crystallization from methanol yielded 231.2 mg (11%) of colorless crystals of the deuterated mixture **10** and **11**, m.p. 74–76° (lit. (5)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

77.0–77.5°); n.m.r. (CCl_4) τ 2.78–3.21 (m, aromatic and vinyl, 5.01 ± 0.08 H), 4.82–4.90 (m, bridgeheads, 1.92 ± 0.10 H), and 6.38 (s, OCH_3, 6.00 H, assumed).

*Direct Irradiations of Deuterated Barrelene Mixture **10** and **11***

Approximately 4.0 m*M* solutions of the barrelene mixture **10** and **11** in either cyclohexane or methanol solvent contained in a 250 ml water-cooled photolysis well, were irradiated with Pyrex-filtered light provided by a 450 W Hanovia medium pressure mercury arc. The solutions were purged with nitrogen prior to and during irradiations. The photolysates were concentrated *in vacuo* and the percentage conversion of starting material was determined by n.m.r. spectroscopy; see Table 1. The residues were then chromatographed on a silicic acid column (2.5 × 200 cm) with 5% ether in cyclohexane as eluting agent; 250 ml fractions were collected. In a typical run (entry 2, Table 1), 248.0 mg of mixture **10** and **11** in 250 ml of cyclohexane was irradiated for 1 h. The residue was chromatographed and the contents of fractions 32–34 were short-path distilled (85°/0.1 mm Hg) then crystallized from methanol to give 21.5 mg of COT product, m.p. 74–76° (lit (5) 77.0–77.5°); see Table 1 for deuterium distributions. Fractions 35–50 contained 189.3 mg of an oily mixture of starting material and COT product.

Quantum Yield Determinations

Quantum yields of the direct irradiation of barrelene **4** (5) were determined on a "merry-go-round" fitted with a 450 W Hanovia medium pressure mercury arc and surrounded by a water-cooled quartz immersion well. Light of wavelength 276 nm was isolated by a two compartment quartz cell fitting concentrically around the immersion well. One compartment contained a 2.0 cm path length of a solution of 533 g of nickel sulfate hexahydrate and 300 g of cobaltous sulfate heptahydrate per 1.0 l of 5% aqueous H_2SO_4. The other compartment contained a 0.2 cm path length of a solution of 1 g of bismuth trichloride per 0.5 l of 10% HCl; transmittance was 263–290 nm with a maximum at 276 nm (8%). Before irradiation, solutions of **4** (*ca.* 0.04 mmol) contained in calibrated (for differences in light transmittance) 20 × 150 mm quartz test-tube-like photolysis cells were deoxygenated by flushing with dried, pyrogallol scrubbed, commercial high-purity nitrogen. The tubes were sealed under a positive pressure of nitrogen which was maintained throughout the course of the irradiation. For each run two samples of **4** were irradiated; one sample was a solution of **4** in cyclohexane and the other was a solution of **4** in methanol. The lamp output was determined by potassium ferrioxalate actinometry (12). The photolysates were concentrated *in vacuo*, a known amount of *p*-xylene was added as internal standard, and the product composition was determined by n.m.r. analysis; the peak areas were calibrated against authentic mixtures of similar constitution. Conversions were kept below 17% and the quantum yields were determined from the average of two runs for each solvent. The Φ for the appearance of COT **6** were: $\Phi_{MeOH} = 0.10 \pm 0.01$ and $\Phi_{cyclohexane} = 0.16 \pm 0.02$.

*Effect of Lanthanide Shift Reagent on the Nuclear Magnetic Resonance Spectrum of COT **6***

The n.m.r. spectrum of COT **6** (30 mg) was recorded in CCl_4 (0.65 ml containing 1% TMS) in the presence of increasing amounts of a solution of $Eu(fod)_3$ in CCl_4 (107 mg in 2.00 ml). The shift reagent was dispensed by syringe. At molar ratio 0.27 of $Eu(fod)_3$:COT the olefinic protons coalesced to a singlet at τ 2.92 as did the aromatic protons at τ 2.69. The results are summarized in Fig. 1.

The authors thank the Spectroscopic Services Laboratory of the University of Alberta for the 100-MHz n.m.r. spectra, and gratefully acknowledge the financial support of the National Research Council of Canada, the University of Lethbridge Research Committee, and the President's Research Scholarship in Arts and Science (awarded to D. W. B., 1974). We also thank the referees for their helpful comments.

Agelasine: A Novel Quaternary 9-Methyladenine from the Sponge *Agelas dispar*

ERNEST CULLEN AND JOHN P. DEVLIN
Pharma Research Canada Ltd., Pointe Claire, Quebec H9R 1G8

Received February 26, 1975

ERNEST CULLEN and JOHN P. DEVLIN. Can. J. Chem. **53**, 1690 (1975).

The isolation of a novel quaternary 9-methyladenine from the sponge *Agelas dispar* is described. The constitution (**1**) is assigned on the basis of degradative and spectroscopic data.

ERNEST CULLEN et JOHN P. DEVLIN. Can. J. Chem. **53**, 1690 (1975).

On décrit la méthode de séparation d'un nouveau sel quaternaire de la méthyl-9 adénine provenant de l'éponge *Agelas dispar*. On attribue la structure (**1**) en se basant sur les données spectroscopiques et les résultats obtenus par dégradation de la molécule.

[Traduit par le journal]

We have examined the pharmacological behavior of the extractives of a large number of marine organisms with the aim of uncovering novel directives for drug design. We herein report the isolation and characterization of a major constituent, agelasine (**1**), of the sponge *Agelas dispar* Duchassaing and Michelotti.

The residue on evaporation of the ethanol extract of a freeze-dried preparation of *A. dispar* was triturated with benzene. The insoluble portion on recrystallization from acetonitrile yielded **1**[1] (2% on dry weight basis) as colorless plates, m.p. 190–195° dec.; ν_{max} (KBr) 3320, 3140, 1652, 1610 cm^{-1}; and λ_{max} (CH_3OH) 271 nm (log ε 3.91). Elemental analyses indicated the empirical formula $C_{26}H_{40}N_5Cl \cdot \frac{1}{2}H_2O$. Recrystallization from 2-butanone–dimethylformamide provided the anhydrous form ($C_{26}H_{40}N_5Cl$), m.p. 197–200° dec. While a molecular ion was not observed in the mass spectrum, principle ions were found at *m/e* 421 ($C_{26}H_{38}N_5$), 308/310 ($C_{20}H_{33}Cl$), 273 ($C_{20}H_{33}$), 272 ($C_{20}H_{32}$), 191 ($C_{14}H_{23}$), and 149 ($C_6H_7N_5$). The n.m.r. spectrum ($CDCl_3$) exhibited a complex group of signals at δ 0.5–2.3 (29H); the remaining signals were as follows: δ 4.12 (s, 3H, —N—CH_3), 5.3–5.9 (m, 4H), 7.67 (broad s, 2H, —NH_2, disappeared on addition of D_2O), 8.47 (s, 1H), and 10.84 (s, 1H).

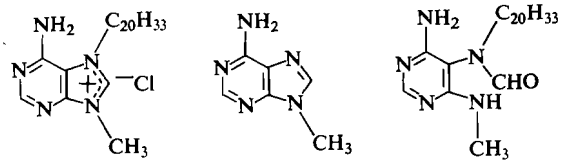
When agelasine was heated under reflux in xylene and the reaction mixture cooled a crystalline solid separated, m.p. 300–302° (from CH_3OH); ν_{max} (KBr) 3280, 3110, 1672, 1600, 1575 cm^{-1}; and λ_{max} (H_2O) 261 nm (log ε 4.03) (at p*H* 2, 7, and 11). The n.m.r. and mass spectra identified this substance as a mono-*N*-methyladenine. The i.r. and u.v. absorptions were in agreement with those reported (1, 2) for 9-methyladenine (**2**). This assignment was confirmed by a comparison with synthetic **2** prepared by the direct methylation of adenine (3).

The aforementioned mass spectral data and the thermal behavior described above suggested that agelasine was a quaternary derivative of 9-methyladenine. The quaternary iodide ($C_{26}H_{40}N_5I$), m.p. 171–173°, was readily obtained by treatment of an aqueous solution of **1** with KI. The nitrate ($C_{26}H_{40}N_6O_3$), m.p. 174–175°, was similarly formed.

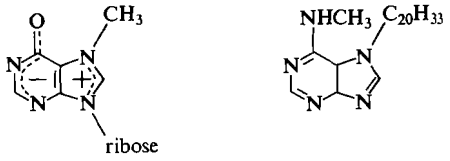
The release of the 9-methyladenine moiety as the hydrochloride was rapidly effected by hydrogenation of **1** (H_2/5% Pd–C) in ethanol. A nonpolar fragment was also isolated as a colorless oil which by analysis and mass spectroscopy (M^+ 274, *m/e* 259, *m/e* 205, *m/e* 191) was assigned the molecular formula $C_{20}H_{34}$; two olefinic protons were present in the n.m.r. spectrum ($CDCl_3$) as a broad multiplet at δ 5.0–5.5. Further hydrogenation (H_2/Pt_2O/ethyl acetate – HCl) of this oil provided the tetrahydro derivative $C_{20}H_{38}$ (M^+ 278, *m/e* 263, *m/e* 193); the n.m.r. spectrum ($CDCl_3$) exhibited only a complex group of signals at δ 0.7–2.0. The nonpolar fragment can therefore be classified as a dicyclic hydrocarbon con-

[1]The i.r., n.m.r., and mass spectra of all compounds have been recorded and are in agreement with the structures assigned. Only specially relevant spectral data are reported. All crystalline compounds gave correct elemental analyses.

taining two double bonds. The fragmentation patterns observed in the mass spectra of both the nonpolar fragment and its tetrahydro derivative are similar to the patterns observed with the carbodicyclic diterpenes (4). The precise constitution of this substance is presently under investigation.



1 2 3



4 5

Treatment of an aqueous solution of **1** with 2 *N* Na_2CO_3 precipitated a white crystalline solid (**3**), m.p. 105–108° (from isopropyl ether); ν_{max} (KBr) 3440 (sh), 3340, 3220, 2920, 1660, and 1590 cm^{-1}; λ_{max} (C_2H_5OH): p*H* 7, 260 nm (log ε 3.77); p*H* 2, 271 nm (log ε 3.98); p*H* 11, 260 nm (log ε 3.80). The molecular formula ($C_{26}H_{41}N_5O$) was supported by analyses and the mass spectrum (M^+ 439). The n.m.r. ($CDCl_3$) spectrum exhibited signals at δ 2.9 (d, 3H, $NHCH_3$; $+D_2O$, s, 3H), 7.9 (s, 1H, C2-H or —NC*H*O), and 8.1 (s, 1H, —N—C*H*O or C2-H). The —$NHCH_3$ signal at δ 2.9 demonstrated that the nucleophilic attack occurred at C-8, with subsequent ring cleavage. The ease with which this hydrolysis occurred, encouraged us to assign N-7 as the site of quaternization with the positive charge delocalized as shown (**1**); an assignment which was supported (5) by the rapid exchange of the C8-H (δ 10.84 in $CDCl_3$; δ 10.13 in CD_3SOCD_3; δ 11.5 in C_5D_5N) of agelasine with D_2O when the n.m.r. spectrum was run in C_5D_5N. The low-field position of this proton is in agreement with that of the C-8 proton of 7-methylinosine (6) (**4**, δ 9.64 in CD_3SOCD_3) which is in a similar environment.

The constitution **1** was therefore considered for agelasine and **3** for that obtained upon treatment with 2 *N* Na_2CO_3. This assignment was supported by the ring closure of **3** with NaH in dimethylacetamide to provide **5**, $C_{26}H_{39}N_5$ (M^+ 421), as colorless plates, m.p. 163–165° (from acetonitrile); ν_{max} (KBr) 3280, 2940, 1615, 1550 cm^{-1}. The u.v. absorption (λ_{max} (C_2H_5OH): p*H* 7 and 11, 272 (log ε 4.12); p*H* 2, 282 nm (log ε 4.17)) corresponded to that anticipated for a 7-alkyladenine (7). The n.m.r. spectrum ($CDCl_3$) exhibited signals at δ 3.50 (d, 3H, —$NHCH_3$; $+D_2O$, s, 3H), 7.85 (s, 1H, C2-H), and 8.55 (s, 1H, C8-H).

To our knowledge, agelasine is the first quaternary derivative of adenine to be found in nature. Agelasine has a very broad spectrum of pharmacological activity although many of these effects can be ascribed to its saponin-like nature. These aspects will be described in a forthcoming paper.

We are grateful to Dr. K. R. Freter for his interest and encouragement, to Dr. H. J. Förster for high resolution mass spectral data, and to Dr. Finn Sander and Dr. Reiswig of the Bellairs Research Institute of McGill University at St. James, Barbados for the collection and identification of *Agelas dispar*. The technical assistance of Mr. R. Becker is gratefully acknowledged.

Synthesis of some A-Ring Steroidal Cyclopropanols

J. F. TEMPLETON AND C. W. WIE

Faculty of Pharmacy, University of Manitoba, Winnipeg, Manitoba R3T 2N2

Received November 28, 1974

J. F. TEMPLETON and C. W. WIE. Can. J. Chem. **53**, 1693 (1975).

The preparation of two epimeric secondary cyclosteroid alcohols in the steroidal A-ring by an intramolecular 1,3-elimination of bromide with zinc–copper couple is described. Isomerization of the *endo*-cyclopropanol to the *exo*-cyclopropanol is shown to occur with either the couple or zinc acetate. Solvolysis of the cyclopropyl tosylates is discussed. Spectral data are recorded.

J. F. TEMPLETON et C. W. WIE. Can. J. Chem. **53**, 1693 (1975).

On décrit la préparation, par une élimination intramoléculaire 1,3 d'ion bromure par le couple zinc–cuivre, de deux alcools secondaires épimères d'un cyclostéroide dans le cycle A. On montre que l'isomérisation du cyclopropanol *endo* en cyclopropanol *exo* se produit avec le couple zinc–cuivre ou avec l'acétate de zinc. On discute de la solvolyse des tosylates de cyclopropyle. On rapporte les données spectrales. [Traduit par le journal]

Introduction

Few examples of steroids containing the cyclopropanol moiety have been reported. Recently several cyclopropanosteroids which contain a tertiary cyclopropanol, prepared by means of methylene addition to enolic derivatives have been prepared (1–3) and a photochemical product isolated (4). We describe here a short synthesis under mild conditions of two epimeric secondary cyclosteroid cyclopropanols prepared by an intramolecular 1,3-elimination.

Results and Discussion

Treatment of 17β-hydroxy-5α-androstan-3-one (**1**) with 2 mol of bromine in acetic acid affords the dibromoacetate (**2**) (5). Reduction of this sterically hindered ketone with sodium borohydride proceeds rapidly to give a mixture of the 3α- and 3β-hydroxy epimers (**3***a* and **4***a*). Fractional crystallization of the epimers gave a low yield of the pure dibromoalcohols. The major product from the reduction is the 3α-epimer determined by the p.m.r. spectra of the alcohols (**3***a* and **4***a*) and the acetates (**3***b* and **4***b*). The alcohols (**3***a* and **4***a*) show the presence of a triplet at 4.27 δ (J = 2.5 Hz) and 3.80 δ (J = 10.0 Hz) consistent with axial–equatorial coupling of an equatorial proton at C-3 and diaxial coupling of an axial proton at C-3, respectively (6). Similarly the p.m.r. spectra of the acetate (**3***b*) contain a triplet at 5.70 δ (J = 2.5 Hz) and the acetate (**4***b*) a triplet at 5.27 δ (J = 10.0 Hz), in agreement with the assignment of **3***a* as the 3α- and **4***a* as the 3β-derivatives.

Treatment of the 3α-dibromoalcohol (**3***a*) with a freshly prepared 2% zinc–copper couple in ethanol at room temperature showed by t.l.c. and g.l.c. analysis the formation of three major products and no starting material after ½ h. The less polar material (by t.l.c.) was largely dissolved by petroleum ether and extraction of the crude reaction mixture gave a crystalline compound from the petroleum ether soluble portion shown by p.m.r. (7*a*) and mass spectra

(*7b*) to be an isomeric mixture of 17β-acetoxy-5α-androstan-2- and 3-ene (**5**) which was not further purified. The petroleum ether mother liquor gave a further crystalline substance as a minor product. This product was identified as 2β,4β-cyclo-5α-androstane-3β,17β-diol 17-acetate (**6***a*) which gave a diacetate (**6***b*) (see below). The petroleum ether insoluble residue on fractional crystallization from ether gave as the major product 2β,4β-cyclo-5α-androstane-3α,17β-diol 17-acetate (**7***a*) which yielded a diacetate (**7***b*) identified on the basis of the following evidence. Carbon and hydrogen analysis and the presence of an ion at *m/e* 332 in the mass spectrum was

For personal use only.

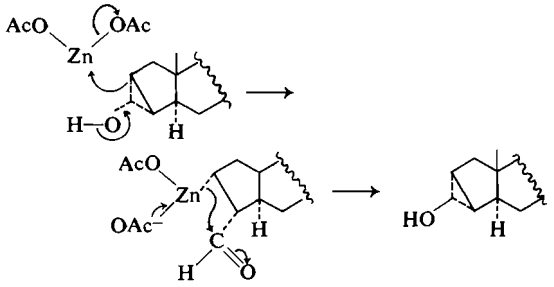
consistent with the molecular formula of **7***a*. The i.r. spectrum of **7***a* showed the presence of hydroxyl absorption and a weak absorption at 3030 and 3049 cm^{-1} consistent with cyclopropyl C—H stretching vibrations. Acetylation incorporated a second acetyl group indicating the presence of a single hydroxyl function. The p.m.r. spectrum of the diacetate (**7***b*) showed no olefinic protons, however, the presence of a triplet at 4.25 δ (J = 6.0 Hz) is consistent with a cyclopropyl acetate having an acetoxy function at C-3 with the *endo* configuration. Compound **7***a* on treatment with alcoholic potassium hydroxide was converted into a noncrystalline product which showed the presence of aldehyde carbonyl absorption (1720 cm^{-1}) and C—H stretching (2700 and 2800 cm^{-1}) which would be expected from opening of the cyclopropanol ring in **7***a* to give the A-nor derivatives (**8**) containing an aldehyde function in either the C-2 or C-3 position. The p.m.r. spectrum also contained an aldehyde proton and loss of the signals associated with the cyclopropanol ring.

Similar treatment of the 3β-dibromoalcohol (**4***a*) with a zinc–copper couple gave only one major product identical with the minor product (**6***a*) from the reaction with the 3α-dibromoalcohol (**3***a*). The chemical shift and coupling constant of the proton at C-3 of the diacetate (**6***b*) (δ 3.63, unresolved triplet) demonstrates the *exo* configuration of the cyclopropanol (8). Reaction of **6***a* with alcoholic potassium hydroxide, as with compound **7***a*, gave an uncrystalline aldehyde product having an identical i.r. and p.m.r. spectrum with the previous product (**8**) from **7***a*. The greater formation of the olefinic products (**5**) from the 3α- rather than the 3β-dibromoalcohol is consistent with the greater ease of elimination of the 3α- (axial) alcohol and the lesser stability of the *endo* alcohol.

The formation of the 3β-cyclopropanol (**6***a*) from the 3α-epimer (**7***a*) occurs under the reaction conditions with the zinc–copper couple. Also the 3α-cyclopropanol in methanol containing zinc acetate is converted slowly into the 3β-epimer. This conversion most probably involves the opening and reclosing of the cyclopropane ring. A proposed mechanism is shown in Scheme 1 showing addition of zinc acetate at either C-2 or C-4. Sterically the *endo* isomer will be the thermodynamically less stable product and ring closure then yields the more



SCHEME 1

stable *exo* isomer. An analogous ring opening has been shown to occur by reaction of a cyclopropanol with mercuric acetate (9).

The *endo* and *exo* assignments of the cyclopropanols **7***a* and **6***a* are in agreement with the assignments of the configuration for the dibromoalcohols **3***a* and **4***a*, respectively.

When the dibromoacetates (**3***b* and **4***b*) were similarly treated with zinc–copper couple only a mixture of the olefinic products was detected in the reaction as determined by t.l.c.

Further evidence for the stereochemical assignment of the epimeric alcohols was provided by solvolysis of the corresponding tosylates (**6***c* and **7***c*) with sodium acetate in acetic acid. In the case of the isomers, *endo*-bicyclo[3.1.0]-hexyl 6-*p*-toluenesulfonate and *exo*-bicyclo-[3.1.0]hexyl 6-*p*-toluenesulfonate, a solvolysis rate of 25 000 and <0.01, respectively, relative to cyclopropyl *p*-toluenesulfonate was found (8). The *endo* isomer gave *cis*-2-cyclohexen-1-yl acetate as the isolated product. 2β,4β-Cyclo-5α-androstane-3β,17β-diol 17-acetate 3-tosylate (**6***c*) was recovered unchanged after refluxing for 20 h with sodium acetate in acetic acid. Similar treatment of 2β,4β-cyclo-5α-androstane-3α,17β-diol 17-acetate 3-tosylate (**7***c*) gave no starting material and a mixture of products after 15 min. The u.v. and p.m.r. spectrum of the less polar material indicated it to be principally 17β-acetoxyandrosta-2,4-diene (**9**) (10). The more polar material could be separated by chromatography into two pure substances identified as 5α-androst-2-ene-4α,17β-diol diacetate (**10**) and 5α-androst-3-ene-2α,17β-diol diacetate (**11**). Hydrolysis of these products followed by oxidation led to 5α-androst-2-ene-4,17-dione (**12**) and 5α-androst-3-ene-2,17-dione (**13**), respectively. The position of the unsaturated ketone was established by comparison of the p.m.r. spectrum with that of the known corresponding 17β-

For personal use only.

acetates (11). The stereochemistry of the acetates was not determined directly; however, addition to the least hindered side of the intermediate cation would yield the 2α- and 4α-acetates.

Experimental

For general experimental details and apparatus see ref. 12; 220 MHz spectra were recorded by the Canadian 220 MHz NMR Centre, Ontario Research Foundation, Sheridan Park, Ontario for compounds **3***a*, **4***a*, **10**, **11**, **12**, and **13**.

Work-up Procedure

Reactions were extracted with ether (unless otherwise stated) and the combined extracts washed with water, saturated brine, dried over anhydrous sodium sulfate, filtered, and evaporated at reduced pressure to give the crude reaction product.

Thin-layer Chromatography

Silica gel coated glass plates were developed in 5% ethyl acetate in chloroform.

Gas–Liquid Chromatography

A Varian Aerograph Series 1800 chromatograph equipped with a hydrogen flame ionization detector and a Pyrex glass column packed with 2% OV-17 on Chromosorb GHP, 60–80 mesh, internal diameter 2 mm, length 180 cm was used. The detector temperature was 300°, column temperature 240°, and the carrier gas (N_2) flow rate was 40 ml/min. All compounds were injected as their trimethylsilyl derivatives at a concentration of 10 μg/μl.

Acetylation

To a 10% solution of the steroid in dry pyridine was added one-half the volume of acetic anhydride. After standing overnight at room temperature, the reaction was poured into an ice-water mixture and allowed to stand for 30 min followed by acidification with dilute hydrochloric acid and ether extraction.

Zinc–Copper Couple

A homogenous, consistently active, zinc–copper couple was prepared as follows. Finely powdered cupric acetate monohydrate (8 g, 0.04 mol) and zinc dust (130 g, 2 mol) were thoroughly mixed with a pestle and mortar. To avoid excessive frothing the mixture was added portionwise to a mechanically stirred solution of boiling glacial acetic acid (275 ml). After addition a further 200 ml of cold acetic acid was added and the slurry filtered with suction and washed several times with ether without allowing all of the ether to evaporate. The ether-moist couple was kept under ether and used as soon as possible.

2α,4α-Dibromo-17β-acetoxy-5α-androstan-3-one (2)

Prepared by the method of Jones and Ship (5). Material of m.p. 184–190° was used for reduction.

2α,4α-Dibromo-5α-androstane-3α,17β- and 3β,17β-diol 17-Acetate (3a) and (4a)

Sodium borohydride (946 mg) in ethanol (50 ml) was added to a slurry of 17β-acetoxy-2α,4α-dibromo-5α-androstan-3-one (**2**) (15 g) in ethanol (200 ml). The mixture was stirred for 5 min at room temperature, during which time dissolution occurred, and poured into ice-cold 1 *N* sulfuric acid (1 l). Extraction with dichloromethane yielded a crude product which on crystallization from chloroform gave 2α,4α-dibromo-5α-androstane-3β,17β-diol 17-acetate (4*a*) (527 mg); m.p. 248–252°, second crop (982 mg), m.p. 235–240°. Further recrystallization from dichloromethane gave **4***a*, (746 mg); m.p. 253–255°; $[\alpha]_D$ −46°; i.r. ν_{max} (KBr) 3413 (hydroxyl), 1706 (ester C=O) cm^{-1}; p.m.r. δ ($CDCl_3$) 4.59 (1, t, J = 8.0 Hz, 17α-proton), 4.10 (1, m, 2β-proton), 3.94 (1, t, J = 10.0 Hz, 4β-proton), 3.80 (1, t, J = 10.0 Hz, 3α-proton), 2.39 (1, q, J = 13.0 and 5.0 Hz, 1β-proton), 2.03 (3, s, 17-acetoxy methyl), 0.88 (3, s, 19-methyl), 0.78 (3, s, 18-methyl) p.p.m.

Anal. Calcd. for $C_{21}H_{32}O_3Br_2$: C, 51.23; H, 6.55; Br, 32.25. Found: C, 51.08; H, 6.42; Br, 33.81.

The mother liquor was evaporated and crystallized from acetone–dichloromethane to give 2α,4α-dibromo-5α-androstane-3α,17β-diol 17-acetate (3.2 g); m.p. 202–205°. Further recrystallization gave **3***a*, m.p. 206–207°; $[\alpha]_D$ −24°; i.r. ν_{max} (KBr) 3472 (hydroxyl), 1706 (ester C=O) cm^{-1}; p.m.r. δ ($CDCl_3$) 4.59 (1, t, J = 8.0 Hz, 17α-proton), 4.35 (1, m, 2β-proton), 4.27 (1, t, J = 2.5 Hz, 3β-proton), 4.20 (1, q, J = 11.0 and 2.5 Hz, 4β-proton), 2.03 (3, s, 17-acetoxy methyl), 0.89 (3, s, 19-methyl), 0.77 (3, s, 18-methyl) p.p.m.

Anal. Calcd. for $C_{21}H_{32}O_3Br_2$: C, 51.23; H, 6.55; Br, 32.25. Found: C, 51.09; H, 6.42; Br, 33.07.

Column chromatographic separation of the acetylated crude 2,4-dibromoalcohols gave a 4:1 ratio of 3α- to 3β-acetates.

2α,4α-Dibromo-5α-androstane-3α,17β-diol Diacetate (3b)

2α,4α-Dibromo-5α-androstane-3α,17β-diol 17-acetate (**3***a*) (95 mg) (m.p. 206–207°) was acetylated. The crude reaction product was recrystallized from methanol to give 2α,4α-dibromo-5α-androstane-3α,17β-diol diacetate (77 mg); m.p. 228–229°; $[\alpha]_D$ −19°; i.r. ν_{max} (CCl_4) 1761, 1742 (ester C=O) cm^{-1}; p.m.r. δ (CCl_4) 5.70 (1, t, J = 2.5 Hz, 3β-proton), 4.58 (1, t, J = 8.0 Hz, 17α-proton), 4.33 (1, m, 2β-proton), 4.16 (1, q, J = 11.0 and 2.5 Hz, 4β-proton), 2.18 (3, s) and 2.02 (3, s, 3- and 17-acetoxy methyl), 0.90 (3, s, 19-methyl), 0.76 (3, s, 18-methyl) p.p.m.; m.s. *m/e* 534 (M^+, weak).

2β,4β-Cyclo-5α-androstane-3β,17β-diol-17-Acetate (6a)

To a slurry of 2α,4α-dibromo-5α-androstane-3β,17β-diol 17-acetate (**4***a*) (600 mg) in ethanol (18 ml), was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

added freshly prepared 2% zinc–copper couple (9 g). The mixture was mechanically stirred for ½ h at room temperature. The reaction was filtered and the ethanol evaporated at reduced pressure with minimal heating. Cold aqueous sodium bicarbonate was added and the products extracted with ether. The crude product showed one major spot on t.l.c. and contained >98% 2β,4β-cyclo-5α-androstane-3β,17β-diol 17-acetate on g.l.c. Successive recrystallization from methanol gave the alcohol (222 mg); m.p. 130–132°; $[\alpha]_D$ +24° (dioxane); i.r. ν_{max} (KBr) 3546 (hydroxyl), 3040 (cyclopropyl C—H), 1727 (ester C=O) cm^{-1}; m.s. *m/e* 332 (M^+).

Anal. Calcd. for $C_{21}H_{32}O_3$: C, 75.85; H, 9.70. Found: C, 75.97; H, 9.75.

2β,4β-Cyclo-5α-androstane-3α,17β-diol 17-Acetate (7a)

2α,4α-Dibromo-5α-androstane-3α,17β-diol 17-acetate (**3***a*) (1 g) was treated with zinc–copper couple similarly to (**4***a*). The crude product showed three spots on t.l.c. and three peaks on g.l.c. On stirring with petroleum ether (7 ml), the insoluble material was collected (456 mg, m.p. 134–136°). Successive recrystallization from acetone ether gave 2β,4β-cyclo-5α-androstane-3α,17β-diol 17-acetate (350 mg); m.p. 143–146°; $[\alpha]_D$ +17° (dioxane); i.r. ν_{max} (KBr) 3509 (hydroxyl O—H), 3049 and 3030 (cyclopropyl C—H), 1727 (ester C=O) cm^{-1}; m.s. *m/e* 332 (M^+).

Anal. Calcd. for $C_{21}H_{32}O_3$: C, 75.85; H, 9.70. Found: C, 76.12; H, 9.63.

From the petroleum ether solution was recovered 85 mg, m.p. 105–127° of crystalline material which was stirred with petroleum ether (10 ml). The petroleum ether soluble portion was filtered through alumina, the p.m.r. spectrum (7) of the combined fractions (41 mg) corresponded to a mixture of 17β-acetoxy-5α-androst-2- and 3-ene; p.m.r. δ (CCl_4) 5.14–5.62 (2, m, olefinic protons), 4.56 (1, t, J = 8.0 Hz, 17α-proton), 1.96 (3, s, acetoxy methyl), 0.76, (6, s, 18- and 19-methyl) p.p.m. (*7a*); m.s. *m/e* 316 (M^+), 262 ($M^+ - 54$)(*7b*). The petroleum ether insoluble material (12 mg) was recrystallized from methanol to give a sample which was identical to **6***a* by mixed melting point and i.r. and m.s. spectra.

Higher overall yields of the cyclopropanols were obtained by treating the mixture of 3α- and 3β-dibromo-alcohols (**3***a* and **4***a*) directly with the zinc–copper couple. Separation of the products was carried out by extraction of the crude solid residue with petroleum ether (10% w/v). The 3α-cyclopropanol was recrystallized from the petroleum ether insoluble portion. The 3β-cyclopropanol and olefinic mixture was fractionally recrystallized from the petroleum ether soluble portion.

Similar treatment of the diacetates (**3***b* and **4***b*) gave only the olefinic mixture (**5**) by t.l.c. and i.r.

2β,4β-Cyclo-5α-androstane-3β,17β-diol Diacetate (6b)

2β,4β-Cyclo-5α-androstane-3β,17β-diol 17-acetate (**6***a*) (120 mg) was acetylated. The crude reaction product showed a single spot on t.l.c. Recrystallization of the crude product from methanol gave the 2β,4β-cyclo-5α-androstane-3β,17β-diol diacetate (100 mg); m.p. 142–143°; $[\alpha]_D$ +23°; i.r. ν_{max} (CCl_4) 3050 (cyclopropyl C—H); 1736 (ester C=O), cm^{-1}; p.m.r. δ ($CDCl_3$) 4.51 (1, t, J = 8.0 Hz, 17α-proton), 3.63 (1, unresolved t, 3α-proton), 1.94 (3, s) and 1.90 (3, s, 3- and 17-acetoxy methyl), 0.85 (3, s, 19-methyl), 0.74 (3, s, 18-methyl) p.p.m.; m.s. *m/e* M^+ (not detected), 332 ($M^+ - CH_2CO$).

Anal. Calcd. for $C_{23}H_{34}O_4$: C, 73.76; H, 9.15. Found: C, 73.93; H, 9.07.

2β,4β-Cyclo-5α-androstane-3β,17β-diol 3-Tosylate 17-Acetate (6c)

To a solution of 2β,4β-cyclo-5α-androstane-3β,17β-diol 17-acetate (**6***a*) (500 mg) in anhydrous pyridine (5 ml) was added *p*-toluenesulfonyl chloride (600 mg). The mixture was allowed to stand overnight at room temperature and the brown solution was poured into ice water. The product was extracted with ether and the ether solution was washed with cold 1 *N* sulfuric acid. The crude reaction product was dissolved in acetone and the solution was stirred with activated charcoal and filtered. Successive recrystallization from acetone at room temperature gave 2β,4β-cyclo-5α-androstane-3β,17β-diol 17-acetate 3-tosylate (**6***c*) (450 mg); m.p. 155–156°; $[\alpha]_D$ +19°; i.r. ν_{max} (CCl_4) 3030 (broad, cyclopropyl and aromatic C—H), 1730 (ester C=O), 1595 (aromatic C=C), 1188 and 1176 (tosyl S=O) cm^{-1}; p.m.r. δ ($CDCl_3$) 7.62 (4, q, AA′XX′, $J_{AX} = J_{A'X'}$ = 8.0 Hz, *p*-substituted aromatic protons), 4.61 (1, t, J = 8.0 Hz, 17α-proton), 3.56 (1, unresolved t, 3α-proton), 2.47 (3, s, aromatic methyl protons), 2.01 (3, s, acetoxy methyl), 0.75 (6, s, 18- and 19-methyl) p.p.m.

Anal. Calcd. for $C_{28}H_{38}O_5S$: C, 69.10; H, 7.87; S, 6.59. Found: C, 69.00; H, 7.86; S, 6.50.

2β,4β-Cyclo-5α-androstane-3α,17β-diol 17-Acetate (7a) with Zinc–Copper Couple

To 2β,4β-cyclo-5α-androstane-3α,17β-diol 17-acetate (*7a*) (100 mg) in ethanol (5 ml) was added freshly prepared 2% zinc–copper couple (1.5 g). Conversion of *7a* to **6***a* was monitored by t.l.c. and g.l.c. After 48 h the reaction was filtered, poured into aqueous sodium bicarbonate, and ether extracted. The crude product was acetylated followed by chromatography on alumina. A combined fraction of 58 mg corresponding to **6***b* was obtained. Recrystallization from methanol gave 26 mg of material identical to **6***b* by mixture m.p. and i.r. spectrum.

2β,4β-Cyclo-5α-androstane-3α,17β-diol 17-Acetate (7a) with Zinc Acetate

2β,4β-Cyclo-5α-androstane-3α,17β-diol 17-acetate (*7a*) (100 mg) was dissolved in a saturated solution of zinc acetate in ethanol (30 ml). The reaction was allowed to stand at room temperature for 5 days, poured into water, and the products extracted with ether. The crude product which gave two major spots on t.l.c., corresponding to **6***a* and *7a* was acetylated. The acetylation product was chromatographed on alumina, from which a combined fraction of 64 mg corresponding to **6***b* was obtained. Recrystallization from methanol gave 30 mg of material which was identical to **6***b* by mixture melting point and i.r. spectrum.

2β,4β-Cyclo-5α-androstane-3α,17β-diol Diacetate (7b)

2β,4β-Cyclo-5α-androstane-3α,17β-diol 17-acetate (115 mg) (*7a*) was acetylated. Successive recrystallization of the crude product from methanol gave the 2β,4β-cyclo-5α-androstane-3α,17β-diol diacetate (58 mg); m.p. 147–148°; $[\alpha]_D$ +14°; i.r. ν_{max} (CCl_4) 3049 (cyclopropyl C—H), 1736 (ester C=O), cm^{-1}; p.m.r. δ ($CDCl_3$) 4.60 (1, t, J = 8.0 Hz, 17α-proton), 4.25 (1, t, J = 6.0 Hz,

2β,4β-Cyclo-5α-androstane-3β,17β-diol 17-Acetate (6a) with Methanolic Potassium Hydroxide

2β,4β-Cyclo-5α-androstane-3β,17β-diol 17-acetate (100 mg) in methanolic potassium hydroxide (0.36 *M*, 5 ml) was refluxed for 1 h. No starting material was detected on t.l.c. after 30 min of reaction. The solution was poured into water and neutralized with dilute sulfuric acid. The products were extracted with ether and showed i.r. ν_{max} (CCl_4) 3620 (hydroxyl), 2800 and 2700 (aldehyde C—H), 1720 (aldehyde C=O) cm^{-1}; p.m.r. δ (CCl_4) 9.62 (aldehyde proton), 3.58 (17α-proton), 0.78 (19-methyl), 0.70 (18-methyl) p.p.m.

2β,4β-Cyclo-5α-androstane-3α,17β-diol 17-Acetate (7a) with Methanolic Potassium Hydroxide

2β,4β-Cyclo-5α-androstane-3α,17β-diol 17-acetate (100 mg) was treated with methanolic potassium hydroxide as for **6a**. Spectra (i.r. and p.m.r.) of thc crude product were identical to the above product from **6a**.

2β,4β-Cyclo-5α-androstane-3α,17β-diol 17-Acetate 3-Tosylate (7c)

2β,4β-Cyclo-5α-androstane-3α,17β-diol 17-acetate (**7a**) (1.9 g) was treated with *p*-toluenesulfonyl chloride (2.4 g) in anhydrous pyridine (20 ml) as for **6a**. The crude reaction product was recrystallized from acetone to give the tosylate (**7c**) (1.7 g); m.p. 111–112° (dec.); $[\alpha]_D$ +36°; i.r. ν_{max} (CCl_4) 3020 (broad, cyclopropyl and aromatic C—H), 1730 (ester C=O), 1595 (aromatic C=C), 1190 and 1175 (tosyl S=O), cm^{-1}; p.m.r. δ ($CDCl_3$) 7.62 (4, q, AA′XX′, $J_{AX} = J_{A'X'} = 8.0$ Hz, *p*-substituted aromatic protons); 4.63 (1, t, $J = 8.0$ Hz, 17α-proton), 4.53 (1, t, $J = 6.0$ Hz, 3β-proton), 2.45 (3, s, aromatic methyl), 2.02 (3, s, acetoxy methyl), 0.83 (3, s, 19-methyl), 0.75 (3, s, 18-methyl) p.p.m.

Anal. Calcd. for $C_{28}H_{38}O_5S$: C, 69.10; H, 7.87; S, 6.59. Found: C, 69.05; H, 7.66; S, 6.54.

Acetolysis of 2β,4β-Cyclo-5α-androstane-3β,17β-diol 17-Acetate 3-Tosylate (6c)

A solution of anhydrous sodium acetate (400 mg) and acetic anhydride (1 ml) in acetic acid (10 ml) was refluxed for 1 h. The solution was cooled to 100–105°, the tosylate (**6c**) was added (100 mg) and the resulting mixture was stirred and maintained at 100–105° in an oil bath. The reaction was followed by t.l.c. at appropriate time intervals. After 20 h the solution was poured into ice water (100 ml) and the product immediately crystallized. The crystals were filtered and washed with water, dried *in vacuo* over P_2O_5 at room temperature for 4 days. The crude product (98 mg, m.p 153.5–155.5°) was further recrystallized from acetone to give a sample (82 mg) of 155–156°; the mixture m.p. of this sample with the starting material showed no depression and gave an identical i.r. spectrum with that of the starting material.

Acetolysis of 2β,4β-Cyclo-5α-androstane-3α,17β-diol 17-Acetate 3-Tosylate (7c)

2β,4β-Cyclo-5α-androstane-3α,17β-diol 17-acetate 3-tosylate (500 mg) was treated with a solution of anhydrous sodium acetate (2.2 g) and acetic anhydride (5.5 ml) in acetic acid (55 ml) as for **6c**. No starting material was detected on t.l.c. after 15 min of reaction time. The reaction was poured into ice water and the products were extracted with ether. The crude product (394 mg) was chromatographed on alumina. Elution with 2–5% benzene – petroleum ether (60:90) gave 93 mg crystalline material; p.m.r. δ (CCl_4) 5.75–5.32 (m, olefinic protons), 4.52 (t, 17α-proton), 1.95 (s, acetoxy methyl), 0.91 (s, 19-methyl), 0.77 (s, 18-methyl) p.p.m.; which on recrystallization from methanol gave 17β-acetoxyandrosta-2,4-diene (**9**); m.p. 98–99°; u.v. λ_{max} (EtOH) 266 (log ε, 3.69), 272–273 nm (log ε, 3.65) (lit. (10) m.p. 102–104°; u.v. λ_{max} 266 (log ε, 3.78), 272–273 nm (log ε, 3.74).

Elution with 25–50% benzene – petroleum ether gave 113 mg which was recrystallized from methanol to give 5α-androst-2-ene-4α,17β-diol diacetate (**10**); m.p. 188–189°; $[\alpha]_D$ +153°; i.r. ν_{max} (CCl_4) 3030 (vinylic C—H), 1735 (ester C=O), 1728 (allylic ester C=O), 1650 (alkene C=C) cm^{-1}; p.m.r. δ ($CDCl_3$) 5.86 (1, m, olefinic proton), 5.73 (1, m, olefinic proton), 5.20 (1, m, 4β-proton), 4.57 (1, t, $J = 8.0$ Hz, 17α-proton), 2.02, 2.01 (6, 2s, acetoxy methyl), 0.95 (3, s, 19-methyl), 0.77 (3, s, 18-methyl) p.p.m.; m.s. *m/e* 374 (M^+).

Anal. Calcd. for $C_{23}H_{34}O_4$: C, 73.76; H, 9.15. Found: C, 73.86; H, 8.92.

Elution with 50–75% benzene – petroleum ether gave 67 mg which was recrystallized from methanol to give 5α-androst-3-ene-2α,17β-diol diacetate (**11**); m.p. 147–148°; $[\alpha]_D$ −47°; i.r. ν_{max} (CCl_4) 3030 (vinylic C—H), 1735 (ester C=O), 1728 (allylic ester C=O), 1650 (alkene C=C) cm^{-1}; p.m.r. δ ($CDCl_3$) 5.59 (2, m, olefinic protons), 5.27 (1, m, 2β-proton), 4.57 (1, t, $J =$ 8.0 Hz, 17α-proton), 2.02, 2.01 (6, 2s, acetoxy methyl) 0.86, (3, s, 19-methyl), 0.77 (3, s, 18-methyl) p.p.m.; m.s. *m/e* 374 (M^+).

Anal. Calcd. for $C_{23}H_{34}O_4$: C, 73.76; H, 9.15. Found: C, 73.71; H, 9.00.

5α-Androst-2-ene-4,17-dione (12) from 10

5α-Androst-2-ene-4α,17β-diol diacetate (**10**) (60 mg) was refluxed with methanolic potassium hydroxide (0.36 *M*, 1.5 ml) for 1 h. The reaction was poured into water and the product was extracted with ether. The crude product was oxidized with Jones' reagent (13) and the resulting dione recrystallized from ether (24 mg); m.p. 180–180.5° (lit. (14) m.p. 172–175°); i.r. ν_{max} (KBr) 3040 (vinylic C—H), 1730 (five-membered ring C=O), 1675 (α,β-unsaturated six-membered ring C=O) cm^{-1}; p.m.r. δ ($CDCl_3$) 6.81 (1, octet, $J = 10.0$, 6.0, and 2.5 Hz, C-2 olefinic proton), 6.01 (1, octet, $J = 10.0$, 3.0, and 1.0 Hz, C-3 olefinic proton), 0.90 (3, s, 19-methyl), 0.88 (3, s, 18-methyl) p.p.m.; m.s. *m/e* 286 (M^+).

5α-Androst-3-ene-2,17-dione (13) from 11

5α-Androst-3-ene-2α,17β-diol diacetate (**11**) (50 mg) was treated with methanolic potassium hydroxide and Jones' reagent (13) as for compound **10**. The crude product was recrystallized from ether to give the dione (21 mg); m.p. 146–147°; i.r. ν_{max} (KBr) 3030 (vinylic C—H), 1745 (five-membered ring C=O), 1667 (α, β-unsaturated six-membered ring C=O) cm^{-1}; p.m.r. δ ($CDCl_3$) 6.59 (1, q, $J = 10.0$ and 2.0 Hz, C-4 olefinic

proton), 5.99 (1, octet, J = 10.0, 3.0, and 1.0 Hz, C-3 olefinic proton), 0.92 (3, s, 19-methyl), 0.88 (3, s, 18-methyl) p.p.m.; m.s. m/e 286 (M^+).

Investigation on the Favorable Formation of 5α-Cholestan-3α-ol and 5-Cholesten-3α-ol by Catalytic Hydrogenation

MASAYOSHI ISHIGE AND MICHIO SHIOTA

Chemical Laboratory, Ochanomizu University, Otsuka, Bunkyo-ku, Tokyo, Japan

Received December 5, 1974

MASAYOSHI ISHIGE and MICHIO SHIOTA. Can. J. Chem. **53**, 1700 (1975).

Catalytic hydrogenation of 5α-cholestan-3-one was investigated to examine the factors influencing the selective formation of the axial 3α-ol and it has been found that the most satisfactory yield of 3α-ol is realized using Urushibara nickel A, the nickel catalyst treated by acid, in hydrocarbon solvents at lower temperatures under high pressure. Preparation of epicholestanol and epicholesterol by this method is described.

MASAYOSHI ISHIGE et MICHIO SHIOTA. Can. J. Chem. **53**, 1700 (1975).

On a examiné l'hydrogénation catalytique de la 5α-cholestanone-3 afin d'examiner les facteurs influençant la formation sélective de l'alcool axial-3α; on a trouvé que le meilleur rendement de cet alcool est obtenu en utilisant un nickel A d'Urushibara alors que le catalyseur de nickel est traité par de l'acide, que des hydrocarbures sont utilisés comme solvant à température plus basse et à plus haute pression. On décrit la préparation, par cette méthode, de l'épicholestanol et de l'épicholestérol. [Traduit par le journal]

Introduction

Previously we reported a study on the stereochemistry of the reduction of 5α-cholestan-3-one with water as a hydrogen donor in the presence of precipitated metals (1).

In continuation, we investigated the catalytic hydrogenation of 5α-cholestan-3-one with Urushibara nickel (U-Ni in abbreviation), U-Co, Raney-Ni, and platinum catalysts in hydrocarbon and alcohol solvents to examine the conditions for the selective hydrogenation of the ketone to 3α-ol.

Two types of catalytic reductions have hitherto been known for the stereoselective formation of the axial steroid 3α-alcohols, which have attracted attention with experimental and theoretical interests (2–7); these are the ordinary hydrogenation catalyzed by metallic catalysts in strong acidic media (2–4, *cf.* ref. 5) and the reduction with homogeneous iridium and rhodium complexes in aqueous isopropyl alcohol under reflux (8–12). Unfortunately, it is difficult to apply these methods to the selective hydrogenation of unstable steroidal ketones which are sensitive to acid and heat, *e.g.* 5-cholesten-3-one. The reduction of these compounds must be performed under the fairly milder reaction condition.

Among a few examples of the prepondrance of steroid 3α-alcohols attained in neutral media (13–17), an intriguing experiment has been demonstrated by Ruzicka and Goldberg (13); that is, epicholesterol (5-cholesten-3α-ol) is obtained by the nickel-catalyzed hydrogenation of 5-cholesten-3-one in cyclohexane at ambient temperature and hydrogen pressure. This hydrogenation might fulfill the requirements for the reduction of unstable ketones to 3α-alcohols. However, no examples have been shown on the application of the method to other cases and the details of the yield of the product and a part of the procedure are unavailable from the literature.[1] The solvent effect of hydrocarbons on stereochemistry in the hydrogenation of steroidal ketones has never been investigated sufficiently. We have thus undertaken a more extensive study of the catalytic hydrogenation of 5α-cholestan-3-one in neutral solvents at low temperature under high hydrogen pressure.

In this paper we will describe the results of the study on the factors which influence the selective formation of the axial 3α-ol and also a convenient route for the preparation of epicholestanol (5α-cholestan-3α-ol) and epicholesterol (5-cholesten-3α-ol).

[1]They have described that 631 mg of 5-cholesten-3-one is hydrogenated to 535 mg of crude epicholesterol (*ca.* 84%), from which the product melting sharply at 141 °C is obtained by repeating recrystallizations from EtOH. The method of replacement of water on the nickel catalyst by cyclohexane was not reported.

Results and Discussion

Hydrogenation of 5α-Cholestan-3-one

Catalysts and Solvents

Some workers have proposed generalized rules to predict the stereochemistry of the reduction products from cyclic ketones by catalytic hydrogenation (ref. 18 footnote 23 and refs. 19 and 20) but their application seems to be restricted.

It has been shown that in the reduction of the substituted cyclohexanones catalysts and solvents have some effect on the stereochemistry of the products (cf. ref. 20 and references therein; 21). Therefore, the effects of catalysts and solvents were investigated in the reduction of 5α-cholestan-3-one in *t*-BuOH and cyclohexane. The results are tabulated in Table 1.

In *t*-BuOH, the use of U-Ni-A and Raney-Ni catalysts resulted in the formation of almost equivalent amounts of 3α-ol and 3β-ol. The reactions with U-Ni-A in other alcohols, such as *n*-propyl, isopropyl, and *n*-butyl alcohol, gave almost the same results as in the case in *t*-BuOH (47–52% of 3α-ol). Under similar conditions, U-Co-A was slightly selective for the formation of 3α-ol, whereas U-Co-B and Raney-Co were less selective.

As is shown in Table 1, it is noteworthy that a good yield of epicholestanol has been realized by using cyclohexane as a solvent, especially, the excellent result in the presence of U-Ni-A. In the case with the active catalyst possessing basic surface, such as U-Ni-B, Raney-Ni, and platinum catalysts, the proportion of 3α-ol was somewhat decreased as compared with the above case with U-Ni-A and little difference among the results with the above three catalysts was observed.

In the reduction with U-Ni-A in other hydrocarbons, including *n*-pentane, *n*-hexane, *n*-heptane, isooctane, and methylcyclohexane, epicholestanol was found to predominate in the products. The results are given in Table 2.

The results in the table show that the stereoselectivity is generally independent of the kinds of hydrocarbons. Decalin and benzene were undesirable as solvents, for they caused the strong diminution of the reduction rate and selectivity.

It should be noted that the replacement of the water on catalyst by organic solvents is a quite critical procedure for the reduction because a small quantity of the remaining water causes the decrease of the reduction rate and selectivity. Thus, the catalyst must be repeatedly rinsed with *t*-BuOH before washing with the hydrocarbons used as reaction media. A trace of *t*-BuOH, of course, remains unremoved on the catalyst surface but the residual alcohol brings about no troubles for practical usage.

The result was also fairly satisfactory in ethyl ether (78% of 3α-ol) but not so promising in dioxane (56%). As usual, the reduction was strongly retarded in dioxane.

Reaction Temperature and Hydrogen Pressure

It has been suggested that the general factors influencing the composition of two epimers resulting from cyclohexanone derivatives include

acidity or basicity of media, reaction temperature, hydrogen pressure, and catalytic activity (21). In the hydrogenation of 5α-cholestan-3-one, we also observed that the selectivity of the products was variable with the changes of reaction temperature and hydrogen pressure. The results of the hydrogenation of 5α-cholestan-3-one with U-Ni-A in cyclohexane are summarized in Table 3.

From the results cited in the table and other observations, the general tendencies of these effects are represented as follows. (*i*) The proportion of 3α-ol decreases with an increase in reaction temperature. The reaction at lower temperatures (below 15 °C), even at high pressure, is very slow and gives poor results; a suitable temperature range is 30–35 °C. (*ii*) A high pressure of hydrogen is favorable for the formation of 3α-ol; generally, a pressure greater than 50 kg/cm² is recommended.

Epimerization and Tautomerization

Considerable work indicates that the reaction rate should be considered to be an important factor controlling the proportion of epimers obtained. Additional factors influencing stereochemistry in hydrogenation of cyclic ketones have been shown to be the epimerization between the alcohols produced (20, 22, 23) and intermediacy of the enol form of ketone during the reduction (24–26).

Eliel has described (27) that, as the fast hydrogenation is favorable for the formation of axial alcohol, the reaction facilitated by adding mineral acid is the most likely to yield products rich in axial alcohol, since the acid medium may promote rapid desorption of the alcohol once formed and decrease the chance for equilibration between two epimers.

In our experiments, the hydrogenation of 5α-cholestan-3-one proceeded more slowly in cyclohexane than in *t*-BuOH; for example, after the 1-h reaction, 95% of the starting ketone was found to be reduced in *t*-BuOH, whereas only 45% of the ketone reacted in cyclohexane.

From these results, it is suggested that the fast reaction does not necessarily favor the occurrence of the axial alcohol.[2]

With regard to epimerization, we confirmed that no more than 2% of cholestanol and 10% of epicholestanol could be epimerized when the conversion was effected by maintaining each epimer in cyclohexane at 35 °C for 48 h in the presence of excess amounts of U-Ni-A under a hydrogen pressure of 100 kg/cm². In *t*-BuOH, the epimerization proceeded about twice as fast as that in cyclohexane. It may be concluded from these facts that, in the present reduction, the isomerization between two steroid alcohols proceeds very slowly and consequently that the stereoselectivity in question is scarcely affected by epimerization. However, the situation would be more complex at elevated reaction temperatures. At 60 °C, conversion of epicholestanol to cholestanol, in fact, occurred more readily, with the accompanying formation of a small amount of hydrocarbons. After periods as long as 12 h, the resulting mixture was, for example, found to

[2]At lower reaction temperatures (below 15 °C), the reduction was strongly retarded and the portion of 3α-ol was decreased.

contain 16% of cholestanol and some hydrocarbons (*ca.* 1%) by gas chromatographic analysis.

According to Anderson and MacNaughton (24), and Friedman and Turkevich (25), it is to be expected that the reduction of 5α-cholestan-3-one takes place mainly through direct addition of hydrogen across the C=O double bond when the ketone undergoes the hydrogenation at 35 °C. In some cases, the enol mechanism might, however, participate in the course of the reaction. For example, when the cobalt-catalyzed reduction of 5α-cholestan-3-one in *t*-BuOH, which gave 61% of 3α-ol, was stopped at 30–50% completion of the run, the gas chromatogram of the reaction mixture, treated with a trimethylsilyl reagent, often showed a small peak of unknown substance in the region of alcohols, together with three peaks of known compounds. It was found that the compound giving this peak was readily converted to 5α-cholestan-3-one when the sample was filtered through silica gel layer with *n*-hexane eluent. The pure steroidal ketone did not react with trimethylsilyl reagent but a sample of ketone in contact with a trace of acid reacted with the reagent to yield the trimethylsilyl ether, which gave the identical gas chromatogram peak as in the above case. From these facts, the peak is reasonably assigned to the trimethylsilyl ether resulting from the enol tautomer of the ketone. When the reduction was carried out in the presence of a trace of hydrochloric acid, the yield of 3α-ol was raised to 77% and the peak area of the enol in the gas chromatogram was observed to be increased as compared with the one in the absence of acid.

These results would suggest the possibility of participation of the enol form in the present reaction.

Steric Factor

On the basis of the fact that substituted cyclohexanones are hydrogenated preferably to give the corresponding axial alcohols in EtOH with Raney-Ni, Mitsui *et al.* (28) have stated that the favorable formation of axial alcohols will take place from the cyclohexanone derivatives in the presence of Raney-Ni catalyst. The results have been interpreted in terms of the stabilities of the adsorbed transition complexes due to the catalyst hindrance.

In the nickel-catalyzed reduction of 5α-cholestan-3-one in alcohol media, the preferential production of axial alcohol could not be observed under the conditions employed, as was described above. If the product-determining step is related to the one of formation of adsorbed species, this fact indicates that the equatorial side at C-3 of the steroid may be shielded from the attack of the metal. It is generally inferred that alcohol media strongly adsorbed on the catalyst surface may act not only as useful proton donors to facilitate the reaction but also as materials influencing the stereochemistry of the adsorption of cyclic ketones. If this is the case, the angular methyl group at C-10 and the rigid ring system of the steroidal ketone might behave as the catalyst hindrance for the β-side approach of the catalyst.

On the other hand, hydrocarbon solvents may be weakly adsorbed on the metal surface. Thus, the substrate could be allowed to interact with the metal surface freely enough to form the more stable species adsorbed on the equatorial side (28).

Preparation of Epicholestanol and Epicholesterol

It has now been found that nickel catalysts are effective for the preparation of epicholestanol when they are used in cyclohexane at 30–35 °C under the high pressure of hydrogen. Of all the catalysts used, U-Ni-A is the most suitable because the catalyst is easily obtained and the yield of the axial 3α-alcohol is excellent.

It is notable that this hydrogenation method could be applied to the reduction of 5-cholesten-3-one to epicholesterol without any isomerization or saturation of the 5,6-double bond of the ketone. No hydrogenolysis occurred during the reaction, as well. Some results are listed in Table 4.

With an analogous trend as in the case of epicholestanol, cyclohexane as a solvent played an important part in increasing the yield of epicholesterol and this solvent effect was conspicuously marked under high hydrogen pressure. The reactions at higher temperatures (*e.g.* at 80 °C) decreased the yield of the 3α-ol and caused the formation of some by-products.

Urushibara cobalt A (U-Co-A) also catalyzed the hydrogenation of 5-cholesten-3-one when used in *t*-BuOH but the catalyst was less proper for the present purpose because the formation of the 3α-ol was not so predominant.

Experimental

All melting points were measured on a hot stage and are uncorrected. Infrared spectra were recorded on KBr discs with a JASCO IR-G instrument and n.m.r. spectra were taken in chloroform-*d* and carbon tetrachloride with a JEOL C-60HL spectrometer using tetramethylsilane as an internal reference.

Catalysts

Preparation of Precipitated Nickel (1, 29)

A warmed aqueous solution of nickel chloride (4.04 g of $NiCl_2 \cdot 6H_2O$ in 10 ml of water) (*ca.* 80 °C) was added to hot zinc dust mud (10 g of zinc powder and 3 ml of water) at once with vigorous shaking. The deposit was collected and washed successively with water, ethanol, and ether and then dried on a filter paper;[3] yield, 10–11 g.

U-Ni-A Catalyst (16, 29)

A 13% aqueous solution of acetic acid (*ca.* 6 ml) was added all at once to precipitated nickel (10 g). The reaction vessel was occasionally shaken to prevent the contents from foaming over due to the violent evolution of hydrogen. When the reaction subsided, additional aqueous acetic acid was added until the solid matter settled, and then the supernatant liquid was decanted. Twice more the acid treatment was carried out using each *ca.* 30 ml of aqueous acetic acid and at an end of the acid treatment we could observe the faint green of the solution. The nickel catalyst thus obtained was washed by suspension in water and decantation until the washings were neutral to litmus. When we used hydrocarbon as a solvent in hydrogenation, the further washing processes were repeated several times with *t*-butyl alcohol and the hydrocarbon successively. The catalyst contains about 0.8 g of nickel (29).

U-Ni-B Catalyst (29, 30)

This catalyst was obtained from precipitated nickel (5 g) by using a 10% aqueous solution of sodium hydroxide (*ca.* 100 ml), instead of acetic acid solution in the case of U-Ni-A. The catalyst is dark grey and contains about 1 g of nickel and large amounts of zinc.

U-Co-A and U-Co-B Catalysts (29)

U-Co catalysts were prepared from 4.04 g of $CoCl_2 \cdot 6H_2O$ and 10 g of zinc powder by a similar procedure described in the preparation of U-Ni catalysts.

Raney-Ni Catalyst (W5)

Raney nickel catalyst (W5) was obtained from 1.5 g of Raney alloy according to the usual procedure (31). The nickel was washed successively with water (about 50 °C), *t*-butyl alcohol, and cyclohexane.

Hydrogenation of 5α-Cholestan-3-one

Hydrogenation with U-Ni-A in Cyclohexane

As a typical example, the hydrogenation with U-Ni-A in cyclohexane will be described. The freshly obtained U-Ni-A (from 5 g of precipitated nickel) and cyclohexane (30 ml) were transferred to a 100-ml autoclave equipped with a magnetic stirring device. 5α-Cholestan-3-one (1.5 g) was added and the hydrogenation was conducted at 35 °C for 3 h with stirring of 1000 cycle/min under the hydrogen pressure of 100 kg/cm². From the resultant mixture, the nickel was removed by filtration and then the filtrate was evaporated *in vacuo*. Recrystallization of the crude crystals from methanol yielded *ca.* 1.2 g of epicholestanol (80% yield); m.p. 188–189 °C (lit. (32) m.p. 186–187 °C); i.r. (KBr, cm^{-1}): 3300 (sharp, strong), 1030 and 1000; n.m.r. (CCl_4, TMS): δ 3.90 (broad equatorial H at C-3).

Small-scale Hydrogenation under High Pressure

The reduction using no more than 100 mg of 5α-cholestan-3-one was carried out in an autoclave equipped with a magnetic stirring device in the following manner. To a 5-ml Erlenmeyer flask was added 5α-cholestan-3-one (100 mg), cyclohexane (3 ml), and a given amount of catalyst (*cf.* Tables 1–4). The flask was attached to the adaptor and then settled in the autoclave as shown in Fig. 1. The hydrogenation was performed under the given condition in the usual manner. By this method, small amount of sample (1–100 mg) can be easily hydrogenated under high pressure without any special device.

Hydrogenation of 5-Cholesten-3-one

Hydrogenation with U-Ni-A in Cyclohexane

By using U-Ni-A (from 5 g of precipitated nickel), 5-cholesten-3-one (1.5 g) was hydrogenated in cyclohexane (30 ml) at 35 °C for 2.5 h with stirring of 1000 cycle/min at 100 kg/cm² pressure. After the removal of solid matter from the resultant mixture by filtration, evaporation of the filtrate *in vacuo* gave the crystals. The crystals gave 1.38 g of epicholesterol (92% yield) and 0.08 g of cholesterol (5% yield), when they were chromatographed on silica gel (150 g, 3.5 cm(ϕ) × 31 cm column) with an eluent of *n*-hexane–ether (9:1).

Epicholesterol: m.p. 139–140 °C (lit. (13) m.p. 141 °C); i.r. (KBr, cm^{-1}) 3350 (sharp, strong), 1022, 1007, 993, and 800; n.m.r. (chloroform-*d*, TMS): δ 5.45 (olefinic proton, broad doublet, J = 5.0 Hz) and 4.03 (equatorial proton at C-3, broad). The relative intensities of these peaks were approximately 1:1. By addition of a few drops of D_2O, the collapsed peak centered at δ 4.03 changed into the broad triplet peak with J = 3.0 Hz. Acetylation of the above-obtained epicholesterol af-

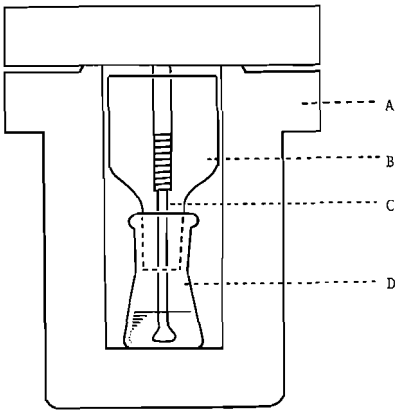

FIG. 1. Small-scale High-pressure Hydrogenator: *A*, autoclave; *B*, adaptor; *C*, stirrer (glass); *D*, Erlenmeyer flask.

[3]When the precipitated nickel thus obtained is used immediately after the preparation, we can neglect the washing processes with ethanol and ether. The dried precipitated nickel can be stored in a desiccator for a long period.

forded the acetate of m.p. 84–85 °C (lit. (13) m.p. 85 °C).[4]

Hydrogenation with U-Co-A in t-BuOH

The hydrogenation of 5-cholesten-3-one (1.5 g) catalyzed by U-Co-A was carried out in *t*-BuOH at 35 °C for 4 h at 115 kg/cm² hydrogen pressure. From the crude product, 0.75 g of epicholesterol (50% yield) and 0.74 g of cholesterol (49% yield) were isolated by column chromatography using silica gel. When cyclohexane solvent was used instead of *t*-BuOH, the reduction with U-Co-A proceeded very slowly and the proportion of 3α-ol in the products was lower than that obtained using *t*-BuOH.

Hydrogenation with Raney-Ni in Cyclohexane

By using the Raney-Ni freshly obtained as described above, 5-cholesten-3-one (1.5 g) was hydrogenated in cyclohexane (25 ml) at 35 °C for 1 h at 105 kg/cm² hydrogen pressure. The crude product was chromatographed on silica gel to give 1.22 g of epicholesterol (81% yield).

Gas–Liquid Partition Chromatographic Analyses

The analyses for data in Tables 1–4 were made by gas chromatography, after treatment of the products with *N,O*-bis(trimethylsilyl)acetamide. Gas–liquid partition chromatography analytical conditions: 3 m glass column packed with 1.5% Silicone OV-17 on silanized Shimalite W (80–100 mesh); temperature, *ca.* 250 °C; detector, HFID. All the chromatograms showed that the starting material was completely converted into the alcohols under the conditions employed.

Acid Catalyzed Rearrangements of Conjugated Cyclopropyl and Epoxy Ketones

E. LEE-RUFF AND P. KHAZANIE
Department of Chemistry, York University, Toronto, Ontario M3J 1P3

Received October 11, 1974

E. LEE-RUFF and P. KHAZANIE. Can. J. Chem. **53**, 1708 (1975).

A series of spiro[*n*.2]alkan-2-ones and their 6 and 7 oxa derivatives were subjected to acid catalysis. In the former series, products arising from hydroxy(cyclopropyl)carbinyl cations are observed, while in the latter series epoxide oxygen protonation appears to be the dominant reaction pathway. A novel oxavinylcyclopropane rearrangement is reported.

E. LEE-RUFF et P. KHAZANIE. Can. J. Chem. **53**, 1708 (1975).

On a soumis à une catalyse acide une série de spiro[*n*.2]alkanones-2 ainsi que leurs dérivés oxa 6 et 7. Dans la première série, on a observé des produits dérivant des cations hydroxy(cyclopropyl)carbinyles alors que dans les dernières séries, il semble que la protonation de l'oxygène de l'époxyde soit le chemin réactionnel prédominant. On rapporte un nouveau réarrangement oxavinylcyclopropane. [Traduit par le journal]

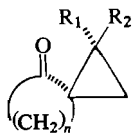
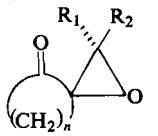
The interaction of cyclopropyl and epoxide groups with an adjacent electron-deficient center continues to be a topic of extreme interest. The recent results on the acid catalyzed rearrangements of epoxy ketones reported by Williams *et al.* (1) and the interest in the protonation of cyclopropanes and epoxides (2) prompted us to report the results of the acid rearrangements of a series of spiro[*n*.2]alkanones and their 6 and 7 oxa derivatives. These systems were chosen because of their conformational semblance to the bisected forms of cyclopropylcarbinyl and epoxycarbinyl cations allowing for maximum conjugation of the three-member ring with the adjacent carbocationic center (3, 4).

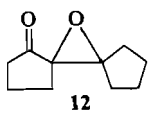
Ketones **1**–**8** were prepared from the corresponding alkylidene cycloalkanones by a slightly modified three step sequence described in ref. 5. The *syn* and *anti* isomers **2**, **4** and **3**, **5**



1 $R_1 = R_2 = H; n = 3$
2 $R_1 = CH_3; R_2 = H; n = 3$
3 $R_1 = H; R_2 = CH_3; n = 3$
4 $R_1 = R_2 = CH_3; n = 3$
5 $R_1 = R_2 = H; n = 4$
6 $R_1 = CH_3; R_2 = H; n = 4$
7 $R_1 = H; R_2 = CH_3; n = 4$
8 $R_1 = R_2 = CH_3; n = 4$



9 $R_1 = R_2 = CH_3; n = 3$
10 $R_1 = H; R_2 = CH_3; n = 4$
11 $R_1 = R_2 = CH_3; n = 4$



12

were obtained from the corresponding *syn*- and *anti*-2-ethylidenecycloalkanones, respectively.

The rearrangements of all cyclopropyl ketones were carried out in acidic benzene solutions at room temperature or under reflux. The results for the spiroheptanones are shown in Scheme 1. Ketone **1** appeared to be stable at room temperature in acidic benzene. Upon reflux it was slowly polymerized. However with polyphosphoric acid (PPA) a small amount (10%) of 2-ethylcyclopent-2-enone (**13**) was isolated as was also reported by Conia and Amice (6).

Ketones **2** and **3** were slightly more reactive and in refluxing H_2SO_4–C_6H_6, both gave identical mixtures of **14** and **15**. The structure of **14** was established by its synthesis from condensation of cyclopentanone and propionaldehyde. The structure of **15** was confirmed by its independent synthesis from the PPA rearrangement of **14**, a reaction which has been reported for several 2-alkylidenecyclopentanones (7). Upon prolonged reaction of **2** or **3** increasing amounts of **15** were obtained at the expense of **14**. In a separate study it was shown that **14** rearranged

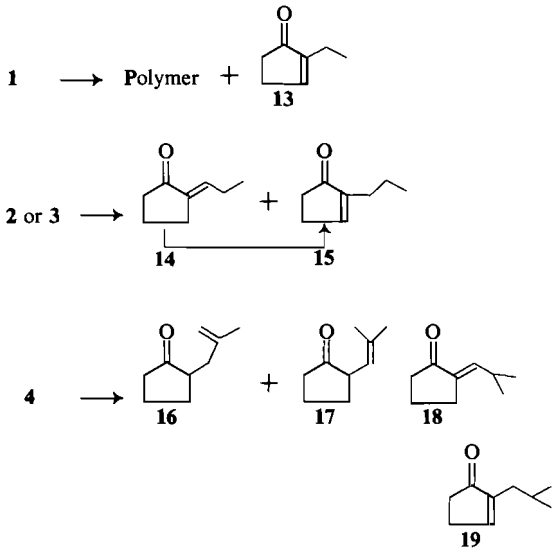
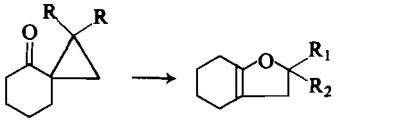


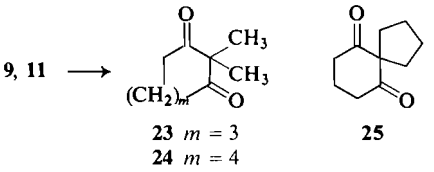
SCHEME 1. Rearrangement of spiroheptanones

to **15** under the same conditions. Reaction of the dimethyl derivative **4** gave a mixture of ketones **16** and **17**. The identity of these ketones was established on the basis of their spectral data and hydrogenation to 2-isobutylcyclopentanone which was independently synthesized. There was no evidence for the formation of ketones **18** and **19**. The relative rates for the acid catalyzed rearrangements determined by g.l.c. monitoring of starting material were found to be in the order **4** > **2** and **3** > **1**.

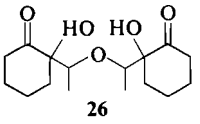


The homologous cyclohexanones appeared to be quite acid labile relative to the cyclopentanones and *at room temperature* all gave the corresponding hexahydrobenzofurans **20–22** as the only products. The structural assignments of the products were based on spectral data and independent synthesis (8). In a qualitative study, it was shown that the rearrangement rates of these ketones were in the order **8** > **7** and **6** > **5**.

The rearrangements of the epoxy ketones followed a different course from the cyclopropyl ketones. Reaction of ketones **9**, **11**, and **12** all gave the ring expanded β-diketones **23**, **24**, and **25**, respectively. The structures of diketones

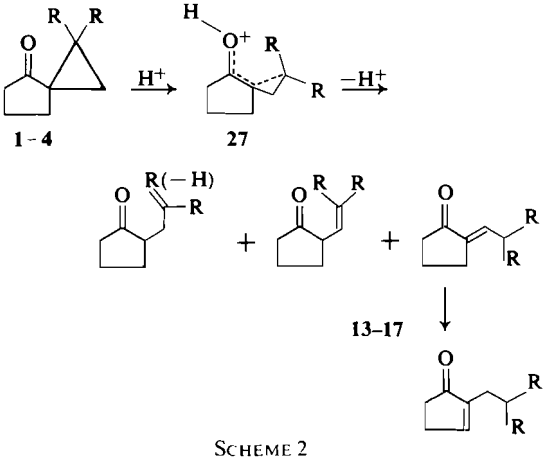


23 and **24** were unequivocally established by their independent syntheses from dimethylation of cyclohexan-1,3-dione and cycloheptan-1,3-dione (9, 10), respectively. The structure of **25** was inferred on the basis of its spectral data and comparison of this with a previously reported preparation (1, 11). The reaction of ketone **10** in acid gave a complex mixture containing no volatile material. The major product (23%) was a crystalline material which analyzed for 2 equiv. of **10** and 1 equiv. of water. The spectral data indicated the structure **26**.



Discussion

The rearrangements of cyclopropyl ketones **1–4** to the enones **13–17** can be rationalized in terms of the mechanistic sequence shown in Scheme 2. Initial protonation of the carbonyl oxygen leads to the formation of a delocalized oxahomoallylic cation **27** and subsequent 1,2



SCHEME 2

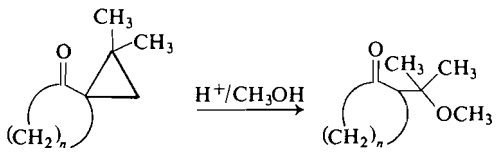
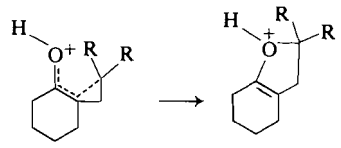
hydrogen transfer followed by loss of proton or direct proton elimination would result in the observed products. Cyclopentanones **13** and **15** are most likely secondary products since it was shown independently by Conia and us (7) that 2-alkylidenecyclopentanones rearrange under acidic conditions to the more stable 2-cyclopentenones. Although there is evidence for the delocalization of the positive charge in protonated cyclopropyl ketones from n.m.r. deshielding effects (12, 13), there have not been any reported products exhibiting this effect after quenching with base. Our present study indicates that there is significant positive charge developed at C-7 (**5–8**, C-6 in **1–4**) in the transition state of the rate determining step in these systems based upon the relative rates of rearrangement of ketones **1–4** and **5–8**. Furthermore reaction of **4** and **8** with acidic methanol led to their instantaneous conversion to ketoethers **28** and **29**, respectively.



4, 8 **28** $n = 3$ **29** $n = 4$

The rearrangements of ketones **5–8** to the hexahydrobenzofurans **21–23** is formally analogous to a protonated version of the oxavinylcyclopropane rearrangement (14). Conceivably a 1-oxacyclopent-2-enyl cation **31** is formed from protonated cyclopropylketone **30** by a symmetry



30 **31**

allowed cyclization. A similar observation was reported by Pittman and McManus (15); however in their systems there was evidence only for the formation of the tautomeric 1-oxacyclopent-1-enyl cation. That no bicyclic dihydrofurans are detected in the cyclopentanone series can be rationalized in terms of ring strain effects due to the difference in ring size.

The acidic rearrangements of the epoxy ketones follow a completely different course from the cyclopropyl ketones. All of the products can be explained in terms of an initial epoxide oxygen protonation followed by 1,2 acyl shifts. The difference in reactivities between cyclopropyl and epoxy ketones is due to the inclusion of an additional and equally competing basic oxygen in the latter. Similar observations were made by other workers (1, 16, 17) and in all cases 1,3-diketones resulting from C_β—O cleavage and acyl shift were obtained. These results are in contrast to the thermolytic study on the identical systems (18) where 1,3-diketones were obtained from initial C_α—O cleavage followed by 1,2 alkyl shift. The selectivity of these rearrangements provide a useful synthetic pathway for the preparation of 2,2-dialkylated or 2-monoalkylated (provided the alkyl group stabilizes a positive charge) two carbon ring-expanded 1,3-diketones from cyclic monoketones. That the epoxycarbinyl cation or the 1-oxabicyclobutonium ion does not play an important role in these rearrangements is evident from the absence of any oxetanyl derivatives as would be expected if these ions were quenched by base (19).

Experimental

Melting points were uncorrected. The i.r. spectra were recorded with a Unicam SP 1000 instrument. The n.m.r. spectra were measured on a Varian A-60, Ha-100, and EM-360 spectrometers. Samples were dissolved in CCl_4 and $CDCl_3$ solvents using TMS as the internal standard. Vapor phase chromatographic analyses and collections were performed on a Varian Aerograph Series 1700 instrument using the following columns: (*A*) a 5 ft 4 in. steel column (0.25 in. o.d.) packed with 3% SE-30 on Varaport 30, (*B*) a 6 in. aluminum column (0.25 in. o.d.) packed with 10% FFAP on Chromosorb P, (*C*) a 6 ft glass column (0.25 in. o.d.) packed with 6% SE-30 + 4% QF-1 on Chromosorb W AW, DMCS treated, and (*D*) a 9 ft alumina column (0.25 in. o.d.) packed with 3% OV 25 on Chromosorb W, high performance, 80–100 mesh. Microanalysis were performed by Gygli Microanalytical Labs, Toronto. All of the starting materials were prepared according to procedures described in refs. 18 and 20.

Rearrangement of Spiro[2.4]heptan-2-one (1) with Sulfuric Acid

The title compound (100 mg) was dissolved in 10 ml benzene containing 100 mg of 95% sulfuric acid. The solution was refluxed on an oil bath for 15 min. The work-up of the reaction mixture gave a polymeric material and 18 mg of the starting material.

Rearrangement of anti-6-Methylspiro[2.4]heptan-2-one (3) with Sulfuric Acid

Ketone **3** (80 mg) was dissolved in 10 ml benzene containing 80 mg of 95% sulfuric acid. The solution was refluxed for 10 min. It was then cooled in an ice bath and worked-up by standard procedures. Vapor phase chroma-

Compound ***15***: b.p. 59–60°/113 mm; i.r. (CCl_4) 1060, 1105, 1715, 3040 cm^{-1}; n.m.r. (CCl_4) δ 0.92 (3H, t, J = 7 Hz), 1.12–2.70 (8H, m), 7.2 (1H, m); *m/e* 124.

Anal. Calcd. for $C_8H_{12}O$: C, 77.41; H, 9.67. Found: C, 77.30; H, 9.63.

*Rearrangement of syn-6-Methylspiro[2.4]heptan-2-one (**2**) with Sulfuric Acid*

The same procedures employed for ketone **3** was used. Reaction of 70 mg of **2** gave 17 mg of ketone **15**. Ketone **14** was detected in the mixture by v.p.c. to the extent of 6% after 10 min of reaction.

*Preparation of anti-2-Propylidenecyclopentanone (**14**)*

A mixture of cyclopentanone (16.8 g, 0.2 mol), propionaldehyde (11.6 g, 0.2 mol), and 0.5% KOH (20 ml) was stirred at 0° for 30 min and then at room temperature for 15 h. Using standard work-up conditions 11.2 g of a fraction, b.p. 70–100°/1.2 mm, was obtained. This fraction was then treated with orthophosphoric acid and benzene and worked-up in the usual manner to give 6.9 g (27%) of *anti*-2-propylidenecyclopentanone (**14**) identical in all respects with a sample obtained above.

*Preparation of 2-n-Propyl-2-cyclopentenone (**15**)*

A mixture of *anti*-2-propylidenecyclopentanone (1.0 g) and polyphosphoric acid (1:1 mixture of P_2O_5 and H_3PO_4 aged for 10 h at 100°) was heated at 100° for 30 min in a flask equipped with a condenser. Water (7 ml) was added to the cooled mixture and 50 ml of ether was added for extraction. The ether layer was washed with brine, dried over anhydrous magnesium sulfate, and ether evaporated to give 0.85 g of a crude liquid which was purified by distillation, b.p. 59–60°/1.3 mm; yield 0.51 g (51%). This was identical in all respects with a sample prepared above.

*Rearrangement of anti-2-Propylidenecyclopentanone (**14**) with Sulfuric Acid*

anti-2-Propylidenecyclopentanone (80 mg) was dissolved in 10 ml benzene containing 80 mg 95% sulfuric acid. The reflux and work-up as described in the rearrangement of **3**, gave 33 mg of 2-propyl-2-cyclopentenone (**15**) and approximately 7 mg of the starting ketone.

*Rearrangement of 6,6-Dimethylspiro[2.4]heptan-2ψone (**4**) in Sulfuric Acid*

Ketone (**4**) (75 mg) was dissolved in 6 ml Anal R benzene and the solution was cooled in an ice bath. The benzene which froze at this temperature was allowed to thaw and to this solution 125 mg of 95% sulfuric acid was added at the thawing temperature. The solution was stirred at this temperature for 1 min. It was then neutralized with sodium bicarbonate solution and worked-up in the usual way to give 56 mg of a crude mixture, which when analyzed by v.p.c. (column *C*) showed enone **16** (11 mg), **17** (10 mg), and unreacted **4** (22 mg). Compounds **16** and **17** were collected on v.p.c.

Compound ***16***: i.r. 3080, 1740, 1155, 897 cm^{-1}; n.m.r. δ 1.71 (3H, s), 2.70–1.60 (9H, m), 4.69 (2H, bs) p.p.m.

Anal. Calcd. for $C_{10}H_{14}O$: C, 78.92; H, 10.67. Found: C, 78.72; H, 10.53.

Compound ***17***: i.r. 3050–3100, 1745, 1150 cm^{-1}; n.m.r δ 1.55 (3H, s), 1.62 (3H, s), 1.6–3.0 (7H, m), 4.90 (1H, d).

Anal. Calcd. for $C_{10}H_{14}O$: C, 78.92; H, 10.67. Found: C, 78.80; H, 10.45.

*Preparation of anti-2-Isobutylidenecyclopentanone (**18**)*

A mixture of 16.8 g (0.2 mol) of cyclopentanone, 14.4 g (0.2 mol) of isobutyraldehyde, and 20 ml of 0.5% KOH was stirred at 0° for 30 min and then at room temperature for 12 h. The reaction mixture was worked-up to give 12.4 g of a fraction, b.p. 80–100°/1.2 mm which was then treated with orthophosphoric acid C_6H_6; yield of product, 7.7 g (28%); b.p. 62–63°/1.5 mm (lit. (22) b.p. 86°/11 mm); i.r. (CCl_4) 945, 1142, 1178, 1205, 1290, 1410, 1466, 1653, 1722, 2960 cm^{-1}; n.m.r. (CCl_4) δ 1.02 (6H, d), 1.62–2.8 (7H, m), 6.23 (1H, a doublet of triplets); λ_{max} (EtOH) 246 nm (ε 8004); *m/e* 124.

*Hydrogenation of anti-2-Isobutylidenecyclopentanone (**18**)*

The title ketone (58 mg) was hydrogenated at atmospheric pressure with 8 mg of platinum oxide in 6 ml of ethyl acetate. One equivalent of hydrogen was taken up whereupon the hydrogen uptake ceased. The solution was filtered and the solvent removed under reduced pressure to give 53 mg of essentially pure 2-isobutylcyclopentanone (analyzed by v.p.c., column *A*); i.r. (neat) 1183, 1392, 1410, 1432, 1480, 1492, 1756 (C=O stretch) cm^{-1}; n.m.r. (CCl_4) δ 0.77–1.1 (6H, two doublets centered at 0.83 (J = 1.5 Hz) and 0.9 (J = 1.5 Hz), 1.15–2.4 (10H, m): *m/e* 126.

*Hydrogenation of Compound **16***

A solution of 25 ml of the title compound in 6 ml ethyl acetate was hydrogenated over 5 mg of platinum oxide. Work-up and isolation gave 2-isobutylcyclopentanone in almost quantitative yield. This ketone had i.r. and n.m.r. spectra identical with those of a sample prepared by hydrogenation of *anti*-2-isobutylidenecyclopentanone.

*Hydrogenation of Compound **17***

This compound was hydrogenated just as ketone **16** and gave 2-isobutylcyclopentanone in quantitative yield. The i.r. and n.m.r. of this compound were identical with those of a sample prepared by hydrogenation of **16**.

*Rearrangement of Spiro[2.5]octan-2-one (**5**) with Sulfuric Acid*

Ketone **5** (75 mg) was dissolved in 6 ml Anal R benzene containing 130 mg of 95% sulfuric acid. The solution was stirred for 83 h at room temperature and then neutralized with 7% sodium bicarbonate solution. The mixture was taken up with an additional 25 ml benzene, the benzene layer washed neutral with saturated sodium chloride solution, dried, and evaporated to give 76 mg of a crude

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

product. Vapor phase chromatography (column *C*) of this sample showed **5** and 2,3,4,5,6,7-hexahydrobenzofuran (**20**) in a ratio of 1:6. The mixture was purified by preparative t.l.c. (silica gel) to give 42 mg of **20**. The i.r. and n.m.r. spectra of this compound were identical with those of the sample obtained by independent synthesis described below.

Synthesis of 2,3,4,5,6,7-Hexahydrobenzofuran (20)

Starting from the ethylene ketal of 2-cyclohexanoneacetate, the title compound was prepared by the following steps according to ref. 8.

Lithium Aluminum Hydride Reduction of the Ketal Ester

Following standard procedures for the LAH reductions of esters using 1.4 g (0.005 mol) of the above ketal ester and 300 mg (0.008 mol) of lithium aluminum hydride in 30 ml anhydrous ether, 1.1 g of ketal alcohol was obtained. This compound was purified by vacuum transfer: i.r. (CCl_4) 925, 952, 1057, 1090, 1160, 1445, 2920, 3400 cm^{-1}; n.m.r. (CCl_4) δ 1.0–2 (11H, m), 3.33–4.2 (7H, m, 3.88, s).

Hydrolysis of the Ketal Alcohol

Using the procedure described for the hydrolysis of ketal alcohol (8) from 0.8 g of ketal alcohol in 15 ml acetone and 5 ml water containing 15 mg of *p*-toluenesulfonic acid was obtained 0.6 g of hemiketal: i.r. (CCl_4) 900, 947, 1008, 1084, 1447, 2940, 3400 cm^{-1}; n.m.r. (CCl_4) δ 0.83–2.6 (11H, m), 3.3–4.05 (2H, m), 4.45 (1H, s).

Preparation of 2,3,4,5,6,7-Hexahydrobenzofuran (20)

The above hemiketal was heated to 125° and distilled at 28 mm to give the title compound in quantitative yield with the elimination of water: i.r. (CCl_4) 890, 933, 982, 1202, 1282, 1382, 1443, 1610, 2850, and 2930 cm^{-1}; n.m.r. (CCl_4) δ 4.17 (2H, t, J = 9 Hz), 2.47 (2H, t, J = 9 Hz), 1.2–2.2 (8H, m). These spectra were identical with the spectra described in the literature (8) and the product obtained in the rearrangements of **20**.

Rearrangement of anti-7-Methylspiro[2.5]octan-2-one (7) with Sulfuric Acid

Ketone 7 (75 mg) was dissolved in 8 ml Anal R benzene containing 120 mg of 95% sulfuric acid. The solution was stirred for 7 h at room temperature. It was then worked-up in ether by standard procedure to give 54 mg of 2-methyl-2,3,4,5,6,7-hexahydrobenzofuran (**21**) as the sole product. This compound displayed i.r. and n.m.r. spectra identical with those of the compound obtained by independent synthesis (8).

Rearrangement of syn-7-Methylspiro[2.5]octan-2-one (6) with Sulfuric Acid

The above procedure was used for the acid reaction of ketone **6**. Using 80 mg of **6**, 60 mg of 2-methyl-2,3,4,5,6,7-hexahydrobenzofuran (**21**) was obtained as the sole product. Its spectral data were identical with the sample prepared above.

Rearrangement of 7,7-Dimethylspiro[2.5]octan-2-one (8) with Sulfuric Acid

The same conditions described in the acid catalysis of **5** were used and from 75 mg of ketone **8**, 51 mg of 2,2-dimethyl-2,3,4,5,6,7-hexahydrobenzofuran was obtained after 8 h. The spectral data of this compound were identical with the compound obtained by independent synthesis described below.

Synthesis of 2,2-Dimethyl-2,3,4,5,6,7-hexahydrobenzofuran (22)

From ethyl 2-cyclohexanone acetate (23), the title compound was prepared as follows.

Preparation of Ethylene Ketal of 2-Cyclohexanoneacetate

A solution of ethyl 2-cyclohexanone acetate (3.68 g, 0.02 mol), ethylene glycol (1.24 g, 0.02 mol), and *p*-toluenesulfonic acid (20 mg) in 75 ml benzene was refluxed with a Dean Stark trap until no more water was collected. The reaction mixture was neutralized with sodium methoxide and worked-up with additional 75 ml benzene to give 4 g (89%) of the ketal: i.r. (neat) 927, 950, 1038, 1097, 1160, 1280, 1293, 1450, 1733; n.m.r. (CCl_4) δ 1.05–2.65 (14H, m, a triplet at 1.19, J = 7 Hz), 3.85 (4H, s), 4.5 (2H, q, J = 7 Hz), 3.85 (4H, s), 4.5 (2H, q, J = 7 Hz).

The Reaction of 2-Cyclohexanone Ethylene Ketal with Methylmagnesium Iodide

To a solution of methyl magnesium iodide (0.03 mol) in 40 ml anhydrous ether was added ketal ester (3.42 g, 0.015 mol) in 60 ml ether over a period of 30 min at room temperature. The mixture was refluxed for 1 h, decomposed with a saturated solution of ammonium chloride, and worked-up in the usual way to give 2.3 g (72%) of dimethyl carbinol: i.r. (neat) 912, 948, 1020, 1045, 1085, 1130, 1150, 1223, 1258, 1366, 1380, 1450, 1465, 3430 cm^{-1}; n.m.r. (CCl_4) δ 1–1.95 (17H, m, singlet at 1.1), 3 (1H, OH, disappeared with D_2O), 3.92 (4H, s).

Hydrolysis of the Ketal Alcohol

The ketal alcohol was dissolved in 50 ml acetone and 15 ml water containing 40 mg of *p*-toluenesulfonic acid. The solution was heated to reflux on an oil bath for 1 h. The mixture was cooled, excess acetone removed under reduced pressure and extracted with ether to give the hemiketal in equilibrium with some 2-(2′-methyl-2′-hydroxypropyl)cyclohexanone in 86% yield: i.r. (neat) 878, 948, 970, 1025, 1080, 1140, 1157, 1275, 1364, 1382, 1450, 1712 (weak), 3400 cm^{-1}; n.m.r. (CCl_4) δ 0.93–2.4 (17H, m, with a singlet at 1.33), 3.2–3.8 (1H, a broad multiplet.)

Preparation of 2,2-Dimethyl-2,3,4,5,6,7-hexahydrobenzofuran (22)

The hemiketal was heated to 130° and distilled to give 2,2-dimethylhexahydrobenzofuran with the elimination of water in quantitative yield, b.p. 80–82°/18 mm (lit. (24) b.p. 85°/15 mm); i.r. (neat) 785, 868, 907, 1086, 1143, 1193, 1220, 1235, 1270, 1298, 1369, 1380, 1450, 1711, 2840, 2930, 2970 cm^{-1}; n.m.r. (CCl_4) δ 1.28 (6H, s), 1.66 (4H, m), 1.93 (4H, m), 2.29 (2H, m).

Rearrangement of 2-Isopropylidenecyclopentanone Oxide (9)

A solution of ketone **9** (100 mg) in 10 ml benzene containing 50 mg of 95% sulfuric acid was stirred at room temperature for 15 min. The reaction was quenched with 4 ml of 10% sodium bicarbonate solution and worked-up using the usual procedure. The sole product from **9** was identified as 2,2-dimethylcyclohexane-1,3-dione (71%): i.r. (neat) 1000, 1028, 1132, 1285, 1315, 1380, 1463, 1695,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

1725 cm^{-1}; n.m.r. (CCl_4) δ 1.21 (6H, s), 1.65–2.25 (2H, m), 2.43–2.83 (4H, m). This compound was synthesized independently (9). The spectra of the synthesized sample were identical with those of the sample obtained by acid catalysis of **9**.

Rearrangement of 2-Isopropylidenecyclohexanone Oxide (11)

The procedure described for the acid catalysis of **9** was followed and from 200 mg of epoxyketone 131 mg of 2,2-dimethylcyclopentane-1,3-dione was obtained as the sole product in 15 min: i.r. (CCl_4) 868, 950, 1100, 1313, 1380, 1447, 1462, 1702, 2860, and 2950 cm^{-1}; n.m.r. (CCl_4) δ 1.17 (6H, s), 1.6–2.05 (4H, m), 2.2–2.6 (4H, m). This compound was synthesized independently from dimethylation of cyclopentane-1,3-dione (9) and the spectra of the two samples were identical.

Rearrangement of 2-Cyclopentylidenecyclopentanone Oxide (12)

Following the procedure described for the acid catalysis of **9**, using 200 mg of **12** and 75 mg of 95% sulfuric acid in 20 ml benzene, 158 mg of the product **25** was obtained. The reaction was complete in 10 min: i.r. (neat) 1032, 1080, 1104, 1275, 1313, 1450, 1692, 1722, 2865, 2950 cm^{-1}; n.m.r. ($CDCl_3$) δ 2.62 (4H, t), 1.40–2.35 (10H, m). The spectral properties of this compound were identical with those described in the literature (1).

Rearrangement of 2-Ethylidenecyclohexanone Oxide (10)

Ketone **10** (150 mg) was dissolved in 15 ml benzene containing 60 mg of 95% sulfuric acid and the solution stirred at room temperature for 3 h. The mixture was extracted with an additional 30 ml benzene, and the extract washed with saturated aqueous sodium chloride solution until neutral. The benzene was removed under reduced pressure. The v.p.c. of the residual sample showed a multitude of peaks. A comparison of the i.r. and the n.m.r. spectra of the crude mixture with those of the products collected on v.p.c. indicated decomposition of the products on the column. Upon addition of 15 ml ether a white solid precipitated, m.p. 109–111° (23%). This was filtered off and recrystallized from a mixture of *n*-hexane and benzene.

The structure of this compound was identified as the condensation product **26** on the basis of its spectral properties: i.r. (KBr pellet) 790, 835, 930, 1006, 1032, 1093, 1170, 1195, 1253, 1385, 1450, 1712, 2860, 2940, 3480 cm^{-1}; n.m.r. ($CDCl_3$) δ 1.32 (6H, d, J = 6 Hz), 1.48–2.9 (16H, m), 5.3 (2H, quartet), 3.62 (2H, a broad singlet, disappeared with D_2O); *m/e* 298 (M^+), 280 ($M^+ - 18$), 262 ($M^+ - 36$).

We would like to thank the National Research Council of Canada for financial support of this work.

^{13}C Chemical Shifts of Quinolizidines. 2. ^{13}C Spectra of Some *Nuphar* Alkaloids[1]

ROBERT T. LALONDE, THOMAS N. DONVITO, AND AMY I-M. TSAI

Department of Chemistry, State University of New York, College of Environmental Science and Forestry, Syracuse, New York 13210

Received December 2, 1974

ROBERT T. LALONDE, THOMAS N. DONVITO, and AMY I-M. TSAI. Can. J. Chem. **53**, 1714 (1975).

The ^{13}C n.m.r. spectra of nine *Nuphar* alkaloids: deoxynupharidine, 7-epideoxynupharidine, nupharidine, 7-epinupharidine, nupharolutine, 7-epinupharolutine, thiobinupharidine, thionuphlutine B, and neothiobinupharidine, have been determined. Also examined were the spectra of five model compounds, 2,2,4,4-tetramethylthiolane, 3(a)-methyl-3(e)-methylthiomethylquinolizidine, 3(e)-methyl-3(a)-methylthiomethylquinolizidine, 3(e)-methylthio-3(a)-methylquinolizidine, and 3-methylfuran. This latter group of spectra were used to assist the chemical shift assignments of the *Nuphar* alkaloids. The most significant findings of this study are: (*i*) axial methyl and thiomethylene groups are shielded more than their equatorial counterparts in all cases; (*ii*) axial and equatorial hydroxyl groups substituted at C-7 of deoxynupharidine and 7-epideoxynupharidine give α-, β-, and γ-effects in ring B similar to those in carbocyclic systems but also produce small upfield shifts in ring A especially at the carbons α to nitrogen; (*iii*) the effect of a 3-furyl group located at C-4 appears to have nearly the same effect on quinolizidine ring carbons as a methyl group in the same position, the effects being shielding and deshielding at the various ring carbons; (*iv*) *N*-oxide formation results in α-, β-, γ-, and δ-shielding and deshielding effects consistent with the incorporation of an axial oxygen into a *trans*-fused system or the formation of a *cis*-fused quinolizidine *N*-oxide; and (*v*) methylene or methyl groups attached to C-2 and C-4 of a thiolane, including that in the skeleton of the C_{30} thiaspirane alkaloids, experience deshielding δ-effects.

ROBERT T. LALONDE, THOMAS N. DONVITO et AMY I-M. TSAI. Can. J. Chem. **53**, 1714 (1975).

On a déterminé les spectres r.m.n. ^{13}C de neuf alkaloides *Nuphar*: la déoxynupharidine, l'épi-7 déoxynupharidine, la nupharidine, l'épi-7 nupharidine, la nupharolutine, l'épi-7 nupharolutine, la thiobinupharidine, la thionuphlutine B et la néothiobinupharidine. On a aussi examiné les spectres de 5 composés modèles soit le tétraméthyl-2,2,4,4 thiolanne, la méthyl-3(a) méthyl-3(e) thiométhylquinolizidine, la méthyl-3(e) méthyl-3(a) thiométhylquinolizidine, la méthylthio-3(e) méthyl-3(a) quinolizidine et la méthyl-3 furanne. On a utilisé ce dernier groupe de spectres pour aider dans les attributions de déplacements chimiques des alkaloides du *Nuphar*. Les résultats les plus significatifs de cette étude sont: (*i*) que dans tous les cas les groupes méthyles axiaux et les groupes thiométhylènes sont plus blindés que leur contrepartie équatoriale; (*ii*) lorsque des groupes hydroxyles axiaux et équatoriaux sont attachés en position C-7 de la déoxynupharidine et de l'épi-7 déoxynupharidine, des effets α, β et γ sont obtenus dans le cycle B et ces derniers sont semblables à ceux observés dans des systèmes carbocycliques; ils produisent toutefois aussi de petits déplacements vers les hauts champs dans le cycle A particulièrement pour les carbones en position α de l'azote; (*iii*) il semble qu'un groupe furyl-3 situé en position C-4 a le même effet sur les carbones du cycle quinolizidine qu'un groupe méthyle dans la même position; les effets sont du blindage et du déblindage pour divers atomes de carbone du cycle; (*iv*) la formation d'un oxyde d'azote conduit à des effets de blindage et de déblindage α, β, γ et δ qui sont en accord avec l'incorporation d'un oxygène axial dans un système lié d'une façon *trans* ou à la formation d'une *N*-oxyde quinolizidine *cis*; et (*v*) les groupes méthylènes et méthyles attachés aux positions C-2 et C-4 d'un thiolanne, y compris ceux dans le squelette des alkaloides du thiaspirane en C_{30}, sont soumis à des effets de déblindage δ.

[Traduit par le journal]

Introduction

In a continuation of the study of the ^{13}C nuclear magnetic resonance spectra (c.m.r.) of quinolizidine systems (**1**), the spectra of nine *Nuphar* alkaloids have been determined. These include the six C_{15} alkaloids deoxynupharidine (DON) (**1**), 7-epideoxynupharidine (7-epiDON) (**2**), nupharidine (**3**), 7-epinupharidine (**4**), nupharolutine (**5**), and 7-epinupharolutine (**6**), and also the three C_{30} alkaloids thiobinupharidine

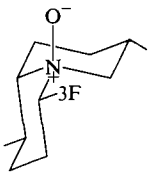
1 $R_1 = H; R_2 = \underset{12}{CH_3}$

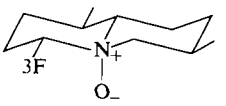
2 $R_1 = \underset{12}{CH_3}; R_2 = H$

5 $R_1 = OH; R_2 = \underset{12}{CH_3}$

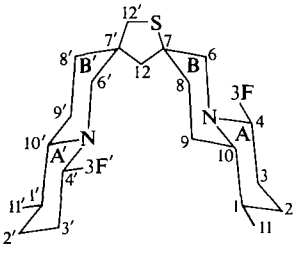
6 $R_1 = \underset{12}{CH_3}; R_2 = OH$



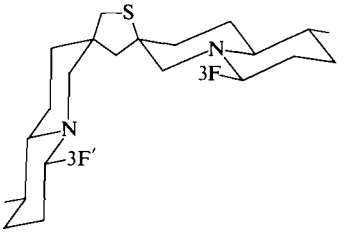
3



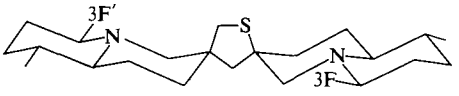
4



7

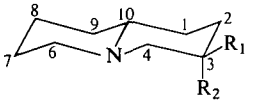


8



9

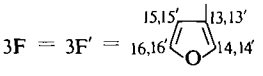
10



11 $R_2 = \underset{12}{CH_2}\underset{13}{SCH_3}; R_1 = \underset{11}{CH_3}$

12 $R_2 = \underset{11}{CH_3}; R_1 = \underset{12}{CH_2}\underset{13}{SCH_3}$

13 $R_2 = \underset{11}{CH_3}; R_1 = \underset{12}{SCH_3}$



(TBN) (**7**), thionuphlutine B (TN-B) (**8**), and neothiobinupharidine (NTBN) (**9**). The c.m.r. of the five model compounds 2,2,4,4-tetramethylthiolane (**10**), 3(e)-methyl-3(a)-methylthiomethylquinolizidine (**11**)[2], 3(a)-methyl-3(e)-methylthiomethylquinolizidine (**12**), 3(e)-methylthio-3(a)-methylquinolizidine (**13**), and 3-methylfuran were also determined to assist in the chemical shift assignments of the above-mentioned *Nuphar* alkaloids. The c.m.r. of other naturally occurring and synthetic quinolizidine derivatives have been reported (3), however this is the first report of the c.m.r. of *Nuphar* alkaloids, a group of *trans*-fused quinolizidines whose conformational rigidity is enhanced principally by the C-4 located 3-furyl, the strong equatorial preference (4) of which confines the A-ring to one chair form and thereby furnishes a quinolizidine system somewhat simplified for the study of n.m.r. properties. Thus the *Nuphar* alkaloids were studied to obtain information helpful in future structure studies of not only this one class of alkaloids but other quinolizidine systems as well.

[2]The letters e and a refer to equatorial and axial and are applicable here because the quinolizidine system is *trans*-fused (2). This nomenclature is used for purposes of clarity instead of the *t* and *c* nomenclature method used previously (1, 2).

Experimental

Spectra

The spectra were obtained as follows: p.m.r. with Varian A-60A and XL-100-15 spectrometers using $CDCl_3$ solutions; i.r. with a Perkin-Elmer 137, neat; mass with a Hitachi-Perkin-Elmer RMU6E using an all-glass heated inlet system at 200° and 70 eV; c.m.r. with a Varian

XL-100-15 operating in the FT mode at 25.16 MHz and ambient temperature. Solutions for c.m.r. were 0.3–0.5 *M* in $CDCl_3$ containing 1% TMS (δ 0.00 p.p.m.) in 12 mm tubes. Field/frequency lock was established on the deuterium resonance of $CDCl_3$. Between 1 and 10K transients were used for fully decoupled spectra and nearly four times that number for off resonance decoupled spectra. Single frequency decoupling (s.f.d.) experiments were carried out with the decoupler in the low power mode (about 110 dB) and adjusted to the resonance frequency of the individual proton to determine the decoupled carbon signal. Chemical shifts are accurate to ±0.1 p.p.m.

Analyses

The g.l.c. were carried out on a Varian-Aerograph 200 chromatograph using a stainless steel 5 ft × 0.25 in. column containing 20% SE-30 on Chromosorb W, 60–80 mesh at 98°. Retention times (R_t) are given in minutes.

The elemental analysis was performed by Galbraith Laboratories, Knoxville, Tennessee.

Materials

Compounds **11** and **12** were prepared as previously reported (5). The preparation and isolation of the deuterium labeled and unlabeled *Nuphar* alkaloids **1–9** (6–12) and **7-6-d_1** have been previously reported. Some samples were obtained by the transformation of the more abundant *Nuphar* alkaloids. In these cases the identity of the synthetic sample was established by physical and spectral evidence. The synthesis of 3(e)-methylthio-3(a)-methylquinolizidine (**13**) has been accomplished in this laboratory and will be reported in a future publication.

2,2,4,4-Tetramethylthiolane (10)

A 100 g sample of 2,2,4,4-tetramethyltetrahydrofuran, used as obtained from Eastman Organic Chemicals, was dissolved in 75 ml of benzene and the resulting solution was heated to reflux and stirred vigorously for 16 h with 64 g of phosphorus pentasulfide in a manner similar to a previously reported procedure for preparing 2,4-dimethylthiazole (13). The liquid was decanted from the red solid, filtered, concentrated on a rotary evaporator, and refiltered. Gas–liquid chromatography of the filtrate showed three major and several minor components. Distillation gave a 45 g mixture of the three major components in a ratio of 29:52:19 by g.l.c. with retention times of 3.2, 4.8, and 5.9 respectively. Separation by spinning band distillation gave three components each having *m/e* 144 (M^+). Fraction 1 (R_t 3.2) contained a double bond by p.m.r. and i.r. but was not further characterized. The major fraction was 2,2,5,5-tetramethylthiolane: g.l.c. R_t 4.8; b.p. 41–43°/13.6 mm (lit. (14) b.p. 56°/25 mm); p.m.r. δ 1.43 (s, 12H, CH_3), 1.96 (s, 4H, CH_2) (lit. (15) 1.41, 1.91, CCl_4); c.m.r. δ 55.10 (q, CH_3), 44.89 (t, C-3) 32.69 (s, C-2); i.r. 3.39, 3.43, 6.88, 7.33, 8.82 μ; mass spectrum, *m/e* (relative intensity) 144 (M^+, 30), 129(100), 95(50), 75(36), 59(24), 55(25), 41(27).

The third fraction was **10**: g.l.c., R_t 5.9; b.p. 49–50°/13.9 mm; p.m.r. δ 1.23 (s, 6H, C-7), 1.49 (s, 6H, C-6), 1.71 (s, 2H, C-3), 2.77 (s, 2H, C-5); i.r. 3.39, 3.48, 6.90, 7.23, 7.37, 8.87, 8.96 μ; mass spectrum, *m/e* (relative intensity) 144 (M^+, 33), 129(100), 95(18), 59(28), 55(53), 41(33).

3-Methylfuran

The method of Gilman and Burtner (16) was employed to prepare 3-methylfuran: c.m.r. δ 9.60 (q, CH_3), 112.50 (d, C-4), 120.13 (s, C-3), 139.63 (d, C-2), 143.06 (d, C-5), s.f.d. was employed to make the assignments of the doublets.

Assignments and Results

The resonance assignments were assisted by off-resonance decoupling, single frequency decoupling (s.f.d.), and our earlier c.m.r. study of the isomeric methylquinolizidines (1). The values and assignments of the chemical shifts of the C_{15} alkaloids and the model compounds are presented in Table 1 and those of the C_{30} alkaloids in Table 2. A comparison of the shift positions of the alkaloids and the model compounds is made in Fig. 1.

The reporting of assignments and results will begin with a treatment of the C_{15} amines and *N*-oxides. Thereafter the sulfur-containing model compounds will be dealt with and finally the sulfur-containing C_{30} alkaloids will be treated.

C_{15} Amines and N-Oxides

The off-resonance proton decoupled spectra of DON (**1**), 7-epiDON (**2**), nupharidine (**3**), and 7-epinupharidine (**4**) show two quartets, five triplets, seven doublets, and one singlet which fall in three distinct regions, 15–40, 55–80, and 110–145 p.p.m. The singlet obviously results from C-13, the only quaternary carbon in these molecules. The signals of nupharolutine, **5**, and 7-epinupharolutine, **6**, fall in the same three regions and show the same splittings as those above except in both cases one doublet is replaced by a singlet. This new singlet is assigned to C-7 which, as expected and shown in Fig. 1, is greatly deshielded relative to DON and 7-epiDON as a result of equatorial or axial α-hydroxyl substitution.

In the case of DON, the quartet at 19.07 p.p.m. is assigned to C-11 and that at 17.57 p.p.m. to C-12. These DON quartet assignments are consistent with finding the two 7-epiDON equatorial methyls at 19.26 and 20.13 p.p.m. The more shielded of the two quartets exhibited by both **5** and **6** correlates with the position of C-11 in the spectra of DON and 7-epiDON, and is assigned accordingly, whereas the second quartet is deshielded in both cases because of β-hydroxyl substitution and therefore is assigned to C-12.

[a]In p.p.m. from TMS.
[b]s = singlet, d = doublet, t = triplet, q = quartet.
[c]Single peak due to two carbons.
[d]These four peaks may be interchanged; most likely assignment is given.
[e]May be (d,t).
[f]At least one of these is (d).
[g]One of these values can be assigned to C-6, the other to C-6′.

The most deshielded DON triplet is assigned to C-6 since C-6 is α to nitrogen. Of the four remaining triplets, C-2 (33.98 p.p.m.) and C-8 (30.56 p.p.m.) can be assigned by direct comparison with the corresponding carbons in 1(e)- and 3(a)-methylquinolizidine.[3] The triplet at 34.96 p.p.m. is assigned to C-3 because this is the signal closest to the 35.45 p.p.m. resonance of C-3 in 4(e)-methylquinolizidine. The chemical shift of C-9 in 1(e),7(a)-dimethylquinolizidine, estimated by the method (1) of calculating methyl decalin chemical shifts and adjusting for the presence of nitrogen, is 26.15 p.p.m. Because the 3-furyl group will have little effect on C-9, the DON triplet at 25.74 p.p.m. is assigned to this carbon.

Three of the seven DON doublets are much more deshielded than the rest and of these three the two most deshielded ones are assigned to C-14 and -16, the carbons next to oxygen in the furan ring. The correspondence of chemical shift values with those of the same two carbons in 3-methylfuran[4] is good. The most shielded furan doublet is assigned to C-15, the chemical shift of which is moved upfield by 2.6 p.p.m. relative to C-4 in 3-methylfuran. However the shielding of C-15 in DON is reasonable if the furan ring assumes a conformation in which the C-14 and -4 protons are eclipsed. C-15 is then γ-gauche to both C-3 and nitrogen. Such a conformation of the 3-furyl group is observed for deoxynupharidine hydrobromide in the crystalline state (17).

Of the remaining four DON doublets the two most deshielded ones are assigned to the carbons α to nitrogen. Thus, C-10 and -4 are assigned to 69.75 and 60.30 p.p.m., respectively, based on the shift positions of C-10 in 1(e)-methylquinolizidine and C-4 in 4(e)-methylquinolizidine (1). Further support for the assignment of these doublets will be given in the discussion of the single frequency decoupled spectrum of NTBN. The remaining two DON doublets at 35.72 and 28.66 p.p.m. are assigned

[3]Our earlier study showed that the presence of a methyl substituent on the quinolizidine system had little effect on the carbons more distant than two bonds away unless γ-gauche interactions resulted (1). This finding makes it possible to use the methylquinolizidine shift data to assist the assignments of some of the *Nuphar* alkaloid signals notwithstanding the presence of two methyl groups in the alkaloids.

[4]See the Experimental section for the chemical shift values of 3-methylfuran.

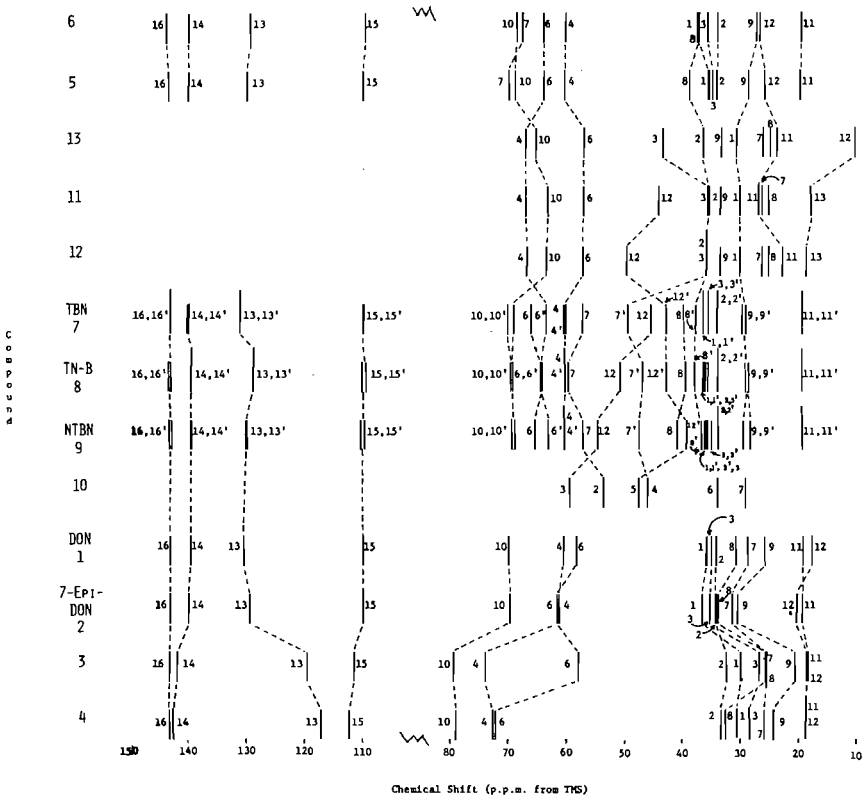

FIG. 1. Chemical shift correlation of some C_{15} and C_{30} *Nuphar* alkaloids.

to C-1 and -7, respectively, based on chemical shift agreement with the corresponding carbons in 1(e)- and 3(a)-methylquinolizidine (1).

As expected the resonances of the five ring-A carbons, including C-10, are nearly the same in the spectra of DON (**1**), 7-epiDON (**2**), nupharolutine (**5**), and 7-epinupharolutine (**6**). The assignments of the five carbons constitute consistent sets, the largest variations in which will be considered in the discussion section. However, because the C-7 methyl group is equatorial in 7-epiDON, the resonances of ring-B carbons 6, 7, 8, and 9 as well as the 7(e)-methyl (C-12) are deshielded relative to DON by amounts consistent with the observed differences between 3(e)- and 3(a)-methylquinolizidine. Of the 7-epiDON peaks at 33.71, 34.13, and 35.17 p.p.m., the first or second may be assigned to C-8 and the remaining two to C-2 and -3, the most likely assignments being shown in Table 1. As for the ring-B carbons in **5** and **6**, the assignment of C-7 has already been treated above; the assignments of the remaining carbons are made with the assistance of those for DON and 7-epiDON and known β- and γ-hydroxyl substituent effects (18). Thus replacement of the C-7 hydrogen of 7-epiDON by an axial hydroxyl results in the deshielding of C-6 and -8 by the amounts given in Table 3, amounts slightly less than half of those observed in the replacement of the C-7 hydrogen by an equatorial hydroxyl in DON. The γ-gauche effect of the axial hydroxyl in **6** shields C-9 relative to 7-epiDON. In contrast the antiperiplanar effect of the equatorial tertiary hydroxyl in **5** deshields C-9 relative to DON. This deshielding is consistent with that observed in 1-substituted adamantanes (19) but is opposite to the γ-effect caused by substituting an equatorial heteroatom at a secondary carbon (20).

Because 7-epinupharidine is *trans*-fused[5] the *N*-oxide oxygen is axial in both A- and B-rings. Therefore shielding of all the carbons γ to the

[f]$\Delta\delta_C{}^{7(e)OH} = \delta_C{}^i$ nupharolutine $- \delta_C{}^i$ DON.
[g]$\Delta\delta_C{}^{7(a)OH} = \delta_C{}^i$ 7-epinupharolutine $- \delta_C{}^i$ 7-epiDON.

new oxygen occurs. Thus C-1, -3, -7, -9, and -13 are shielded by 6.05, 6.64, 5.33, 6.04, and 12.38 p.p.m., respectively, relative to 7-epiDON. The 7-epinupharidine triplets due to C-2 and -8 and the intensity enhanced quartet due to the two equatorial methyl groups occur close to the corresponding signals exhibited by 7-epiDON and are assigned accordingly.

Three 7-epinupharidine peaks, one triplet and two doublets, are assigned to the carbons α to nitrogen. Relative to 7-epiDON, these signals are deshielded because of the β axial substituent, oxygen, and the positive charge on nitrogen. The triplet is assigned to C-6, the only methylene adjacent to nitrogen. The doublets at 72.56 and 79.03 p.p.m. are assigned to C-4 and -10, respectively, because C-4 always occurs upfield from C-10 in DON and 7-epiDON as well as in the C_{30} *Nuphar* alkaloids, discussed below.

As for the *cis*-fused nupharidine (**3**) (21), the resonances of ring-A C-1, -4, -10 (doublets), C-2 and -3 (triplets) and C-11 (quartet), occur close to the chemical shifts of the same carbons in 7-epinupharidine (**4**). The C-12 quartet also occurs very close to the corresponding methyl quartet of **4** because these methyls have the same substitution pattern and a similar stereochemical environment. The same is true for the C-7 doublet. The only triplet in the region occupied by carbons α to nitrogen is assigned to C-6. The remaining two triplets are from C-8 and -9, shifted upfield from their positions in 7-epinupharidine. C-8 undergoes a γ-gauche interaction with C-1 whereas C-9 feels a β-axial effect from C-1 instead of the β-equatorial effect experienced by the same carbon in 7-epinupharidine.

Sulfur-containing Model Compounds

The off-resonance proton decoupled spectrum of 2,2,4,4-tetramethylthiolane (**10**) shows two quartets, each due to two carbons, two triplets, and two singlets. The C-2 methyl protons are differentiated from those at C-4 by their lower chemical shift which follows from analogy with 2,2,4,4-tetramethyloxolane (22). As a result, an s.f.d. experiment allows the assignment of the 33.74 p.p.m. quartet to the C-2 methyls. This chemical shift value is close to the 32.69 p.p.m. methyl resonance of 2,2,5,5-tetramethylthiolane. The remaining quartet at 29.00 is assigned to the C-4 methyls. Similarly the C-3 and -5 hydrogens are clearly differentiated by chemical shift differences of their proton resonances. Therefore, of the two c.m.r. triplets, that at 59.36 p.p.m. is assigned to C-3 because it collapses to a singlet when the protons on C-3 are irradiated. Irradiation of the C-5 protons collapses the 47.34 p.p.m. triplet. The singlets at 53.52 and 45.84 p.p.m. are assigned to C-2 and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

C-4, respectively, because the chemical shift of the former agrees with that of C-2 of 2,2,5,5-tetramethylthiolane found at 55.10 p.p.m.

The ring carbons in **10** are deshielded 28.2 to 14.7 p.p.m. relative to those reported for thiolane (23). The direction and magnitudes of these shifts are reasonable considering the methyl cyclopentane parameters of Roberts and coworkers (24).

The off-resonance proton decoupled spectrum of 3(e)-methyl-3(a)-methylthiomethylquinolizidine (**12**) shows two quartets, eight triplets, one doublet, and one singlet which is nearly coincidental with one of the triplets. The assignment of the doublet is obvious since each stereoisomer contains a single methine (C-10). The resonances of C-6, -7, -8, and -9 in **11** and **12** are assigned by assuming that they resonate close to the corresponding carbons of quinolizidine. The CH_2—S resonance of **11** is at 43.38 p.p.m. based on s.f.d. C-2 and -3 are assigned to the peaks at 35.17 and 35.20 p.p.m. on the expectation of the effects α and β substitution will have on quinolizidine. γ-Axial shielding puts the C-1 resonance at 29.82 p.p.m., upfield from C-1 of quinolizidine (33.62 p.p.m.) and near the C-1 resonance (28.50 p.p.m.) of 3(a)-methylquinolizidine. Of the two quartets, the one at lower field (26.64 p.p.m.) is assigned to the axial methyl since it has greater β substitution. The methyl attached to sulfur has no substituents closer than three bonds away and accordingly is assigned to the higher field quartet at 17.68 p.p.m.

The only significant spectral differences between **11** and **12** are those expected on the basis of the stereochemical differences; the thiomethylene is deshielded and the C-3 methyl group is shielded in the latter compound. The different chemical shift of the C-3 methyls and the nearly identical chemical shift of the methylthio methyls adds support to the assignment of all the quartets.

The off-resonance proton decoupled spectrum of **13**, relative to that of **11** and **12**, contains one less triplet due to the replacement of the methylthiomethylene by a methylthio group. Two additional features distinguish the spectrum of **13** from that of **11** and **12**. One is the low field position of C-3, caused by the directly attached sulfur. The other is the appearance of the thiomethyl group at 9.89 p.p.m., a position considerably higher than that exhibited by the same group in **11** and **12**. This observation seems to indicate a γ-gauche interaction of the C-3 axial methyl with the C-3 thiomethyl.

The C_{30} Alkaloids

The C_{30} alkaloids include two DON or 7-epiDON moieties joined at C-7 and the C-7 methyl directly and through sulfur. Appropriately, the three C_{30} alkaloids examined gave spectra very similar to the C_{15} alkaloid, DON, with the following exceptions: the C-7 doublet of DON becomes a pair of widely separated singlets displaced downfield in the spectra of the C_{30} alkaloids; the peak due to the C-7 methyl group is absent and two new methylene resonances appear; each of the other peaks in DON appears as a pair of closely spaced or coincidental peaks and each of the ring B (or B′) carbons resonate downfield from those of DON. The resonance assignments are treated below.

The furan ring and methyl carbon signals of the three alkaloids appear close to the chemical shifts of the corresponding carbons in DON and 7-epiDON. The assignments are made accordingly. Each of the alkaloids gives two triplets and three or four apparent doublets in the region characteristic of carbon α to nitrogen. However the display of three apparent doublets by TN-B and NTBN really represents two distinguishable doublets plus an additional coincidental pair of doublets as indicated by signal intensity. In the case of NTBN, the two coincidental doublets at 60.24 p.p.m. are assigned to C-4 and -4′ on the basis of s.f.d., the result of which also supports the assignment of the C-4 resonance of DON and 7-epiDON (*vide ultra*). C-10 and -10′ doublets at 68.63 and 69.29 p.p.m. are assigned by elimination. C-10, -10′, -4, and -4′ in TBN and TN-B then are assigned by chemical shift matching with NTBN. The triplets in the same region are assigned to C-6 and -6′, an assignment supported in the case of TBN by the disappearance of the 65.97 p.p.m. triplet in the spectrum of TBN-*6*-d_1. Disappearance of this signal is attributed to the reduction of nuclear Overhauser enhancement and development of unperturbed carbon–deuterium coupling (3*c*).

Each of the alkaloids gives a pair of singlets in the 47–57 p.p.m. region. The one further downfield in each case is less intense and is assigned to the quaternary carbon (C-7) adjacent

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

to sulfur, as in the case of **10** (*vide ultra*). The remaining higher field singlet is assigned to C-7′. These assignments are supported by observing the disappearance of the less intense singlet in the spectrum of TBN-*6*-d_1. The loss of the C-7 signal is attributed to the lengthening of the relaxation time of C-7 as hydrogen on C-6 is replaced by deuterium. A similar observation has been made for deuterium derivatives of phenanthrene (**25**). Interestingly, the deshieldings of C-7 relative to C-3 in **13**, and C-7′ relative to C-3 in **11** and **12**, are consistent with the shift observed for a quaternary ring carbon upon making it the spiro carbon in a spiro[5.4]alkane (**26**).

The only remaining nontriplet signals needing attention are the C-1 and -1′ doublets which in the case of TBN are coincident at 36.30 p.p.m., a chemical shift agreeing well with that of C-1 in DON. C-1 and -1′ are separate doublets appearing in the 35.5–36.2 p.p.m. region of the spectra of TN-B and NTBN. Their exact position cannot be located with certainty because some C-3 and -3′ signals occur within the same narrow region.

The remaining peaks are all triplets. The spectrum of each of the three alkaloids shows four triplets in a region (36–55 p.p.m.) completely devoid of peaks in the spectra of the C-15 compounds. Through s.f.d. of the thiomethylene protons of NTBN, the 39.14 p p.m. triplet is assigned to C-12′ and, by another similar decoupling, the 54.54 p.p.m. triplet is assigned to C-12. The triplets at 45.26 and 42.69 p.p.m. in the spectrum of TBN are assigned to C-12 and -12′, respectively, because C-12 is expected to become shielded and C-12′ deshielded as a result of the change in the stereochemistry of these carbons relative to the quinolizidine rings. The 50.59 p.p.m. triplet given by TN-B is assigned to C-12 since this chemical shift is between that of C-12 in the spectra of TBN and NTBN. Thus the C-12 assignments are consistent with the number of axial and equatorial interactions in which C-12 is involved. The 42.77 p.p.m. triplet given by TN-B is assigned to C-12′ since the chemical shift agrees well with that of C-12′ in TBN and both methylenes are axial in the A′B′ quinolizidines.

The second pair of triplets which appears in the 36–55 p.p.m. region is assigned to C-8 and -8′. C-8 is assigned the lower field position in each case for two reasons. First, the methyl groups substituted at the α position in model thiolane **10** appear at lower field than those attached to the β′ position. C-8 and -8′ methylenes are in the same relation to the thiolane ring as the two kinds of methyl groups are in **10**. Secondly, sulfur and C-6 and -8 are similarly juxtaposed as are sulfur and C-6′ and -8′. Since the spectrum of TBN-*6*-d_1 puts C-6 at lower field than C-6′, the analogy is extended to C-8 and -8′. The latter two are shifted downfield from the corresponding carbon (C-2) in **11**, **12**, and **13**. The deshieldings are consistent with the δ-effect on methyl carbon in 1,1,3,3-tetramethylcyclohexane (27) but more closely analogous to the δ-effect on the corresponding methylene carbons in dispiro[5.1.5.2]pentadecane (26).

The two triplets furthest upfield are assigned to C-9 and -9′ because they appear close to the chemical shift of C-1 in **11** and only 2 p.p.m. upfield from C-9 of 7-epiDON. The remaining triplets are assigned to C-2, -2′, -3, and -3′ on the basis of chemical shift correspondence with the same carbons in DON and 7-epiDON.

Discussion

The most significant observations made in this study are: the chemical shift differences of methyl and thiomethylene groups as a function of conformation; the effect of the equatorial 3-furyl group on the chemical shift of quinolizidine ring carbons; the effect of *N*-oxide formation; the effect of C-7 hydroxyl group incorporation; and the δ-effect on some quinolizidine methylene groups. The last two topics have already been discussed briefly in connection with the assignments and will not be treated further. The first four topics will be discussed below in the order just given, but before doing so, a brief comment will be made regarding the general spectral appearance related to gross symmetry characteristics of the C_{30} alkaloids.

TBN and NTBN appear to have pseudo C_2 symmetry whereas TN-B does not. Therefore, relative to TN-B, TBN, and NTBN might be expected to show greater numbers of coincidental or nearly coincidental signals arising from the near equivalence of carbons, especially those furthest removed from the pseudo twofold axis of symmetry. That such is not the case is likely due to preferred conformations of two quinolizidine moieties twisted about the spiro carbons of the thiolane ring, a factor which would enhance the intrinsic shielding difference due to nonequivalence. It is true that the shielding non-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

equivalence of carbon is manifest differently by rings B and B′ on the one hand and A and A′ on the other, but in the direction opposite to what might be expected on the basis of apparent symmetry alone. Thus Fig. 1 will show that both C-6, -6′ and C-8, -8′ are more widely separated in the two C_{30} alkaloids possessing pseudo C_2 symmetry than they are in the less symmetrical structure, TN-B. Therefore it appears that the microscopic electronic effects and steric interactions are much more important than symmetry in influencing overall spectral appearance.

The axial C-7 methyl of DON appears upfield from the equatorial counterpart in 7-epiDON, a relation reversed from that of the p.m.r. where the axial methyl protons are deshielded relative to the equatorial ones (5, 7, 10, 11). However the 2.56 p.p.m. increment in the c.m.r. is somewhat greater than the 1.51 p.p.m. shift difference for the methyl groups in 3(e)- and 3(a)-methylquinolizidine (1). Indeed there appears to be no regular increment between equatorial and axial methyls in any of the 1-, 2-, and 3-methylquinolizidine pairs (1).[6] Thus the equatorial–axial shift observed for the C-7 methyl group in DON and 7-epiDON is in the right direction but the magnitude of the shift is inexplicable.

The thiomethylene and methylene carbons of **11**, **12**, and the C_{30} alkaloids follow the equatorial–axial shift relation observed for the C-7 methyl of DON and 7-epiDON as well as that reported for the exocyclic methylene of the epimeric lupinine benzoates (3*b*). The C-12 and 12′ resonances are shielded in direct relation to the number of axial interactions in which these carbons are involved. One of the major problems associated with the structure determination of the C_{30} thiaspirane alkaloids was the configuration of C-7 and -7′, the full solution of which was not obtainable from the p.m.r. studies but as illustrated here, is readily achieved from the c.m.r. examination of the C-12 and -12′ carbons.

Also noteworthy is the shielding of C-12 and -12′ in the C_{30} alkaloids relative to the corresponding carbons, C-3 and -5, respectively, in the tetramethylthiolane **10**. This result is attributed to the increased steric compression of C-12 and -12′ caused by replacing the methyl groups of **10** by the quinolizidine moieties.

One way to ascertain the effect of the 4(e)-(3-furyl) group on quinolizidine carbons is to calculate the chemical shift values for 1(e), 7(e)-, and 1(e),7(a)-dimethylquinolizidine, using Grant's hydrocarbon parameters (28) and our CH to N parameters (1), and then to compare these values, by difference, with those observed for each of the corresponding carbons in DON and 7-epiDON. The result of such a comparison is given in Table 4 which demonstrates that the effect of the 3-furyl group is to shift corresponding carbons in DON and 7-epiDON in the same direction within 1 p.p.m.[7] The extent and direction of the shift resulting from the presence of the 4(e)-(3-furyl) group is nearly the same as that observed from the substitution of an equatorial methyl group at the same position (1, 29).

The effect of changing a quinolizidine to a quinolizidine *N*-oxide, without the complications of changing the ring fusion, is seen by comparing the spectra of 7-epiDON (2) and 7-epinupharidine (4). Quinolizidine carbons β, γ, and δ to the new oxygen atom shift, on the average, +10.53, −6.02, and +0.99 p.p.m., respectively, on transforming the amine to the *trans*-fused *N*-oxide. The β- and γ-carbon shifts agree with the +10.16 β-carbon and −5.78 p.p.m. γ-carbon shifts associated with converting 1,2-, 1,3-, and 1,4-dimethylpiperidines to the corresponding *N*-oxides (3*a*). The magnitude of the shielding of the carbons γ to oxygen is nearly that expec-

[6]The methyl resonances of the two 2-methylquinolizidines differ by 4.33 p.p.m. giving an increment per γ-*gauche* interaction difference equal to −2.16. The gauche interactions include those of the nonbonding electron pair on nitrogen. The methyl resonances of the two 1-methylquinolizidines differ by 4.98 p.p.m. giving an increment per *gauche* interaction equal to −2.49 p.p.m., a value considerably in excess of the −0.76 value given by the pair of 3-methylquinolizidines. Possibly a partial answer to the problem rests in the γ-antiperiplanar effect of nitrogen on the C-3 equatorial methyl. This effect is shielding and even more so than a γ-*gauche* effect (20). Consequently, the small equatorial–axial increment might result from such antiperiplanar shielding of an equatorial methyl rather than an abnormally small γ-*gauche* shielding of an axial methyl. However this explanation fails to explain the different increments for C-1 and -3 pairs although some difference might be expected since the substitution patterns of the two antiperiplanar systems are not the same.

[7]The one anomaly at C-7 results from the failure of the method in predicting the chemical shift at C-3 of the methyl substituted quinolizidines (C-7 of DON and 7-epiDON). Thus the method gives chemical shifts for C-3 of 3(a)- and 3(e)-methylquinolizidine which are 2.51 p.p.m. upfield and 2.48 p.p.m. downfield respectively from the values observed (1).

ted from γ-axial substitution (1, 28). However the deshielding of the β-carbon is larger by about 4.7 p.p.m. than the usually observed β-axial substitution effect and is attributed in part to the positive charge on nitrogen.

The comparison of DON (**1**) with nupharidine (**3**) is somewhat more complicated, in relation to the comparison of **2** with **4**, because of the change in the ring fusion stereochemistry. Both C-7 and -8 in **3** are shielded, C-7 as a result of the *N*-oxide oxygen being axial in ring-B and C-8 by the axial C-1. Also C-1, -3, and -9 are shielded, entirely or partially, as a result of new axial interactions. The resonance of C-6 in nupharidine is maintained near its DON position as a result of the shielding C-1, -3, and -13 γ-gauche interactions offsetting the deshielding effects of the positive charge at adjacent nitrogen, a β-axial interaction with *N*-oxide oxygen and a δ-interaction with C-15. In contrast, C-4, -6, and -10 in 7-epiDON and C-4 and -10 in DON undergo, upon *N*-oxidation, large downfield shifts which are attributed to charge and β-axial effects.

N-Oxidation also results in shifts of furan ring carbons 13, 14, and 15 but not 16. C-14 and -15 are deshielded by nearly the same amount, of the order of 1.6–2.6 p.p.m. but C-13 is shielded 10.89 and 12.38 p.p.m., respectively, in the *N*-oxidation of DON and 7-epiDON. These larger upfield shifts undoubtedly are due, at least in part, to the newly developed γ-gauche interaction of C-13 with the *N*-oxide oxygen atom. The smaller deshieldings of C-14 and -15 are consistent with known δ effects in general (30) but *syn*-diaxial effects in particular (31). The nature of the δ interaction in the *N*-oxides is illustrated through the use of Newman projections and the results of the X-ray studies (21).[5] The latter show that the C-14 hydrogen and the axial hydrogen are eclipsed in both *N*-oxides. As a result there are in each of the *N*-oxides two δ interactions which are analogous to the *syn*-diaxial interaction in polycyclic cyclohexane systems. In the case of nupharidine, C-15 interacts with C-6; C-14 interacts with *N*-oxide oxygen. But in the case of 7-epinupharidine, C-15 interacts with *N*-oxide oxygen; C-14 interacts with C-6.

The outcome of the DON and 7-epiDON oxidation represents two different stereochemical possibilities open to *N*-oxidation of a quinolizidine, the one being oxidation with inversion of nitrogen, the other being retention.[8] Of all the spectral changes resulting from *N*-oxidation of the two amines, the magnitude of the C-6 shift appears to reflect in the most obvious manner the difference in the stereochemical outcome.

The authors are grateful to the National Science Foundation for an equipment grant to the Department of Chemistry, State University of New York, College of Environmental Science and Forestry toward the purchase of the XL-100-15 spectrometer and the VFT 100

[8]Inversion and retention refer here to the overall result relative to the more stable ring-fusion stereochemistry of the starting quinolizidine. In principle however, DON and 7-epiDON may undergo oxidation in the same stereochemical mode, one as the *cis*-fused amine, the other as the *trans*-fused amine.

Theoretical and Experimental Investigation of Primary Reactions in Sodium Diffusion Flames[1,2]

KENNETH J. MINTZ[3] AND DONALD J. LE ROY[4]

Lash Miller Chemical Laboratories, Department of Chemistry, University of Toronto, Toronto, Ontario M5S 1A1

Received December 18, 1974

KENNETH J. MINTZ and DONALD J. LE ROY. Can. J. Chem. **53**, 1726 (1975).

The determination of rate constants of reactions of the type Na + RX = NaX + R by the diffusion flame method is critically investigated, both theoretically and experimentally. More precise methods than those used heretofore are developed for calculating rate constants from experimental data, *viz.* evaluation of the effective nozzle radius, a generalization of the Heller criterion, an improvement in the theory of the visibility limit, and allowance for wall reaction and halide consumption. These methods were applied to previous data on the reaction Na + C_2H_5Cl as well as to new data on the reaction of sodium with CH_3Cl, CH_3Br, CH_3I, and C_2H_5Br.

KENNETH J. MINTZ et DONALD J. LE ROY. Can. J. Chem. **53**, 1726 (1975).

On a examiné d'une façon critique, sur des bases théoriques et expérimentales, la détermination, par la méthode de diffusion de flamme, des constantes de vitesse de réactions du type Na + RX = NaX + R. On a développé des méthodes plus précises que celles utilisées jusqu'à maintenant pour calculer les constantes de vitesse à partir des données expérimentales à savoir une évaluation du rayon effectif du bec, une généralisation du critère de Heller, une amélioration de la théorie de la limite de la visibilité et une allocation pour les réactions des parois et la consommation des halogénures. On a appliqué ces méthodes à des données antérieures pour la réaction de Na + C_2H_5Cl de même qu'à de nouvelles données pour la réaction du sodium avec CH_3Cl, CH_3Br, CH_3I et C_2H_5Br. [Traduit par le journal]

(I) Introduction

Reactions between alkali metal atoms and halogenated compounds have been studied extensively, both by the diffusion flame method of Polanyi (1) and by molecular beam techniques. However, relatively few comparisons have been made between rate constants determined by the two methods (2, 3). Since improvements in molecular beam technology will undoubtedly enable more precise reaction cross sections to be determined in the future it seemed desirable to reexamine the theoretical basis of the diffusion flame method so that meaningful comparisons can be made. A more immediate reason for undertaking the present investigation was that a thorough understanding of these primary reactions was a necessary prelude to the quantitative investigation of the reactions of free radicals formed in diffusion flames, which will be the subject of a forthcoming publication of the present authors (4).

In a typical diffusion flame reaction atomic sodium, at a known vapor pressure and mixed with an inert carrier gas, enters the reactor through a nozzle where it comes into contact with the other reagent. Ideally, the velocity in the nozzle is sufficiently high to avoid diffusion of the "atmospheric" reagent into the nozzle but low enough so that diffusion is the major means of mass transport of the sodium after it issues from the nozzle. The halide atmospheric reagent is normally at much higher concentration than the sodium and moves through the reactor relatively slowly so that the concentration of sodium in the reactor as it diffuses away from the nozzle will be approximately spherically symmetrical about the nozzle tip. Under these conditions

$$[1] \quad \frac{\partial^2 N}{\partial r^2} + (2/r)\frac{\partial N}{\partial r} - k_1 NA/D_N = 0$$

where N is the concentration of nozzle reagent, A is the concentration of the atmospheric reagent, D_N is the diffusion coefficient of the

nozzle reagent, r is the radial distance from the nozzle opening, and k_1 is the rate constant of the primary reaction to be determined.

By assuming that A is constant throughout the reaction but vanishes inside the nozzle, eq. 1 is readily solved to yield the well-known equation of Hartel and Polanyi (5)

$$[2] \qquad k_1 = \left[\frac{\ln [(N_0 r_0)/(N_R R)]}{R - r_0}\right]^2 D_N/A$$

in which N_R is the concentration of the nozzle reagent at some distance R from the nozzle and N_0 is its concentration at the origin, *i.e.* a radius r_0 close to the nozzle.

Hartel and Polanyi equated r_0 to the nozzle radius, r_n, and N_0 to the concentration of the nozzle reagent issuing from the nozzle, N_n. They also assumed that the value of N_R at the radial distance R was a fixed observable quantity. In sodium flame work N_R is taken to be the visibility limit of the sodium fluorescence observed when the system is illuminated with yellow sodium D resonance radiation (*ca.* 10^{-5} Torr).

Equation 2, with the above assumption regarding N_0, r_0, and N_R, has been used in most sodium diffusion flame work. As the result of a careful investigation, Heller (6) found empirically that for satisfactory results the linear velocity in the jet, $\bar{v}$, should be related to the diffusion coefficient, D_N, through the equation

$$[3] \qquad 5 \leqslant \bar{v}/D_N \leqslant 12 \text{ cm}^{-1}$$

Cvetanović and Le Roy (7), and later Smith (8) took into consideration the nonuniformity of the atmospheric reagent (the halide) resulting from its consumption in the primary reaction. Although the simultaneous partial differential equations involved could not be solved in closed form, approximate equations were derived and extensive numerical calculations made (9).

Reed and Rabinovitch (10, 11) pointed out that the total rate of consumption of the nozzle reagent calculated from eq. 2 on the assumption that $r_0 = r_n$ and $N_0 = N_n$ would not necessarily be equal to the rate of influx of the nozzle reagent. To get around this discrepancy they proposed that in general $N_0 \neq N_n$, but they retained the relation $r_0 = r_n$.

The same authors showed that the visibility limit of sodium resonance fluorescence corresponding to the quantity N_R in eq. 2 would not be independent of R because the light reaching the eye of the observer as one looks at the edge of the "flame" comes, not from a single point at radius R, but from all points within the reactor along the line of sight tangent to the visible flame. It follows that the apparent visibility limit will depend on the value of R. Various approximate formulae have been given to make allowance for this effect (11, 12). The subject of visibility limit has also been treated by the present authors (13).

(II) The Diffusion Flame in a Nonreactive System

In this section we examine the case in which there is no halide present in the atmospheric gas. For spherical diffusion in such a system the third term of eq. 1 vanishes, and if we let $N \to 0$ as $r \to \infty$ the solution is

$$[4] \qquad N = B/r$$

where B is to be determined by a boundary condition.

Mass conservation requires that the flow rate of nozzle reagent (*e.g.* Na) in the nozzle be equal to the rate at which it diffuses across the boundary of any sphere of radius r in the reactor at some distance from the nozzle, *viz.*

$$[5] \qquad \pi r_n^2 \bar{v} N_n = -4\pi D_N r^2 (dN/dr)_r$$

Thus, from eqs. 4 and 5

$$[6] \qquad N = \bar{v} r_n^2 N_n/(4 D_N r)$$

For spherical diffusion to obtain at a small radius r_0 this requires that

$$[7] \qquad N_0 = \bar{v} r_n^2 N_n/(4 D_N r_0)$$

Two simple options are evident:

(*1*) We can equate r_0 to r_n, *i.e.* assume that spherical diffusion occurs from the surface of a sphere of radius r_n. In this case the concentration of the nozzle reagent on the surface of that sphere is not, in general, equal to N_n but is given by the relation

$$[8] \qquad \text{e.i.c.: } N_0 = \bar{v} r_n N_n/(4 D_N)$$

This is referred to as the "effective initial concentration" or e.i.c. model, and is equivalent to that used by Reed and co-workers for the case of a reactive atmospheric reagent (10–12).

(*2*) We can equate N_0 to N_n, *i.e.* assume that spherical diffusion occurs from the surface of a sphere on which the concentration of nozzle

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

reagent is equal to N_n. The radius of the sphere will not, in general, be equal to r_n but will be given by the relation

[9] e.n.r.: $r_0 = \bar{v}r_n^2/(4D_N)$

This is referred to as the "effective nozzle radius" or e.n.r. model.

It should be noted that Hartel and Polanyi's assumptions that $N_0 = N_n$ *and* $r_0 = r_n$ cannot be true in general for a nonreactive atmospheric reagent, but only if $\bar{v}/D_N = 4/r_n$.

A reasonable assumption to make would be that for spherically symmetrical diffusion to take place from the surface of a sphere of radius r_0 the diffusion velocity, V, across the surface of this sphere should be equal to the maximum velocity of the nozzle reagent inside the nozzle, *i.e.* the velocity in the center of the nozzle, which is equal to $2\bar{v}$. The value of V for a radius r_0 is given by (ref. 14, p. 462)

[10] $V = -D_N[\mathrm{d} \ln N/\mathrm{d}r]_{r_0}$

Thus, on the basis of the above assumption $\bar{v}/D_N$ should be equal to $1/2r_0$. For the e.i.c. and e.n.r. models this predicts that $\bar{v}/D_N$ should be equal to $1/2r_n$ and $\sqrt{2}/r_n$, respectively. In our experiments with a nonreactive atmospheric gas and a nozzle of radius 0.095 cm we found empirically that $\bar{v}/D_N$ had to be in the range 15 to 20 cm^{-1} in order to obtain good spherical flames. This is very close to the value predicted by the e.n.r. model, which is therefore preferred for a nonreactive atmospheric gas.

(III) The Diffusion Flame in a Reactive System

If the only process leading to depletion of the nozzle reagent is its chemical reaction in the primary process then, for spherical diffusion and A constant, eqs. 1 and 2 apply and

[11] $N_r = (N_0 r_0/r) \exp[-\beta(r - r_0)]$

where $\beta = (k_1 A/D_N)^{1/2}$.

Mass conservation requires that the total rate of reaction of sodium from $r = r_0$ to $r = R$, say, plus its rate of diffusion out of a sphere of radius R, be equal to its rate of influx into the reactor. Thus from eq. 11

[12] $\pi r_n^2 \bar{v} N_n = 4\pi D_N N_0 r_0 (1 + \beta r_0)$

From eq. 12 it follows that for the e.i.c. model

[13] $r_0 = r_n$

$$N_0 = \frac{N_n \bar{v} r_n}{4D_N(1 + \beta r_n)}$$

while for the e.n.r. model

[14] $N_0 = N_n$

$$r_0 = [-1/\beta + (1/\beta^2 + \bar{v}r_n^2/D_N\beta)^{1/2}]/2$$

The method used in Part II to calculate reasonable values of $\bar{v}/D_N$ can also be applied here. For the e.i.c. model this yields

[15] $\bar{v}/D_N = 1/2r_n + \beta/2$

For the e.n.r. model

[16] $\bar{v}/D_N = \sqrt{2}/r_n + \beta/2$

The value of β is typically of the order of 2 cm^{-1}. Heller developed his criterion (eq. 3) using a nozzle of radius 0.25 cm, for which the e.i.c. and e.n.r. models predict values of $\bar{v}/D_N$ of *ca.* 3 and 6.6 cm^{-1} respectively. Thus the e.n.r. model is more in line with Heller's criterion for reactive systems. It was shown in Part II that the e.n.r. model provided an excellent criterion for spherical flames in nonreactive systems. We therefore propose that rate constants derived from diffusion flame experiments should be based on the e.n.r. model and that Heller's criterion be replaced by eq. 16.

The assumption that A is constant throughout the system and vanishes at $r = r_0$ was eliminated by Cvetanović and Le Roy (7), who used approximate methods to solve the simultaneous differential eqs. 1 and 17

[17] $$\frac{\partial^2 A}{\partial r^2} + \frac{2}{r}\frac{\partial A}{\partial r} - k_1 N A/D_A = 0$$

In the present work we have solved these equations by the boundary-value finite-difference method (15) with an optimized variable step-size, using an IBM 370/65 computer (see also Parts V and VI).

(IV) Wall Effects

Previous workers have assumed that as long as the visible flame did not touch the walls of the reactor the latter could be assumed to have an *infinite* radius insofar as the solution of eq. 1 was concerned. This assumption is easily tested. By comparing the rate of influx of nozzle reagent

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

with its total rate of consumption within a sphere of radius R_w equal to the radius of the reaction vessel,[5] using the "infinite reactor" eq. 11, it is easily shown that in much of the previous research on sodium diffusion flames an appreciable fraction of the sodium must have reached the walls of the reactor. It follows that the boundary condition $N \to 0$ as $r \to \infty$ was not applicable.

In setting up a "finite reactor" model some assumption has to be made about the fate of the sodium atoms reaching the wall. The assumption made here is that the concentration of sodium approaches zero at the walls as the result of adsorption on the finely divided sodium halide deposit and reaction with the organic halide reagent.

Using the e.n.r. conditions that $N_0 = N_n$, the nozzle reagent concentration distribution is given by

$$[18] \quad N_r = (N_n r_0'/r)\frac{\sinh[\beta(R_w - r)]}{\sinh[\beta(R_w - r_0')]}$$

When r_0' is calculated from eq. 18 in the same manner that r_0 was calculated in Part III we obtain the expression

$$[19] \quad \beta \coth[\beta(R_w - r_0')](r_0')^2 + r_0' = r_n^2\bar{v}/4D_N$$

However, the magnitudes of the quantities concerned are such that coth $[\beta(R_w - r_0')]$ can be equated to unity, and so r_0' is given by eq. 14.

Using the correct visibility limit (Part V), it was found that the "infinite reactor" model always overestimates the value of the rate constant k_1 when wall reaction occurs. Furthermore, the extent of wall reaction is underestimated by a considerable amount when N is calculated according to the "infinite reactor" model. It was found that the percentage of wall reaction increases with increasing flame radius and with decreasing N_n. Systematic errors in rate constants can therefore arise by simply following the recommendation (6) to use flames 1.8 cm in radius or more, or the recommendation (16) to use low values of N_n when studying fast reactions.

In the new experimental work reported later in this paper we have minimized the amount of wall reaction by using a reactor with a diameter of 17.8 cm, several times that used in previous work.

[5]The reactor is normally a cylinder of radius R_w.

(V) Visibility Limit and the Evaluation of Primary Rate Constants

We have previously discussed the visibility limit in nonreactive systems, with particular emphasis on its application to the determination of cross sections for the quenching of Na(^{2}P) atoms (13). In this section we describe its numerical evaluation, derived from a calibration experiment in a nonreactive system, and then discuss its application to the evaluation of primary rate constants in reactive systems.

For a nonreactive atmospheric gas the concentration of sodium at a point p on the line of sight perpendicular to the nozzle axis and tangent to the edge of the visible flame of radius R at a distance S from the nozzle axis is, from eq. 4, given by

$$[20] \quad N_p = B(R^2 + S^2)^{-1/2}$$

where $B = \bar{v}r_n^2N_n/4D_N$ (eq. 6).

For the purpose of the following treatment we assume that the sodium D radiation enters the reaction vessel as a parallel beam having an intensity I_F at the entrance window, which is perpendicular to the nozzle axis and at a distance R_F from the nozzle. It is evident that this beam will be attenuated as it passes through the sodium vapor between the visible flame and the entrance window and, furthermore, the attenuation will not be uniform across the axis of the reactor. The greatest attenuation will be along the nozzle axis. At a point on the axis x cm from the entrance window the sodium concentration will be given by the expression

$$[21] \quad N_x = B/(R_F - x)$$

Assuming Beer's law absorption, the rate of attenuation at the point x will be given by

$$[22] \quad -\mathrm{d}\ln I/\mathrm{d}x = \varepsilon N_x = \varepsilon B/(R_F - x)$$

where ε is the extinction coefficient. The intensity at the flame edge on the nozzle axis is then equal to $I_F(R/R_F)^{\varepsilon B}$.

From measurements made by Cvetanović (17) using the usual type of commercial sodium lamp, $\varepsilon \approx 3.6 \times 10^{10}$ cm^2 mol^{-1}. Values of B are usually of the order of 10^{-14} mol cm^{-2}. Thus the attenuation of the incident light beam due to

absorption between the entrance window and the line of sight can be neglected and the intensity along the line of sight can be considered to be uniform and equal to I, say.

The rate of light absorption, I_a, at the point p will be given by

$$[23] \quad (I_a)_p = I\varepsilon N_p = I\varepsilon B/(R^2 + S^2)^{1/2}$$

The rate of fluorescence at that point will be given by the Stern–Volmer expression

$$[24] \quad F_p = (I_a)_p/(1 + \tau k_Q(Q)) = I\varepsilon B(R^2 + S^2)^{-1/2}/(1 + \tau k_Q(Q))$$

where τ is the lifetime of the radiating state, k_Q is the rate constant for the quenching of the resonance fluorescence, and (Q) is the concentration of the quencher.

If α is the area of the aperture of the eye and D is its distance from the nozzle axis then the total amount of fluorescence originating on the line of sight that can be seen is equal to the visibility limit ν, where

$$[25] \quad \nu = [\alpha I\varepsilon B/4\pi(1 + \tau k_Q(Q))] \times \int_{-R_w}^{R_w} \frac{dS}{(R^2 + S^2)^{1/2}(D + S)^2}$$

where R_w is the radius of the reactor.[6]

The above treatment differs from that of Reed and co-workers (11, 12, 18) by the inclusion of the solid angle effect. Serious errors can be made for large values of R_w and small values of D if this effect is neglected. The effect of the quenching term was first noted, and utilized, by the present authors (13). It will not be discussed further here, except to note that it could be of some importance when applying the visibility limit (evaluated in a nonreactive system) to a reactive system where the quenching cross section of the halide is large.

In applying the visibility limit to the evaluation of primary rate constants it will be assumed that the quantities α, I, ε, and (Q) of eq. 25 remain the same as in the nonreactive system. We can then define a working value of the visibility limit

$$[26] \quad L = 4\pi\nu[1 + \tau k_Q(Q)]/\alpha I\varepsilon = B\int_{-R_w}^{R_w} \frac{dS}{(R^2 + S^2)^{1/2}(D + S)^2} = BC$$

For the present observer (K.J.M.), L was equal to $3.2_5 \times 10^{-16}$ mol cm^{-4}. If we multiply this value by D^2 (400 cm^2) the result (1.3×10^{-13} mol cm^{-2}) can be compared with the values of 4.7×10^{-14}, 6.13×10^{-14}, and 5.98×10^{-14} mol cm^{-2} obtained by Reed and co-workers (11, 18, 12). The differences could be accounted for by assuming that the eye of their observer was *ca.* 14 cm from the nozzle axis, rather than 20 cm, as in our experiments.

To apply the visibility limit in evaluating k_1 in a reactive system in which A is assumed to be constant, the e.n.r. formulation is used and wall effects are neglected, we note that the analog of eq. 26 is

$$[27] \quad L = BC = N_n r_0 \times \int_{-R_w}^{R_w} \frac{\exp\{-\beta[R^2 + S^2)^{1/2} - r_0]\}\, dS}{(R^2 + S^2)^{1/2}(D + S)^2}$$

where r_0 is given by eq. 14. The value of β, and hence k_1, is obtained by using a computer program to adjust β until the integral is equal to the known quantity $BC/N_n r_0$.

If we wish to allow for halide depletion it becomes necessary to consider eqs. 1 and 17 in the context of the visibility limit. Equation 27 is no longer an exact expression for the latter, but the value of β obtained by neglecting halide depletion can be used to give a first approximation to N_R when solving eqs. 1 and 17 simultaneously. In the latter stages of the calculation we approach self-consistency among eqs. 1 and 17 and the equation

$$[28] \quad L = BC = \int_{-R_w}^{R_w} \frac{\phi[(R^2 + S^2)^{1/2}]\, dS}{(D + S)^2}$$

where $\phi[(R^2 + S^2)^{1/2}]$ is the appropriate distribution function for sodium calculated numerically.

(VI) The Reaction Na + C_2H_5Cl

The work of Cvetanović and Le Roy (19) on the reaction Na + C_2H_5Cl remains as the most extensive investigation of the effect of temperature on the rate constant of a diffusion flame

[6]Reference 13 treats the problem in a somewhat different, but equivalent, way but unfortunately contains a number of typographical errors: in eq. 6 and subsequent equations the quantities $D + S$ and D should read $(D + S)^2$ and D^2.

reaction. Previous workers calculated "single temperature" activation energies by measuring k_1 at a single temperature and calculating E from the expression

$$[29] \quad k_1 = p\sigma^2(8\pi RT/\mu)^{1/2} \exp(-E/RT)$$

assuming p = unity and $\sigma^2 = 35$ Å^2 for all sodium flame reactions.

Cvetanović and Le Roy (19) measured k_1 over the range 533 to 653 K. Allowance was made for halide depletion (7) but they used the Hartel–Polanyi assumptions $r_0 = r_n$ and $N_0 = N_n$ and a simple visibility limit ($N_R = 7 \times 10^{-6}$ Torr). By assuming $\sigma^2 = 35$ Å^2 they found $p = 1.0 \pm 0.3$, in good agreement with the original proposal of Hartel and Polanyi (5). In the light of the improvements in the theory discussed in this paper it seemed worthwhile to reanalyze their results. The appropriate diffusion coefficients are described in Appendix 1.

The original data (19) were used to calculate k_1 to four degrees of approximation: (*a*) the infinite reactor model (eq. 2) using the Hartel–Polanyi assumptions and the simple visibility limit; (*b*) the infinite reactor model and the simple visibility limit, but with the e.n.r. assumption; (*c*) the infinite reactor model with the e.n.r. assumption and a corrected visibility limit (LD^2 was estimated to have been 6×10^{-14} mol cm^{-2} in their experiments); (*d*) the finite reactor model (eq. 19) with the e.n.r. assumption, the corrected visibility limit, and with correction for halide consumption.

The rate constants calculated according to (*b*) were between $\frac{1}{5}$ and $\frac{1}{8}$ as large as those for (*a*). However, this decrease was more than overcome when the corrected visibility limit was used; the values for (*c*) were 20 to 40% larger than for (*a*). The additional refinement of calculation (*d*) gave values very close to those of (*c*), averaging less than 2% greater.

Use of the e.i.c. rather than the e.n.r. assumption made very little difference in calculations (*b*) and (*c*). The Arrhenius parameters derived from (*d*) and based on eq. 30,

$$[30] \quad k_1 = A \exp(-E/RT)$$

where $\log A = 14.9 \pm 0.1$, $E = 10.3 \pm 0.4$ kcal mol^{-1}, as compared to 15.1 ± 0.2 and 11.2 ± 0.4, respectively, obtained by Cvetanović and Le Roy (19).[7] By assuming $\sigma^2 = 35$ Å^2 the value of p in eq. 29 derived from calculation (*d*) was 0.9 ± 0.3. Thus the main conclusions derived from the earlier work are substantiated.

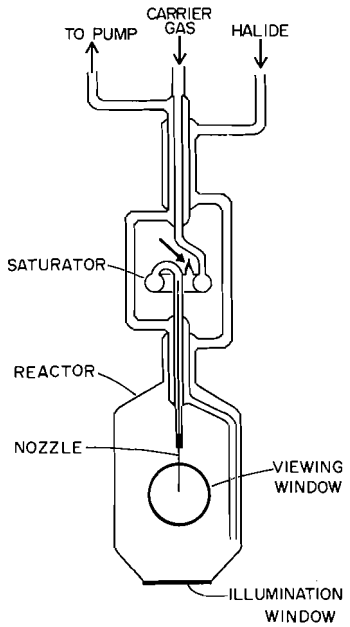

FIG. 1. Sodium diffusion flame apparatus.

It should be emphasized that large effects were produced by introducing the e.n.r. (or e.i.c.) assumption and the corrected visibility limit, and although these largely cancelled each other out in the present calculations they cannot be expected to do so in general. Furthermore, the corrections for halide depletion and wall reaction, although small in this case, can be expected to be quite important for faster reactions or different experimental conditions.

(VII) Experimental

The apparatus is shown in Fig. 1. The sodium still was glass-blown onto the apparatus at the point marked with an arrow during the preparatory stage. The sodium was carefully distilled in several stages under vacuum, after which the still was removed. The halides used were reagent grade, purified by trap-to-trap distillation under vacuum. The carrier gases used were prepurified grade N_2 and ultrahigh purity grade helium. They were passed through a quartz tube filled with copper turnings at

[7]Throughout this paper bimolecular rate constants are expressed in units of cm^3 mol^{-1} s^{-1}.

about 600 °C, a red-hot tungsten filament, and a liquid N_2 trap before passing over the molten Na in the saturator. A mass-flowmeter was used to measure the flow rate of the carrier gas.

The nozzle consisted of a 0.175 cm diameter nickel tube welded to Kovar which in turn was joined to Pyrex. This design allowed the saturated stream of Na in the carrier gas to contact only nickel once it left the saturator. The degree of saturation of sodium in the carrier gas was estimated by total product analysis together with the literature data (20, 21) on the vapor pressure of Na. Using a reactor with a glass nozzle and N_2 as the carrier gas, the degree of saturation ranged from 57% at 241 °C to 25% at 321 °C (with considerable scatter in the data). With He as the carrier, the degree of saturation was even smaller. Using the reactor with the nickel nozzle, 80% saturation of Na in N_2 could be achieved even at higher temperatures. However, for He used as the carrier, the degree of saturation was found to be a strong function of its pressure, ranging from 25% at 3 Torr to near 80% at 10 Torr or higher. This is apparently the first time that the assumption that the carrier gas is saturated with Na has actually been tested. Clearly, reaction of Na with glass decreases the apparent percent saturation, though obviously that is not the only factor involved. Since the degree of saturation depends on the design of the apparatus and is rather unreproducible, it would seem most advisable to measure in each experiment the total amount of product in order to be able to apply the formula for the rate constant with confidence.

The Na lamp was placed under the reactor so that the light entered through the bottom plane glass window. The resonance emission was observed through the window of the reactor at right angles to the incident beam. The outside of the reactor was painted black to help in seeing the emission.

Separate electrical resistance furnaces were constructed for the saturator and the reactor. Their temperatures were controlled by Wheatstone bridge circuits with platinum resistance thermometers as the sensors. Although the furnaces were controlled to 0.1 °C, the spatial variations inside the furnaces were of the order of a degree.

A F & M Model 700 dual column gas chromatograph equipped with flame ionization detectors was used for the analysis of the products. Several aliquots of the product mixture (which also contained excess halide reagent) were analyzed for each run.

(VIII) The Reaction Na + CH_3Br

Nineteen separate experiments were done on this reaction using a wide variety of conditions (with either N_2 or He as the carrier gas): temperatures from 241–389 °C, total pressure 2.8–98 Torr, flame diameter 0.68–1.68 cm, Na_n 2.1–289 × 10^{-11} mol/cm^3. Careful analysis of our data indicated that the rate constants did not drift with any experimental parameter other than temperature. Therefore we believe that the diffusion flame method properly applied does yield accurate absolute values of the rate constant, rather than merely relative values in homologous series as has been suggested. An Arrhenius plot of our rate constants yields: log A = 14.0 ± 0.4, E = 2.1 ± 1.2 kcal/mol. Our rate constants fall in between those determined by previous diffusion flame studies (log k_1 = 13.3 at 240 °C (22), 12.6 at 250 °C (16), 12.8 at 270° (23)). Frommer and Polanyi (24) using the mean life method found log k_1 = 12.2 at 200 °C and 12.8 at 240 °C, a much steeper temperature dependence than that found here. From our results, the reaction cross section, assuming p = 1.0, is 10 Å^2 for this reaction, compared to 31 Å^2 for the reaction Na + C_2H_5Cl (section VI). Hence it seems quite possible that the suggestion by Hartel and Polanyi that all reactions of this type have the same σ^2 (35 Å^2) is only a rough approximation. It should be pointed out that no attempt was made to reanalyze any of the earlier work. This also applies to previous work referred to in the subsequent sections of this paper.

(IX) The Reaction Na + CH_3Cl

The rate constants obtained here as well as in previous work are shown in Table 1. From our data, the Arrhenius parameters are: log A = 16, E = 8 kcal/mol. The other data are in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

reasonable agreement with ours, except that determined by the mean life method.

(X) The Reaction Na + C_2H_5Br

The results are shown in Table 1. There appears to be a significant discrepancy between our results and those of previous workers. From our work, there does not seem to be any difference between the rate constant of this reaction and that of Na + CH_3Br in this temperature range.

(XI) The Reaction Na + CH_3I

Our one value is $\log k_1 = 14.7 \pm 0.1$ at 249 °C, compared to previous values of 14.0 at 240–270 °C (5) and 14.3 at 276 °C (26). Because of the speed of this reaction, the correction for depletion of the halide is quite appreciable; hence the discrepancy between our results and previous work (in which no correction was made) may be due to this effect. Assuming, as seems most probable, that the activation energy of this reaction is zero, then $\sigma^2 = 35$ Å^2, exactly the value assumed by Hartel and Polanyi (5).

Appendix

The effective diffusion coefficient for a species i, whose mole fraction is very small, has been approximated by (28–30)

$$[31] \qquad D_i = \left(\sum \frac{x_j}{D_{ij}}\right)^{-1}$$

where x_j are the mole fractions and D_{ij} are the binary diffusion coefficients. It can be shown on the basis of rigorous kinetic theory applied to a ternary mixture of uniform density that the maximum error in eq. 31 is less than 0.1% for $x_i < 0.001$.

The binary diffusion coefficients were calculated from eq. 32 (ref. 14, p. 539)

$$[32] \quad D_{ij} = 0.0026280 \times \frac{(T^3(M_i + M_j)/2M_iM_j)^{1/2}}{P\sigma_{ij}{}^2\Omega^{(1,1)*}T/(\varepsilon_{ij}/k)}$$

where M is the molecular weight, P is the pressure, Ω is the collision integral, values of which are tabulated (ref. 14, p. 1126). σ, ε are Lennard–Jones parameters calculated by the usual combination rules for nonpolar molecules

$$\sigma_{ij} = (\sigma_i + \sigma_j)/2$$

$$\varepsilon_{ij} = (\varepsilon_i\varepsilon_j)^{1/2}$$

For nonpolar–polar mixtures, the values of σ_{ij} and ε_{ij} were calculated by the method given by Hirschfelder *et al.* (ref. 14, p. 600).

Lennard–Jones parameters used are from Hirschfelder *et al.* (ref. 14, p. 1111) with the exception of Na which comes from Ashton and Hayhurst (31). These predict a value of 0.70 cm^2/s for D_{Na-N_2} at 527 K, in good agreement with the experimental value of 0.68 ± 0.03 cm^2/s determined by Cvetanović and Le Roy (32).

On a étudié la cinétique de la réaction d'isomérisation unimoléculaire suivante:

$$M(CO)_4M'(CO)_4As(CH_3)_2C{=}CAs(CH_3)_2CF_2CF_2 \rightarrow M(CO)_4As(CH_3)_2M'(CO)_4C{=}CCF_2CF_2$$

Les valeurs de ΔH^* sont de 36.8 ± 2.0 (M = M′ = Mn), 46.8 ± 0.5 (M = M′ = Re), 39.2 ± 2.8 (M = Mn, M′ = Re) kcal/mol. On discute du mécanisme de ce réarrangement.
[Traduit par le journal]

Introduction

The ligand $f_4$fars,

$$(CH_3)_2AsC{=}CAs(CH_3)_2CF_2CF_2$$

has an almost unique ability to react with metal carbonyl clusters to give stable complexes in which the ligand has displaced two terminal carbon monoxide molecules from different metal atoms (1). For example, in $f_4farsFe_3(CO)_{10}$ the ligand bridges the two equivalent iron atoms which are also bridged by two CO and an $Fe(CO)_4$ moiety (2, 3). This particular complex on warming undergoes a rearrangement with cleavage of an As–cyclobutene bond and formation of a new Fe–cyclobutene bond. The structure of the product of formula "$f_4$fars"$Fe_3(CO)_9$ is shown in Fig. 1 (3, 4). This was an early example of a ligand cleavage reaction. Recently the phenomenon has been recognized in a number of instances (5, 6).

It is important to understand the bond-making and breaking which occurs in these reactions since some are analogous to processes of catalytic importance; but most systems are not convenient for quantitative study. Fortunately the rearrangement reaction shown in Fig. 2 is quantitative. Here, the bridged derivative $f_4farsMn_2(CO)_8$, **1**, (6, 7) is converted quantitatively into its isomer "$f_4$fars"$Mn_2(CO)_8$, **2**, on heating (7, 8).

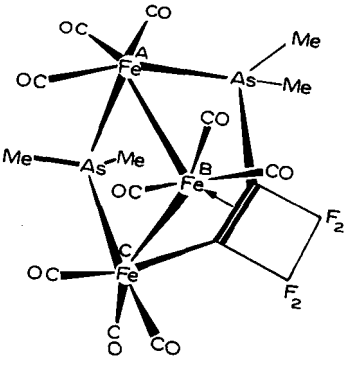

FIG. 1. The structure of "$f_4$fars"$Fe_3(CO)_9$.

The present investigation is concerned with a kinetic study of this reaction and the related ones involving $f_4farsRe_2(CO)_8$ and $f_4farsMnRe(CO)_8$.

Experimental

The complexes $f_4farsM_2(CO)_8$ (M = Mn or Re) were prepared as described previously (7).

FIG. 2. The structures of $f_4farsMn_2(CO)_8$, **1**, and its isomer "f_4fars"$Mn_2(CO)_8$, **2**, which is produced on heating **1**.

Reaction of f_4fars with $MnRe(CO)_{10}$

f_4fars (1.8 g, 5.4 mmol) and $MnRe(CO)_{10}$ (1.7 g, 3.3 mmol) were refluxed in *m*-xylene for 6 h. The solvent was removed and the residue chromatographed on Florisil. The second yellow band which eluted with 95:5 petroleum ether/diethyl ether contained the product $f_4farsMnRe(CO)_8$. This was crystallized from *n*-hexane at −78° (0.25 g, 3%), ^1H n.m.r. (C_6D_6 solution): singlets at 0.72 and 0.80 p.p.m. downfield from TMS; ^{19}F n.m.r. (C_6D_6 solution): singlet at 106.2 p.p.m. upfield from $CFCl_3$; ν(CO) (C_6H_{12} solution): 2086(6), 2008(9), 1997(8), 1976(10), 1950(5), 1933(9), 1924(8), 1914(6) cm^{-1}.

Kinetic Studies

In a typical experiment 0.0206 g of $f_4farsMn_2(CO)_8$ was dissolved in 0.5402 g of C_6H_6 in an n.m.r. tube. The tube was degassed, sealed, and heated to 139°. The progress of the thermal rearrangement was followed by taking the ^1H n.m.r. spectrum every 15 min. Integration of one of the two product absorptions shown in Fig. 3*a* gave the extent of reaction. The results are shown in Table 1. The graph of log [$f_4farsMn_2(CO)_8$] at time *t* *vs.* *t* is linear indicating the conversion is first order in $f_4farsMn_2(CO)_8$. The slope gives $k = 3.00 \times 10^{-2}\ min^{-1}$.

The thermal rearrangements of $f_4farsRe_2(CO)_8$ and $f_4farsMnRe(CO)_8$ were followed in a similar manner. The former compound, in addition to undergoing the expected known rearrangement, also seemed to decompose slowly by a different route at the high temperatures used. Typical n.m.r. spectra obtained from $f_4farsMnRe(CO)_8$ are seen in Fig. 3*b*. The reaction does not go to completion as the spectrum after 95 min does not change on further heating. Furthermore there seem to be two products (see discussion). However in both cases integration of the major product peaks gave data which resulted in good first order plots. In the case of the mixed carbonyl only initial data (~2 half-lives) were used, since it is possible that the products achieve equilibrium with the starting complex which is present in about 10% of its original concentration.

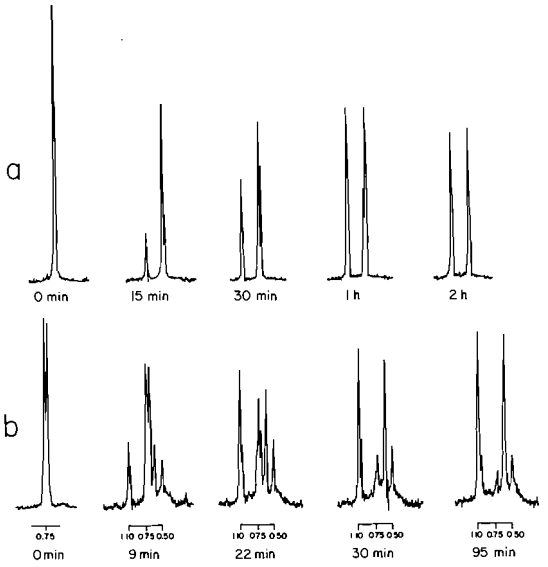

FIG. 3. Nuclear magnetic resonance spectra as a function of time obtained after heating (*a*) $f_4farsMn_2(CO)_8$, (*b*) $f_4farsMnRe(CO)_8$.

The rate constants derived in this way at various temperatures are listed in Table 2.

Results and Discussion

The new complex $f_4farsMnRe(CO)_8$ is obtained by heating f_4fars with $MnRe(CO)_{10}$. It presumably has the same bridged structure, **3**, as $f_4farsMn_2(CO)_8$ (Fig. 2, **1**). The n.m.r. spectrum of the mixed carbonyl derivative shows two arsenic methyl resonances (seen in Fig. 3*b* at zero time) and these must be due to the inequivalent ends of the ligand once com-

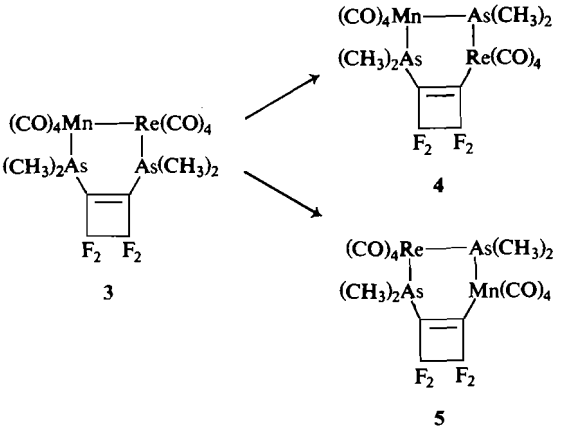
plexed. The symmetrical manganese and rhenium analogs show only a singlet (Fig. 3*a*) so the "cyclohexene" ring (**1** in Fig. 2) is conformationally mobile.

The mass spectrum of $f_4farsMn_2(CO)_8$ and its isomer (Fig. 2, **1** and **2**) are identical indicating that the thermal isomerization under investigation takes place in the mass spectrometer. Thus the mass spectrum of $f_4farsMnRe(CO)_8$ should be that of the product isomers, **4** and **5**, since two are possible in this case.



Apart from the usual parent ion followed by the loss of eight CO groups the mass spectrum shows a weak series of peaks corresponding to the sequence $\overline{C{=}CAs(CH_3)_2CF_2CF_2}.Mn(CO)_n$, n = 4–0. The corresponding sequence from a $Re(CO)_n$ moiety is absent. This indicates that only one of **5** or **4** is produced to any great extent and it seems likely that **5** would fragment in the observed manner.

In solution the rearrangement produces a major product with singlets at 1.10 and 0.60 p.p.m., which is presumably **5**, and a minor one with singlets at 1.08 and 0.50 p.p.m., presumably **4** (Fig. 3*b*).

Kinetic Results

The observed rate constants for the isomerization reaction are listed in Table 2. The activation enthalpies $\Delta H^{\ddagger}$ were derived from the Arrhenius plots. Although the temperature studies were minimal we consider that the magnitudes and trends of the parameters are significant.

The magnitude of $\Delta H^{\ddagger}$ for the manganese reaction is very similar to that reported by Poë and co-workers (9, 10) for the reaction of $Mn_2(CO)_{10}$ with oxygen (36.8 ± 0.4 kcal mol^{-1}). Substitution reactions of the type $Mn_2(CO)_9P(OC_6H_5)_3 + P(OC_6H_5)_3$ have similar activation energies (9, 10) and it seems that steric effects result in a lowering of the value for both types of reactions. It is argued that these reactions proceed via homolytic fission of the Mn—Mn bond. The analogous intermediate in the present set of reactions would be **6** in Fig. 4.

The σ–σ* transition (11) for $f_4farsMn_2(CO)_8$ occurs at 365 nm (ε = 9700) which is at longer wavelength than the parent carbonyl (343 nm) possibly indicating a weaker Mn—Mn bond. The bond length of the Mn—Mn bond in the parent carbonyl is 2.92 (3) Å whilst that of the f_4fars derivative is 2.971 (3) Å (8) again indicating a weaker interaction. The wavelength of the σ–σ* transition in the other complexes is 330 nm for $f_4farsRe_2(CO)_8$ and 340 nm for $f_4farsMnRe(CO)_8$, and thus the order of energy (and possibly of bond strength) for the three complexes is Mn_2 < MnRe < Re_2 which is that obtained for our kinetic $\Delta H^{\ddagger}$ values (Table 2). Even so homolytic cleavage as a first step cannot be regarded as being substantiated, and some contradiction comes from the observation that the free radical scavenger 3,5-di-*tert*-butyl-*O*-benzoquinone failed to affect the rate of isomerization of $f_4farsMn_2(CO)_8$.

In addition to the homolytic cleavage intermediate **6**, two other possible candidates are shown in Fig. 4. In **7**, coordinative unsaturation is achieved by forming the carbonyl bridged species. This type of intermediate has been postulated for halogen cleavage reactions (12, 13). In **8**, unsaturation is achieved by breaking the arsenic–metal bond.

	435	1.68×10^{-1}		

*Errors are estimated from the Arrhenius plots.

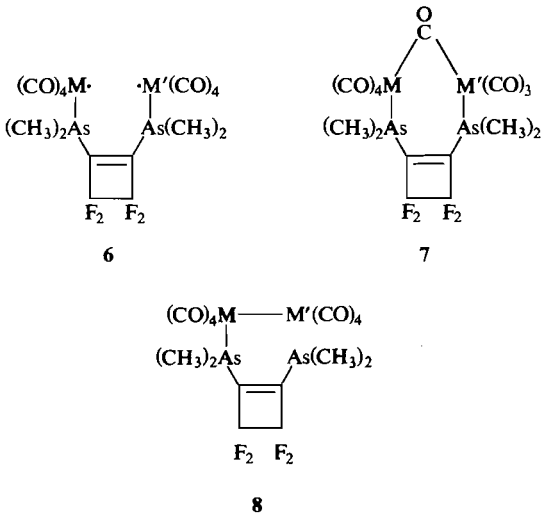

FIG. 4. Possible reaction intermediates for the thermal isomerization of $f_4$farsMM′$(CO)_8$.

In the case of all three intermediates it is possible to devise reasonable reaction paths leading to the final product. For example, oxidative addition of the As—C bond of **8** to the M′$(CO)_4$ moiety gives the correct atomic disposition.[1] Some of the rearrangements could be facilitated by temporary coordination of the double bond of the cyclobutene fragment in a manner analogous to that seen in "$f_4$fars"$Fe_3(CO)_9$ (Fig. 1).

The racemization of h^5-$C_5H_5MnP(C_6H_5)_3(NO)(COOR)$ has an activation enthalpy of 31.1 kcal mol^{-1} (15) and is believed to occur via phosphine dissociation. Thus our value of 36.8 kcal mol^{-1} could indicate arsenic dissociation to give **8**. The high activation entropy values (Table 2) could support some sort of dissociative intermediate.

[1]A similar mechanism has been suggested (14) for the reaction of $Re_2(CO)_{10}$ with $HSiCl_3$.

Configurational Entropy Change of Sodium Pyrophosphate

KIANG Y. LEUNG

School of Physics, University of Science of Malaysia, Penang, Malaysia

Received January 13, 1975

KIANG Y. LEUNG. Can. J. Chem. **53**, 1739 (1975).

Based on an analysis of the observed crystal structures of the phases of anhydrous sodium pyrophosphate, a calculation of the configurational entropy change of the system between the ordered ambient-temperature phase and the disordered hexagonal phase above 600 °C has been carried out. The result is $0.218R$ cal mol^{-1} deg^{-1} where R is the gas constant.

KIANG Y. LEUNG. Can. J. Chem. **53**, 1739 (1975).

En se basant sur une analyse des structures cristallines observés pour les diverses phases du pyrophosphate de sodium anhydre, on a effectué un calcul du changement d'entropie configurationnelle du système entre la phase ordonnée à la température de la pièce et la phase hexagonale désordonnée observée au dessus de 600 °C. Le résultat est $0.218R$ cal mol^{-1} deg^{-1}, où R est la constante des gaz. [Traduit par le journal]

Introduction

Anhydrous sodium pyrophosphate has a number of interesting order–disorder phase transformations between ambient temperature and its melting point. Leung (1) has studied in some detail the crystal structures of the phases of the system and the crystal structure of the ambient phase has been reported (2). A second paper on the crystal structure of the first phase above ambient temperature is under preparation.

Calculations of the configurational entropy of an order–disorder phase transformation have been carried out on a number of systems. Pauling (3) first calculated it for ice and Stephenson and Hooley (4) had worked on the ferroelectric crystal, potassium dihydrogen phosphate, both of which gave good agreement with the experimental values. In 1967, Okada (5) discussed the specific heat anomaly and calculated the configurational entropy change at the phase transition in copper formate tetrahydrate. Similar work was followed by Makita and Miki (6) on sodium trihydrogen selenite in 1970.

In this paper we calculate the configurational entropy change of sodium pyrophosphate based on the observed crystal structures of the phases of the system. Special attention is drawn to the idealized structure of the system discussed in (2) since all the observed phases can be described as a deviant from it. The present entropy calculation is feasible because certain structural features exist in the phase transformations which are summarized in Table 1. First, the ratio of the a and b axes is approximately $\sqrt{3}$ so that it is possible to inscribe a regular hexagon in the ab plane of the unit cell. Second, the sodium atoms and the bridging oxygen atoms of the pyrophosphate groups all lie in planes close to $z = 0$ and $z = \frac{1}{2}c_o$ and they occupy the highly symmetrical positions as shown in Fig. 1. Third, based on structural analysis, Leung and Calvo (2) inferred that the bridging oxygen atom of each pyrophosphate group is bonded to one of the three nearest coplanar sodium atoms (Fig. 1) and it is the change of orientation of this bond that gives rise to the observed phase transformations. Finally, it is found in ref. 1 that it is possible to divide the crystal into layers parallel to the ab plane at intervals $\frac{1}{2}c_o$ and that these layers can be considered as being weakly held together by sodium atoms between the terminal oxygen atoms of pyrophosphate groups in adjacent layers (*cf.* Na(3) and Na(4) of ref. 2).

All these features make it possible to state two basic postulates on the configurations that can exist within the system. From these postulates, we calculate the entropy change which could then be compared with experimental results. Unfortunately, however, at the time of writing, such results are not yet available.

Basic Postulates

Based on the structural features of the system we first divide the crystal into *basic cells*, having dimensions a_o, b_o, and $\frac{1}{2}c_o$, *i.e.* half the size of the crystal unit cell of the ambient-temperature phase. Then we propose the following postu-

TABLE 1. Phase transformations of sodium pyrophosphate*

Phase	Temperature (°C)	Space group	Cell dimensions a (Å)	b (Å)	c (Å)	β (deg)
I	20 → 405	$P2_12_12_1$	9.367(5) $\equiv a_0$	5.390(2) $\equiv b_0$	13.480(8) $\equiv c_0$	
II	405 → 515	$C2/c$	a_0	b_0	$2c_0$	93
III	515 → 520	Cc or $C2/c$	a_0	b_0	$3c_0$	90
IV	520 → 550					
V	550 → 700	$P6_3/mmc$	b_0	b_0	c_0	

*Reference 1.

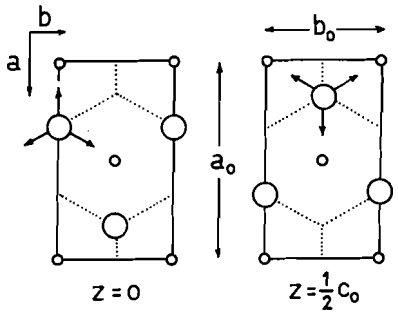

FIG. 1. Unit cell in ab plane at $z = 0$ and $z = \frac{1}{2}c_0$. Ratio $a_0:b_0$ is $\sqrt{3}$ approximately. Small circle represents sodium and large circle represents pyrophosphate group. Arrows from large circle represent the three possible bonds between sodium and bridging oxygen. P–P vector of pyrophosphate group is parallel to c axis. Note the inscribed regular hexagon in dotted lines.

lates regarding the configurations of the cells which can exist in the phases of the system:

Postulate (I). The bridging oxygen atom of each pyrophosphate group must be directed towards one of the three nearest coplanar sodium atoms.

Postulate (II). Each of the sodium atoms coplanar with the bridging oxygen atoms must have one and only one bridging oxygen atom of a pyrophosphate group directed towards it.

Fig. 2 shows that there can be only *eight* basic configurations satisfying these two postulates. We shall see below how a layer of the crystal can by constructed using these basic configurations.

One-Dimensional Checkerboards

We first consider a one-dimensional array of n basic cells along the b axis, each cell to be "filled" with an appropriate basic configuration. Following Okada (5), we call this array a one-dimensional checkerboard. Postulates *I* and *II* are to be observed in the process of filling the cells. Let $R(n)$ be the total number of arrangements of the n cells in this one-dimensional model. Then $R(n)$ can be divided into eight terms $R_i(n)$ $(i = 1, \ldots, 8)$ corresponding to each of the eight possible basic configurations in the nth cell. For example, $R_1(n)$ is the number of arrangements with configuration C_1 in the nth cell. Obviously

$$[1] \qquad R(n) = \sum_{i=1}^{8} R_i(n)$$

An array of $(n + 1)$ cells can be built by adding one cell next to the nth. However, a given configuration in the nth cell cannot take on all the eight possible basic configurations in the $(n + 1)$th cell without violating postulates *I* and *II*. For example, configuration C_1 can be followed only by configurations C_1, C_4, and C_5. In other words, for the case of $(n + 1)$ cells built by adding one cell next to the nth, we have

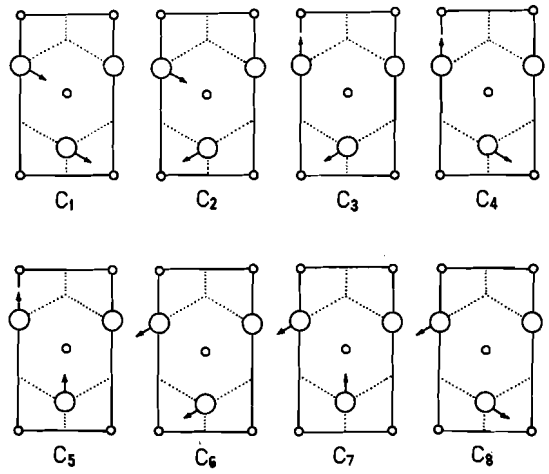

FIG. 2. Basic configurations of the system. Arrow shows orientation of bridging oxygen of a pyrophosphate group (large circle) to a coplanar sodium (small circle).

$$
\begin{aligned}
R_1(n+1) &= R_1(n) + R_2(n) + R_5(n) + R_7(n) \\
R_2(n+1) &= \quad\; R_2(n) + R_5(n) + R_7(n) \\
R_3(n+1) &= \quad\; R_2(n) + R_5(n) + R_7(n) \\
R_4(n+1) &= R_1(n) + R_2(n) + R_5(n) + R_7(n) \\
R_5(n+1) &= R_1(n) + R_2(n) + R_5(n) + R_7(n) \\
R_6(n+1) &= R_3(n) \quad\quad\; + R_6(n) \\
R_7(n+1) &= R_3(n) + R_4(n) + R_6(n) + R_8(n) \\
R_8(n+1) &= R_3(n) + R_4(n) + R_6(n) + R_8(n)
\end{aligned} \qquad [2]
$$

On addition, the l.h.s. of [2] becomes $R(n+1)$ using [1] and the r.h.s. can be simplified using [2] in terms of $R(n)$, $R(n-1)$, and $R(n-2)$. The result is the recurrence relation

$$R(n+1) = 4R(n) - 2R(n-1) + R(n-2) \qquad [3]$$

which is a linear difference equation of the third order

$$R(n+3) - 4R(n+2) + 2R(n+1) - R(n) = 0 \qquad [4]$$

where $n = 1, 2, \ldots$. To solve [4], we assume

$$R(n) = \beta^n \qquad [5]$$

which when substituted in [4] gives the cubic determinantal equation

$$\beta^3 - 4\beta^2 + 2\beta - 1 = 0 \qquad [6]$$

There are three roots to [6]: one real, A, and two complex, B_1 and B_2, which are conjugates to each other. If we write $B_1 = \rho e^{i\phi}$ where ρ = mod B_1 and ϕ = the phase angle, then $B_2 = \rho e^{-i\phi}$. A general solution of [4] can then be taken as

$$R(n) = c_1 A^n + \rho^n(c_2 \cos n\phi + c_3 \sin n\phi) \qquad [7]$$

where the constants c_1, c_2, and c_3 are to be determined from the boundary conditions

$$
\begin{aligned}
R(1) &= 8 \\
R(2) &= 28 \\
R(3) &= 98
\end{aligned} \qquad [8]
$$

which can be readily verified directly.

For later calculations, only the asymptotic value of ln $R(n)$ for very large n is needed. If $A > \rho$, [7] can be written in the form

$$R(n) = A^n\left(c_1 + \left(\frac{\rho}{A}\right)^n \times (c_2 \cos n\phi + c_3 \sin n\phi)\right) \qquad [9]$$

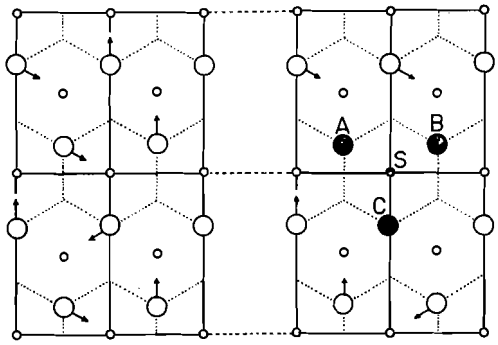

FIG. 3. The matching of two one-dimensional checkerboards to form a two-dimensional checkerboard.

giving

$$\ln R(n) = n \ln A + \ln\left(c_1 + \left(\frac{\rho}{A}\right)^n \times (c_2 \cos n\phi + c_3 \sin n\phi)\right) \qquad [10]$$

For very large n, the second term is negligible with respect to the first. We have, therefore

$$\lim_{n\to\infty} \ln R(n) = n \ln A \quad \text{if} \quad A > \rho \qquad [11]$$

Similarly

$$\lim_{n\to\infty} \ln R(n) = n \ln \rho \quad \text{if} \quad A < \rho \qquad [12]$$

Numerical calculations show that

$$A = 3.5116279 \text{ and } \rho = 0.5336429 \qquad [13]$$

so that [11] will be used in later calculations.

Two-Dimensional Checkerboards

Two-dimensional checkerboards can be obtained by putting two one-dimensional checkerboards alongside each other. It is then necessary to consider the *matching probability* of the individual cells. Referring to Fig. 3, consider a sodium atom such as S. In order to have postulates *I* and *II* satisfied, one of the following cases must hold:

(*a*) Bridging oxygen atom A *away* from S *and* bridging oxygen atom B *away* from S *and* bridging oxygen atom C *towards* S; probability $= \frac{5}{8} \times \frac{5}{8} \times \frac{3}{8}$.

(*b*) Bridging oxygen atom A *away* from S *and* bridging oxygen atom B *towards* S *and* bridging oxygen atom C *away* from S; probability $\frac{5}{8} \times \frac{3}{8} \times \frac{5}{8}$.

(*c*) Bridging oxygen atom A *towards* S *and* bridging oxygen atom B *away* from S *and*

bridging oxygen atom C *away* from A; probability = $\frac{3}{8} \times \frac{5}{8} \times \frac{5}{8}$.

Cases (*a*), (*b*), and (*c*) are mutually exclusive so that the total probability p is their sum, *i.e.* $p = 225/512$. Since there are n sites such as S for two one-dimensional checkerboards of n basic cells, the final matching probability P is given by

$$[14] \qquad P = p^n = (225/512)^n$$

Let $T(n,m)$ be the total number of possible arrangements when m one-dimensional checkerboards each of n basic cells are matched together. By definition

$$[15] \qquad T(n,1) = R(n)$$

For $m > 1$, it is obvious

$$[16] \quad T(n,m) = T(n,m-1) \cdot R(n) \cdot P = R(n)^m \cdot P^{(m-1)}$$

Taking logarithms, we have

$$[17] \quad \ln T(n,m) = m \ln R(n) + (m - 1) \ln P$$

When m and n are large, this can be simplified using [11] and [14]. Neglecting the term $n \ln p$ with respect to the others, the result becomes

$$[18] \qquad \ln T(n,m) = mn \ln (Ap)$$

This is the logarithm of the number of arrangements in a two-dimensional checkerboard, a quantity which is necessary to calculate the entropy. For sodium pyrophosphate the number of basic cells mn in a layer up the c-axis is $N/2$ where N is the number of molecules in that layer. If N refers to one mole of the crystal, and if k_B is Boltzmann's constant, it follows from [18] that the configurational entropy S of the system is given by

$$[19] \qquad k_B \ln T(n,m) = k_B \frac{N}{2} \ln (Ap) = \tfrac{1}{2} R \ln (Ap)$$

where R is the gas constant. Substituting the numerical values of A and p from [13] and [14] respectively, we have

$$[20] \qquad S = 0.218R \text{ cal mol}^{-1} \text{ deg}^{-1}$$

Actually, two-dimensional checkerboards themselves are stacked to form a three-dimensional crystal. Since interactions between adjacent layers are weak and the crystal is large enough to neglect the edge effect, no modification is necessary and [20] holds for the entire crystal.

Discussion

Equation 20 represents the configurational entropy change when the system changes from an ordered state to a disordered state when *any one* of the eight basic configurations (Fig. 2) is equally likely to occur in the system. This state of affairs corresponds to the transformations from the ordered ambient-temperature phase to the completely disordered hexagonal phase above 600 °C.

Experimentally we can measure the enthalpy ΔQ_i at each of the observed phase transition temperatures T_i of the system, and the total change of entropy is then given by

$$[21] \qquad \Delta S = \sum_i \frac{\Delta Q_i}{T_i}$$

where the summation is over the entire range of the phase transformations.

In the absence of experimental data which, at the time of writing, are in the process of being measured, it is of some interest to compare the anticipated results with some known entropy changes for orientational transformations in general. In the present calculation, we have neglected statistical Boltzmann factors in the partition function; that is, we assumed that all the eight basic configurations were energetically equivalent. Without neglecting this factor the calculated value would be smaller. Secondly, the transformations of the system between 500 and 600 °C as determined by differential thermal analysis (1), are generally such that the transition temperatures can only be estimated within about 3°. This means in measuring the enthalpy of the system, we would have to drop part of it over the temperature range. This was probably the case in copper formate tetrahydrate where Okada (5) observed a slightly higher theoretical value of the entropy, namely, 1.06 *vs.* 0.78 cal mol^{-1} deg^{-1}. In the case of sodium trihydrogen selenite (6), the agreement was very much better (1.59 *vs.* 1.53 cal mol^{-1} deg^{-1}) even though the statistical Boltzmann factors are again neglected.

It must be emphasized finally that result [20] follows directly from postulates *I* and *II* imposed on the system and it remains for measurements such as [21] to provide an experimental verification. A positive outcome will certainly lead to a better understanding of the mechanisms responsible for the phase transformations of the system of sodium pyrophosphate.

The author wishes to acknowledge with thanks many interesting discussions with Dr. Liew Yong Choy and Professor G. W. Groves, of the School of Physics, University of Science of Malaysia, Penang, Malaysia and with Professor Crispin Calvo of the Department of Chemistry, McMaster University, Hamilton, Ontario.

Mechanism of the Direct Photochemical Decomposition of Thietane and its Derivatives in the Vapor Phase, in Solution, and in Glassy Matrices

DAVID R. DICE[1] AND RONALD P. STEER[2]

Department of Chemistry and Chemical Engineering, University of Saskatchewan, Saskatoon, Saskatchewan S7N 0W0

Received January 8, 1975

DAVID R. DICE and RONALD P. STEER. Can. J. Chem. **53**, 1744 (1975).

The direct photolyses of thietane, 3-ethyl-2-propylthietane, and 3-methylthietane in the vapor phase, in solution, and in glassy matrices at low temperatures have been examined. The effects of varying the photolysis wavelength, the temperature, the pressure and the phase of the substrate, and of adding inert thermalizers on the nature and yields of the various products have been measured. The results are interpreted in terms of initial C—S cleavage to give a 1,4-biradical which may, in the gas phase, decompose or ring close before complete equilibration of the various rotamers is achieved, or which may be thermalized in condensed media and trapped in glassy matrices at low temperature.

DAVID R. DICE et RONALD P. STEER. Can. J. Chem. **53**, 1744 (1975).

On a étudié la photolyse directe du thiétanne, de l'éthyl-3 propyl-2 thiétanne et du méthyl-3 thiétanne en phase vapeur, en solution et dans des matrices vitreuses à basse température. On a mesuré les effets de la longueur d'onde de photolyse, de la température, de la pression, de la phase du substrat et de l'addition de thermaliseurs inertes sur la nature et le rendement des différents produits. On interprète les résultats en invoquant tout d'abord la rupture du lien C—S conduisant à un biradical-1,4 qui, en phase gazeuse, peut se décomposer ou reformer le cycle avant qu'un équilibre complet entre les divers rotamères ait pu s'établir, ou qui peut être thermalysé en milieux condensés et rester pris dans les matrices vitreuses à basse température.

[Traduit par le journal]

Introduction

Biradical intermediates have been postulated in numerous systems to explain the differences between the stereochemistry which is observed and that which is predicted for concerted reactions on the basis of the Woodward–Hoffmann "rules". In particular, the photodecomposition of the cyclic ketones (1) and cyclic azo compounds (2) have been extensively studied and compelling evidence for biradical intermediates has been obtained in these systems. Less complete investigations have been carried out on the cyclic ethers (3) and cyclic sulfides (4, 5).

The photochemistry of the thietane ring system in solution has been previously examined by Padwa and Gruber (4*a*) and in the gas phase by Weibe and Heicklen (4*b*). In the former work, the intermediacy of 1,4-biradicals was suggested although conclusive evidence for them was not obtained. In the latter work several intermediates of unspecified structure were introduced to explain the effects of varying the excitation wavelength on the yields of the C_2 and C_3 products. Subsequent investigations showed (5*b*) that the mechanism proposed in this study was unnecessarily complicated and could be simplified by taking into account the fact that propylene was the product of a slow secondary reaction between the reaction products and the substrate.

In previous communications we have presented evidence that 1,4-biradicals are intermediates in both the direct (5*a*) and mercury sensitized (5*b*) decomposition of 3-ethyl-2-propylthietane (EPT) in the gas phase. Triplet 1,4-biradicals from the mercury sensitized decomposition of EPT exhibit substantially longer lifetimes than the corresponding singlets produced on direct excitation and may readily be brought into thermal equilibrium with their surroundings by the addition of moderate pressures of inert thermalizing gases. The question of the nature of the biradicals produced on direct excitation has remained in doubt, however.

In this paper the results of experiments to elucidate the mechanism of the direct photolysis of thietane in the vapor phase and in solution are presented. It is shown that the primary process in the photodecomposition of thietanes

involves the formation of 1,4-biradical intermediates and that subsequent reactions of these species lead to the observed products. Evidence that singlet biradicals formed under different conditions exhibit different chemistries is presented.

Experimental

Apparatus

The vapor phase photolysis apparatus and light sources have been previously described (*5b*). Liquid phase photolyses were conducted in a 5 mm inside diameter quartz tube which could be connected to a vacuum system for degassing of samples and analysis of gaseous products. The light source for the liquid phase photolysis was a Hanovia 100 W medium pressure mercury lamp used in conjunction with a Vycor 7910 filter to isolate wavelengths greater than 250 nm. Photolyses of low temperature glasses were carried out using this same light source together with a 10 cm cell constructed of stainless steel and quartz which was cooled in a cryostat compatible with the Cary 14 spectrophotometer (6).

The light source used in the measurement of the direct photolysis quantum yields was an Osram 450 W high pressure xenon arc lamp. The desired region of the spectrum was isolated using a Zeiss M4Q-III quartz prism monochromator adjusted for a 10 nm bandwidth. Diethyl ketone (Koch-Light) was used as the primary actinometer, assuming that $\Phi(CO) = 1.0$ at 200 °C (7).

Materials

3-Ethyl-2-propylthietane (EPT), synthesized by the method of Searles *et al.* (8), was purified and separated into its *cis* and *trans* isomers by preparative gas chromatography using dinonylphthalate and Ucon Polar 50-HB-2000 columns. The purified starting materials were determined by g.c. analysis to be 99.9+% *trans*-EPT and 99.6% *cis*-EPT. 3-Methylthietane was prepared by the method of Bordwell and Hewett (9) and was purified by preparative g.c. Thietane (Eastman) was purified by preparative g.c. and was 99.99% pure.

Solvents for the liquid phase photolyses (cyclohexane and 3-methylpentane) were purified by repeated shaking with concentrated H_2SO_4 followed by washing with saturated aqueous $NaHCO_3$ and distilled water. The resulting materials were dried over molecular sieve and finally distilled through a spinning band column.

CO_2 and SF_6 (Matheson) were trap-to-trap vacuum distilled at temperatures at which their vapor pressures were less than 1 Torr, and were degassed at −196 °C prior to use. Traces (<1 p.p.m.) of an unidentified, innocuous impurity which could not be removed by this method remained in the SF_6. Ar (Matheson) was passed through a 10 ft by $\frac{1}{4}$ in. copper column which was packed with cleaned copper shot and which was heated to the temperature at which the characteristic color of copper oxide appeared on the outside of the tubing. No oxygen could be detected in these gases by g.c.

Analysis

Products were separated from one another and from residual reactants by low temperature trap-to-trap distillation prior to g.c. analysis, using standard high vacuum techniques. To prevent losses of ethylene when separating Ar from the other reactants and products, distillation at −210 °C (solid N_2) was necessary.

A Gow-Mac 69-500 thermal conductivity g.c. with a 10 ft by $\frac{1}{4}$ in. stainless steel column packed with Porapak Q was used to analyze the products which were noncondensable at −130 °C; condensables were analyzed using an F & M dual column flame ionization g.c. A 10 ft by $\frac{1}{8}$ in. stainless steel column packed with 10% tricresyl phosphate on Chromosorb P was used for most of the analyses. A 10 ft by $\frac{1}{8}$ in. column of 40% $AgNO_3$ in ethylene glycol on Chromosorb P preceded by a 1 ft length of tricresyl phosphate was used to separate the 3-heptene isomers. Products were identified by comparing their g.c. retention times with those of authentic samples. Identitities were confirmed by mass spectrometry. For some analyses a g.c. coupled to an AEI-MS12 mass spectrometer with a Biemann-Watson type helium separator was used.

Results

Vapor Phase Photolysis

In addition to the ethylene and propylene previously reported (*5b*), subsequent investigation has revealed that 1,2-dithiocane (DTO) is also formed in small yields when thietane (THT) is photolyzed in the vapor phase. The quantum yields of these products determined at wavelengths of 254, 290, and 313 nm, and temperature of 25 and 200 °C are shown in Table 1. Within experimental error, $\Phi(C_2H_4) + \Phi(DTO) = 1.0$ at all wavelengths for temperatures $\geq$200 °C. There is, however, a marked drop in $\Phi(DTO)$ on going from a wavelength of 313 nm to 254 nm and at 25 °C $\Phi(C_3H_6) + \Phi(DTO) < 1.0$. Within experimental error the rates of formation of both ethylene and propylene are independent of exposure time to at least 1% decomposition. However, it has been previously shown (*5b*) that propylene results from a slow reaction involving primary photoproducts and the measured $\Phi(C_3H_6)$ therefore depends on the extent of decomposition.

At 313 nm increasing the temperature from 25 to 235 °C caused an increase in the rates of formation of all products measured. These results are shown in Table 2. The results at low temperatures are somewhat less accurate than those at higher temperatures because of the tendency for polymer to collect on the cell windows and thereby reduce the intensity slightly as the run progressed. The decrease in intensity of the transmitted light over the course of a run was less than 5% at the lowest temperatures measured, however, and most of the data were collected at 200 °C where the deposition of polymer was insignificant. At temperatures

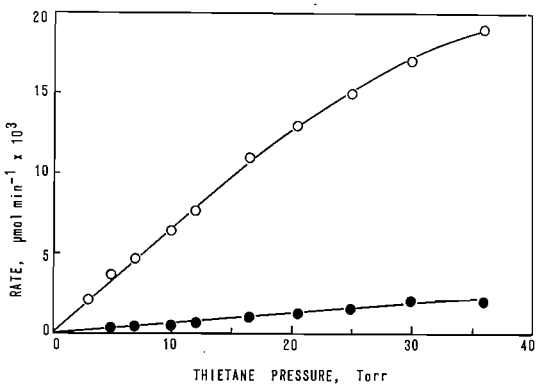

FIG. 1. Variation of $R(C_2H_4)$ and $R(C_3H_6)$ as functions of P(THT) in the direct photolysis of thietane vapor at 313 nm and 200 °C: ○, C_2H_4; ●, C_3H_6.

greater than about 235 °C, thermal decomposition of thietane took place at a significant rate.

The effect of varying the substrate pressure on the rates of formation of ethylene and propylene when thietane was photolyzed at 313 nm and 200 °C is shown in Fig. 1. The deviation from linearity of $R(C_2H_4)$ as a function of thietane pressure at higher pressures is to be expected in systems which follow the Beer–Lambert Law. The addition of up to an atmosphere of inert deactivating agents, CO_2, SF_6, or Ar, had no appreciable effect on the yields of either ethylene or propylene (*cf.* Table 3).

The major products detected in the direct photolysis of either *cis*- or *trans*-EPT at a wavelength of 254 nm and a substrate pressure of approximately 0.5 Torr were isomerized substrate, 1-butene, and *cis*- and *trans*-3-heptene. Small amounts of ethane, ethylene, propane, and propylene were also present, but were not analyzed routinely as the sum of the yields of the C_2 and C_3 products was less than 0.1% of the sum of the yields of C_4 and C_7 products.

The yields of 1-butene and of *cis*- and *trans*-3-heptene were directly proportional to substrate pressure (*cf.* Table 4), within experimental error. The addition of 760 Torr of CO_2 as an inert thermalizer, or of 10 Torr of NO as a radical scavenger, had no significant effect on the rates of formation of the measured products.

The only −130 °C noncondensable product in the photolysis of 3-methylthietane at 313 nm and 25 °C was propylene. At 60 or 205 °C traces of 2-methyl-1-propene were also present in the reaction products. There was no evidence for any ethylene formation under any of the conditions of photolysis investigated.

Condensed Phase Photolysis

Photolysis of thietane either as a neat liquid or in hydrocarbon solvents at room temperature is complicated both by the large numbers of products formed and by the formation of extensive amounts of a solid white material. Mass spectral analysis of this solid, which was insoluble in benzene, acetone, or carbon disulfide, indicated that this product is likely polymeric. There was no evidence of any product with a molecular weight of 138 (thioformaldehyde trimer) either in the solid itself or in benzene washings of the solid.

The major −130 °C noncondensable product in the liquid phase photolysis was ethylene. No propylene was detected. At least 20 different products condensable at −130 °C were detectable by gas chromatography, but only one of these, *n*-propyl disulfide, was present in sufficient quantities to be identified on the g.c.–m.s. combination. Traces of a product with a retention time identical to that of cyclohexene were also detected when cyclohexane solutions were photolyzed.

The relative rates of formation of ethylene and *n*-propyl disulfide are shown in Table 5. The decrease in the rates of product formation with increasing photolysis time is due to the consumption of the substrate and the increasing amount of light scattered from the cell by the solid material formed during the course of the run. However, within experimental error, the ratio of the rate of formation of ethylene to that of *n*-propyl disulfide is independent of the length of photolysis, indicating that these two products are not likely formed as a result of secondary photodecomposition.

Thietane was also photolyzed in several glassy matrices at low temperatures, and the u.v.–visible absorption spectra of the resulting mixtures were measured. Photolysis of thietane at −180 °C at a concentration of 0.02% by volume in EPA (diethylether:isopentane:ethanol, 5:5:2 by volume) or 3-methylpentane resulted in a new absorption with λ_{max} = 310 nm. Upon warming there was a slight decrease in intensity of this absorption (*cf.* Fig. 2). Near the softening point of the glass a reaction producing a white solid took place, and the λ_{max} of the photoinduced absorption shifted to shorter wavelengths. At about −50 °C, λ_{max} of this absorption was 300 nm. Recooling the mixture produced no significant spectral changes other than about a 20% increase in the absorbance due to contraction of the solvent.

Analysis of the solid product formed upon warming of the mixture was done by mass spectrometry. The low eV mass spectrum indicated that at least two products having molecular weights of 120 and 138 are present in the

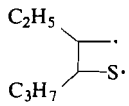
Discussion

Vapor Phase Photolysis

Partial isomerization of the 3-heptene products and of the EPT substrate on direct photolysis of either *cis*- or *trans*-EPT is consistent with the formation of biradical intermediates in the primary photochemical step. From a consideration of molecular orbital symmetries (10) it is apparent that if a concerted photocycloreversion reaction were to occur from the excited state of thietanes, it should involve the *supra-supra* mode with 100% retention of configuration. The corresponding *antara-antara* split can likely be ruled out on steric grounds (10*b*). Therefore, the major mechanistic route in the photodecomposition of EPT and, by analogy, of thietane itself, must involve biradicals.

Cleavage of either *cis*- or *trans*-EPT at C_2—S would form 1,4-biradical **1**, while cleavage at C_4—S would result in the formation of 1,4-biradical **2**.

[1] 
1



2

1 could subsequently ring close, or decompose to form 3-heptene and thioformaldehyde while **2** could ring close, or decompose to 1-butene and butanethial. Because of their thermal instability the thials would not have been detected with the analytical techniques used.

Biradical **1** is of principal interest because the isomeric composition of the 3-heptene product indicates the conformation of this biradical at the instant of its decomposition. If internal rotations about the C—C bonds of this biradical are fast compared with either its rate of decomposition or its rate of ring closure, thermal equilibrium would be achieved among the various biradical rotamers. On subsequent decomposition an equilibrium value of the ratio *R*(*trans*-3-heptene)/*R*(*cis*-3-heptene) would then be obtained. Such a thermal equilibrium distribution of the rotational conformers of the biradical is obviously not achieved in the direct photolysis of EPT as the value of *R*(*trans*-3-heptene)/*R*(*cis*-3-heptene) depends on the conformation of the starting isomer of EPT. This ratio equals 0.506 for the photolysis of *cis*-EPT and 6.88 for the photolysis of *trans*-EPT, independent of pressure. Internal rotation about the C—C bonds of biradical **1** must therefore occur at a rate which is comparable to the rate of its decomposition into 3-heptene and thioformaldehyde. Since the amount of isomerized substrate is also of the same order of magnitude as the amount of 3-heptene formed, the rate of ring

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

For personal use only.

closure must be comparable to that of internal rotation.

A minimum of 57% of the products must come from the decomposition or ring closure of biradicals **1** and **2**. In such a "worst case" calculation it is first assumed that isomerized products have a 1,4-biradical precursor. Second, it is assumed that the *minimum* amount of unisomerized product resulting from the biradical can be calculated by assuming that there is an equilibrium in the *cis*- and *trans*- conformations (about bond C_3—C_4) of biradical **1**. The equilibrium constant used in this calculation was derived from a value of $\Delta G_{298}^0 = 0.33$ kcal mol^{-1} for the *trans*- and *cis*-rotamers of the triplet biradical (*trans*- lower in energy), measured in the mercury sensitized decomposition of EPT (*5d*). Since the value of *R*(*trans*-3-heptene)/*R*(*cis*-3-heptene) observed in the direct photolysis differs greatly from the equilibrium value, the actual amount of product resulting from an intermediate biradical should be substantially greater than 57%. While a molecular split cannot be ruled out unequivocally from this data, it is apparent that, if such a process occurs at all, it must be of minor importance in the direct photolytic decomposition of gaseous EPT.

The yield of 1-butene, the product resulting from initial C_4—S cleavage of EPT, is less than the total yield of the isomeric 3-heptenes, the ultimate products of initial C_2—S cleavage. This inequality is more pronounced for *trans*-EPT (*R*(3-heptene)/*R*(1-butene) = 1.71:1) than for *cis*-EPT (*R*(3-heptene)/*R*(1-butene) = 1.13:1). Two factors may contribute to this. First, a preference for C_2—S (compared to C_4—S) cleavage of EPT might be due to electronic effects because the biradical from C_2—S cleavage has one secondary radical center and should therefore be somewhat more stable than the biradical from C_4—S cleavage, which has only primary radical centers. However, even if C_2—S and C_4—S were to cleave with equal probability in EPT, steric effects in the resulting biradicals should yield the observed trend in the product ratios. From a consideration of biradical geometries it is apparent that cleavage of *cis*-EPT between C_4—S forms a biradical which is initially *cis-cis*[3] and which can rotate to a lower energy *trans-trans* biradical (see Fig. 3). There should therefore be a preponderance of the conformers of biradical **2** in the *trans-trans* conformation. However, cleavage of *trans*-EPT between C_4—S gives a *cis-trans* biradical that can only rotate to an approximately equiergic *trans-cis* conformation. A 1,4-biradical which is *trans* across C_2—C_3 cannot ring close, but can only decompose (11–13). Thus, biradical **2** from *trans*-EPT should undergo a greater amount of ring closure than biradical **2** from *cis*-EPT. Moreover, as rotation about bond C_2—C_3 appears somewhat less restricted in biradical **1** than in biradical **2**, there should be a higher proportion of biradical **1** in the *trans*-(C_2—C_3) conformation than there will be for biradical **2**. This should make decomposition more favorable from biradical **1** than from biradical **2**, and

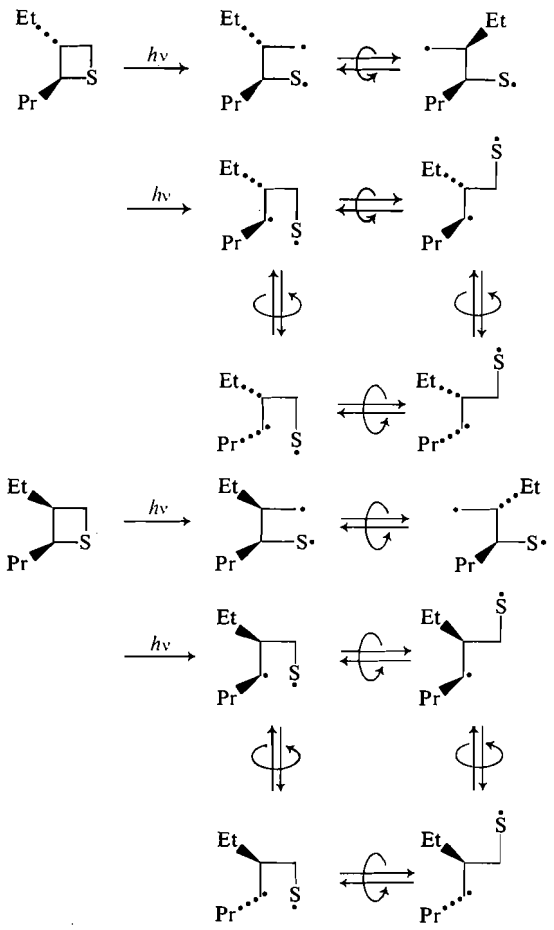

FIG. 3. Rotational conformations of biradicals **1** and **2**: Et = C_2H_5; Pr = C_3H_7; ↻ rotation about a biradical C—C bond.

[3]The conformation of the biradical is labelled first with respect to its conformation about the C_2—C_3 bond, and second, with respect to the conformation of the substituents.

even more favored when the substrate is *cis*-EPT.

Evidence that the direct photolysis of thietane vapor must also produce a biradical intermediate is (*a*) that DTO is formed, (*b*) that $\Phi(C_2H_4)$ is less than unity under certain conditions, (*c*) that $\Phi(C_2H_4)$ is temperature dependent, and (*d*) that the direct photolysis of thietane vapor with added cyclopentadiene results in the formation of a product which has its origin in the addition of a 1,4-biradical to cyclopentadiene (5*c*). These observations are inconsistent with molecular scission. Because substitution of the ring by alkyl groups does not substantially alter the nature of the primary process in the photolysis of the cyclobutananones (1*a*, *b*, *d*) and other compounds yielding biradical intermediates, it might also be expected that the photolyses of thietane and EPT in their lowest lying singlet states both involve biradical intermediates. The lack of ethylene formation in the photolysis of 3-methylthietane indicates that it is unlikely that any cross ring reactions are taking place. Therefore, the sole primary process in the direct photolysis of thietane vapor is likely cleavage of either C—S bond to form a 1,4-biradical, reaction 2.

[2] 
3

The lifetime of biradical **3** is probably at least as short as that of biradical **1** since the former has considerably fewer vibrational modes with which to dissipate any "excess" vibrational energy. It is apparent, therefore, that DTO must be formed by the attack of **3** on thietane, rather than by the combination of two biradicals. Even if the biradical combination reaction were diffusion controlled and had zero activation energy, the steady state concentration of biradicals would be so low that, under the conditions of these experiments, the rate of biradical combination would be about 10^{15} times slower than the observed rate of DTO formation. Thus, reaction of biradical **3** with the substrate to form a secondary intermediate biradical, **4**, which subsequently ring closes to form DTO (5*c*) is indicated. The reactions are:

[3] 
4

[4] **4** ⟶ DTO

Electrophilic attack by the thiyl portion of the biradical is predicted to occur predominately at the sulfur atom of thietane (16). This prediction is borne out by experiment as no products of the addition of **3** to thietane other than the cyclic disulfide were detected.

The question of the nature of biradicals **1**, **2**, and **3** at the instant of their formation and at the time of their subsequent reactions now must be considered. The biradical formed by breaking a C—S bond in the ground electronic state of thietane (*i.e.* by thermal decomposition) must be in its lowest lying singlet state initially and must lie on the same potential hypersurface as ground state thietane. Electronic excitation requires a transition between two different potential surfaces, however. Therefore, if photoexcitation of thietane results in C—S cleavage without intervening radiationless transitions, the initially formed biradical must lie on an excited singlet state potential surface. If, however, the excited state of thietane is not wholly unbound with respect to C—S separation then the biradical could be formed in a highly vibrationally excited ground state via predissociation (15). While it is not possible to determine unequivocally from the present data which of these processes is occurring in thietane, because no hint of any structure is apparent in the long wavelength band of the gas phase u.v. absorption spectrum (14), we assume that the upper state is unbound and that predissociation is not occurring. In any event, the lack of effect of thermalizing gases on the absolute or relative yields of the olefin products from either thietane or EPT indicates that hot triplet biradicals which are readily deactivated at moderate pressures (5*c*) are not involved in the direct photolysis mechanism. Intersystem crossing in either the excited thietane or the initially formed biradicals is therefore ruled out.

In this biradical mechanism both ethylene and thioformaldehyde would be formed by the unimolecular decomposition of biradical **3**, reaction 5.

[5] $\mathbf{3} \rightarrow C_2H_4 + CH_2S$

From thermochemical (17, 18) and spectroscopic data (19*a*, *b*, *c*), theoretical calculations (19*d*), and on the basis of the above arguments it is evident that thioformaldehyde could be formed in a low lying singlet excited state via

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

the dissociation of an electronically excited singlet biradical. There is at present insufficient evidence to draw any conclusions about the electronic state of the initial products of biradical decomposition, however.

If reaction 2 is the only primary process in the photolysis of thietane, it is apparent that biradical **3** must undergo reactions other than [3] and [5], as only at high temperatures does $\Phi(C_2H_4) + \Phi(DTO)$ approach 1.0 for photolysis at 313 nm. No other products were detected which could result from reaction of biradical **3**, other than the polymer which deposited on the cell walls. It therefore appears that a reasonable additional reaction of a ground state biradical **3** is ring closure, reaction 6, forming a vibrationally hot ground state thietane molecule.

[6] 
Such a hot molecule is expected to undergo the following further reactions:

[7] 
[8] 
[9] 
The corresponding overall ring closure process does occur to a significant extent on direct photolysis of EPT because substantial amounts of isomerized substrate are detected in that system. Thietane itself should exhibit similar behavior.

The biradical formed in reaction 8 need not necessarily be on the same potential hypersurface as the biradical formed in reacion 2, and might therefore undergo different reactions. The relative importance of reactions 6 to 9 is difficult to assess because the amount of polymer formed could not be measured. Qualitatively, less polymer is formed at higher temperatures, in agreement with the proposed mechanism. However, the lack of effect of up to an atmosphere of deactivating gases on the yield of ethylene in the thietane photolysis, or on the yields of any measured products in direct EPT photolysis, indicates either that the hot ring-closed molecule is efficiently quenched even at low pressures, or more likely, that any hot ring-closed products do not decompose or react further to give products which would be detected using the analytical techniques employed.

We believe that this latter alternative is correct. Thermal decomposition of thietane at temperatures of 250 °C in the dark photolysis cell yielded considerable amounts of an involatile, polymeric, yellow oil together with small amounts of hydrogen sulfide, ethylene, ethane, propylene, and propane. Ethylene was not a major product under the conditions employed. The polymer formed in the vapor phase photolysis may therefore be formed via the reaction of hot ground state thietane in a process analogous to thermolysis. The formation of small amounts of ethane, ethylene, propane, and propylene in the photolysis of EPT is also consistent with the fragmentation of a hot precursor.

The fraction of biradicals forming ring-closed products is greater in the EPT photolysis than in the photolysis of thietane itself. Not less than 43% of the observed products results from the ring closure of the biradical in the photolysis of *cis*-EPT at 200 °C and 313 nm for example. (Since this excludes the contribution of ring closure forming unisomerized substrate, the actual amount of ring closure will in fact, be greater than 43%.) However, by comparison, at 200 °C ring closure accounts for less than 4% of the products in the photolysis of thietane at 313 nm. ($\Phi(C_2H_4) + \Phi(DTO) = 0.96$.) Thus ring closure is less efficient in the unsubstituted thietane, consistent with its smaller number of vibrational modes.

The observed decrease in $\Phi(C_2H_4)$ as the wavelength of photolysis is decreased may be explained on a similar basis. As the energy input to the biradical is increased its rate of unimolecular decomposition must also increase. Consequently, the lifetime of the biradical will decrease, as will the probability of its collision with a thietane molecule to form DTO via reactions 3 and 4.

If one assumes that reaction 3 is the rate determining step in the formation of DTO, a plot of $\ln \{\Phi(C_2H_4)/\Phi(DTO)\}$ as a function of $1/T$ should be linear with an intercept of $\ln (A_5/A_3[THT])$ and slope of $(E_{a_3} - E_{a_5})/R$ (where A's are the Arrhenius preexponential factors, E_a's are the activation energies, and R is the gas constant). This plot is shown in Fig. 4, and is linear within experimental error. The

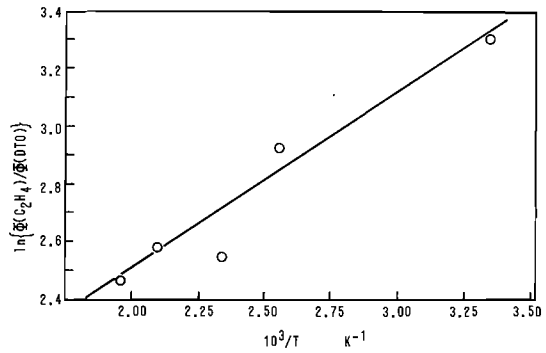

FIG. 4. Plot to determine the activation energy difference of reactions 3 and 6.

calculated activation energy difference, $E_{a_3} - E_{a_5} = 0.32 \pm 0.04$ kcal mol^{-1}.

Also, the lack of effect of adding high pressures of inert gases tends to indicate that reaction 8 is of limited importance in producing analyzable products. If one assumes that feedback via reaction 8 to produce ethylene does not occur to any significant extent, then

$$R(C_2H_4) = \frac{k_5\Phi I_a}{k_5 + k_6 + k_3[THT]}$$

At low pressures $I_a \simeq I_0\{\varepsilon l\}[THT]$ and therefore

$$R(C_2H_4) = \frac{k_5\Phi I_0\varepsilon l[THT]}{k_5 + k_6 + k_3[THT]}$$

and

$$1/R(C_2H_4) = \frac{k_3}{k_5\Phi I_0\varepsilon l} + \frac{k_5 + k_6}{k_5\Phi I_0\varepsilon l[THT]}$$

A plot of $1/R(C_2H_4)$ *vs.* 1/[THT] should therefore give a straight line with the ratio of slope/intercept $= (k_5 + k_6)/k_3$ at low thietane pressures. This plot is shown in Fig. 5. The value of $(k_5 + k_6)/k_3 = 6.3 \pm 1.1 \times 10^{-3}$ mol/l.

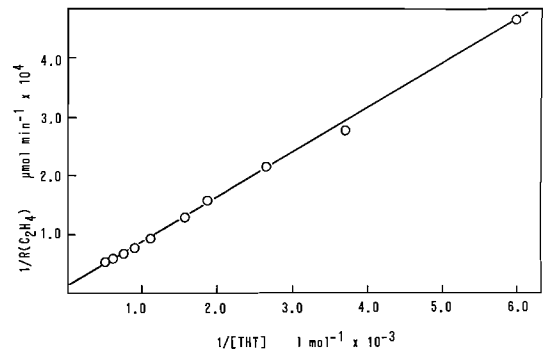

FIG. 5. Plot to determine the value of $(k_5 + k_6)/k_3$.

Condensed Phase Photolysis

There are three mechanisms which could lead to the formation of *n*-propyl disulfide in the photolysis of thietane in liquid solution. The first of these, the combination of two biradicals followed by H-abstraction, can be eliminated because the steady state concentration of biradicals must be small and it is very unlikely that the 1,4-biradical would have a lifetime sufficiently long to migrate from the solvent cage and encounter another biradical. A second mechanism might involve attack of the vibrationally relaxed (21) biradical on thietane in a reaction analogous to that postulated to lead to DTO in the gas phase. Subsequent H-abstraction from the solvent by biradical **4** could then yield the observed product. This reaction also seems unlikely as no DTO was detected in the liquid phase photolysis and it is difficult to see why H-abstraction should be so much more highly favored than ring closure in solution. The most probable mechanism involves H-abstraction by the alkyl portion of the biradical **3** to form a monoradical, *n*-propanethiyl, reaction 10.

[10] $\quad 3 + RH \rightarrow CH_3CH_2CH_2S\cdot + R\cdot$

Similar H-abstraction reactions have been observed in other systems involving biradicals in solution (22). Subsequently the combination of two *n*-propanethiyl radicals lead to the formation of *n*-propyl disulfide via reaction 11.

[11] $\quad 2CH_3CH_2CH_2S\cdot \rightarrow C_3H_7SSC_3H_7$

The fact that no 1,6-hexanedithiol is formed is consistent with this third mechanism because the rate of H-abstraction from solvent by the thiyl portion of the biradical will not be competitive with reaction 10 as shown by the following calculation. If it is assumed that the 1,4-biradical behaves essentially as if it were two independent monoradicals (a good assumption (20)), then very satisfactory estimates of the activation energies of H-abstractions by each end of the biradical can be calculated using the approach of Zavitsas (23). Using a C—S stretching frequency of 725 cm^{-1}, a C—S bond distance of 1.82 Å, and a C—S bond dissociation energy of 74.5 kcal mol^{-1} (23), the calculated E_a for H-abstraction from cyclohexane by a thermal thiyl radical is 16 kcal mol^{-1}. If a value of $E_a = 10$ kcal mol^{-1} is used for H-abstraction from cyclohexane by *n*-propyl radicals

(24) and similar Arrhenius preexponential factors are assumed for the two reactions, H-abstraction by the alkyl end of the 1,4-biradical should be of the order of 10^4 times faster than H-abstraction by the thiyl end at 298 °K.

Concentration changes due to thermal expansion of the solvent accounts for the slight decrease in the intensity of the absorption band centered near 310 nm on warming from −180 to −140 °C after photolysis of thietane in glassy matrices. It is quite clear, however, that at the softening point of the glass (∼ −140 °C) a chemical reaction takes place producing a second absorber having $\lambda_{max} \simeq 300$ nm and a white solid. While it is impossible to draw definite conclusions about the nature of the species responsible for these absorption bands, the following is nonetheless apparent. First it is unlikely that the absorption at 310 nm is due to trapped thioformaldehyde, as monomeric CH_2S should have a considerably different electronic absorption spectrum (19). The only other unstable species which could have the observed spectrum is trapped biradical **3**. Second, because the disappearance of the unstable absorber occurs concomitantly with the appearance of both a new stable absorber having $\lambda_{max} = 300$ nm and two new products of molecular weight 120 and 138, reactions converting trapped biradical **3** to other stable products must be occurring at the softening point of the glass. The solid of molecular weight 138 is likely a mixture of symmetrical and unsymmetrical trimers of thioformaldehyde, while the product of molecular weight 120 is almost certainly *o*-dithiane. This latter species has an absorption at $\lambda_{max} = 300$ nm ($\varepsilon = 290\ M^{-1}\ cm^{-1}$) (25) and may be produced by the reaction of thioformaldehyde with either biradical **3** or thietane. The high concentrations of both biradicals and thioformaldehyde which could be obtained by trapping these species at low temperatures might make these reactions feasible in the warmed glass even though they do not occur in the liquid phase at room temperature or in the gas phase.

Entropy Production in Simple Chemical Reactions

HUW O. PRITCHARD

Centre for Research in Experimental Space Science, York University, Downsview, Ontario M3J 1P3

Received November 29, 1974

HUW O. PRITCHARD. Can. J. Chem. **53**, 1756 (1975).

It is shown that entropy production appears to be a completely monotonic function of time for several chemical reactions or reaction sequences taking place in closed systems at constant temperature; however this monotonicity principle does not extend to autocatalytic or oscillatory processes. Where it occurs, the complete monotonicity of entropy production stems essentially from the completely monotonic behavior of the species number densities as functions of time in the evolution of the reaction.

HUW O. PRITCHARD. Can. J. Chem. **53**, 1756 (1975).

On montre que la production d'entropie, pour plusieurs réactions chimiques ou pour des séquences de réactions se produisant en système circuit fermé et à température constante, est une fonction du temps qui est complètement monotone; toutefois cette monotonie ne s'applique pas aux processus autocatalytiques ou oscillatoires. Quand elle se produit, cette monotonie complète dans la production d'entropie dérive principalement d'un comportement complètement monotone des "densités en nombres des espèces" en fonction du temps lors de l'évolution de la réaction. Introduction

We have shown recently that there appear to exist certain chemically reacting systems for which the time derivatives of the total entropy production have the following property

$$[1] \qquad (-1)^n \mathrm{d}^n S/\mathrm{d}t^n \leqslant 0$$

known as "complete" monotonicity; the process for which this apparent behavior was established was the vibrational relaxation and dissociation of a dilute diatomic gas at constant enthalpy in a shock wave, and eq. 1 was found to hold whether the system was considered to be isolated or whether there was a constant rate of loss of energy or mass from the flowing gas (1). Such a system is obviously far too complex to disentangle, and the origin of this special kind of monotonic behavior is not clear. This paper therefore presents the results of a ranging investigation intended to establish some limits on the validity of eq. 1 using a selection of simple chemical reactions or reaction sequences taking place isothermally and in closed systems.

The approach we have taken is a rather empirical one. No theorems exist for determining whether a given function is monotonic in the sense of eq. 1, nor does proof by induction appear to be possible (except for certain very simple cases, see *e.g.* eq. 16 below and discussion thereof). Thus, as we did before (1), we have chosen to work out numerically the derivatives of the entropy with respect to time to see whether their signs alternate. This is very time-consuming and so we chose only to inspect the first four derivatives, the expectation being that if the first four derivatives have the appropriate signs, all succeeding derivatives *may* also behave. In saying this, we recognize that examples exist in physics of functions which either converge or alternate up to a given order, and then the pattern suddenly breaks down; thus, our inspection of only the first four derivatives really can do no more than establish that this kind of monotonicity is not impossible. From a practical point of view, it is hard to imagine that derivatives of the entropy beyond the third could have any observational effect, and so from this point of view, inspection of four derivatives is plenty. However, from a theoretical point of view, had it been the case that eq. 1 had wide validity, it would have been very important, not only for its curiosity value, but as a stringent test of the correctness of the solutions of complex reaction sequences, in particular oscillating reaction sequences.

Elementary Processes

The rate equations for certain simple reactions *i.e.*

$$[2] \qquad \mathrm{A} \rightleftarrows \mathrm{B}$$

$$[3a] \qquad \mathrm{A} \rightleftarrows \mathrm{B} + \mathrm{C}$$

$$[3b] \qquad \mathrm{A} \rightleftarrows 2\mathrm{B}$$

$$[4] \qquad \mathrm{A} + \mathrm{B} \rightleftarrows \mathrm{C} + \mathrm{D}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

can be integrated analytically (2) and it is therefore possible to write down successive derivatives of the entropy production with respect to time, *ad infinitum*. The following analysis of reaction 2 can be extended easily to reactions 3 and 4, and in fact exemplifies the problem perfectly. Starting from the Sackur–Tetrode equation it follows quite simply that at constant temperature

$$[5] \qquad \frac{1}{R}\frac{dS}{dt} = \frac{dN_A}{dt}\ln\left(\frac{\tilde{P}_A P_B}{P_A \tilde{P}_B}\right)$$

where S is the *total* entropy, P_A and P_B are the actual pressures of the species, and $\tilde{P}_A$ and $\tilde{P}_B$ refer to their pressures at equilibrium; the well-known result (3) that

$$[6] \qquad dS/dt \geqslant 0$$

falls out because

(*a*) dN_A/dt is negative when $P_A > \tilde{P}_A$ and $P_B < \tilde{P}_B$

(*b*) dN_A/dt is positive when $P_A < \tilde{P}_A$ and $P_B > \tilde{P}_B$

(*c*) dN_A/dt is zero when $P_A = \tilde{P}_A$ and $P_B = \tilde{P}_B$

Differentiation of eq. 5 then gives

$$[7] \qquad \frac{1}{R}\frac{d^2S}{dt^2} = \frac{d^2N_A}{dt^2}\ln\left(\frac{\tilde{P}_A P_B}{P_A \tilde{P}_B}\right) + \frac{dN_A}{dt}\left(\frac{d\ln P_B}{dt} - \frac{d\ln P_A}{dt}\right)$$

$$= \frac{d^2N_A}{dt^2}\ln\left(\frac{\tilde{P}_A P_B}{P_A \tilde{P}_B}\right) - \left(\frac{dN_A}{dt}\right)^2\left(\frac{1}{N_A} + \frac{1}{N_B}\right)$$

signs: (+ve) (−ve) − (−ve)^2 (+ve)

whence

$$[8] \qquad d^2S/dt^2 \leqslant 0$$

the signs shown under each term in eq. 7 relate to the process going from A → B *i.e.* condition (*a*); this is all well-known, since eqs. 5 and 7 are familiar equations (3) cast in the specific form appropriate to reaction 2. Continuing in the same fashion

$$[9] \qquad \frac{1}{R}\frac{d^3S}{dt^3} = \frac{d^3N_A}{dt^3}\ln\left(\frac{\tilde{P}_A P_B}{P_A \tilde{P}_B}\right) - 3\left(\frac{d^2N_A}{dt^2}\right)\left(\frac{dN_A}{dt}\right)\left(\frac{1}{N_A} + \frac{1}{N_B}\right) + \left(\frac{dN_A}{dt}\right)^3\left(\frac{1}{N_A{}^2} - \frac{1}{N_B{}^2}\right)$$

signs: (−ve) (−ve) − (+ve) (−ve) (+ve) + (−ve)^3 (?)

and

$$[10] \qquad \frac{1}{R}\frac{d^4S}{dt^4} = \frac{d^4N_A}{dt^4}\ln\left(\frac{\tilde{P}_A P_B}{P_A \tilde{P}_B}\right) - \left[4\left(\frac{d^3N_A}{dt^3}\right)\left(\frac{dN_A}{dt}\right) + 3\left(\frac{d^2N_A}{dt^2}\right)^2\right]\left(\frac{1}{N_A} + \frac{1}{N_B}\right)$$

signs: (+ve) (−ve) − [(−ve) (−ve) + (+ve)^2] (+ve)

$$- 2\left(\frac{dN_A}{dt}\right)^4\left(\frac{1}{N_A{}^3} + \frac{1}{N_B{}^3}\right) + 6\left(\frac{d^2N_A}{dt^2}\right)\left(\frac{dN_A}{dt}\right)^2\left(\frac{1}{N_A{}^2} - \frac{1}{N_B{}^2}\right)$$

− (−ve)^4 (+ve) + (+ve) (−ve)^2 (?)

both of which are unambiguously in conformity with the monotonicity principle, eq. 1, provided that $N_A \geqslant N_B$ if the reaction is proceeding from A → B *or* that $N_A \leqslant N_B$ if the reaction is proceeding in the opposite direction; this is because the last term in each expression contains the difference between N_A and N_B.

However, numerical examination of eqs. 9 and 10 suggests (within the limitations outlined earlier) that they do conform to the monotonicity principle for all N_A and N_B. Given a pair of forward and reverse rate constants and an initial concentration of one of the reactants, the standard form of the rate law (2) enables us to write down N_A, N_B, and dN_A/dt at any time t, in analytic form; simple differentiation of the latter leads to d^nN_A/dt^n, again in analytic form. Thus, assigning a self-consistent set of arbitrary

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

numerical magnitudes to the constants associated with reaction 2, *i.e.* equilibrium constant, temperature, energy change, standard entropy change, and so on, eqs. 9 and 10, can be computed exactly, and for a very wide range of sets of trial values, the third derivative of the total entropy with respect to time was always found to be positive, and the fourth was always negative. This implies that the last term in either eq. 9 or eq. 10, whose sign is indefinite, must be relatively unimportant, and examination of the numerical magnitudes reveals in fact that the dominant term is the first one in each of the eqs. 7, 9, or 10. The domination of the entropy derivatives d^nS/dt^n by the corresponding derivative of the number density d^nN_A/dt^n means therefore that since N_A is an exponential function (thus having alternating derivatives with respect to time) the derivatives of the entropy must also alternate; it is not surprising therefore to find that for those simple reaction systems, plots of $\ln|d^nS/dt^n|$ against time for $n = 1, 2, 3$, and 4, whilst not exactly so, are very close to being linear.

Consecutive Reactions

The behavior of the total entropy as a function of time was then investigated for a number of simple reaction schemes which are not amenable to analytic integration, *viz.*

[11] $A \rightleftarrows B \rightleftarrows C$

[12] $A \rightleftarrows B; \quad A + B \rightleftarrows C$

[13] $A \rightleftarrows B; \quad 2B \rightleftarrows C$

all taking place at constant volume, constant mass, and constant temperature. The technique used in these cases was a simple extension of the numerical work described for reaction 2 in the preceding paragraph. A complete self-consistent set of numerical rate constants and thermodynamic parameters was assigned to each reaction scheme, and the rate law was integrated by standard Runge–Kutta methods to give the concentrations of A, B, and C at any time t, starting from an arbitrary set of initial concentrations; such integrations can be performed to any desired numerical accuracy. Expressions analogous to eq. 5 were then constructed for the total rate of entropy production, and were differentiated analytically. Evaluation of these entropy derivatives then only required the knowledge of the successive derivatives of the concentrations d^nN_A/dt^n etc., and once N_A, N_B, and N_C have been determined numerically, these may be obtained analytically by differentiating the rate expression. For example, for reaction 11 we would have

$$\frac{dN_A}{dt} = -k_{1_f}N_A + k_{1_r}N_B$$

whence

$$\frac{d^2N_A}{dt^2} = -k_{1_f}\frac{dN_A}{dt} + k_{1_r}\frac{dN_B}{dt}$$
$$= -k_{1_f}(-k_{1_f}N_A + k_{1_r}N_B) + k_{1_r}(k_{1_f}N_A - [k_{1_r} + k_{2_r}]N_B + k_{2_r}N_C)$$

and so on; thus, once the actual concentrations are known, all their time derivatives follow automatically, and there is no need for numerical differentiations such as we were forced to use in our earlier work (1), and which are very difficult to perform with high precision. Again, the first four time derivatives of the total entropy alternated in sign in conformity with eq. 1; however, for reactions 12 and 13 only one set of arbitrary parameters was examined, and in view of other discussions of these reactions (4), it would seem prudent not to infer at this stage that these two processes could obey eq. 1 under all conditions.

Autocatalytic Processes

Two autocatalytic processes are commonly invoked in discussions of oscillatory phenomena (5), namely

[14] $A + B \rightleftarrows 2A$

[15] $2A + B \rightleftarrows 3A$

Applying the same techniques to these two reactions with a few sets of trial parameters, it is soon found that $dS/dt \geqslant 0$ always, but $d^3S/dt^3 < 0$ often, and $d^2S/dt^2 > 0$ sometimes; as before, the reactions are considered to be taking place at constant volume, mass, and temperature. The following empirical observation is strongly indicative that this failure to obey eq. 1 results from the fact that the rate law itself is no longer predominantly exponential. Reaction 14 can be considered as nothing more than reaction 2 with a time-dependent rate law, and in fact reaction 2 with a factor of $(1 + at)$ multiplying both forward and reverse rate constants could well be used to simulate the early stages of reaction 14. A logical step in developing the algorithm for this hypothetical process is to take

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

the numerical integration algorithm for reaction 2 and superimpose upon it the time dependence of the rate constants, and when this is done the (incorrectly) computed entropies actually conform to eq. 1. However, when the additional terms arising from the rate of change of the rate constant with time are added into the expressions for the entropy derivatives, eq. 1 fails; since each individual step of the numerical integration is piecemeal exponential in character, it is only through the inclusion of these terms that the nonexponential behavior of the rate law is carried through into the entropy derivatives in the numerical procedures.

At the time these calculations were performed, we were unaware that the rate equation for reaction 14 can be integrated analytically (5), and the segments of the trajectory for which $d^2S/dt^2 > 0$ can be located rigorously, obviating our trial-and-error numerical techniques.[1]

Tossing Coins

An interesting analog to reaction 2 can be constructed in the following way. Consider a tray containing a large number N of coins, all the same way up. A number a of the coins is then selected at random and thrown down, and the process repeated t times, always taking a coins each time. If the coins are loaded with a bias factor $\mathscr{H}/\mathscr{T}$ such that $\mathscr{H} + \mathscr{T} = 1$, then the information theory result for entropy production is

$$[16] \quad \frac{dS}{dt} = \frac{k}{N} e^{-at/N} \ln \left(\frac{a\mathscr{H} + e^{-at/N}}{a\mathscr{T} - e^{-at/N}} \right)$$

This expression is rather similar to eq. 5, and if the coins are unbiased, *i.e.* $\mathscr{H} = \mathscr{T} = \frac{1}{2}$, it is easily shown to be monotonic in the sense of eq. 1; if $\mathscr{H} \neq \mathscr{T}$, a term of indefinite sign appears in the third derivative and persists, as in the molecular case.

Developing further, if in using unbiased coins the handful is not constant in size, but is of the form $a = a_0(1 + bt)$, a situation closely similar to the autocatalytic reaction case is found. The first derivative of the entropy is unambiguously positive, but the second and successive derivatives contain terms of both signs and monotonicity is dependent upon the magnitudes of the various terms. However, it if is assumed that the signs of successive derivatives of the head or tail counts alternate in sign, the entropy derivatives can be shown also to alternate.

[1]J. Keizer. Personal communication.

Conclusions

The numerical experiments undertaken in this investigation show that for a number of simple reactions or reaction schemes, namely reactions 2, 3, 4, 11, and perhaps 12 and 13, taking place at constant volume, mass, and temperature, the time derivatives of the total entropy are probably completely monotonic in the sense of eq. 1; autocatalytic reaction steps like [14] and [15] however may have positive second derivatives, and subsequent calculations show that this quality persists in some parts of the path of the oscillatory reaction scheme

$$A \rightleftarrows X$$
$$B + X \rightleftarrows Y + D$$
$$2X + Y \rightleftarrows 3$$
$$X \rightleftarrows E$$

(treated as being a closed system with all reactions reversible; note also that under these conditions no trial sets of parameters were found which led to a cycling of the concentrations of the X and Y intermediates, see also ref. 7).

Moreover, several indications have been found that when monotonic behavior occurs, it is in a sense accidental, arising because the approach to equilibrium in simple reaction systems follows a monotonic path. Thus, as far as chemical kinetics is concerned, there seems to be no fundamental thermodynamic "meaning" to the monotonicity principle, eq. 1, despite the fact that many physical examples have been established (see refs. 3–11 of ref. 1). Such monotonicity will arise whenever the signs of d^nN_A/dt^n etc. alternate *and* these terms dominate numerically the expressions for the successive derivatives of the entropy with respect to time. Consequently, we have to assume that in our two previous observations of monotonic behavior (1, 6) for calculations on the vibration–dissociation coupling of a diatomic gas, essentially

$$A \rightleftarrows B \rightleftarrows 2C$$

the entropy production resembled that of a coupled pair of monotonic chemical processes, (rather like reaction 11, admittedly with very different time constants for the two steps) and that the accompanying changes in temperature, pressure, etc., were either themselves virtually

monotonic, or otherwise unimportant. Thus, whilst there seems to be no new principle of fundamental importance for entropy production in chemistry, there are aspects of the problem which are intriguing and worthy of further investigation, most of which can be approached analytically or semi-analytically using reactions 2, 11, and 14, and possibly some simple coin tossing analogs.

This work was supported by the National Research Council of Canada, and owes much to a great deal of careful algebraic and numerical work by Miss Peggy R. Hill.

Properties of Concentrated Solutions of Indium Chloride

ALAN N. CAMPBELL

Department of Chemistry, University of Manitoba, Winnipeg, Manitoba R3T 2N2

Received January 13, 1975

ALAN N. CAMPBELL. Can. J. Chem. **53**, 1761 (1975).

Certain properties of concentrated solutions of indium trichloride, ranging in strength from 9.889 to 0.4070 *m*, have been investigated. These properties are: density, molar volume, specific and equivalent conductance, degree of ionization, ionization constant, relative viscosity, activities, and activity coefficients of solvent water and of solute. Two interesting results emerge, *viz.*, the specific conductance passes through a maximum at 3.5 *m*, and, if the ionization of indium chloride is treated as that of a binary electrolyte, the expression $\alpha^2 c/(1 - \alpha)$ is constant within 10% over the range 6.267 to 0.7363 *m* (13.90 to 2.122 *N*).

ALAN N. CAMPBELL. Can. J. Chem. **53**, 1761 (1975).

On a examiné certaines propriétés de solutions concentrées (de 9.889 à 0.4070 *m*) de trichlorure d'indium. Ces propriétés sont les densités, les volumes molaires, les conductivités spécifiques et équivalentes, les degrés d'ionisation, les constantes d'ionisation, les viscosités relatives, les activités et les coefficients d'activité de l'eau agissant comme solvant et des solutés. On note deux résultats intéressants: la conductivité spécifique passe par un maximum à 3.5 *m* et si l'on considère que le chlorure d'indium est un électrolyte binaire, l'expression $\alpha^2 c/(1 - \alpha)$ est une constante à 10% près entre 6.267 à 0.7363 *m* (13.90 à 2.122 *N*).

[Traduit par le journal]

Introduction

In previous communications (1–4) such properties as conductance, heats of solution and dilution, e.m.f.'s and activities, change of volume on dilution, etc., of relatively dilute solutions of indium trichloride ($m < 1$) have been studied. Because indium trichloride is very soluble, it appeared that it would be interesting to study the corresponding properties in the concentrated range, just as Campbell and Kartzmark, some years ago, studied the conductances of silver nitrate and of ammonium nitrate (5).

The properties reported in this paper are: density, specific and equivalent conductance, relative viscosity, and activity. The range of composition is from 9.889 to 0.4070 *m*, corresponding to 19.93 *N* (equivalent normal) down to 1.152 *N*.

Experimental

Materials

The indium chloride used consisted partly of a very pure strong (58 wt.%) solution, supplied gratuitously by Cominco, and of a solid prepared in the following way. Metallic indium was refluxed with excess of concentrated hydrochloric acid until all the indium had dissolved, a process requiring about 12 h. The product was evaporated on the water bath to syrupy consistency; on cooling, it solidified. Analysis at this point showed that the product contained slightly less chlorine (about 2%) than corresponded to $InCl_3 . 3H_2O$, *i.e.*, the product was slightly damp, but contained no free HCl. The salt was then dissolved in water and the crystallization repeated. Provided excess of concentrated hydrochloric acid is used in the preparation, the sole product is the trichloride, uncontaminated by the mono- or dichloride.

Anhydrous indium chloride cannot be otained by heating the trihydrate in a drying oven at 110°, because of the occurrence of the hydrolysis reaction

$$InCl_3 . 3H_2O \rightarrow In(OH)_3 + 3HCl$$

followed, no doubt, by dehydration to the oxide. The product of the above treatment is not more than 50% anhydrous chloride. The anhydrous chloride can, however, be obtained by heating in high vacuum at 70°.

Anhydrous chloride was used only in the preparation of solutions lying between 9.889 and 6.919 *m*; otherwise, the pure concentrated solution obtained from Cominco was used. Each individual solution was analyzed gravimetrically by precipitation as silver chloride.

Apparatus and Procedure

All measurements, except those of boiling point, were made at 25 °C. All the methods are standard and have been described elsewhere (1–3). A few words should be said about the determination of activity. This was done by the boiling point method, using a Cottrell apparatus. It was found that by sealing a stout platinum wire vertically through the bottom of the boiling tube, allowing about ¼ in. of wire to project on each side, bumping and superheating were entirely eliminated; boiling points were constant to ± 0.01°. The procedure was first to read the barometer (p). From this and tables of vapor pressure, the boiling point of water on the Centigrade scale was obtained. The apparatus was then charged with conductance water and the boiling point observed on the Beckman thermometer of the apparatus.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

The apparatus was then charged with a solution of known concentration and the boiling point observed. This gave the vapor pressure of water at the boiling temperature of the solution ($p°$). The activity of the solvent water was then taken as $p/p°$ and from this, knowing the composition, the activity coefficient of the solvent was obtained. The activity coefficient of the solute results from the Gibbs–Duhem theorem, using the procedure described in Glasstone's *Thermodynamics for Chemists* (6). Since the measurements were made in the neighborhood of 100°, the results are not strictly comparable with those made at 25°. An objection might also be raised that since individual measurements were made over a range of 18°, they are not really comparable with one another, but it is known that activity coefficients are not very sensitive to temperature change.

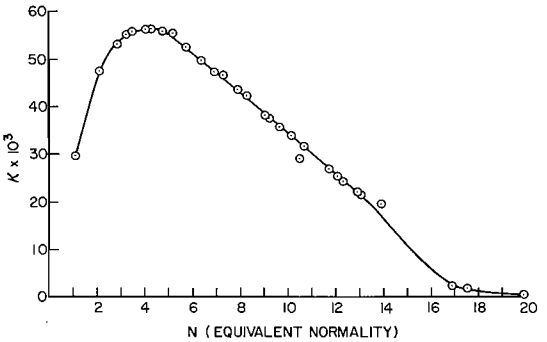

FIG. 1. Specific conductance κ, at 25°, *vs.* equivalent normality.

Results and Discussion

The numerical results are to be found in the Depository of Unpublished Data.[1] For the general reader, they are here represented graphically.

The densities of solutions can be calculated from the expression, derived from the experimental results, $d_4^{25} = 0.99707 + \alpha m^{1/2} + \beta m$ where m is the molality and α and β have the values 0.06374 and 0.09957 respectively. The molar volumes are readily calculated from the density data, when it is found that they decrease smoothly from a value of 22.74 ml mol^{-1} for a concentration of 9.889 m to 18.44 ml mol^{-1} at 0.5533 m. Since densities were determined with a pycnometer, and are therefore only accurate to the fourth decimal, at best, the figures for the apparent molar volume of the solute have no quantitative significance.

It is known theoretically that the specific conductance should pass through a maximum at some high concentration but this phenomenon is rarely realised because of the limited solubility in water. The reason for such a maximum is discussed by Campbell *et al.* (7). Figure 1, a plot of κ *vs.* concentration, shows very clearly that the specific conductance of indium trichloride passes through a maximum at 3.5 m.

The most interesting result is that, in the range of concentration 6 to 0.5 m, indium chloride behaves as a binary electrolyte

$$AB \rightleftarrows A^+ + B^-$$

having an ionization constant of $14.5 \times 10^{-2} \pm 0.5 \times 10^{-2}$, calculated on the basis of $\Lambda° = 132.6\ \Omega^{-1}\ cm^2\ equiv.^{-1}$. In the calculation of the ionization constant ($k = \alpha^2 c/(1 - \alpha)$), α was evaluated as $\alpha = \Lambda\eta/\Lambda°$, where η is the relative viscosity and Λ° the limiting equivalent conductance. This corresponds to the procedure used, for lack of a better, to reconcile calculated values of Λ with observed values; obviously the viscosity must have the effect of reducing Λ. Such a procedure is incorrect, since the Λ° used corresponds to the sum of $\lambda°In^{3+}/3$ and $\lambda°Cl^-$, whereas the binary ionization, corresponding to something like

$$InCl_3 \rightleftarrows InCl_2^+ + Cl^-$$

would require for its limiting conductance the sum of the ionic conductances of the products of the binary ionization. Nevertheless, since the ionization constant can be written

$$k = \frac{\Lambda^2 c}{\Lambda°(\Lambda° - \Lambda)}$$

it is apparent that, while the numerical value of k changes with the assumed value of Λ°, its constancy does not. Moreover, since the limiting conductances of most salts are constant within ~20 mho, even the numerical value of k should be acceptable as to order of magnitude.

The old formula of Ostwald, used in the calculation of k, is not accurate. The true "thermodynamic" dissociation constant K is connected with the conventional k by the formula

$$K = k f_{M^+} f_{A^-} / f_{MA}$$

where the f's represent the activity coefficients of ions and of undissociated salt. In very dilute

[1]Complete set of tabular data is available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Canada K1A 0S2.

						1.247	2.34

*$t = 25$ °C.

solutions the above formula can be reduced to

$$\log K = \log k - 2A\sqrt{ac}$$

where A represents the Debye–Hückel slope. This formula will not be applicable to the concentrated solutions of this paper but if it can be assumed that A is a constant, any constant, then the above formula should be a test of constancy. At all events, it is worth trying. When this is done, the deviation from constancy is so slight that it cannot be shown on the graph used for plotting k (Fig. 2). The figures are therefore given in Table 1. Over the range of concentration for which k is roughly constant, *viz.* 1 to 6 m, K approaches much closer to constancy, but does show a small but steady increase from 0.98×10^{-2}, most of the increase occurring below 2 m. It is difficult to believe that such constancy is purely fortuitous.

Ferri (8) assumes the existence in solution of both $InCl_2^+$ and $InCl^{2+}$ ions.

The relative viscosity of the most concentrated solution (Fig. 3) is very high, 203.3 for 9.889 m, but it drops rapidly to 9.46 for 6.267 m, after which the decrease in viscosity with dilution is more normal. The region of abnormally high viscosity is also the region of low conductance. Ionization of any kind must be small in this region.

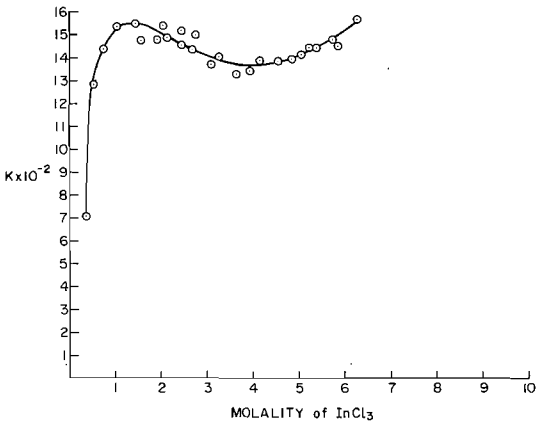

FIG. 2. Ionization constant k *vs.* molality, at 25°.

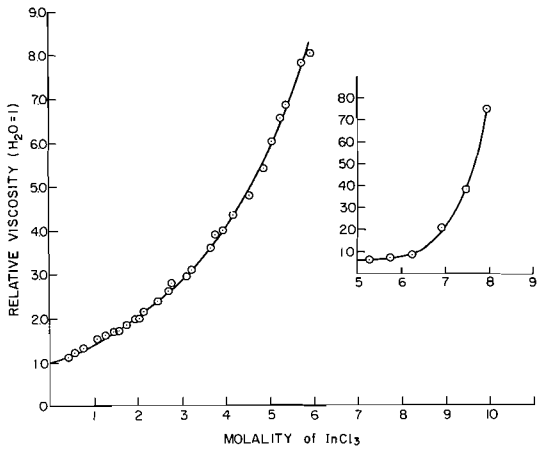

FIG. 3. Relative viscosity ($H_2O = 1$), at 25°, *vs.* molality.

The boiling points are not given because, since the barometric pressure in this region varies between 730 and 760 mm, they are not comparable. Table 2 reproduces the mean molal activities of the solvent water, as well as the activity coefficients of the solvent and of the solute. The latter are not comparable with the activity coefficients previously obtained (3) for the more dilute range because the present figures are calculated on the basis of $\nu = 2$ (binary ionization) but the former figures on the basis of $\nu = 4$, reasonable assumptions in both cases. Perhaps it is merely coincidental that the numerical values are not greatly different for the two regions.

Received December 20, 1974

H. P. CALHOUN, N. L. PADDOCK, and J. N. WINGFIELD. Can. J. Chem. **53**, 1765 (1975).

The preparation of complexes DDPN.$2MCl_2$ (M = Mn, Fe, Co, Zn), DDPN.$M(NO_3)_2$, (M = Mn, Co, Ni, Cu, Zn), (DDPN = $N_6P_6(NMe_2)_{12}$), and $N_9P_9(NMe_2)_{18}.2CoCl_2$ is described. All the complexes of the hexamer are of the high spin type and contain the cations $DDPNMX^+$ (X = Cl, NO_3). Their infrared and electronic spectra show that their molecular structures are essentially the same as those established crystallographically for the chlorocations (M = Co, Cu), in which, as a consequence of steric interactions, the metal has a distorted trigonal–bipyramidal environment. The complex with $Cu(NO_3)_2$ is exceptional in that the $DDPNCu^{2+}$ ion is formed in ionizing solvents, with a change in the stereochemistry of the metal. Coordination localizes π-electrons in nitrogen, weakens the ring bonds, and strengthens the exocyclic P—N bonds, as expected theoretically. Approximate values of ligand field parameters of the $Co(NO_3)_2$ and $Ni(NO_3)_2$ complexes are similar to those of complexes formed by simple amines; the phosphazenes act as σ-donors, their acceptor levels not being used significantly.

H. P. CALHOUN, N. L. PADDOCK et J. N. WINGFIELD. Can. J. Chem. **53**, 1765 (1975).

On décrit la préparation de complexes DDPN.$2MCl_2$ (M = Mn, Fe, Co, Zn), DDPN.$M(NO_3)_2$ (M = Mn, Co, Ni, Cu, Zn), (DDPN = $N_6P_6(NMe_2)_{12}$) et $N_9P_9(NMe_2)_{18}.2CoCl_2$. Tous les complexes de l'hexamère sont du type à haut spin et contiennent les cations $DDPNMX^+$ (X = Cl, NO_3). Les spectres électroniques et infrarouges montrent que leurs structures moléculaires sont pratiquement les mêmes que celles déterminées par cristallographie pour les chlorocations (M = Co, Cu) dans lesquels le métal est dans un environnement trigonal–bipyramidal à cause des interactions stériques. Considérant que l'ion $DDPNCu^{2+}$ se forme dans des solvants ionisants avec un changement de stéréochimie au niveau du métal, on peut considérer que le complexe avec $Cu(NO_3)_2$ est exceptionnel. Comme on peut le prédire sur une base théorique, la coordination localise les électrons π sur l'azote, affaiblit les liens du cycle et renforcit les liens P—N exocycliques. Les valeurs approximatives des paramètres de la théorie des champs de ligand pour les complexes de $Co(NO_3)_2$ et $Ni(NO_3)_2$ sont semblables à celles de complexes formés par des amines simples; les phosphazènes agissent comme donneurs d'électrons σ alors que leurs niveaux accepteurs ne sont pas utilisés d'une façon importante.

Introduction

Cyclic phosphazenes $(NPX_2)_n$ act as donors to many types of acceptor, such as the proton (1), neutral (2) or cationic (3) metals, alkyl halides (4, 5), molecules such as iodine (3*a*, 6), and even phosphazenes themselves (7). In solution the alkyl and alkylamino derivatives are the strongest bases (8).

The effect of the substituent in the alkylphosphazenes is primarily to facilitate electron localization on nitrogen, by reducing the electronegativity of the phosphorus atom (5). The origin of the base properties of the dimethylaminophosphazenes $N_nP_n(NMe_2)_{2n}$ is different. The exocyclic groups are moderately electronegative, the donor properties now being a result of conjugative electron release by the substituents. Coordination may now occur at the ring atoms (normally), at the exocyclic nitrogen atoms (9), or at both ring and exocyclic sites (10); the dimethylaminophosphazenes are clearly more versatile ligands than the methylphosphazenes. We have studied some of their complexes with transition metal ions to find out, from their stereochemistry, magnetism, and spectra, how the metal and ligand interact.

Qualitatively, it was found easier to obtain complexes of the hexamer $N_6P_6(NMe_2)_{12}$ than of $[NP(NMe_2)_2]_{3-5}$, possibly because the cations can fit inside the larger ring, which then acts as a macrocyclic ligand (3*i*, 11). Most of the work reported concerns the complexes of

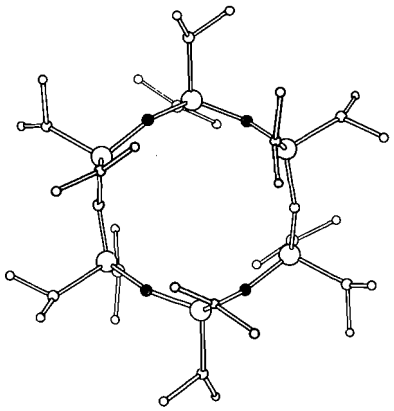

FIG. 1. The molecular structure of $N_6P_6(NMe_2)_{12}$. The shaded nitrogen atoms are those coordinated to metal.[4]

the hexameric dimethylamide (Fig. 1) with the chlorides MCl_2 (M = Mn, Fe, Co, Zn) and nitrates $M(NO_3)_2$ (M = Mn, Co, Ni, Cu, Zn). Complexes such as $N_9P_9(NMe_2)_{18}.2CoCl_2$ were formed with ligands of greater ring size, but they were harder to purify, and were not investigated systematically.

Experimental

Manganese(II) chloride, cobalt(II) chloride, and nickel(II) chloride were dehydrated by heating them with thionyl chloride under reflux. Iron(II) chloride was prepared by heating iron(III) chloride in boiling chlorobenzene (12). Zinc chloride was dried by heating it *in vacuo* at 200°; copper(II) chloride (Fisher) was used as received. Acetonitrile was distilled from calcium hydride, and diethyl ether, benzene, and petroleum ether from lithium aluminum hydride. Triethylamine was dried with calcium oxide. Dodecachlorocyclohexaphosphazene (13) and octadecafluorocyclonaphosphazene (14) were prepared by standard methods.

Ligands

Dodeca(dimethylamino)cyclohexaphosphazene(DDPN) was prepared as described (15). The nonameric dimethylamide was prepared from the fluoride. Dimethylamine (5.0 g, 0.11 mol) in 50 ml diethyl ether was added to an ice-cold solution of butyllithium in pentane (2.37 *N*, 34 ml) and stirred under reflux at −78° for 30 min. The excess of dimethylamine was allowed to evaporate and a solution of octadecafluorocyclononaphosphazene $N_9P_9F_{18}$ (2.0 g, 2.68 mmol) in 30 ml diethyl ether was added dropwise with stirring. The reaction mixture was stirred for 7 d at room temperature and then heated under reflux for a further 48 h. After extraction with water, the ether was removed. Elution of a solution of the product in petroleum ether (30–60°) on a silica column gave white crystals of octadeca(dimethylamino)cyclononaphosphazene, $N_9P_9(NMe_2)_{18}$, m.p. 232–234° (2.0 g, 62%).

Anal. Calcd. for $C_{36}H_{108}N_{27}P_9$: C, 36.1; H, 9.0; N, 31.6. Found: C, 36.2; H, 9.0; N, 31.7.

Complexes of DDPN with Metal Chlorides

Cobalt(II) chloride (0.136 g, 1.05 mmol) and DDPN (0.83 g, 1.04 mmol) were heated under reflux in acetonitrile for 84 h. The blue color became steadily darker as all the ligand went into solution. Removal of the solvent gave a pale blue solid which was washed with petroleum ether and recrystallized from $CHCl_3/CCl_4$ as blue crystals of $DDPN.2CoCl_2.CHCl_3$.

Anal. Calcd. for $C_{25}H_{73}Cl_7Co_2N_{18}P_6$: C, 25.5; H, 6.2; N, 21.4. Found: C, 25.6; H, 6.4; N, 21.2.

Other solvents used for recrystallization, such as benzene, were also incorporated into the lattice.

In a similar experiment with iron(II) chloride, attempted crystallization of the product from mixtures, including acetonitrile/toluene and methylene chloride/cyclohexane, gave semicrystalline products which contained solvent, which was removed *in vacuo* at 135° to give $DDPN.2FeCl_2$ as a brown powder.

Anal. Calcd. for $C_{24}H_{72}Cl_4Fe_2N_{18}P_6$: C, 27.4; H, 6.9; Cl, 13.5; Fe, 10.6; N, 24.0; P, 17.7. Found: C, 27.3; H, 7.0; Cl, 13.5; Fe, 10.7; N, 24.1; P, 17.3.

Similar complexes, of the general formula $DDPN.2MX_2$ were obtained with $MnCl_2$, $NiCl_2$, $NiBr_2$, and, $ZnCl_2$, but analyses, especially of the nickel complexes, showed variable and irreproducible incorporation of solvent, which could not be completely removed by heating *in vacuo*, though for the $MnCl_2$, $ZnCl_2$ complexes it did not interfere with the infrared spectra. This difficulty, probably arising from the presence in the crystal of bulky polynuclear anions, was avoided by the use of metal nitrates.

Complexes of DDPN with Metal Nitrates

Silver nitrate (0.17 g, 1 mmol) was added with stirring to a solution of cobalt(II) chloride (0.064 g, 0.49 mol) in 20 ml acetonitrile. A slight excess of DDPN (0.4 g, 0.5 mmol) was added to the filtered red solution and the reaction mixture was heated under reflux for 18 h. The solution was filtered from a small amount of brown precipitate and the solvent removed to give a purple solid. The product was washed with light petroleum (30–60) to remove the excess of DDPN, the yield of $DDPN.Co(NO_3)_2$ being quantitative. It was recrystallized from acetonitrile/toluene as blue air-stable crystals which appeared purple in reflected light.

Anal. Calcd. for $C_{24}H_{72}CoN_{20}O_6P_6$: C, 29.4; H, 7.4; Co, 6.0; N, 28.5; P, 18.9. Found: C, 29.5; H, 7.5; Co, 5.6; N, 28.6; P, 18.9.

A similar method was used to prepare $DDPN.Mn(NO_3)_2$, a buff powder, DDPN $Ni(NO_3)_2$, green crystals, $DDPN.Cu(NO_3)_2$, a green powder, and $DDPN.Zn(NO_3)_2$, a buff powder.

Anal. Calcd. for $C_{24}H_{72}MnN_{20}O_6P_6$: C, 29.5; H, 7.4; Mn, 5.6; N, 28.7; P, 19.0. Found: C, 29.3; H, 7.7; Mn, 5.3; N, 28.9; P, 19.1.

Anal. Calcd. for $C_{24}H_{72}N_{20}NiO_6P_6$: C, 29.4; H, 7.4; N, 28.5. Found: C, 29.1; H, 7.2; N, 28.5.

Anal. Calcd. for $C_{24}H_{72}CuN_{20}O_6P_6$: C, 29.2; H, 7.4; Cu, 6.4; N, 28.4; P, 18.8. Found: C, 29.0; H, 7.4; Cu, 6.1; N, 28.5; P, 19.0.

Anal. Calcd. for $C_{24}H_{72}N_{20}O_6P_6Zn$: C, 29.2; H, 7.3; N, 28.4; P, 18.8; Zn, 6.6. Found: C, 28.9; H, 7.4; N, 28.5; P, 19.0; Zn, 5.9.

Only the cupric nitrate complex appeared to be sensitive to air and moisture.

Complexes of the Nonameric Dimethylamide

Cobalt(II) chloride (0.026 g, 0.2 mmol) was treated under reflux with $N_9P_9(NMe_2)_{18}$ (0.24 g, 0.2 mmol) in acetonitrile for 20 h. Removal of solvent from the clear blue solution gave a blue solid which, after washing with petroleum ether, was reextracted with acetonitrile. The complex $N_9P_9(NMe_2)_{18}.2CoCl_2$ was obtained as a blue solid.

Anal. Calcd. for $C_{36}H_{108}Cl_4N_{27}P_9$: C, 29.7; H, 7.4; N, 25.9. Found: C, 29.6; H, 7.3; N, 25.9.

Reactions with $NiCl_2$, $NiBr_2$, gave similar products, but containing variable amounts of solvent. A complex with $Ni(NO_3)_2$ was obtained as an impure sticky brown solid.

Physical Measurements

Electrical conductivities of solutions of the complexes in acetonitrile and (in one case) in nitroethane were determined at room temperature, using a Wayne Kerr Universal Conductivity Bridge, Model B 221A (Table 1). The magnetic susceptibilities (Table 2) of the complexes DDPN.$M(NO_3)_2$ were measured at room temperature by the Gouy method. Corrections for the diamagnetism of the metal nitrate and the ligand were made by using Pascal's constants (16), combined with the result of a direct measurement on $N_6P_6Cl_{12}$ (17). Their electronic spectra were determined at frequencies less than 29 000 cm^{-1} (Table 3) using a Cary Model 14 spectrophotometer. Infrared spectra of all the complexes were obtained on a Perkin–Elmer Model 457 instrument, using mulls with either Nujol or hexachlorobutadiene, and a Perkin–Elmer Model 301 for the range 300–100 cm^{-1}. Figure 2 shows the spectrum of DDPN for the region 250–1350 cm^{-1}. Higher frequencies are given in Table 4 for the ligand and its complex with $Mn(NO_3)_2$, typical of all. The spectra of all the complexes are complicated but very similar, the lines falling into the groups shown in Fig. 3; detailed frequencies are given in Table 5.

Discussion

Conductivities

Crystal structure determinations (3*i*, 11) show that two DDPN complexes are ionic, the cation being of the form DDPN.MCl^+, the metal being 5-coordinated. If the metal:ligand ratio in the complex cation is assumed to be 1:1 in the other complexes, the nitrate complexes in solution can then (18) be assigned the formulae (DDPN.$MNO_3)^+NO_3^-$, (M = Mn, Co, Ni, Zn) and (DDPN.$M)^{2+}(NO_3^-)_2$, (M = Cu). The nitratonickel cation also appears to be partially dissociated. Although nitrogen ligands are known to displace oxygen ligands increasingly in the series Mn^{2+}–Cu^{2+} (19), the high conductivities are unlikely to be a result of solvolysis, since

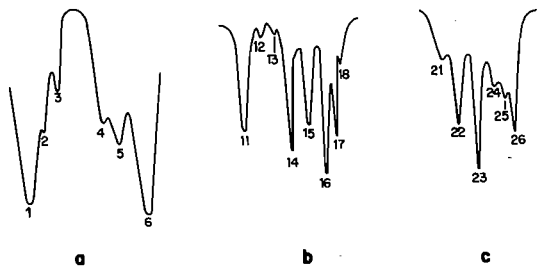

FIG. 3. Groups of bands in the infrared spectra of DDPN complexes; band numbers and frequencies are given in Table 5.

the conductance of the cupric nitrate complex in the less strongly coordinating solvent nitroethane is also about that expected for a 1:2 electrolyte (20). Solvent effects on the electronic spectra are referred to later. The chloride complexes have a different stoichiometry, consistent with the occurrence of metal in both cation and anion. In the crystal, the cobalt chloride complex is $(DDPNCoCl^+)_2.Co_2Cl_6^{2-}$, but a single conductance measurement cannot rule out dissociation of the anion; the nature of the anion in the ferrous chloride complex is similarly undecided. There is, however, no sign of dissociation in the cation, and it seems likely that the metal is always 5-coordinated in the crystal, and always in solution with the exception of the cupric (and possibly the nickel) nitrate complex.

Infrared Spectra

The infrared spectra of the complexes confirm that they all have the same structural pattern. The simplicity of the spectrum of the free ligand (Fig. 2) indicates a high symmetry (possibly as high as the S_6 found in the crystal (21)) which is entirely lost on complex formation. Only a few bands (Table 5, *7–10*) are related in an obvious way to the spectrum of the free ligand. The remainder of the lines now fall into well-defined groups (Fig. 3), and within each group not only the frequencies but also the relative intensities vary little between the different complexes.

There are some exceptions to these general statements. All the nitrate complexes have a band at 1343–1344 cm^{-1} attributed to the E' asymmetric stretching vibration of the free nitrate ion (22). The nitrate complexes also have an additional band at 1241–1251 cm^{-1}, and the band near 1295 cm^{-1} is much more intense than it is in the chloride complexes. Both bands may arise from interaction between the A_1 symmetric stretching vibration of a coordinated nitrate ion and a ring vibration. The band corresponding to the asymmetric stretching mode, which is found in nitrato tetraamino complexes of nickel at 1420–1495 cm^{-1} (23), may be obscured by $\delta(CH_3)$; the A_2'' out of plane bending vibration of the free nitrate ion may contribute to the weak band at $\sim$830 cm^{-1}. Bands specific to the chloride complexes are found below 400 cm^{-1} and are mostly weak and poorly resolved. No metal–ligand vibrations could be detected with certainty (some possibly obscured by the strong $\tau(CH_3)$ band at 315–333 cm^{-1}, 290 cm^{-1} in the free ligand); the distinctive low frequency bands in the spectra of the $FeCl_2$, $CoCl_2$, and $ZnCl_2$ complexes may reflect differences in anion structure or arrangement.

The stretching and deformation frequencies of the methyl groups (Table 4) are similar in range

to those in the free ligand, in dimethylamine itself (24), and in Me_2NPSF_2 and $(Me_2N)_2PSF$ (25). There are shifts in individual frequencies and intensities, especially for the Cu(NO$_3$)$_2$ complex, but the band at 2790 cm^{-1}, although weakened, does not disappear, as it does when an Me_2N group is complexed through nitrogen (26). The bands at 1198, 1071/1063, and 993/972 cm^{-1} in the spectrum of the free ligand are characteristic of NC_2 stretching and methyl rocking modes of the NMe_2 group in $N_3P_3Cl_5NMe_2$ (1173, 1063, 998 cm^{-1}) (27) and $N_4P_4Cl_7NMe_2$ (28), though detailed assignments differ (25, 29). In the complexes the lowest frequency bands are broadened and split (Table 5, bands *8–10*), and the bands at 1064 cm^{-1} are sufficiently broadened to obscure the doublet structure without change of frequency. Again, there is no indication of coordination of the exocyclic nitrogen atoms to the metal.

The skeletal modes are hard to assign and are in any case greatly changed on complex formation; the band which occurs at 652 cm^{-1} in the spectrum of the free ligand disappears completely. The free ligand has a very strong band at 1323 cm^{-1}, arising from a degenerate asymmetric stretching vibration. On complex formation its frequency is reduced (upper limit ~1295 cm^{-1}) and probably split, though possible lower frequency components could not be distinguished from $\nu(NC_2)$ and $\rho(CH_3)$. The lower frequency ranges (Fig. 3*b* and *c*) are very similar for all the complexes, only the Cu(NO$_3$)$_2$ complex showing some variation (Table 5). The general qualita-

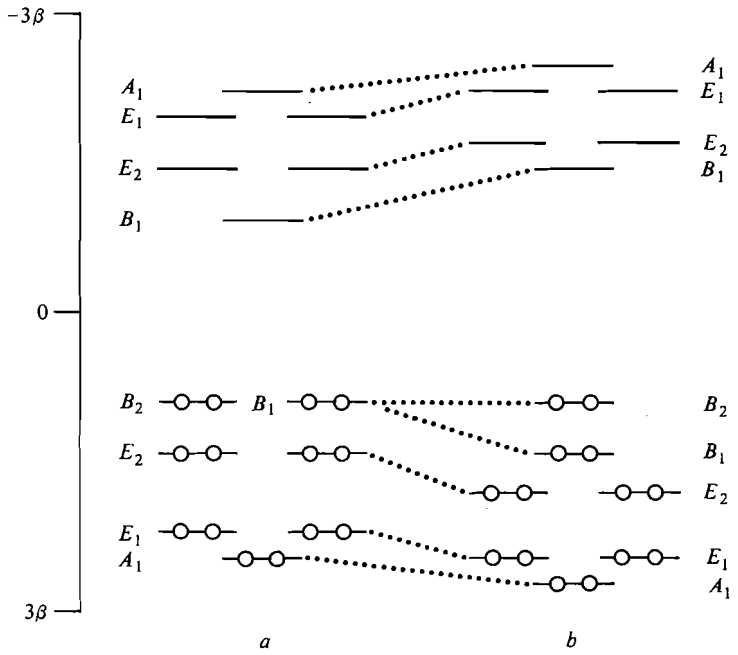

FIG. 4. The π-electron levels of homomorphic N_6P_6 ring (*a*) without (*b*) with exocyclic conjugation. Assumptions: symmetry C_{6v}, one interacting Me_2N group at each phosphorus atom, $\alpha_N = \alpha_P + 2\beta$, all β's equal. For both (*a*) and (*b*), there are additional nonbonding levels ($E = \alpha + \beta$) of species A_1, E_1, E_2. These are localized on the exocyclic groups in (*a*), shared with the ring nitrogen atoms in (*b*).

tive result is that, although the high symmetry of the ligand is lost on complex formation, the conformational changes are very similar for all the complexes. Conclusions drawn from the detailed study of the molecular structure of one of them, specifically $DDPNCoCl^+$, are therefore likely to be general.

Molecular Structures

Phosphazenes differ from most other cyclic ligands (30) in that reaction with acceptors localizes π-electrons and changes bond orders and bond lengths within the ring. The interpretation of several methylphosphazene structures in these terms (5) requires extension for the dimethylaminophosphazenes, because the exocyclic groups now form part of the conjugated system. Figure 4 shows the results of an HMO calculation on a simple model. Bond orders (in parentheses) and charge densities for the unconjugated (above) and conjugated (below) repeating units are:

2.000 (0) 0.356 (0.516) 1.644
N (*exo*)——————P——————N (*endo*)
1.815 (0.527) 0.473 (0.456) 1.712

Electron release from the exocyclic group strengthens the molecule as a whole, appreciable exocyclic π-bonding being attained partly at the expense of the ring bonds. If both π-systems are included, the exocyclic:endocyclic bond orders are in the ratio 0.58:1, in satisfactory agreement with typical bond lengths, P—N (*exo*) 1.67, (*endo*) 1.60 Å. Electron density is increased at phosphorus, diminishing its sensitivity to nucleophilic attack, and at nitrogen, where a reduction in the two-electron localization energy corresponds to an increased base strength as a consequence of conjugation. A less obvious result is the raising of the first unoccupied level through mixing of the B_1 exocyclic lone pair combination with the formally nonbonding phosphorus orbital, making it less accessible to metal back-bonding orbitals.

In spite of the large structural changes which take place on complex formation, the simple model is still useful, principally because the two π-systems tend to compensate each other as the molecule is deformed. If two electrons are localized at each complexed nitrogen, the expected bond orders and charge densities (for the

For personal use only.

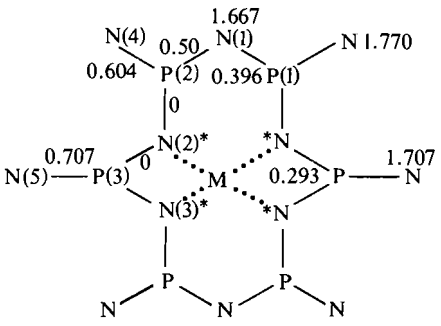

FIG. 5. Bond orders (l.h.s.) and charge densities (r.h.s.) for DDPN ring (assumptions as Fig. 4), two electrons localized at each N*.

perturbed π-system) are as shown in Fig. 5. The mean geometry of DDPN.$CoCl^+$ is given in Table 6, compared with that of the free ligand. The theoretical treatment accounts successfully for (*1*) the increase of mean ring bond length, the bonds to the coordinated nitrogen atoms being the longest, and (*2*) the strengthening (previously recognized (1*b*)) of the exocyclic P—N bonds, P(3)N(5) more than P(2)N(4). The expected slight strengthening of P(2)N(1) is not found, however, possibly because electron repulsion is not directly included in the HMO method. Apart from this, the conjugative model gives a good qualitative account of the structural features of both the free and complexed ligand. Quantitatively, the lengths of such bonds as P(2)N(2) (1.618 Å) show, by comparison with the 1.669 Å found for the bonds to the protonated center in $N_3P_3(NMe_2)_6H^+$ (1*d*) that the $CoCl^+$ group localizes electrons less effectively than H^+; a similar conclusion was reached for a copper(II) complex of $N_4P_4Me_8$ (5).

[d]P(2)N(1) 1.570 Å, P(2)N(2), P(3)N(2) 1.618 Å.
[e]N(2)P(3)N(3) 100.9°, N(2)P(2)N(1) 113.8°.
[f]P(2)N(2)P(3) 135.1°, P(2)N(1)P(1) 134.7°.
[g]P(2)N(4) 1.652, P(3)N(5) 1.637 Å.

The 5-coordination of the central atom is principally a steric effect. Planar coordination by four nitrogen atoms, necessary for the normal octahedral coordination, is prevented by repulsive interactions between the fifth ligand and near dimethylamino groups, typically those at P(3) and its symmetrically related atom. The molecule bends about the axis N*MN*, excluding a sixth ligand, but allowing the attainment of normal van der Waals distances on both sides of the molecule. The coordination polyhedron of the metal is then a strongly distorted trigonal bipyramid, like that of the aluminum atom in a structurally similar aluminosiloxane (31), and of the iron atom in $[Fe(C_6H_{32}N_4)Cl]I$, (coordinating atoms N_4Cl) in which the steric constraints of the macrocyclic ligand do not allow 6-coordination (32).

Although steric interactions are important (as they are in the neutral ligand (21)) they do not obscure the characteristic stereochemical differences between the metal ions in the two complexes of known structure. The immediate environments of the metals are shown in Fig. 6. For the Cu^{2+} ion, the lengthening of axial bonds by steric repulsion (33, 34) is more than offset by an equatorial elongation arising from the filled $d_{x^2-y^2}$, and d_{xy} orbitals; in DDPN.$CuCl^+$, as in most other 5-coordinated Cu(II) compounds (34–36) axial bonds are the shorter. In high spin Co(II), the $d_{x^2-y^2}$, d_{xy}, and d_{z^2} orbitals are occupied equally, no equatorial expansion is expected, and axial elongation occurs instead (37, 38); it is exceptionally and unexpectedly large (0.2 Å) in the present case. Low spin TBP Co(II), on the other hand, shows axial contraction (39). DDPN is evidently a weak field donor to Co(II), in agreement with the magnetic results discussed below. Similar inequalities in apical and equatorial bond lengths occur in such complexes as $[M(Me_6tren)Br]^+Br^-$, in which the ligand [Me_6tren = tris(2-dimethylaminoethyl)amine] is a simple amine (40).

Magnetism and Electronic Spectra

Measurements of magnetic susceptibility on the nitrate complexes (Table 2) confirm both the weak-field nature of the ligand and the 5-coordination. The moments all correspond to high-spin behavior, but only those of the Co(II) and Ni(II) complexes are stereochemically sensitive. For Co(II) the moment is raised above the spin-only value (3.87 B.M.) by spin–orbit coupling,

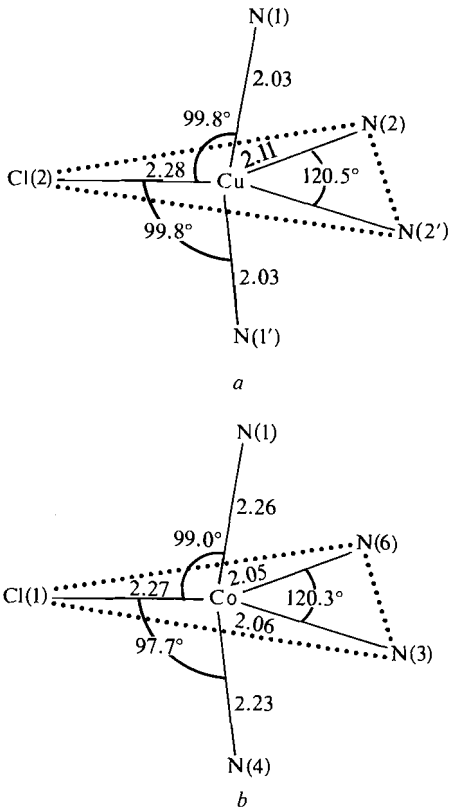

FIG. 6. Environments of the metal in (*a*) DDPNCuCl$^+$, (*b*) DDPNCoCl$^+$.

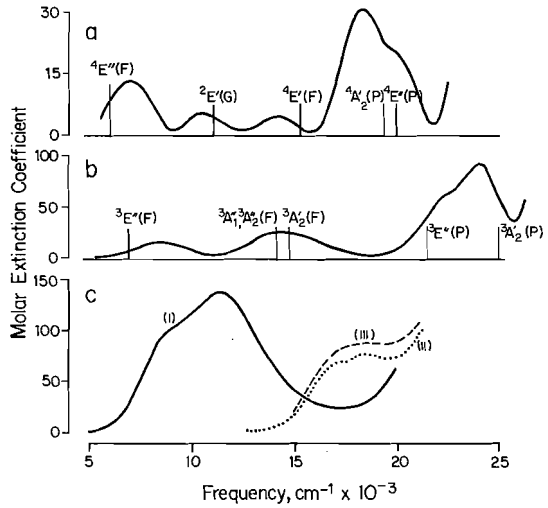

FIG. 7. Electronic spectra of (*a*) [DDPN.Co(NO$_3$)]-NO$_3$ in CH$_3$CN, (*b*) [DDPN.Ni(NO$_3$)]NO$_3$ in CH$_3$CN, (*c*) (*i*) DDPN.Cu(NO$_3$)$_2$ in CHCl$_3$, (*ii*) in CH$_3$CN, (*iii*) in MeNO$_2$. The vertical lines in (*a*) and (*b*) correspond to frequencies calculated for a model of D_{3h} symmetry, using parameters given in the text.

but it is still less than moments typical of octahedral coordination (4.9–5.3 B.M.) (41), since the ground state is nondegenerate. It is near that (4.45 B.M.) of the complex [Me$_6$trenCoCl$^+$]-Cl$^-$ (20), in which the set of donor atoms (N$_4$Cl) has crystallographic C_{3v} symmetry. Five-coordinate high-spin nickel complexes have lower moments (3.1–3.4 B.M.) than tetrahedral complexes (3.6–4.0 B.M.), and the value obtained for DDPN.Ni(NO$_3$)$_2$ is fully consistent with five-coordination, though octahedral coordination cannot be ruled out by the magnetic measurements alone.

The electronic spectra of the cobalt, nickel, and cupric nitrate complexes (Table 3), provide more detailed information on the interaction of the metal with the ligand. Qualitatively, the spectrum of DDPN.Co(NO$_3$)$_2$ is quite different from those of octahedral or tetrahedral complexes of Co(II), but it is generally similar (42) to those of 5-coordinate complexes of known structure, such as [Co(Me$_6$tren)Br]Br (C_{3v}) (43) or [Co(OAsMePh$_2$)$_4$ClO$_4$]ClO$_4$ (C_{4v}) (44). The same is true of the nickel and copper complexes.

Estimates of ligand field parameters can only be approximate, even for the ideal symmetries D_{3h} or C_{4v} (45), but the results, though crude, are of comparative value even when the symmetry is lower. Adjustment of the ligand field and interelectron repulsion parameters (46) to fit the observed spectrum of DDPN.Co(NO$_3$)$_2$ gave Dq 1240 cm^{-1}, B 738 cm^{-1}, β 0.66. The degree of correspondence between the observed and calculated spectra is shown in Fig. 7*a*. Another calculated band (4410 cm^{-1}) is presumably of too low a frequency to be observed. Application of the same method to the spectrum of [Co(Me$_6$tren)Cl]Cl (47) gave Dq 1130 cm^{-1}, B 783 cm^{-1}, β 0.70; Dq = 1100 cm^{-1} if interelectron repulsion is neglected (47). The values of Dq are typical of simple amine ligands, suggesting that DDPN and Me$_6$tren are similar and typical weak-field donors, the former being slightly the stronger. The values obtained for the nephelauxetic parameter β indicate that neither ligand accepts electron density from the metal, a conclusion which agrees with the low intensities of the bands.

No theoretical treatment of the d^8 case which includes interelectron repulsion appears to have

been carried out. Band frequencies calculated from the energy diagram of ref. 48 (*Dq* 1390 cm^{-1}) are compared with the observed spectrum in Fig. 7*b*. The spectrum of [Ni(Me_6tren)Br]Br, in which the cation is known to have the symmetry C_{3v} (49), was matched by using *Dq* 1250 cm^{-1} (42, 48).

The spectrum of DDPN.$Cu(NO_3)_2$ differs from those of the cobalt and nickel complexes in being strongly dependent on the solvent. In chloroform (Fig. 7*c*(*i*)) two d–d bands are observed (Table 3) as for $CuCl_5^{3-}$, (8300, 10 400 cm^{-1}) (50), which has D_{3h} symmetry (34). The complexes [Cu(Me_6tren)X]X (X = Br, ClO_4, NO_3) also have two bands, at 10 300, 13 500 cm^{-1} for X = Br (20). It is therefore most likely that the DDPN complex in chloroform is properly formulated as [Cu(DDPN)NO_3]NO_3, analogously to the cobalt and nickel complexes. Since the band assignments are still controversial (42) no estimate of *Dq* is made.

In acetonitrile the spectrum is quite different (Fig. 7*c*(*ii*)), its single broad peak being similar in position to that of [Cu(dach)$_2NO_3$]NO_3 (18 700 cm^{-1}) (51) (dach = 1,4-diazacycloheptane), in which the metal has square pyramidal coordination, the nitrate ion being apical (52). The spectrum of DDPN.$Cu(NO_3)_2$ is almost unaltered in the less strongly coordinating solvent nitromethane (Fig. 7*c*(*iii*)), and is very much like that of the 4-coordinate Cu(dach)$_2(ClO_4)_2$ in the same solvent (ν_{max} 19 800 cm^{-1}, ε_{max} 172 l cm^{-1} mol^{-1}) (51). It is clear that the ionization of the second nitrate ion which occurs as the solvent is changed from chloroform to either acetonitrile or nitromethane is accompanied by a significant change in coordination, the four nitrogen atoms becoming more nearly coplanar. These results confirm the conclusion from the conductivity measurements that the dissociation in acetonitrile is electrolytic, and not a result of the displacement of a nitrate ion by a solvent molecule.

Conclusion

Cations in the series Mn^{2+}–Zn^{2+} are coordinated by four nitrogen atoms of DDPN. The molecule is folded about one NMN axis by repulsive interactions between the dimethylamino groups and the anionic fifth ligand, so preventing the coordination of a sixth group. In the solid state, the metal in the complex cation [DDPN.MX]$^+$ has a distorted trigonal bipyramidal environment; further dissociation of the cupric nitrate complex takes place in ionizing solvents, the cation [DDPN.Cu]$^{2+}$ probably having four coplanar nitrogen atoms. The magnetic moments and electronic spectra of the complexes show that DDPN acts as a weak-field donor, similar to, but rather stronger than, tetradentate amines. It is possible that ligands of the same type, but of sufficiently large ring size to allow planar coordination, might cause spin pairing (53). DDPN does not act as a π-acceptor (although this is not precluded by the trigonal bipyramidal coordination (54)), because the difference of orbital electronegativities of phosphorus and nitrogen is too great to allow appreciable mixing of metal and ligand antibonding orbitals. In contrast, the bonding levels are significantly perturbed by the partial localization of π-electrons by the metal. The significant bond length inequalities induced in this way extend, through conjugation, to the exocyclic groups.

Synthetic Studies in the *Veratrum* Alkaloid Series. I.[1] Introduction and the Total Synthesis of Appropriate C-Nor-D-homo Steroid Derivatives

JAMES P. KUTNEY, ARNOLD BY, JOHN CABLE, WILLIAM A. F. GLADSTONE, TADANOBU INABA, SIM Y. LEONG, PETER ROLLER, EDWARD J. TORUPKA, AND WILLIAM D. C. WARNOCK

Department of Chemistry, University of British Columbia, Vancouver, British Columbia V6T 1W5

Received May 22, 1974[2]

JAMES P. KUTNEY, ARNOLD BY, JOHN CABLE, WILLIAM A. F. GLADSTONE, TADANOBU INABA, SIM Y. LEONG, PETER ROLLER, EDWARD J. TORUPKA, and WILLIAM D. C. WARNOCK. Can. J. Chem. **53**, 1775 (1975).

An introduction to the synthetic approach leading to the total synthesis of various *Veratrum* alkaloids is presented. The total synthesis of a series of C-nor-D-homo steroid derivatives is described. These substances are important intermediates in the laboratory synthesis of these natural products.

JAMES P. KUTNEY, ARNOLD BY, JOHN CABLE, WILLIAM A. F. GLADSTONE, TADANOBU INABA, SIM Y. LEONG, PETER ROLLER, EDWARD J. TORUPKA et WILLIAM D. C. WARNOCK. Can. J. Chem. **53**, 1775 (1975).

On présente une introduction à l'approche d'une synthèse menant à la synthèse totale de divers alkaloides du *Veratrum*. On décrit la synthèse totale d'une série de dérivés de C-nor D-homo stéroides. Ces substances sont des intermédiaires importants dans la synthèse au niveau du laboratoire de ces produits naturels. [Traduit par le journal]

The *Veratrum* alkaloid family (1, 2) occupies a position of importance among the various groups of steroidal alkaloids mainly because many of its members possess a rearranged C-nor-D-homo steroidal skeleton and some of them exhibit interesting pharmacological activities. For example, their application in the control of hypertension is well known (3) and some interest in the insecticidal area (4) and their teratogenic activity (5) has been noted.

The division of the *Veratrum* alkaloids into the *Jerveratrum* and *Ceveratrum* groups originally proposed by Fieser and Fieser (6) is now generally accepted. Examples of the former group, which are directly relevant to the present discussion, are verarine (**1**), veratramine (**2**), and jervine (**3**) while verticine (**4**) is cited as an example of the latter group.

There are now several published syntheses of various members of this family. Johnson *et al.* (7) have described a synthesis of veratramine while Masamune *et al.* (8) have completed a synthesis of jervine. Both groups have employed

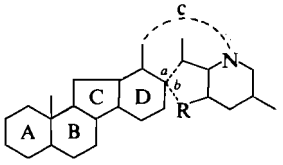
the same 17-acetyl-5α-etiojervane derivative for the steroidal unit but different pathways for the elaboration of the heterocyclic portion of the molecule. The Johnson synthesis involves a sequence of reactions in which the piperidine system is attained via a cyclization of an appropriately functionalized acyclic unit initially attached to the carbonyl side chain of the etiojervane analog. In the Masamune approach, an enamine derivative of the appropriate piperidine is attached directly onto the side chain of the C-nor-D-homo steroidal unit. Our own approach, also published in preliminary form (4), is rather different and this as well as the accompanying publication (9) provide a more detailed description of the overall strategy which we have employed.

An analysis of the structural features inherent in these natural systems reveals that they possess two main structural units: (*i*) the interesting C-nor-D-homo steroid unit and (*ii*) an appropriate heterocyclic system attached in a variety of ways to ring D of the steroidal component. A schematic representation is shown in **5**.



5

a veratranine bases
a + *b* jervanine bases
a + *c* cevanine bases

Thus for the synthesis of verarine (**1**) and veratranine (**2**) according to this analysis, a requisite piperidine unit must be attached at position *a* in **5** whereas the jervine system requires bond formation at both *a* and *b*. The hexacyclic *Ceveratrum* group involves the attachments of such a unit at *a* and *c*. This overall plan was adopted in our laboratory investigations and these provided the synthesis of various members within the *Veratrum* family.

To accommodate this overall strategy, it is essential to direct the investigations at several distinct phases. These are (*i*) synthesis of the required C-nor-D-homo steroid intermediates; (*ii*) synthesis of the appropriately substituted heterocyclic unit; (*iii*) attachment of the latter to ring D of the steroidal template; and (*iv*) elaboration of the coupled product to the final natural product. The results in this and the accompanying publication will be presented in this manner.

In previous studies (10–12) we reported stereospecific syntheses of certain hydrochrysene analogs via multistep sequences starting from β-naphthol. As already noted (10–12), the crucial steps in the synthesis of these molecules involved application of the "hydrochrysene approach" originally developed by Johnson and co-workers (7). The *trans-anti-trans* acetate, **6**, was chosen as the intermediate for elaboration to the C-nor-D-homo steroid system. For this purpose we considered the introduction of a suitable functional group into ring C of the hydrochrysene skeleton to provide an entry into synthetic intermediates where ring C had been opened. A brief discussion of the various experiments in this direction has been presented previously (11) but a more detailed description of our more recent investigations is now in order.

The introduction of substituents at C_{12} (see **6**), the desired site of reaction, is not a straightforward process. It must be recognized that another benzylic center C_{4b}, by virtue of its *para* relationship to the methoxyl function, would be expected to provide serious competition. Indeed electronic considerations would favor substitution at this position while steric factors would tend to favor the secondary center (C_{12}). It was felt that ultimate success could be achieved by the use of a sterically large oxidant such as *tert*-butyl chromate and this proved to be the case. A number of other reagents met with failure (11).

Reaction of *trans-anti-trans* acetate **6** with *tert*-butyl chromate provided a complex reaction mixture from which four products could be isolated and characterized. Fortunately the major product was the desired keto acetate (**7**) mentioned previously (11), while the three minor components (**8**–**10**) were clearly the result of further oxidation. In each instance the spectroscopic properties were very instructive (see Experimental) and provided strong evidence in favor of aromatization of ring C as well as further reaction in ring B in two of the compounds. Chemical correlations between the various products were performed to establish their structures. A summary of these experiments is provided in Fig. 1.

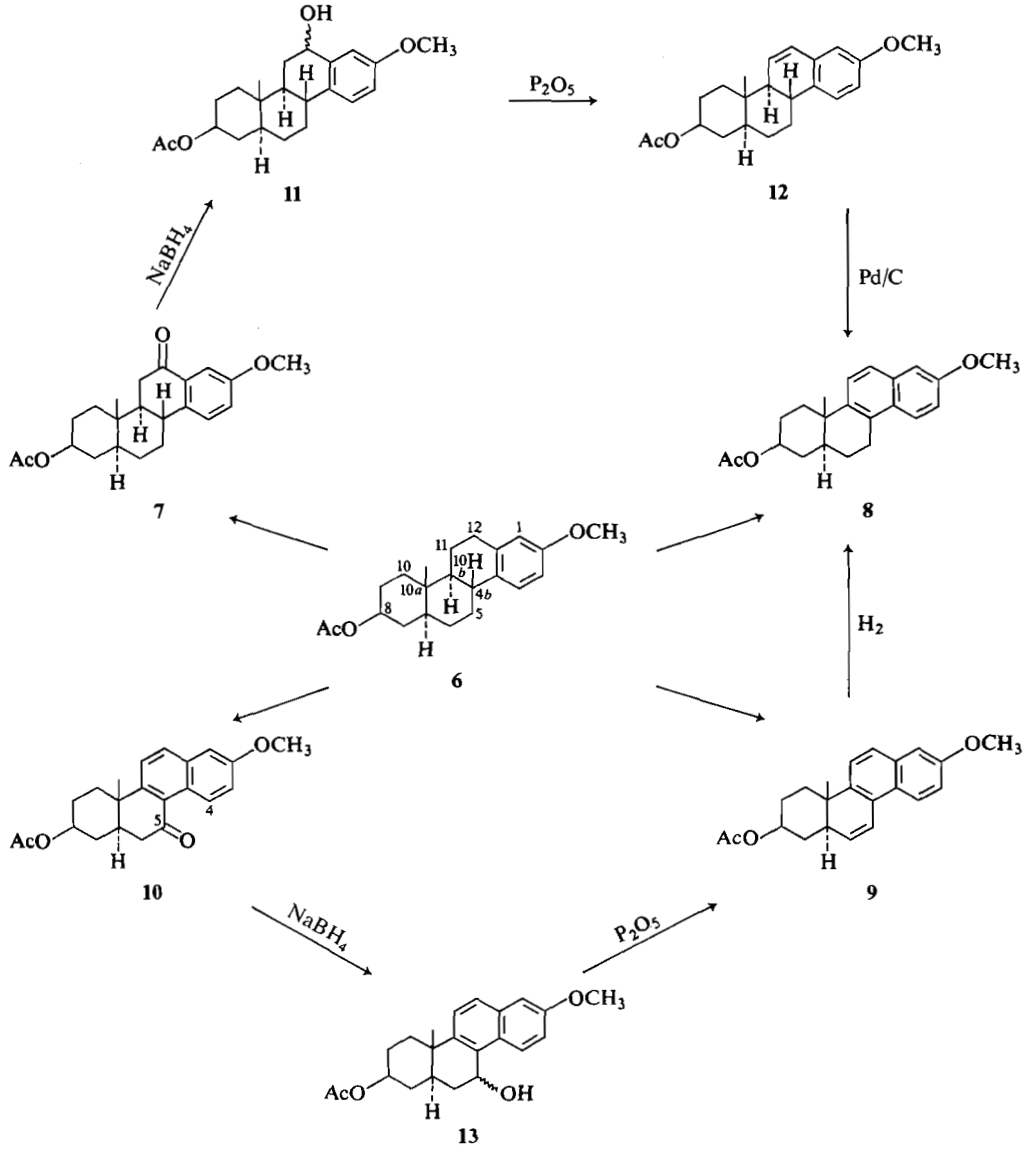


FIG. 1. Oxidation studies on *trans-anti-trans* acetate (**6**) and interrelationships between the various products.

It was now clear from this detailed investigation that, as previously mentioned (12), the oxidation pathway in the *trans-anti-trans* series is substantially different from the corresponding *cis-syn-cis* series. In the latter, the formation of hydrochrysene derivatives analogous to **10** (A/B *cis*) represents the predominant course of reaction. The reasons for this difference are readily apparent from molecular models (12).

The keto acetate (**7**) was selected as the crucial intermediate for ultimate conversion to the C-nor-D-homo series and the successful sequence is outlined in Fig. 2. For this purpose a more detailed investigation of the carbonyl reduction at C_{12} was essential in order to obtain optimum conditions and/or yields in the subsequent steps. When **7** was reduced with sodium borohydride at room temperature, a high yield of a mixture of the expected C_{12}-hydroxy compounds (**11**) was obtained. The major isomer could be obtained crystalline and on the basis of the spectral data, could be assigned the 12β

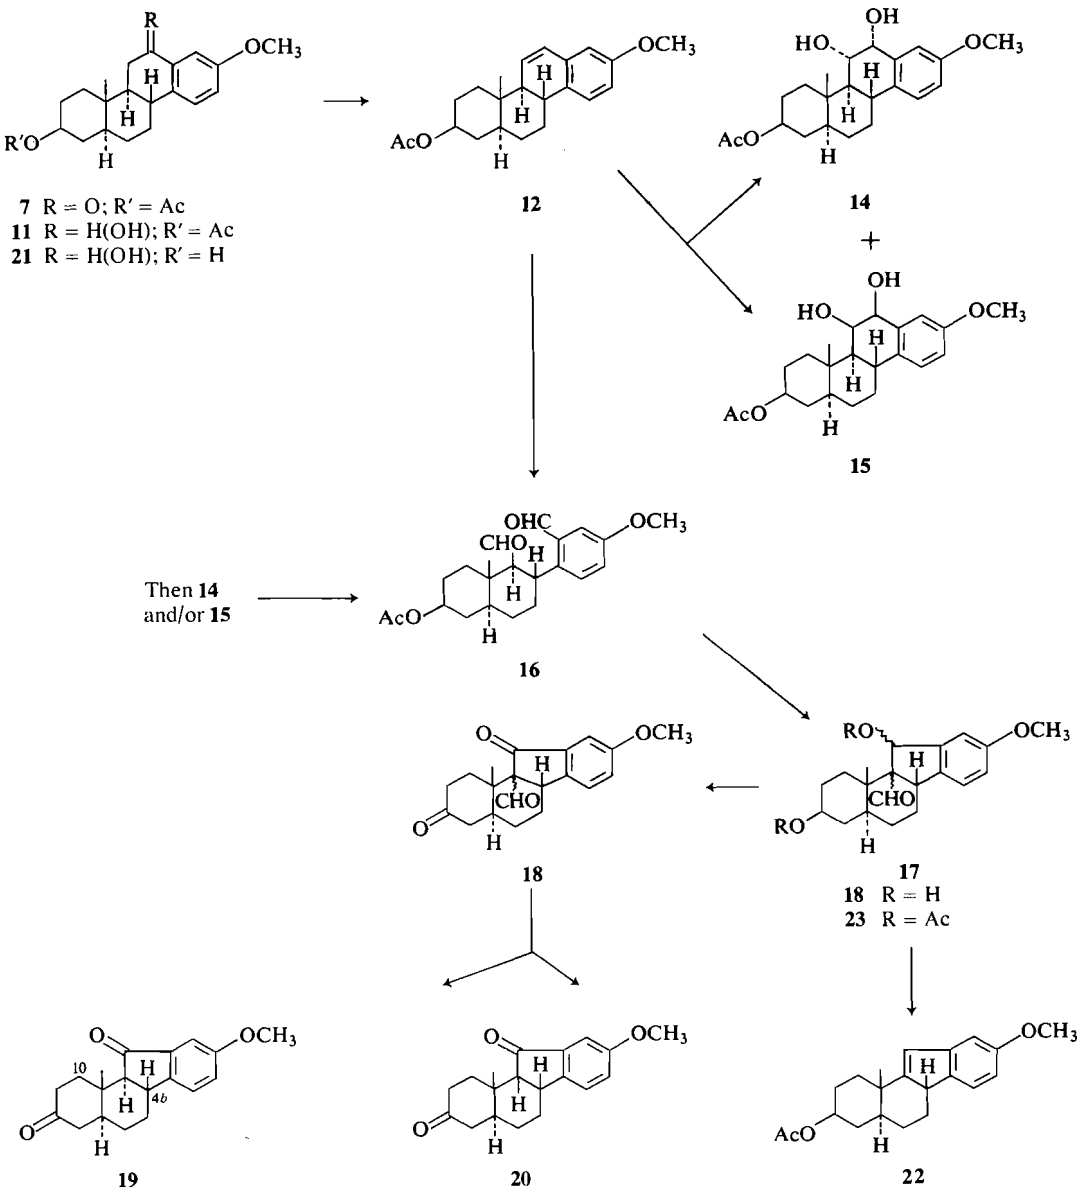

FIG. 2. The synthesis of C-nor-D-homo steroid intermediates from the hydrochrysene analog (7).

configuration (**11**, $C_{12}\beta$-OH). Analysis of the n.m.r. spectrum revealed a two-proton multiplet centered at τ 5.3 due to the C_{12} and C_8 protons. Acetylation of the C_{12} hydroxyl function resolved these signals into two distinct multiplets (τ 5.35, septet, C_8H; τ 4.09, quartet, $J_{11e,12a}$ = 6 Hz, $J_{11a,12a}$ = 9 Hz, $C_{12}\alpha$-H) and allowed the stereochemical assignment at C_{12}.

If the sodium borohydride reduction mixture is refluxed, not only is the 12-keto group reduced but hydrolysis of the C_8 acetoxy function is also observed and the diol **21** ($C_{12}\beta$-OH) is obtained in good yield.

The olefin (**12**) obtained by dehydration of the mixture of alcohols or the pure 12β-alcohol, was utilized for the ring opening studies. Our initial investigations on the transformation of olefin **12** to the secodialdehyde (**16**) involved ozonolysis under various conditions followed by reductive cleavage of the resulting ozonide.

In all instances the yield of **16** was very low. On the other hand, hydroxylation with osmium tetroxide proceeded smoothly to provide both possible 11,12-diols (**14** and **15**). The yield in this reaction was very sensitive to the reaction conditions. Initially a trace of pyridine was used since it was felt that this compound might catalyze the reaction but subsequent experiments showed that the yield was higher if no pyridine was present. The optimum yield of the mixture of diols was achieved by keeping the amount of ethyl ether used and the time required for the reaction work-up to a minimum. Although the reaction produced two isomeric diols, one of these (**15**) is by far the predominant isomer and its characterization will be discussed. The minor component was not isolated in pure state.

The n.m.r. spectrum of **15** (in pyridine) showed no absorption in the olefinic region but now new signals at τ 5.24 ($C_{12}H$, $J_{12,11}$ = 4 Hz) and τ 5.61 ($C_{11}H$, triplet, $w_{1/2}$ = 9 Hz) confirmed the structural assignment for the diol. Furthermore, the β orientation for the hydroxyl functions was clear from two points of view: (*a*) the small coupling constant, $J_{10b,11}$ = 4.5 Hz, revealing coupling of the C_{10b} axial proton with an equatorial C_{11} proton and (*b*) the downfield shift of the angular methyl group (for example, τ 9.26 in **6** $\rightarrow$ τ 9.13 in **15**) (13, 14). It should be noted here that in a related hydrochrysene series, Johnson *et al.* (15) also observed β-hydroxylation in the osmium tetroxide reaction.

The conversion of either diol to dialdehyde **16** was performed in a straightforward manner with periodic acid in methanol. For preparative purposes, the mixture resulting directly from the hydroxylation reaction was immediately treated with this reagent. The extent of the conversion could be conveniently followed by u.v. spectroscopy (λ_{max} 225, 255.5, and 321 nm) while the i.r. spectrum with three carbonyl absorptions (5.79, 5.87, and 5.97 μ) as well as a band at 3.63 μ for the aldehydic C—H stretching vibration and the n.m.r. spectrum confirmed the presence of equatorial aliphatic (0.50, doublet, $J_{11,10b}$ = 4.5 Hz, $J_{10b,4b}$ = 12 Hz) and aromatic (−0.27, singlet) aldehydic functions demanded by structure **16**. The stereochemistry of this product with respect to centers C_{10b} and C_{4b} was established by spin decoupling experiments. Thus irradiation at the frequency of the aliphatic aldehydic proton (τ 0.50) caused collapse of the quartet at τ 7.63 (α-H at C_{10b}) to a doublet (J = 12 Hz) while irradiation at τ 5.5 (β-H at C_{4b}) similarly caused collapse of this signal to a doublet (J = 4.5 Hz). The n.m.r. data confirm the *trans* stereochemistry of the C_{10b} and C_{4b} positions since the coupling constant, $J_{10b,4b}$ = 12 Hz, is only consistent with diaxial coupling.

The synthesis of the desired C-nor-D-homo skeleton was accomplished by an internal aldol condensation using alcoholic sodium hydroxide. Again the u.v. spectrum, now typical of the anisole-type chromophore (λ_{max} 284 and 289sh, nm), already well known from our previous studies, could be used to recognize the desired cyclization product (**18**). The i.r. spectrum with absorptions at 2.80, 2.89, 3.64, and 5.90 μ was in accord with the presence of only hydroxyl and saturated aldehyde functions.

Confirmatory evidence to support the desired cyclization became available from the crystalline diacetate derivative (**23**). The n.m.r. spectrum of the latter showed singlets at τ 9.02 (C_{10a} methyl), 8.02 (C_8 acetate), 7.84 (C_{11} acetate), and 6.35 (OCH_3). A quartet, which was assigned to the single C_{4b} benzylic proton appeared at τ 6.58. Axial–axial ($J_{4b,5\alpha}$ = 12 Hz) as well as axial–equatorial ($J_{4b,5\beta}$ = 7 Hz) couplings are observed between this proton and the pair of C_5 protons, giving rise to the above mentioned quartet. This confirms that the C_{4b} proton is axial and thereby β oriented.

The diol aldehyde on oxidation with Jones' reagent (16) provided the unstable diketo aldehyde **18**. Purification of this product was complicated by its facile loss of the aldehyde function so that spectral data could only be obtained on the crude product. For example, chromatography on neutral alumina converted **18** to a mixture of ketones which proved to be identical with diketones **19** and **20** as obtained in subsequent studies.

Although removal of the aldehydic function in **18** could be accomplished by contact with alumina, it proved more convenient to utilize alkaline conditions for this reaction. While our studies were in progress, Johnson and coworkers (17) described their results in a related series where an alkaline medium had also been employed in a deformylation reaction. Thus treatment of **18** with potassium hydroxide in refluxing dioxane provided an approximate 1:1 mixture of two compounds for which the struc-

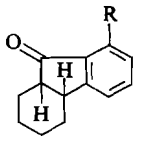
For personal use only.

tures **19** and **20** were deduced. Separation of these latter isomers proved extremely difficult and all attempts at separation by chromatography failed. Fractional crystallization allowed the eventual separation into two crystalline components whereupon complete spectral and analytical data could be obtained. The n.m.r. spectra of **19** and **20** showed some interesting differences. Of particular note was the angular methyl group region which showed singlets at τ 8.85 and 8.74 for **19** and **20**, respectively, thereby allowing assignment of the *trans-anti-trans* stereochemistry to the diketone **19** and the *trans-syn-cis* stereochemistry to isomer **20**.

It is well known (18) that the influence of the carbonyl group on protons in close proximity to it depends on the relative orientation of these protons to the plane in which the carbonyl group resides. Molecular models of **19** and **20** reveal that in the former the angular methyl group lies in a plane perpendicular to that of the carbonyl group whereas in the latter this group lies essentially in the plane of the trigonal carbon atom. Johnson and co-workers (19) have arrived at similar conclusions in their studies on a closely analogous system.

Finally to confirm the isomeric nature of the above diketones, a mass spectroscopic analysis was carried out. The mass spectra of **19** and **20** reveal the virtually complete identity in the region *m/e* 80–225. Minor intensity differences occur in the region *m/e* 225–280 while one significant difference is noted above *m/e* 280. Only the *trans-anti-trans* diketone **19** possesses a significant $M - 15$ peak (*m/e* 283) which indicates loss of the angular methyl group. It is interesting to compare the fragmentation process of the *trans-anti-trans* ketone in the normal hydrochrysene series which also reveals significant $M - 15$ and $M - 18$ fragments. It seems clear that the loss of the angular methyl group is a more significant process when the normal steroid stereochemistry prevails in the above hydrochrysene analogs. These results are in good agreement with the detailed investigations of Djerassi and collaborators (ref. 20, Chapt. 20) on steroidal ketones. In steroid 11-ketones, for example, fragmentation of bonds 9,10 and 6,7 occurs readily to provide the fragment ions normally observed. By analogy, cleavage of bonds 10a, 10b and 5,6 in the above compounds would be expected. Indeed plausible mechanistic pathways

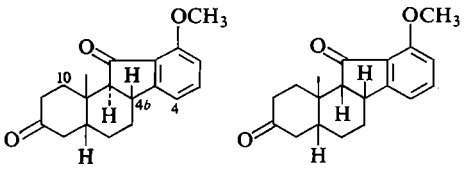


24 R = H
25 R = CH_3

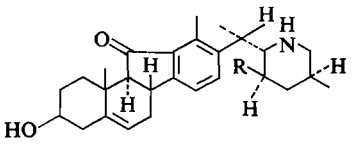
similar to those presented by Djerassi and co-workers (ref. 20, Chapt. 20) can be presented to explain the formation of the various fragments.

Before proceeding to the next series of reactions, it is appropriate to discuss the interesting problem of *cis–trans* isomers in the indanone series and to compare these results with the above C-nor-D-homo ketones. House *et al.* (21) have shown that the *cis*-fused benzindanone (**24**) is more stable than the *trans* isomer. Under equilibrating conditions it was established that the equilibrium lies 85% in favor of the *cis* system. In a further study (22) these workers found that the methyl substituted *cis* indanone (**25**) was stable to refluxing methanolic sodium methoxide. Other workers (23–27) have made observations in favor of *cis* configuration in the hydrindanone series. There are also examples in the literature (28–32) where *trans*-fused hydrindanones are more stable. With respect to somewhat more complicated examples, Johnson and co-workers (19) have synthesized the *cis-anti-trans* diketone (**26**) and its *cis-syn-cis* epimer (**27**) and have shown that at equilibrium the ratio of *cis*:*trans* was about 7:3. On the other hand, 11-ketoveratramine (**28**) (19) is very stable in the *trans* B/C ring fused system.

The above workers explain their observations by stating that the most unstable isomer is obviously the one which has the most steric interactions. With this in mind, the models of 11-ketoveratramine (**26** and **27**) as well as our diketones **19** and **20** were examined. It was apparent that two interactions, apart from the usual types associated with these molecules, seemed to require consideration. These are as follows: (*a*) The interaction between the oxygen atom of the carbonyl group and the hydrogen atoms on C_{10} (hydrochrysene numbering) and (*b*) the interaction between the angular methyl group and the hydrogen atom on C_{4b}. In the case of **28**, which can exist with rings A and B in a nonsteroidal conformation (angular methyl group is equatorial to ring B), these interactions are not appreciable. On the other



26 27



28 R = OH

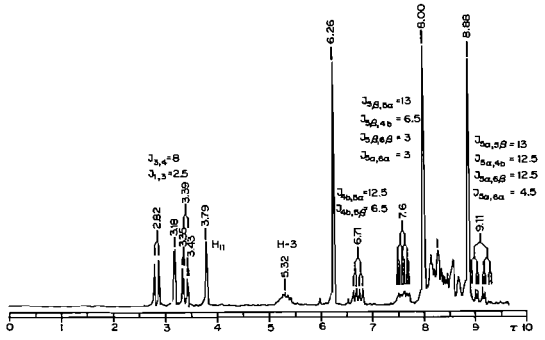


FIG. 3. Nuclear magnetic resonance spectrum of olefin **22**.

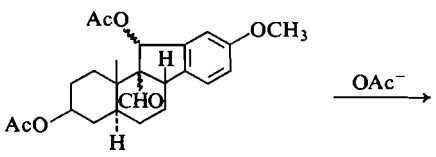
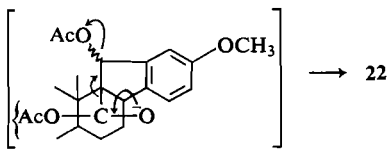
hand **26** shows the *b* type interaction. Therefore the ratio observed by Johnson is explicable in these terms. In *trans-anti-trans* diketone **19** the *b* type interaction is also present but in *trans-syn-cis* isomer **20**, where no such interaction exists, a more serious *a* type interaction is noticed. Thus the approximate ratio of 1:1 observed in our experiments is in good agreement with what one would expect from molecular models. In the case of 11-ketoveratramine the 5,6-double bond decreases the interaction of the methyl group with the C_{4b} proton thus making the B/C *trans* isomer more stable with respect to the *cis* one.

Another approach to the removal of the oxygen functionality in ring C of the aldol product **17** was considered and this proved to be highly successful. It was envisaged that the acetate derivative (**23**) mentioned previously might undergo elimination in the manner indicated, **23** → **29** → **22**, and the latter could also prove useful in its subsequent elaboration to the desired C-nor-D-homo steroidal template.



23



29

Johnson and co-workers (17) had employed a similar reaction in their studies.

Upon heating **23** for 8 days in a sodium acetate – acetic acid mixture an 80% yield of crystalline olefin **22** was obtained. Extensive n.m.r. studies (Fig. 3) were performed on this compound to establish its structure and, in particular, the stereochemistry at C_{4b}, the latter information being vital to the subsequent use of this intermediate in further studies. A few features are worthy of note at this point.

The C_{4b} hydrogen appeared at τ 6.71 as a quartet while the $C_{5\alpha}$ and β hydrogen were evident at τ 9.1 and 7.60, respectively, as multiplets. A possible explanation for the observed deshielding of the $C_{5\beta}$ hydrogen was provided in our studies as well as those of Nagata *et al.* (33). This latter group in studying a series of hydrophenanthrene derivatives noted that a strong deshielding of the aromatic C_4 protons had occurred. They attributed this result as being due to the steric effect of an equatorial C_5 proton. The degree of this deshielding was correlated to the van der Waals compression between the C_4 and C_5 protons which is determined by the interatomic distance between them. A conformational structure of **22** (see **22***a*) clearly reveals the significant difference in the relative orientations of the $C_{5\beta}$ and $C_{5\alpha}$ hydrogens, the latter being in the ring current of the aromatic ring.

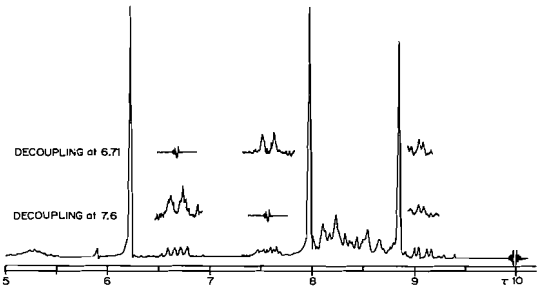

FIG. 4. Nuclear magnetic resonance decoupling studies of olefin **22**.

In all the previously studied compounds no C_5 proton resonances had been observed and thus olefin **22** provided a unique opportunity to evaluate stereochemistry by means of n.m.r. spectroscopy. Decoupling studies (Fig. 4) established the above assignments and provided the essential coupling constants.

Thus irradiation at τ 6.71 caused a collapse of the multiplet at τ 7.60 to a pair of triplets ($J_{5\alpha,5\beta}$ = 13 Hz, $J_{6\alpha,5\beta} = J_{6\beta,5\beta}$ = 3 Hz). Irradiation at τ 7.60 caused a collapse of the quartet at τ 6.71 to a doublet (J = 12 Hz). In each of the above experiments changes were observed at τ 9.1, thus establishing conclusively the identity of the proton resonating at τ 9.1. As for the stereochemistry at C_{4b} the second experiment shows that a *trans–trans* coupling exists. This could only be possible if the C_{4b} proton was β oriented.

The above studies completed the synthesis of several types of C-nor-D-homo steroid intermediates and their elaboration to the requisite unit for the *Veratrum* alkaloids was now considered. The ultimate objective was the synthesis of C-nor-D-homo derivatives bearing a carbonyl function in ring D since this functional group could serve as the site of reaction with the appropriate heterocyclic unit.

Previous investigations (11, 35) had revealed that in the Birch reduction of various hydrochrysene analogs, it was possible to control conditions so as to provide intermediates in which the aromatic ring D is maintained (11) or in which an α,β-unsaturated ketone was present (35). Thus reduction of olefin **22** with lithium metal in anhydrous ammonia and tetrahydrofuran provided a good yield of a crystalline product possessing a conjugated carbonyl chromophore (λ_{max} 242 nm; τ 4.07, 1H) and clearly lacking any other olefinic protons. Thus both the olefin and aromatic functions had been reduced and structure **30** could be assigned to this product. It was tempting, on the basis of the results obtained in the hydrochrysene series (11, 35) to assign the *trans-anti-trans-anti* stereochemistry, to this reduction product. However, the obvious importance of establishing, beyond doubt, the correct stereochemistry particularly at C_{10b}, demanded additional investigations in this direction. For this purpose olefin **22** was hydrogenated and the resultant sharp-melting product was carefully evaluated by various spectroscopic techniques. Of particular relevance to the present discussion are the n.m.r. spectral data since direct comparison could be made with the extensive results already available for the starting olefin as discussed previously (see Figs. 3 and 4). A quintet (J = 6.5 and 12.5 Hz) which appeared at τ 7.00 was attributed to the C_{4b} axial proton. Molecular models show that the conformation of the molecule is not significantly altered by removal of the double bond. On this basis it was possible to conclude that the coupling constant between the C_{4b} and C_{10b} protons is 6.5 Hz, hence the C_{10b} proton must be β. Similarly, an ABX type pattern was observed for the C_{10b}, $C_{11\alpha}$, and $C_{11\beta}$ protons in which the resonance for the C_{10b} proton also appeared as a quintet consistent with $J_{10b,11\alpha}$ = 12.5 Hz, $J_{10b,11\beta}$ = 6.5 Hz, complementing the above conclusion about the C_{10b} stereochemistry. These results left little doubt that hydrogenation of **22** had proceeded from the β face of the molecule and the reduction product could be assigned structure **31**. When the latter substance was exposed to Birch reduction conditions it yielded a product *identical* in every respect with **30**, obtained directly from the reduction of olefin **32**. It was now clear that in the C-nor-D-homo series, the Birch reduction procedure was providing the undesired stereochemistry at C_{10b} and the resultant fusion of rings A, B, and

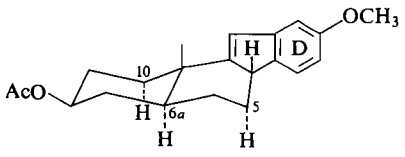
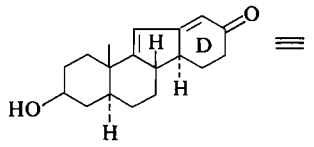
C was *trans-syn-cis* rather than the required *trans-anti-trans* backbone obtained in the hydrochrysene compounds. Unambiguous confirmation of the above stereochemical assignments was obtained in later studies, as described below, when the desired intermediate was synthesized and compared with the above compounds.

An alternative approach to the generation of the desired stereochemistry at C_{10b} was considered in terms of electrophilic addition to the double bond of olefin **22**. Hydroboration of **22** in diglyme, followed by addition of propionic acid under reflux, gave a complex mixture. This mixture was simplified somewhat by hydrolysis in aqueous methanolic potassium carbonate followed by reacetylation. Column chromatography followed by preparative layer chromatography gave a poor yield (14%) of a compound identical with that of the product obtained in the catalytic reduction of **22**. On the other hand, hydroboration of **22** followed by an oxidative treatment allowed isolation of a crystalline product in much higher yield (68%). This product was the expected alcohol **32** again indicating *cis* attack from the β face of the molecule. Again n.m.r. spectroscopy could be utilized to establish stereochemistry at C_{10b} and C_{11} ($J_{4b,10b} = 12.5$; $J_{10b,11\alpha} = 10$ Hz). It was now clear that olefin **22** could not be utilized effectively in any of these ways to generate the desired stereochemistry at C_{10b} and an alternative approach must be developed.

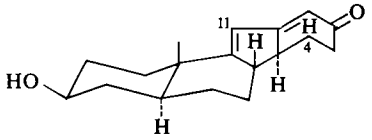
Consideration of the conformational structure **33** for the olefin does reveal some preference for β attack since approach from the α side of the bent backbone receives interference particularly from the axial α hydrogen atoms at C_5, C_{6a}, and C_{10}. On the other hand the axial methyl group and the hydrogen atom at C_{4b} provide some steric hindrance for β approach. Alteration in molecular shape, in particular with respect to rings C and D, may encourage α approach of reactants to the olefinic linkage and for this purpose the unsaturated ketone **34**



33



34

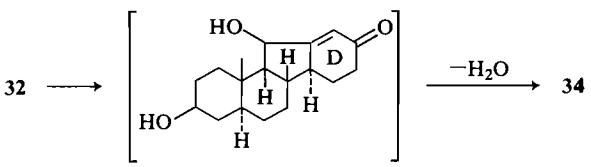


34*a*

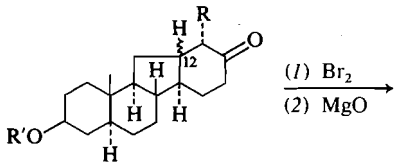
was selected as a possible intermediate. The latter, with a nonplanar ring D (**34***a*), reveals increased hindrance to β attack at C_{10b}—C_{11}. One possible route to **34** is presented by the sequence **32** → **35** → **34** and the requirement for retaining the oxygen function in ring C during Birch reduction of the aromatic system in **32** became obvious.

When the C-nor-D-homo intermediate **32** was reacted with lithium in ammonia, dioxane, and isopropanol, a crystalline product could be obtained which revealed interesting spectroscopic characteristics. The i.r. spectrum indicated a conjugated carbonyl absorption (6.12 μ) while the u.v. spectrum (λ_{max} 295 nm) and the n.m.r. signals (broad singlets at τ 4.05 and 4.25) demanded a dienone chromophore as shown in **34**. It was clear that the desired reduction had occurred and the resultant intermediate **35** was dehydrated under the reaction conditions to provide the desired C-nor-D-homo intermediate **34**.

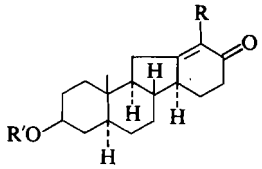
Catalytic hydrogenation of **34** provided a product mixture of the saturated ketone **36**



35



36 R = R′ = H
38 R = CH_3; R′ = Ac



37 R = R′ = H
39 R = CH_3; R′ = Ac

(no stereochemistry implied at C_{12}) and the conjugated ketone **37**. These compounds proved difficult to separate and since **37** was the desired compound it was found convenient to react the hydrogenation mixture initially with bromine and then magnesium oxide so as to transform **36** to **37** thereby permitting isolation of the latter. Comparison of **37** with **30** discussed previously, clearly established that they were different substances and allowed the assignment of the sought for *trans-anti-trans-anti* stereochemistry shown in **37**. The correctness of this assignment was established unambiguously as will be shown below.

The veratramine–jervine series of alkaloids, as already noted, carry a methyl substituent at C_{13} in the C-nor-D-homo steroidal component and it was now essential to develop methods for the introduction of this substituent into the available substances. More specifically the synthesis of intermediates **38** and **39** became the next requirement in the synthetic pathway.

The substance utilized in the initial investigations was the α,β-unsaturated ketone **40** since it was available in larger quantity from previous studies (11). The first method evaluated involved the enamine alkylation technique (36) since it could be shown that **40** undergoes essentially quantitative conversion to the dienamine derivative **41** (λ_{max} 276 nm) by reaction with pyrrolidine in refluxing benzene. Subsequent treatment of **41** with methyl iodide, alkaline hydrolysis, and finally rearrangement of the double bond under acidic conditions provided a product which exhibited spectral characteristics in accord with the desired alkylation product **42**. Thus the u.v. spectrum (λ_{max} 250 nm) showed the expected bathochromic shift of 10 nm relative to that of the starting ketone **40**, while the n.m.r. spectrum clearly revealed a vinyl methyl group (τ 8.22). In addition to this signal, a very interesting doublet was observed at τ 7.10 (J = 12 Hz). The starting conjugated ketone has no peaks in the region τ 6.7–7.3 and it was obvious that this absorption must be characteristic of the alkylation product. Pertinent to this last observation, another group (37) has noted a doublet at about τ 7.21 (J = 14.5 Hz) in the n.m.r. spectrum of 4-methyl-cholest-4-en-3-one and were able to assign this absorption to the $C_{6\alpha}$ equatorial proton. They indicated that a spatial interaction between the C_4 methyl group and the $C_{6\alpha}$ proton is the cause of the deshielding. A comparison with the system shown in **42** reveals that the $C_{12\beta}$ equatorial proton is identically oriented with respect to the methyl group at C_1. On this basis we assign our low-field doublet to this proton.

Finally, a comparison of the mass spectra of **40** and **42** also supported the structure of

the latter molecule. First of all, the molecular ion peak at *m/e* 302 in the mass spectrum of **42** relative to the corresponding peak at *m/e* 288 for **40** established an additional methyl group in the former compound. Moreover, the $M - 42$ peaks (*m/e* 246 and 260, respectively) are due to the loss of ketene, $CH_2{=}C{=}O$, and are indicative of a compound having the system, —C=CR—CO—CH_2 (ref. 20 pp. 87–91 and ref. 28). Steroids bearing the Δ^4-3-keto chromophore and their corresponding 19-nor analogs have prominent peaks at *m/e* 124 and 110, respectively (ref. 20, pp. 87–91 and refs. 37–39). These fragments are due to cleavage of the 9,10 and 6,7 bonds (steroidal nomenclature) plus the transfer of two protons to the charged fragment. In the mass spectrum of **42** an intense peak is observed at *m/e* 124, whereas in that of **40** one is noted at *m/e* 110. It is seen that these latter facts are in excellent agreement with the steroid series and offer further confirmation that the relationship between **42** and **40** is as suggested above.

Unfortunately, although the desired substance was now clearly available from the above approach, the observed low yields (about 10%) were discouraging. Various attempts to improve this reaction failed and this approach was abandoned.

Stork *et al.* (40) developed an interesting method which involves the trapping of an enolate anion formed during the Birch reduction of an α,β-unsaturated ketone and subsequent alkylation thereby providing introduction of the alkyl group at the α-olefinic carbon atom. Utilization of this technique proved successful in both the normal hydrochrysene and C-nor-D-homo series.

When the unsaturated ketone **40** in the form of its C_8-tetrahydropyranyl ether, prepared *in situ*, was reacted with lithium in ammonia followed by treatment with methyl iodide, a crystalline product was obtained. The mass spectrum of the latter revealed a molecular ion peak at *m/e* 304 thereby indicating introduction of a methyl group into the system, while the n.m.r. spectrum with a new secondary methyl signal (doublet, τ 9.02) and the saturated carbonyl absorption in the i.r. suggested entry of this substituent at C_1 of the tetracyclic skeleton. Confirmatory evidence was obtained when this alkylation product was first brominated and then dehydrobrominated to provide a conjugated ketone identical in all respects with **42** obtained and characterized previously in the pyrrolidine enamine studies.

The C-nor-D-homo unsaturated ketone **37** was now reacted with lithium, in a mixture of ammonia and dioxane followed by addition of methyl iodide. The amorphous product thus formed was acetylated directly to yield a crystalline acetate, m.p. 169–171.5°, which exhibited spectral properties (n.m.r. signal at τ 9.02, $J = 12$ Hz; i.r. at 5.85 μ) in accord with the desired alkylation product. The unambiguous proof of structure and stereochemistry of this substance was obtained when it was shown to be identical with 3β-acetoxy-5α-etiojervan-17-one (**38**, α-H at C_{12}) prepared from hecogenin as mentioned below.

Introduction of the 12,13 olefinic linkage into **38** was achieved by the bromination and dehydrobromination procedure used previously. The crystalline product thus obtained could be readily assigned the desired structure **39** and, as indicated below, this substance was subsequently resolved into an optically active isomer identical with 3β-acetoxy-5α-etiojerv-12(13)-en-17-one (**39**) obtained from the hecogenin degradation sequence.

At this stage of the investigations it was important to substantiate the structural and stereochemical assignments in the above C-nor-D-homo compounds since heavy reliance on spectroscopic data had been made. An unambiguous correlation could be made with compounds derived from a degradation of the steroid sapogenin hecogenin acetate (**43**) according to the scheme developed by Johns and Laos (41) and outlined in Fig. 5. In several instances, minor modifications in the sequence, **43** → **44** → **45** → **38**, originally presented (41) were made and these are documented in the experimental portion. Comparison of both **38** and **39** (i.r., n.m.r., t.l.c.) obtained in racemic form with the optically active isomers derived from the hecogenin series established their complete identity.

Resolution of racemic **39** was achieved by one of us (G.V.N.) during subsequent studies with Fried (42). During these latter investigations microbiological resolution involving the steroid dehydrogenase of *Arthrobacter simplex* was performed and the isolated substance was identical in every respect with 3β-acetoxy-5α-

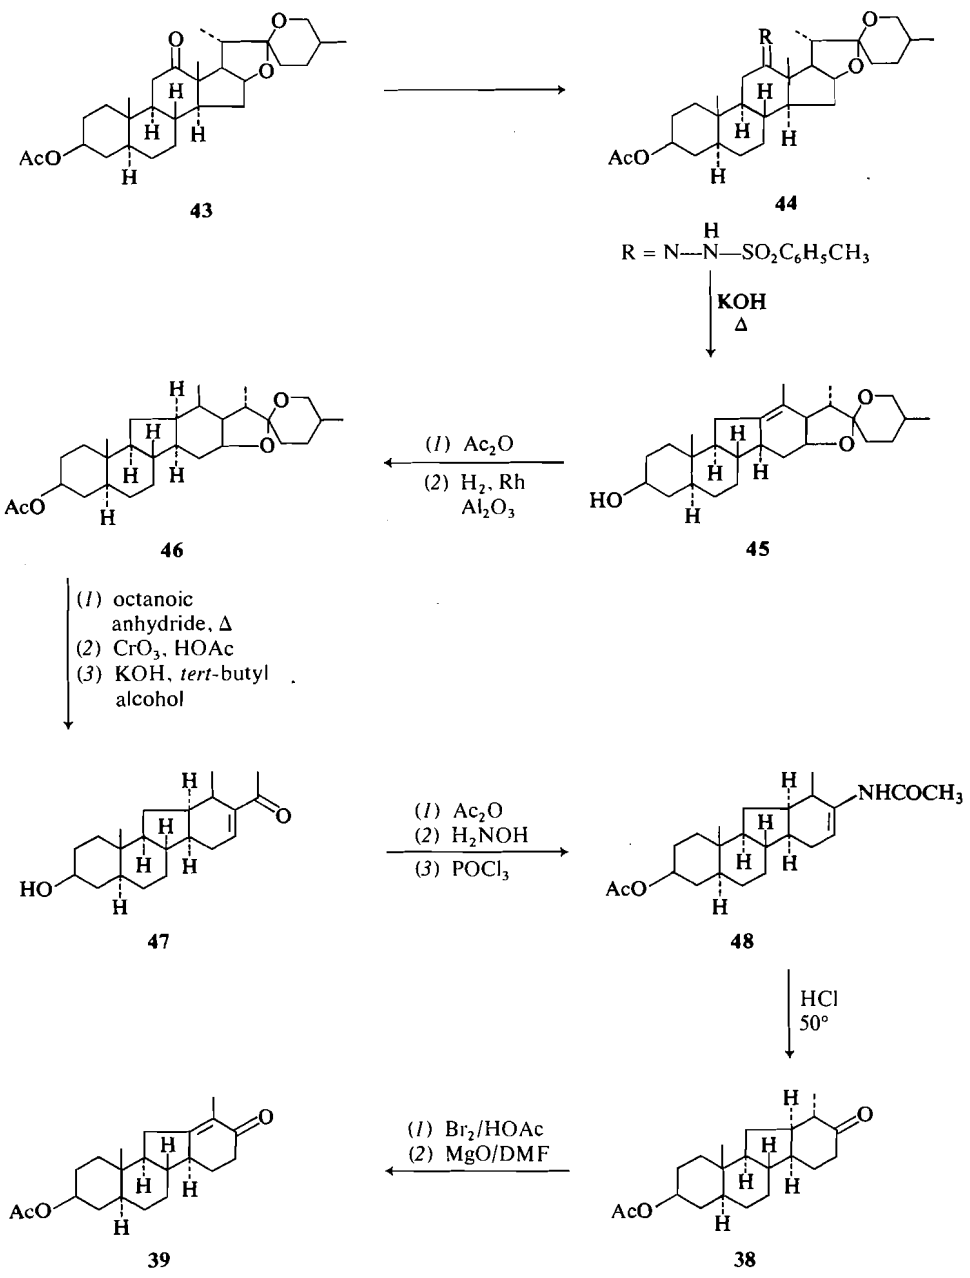

FIG. 5. Degradation scheme of hecogenin acetate (**43**) to 3β-acetoxy-5α-etiojerv-12(13)-en-17-one (**39**).

etiojerv-12(13)-en-17-one (**39**) as obtained from the sequence in Fig. 5.

In summary, the above discussion presents the completion of a crucial phase in the *Veratrum* alkaloid synthesis. The C-nor-D-homo steroid derivatives now available can be effectively employed for the further elaboration to the natural series and experiments in this direction are presented in the accompanying publication.

Experimental

The melting points were determined on a Kofler block unless otherwise stated and are uncorrected. The u.v. spectra were recorded in 95% ethanol on a Cary 11 or 14

recording spectrophotometer and the i.r. spectra were taken on a Perkin-Elmer Model 21 spectrometer as potassium bromide pellets unless otherwise stated. The n.m.r. spectra were measured at 60 or 100 MHz on Varian A60, HA 100, or XL100 spectrometers. The centers of multiplets or positions of singlets are given in the Tiers τ scale with reference to tetramethylsilane as the internal standard. The type of protons, integrated area, multiplicity, half-height width ($W_{1/2}$) in Hz, the spin–spin coupling constant (J) in Hz, and peak positions in Hz are indicated in parentheses. Deuteriochloroform was used as the solvent unless otherwise stated. The analyses were performed by Dr. A. Bernhardt and his associates, Mulheim (Ruhr) Germany, and by Mrs. Aldridge, Mrs. C. Jenkins, and Mr. P. Borda, University of British Columbia. Every molecular weight quoted was determined on either the AEI MS9 or the Atlas CH-4 mass spectrometer.

*Oxidation of trans-anti-trans-2-Methoxy-8β-acetoxy-10a-methyl-4b,5,6,6a,7,8,9,10,10a,10b,11,12-dodecahydrochrysene (**6**)*

A solution of *tert*-butyl chromate in carbon tetrachloride was prepared according to the procedure of Heusler and Wettstein (34) except the final solution was concentrated to 600 ml instead of 1000 ml. Aliquots of this solution were then used for the various experiments.

The methoxy acetate (**6**; 6.70 g) was dissolved in carbon tetrachloride (180 ml) and the *tert*-butyl chromate solution (90 ml), which was mixed with acetic anhydride (15 ml), was added. The mixture was stirred under reflux for 4 h and the excess oxidant was then destroyed by stirring with a solution of oxalic acid (75 g) in water (500 ml) for 2 h. The carbon tetrachloride layer was separated and the solvent was removed *in vacuo*. The residue was taken up in ether. The ether solution was washed with aqueous sodium bicarbonate to remove any residual acetic acid and then washed with a 1:1 mixture of a saturated aqueous sodium bicarbonate and a 1 *N* potassium carbonate solution. The organic layer was dried over anhydrous magnesium sulfate and, after removal of the solvent, provided 6.25 g of a crude neutral product. The material was purified by chromatography on alumina (300 g, grade III). Elution with 7:3 benzene – petroleum ether provided starting material (3.74 g, 56%) and further elution with 9:1 benzene–ether yielded the desired ketone **7** (1.16 g, 16%) as described previously (11).

The mother liquor from the recrystallization of the 12-keto compound **7** was investigated in more detail. After evaporating the solvent the gummy product was purified by another alumina chromatography (Woelm, grade I). Elution with 15:1 benzene–chloroform yielded a very small amount of crystalline fraction. Fractional crystallization from 95% ethanol gave two compounds: *First*, less soluble component, *trans*-2-methoxy-8β-acetoxy-10a-methyl-5,6,6a,7,8,9,10,10a-octahydrochrysene (**8**; 65 mg), m.p. 169–172.5°; i.r.: 5.82 μ; u.v.: λ_{max} 227 (4.74), 256 (3.54), 266 (3.64), 276 (3.66), 287 (3.46), 307 (2.96), 314 (3.04), 319 (3.18), 328 (3.10), and 334 nm (3.27); λ_{min} 254 (3.53), 259 (3.54), 271 (3.60), 284 (3.29), 302 (2.91), 309 (2.96), 324 (3.06) and 331 nm (2.09); n.m.r.: 8.81 (angular methyl, 3H), 6.11 (CH_3O—, 3H), broad signal centered at 5.2 (H—C—OAc, 1H) multiplet centered at 2.5 (aromatic H, 5H).

Anal. Calcd. for $C_{22}H_{26}O_3$: C, 78.01; H, 7.69; O, 14.20. Found: C, 77.89; H, 8.02; O, 14.76.

Second, more soluble component, *trans*-2-methoxy-8β-acetoxy-10a-methyl-6a,7,8,9,10,10a-hexahydrochrysene (**9**; 40 mg), m.p. 158.5–160.5°; i.r.: 5.82 μ; u.v.: λ_{max} 244 (4.59), 276 (3.57), 288 (3.65), 301 (3.82), 314 (3.89), 335 (3.53), and 351 nm (3.54); λ_{min} 273 (3.56), 281 (3.55), 293 (3.64), 307 (3.73), 327 (3.38), and 342 nm (3.41); n.m.r.: 8.93 (angular methyl, 3H), 7.94 (CH_3COO—, 3H), 6.10 (CH_3O—, 3H), broad signal centered at 5.2 (H—C—OAc, 1H), quartet centered at 4.2 (C_6 olefinic H, 1H), multiplet centered at 2.4 (aromatic H, C_5 olefinic H, 6H).

Anal. Calcd. for $C_{22}H_{24}O_3$: C, 78.54; H, 7.69; O, 13.72. Found: C, 78.55; H, 7.67; O, 13.64.

Further elution with 8:2 benzene–chloroform provided a mixture of two compounds, one of which was found to be 12-keto compound 7. Since the other compound was less soluble than the 12-keto compound (**7**), the former was purified by fractional crystallization from ether to give an analytical sample of *trans*-2-methoxy-8β-acetoxy-5-keto-10a-methyl-5,6,6a,7,8,9,10,10a-octahydrochrysene (**10**), m.p. 156–157.5°; i.r.: 5.82 and 6.02 μ; u.v.: λ_{max} 219.5 (4.66), 248 (4.43), and 315 nm (3.79), broad shoulder at 348 nm (3.48); λ_{min} 233 (4.23) and 278 nm (3.02); n.m.r.: 8.76 (angular methyl, 3H), 7.94 (CH_3COO—, 3H), 6.10 (CH_3O—, 3H), broad signal centered at 5.3 (H—C—OAc, 1H), multiplet centered at 2.5 (aromatic H, 4H), doublet centered at 0.93 (C_4H, aromatic H, 1H).

Anal. Calcd. for $C_{22}H_{24}O_4$: C, 74.97; H, 6.86; O, 18.16. Found: C, 75.10; H, 7.25; O, 17.82.

*Synthesis of trans-anti-trans-2-Methoxy-8β-acetoxy-10a-methyl-12-hydroxy-4b,5,6,6a,7,8,9,10,10a,10b,11,12-dodecahydrochrysene (**11**)*

The 12-keto acetate (**7**; 3.2 g) was dissolved in methanol (400 ml) and a solution of sodium borohydride (1.0 g) in methanol (400 ml) and water (20 ml) was added. The mixture was stirred at room temperature for 3.5 h. Acetic acid (15 ml) was added and the solution was stirred for a further ½ h. The reaction mixture was partitioned between water and ethyl ether then washed with sodium bicarbonate solution and water. After drying the organic layer over magnesium sulfate (anhydrous) and removal of the liquid, a gum (3.2 g) was isolated. On t.l.c. two spots of ratio 2:1 were observed. The product of lower R_f value crystallized from ethanol or benzene – high boiling petroleum ether gave an analytical sample of *trans-anti-trans*-2-methoxy-8β-acetoxy-10a-methyl-12β-hydroxy-4b,5,6,6a,7,8,9,10,10a,10b,11,12-dodecahydrochrysene (**11**), m.p. 147.5–149°; i.r.: 2.86, 5.85, 6.22, 6.65 μ; u.v.: λ_{max} 226 (3.86), 281 (3.33), 288 nm (3.31); λ_{min} 247 (2.77), 286 nm (3.27); n.m.r.: 9.15 (angular methyl, 3H, singlet), 8.03 ($C_{8\beta}$ acetoxyl, 3H, singlet), 7.93 ($C_{12\beta}$ hydroxyl, 3H, singlet removed by D_2O exchange), 6.29 (C_2 methoxyl, 3H, singlet), 5.3 ($C_{8\alpha}$, $C_{12\alpha}$H, 2H, multiplet), 3.30 (C_3, 1H, quartet, $J_{1,3}$ = 3 Hz), 2.96 (C_1, 1H, doublet, $J_{1,4}$ = 0 Hz), 2.90 (C_4, 1H, doublet, $J_{3,4}$ = 9 Hz); mass spectrometry: *m/e* 358 (M^+) prominent peaks at *m/e* 158, 159, 171, 172, 173, 174, 185, 265, 280, 296, 316, 340, 342, 356.

Anal. Calcd. for $C_{22}H_{30}O_4$: C, 73.71; H, 8.44; O, 17.85. Found: C, 73.91; H, 8.31; O, 17.70.

If the above sodium borohydride reaction mixture is refluxed for as little as 1 h the major product is a

mixture of C_{12} epimeric diols, *trans-anti-trans*-2-methoxy-8β,12β-dihydroxy-10a-methyl-4b,5,6,6a,7,8,9,10,10a,10b,11,12-dodecahydrochrysene, m.p. 190°; i.r.: 2.80, 3.02, 6.19, 6.36, 6.69, 11.3 μ; u.v.: λ_{max} 224 (3.81), 280 (3.24), 288 nm (3.21); λ_{min} 247 (2.05), 286 nm (3.18); n.m.r.: (in pyridine) 9.22 (angular methyl, 3H, singlet), 6.38 (C_2 methoxyl, 3H, singlet), 6.24 ($C_{8\alpha}$, 1H, septet, $J_{7,8} = J_{8,9} = 5.5$ Hz, $J_{7,8} = J_{8,9} = 11$ Hz), 5.00 ($C_{12\alpha}$, 1H, quartet, $J_{11\beta,12\beta} = 10$ Hz, $J_{11\alpha,12\alpha} = 5$ Hz); mass spectrometry: *m/e* 316 (M^+) prominent peaks at *m/e* 298, 185, 175, 174, 173, 159, 158, 150, 149.

Anal. Calcd. for $C_{20}H_{28}O_3$: C, 75.91; H, 8.92; O, 15.17. Found: C, 76.02; H, 8.97; O, 15.16.

The diacetate of the above compound was synthesized in the usual manner, *trans-anti-trans*-2-methoxy-8β,12β-diacetoxy-10a-methyl-4b,5,6,6a,7,8,9,10,10a,10b,11,12-dodecahydrochrysene, m.p. 175°; i.r.: 5.78, 5.81, 6.22, 6.64, 7.26 μ; u.v.: λ_{max} 226 (3.84), 281 (3.33), 288 nm (3.30); λ_{min} 246 (2.18), 286 nm (3.28); n.m.r.: 9.16 (angular methyl, 3H, singlet), 8.03 ($C_{8\beta}$ acetoxyl, 3H, singlet), 7.92 ($C_{12\beta}$ acetoxyl, 3H, singlet), 6.30 (C_2 methoxyl, 3H, singlet), 5.35 ($C_{8\alpha}$, 1H, septet, $J_{7e,8} = J_{8,9e} = 5$ Hz, $J_{7a,8} = J_{8,9a} = 10$ Hz), 4.09 ($C_{12\alpha}$, 1H, quartet, $J_{11e,12a} = 6$ Hz, $J_{11a,12a} = 9$ Hz), 3.35 (C_1, 1H, doublet, $J_{1,4} = 0$ Hz), 3.28 (C_3, 1H, quartet, $J_{1,3} = 3$ Hz), 2.86 (C_4, 1H, doublet, $J_{3,4} = 8.5$ Hz); mass spectrometry: *m/e* 400 (M^+), prominent peaks at *m/e* 158, 159, 171, 172, 173, 174, 184, 185, 265, 280, 325, 340, 358.

Anal. Calcd. for $C_{24}H_{32}O_5$: C, 71.91; H, 8.05; O, 19.98. Found: C, 71.72; H, 7.91; O, 20.20.

Dehydration of Crude Alcohol **11**

The crude alcohol (3.2 g) was dissolved in anhydrous benzene (150 ml) and phosphorus pentoxide (3.2 g) was added. After 2 h of reflux the reaction mixture was cooled in ice water then transferred into another flask. A small amount of ice was added and the yellow-green fluorescent solution was swirled occasionally while most of the residue in the reaction flask was dissolved in ice water. To the suspension in the reaction flask, ethyl ether and saturated sodium chloride solution were added. Sodium bicarbonate was added in small portions until the solution became basic. At this point it was as difficult to destroy the emulsions formed as it was to dissolve the residue completely. The aqueous layer was extracted several times with ether and combined with the decanted solution. The organic phase was washed with sodium bicarbonate, water, and dried over magnesium sulfate. On removal of solvent the crude material (2.7 g) was isolated. Purification by column chromatography on alumina (grade III, 100 g) gave the desired olefin **12** (2.2 g) with benzene – petroleum ether (1:1). Recrystallization from ethanol gave pure *trans-anti-trans*-2-methoxy-8β-acetoxy-10a-methyl-4b,5,6,6a,7,8,9,10,10a,-10b-decahydrochrysene (**12**), m.p. 105–106.5°; i.r.: 5.80, 6.14, 6.25, 6.39, 6.73 μ; u.v.: λ_{max} 221 (4.44), 262.5 (3.84), 270 (3.88), 302 (3.51), 312 nm (3.40); λ_{min} 247 (3.83), 284 nm (3.48); n.m.r.: 9.11 (angular methyl, 3H, singlet), 8.15 (C_{10a}, 1H, multiplet), 8.04 (C_8 acetoxyl, 3H, singlet), 6.32 (C_2 methoxyl, 3H, singlet), 5.33 ($C_{8\alpha}$, 1H, septet, $J_{7e,8a} = J_{8a,9e} = 5.5$ Hz, $J_{7a,8a} = J_{8a,9a} = 11$ Hz), 4.11 (C_{12}, 1H, quartet, $J_{10a,12} = 2$ Hz), 3.67 (C_{11}, 1H, quartet, $J_{11,12} = 10$ Hz, $J_{10b,11} = 3$ Hz), 3.49 (C_1, 1H, doublet, $J_{1,4} = 0$ Hz), 3.39 (C_3, 1H, quartet, $J_{1,3} = 2.5$ Hz, $J_{3,4} = 8$ Hz), 2.98 (C_4, 1H, doublet); mass spectrometry: *m/e* 340 (M^+), prominent peaks at *m/e* 158, 159, 160, 161, 171, 172, 173, 184, 185, 197, 263, 265, 280, 325, 338.

Anal. Calcd. for $C_{22}H_{28}O_3$: C, 77.61; H, 8.29; O, 14.10. Found: C, 77.48; H, 8.23; O, 14.44.

*Synthesis of trans-2-Methoxy-8β-acetoxy-10a-methyl-5,6,6a,7,8,9,10,10a-octahydrochrysene (**8**)*

The olefinic methoxy acetate (7; 286 mg) was mixed and powdered with 10% palladium-on-charcoal (215 mg) in a 50 ml Erlenmeyer flask. The flask was then heated for 3 min at 240–245° with nitrogen passing over the mixture. Some acetic acid was evolved near the end of the heating period. After the flask had cooled to room temperature, the residue was treated with chloroform, the catalyst was filtered, and the solvent was removed *in vacuo* to yield 232 mg of product. This material was dissolved in benzene and chromatographed on alumina (14 g Woelm, activity grade I). Elution with 10:1 benzene–chloroform yielded first a solid material (140 mg) which, after three recrystallizations from 95% ethanol, gave an analytical sample of *trans*-2-methoxy-8β-acetoxy-10a-methyl-5,6,6a,7,8,9,10,10a-octahydrochrysene (**8**), m.p. 169–172.5°. This compound was completely identical with one of the *tert*-butyl chromate oxidation products (mixture m.p., u.v. and i.r. spectra).

*Catalytic Hydrogenation of Hexahydrochrysene Analog (**9**)*

The naphthalene olefin (**9**; 10 mg or 29.7 mmol) was dissolved in chloroform (3 ml). Palladium-on-charcoal (10%; 3 mg) was put into a microhydrogenation apparatus. After the absorption of an equimolar amount of hydrogen, the catalyst was filtered off. Evaporating the solvent *in vacuo* yielded 10 mg of oily product (**8**). When petroleum ether was poured into the oil, it solidified and gave a m.p. 169–172°. The melting point on admixture with the dehydrogenation product of the styrene compound (**12**) gave no depression. The u.v. and i.r. spectra were also identical.

*Synthesis of trans-2-Methoxy-8β-acetoxy-10a-methyl-6a,7,8,9,10,10a-hexahydrochrysene (**9**)*

A solution of the ketone (**10**; 100 mg) in methanol (50 ml) was treated with a solution of sodium borohydride (100 mg) in 80% methanol – 20% water (50 ml) and the mixture was stirred at room temperature for 2 h. The mixture was then treated with 10% acetic acid (5 ml). The solution was concentrated *in vacuo* to a volume of 10 ml, water and ether were added, and the ether layer was separated. The ether layer was washed with water, aqueous sodium bicarbonate, and water, and then dried over anhydrous magnesium sulfate. Removal of the solvent provided an oily product (**13**; 101 mg). The i.r. spectrum showed no conjugated carbonyl band but had an intense hydroxyl absorption (2.78 μ). The u.v. spectrum showed typical complex peaks for the saturated naphthalene chromophore (λ_{max} 227, 256, 266, 276, 287, 307, 314, 319, 328, and 334 nm). This oil (**13**) was dissolved in dry benzene (50 ml, dried over sodium) and phosphorus pentoxide (100 mg) was added. After refluxing for 2 h, the mixture was poured onto crushed ice. Ethyl ether was added and the ether layer was separated. The ether layer was washed with water, with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

aqueous sodium bicarbonate, and finally with water. After drying over anhydrous magnesium sulfate, the solvent was removed to yield an oily material (94 mg). The material was purified by chromatography on alumina (10 g, Woelm activity grade 1). Elution with petroleum ether – benzene yielded the desired olefin (**9**) (61 mg) which melted at 158.5–160.5° after recrystallization from cyclohexane. This compound was identical with one of the minor components of the *tert*-butyl chromate oxidation reaction (mixture m.p., i.r., u.v.).

*Synthesis of trans-anti-trans-11,12-Seco-2-methoxy-8β-acetoxy-10a-methyl-11,12-dioxo-4b,5,6,6a,7,8,9,-10,10a,10b,11,12-dodecahydrochrysene (**16**) by Ozonolysis*

The olefinic compound (7; 485 mg) was dissolved in dry ethyl acetate (40 ml) and ozonized oxygen was passed through the solution at −78° over a period of 20 min. When the reaction was over, the solution was pale blue in color. The ozonide was catalytically cleaved by shaking with hydrogen and 10% palladium-on-charcoal under a pressure of about 3 atm (Parr instrument). After shaking for 20 h, the catalyst was removed. The solvent was evaporated off *in vacuo* to yield a crude product (609 mg). This material was purified by chromatography (30 g silica gel, B.D.H.). Elution with chloroform yielded the desired dialdehyde **16** (243 mg). Purification and characterization data for this compound are presented in the periodate cleavage experiment given below.

*Synthesis of trans-anti-trans-2-Methoxy-8β-acetoxy-11β,12β-dihydroxy-10a-methyl-4b,5,6,6a,7,8,9,-10,10a,10b,11,12-dodecahydrochrysene (**15**)*

The olefin (**12**; 600 mg) was dissolved in dry ethyl ether (10 ml). Osmium tetroxide (500 mg, 12% excess) was dissolved in dry ethyl ether (10 ml) and latter and former solutions were rapidly mixed. The osmium tetroxide container was rinsed with more ether (10 ml) and added. The solution was allowed to stand at room temperature in the dark for 57 h. The dark precipitate which separated was treated with methanol (6 ml) and water (1 ml). Hydrogen sulfide gas was passed into the solution for 5 min, the solution was stirred for a further 5 min, and the precipitate filtered in a sintered glass funnel. The precipitate was washed with methanol then removed and subjected to the hydrogen sulfide treatment twice more to insure decomposition of the osmate ester. When for some unknown reason the osmium sulfide did not aggregate sufficiently and was passed through the sintered glass funnel, it was found that only centrifugation was able to remove this impurity. When the solvent was removed from the filtrate solution a crude solid product (0.688 g) was obtained. This substance was refrigerated until purified by chromatography. Elution of the product (590 mg), from Woelm silica gel was accomplished with 5% methanol in chloroform. Thin-layer chromatography showed two isomers with R_f values 0.17 and 0.13, the latter being the major constituent. Recrystallization of the polar fractions from chloroform and petroleum ether (65–110°) produced an analytical sample m.p. 225–226°; i.r.: 2.90, 5.86, 6.12, 6.31 μ; u.v.: λ_{max} 276 (3.21), 282 nm (3.19); λ_{min} 244.5 (2.13), 280 nm (3.16); n.m.r.: 9.05 (angular methyl, 3H, singlet), 8.48 (C_{11} or C_{12} hydroxyl, 1H, doublet, removed by D_2O exchange), 8.02 ($C_{8\beta}$ acetoxyl, 3H, singlet), 7.22 (C_{11} or C_{12} hydroxyl, 1H, doublet, removed by D_2O exchange), 6.24 (C_2 methoxyl, 3H, singlet), 5.94 (C_{11}, 1H, multiplet, to triplet on D_2O addition), 5.60 (C_{12}, 1H, quartet, to doublet on D_2O addition), 5.3 (C_8, 1H, multiplet), 3.25 (C_3, 1H, quartet, $J = 2.5$ Hz), 2.94 (C_4, 1H, doublet, $J_{3,4} = 8.5$ Hz), 290 (C_1, 1H, doublet).

Anal. Calcd. for $C_{22}H_{30}O_5$: C, 70.56; H, 8.08; O, 21.36. Found: C, 70.18; H, 7.99; O, 21.83.

*Acetylation of Diol Acetate **15***

The above diol acetate (**15**) was acetylated in the usual manner to give the triacetate, *trans-anti-trans*-2-methoxy-8β,11β,12β-triacetoxy-10a-methyl-4b,5,6,6a,7,8,9,10,10a,-10b,11,12-dodecahydrochrysene, m.p. 194–195.5°; i.r.: 5.77, 6.20, 6.68 μ; u.v.: λ_{max} 283 (3.32), 277 (3.33), 225 nm (3.88); λ_{min} 280 (3.30), 243 nm (2.48); n.m.r.: 8.95 (angular methyl, 3H, singlet), 8.11 (C_{11} acetoxyl, 3H, singlet), 8.00 ($C_{8\beta}$ acetoxyl, 3H, singlet), 7.87 (C_{12} acetoxyl, 3H, singlet), 6.22 (C_2 methoxyl, 3H, singlet), 5.33 ($C_{8\alpha}$, 1H, septet), 4.33 (C_{11}, C_{12}, 2H, multiplet), 3.19 (C_3, 1H, quartet), 3.13 (C_1, 1H, doublet), 2.87 (C_4, 1H, doublet); mass spectrometry: *m/e* 458 (M^+), prominent peaks at *m/e* 149, 159, 161, 171, 174, 175, 176, 187, 188, 230, 263, 279, 296, 313, 338, 356, 372, 383, 398, 416, 443.

Anal. Calcd. for $C_{26}H_{34}O_7$: C, 68.10; H, 7.47; O, 24.43. Found: C, 68.89; H, 7.24; O, 23.87.

*Synthesis of trans-anti-trans-11,12-Seco-2-methoxy-8β-acetoxy-10a-methyl-11,12-dioxo-4b,5,6,6a,7,8,9,10,-10a,10b,11,12-dodecahydrochrysene (**16**) by Periodate Cleavage*

The above diol mixture (166.7 mg) obtained directly from the osmium tetroxide reaction was dissolved in methanol (77.5 ml) and a solution of periodic acid in water (24 ml; 0.0219 *M* in acid) was added to the reaction mixture. A 10% increase in temperature was noted. The reaction, which was followed by u.v. spectroscopy proceeded rapidly. After 2 h in the dark at room temperature ethylene glycol (0.39 ml) was added and mixed. On standing for 1 h the reaction mixture was partitioned between aqueous sodium bicarbonate and benzene, washed with water, and dried over anhydrous sodium sulfate. After removing the solvent the expected acetoxy dialdehyde (**16**; 173.4 mg) was obtained. Thin-layer chromatography showed one spot. Recrystallization from benzene – petroleum ether (65–110°) produced an analytical sample of *trans-anti-trans*-11,12-seco-2-methoxy-8β-acetoxy-10a-methyl-11,12-dioxo-4b,5,6,6a,7,-8,9,10,10a,10b,11,12-dodecahydrochrysene (**16**), m.p. 135–137°; i.r.: 3.64, 5.78, 5.83, 5.96, 6.24, 6.66 μ; u.v.: λ_{max} 225 (4.33), 255.5 (3.86), 321 nm (3.50); λ_{min} 242.5 (3.75), 281 nm (2.70); n.m.r.: 8.87 (angular methyl, 3H, singlet), 8.01 (C_8 acetoxyl, 3H, singlet), 7.63 (C_{10b}, 1H, quartet, $J_{10b,11} = 6.5$ Hz, $J_{10b,4b} = 12$ Hz), 6.23 (C_2 methoxyl, 3H, singlet), 5.5 (C_{4b}, 1H, multiplet), 5.3 (C_8, 1H, multiplet), 2.98 (C_3, 1H, quartet, $J_{1,3} = 2.5$ Hz), 2.74 (C_1, 1H, doublet), 2.74 (C_4, 1H, doublet, $J_{3,4} = 9$ Hz), 0.05 (C_{11}, 1H, doublet, $J_{10b,11} = 6.5$ Hz), −0.27 (C_{12}, 1H, singlet).

Anal. Calcd. for $C_{22}H_{28}O_5$: C, 70.94; H, 7.58; O, 21.44. Found: C, 70.96; H, 7.46; O, 21.84.

Since chromatography of this compound gave a very

For personal use only.

poor recovery it was used directly for the next reaction, both these reactions being carried out on the same day.

Aldol Condensation of Dialdehyde **16**

A solution of crude dialdehyde (**16**; 480 mg) in methanol (110 ml) was added to a solution of sodium hydroxide (100 mg in 1.4 ml water). Reflux was continued for 3 h, after which time the reaction mixture was partitioned between chloroform and water several times. After drying over sodium sulfate and removing the solvent, a crude orange reaction product was obtained (397 mg). Thin-layer chromatography of the latter showed an intense orange fluorescent spot when sprayed with antimony trichloride – acetic acid (1:1) and heated in the oven. Recrystallization from benzene – petroleum ether (65–110°) gave an analytical sample of C-nor-2-methoxy-8β,11ξ-dihydroxy-10a-methyl-10bξ-formyl-4b,5,6,6a,7,8,9,10,10a,10b,11-undecahydrochrysene (**17**), m.p. 192°; i.r.: 2.96, 3.65, 5.84, 5.90, 6.19, 6.30, 6.75 μ; u.v.: λ_{max} 284 (3.36), 2.89 nm (3.32); λ_{min} 257 nm (2.74); n.m.r.: 8.91 (angular methyl, 3H, singlet), 6.6 (C_{4b}, 1H, quartet), 6.35 ($C_{8\alpha}$, 1H, multiplet—obscured), 6.27 (C_2, methoxyl, 3H, singlet), 4.6 (C_{11}, 1H, doublet), 3.08 (C_4, 1H, doublet—overlaps with C_1), 3.02 (C_1, 1H, doublet), 0.30 (C_{10b} formyl, 1H, doublet); mass spectrometry: *m/e* 330 (M^+) prominent peaks at *m/e* 158, 171, 172, 173, 174, 175, 186, 204, 213, 225, 235, 251, 269, 279, 284, 297, 312, 328.

Anal. Calcd. for $C_{20}H_{26}O_4$: C, 72.70; H, 7.93; O, 19.37. Found: C, 72.66; H, 7.85; O, 19.49.

Synthesis of C-Nor-2-methoxy-8,11-diketo-10bξ-formyl-10a-methyl-4bβ,5,6,6aα,7,8,9,10,10a,10b,11-undecahydrochrysene (18)

Jones' reagent (16) (0.6 ml; 3 at. O per molecule) was added rapidly with stirring to a solution of diol aldehyde (260 mg, m.p. 175–182°) in acetone (20 ml). After stirring at room temperature for 30 min, the excess chromic acid was decomposed with a small amount of methanol. The solvent was removed *in vacuo* on a steam bath and to the residue, water and benzene were added. The aqueous solution was extracted three times with benzene and the combined benzene extract was washed with water and then dried over anhydrous magnesium sulfate. Evaporation of the solvent yielded a pale yellow gummy product (260 mg) which had the desired u.v. (λ_{max} 220, 255, 326 nm; λ_{min} 244, 282 nm) and i.r. spectra (CCl_4 film, 5.82, 5.91 μ). Two recrystallizations from benzene and cyclohexane gave crystals melting at 140–152°; n.m.r.: 0.32 (—CHO, 1H, singlet), 8.78 (angular methyl, 3H, singlet), 6.19 (CH_3O—, 3H, singlet), 6.17 (C_{10}, 1H, doublet), 6.71 (C_{4b}, 1H, multiplet). This crystalline material was chromatographed on a plate in a manner somewhat different from conventional thin-layer chromatography. In this instance Woelm neutral alumina suitable for column chromatography was placed in dry powder form on a flat plate of glass which was held in an almost horizontal position. This chromatoplate was then developed with chloroform as eluant. The solvent was allowed to run to the top of the plate; the latter was removed from the chromatography tank and allowed to dry after which time it was placed back into the tank and redeveloped with chloroform. This operation was repeated twice and at this time four distinct bands were noted on the chromatoplate. The bands were cut out and eluted with methanol to yield four fractions (order of decreasing R_f; 69, 17, 44, 21 mg). The largest fraction gave a n.m.r. spectrum identical to that of a 1:1 mixture of the diketo isomers **19** and **20** obtained by deformylation of **18** with potassium hydroxide as mentioned below. This isomeric mixture on recrystallization from benzene and cyclohexane provided a crystalline material which was obviously still a mixture (m.p. 150–205°). No further characterization was performed due to lability of this substance.

The other major fraction (44 mg) also showed no aldehyde proton absorption in the n.m.r. spectrum (angular methyl protons at 8.74) as well as only one carbonyl peak in the i.r. spectrum. The most polar fraction (21 mg) had a R_f 0 and therefore was not examined. Since the second fraction (17 mg) was a mixture of compounds and in small quantity, it was not investigated.

The amount of acidic material (extractable with sodium bicarbonate solution) obtained from this oxidation was always very low (less than 10% of total reaction mixture).

Potassium Hydroxide Deformylation of C-Nor-2-methoxy-8,11-diketo-10bξ-formyl-10a-methyl-4bβ,5,6,6aα,7,8,9,10,10a,10b,11-undecahydrochrysene

The crude diketo aldehyde **18** obtained directly from the Jones' oxidation mixture (147 mg) was taken up in dioxane (37 ml) and water (3.7 ml) and to this solution potassium hydroxide (214 mg) was then added. The mixture was refluxed for 100 min after which time most of the dioxane was removed *in vacuo*. The residue was treated with water and benzene and dilute hydrochloric acid was added until the mixture was acidic. The aqueous solution was extracted three times with benzene. Thereafter the combined benzene extract was washed twice with water. After drying over anhydrous magnesium sulfate and evaporating the solvent, a neutral product (94 mg) was obtained. The yellow basic aqueous solution from the sodium bicarbonate washings was acidified with hydrochloric acid and then extracted three times with benzene. The benzene solution was washed with water until neutral, dried over anhydrous magnesium sulfate, and then evaporated to give the acidic material (24 mg). The acidic product had λ_{max} 308 nm and λ_{min} 273 nm in its u.v. spectrum.

The n.m.r. spectrum on the neutral product showed no low-field protons due to a formyl group but two angular methyl peaks in an intensity ratio of about 1:1 were evident at high field. It was therefore obvious that two compounds were in fact present. All attempts to separate these compounds (shown later to be the isomers **19** and **20**) on silica gel or alumina chromatography met with failure. These substances possess a slightly larger R_f value than the starting material **18** but all three compounds show the same behavior towards 20% antimony pentachloride in carbon tetrachloride on thin-layer chromatoplates. Prior to heating the spots slowly turn from yellow to tan color but when heated to 110° they become pink in colour. From thin-layer chromatography on the neutral product it was possible to exclude the presence of any unreacted starting material. Ultraviolet spectra on the reaction mixture showed that the reaction was essentially completed in 30 min; a change in the maxima from 329 to 318 nm occurred in this time.

For personal use only.

Fortunately, the *trans-anti-trans* isomer (**19**) was less soluble than the *trans-syn-cis* isomer (**20**) and thus these two compounds could be separated by careful fractional crystallization. Since these compounds crystallized in different crystal types, hand separation of these crystals greatly facilitated purification on a small scale. To remove trace impurities which hampered crystallization, the crude reaction product was first chromatographed on neutral Woelm alumina and the fractions (60 mg) containing **19** and **20** were combined. Recrystallization from benzene and petroleum ether (65–110°) or cyclohexane gave orange needles and colorless plates. A mixture of these crystals, m.p. 137–150 and 175–195°, was used for microanalysis.

Anal. Calcd. for $C_{19}H_{22}O_3$: C, 76.48; H, 7.43; O, 16.09. Found: C, 76.30; H, 7.35; O, 16.48.

After several more recrystallizations the pure *trans-anti-trans* diketone (**19**) was obtained as orange needles, m.p. 198.5–201.5° (dec.); i.r.: 5.85, 6.22, 6.32, 6.71 μ; u.v.: λ_{max} 219 (4.44), 249 (3.92), 319 nm (3.59); λ_{min} 237 (3.83), 273 nm (2.98); n.m.r.: 8.85 (angular methyl, 3H, singlet), 6.23 (CH_3O—, 3H, singlet), 7.06 (C_{10b} and C_{4b}, 2H, multiplet), 2.74–2.96 (aromatic H, 3H, multiplet); n.m.r.: (C_6H_6): 9.20 (angular methyl, 3H, singlet), 6.70 (CH_3O—, 3H, singlet), 7.16 (C_{10b} and C_{4b}, 2H, broad multiplet).

Three crystallizations from benzene and cyclohexane produced an analytical sample of the *trans-syn-cis* diketone (**20**) as colorless plates, m.p. 140–142° (no decomposition); i.r.: 5.87, 6.20, 6.70 μ; u.v.: λ_{max} 218 (4.47), 249 (3.98), 318 nm (3.58); λ_{min} 236 (2.88), 272 nm (2.09); n.m.r.: 8.74 (angular methyl, 3H, singlet), 6.18 (CH_3O—, 3H, singlet), 6.57 ($C_{10\alpha}$ and C_{4b}, 2H, broad multiplet), 2.81 (aromatic, 3H, singlet); n.m.r.: (C_6H_6): 9.24 (angular methyl, 3H, singlet), 6.69 (CH_3O—, 3H, singlet), 6.40 ($C_{10\alpha}$, 1H, quintet), 7.08 (C_{4b}, 1H, quintet).

Both isomers decompose at about 200° to give rise to new maxima at about 234, 270, and 281 nm in the u.v. spectra in addition to the other three maxima already mentioned.

Acetylation of Dihydroxy Aldehyde ***17***

Upon acetylating the analytical sample of the above C-nordihydroxy aldehyde (**17**) under the usual conditions an 85% yield of C-nor-2-methoxy-8β,11ξ-diacetoxy-10a-methyl-10bξ-formyl-4b,5,6,6a,7,8,9,10,10a,10b,11-undecahydrochrysene (**23**) was obtained, m.p. 158.5–159.5°; u.v.: λ_{max} 222 (3.91), 286 (3.50), 291 nm (3.44); λ_{min} 252 nm (2.57); n.m.r.: 9.02 (angular methyl, 3H, singlet), 8.02 ($C_{8\beta}$ acetoxyl, 3H, singlet), 7.84 (C_{11}, acetoxyl, 3H, singlet), 6.58 (C_{4b}, 1H, quartet, $J_{4b\alpha,5\alpha}$ = 7 Hz, $J_{4b\alpha,5\beta}$ = 12 Hz), 6.35 (C_2 methoxyl, 3H, singlet), 5.30 ($C_{8\alpha}$, 1H, multiplet), 2.51 (C_1, 1H, doublet), 2.32 (C_3, 1H, quartet), 2.26 (C_{11}, 1H, singlet), 2.00 (C_4, 1H, doublet), 0.10 (C_{10b} formyl, 1H, singlet); mass spectrometry: parent peak, not visible, prominent peaks at *m/e* 158, 172, 251, 266, 211, 324, 326, 356.

Anal. Calcd. for $C_{24}H_{30}O_6$: C, 69.54; H, 7.30; O, 23.16. Found: C, 69.81; H, 7.40; O, 22.79.

*Synthesis of trans-C-Nor-2-methoxy-8β-acetoxy-10a-methyl-4b,5,6,6a,7,8,9,10,10a-nonahydrochrysene (****22****)*

The diacetate (**23**) was dissolved in glacial acetic acid (15.0 ml) containing sodium acetate (50 g, 4 *M*) and acetic anhydride (3 ml) and refluxed for 20 h. The reaction mixture was poured into water, partitioned between aqueous sodium bicarbonate – benzene, washed with water, and dried over sodium sulfate. After removal of the solvent the crude product was chromatographed on 50 g of alumina. Elution with benzene–hexane (1:9) gave olefin **22** (621 mg, 57.6% yield). Elution with chloroform gave a polar material (521 mg) which was reacted once more and worked-up in the above manner to give more olefin **22** (293 mg). The overall yield was 84.8%. Crystallization of this compound from hexane–benzene gave an analytical sample of **22** in the form of large plates, m.p. 140–141°; i.r.: 5.78, 6.21, 6.36, 6.75, 6.80, 6.91 μ; u.v.: λ_{max} 227 (4.41), 239 (4.21), 263 (3.88), 293 (3.54), 305 nm (3.51); λ_{min} 248 (3.75), 289 (3.47), 301 nm (3.42); n.m.r.: 9.11 ($C_{5\alpha}$, 1H, multiplet, by spin decoupling), 8.89 (angular methyl, 3H, singlet), 8.02 ($C_{8\beta}$ acetoxyl, 3H, singlet), 7.61 ($C_{5\beta}$, 1H, multiplet, $J_{5\alpha,5\beta}$ = 13 Hz, $J_{4b,5\beta}$ = 6.5 Hz, $J_{5\beta,6\beta}$ = $J_{5\beta,6\alpha}$ = 3 Hz), 6.72 (C_{4b}, 1H, quartet, $J_{4b,5\beta}$ = 6.5 Hz, $J_{4b,5\alpha}$ = 12.5 Hz), 6.27 (C_2 methoxyl, 3H, singlet), 3.80 (C_{11}, 1H, singlet), 3.40 (C_3, 1H, quartet), 3.19 (C_1, 1H, doublet), 2.86 (C_4, 1H, doublet); mass spectrometry: *m/e* 326 (M^+), prominent peaks at *m/e* 158, 172, 249, 251, 311, 324.

Anal. Calcd. for $C_{21}H_{26}O_3$: C, 77.27; H, 8.03; O, 14.71. Found: C, 77.55; H, 7.97; O, 14.48.

*Synthesis of trans-syn-cis-trans-C-Nor-2-keto-8β-hydroxy-10a-methyl-3,4,4a,4b,5,6,6a,7,8,9,10,10a,10b,11-tetradecahydrochrysene (****30****)*

The olefin (**22**; 350 mg) was dissolved in *tert*-butyl alcohol (15 ml) and tetrahydrofuran (20 ml). Dry ammonia was condensed into the three-necked flask and lithium (1 g) was added. After refluxing for 5 h the blue color disappeared, ammonia was evaporated in a stream of nitrogen, and the residue was partitioned between benzene and water. The dry solvent was evaporated to give a crystalline product. The product was dissolved in methanol (100 ml) and 12 *N* hydrochloric acid (5 ml). The mixture was heated under reflux for 3 h and then partitioned between the ethyl ether and water. Removal of the solvent provided the crude product (290 mg). Chromatography on alumina (30 g, activity III) gave a mixture (248 mg) when the eluent was benzene – ethyl acetate (9:1). Several crystallizations gave an analytical sample (235 mg) of **30**, m.p. 178–180°; i.r.: 5.79, 6.17, 6.31, 6.71, 6.78 μ; u.v.: λ_{max} 242 nm (4.19); n.m.r.: 8.99, (angular methyl, 3H, singlet) 7.78 (C_8 hydroxyl, 1H, singlet, removed by D_2O), 6.45 ($C_{8\alpha}$, 1H, septet), 4.07 (C_1, 1H, broad singlet).

Anal. Calcd. for $C_{18}H_{26}O_2$: C, 78.79; H, 9.55; O, 11.66. Found: C, 78.51: H, 9.58; O, 11.91.

Catalytic Hydrogenation of C-Nor-D-homo Olefin ***22***

The olefin (47 mg) dissolved in ethanol (10 ml) was hydrogenated over palladium-on-charcoal (100 mg) at slightly over 1 atm for 24 h. The reaction mixture was diluted with ethanol (40 ml) and filtered. The filtrate was evaporated and the residue dissolved in chloroform and the solution filtered again to leave a clear gum. The n.m.r. spectrum showed that no olefinic proton was present. On crystallization from methanol an analytical sample (40 mg) of *trans-syn-cis*-C-nor-2-methoxy-8β-acetoxy-10a-methyl-4b,5,6,6a,7,8,9,10,10a,11-undecahydrochrysene (**31**), m.p. 98.5–100°; i.r.: 5.79, 6.17,

Anal. Calcd. for $C_{21}H_{28}O_3$: C, 76.79; H, 8.59; O, 14.61. Found: C, 76.52; H, 8.81; O, 14.67.

Birch Reduction of C-Nor-D-homo Hydrochrysene Analog 31

Reduction of **31** under exactly the conditions mentioned above in the conversion, **22** → **30**, gave an 80% yield of **30**, identical in every respect with the sample obtained and characterized above.

Reductive Hydroboration of C-Nor-D-homo Olefin 22

Diborane generated by the slow addition of sodium borohydride (0.6 g) in diglyme (30 ml) to boron trifluoride etherate (5 ml) in diglyme (20 ml) was passed in a stream of nitrogen into a solution of the olefin (225 mg) in diglyme (30 ml). Generation of the diborane took 2 h and the solution of olefin was allowed to stand overnight in contact with the gas. One drop of water was added followed by propionic acid (7 ml) and the mixture was heated under reflux for 5 h, poured into water, and extracted with ethyl ether. The ether extract was washed with dilute aqueous sodium chloride solution and dried over magnesium sulfate. The solvent was removed to give a brown gum (290 mg). This material showed several blue spots on t.l.c. when sprayed with antimony trichloride. This material (290 mg) was dissolved in a mixture of methanol (35 ml), water (15 ml), and potassium carbonate (1 g). Reflux was maintained for 2 h. The product was partitioned between chloroform and water and dried over sodium sulfate. The residue was reacetylated in the usual manner. The usual work-up gave an oil (236 mg) which was chromatographed on alumina (50 g, activity III). Elution with hexane–benzene (17:3) gave (69 mg) a material with R_f comparable to that of the previous Birch reduction products of the reaction mentioned above. Further elution with hexane–benzene (3:1) gave a complex mixture (121 mg) not further investigated. The major product (32 mg, 14%), after two preparative layer chromatographs of the first fractions, was submitted to n.m.r. spectroscopy. The product consisted of two isomers in a ratio of 5:1 with the major component being *trans-syn-cis*-C-nor-2-methoxy-8β-acetoxy-10a-methyl-4b,5,6,6a,7,8,9,10,10a,10b,11-undecahydrochrysene (**31**).

Oxidative Hydroboration of C-Nor-D-homo Olefin 22

The olefin (130 mg) and the ethyl ether adduct of boron trifluoride (0.5 ml) were dissolved in ethyl ether (10 ml) and stirred under nitrogen at 0°. Sodium borohydride (130 mg) in ether (15 ml) was added gradually over 45 min. Stirring was continued for 2 h during which time the temperature was allowed to rise to 20°. The solution was worked up in the usual manner and 70% ethanol (10 ml) containing sodium hydroxide (0.25 g) was added to the residue. Hydrogen peroxide solution (3 ml, 20%) was added dropwise. When effervescence subsided the solution was heated to 70°. Further effervescence was observed for 10 min. The solution was cooled, diluted, and neutralized with acid. This solution was partitioned between water and chloroform. The product (125 mg) was purified by preparative t.l.c. on silica gel GF (0.5 mm thick, developed with ethyl acetate – petroleum ether (2:1)) and bands were located by water spray. The main band was removed and extracted to give a 68% yield (98 mg) of *trans-syn-cis*-C-nor-2-methoxy-8β,11β-dihydroxy-10a-methyl-4b,5,6,6a,7,8,9,10,10a,10b,11-undecahydrochrysene (**32**), m.p. 180–181°; n.m.r. 8.97 (angular methyl, 3H, singlet), 8.39 (C_8 and C_{11} hydroxyls, 2H, singlets, removed by D_2O exchange), 6.86 (C_{4b}, 1H, quintet, $J_{4b,10b}$ = 12.5 Hz, $J_{4b,5\alpha} = J_{4b,5\beta}$ = 6 Hz), 6.3 ($C_{8\alpha}$, 1H, multiplet), 6.24 (C_2 methoxyl, 3H, singlet), 4.91 (C_{11}, 1H, doublet, $J_{10b,11}$ = 10 Hz), 3.27 (C_3, 1H, quartet, $J_{1,3}$ = 2.5 Hz), 3.07 (C_1, 1H, doublet, $J_{3,4}$ = 8 Hz), 2.98 (C_4, 1H, doublet).

Anal. Calcd. for $C_{19}H_{26}O_3$ (mol. wt. 302.1881): C, 75.46; H, 8.67. Found (high resolution mass measurement, 302.1878): C, 75.46; H, 8.58.

Modified Birch Reduction of trans-syn-cis-C-Nor-D-homo Diol 32

Small pieces of lithium metal (500 mg) were added cautiously with stirring to a solution of **32** (500 mg) in dry dioxane (25 ml), isopropanol (25 ml), and ammonia (100 ml). The mixture was then stirred under reflux for 6 h. Removal of the solvents in a stream of nitrogen provided a residue (497 mg) which was taken up in methanol (50 ml) and 12 *N* hydrochloric acid (5 ml) and refluxed for 3 h. The resultant mixture was partitioned between ethyl ether and water. Removal of the ether provided a colorless gum (450 mg). Chromatography on alumina (40 g, activity III) using benzene – ethyl acetate (9:1) provided 400 mg of a white solid. Crystallization from methanol–water gave A/B *trans*-C-nor-2-keto-8β-hydroxy-10a-methyl-3,4,4a,4b,5,6,6a,7,8,9,10,10a-dodecahydrochrysene (**34**; 350 mg), m.p. 199–203°; i.r.: 6.12 μ; u.v.: λ_{max} 295 nm (4.38); n.m.r.: 8.97 (angular methyl, 3H, singlet), 4.25 and 4.05 (C_{11} and C_1, 2H, broad singlets).

Anal. Calcd. for $C_{18}H_{24}O_2$ (mol. wt. 272.1776): C, 79.37; H, 8.88; O, 11.75. Found (high resolution mass measurement, 272.1754): C, 79.29; H, 8.74; O, 11.51).

Catalytic Reduction of C-Nor-D-homo Dienone 34

The dienone (**34**; 350 mg) was taken up in ethanol and hydrogenated over a 10% platinum-on-charcoal catalyst (150 mg). After 1 h, during which time 1.5 mol of hydrogen had been absorbed, the hydrogenation was terminated. Evaporation of the solvent provided the crude product (345 mg) which on t.l.c. was a mixture of two main components. These compounds proved extremely difficult to separate and for preparative purposes the total mixture was subjected to the bromination–dehydrobromination sequence as noted below.

In one experiment, extensive column chromatography on alumina (activity III) followed by high vacuum distillation, did provide a small sample of saturated ketone (**36**, epimeric mixture at C_{12}) as a clear glass, b.p.

125°/0.1 mm; i.r.: ($CHCl_3$) 5.89 μ; no u.v. absorption; n.m.r.: 9.22 (angular methyl, 3H, singlet) 6.45 (C_8, 1H, multiplet).

Anal. Calcd. for $C_{18}H_{28}O_2$ (mol. wt. 276.2089): C, 78.21; H, 10.21. Found (high resolution mass measurement, 276.2110): C, 78.08; H, 10.21.

The crude product mixture (345 mg) was treated with a solution of bromine in acetic acid (10 ml, 0.19 *M*) at room temperature. Decolorization of the bromine was immediate. The solution was diluted with water and extracted with benzene. The extract was washed with water, the solvent removed, and the residue taken up in dimethylformamide (10 ml) and treated with magnesium oxide (700 mg). After refluxing for 1 h, the mixture was diluted with water and extracted with benzene. Removal of the solvent provided a crude product mixture (300 mg). Chromatography of the latter on alumina (30 g, activity III) and elution with benzene – ethyl acetate (9:1) provided A/B *trans*-C-nor-2-keto-8β-hydroxy-10a-methyl-3,4,4a,4b,5,6,6a,7,8,9,10,10a,10b,11-tetradecahydrochrysene (**37**; 260 mg). Purification of **37** for analytical purposes was achieved by high vacuum distillation whereupon **37** was obtained as a clear glass, b.p. 142°/0.1 mm; i.r.: ($CHCl_3$) 6.06 μ; u.v.: λ_{max} 238 nm (4.20); n.m.r.: 9.22 (angular methyl, 3H, singlet), 4.13 (C_1, 1H, broad singlet).

Anal. Calcd. for $C_{18}H_{26}O_2$ (mol. wt. 274.1932): C, 78.79; H, 9.55; O, 11.66. Found (high resolution mass measurement, 274.1928): C, 78.61; H, 9.47; O, 11.54.

Synthesis of trans-anti-trans-2-Keto-8β-hydroxy-1,10a-dimethyl-2,3,4,4a,5,6,6a,7,8,9,10,10a,10b,11,12-hexadecahydrochrysene (42) via Enamine Alkylation

The conjugated ketone (**40**; 251 mg) was dissolved in a mixture of benzene (10 ml) and pyrrolidine (0.4 ml). The reaction mixture was heated under reflux for 190 min during which time water was gradually removed from the reaction by azeotropic distillation with benzene with the help of a Dean–Stark apparatus. After this time all the solvent was evaporated *in vacuo* and the residual product showed in its u.v. spectra a strong maximum at 276 nm in methanol and at 274.5 nm in a mixture of hydrochloric acid and methanol. The dienamine was refluxed under a dry nitrogen atmosphere with anhydrous methanol (6 ml) and methyl iodide (0.9 ml) for 47 h. On addition of methyl iodide to the methanolic solution of the dienamine a white precipitate formed immediately but it dissolved when the solution was heated. After this reflux period, the solvent was evaporated *in vacuo* on a steam bath. The reaction product was then refluxed under nitrogen with methanol (4 ml), water (1 ml), acetic acid (0.4 ml), and sodium acetate (500 mg, anhydrous) for 4 h. After removal of the solvent, the residue was treated with water and chloroform. The chloroform extract, after drying over anhydrous sodium sulfate, was concentrated to yield an orangish-brown solid glassy product (272 mg). This material showed a maximum at 242 nm (methanol) in the u.v. spectrum as well as a small band due to a saturated carbonyl group in its i.r. spectrum. The product was then dissolved in methanol (15 ml) and refluxed for 1.5 h with dilute hydrochloric acid (2 ml of concentrated acid in 3 ml of water). After this period, the solvent was removed and the residue was extracted with chloroform. The chloroform extract was then washed with water until neutral to p*H* paper, dried over anhydrous sodium sulfate, filtered, and evaporated to dryness to give 240 mg of crude product. The i.r. spectrum of the latter showed that this product contained less unconjugated ketonic material than from the previous work-up. Chromatography on alumina (20 g, activity II–III) with a mixture of chloroform and benzene (1:4) gave four fractions (62 mg) which contained the desired **42** (about 40 mg, 15% yield). The earlier fractions of the chromatography yielded 29 mg of a substance while the later fractions contained 143 mg. The latter fractions possessed mostly starting ketone **40**. The desired material could be easily identified on thin-layer chromatography, since it behaved differently from starting ketone **40**. The methylated compound (**42**) formed an orange spot on silica gel G chromatoplates when sprayed with a mixture of antimony trichloride and acetic acid (1:1) followed by heating to 110°. Its R_f value of about 0.25 (ethyl acetate – chloroform (1:10) as eluant) was slightly greater than that of **40** which gave a red spot with this spray reagent. Further purification of the fractions (62 mg) on preparative silica gel (0.5 mm thick 50 g) chromatoplates (eluant was ethyl acetate – chloroform (1.5:10), run three times) gave 25 mg of **42** (10% yield). Recrystallization from benzene and cyclohexane gave crystals, m.p. 170–183°; i.r.: (CCl_4) 6.05 μ; u.v.: λ_{max} 250, 309 nm; λ_{min} 287 nm; n.m.r.: 9.25 (angular methyl, 3H, singlet), 8.22 (C_1 methyl, singlet), 6.38 ($C_{8\alpha}$, 1H, broad multiplet), 8.11 (HO—, singlet), 7.10 ($C_{12\beta}$, 1H, doublet).

Anal. Calcd. for $C_{20}H_{30}O_2$: C, 79.42; H, 10.00; O, 10.58. Found: C, 79.21; H, 9.87; O, 10.31.

Synthesis of 42 via Enolate Trapping and Alkylation

The tetrahydropyranyl ether derivative of ketone **40** was prepared by dissolving the ketone (624 mg) in freshly distilled tetrahydropyran (10 ml) along with several milligrams of *p*-toluenesulfonic acid. After 16 h powdered potassium carbonate was added. Stirring was continued for 6 h. The mixture was diluted with ether, filtered, and the filtrate evaporated to leave a gum (1.04 g). A solution containing the tetrahydropyranyl ether in dry tetrahydrofuran (25 ml) was added to scrupulously dry solution of ammonia (50 ml) containing lithium (49 mg) and a further amount of lithium (20 mg) was added to maintain the blue color. The solution was allowed to evaporate slowly while more tetrahydrofuran (50 ml) was added. When the ammonia was completely removed, methyl iodide (20 ml), which had been freshly distilled, was added and the solution refluxed for 3 h. Most of the solvent was removed and the rest partitioned between benzene and water. The dried benzene layer was evaporated and replaced with 3% aqueous oxalic acid (20 ml) in ethanol (25 ml). After the usual work-up the residue (890 mg) was chromatographed on alumina (85 g, activity III). Benzene–chloroform (4:1) gave a ketone fraction (393 mg) which was then rechromatographed on alumina (60 g, activity III). The center fractions (278 mg) were crystalline. Recrystallization from acetone–hexane gave an analytical sample of *trans-anti-trans*-1-methyl-2-keto-8-hydroxy-10a-methyl-1,3,4,4a,4b,5,6,6a,7,8,9,10,10a,10b,11,12,13-heptadecahydrochrysene (**42**, no double bond), m.p. 182–183°; n.m.r.: 9.26 (angular methyl, 3H, singlet),

9.02 (C_1 methyl, 3H, doublet), 8.24 (C_8 hydroxyl, 1H, singlet, removed by D_2O) 6.43 ($C_{8\alpha}$, 1H, septet); mass spectrometry: *m/e* 304 (M^+), prominent peaks at *m/e* 149, 232, 247, 271, 272, 286, 290.

Anal. Calcd. for $C_{20}H_{32}O_2$: C, 78.89; H, 10.59; O, 10.51. Found: C, 78.62; H, 10.41; O, 10.40.

This ketone (213 mg) was treated with a solution of bromine in acetic acid (7 ml, 0.19 *M*) at room temperature. An immediate decolorization of bromine was observed. The mixture was diluted with water and extracted with benzene. The extract was washed with water, the solvent removed, and the residue taken up in dimethylformamide (25 ml) and treated with magnesium oxide (2 g). After refluxing for 1 h, the mixture was diluted with water and extracted with benzene. Removal of the solvent provided a crude product (197 mg). Chromatography on alumina (35 g, activity III) and elution with petroleum ether – benzene provided a product identical with **42** as obtained above in the enamine alkylation reaction.

Synthesis of C-Nor-D-homo Ketone 38 via Enolate Trapping and Alkylation

The C-nor-D-homo enone (**36**; 300 mg) was reacted with lithium (70 mg) in ammonia (50 ml) and dioxane (25 ml), then methyl iodide (15 ml), in exactly the manner described above in the synthesis of **42**. The crude product (280 mg) was acetylated directly with pyridine and acetic anhydride to yield after chromatography on alumina (40 g, activity III) and crystallization (methanol–water) an analytical sample (190 mg) of **38**, m.p. 169–171.5°; i.r. 5.85 μ; n.m.r.: 9.02 (C_{18}, methyl, 3H, doublet, $J = 12$ Hz), 9.20 (angular methyl, 3H, singlet).

Anal. Calcd. for $C_{21}H_{32}O_3$ (mol. wt. 332.2331): C, 75.86; H, 9.70. Found (high resolution mass measurement, 332.2349): C, 75.71; H, 9.75.

This compound was found identical (t.l.c., i.r., n.m.r., and mass spectra) with 3β-acetoxy-5α-etiojervan-17-one (**38**) obtained in the hecogenin degradation sequence as described below.

Synthesis of 3β-Acetoxy-5α-etiojerv-12(13)-en-17-one (39) via Hecogenin Degradation

Throughout the entire project this compound occupied a position of prime importance since it provided the etiojervane portion of most of the compounds synthesized. It was prepared from hecogenin acetate employing degradation procedures well documented by Johns (41). Details of the quantities used and the yields obtained in this work for the various steps are given below. Wherever modifications in the experimental procedure or additional data were obtained, for characterization of the intermediates in the degradation, these are included.

Hecogenin p-Toluenesulfonylhydrazone (44)

A solution of hecogenin acetate (400 g) in glacial acetic acid yielded hecogenin *p*-toluenesulfonylhydrazone (560 g) when treated with *p*-toluenesulfonylhydrazine hydrochloride as outlined by Hirschmann *et al.* (43). The product was not further purified but subjected to the next reaction.

13-Methyl-C-nor-D-homo-18-nor-5α,22α-spirost-12(13)-en-3β-ol (45)

A solution of hecogenin *p*-toluenesulfonylhydrazone (560 g) in potassium hydroxide – ethylene glycol was heated under nitrogen as outlined by Johns (41). The product was obtained crystalline from ethanol–water as colorless needles, m.p. 108–111° (lit. (41) m.p. 108–118°); n.m.r.: 9.28 (angular methyl, 3H, singlet), 9.24 (C_{26} methyl, 3H, doublet, $J = 6$ Hz), 8.91 (C_{21} methyl, 3H, $J = 6$ Hz), 8.40 (C_{18} methyl, 3H, broad singlet); mass spectrometry: *m/e* 414 (M^+) prominent peaks at *m/e* 300, 271, 263.

13-Methyl-C-nor-D-homo-18-nor-5α,22α-spirostan-3β-ol Acetate (46)

13-Methyl-C-nor-D-homo-18-nor-5α,22α-spirost-12(13)-en-3β-ol acetate (280 g), which had been prepared by treatment of the olefin-3β-ol with pyridine – acetic anhydride overnight, was hydrogenated in acetic acid over 5% rhodium-on-alumina as outlined by Johns (41). The product was readily obtained crystalline (from methanol) as needles, m.p. 168–173° (220 g) (lit. (41) m.p. 173–177°); n.m.r.: 9.20 (C_{19} methyl, 3H, singlet), 8.01 (acetoxy, 3H, singlet); mass spectrometry: *m/e* 458 (M^+) base peak at *m/e* 342.

17-Acetyl-5α,13β-etiojerv-16-en-3β-ol (47)

The hydrogenation product (110 g) was subjected to ring opening by octanoic anhydride, oxidation with chromic acid, and elimination employing potassium hydroxide in *tert*-butyl alcohol, according to the procedures outlined by Johns (41). Chromatography of the product on alumina (2 kg, activity III) eluting with 20% chloroform in benzene gave 17-acetyl-5α,13β-etiojerv-16-en-3β-ol (34 g) which was crystallized from acetone – petroleum ether, m.p. 162–165° (lit. (41) m.p. 164–168°); n.m.r.: 9.22 (C_{19} methyl, 3H, singlet), 9.19 (C_{18} methyl, 3H, doublet, $J = 7$ Hz), 7.0 (C_{13}, 1H, quintet), 3.1 (C_{16}, 1H, two doublets, $J = 3$ and 7.5 Hz).

Conversion to 17-acetyl-5α,13β-etiojerv-16-en-3β-ol acetate was accomplished by dissolving the product in acetic anhydride – pyridine (1:1) and allowing the solution to stand at 20° for 12 h. Recrystallization of the product from acetone – petroleum ether gave needles (34.2 g), m.p. 143–144°.

17-Acetyl-5α,13β-etiojerv-16-en-3β-ol 3-Acetate 20-Oxime

A solution of 17-acetyl-5α,13β-etiojerv-16-en-3β-ol acetate (33 g) in pyridine was treated with hydroxylamine hydrochloride according to the procedure of Johns (41). The product was obtained crystalline from acetone as needles (33.5 g), m.p. 198–202° (lit. (41) m.p. 205–210°); n.m.r.: 9.18 (C_{19} methyl, 3H, singlet), 9.07 (C_{18} methyl, 3H, doublet, $J = 7$ Hz), 8.0 (*O*-acetate and enamide methyl, 6H, singlet) 7.03 (C_{13}, 1H, quintet), 3.82 (C_{16}, 1H, two doublets, $J = 7$ Hz); mass spectrometry: *m/e* 373 (M^+), prominent peaks at *m/e* 358, 296, and 255.

3β-Acetoxy-5α-etiojervan-17-one (38)

A solution of 17-acetyl-5α,13β-etiojerv-16-en-3β-ol acetate 20-oxime (33.0 g) in pyridine (400 ml) was treated with phosphorus oxychloride following the procedure of Johns (41). The product, obtained by filtration after pouring the reaction mixture into aqueous hydrochloric acid at 60°, was chromatographed on alumina (700 g, activity III). Elution with 15% chloroform in benzene gave pure 3β-acetoxy-5α-etiojervan-17-one (24.8 g) which was crystallized from methanol–water giving colorless needles, m.p. 169–171.5° (lit. (41) m.p. 175–177°). This

compound was compared with the product obtained via enolate trapping and alkylation of **36**. Both were shown to be identical.

3β-Acetoxyetiojerv-12(13)-en-17-one (39)

Bromination of 3β-acetoxy-5α-etiojervan-17-one (**38**) using an equimolar quantity of bromine followed by dehydrobromination as outlined by Johns (41) gave a mixture of compounds. Chromatography on alumina (400 g, activity III) eluting with 15% chloroform–benzene gave 3β-acetoxyetiojervan-17-one while further elution with the same solvent provided 3β-acetoxyetiojerv-12(13)-en-17-one (**39**), m.p. 167–168°; i.r.: 6.06 μ; u.v.: λ_{max} 246 nm (4.19); n.m.r.: 9.18 (C_{19} methyl, 3H, singlet), 8.31 (C_{18} methyl, 3H, singlet), 8.01 (acetate, 3H, singlet); mass spectrometry: *m/e* 330 (M^+), prominent peaks at *m/e* 288, 272, 270, and 255.

Financial aid from the National Research Council of Canada and the B.C. Heart Foundation is gratefully acknowledged. We would also wish to express our thanks to Syntex S.A., G. D. Searle and Company, and Smith Miller and Patch Inc., for supplying generous samples of hecogenin and hecogenin acetate.

Received May 22, 1974[2]

JAMES P. KUTNEY, JOHN CABLE, WILLIAM A. F. GLADSTONE, HARALD W. HANSSEN, G. VIJAY NAIR, EDWARD J. TORUPKA, and WILLIAM D. C. WARNOCK. Can. J. Chem. **53**, 1796 (1975).

Coupling of 3β-acetoxy-5α-etiojerv-12(13)-en-17-one (**1**) with the lithio derivative of 2-ethyl-5-methylpyridine provides the crucial intermediate (**3**) for the subsequent elaboration to verarine. Aromatization of **3** to **4** and reduction of the latter provides a mixture from which *N*-acetyl-5α,6-dihydroverarine (**11**) was isolated. Subsequent introduction of the 5,6-double bond in the latter and removal of the *N*-acetate function completed the synthesis of verarine (**31**). In a similar sequence of reactions employing **1** and the lithio derivative of 2-ethyl-3-methoxy-5-methylpyridine, the resultant intermediate (**54**), was elaborated to 5α,6-dihydroveratramine (**56**). Due to known conversions of the latter to veratramine (**14**), jervine (**32**), veratrobasine (**33**), and 11-deoxojervine (**34**), the formal total synthesis of these natural products is complete.

JAMES P. KUTNEY, JOHN CABLE, WILLIAM A. F. GLADSTONE, HARALD W. HANSSEN, G. VIJAY NAIR, EDWARD J. TORUPKA et WILLIAM D. C. WARNOCK. Can. J. Chem. **53**, 1796 (1975).

Le couplage de l'acétoxy-3β(5α)-étiojervène-12(13) one-17 (**1**) avec le dérivé lithié de l'éthyl-2 méthyl-5 pyridine fournit l'intermédiaire (**3**) crucial pour l'élaboration subséquente de la véranine. L'aromatisation de **3** en **4** et la réduction de ce dernier dérivé fournit un mélange duquel on peut isoler la *N*-acétyldihydro-5α,6 véranine (**11**). L'introduction subséquente d'une double liaison en position 5,6 et l'élimination de la fonction *N*-acétate, complète la synthèse de la véranine (**31**). Utilisant une séquence semblable de réactions faisant appel à **1** et au dérivé lithié de l'éthyl-2 méthoxy-3 méthyl-5 pyridine, on a obtenu l'intermédiaire (**54**) qui a été transformé en dihydro-5α,6 vératramine (**56**). En se basant sur le fait que ce dernier composé peut être transformé, à l'aide de séquences connues, en vératramine (**14**), en jervine (**32**), en vératrobasine (**33**) et en déoxo-11 jervine (**34**), on peut considérer que la synthèse totale formelle de ces produits naturels est maintenant complète. [Traduit par le journal]

In the previous publication (26) we described the total synthesis of various C-nor-D-homo steroidal analogs to be employed as intermediates in the synthesis of *Veratrum* alkaloids. We also outlined a synthetic plan which envisages the *Veratrum* skeleton as consisting of a C-nor-D-homo steroid or etiojervane portion to which is attached at the 17-position, an appropriate heterocyclic unit. We would now like to present the experiments which demonstrate the application of this plan to the total synthesis of the alkaloid verarine (**31**) (1, 2).

The structure of verarine reveals that the required heterocyclic unit attached to the steroid portion is a 2,5-disubstituted piperidine and it was felt that the latter is readily available from the appropriate pyridine by well known reduction methods. On this basis, the essential features of the synthetic plan, as outlined in Fig. 1, were to couple the pyridine system at C_{17} of the already available 3β-acetoxy-5α-etiojerv-12(13)-en-17-one (**1**)[1] and the resultant product **3** could, hopefully by aromatization of ring D (**4**) and subsequent reduction, lead to the desired 5,6-dihydroverarine (**5**, R = R′ = H) system. It should be noted here that *both* racemic and optically active forms of **1** are available from total synthesis, the former from our previous work (26, 27) and the latter from that of Sondheimer and co-workers (3) who presented a total synthesis of optically active hecogenin from isoandrosterone. For the purposes of the synthetic experiments discussed here we have employed optically active **1** obtained via degradation of hecogenin acetate as outlined in Part I of this series.[1]

To evaluate the feasibility of the approach

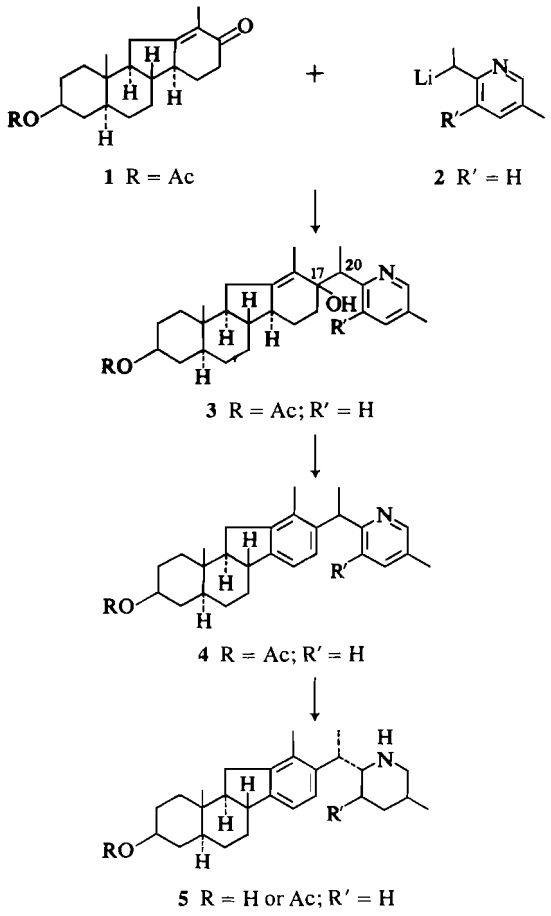

FIG. 1. General outline of synthetic plan for the synthesis of verarine (**31**).

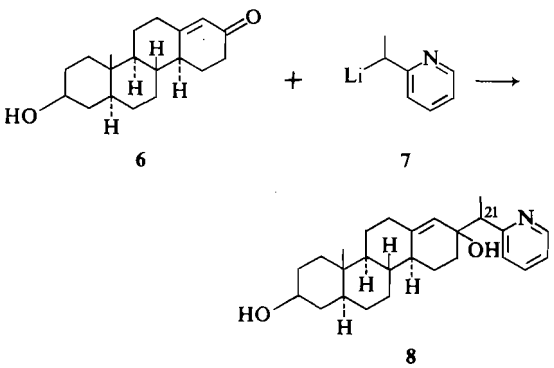
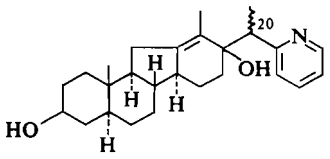
presented in Fig. 1, the readily available (26, 27) hydrochrysene derivative **6** was utilized as the model substance and this was condensed with the lithio derivative of 2-ethylpyridine (**7**).



Addition of **6** to the red solution of 2-ethylpyridine and methyl lithium provided a reaction mixture which after chromatographic purification yielded the desired product. Its u.v. spectrum showed peaks at 257, 262, and 270 nm corresponding to the pyridine chromophore while the mass spectrum exhibited a peak at *m/e* 395 corresponding to the parent ion for compound **8**. The absence of a carbonyl peak in the i.r. supported the 1,2-addition of the organolithium derivative to the α,β-unsaturated carbonyl compound as opposed to any 1,4 addition.

This procedure was then extended to the reaction of **7** with 3β-acetoxy-5α-etiojerv-12(13)-en-17-one (**1**). Column chromatography of the products from this reaction gave primarily some material which appeared as one compound on t.l.c. The spectroscopic properties of the reaction product (λ_{max} 257, 262, and 269 nm; *m/e* 395) were again in accord with the desired coupling product although the n.m.r. spectrum (two doublets in the region τ 8.84) revealed that a mixture of two isomers, most likely epimeric at C_{20}, had been obtained (**9**).



These model studies indicated that the required attachment of a heterocyclic unit at C_{17} of the C-nor-D-homo compound could be achieved and our efforts turned to the consideration of substituted 2-ethylpyridines which would allow entry to the skeleton of some of the naturally occurring *Veratrum* alkaloids.

Methylation of 2,5-lutidine employing phenyl lithium and methyl iodide afforded the known (4) 2-ethyl-5-methylpyridine and this in the form of its lithium salt (**2**) was condensed with the etiojervene derivative (**1**). The resultant product mixture upon t.l.c. examination, revealed two major components with similar R_f values but attempts to separate these proved fruitless. Conversion to the C_3-acetate derivatives did allow purification of this mixture.

It is to be noted that the coupling reaction creates two new asymmetric centers and consequently there exists the possibility of obtaining

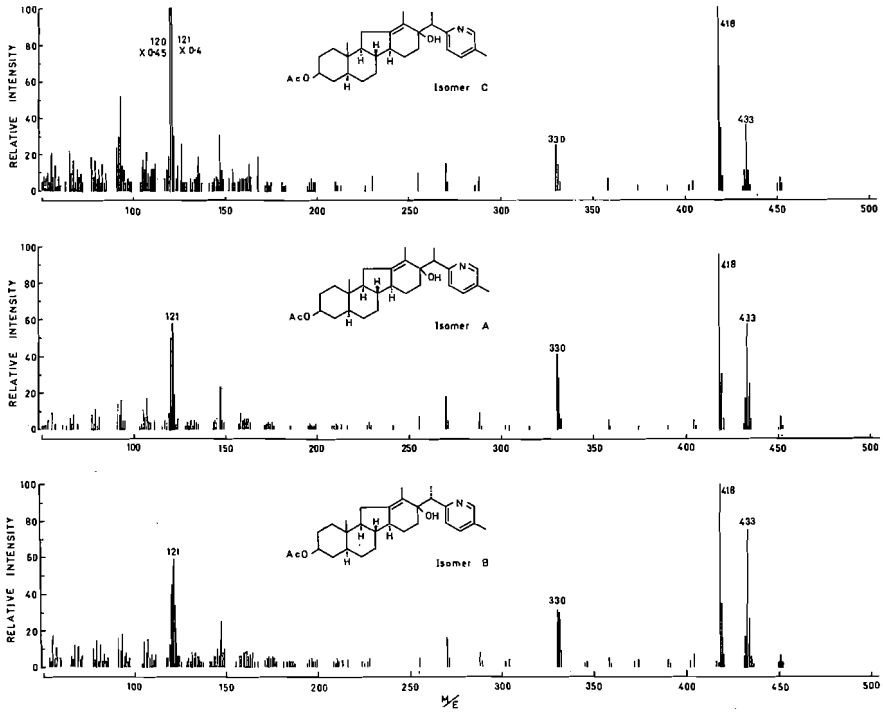


FIG. 2. Mass spectra of isomers **A**, **B**, and **C**.

four compounds possessing the gross structure **3** and differing in stereochemistry at C_{17} and/or C_{20}. All of these could be obtained in pure form.

One of the major components which could be obtained crystalline, m.p. 189–190°, was designated compound **A**. Spectral data allowed the assignment of structure **3** to this substance. Apart from the pyridine chromophore in the u.v., the n.m.r. spectrum was particularly instructive. A quartet occurring at τ 6.71 was assigned to the proton at C_{20} since a decoupling experiment showed this signal to be coupled to the C_{21} methyl doublet at τ 8.79. The C_{19} methyl signal appeared as a sharp three-proton singlet at τ 9.21. The pyridine protons were readily discernible in the aromatic region of the spectrum with a one-proton doublet at τ 2.82, $J = 8$ Hz, corresponding to $C_{23}H$ whereas $C_{24}H$ gave rise to two doublets at τ 2.52 ($J = 8$ and 2 Hz) and $C_{25}H$ appeared as a broad singlet at τ 1.67. The mass spectrum of **A** (Fig. 2) revealed the desired molecular ion (*m/e* 451) and expected fragmentation pattern.

Column chromatography of the mother liquors from the crystallization of compound **A** gave a second crystalline component, m.p. 191–192°, designated as compound **B** which also revealed spectral data in accord with structure **3**. The isomeric nature of **B** and **A** is seen from the close similarity in the mass (Fig. 2) and n.m.r. spectra of these compounds. In general the n.m.r. features already noted for **A** also appear in **B** although there are some differences in the chemical shifts. The largest differences are seen in the positions of the C_{18} and C_{21} methyl group signals and the pyridine protons (see Experimental).

Additional purification of chromatography fractions, obtained during isolation of **B** by means of preparative layer chromatography, allowed the isolation of two minor components, **C** and **D**, which constituted about 4 and 1% of the total product mixture. Neither of these could be induced to crystallize but satisfactory spectral data could also be accumulated for these substances and again the gross structure **3** could be assigned. At this stage of the investigations no assignments of stereochemistry at C_{17} and/or C_{21} could be made to these four coupling products but evidence in this direction was obtained during later studies as discussed below.

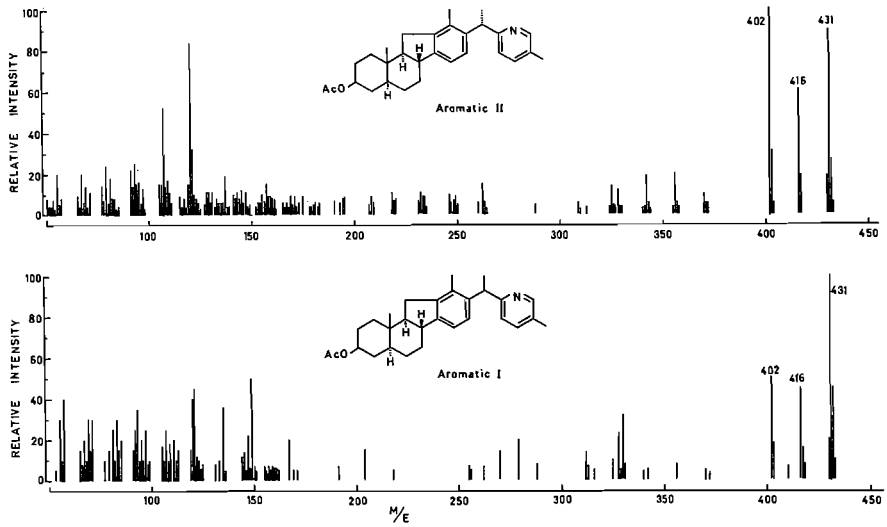

FIG. 3. Mass spectra of aromatic **I** and **II**.

The further extension of this sequence to the ring D aromatized series only involved the compounds **A** and **B** as the small amounts of **C** and **D** which were available precluded any useful reactions.

Compound **B** was ground with 10% palladized charcoal until the two substances were thoroughly mixed and then the powder was heated at 200° for 10 min. Examination of the reaction product mixture by t.l.c. indicated that compound **B** had been converted to a new compound possessing a similar R_f value. Separation by preparative layer chromatography indicated this new compound, which was designated 'aromatic **II**', had been produced in 80% yield. The u.v. spectrum showed no qualitative difference from that of compound **B** but the extinction coefficient at 270 nm increased from 4130 in the latter to 5400 in this compound. The mass spectrum exhibited a peak at *m/e* 431 corresponding to the molecular ion for a compound of structure **4**. The mass spectrum (Fig. 3) shows a completely different pattern to that observed with the series of compounds **A** to **D**. The n.m.r. spectrum was particularly useful in confirming that the desired ring **D** aromatization had occurred. The most significant feature is the appearance of a second pair of doublets in the downfield region of the spectrum corresponding to the expected AB system for the protons at C_{15} and C_{16}. In addition the broad three-proton singlet which corresponds to the C_{18} methyl in the starting material has disappeared but a new sharp singlet appears at τ 7.89 in the product in accord with the aromatization of ring **D**.

Isomer **A** was similarly treated with 10% Pd/C at 200° and the residue examined by t.l.c. Three compounds could be isolated in pure form by thick-layer chromatography. Two of these could be identified as the α,β-unsaturated ketone (**1**) and 2-ethyl-5-methylpyridine. The third compound which was formed in 25% yield appeared similar in properties to the aromatic compound from isomer **B** and was designated 'aromatic **I**'. The mass spectrum exhibited a peak at *m/e* 431 corresponding to the molecular ion for a compound of structure **4** and, in general, the fragmentation pattern was very similar to that of aromatic **II** (Fig. 3). This and other data suggested that these two aromatic substances were merely isomeric at C_{20} and support for this postulate came forth from further experiments as noted below.

In view of the different extent of ring D aromatization encountered with isomers **A** and **B**, the relative stability of these two compounds was further investigated. The C_{17}—C_{20} bond cleavage, which occurs with isomer **A** under the conditions for the D ring aromatization, appears to be very facile since this cleavage also occurs slowly in methanol or ethanol. The cleavage is slightly enhanced when the compound is dissolved in 0.1 *N* methanolic potassium hydroxide. Isomer **A** is stable in dimethylformamide or benzene but is converted to 3β-acetoxy-5α-etiojerv-12(13)-en-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

For personal use only.

17-one and 2-ethyl-5-methylpyridine when dissolved in aqueous dimethylformamide containing potassium hydroxide (p*H* 9).

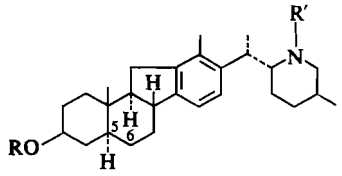
Isomer **B** is stable under the above conditions and shows no C_{17}—C_{20} bond cleavage. Dehydration of the tertiary alcohol appears to be the main process for both isomers **A** and **B** in acidic methanol solution.

Thus two compounds of structure **4** had been prepared and the selective reduction of the pyridine to a piperidine ring was investigated. One of these aromatic compounds should lead to an isomeric mixture of 5α,6-dihydroverarines while the other would lead to a mixture of isomers of similar structure but differing in configuration at C_{20} from the naturally occurring alkaloid verarine.

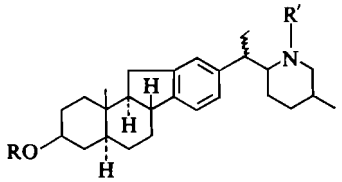
Catalytic reduction (5) of aromatic compound **II** provided a reaction mixture, which upon examination by t.l.c. indicated that four new compounds possessing very similar R_f values had been formed. These compounds, which were numbered **i** to **iv** in order of decreasing R_f values on silica gel, were separated by careful preparative layer chromatography. These compounds were suspected to be isomers of 3-*O*-acetyl-5α,6-dihydroverarine (**10**). However, preparation of a sample of this compound from verarine for comparison purposes is difficult since acetylation of verarine yields *N*-acetylverarine or 3-*O*,*N*-diacetylverarine.

None of the four compounds from the hydrogenation of aromatic compound **II** could be induced to crystallize but it was found from other investigations that *N*-acetyl-5α,6-dihydroverarine (**11**) crystallizes readily from an ethereal solution. Consequently it was decided to convert the four compounds obtained above to the *N*-acetyl derivatives (gross structure **12**) via acetylation to the 3-*O*,*N*-diacetates (**13**) followed by selective hydrolysis of the 3-acetoxyl group. The conversion to the respective diacetates was accomplished with acetic anhydride–pyridine (1:1) while hydrolysis of the 3-acetoxyl group was achieved with 0.1 *M* potassium hydroxide in methanol.

The appropriate verarine derivatives required for the above comparison were prepared from the more readily available alkaloid veratramine (**14**) essentially according to the scheme developed by Masamune (1) with modifications at appropriate stages (**14** → **15** → **16** → **17**).



10 R = Ac; R′ = H
11 R = H; R′ = Ac



12 R = H; R′ = Ac
13 R = R′ = Ac

The diacetate **17** was identified by t.l.c. comparison with an authentic sample[3], melting point, rotation, mass spectrum, and n.m.r., all of which were in accord with the published data (6). Subsequent hydrolysis of the 3-acetoxyl compound gave *N*-acetylverarine.

Hydrogenation of the 5,6-double bond in veratramine employing Adams' catalyst in acetic acid had been reported to give mainly the 5α,6-dihydroveratramine (7). By analogy it was expected that the hydrogenation of the 5,6-double bond in 3-*O*,*N*-diacetylverarine (**17**) using these conditions would provide mainly the desired 3-*O*,*N*-diacetyl-5α,6-dihydroverarine. This hydrogenation was carried out and careful examination of the product by t.l.c. indicated that only one compound had been formed. However, a close examination of the n.m.r. spectrum particularly in the region τ 8.5–9.5 indicated that both the 5α and the 5β compounds had been formed.

The n.m.r. spectrum of 3-*O*,*N*-diacetylverarine exhibited a three-proton doublet at τ 9.02 which was attributed to the C_{26} methyl while the C_{19} methyl appeared as a three-proton singlet at 8.85.

The n.m.r. spectrum of the hydrogenation product exhibited a sharp singlet at 8.92 and a doublet at 9.03. The upfield half of the doublet centered at 9.03 was, however, very intense and the integral of this doublet corresponded to 4.5 protons. From the excellent n.m.r. study of 22,27-

[3]We are grateful to Dr. J. Tomko, Slovak Academy of Sciences, Bratislava, Czechoslovakia, for a gift of this sample.

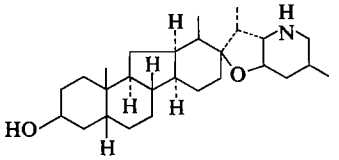
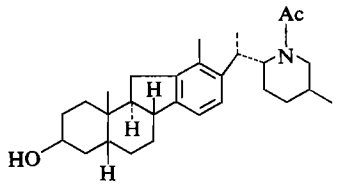
18



19



20

imino-17,23-oxidojervane derivatives by Masamune *et al.* (8) one would expect the C_{19} methyl signal for the 5α compound to be at a higher field position than in the 5β compound. This difference is due to the shielding of the C_{19} methyl group by the ring A protons which are in close proximity in the 5α derivatives but removed to a large extent in the 5β derivatives. This effect has been noted in various steroids (9) where the stereochemistry of the molecule is fixed.

The difference in chemical shift between the singlet at 8.92 and the upfield half of the doublet due to the C_{26} methyl group was 13 Hz and it was informative to compare this difference with the C_{19} methyl resonances in compounds **18** and **19**.

The n.m.r. spectra of these two compounds have been studied by Masamune *et al.* (8) who found the C_{19} methyl resonance in **18** to occur at τ 9.19 whilst in **19** the three proton-singlet is observed at τ 9.07, a separation of 12 Hz.

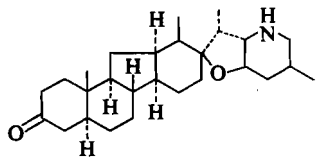
It therefore appeared that the hydrogenation of 3-*O*,*N*-diacetylverarine had given both the 5α and 5β compounds. In an attempt to obtain some separation of these two compounds and verify their existence the product was converted to the monoacetate by hydrolysis of the 3-acetoxyl group by means of 0.1 *N* potassium hydroxide in methanol. A t.l.c. examination of the resulting *N*-acetyl-5,6-dihydroverarines showed clearly that two compounds (**11** and **20**) were present. The n.m.r. spectra of the two compounds after separation by thick-layer chromatography, supported the analysis of the C_{19} methyl group positions outlined above.

Additional support for the configurational differences at C_5 was evident from the C_3 proton signals (τ 5.97, narrow multiplet in **11**, equatorial H; 6.3–6.5, broad multiplet in **20**, axial H).

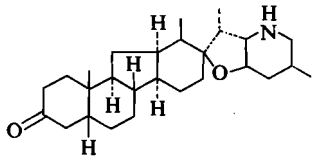
It was vital to provide additional data which establish more firmly the identity and stereochemistry of these compounds. The o.r.d. curves of 3-keto steroids with the 5α and 5β configuration have been extensively studied and Masamune *et al.* (8) have recorded the o.r.d. curves of compounds **21** and **22**. These latter substances provide a very good analogy with the compounds under consideration.

Compound **21** exhibits a strong positive Cotton

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.



21

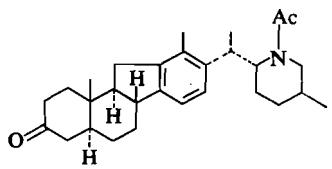


22

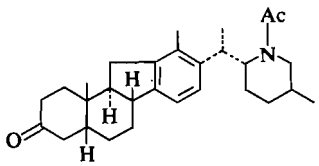
effect curve with values of $[\phi]_{304}^{peak}$ +2740° and $[\phi]_{265}^{trough}$ −1180° whereas **22** exhibits a negative Cotton effect curve with values of $[\phi]_{304}^{trough}$ +265° and $[\phi]_{265}^{peak}$ +2340°.

The hydrogenation products which had tentatively been assigned the 5α (**11**) and 5β (**20**) configurations were converted to the respective 3-keto compounds (**23** and **24**) using Jones' reagent as the oxidizing agent. The presence of the *N*-acetyl group tended to complicate the o.r.d. curves to some extent since it had a strong absorption at 230 nm but the absorption at 300 nm was not sufficient to affect the curve in this region. Compound **23** showed a strong positive Cotton effect curve with a peak at 305 nm while compound **24** showed only a very weak trough at 305 nm.

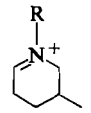
After this work had been completed, a publication (10) appeared in which the hydrogenation of veratramine employing Adams' catalyst in acetic acid has been more closely examined. Saito (7) had reported only the formation of the 5α-6,



23



24



25 R = H
26 R = Ac

dihydroveratramine but the recent work indicates that a mixture of 5α,6-dihydroveratramine (41%) and 5β,6-dihydroveratramine (44%) is produced. It is interesting to note that these workers also distinguished the two compounds on the basis of the chemical shifts of the C_{19} methyl resonances in the n.m.r. spectra.

Having established the identity of the desired *N*-acetyl-5α,6-dihydroverarine (**11**) the comparison of this compound with the *N*-acetyl derivatives of the four compounds obtained from the hydrogenation of aromatic compound **2** was now undertaken. These crystalline acetates of compounds **i–iv** were compared in the usual manner (m.p., t.l.c., i.r., n.m.r., and mass spectra) with authentic **11**. It was established that **i**, *N*-acetate, was identical in every respect with **11** as prepared above.

Careful analysis of the mass spectra of all five compounds (**11** and **i–iv**) reveals an essentially identical fragmentation pattern with very intense peaks at *m/e* 140 and 98. Budzikiewicz (11) has examined the mass spectra of veratramine, *N*-acetylveratramine, and verarine and has postulated cleavage of the benzylic C_{20}—C_{22} bond which, in the present instance, would allow the fragments **25** and **26** to account for strong peaks at *m/e* 98 and 141, respectively.

Aromatic compound **I** which was obtained in 25% yield from isomer **A** was subjected to hydrogenation under the same conditions as applied to aromatic compound **II**. Examination of the product by t.l.c. indicated that four new compounds of similar R_f values had been formed. For the sake of convenience these were designated **v–viii** in order of decreasing R_f values on a thin-layer chromatoplate. These compounds were separated by thick-layer chromatography and then converted via the diacetates to the respective *N*-acetyl derivatives. A t.l.c. comparison of the four *N*-acetates with *N*-acetyl-5α,6-dihydroverarine (**11**) indicated that only compounds **v** and **vi** had a similar R_f value. Surprisingly none of these *N*-acetyl derivatives could be induced to crystallize from ether in contrast to *N*-acetyl-5α,6-dihy-

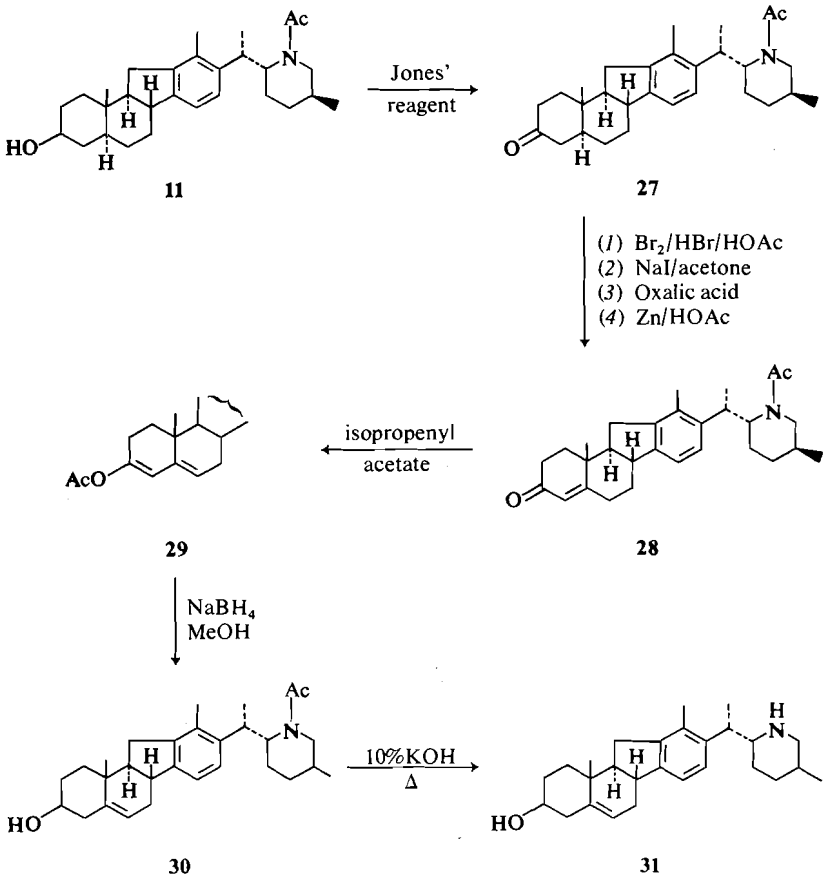

FIG. 4. Conversion of *N*-acetyl-5α,6-dihydroverarine (**11**) to verarine (**31**).

droverarine and the *N*-acetates of compounds **i–iv** which all crystallize very readily from this solvent. The mass spectra of the compounds **v–viii** exhibited a peak at *m/e* 437 corresponding to the molecular ion for *N*-acetyl-5α,6-dihydroverarine as well as prominent peaks at *m/e* 98 and 140.

To complete the synthesis of verarine (**31**) it was necessary to introduce the 5,6-double bond and remove the *N*-acetate function in *N*-acetyl-5α,6-dihydroverarine (**11**). The steps involved in achieving these goals are outlined in Fig. 4. The procedure for introduction of the double bond is taken from the investigations of Evans *et al.* (12) in the cortisone series. A similar pathway has been employed by Johnson *et al.* (13) in the conversion of 23-*O*,*N*-dibenzoyl-5α,6-dihydroveratramine to veratramine.

Having completed the synthesis of the simplest member of the *Veratrum* series, it was decided to extend the above strategy to encompass some of the more oxygenated *Veratrum* alkaloids and 5α,6-dihydroveratramine (**56**) became the target compound. Since the latter had already been converted to veratramine (**14**) (13), jervine (**32**) (14, 15), veratrobasine (**33**) (15, 16), and 11-deoxojervine (**34**) (17), a synthesis of this intermediate represents in a formal sense the total synthesis of these natural products.

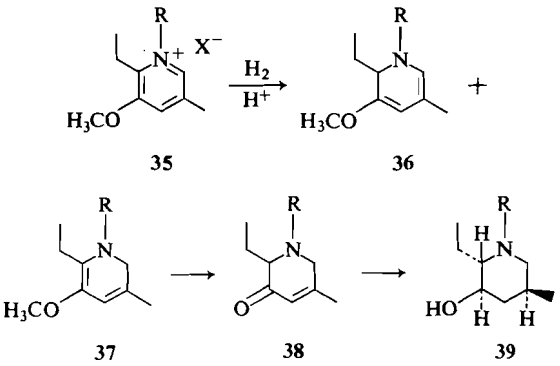
example, reveals that the substituents attached to the three chiral centers (C_{22}, C_{23}, and C_{25}) involving the piperidine ring are in equatorial orientations. It was thus felt that reduction of an appropriately substituted pyridinium system, under equilibrating conditions, should lead predominantly to the desired stereochemistry in the resultant product (see **35** → **36** + **37** → **38** → **39**).



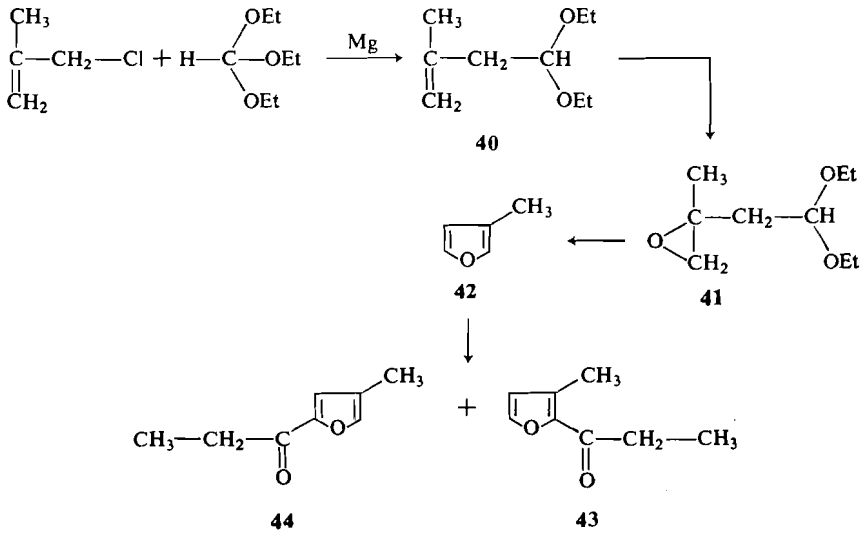
35 **36** **37** **38** **39**

The obvious heterocyclic unit required for achieving the synthesis in this direction was an unknown pyridine derivative, 2-ethyl-3-hydroxy-5-methylpyridine, and its synthesis was first considered. We chose an approach which made use of the reaction of furyl ketones with ammonia (18) since it seemed to be more direct and suitable for our purposes. In this connection we have developed two independent sequences for the synthesis of the desired pyridine. In effect, both sequences depend on the availability of crucial furan intermediates and therefore the synthesis of these substances was initially considered. Figures 5 and 6 outline the reactions involved in the preparation of these materials. Figure 5 reveals the preparation of 2-propionyl-4-methylfuran (**44**) via a Friedel–Crafts reaction on 3-methylfuran.

A survey of the literature at this time indicated that there had been no work on the Friedel–Crafts reaction of 3-methylfuran. In fact only limited data on the electrophilic substitution of 3-alkylfurans in general was available and the data indicated that the substitution takes place exclusively at the 2-position (19–21). However, we did not rule out the possibility of substitution at the 5-position and hence decided to investigate this further. The desired starting material, 3-methylfuran (**42**), was prepared according to the procedure of Cornforth (22, 23) as outlined in Fig. 5.

Reaction of 3-methylfuran with propionic anhydride and orthophosphoric acid as the catalyst at 60° provided a product which upon examination by v.p.c. indicated that it was a mixture of two compounds in the ratio 70:30. Separation of the mixture by means of preparative v.p.c. using a FFAP column allowed the isolation of 2-propionyl-3-methylfuran (**43**) and 2-propionyl-4-methylfuran (**44**).

It is noteworthy that indeed substitution takes place at both C_2 and C_5 positions of 3-methylfuran and this was the first demonstrated example of electrophilic substitution at the C_5 position of



40 **42** **41** **44** **43**

FIG. 5. Synthesis and propionylation of 3-methylfuran.

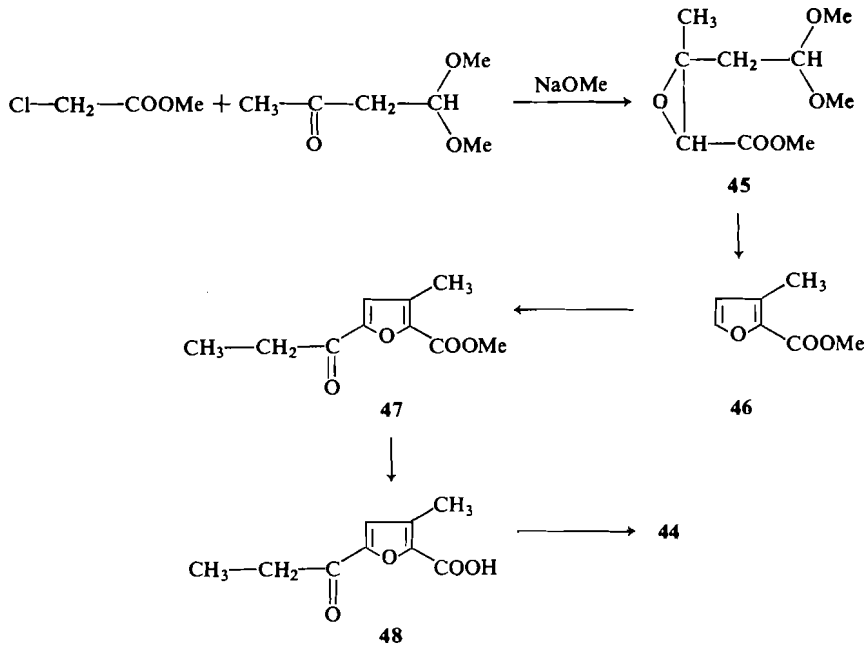


FIG. 6. Synthesis of 2-propionyl-4-methylfuran (**44**).

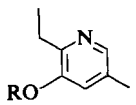
a 3-alkylfuran unsubstituted at the 2-position. Documented data indicate that only furans with electron-withdrawing substituents (*e.g.*, —COOR group) at C_3 can direct substitution to C_5 whereas the presence of electron-donating substituents invariably direct the substitution to C_2 (20). A more detailed investigation is now reported from our laboratory (24).

The difficulties encountered in the separation of the reaction mixture as well as the poor yield of the desired ketone **44** compelled us to discard the above sequence in favor of an alternate direct route to the preparation of this compound.

This latter route makes use of methyl 3-methyl-2-furoate (**46**) as the starting material. The preparation of this compound by a known procedure (25) and the subsequent reactions leading to 2-propionyl-4-methylfuran are schematically presented in Fig. 6.

The next stage in the synthesis was the conversion of 2-propionyl-4-methylfuran to 2-ethyl-3-hydroxy-5-methylpyridine (**49**). This conversion was effected by a known procedure (18). The resultant product (**49**) was crystalline and revealed spectral data in agreement with the assigned structure (λ_{max} 287 nm; τ 8.75, triplet, CH_3CH_2; 7.8, singlet, C_5—CH_3; 2.9 and 2.1, singlets, C_4 and C_6H).

In our initial studies on the coupling of the substituted pyridine with the steroidal enone, it was decided to use the lithio derivative of 2-ethyl-3-*O*-benzyl-5-methylpyridine (**50**). This compound was prepared by heating a solution of 2-ethyl-3-hydroxy-5-methylpyridine in aqueous



49 R = H
50 R = $CH_2C_6H_5$
51 R = CH_3

sodium hydroxide with benzyl chloride. However these investigations were unsuccessful and hence we discarded the use of the *O*-benzyl ether in favor of the corresponding *O*-methyl ether (**51**) which was readily available from the reaction of **49** with diazomethane.

Thus with the desired steroidal enone, 3β-acetoxy-5α-etiojerv-12(13)-en-17-one (**1**), and the appropriately substituted pyridine, 2-ethyl-3-methoxy-5-methylpyridine (**51**), in hand the stage was set for the coupling reaction of these units. The actual reaction sequence employed for the synthesis of 5α,6-dihydroveratramine (**56**) is

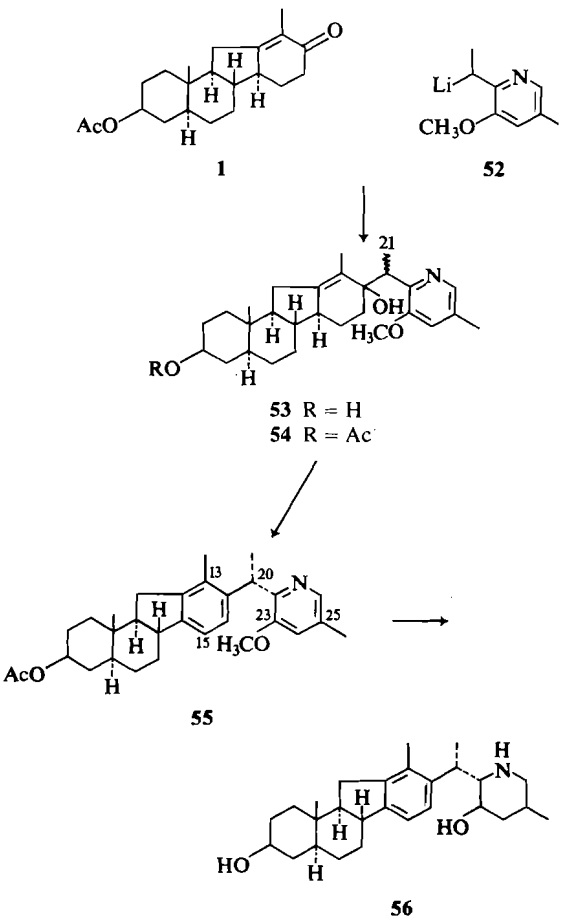

FIG. 7. Synthesis of 5α,6-dihydroveratramine (**56**).

shown in Fig. 7 and follows the strategy outlined previously.

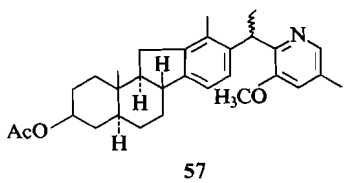
Coupling of the lithio derivative **52** and **1** provided a reaction product which in the u.v. spectrum (λ_{max} 283 nm) showed a pyridine chromophore while the mass spectrum exhibited a peak at *m/e* 439 corresponding to the parent ion for a substance bearing the gross structure **53**.

That the material obtained above, although homogeneous on t.l.c., was a mixture of two compounds was indicated by the n.m.r. spectrum which exhibited two sharp singlets at τ 6.21 and 6.24 due to the presence of two methoxyl groups. Two doublets were also seen at τ 8.81 and 8.84 which were probably due to the C_{21} methyl group in each of the two compounds. Attempts at the separation of this mixture by chromatographic techniques were unsuccessful since both the compounds had identical R_f values on t.l.c. in numerous solvent systems.

In an attempt to achieve separation of these two compounds the mixture was subjected to acetylation by means of acetic anhydride and pyridine. The resulting reaction mixture on t.l.c. examination showed the presence of two compounds possessing very different R_f values. These were separated by column chromatography on alumina. For the sake of discussion the more polar compound is referred to as compound **E** while the less polar one is designated as compound **F**.

Examination of compound **E** revealed the following spectral data. The u.v. spectrum showed a peak of 283 nm with a shoulder at 225 nm indicative of the pyridine chromophore while the mass spectrum exhibited the parent peak at *m/e* 463 which indicated that dehydration of the coupled product (**54**) has occurred in the mass spectrometer. The n.m.r. spectrum of **E** was particularly instructive and a detailed analysis was carried out. Thus a sharp singlet at τ 9.22 with a three-proton integral was assigned to the C_{19} methyl resonance. The doublet at 8.82 was attributed to the C_{21} methyl protons, which were coupled with the C_{20} proton, $J_{20,21}$ = 7.0 Hz. The sharp singlets at τ 8.79, 8.0, and 7.7 were due to C_{18} methyl, C_3 acetate, and C_{26} methyl protons, respectively, while the three proton signal at 6.22 was easily recognized as due to the C_{23} methoxyl protons. The protons on the pyridine ring appeared as sharp singlets at τ 3.08 (C_{24}H) and 2.0 (C_{27}H).

The u.v. spectrum of compound **F** was similar to that of **E** while the mass spectrum exhibited the parent peak at *m/e* 461 corresponding to an ion which accounts for the loss of 20 units from the desired compound of gross structure **54**. In the n.m.r. spectrum, the C_{18} methyl signal was shifted downfield (τ 7.7) and was in the position expected for a methyl group on an aromatic ring. Further evidence in support of aromatization of ring D came from an examination of the low field (τ 4–2) region in the spectrum where, in



57

addition to the pyridine proton signals, an AB quartet centered at τ 3.05 was noted. This signal is clearly due to the C_{15} and C_{16} protons in a ring D aromatic compound with the expected large *ortho* coupling ($J = 7$ Hz).

Since the above spectral data was consistent for the structure **57**, it was clear that compound **F** arises via dehydration of the C_{17} hydroxyl function in the condensation product (**53**) followed by aromatization of the resulting diene.

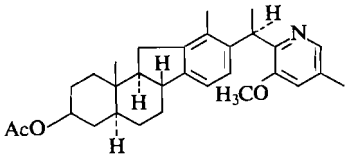
It can be seen from Fig. 7 that the coupling reaction generates two chiral centers and consequently there exists the possibility of obtaining four compounds possessing structure **53**. However in our studies only two compounds could be isolated and characterized.

The above results suggest that the coupling reaction afforded a mixture of alcohols of gross structure **53** and that one of them fortuitously underwent dehydration followed by aromatization during the subsequent work-up. There existed the possibility of this sequence of reactions occurring either during acetylation of the reaction mixture or during the chromatographic separation on alumina.

We set out to explore this phenomenon by monitoring a typical experiment by n.m.r. spectroscopy. The product obtained in the coupling reaction was subjected directly to acetylation with acetic anhydride and pyridine at room temperature. After allowing the reaction mixture to stand overnight followed by the usual work-up, the n.m.r. spectrum of this material displayed the low field AB quartet noted earlier. The results of the experiment allowed us to conclude that one of the two alcohols undergoes dehydration and aromatization to **F** (**57**) during the acetylation step.

In our subsequent studies we have been able to convert the alcohol acetate **54** (compound **E**) to an aromatic compound isomeric with **F**. In a typical experiment, compound **E** was reacted with palladized charcoal at 200° and three compounds, the α,β-unsaturated ketone **1**, 2-ethyl-3-methoxy-5-methoxypyridine (**52**), and a new substance designated as compound **G**, were isolated in a pure state. The spectral properties of **G** were remarkably similar to those of **F** and it was clear that these compounds were diastereoisomeric at C_{20}, the chiral center created during the coupling reaction.

Since in subsequent experiments the aromatic compound **F** gave rise to compounds in the natural series, the stereochemistry at C_{20} in this compound is known and is indicated in **55**. This leads to the conclusion that compound **G** is the C_{20} epimer of **F** and has the stereochemistry as indicated in **58**.



58

After having established that the condensation product of 2-ethyl-3-methoxy-5-methylpyridine and 3β-acetoxy-5α-etiojerv-12(13)-en-17-one is a mixture of epimeric alcohols **53** and that one of these alcohols undergoes dehydration and aromatization to give compound **F** during the subsequent work-up, we set out to assign the stereochemistry of the condensation products. One of the several rational interpretations of the results is advanced in the following paragraphs. We wish to emphasize that we are unable at this time to distinguish clearly between several alternative explanations.

It is clear that several important factors must be considered in proposing any stereochemical assignments to the condensation products possessing the gross structure **53**. (*i*) Is the stereochemistry at C_{20} determined during the approach of the anion to form the C_{17}—C_{20} bond or is the product composition a result of equilibration *after* the initial reaction has occurred? It is well known that protons adjacent to a pyridine ring (as at C_{20}) are readily removed by strong base. (*ii*) Is the approach of the anion equally favorable from the 'equatorial' and 'axial' sides of the molecule since this factor determines the stereochemistry at C_{17}? With regard to the latter, an investigation of molecular models quickly revealed that no distinct preference for either approach is apparent. In other words, one would expect the epimers at C_{17} as the most likely course of events. In the explanation given below we have assumed that such is the case, *i.e.*, the two condensation products differ in stereochemistry at C_{17} but not at C_{20}. In actual fact the discussion below indicates that the results obtained are explicable, regardless whether a definite stereochemistry is initially assigned to C_{20} in the condensation products. For the sake of clarity the

For personal use only.

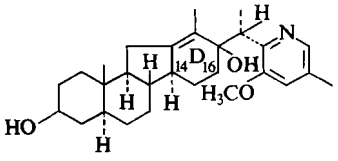
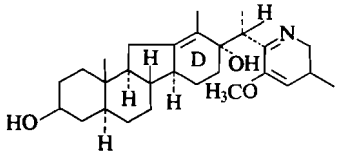
particular stereochemistry chosen for C_{20} was the one which is present in the natural *Veratrum* series. The reasons for the latter choice are twofold: (*a*) there is a minimal interaction between the various groups on ring D and the heterocyclic portion when this stereochemistry is considered and (*b*) one of the above condensation products leads to 5α,6-dihydroveratramine.

Once a tentative assignment of the stereochemistry at C_{20} in the condensation products is advanced one is left with the task of advancing a reasonable explanation for the difference in the stability of the alcohols and the observed facile dehydration followed by aromatization in one case as opposed to the sluggishness in the other. An acceptable explanation for the difference in their behaviour is given in the following paragraphs. Here again, it should be emphasized that there can be alternate explanations but the one chosen appears to be the most reasonable.

If we consider the 'axial' alcohol (**58***a*) and its possible conversion to the ring D aromatic derivative (**55**) it is clear that the allylic hydroxyl can undergo 1,4-elimination making use of the C_{14} proton, or alternatively a 1,2-elimination involving the α-(axial) proton at C_{16} is also a feasible process. Either of these eliminations would yield a highly strained cyclohexadiene system (with regard to ring D) which would be expected to aromatize rapidly to yield a compound of structure **55**.

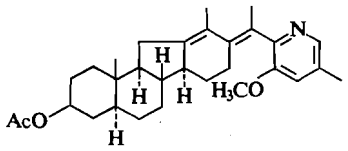


58*a*



69

On the other hand, examination of molecular models for the 'equatorial' alcohol (**69**) reveals that in this compound there are no ring D protons which are *trans* and coplanar to the hydroxyl group. The desired stereochemistry for the elimination can be attained at C_{20} by rotation around the C_{17}—C_{20} bond but such a process leads to an eclipsing of the C_{18} and C_{21} methyl groups and an increase in nonbonded interactions between ring D (particularly C_{16}) and the substituents on the heterocyclic ring. Hence the sluggishness of this alcohol to dehydrate may be related to the energy required to force the molecule into this sterically unfavorable conformation. The higher temperature (200°) as noted above, under which this alcohol converts to a substance possessing an aromatic D ring would then provide the necessary energy. Dehydration in this event will lead to a diene **70**, which via



70

double bond rearrangement and aromatization would provide the aromatic compound **57**. Obviously such a process can lead to epimerization at C_{20}. In fact the aromatic compound (**G**) isolated in this reaction is isomeric with compound **F** and must therefore be its C_{20} epimer (*i.e.* **58**).

Now that the desired D ring aromatized compound had been obtained, it was essential to find suitable methods to reduce the pyridine ring to the appropriately functionalized piperidine moeity present in veratramine. For this purpose catalytic hydrogenation was selected as the method of choice. Compound **F** when subjected to hydrogenation in ethanol at pressures ranging from 40–65 p.s.i. did not undergo any change. However, it was found that this substance undergoes hydrogenation in an acid–alcohol medium (Pt as catalyst). Thin-layer chromatography examination of the reaction product revealed the presence of three major compounds along with trace amounts of several other components. One of the major compounds had the same R_f value as 5α,6-dihydroveratramine. Indeed, separation of the mixture afforded an 18% yield of 5α,6-dihydroveratramine (**56**), identical with the natural sample prepared by the hydrogenation of veratramine (7, 10) (i.r., n.m.r., mass spectra, mixture m.p.).

The two other compounds isolated in the hydrogenation experiment were found to be extremely unstable and the limited quantities of these available prevented any meaningful investigation. However, a preliminary inspection of the n.m.r. spectra of the impure compounds

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

revealed that in both instances the pyridine ring was only partially reduced (to the dihydro or tetrahydropyridine stage) while the methoxyl group was still intact.

As mentioned earlier, the synthesis of 5α,6-dihydroveratramine was sufficient for our purpose because this material has already been converted to veratramine (**14**), jervine (**32**), veratrobasine (**33**), and 11-deoxojervine (**34**).

Experimental

All details concerning spectral measurements, chromatographic separations, etc., are described in part I of this series.

18-Nor-C-homo-26-nor-22,27-iminojerva-12α(13),22,24,27-tetraene-3β,17-diol (8)

An ether solution of 1.88 *M* methyl lithium (1.0 ml) was added to anhydrous tetrahydrofuran (4 ml) in a round-bottom flask which had been flame dried and flushed with dry nitrogen. A tetrahydrofuran solution of 2.0 *M* 2-ethylpyridine (1 ml) was added immediately and the mixture refluxed under nitrogen for 30 min. During this time the solution developed a deep red color. After the period of reflux the α,β-unsaturated ketone (**6**) in the form of a fine powder was added slowly until the color faded (120 mg) and the reaction mixture refluxed for a further 30 min while the flask was still under nitrogen. Water was then added cautiously to destroy any alkyl lithium remaining and the resulting mixture diluted with ether (10 ml). The organic phase was separated and washed with water (4 × 10 ml), before drying over anhydrous sodium sulfate. Evaporation of the ether gave a light oil (100 mg) which appeared as one major and several minor components when examined by thin-layer chromatography. The major component was obtained pure by preparative thin-layer chromatography on Woelm neutral alumina (20 × 20 cm, 0.4 mm, 2% methanol in chloroform). Spectral data indicated this was the desired condensation product (**8**) although the n.m.r. indicates the material is probably a mixture of two isomers; i.r.: 6.3, 6.4 (pyridine), 3.1 μ (hydroxyl); u.v.: λ_{max}: 257 (3.55), 262 (3.58), 270 nm (3.45); n.m.r.: 9.26 (angular methyl, 3H, singlet), 8.8, 8.75 (two overlapping doublets due to the presence of two isomers in the product (CH_3—C—H, J=7 Hz, 3H), 6.53 (CH_3CH, 1H, J = 7 Hz, quartet), 5.1 (C_{13}, 1H, singlet), 2.0, 3.0 (pyridine, 3H, multiplet), 1.5 (pyridine, 1H, multiplet).

26-Nor-22,27-iminojerva-12(13),22,24,27-tetraene-3β,17-diol (9)

An ether solution of 1.88 *M* methyl lithium (1.0 ml) was added to anhydrous tetrahydrofuran in a dry round-bottom flask under nitrogen. A solution of 2-ethylpyridine (1.0 ml of 2.0 *M*) in tetrahydrofuran was added immediately and the mixture refluxed for 30 min during which time a deep red color developed. Addition of 3β-acetoxy 5α-etiojerv-12(13)en-17-one (**1**) in the form of a finely ground dry solid was continued until the color faded (90 mg added) and the mixture stirred for a further 30 min, while the flask was still under nitrogen. Water was added to quench the reaction and the mixture diluted with ether (10 ml). The organic phase was separated and then washed with water (4 × 10 ml) before drying over anhydrous sodium sulfate. Examination of the ethereal extract by thin-layer chromatography indicated one major component which appeared as a bright yellow spot when the chromatoplate was developed with 1:1 antimony pentachloride – carbon tetrachloride (1:1) spray reagent. Column chromatography on alumina (Shawinigan, activity III, 25 g) eluting with benzene–chloroform (4:1) enabled purification of this component which was crystallized from benzene–ether as needles (42 mg), m.p. 204–206°; i.r. ($CHCl_3$): 6.30, 6.41 μ (pyridine); u.v.: λ_{max} 257sh, 262.5 (3.58), 269sh nm; n.m.r.: 9.26 (angular methyl, 3H, singlet), 8.84 (C_{21} methyl, 3H, $J_{20,21}$ = 7 Hz, doublet), 8.26 (C_{18} methyl, 3H, singlet), 2.8 (pyridine, 2H, multiplet), 2.34 (pyridine, 1H, multiplet), 1.5 (pyridine, 1H, multiplet) mass spectrometry: *m/e* 395 (M^+), prominent peaks at *m/e* 377, 362, 288.

Anal. Calcd. for $C_{26}H_{37}O_2N$: C, 78.94; H, 9.43; N, 3.54. Found: C, 78.85;, H, 9.50; N, 3.50.

2-Ethyl-5-methylpyridine

An anhydrous ether solution (250 ml) of bromobenzene (31.4 g, 0.2 mol) was added slowly to a dry round-bottom flask which had been flushed with nitrogen and which contained lithium wire (2.8 g, 0.4 mol). When the lithium had largely dissolved an ethereal solution (100 ml) of 2,5-lutidine (21 g, 0.2 mol) was added and the mixture refluxed for 30 min, during which time a deep red color developed in the solution. Methyl iodide (14.2 g, 0.1 mol) in ether (40 ml) was added slowly to this red solution over a period of 15 min and the mixture stirred for 10 min. The excess lithium and phenyl lithium were removed by the careful addition of water (100 ml) to the reaction mixture while the flask was still under nitrogen. A further 200 ml of water was then added and the organic phase separated, and washed with water (2 × 50 ml). The ethereal solution was reduced in volume to 40 ml by use of a rotary evaporator. This 40 ml was then carefully distilled at a pressure of 10 mm, employing a spinning band column. The first fraction, distilling at 50–55° was shown by n.m.r. to be recovered 2,5-lutidine whereas that distilling at 62–63° was shown to be 2-ethyl-5-methylpyridine; i.r. (film): 6.3, 6.4, 6.8, 7.02 μ; u.v.: λ_{max} 265sh (3.54), 269 (3.60), 276 nm (3.48); n.m.r.: 8.70 (CH_3CH_2, 3H, J = 7.5 Hz, triplet), 7.72 (CH_3—C, 3H, singlet), 7.20 (CH_2CH_3, 2H, J = 7.5 Hz, quartet), 2.93 (C_3, 1H, $J_{3,4}$ = 8 Hz, doublet), 2.59 (C_4, 1H, $J_{4,3}$ = 8.0 and $J_{4,6}$ = 2.0 Hz, two doublets), 1.63 (C_6, 1H, $J_{6,4}$ = 2.0 Hz, doublet). Picrate derivative from acetone, m.p. 143–144° (lit. (7) m.p. 144°).

3β-Acetoxy-22,27-iminojerva-12(13),22,24,27-tetraene-17-ol (3)

A 2.05 *M* ethereal solution of methyl lithium (25 ml, 0.051 mol) was added to a flame dried round-bottom flask containing anhydrous tetrahydrofuran (40 ml) under nitrogen. A mixture of anhydrous tetrahydrofuran (10 ml) and 2-ethyl-5-methylpyridine (6 g, 0.05 mol) was added immediately and the reaction mixture refluxed for 1½ h. During this period a deep red color developed in the solution. A faint pink color persisted after 3β-acetoxy-5α-etiojerv-12-en-17-one (**1**) (2.0 g, 0.006 mol) was added as a fine powder to the cooled solution and the mixture stirred for 10 min. Water (50 ml) was added cautiously to the reaction mixture while still under nitrogen, followed by ether (50 ml) prior to separation of the organic and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

aqueous phases. The organic phase was washed with water (3 × 25 ml) and then dried over anhydrous sodium sulfate. Removal of the solvent *in vacuo* gave a light oil (2.3 g) which appeared to consist of two new components when examined by thin-layer chromatography. Attempts to obtain these compounds in a pure state were unsuccessful. However a small scale investigation indicated that the compounds could be separated more readily as the C_3 acetates rather than as the C_3 alcohols which were formed in the reaction.

Conversion to the C_3 acetates was achieved by dissolving the crude product from the reaction in acetic anhydride – pyridine (1:1, 20 ml) and allowing the solution to stand at room temperature for 12 h. The solution was then poured onto crushed ice and the resultant flocculant solid extracted into ether. The combined ethereal extracts were washed with saturated aqueous sodium hydrogen carbonate solution and then several times with water before drying over anhydrous sodium sulfate. The volume of the ethereal solution was reduced *in vacuo* to 20 ml and then allowed to stand whereupon colorless needles were deposited, m.p. 187–189° (370 mg). Examination of the crystals by thin-layer chromatography indicated only one compound was present and recrystallization from ether gave an analytical sample, m.p. 189–190°. This compound was designated **A** and the physical and spectral data are in accord with structure **3**; i.r. ($CHCl_3$): 5.83 (OAc) 6.25, 6.37 (pyridine) μ; u.v.: λ_{max} 270 nm (3.61); $[\alpha]_D$ +83° (*c*, 1.24); n.m.r.: 9.21 (angular methyl, 3H, singlet), 8.79 (C_{21} methyl, 3H, $J_{21,20}$ = 7.0 Hz, doublet), 8.40 (C_{18} methyl, 3H, singlet), 8.01 (acetate, 3H, singlet), 7.70 (C_{26} methyl, 3H, singlet), 6.71 (C_{20}H, 1H, $J_{20,21}$ = 7.0 Hz, quartet), 3.89 (OH, 1H, broad multiplet, disappears on D_2O addition), 2.82 (C_{23}, 1H, $J_{23,24}$ = 8 Hz, doublet), 2.52 (C_{24}, 1H, $J_{24,23}$ = 8 and $J_{24,27}$ = 2 Hz, two doublets), 1.67 (C_{27}, 1H, $J_{27,24}$ = 2 Hz, doublet); mass spectrometry: *m/e* 451 (M^+), prominent peaks at *m/e* 433, 330, 147, and 121.

Anal. Calcd. for $C_{29}H_{41}O_3N$: C, 77.12; H, 9.15; O, 10.63; N, 3.10. Found: C, 76.92; H, 8.95; O, 10.46; N, 3.21.

Examination by thin-layer chromatography of the mother liquors from the crystallization of compound **A** indicated the presence of a further compound of similar color reaction when sprayed with antimony pentachloride – carbon tetrachloride reagent. These mother liquors were combined and chromatographed on alumina (60 g, activity III). Elution with benzene yielded unreacted 2-ethyl-5-methylpyridine initially, while further elution provided an additional compound (350 mg) which was obtained crystalline from a small volume of ether, m.p. 190–192°. Recrystallization from acetone – petroleum ether gave an analytical sample (250 mg), m.p. 190–192°. This compound was designated compound **B** and was slightly less polar than compound **A** on a silica gel chromatoplate developed with 2% methanol in chloroform; i.r. ($CHCl_3$): 5.83 (OAc), 6.25, 6.37 (pyridine) μ, u.v.: λ_{max} 265sh (3.57), 270 (3.61), 276sh nm (3.51); $[\alpha]_D$ −126° (*c*, 1.26); n.m.r.: 9.23 (angular methyl, 3H, singlet), 8.88 (C_{21} methyl, 3H, $J_{20,21}$ = 7.0 Hz, doublet), 8.28 (C_{18} methyl, 3H, singlet), 8.02 (CH_3CO, 3H, singlet), 7.72 (C_{26} methyl, 3H, singlet), 6.71 (C_{20}, 1H, $J_{20,21}$ = 7.0 Hz, quartet), 4.20 (OH, 1H, broad signal, disappears on D_2O addition), 2.92 (C_{23}, 1H, $J_{23,24}$ = 8.0 Hz, doublet), 2.70 (C_{24}, 1H, $J_{24,23}$ = 8 and $J_{24,27}$ = 2.0 Hz), 1.75 (C_{27}, 1H, $J_{27,24}$ = 2.0 Hz, doublet); mass spectrometry: *m/e* 451 (M^+), prominent peaks at *m/e* 433, 418, 330, 147, and 121.

Anal. Calcd. for $C_{29}H_{41}O_3N$: C, 77.12; H, 9.15; N, 3.10. Found: C, 77.19; H, 9.21; N, 3.19.

Elution with 20% ether in benzene gave additional compound **A** (150 mg) while two fractions appeared to contain two further compounds of similar reaction to the spray reagent when examined by thin-layer chromatography. Separation by preparative layer chromatography (20 × 20 cm, 0.3 mm, 1% methanol in chloroform, chromatoplate developed twice) yielded 35 mg and 8 mg of these compounds which were designated **C** and **D**, respectively. Compound **C** could not be induced to crystallize and an analytical sample was prepared by sublimation at 190°/0.1 mm which gave a clear glass. The spectral data were consistent with this compound being isomeric with **A** and **B**; i.r.: 5.8 (—OAc), 6.25, 6.39 (pyridine) μ; u.v.: λ_{max} 270 nm (3.60); n.m.r.: 9.26 (angular methyl, 3H, singlet), 8.77 (C_{21} methyl, 3H, $J_{21,20}$ = 7.02 Hz, doublet), 8.43 (C_{18} methyl, 3H, broad singlet), 8.01 (CH_3CO, 3H, singlet), 7.73 (C_{26} methyl, 3H, singlet), 6.90 (C_{20}H, 1H, $J_{20,21}$ = 7.0 Hz, quartet), 2.97 (C_{23}, 1H, $J_{23,24}$ = 8.0 Hz, doublet), 2.65 (C_{24}, 1H, $J_{24,23}$ = 8.0 and $J_{24,27}$ = 2.0 Hz, two doublets), 1.72 (C_{27}H, 1H, $J_{27,24}$ = 2.0 Hz, doublet); mass spectrometry: *m/e* 451 (M^+), prominent peaks at *m/e* 433, 418, 330, and 120.

Anal. Calcd. for $C_{29}H_{41}O_3N$: C, 77.12; H, 9.15. Found: C, 77.05; H, 9.33.

Compound **D** could not be induced to crystallize but the n.m.r. and mass spectrum indicate this compound is probably isomeric with the three characterized above; i.r. ($CHCl_3$): 5.83 (OAc), 6.25, 6.37 (pyridine) μ; u.v.: λ_{max} 270 nm (3.62); n.m.r. 9.21 (angular methyl, 3H, singlet), 8.63 (C_{21} methyl, 3H, $J_{21,20}$ = 7.0 Hz, doublet), 8.27 (C_{18} methyl, 3H, singlet), 8.01 (CH_3CO, 3H, singlet), 7.74 (C_{26} methyl, 3H, singlet), 6.89 (C_{20}, 1H, $J_{20,21}$ = 7.0 Hz, quartet), 3.08 (C_{23}, 1H, $J_{23,24}$ = 8.0 Hz, doublet), 2.62 (C_{24}, 1H, $J_{24,23}$ = 8.0 and $J_{24,27}$ = 2.0 Hz, two doublets), 1.70 (C_{27}, 1H, $J_{27,24}$ = 2.0 Hz, doublet); mass spectrometry: *m/e* 451 (M^+), prominent peaks at *m/e* 433, 418, and 121.

3β-Acetoxy-22,27-iminojerv-12(13),14(15),16,22,24,27-hexaene (4)

Aromatic I

Compound **A** (118 mg) was thoroughly ground with 10% palladized charcoal (30 mg) until a homogeneous powder was obtained. This powder was heated at 200° for 7 min and the resultant solid residue washed several times with chloroform. Thin-layer chromatography of the chloroform extract indicated the product contained three major components and these were separated by preparative layer chromatography (20 × 20 cm, 0.4 mm, 2% methanol in chloroform). One of these three components was shown to be 2-ethyl-5-methylpyridine by n.m.r. The band which exhibited a strong fluorescence when the chromatoplate was viewed under u.v. light was extracted and yielded a light oil which crystallized from acetone – petroleum ether as needles, m.p. 167°. This compound was identified as 3β-acetoxy-5α-etiojerv-12(13)-en-17-one (**1**) by its u.v. spectrum and by mixture melting point with an authentic sample. The third compound which appeared as a light orange spot when the chromatoplate was sprayed with

antimony pentachloride – carbon tetrachloride reagent was extracted to yield a light oil which could not be induced to crystallize. An analytical sample of this compound which was designated aromatic **1** was obtained as a clear glass after sublimation at 185°/0.1 mm. Spectral data indicated this compound possessed structure **4**; i.r.: 5.82, 6.26, 6.39 μ; u.v.: λ_{max} 265sh, 269 (3.73) 277 nm (3.62); $[\alpha]_D$ +13° (*c*, 0.84); n.m.r.: 9.10 (angular methyl, 3H, singlet), 8.41 (C_{21} methyl, 3H, $J_{21,20}$ = 7.0 Hz, doublet), 8.03 (CH_3CO, 3H, singlet), 7.90 (C_{18} methyl, 3H, singlet), 7.80 (C_{26} methyl, 3H, singlet), 5.61 (C_{20}, 1H, $J_{20,21}$ = 7.0 Hz, quartet), 3.22–3.0 (C_{15} or C_{16} and C_{23}, 2H, two overlapping doublets), 2.94 (C_{15} or C_{16}, 1H, J = 8 Hz, doublet), 2.72 (C_{24}, 1H, $J_{24,23}$ = 8.0 and $J_{24,27}$ = 2 Hz, two doublets), 1.7 (C_{27}H, 1H, $J_{27,24}$ = 2 Hz, doublet); mass spectrometry: *m/e* 431, prominent peaks at 416, 402.

Mol. Wt. Calcd. for $C_{29}H_{37}O_2N$: 431.2824. Found (high resolution mass measurement): 431.2809.

Aromatic II

Compound **B** (80 mg) was ground with 10% palladized charcoal (20 mg) until a homogeneous powder was formed. This powder was heated at 200° for 7 min and the solid residue washed several times with chloroform. Thin-layer chromatographic examination of the chloroform extract indicated the major component was a new compound which appeared as a light orange spot when the chromatoplate was sprayed with antimony pentachloride – carbon tetrachloride reagent. This compound was separated from the reaction mixture by preparative layer chromatography (20 × 20 cm, 0.4 mm, 1% methanol in chloroform, developed twice) as a light oil (60 mg) which could not be induced to crystallize. An analytical sample of the compound, which was designated 'aromatic **II**', was obtained as a clear glass after sublimation at 185°/0.01 mm; i.r.: 5.82, 6.26, 6.39 μ; u.v.: λ_{max} 265sh, 269 (3.73), 277 nm (3.62); n.m.r.: 9.10 (angular methyl, 3H, singlet), 8.40 (C_{21} methyl, 3H, $J_{21,20}$ = 7 Hz, doublet), 8.02 (CH_3CO, 3H, singlet), 7.89 (C_{18} methyl, 3H, singlet), 7.80 (C_{26} methyl, 3H, singlet), 5.58 (C_{20}, 1H, $J_{20,21}$ = 7.0 Hz, quartet), 3.14 (C_{23}, 1H, $J_{23,24}$ = 8 Hz, doublet), 3.09 (C_{15} or C_{16}, 1H, J = 8 Hz, doublet), 2.91 (C_{15} or C_{16}, 1H, J = 8 Hz, doublet), 2.75 (C_{24}, 1H, $J_{24,23}$ = 8 and $J_{24,27}$ = 2 Hz, two doublets), 1.73 (C_{27}, 1H, $J_{27,24}$ = 2 Hz, doublet); mass spectrometry: *m/e* 431 (M^+), prominent peaks at *m/e* 416, 402.

Mol. Wt. Calcd. for $C_{29}H_{37}O_2N$: 431.2824. Found (high resolution mass measurement): 431.2809.

N-Acetyl-22,27-iminojerva-12(13),14(15),16-triene-3β-ol (5)

Isomers i–iv

Aromatic compound **II** (50 mg) was dissolved in glacial acetic acid (10 ml) and the solution hydrogenated at 20° and 45 p.s.i. over Adams' catalyst (PtO_2, 20 mg) for 3 h. The mixture was filtered to remove the catalyst which was carefully washed with additional acetic acid (5 ml). The combined filtrates were reduced in volume to 2 ml *in vacuo*, then diluted with water (20 ml) and made basic with ammonia solution. The resultant suspension was extracted with methylene chloride (3 × 10 ml) before drying over anhydrous sodium sulfate. Thin-layer chromatography revealed the presence of four compounds of similar R_f value and color reaction with various spray reagents. These compounds were designated **i–iv** in order of decreasing R_f value, (silica gel G, 5% methanol in chloroform) and were separated by careful preparative layer chromatography (20 × 20 cm, 0.3 mm, 1% methanol in chloroform, plates developed three times). The bands corresponding to the four compounds were delineated by inspection of the developed plates under u.v. light. Extraction of the various bands and removal of the solvent (methanol–chloroform 1:1) gave each of the compounds as a clear oil. None of the compounds could be induced to crystallize.

All four compounds were separately converted via the 3-*O*,*N*-diacetates (**13**) to the *N*-acetyl derivatives **12** (since a sample of *N*-acetyl-5α,6-dihydroverarine was available for comparison) as outlined for one of the isomers below.

Compound **ii** was dissolved in pyridine – acetic anhydride (2 ml, 1:1) and allowed to stand for 12 h at 20°. The solution was then poured into ice water (5 ml) and the resulting suspension extracted with methylene chloride (3 × 3 ml). The combined extracts were washed with saturated aqueous sodium hydrogen carbonate (10 ml) and then with water (2 × 5 ml), before drying over anhydrous sodium sulfate. Removal of the methylene chloride *in vacuo* gave a light oil which crystallized from ether (the diacetates of compounds **i**, **iii**, and **iv** were not obtained crystalline) as needles, m.p. 203–205°; i.r. ($CHCl_3$): 5.80 (OAc), 6.19 (NAc) μ; u.v.: λ_{max} 268 (2.7), 277 nm (2.7).

The diacetate (20 mg) was refluxed with 0.1 *M* potassium hydroxide in methanol (5 ml) for 1 h, the solution cooled, and diluted with water (20 ml). The aqueous suspension was extracted with methylene chloride (3 × 5 ml) and the combined extracts washed with water (2 × 5 ml) prior to drying over anhydrous sodium sulfate. Evaporation of the solvent *in vacuo* gave a light oil which was readily crystallized from anhydrous ether. (All four *N*-acetyl derivatives were obtained crystalline via this procedure.)

The *N*-acetyl derivatives of compounds **i** and **ii** had R_f values comparable with that of *N*-acetyl-5α,6-dihydroverarine whereas those of the *N*-acetyl derivatives of compounds **iii** and **iv** were slightly smaller. All compounds showed similar color reactions when the chromatoplate was sprayed with various reagents. The *N*-acetyl derivatives were characterized as follows.

*Compound **i**, N-acetate;* prisms, m.p. 249–250° (6 mg); i.r. ($CHCl_3$): 6.20 9.70 μ; u.v.: λ_{max} 268 (2.68), 277 nm (2.66); $[\alpha]_D$ +36° (*c*, 0.605); n.m.r.: 9.07 (angular methyl, 3H, singlet), 8.19 (CH_3CON, 3H, singlet), 7.74 (C_{18} methyl, 3H, singlet), 3.15 (C_{15} or C_{16}, J = 8 Hz, doublet), 2.96 (C_{15} or C_{16}, J = 8 Hz, doublet); mass spectrometry: *m/e* 437 (M^+), prominent peaks at *m/e* 297, 140, 98.

Mol. Wt. Calcd. for $C_{29}H_{43}O_2N$: 437.329. Found (high resolution mass measurement): 437.325.

*Compound **ii**, N-acetate;* prisms, m.p. 263–264° (17 mg); i.r. ($CHCl_3$): 6.19, 9.70 μ; u.v.: λ_{max} 268 (2.65), 277 nm (2.61); $[\alpha]_D$ +26° (*c*, 1.71); mass spectrometry: *m/e* 437 (M^+), prominent peaks at *m/e* 298, 297, 140, 98.

*Compound **iii**, N-acetate;* rosettes, m.p. 270–274° (5 mg); i.r. ($CHCl_3$): 6.20, 9.70 μ; u.v.: λ_{max} 268, 277 nm; mass spectrometry: *m/e* 437 (M^+), prominent peaks at *m/e* 297, 140, 98.

*Compound **iv**, N-acetate;* long needles, m.p. 260–261° (10 mg); i.r. ($CHCl_3$): 6.20, 9.70, 9.80 μ; u.v.: λ_{max} 268, 277 nm; mass spectrometry: *m/e* 437 (M^+), prominent peaks at *m/e* 298, 297, 140, 98.

Isomers v–viii

Aromatic compound **I** (50 mg) was dissolved in glacial acetic acid (10 ml) and the solution shaken with Adams' catalyst (PtO_2, 20 mg) in an atmosphere of hydrogen at 45 p.s.i. and 20° for a period of 3 h. The mixture was filtered to remove the catalyst which was washed with a further 10 ml of glacial acetic acid and the filtrates combined. The volume of the acetic acid was reduced to 2 ml by use of a rotary evaporator before dilution with water (20 ml). The aqueous acid solution was made basic with dilute ammonia and the resulting suspension extracted several times with methylene chloride (3 × 10 ml) prior to drying over anhydrous sodium sulfate. Thin-layer chromatographic investigation of the light oil (45 mg) obtained by removal of the methylene chloride indicated the presence of four compounds, of similar R_f value and color reaction to the spray reagent. These compounds were numbered **v–viii** in order of decreasing R_f value and were separated by careful preparative layer chromatography (silica gel G 20 × 20 cm, 0.3 mm, 1% methanol in chloroform, plates developed three times). The compounds were obtained as colorless oils which could not be crystallized. Conversion of these compounds via the 3-*O*,*N*-diacetates to the *N*-acetyl derivatives was accomplished as outlined above for the 3β-acetoxy-22,27-iminojerva-12(13),14(15),16-triene isomers **i–iv** obtained from aromatic compound **II**. None of the *N*-acetyl derivatives of compounds **v–viii** could be induced to crystallize although compounds **v** and **vi** had R_f values comparable with *N*-acetyl-5,6-dihydroverarine. These compounds were not fully characterized but their spectral properties were in accord with structure **5**.

Compound v, N-acetate: i.r.: 6.19, 9.28 μ; u.v.: λ_{max} 267, 276 nm; mass spectrometry: *m/e* 437 (M^+), prominent peaks at *m/e* 298, 297, 98.

Spectral properties for the *N*-acetyl derivatives of compounds **vi–viii** are virtually the same as for the acetate of ***v*** and no additional data were obtained for any of these compounds.

Hydrogenation of 3-O,N-Diacetylverarine

The 3-*O*,*N*-diacetylverarine utilized in this reaction was prepared from veratramine (1) and had the following physical constants, m.p. 189–190° (lit. (1) m.p. 189–190°); $[\alpha]_D$ −23 ±2° (ethanol).

A solution of 3-*O*,*N*-diacetylverarine (190 mg) in glacial acetic acid (5 ml) was stirred with Adams' catalyst (PtO_2, 60 mg) in an atmosphere of hydrogen at 20°. After 14 h, 9.1 ml of hydrogen had been consumed and the mixture was filtered to remove the catalyst which was washed with a further 10 ml of acetic acid. The combined filtrates were reduced in volume (to 2 ml) *in vacuo* and diluted with water (30 ml) to give a white precipitate which was taken up in ether. The ethereal phase was washed with water (3 × 10 ml) before drying over anhydrous sodium sulfate. Thin-layer chromatographic examination on both silica gel and alumina using a variety of solvents indicated that a single new compound had been formed.

Removal of the ether *in vacuo* gave an oil which could not be induced to crystallize. A small scale investigation revealed that after selective hydrolysis of the 3-*O*-acetate the product appeared as two components of similar R_f value on a silica gel chromatoplate. Consequently 3-*O*,*N*-diacetyl-5,6-dihydroverarine (170 mg) was refluxed with 0.1 *N* methanolic potassium hydroxide (5 ml) for 1 h, the solution cooled, and then diluted with water (20 ml). The resulting aqueous suspension was extracted with methylene chloride (3 × 10 ml) and the combined extracts washed with water (3 × 10 ml) before drying over anhydrous sodium sulfate. Removal of the solvent *in vacuo* gave a light oil which on trituration with ether gave crystals, m.p. 190–225°. Thin-layer chromatography showed the crystalline product to consist of two compounds which were separated by preparative layer chromatography on silica gel (20 × 20 cm, 0.4 mm, 2% methanol in chloroform). The least polar compound (75 mg) was tentatively assigned the 5β configuration on the basis of its n.m.r. spectrum. Recrystallization from ether gave an analytical sample of *N*-acetyl-5β,6-dihydroverarine (**20**), m.p. 198–199°; i.r. ($CHCl_3$): 6.21 (—NC(=O)—CH) μ; u.v.: λ_{max} 267 (2.74), 276 nm (2.74); n.m.r.; 9.02 (C_{26} methyl, 3H, $J_{26,25}$ = 7 Hz, doublet), 8.94 (angular methyl, 3H, singlet), 8.82 (C_{21} methyl, 3H, $J_{21,20}$ = 8 Hz, doublet) 8.14 (CH_3CON, 3H, singlet), 7.71 (C_{18} methyl, 3H, singlet), 6.45 (C_{20}, 1H, $J_{20,21}$ = 8 and $J_{20,22}$ = 10 Hz, multiplet), 5.97 (*H*—C—OAc, 1H, multiplet), 3.12 (C_{15} or C_{16}, 1H, J = 8 Hz, doublet), 2.96 (C_{15} or C_{16}, J = 8 Hz, doublet); mass spectrometry: *m/e* 437 (M^+), prominent peaks at *m/e* 297, 140, 98.

Anal. Calcd. for $C_{29}H_{43}O_2N$: C, 79.58; H, 9.90; N, 3.20. Found: C, 79.51; H, 10.02; N, 3.25.

The more polar compound was crystallized from ether as prisms, m.p. 249–250°. This compound was tentatively assigned the 5α configuration on the basis of its n.m.r. spectrum and an analytical sample of *N*-acetyl-5α,6-dihydroverarine (**11**) was prepared by sublimation at 220°/0.01 mm, as prisms, m.p. 249–250°; i.r.: 6.22 (N—C(=O)CH_3), 12.23 μ; u.v.: λ_{max} 267 (2.69), 276 nm (2.68); $[\alpha]_D$ +41° (*c*, 0.961); n.m.r.: 9.06, 9.02 (angular and C_{26} methyl, 6H, singlet and doublet), 8.19 (CH_3CON, 3H, singlet), 7.72 (C_{18} methyl, 3H, singlet), 3.13 (C_{15} or C_{16}, 1H, J = 8 Hz, doublet), 2.99 (C_{15} or C_{16}, 1H, J = 8 Hz, doublet); mass spectrometry: *m/e* 437 (M^+), prominent peaks at *m/e* 394, 297, 140.

Anal. Calcd. for $C_{29}H_{43}O_2N$: C, 79.58; H, 9.90. Found: C, 79.32; H, 9.99.

*N-Acetyl-3-keto-5α,6-dihydroverarine (**23**)*

A solution of *N*-acetyl-5α,6-dihydroverarine (**11**; 212 mg) in acetone (75 ml) was treated with Jones' reagent (0.3 ml) and allowed to stand at 20° for 2 min. Isopropanol (2 ml) was added to remove the excess oxidant and the mixture diluted with water (600 ml). The aqueous acetone solution was extracted with methylene chloride (3 × 30 ml) and the combined extracts washed with water (3 × 30 ml) before drying over anhydrous sodium sulfate. Evaporation of the methylene chloride gave a colorless oil (191 mg) which could not be crystallized but appeared homogeneous when examined by thin-layer chromatography. An analytical sample was obtained as a clear glass after sublimation at 185°/0.01 mm; i.r.: 5.89 (saturated carbonyl), 6.14 (N—C(=O)—CH_3) μ; u.v.: λ_{max} 267 (2.73), 276

nm (2.71); $[\alpha]_D$ +66° (*c*, 1.15); o.r.d. $[\phi]^{peak}_{305}$ +1090°, $[\phi]^{trough}_{270}$ +115°, $[\phi]^{peak}_{230}$ +3910°; n.m.r.: 9.03 (C_{26} methyl, 3H, $J_{26,25}$ = 7.0 Hz, doublet), 8.88 (angular methyl, 3H, singlet), 6.45 (C_{20}, 1H, $J_{20,21}$ = 7.5, $J_{20,22}$ = 9.0 Hz, multiplet), 3.13 (C_{15} or C_{16}, 1H, J = 8 Hz, doublet), 2.95 (C_{15} or C_{16}, 1H, J = 8 Hz, doublet); mass spectrometry: *m/e* 435 (M^+), prominent peaks at *m/e* 392, 295, 140, 98.

Mol. Wt. Calcd. for $C_{29}H_{41}O_2N$: 435.313. Found (high resolution mass measurement): 435.312.

*N-Acetyl-Δ⁴-3-keto-5,6-dihydroverarine (**28**)*

A solution of *N*-acetyl-3-keto-5α,6-dihydroverarine (162 mg, 0.372 mmol) in acetic acid (6 ml) containing hydrogen bromide (60 mg, 0.744 mmol) was placed in a dry round-bottom flask. Bromine (130 mg, 0.8 mmol) in acetic acid (5 ml) was added slowly and the mixture stirred at 20° for 20 min and then diluted with water (25 ml). The resulting heavy white precipitate was taken up in methylene chloride and the extract washed with water (3 × 10 ml) prior to drying over anhydrous sodium sulfate. Removal of the solvent *in vacuo* gave a colorless gum (225 mg) which was shown by thin-layer chromatography to consist of one major compound. This crude product was immediately subjected to the conditions of Evans (12) for introduction of the 4,5-double bond as outlined below. Bromine (0.26 ml) was added to acetone (7.5 ml) at 0° and the solution stirred until the color disappeared. Sodium carbonate (0.7 g) was then added and the mixture was stirred for a further 30 min, then filtered directly into hot acetone containing sodium iodide (7.0 g). This solution was refluxed for 15 min during which time a precipitate of sodium bromide was formed.

A portion (6 ml) of the supernatant of this hot solution was added to a round bottom-flask containing 2,4-dibromo ketone (220 mg) and the solution refluxed for 2½ h. During this time more sodium bromide precipitated, indicative of the exchange of the 2-bromine for an iodine atom. Oxalic acid (220 mg) was added as a fine powder and the solution refluxed for a further hour before cooling. The reaction mixture was diluted with ethyl acetate (20 ml) and filtered. This filtrate was washed with water (2 × 10 ml), saturated aqueous sodium hydrogen carbonate (2 × 10 ml), and water (2 × 10 ml). The ethyl acetate was decolorized by adding zinc dust (600 mg) and acetic acid (0.2 ml) and then shaking. When the solution had attained a light yellow color the zinc dust was removed by filtration and the ethyl acetate filtrate washed with water (2 × 10 ml), sodium hydrogen carbonate solution (2 × 10 ml), and water (2 × 10 ml) before drying over anhydrous sodium sulfate.

Removal of the ethyl acetate *in vacuo* gave a light yellow gum (158 mg) which was examined by thin-layer chromatography. The spot on the chromatoplate corresponding to the major product exhibited an intense fluorescence under u.v. light and appeared purple when the plate was sprayed with antimony pentachloride – carbon tetrachloride reagent. Preparative layer chromatography on silica gel (20 × 60 cm, 0.4 mm, developed twice with 1% methanol in chloroform) gave this compound as a light gum (110 mg, 50% yield) which was not crystallized. An analytical sample was prepared by sublimation at 180°/0.01 mm which gave a light yellow glass; i.r.: 6.03 (α,β-unsaturated carbonyl), 6.14 (N—Ac) μ; $[\alpha]_D$ +74° (*c*, 1.26); n.m.r.: 9.02 (C_{26} methyl, 3H, $J_{26,25}$ = 7 Hz, doublet), 8.72 (angular methyl, 3H, singlet), 8.18 (CH_3C—N, 3H, singlet), 6.45 (C_{20}, 1H, $J_{20,21}$ = 7.5, $J_{20,22}$ = 10 Hz, multiplet), 4.22 (C_4, 1H, singlet), 3.10 (C_{15} or C_{16}, 1H, J = 8Hz, doublet), 2.94 (C_{15} or C_{16}, 1H, J = 8Hz, doublet); mass spectrometry: *m/e* 433 (M^+), prominent peaks at *m/e* 390, 293, 140, 98.

Mol. Wt. Calcd. for $C_{29}H_{39}O_2N$: 433.2980. Found (high resolution mass measurement): 433.2974.

*N-Acetylverarine (**30**)*

A solution of *N*-acetyl-Δ⁴-3-keto-5,6-dihydroverarine (100 mg) in isopropenyl acetate (3 ml) containing 0.5% sulfuric acid was refluxed for 1 h. Anhydrous sodium acetate (60 mg) was then added and most of the isopropenyl acetate removed by use of a rotary evaporator. The residue was diluted with methylene chloride (10 ml) and then filtered. Thin-layer chromatography of the filtrate indicated the complete absence of (**23**) and the formation of a less polar compound. Evaporation of the methylene chloride gave an oil (100 mg) the i.r. spectrum of which exhibited a carbonyl band at 5.75 μ indicative of an enol acetate.

This oil was dissolved in a mixture of methanol (10 ml) and ether (3 ml) and heated to reflux. During the refluxing a methanolic solution of sodium borohydride (150 mg in 5 ml) was added slowly over a period of 15 min. The solution was refluxed for a further 1 h and then concentrated hydrochloric acid (1 ml) was added and the refluxing continued with stirring for 30 min. During this final period vigorous stirring was necessary to overcome severe bumping.

The reaction mixture was cooled and then diluted with ether (50 ml). The ethereal solution was washed with water and then dried over anhydrous sodium sulfate. Removal of the solvent gave a light oil (70 mg) which was shown to contain a compound of identical R_f value to that of *N*-acetylverarine. Separation by preparative layer chromatography (20 × 20 cm, 0.3 mm, 2% methanol in chloroform) and extraction of the band corresponding to this product yielded an oil (30 mg). This compound was shown to be identical with *N*-acetylverarine by thin-layer chromatography and superimposable i.r. and n.m.r. spectra; i.r. ($CHCl_3$): 6.19 ($NC(=O)CH_3$) μ; u.v.: λ_{max} 268 (2.76) 277 nm (2.65); n.m.r.: 9.03 (C_{26} methyl, 3H, $J_{26,25}$ = 7 Hz, doublet), 8.87 (angular methyl, 3H, singlet), 8.18 (CH_3CON, 3H, singlet), 4.56 (C_6 1H, multiplet), 3.12 (C_{15} or C_{16}, 1H, J = 8 Hz, doublet,), 2.94 (C_{15} or C_{16}, 1H, J = 8 Hz, doublet); mass spectrometry: *m/e* 435 (M^+), prominent peaks at *m/e* 295, 140, 98.

*Verarine (**31**)*

A solution of *N*-acetylverarine (20 mg) in ethylene glycol (5 ml) containing 10% potassium hydroxide was refluxed for 12 h. The reaction mixture was cooled, diluted with water (20 ml), and extracted with methylene chloride (3 × 5 ml). Examination of the extract by thin-layer chromatography indicated the presence of *N*-acetylverarine and a more polar compound which had the same R_f value and color reaction to the spray reagent, as an authentic sample of verarine. The more polar compound was separated by preparative layer chromatography (20 × 20 cm, 0.3 mm, 5% methanol in chloroform) as a light oil

For personal use only.

(8 mg) which crystallized from ether. This compound was shown to be identical with verarine by thin-layer chromatography, i.r., and n.m.r. comparison; i.r. ($CHCl_3$): 9.57 μ; u.v.: λ_{max} 267 (2.74) 276 nm (2.73); n.m.r.: 9.15 (C_{26} methyl, 3H, $J_{26,25}$ = 6 Hz, doublet), 8.88 (angular methyl, 3H, singlet), 7.73 (C_{18} methyl, 3H, singlet), 4.55 (C_6, 1H, broad doublet), 3.02 (C_{15} and C_{16}H, 2H, singlet); mass spectrometry: *m/e* 393 (M^+), prominent peaks at *m/e* 392, 376, 295, 284, 256, 98.

Mol. Wt. Calcd. for $C_{27}H_{39}ON$: 392.2953. Found (high resolution mass measurement): 392.2922.

*3-Methylbut-3-enal Diethyl Acetal (**40**)*

This compound was prepared according to the procedure of Cornforth and Firth (23) with small modifications as indicated. The additional data obtained in our investigations in this and the next few experiments are also provided. Triethyl orthoformate (45 g) and magnesium (17.5 g) were stirred and heated at 60°. 2-Methylallyl chloride (24.5 g) was then added gradually (about 2.5 h) and the reaction mixture left overnight. The flask was cooled in ice and saturated aqueous ammonium chloride (20 ml) was added dropwise until the mixture set solid; the cake was filtered and washed well with ether. The filtrate on work-up afforded the acetal (**40**, 19 g), b.p. 60–61°/20 mm (lit. (25) b.p. 60°/19 mm). The compound was found to be pure by v.p.c. examination using a FFAP column; i.r. (film): 6.25 μ; n.m.r. 8.85 (2 × CH_3—CH_2, 6H, triplet), 8.25 (C_2—CH_3, 3H, singlet), 7.7 (C_3—CH_2, 2H, doublet, J = 6.0 Hz), 6.5 (CH_2's of —O—CH_2—CH_3, 4H, multiplet), 5.4 (C_4H, 1H, triplet), 5.2 (CH_2=C<, 2H, singlet).

*3,4-Epoxy-3-methylbutanal Diethyl Acetal (**41**)*

A solution of 3-methylbut-3-enal diethyl acetal (**40**, 6.6 g) in anhydrous ether (10 ml) was cooled in ice and treated gradually with a solution of *m*-chloroperbenzoic acid (9 g) in ether (30 ml). The reaction mixture was then allowed to warm up and kept at 30° by occasional cooling until the reaction subsided. Next day the reaction mixture was washed repeatedly with saturated sodium bicarbonate solution until the whole of *m*-chlorobenzoic acid was removed. The ether layer was separated and dried over magnesium sulfate. The solvent was removed under reduced pressure and distillation of the residual liquid afforded the epoxide (**41**) as a colorless oil (4.1 g), b.p. 82–86°/18 mm (lit. (22) b.p. 83–84°/17 mm). The compound was found to be homogeneous by v.p.c. examination; i.r. (film): 10.0, 10.5, 12.5 μ (epoxide); n.m.r.: 8.85 (2 × CH_3—CH_2—O—, 6H, triplet), 8.7 (C_3—CH_3, 3H, singlet), 8.2 (C_2—CH_2, 2H, doublet, J = 7.0 Hz), 7.5 (O<, 2H, AB quartet, $J_{A,B}$ = 5.5 Hz), 6.5 (CH_2's of —O—CH_2—CH_3, 4H multiplet), 5.4 (C_1H, 1H, triplet).

*3-Methylfuran (**42**)*

A mixture of 3,4-epoxy-3-methylbutanal diethyl acetal (**41**, 5.0 g) and 0.1 *N* sulfuric acid (500 ml) were heated under a fractionating column for 3 h, the methylfuran and ethanol being removed intermittently by distillation. The distillate was washed once with half-saturated aqueous calcium chloride (10 ml) and twice with saturated aqueous ammonium chloride, dried over sodium, and redistilled to give pure 3-methylfuran (1.1 g); b.p. 65–66° (lit. (22) b.p. 65–65.5°); i.r. (chloroform): 6.67, 8.33, 11.2 μ; n.m.r.: 8.0 (C_3—CH_3, 3H, singlet), 3.85 (C_4H, 1H, singlet), 2.87 (C_2H, 1H, broad singlet), 2.75 (C_5H, 1H, broad singlet).

Propionylation of 3-Methylfuran

3-Methylfuran (1 g) and propionic anhydride (1.6 g) were mixed and to the mixture 2 drops of orthophosphoric acid (85%) were added. The mixture was stirred vigorously and the heat generated was removed by cooling. Gradually the reaction mixture acquired a dark red color. It was then heated to 60–65° and maintained at this temperature for 2 h. The reaction mixture was then cooled and stirred with water (2 ml) for 1 h. The dark organic layer was separated and again stirred with saturated sodium carbonate solution (5 ml) for 24 h. It was then washed thoroughly with water, extracted with ether (2 × 5 ml), and dried over magnesium sulfate. The solvent was removed under reduced pressure and the residual reddish brown oil obtained was distilled *in vacuo* in a hot box. A colorless fragrant liquid (0.5 g) was collected, b.p. 125–130°/25 mm. The i.r. spectrum (film) of the product showed a double carbonyl absorption (~5.88 μ). Examination of this material by v.p.c. using a FFAP column (172°) indicated that it was a mixture of two compounds in the ratio 70:30, with retention times 1.8 and 2.8 min, respectively. These were separated by v.p.c. using a FFAP column (172°). The major component was characterized as 2-propionyl-3-methylfuran (**43**), b.p. 77–80°/5 mm; i.r. (film): 5.99, 6.65, 11.3 (furan) μ; u.v.: λ_{max} 278, 230 nm; n.m.r.: 8.85 (CH_3—CH_2—, 3H, triplet), 7.65 (C_3—CH_3, 3H, singlet), 7.2 (—CO—CH_2—CH_3, 2H, quartet), 3.65 (C_4H, 1H, doublet, $J_{4,5}$ = 2.5 Hz), 2.65 (C_5H, doublet, $J_{4,5}$ = 2.5 Hz); mass spectrometry: *m/e* 138 (M^+), prominent peak at *m/e* 109.

Anal. Calcd. for $C_8H_{10}O_2$: C, 69.56; H, 7.24. Found: C, 69.71; H, 7.27.

The second component was characterized as 2-propionyl-4-methylfuran (**44**), b.p. 78–82°/5 mm; i.r. (film): 5.97, 6.65, 11.3 μ; u.v.: λ_{max} 280, 230 nm; n.m.r.: 8.85 (CH_3—CH_2—, 3H, triplet), 7.9 (C_4CH_3, 3H, singlet), 7.2 (—CO—CH_2—CH_3, 2H, quartet), 3.05 (C_3H, 1H, singlet), 2.75 (C_5H, 1H, broad singlet); mass spectrometry: *m/e* 138 (M^+), prominent peak at *m/e* 109.

Anal. Calcd. for $C_8H_{10}O_2$: C, 69.56; H, 7.24. Found: C, 69.68; H, 7.26.

*Methyl 5,5-Dimethoxy-3-methyl-2,3-epoxypentanoate (**45**)*

This compound was prepared according to the procedure of Burness (25).

*Methyl 3-Methyl-2-furoate (**46**)*

This compound was prepared according to the procedure of Burness (25); i.r. (chloroform): 5.80 μ; u.v.: λ_{max} 252 nm; n.m.r.: 7.65 (C_3—CH_3, 3H, singlet), 6.2 ($COOCH_3$, 3H, singlet), 3.68 (C_4H, 1H, doublet, J = 2.0 Hz), 2.6 (C_5H, 1H, doublet, J = 2.0 Hz).

*Methyl 3-Methyl-5-propionyl-2-furoate (**47**)*

Methyl 3-methyl-2-furoate (25.6 g, 0.2 mol) was dissolved in propionic anhydride (75 ml) and orthophosphoric acid (7.0 g) was added to it with vigorous stirring. The heat generated was removed by cooling with ice. The reaction mixture was then stirred at 65–70° for 48 h. It

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

was then cooled and stirred into water. The dark brown organic layer was extracted with chloroform and the chloroform extract was washed with bicarbonate solution until neutral to litmus and dried over sodium sulfate. The solvent was distilled off under reduced pressure. The unreacted starting materials were removed by distillation *in vacuo* and the semisolid residue was distilled at 120°/0.3–4 mm. A pale yellow crystalline material was collected in the receiver (23.5 g), m.p. 109–111°. It was recrystallized from aqueous ethanol (70%), colorless shining needles, m.p. 113–114°; i.r. (chloroform): 5.73, 5.88 μ; u.v.: λ_{max} 280, 285sh, 212 nm; n.m.r.: 8.8 (—CH_2—CH_3, 3H, triplet), 7.65 (C_3CH_3, 3H, singlet), 7.2 (—CO—CH_2—, 2H, quartet), 6.1 (—$COOCH_3$, 3H, singlet), 3.0 (C_5H, 1H, singlet); mass spectrometry: *m/e* 196 (M^+), prominent peaks at *m/e* 167, 138, 123, 109.

Anal. Calcd. for $C_{10}H_{12}O_4$: C, 61.22; H, 6.12. Found: C, 61.01; H, 5.97.

*3-Methyl-5-propionyl-2-furoic Acid (**48**)*

A solution of methyl 3-methyl-5-propionyl-2-furoate (**47**, 9.8 g) in aqueous sodium hydroxide (10%, 100 ml) was heated under reflux for 1.5 h. The solution was then cooled and acidified with concentrated hydrochloric acid and stirred for a few minutes. The product which separated as a brown granular solid was collected by filtration. It was washed with a little ice cold water and dried *in vacuo*. Crystallization from methanol afforded pale yellow shining prisms (7.6 g), m.p. 179–181°; i.r. (chloroform): 5.67, 5.88 μ; u.v.: λ_{max} 282, 212 nm; n.m.r.: 8.8 (CH_3—CH_2—, 3H, triplet), 7.6 (C_3CH_3, 3H, singlet), 7.0 (—CH_2—CO—, 2H, quartet), 2.85 (C_4H, 1H, singlet), −0.2 (—COOH, 1H, singlet); mass spectrometry: *m/e* 182 (M^+), prominent peak at *m/e* 137.

Anal. Calcd. for $C_9H_{10}O_4$: C, 59.33; H, 5.49. Found: C, 59.21; H, 5.50.

*2-Propionyl-4-methylfuran (**44**)*

A mixture of 3-methyl-5-propionyl-2-furoic acid (9.1 g, 0.05 mol), anhydrous quinoline (20 ml), and powdered copper (2.0 g) was heated 200–210° under a nitrogen atmosphere for 3 h. The evolution of carbon dioxide ceased by this time and the reaction mixture was extracted with chloroform (50 ml). The chloroform extract was filtered to remove the copper powder and washed successively with 1 *N* hydrochloric acid (3 × 50 ml), water (100 ml), and finally with sodium bicarbonate solution until neutral to litmus. It was then dried over sodium sulfate and the solvent was distilled off under reduced pressure. The residual dark oil was distilled using a short fractionating column. The fraction boiling at 78–82°/5 mm was collected as a colorless fragrant liquid (5.4 g). Examination of the compound by t.l.c. and v.p.c. indicated that it was pure. The physical and spectral data of the compound were identical with those of **44** obtained by the propionylation of 3-methylfuran.

*2-Ethyl-3-hydroxy-5-methylpyridine (**49**)*

2-Propionyl-4-methylfuran (**44**; 1.0 g) and aqueous ammonia (11 *N*, 25 ml), were heated in a sealed tube for 20 h (18). The reaction mixture was filtered off the residual solid matter and the filtrate was evaporated to dryness under a stream of nitrogen. The residue was extracted with chloroform and dried. The solvent was removed under reduced pressure and the dark brown semisolid residue distilled at 150°/0.3–5 mm. A small quantity of pale yellow liquid which collected in the receiver soon solidified into shining prisms (202 mg), m.p. 140–144°. Crystallization from chloroform provided an analytical sample as colorless shining prisms, m.p. 145–147°; i.r. (chloroform): 3.11, 6.29 μ; u.v.: λ_{max} (log ε): 287 (3.95), 225sh nm; n.m.r.: 8.75 (CH_3—CH_2—, 3H, triplet), 7.8 (C_5CH_3, 3H, singlet), 7.1 (—CH_2—CH_3, 2H, quartet), 2.9 (C_4H, 1H, singlet), 2.1 (C_6H, 1H, singlet), 1.0 (C_3OH, 1H, multiplet); mass spectrometry: *m/e* 137 (M^+), prominent peaks at *m/e* 136, 121, 94, 93.

Anal. Calcd. for $C_8H_{11}NO$: C, 70.07; H, 8.02. Found: C, 70.11; H, 8.10.

*2-Ethyl-3-O-benzyl-5-methylpyridine (**50**)*

2-Ethyl-5-methyl-3-hydroxypyridine (274 mg, 0.002 mol) was dissolved in aqueous sodium hydroxide (5%, 10 ml) and benzyl chloride (240 mg, 0.002 mol) was added to it. The mixture was heated at 100° for 2.5 h. During this time the benzyl chloride gradually dissolved and a pale yellow oil separated in the flask. The reaction mixture was cooled and extracted with chloroform (2 × 10 ml). The chloroform extract was washed with water until neutral to litmus and dried over sodium sulfate. The residual oil obtained after the removal of the solvent was distilled *in vacuo*. A colorless oil collected in the receiver (228 mg), b.p. 118–120°/0.4–5 mm. Thin-layer chromatography on alumina indicated that the compound was pure; i.r. (film): 6.27, 7.87, 9.52 μ; u.v.: λ_{max} 285, 225sh nm; n.m.r.: 8.8 (CH_3—CH_2—, 3H, triplet), 7.75 (C_5CH_3, 3H, singlet), 7.2 (—CH_2—CH_3, 2H, quartet), 5.0 (—O—CH_2—C_6H_5, 2H, singlet), 3.15 (C_4H, 1H, singlet), 2.65 (C_6H_5—CH_2—O—, 5H, singlet), 2.1 (C_6H, 1H, singlet).

*2-Ethyl-3-methoxy-5-methylpyridine (**51**)*

A solution of 2-ethyl-3-hydroxy-5-methylpyridine (2.74 g, 0.02 mol) in methanol (40 ml) containing 10% water was chilled in an ice-salt bath. To this was added a solution of diazomethane (4.2 g, 0.1 mol) in ether (175 ml) with constant swirling from a dropping funnel, the stem of which projected below the surface of the liquid. A brisk effervescence accompanied the addition which was interrupted several times in order to boil off the accumulated ether. The latter procedure serves to keep the polarity of the solution at a maximum. After being allowed to stand overnight, the methanolic solution was acidified with hydrochloric acid and most of the ether and methanol removed by concentration on the steam bath. The resulting syrup was diluted with water and the solution exhausted with ether. It was then made alkaline with sodium hydroxide pellets and again extracted with ether (3 × 100 ml). This second extract was dried over potassium carbonate, the ether removed by distillation, and the residual oil distilled *in vacuo*. The product (2.01 g) was a colorless oil, b.p. 100°/10 mm.

Some of the starting material was recoverable by the following procedure. The alkaline solution after exhaustion with ether was neutralized and evaporated to dryness followed by extraction with chloroform. Removal of the chloroform afforded a dark brown solid (480 mg) which was identified as 2-ethyl-3-hydroxy-5-methylpyridine (**49**).

The methyl ether was characterized as follows; i.r. (film): 6.26, 6.41, 7.91, 9.52 μ; u.v.: λ_{max} (log ε): 283 (3.86), 2.25sh nm; n.m.r.: 8.8 (CH_3—CH_2—, 3H, triplet),

*23-Methoxy-22,27-iminojerva-12(13),22,24,27-tetraene-3β-17-diol(s) (**53**)*

An ether solution (7.0 ml) of 2.0 *M* methyl lithium was added to anhydrous tetrahydrofuran (50 ml) in a dry round bottom flask which had been flushed with nitrogen. A solution of 2.0 *M* 2-ethyl-3-methoxy-5-methylpyridine (6.9 ml) was added immediately and the mixture refluxed for 1 h. A deep red color slowly developed in the solution. It was then cooled and 3β-acetoxy-5α-etiojerv-12(13)-en-17-one (**1**) was added as a fine powder until the color faded (800 mg). The mixture was stirred under reflux for a period of 20 min. Saturated ammonium chloride solution (20 ml) was added cautiously while the mixture was still under nitrogen. Ether (50 ml) was added to the reaction mixture and the organic phase washed with water before drying over sodium sulfate. Evaporation of the solvent *in vacuo* gave a pale yellow oil (1.1 g) which appeared primarily as one spot when examined by thin-layer chromatography; (canary yellow spot when the chromatoplate is developed with antimony pentachloride – carbon tetrachloride spray reagent). Column chromatography on alumina (55 g, activity III) eluting with 50% ligroin in benzene removed the unreacted pyridine (**51**). Continued elution with benzene removed the unreacted enone (**1**). The desired condensation product was eluted with 5% chloroform in benzene. Evaporation of the solvent afforded 23-methoxy-22,27-iminojerva-12(13),22,24,27-tetraene-3β,17-diol(s) as a pale yellow oil which crystallized from 5% chloroform in ether (700 mg), m.p. 209–214°. The spectral data indicated that the product is a mixture of two compounds of gross structure, **53**; i.r. (chloroform): 3.05, 6.27 μ; u.v.: λ_{max} (log ε) 283.5 nm (3.86); n.m.r.: 9.22 ($C_{19}CH_3$, 3H, singlet), 8.84, 8.81 ($C_{21}CH_3$, 3H, two overlapping doublets $J_{20,21}$ = 7.0 Hz), 6.24, 6.21 (—OCH_3, 3H, two singlets), 3.10 ($C_{24}H$, 1H, singlet), 2.04 ($C_{27}H$, 1H, singlet); mass spectrometry: *m/e* 421 (M^+), prominent peaks at *m/e* 406 and 288.

*Acetylation of 23-Methoxy-22,27-iminojerva-12(13),22,24,27-tetraene-3β,17-diols (**53**)*

A mixture of acetic anhydride and pyridine (1:1, 5 ml) was added to the condensation product (**53**; 390 mg) obtained in the above experiment and left overnight at room temperature. The solution was then poured into crushed ice and the resultant oil was extracted with ether (3 × 20 ml). The combined ether extracts were washed with saturated sodium bicarbonate solution and several times with water before drying over sodium sulfate. The solvent was distilled off *in vacuo* when a pale yellow semisolid residue (330 mg) was obtained. Thin-layer chromatographic examination of the product revealed the presence of two compounds with very different R_f values. The less polar compound appeared as an orange-yellow spot when the chromatoplate was developed with antimony pentachloride reagent, while the second component appeared as a canary yellow spot. This mixture of acetates was separated by column chromatography on alumina (30 g, activity III). Elution with benzene afforded the less polar compound (designated as compound **F**) in essentially pure state (125 mg). Further elution with 5% chloroform afforded the second component (designated as compound **E**, 191 mg).

An analytical sample of **E** was prepared by crystallization from 5% chloroform in ether whereupon colorless shining prisms were obtained, m.p. 181–182°; i.r.: 3.05, 5.84, 6.25, 6.39 μ; u.v.: λ_{max} (log ε) 284 nm (3.86); n.m.r.: 9.22 ($C_{19}CH_3$, 3H, singlet), 8.82 ($C_{21}CH_3$, 3H, doublet, $J_{20,21}$ = 7.0 Hz), 8.79 ($C_{18}CH_3$, 3H, singlet), 8.0 ($OCOCH_3$, 3H, singlet), 7.7 ($C_{26}CH_3$, 3H, singlet), 6.22 (OCH_3, 3H, singlet), 3.90 ($C_{17}OH$, 1H, broad multiplet, disappears on D_2O addition), 3.08 ($C_{24}H$, 1H, singlet), 2.0 ($C_{27}H$, 1H, singlet); mass spectrometry: *m/e* 463 (*M* − 18), prominent peaks at *m/e* 448, 330, 288, 255, 146.

Anal. Calcd. for $C_{30}H_{41}NO_3$: C, 74.84: H, 8.94. Found: C, 74.65; H, 8.97.

Compound **F**, on the other hand, could not be induced to crystallize. An analytical sample of this material was prepared by subliming a small amount of **B** at 170°/0.2 mm, when a colorless glassy solid was obtained; i.r.: 5.83, 6.27, 6.39 μ; u.v.: λ_{max} (log ε) 283.5 nm (4.03); n.m.r.: 9.08 ($C_{19}CH_3$, 3H, singlet), 8.45 ($C_{21}CH_3$, 3H, doublet, $J_{20,21}$ = 7.0 Hz), 8.0 ($OCOCH_3$, 3H, singlet), 7.7 ($C_{18}CH_3$ and $C_{26}CH_3$, 6H, singlet), 6.3 ($C_{23}OCH_3$, 3H, singlet), 3.05 ($C_{15}H$ and $C_{16}H$, 2H, AB quartet, $J_{15,16}$ = 7.0 Hz), 3.16 ($C_{24}H$, 1H, singlet), 2.0 ($C_{27}H$, 1H, singlet); mass spectrometry: *m/e* 461 (*M* − 20), prominent peaks at *m/e* 461, 446, 432, 298, 150.

Anal. Calcd. for $C_{30}H_{39}NO_3$ (mol. wt. 461.293): C, 78.09; H, 8.45. Found (high resolution mass measurement, 461.291): C, 77.78; H, 8.47.

*3β-Acetoxy-23-methoxy-22,27-iminojerv-12(13),14(15),16(17),22,24,27-hexaene: Compound **G** (**57**)*

Compound **E** (**54**; 150 g) was thoroughly ground with 10% palladized charcoal (37 mg) until a homogeneous powder was obtained. This powder was heated at 200° under nitrogen for 7 min and the resultant solid residue washed several times with chloroform. Thin-layer chromatography of the chloroform extract indicated that the product contained three major components and these were separated on preparative layer plates (20 × 20 cm, 0.4 mm, chloroform). One of these three components was shown to be 2-ethyl-3-methoxy-5-methylpyridine (**51**) by n.m.r. The second band on extraction yielded a light oil which crystallized from acetone – petroleum ether as needles, m.p. 167°. This compound was identified as 3β-acetoxy-5α-etiojerv-12(13)-en-17-one (**1**) by its u.v. spectrum and mixture m.p. with an authentic sample. The third component which appeared as a light orange yellow spot when the chromatoplate was developed with antimony pentachloride – carbon tetrachloride reagent was extracted to yield a light oil which could not be induced to crystallize. An analytical sample of this compound, designated as compound **G** was obtained as a clear glass after distillation at 170°/0.1 mm; i.r.: 5.84, 6.27, 6.39 μ; u.v.: λ_{max} (log ε) 283.5 nm (4.04); n.m.r.: 9.07 ($C_{19}CH_3$, 3H, singlet), 8.4 ($C_{21}CH_3$, doublet, $J_{20,21}$ = 7.0 Hz), 8.0 ($OCOCH_3$, 3H, singlet), 7.74 ($C_{18}CH_3$ and $C_{26}CH_3$, 6H, singlet), 6.3 (OCH_3, 3H, singlet), 3.1 ($C_{15}H$ and $C_{16}H$, AB quartet, $J_{15,16}$ = 8.0 Hz), 3.18 ($C_{24}H$, 1H, singlet), 2.02 ($C_{27}H$, 1H, singlet); mass spectrometry: *m/e* 461 (M^+), prominent peaks at *m/e* 461, 446, 432, 298, 150.

Anal. Calcd. for $C_{30}H_{39}O_3$ (mol. wt. 461.293): C,

78.09; H, 8.45. Found (high resolution mass measurement, 461.293): C, 77.80; H, 8.46.

5α,6-Dihydroveratramine (56)

A solution of compound **F** (45 mg) in 95% ethanol (10 ml) containing 2% 12 *N* hydrochloric acid was stirred with Adams' catalyst (PtO_2, 20 mg) at 20° for 18 h. The mixture was filtered to remove the catalyst which was carefully washed with additional ethanol (5 ml). The combined extracts were neutralized with sodium bicarbonate solution and then reduced in volume to 2 ml *in vacuo*. It was diluted with water and extracted with chloroform (3 × 10 ml) before drying over sodium sulfate. Thin-layer chromatography on silica gel G (6% methanol in chloroform) revealed the presence of three major compounds. The two less polar components had similar R_f values, while the third compound had an R_f value identical with that of 5α,6-dihydroveratramine. Besides these three compounds, there were several other compounds present in the product mixture in trace amounts. The three major components were separated by thick-layer chromatography on neutral alumina (20 × 20 cm, 0.4 mm, 3% methanol in chloroform, plates developed three times). Extraction of the bands followed by the usual work-up afforded the two less polar compounds as pale yellow oils. The third compound, with an R_f value corresponding to that of 5α,6-dihydroveratramine, was obtained crystalline from 5% methanol in chloroform as colorless fluffy crystals (8 mg), m.p. 198°. This material was characterized as 5α,6-dihydroveratramine; undepressed m.p. (197–198°) and identical i.r., n.m.r., and mass spectra with an authentic sample.

The two less polar components obtained (17 and 13 mg, respectively) were found to be very unstable and hence no detailed investigation of these were carried out. A preliminary examination of the n.m.r. spectra revealed that the pyridine ring was only partially reduced in both the compounds (signals at 3.8 and 4.2) while the 23-methoxyl group was intact (signal at 6.3).

The 7-Cycloheptatrienylmethyl/7-Norcaradienylmethyl Cation System[1]

IVAN PIKULIK AND RONALD F. CHILDS[2]
Department of Chemistry, McMaster University, Hamilton, Ontario L8S 4M1
Received November 11, 1974

IVAN PIKULIK and RONALD F. CHILDS. Can. J. Chem. 53, 1818 (1975).

Reaction of 7-carbomethoxycycloheptatriene with either BCl_3 or BBr_3 gave a 1:1 complex in which the Lewis acid was complexed to the carbonyl oxygen. The low temperature p.m.r. and u.v. spectra of these zwitterions indicated that they existed almost entirely in the norcaradiene forms **10** and **14**, respectively. In contrast, reaction of *N,N*-dimethyl-1,3,5-cycloheptatriene-7-carboxamide with BCl_3 was found to result in the formation of a mixture of the cycloheptatriene **12** (65%) and norcaradiene **13** (35%). Comparison of the chemical shifts of the cyclopropyl proton resonances of **10** and **14** with model compounds showed that their positions were anomolous, the C_7 protons resonating at much higher and the C_1 and C_6 protons resonating at much lower field than expected and to account for this it is suggested that these norcaradienes are aromatic systems. Both **10** and **14** were thermally unstable and underwent an irreversible rearrangement to form the complex of methyl phenylacetate, the phenylmethylacylium cation and the appropriate counterion, $CH_3O\bar{B}Cl_3$ or $CH_3O\bar{B}Br_3$, respectively. The rate of these rearrangements and the product distribution was found to be dependent upon both the ratio of Lewis acid to ester used and the nature of the Lewis acid.

IVAN PIKULIK et RONALD F. CHILDS. Can. J. Chem. 53, 1818 (1975).

La réaction du carbométhoxy-7 cycloheptatriène avec soit le BCl_3 soit le BBr_3 donne un complexe 1:1 dans lequel l'acide de Lewis est complexé à l'oxygène du carbonyle. Les spectres r.m.n. et u.v. à basse température de ces ions hermaphrodites indiquent qu'ils existent presque entièrement dans les formes respectives **10** et **14** du norcaradiène. Par opposition avec ces résultats, la réaction de la *N,N*-diméthylcycloheptatriène-1,3,5 carboxamide-7 avec BCl_3 conduit à la formation d'un mélange de cycloheptatriène **12** (65%) et de norcaradiène **13** (35%). La comparaison des déplacements chimiques des résonances des protons du cyclopropyle de **10** et **14** avec ceux de composés modèles montrent que leurs positions sont anormales; les protons C_7 présentent une résonance à des champs beaucoup plus haut et les protons en C_1 et C_6 présentent des résonances à des champs beaucoup plus bas que ceux attendus et pour tenir compte de ces résultats, on suggère que ces norcaradiènes sont des systèmes aromatiques. Les composés **10** et **14** sont thermiquement instables et subissent des réarrangements irréversibles pour former respectivement le complexe du phénylacétate de méthyle, le cation phénylméthylacylium et l'ion antagoniste approprié $CH_3O\bar{B}Cl_3$ ou $CH_3O\bar{B}Br_3$. On a trouvé que les vitesses de ces réarrangements et la distribution des produits dépendent à la fois du rapport d'acide de Lewis l'ester utilisé et de la nature de l'acide de Lewis. [Traduit par le journal]

Just as the monocyclic $(CH)_n^+$ cations, such as the cyclopropenium (1), cyclopentadienyl (2), and tropylium (3) cations, have been important in the development of the concept of aromaticity, so their monohomo counterparts, **1**, **2**, and **3**, have been of consequence in the evolution of the concepts of homoaromaticity (4). More recently, following the observation of a degenerate circumambulation of the cyclopropane around the periphery of the five-membered ring of **2** and its derivatives (5), cations **1**, **2**, and **3** have taken on a new significance in terms of the importance of orbital symmetry control of a molecular rearrangement. The degenerate rearrangement exhibited by **2**, which can be regarded as a 1,4 sigmatropic shift, takes place with a very high stereoselectivity in just that mode demanded by the dictates of orbital symmetry (6). The transition state for the rearrangement can be regarded as the cyclopentadienylmethyl cation **4**, in which, despite the overlap of the formally vacant p orbital on C_6 with the diene unit, a substantial fraction of the positive charge is localized on this carbon (5).

While comparable rearrangements of **1** and **3** have been considered from a theoretical viewpoint, as yet they have not been detected experimentally (7, 8). For example, with **3** and its

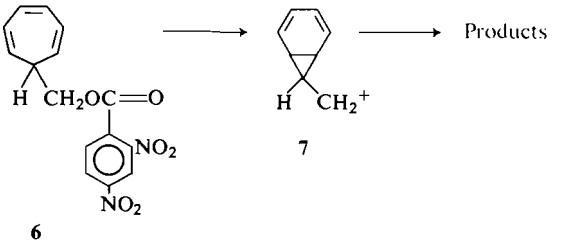
derivatives, competing reactions such as ring contraction or decomposition set in before the onset of any degenerate rearrangement. By analogy with the circumambulatory isomerization of **2**, a cycloheptatrienyl cation might well be expected to be involved in a degenerate rearrangement of **3**. However, as yet no consideration has been given to the importance of the structure and properties of a cation such as **5** in determining the possible occurrence of a degenerate isomerization of a homotropylium cation.

Information about the cycloheptatrienylcarbinyl cation, available at the outset of this work, derived very largely from the results of a solvolytic study of **6** reported by Sargent *et al.* (9), and a number of others (10).[3] It was suggested by Sargent that the cation involved in this solvolysis was **7** rather than **5** and that no products derived from the homotropylium cation, which could have been formed by rearrangement of **5**, could be detected. Factors affecting the position of the equilibrium between cycloheptatriene and norcaradiene valence tautomers, such as **5** and **7**, have recently been considered by both Hoffmann (11) and Günther (12) and it was pointed out that a carbonium ion center attached to C_7 should very effectively stabilize the bicyclic form.

To examine the question of the structure of **5** and whether degenerate migrations of C_8 of a homotropylium cation can occur or not, we have attempted the preparation of some 7-cycloheptatrienylmethyl cations. As previously it had been shown to be possible to prepare derivatives of **4** by reaction of a 5-acylcyclopentadiene with strong Lewis acids (12), the extension of these techniques to cycloheptatriene derivatives has been investigated. We report here on the preparation of derivatives of **5** and **7**, on the role of the C_7 substituents in determining the equilibrium position, on the thermal rearrangement of these cations, and on the possible aromatic nature of **7**. Recently in a series of papers Betz and Daub (14) have reported the preparation of some differently substituted derivatives of these cations and in some respects our results parallel their findings.



6 7

Results and Discussion

Treatment of a CD_2Cl_2 solution of 7-carbomethoxycycloheptatriene, **8**, with BCl_3 in CD_2Cl_2 at $-60°$ resulted in the quantitative formation of a 1:1 complex of the ester and Lewis acid. The low temperature p.m.r. spectrum of the complex was independent of the ratio of the Lewis acid to ester used provided that there was at least a molar equivalent of the acid present. The complex was found to be stable at low temperatures and could be reacted with dimethylamine to regenerate **8** in high yield.

*In p.p.m. from TMS using $CHCl_3$ (taken as 7.30) as a secondary standard for the solutions of the zwitterions.
†Numbering schemes of cycloheptatriene maintained so as to facilitate comparison (ester grouping is then assumed to be attached to C_7).

The p.m.r. spectrum of the complex (Table 1 and Fig. 1) was completely consistent with the formation of a zwitterion in which the Lewis acid has reacted with the carbonyl oxygen of the ester. For example, the resonance attributable to the methoxy group is deshielded by the appropriate amount on reaction with BCl_3 and the signals due to the ring protons retain their plane of symmetry. It is also clear from the resonance position of the ring protons that the complex cannot be simply regarded as having the structure **9** but must be very largely in the norcaradiene form **10**. Thus the signals of the hydrogens in C_1, C_6, and C_7 all occur at considerably higher field than those of **8** and appear in similar regions to those encountered for other norcaradienes (14, 15).

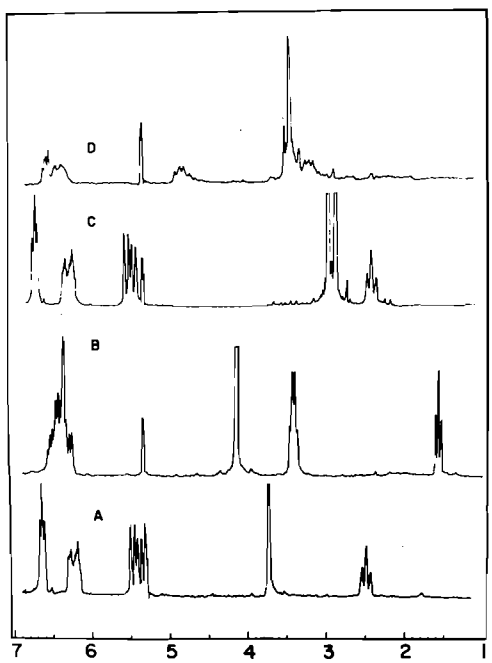

FIG. 1. Proton magnetic resonance spectra of cycloheptatrienes and their BCl_3 complexes in CD_2Cl_2. 7-Carbomethoxycycloheptatriene, **8**, spectrum *A*, and its BCl_3 complex **10**, spectrum *B*. *N*,*N*-Dimethylcycloheptatriene-7-carboxamide, **11**, spectrum *C*, and its BCl_3 complexes **12** and **13**, spectrum *D*. (Resonance at 5.38 due to $CHDCl_2$.)

Ciganek (16) has shown the rate of interconversion of a substituted cycloheptatriene and norcaradiene to be slow enough at −110° to enable them to be observed as separate species by p.m.r. No additional p.m.r. signals could be detected when a CD_2Cl_2/CF_2ClH solution of the complex was cooled to −135°, indicating that the zwitterion exists predominantly in one form.

The low temperature u.v. spectrum of the complex in CH_2Cl_2 exhibited a single, fairly intense band at λ_{max} 284 (log ε 4.3). The position of this absorption is again indicative of the structure of the zwitterion being **10**, the absorption being at too long a wavelength to be attributable to a structure such as **9**.

Formally, two stereoisomers of **10** are possible in which the C_7 substituent can be either in the *exo* or *endo* position, **10***a*, and **10***b*, respectively. From the n.m.r. spectrum obtained, it is clear that only one of these two isomers is present. Comparison of the magnitude of the coupling constant between the protons on C_7 and C_1/C_6 (J = 3.1 Hz) with that reported for other cyclopropylcarbinyl cations, would indicate that the isomer formed is **10***a* (17). Stohrer and Daub have found a similar preference for the formation of the *exo* isomer and this has been attributed to unfavorable secondary interactions in the *endo* isomer, **10***b*, between the p orbital on C_7 and the diene molecular orbitals (18).

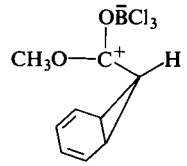
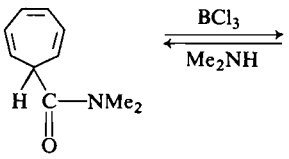
10*a*

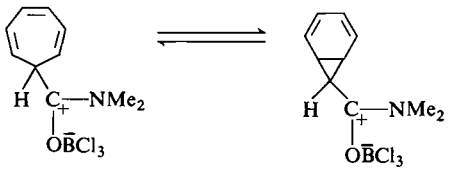


10*b*

The dimethylamide **11** when reacted with BCl_3 in CD_2Cl_2, gave a zwitterion with a p.m.r. spectrum at $-40°$ that indicated complexation had occurred with the carbonyl oxygen (19). However, the chemical shifts of the ring proton resonances (Table 1, Fig. 1) were now intermediate between those observed for **10** and **11**. It would appear that both **12** and **13** are being produced on reaction of **11** with BCl_3 and that these valence tautomers are interconverting sufficiently rapidly at $-40°$ for their p.m.r. spectra to be averaged. The low solubility of these amide complexes prevented p.m.r. spectra from being obtained at sufficiently low temperatures to stop this interconversion. Reaction of **12** and **13** with dimethylamine regenerated **11** in high yield.



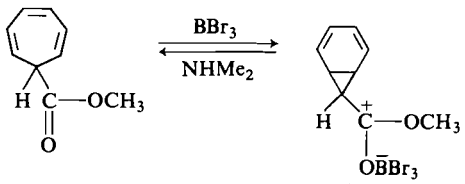
11



12 13

As a dimethylamino group is known to be more effective at stabilizing a positive charge than is a methoxy group (20), it would appear that the position of the equilibrium between the norcaradiene and cycloheptatriene forms of these zwitterions is dependent on the electron deficiency of C_8. The more electron deficient C_8 becomes, the greater is the amount of norcaradiene present.

Confirmation that the complex derived from **8** existed almost entirely in the norcaradiene form **10** was obtained by reaction of **8** with BBr_3. The zwitterion so obtained, which was stable at low temperatures and could be reacted with dimethylamine to give back **8**, exhibited a p.m.r spectrum that was directly comparable to that of **10**, suggesting that its structure can be regarded as **14**. Complexation of the oxygen atom of a carbonyl group with BBr_3 results in the accumulation of a larger fraction of the positive charge on the carbon atom of the group than similar BCl_3 complexes (13, 21). Thus replacement of the BCl_3 in the complexes derived from **8** by BBr_3 would be expected to result in an increase in the amount of norcaradiene present and unless the equilibrium mixture of **9** and **10** was almost completely in favor of **10** with BCl_3, a net upfield shift of C_1/C_6 and C_7 protons would occur. As no such change was observed (Table 1) it is clear that the complexes of **8** with both BCl_3 and BBr_3 must exist almost completely in the norcaradiene forms **10** and **14**, respectively.



8 14

To evaluate the position of the equilibrium between **12** and **13**, it is necessary to know the resonance positions of the signals of some of the protons in unaveraged spectra of **12** and **13**. An estimate for the position of the C_7 and C_1/C_6 proton resonances of **12** can be obtained by adding to the values found for the corresponding protons of the uncomplexed cycloheptatriene, the appropriate changes in chemical shifts observed on complexation of the model compound **15**.[4] As the zwitterion formed from reaction of **8** with BCl_3 has been shown to be in the norcaradiene form, the resonance positions of the C_1/C_6 and C_7 protons of **13** were taken to be those observed for **10**. On this basis the amount of norcaradiene **13** present in the equilibrium mixture of **12** and **13** was found to be 35%.

[4]Compound **15** was prepared by the addition of 4-phenyl-1,2,4-triazoline-3,5-dione to 7-carbomethoxycycloheptatriene, reduction of the so formed adduct with H_2/Pd and subsequent hydrolysis, oxidation, nitrogen elimination, and esterification. Experimental details will be given in a forthcoming full paper.

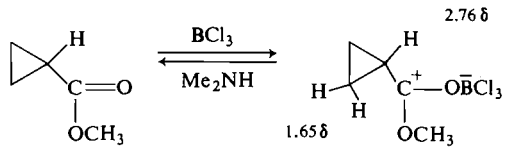
The Structure of Norcaradienes 10 and 14

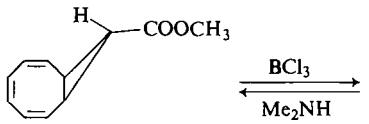
It is instructive to compare the position of the C_7 and C_1/C_6 proton resonances of **10** and **14** with that generally encountered for the comparable protons of cyclopropylcarbinyl cations. Frequently, the ring proton resonances of a protonated cyclopropyl ketone or carboxylic ester are observed as overlapping multiplets; however, typically the range over which the α-proton resonates is at lower field than that of the β-protons. For example the α-proton signal is usually found in the range 1.9 to 3.4 p.p.m. whereas the β-proton signal is found between 1.75 and 2.40 p.p.m. (25). This is quite the reverse of the situation encountered with the cyclopropyl proton resonances of **10** and **14**, in which the signal attributable to the α-proton is found to be more than 1.8 p.p.m. upfield from that of the β-protons. To ensure that these seemingly anomolous positions of the proton resonances of **10** (and **14**) cannot be attributed to the use of a boron halide rather than proton to induce the positive charge, complexes of some model cyclopropylcarbonyl compounds were prepared.

Reaction of the cyclopropyl ester **17** with BCl_3 in CD_2Cl_2 gave the zwitterion **18**. The p.m.r. spectrum of **18** exhibited a single, sharp, three proton resonance at 4.10 δ, a four proton signal at 1.65 δ, and a single proton resonance at 2.76 δ which is similar to that encountered for comparable protonated species and is quite different from that of **10** (17).

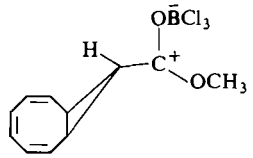


17 18

As the cyclopropane of **10** bears vinyl substituents, perhaps a better model for the expected chemical shifts of the protons is provided by the zwitterion **19**. This complex, which was readily formed by reaction **20** (22) with BCl_3 in CD_2Cl_2, was stable at temperatures below 0° and gave back **20** on reaction with dimethylamine. The p.m.r. spectrum of the complex was consistent with its structure being that shown for **19**. The cyclopropyl proton resonances of **19** occurred as an overlapping multiplet in the range 2.56 to 2.83 δ and individual α- and β-proton resonances could not be assigned. However, it is apparent that the vinyl groups on the β-carbons do deshield the β-protons to some extent.



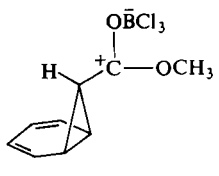
20



19

While neither **18** nor **19** is a perfect model for **10**, they do suggest that the position of the cyclopropyl proton resonances of **10** cannot be adequately described by the effect of the adjacent positively charged group. Clearly the six-membered ring of **10** must be influencing the cyclopropyl protons in some different way to the effect of the eight-membered ring of **19**. The complexes **10** and **19** differ in two respects. Firstly the geometry of these two systems is expected to be different, the six-membered ring of **10** being almost flat (23) while the eight-membered ring of **19** would be expected to exist preferentially in a tub conformation with the cyclopropane ring being in a pseudo-equatorial position. Secondly, **10** and **19** differ in the number of π electrons in the unsaturated ring.

A major consequence of the first factor is that the cyclopropyl protons of **10** could be affected by the diamagnetic anisotropy of the carbon–carbon double bonds (24). However using the



10

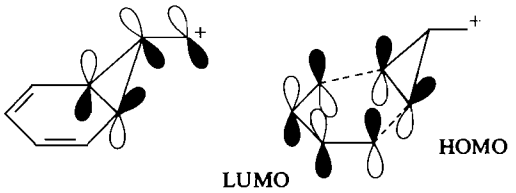
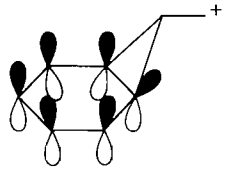
values of either Tillieu (25) or Pople (26) for the long range shielding of a double bond, the effect on the C_7 proton is found to be very small. With the data of Tillieu, the C_7 proton was found to be shielded by less than 0.1 p.p.m. and with that of Pople a deshielding of 0.1 p.p.m. was estimated. In either case the effect is very much smaller than the observed *ca.* 1 p.p.m. upfield shift of the resonance of this proton as compared to the corresponding proton of **19**. Similarly, the downfield position of the C_1/C_6 proton signals cannot be accounted for on this basis.

Both Hoffmann (11) and Günther (12) have suggested a way in which an electron withdrawing substituent on C_7 of a cycloheptatriene can affect the equilibrium between this and its norcaradiene valence tautomer. In essence, the lowest unoccupied molecular orbital of a π electron withdrawing substituent, and a carbonium ion is such a group 'par excellence', can interact with the antisymmetric, highest occupied Walsh molecular orbital of the cyclopropane ring of a norcaradiene, resulting in electron transfer from the three membered ring to its substituent. The net effect is that the C_1/C_6 antibonding component is weakened and this bond should become stronger.



The remaining symmetric Walsh orbital of the cyclopropane, which is bonding between C_1 and C_6 and contains two electrons, has the correct symmetry to interact with the lowest unoccupied orbital of the diene component of the norcaradiene (27). Moreover, the symmetry of the highest occupied molecular orbital of the diene is the same as the antisymmetric Walsh orbital from which electron transfer to the C_7 substituent has occurred. Such interactions should lead to a net stabilization of the norcaradiene structure.

It is of importance to note that this involvement of the diene with the cyclopropane results in an aromatic system. Viewed from the Hückel–Möbius viewpoint, in these norcaradienes there are formally six electrons contained in a Hückel array of atomic p orbitals (8, 28). One result of this should be that in a magnetic field, a diamagnetic ring current should be induced which would shield the *endo* C_7 proton and deshield the C_1 and C_6 bridgehead protons, *just as is observed with both* ***10*** *and* ***14*** (4).



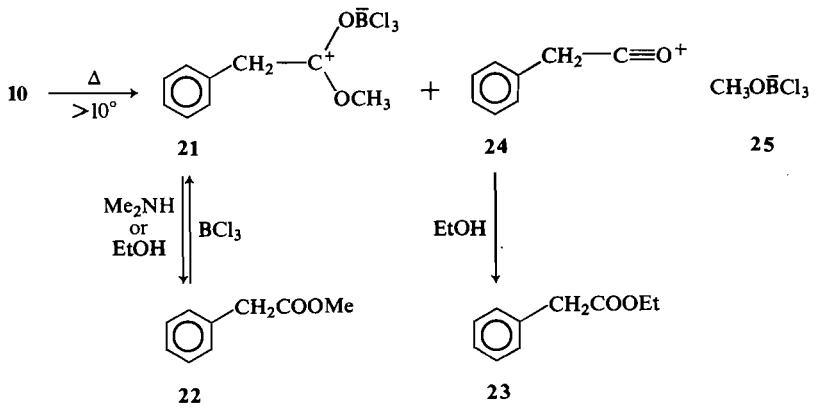
Hückel array: 6π electrons, aromatic.

We would suggest then that the norcaradienes **10** and **14** can be regarded as homoaromatic molecules and that to some degree such cyclic delocalization is required to account for their p.m.r. spectra. It is interesting that Sargent *et al.* (9) in their initial communication recognized that formulating the cyclopropylcarbinyl portion of these cations in the usual way imparted partial benzenoid character to the norcaradiene six-membered ring.

Thermal Rearrangement of Zwitterions

While the norcaradiene complexes were stable at low temperatures, on heating they underwent a ring contraction to give benzenoid compounds. Thus **10** at temperatures above 0° gave three products, one of which was identified as the methyl phenylacetate complex **21** by its p.m.r. spectrum (resonances at 4.19, 4.62, and 7.4 δ) and by the recovery of **22** when the solution containing the rearranged product was reacted with dimethylamine. Reaction of **22** with BCl_3 in CD_2Cl_2 gave **21**, with a p.m.r. spectrum identical to that obtained by the rearrangement of **10**.

The p.m.r. spectrum of the rearrangement products of **10** contained resonances over and above those attributable to **21** (Table 2). In particular, signals at 3.87, 4.16 δ and part of the multiplet of aromatic protons remained to be accounted for. Reaction of a solution of the rearranged products with ethanol gave rise to two esters which were isolated and characterized as **22** and the ethyl ester **23**. On this basis and by comparison with the results obtained with the BBr_3 complexes (*vide infra*), it is suggested that the additional products formed on the rearrangement of **10** are the acylium cation **24** and its counterion **25**. The methyl resonance of **25** occurs in a very similar region to that of the BCl_3 complex of methanol (3.95 δ). Comparable



anions to **25** involving BF_3 have been described (29).

While the formation of acylium cations from protonated carboxylic acid derivatives is well known (30), in this case **24** is not being formed directly from **21**. On heating a solution of **21**, prepared by reacting **22** with BCl_3, at 50° for 1 h, no formation of **24** and **25** could be detected by p.m.r. Thus **21**, **24**, and **25** must be primary products of the rearrangement of **10**.

The rate of rearrangement of **10** and the distribution of products was found to be dependent on the ratio of the Lewis acid to ester used. Increase in the ratio of BCl_3 to **8** resulted both in an increase in the rate of rearrangement of **10** and also an increase in the amount of the acylium cation **24**, formed (Tables 3 and 4).

A possible reaction sequence which can account for these observations is shown in Scheme 1. In its simplest form the cyclobutyl cation **26**, which can be considered to be in equilibrium with **10** (31), undergoes a 1,2 hydride shift to give **27**. This hydride shift could well be the slow step in the rearrangement for two reasons. Firstly, the free energy difference between **26** and **27** might not be all that great in that the hexadienyl cation in **27** is forced to be twisted by the fused cyclobutane ring. Secondly, the rigidity of the system makes it difficult for the appropriate geometry for this hydride shift to be attained (32). Comparable cyclobutyl cations have been suggested to be involved in the ring contraction reactions of certain homotropylium cations (33).

In the cyclobutyl cation **26**, the positive charge has been formally removed from the oxygen atoms and further reaction of the ether oxygen with additional BCl_3 could take place. The extra positive charge so induced in the system could result in an enhancement of the rate of the 1,2 hydride shift to give **28**, which could then give the acylium ion **24** or complex **21** as indicated. Comparable ring openings of

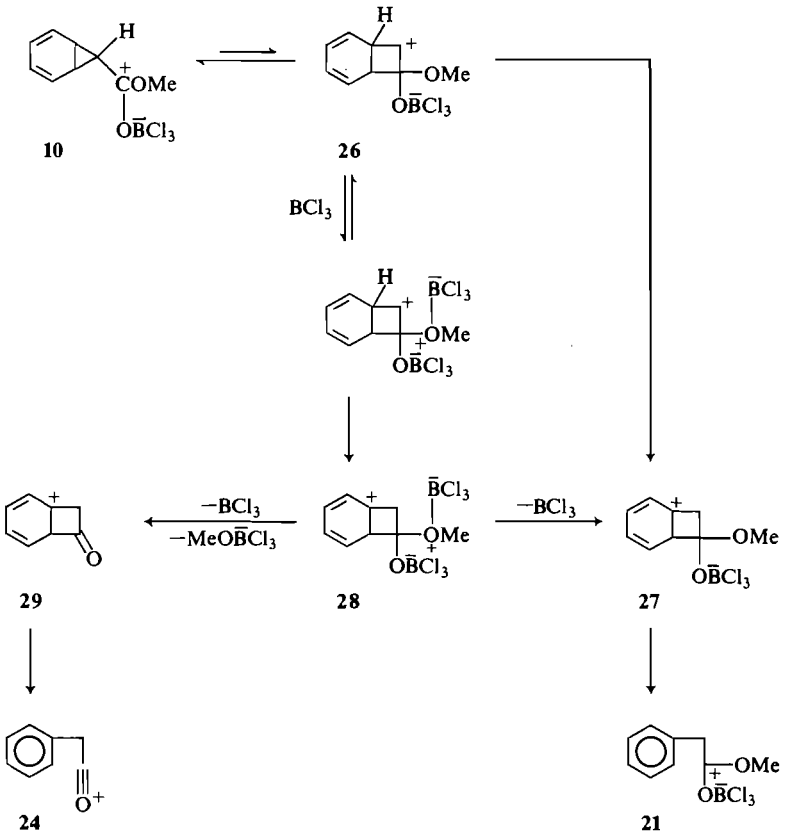

SCHEME 1

cyclobutanone cations such as **29** have been reported (34).

The BBr_3 complex **14** rearranged in an analogous manner to that described for **10** to give the BBr_3 complex of methylphenylacetate, **30**, **24** and $MeO\bar{B}Br_3$, however in this case, **30** was slowly converted into **24** and its counterion under the isomerization conditions. The formation of the acylium cation on rearrangement of **14** was confirmed by examination of its i.r. spectrum when an absorption at 2270 cm^{-1} was found. Acylium cations typically exhibit a carbonyl absorption in this region, the phenylmethylacylium cation with a SbF_6^- counterion being reported to absorb at 2279 cm^{-1} (30). The temperature at which this rearrangement of **14** occurred was found to be much lower than that required for **10**. With a two-fold excess of BBr_3, **14** rearranged at $-43°$ with a half-life of 40 min. The amide complex mixture of **12** and **13** did not rearrange until heated to above $+20°$, the BCl_3 adduct of *N*,*N*-dimethylphenylacetamide being the major product. Clearly, both the amount of norcaradiene present in these tautomeric mixtures and also the ease of their rearrangement to aromatic systems are directly related to the ability of the C_8 substituents to stabilize the positive charge.

The existence of these complexes almost entirely in the norcaradiene form does not necessarily preclude the migration of C_8 around the periphery of the system. This could either occur in the norcaradiene form in a comparable manner to that found by Berson *et al.* for related systems (35) or by intervention of a homotropylium cation species as outlined at the start of this paper. However, at the temperatures at which the thermal ring contraction reaction occurred, no line broadening could be detected in the p.m.r. spectra of either **10** or **14**, indicating that no degenerate rearrangement was occurring at those temperatures with a sufficiently high rate to cause averaging of the p.m.r. signals.

Based on the characteristics of the analogous migrations observed with derivatives of **4** (13), one way to lower the energy barrier for the

degenerate rearrangement of these norcaradienyl/cycloheptatrienyl methyl cations would be to decrease the ability of the C_8 substituents to stabilize positive charge. However, as has been shown, this would also result in an increase in the rate of the collapse of these cations to benzenoid systems. Indeed, in the limit, it is known that the rearrangement of the unsubstituted ion **7** to styrene under acetolysis conditions is sufficiently rapid to completely exclude either collapse of **7** with solvent to give cycloheptatriene derivatives or formation of the homotropylium ion and its subsequent products.[3] We are then in a dilemma, as changes made with these systems intended to enhance the rate of the degenerate migration, also increase the rate of their collapse to benzene derivatives and it would appear that we are unlikely to be able to devise a system in which the degenerate rearrangement can compete with this facile ring contraction. Taking this further, it would also seem that the production of a cycloheptatrienylmethyl cation as the first step of a degenerate rearrangement of a homotropylium cation would lead irreversibly to a benzenoid cation and not to the regeneration of the homotropylium cation. Perhaps, indeed, the often encountered ring contraction reactions of homotropylium cations involve just such a pathway.

Experimental

Proton magnetic resonance spectra were recorded on a Varian HA-100 spectrometer fitted with a variable temperature probe controlled by a Varian V-6040 temperature controller. The probe temperature was measured with a copper–constantan thermocouple and Leeds and Northrup 8692 potentiometer. The thermocouple was mounted at the appropriate depth in a nonrotating sample tube. Chemical shifts are referred to TMS or $CHCl_3$ (taken as 7.30 δ) for the zwitterions. Vapor phase chromatographic separations were performed with either an Aerograph A-90P3 instrument (preparative) using a 10 ft × ¼ in. column with 15% carbowax on chromosorb W, or with a Varian-Aerograph 204-1B instrument (analytical) using a 10 ft × ⅛ in. column with 5% carbowax on chromosorb W. Ultraviolet spectra were measured with a Carry 14 spectrometer.

CD_2Cl_2, BCl_3, and BBr_3 were purified by distillation, stored over P_2O_5 and further distilled immediately before use. All manipulations were carried out on a vacuum line. $CHCl_3$ was washed with H_2O, H_2SO_4, 0.1 *N* $NaHCO_3$, and H_2O, dried over P_2O_5 and distilled twice. CF_2ClH was doubly distilled before use.

*7-Carbomethoxycycloheptatriene (**8**)*

7-cyanocycloheptatriene (10 g) was refluxed under N_2 in MeOH (150 ml) containing concentrated H_2SO_4 (30 g) for 30 h. The bulk of the solvent was removed *in vacuo* and the residue poured into H_2O (400 ml). The solution was extracted with petroleum ether (30–60°) (3 × 100 ml), the extract dried over $MgSO_4$, and the solvent removed *in vacuo* to give the crude ester. Distillation gave 9.0 g (80%) of **8** (b.p. 60° at 0.5 mm) containing a small amount of methyl phenylacetate (~2%). Pure material was obtained by preparative v.p.c. at a temperature below 130°.

*N,N-Dimethyl-1,3,5-cycloheptatriene-7-carboxamide (**11**)*

An excess of gaseous dimethylamine was added to a 10% solution of 7-chlorocarbonylcycloheptatriene in anhydrous ether. The dimethylamine hydrochloride formed was filtered off and the filtrate concentrated *in vacuo* to give a brown oil. This was chromatographed on neutral alumina eluting with ether to give a colorless solid. Recrystallization from pentane gave **11** as colorless crystals (m.p. 64.5°) which slowly became colored on standing. Nuclear magnetic resonance spectral data are given in Table 1.

*9-Carbomethoxybicyclo[6.1.0]nona-2,4,6-triene (**20**)*

Compound **20**, prepared by ester exchange of the corresponding ethyl ester, had properties identical to those previously reported (22).

Preparation of Complexes, General Procedure

All manipulations were carried out under high vacuum conditions. The starting organic compound (*ca.* 30 mg) was weighed into a small reaction vessel which contained a magnetic stirrer, was fitted with a sealed on n.m.r. tube, and could be attached to a vacuum line through a suitable high vacuum stopcock. The reactor was cooled and CD_2Cl_2 (1 ml) was transferred from a reservoir where it had been stored over P_2O_5. The organic material was dissolved and then a weighed amount of the appropriate Lewis acid was slowly distilled in while the solution was being stirred and maintained at −78°. On completion of the addition, the reactor was separated from the vacuum line and the appropriate amount of the solution transferred to the n.m.r. tube which was then sealed. During this transfer the apparatus was kept at −78°.

For the u.v. determinations, a similar technique was used except that a larger reaction vessel with an attached 0.2 cm u.v. cell was employed.

Infrared spectra of **24** and its counterion were obtained as Nujol mulls of the residue left after evaporation of the solvent *in vacuo*.

Quenching of Complexes

An excess of gaseous $(CH_3)_2NH$ was passed into the CD_2Cl_2 solution of the zwitterions at −78°. The resulting mixture was treated with water and the organic material was extracted three times with ether. The combined ether extracts were dried over $MgSO_4$ and the solvent removed *in vacuo* prior to analysis by g.l.p.c. and n.m.r. Hexamethylbenzene was used as an internal standard in some of the reactions in order to quantitatively measure the recovery of the starting compounds. The results of these quenches are shown in Table 5.

*Reaction of the Rearrangement Products of **10** with EtOH*

Ethanol (2 ml) was slowly added to a CD_2Cl_2 solution

TABLE 5. Products obtained on quenching zwitterions

Complex(es)	Quenching agent	Product (%recovery)*

of the rearrangement products of **10** at −78°. Water (10 ml) was added, the mixture extracted with ether (3 × 5 ml), and the extract dried over $MgSO_4$. Evaporation of the ether gave an oil which was analyzed by both p.m.r. and also analytical g.l.p.c. using authentic samples of **22** and **23** for comparison purposes. The two esters, **22** and **23** in the quenched material were separated by preparative g.l.p.c. and the p.m.r. spectra of the isolated compounds were identical in all respects to that of the authentic samples.

Carbon-13 Nuclear Magnetic Resonance Spectra of Carcinogenic Polynuclear Hydrocarbons. II. Benzo[*a*]pyrene

GERALD W. BUCHANAN AND RICHARD S. OZUBKO[1]

Department of Chemistry, Carleton University, Ottawa, Canada K1S 5B6

Received December 31, 1974

GERALD W. BUCHANAN and RICHARD S. OZUBKO. Can. J. Chem. **53**, 1829 (1975).

^{13}C n.m.r. signal assignments are presented for the carcinogenic polynuclear hydrocarbon benzo[*a*]pyrene. In addition to selective ^{1}H decoupling, valuable information is obtained from the magnitudes of the α-, β-, and "*peri*" deuterium isotope shifts in the 1,3,6-trideuterio analog. The applicability of the model compound approach to signal assignment is explored in detail.

GERALD W. BUCHANAN et RICHARD S. OZUBKO. Can. J. Chem. **53**, 1829 (1975).

On présente les attributions de signaux en r.m.n. du ^{13}C pour l'hydrocarbure polynucléaire cancérigène benzo[*a*]pyrène. On obtient des informations intéressantes par découplage sélectif du ^{1}H et aussi à partir de l'amplitude des déplacements isotopiques du deutérium pour les positions α, β, et "*peri*" des analogues trideutério-1,3,6. On examine en détail la possibilité d'appliquer l'approche du composé modèle pour l'attribution des signaux.

[Traduit par le journal]

Introduction

Considerable effort has been directed toward the elucidation of the ^{1}H n.m.r. spectra of polynuclear hydrocarbons. For the potent carcinogen benzo[*a*]pyrene, precise analysis has been accomplished only by utilization of 220 MHz instruments and iterative computer fitting due to the complex nature of the ^{1}H spectrum (1, 2).

Molecules such as benzo[*a*]pyrene are the objects of intense theoretical interest, and several theories attempting to relate electronic structure with carcinogenic activity have been advanced (3 and references therein). It is in connection with the electronic properties of these systems, however, that the ^{13}C n.m.r. parameters are of greatest interest, since the carbon shieldings should give more valuable information regarding local electronic properties at carbon than those for the bonded protons. Furthermore, an earlier report from these laboratories (4) has demonstrated the utility of ^{13}C n.m.r. for analysis of related systems such as 3-methylcholanthrene and the benzanthracenes.

Results and Discussion

The numbering scheme (5) and structures for the five compounds included in the present study are illustrated in Fig. 1.

Assignments of resonances were accomplished using several methods. Initially, reduced intensities for all quaternary centers were evident, permitting ready distinction between these resonances and those due to carbons bearing hydrogen. Increased relative intensities for quaternary carbons were observed in the presence of 5×10^{-2} molar-equiv. of the relaxation reagent Cr(acac)$_3$, which is known to attenuate greatly the spin–lattice relaxation times (6). In cases where the ^{1}H spectra have been assigned, selective ^{1}H decoupling at low r.f. power (4) was employed. Model compounds, empirical chemical shift additivity correlations and deuterium substitution were also utilized. All spectra were recorded using $CDCl_3$ solutions and the chemical shifts are presented in Table 1.

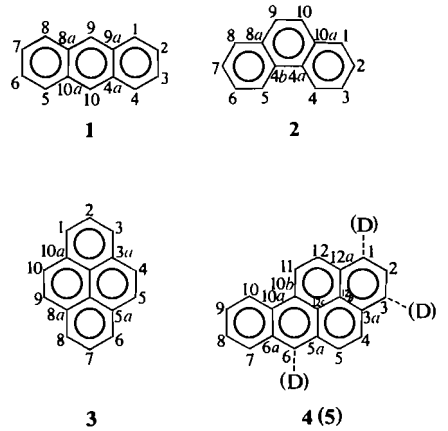

FIG. 1. Numbering scheme for polynuclear hydrocarbons.

12c				123.58	not obs'd

NOTE: d, e, f, denote possible interchange of assignments.

Results for anthracene **1** and phenanthrene **2** are included from our earlier work (4) since these will be used as model compounds. Shieldings for pyrene **3** are in good agreement with those reported for a $CDCl_3$ solution (7). The ^{13}C Fourier transform spectrum of benzo[*a*]pyrene **4**, obtained under conditions of complete ^1H noise decoupling is shown in Fig. 2. Preliminary inspection indicates 8 quaternary carbon resonances and 12 CH resonances as expected. Addition of $Cr(acac)_3$ verified the reality of the low intensity absorptions.

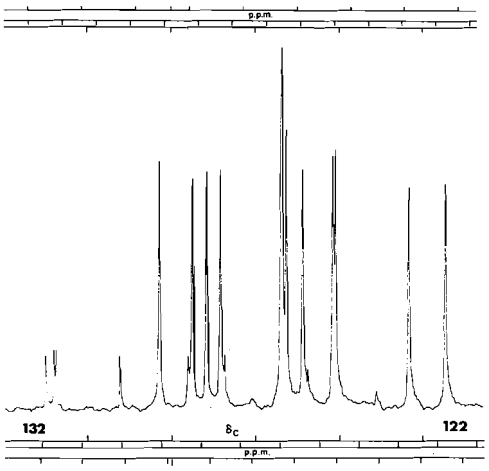

FIG. 2. ^{13}C n.m.r. spectrum of benzo[*a*]pyrene.

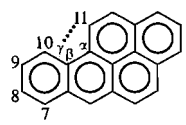
In the ^1H spectrum of **4** (2) only the protons at C-10, C-11, and C-6 are sufficiently separated to allow selective decoupling. Resonances for the remaining protons appear at higher field and take the form of overlapping multiplets. Selective ^1H decoupling at δ 8.9 sharpens carbons at 122.00 and 122.87, corresponding to C-11 and C-10, respectively, which are shielded from the well known "γ" steric shift (8, 9). Due to its similarity with C-4,5 of phenanthrene **2**, C-10 is assigned as 122.87. Irradiation at δ 8.3, the C-6 proton shift, selectively sharpens the carbon resonance at δ 125.38.



The majority of the remaining carbons of **4** were assigned using simple model compounds and additivity. To check the predicted values, compound **5** with 99% selective deuteration at

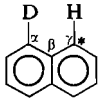
For personal use only.

C-1,3 and 6 (10, 11) was examined. Deuterium isotope shifts at various carbons were compared with our earlier findings (4) and those recently reported by Martin *et al.* (12).

Employing C-1,3 of pyrene **3** as models for C-1,3 of **4**, shifts near 124.6 p.p.m. are predicted for the latter carbons. Careful study of the 1,3,6-trideuterio system **5** verified these predictions, since resonances at 124.61 and 124.68 in **4** were absent in **5** and in their place are two triplets, each shielded by 0.31 p.p.m. These spectral changes are consistent with previously observed α-deuterium isotope effects on carbon spectra of related compounds (12–14).

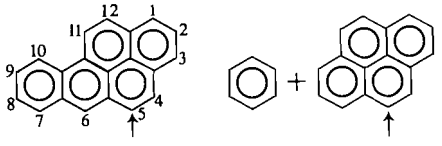
Similarly, C-2 of **4** is expected to resonate near C-2 of **3**, which appears at δ 125.5. After deuteration, the resonance at δ 125.78 in **4** broadens and shifts upfield by 0.11 p.p.m., indicative of β-deuterium substitution. Martin *et al.* (12) have found that the β-deuterium isotope shift is *ca.* 0.12 p.p.m. for carbons bearing a proton but only 0.07 p.p.m. for carbons lacking directly bonded hydrogens. Interestingly, although there are two deuteriums β to C-2 of **5** the observed effect indicates that these isotope shifts cannot be considered additive.

A further important observation of Martin *et al.* (12) is the "*peri*" deuterium isotope shift. The γ carbon bearing a hydrogen *peri* to deuterium is shielded by *ca.* 0.04 p.p.m. and such shifts in **5** permit assignment of resonances for carbons 4, 5, 7, and 12 of **4**. For C-4 of **4**, C-4 of **3**, resonating



at δ 127.0, was used as a model. The 127.33 p.p.m. resonance in **4** shifts to 127.28 p.p.m. in **5** consistent with *peri* deuterium incorporation.

A shift for C-5 of **4** was predicted in the following way: using C-5 of **3** as a starting point (δ 127.0) one must then consider the effect due to addition of the extra benzenoid function, *i.e.*



An estimation of the annelation effect is available by comparison of C-1,4,5,8 of **1** (δ 128.3) with C-1,4,5,8 of naphthalene (δ 127.7). Thus, one predicts a shift of 127.0 + 0.6 = 127.6 for C-5 of **4**. The resonance at δ 127.66 in **4** shifts to 127.61 in **5** indicating a *peri* deuterium and lending support to this method of analysis.

For C-7 of benzo[*a*]pyrene again the C-1,4,5,8 resonance of **1** serves as a model, as does C-8 of benz[*a*]anthracene (4). Accordingly a shift near δ 128.3 is predicted. In **4** the resonance at δ 128.77 shifts to 128.71 in **5** mirroring the influence of the γ deuterium and supporting the model compound approach.

Now, with respect to carbons bearing hydrogens, we are left with C-8,9, and -12 of **4** to assign, and resonances at δ 125.88, 125.91, and 128.00, respectively. One would expect that C-8,9 of **4** should be rather similar to C-2,3,6,7 of **1** (δ 125.2) and thus we assign resonances at 125.88 and 125.91 to C-8,9 of **4**. Support for this comes from the absence of any observable changes in these resonances in the trideuterio derivative **5**. The remaining resonance at δ 128.00 in **4** is attributed to C-12 and in **5**, the expected γ deuterium isotope shift to 127.95 is found.

Quaternary Carbons

For carbons lacking bonded protons in aromatic hydrocarbons, Martin *et al.* (12) have observed shielding β-deuterium isotope effects of *ca.* 0.07 p.p.m. In **5** there are four quaternary centers (3a, 5a, 6a, and 12a) which are β to deuterium. The resonance at δ 131.46 in **4** is shifted to δ 131.39 in **5**. Employing C-4a of **1** as a model (δ 131.6) for C-6a of **4** allows an assignment to be made with a reasonable degree of confidence. Carbon 3a of **3** (δ 130.9) furnishes a good model for positions 3a and 12a of **4**. Accordingly the peaks at δ 131.27 and 131.21 in **4**, which shift to 131.20 and 131.14 respectively in **5**, are assigned to 3a and 12a. No distinction between these, however, is possible. By elimination, the quaternary resonance at 129.71 in **4** which shifts to 129.62 in **5** must correspond to position 5a.

Employing C-10b and -10c of **3** as models (δ 124.6), it is clear that resonances for C-12b and -12c of **4** will be the most shielded of those arising from quaternary centers. In **5**, resonances for 12b and 12c are not visible. Vicinal coupling to the deuteriums on C-1 and C-3 will extensively broaden the C-12b resonance, whereas the resonance for 12c, in addition to its vicinal coupling with the deuterium on C-6, is obscured by the triplet for C-6 centered at δ 125.06.

Differentiation between the remaining quaternary resonances for C-10a and -10b is made on

the basis of observed broadening of the C-10a resonance at δ 127.22 in **4** on becoming vicinal to the deuterium at C-6 of **5**. Thus the remaining resonance at δ 128.10 of **4** is attributed to C-10b. No recognizable difference in position or linewidth of this resonance is observed in **5** *vs.* **4**.

To conclude, it is clear that Fourier transform ^{13}C n.m.r. represents a valuable addition to the available physical methods for the study of polynuclear hydrocarbons. For cases where unambiguous assignments are not possible due to peak overlap or insufficient sensitivity, it can be envisaged that high field spectrometers utilizing larger sample tubes will be valuable.

Experimental

Materials

The compound benzo[*a*]pyrene was purchased from K & K Laboratories Inc., Plainview, New York. The 1,3,6-trideuterio derivative was prepared according to the method of Cavalieri and Calvin (10, 11).

Spectra

Nuclear magnetic resonance spectra of ^{13}C in natural abundance were obtained by the pulsed Fourier transform technique at 25.16 MHz on a Varian XL-100-15 spectrometer. The free-induction decays were stored in a Varian 620/L computer (16K memory) and were Fourier transformed after a sufficient number had been accumulated. Before transformation all interferograms were smoothed with an exponential function to enhance signal-to-noise. The maximum number of data points used in accumulating the interferograms was 8192.

Samples were studied in tubes of 12 mm outer diameter with concentrations at 0.24 *M* in $CDCl_3$. The deuterium of the solvent was used as a field-frequency lock and all chemical shifts are expressed as downfield from internal TMS. Routinely, spectra were recorded with complete proton noise decoupling at a probe temperature of 32 °C. For the selective decoupling experiments, proton irradiation was carried out at low decoupler power with no noise modulation. The decoupler was calibrated by irradiating the protons of TMS (in $CDCl_3$) under low power conditions.

The isotope shifts observed in 1,3,6-trideuteriobenzo[*a*]pyrene were obtained by comparing its spectrum with that of benzo[*a*]pyrene run under identical experimental conditions. Both compounds were 0.24 *M* in $CDCl_3$ and each spectrum was obtained using a 1000 Hz sweep width, 8192 data points, and the same sweep offset (as verified with the spectrometer's digital frequency counter). The line positions (as measured in Hz from the carrier frequency) of the folded back $CDCl_3$ triplet were found to be the same in the two spectra, a further proof for the experimental conditions being identical.

Financial support from the National Cancer Institute of Canada and the National Research Council of Canada is gratefully recognized.

Equilibria between Palladium(II) Acetate and Olefins in Acetic Acid containing Sodium Acetate[1]

RAJ N. PANDEY AND PATRICK M. HENRY

Guelph-Waterloo Centre for Graduate Work in Chemistry, University of Guelph, Guelph, Ontario N1G 2W1

Received November 12, 1974

RAJ N. PANDEY and PATRICK M. HENRY. Can. J. Chem. **53**, 1833 (1975).

π-Complex equilibria between dimeric Pd(II) acetate and various olefins (ethylene, styrene, 3,3-dimethyl-1-butene, vinylic and allylic esters) in acetic acid solvent have been investigated by spectral means. The results indicate two π-complexes are formed. The first π-complex, which is formed rapidly, is a dimeric π-complex (ol = olefin).

$$Na_2Pd_2(OAc)_6 + ol \underset{\longleftarrow}{\overset{K_{\pi 22}}{\longrightarrow}} NaPd_2(OAc)_5(ol) + NaOAc$$

The Benesi–Hildebrand plots for these complexes are linear for all olefins and thus values of $K_{\pi 22}$ can be readily evaluated. The values of the equilibrium coefficient, $K_{\pi 22}$, do not change with solution composition or [NaOAc]. The second π-complex is formed slowly. The data are consistent only with the equilibrium

$$Na_2Pd_2(OAc)_6 + 2ol \underset{\longleftarrow}{\overset{K_{\pi 21}}{\longrightarrow}} 2NaPd(OAc)_3(ol)$$

The data are inconsistent with the equilibrium

$$Na_2Pd_2(OAc)_6 + 2ol \underset{\longleftarrow}{\overset{K'_{\pi 22}}{\longrightarrow}} Pd_2(OAc)_4(ol)_2 + 2NaOAc$$

which is analogous to that reported for the $Na_2Pd_2Cl_6$ reaction with olefins in acetic acid. Furthermore, previous assumptions as to the equilibria between ethylene and Pd(II) in the all-acetate system have proved incorrect, and so the kinetics of oxidation of ethylene in this system must be reinterpreted in view of the present results.

RAJ N. PANDEY et PATRICK M. HENRY. Can. J. Chem. **53**, 1833 (1975).

On a étudié, à l'aide de méthodes spectrales, l'équilibre dans l'acide acétique, des complexes π entre l'acétate de Pd(II) dimère et diverses oléfines (éthylène, styrène, diméthyl-3,3 butène-1, esters vinyliques et allyliques). Les résultats indiquent qu'il y a formation de deux complexes π. Le premier complexe π, qui se forme rapidement, est un complexe π dimère (ol = oléfine)

$$Na_2Pd_2(OAc)_6 + ol \underset{\longleftarrow}{\overset{K_{\pi 22}}{\longrightarrow}} NaPd_2(OAc)_5(ol) + NaOAc$$

Les courbes de Benesi–Hildebrand de ces complexes sont linéaires pour toutes les oléfines et on peut donc évaluer facilement les valeurs de $K_{\pi 22}$. Les valeurs du coefficient d'équilibre $K_{\pi 22}$, ne changent pas avec la composition de la solution ou avec [NaOAc]. Le deuxième complexe se forme lentement. Les données sont seulement en accord avec l'équilibre.

$$Na_2Pd_2(OAc)_6 + 2ol \underset{\longleftarrow}{\overset{K_{\pi 21}}{\longrightarrow}} 2NaPd(OAc)_3(ol)$$

Les données ne sont pas en accord avec l'équilibre

$$Na_2Pd_2(OAc)_6 + 2ol \underset{\longleftarrow}{\overset{K'_{\pi 22}}{\longrightarrow}} Pd_2(OAc)_4(ol)_2 + 2NaOAc$$

qui est analogue à l'équilibre suggéré pour la réaction de $Na_2Pd_2Cl_6$ avec les oléfines dans l'acide acétique. De plus on a prouvé que des hypothèses antérieures concernant l'équilibre entre l'éthylène et le Pd(II) dans des systèmes ne contenant que des acétates sont incorrectes; on doit donc réinterpréter la cinétique de l'oxydation de l'éthylène dans ce système en tenant compte des nouveaux résultats. [Traduit par le journal]

Introduction

In the past several years, the field of palladium(II) catalyzed reactions has been extensively studied (for recent reviews, see refs. 1 and 2). Important intermediates in the olefin reactions are palladium(II)–olefin π-complexes and a large number of π-complexes of mono and diolefins have been prepared and characterized (1–3). The equilibria between palladium(II)

For personal use only.

chloride salts and olefins in acetic acid have also been studied by spectral means. Cruikshank and Davies (4) studied the interaction of $Na_2Pd_2Cl_6$ with allylbenzene and postulated the presence of $Na[Pd_2Cl_5(olefin)]$, $[Pd_2Cl_4(olefin)_2]$, and $[PdCl_2(olefin)_2]$. They proposed that the latter complex is the catalytically active species in olefin isomerization. Hartley and Wagner (5), using 1-hexene and 1-octene as olefins, also postulated that the first two species were formed in the following equilibria

[1] $Na_2Pd_2Cl_6 + olefin \rightleftarrows Na[Pd_2Cl_5(olefin)] + NaCl$

[2] $Na[Pd_2Cl_5(olefin)] \rightleftarrows [Pd_2Cl_4(olefin)_2] + NaCl$

but found no evidence for $PdCl_2(olefin)_2$. They postulated that Cruikshank and Davies did not take into account the presence of $Na[Pd_2Cl_5(CH_3COOH)]$. Hartley and Wagner postulated the formation of $Pd_2Cl_4(olefin)_2$ because their results required a complex with a Pd:olefin ratio of 1. However it is not clear that these workers ruled out the formation of $Na[PdCl_3(olefin)]$ which would have the same Pd:olefin ratio as $Pd_2Cl_4(olefin)_2$.

In the lithium chloride system containing excess LiCl, spectral and kinetic studies on allylic ester exchange indicated the main equilibrium between allylic esters and $Li_2Pd_2Cl_6$ was formation of the monomeric species while the kinetics

[3] $Li_2Pd_2Cl_6 + 2\ allyl\ ester \rightleftarrows 2Li[PdCl_3(allyl\ ester)]$

require that a dimeric π-complex be present in at least kinetically significant amounts.

[4] $Li_2Pd_2Cl_6 + allyl\ ester \rightleftarrows Li[Pd_2Cl_5(allyl\ ester)]$

Olefin π-complex formation in the palladium(II) acetate system has not been studied as extensively as the chloride containing system. To our knowledge the only previous study is the reaction of ethylene with palladium(II) acetate in acetic acid containing sodium acetate (7). However, the interpretation of the data was based on the assumption that in the range of sodium acetate concentrations from 0.3 to 1 *M*, the palladium was entirely in the form of the monomeric species, $Na_2Pd(OAc)_4$. As discussed below, this assumption is incorrect.

A previous report (8) from these laboratories described a study of the equilibria between palladium(II) acetate and sodium acetate. The following equilibria were found to be operative.

[5] $2Pd_3(OAc)_6 + 6NaOAc \overset{K_{32}}{\rightleftarrows} 3Na_2Pd_2(OAc)_6$

[6] $Na_2Pd_2(OAc)_6 + 2NaOAc \overset{K_{21}}{\rightleftarrows} 2Na_2Pd(OAc)_4$

The value of K_{32} was such that the trimer was completely converted to dimer at 0.2 *M* NaOAc while even at the highest [NaOAc] used (*ca.* 1.0 *M*) the conversion of dimer to monomer was incomplete.

A previous study of the analogous equilibria in the chloride system indicated that only the dimer–monomer equilibrium is important (9).

[7] $Li_2Pd_2Cl_6 + 2LiCl \rightleftarrows 2Li_2PdCl_4$

However, an even more important difference between the two systems is that the attainment of equilibria in the acetate system is a slow process while the reactions in the chloride system are instantaneous. Thus bridging acetates react slowly while bridging chlorides react fast. The lability of terminal acetates could not be determined in this study since no net chemical change occurs by terminal acetate exchange.

The present work will describe a study of the interaction of palladium(II) acetate with several olefins in the sodium acetate concentration range in which the predominant palladium(II) species is the acetate-bridged dimer $Na_2Pd_2(OAc)_6$. This study should detect differences in lability between terminal and bridging acetates. In addition, it will provide more of the basic equilibrium data required to interpret the kinetics of Pd(II) catalyzed reactions of olefins in this system.

Experimental

Materials

Palladium acetate (purchased from Engelhard Chemicals and Catalysts, New Jersey) was purified by the method of Stephenson *et al.* (10). The acetic acid (Baker Chemical Co.) was dried by refluxing over triacetylborate, $B(OAc)_3$, and distilled (11). The determination of water by Karl Fisher analysis indicated water contents of less than 0.01%. Sodium acetate (Baker Chemical Co.) was reagent grade. Allylic esters, styrene (Eastman, Rochester, N.Y.), vinylic esters (J. T. Baker Chemical Co.), 3,3-dimethyl-1-butene (Aldrich Chemical Co.), and C.P. grade ethylene (Matheson of Canada Ltd.) were used without further purification. The Pd(II) stock solutions were analyzed by the dimethylglyoxime procedure (12).

Equilibrium Measurements

The formation of π-complexes between Pd(II) species and olefins was followed spectrophotometrically. Spectra

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

were recorded on a Unicam S.P. 800, Cary 14, and Cary 118 spectrophotometer using cells of 1, 5, and 10 mm pathlengths. All measurements were made at 25 °C.

Solutions of palladium(II) acetate and sodium acetate were equilibrated at 25 °C for *ca.* 24 h prior to addition of olefins. Usually 2 ml of total solution was used. Aliquots (0.001 to 0.1 ml) of the pure liquid olefin were added to these solutions. In case of ethylene, a saturated solution of ethylene in acetic acid was prepared. A creased flask containing a known volume of acetic acid was placed in a constant temperature (25 °C) bath and connected to a gas burette (also at 25 °C) which was connected to a vacuum system. A magnetic stirrer was used to agitate the contents of the flask. The system was evacuated for several minutes with the stirrer running. The stirring was then turned off and the system was filled with approximately 1 atm of ethylene. The mercury in the gas burette and leveling bulb was then equalized, an initial reading taken, and the stirrer turned on to allow the ethylene to dissolve. During this time the pressure was continually kept constant by equalizing the level of mercury in the bulb and burette. The solution was considered saturated when the ethylene uptake stopped. A final burette reading was recorded. The difference (ΔV) between the initial and final volume at 1 atm was used in determining the solubility of the gas. The solubility of ethylene was found to be 0.082 *M*. The flask containing this solution was tightly stoppered and removed. A measured volume of this solution was withdrawn by means of a glass syringe and mixed in a closed container filled almost entirely by the reacting solution. This solution was then quickly transferred via glass syringe to a cell for spectral measurements.

Addition of olefins caused an instantaneous change in the spectra followed by a slow change. The slower reaction in fact took a period of hours to come to equilibrium. The initial isosbestic point observed at λ_{365nm} shifts gradually with time towards lower wavelength $\simeq\lambda_{350nm}$ as the reaction proceeds.

The equilibrium optical density for the fast reaction was reached in less than 2 min. In that period no measurable amount of the second slow reaction had taken place. The equilibrium optical density for the slow reaction was reached in several hours.

The wavelength region used for the spectral measurements was 400–275 nm. All olefins but styrene were transparent in this region. However, at 300 nm styrene has a negligible absorption so this wavelength was used in the determinations with this olefin.

The equilibrium measurements were made in the [NaOAc] range in which the main species is $Na_2Pd_2(OAc)_6$. However correction was made for the amount of dimer converted to monomer (reaction 6) using the previously determined value of K_{21}.

Method of Continuous Variation

The Job (13) method was used to determine the stoichiometry of the complexes formed by the interaction of dimeric Pd(II) and olefin. For reason of greater stability to oxidative decomposition as well as high values of the equilibrium constants for π-complex formation, allyl acetate was the olefin selected for this purpose. Solutions were prepared in which the mole fraction of metal (x) varied from 0 to 1 and in which the olefin concentration was adjusted to $1 - x$. The changes in optical density were low because of the low solubility of $Na_2Pd_2(OAc)_6$ in acetic acid (*ca.* 0.02 *M*). To increase accuracy the difference in optical density (ΔD) between the metal–olefin solution and a solution containing the same concentration of metal without olefin was measured. Solutions of 5 ml volume containing the palladium(II) acetate plus sodium acetate were allowed to come to equilibrium. Then the appropriate amount of an allyl acetate stock solution (0.1 *M*) was added followed by another period of several hours to allow complete equilibration between Pd(II) and olefin. Results are shown in Figs. 1 and 2.

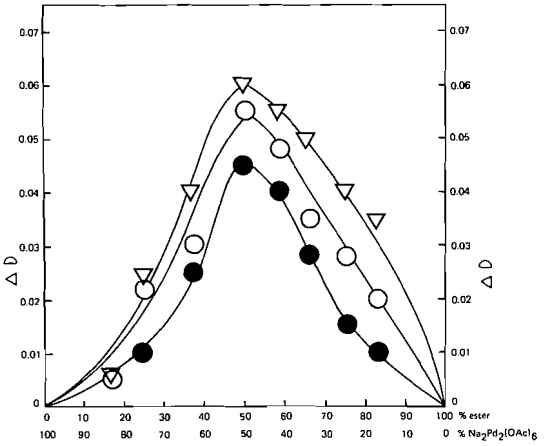

FIG. 1. Job plots for the system $Na_2Pd_2(OAc)_6$ and allyl acetate in dry acetic acid: Σ ($[Na_2Pd_2(OAc)_6]$ + [ester]) = 3.78×10^{-3} *M*. ΔD = difference in optical density (in 5 mm optical pathlength) of the two solutions differing only in that [ester] = 0 in one of them. ▽, λ = 320 nm; ○, λ = 330 nm; ●, λ = 335 nm.

Figure 1 has a maxima corresponding to 1:1 complexing. However the curve in Fig. 2 gives a maxima when dimer to ester molar ratio is 1 to ~2. Plots of optical density *vs.* [dimer] at all wavelengths used for the Job plots were found to be linear indicating that Beer's law is obeyed.

The following equilibria must be considered on the basis of the Job plots (ol = vinyl, allyl propionate (or acetate), ethylene, styrene, and neohexene).

$$[8]\quad Na_2Pd_2(OAc)_6 + ol \underset{}{\overset{K_{\pi 22}}{\rightleftharpoons}} Na[Pd_2(OAc)_5(ol)] + NaOAc$$

$$[9]\quad Na_2Pd_2(OAc)_6 + 2ol \overset{K_{\pi 21}}{\rightleftharpoons} 2Na[Pd(OAc)_3(ol)]$$

$$[10]\quad Na_2Pd_2(OAc)_6 + 2ol \overset{K'_{\pi 22}}{\rightleftharpoons} [Pd_2(OAc)_4(ol)_2] + 2NaOAc$$

This complicated set of equilibria can be simplified since the Job plots (see Results section) indicate reaction 8 is the fast equilibrium. This 1:1 type of complex formation can be treated by the Benesi–Hildebrand type of plot (14). For reaction 8 the equilibrium can be written

$$[11]\quad K_{\pi 22} = \frac{[NaPd_2(OAc)_5(ol)][NaOAc]}{[Na_2Pd_2(Ac)_6][ol]}$$

which at constant acetate becomes

$$[12]\quad K''_{\pi 22} = \frac{[NaPd_2(OAc)_5(ol)]}{[Na_2Pd_2(OAc)_6][ol]}$$

The difference in optical density, D_i, at a given olefin concentration and that at zero olefin concentration can be expressed as follows;

$$[13]\quad \frac{D_i - D_0}{l} = \varepsilon_{\pi_2}\pi_2 + \varepsilon_{P_2}P_2 - \varepsilon_{P_2}P_{20}$$

where π_2 is the concentration of $[NaPd_2(OAc)_5(ol)]$, P_2 is the concentration of $[Na_2Pd_2(OAc)_6]$ at a given olefin concentration, and P_{20} is the concentration in the absence of olefin. ε_{π_2} and ε_{P_2} are the corresponding extinction coefficients and l is the path length of the cell. Since $\pi_2 = P_{20} - P_2$, and $D_i - D_0 = \Delta D$, eq. 13 can be rewritten as eq. 14.

$$[14]\quad \frac{\Delta D}{l} = \pi_2(\varepsilon_{\pi_2} - \varepsilon_{P_2}) = \pi_2\Delta\varepsilon$$

Substituting eq. 14 into eq. 12 and rearranging gives eq. 15.

$$[15]\quad \frac{P_{20}}{\Delta D} = \frac{1}{\Delta\varepsilon l} + \frac{1}{\Delta\varepsilon l K''_{\pi 22}[ol]}$$

Equation 15 predicts that a plot of $P_{20}/\Delta D$ *vs.* 1/[ol] should be linear. In fact such plots were linear for all the olefins studied. From the slope and intercept of these lines could be obtained values of $K''_{\pi 22}$ (and thus $K_{\pi 22}$). Some representative plots are given in Figs. 3 and 4. Values of $K_{\pi 22}$ are summarized in Table 1. At sodium acetate concentrations of over 0.2 *M* a correction was made for conversion of $Na_2Pd_2(OAc)_6$ to $Na_2Pd(OAc)_4$ via reaction 6.

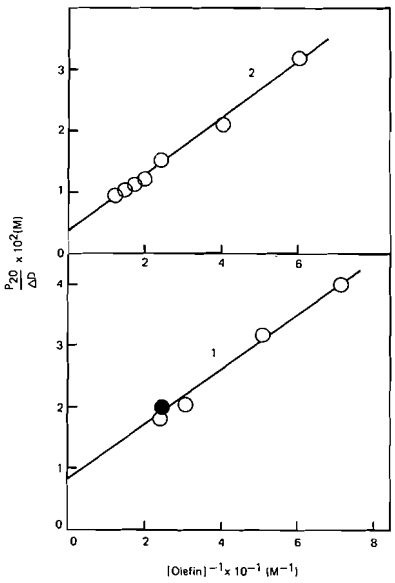

FIG. 3. Plots of $P_{20}/\Delta D$ *vs.* inverse of olefin concentration: (*1*) olefin = ethylene; ○, $[Na_2Pd_2(OAc)_6]$ = 0.0032 *M*; ●, $[Na_2Pd_2(OAc)_6]$ = 0.0016 *M*; [NaOAc] = 0.200 *M*; optical pathlength = 5 mm; (*2*) olefin = styrene; $[Na_2Pd_2(OAc)_6]$ = 0.0063 *M*; [NaOAc] = 0.400 *M*; optical pathlength = 1 mm.

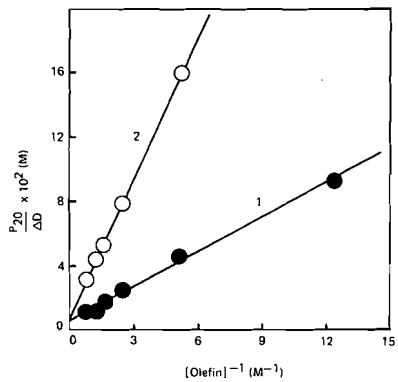

FIG. 4. Plots of $P_{20}/\Delta D$ *vs.* inverse of allylic propionate concentration. $[Na_2Pd_2(OAc)_6]$ = 0.0064 *M*; optical pathlength = 1 mm. (*1*) [NaOAc] = 0.200 *M*; (*2*) [NaOAc] = 1.00 *M*.

The second equilibrium, which took several hours to attain, was studied for vinyl acetate, allyl acetate, and allyl propionate only since the other olefins give a precipitate of Pd metal upon standing this length of time. This precipitate no doubt resulted from oxidation of the ethylene, styrene, and neohexene.

The determination of equilibrium constants for the second equilibria was simplified by the fact that the con-

version to π-complex was complete at easily attainable olefin concentrations. Thus the extinction coefficients for both initial and final species are known. Either reaction 9 or 10 can be assumed to be the correct equilibrium and constants calculated. Whichever of $K_{\pi 21}$ or $K'_{\pi 22}$ remains constant with changing reaction conditions is correct. Sample calculations for allyl acetate are given in Table 2.

Results

Composition of Complexes, Job Plots

Plots of absorption of light (ΔD) *vs.* composition of dimer–olefin solutions, Figs. 1 and 2, show a wavelength dependence of maxima. Such a result would not be expected when only a single complex is formed. In fact for a single complex the maxima or minima in ΔD should be independent of the wavelength of light used. Similar results have been reported by Vosburgh and Cooper (15) for *o*-phenanthroline and nickel ion complexes. A critical review of the application of the method of continuous variation in the case of mixed complexes has been discussed by Rossotti and Rossotti (16). As shown below the application of this method in determining the stoichiometry of the complexes formed in the present work proved particularly simple. First under the experimental conditions of Job plots (Figs. 1 and 2) the species formed are stable. Second, the difference between the extinction coefficients of the two complexes and dimeric species in different regions of spectrum is great.

Now assume that reaction 8 and either reaction 9 or 10 are operative. Since the Job plot will not distinguish between [9] or [10] assume for simplicity that [8] and [9] are the two equilibria and designate π_2' for $[Pd_2(OAc)_4(ol)_2]$ and ε_{π_2}' its corresponding extinction coefficient. Then since ε_{ol} is negligible at the wavelength used, for sample (S) and reference (R) solutions, the optical density is given by

$$[16] \qquad D_S = l(\varepsilon_{P_2}P_2 + \varepsilon_{\pi_2}\pi_2 + \varepsilon_{\pi_2}'\pi_2')$$

$$[17] \qquad D_R = l(\varepsilon_{P_2}M(1 - x))$$

where x is the mole fraction of olefin.

Subtracting eq. 17 from eq. 16 gives eq. 18

$$[18] \quad \Delta D = D_S - D_R = l(\varepsilon_{P_2}P_2 + \varepsilon_{\pi_2}\pi_2 + \varepsilon_{\pi_2}'\pi_2' - \varepsilon_{P_2}M(1 - x))$$

The mass balance is given by eqs. 19 and 20

$$[19] \qquad P_2 = M(1 - x) - \pi_2 - \pi_2'$$

$$[20] \qquad \frac{dP_2}{dx} = -M - \frac{d\pi_2}{dx} - \frac{d\pi_2'}{dx}$$

Differentiating eq. 18 and substituting for dP_2/dx from eq. 20, eq. 21 follows:

$$[21] \quad \frac{d}{dx}(\Delta D) = l\left\{(\varepsilon_{\pi_2} - \varepsilon_{P_2})\frac{d\pi_2}{dx} + (\varepsilon_{\pi_2}' - \varepsilon_{P_2})\frac{d\pi_2'}{dx}\right\}$$

If the complex formed is assumed to be $[NaPd(OAc)_3(ol)](\pi_1)$, (reaction 10), then the corresponding relation for $d(\Delta D)/dx$ is given by

$$[22] \quad \frac{d}{dx}(\Delta D) = l\left\{(\varepsilon_{\pi_2} - \varepsilon_{P_2})\frac{d\pi_2}{dx} + (\varepsilon_{\pi_1} - \tfrac{1}{2}\varepsilon_{P_2})\frac{d\pi_1}{dx}\right\}$$

Equations 21 and 22 imply that the maxima will depend on the extinction coefficients at the wavelengths used. If $\varepsilon_{\pi_2} - \varepsilon_{P_2}$ is much greater than $\varepsilon_{\pi_2}' - \varepsilon_{P_2}$ or $\varepsilon_{\pi_1} - \frac{1}{2}\varepsilon_{P_2}$ then the maxima will occur at the 1:1 complex. This is apparently the case at λ = 320, 330, and 335 nm while at λ = 280 and 290 nm the opposite is the case and the maximum occurs at the 2-olefin:1-$Na_2Pd_2(OAc)_6$ complex.

Note that because of the lack of precision of the data (see Experimental) the Job plots cannot be treated in a quantitative fashion. Thus, the plots are not linear on either side of the maxima as would be expected from high quality Job plots. However, the maxima do occur at approximately the expected compositions.

Labile π-Complex

The wavelengths at which the 1:1 maxima appears on the Job plots are those wavelengths at which the initial rapidly formed complex absorbs strongly.

If, as this result indicates, reaction 8 represents the rapid equilibrium, then the data can be treated by the Benesi–Hildebrand method (14). This treatment predicts a linear plot of $P_{20}/\Delta D$ *vs.* 1/[olefin]. As shown in Figs. 3 and 4 linear plots were obtained for which an equilibrium constant, $K''_{\pi 22}$ (eq. 12), could be calculated at any given [NaOAc]. Since a single run does not give the [NaOAc] term in the equilibrium, runs were made in some cases at more than one [NaOAc]. As can be seen from

TABLE 3. Values of the equilibrium constants $K_{\pi 21}$ at 25 °C for various olefin complexes of Pd(II)

Olefin	$K_{\pi 21}$ (M^{-1})
$H_2C{=}C(O_2CCH_3)H$	0.51 ± 0.05*
$H_2C{=}CH{-}CH(O_2CCH_3)H$	6.7 ± 1.2
$H_2C{=}CH{-}CH(O_2CCH_2CH_3)H$	8.8 ± 2.1

*Standard deviation.

Table 1, $K''_{\pi 22}$ varies with [NaOAc] but the true equilibrium constant, $K_{\pi 22}$ does not.

Nonlabile π-complex

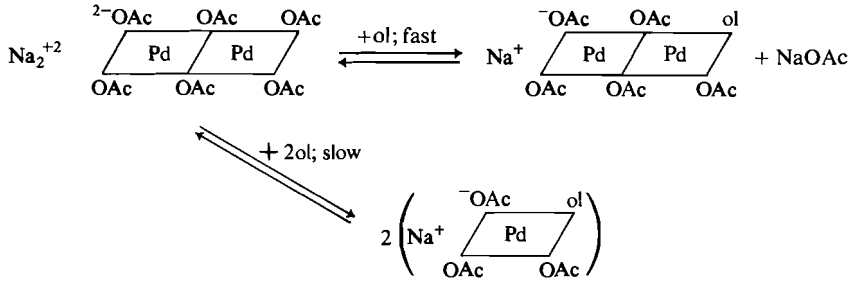
The wavelengths for the Job plot at which the maximum for a 2:1 olefin to $Na_2Pd(OAc)_6$ π-complex was obtained corresponded to the region in which the slowly formed complex absorbed strongly. This suggests the equilibrium is represented either by reaction 9 or 10. Sample calculations of the values of $K_{\pi 21}$ and $K'_{\pi 22}$ with allyl acetate as substrates are given in Table 2. It is apparent that $K'_{\pi 22}$ varies much more than $K_{\pi 21}$. This is particularly evident when the sodium acetate concentration is varied. This type of result was obtained with all three olefins. Thus reaction 9 must be the correct equilibrium for the slow reaction. The values of $K_{\pi 21}$ for the three olefins are given in Table 3.

Discussion

The evidence for the types of equilibrium in this system is twofold. First there are the Job plots shown in Figs. 1 and 2. Unfortunately these plots are not of the highest quality because of the limited solubility of $Na_2Pd_2(OAc)_6$ (see Experimental) and are only semiquantitative indications of the compositions of the complexes. However, it is interesting that both the rapidly and slowly formed π-complexes could be detected and their approximate stoichiometry determined.

The second type of evidence involves the Benesi–Hildebrand plots for the labile complex (Figs. 3 and 4) and the calculation of equilibrium constants from spectral data at final equilibrium (Table 2). This second type of evidence is certainly the most quantitative and conclusive evidence for the correct modes of complexing since the accuracy of the data is not limited by $Na_2Pd_2(OAc)_6$ solubility.

In any case both types of results are in agreement and clearly indicate that replacement of terminal acetates on palladium(II) acetate by olefins is a fast reaction while breaking of acetate bridges is a slow reaction. The nonlability of bridging



[23]

acetates was demonstrated by the previous study on reaction of palladium(II) acetate with sodium acetate in acetic acid (8) but the demonstration of lability of terminal acetates is new. The exact reason for the nonlability of bridging acetates is not known. It could be that the acetate in the bridging form is particularly stable or it could be related to the fact that two acetate bridges must be broken simultaneously to give the monomer π-complexes. A kinetic study of the interaction of $Na_2Pd_2(OAc)_6$ with allyl acetate, presently in progress,[2] could shed some light on this question.

The two equilibria found in the all-acetate

system are analogous to those found for allylic esters in the chloride system containing lithium chloride (6). In that system only the dimeric to monomeric π-complex was observed by equilibrium measurements (reaction 3) but small amounts of dimeric π-complex (reaction 4) were inferred from kinetic measurements on allylic ester exchange. In the present study the amount of dimeric π-complex at equilibrium was also much smaller than the monomeric π-complex. However the dimeric π-complex could be detected in the all-acetate system only because it was formed much more rapidly than monomeric π-complex. The formation of $[Pd_2(OAc)_4(ol)_2]$ which would be analogous to one of the species postulated in the sodium chloride containing system (4, 5) was not found. However it may well be formed in the sodium chloride system since sodium chloride is sparingly soluble (0.013 *M*) in acetic acid and the form of $[Pd_2Cl_4(ol)_2]$ would be strongly inhibited by free chloride. In the present study a sodium acetate level of at least 0.2 *M* had to be used to maintain the palladium(II) acetate in the dimeric state.

As was pointed out previously (8) the fact that sodium acetate equilibrates with palladium(II) acetate slowly complicates kinetic studies of Pd(II) catalysis in this system. The present results indicate further complications. For fast Pd(II) catalyzed reactions of olefins only the formation of dimeric π-complex will be important while for slow reactions the monomeric species will predominate. For systems in which the rate of catalysis is about equal to the rate of formation of $NaPd(OAc)_3(ol)$ the kinetics will be very complicated. Previous studies in the chloride system indicated the dimer was catalytically active while the monomer was not and preliminary results in this laboratory (17) indicate the same is true in the all-acetate system. Thus an olefin will inhibit its own reaction with Pd(II) by forming unreactive monomeric π-complex. In the acetate system the rate will change with time as reactive $NaPd_2(OAc)_5(ol)$ is slowly converted to unreactive $NaPd(OAc)_3(ol)$. In any case previous work on ethylene oxidation in this system (7) must be reinterpreted in light of the present results.

The fact that both monomeric and dimeric π-complexes were detected by the Job plots deserves brief comment. Since the formation constants for the monomeric π-complexes are much higher than those for the dimeric complexes one might expect that only the former be produced at complete equilibrium and in fact at the olefins concentrations used in most of the equilibrium work this is by far the predominate species. However because of the limited solubility of $Na_2Pd_2(OAc)_6$ the olefin concentration also had to be very low. Because of the nature of the equilibria (reactions 8 and 9), lower olefin concentrations favor $[NaPd_2(OAc)_5(ol)]$ more than $[NaPd(OAc)_3(ol)]$ and it was fortuitous that at the olefin concentrations used both were formed in sufficient amounts for detection.

The *trans*-Effect in Octahedral Complexes. VI. Base Hydrolysis of *trans*-Hydroxybromo and *trans*-Hydroxychlorobis(ethylenediamine)-rhodium(III) Complexes

ANTHONY POË AND CAROL VUIK

Erindale College and the Department of Chemistry, University of Toronto, Mississauga, Ontario L5L 1C6

Received January 22, 1975

ANTHONY POË and CAROL VUIK. Can. J. Chem. **53**, 1842 (1975).

The kinetics of base hydrolysis of the complexes *trans*-$[Rh(en)_2(OH)X]^+$ (X = Br or Cl) follow the pseudo first order rate equation $k_{obs} = k_1 + k_2[OH^-]$. The small contribution of the $[OH^-]$-dependent term is due to lower values of $\Delta S_2^* - \Delta S_1^*$ than are observed for the complexes *cis*-$[Rh(en)_2(OH)Cl]^+$ and $[Rh(NH_3)_5X]^{2+}$ (X = Cl, Br, or I). The values of ΔH_1^* are used to obtain new values of the *intrinsic kinetic trans*-effect (i.k.t.e.) of hydroxide that agree with that determined from aquation of *trans*-$[Rh(en)_2(OH)I]^+$ and place hydroxide in the i.k.t.e. series $I \gg Br > NH_3 > OH \gtrsim Cl$. The new data also allow hydroxide to be placed in a thermodynamic *trans*-effect (t.t.e.) series $I > OH > NH_3 > Br > Cl > OH_2$, and the different position of hydroxide in the two series is discussed.

ANTHONY POË et CAROL VUIK. Can. J. Chem. **53**, 1842 (1975).

La cinétique de l'hydrolyse basique des complexes $[Rh(en)_2(OH)X]^+$ *trans* (X = Br ou Cl) suit l'équation de vitesse du pseudo premier ordre: $k_{obs} = k_1 + k_2[OH^-]$. La faible contribution du terme dépendant de $[OH^-]$ est dû aux valeurs plus faibles de $\Delta S_2^* - \Delta S_1^*$ que celles observées pour les complexes $[Rh(en)_2(OH)Cl]^+$ *cis* et $[Rh(NH_3)_5X]^{2+}$ (X = Cl, Br ou I). On utilise les valeurs de ΔH_1 pour obtenir de nouvelles valeurs de l'effet *cinétique intrinsèque trans* (i.k.t.e.) de l'hydroxyde qui sont en accord avec celle déterminée à partir de l'aquation du $[Rh(en)_2(OH)I]^+$ *trans*; ces résultats indiquent que dans la série i.k.t.e. l'hydroxyde se range de la façon suivante: $I \gg Br > NH_3 > OH \gtrsim Cl$. Les nouvelles données permettent aussi de ranger l'hydroxyde dans une série d'effet thermodynamique *trans* (t.t.e.) $I > OH > NH_3 > Br > Cl > OH_2$; on discute de la position d'hydroxyde des deux séries.

[Traduit par le journal]

A kinetic study of the base hydrolysis of *trans*-$[Rh(en)_2(OH)I]^+$ has been reported (1). The reaction followed the rate equation $k_{obs} = k_1 + k_2[OH^-]$ and the value of ΔH_1^* was combined with the enthalpy of activation for the anation of *trans*-$[Rh(en)_2(OH)OH_2]^{2+}$ by iodide (2) to provide a single measure of the *intrinsic kinetic trans*-effect (i.k.t.e.) (3) of hydroxide in such complexes. Since the i.k.t.e. of any ligand is obtained in such a way that it should be independent of the particular interchange reaction used to measure it we now report kinetic studies of the base hydrolysis of the analogous hydroxybromo and hydroxychloro complexes which confirm this independence for the *trans*-hydroxy complexes. The second-order term in the rate equation for reaction of *trans*-$[Rh(en)_2(OH)I]^+$ (not previously found in such *trans*-diacido complexes (4, 5)) has also been found in these reactions.

Experimental

The complexes *trans*-$[Rh(en)_2X_2]ClO_4$ (X = Cl or Br) were prepared by standard methods (6, 7). Satisfactory analyses were obtained for carbon, nitrogen, and hydrogen and the electronic spectra (Table 1) of aqueous solutions of the complexes were in satisfactory agreement with published results (6, 8) although there are some slight differences in the extinction coefficients, particularly of the highest energy band of the dibromo complex (*cf.* $\varepsilon = 31\,000\ cm^{-1}\ l\ mol^{-1}$ (8)). Two previously unreported higher energy bands for the dichloro complex are also listed. Solutions of the *trans*-hydroxyhalogeno complexes were obtained by dissolving *ca.* 1 mmol of the *trans*-dihalogeno complexes in the minimum of hot water and refluxing with 1 cc of 0.1 *M* perchloric acid and 10 cc of *ca.* 0.1 *M* silver perchlorate (1 equiv.) for 200 min (X = Cl) or 40 min (X = Br). Curved rate plots were obtained when the base hydrolyses of such solutions were studied spectrophotometrically and it was evident that the solutions contained mixtures of complexes. Pure solutions of the hydroxyhalogeno complexes were obtained by pressure chromatography through a 12 cm-long column of Dowex 50W (100–200 mesh). Elution with 0.5 *M* sodium perchlorate

completely removed the *trans*-dihalogeno complexes (detected and identified by their electronic spectra) and subsequent elution with a solution 0.1 *M* in sodium hydroxide and 0.5 *M* in sodium perchlorate removed what was believed to be the *trans*-hydroxyhalogeno complexes. Reaction with acid solutions of the appropriate halide reconverted these into spectroscopically pure solutions of the corresponding *trans*-dihalogeno complexes. A knowledge of the absorbances of the particular eluate used, of the sum of the absorbances and volumes of all the eluates containing particular complexes, and of the appropriate extinction coefficients of the *trans*-dihalogeno complexes, enabled an estimate to be made of the proportion of the unreacted *trans*-dihalogeno complexes in the original solutions of the reaction products (*ca.* 15% in both cases). The concentration of hydroxyhalogeno complexes in a particular eluate was also easily obtained from the absorbances of the *trans*-dihalogeno complexes produced after anation with acid halide solutions. The spectroscopic data for the hydroxyhalogeno complexes are also reported in Table 1 together with those for the dihydroxy product of base hydrolysis. It can be seen that the latter are essentially independent of the nature of the starting complex and the hydroxide concentration. The assignment of a *trans*-structure to these complexes is made on the grounds (*a*) that the kinetic behavior (see below) shows that the solutions are "kinetically" pure, *i.e.* they contain only one species since it is highly unlikely that *cis* and *trans* complexes would react at the same rates, (*b*) the product of base hydrolysis is spectroscopically pure *trans*-$[Rh(en)_2(OH)_2]^+$ (2), and (*c*) that complete *trans* → *cis* rearrangement during the reaction of *trans*-$[Rh(en)_2X_2]^+$ with silver ions, and complete *cis* → *trans* rearrangement on anation of the aquohalogeno complexes and on base hydrolysis of the hydroxyhalogeno complexes is not in accord with the known stereochemical retention that occurs in all reactions of *trans*-dihalogeno complexes studied so far (5, 7–9). The only cases where substantial *trans* → *cis* rearrangements have been found in such diacido complexes are in base hydrolysis of the *trans*-dihalogeno complexes (10). These rearrangements were shown to be associated with the $[OH^-]$-dependent term that appears in the rate equation. The mixed *cis* and *trans* products of such reactions were easily detected by their own u.v.–visible spectra, by the spectra of the mixed dihalogeno products of their anation reactions, and by their separation by ion exchange chromatography (10).

Spectroscopic Changes During Base Hydrolysis

The spectra changed smoothly from those characteristic of the *trans*-hydroxyhalogeno complexes to that of the *trans*-dihydroxy complex. Absorbance changes in the 300–400 nm range were quite small but clear isosbestic points were observed at 301 and 360 nm (hydroxybromo reaction) and at 296 and 358 nm (hydroxychloro reaction). In both cases quite large absolute decreases in absorbance occurred below *ca.* 250 nm because of a shift in a very high intensity band to lower wavelengths, this shift being greater during reaction of the hydroxybromo complex. In the reactions of the hydroxychloro complex the spectral changes at *ca.* 250 nm depended slightly on the concentration of hydroxide, isosbestic points that appeared at 253 and 266 nm in 0.07 *M* not being evident in 0.7 *M* hydroxide.

Kinetics of Base Hydrolysis

Reactions were followed spectrophotometrically, the reacting solutions being contained in 10 mm cells in thermostatted cell holders of a Perkin–Elmer 402 or Cary 16K spectrophotometer, up to five reactions being followed simultaneously. Temperatures were measured either with a thermistor (Cary 16K) or precision thermometer (Perkin–Elmer 402). Reaction mixtures came to constant temperature within 10 min and exposure to the spectrophotometer light for different amounts of time had no effect on the rates. The kinetics were followed at 250 or 255 nm (hydroxybromo complex; absorbance decreased from *ca.* 1.2 to 0.6) and at 240 nm (hydroxy-

*$\Delta H_{obs}^{\ddagger} = 26.38 \pm 0.10$ kcal mol^{-1}; $\Delta S_{obs}^{\ddagger} = 3.11 \pm 0.29$ cal mol^{-1} deg^{-1}; $\sigma(k_{obs}) = \pm 2.0\%$.

chloro complex; absorbance decreased from *ca.* 1.0 to 0.6). Excellent first order rate plots were obtained (linear for three half-lives) and the dependence of the pseudo-first-order rate constants (Tables 2 and 4) on $[OH^-]$ was determined up to $[OH^-] = ca.$ 0.8 *M*, the ionic strength being maintained at 1.0 *M* with sodium perchlorate. A small but significant dependence was observed and the data were analyzed by a linear weighted least squares treatment according to the rate equation $k_{obs} = k_1 + k_2[OH^-]$, all values of k_{obs} being assumed to have the same percentage standard deviation. When values at a given temperature were considered separately there seemed to be no significant change of $\sigma(k_{obs})$ with temperature so values of k_{obs} at all temperatures were assumed to have the same standard deviation, the number of degrees of freedom being thereby greatly increased. When this pooling was applied to data for the reaction of *trans*-$[Rh(en)_2(OH)I]^+$ (1) the activation parameters previously reported were modified very slightly and the new values are given in Table 5 for comparison. Values of k_1, k_2, and $\sigma(k_{obs})$ are shown in Table 5, the uncertainties (standard deviations) having been corrected according to the number of degrees of freedom so that good estimates of 95% confidence levels can be obtained by doubling the standard deviations. Activation parameters (Table 5) were estimated by a linear weighted least squares analysis of the dependence of $\log(k_1/T)$ and $\log(k_2/T)$ on $1/T$, the uncertainties in $\log(k_1/T)$ and $\log(k_2/T)$ being derived from the uncertainties in k_1 and k_2. In the case of reactions of the *trans*-hydroxybromo complex with 0.032 *M* hydroxide (Table 3) the k_2 term contributed less than 1% to the value of k_{obs} (Table 5) and values of $\Delta H_1^{\ddagger}$ and $\Delta S_1^{\ddagger}$ for this reaction were calculated by a least squares analysis, all the rate constants in Table 3 being assumed to have the same percentage standard deviation.

Discussion

The Intrinsic Kinetic trans-Effect of Hydroxide

If the kinetic *trans*-effects of various ligands L in *trans*-$[RhA_4LX]^{n+}$ complexes (A = NH_3 or $\frac{1}{2}$en) are defined simply in terms of the relative rate constants or activation enthalpies for displacement of X by a water molecule (or for the reverse, anation reaction) then it is found that the *trans*-effect order depends on the nature of X (1–3). However, it has been shown (3) that an *intrinsic kinetic trans*-effect (i.k.t.e.) can be defined by comparing the activation enthalpy for a particular reaction with that found ($\Delta H_{ref}^{\ddagger}$) for a hypothetical reaction

[1] *trans*-$[Rh(en)_2IY]^{n+} + OH_2 \rightleftharpoons$ *trans*-$[Rh(en)_2I(OH_2)]^{(n+1)+} + Y^-$

that has the same value of ΔH^0. The latter values are obtained by interpolation of plots of $\Delta H^{\ddagger}$

against ΔH^0 for reactions of the *trans*-iodo complexes, these being a useful reference since iodide has the strongest *trans*-effect of the ligands so far studied, and the data obtained for these complexes are among the most precise found (9, 11). The larger the value for $\Delta H_{obs}^{\ddagger} - \Delta H_{ref}^{\ddagger}$ the smaller the i.k.t.e.

Kinetic data for the reactions

[2] *trans*-$[Rh(en)_2(OH)I]^+ + OH_2 \rightleftharpoons$ *trans*-$[Rh(en)_2(OH)OH_2]^{2+} + I^-$

showed, by comparison with other reactions involving interchange of iodide and OH_2 ligands but with different groups in the position *trans* to the reaction site, that the simple kinetic *trans*-effect of hydroxide did depend on the nature of the reaction chosen to measure it (1). Derivation of the i.k.t.e. removed this ambiguity and a value very close to that for chloride was obtained. The data reported here enable a further test to be made of the conclusion that values of the i.k.t.e. should be independent of the particular reactions used to measure it since the values of $\Delta H_1^{\ddagger}$ obtained (Table 5) can be taken to be the activation enthalpies for the aquation reactions of the *trans*-hydroxybromo and *trans*-hydroxychloro complexes, the hydroxide being necessary only to drive the re-

action to completion by converting the aquo product to the hydroxy form.

Values of the activation enthalpies for the reactions

[3] *trans*-$[Rh(en)_2(OH)OH_2]^{2+} + X^- \rightarrow$ *trans*-$[Rh(en)_2(OH)X]^+$

(X = Cl or Br) are not known because, at the p*H* at which the hydroxyaquo complex exists as the preponderate species compared with the dihydroxy and diaquo complexes, the products of this reaction are the chloro and bromoaquo complexes that undergo further reaction in such a way as to make study of the first step extremely difficult (2). However, the enthalpies of activation for anation of such rhodium(III) complexes depend on the nature of the halide in a way which seems to be essentially independent of the nature of the complex. Thus $\Delta H^{\ddagger}$ for anation of *trans*-$[Rh(en)_2LOH_2]^{2+}$ by chloride is 0.9 ± 0.4, -0.3 ± 0.6, and 0.9 ± 0.1 kcal mol^{-1} greater than that for anation by bromide when L is Cl, Br, and I, respectively (11). Similarly, $\Delta H^{\ddagger}$ for anation of $[Rh(NH_3)_5OH_2]^{3+}$ by chloride, is 0.2 ± 0.6 kcal mol^{-1} greater than for anation by bromide (3). These values are not distinguishably different within the precision of the measurements. (The constancy of these differences in relative nucleophilic character, when the latter is defined in terms of $\Delta H^{\ddagger}$ for anation, is also generally implied by the fact that a plot of $\Delta H^{\ddagger}$ against ΔH^0 for anation or aquation of complexes with a particular *trans* group lies a constant value of $\Delta H^{\ddagger}$ above the corresponding plot for reactions involving a different *trans* group (3).) Quite precise values of differences in $\Delta H^{\ddagger}$ for anation of *trans*-$[Rh(en)_2IOH_2]^{2+}$ by chloride and iodide (1.4 ± 0.2 kcal mol^{-1}), and by bromide and iodide (0.6 ± 0.1 kcal mol^{-1}) were obtained directly by competition studies (11) and compare quite well with corresponding differences of 1.1 ± 0.5 and 0.9 ± 0.4 kcal mol^{-1} for anation of $[Rh(NH_3)_5OH_2]^{3+}$ for which each anation reaction was studied separately (3), thus leading to lower precision. We therefore assume that the relative nucleophilicities (in terms of $\Delta H^{\ddagger}$ for anation) of chloride, bromide, and iodide are the same for *trans*-$[Rh(en)_2(OH)OH_2]^{2+}$ as for *trans*-$[Rh(en)_2IOH_2]^{2+}$ and obtain values of $\Delta H^{\ddagger} = 25.2 \pm 0.2_5$ and $24.4 \pm 0.1_9$ kcal mol^{-1} for anation of *trans*-$[Rh(en)_2(OH)OH_2]^{2+}$ by chloride and bromide, respectively. These lead to values of -0.1 ± 0.3 (X = Cl) and 1.9 ± 0.2 (X = Br) kcal mol^{-1} for ΔH^0 for the reactions

[4] *trans*-$[Rh(en)_2(OH)X]^+ \rightarrow$ *trans*-$[Rh(en)_2(OH)OH_2]^{2+} + X^-$

The reference values $\Delta H_{ref}^{\ddagger}$ for the hypothetical reactions of *trans*-iodo complexes that have the same values of ΔH^0 as reaction 4 are 20.3 ± 0.2 and 21.4 ± 0.1 kcal mol^{-1} for X = Cl and Br, respectively, and 20.4 ± 0.2 and 19.4 ± 0.1 kcal mol^{-1} for reaction 3 with X = Cl and Br, respectively. The differences between the values of $\Delta H^{\ddagger}$ obtained for reactions of the *trans* hydroxy complexes and these $\Delta H_{ref}^{\ddagger}$ reference values are 4.8 ± 0.3, 4.9 ± 0.2, 4.8 ± 0.3, and 5.0 ± 0.3 kcal mol^{-1}, respectively, as compared with values (1) of 5.1 ± 0.3 and 5.1 ± 0.2 kcal mol^{-1} from aquation of *trans*-$[Rh(en)_2(OH)I]^+$ and anation by iodide of *trans*-$[Rh(en)_2(OH)OH_2]^{2+}$, respectively. These values are a measure of the i.k.t.e. relative to iodide as a standard, the larger the difference $\Delta H^{\ddagger} - \Delta H_{ref}^{\ddagger}$ the smaller the *trans*-effect.

It is clear, therefore, that this measure of the i.k.t.e. of hydroxide is indeed independent of the actual reaction used to study it provided appropriate reference values are used. The average of the six values obtained is $4.9_3 \pm 0.1_2$ kcal mol^{-1} which can be compared with values (3) of $5.0_2 \pm 0.1_8$, $4.7_5 \pm 0.1_5$, and $3.2_0 \pm 0.2_0$ kcal mol^{-1} for the corresponding i.k.t.e. of chloride, ammonia, and bromide, respectively, and the *trans*-effect order is therefore $I \gg Br > NH_3 > OH \gtrsim Cl$. This order correlates qualitatively with the polarizability of the *trans* group as measured by the molar refraction (12) of the free ligands. Indeed, as shown in Fig. 1, a linear relation is observed for the three halide ligands but the values for hydroxide and ammonia lie 1–2 kcal mol^{-1} below this line. A factor which could contribute to deviations of this sort is the different nature of the solvation of the complex in the vicinity of the *trans* ligand. When this is a halide ion the solvent water molecules will tend to be attracted to the ligand through H—O—H· · ·X—Rh hydrogen bonding. As the transition state is approached the halide ligand will tend to

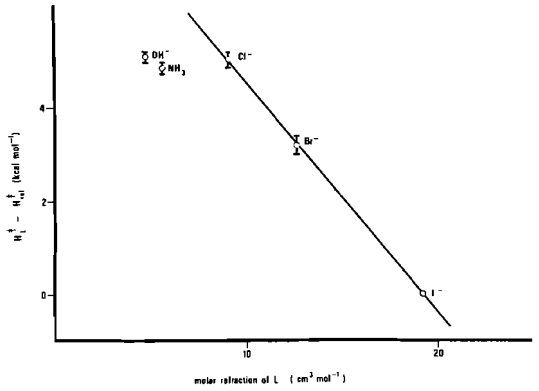

FIG. 1. The dependence of the i.k.t.e. of L on the polarizability of the *trans* ligand where i.k.t.e. = $-(\Delta H_L^{\ddagger} - \Delta H_{ref}^{\ddagger})$.

become more strongly bound to the metal as the leaving group withdraws its electrons.[1] This will tend to decrease the negative charge on the halide and decrease the strength of the H—O—H· · ·X—Rh interaction. On the other hand, when the *trans* ligands are hydroxide or ammonia the solvation will tend to involve hydrogen bonding of the type H_2O· · ·H_3N—Rh and H_2O· · ·HO—Rh so that the effect of the strengthening of the NH_3—Rh and HO—Rh bonds as the transition state is approached will be to increase the positive charge on the hydrogen atom(s) of the *trans* ligand and increase the strength of the hydrogen bonding to the solvent.

The Thermodynamic trans-Effect of Hydroxide

The new data also enable an estimate to be made of the thermodynamic *trans*-effect (t.t.e.) of hydroxide. This has been defined (3, 7, 11) in terms of the standard enthalpies of the complexes *trans*-$[Rh(en)_2LX]^{n+}$, the enthalpies increasing along the series X = Cl < Br < I, and being measured relative to that of *trans*-$[Rh(en)_2LI]^{n+}$ as standard. The thermodynamic *trans*-effect can be quantitatively expressed by the gradient of a plot of H^0(*trans*-$[Rh(en)_2LX]^{n+}$) against H^0(*trans*-$[Rh(en)_2ClX]^+$). Lower gradients are associated with higher thermodynamic *trans*-effects, the latter having been associated (3, 7) essentially with the class (*b*), or soft, nature (13) of the $[Rh(en)_2L]^{(n+1)+}$ moiety. This is not entirely arbitrary as it is the softness or polarizability of the *trans*-ligand that seems to lead to high kinetic *trans*-effects (see above and refs. 7 and 9) and also leads to high thermodynamic *trans*-effects when they are defined in this way. The relative enthalpies of the complexes *trans*-$[Rh(en)_2(OH)X]^+$ are calculated from the values of ΔH^0 for the reactions

[5] *trans*-$[Rh(en)_2(OH)Y]^+ + I^-$
$\rightleftharpoons$ *trans*-$[Rh(en)_2(OH)I]^+ + Y^-$

(Y = Cl and Br) by subtracting the enthalpy contribution due to the different hydration enthalpies of the free halides. In order to obtain values consistent with our earlier data we have used the older values (14) for the enthalpies of hydration of the halides rather than the newer ones (15) that are significantly, though not greatly, different. (The choice of values will not affect the gradients of the plots of H^0(*trans*-$[Rh(en)_2LX]^{n+}$) against H^0(*trans*-$[Rh(en)_2ClX]^+$ although the magnitude of individual relative H^0 values will be changed.) The value of the gradient for the *trans*-OH complexes is 0.77 which places the t.t.e. of hydroxide in the series I > OH > NH_3 > Br > Cl > OH_2. This order is quite different from that of the i.k.t.e. discussed above, although it is likely that the i.k.t.e. of OH_2 will also turn out to be very low, since the polarizability of H_2O is low. The t.t.e. of a ligand L has been shown to be a function both of the intrinsic *trans* bond weakening effect (t.b.w.e.) of the *trans* ligand L due to its σ donor capacity and of the susceptibility to the *trans* bond weakening effect (s.t.b.w.e.) of the halide ligands on the Rh—L bond itself (7). The latter is an effect which does not show up in the i.k.t.e. which is independent of the leaving group. A high t.t.e. can arise from a high t.b.w.e. and/or from a low s.t.b.w.e. The higher position of NH_3 in the t.t.e. series than in the i.k.t.e. series was ascribed to a low t.b.w.e. coupled with a low s.t.b.w.e. (3*b*) and this could equally well be true for the hydroxide ligand. It is interesting that the order of decreasing t.t.e. parallels the order of decreasing intensity of the first ligand field (l.f.) band of *trans*-$[Rh(en)_2LCl]^{n+}$. It is tempting to say that this correlation arises because the intensity series

[1]Although it has been suggested (19, 20) that anation reactions of $[Rh(NH_3)_5OH_2]^{3+}$ may involve some associative character it seems unlikely that this will be sufficient actually to *increase* the electron density at the metal as the transition state is approached.

For personal use only.

measures the covalency of the Rh—L bond when it is *trans* to a halide, and therefore takes into account the susceptibility of L to *trans* bond weakening which is important in the t.t.e. series. However, the complicated nature of the factors which determine the intensity of l.f. transitions probably preclude such a simple approach. Finally, the position of NH_3 in the t.t.e. series does not correlate with the nephelauxetic ratio which has been suggested (11) as a parameter that might determine the magnitude of the t.t.e. Similarly, nephelauxetic ratios are not known for hydroxy complexes of rhodium(III) but they may be expected to be high by comparison with other anionic oxygen donor ligands (16). Clearly the t.t.e. is a complicated one for which no single simple explanation is likely to prove satisfactory.

The $[OH^-]$-dependent Reaction

The kinetic parameters for the $[OH^-]$-dependent reactions of the *trans*-hydroxybromo and *trans*-hydroxychloro complexes are very similar to those for the *trans*-hydroxyiodo complex (1). Those for other amine complexes of rhodium(III) (4, 5, 17) are characterized by values of $\Delta S_2^{\ddagger} - \Delta S_1^{\ddagger}$ of between 20 and 40 cal mol^{-1} deg^{-1} whereas these *trans* complexes have values of $\Delta S_2^{\ddagger} - \Delta S_1^{\ddagger}$ which are not significantly different from zero. The *trans* complexes have values of $\Delta H_2^{\ddagger} - \Delta H_1^{\ddagger}$ that are about the same or slightly smaller than those (4) for the complexes *cis*-$[Rh(en)_2(OH)Cl]^+$ (3.8 kcal mol^{-1}) and *cis*-$[Rh(en)_2(NO_2)Cl]^+$ (0.7 kcal mol^{-1}) so it is the entropy contribution that is decisive. In this connection it is interesting that reactions of both the *cis* complexes (4) and these *trans* complexes are stereoretentive so that the high values of $\Delta S_2^{\ddagger} - \Delta S_1^{\ddagger}$ observed for the *cis* complexes cannot be correlated with stereochemical change in the way expected from Tobe's correlation (18) in the analogous cobalt(III) complexes.

Crystal Structure of the Glaserite Form of $BaNaPO_4$

CRISPIN CALVO AND ROMOLO FAGGIANI
Institute for Materials Research, McMaster University, Hamilton, Ontario L8S 4M1

Received November 6, 1974

CRISPIN CALVO and ROMOLO FAGGIANI. Can. J. Chem. **53**, 1849 (1975).

Crystals of $BaNaPO_4$ were grown from a $Ba_3P_2O_8$–$Na_2B_4O_7$ melt. The crystals are trigonal, space group $P\bar{3}m1$ with $a = 5.622(4)$ and $c = 7.259(5)$ Å. The structure, isotypic with that of glaserite, was refined by full-matrix least-squares methods to a final R value of 0.042 using 218 unique reflections. There are three different cation sites. Na and Ba lie at sites of $\bar{3}m$ symmetry and are coordinated to 6 and 12 oxygen atoms respectively. The Na—O bond lengths are 2.344(7) Å and the two unique Ba—O bond lengths are 2.788(7) and 3.247(9) Å. The remaining cation site has $3m$ symmetry, a coordination number of 10, and contains equal amounts of Na^+ and Ba^{2+}. The bond lengths range from 2.548(12) to 3.017(7) Å. The phosphate group also has $3m$ symmetry with mean P—O bond lengths of 1.538 Å. The underbonded apical P—O bond length is 1.520 Å.

CRISPIN CALVO et ROMOLO FAGGIANI. Can. J. Chem. **53**, 1849 (1975).

On a fait croître des cristaux de $BaNaPO_4$ à partir d'un mélange de $Ba_3P_2O_8$–$Na_2B_4O_7$ en fusion. Les cristaux trigonaux appartiennent au groupe d'espace $P\bar{3}m1$ avec $a = 5.622(4)$ et $c = 7.259(5)$ Å. La structure qui est isotypique avec celle de la glaserite a été affinée par la méthode des moindres carrés (matrice complète) jusqu'à une valeur finale de R de 0.042 utilisant 218 réflexions indépendantes. Il y a trois sites différents pour les cations. Le Na et le Ba occupent des sites de symétrie $\bar{3}m$ et sont respectivement coordonnés à 6 et 12 oxygènes. Les longueurs de liaisons Na—O sont 2.344(7) Å et les deux longueurs des liaisons Ba—O sont 2.788(7) et 3.247(9) Å. Le dernier cation occupe un site de symétrie $3m$; il possède un nombre de coordination de 10 et contient des quantités égales de Na^+ et de Ba^{2+}. Les longueurs de liaisons varient de 2.548(12) à 3.017(7) Å. Le groupe phosphate possède aussi une symétrie $3m$ avec une valeur moyenne de 1.538 Å pour la longueur du lien P—O. La longueur de la liaison P—O vers le sommet en dessous de la molécule est de 1.520 Å. [Traduit par le journal]

Introduction

Wells (1) has outlined the variety of structures available to a system with stoichiometry $ABXO_4$, where X is a tetrahedrally coordinated ion. When A and B are both small the preferred structure type is phenacite with all cations tetrahedrally coordinated. For cations of intermediate size relative to that of oxygen atoms the most common structural types are olivine and spinel with the cations in octahedral sites. Here it appears that the interplay between the radius of X and those of A and B determine which of these structure types is stable (2, 3). If either A or B has a radius comparable to that of the oxygen ion the glaserite structure is stable, at least in some temperature range.

Polymorphic transformations abound even when A and B are chemically identical. Na_2SO_4 is said to have four phases (4), K_2SO_4 has two (5), and Ca_2SiO_4 has five (6). The number of structural possibilities increase substantially if A and B are different. Phosphates with this stoichiometry have been studied for their luminescence characteristics (7). Klement and Kresse have prepared a number of vanadates and arsenates in addition to phosphates with this stoichiometry (8). A tetragonal form of $BaNaPO_4$, stable at high temperatures, in addition to a glaseritelike phase has been reported (9). It has been proposed that glaserite, $K_3Na(SO_4)_2$, has K at $0,0,\frac{1}{2}$ and $\frac{1}{2},\frac{2}{3},z$ and Na at 0,0,0 (10). Although glaserite is regarded as a solid solution of αK_2SO_4 and $NaKSO_4$ (aphthitalite) the latter structure is said to have Na in the two cation sites of $\bar{3}m$ symmetry (0,0,0, $0,0,\frac{1}{2}$) and K in the remaining site (11). The $K_3Na(SO_4)_2$ structure is compatible with the expectation that K should prefer the sites of higher coordination number leaving the octahedrally coordinated site for Na. No reliable single crystal studies have been reported concerning this site preference.

Experimental

Crystals of $BaNaPO_4$ were obtained from a mix of $Ba_3(PO_4)_2$ and $Na_2B_4O_7$ in the molar ratio of 1 to 3. This mix was chosen in an attempt to prepare a barium analog of the Sr–apatite containing BO_2 groups (12). The mix

O(1)	2d	1/3	2/3	0.5091(17)	0.016(6)	0.010(5)
O(2)	6i	0.1849(16)	−x	0.2068(9)	0.020(4)	0.014(3)

*The thermal parameters appear in the structure factor expression as $T = \exp -2\pi^2(h^2b_1^2U_{11} + \ldots + 2hkb_1b_2U_{12} + \ldots)$ and the b_i's are reciprocal lattice vectors.

was heated to 1400 °C and slowly cooled. The resulting sample showed a few crystals on the surface of the amorphous looking mass.

A crystal with dimensions 0.1 × 0.1 × 0.4 mm was used to collect lattice parameters and intensity data. Unit cell parameters were determined by least-squares methods using 2θ values between 20 and 25°. The crystal data are as follows:

$BaNaPO_4$ f.w. = 255.30

Trigonal, $a = 5.622(5)$ Å, $c = 7.259(5)$ Å, $V = 198.7$ Å³, $Z = 2$, $\rho_x = 4.267$, $\rho_m = 4.17$ (13), space group $P\bar{3}m1$, $T = 21 \pm 2$ °C, $\lambda_{Mo\alpha} = 0.71069$ Å.

All the reflections in a hemisphere defined by $2\theta_{max} = 55°$ were scanned using a Syntex $P\bar{1}$ and graphite monochromatized Mo radiation. Peaks were scanned at a rate between 2 and 24 deg/min and backgrounds were determined at either side of the peak. Those reflections whose intensity measures were zero or less were discarded and of the remainder those with intensities less than 3σ were considered unobserved. σ was derived from the counting statistics for the peaks and backgrounds. A total of 218 reflections, 23 of them unobserved, remained after averaging symmetry equivalent reflections. The data were corrected for Lorentz and polarization effects. Absorption corrections ($\mu = 104.1$ cm^{-1}) were made assuming the crystal to be a cylinder.

The parameters reported for glaserite (10) were used as initial values in the least-squares refinement. Equal amounts of Na^+ and Ba^{2+} were assigned to each cation site. The scattering curves for Ba^{2+}, Na^+, P, and O^- were taken from the *International Tables for X-ray Crystallography* (14). Subsequent refinement indicated that the cations on the threefold axis through the origin were ordered. Thus Na^+ was placed at 0,0,0, Ba^{2+} at 0,0,½, and an equal mixture of Na^+ and Ba^{2+} at site 2d. Weights, chosen so that $\omega\Delta F^2$ would be independent of F_o, were assigned according to $[75 + 0.1F_o + 0.0003F_o^2]^{-1}$. This model refined readily to an R value of 0.042 and R_ω $(= \Sigma\omega(F_o - F_c)^2/\Sigma\omega F_o^2)^{1/2}$ of 0.052. The final values of the atomic and thermal parameters are in Table 1. The observed and calculated structure factors are in Table 2.[1]

[1]Photocopies of Table 2 are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Canada K1A 0S2.

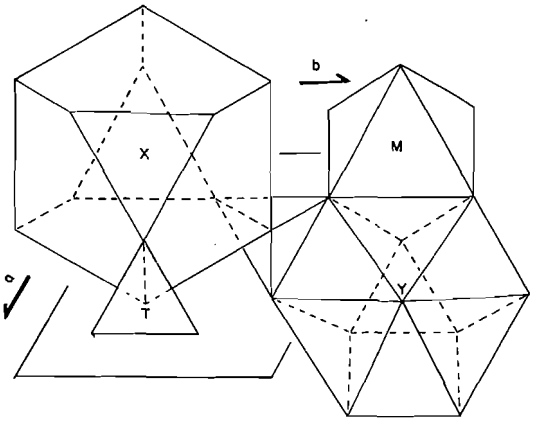

FIG. 1. A composite view of the $BaNaPO_4$ structure. Oxygen atoms are at the corners of the polyhedra enclosing the cations. The X polyhedron is at the origin. The M polyhedron is drawn displaced by a b axis length to prevent superposition and lies at 0,1,1/2. Tetrahedral groups are shown at 1/3,2/3 and 2/3,1/3 while the Y group is at 2/3,4/3.

Description of the Structure

$BaNaPO_4$ contain chains of polyhedra parallel to c. These alternately involve 6 and 12 oxygen atoms and are called the A chains. In each case six oxygen atoms, arising from six separate PO_4 groups, form a distorted octahedron about the cation (Fig. 1). The 12 coordinate site is generated by an additional long interaction $(=a/\sqrt{3})$ per phosphate group so that this cation, Ba^{2+} in the present case, shares six O(I)—O(II) edges. These edges lie in mirror planes containing the threefold axis. The six apical oxygen atoms, O(I)'s, are nearly coplanar and they together with the Ba^{2+} are said to lie in the equatorial plane of this cation. Na^+ and Ba^{2+} ions alternate in this chain sharing an octahedral face between neighbors.

The remaining cations (Y) lie at sites of $3m$ symmetry with 10 neighboring atoms in the B chains (Fig. 2). PO_4 groups and these cations alternate in a chain parallel to the c axis. The PO_4 groups share O(1) and a face composed of three O(II) atoms with alternate cations in this chain. The Y—O bond lengths to these oxygen atoms, at 3.017 Å, are long enough to indicate cationic repulsion. The remaining six arise from three edges shared with three PO_4 groups on neighboring B chains.

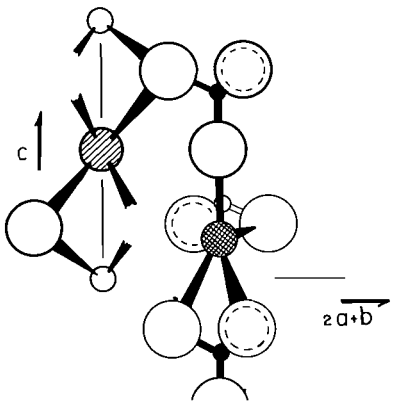

FIG. 2. The $BaNaPO_4$ structure near the plane $(1\bar{2}0)$. The large circles are oxygen atoms. The striped circle represents the X ion with the M (small open circle) on the same threefold axis. The Y ion is crosshatched. The full environment of the cations are generated by the threefold axes.

The pertinent bond lengths and angles are in Table 3. The Ba^{2+} has six nearest neighbors at 2.788 Å involving O(2) and six further interactions with O(1) type oxygen atoms at 3.247 Å. The six neighbors deviate from an ideal octahedron by a substantial elongation along the threefold axis as indicated by O(2)—Ba—O(2)′ angle of 68.0°. The NaO group is a more regular octahedron since the O(2)—Na—O(2)′ angle is 83.4°. The O(1) atoms are within 0.07 Å of coplanarity with the Ba^{2+}.

The remaining cation site contains Na^+ and Ba^{2+} randomly distributed. These cations are displaced by 2.548 Å from the apical oxygen atom lying on the same threefold axis. Since this latter oxygen atom is underbonded it also subtends the shortest P—O bond length in the PO_4 group. This group is distorted from regularity by a displacement of the phosphorus atom towards the O(1) yielding O(1)—P—O(2) bond angles of 110.6° compared to O(2)—P—O(2) bond angles of 108.4°. Alternately the repulsion between the Ba^{2+} and P atoms across the shared tetrahedral face could be responsible for these distortions since they are separated by only 3.19 Å.

Discussion

The structure of $BaNaPO_4$ is consistent with the packing constraints since the ions with the largest and smallest radii are partitioned between the sites with largest and smallest coordination numbers.

Struck and White showed that in the βK_2SO_4 form of $BaKPO_4$ K^+ lies in a site with 10-fold coordination, much like the Y site of glaserite, and Ba^{2+} in a 9-fold coordinated site (15). Since Ba^{2+} and K^+ ions have nearly the same radii some disorder between these sites might be expected but this has not been investigated. The change to the glaserite structure involves a transformation of the 9-fold coordinated site to an equal number of 6- and 12-fold coordinated sites. However, the ordered Y site in the glaserite form of $BaKPO_4$ is not compatible with the disordered Y site in the glaserite form of $BaNaPO_4$. $CaNaPO_4$ and $CaKPO_4$ (13) also have the βK_2SO_4 structure as low temperature phases and high temperature phases isotypic with glaserite. Again a disorder amongst the nearly equivalent sized Ca^{2+} and Na^+ would also not be surprising. A further reduction in the radii of one of the cations, as in $CaLiPO_4$, leads to structures isotypic with olivine (ref. 16, confirmed from single crystal measurements by Marrow in this laboratory). The correlations between ionic radii, based upon a coordination of six, and the structure type is found in Fig. 3. Both the βK_2SO_4 and glaserite structure types are stable when at least one of the cations is

TABLE 3. Bond lengths and angles in $BaNaPO_4$ with estimated standard deviations in parentheses

Bond	Distance (Å)		Bonds	Angle (deg)

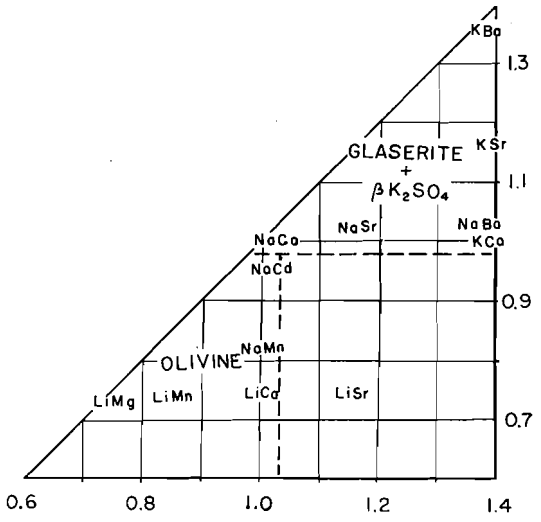

FIG. 3. Regions of structural stability of the olivine and glaserite–βK_2SO_4 *vs.* cation radius. The ion, A or B with the larger radius is plotted vertically and the other horizontally. The AB pair of the $ABPO_4$ species is shown. These data are from refs. 8, 22, or 23.

large and the olivine structure type when both cations are small.

Moore (17) has shown that the cationic coordination polyhedra found in glaserite are features common to a number of structure types. He showed that there are 13 possible ways in which six tetrahedra can be arranged at the corners of an octahedron in a pseudoglaserite arrangement. Only a few of these possibilities have been identified and these are consistent with short periodicities. In glaserite the tetrahedra about the M and X ions have an arrangement with $\bar{3}2m$ symmetry. This leads to the apical oxygen near the equatorial plane of one of the cations at the center of the octahedron. In the βK_2SO_4 structure (15) three of the tetrahedra have their apical oxygens bond pointing in the same direction leading to a site with a coordination of nine containing a crystallographic mirror plane. Distortion can yield lower coordination numbers. Olivine is based upon a close packed arrangement of oxygen atoms, in contrast to glaserite and βK_2SO_4. Although the octahedral cation site can be generated from the X sites of glaserite it would appear not to be worth pursuing this unless structures with mixed glaserite- and olivinelike arrangements are found.

The idealized glaserite structure will be defined by (*a*) perfect octahedral and tetrahedral geometries for the MO_6 and TO_4 groups and (*b*) the coplanarity of the six apical oxygen atoms O(1) with X. The perfect octahedral geometry for $XO(2)_6$ follows from condition (*a*). This also leads to the equivalence of the M—O and X—O bond lengths. The axes lengths are: $a = \sqrt{2}(\text{M—O}) + \sqrt{8/3}(\text{T—O})$ and $c = (4/\sqrt{3})(\text{M—O} = (4 \times 4/3)(\text{T—O})$. The minimum X—O(1) bond length is $a/\sqrt{3}$, whether (*b*) is true or not, and if this is equal to X—O(2) the ratio M—O/T—O is $2\sqrt{2}/(3 - \sqrt{6}) = 5.13$. This is unreasonable, suggesting that X—O(1) > X—O(2), as was concluded by Moore (17). On the other hand, (*a*) and (*b*) require that the height of the octahedron be twice that of the tetrahedron and lead to M—O/T—O $= 4/\sqrt{3} = 2.309$ and thus to $c/a = (11/32)\sqrt{6} = 1.188$. All experimental values for this ratio lie between 1.29 and 1.41 (18, 8).

The position of Y, aside from lying on the threefold axis, is unrestricted. However, $c = (4/3)(\text{T—O}) + \text{Y—O(1)} + [\text{Y—O(2)}']_{\|}$ where $[\text{Y—O(2)}']_{\|}$ is the component of the bond length between Y and the oxygens of the shared face parallel to the *c* axis. Thus, $\text{Y—O(1)} + [\text{Y—O(2)}']_{\|} \geq 4(\text{T—O})$ and since X—O(1) > X—O(2), then Y—O(1) < Y—O(2)′ in order to compensate for the otherwise underbonded O(1). The free atomic parameters then are $z_Y \simeq 0.865$, $z_p = 5/16$, $z_{O(1)} = 1/2$, $x_{O(2)} = 0.2326$, and $z_{O(2)} = 1/4$. These predictions can be improved for a particular composition using the least-squares routine developed by Meier and Villiger (19, 20). For the present qualitative considerations will suffice.

The M and X sites will be stabilized by cations of different radii with the smaller preferentially in the M site. Radii for K^+, Sr^{2+}, and Ba^{2+} in sites of 12-fold coordination are $\sim\frac{1}{4}$ Å larger than the individual "octahedral" radii. This is consistent with a difference of $\sim\frac{1}{2}$ Å between X—O(2) and X—O(1) as has been found in $BaNaPO_4$ and in $Ba_3V_2O_8$ (21). This could be used to provide another relationship between M—O and T—O. The smaller M—O bond length is achieved by a displacement of the TO_4 group resulting in a contraction of the MO_6 octahedra and a dilation of XO_6 octahedra both along the *c* axis. In $BaNaPO_4$ both groups are dilated but the latter more than the former, suggesting that the *c* axis is "abnormally" en-

For personal use only.

larged because of the repulsion between the ions in the M and X sites.

The *a* axis also appears to be contracted leading to a greater *c*/*a* ratio than predicted. In the idealized structure the Y—O(2) length is too long relative to the Y—O(2)′ length, since these are expected to be roughly comparable in length. The Y—O(2) vector, nearly lying on the *ab* plane, can be reduced in magnitude by a contraction of the *a* and *b* axes. Y should be displaced away from the plane containing the O(2)—O(2) edges as a result of the repulsion between Y and T across the shared face. The repulsion between the oxygen atoms also plays a role in that, for example, the Y—O(2) bond length cannot be so small as to lead to the O(2)—O(2) interactions between different TO_4 equal to or smaller than an edge of the TO_4 group.

The Y ion should be of a size intermediate between that of the M and X ions. If a small ion attempted to bond strongly to the oxygen atoms of the shared face and the apical oxygen atom, this *c* length would be too small to be compatible with the requirements of M and X. Further the *ab* plane would be enlarged in order to remove the remaining six O(2) atoms from the coordination sphere of Y. Alternately, a large ion in the Y site would also enlarge this plane and in both cases result in a six coordinate X ion with an underbonded O(1) atom.

It is apparent that both the glaserite and βK_2SO_4 are pliable to a variety of ionic substitutions. Thus the investigation of systems where the M, Y, and X are chemically distinct should be fruitful in determining the limits of phase stability. The mechanism for the phase transformation needs further investigation. Systems with cations having nearly equal radii, such as $NaCoPO_4$ (22) and $NaCdPO_4$ (23) show the olivine structure in addition to structures related to those occurring in Na_2SO_4. These look particularly promising.

I am indebted to Whitlow and Gabe[1] for a preprint of their work on the single crystal structure analysis of compound A in Fig. 4, p. 3461, which I reported to have formula $InCl_3 \cdot 3$dioxane$\cdot 2H_2O$ (6.9% H_2O); from the X-ray analysis, the correct formula appears to be $InCl_3 \cdot 3$dioxane$\cdot 3H_2O$ (10.0% H_2O). The method of "wet rest" analysis which relies on the point of intersection of tie-lines, is subject to error in water content, because of the low molecular weight of water in comparison with the high molecular weight hydrated compound. It is also possible that the formula of B should be $InCl_3 \cdot 2$dioxane$\cdot 3H_2O$ (12% H_2O) rather than $InCl_3 \cdot 2$dioxane$\cdot 2H_2O$ (8.3% H_2O). According to Whitlow and Gabe, the water of hydration of $InCl_3 \cdot 3H_2O$ is not affected by the dioxane in the compound, which consists of "layers of distorted In octahedra which interleave with dioxane layers".

ROBERT MICHAEL CHEYNE, COLIN HENRY WILSON JONES, and STEINAR HUSEBYE. Can. J. Chem. **53**, 1855 (1975).

The ^{125}Te Mössbauer spectra of a number of Te(II) and Te(IV) complexes with sulfur-containing ligands have been measured. The Te(II) compounds exhibit large quadrupole splittings of 12.4 to 15.2 mm s^{-1} and isomer shifts (^{125}I/Cu) of +0.33 to +0.91 mm s^{-1}. These data are interpreted as evidence for the incorporation of some 5s character in the bonding scheme for several of the compounds, consistent with the interpretation of X-ray crystal structure data. For the Te(IV) compounds 6, 7, and 8 coordinate molecules have been studied containing tellurium in distorted octahedral, pentagonal bipyramidal, and dodecahedral coordination.

ROBERT MICHAEL CHEYNE, COLIN HENRY WILSON JONES et STEINAR HUSEBYE. Can. J. Chem. **53**, 1855 (1975).

On a mesuré les spectres Mössbauer ^{125}Te d'un certain nombre de complexes Te(II) et Te(IV) portant des ligands contenant du soufre. Les composés du Te(II) présentent de grands couplages quadrupolaires de 12.4 à 15.2 mm s^{-1} et des déplacements d'isomères (^{125}I/Cu) de +0.33 à +0.91 mm s^{-1}. On interprète ces données comme signifiant qu'il y a incorporation d'un certain caractère 5s dans les liaisons de plusieurs de ces composés; cette conclusion est en accord avec l'interprétation de données structurales dérivées d'études par rayons-X. Pour les composés du Te(IV), on a étudié des molécules hexa-, hepta- et octa coordonnées contenant du tellure dans des coordinations octaédrique, pentagonale bipyramidale et dodécaédrique déformées. [Traduit par le journal]

Introduction

In an earlier paper (1) we reported the Mössbauer data for a number of complexes of tellurium(II) and tellurium(IV) with thiourea (Tu) and related derivatives. For many of those compounds there is considerable evidence from the structural work of Foss (2) and Husebye (3) that the tellurium $5s^2$ electrons form a stereochemically inert lone-pair and that only the 5p electrons are involved in bonding. Thus the common occurrence of bond angles close to 90° and the large Te—S bond lengths, for example in the $TeTu_4^{2+}$ cation, are consistent with the presence of three-center bonds (2 electrons bonding, 2 nonbonding) in which the tellurium 5p orbitals participate.[1] The Mössbauer data for these compounds (1) were found

[1]In the previous discussion (1) these bonds were described as three-center two-electron bonds since the two nonbonding electrons are localized entirely on the sulfur atoms and only the bonding electrons directly influence the tellurium Mössbauer parameters.

to be consistent with the bonding scheme proposed by Foss, exhibiting relatively large, positive isomer shifts, and large quadrupole splittings, indicating the presence of a lone-pair of $5s^2$ electrons and a large imbalance in the 5p orbital populations respectively (1).

Aleksandrov *et al.* (4) have reported briefly on the ^{125}Te Mössbauer spectra of tellurium(II) thiourea complexes but these authors were evidently unaware of the work of Foss (2) and interpreted their results together with the i.r. data in terms of a tetrahedral structure for these molecules.

In the present work we have studied several other compounds where sulfur is coordinated to tellurium(II) or tellurium(IV). This investigation has included several compounds where the bond angles about the tellurium show significant deviations from 90°, this being used as a criterion to identify examples where the bonding may not be explained solely by the presence of linear 3-center bonds, and where the participation of 5s and/or 5d orbitals may be invoked.

Results

The Mössbauer parameters for the compounds investigated are reported in Table 1 and sample spectra are shown in Fig. 1. The Te(II) compounds studied were tellurium(II) bis(dimethyldithiophosphate), $Te((CH_3O)_2PS_2)_2$, tellurium(II) bis(thiopropionic acid), $Te(SCH_2CH_2CO_2H)_2$, sodium and rubidium telluropentathionate, $M_2Te(S_2O_3)_2$, bis(diethyldithiocarbomato)tellurium(II), $Te(Et_2NCS_2)_2$, tellurium di(methylxanthate), $Te(MeOCS_2)_2$, and *trans*-dibenzenethiosulfonatobis(tetramethylthiourea)tellurium(II), *trans*-$Te(SC[N(CH_3)_2]_2)_2(S_2O_2C_6H_5)_2$. The Te(IV) compounds studied included tetrakis(diethyldithiocarbamato)tellurium(IV), $Te(Et_2NCS_2)_4$, tetrakis(4-morpholinecarbodithioato)tellurium(IV) containing benzene molecules of crystallization $Te[(OC_4H_8NCS_2)_4]\cdot 3C_6H_6$, tris(diethyldithiocarbamato)phenyltellurium(IV), $Te[(Et_2NCS_2)_3C_6H_5]$, and the dimethyl analog $Te[(Me_2NCS_2)_3C_6H_5]$, and the monoclinic form of *trans*-tetrachlorobis(tetramethylthiourea)tellurium(IV), *trans*-$TeCl_4[SC(N(CH_3)_2)_2]_2$. In addition, several tellurium thiourea complexes were used as intercalibration standards and their parameters are given in Table 2.

In these experiments a $Pb^{125m}Te$ source was used rather than a ^{125}I/Cu source because it gave somewhat narrower line-widths. To facilitate comparison of the data with previous work the isomer shifts are quoted with respect to an ^{125}I/Cu source and the conversion was made using the data for the thiourea complexes given in Table 2. The spectra of the thiourea complexes were measured with the present source in connection with anisotropy studies which have previously been reported (5). The isomer shift conversion factor was found to be $\delta(^{125}I/Cu) =$

Discussion

Tellurium(II) Compounds

As can be seen from Table 1 the general features of the results for the Te(II) compounds (**1**–**7**) are that the isomer shifts are positive and that all of these compounds exhibit large quadrupole splittings. Given that $\Delta R/R$ for the ^{125}Te transition is positive (6, 7), the isomer shifts correspond to relatively large s-electron densities at the tellurium nucleus, and this in turn implies that the $5s^2$ electrons in these compounds are predominantly nonbonding in character. The large quadrupole splittings, Δ, arise from a large imbalance in the tellurium 5p orbital populations. In all of these Te(II) compounds, the tellurium is coordinated in a planar environment and the large Δ values are consistent with the presence of a lone-pair with predominantly $5p_z$ character directed out of the plane, the $5p_x$ and $5p_y$ orbitals in the plane bonding to the ligands.

However, it is apparent from Table 1 that the isomer shifts and quadrupole splittings of the Te(II) compounds are not all the same and in some instances show very significant differences from the parameters for the thiourea complexes (Table 2). Given the above model for the bonding in these compounds, changes in the donor character of the ligands would produce changes in the population of the 5p orbitals in the *xy*

plane. In the Townes and Dailey theory (8, 9) the quadrupole splitting is directly proportional to the 5p orbital imbalance as expressed in the parameter U_p, where

$$U_p = -U_z + \frac{U_x + U_y}{2}$$

and the U terms are the 5p orbital populations. The isomer shift may be expected to show a simple linear dependence on the 5p orbital populations in analogy with ^{129}I Mössbauer data (8, 10). In the limit, when $U_x = U_y = U_z = 2$, the quadrupole splitting would be zero and the isomer shift would approach zero. From Tables 1 and 2 it can be seen that the isomer shifts for the Te(II) compounds span a range of values from 0.9 to 0.31 mm s^{-1} while the quadrupole splittings range only from 16 to 12.4 mm s^{-1}. These trends in δ and Δ cannot be explained simply in terms of changes in the tellurium $5p_x$ and $5p_y$ orbital populations as the ligand is changed, the isomer shifts showing too large a range of values in comparison with the small changes observed in Δ.

A possible explanation for the relatively small values of the isomer shifts in compounds **1–6** may lie in the direct participation of some fraction of the 5s electrons in the bonding. For several of the compounds studied here there is direct evidence from X-ray crystal structure data for considerable distortion of the S—Te—S bond angles from 90° and 180° which may indicate that the 5s electrons are stereochemically active. Thus in $Te((CH_3O)_2PS_2)_2$ (11) the S—Te—S bond angle between the strongly coordinated sulfur atoms is 98.3° while in $Rb_2Te(S_2O_3)_2$ (2) this angle is 101.1°. Such distortions are further exemplified by $Te(Et_2NCS_2)_2$ (12, 13) and $Te(MeOCS_2)_2$ (14) in which a marked tendency to 5-coordination is observed. In *trans*-$Te(SC[N(CH_3)_2]_2)_2(S_2O_2C_6H_5)_2)$ (15) the S—Te—S bond angles are found to be 79.5 and 100.5°.

Assuming, as for ^{129}I, that the removal of one 5s electron has approximately six times the influence on the isomer shift as the removal of one 5p electron (the two effects being of opposite sign) (10), then the results for compounds **1–6** of Table 1 are consistent with the presence of 5–12% s-character in the bonding scheme, the large quadrupole splittings in these compounds indicating that the number of 5p electrons involved in bonding does not change greatly. Compound **7**, however, exhibits both an isomer shift and quadrupole splitting very similar to that of the thiourea complexes, even though the molecule exhibits distortion from 90° bond angles. In this instance all four Te—S bonds are comparable in length with those observed in the linear 3-center bonds and it appears that in this instance crystal packing effects, dictated by the bulky $—S_2O_2C_6H_5$ ligands, are responsible for the molecular distortion.

Two other points which should be noted concerning the parameters of compounds **1** through **7**. Compounds **2** and **3** exhibit the smallest quadrupole splittings of the Te(II) compounds studied, and this is consistent with a greater population of the $5p_x$ and $5p_y$ orbitals in these compounds, compared with the other Te(II) complexes, as might be expected given the negative charge on the pentathionate ion. The similarity in Δ for the $Te(thiourea)_4^{2+}$ cation, the neutral molecules **1** and **4–7**, and the pentathionate anion support the general assumption that the electrostatic field gradient at the tellurium originates primarily from the valence-shell electrons and that any lattice contributions must be small.

Tellurium(IV) Compounds

In compounds **8** and **9** the tellurium is 8 coordinate and is found in a distorted dodecahedral environment (16, 17), in which two almost planar TeS_4 trapezoids interleave at approximately 90° to one another. No measurable quadrupole splitting was observed, as might be expected given the high coordination number and more or less symmetrical disposition of ligands about the tellurium. The isomer shifts are large and positive, corresponding to Te(IV) and a predominately lone-pair of $5s^2$ electrons on the tellurium. It is interesting that the isomer shifts of $Te[Et_2NCS_2]_2$ and $Te[Et_2NCS_2]_4$ appear to be a simple additive property of the ligand.

The isomer shifts of compounds **8** and **9** are not as large as those of octahedral TeX_4Tmtu_2 or TeX_6^{2-} (X = Cl, Br) (1), and this may again be explained by some small participation of the 5s electrons in the bonding, although other factors may also be involved. Thus there is a significant increase in the Te—S bond length in going from TeX_4Tmtu_2 to $Te(Et_2NCS_2)_4$ (16) and this may reflect the stronger ligand–ligand

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

repulsions on increasing the coordination number, together with the increasing use of high-energy d-orbitals on the tellurium, and the possible antibonding character of the lone-pair. The isomer shifts in **8** and **9** are consistent with a smaller charge on tellurium than in TeX_4Tmtu_2 which would be expected given the change in Te—S bondlengths.

The role of d-orbitals in bonding in compounds **8** and **9**, and presumably in **5** and **6**, is a point of some interest. In the interpretation of the Mössbauer parameters of ^{119}Sn, ^{121}Sb, ^{125}Te, and ^{129}I it is generally assumed that d-orbital electrons will not contribute to the quadrupole coupling and that they will not shield the 5s electrons to any great extent. Jung and Triftshäuser have estimated that d-orbital electrons will exhibit about one-third the shielding of 5p electrons (18). From the data for compounds **8** and **9** little can be said about the role of d-orbitals. However compounds **5** and **6** have very similar Δ values to those of the thiourea complexes, and this would appear to imply similar 5p orbital populations and that 5d orbitals do not play a major role, since any removal of $5p_x$ and $5p_y$ electrons into tellurium d-orbitals would be reflected in an increase in Δ and in δ.

In compounds **10** and **11** the tellurium is 7-coordinate and the geometry may be best described as distorted pentagonal bipyramidal (19), in which two of the bidentate ligand form an approximately planar TeS_5 equatorial grouping, with the second sulfur of the third ligand and the phenyl group occupying *trans* axial positions.

The positive isomer shifts again confirm that the 5s electrons are predominantly nonbonding. However the δ values are significantly smaller than those of other Te(IV) compounds and indeed overlap those of the Te(II) compounds. This must in part be attributed to the presence of the phenyl group and significant tellurium 5s character in the Te—C bond. This behavior is similar to that of triphenylstibine (20) and iodobenzene (21) where the isomer shifts for ^{121}Sb and ^{127}I are also consistent with significant 5s character in the Sb—C and I—C bonds.

The quadrupole splittings of *ca.* 5 mm s^{-1} in these compounds correspond to coupling constants, $e^2q^{125}Q$, of *ca.* 290 MHz, assuming $\eta = 0$. For IF_7, which is also pentagonal bipyramidal, $e^2q^{127}Q$ is reported to be -148 MHz, with $\eta = 0$. Expressed in units of $e^2q^{127}Q$, the coupling constants in compounds **10** and **11** are equivalent to *ca.* 1000 MHz. This very considerable difference between the magnitude of the coupling constants in pentagonal bipyramidal tellurium complexes on the one hand and IF_7 on the other is somewhat surprising.

On the basis of the available data it is possible to make a rough estimate of the orbital populations in compounds **10** and **11**. The planar TeS_5 unit in these compounds is structurally similar to that in $Te[Et_2NCS_2]_2$. For the latter, $\Delta = 15$ mm s^{-1} and taking Δ for a one p-electron imbalance as *ca.* 12 mm s^{-1} (1) and assuming the presence of a $5p_z^2$ nonbonding pair, (V_{zz} negative), this implies that in the Townes and Dailey formulation $U_x + U_y = 1.5$. Adopting this value for $U_x + U_y$ in compounds **10** and **11**, the observed Δ of *ca.* 5 mm s^{-1} (assuming $\eta = 0$) then corresponds to $U_z = 1.2$ or 0.3, depending on whether the coupling constant is positive or negative in sign respectively. The value of 1.2 for U_z seems the more realistic and this suggests that e^2qQ is probably positive (V_{zz} negative) *i.e.* there is an excess of 5p electron density along the *z* axis, this axis lying along, or close to, the axial S—Te—C bonds.

The study of compound **12** was motivated by the observation that orthorhombic *trans*-$TeCl_4$-$[SC(NCH_3)_2)_2]_2$ is converted to a monoclinic form on standing for a period of several years, or, more rapidly, an irradiation with X-rays (22). The monoclinic form (22) has been shown to exhibit quite distinct structural differences from the orthorhombic form (23). In particular the center of symmetry observed in the molecules of the orthorhombic form (A) is not observed in the monoclinic form (B). Moreover, whereas three linear three-center S—Te—S, Cl—Te—Cl systems are observed in (A), two of them are quite asymmetric in (B) both with regard to bond length and bond angle. A possible explanation for the considerable distortion from octahedral geometry observed in (B) could lie in stereochemical activity of the lone-pair in the more stable monoclinic form. However the Mössbauer parameters for the two forms were found to be the same within the errors. Thus neither the orthorhombic nor monoclinic forms exhibit a resolvable quadrupole splitting, while the isomer shifts are essentially identical. It is apparent that the distortion in the monoclinic form does not produce a sufficiently large

electrostatic field gradient to result in a measurable quadrupole coupling, while the s-electron density at the tellurium nucleus does not show the marked change that would be expected if the lone-pair were now stereochemically active.

Experimental

Most of the compounds were synthesized on the 100 scale using enriched ^{125}Te (>75%) and using methods described in the literature (2, 3, 11–17, 19, 22). However for compounds **7**, **10**, **11**, and **12** spectra were recorded on naturally abundant samples previously prepared in connection with the X-ray structural work. The compounds were identified using n.m.r., i.r., and Raman spectra and C, H, and N analyses where each was applicable.

The Mössbauer spectra were either recorded in our own laboratory at 80 K and using the methods previously described (4) (compounds **1–5** and **8**) at 4.2 K at the P.C.M.U. at Harwell (compounds **6**, **7**, **9–12**). In both instances $Pb^{125m}Te$ sources chemically prepared in our own laboratory were used and calibration using ^{125}Te-$Etu_4Cl_2 \cdot 2H_2O$ as a standard was employed. The two spectrometers gave values in very good agreement with one another for the same absorber. The spectra obtained in our own laboratory were 2 × 256 channel spectra and average values for the δ, Δ, and 2Γ values are quoted. The spectra recorded at Harwell were single spectra and such averaging was not required. In all instances the spectra gave χ_t^2/N values which lay within the 1% confidence limit.

The authors wish to thank Dr. F. Brown, Head, Solid State Research Branch, Chalk River for assisting in the production of a $Pb^{125m}Te$ source and Dr. Barry Dale of P.C.M.U. Harwell and his staff for their assistance in performing the experiments at 4.2 K. We are also grateful to Dr. O. Foss for his gift of *trans*-$Te(SC(N(CH_3)_2)_2)_2$-$(S_2O_2C_6H_5)_2$.

One of the authors (C.H.W.J.) is grateful to the National Research Council of Canada for a grant supporting this research, and Dr. A. G. Maddock for his hospitality at Cambridge University during 1973.

L'effet de la longueur de la chaîne et du p*H* sur la conformation de polyampholytes alternés du type (L-lysyl-L-aspartyl)$_n$

HUBERT DAOUST ET SERGE ST-PIERRE[1]

Département de chimie, Université de Montréal, C.P. 6210, Montréal, Québec H3C 3V1

Reçu le 2 juillet 1974[2]

HUBERT DAOUST et SERGE ST-PIERRE. Can. J. Chem. **53**, 1861 (1975).

Nous avons réalisé la synthèse, par la méthode en phase solide, d'une série de co-oligopeptides alternés, du type (L-lysyl-L-aspartyl)$_n$, (n = 4–10, dans le but d'étudier le comportement des polyampholytes en solution aqueuse, en fonction du p*H* et de la longueur de la chaîne peptidique. Nous avons observé que les spectres de dichroïsme circulaire variaient moins, en fonction de la longueur de la chaîne et du p*H*, que ceux observés avec des homooligoélectrolytes ne possédant pas de caractère polyampholytique. Nos résultats suggèrent une structure globulaire pour les peptides au point isoélectrique et une structure étendue en milieu fortement acide ou basique.

HUBERT DAOUST and SERGE ST-PIERRE. Can. J. Chem. **53**, 1861 (1975).

The synthesis of alternating (L-lysyl-L-aspartyl)$_n$ co-oligopeptides (n = 4–10) was realized by the solid phase method, to study the effect of chain length and p*H* on the conformation of polyampholytes in aqueous solution. The c.d. spectra do not show as important a dependance on p*H* and chain length as those observed with the nonampholytic homooligoelectrolytes. Our results suggest that the peptides are globular in shape when the p*H* of the solution is close to the isoelectric point but are extended in strong acid and base solutions.

Introduction

Depuis le début des années '50, un nombre incalculable de travaux ont été effectués dans le but d'étudier la stabilité intrinsèque de la conformation hélicoïdale des peptides et polypeptides. Pour mieux simuler la structure hélicoïdale qu'on retrouve à l'intérieur des protéines, où les segments hélicoïdaux comprennent rarement plus d'une vingtaine de résidus consécutifs, d'autres auteurs étudiaient l'influence de la longueur de la chaîne peptidique sur l'hélicité.

Une des premières études du genre fut accomplie par Brand et collaborateurs (1–3), sur les propriétés rotatoires de la poly-L-lysine (PLL) en fonction de la longueur de la chaîne. Robinson et Bott (4), utilisant un copolymère de D,L-phénylalanine et de γ-L-glutamate de benzyle de poids moléculaire variable, proposèrent une relation entre la longueur de la chaîne et son degré d'hélicité. Doty et collaborateurs (5–7) firent de même avec le poly-γ-L-glutamate de benzyle. Les polypeptides de masse moléculaire élevée formaient des hélices stables dans des solvants tel le chloroforme, alors que les chaînes de faible masse moléculaire étaient désordonnées en solution diluée et de structure-β en solution plus concentrée. Goodman et collaborateurs (8–22) effectuèrent le plus grand nombre de travaux dans le domaine, en milieu non-aqueux. Dans le cas des oligomères de γ-L-glutamate de méthyle, ils proposèrent que l'hélicité s'amorce entre l'hepta et le nonamère, utilisant b_0 comme critère d'hélicité. Les oligomères de masse moléculaire plus faible (d.p. < 12) avaient tendance à s'associer dans le dioxanne, alors que les fractions de masse moléculaire supérieure formaient plus spontanément des hélices (12). Tous les oligopeptides adoptaient la conformation désordonnée dans les acides forts, tel l'acide dicloroacétique (DCA). Pour les oligopeptides correspondants du β-L-aspartate de méthyle, la structure-β commençait à l'octamère et l'hélicité à l'undécamère, dans une solution à 3% de DCA dans le chloroforme.

Un travail similaire fut accompli avec des oligopeptides solubles dans l'eau. En 1952, Becker et Stahmann (23) mesuraient la rotation spécifique, $[\alpha]_D^{25}$, d'oligomères de longueur croissante de L-lysine·HCl. Alors que la rotation spécifique de la poly-L-lysine, de poids moléculaire élevé, atteignait −80°, celle du 22-mère se rapprochait de −70°. Schellman (24), en 1958, avait prédit que la longueur critique d'une hélice-α, en solution aqueuse, était de 15–20

résidus, mais que les interactions entre les chaînes latérales étaient responsables d'une stabilité moindre de cette conformation. De même, les effets de bouts de chaîne, négligeables pour un polypeptide de masse moléculaire élevé, devenaient un facteur prédominant pour la stabilité des oligopeptides.

En 1971, Fasman et collaborateurs (25) publiaient les résultats d'une étude par dispersion optique rotatoire (d.o.r.) sur la relation entre la longueur de la chaîne d'oligopeptides de L-lysine et leur hélicité. Ils démontrèrent qu'une chaîne comprenant jusqu'à 22 résidus de lysine n'avait pas le même spectre d.o.r. que le polypeptide correspondant. L'hélicité s'amorçait à $n = 12$; le 22-mère ne contenait que 13% d'hélicité à p*H* 11.9. De même, une étude des oligomères de l'acide L-glutamique à p*H* 3.5, par Snipp *et al.* (26) n'attribuait que 40% d'hélicité à la chaîne de 17 résidus et 70% à la chaîne de 40 résidus.

En 1971, Schechter *et al.* (27) effectuaient une des premières études sur une série de co-oligopeptides de longueur croissante en solution aqueuse. La détermination de la conformation des homologues de la série (L-tyrosyl-L-alanyl-L-alanyl)$_n$ dans le but d'étudier l'effet de la longueur de la chaîne et de la densité de charge sur les propriétés antigéniques et immunogéniques de ces peptides.

Quoique les protéines soient avant tout des polyampholytes, aucun travail n'a été rapporté concernant l'influence de la longueur de la chaîne sur la conformation de peptides possédant cette propriété. On relève cependant plusieurs travaux relatifs à la synthèse et à l'étude conformationnelle de polypeptides possédant des propriétés ampholytiques, de séquence aléatoire (29, 30) et alternée (31–37). Une des principales limitations à ce genre d'étude est la synthèse de fractions d'oligopeptides homogènes et exempts de racémisation. Yaron et collaborateurs (25, 28) a utilisé une méthode chromatographique pour obtenir des fractions dont l'homogénéité, pour les homologues de masse moléculaire supérieure, laissait à désirer. Récemment, Bonora *et al.* (38), utilisaient la synthèse en phase solide pour obtenir des oligopeptides de longueur croissante de l'acide glutamique.

Nous avons également utilisé la méthode de synthèse en phase solide (39) pour obtenir la série de peptides (L-lysyl-L-aspartyl)$_n$ ($n = 1$–10). Les couplages ont été réalisés à l'aide du réactif de Belleau, soit le *N*-éthoxycarbonyl-éthoxy-2-dihydroquinoline-1,2 (EEDQ) (40–42). Cet agent de couplage, appliqué pour la première fois à la synthèse en phase solide par Sipos et Gaston (42), permet de former l'anhydride mixte de l'acide aminé qu'on veut ajouter à la chaîne et donne lieu à des couplages rapides, avec un rendement élevé. Ce réactif n'occasionne pas la formation de produit secondaire indésirable comme c'est le cas pour la dicyclohexylcarbodiimide (DCCI) (39); on peut par conséquent utiliser des excès moindres de dérivé Boc[3] d'acide aminé et diminuer le coût de la synthèse.

Nous avons étudié la variation des spectres de dichroïsme circulaire de ces peptides en fonction de la longueur de la chaîne et du p*H*. L'influence des bouts de chaîne sur les spectres d.c. des peptides a été évaluée par une méthode similaire à celle de Fasman et collaborateurs (25). Nous présentons également l'évaluation des fractions d'hélice-α, de structure-β et désordonnée par une méthode basée sur celle que Yang et collaborateurs (43, 44) ont mise au point pour évaluer la structure secondaire des protéines à partir de spectres d.c. Au lieu des standards protéiniques de Yang, nous avons utilisé les valeurs de Greenfield et Fasman (45) des spectres d.c. de la poly-L-lysine en solution aqueuse, sous les formes hélice-α, structure-β ou désordonnée. Nos résultats tendent à démontrer que la longueur de la chaîne est un critère de stabilité conformationnelle moins important pour les polyampholytes qu'elle ne l'est pour les homopolypeptides ioniques.

Partie expérimentale

Solvants et réactifs

Les solvants et réactifs pour la synthèse en phase solide ont été purifiés comme suit. Le dichlorométhane a été redistillé sur P_2O_5 et utilisé immédiatement après. La triéthylamine était refluée et distillée sur sodium et conservée sous atmosphère d'azote au réfrigérateur. L'acide trifluoroacétique était refluë et distillé sur P_2O_5 et conservé dans des bouteilles scellées. Tous les autres réactifs et solvants étaient de qualité réactif analytique et ont été utilisés comme tels.

La résine de Merrifield, soit un copolymère de styrène et de divinyl-benzène (1%) provenait de la compagnie Bio-Rad; elle contenait 1.25 mequiv. de chlore par gramme. Le EEDQ (Aldrich Chemicals, qualité Gold Label, +99%) a été utilisé sans purification supplémentaire.

Le *N*-α-Boc-β-L-aspartate de benzyle et le *N*-α-Boc-*N*-ε-tosyl-L-lysine furent préparés dans notre laboratoire,

[3] *t*-Butyl-oxycarbonyle.

selon des méthodes déjà décrites (39, 46–48). Le copoly (L-lysyl-L-aspartyl) a été synthétisé dans nos laboratoires et cette synthèse est rapportée dans une autre publication (49). Son poids moléculaire moyen en poids est de 31 700, tel que déterminé par approche à l'équilibre de sédimentation.

Purification et analyse des peptides

L'appareil "Osmolyser" (Bio-Rad) a été utilisé pour le dessalage des peptides. Les résines Sephadex G-10 et G-25 provenaient de la compagnie Pharmacia Canada Ltd., de Montréal.

Les chromatographies sur couche mince ont été effectuées sur des plaques de gel de silice G, de la compagnie Baker. Les mélanges de solvants suivants ont été utilisés: (*a*) butanol-1:acide acétique:eau:pyridine (15:3:12:10); (*b*) butanol-1:acide acétique: eau (4:1:1); et (*c*) pyridine:acide acétique: eau (10:6:3). Les électrophorèses ont été effectuées sur papier Whatman No. 1, en utilisant une source de courant de 1200 V, 50 mA, dans une solution tampon à p*H* 2.8, pendant 90 min. Les chromatographies sur couche mince et les électrophorèses ont été révélées indépendamment à la ninhydrine (0.2% dans l'acétone) et au réactif hypochlorite de sodium-*o*-toluidine – iodure de potassium (50).

Les analyses d'acides aminés ont été effectuées au moyen d'un appareil automatique Beckman, modèle 120 (51).

Synthèse des oligopeptides

L'attachement du premier acide aminé à la résine, soit le *N*-α-Boc-β-L-aspartate de benzyle, s'est effectué selon le procédé habituel (39), en faisant réagir 20 g de résine chlorométhylée (25 mmol de Cl) avec 6.5 g (20 mmol) de dérivé d'acide aspartique. La quantité d'acide aminé ainsi fixée a été déterminée, par analyse quantitative, à 0.37 mmol/g de résine. Au cours de toutes les opérations de la synthèse en phase solide, nous avons utilisé comme solvant le dichlorométhane. Le EEDQ (15% dans l'éthanol absolu) (42) a été utilisé comme agent de couplage. Pour chaque couplage, nous avons utilisé un triple excès molaire de dérivé d'acide aminé, en solution concentrée dans le dichlorométhane et le même excès de EEDQ dans l'éthanol. A partir du dixième résidu attaché à la chaîne, chaque couplage a été répété avec des quantités fraîches des mêmes réactifs, pour s'assurer d'un rendement quantitatif à chaque étape. La complétion de chaque couplage a été vérifiée par la méthode colorimétrique de Kaiser *et al.* (52), puis par analyse quantitative d'acides aminés, juste avant le couplage suivant.

Après chaque couplage, la résine était lavée avec de larges quantités de dichlorométhane. Après le couplage d'un dérivé de lysine, nous prélevions environ 1 g de résine et procédions ensuite à la réaction de déprotection du dérivé Boc. Cette réaction était effectuée au moyen de l'acide trifluoroacétique (TFA) à 50% dans le dichlorométhane, pendant 20 min. Après de copieux lavages au dichlorométhane, la neutralisation était effectuée au moyen d'une solution de triéthylamine à 10% (v/v) dans le dichlorométhane. Cette même série d'opérations a été répétée jusqu'à l'obtention de l'eicosapeptide.

Le clivage de chaque échantillon de peptide du support a été effectué en faisant barboter un faible courant de HBr anhydre et exempt de brome dans une suspension du complexe de résine–peptide dans le TFA. Avant d'être barboté dans la suspension, le HBr gazeux était préalablement lavé dans du tétrahydronaphtalène-1,2,3,4, puis dans de l'anisole maintenu à 30°, enfin séché sur Drierite et P_2O_5. Le groupement tosyl a été clivé au moyen d'une réduction par le sodium dans l'ammoniac liquide. Nous avons adouci les conditions de la réaction conventionnelle (39) en ajoutant goutte à goutte une solution de peptide dans l'ammoniac liquide. Nous avons ajouté la solution bleu foncé à la solution de peptide jusqu'à ce que cette dernière atteigne une couleur bleue pâle persistante; au bout de 15 s, nous arrêtions la réaction en y ajoutant brusquement de chlorure d'ammonium solide. La solution devenait alors incolore et limpide. Après évaporation de l'ammoniac et séchage sous vide, le peptide et le sel étaient dissous dans un volume minimum d'acide acétique à 2%. La solution était dessalée au moyen de l'"Osmolyser" et lyophilisée. La complétion des réactions de clivage par HBr/TFA et de détosylation était alors vérifiée par r.m.n. et spectroscopie u.v. pour la présence de groupements aromatiques résiduels. De même, les spectres i.r. des peptides ne révèlent aucune bande typique aux esters entre 1750 et 1800 cm^{-1}.

Chaque peptide a ensuite subi une première purification sur résine IRC-50, préalablement regénérée avec une solution d'acide acétique à 50% et lavée à l'eau jusqu'à neutralité. La solution de peptide était alors appliquée à la résine et le peptide était élué dans un gradient de bicarbonate d'ammonium de 0 à 0.5 *M*. Le pic principal de peptide était alors détecté par spectrophotométrie à 230 nm et la fraction lyophilisée. La purification finale de chaque peptide a été effectuée sur résine Sephadex G-10 (de l'octapeptide au dodécapeptide) ou G-25 (du tétradécapeptide à l'eicosapeptide) dans l'eau. Seules les fractions correspondant au maximum d'absorption, détecté comme précédemment, ont été conservées et lyophilisées. Dans tous les cas, un seul maximum d'absorption a été détecté.

Pureté des peptides

Le tableau 1 nous montre les résultats de l'analyse d'acides aminés des peptides et révèle des rapports respectifs lys/asp très voisins de 1. Les chromatographies sur couche mince de tous les peptides, dans les trois systèmes de solvants énumérés précédemment, ne révélaient qu'une seule tache bien définie dans tous les cas, par développement à la ninhydrine ou à l'hypochlorite de sodium-*o*-toluidine – iodure de potassium.

TABLEAU 1. Résultats de l'analyse quantitative d'acides aminés des différents peptides

Peptide $(lys–asp)_n$	Rapport théorique lys/asp	Rapport expérimental lys/asp
4	1.00	0.95
5	1.00	1.07
6	1.00	1.02
7	1.00	1.04
8	1.00	0.95
9	1.00	1.00
10	1.00	0.93

Enfin, l'électrophorèse sur papier, à p*H* 2.8, apporte les mêmes conclusions, utilisant les mêmes réactifs de développement des taches.

Il est difficile de calculer le rendement global de la synthèse jusqu'à l'obtention du peptide pur, à cause des prélèvements que nous avons effectués à chaque étape pour recueillir le peptide de longueur désirée. Nous ne pouvons qu'estimer grossièrement le poids de résine–peptide prélevé; selon nos estimations, le rendement global, basé sur le poids d'acide aspartique attaché à la résine du départ, se situe aux environs de 50% pour l'octapeptide et diminue jusqu'à environ 15% pour l'eicosapeptide.

Mesures de dichroïsme circulaire

Les spectres d.c. ont été enregistrés au moyen d'un spectropolarimètre Durrum-Jasco, de modèle ORD/UV-5, muni d'un attachement d.c. installé par Sproul Scientific (modèle SS-20). Tous les spectres ont été enregistrés à 23 ± 1°, la température étant maintenue constante au moyen d'un bain à circulation d'eau Haake. Les cellules de quartz utilisées étaient de qualité Suprasil (Hellma); les chemins optiques étaient de 1.00, 0.10 et 0.01 cm.

Le spectropolarimètre a été calibré en utilisant les valeurs standards de De Tar (53). L'acide *d*-10-camphorsulfonique nécessaire à la calibration a été préalablement recristallisé deux fois à partir du produit commercial (Aldrich Chemicals, 99%, $[\alpha]_D^{20}$ +19.9° (*c* 2, H_2O), dans l'acide acétique glacial et séché rigoureusement à 50° sous vide, sur P_2O_5. Sous ces conditions, le point de fusion est de 195° et la rotation spécifique $[\alpha]_D^{20}$ +22.1° (*c* 1, H_2O). Ces valeurs restent invariables après une cristallisation supplémentaire. Une valeur de calibration de +8216 deg cm^2 dmol^{-1} a été utilisée et revérifiée périodiquement avec une solution fraîche du standard.

L'ellipticité moyenne par résidu, [θ], exprimée en deg cm^2 dmole^{-1}, a été calculée selon la relation:

$$[1] \qquad [\theta]_\lambda = \frac{\theta_\lambda \text{p.m.r.}}{10Lc}$$

où θ_λ est l'ellipticité observée, en degrés, à la longueur d'onde λ, *L* est le chemin optique de la solution (en cm), p.m.r. est le poids moléculaire moyen d'un résidu de la chaîne et *c* la concentration de peptide en g/cm^3.

Nous avons préparé les solutions pour le dichroïsme circulaire de la façon suivante. Une quantité d'environ 5 mg de peptide était pesée dans un ballon jaugé de 5 ml et dissoute dans l'eau décarbonatée ou dans une solution de NaF 0.05 *M*. La solution était filtrée sur Millipore (type GSWPO-1300, Millipore, Bedford, Mass.). Des échantillons de 0.5 ml de cette solution stock étaient mesurés précisément dans des flacons et gardés au congélateur jusqu'à usage. Une minime fraction de cette solution était utilisée pour la détermination de la concentration par analyse quantitative d'acides aminés.

A l'exception des mesures pour déterminer l'effet de la concentration, des solutions dont la concentration variait entre 0.01 et 0.05% ont été préparées en diluant le volume requis de solution stock avec de l'eau ou la solution à 0.05 *M* de NaF. Nous avons ajusté le p*H* des solutions en y ajoutant lentement du NaOH ou du HCl 4 *N* à l'aide d'une micropipette. Le p*H* était lu avant et après l'enregistrement d'un spectre et la moyenne notée. L'effet de dilution a été étudié en utilisant une solution à 1% de peptide dans une cellule de 0.01 cm et une solution à 0.005% dans une cellule de 1 cm.

Nous avons comparé les spectres d.c. obtenus avec notre appareil avec ceux obtenus par Greenfield et Fasman (45) avec la poly-L-lysine sous les formes hélice-α, structure-β et désordonnée. L'échantillon de poly-L-lysine (Sigma Chemicals) possédait un poids moléculaire moyen de 100 000 (comparativement à 120 000 pour l'échantillon utilisé par Fasman). Nous avons reproduit exactement les conditions utilisées par ces derniers pour la préparation des échantillons et l'enregistrement des spectres, pour les trois formes de la poly-L-lysine. Les valeurs d'ellipticité moyenne par résidu sont en moyenne reproductibles à ±2% de 250 à 215 nm, ±5% de 215 à 205 nm et ±10% de 205 à 200 nm. Cette dernière différence s'explique par le bruit de fond particulièrement intense dans cette région du spectre, dû à une trop grande énergie au photomultiplicateur (0.5 kV à 200 nm, solvant seul) de notre instrument. C'est pourquoi tous nos spectres sont rapportés de 250 à 205 nm.

Pour plus de précaution, les spectres d.c. de quelques solutions de copolypeptide ont été remesurés au moyen d'un spectropolarimètre Cary 61 et ont montré une excellente reproductibilité, de 250 à 205 nm, avec les spectres enregistrés par l'appareil Durrum-Jasco.

Mesure du pH

Les valeurs de p*H* ont été mesurées au moyen d'un p*H* mètre digital Radiometer, modèle PHM52, relié à une électrode combinée Radiometer, de type GK2302G. Le p*H* mètre fut calibré à l'aide de tampons standards (Fisher Scientific Co.) à p*H* 7.00, 10.00 et 4.01, précis à ±0.02 unité de p*H*.

Méthode d'analyse conformationnelle des peptides

Pour évaluer le pourcentage relatif (f_i) d'hélice-α, de structure-β et de structure désordonnée, nous avons utilisé une méthode d'analyse comparable à celle de Yang et collaborateurs (43, 44). L'équation de base peut s'écrire comme suit, à une longueur d'onde donnée:

$$[2] \qquad \theta = f_H\theta_H + f_\beta\theta_\beta + f_R\theta_R$$

où

$$[3] \qquad f_H + f_\beta + f_R = 1$$

et

$$f_i \geq 0$$

où les θ_i représentent les ellipticités respectives des spectres standards de la poly-L-lysine (45) sous la forme hélice-α, structure-β, et désordonnée; θ est la valeur donnée par nos échantillons.

On peut tirer les paramètres f_H, f_β et f_R de la résolution des n équations, où n est le nombre de valeurs de longueur d'onde utilisées. Nous avons résolu, dans tous les cas, un système de 45 équations, incluant toutes les valeurs de θ comprises entre 250 et 205 nm, par la méthode de Cramer, au moyen d'un programme adapté à un ordinateur CDC 6400.

Enfin, le programme a été testé en effectuant le calcul des f_i pour la myoglobine et la papaïne, utilisant les

For personal use only.

valeurs d'ellipticité et les standards de Yang et collaborateurs (43) pour ces protéines. Les valeurs de f_i respectives se comparaient bien à celles de Yang.

Résultats et discussion

La synthèse des peptides

La synthèse en phase solide s'est révélée un moyen remarquablement efficace et rapide pour obtenir des oligopeptides de longueur croissante rigoureusement homogènes. Pour cette première étude sur les oligoampholytes, nous avons préféré choisir deux acides aminés simples, tels la lysine et l'acide aspartique, pour les raisons suivantes.

Premièrement, les dérivés de la lysine sont reconnus pour n'occasionner aucun problème majeur lors de synthèse par la méthode de Merrifield, si le groupe de protection de l'amine en ε est choisi judicieusement (39). Pour une synthèse répétitive comme celle que nous rapportons ici, nous devions choisir un groupe très résistant à la présence d'acide trifluoroacétique à 50% dans le dichlorométhane, pour que la déprotection du groupe *N*-α-Boc soit vraiment sélective. Des essais préliminaires nous ont montré que le groupement carbobenzoxy ne convenait pas à nos besoins, à cause de son instabilité en milieu acide. C'est pourquoi nous avons choisi le groupement tosyle, qui est d'une stabilité remarquable à l'hydrolyse acide et qu'on peut enlever facilement par réduction par le sodium dans l'ammoniac liquide; tel que décrit dans la partie expérimentale, les conditions que nous avons utilisées pour cette déprotection nous ont donné satisfaction.

Deuxièmement, le choix de l'acide aspartique, de préférence à l'acide glutamique, a été fait dans le but d'éviter les difficultés qu'ont rencontrées d'autres chercheurs (38, 54) lors de l'utilisation de cet acide aminé en synthèse en phase solide.

Troisièmement, le choix de la lysine, de préférence à d'autres acides aminés à chaîne latérale basique, tels le tryptophane ou l'histidine par exemple, a été fait dans le but d'obtenir des spectres de dichroisme circulaire dépourvus des complications inhérentes aux acides aminés aromatiques (55–57).

Quatrièmement, la poly-L-lysine est un polypeptide ionique dont le comportement en solution aqueuse a suscité un nombre incalculable de travaux à cause des trois conformations qu'elle peut présenter, selon les paramètres de la solution. Ce polypeptide est reconnu principalement pour la stabilité de son hélice-α, donnant lieu à des spectres de dichroisme circulaire caractéristiques de cette conformation (45). Par contre, les polypeptides de l'acide aspartique et de ses esters (58–60) manifestent des propriétés particulières concernant la stabilité et la chiralité des hélices qu'ils forment en solution aqueuse ou organique. Le comportement en solution aqueuse de polypeptides alternés composés de ces deux résidus d'acides aminés, compliqué des problèmes propres aux polyampholytes, s'avère le sujet d'une étude des plus intéressantes. Dans cette première étude, nous n'avons considéré que l'effet de la longueur de la chaîne et du p*H* sur la conformation des chaînes.

Dichroïsme circulaire

Nous illustrons, dans les figs. 1–3, l'influence de la longueur de la chaîne sur l'allure des spectres de dichroïsme circulaire. Nous avons choisi d'étudier le phénomène à trois p*H* extrêmes, soient 2, 7 et 12, où la charge globale sur le peptide est respectivement positive, nulle et négative. Pour une plus grande clarté, nous n'avons présenté sur les figures que les spectres de quatre peptides. Pour faciliter la comparaison

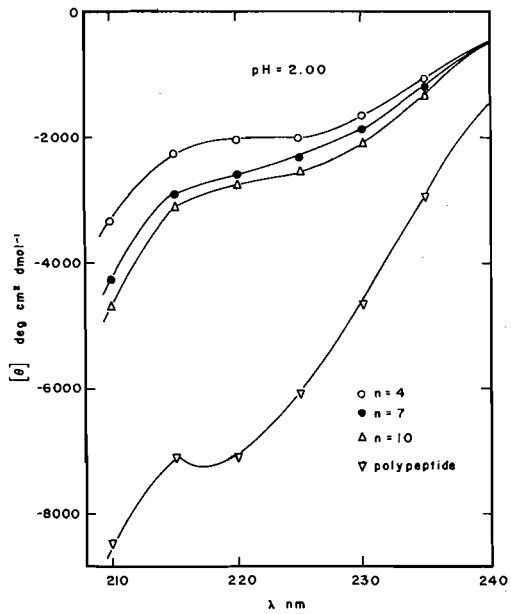

FIG. 1. Influence de la longueur de la chaîne sur le spectre d.c. de quatre peptides de la série $(lys\text{–}asp)_n$ à p*H* 2.00, à 22°, dans une solution aqueuse de NaF 0.02 *M* (concentration en peptides: 0.01% p/v).

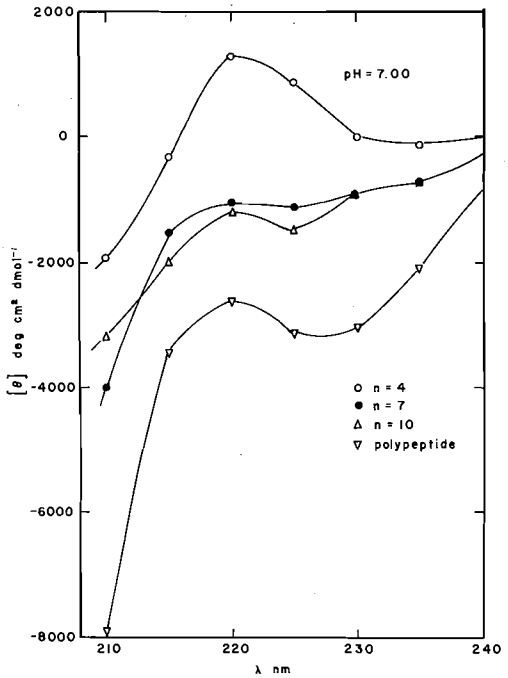

FIG. 2. Influence de la longueur de la chaîne sur le spectre d.c. de quatre peptides de la série $(lys\text{–}asp)_n$ à p*H* 7.00, à 22°, dans une solution aqueuse de NaF 0.02 *M* (concentration en peptides: 0.01% p/v).

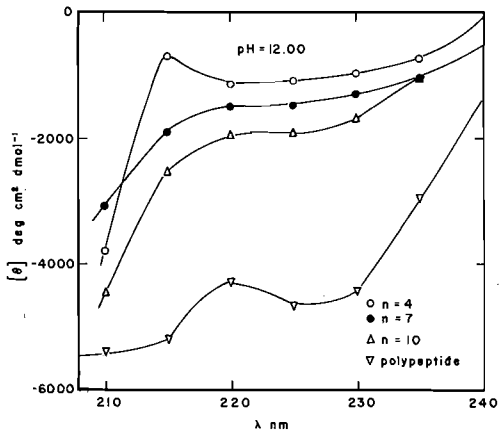

FIG. 3. Influence de la longueur de la chaîne sur le spectre d.c. de quatre peptides de la série $(lys\text{–}asp)_n$ à p*H* 12.00 à 22°, dans une solution aqueuse de NaF 0.02 *M* (concentration en peptides: 0.01% p/v).

entre les divers spectres, nous avons conservé la même échelle pour toutes les figures. Les résultats sont exprimés en degré cm^2 $dmol^{-1}$ et représentent l'ellipticité molaire par résidu d'acide aminé. Le poids moléculaire moyen par résidu a été assigné à 121.65, soit la moyenne pondéré d'un résidu lysyl (128.2) et aspartyl (115.1). On observe en premier lieu, à un p*H* donné, une légère augmentation de la bande d'ellipticité négative autour de 225 nm, de l'octapeptide au polypeptide. A p*H* 7, cependant, on observe une légère bande positive pour l'octapeptide et l'eicosapeptide. La différence d'ellipticité autour de 225 nm est nettement supérieure lorsque l'on compare l'eicosapeptide et le polypeptide. Globalement, l'ellipticité dans cette région du spectre passe, de l'octapeptide au polypeptide, de -1900 à -6700 deg cm^2 $dmol^{-1}$ à p*H* 2.0, de $+1000$ à -3000 deg cm^2 $dmol^{-1}$ à p*H* 7.0 et de -200 à -4000 deg cm^2 $dmol^{-1}$ à p*H* 12.0. Qualitativement, on peut également constater que la bande négative de dichroïsme autour de 200 nm diminue d'intensité lorsque l'on augmente la longueur de la chaîne, quelque soit le p*H*.

Afin de mieux illustrer l'influence de la longueur de la chaîne sur la conformation des peptides, nous avons choisi premièrement une méthode similaire à celle que Yaron *et al.* (25) avaient utilisée pour évaluer la longueur critique d'une hélice et l'importance des effets de bouts de chaîne dans le cas d'oligomères de longueur croissante de L-lysine. Ces derniers avaient supposé l'existence de la relation suivante entre la rotation molaire par résidu et la longueur de la chaîne:

$$[4] \qquad [m]_\lambda = [m]_{\text{interne}} + (1/n)[m]_{\text{bouts}}$$

où $[m]_\lambda$ est la rotation moyenne par résidu dans une chaîne désordonnée à une longueur d'onde λ; $[m]_{\text{interne}}$ et $[m]_{\text{bouts}}$ sont respectivement la rotation due aux résidus situés au centre de la chaîne et en bouts de chaîne; n est le nombre de résidus dans la chaîne. Toute déviation de la linéarité de cette équation devrait indiquer l'amorce d'une forme ordonnée de structure secondaire.

Nous avons supposé qu'une telle relation peut être convertie en termes d'ellipticité molaire et s'écrire:

$$[5] \qquad [\theta]_\lambda = [\theta]_{\text{interne}} + (1/n)[\theta]_{\text{bouts}}$$

où $[\theta]_\lambda$ est l'ellipticité molaire à 220 nm, calculée à partir du spectre d.c.; $[\theta]_{\text{interne}}$, $[\theta]_{\text{bouts}}$ et n correspondent aux termes semblables de l'éq. 4. A partir du graphique de $[\theta]$ en fonction de $1/n$, on doit obtenir les valeurs de $[\theta]_{\text{interne}}$ et de

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

$[\theta]_{bouts}$ comme étant respectivement l'ordonnée à l'origine et la pente des droites. Ces courbes, à p*H* 2.0, 7.0 et 12.0, sont représentées à la fig. 4. Comme le montre la figure, la linéarité de l'éq. 5 est respectée pour tous les oligopeptides, de l'octapeptide à l'eicosapeptide, aux trois p*H* étudiés. On remarque cependant que les trois points correspondant au polypeptide sont en dehors de leur tracé respectif. A p*H* 7.0 et 12.0, l'ellipticité du polypeptide varie d'environ 1000 deg cm^2 $dmol^{-1}$ de la linéarité. A p*H* 2.0, cependant, cette différence est d'environ 2500 deg cm^2 $dmol^{-1}$. La contribution des résidus internes à l'ellipticité est la plus faible (-2500 deg cm^2 $dmol^{-1}$) lorsque la charge globale des peptides est nulle et la plus forte (-4100 deg cm^2 $dmol^{-1}$) lorsque la charge globale est positive. Par contre, la contribution des bouts de chaîne demeure forte, soit de l'ordre de $+1600$ deg cm^2 $dmol^{-1}$, pour toutes les valeurs de p*H*. Quoique très approximative, cette valeur nous donne une excellente idée de l'importante contribution des bouts de chaîne à l'ellipticité. Elle nous permet aussi de justifier les bandes positives d'ellipticité obtenues avec les courtes chaînes. Elle explique enfin les faibles intensités des bandes négatives pour les peptides de masse moléculaire plus élevée.

En deuxième lieu, nous avons choisi de mettre en relief l'effet de la longueur de la chaîne et du p*H* sur la conformation des peptides en calculant, à partir de chaque spectre d.c., la fraction d'hélice et de structures beta et désordonnée de chaque peptide, pour une valeur de p*H* donnée. Le résultat de ce calcul est résumé dans le tableau 2. Comme on pouvait s'y attendre d'après l'allure des spectres d.c., la fraction hélicoïdale calculée est très faible sur toute la gamme des p*H* et longueurs de chaînes. Même pour le polypeptide à p*H* 2.0, qui donne

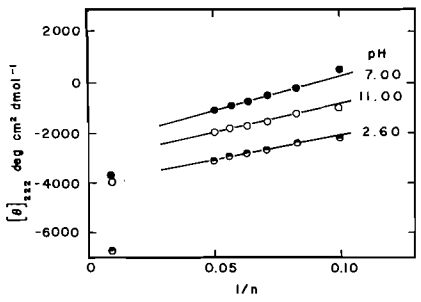

FIG. 4. Ellipticité à 222 nm en fonction de l'inverse de la longueur de la chaîne à différents p*H*.

TABLEAU 2. Calcul des fractions des trois conformations par la méthode de Yang et Martinez

la bande d'ellipticité négative la plus forte autour de 220 nm, f_H ne dépasse par 20%. Par contre, f_β calculé demeure relativement constant, variant entre 10 et 30%. La fraction désordonnée demeure toujours importante, soit plus grande que 60% dans tous les cas. Il faut toutefois se rappeler que le rapport f_H/f_β est sujet à des erreurs importantes, dû à la similarité de l'emplacement de la bande d'ellipticité négative autour de 220 nm dans le spectre d.c. de ces deux conformations de polypeptide. Une autre source d'erreur importante dans l'évaluation des fractions f_H, f_β et f_R par cette méthode est l'existence de charges électrostatiques permanentes sur les chaînes à toutes les valeurs de p*H*. Il en résulte la possibilité toujours existante d'attraction électrostatique intra et intermoléculaire, dont on ne peut tenir compte en utilisant comme modèle un polypeptide ionique simple comme la poly-L-lysine. Cette particularité des polyampholytes contribue certainement à une estimation quelque peu erronée de la structure

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

secondaire au point isoélectrique des peptides. Cette source d'erreur est probablement négligeable aux valeurs p*H* extrêmes, 2 et 12, où les peptides se comportent essentiellement comme la poly-L-lysine ou l'acide poly-L-aspartique chargés.

En dépit des limitations que nous venons d'énumérer, nous considérons cette méthode d'analyse comme étant des plus valables. Son attrait principale est de tenir compte de tous les points d'un spectre, permettant de choisir les intervalles de longueur d'onde désirés. Dans notre cas, nous avons choisi un intervalle de 1 nm, après avoir vérifié que l'utilisation de plus petits intervalles, conséquemment, un plus grand nombre d'équations, ne modifiaient pas sensiblement la valeur des fractions obtenues.

Il ressort de cette étude que la longueur de la chaîne n'est pas un facteur prédominant de la stabilité conformationnelle des polyampholytes alternés, si nous nous basons sur la variation de leurs spectres de dichroïsme circulaire. Nous pensons que l'existence d'une charge permanente sur les chaînes, quelque soit le p*H*, joue le rôle principal dans l'organisation de la structure des molécules en solution, à cause des interactions intra et intermoléculaires qui en résultent. L'effet de la charge empêche en tout temps ces peptides d'acquérir une conformation vraiment stable et organisée, comme on retrouve chez les homopolypeptides ioniques non-chargés. Leur nature ampholytique n'exclut cependant pas une certaine rigidité de la structure. Une étude viscosimétrique, menée en parallèle avec les mesures de dichroisme circulaire, sur le polypeptide (61), jette quelque lumière sur les résultats précédents. Selon la théorie de Harris et Rice (62), la conformation des polyampholytes alternés en solution aqueuse peut être reliée d'assez près à celle des polyélectrolytes simples, lorsque le p*H* de la solution est éloigné du point isoélectrique.

L'effet du pH

A p*H* fortement acide, seuls les groupement amino de la lysine sont sous forme NH_3^+; les carboxyles de l'acide aspartique sont protonés, donc électriquement neutres. Sous ces conditions, la poly-L-lysine donne lieu à un spectre d.c. typique de chaîne étendue, selon Tiffany et Krimm (63, 64). Les spectres d.c. des oligoampholytes et du polyampholyte, en solution acide, diffèrent fortement des spectres de la poly-L-lysine chargée. C'est à ce p*H* que nos spectres d.c. manifestent les valeurs les plus négatives pour la bande d'ellipticité autour de 220 nm, de même que les pourcentages d'hélicité (f_H) les plus élevés. Le graphique de la fig. 4 nous indique également une plus grande contribution des résidus internes à l'ellipticité autour de 220 nm. On voit aussi à cette figure que la déviation à la linéarité du polypeptide à p*H* 2.0 est la plus importante.

La présence de résidus d'acide aspartique, situés à intervalles réguliers entre les résidus de lysine chargés, ne semble donc pas jouer, en solution acide, le simple rôle d'espaceur qu'on pourrait leur attribuer *a priori*. En plus de permettre l'augmentation de la distance entre les charges portées par les groupements NH_3^+, les résidus d'acide aspartique semblent contribuer à la formation de liaisons hydrogène, stabilisant la conformation du squelette du peptide. Toutefois, même pour le copolypeptide, cette conformation, si nous la supposons à tendance hélicoïdale, est fortement déformée, en se basant sur les calculs effectués; il serait logique de supposer dans ce cas une hélice étendue, d'après les constatations suivantes. La chaîne latérale portant le groupement NH_3^+ de la lysine est constituée de quatre CH_2; elle possède donc une longueur qui lui confèrent une certaine flexibilité. Toujours à cause de la longueur de cette chaîne, nous pouvons supposer négligeable l'existence d'interaction ion–dipôle entre le groupe NH_3^+ et les liaisons amide du squelette. Si cette hypothèse s'avère exacte, l'existence de liaisons hydrogène stabilisant la structure secondaire du squelette est concevable. Enfin, la flexibilité de la chaîne latérale de la lysine, relié au fait que chacun de ces résidus est séparé de l'autre par un résidu d'acide aspartique, permet, selon nous, aux groupements NH_3^+ de se placer à une distance d'interaction minimum l'un de l'autre. De cette façon, l'énergie électrostatique de répulsion est inférieure à l'énergie de stabilisation de l'hélice.

Le deuxième fait appuyant ces hypothèses est tiré des travaux de dichroïsme circulaire effectués par Brahms et Spach (58) sur l'acide poly-L-aspartique (APLA). Ces travaux ont démontré que l'APLA, comme l'acide poly-L-glutamique (APLG), forme des hélices-α en solution acide (p*H* 4.3). Toutefois, l'ellipticité manifestée par la transition n–π^* de l'APLA

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

est beaucoup plus faible que pour l'APLG ou la PLL, indiquant une stabilité moins grande de l'hélice en solution. Cependant, la chiralité de cette hélice est la même, soit une hélice-α droite. Nous pouvons donc, à la lumière de ces faits, suggérer pour le polypeptide en milieu fortement acide, une conformation d'hélice-α droite, étendue à cause de la répulsion électrostatique des charges positives, mais partiellement stabilisée par les liaisons hydrogène du squelette. La déformation supplémentaire peut être causée, comme dans le cas de l'APLA, par l'interaction dipôle–dipôle du groupement carboxylique avec les liaisons amides.

Les résultats viscosimétriques appuient également l'existence d'une hélice étendue, le comportement du polypeptide en solution acide ressemblant au cas d'un bâtonnet rigide. Il eut été très intéressant d'étudier le comportement des oligoampholytes par viscosimétrie. Malheureusement, leur faible masse moléculaire ne nous a pas permis d'obtenir des différences de temps d'écoulement suffisantes, même pour l'eicosapeptide. C'est pourquoi les études de structure des autres oligoampholytes en solution aqueuse ne sont basées que sur leurs spectres d.c. et les résultats obtenus avec le polypeptide. L'augmentation de l'ellipticité autour de 220 nm en fonction de la longueur de la chaîne serait imputable à la diminution progressive des effets de bouts de chaîne. On voit par contre que même avec l'eicosapeptide, la courbe en milieu acide de la fig. 4 ne dévie pas de la linéarité. Si on suppose juste l'hypothèse émise à l'éq. 5, cela signifie qu'aucune forme de structure secondaire n'est amorcée lorsque la chaîne contient jusqu'à vingt résidus.

Les spectres d.c. des peptides en solution basique ont l'allure des spectres en solution acide. Toutefois, la bande d'ellipticité autour de 220 nm est toujours moins négative, pour un peptide donné, que dans le cas de la solution acide. On voit également, à la fig. 4, que la contribution à l'ellipticité totale par les résidus internes est moindre qu'en milieu acide. En solution fortement basique, le peptide est chargé négativement, à cause de la présence des groupements carboxyl de l'acide aspartique sous forme COO^-. Les groupements amine de la lysine sont sous forme NH_2. D'une part, on note en milieu basique une plus grande viscosité intrinsèque de la solution qu'en milieu acide. Cette différence est cependant minime. D'autre part, les calculs du pourcentage de chaque forme, tirés des spectres d.c., nous montrent un pourcentage plus faible d'hélicité qu'en milieu acide et un pourcentage plus élevé de chaîne "étendue". Si le raisonnement précédent est applicable, la courte chaîne latérale de l'acide aspartique, moins flexible que celle de la lysine, ne permettrait pas aux groupements carboxyliques chargés de se maintenir à une distance suffisante l'un de l'autre pour annuler l'effet de répulsion électrostatique. De plus, il est possible à l'ion COO^- d'interagir fortement avec les liaisons polaires du squelette et nuire à la formation des liaisons hydrogène. Le niveau d'organisation des courtes chaînes en solution basique semble également moins important que précédemment.

Aux environs du point isoélectrique des peptides, nous avons affaire à un phénomène complètement différent. Les résultats de viscosimétrie indiquent une chute importante de la viscosité intrinsèque, signe d'une forte association des chaînes causée par l'attraction électrostatique d'ions de signe contraire portés par les chaînes latérales des peptides. Un fait intéressant à signaler est la diminution de l'ellipticité de la bande de dichroïsme circulaire autour de 200 nm lorsque les solutions de peptide tendent vers un p*H* neutre. Dans le cas d'homopolypeptides chargés, cette bande est très intense, de l'ordre de $-50\,000$ deg cm^2 dmol^{-1} pour la poly-L-lysine (45). Dans notre cas, l'intensité de cette bande ne dépasse pas $-15\,000$ deg cm^2 dmol^{-1} pour le polypeptide à p*H* 7.0. Ces résultats nous porte à croire à l'adoption, par les polyampholytes, d'une forme globulaire compacte au point isoélectrique. Comme la dilution ne semble pas affecter les spectres d.c. dans ces conditions, du moins dans les limites expérimentales de concentration permissibles (1–0.005%), nous croyons que l'association est surtout intramoléculaire. Des essais de variation de température sur le spectre d.c. nous portent aux mêmes conclusions. Le fait que les chaînes tendent à se replier sur elles-mêmes lorsqu'on approche du point isoélectrique aurait alors pour effet de diminuer le moment dipolaire résultant de chaque chaîne et par conséquent l'ellipticité des transitions n–π^* et π–π^*, comme on l'observe sur les spectres d.c. à p*H* 7.0. Comme le montre la fig. 4, l'effet de la longueur de la chaîne dans ces conditions semble le moins important.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

A la lumière de ces résultats, il nous apparait que la conformation d'un polyampholyte alterné, composé de résidus d'acide aspartique et de lysine, diffère fortement de celles des homopolypeptides respectifs. Cette propriété de polyampholyte confère à ces peptides une ressemblance indéniable avec les protéines globulaires, pour lesquelles ils peuvent éventuellement servir de modèle. Ce travail montre également que la longueur de la chaîne n'est pas un critère primordial pour qu'un polyampholyte adopte sa conformation la plus stable en solution, contrairement aux homopolypeptides ou polyélectrolytes simples. D'autres travaux restent à faire pour déterminer exactement la structure secondaire qu'adoptent ces peptides en solution aqueuse et la raison pour laquelle ils manifestent des propriétés de dichroïsme circulaire aussi compliquées.

Nous remercions le Ministère de l'Education de la Province de Québec ainsi que le Conseil national de recherche du Canada pour l'aide financière apportée à ces travaux de recherche.

Orientation Effects and the Sign of Two-bond ^{13}C–^{1}H Coupling[1,2]

JOSEPH A. SCHWARCZ,[3] NATSUKO CYR, AND ARTHUR S. PERLIN
Department of Chemistry, McGill University, Montreal, Quebec H3C 3G1

Received December 20, 1974

JOSEPH A. SCHWARCZ, NATSUKO CYR, and ARTHUR S. PERLIN. Can. J. Chem. **53**, 1872 (1975).

Signs of two bond (^{2}J) ^{13}C–^{1}H coupling in ^{13}C-enriched carbohydrates have been determined from proton spectra by the double irradiation technique. Instances of both positive and negative ^{2}J values are given and are characterized in terms of the relative orientations of the coupled proton and of oxygen appended to the ^{13}C nucleus; *e.g.*, an oxygen *anti* to the proton appears to make a positive contribution to ^{2}J and a *gauche* oxygen a negative one. Theoretical calculations, using ethanol and 1,1-ethanediol as model compounds, are in accord with these experimental observations.

JOSEPH A. SCHWARCZ, NATSUKO CYR et ARTHUR S. PERLIN. Can. J. Chem. **53**, 1872 (1975).

On a déterminé le signe du couplage sur deux liaisons (^{2}J) ^{13}C–^{1}H dans des carbohydrates enrichis en ^{13}C; ces attributions ont été faites à partir des spectres du proton en utilisant la technique à double irradiation. On présente des cas où les valeurs de ^{2}J sont positives et d'autres où elles sont négatives et ces valeurs sont caractérisées en terme d'orientation relative du proton couplé par rapport à l'oxygène attaché aux noyaux ^{13}C; *e.g.* un oxygène *anti* par rapport à un proton semble apporter une contribution positive à ^{2}J et un oxygène *gauche* apporterait une contribution négative. Des calculs théoriques utilisant l'éthanol et l'éthanediol-1,1 comme composés modèles sont en accord avec les observations expérimentales.

[Traduit par le journal]

The magnitude of coupling between ^{13}C and ^{1}H across two bonds ($^{2}J_{C,H}$) is dependent on the orientation of substituents appended to the ^{13}C nucleus relative to the proton. For example, C-1 of β-D-glucopyranose-*1*-^{13}C (**1**) exhibits coupling of 5.7 Hz with H-2, whereas the corresponding value for the α-anomer (**2**) is <1 Hz (1, 2).[4] Similarly, an orientational dependence has been noted for sp^2 hybridized carbon: coupling between ^{13}C-6 and H-5 is 4 Hz for 1,2-*O*-isopropylidene-α-D-glucofuranurono-6,3-lactone but none is observed (2) for the epimeric β-L-*ido* derivative. In bromoethylene (**3**) two-bond coupling with both of the vinyl protons is observed but $^{2}J_{C,H}$ for the proton *trans* to the halogen has a positive value, whereas that involving the *cis* proton is negative (4). The current study deals with the sign of coupling associated with the orientation of substituents in molecules such as **1**.

The double irradiation technique of sign determination (5) was found to be effective for the present purpose. An AMX spin system is ideal in this type of application and, in principle, should be encountered in the H-1,^{13}C-1,C-2,H-2 portion of **1** ($\nu_{H\text{-}1} - \nu_{H\text{-}2} = 150$ Hz; ^{13}C-1 is the X nucleus). However, due to signal overlap the spectrum of **1** proved to be unsuitable for the double irradiation experiment. A much more satisfactory spectrum (Fig. 1) was obtained for β-D-allopyranose-*1*-^{13}C (**4**), *i.e.*, the 3-epimer of **1**. Since in this instance $J_{H\text{-}1,H\text{-}2}$ and $J_{H\text{-}2,H\text{-}3}$ differ, and neither equals $J_{C\text{-}1,H\text{-}2}$, the H-2 signal is an octet; both the latter signal and the lower H-1 satellite signal are clearly observable in the spectrum.

When irradiation was carried out at the frequency of the upfield half of the H-2 octet (*C*), the low-field portion of the H-1 signal collapsed but it was unaffected at the frequency of the low-field half (*B*) of the H-2 signal (inset, Fig. 1). Analogously, irradiation at the frequency of the low-field half of H-1 (*A*) caused perturbation only of the upfield half of the H-2 signal. Therefore, $^{1}J_{C,H}$ and $^{2}J_{C,H}$ in this system are of opposite sign and hence, since $^{1}J_{C,H}$ is taken to be positive (5), coupling between ^{13}C-1 and H-2 in **4** may be specified as -5 Hz. By implication, the corresponding coupling in **1** is *minus* 5.7 Hz.

In comparing this result with the value of <1 Hz cited for coupling between ^{13}C-1 and H-2 of α-D-glucopyranose-*1*-^{13}C, one way to describe the relative stereochemistry of these isomers is to treat the C-1, O-1, and C-1.O-5 bonds as vectors and consider their "resultant" (v.r.), as in **5** (β-anomer) or **6** (α-anomer) with respect to the C-2, H-2 bond. Accordingly, it appears that the value of $^2J_{C,H}$ becomes more negative as the dihedral angle relating v.r. and H-2 decreases.

The sign of two-bond coupling in an analogous system (**7**) incorporating an *increase* in the angle between v.r. and H-2 was determined from the spectrum of 1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose-*1*-^{13}C (**8**). Since there is no detectable coupling of H-2 and H-3 in this molecule, the H-2, H-3 dihedral angle must be close to 90° and the furanose ring must approximate an

60	−2.2	0	120	−1.9
90	0	30	150	0
120	+3.9	60	180	+2.6
150	+7.2	90	150	+4.9
180	+9.3	120	120	+6.0

envelope conformation (6), which may be partially depicted by projection **7**. In this arrangement, v.r. is almost *trans* to H-2.

Double irradiation experiments with **8** showed that the sign is the same for coupling of ^{13}C-1 with H-1 as with H-2, *i.e.*, collapse of the downfield half of the H-1 signal was effected by irradiation at the frequency of the lower half of the H-2 signal; similarly, the two upfield halves of these signals were correlated. The results were confirmed by reversal of the double irradiation procedure. Hence, for the particular stereochemistry represented by **7** the value of $^{2}J_{C,H}$ is positive (+5.5 Hz).

In summary, coupling between a ^{13}C atom bearing two oxygen atoms and a proton on a neighboring carbon is negative when the dihedral angle relating the C—O bonds with the C—H bond is small. As the angle increases the coupling constant increases, then passes through zero, and its sign becomes positive. Stated alternatively, an oxygen *anti* to the coupled proton may be regarded as making a positive contribution to the coupling, whereas a *gauche* oxygen makes a negative contribution.

A theoretical approach (7) for calculating the sign and relative magnitude of two bond ^{13}C–^{1}H coupling constants has been applied to ethanol (**9**) and 1,1-ethanediol (**10**) for comparison with the observed substituent orientational dependence described above.

The results (Table 1), expressed as a function of J (*i.e.*, $\pi_{\mu v}$(8)), show that the calculated coupling constants qualitatively exhibit a stereochemical dependence analogous to that found experimentally. For ethanol, the positive contribution of an *anti* hydroxyl and the negative one of a *gauche* hydroxyl are clearly demonstrated. The results observed with the *1*-^{13}C enriched carbohydrates are also reproduced with the *gem*-ethanediol system: *i.e.*, coupling is negative when the hydroxyls are oriented 60° with respect to the coupled proton and becomes positive when the dihedral angles become 120° (Table 1).

According to these findings, two bond ^{13}C–^{1}H coupling is, in principle, a more definitive type of stereochemical descriptor than three-bond (vicinal) coupling. Hence, the absolute magnitude of $^{2}J_{C,H}$ varies in a progressive manner, increasing continuously as the dihedral angle (or v.r.) increases, whereas a given value of $^{3}J_{C,H}$ may correspond to either of two different orientational arrangements because of the U-shape of the "Karplus-type" curve for vicinal coupling (2, 9). Improvements in methodology for determining the sign of ^{2}J are needed, however, to facilitate a general application of two bond coupling to stereochemical problems.

Experimental and Calculations

Proton magnetic resonance spectra were recorded at 100 MHz with a Varian HA-100 spectrometer using D_2O

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

(for **4**) or $CDCl_3$ (for **8**) as solvent. The frequency sweep mode was employed in the double irradiation experiments.

1,2:5,6-Di-*O*-isopropylidene-α-D-glucofuranose-*1*-^{13}C (**8**) was synthesized as described previously (2) and β-D-allopyranose-*1*-^{13}C (**4**) from **8** (10) by the route developed (11) for synthesis of the nonenriched sugar.

The equation proposed by Pople and Santry (ref. 8 eqs. 3.4 and 3.5) was utilized for the calculation of coupling constants. Only the Fermi contact terms were considered in the calculations, as is usual (12), and orbital coefficients and energies were obtained by use of the CNDO/2 method (7). In this method the unoccupied orbital's energy (ε_j (8)) is calculated by placing one extra electron in the orbital. For the present purpose, however, the triplet state energy (ε_j (corr.)) was required and this was obtained by subtracting from ε_j the energy of repulsion between the electron in the highest occupied orbital and the remaining electrons, as follows.

$$\varepsilon_j(\text{corr.}) = \varepsilon_j - \sum_{\mu}\sum_{\nu} C^2{}_{\mu j} C^2{}_{\nu k} \gamma_{\mu\nu}$$

where μ and ν are the basic atomic orbitals, k is the highest occupied molecular orbital, and γ is the electron repulsion integral.

The authors express their gratitude to Dr. J. E. Grabenstetter for valuable discussion and to the National Research Council of Canada and the Pulp and Paper Research Institute of Canada for generous support.

Predicting the Most Favored Path and the Overall Rate of Multistep 2-Norbornyl Cation Rearrangements. The Assignment of a Trial Activation Energy for Each Unique Step

R. HASELTINE, E. HUANG, K. RANGANAYAKULU, T. S. SORENSEN, AND N. WONG

Department of Chemistry, University of Calgary, Calgary, Alberta T2N 1N4

Received October 31, 1974

R. HASELTINE, E. HUANG, K. RANGANAYAKULU, T. S. SORENSEN, and N. WONG. Can. J. Chem. **53**, 1876 (1975).

Observable 2-norbornyl cations undergo at least five different rearrangement reactions, all of which are known from previous work on this system. In this paper, these rearrangement categories have been subdivided to reflect secondary–tertiary energy and rate differences and a trial set of activation free energies $\Delta G^{\ddagger}$ is derived for each subdivided step. The most important of these parameters is the energy difference between secondary and tertiary (methyl) systems which was estimated as 5.5 kcal/mol. These parameters allow one, for the first time, to make a rational assessment of the overall reaction course of multistep rearrangement reactions in this system, for example, those observed in a number of bicyclo[2.2.1]heptyl(norbornyl) terpene systems.

R. HASELTINE, E. HUANG, K. RANAGNAYAKULU, T. S. SORENSEN et N. WONG. Can. J. Chem. **53**, 1876 (1975).

Les cations norbornyl-2 que l'on peut observer subissent au moins cinq réactions de réarrangement différentes et elles étaient toutes connues à partir de travaux antérieurs sur ce système. Dans ce travail, on a subdivisé ces catégories de réarrangement afin de mettre en relief les différences d'énergie et de vitesse des cations secondaires *vs.* tertiaires et on a établi des valeurs préliminaires pour les énergies libres d'activation $\Delta G^{\ddagger}$ de chaque étape des subdivisions. Le paramètre le plus important est la différence d'énergie entre les systèmes secondaires et tertiaires (du méthyle) qui serait de 5.5 kcal/mol. En utilisant ces paramètres, on peut pour la première fois faire une attribution raisonable pour l'évolution globale des réactions de réarrangement de ce système impliquant plusieurs étapes; à titre d'exemple on peut faire des attributions pour les réactions observées dans un certain nombre de systèmes terpéniques du bicyclo[2.2.1]heptyle(norbornyle). [Traduit par le journal]

Introduction

Organic molecular rearrangements occur by a variety of mechanisms but for hydrocarbons the most important class involves the intermediacy of carbocations, the actual molecular rearrangement taking place in the carbocation intermediate (eq. 1).

[1] $R_1X \rightleftharpoons [R_1^+ \xrightarrow{k} R_2^+] \rightarrow R_2X$

Working in very stong acids, it is now possible to prepare many of these carbocation "intermediates" and to directly measure the rate of the critical cation$_1$ → cation$_2$ step. For simple reactions of the eq. 1 type, this measurement is mainly of interest to the physical organic chemist since, regardless of the absolute rate of the cation step, the product remains the same. Let us consider, however, a more realistic case, given in eq. 2.

[2] $R_1X \rightleftharpoons [R_1^+ \xrightarrow{k_1} R_2^+ \xrightarrow{k_4} R_5^+;\ R_1^+ \xrightarrow{k_2} R_3^+ \xrightarrow{k_5} R_6^+;\ R_1^+ \xrightarrow{k_3} R_4^+ \xrightarrow{k_6} R_7^+] \rightarrow R_2X, R_3X, R_4X, R_5X, R_6X, R_7X$?

In this case, the product formed is critically dependent on what R_1^+ does and may also be dependent on the behavior of the primary rearrangement ions. If one knew the relative rates (or

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

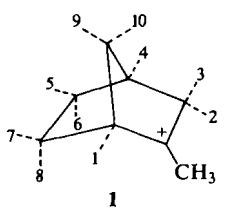
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

activation barriers $\Delta G^{\ddagger}$) of the k_1–k_6 processes, one would be in a position to rationally assess what the probable product might be.

Previously, it has been verified that the products formed from the acid-catalyzed treatment of α-fenchol (which differ greatly in composition depending on the severity of the reaction) correlate with the measured rates of the various rearrangements involving the corresponding observable α-fenchyl cation (1). Since these cation → cation absolute rates were not previously known, one could not of course have predicted the actual products formed in the α-fenchol acid-catalysis reactions. However, in this paper it is suggested that one can build up from a number of these "base" measurements, a reasonably consistent set of activation energy parameters (constants), each constant being characteristic of a particular single-step rearrangement process of the kind given in eq. 2.

The choice of the 2-norbornyl cation system as an illustrative example of eq. 2 is dictated by two factors: (*i*) a given norbornyl cation has at least five different structural "chess moves", *i.e.* given by k_1, k_2, k_3, etc. in eq. 2, which it can undergo at any one stage and (*ii*) there has been an enormous amount of solvolysis and acid-catalysis work (which can be used for comparison purposes) carried out on methyl-substituted 2-norbornyl systems, including all of the monomethyl analogs (2) and a great many di- (3) and trimethyl (4) systems. Many of the di- and trimethyl systems studied (like α-fenchol) are terpenes or rearrangement products derived from these.

Although the division is somewhat artificial (see further), we will use as "base" systems, the activation energy parameters derived from the observed rearrangements of the parent 2-norbornyl cation, the 2-methyl cation, and a number of trimethyl and higher methylated norbornyl cations. One can then test the validity (predictive power) of these parameters on the rearrangement reactions involving the complete set of 10 tertiary dimethyl-2-norbornyl cations **1** (accompanying paper) (5). Six of these ions, and hence their rearrangement reactions, were completely unknown until after the formulation of the trial activation energy parameters and hence offered a genuine test of the validity of these. The other four ions and their rearrangement reactions were known and hence the treatment involving these is somewhat artificial.



1

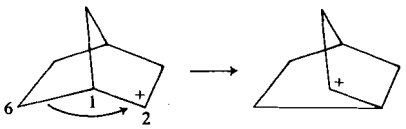
Results and Discussion

Rearrangement Processes Considered

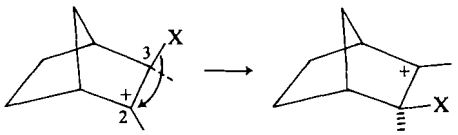
In organizing this paper, it seems best to outline the various rearrangements which the 2-norbornyl system can undergo and then to consider whatever specific subdivision of these main categories which may be necessary. Following this, we will discuss the particular rearrangement (or rearrangements) which allows one to assign an activation energy value to that particular step. Some previously communicated work and procedures (1, 6) will be described in full in this paper but the focus of the presentation differs somewhat (*e.g.* one communication (1) covered a number of sequential rearrangements involving initially the α-fenchyl cation system).

The rearrangement processes considered (the first three are well known) for the 2-norbornyl cation system were the following.

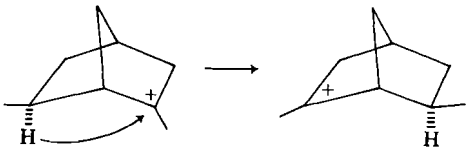
(*1*) A Wagner–Meerwein shift of the C6—C1 bond to C6—C2:



(*2*) An *exo*-3,2-substituent shift:

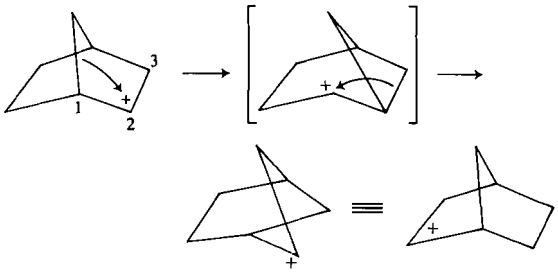


(*3*) An *endo*-6,2-hydride shift:

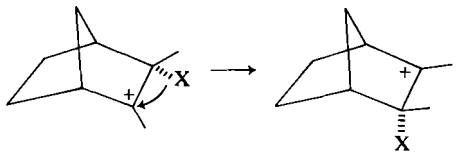


(*4*) An overall two-step process involving the shift of the C1—C7 bond to C2 to give a high energy, unobservable, 2-bicyclo[3.1.1]heptyl cation intermediate and then the shift of the original C2—C3 bond to C1. This overall sequence has been termed a double Wagner–Meerwein

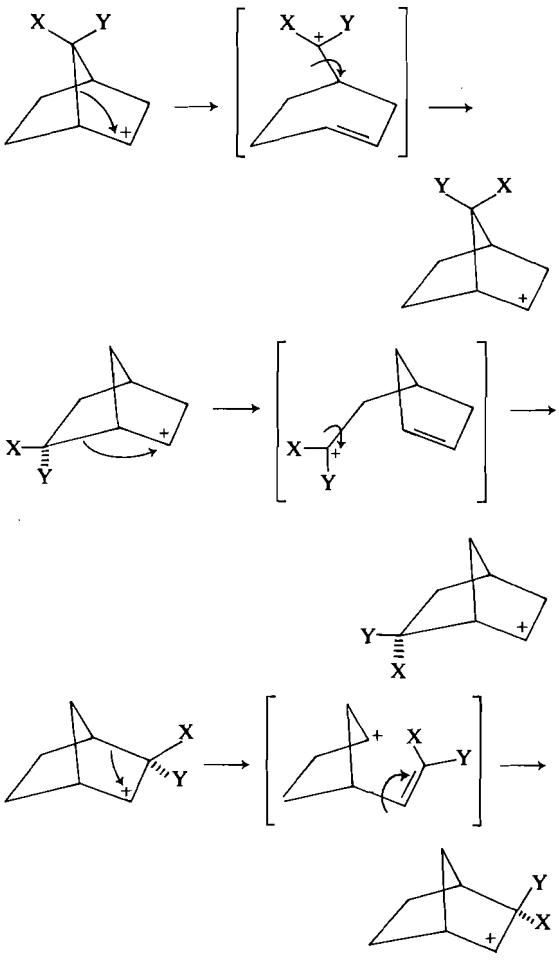
(DWM) rearrangement (7):



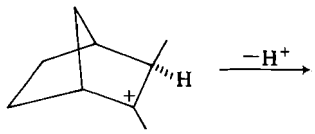
(5) An *endo*-3,2-substituent shift:

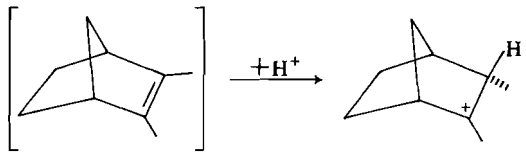


(6) Ring opening – bond rotation – ring closure processes:



(7) In addition to the above, a process involving deprotonation–reprotonation might occur.





This last process is expected to differ from all of the others in that the rate of the reaction should be markedly sensitive to the strength of the strong acid solvent (8). Based on present knowledge (9), the rearrangement rates of processes *1–6* will not be appreciably affected by changes in the strong acid solvent system used.

Subdivision of the Major Categories

One could not possibly expect the rearrangement rates of the processes *1–6* to be insensitive to a variety of substituents on the basic 2-norbornyl ring system. Fortunately, much of the solvolysis and acid-catalysis work in the chemical literature involves only methyl or hydrogen as substituents (*e.g.* terpenes) and in this work, the same restriction is applied. It would also be expected that steric effects would be an important factor, particularly if one had very many methyl substituents. In setting up the "base" activation energy parameters, we have tried to avoid model systems where rearrangement rates might be seriously changed by some steric factor. Nevertheless this must remain a nagging problem.

One factor demonstrably affecting the rates and the thermodynamic stability of the ions which cannot be ignored concerns the substitution at C2, *i.e.* either an H (secondary 2-norbornyl) or CH_3 (tertiary 2-norbornyl). The other factor concerns the *exo*- and *endo*-3,2-substituent shift, *i.e.* the rate is demonstrably different for a methyl *vs.* a proton shift. These considerations lead to the following further subdivision of the major categories (Scheme 1).

5	5HTT 5HTS 5HST 5HSS 5MTT 5MTS 5MST 5MSS

SCHEME 1. Abbreviations: T = tertiary, S = secondary, the first letter refers to the reactant ion and the second to product, H = hydrogen, M = methyl, the major rearrangement processes take the same number as was used to list them.

The ring opening – rotation – ring closure processes, *6a–c*, have been left out of Scheme 1. Although all three rearrangements, *6a* (10, 11), *6b* (12), *6c* (11), have been proposed in part for stable 2-norbornyl cations, it appears that not only is the activation energy quite high but that also, in some cases, a ring opening would lead irreversibly to cycloallyl cations (11). The deprotonation–reprotonation sequence *7* has also been left out since experimentally this process does not appear to play a significant role in the mono- , di- , or trimethyl-2-norbornyl cation rearrangements. In any case, if one uses the strongest acid systems available, *e.g.* $R^+ SbF_6(SbF_5)_n^-$ salts, the activation energy for this process could be made very high and the process effectively shunted aside. Other marginally possible processes, *e.g. endo*-5,2-hydride shifts, have not been observed and likely have a high activation energy barrier associated with them.

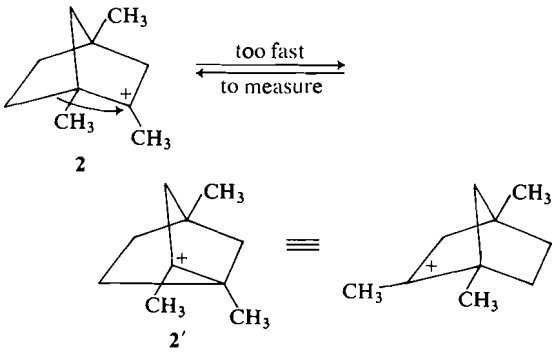
Obtaining the $\Delta G^{\ddagger}$ Parameters for Each Subdivided Rearrangement Process

The experimental evidence available for assigning $\Delta G^{\ddagger}$ parameters comes, as will be seen, in varying degrees of reliability. Some observable 2-norbornyl cation rearrangement processes involve a single specific step and this is then easily assigned a $\Delta G^{\ddagger}$ value. Other rearrangements involve two or more steps but the sequence can be uniquely assigned. However, in other multistep rearrangements it is not possible to assign an unique sequence or to even ascertain the particular rearrangement steps. A good discussion of this situation is given in two recent papers by Collins and co-workers (7). They show that one can bring about any overall 2-norbornyl cation transformation by using only combinations of the first three rearrangement processes given in Scheme 1, albeit the number of steps may be very large. In practice, one is forced to assign a specific mechanism sequence from among many theoretical possibilities. We will use the computerized treatment of Collins and co-workers (7), where appropriate, together with our further subdivision of each major step and then give our reasons for the choice of a specific sequence[1] in discussing an overall multistep rearrangement.

In most cases, only a $\Delta G^{\ddagger}$ activation energy value was experimentally obtained. However, in those rearrangements where both $\Delta G^{\ddagger}$ and $\Delta H^{\ddagger}$ were measured, they have turned out to be very similar, *i.e.* $\Delta S^{\ddagger} \sim 0$ and $\Delta G^{\ddagger} \sim$ constant. Also, since one is dealing with rate *comparisons*, the term $T\Delta S^{\ddagger}$ would become significant only if the temperature of the "base" measurement rearrangement and the observed rearrangement differed considerably.

Rearrangement 1TT

Only a lower limit $\Delta G^{\ddagger}$ value can be obtained for this shift since it cannot be "frozen out" in the n.m.r. spectrum of the 1,2,4-trimethyl-2-norbornyl cation **2** (1) or in higher methylated analogs (12). Cation **2** can be obtained as the



"ultimate rearrangement" product of the tertiary α-fenchenehydro cation (1) and the structure was proven from quenching experiments wherein the

[1]From basic thermodynamic principles, all sequences are probably being followed and the occasional explorer molecule may indeed complete even the most unfavorable path. In the discussion, therefore, one is concerned about the route followed by > 99% of the reactant carbocations.

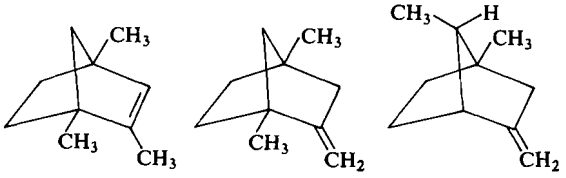
two new "fenchenes" **3** and **4** were obtained and



3 **4** **5**

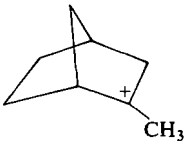
characterized (see Experimental). In addition, a small amount of what is likely the alkene **5** was obtained. The carbon-13 n.m.r. spectrum of **2** is particularly useful for obtaining an upper limit estimate for the 1TT activation energy barrier since the process is degenerate in this ion and the C1—C2 n.m.r. peak is a composite of peaks which are expected to be separated widely in the "frozen out" structure. The rate constant for an n.m.r. averaging process needed to give a sharp coalesced peak is dependent on the intrinsic separation of the individual peaks, and if one makes a reasonable choice of a 4000 Hz separation for C1 and C2 in **2** (based on values for C1 and C2 obtained for the 2-methyl-2-norbornyl cation (ref. 13 and footnote 2)), one can show by standard n.m.r. theory that a rate constant of $>10^6$ s^{-1} (see accompanying paper (17)) is needed to produce the relatively sharp peak observed (14) for **2** at -140 °C. This leads to a maximum possible $\Delta G^{\ddagger}$ value of 4 kcal/mol. Since this barrier is so small, one may wonder whether the ion might not have a symmetrical structure and hence there would be no 1TT process involved at all. Previous work with unsymmetrical cations of this type has shown, however, that the averaged chemical shifts are temperature dependent in exactly the manner expected for an equilibrating pair of ions, where the more stable isomer becomes more dominant at low temperatures (the van't Hoff relationship) (14). Other evidence also indicates equilibrating structures (15, 16).

Rearrangement 1SS

For consistency in the computerized treatment, a secondary 2-norbornyl cation will be treated as an equilibrating structure, *i.e.* as having a 1SS process. (A discussion of the structure problem is given in an accompanying paper (17).) Olah *et al.* have recently published (18) a ^{13}C n.m.r. spectrum of the 2-norbornyl cation which shows a sharp coalesced C1—C2 peak at -150 °C. Using identical calculations to those used for the 1TT case, one calculates a maximum activation energy barrier of 4 kcal/mol.

Rearrangements 1TS and 1ST

Assuming a simple transition state model, these two processes involve the same potential energy surface. If one knew the energy difference between a secondary and a tertiary(methyl) 2-norbornyl cation and only one of the two activation energies, one could always obtain the other. This applies not only for the WM process but for all five major divisions in Scheme 1. Thus, the value assigned to this secondary–tertiary energy difference is quite critical. Fortunately, a method exists for estimating such a value. In the first (fastest rate) degenerate rearrangement of the 2-methyl-2-norbornyl cation **6** (prepared from 2-methylnorbornanol or the corresponding chloride), in a second (slower rate) degenerate rearrangement in the camphenehydro cation (6, 19)



6

and in the overall process interconverting the tertiary α- and β-fenchenehydro cations (1), one has a process which can be unequivocally assigned to the three-step sequence 1TS, 3SS, 1ST. A careful matching of the observed n.m.r. line broadening in **6** with computed spectra has been carried out and from this analysis one obtains, in the usual way, $\Delta G^{\ddagger} = 11.3$ kcal/mol at -49 °C, $\Delta H^{\ddagger} = 11.0 \pm 1$ kcal/mol. Some of the experimental and calculated spectra for the line broadening in **6** are shown in Fig. 2. The activation energy for the 3SS step in the 2-norbornyl cation has been reported by Olah *et al.* (20) $\Delta G^{\ddagger} = 5.8$ kcal/mol at -141 °C, $\Delta H^{\ddagger} = 5.3$ kcal/mol. If this same value is applicable to the 3SS step in a 1-methyl secondary cation, then one can construct the transition state diagram shown in Fig. 1, leading to an estimate of 5.5 kcal/mol for the secondary–tertiary energy difference. Concerning the 1TS and 1ST processes, one would expect the activation energy for the 1ST process to be, at worst, the same as the 1SS process, *i.e.* <4 kcal/mol. This leads to a value of <9.5 kcal/mol for 1TS and, although the argument is

where

$$k_{-1} > k_2$$

and B is a steady state-intermediate.

Rearrangement 2HTT

This process can be directly measured (n.m.r. line broadening) as a single degenerate step in the 1,2-*endo*-3,4-tetramethyl-2-norbornyl cation (11), $\Delta G^{\ddagger} = 7.1$ kcal/mol, and also in even higher methylated analogs, 7.4 kcal/mol (12).

Rearrangement 2HSS

This process occurs as a degenerate rearrangement in the 2-norbornyl cation and has been analyzed by Olah *et al.* (20) $\Delta G^{\ddagger} = 11.4$ kcal/mol at -29 °C, $\Delta H^{\ddagger} = 10.2 \pm 0.6$ kcal/mol. In the analysis of the observed line broadening, one cannot distinguish between an *exo*-3,2-hydride shift and an *endo* equivalent or a mixture of both but, in the corresponding TT process, the *exo* shift is favored over the corresponding *endo* shift by at least 6.9 kcal/mol (see below). There is also much solvolysis evidence showing that *exo* shifts are highly preferred (21) in the secondary system.

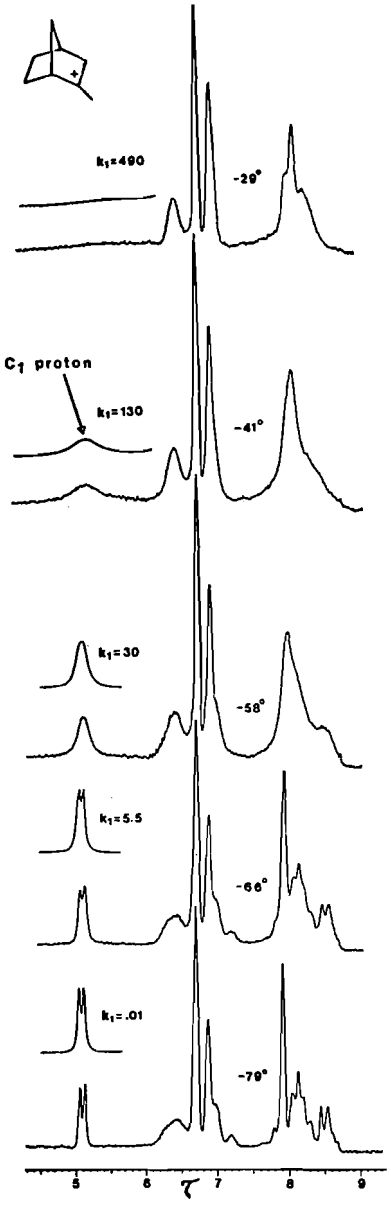

FIG. 2. ^{1}H n.m.r. spectrum of the 2-methyl-2-norbornyl cation showing the experimental line broadening due to the most rapid of two degenerate rearrangements occurring in this ion. The H1 proton at *ca.* τ 5.1 was used for the rate analysis with the calculated spectrum shown above each experimental peak. At temperatures above -40 °C, the amplitude of the H1 signal in the experimental spectra was increased considerably over that shown in this diagram.

Rearrangements 2HTS and 2HST

As explained previously, only one of these needs to be measured. This can be done from an

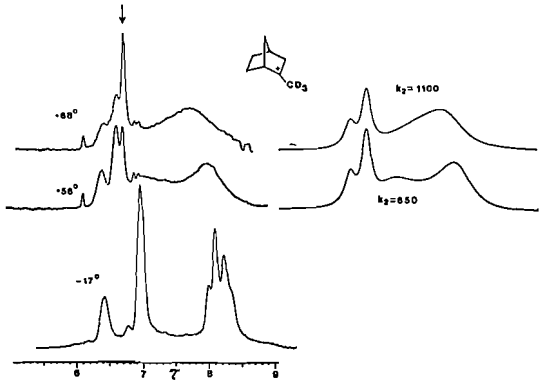

FIG. 3. ^{1}H n.m.r. spectrum of the 2-deuteriomethyl-2-norbornyl cation showing the experimental line broadening (left) due to the slower of two degenerate rearrangements occurring in this ion. At the right are two calculated spectra for this exchange, k_1 being set from the data obtained in Fig. 2. The peak designated by ↓ is the C2 deuteriomethyl group which is being exchanged with H at the higher temperatures.

analysis of the second (slower) degenerate rearrangement observed for the 2-methyl-2-norbornyl cation **6**. Examples of the actual line broadening experimentally observed at 0 °C and above for **6** are illustrated in Fig. 3. The rearrangement sequence responsible for this broadening is not immediately obvious because there appear at first sight to be several degenerate sequences which might cause the observed broadening. However, the fact that the *exo*-6 proton peak (H7 in Fig. 4) does not broaden (at least initially) allows one to assign the process as follows (Scheme 2).

The overall topology of the process is to rotate the protons A, B, C, and D one turn for each six-step sequence. The overall proton equivalences are shown in Fig. 4, together with the kinetic exchange matrix used. This matrix embodies the assumption that one will statistically partition the protons A, B, C, and D equally among the four positions available to these before returning to the tertiary ion via a 2ST step. This requires the rate of the 2ST step to be much slower than the 1SS and 3SS processes, a requirement that may not be strictly true. The calculated $\Delta G^{\ddagger}$ values are <4 and 5.8 kcal/mol for the 1SS and 3SS processes *vs.* a calculated 9.7 kcal/mol for the 2ST process. Even if there is some bias towards returning to the original configuration, as compared to the other three, the effect on the calculated $\Delta G^{\ddagger}$ value will probably not be large (the calculated value will always be on the high side). The specific proton exchanges listed in Fig. 4 were also confirmed using the D1SST technique of Forsén and Hoffmann (22). Thus, irradiation of the averaged C5—C7 protons (Fig. 3) at +15 °C, causes the overlapping C3—C4 signal to nearly disappear and *vise versa*. The *exo*-H6 proton is not appreciably affected.

Using the equivalences shown in Fig. 4, the calculated and experimental line shapes are compared in Fig. 3 for various rate constants. The approximations used in the calculations are detailed in the Experimental. Only the calculated spectra in the intermediate exchange region can validly be used for comparison to experimental spectra. From this, one obtains $\Delta G^{\ddagger}$ = 15.2

kcal/mol, using a matching just before coalescence, *i.e.* the +56 °C spectrum in Fig. 3. Subtracting 5.5 results in the $\Delta G^{\ddagger}$ value of 9.7 kcal/mol for the 2HST process.

At higher temperatures (>65 °C), there is evidence that still another degenerate process in cation **6** is beginning to show up since the *exo*-H6 proton starts to broaden. This is very likely due to the sequence 1TS,2HSS,3SS,2HSS,1ST.

Rearrangement 2MTT

This single-step process has been directly measured as a degenerate process in the camphenehydro cation (6, 19), $\Delta G^{\ddagger} = 8.3$ kcal/mol at −104 °C, $\Delta H^{\ddagger} = 8.2 \pm 1$ kcal/mol, and in two higher methylated analogs (12), $\Delta G^{\ddagger} = 9.4$ kcal/mol.

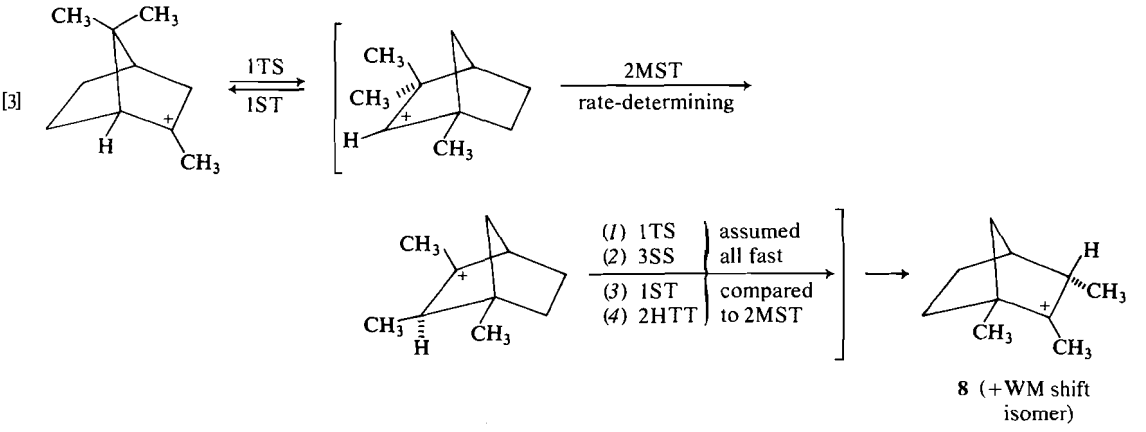
Rearrangement 2MSS

No satisfactory value could be arrived at for this process. However, we believe that the $\Delta G^{\ddagger}$ value should be as high or higher than the process 2MST (which can be determined). Tentatively, therefore, 2MSS is assigned a lower limit value, $\Delta G^{\ddagger} \geq 7.6$ kcal/mol. However in some cases, methyl shifts are slower than the corresponding proton shifts. Since the 2HSS value is 11.4 kcal/mol, it would not be unreasonable to expect a 2MSS value even higher than this.

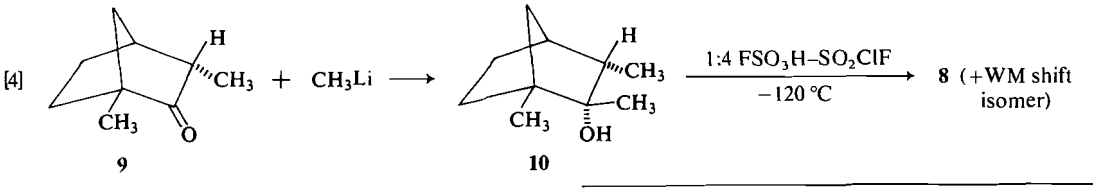
Rearrangements 2MTS and 2MST

The best estimate for the 2MST rearrangement comes from the observed rearrangement of the tertiary α-fenchenehydro cation **7** to the 1,2-*endo*-3-trimethyl-2-norbornyl cation **8**, for which the mechanism in eq. 3 appears the most reasonable (from graph theory there are many other longer sequences possible). The overall activation energy is 13.1 kcal/mol ≡ 2MST. The reverse 2MTS step is assigned a value 13.1 − 5.5 = 7.6 kcal/mol.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.



The structure of cation **8** was confirmed by an unequivocal synthesis starting from the known ketone **9** (eq. 4).



Rearrangement 3TT

No direct measurement of this parameter is available from any of the mono- or trimethyl-2-norbornyl cation rearrangements studied in this work. However a maximum $\Delta G^{\ddagger}$ value of 11.3 kcal/mol is estimated (below) for the 3TS process and the same value is tentatively used for 3TT.

Rearrangement 3SS

This degenerate process has been observed in the 2-norbornyl cation, $\Delta G^{\ddagger} = 5.8$ kcal/mol at −141 °C, $\Delta H^{\ddagger} = 5.3$ kcal/mol (20).

Rearrangements 3TS and 3ST

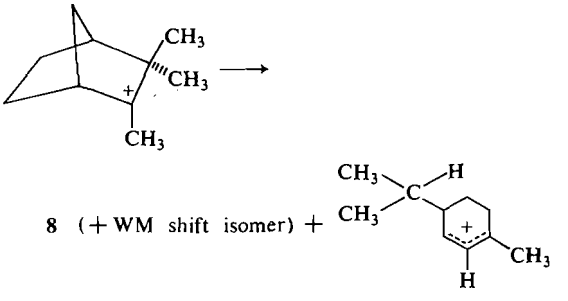
It seems reasonable to assume that the process 3ST will have a $\Delta G^{\ddagger}$ value of no more than the 3SS value, *i.e.* $\Delta G^{\ddagger} = 5.8$ kcal/mol is assigned. This results in a maximum value of 11.3 kcal/mol for 3TS.

Although the $\Delta G^{\ddagger}$ values assigned to the *endo*-6,2-hydride shifts (process *3*) appear rather uncertain, they are all small enough so that this step will rarely be rate determining in an overall multistep rearrangement.

Rearrangement 4

Assigning a $\Delta G^{\ddagger}$ value for this two-step process has proven difficult since, as previously mentioned, one can always find a theoretical sequence of steps for any 2-norbornyl cation rearrangement not *requiring* this process. This point is discussed in detail by Johnson and co-workers (7). There are, however, two kinds of experimental results which offer reasonably good evidence for process *4*.

(*a*) The camphenehydro cation **11** rearrangement to give **8** also yields as a side reaction the cyclohexenyl cation **12** (the ratio of **8** (+WM shift isomer) to **12** is about 62:38) (6, 19). That



the simultaneous formation of both these ions may be indicative of the intermediacy of the 2-bicyclo[3.1.1]heptyl cation formed in process *4* is shown by protonation reactions carried out in this study on α- and β-pinene **13** and **14**. Addition of these to FSO_3H at −50 °C or 1:4

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

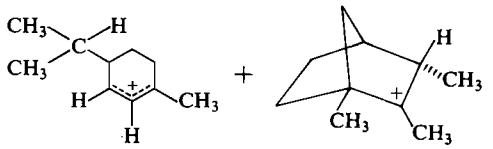
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

FSO_3H–SO_2ClF at −120 °C and then warming to −50 °C yields the same two cations **8** and **12**, although the ratio favors the cycloallyl cation **12** (eq. 5).

[5] 
13 **14**

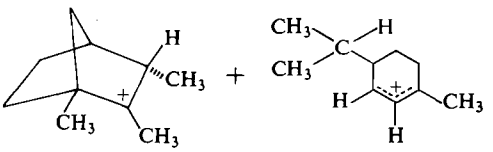


12 **8** (+WM shift isomer)

The actual ratio is somewhat difficult to determine since there is considerable polymer formation but it is about 3:1 favoring **12**. There is often some difference in the partitioning behavior of a steady-state intermediate and the partition which occurs when one attempts to directly prepare the intermediate (see refs. 8 and 23 for some previously discussed examples of this).

(*b*) The addition of α-fenchyl tosylate **15** (*endo* leaving group) to fluorosulfonic acid at −80 °C yields the same two cations **8** and **12** (eq. 6), in about the same proportions as are produced from the camphenehydro cation rearrangement.

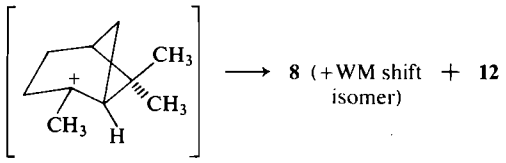
[6] 
15



8 (+WM shift isomer) **12**

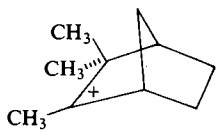
What makes this result odd is that **12** is not a normal product of the tertiary α-fenchenehydro cation **7** rearrangement sequence (which one might have expected from **15** via a WM shift) and mechanistically its formation is difficult to rationalize *unless* there is bond migration (eq. 7) in the solvolysis, to yield the 2-bicyclo[3.1.1.]-heptyl cation intermediate, which then partitions as previously noted. This same problem arises in

[7] 
15



rationalizing the approximately 50% of ring-opened products produced in the deamination of α-fenchylamine (24). However this interpretation of the solvolysis of **15** is negated somewhat by the observation that borneol tosylate **16** in FSO_3H–SO_2ClF at −80 °C does not yield detectable amounts (< 10%) of **8** or **12**, which would be expected if a similar 7,1–7,2 bond migration had occurred. The sole product is the WM shift species, the camphenehydro cation **11** (eq. 8).

[8] 
16



11

The deamination of bornylamine does yield ring-opened products (24); however, the percentage of these is somewhat less than in the fenchyl case, just the opposite of what might have been expected, so it may still mean that the fenchyl system for some reason is directly yielding the 2-bicyclo[3.1.1]heptyl cation system, while the bornyl is not.

On balance, we feel that there is some evidence that the 2-bicyclo[3.1.1]heptyl system is an intermediate in some observable 2-norbornyl cation rearrangements.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Considering the rearrangement *4* subcategories (Scheme 1), one finds that if C1 and C2 are substituted by identical groups, *i.e.* H or CH_3, then a rearrangement *1* process accomplishes the same permutation as a rearrangement *4* process, except that the former interchanges the C1 and C2 carbons and attached substituent while the latter does not. Since none of our labelling can distinguish such differences we can forget about these categories, the $\Delta G^{\ddagger}$ value for process *1* being much lower than that expected for process *4*.

Rearrangements 4TT and 4SS

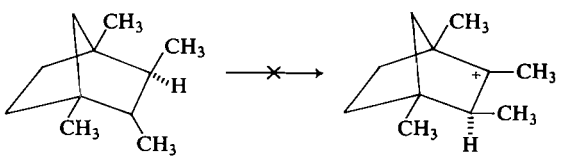
The sequences 4TT and 1TS,4SS,1ST accomplish the same permutations (7) and cannot be distinguished. The experimental barrier for the camphenehydro cation **11** giving **8** and the ring-opened cyclohexenyl cation **12** is 17.5 kcal/mol. As explained previously, one can rationalize the formation of both products on the assumption of common bicyclo[3.1.1]heptyl cation intermediate but the evidence certainly does not require this mechanism. Tentatively, we assign a barrier $\geq$ 18 kcal/mol for either 4TT or 1TS, 4SS,1ST, whichever is less. In other words, if the actual barrier is 4TT, then the 18 kcal/mol is directly appropriate. If the 1TS,4SS,1ST sequence is lower, then the 4SS barrier would be assigned as $\geq 18 - 5.5 = \geq 12.5$ kcal/mol.

Rearrangement 5HSS

Several results (11, 21) suggest that an *exo*-3,2-hydride shift will be much faster than the *endo* shift. The process 5HSS accomplishes the same overall permutations (unless the C2 and C3 protons are labelled) as the apparently much easier 2HSS process and the former need not be considered further (*i.e.* it would represent a very minor pathway).

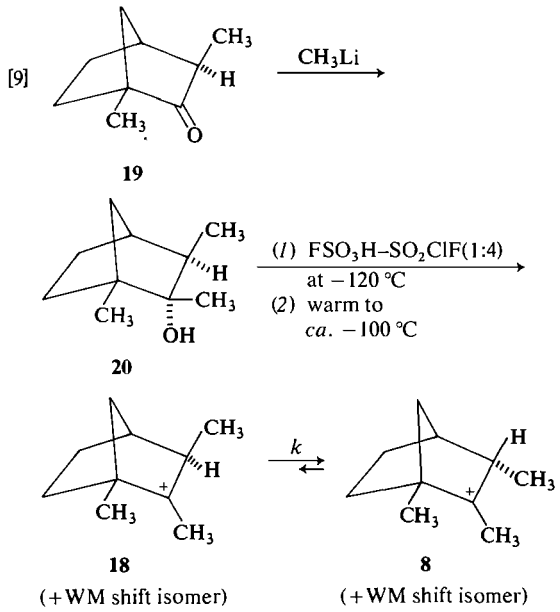
Rearrangement 5HTT

There is no observable n.m.r. line broadening in the 1,2-*exo*-3,4-tetramethyl-2-norbornyl cation (**17**) up to at least -10 °C, such as might have occurred from an *endo*-3,2-hydride shift (11)



17 **17′**

and we can assign a minimum $\Delta G^{\ddagger}$ value of *ca.* 14.2 kcal/mol. The interconversion of the 1,2-*exo*-3-trimethyl-2-norbornyl cation (**18**) prepared by an unambiguous route starting from the known ketone **19** and the alcohol **20** and the 1,2-*endo*-3-trimethyl-2-norbornyl cation (**8**) (eq. 9), for which $k = 3.0 \pm 0.5 \times 10^{-4}\ s^{-1}$ at -90 °C, $\Delta G^{\ddagger} = 13.6$ kcal/mol, can be most expeditiously



explained using an *endo*-3,2-hydride shift, a five-step sequence involving 5HTT,1TS,3SS,1ST, 2HTT. However, there are other ways that this transformation could have occurred, for example, using only the first three processes; this requires a minimum of eight steps for the lowest calculated 15.2 kcal/mol (2HST) barrier, perilously close to the observed 13.6 kcal/mol barrier. Tentatively, a $\Delta G^{\ddagger}$ value of $\leq$ 14.0 kcal/mol is assigned for 5HTT.

Rearrangements 5HTS and 5HST

Starting from a tertiary cation energy base, the 2HTS(2HST) process requires 15.2 kcal/mol. If one looks at the minimum $\Delta\Delta G^{\ddagger}$ difference between 2HTT and 5HTT, *i.e. ca.* 7 kcal/mol, and applies this difference to the 5HTS and 5HST processes, one obtains barriers in excess of 20 kcal/mol. Since these processes are never *required* in any of the overall transformations, the molecules ($\gg$99%) will always find easier routes.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Rearrangement 5MTT

The rearrangement has been observed in a hexamethyl-2-norbornyl cation system (12), $\Delta G^{\ddagger} = 19.5$ kcal/mol. Since a 2MTT process, $\Delta G^{\ddagger} = 8.9$ kcal/mol, accomplishes the same permutation of groups, unless the methyls at C2 and C3 are labelled, one need not consider 5MTT any further.

Rearrangements 5MSS, 5MST, and 5MTS

If one adds the same $\Delta\Delta G^{\ddagger}$ difference observed between 2MTT and 5MTT to the 2MSS, 2MST, and 2MTS values derived previously, one arrives at $\Delta G^{\ddagger} > 20$ kcal/mol (from a tertiary cation energy base) for the title processes. Since these processes are not *required* for any of the overall transformations they could only represent very minor pathways.

Of all the *endo*-3,2-substituent shift processes, only 5HTT appears to have a reasonable chance of being important.

Concluding Discussion

The $\Delta G^{\ddagger}$ values obtained for each of the rearrangements *1–5* represent the "best" values which can be derived from the limited number of "base" measurements investigated to date. The most unsatisfactory situation concerns the 2MSS step. The problems created by this uncertainty are readily apparent when we come to test the predictive power of the parameters (following paper). The uncertainty with process *4* is not as serious since we have some confidence that the barrier for this is quite high and sequences not requiring process *4* can usually be found.

Experimental

Carbocations and protonated alcohol solutions were prepared and referenced using previously described procedures (11, 25). Nuclear magnetic resonance spectra were obtained on a Varian Associates HA-100 equipped with a variable temperature probe. Probe temperatures were monitored by placing a thermocouple directly into the spinning n.m.r. tube. Preparative g.l.c. separations were performed using either (*A*) a 12 ft. × 3/8 in. column of 30% Carbowax 20M on Chromosorb 60–80 or (*B*) a 10 ft. × 3/8 in. column of 20% SE-30 on Chromosorb 60–80.

1,2,4-Trimethyl-2-norbornyl Cation **2**

The ^{1}H n.m.r. chemical shifts for this cation have been reported in a communication (1). The cation was obtained by protonating α-fenchene, prepared from α-fenchyl tosylate and g.l.c. separation (column *A*, 90 °C) from small amounts of ζ-fenchene and cyclofenchene (26); from β-fenchene, prepared by g.l.c. separation (column *A*) of the complex mixture obtained by dehydrating α-fenchol with solid potassium bisulfate (27) (α- and β-fenchene are the highest retention products and are only poorly resolved but by cutting the front part of this combined "peak" pure β-fenchene can be obtained); from cyclofenchene or from α-fenchol itself, obtained by lithium aluminum hydride reduction of fenchone (28). In the α- and β-, and cyclofenchene cases, one initially obtains at −120 °C a mixture of the tertiary α- and β-fenchenehydro cations, the chemical shifts of these have been reported in the communication (1). On warming the solutions one obtains first a 1,2,3-trimethyl-2-norbornyl cation system and finally at around −15 °C, cation **2**. In the case of α-fenchol, one initially obtains in FSO_3H the protonated alcohol, characterized by ^{1}H n.m.r. peaks at τ 8.67, 8.78, and 8.87 (3H each, the methyl groups) and 5.36  . At −18 °C, this solvolyzes within 0.5 h to yield a mixture of the 1,2,3-trimethyl species and **2**. After 0.5 h at 0 °C, only **2** is left.

On cooling a solution of **2** in 4:1 SO_2ClF–FSO_3H down to −120 °C, there is no evidence that the degenerate WM shift is being slowed down enough to see ^{1}H n.m.r. line broadening.

Structure Proof of **2**. *Isolation of Two New Fenchenes*

The structure of cation **2** is reasonably assigned from the n.m.r. spectrum but is confirmed from quenching experiments. Solutions of **2** were prepared at −80 °C using 10% w/v of α-fenchol in FSO_3H and letting the solution stand 0.5 h at 0 °C. This acid solution was then added dropwise to an ice-cold, well stirred, aqueous sodium hydroxide solution containing a small upper ether layer. The aqueous solution was extracted twice with ether and the ether dried over anhydrous potassium carbonate. The organic residue showed two "peaks" on g.l.c. analysis (column *B*): a large shorter retention peak and a more diffuse higher retention one, about 3:1 area ratio. Both were collected in quantity. Rechromatography on column *A* of the first fraction yielded three well-separated peaks. The lowest retention product was very small and not further investigated. The highest retention product was a liquid with *m/e* 136. The n.m.r. spectrum (CCl_4) showed peaks at τ 8.82 and 8.85 (3H each, methyl groups at C1 and C4), 7.94 (broad, 2H, C3 protons), 5.42 and 5.54 (1H each, t, $J = 2$, the C2 *exo*-methylene protons). This allows one to assign the structure as 1,4-dimethyl-2-methylenebicyclo[2.2.1]heptane **4**, which can also be labelled η-fenchene. The structure is further confirmed by ozonolysis of **4**, whereby the pure ketone, 1,4-dimethylbicyclo[2.2.1]heptan-2-one, was obtained by preparative g.l.c. separation (column *B*); i.r. 1750 cm^{-1}, C=O; n.m.r. (CCl_4), τ 8.74 and 8.90 (3H each, the C1 and C4 methyl groups), 8.10 (broad, 2H, the C3 protons); 2,4-DNPH derivative, m.p. 128–130 °C (lit. (29) m.p. 129–129.5 °C). Readdition of **4** to FSO_3H at −80 °C yields the cation **2**. The middle retention product was also a liquid, *m/e* 136; n.m.r. (CCl_4), τ 8.76 and 8.79 (3H each, C1 and C4 methyl groups), 8.41 (d, $J = 1.5$, 3H, C2 methyl group), 4.71 (broad, 1H, the alkene proton at C3). The m.s. fragmentation shows a large even ion at *m/e* 108 (−28 for

For personal use only.

the reverse Diels–Alder product ethylene). These data allow one to assign the structure as 1,2,4-trimethylbicyclo-[2.2.1]hept-2-ene (**3**) which can also be labelled θ-fenchene. Readdition of **3** to FSO_3H at −80 °C gives **2**. The ratio of **4**/**3** is about 4:1. In theory, there should be no more alkenes produced from **2** but rechromatography of the second column *B* peak on column *A* yields a complex series of peaks. The largest is the highest retention peak which was collected, a liquid, *m/e* 136. From the n.m.r. spectrum (CCl_4), the compound is not pure but has major peaks at τ 9.17 (d, J = 6.75), 8.91 and 8.96, 5.34 and 5.57. Readdition of this alkene to 4:1 SO_2ClF–FSO_3H at *ca.* −120 °C yields **2** and in part a cation assigned as 2,4-*anti*-7-trimethyl-2-norbornyl cation; n.m.r. τ 5.37 (d, J = 5.5, C1 proton), 6.78 (C2 methyl), 8.59 (C4 methyl), and 8.86 (possibly an unresolved doublet, *anti*-C7 methyl). This rearranges to **2** at very low temperatures and was not further investigated. The alkene can be assigned as 4-*anti*-7-dimethyl-2-methylenebicyclo[2.2.1]heptane (**5**).

2-Methyl-2-norbornyl Cation **6**. *Degenerate Rearrangements*

Cation **6** was prepared in a number of solvent systems, FSO_3H, FSO_3H–SO_2ClF (1:4), SbF_5–SO_2, FSO_3H–SbF_5 and the rearrangement rates do not vary to any measurable extent. The cation was prepared in *ca.* 5% w/v concentration either from the tertiary alcohol, *exo*-2-methylnorbornan-2-ol or the tertiary chloride, *endo*-2-methyl-2-chloronorbornane. The 2-CD_3 alcohol was used in some cases and was prepared from norbornanone and CD_3MgI. The chemical shifts of **6** have been reported by Olah *et al.* (20) but their assignment should be corrected. Our results show that the C6-*endo* and a C5 proton assignment should be interchanged. Cation **6** undergoes two degenerate rearrangements. The rate of the faster process was obtained by matching computed spectra of the H1 proton doublet (AX) with calculated spectra assuming various exchange rates with the H6-*endo* proton (simulated as a broad singlet of half-width 24 Hz). The experimental coalesced H1–H6-*endo* proton peak appears very close to the C2 methyl peak but could be observed using the 2-CD_3 cation. No peak matchings were attempted at or beyond coalescence because the H6-*exo* and H3 protons interfere to some extent and also the very approximate line shape assigned to H6-*endo* will be a factor in the coalesced peak line shapes (but will not affect the more exact matchings done only on the C1 proton doublet prior to coalescence). The second degenerate rearrangement occurs at temperatures above 0 °C (in FSO_3H–SbF_5 (1:2)) and can be assigned to the process given in Scheme 2. The kinetic matrix used is shown in Fig. 4. Monstrous problems arise in treating this line broadening since all 10 protons are coupled in an interwoven manner, some involving second-order effects. Programs to handle such large exchanges are impossibly expensive even if one could determine all of the unknown coupling constants. The approximations used in the calculations consist in treating all protons (except C2) as uncoupled singlets, using various line widths to mimic coupling to some extent. The values used were as follows: H1, doublet, J = 7, line-width 5 Hz; *exo*-H3, 12; *endo*-H3, 12; H4, 7.5; *exo*-H5, 15; *endo*-H5, 10; *exo*-H6, 19; *endo*-H6, 24; *anti*-H7, 7; *syn*-H7, 7. In spite of these severe approximations, we expect that spectra in the intermediate exchange region should be relatively good since the exchanging protons are separated by large chemical shifts and consequently the peaks are very broad (see Fig. 3) in this region (and relatively unaffected by the exact line shape of the "frozen out" peaks.

Interconversion of the α- *and* β-*Fenchenehydro Cations*

On adding α-, β-, or cyclofenchene to FSO_3H–SO_2ClF (1:4) at *ca.* −120 °C, one obtains only the equilibrium mixture of the α- and β-cations, K being near unity. On warming very rapidly (there is also an irreversible transformation occurring rapidly as one warms the solution, next sextion) to −78 °C, the interconversion becomes rapid enough so that the DISST technique of Forsén and Hoffman (22) can be used to estimate the interconversion rate. Irradiation of the combined *endo*-H6 region (*ca.* τ 8.6) results in a 50% decrease in the combined H1 proton region. Assuming T_1 = 2 s (30), this gives an order of magnitude rate constant, k = 1 s^{-1}, $\Delta G^{\ddagger}$ = *ca.* 11.2 kcal/mol. For confirmation, this technique was also applied to the degenerate rearrangements observed for cation **6**, where both line broadening and the DISST technique can be used. For the faster of the two degenerate rearrangements in **6**, the DISST technique gives k = 1 s^{-1} at −87.0 °C, compared to the extrapolated estimate of 0.85 s^{-1} from the log k *vs.* $1/T$ plot using line-broadening data. The DISST technique was also used to confirm qualitatively the exchanges suggested for the slower degenerate rearrangement in **6**.

α- *and* β-*Fenchenehydro Cations* → *1,2-endo-3-Trimethyl-2-norbornyl Cation* **8** *(+ WM Shift Isomer)*

This rate was followed by determining the height of the growing C1 and C2 methyl peaks of **8** (+ WM shift isomer) as a function of time using a standard first-order plot. At −92 °C, $k = 5.1 \pm 0.2 \times 10^{-4}$ s^{-1}, $\Delta G^{\ddagger}$ = 13.1 kcal/mol (average of two runs).

Structure Proof of Cation **8** *(+ WM Shift Isomer)*

The ketone 1-*endo*-3-dimethylbicyclo[2.2.1]heptan-2-one (**9**), was prepared by first alkylating 1-methylbicyclo-[2.2.1]heptan-2-one using trityl sodium and methyl iodide (31). The product is mainly the *exo*-3-methyl compound **19** (g.l.c.) with traces of **9** and some starting material. Equilibration in refluxing $NaOCH_3$–CH_3OH gives an equilibrium mixture now slightly richer in **9** (*ca.* 55%) and this was isolated by preparative g.l.c. (column *A*, 155 °C). The ketone has been reported (31). Treating 0.210 g (1.52 mmol) of **9** in ether with excess methyl lithium in ether at 0 °C yields, after work-up, an oil, 0.236 g, which solidifies in the freezer; i.r., no C=O, 3420 cm^{-1} (b), OH; n.m.r. (CCl_4), τ 8.97, 9.03, 9.20 (d, J = 7 Hz, all 3H, the three methyl groups of **10**). Judging from the lack of doubling of n.m.r. peaks, the product is likely to be mainly the *exo*-2-methyl isomer. Addition of the alcohol **10** to FSO_3H–SO_2ClF (1:4) at −120 °C and warming to −100 °C gives **8** (+ WM shift isomer). The chemical shifts for **8** (+ WM isomer) have been reported previously (1). Some of these are temperature dependent, as expected (14). Solutions of **8** can be quenched (−20 °C), as for **2**, and pure 1,2,3-trimethylbicyclo[2.2.1]hept-2-ene (ε-fenchene) can be isolated by preparative g.l.c. (column *A*). There are also produced in this quenching a number of other alkenes with an exocyclic methylene group, probably corresponding in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

part to elimination at the C2 methyl in **8** and also from the C2 methyl of the WM shift isomer. However, there are more products than this will account for. Cation **8** (+ WM shift isomer) is produced on adding ε-fenchene to FSO_3H–SO_2ClF (1:4) at *ca.* −120 °C.

1,2-endo-3-Trimethyl-2-norbornyl Cation 8 → 1,2,4-Trimethyl-2-norbornyl Cation 2

The rate of this reaction was measured by following the increase in the C4 methyl peak height of **2** as a function of time. The reaction was run at −15.0 °C in a cryostat and samples were periodically quenched at −78 °C and the n.m.r. spectrum determined at −50 °C. Nitromethane was used to obtain a constant reference peak height, $k = 1.1 \pm 0.2 \times 10^{-4}\ s^{-1}$, $\Delta G^{\ddagger} = 18.5$ kcal/mol (average of two determinations).

Protonation of α- and β-Pinene

α-Pinene or β-pinene was dissolved in an equal volume of $CDCl_3$ and added slowly to either pure FSO_3H with stirring at −50 °C in a 5 ml round-bottom flask or directly to an n.m.r. tube containing a 1:4 mixture of FSO_3H–SO_2ClF at *ca.* −120 °C. The spectra were reasonably clean and could be analyzed at low temperatures but on warming, broad featureless n.m.r. peaks characteristic of polymers appeared. Both products **8** and **12** are stable at these temperatures so the reason for the polymerization is not known.

α-Fenchyl Tosylate and Borneol Tosylate

These compounds were prepared by standard procedures and are both known (32).

1,2-exo-3-Trimethyl-2-norbornyl Cation 18 → 1,2-endo-3-Trimethyl-2-norbornyl Cation 8

Cation **18** (+ WM shift isomer) was prepared from the corresponding tertiary alcohol **20**. The preparation of **20** follows that of **10**, except that the 1-*exo*-3-dimethyl ketone **19**, needed in this case, had to be isolated by a double preparative g.l.c. collection of the initial alkylation mixture referred to in the preparation of **10**. On column *A*, the ketone **19** and the starting material can be separated as a single peak from the 1-*endo*-3-dimethyl ketone **9**. Reinjection on column *B* separates the starting ketone and **19**. Methylation (0.209 g, 1.51 mmol) with excess methyl lithium, as previously, yields an oily tertiary alcohol (0.226 g); i.r., no C=O, 3430 cm^{-1}, OH. The n.m.r. spectrum (CCl_4) indicates a mixture of the *exo*-2 and *endo*-2 methyl alcohols, peaks at τ 8.94, 9.00, 9.06, and 9.14 (d, $J = 7$ Hz). The 8.94 and 9.06 peaks add up to approximately 3H and presumably are the *exo*-2 and *endo*-2 methyl groups, the C1 and C3 methyls overlapping in both isomers. Both isomers yield the same cation so the stereochemistry at C2 is unimportant for our purposes. Addition of **20** to FSO_3H–SO_2ClF (1:4) at *ca.* −120 °C and then warming to −100 °C yields **18** (+ WM shift isomer). The chemical shifts for this rapidly equilibrating pair have been reported (1) and as expected (14), the C1 and C2 methyl shifts are temperature dependent. The interconversion rate was followed by determining the increase of the standardized C1 and C2 methyl peak heights of **8** (+ WM shift isomer) as a function of time. Reversible first-order kinetics were used since a small amount of **18** (+ WM shift isomer) exists at equilibrium, **8**/**18** = 6.3 ± 0.3, $k_{18\rightarrow 8} = 3.0 \pm 0.5 \times 10^{-4}\ s^{-1}$ at −90 °C, $\Delta G^{\ddagger} =$ 13.6 kcal/mol (average of three runs).

The authors wish to thank the National Research Council of Canada for generous financial support.

A Kinetic and Thermodynamic Behavioral Comparison of Observable Secondary and Tertiary 2-Norbornyl Cations

R. HASELTINE, N. WONG, AND T. S. SORENSEN
Department of Chemistry, University of Calgary, Calgary, Alberta T2N 1N4
AND
A. J. JONES
Department of Chemistry, University of Alberta, Edmonton, Alberta
Received October 31, 1974

R. HASELTINE, N. WONG, T. S. SORENSEN, and A. J. JONES. Can. J. Chem. **53**, 1891 (1975).

By analyzing various rearrangement processes, one can deduce the relative stabilities of the following 2-norbornyl cations (kcal/mol): 1,2-dimethyl, 0; 2-methyl, 1; 1-methyl, 6.5; and the parent 2-norbornyl, 8.5. Secondary 2-norbornyl cations have been assigned a "carbonium ion" structure and tertiary a "carbenium ion" structure. Using suitable model systems, an absolute rate comparison has been made of all three common rearrangement processes in the tertiary systems ("carbenium") with those already measured for the 2-norbornyl cation ("carbonium"). The activation free energies, $\Delta G^{\ddagger}$, (in kcal/mol) were: Wagner–Meerwein (WM) shift: tertiary, <4; secondary, <4; *endo*-6,2-hydride shift: tertiary, 7.2; secondary, 5.8; *exo*-3,2-hydride shift: tertiary, 6.6; secondary, 11.4. A discussion of the structure of tertiary and secondary 2-norbornyl cations emphasizes the following points: (*i*) a rationalization of the rapid *endo*-6,2-hydride shift observed in norbornyl cations does *not* necessitate a protonated nortricyclene ("carbonium ion") postulate; (*ii*) on the basis of the results for acyclic cations and the 1,2-dimethyl-2-norbornyl cation, one would *not* expect to "freeze out" the WM shift in an equilibrating 2-norbornyl cation structure; (*iii*) the formation of nortricyclenes may be related to a partial C6—C2 bond in the ions; and (*iv*) the structure of the observable secondary 2-norbornyl cation probably involves partial C6—C2 bonding but, in our opinion, this does not require a symmetrical static formulation.

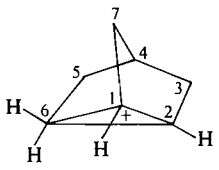
R. HASELTINE, N. WONG, T. S. SORENSEN et A. J. JONES. Can. J. Chem. **53**, 1891 (1975).

En faisant l'analyse des divers processus de réarrangements, on peut déduire les stabilités relatives des cations norbornyl-2 suivants (kcal/mol): diméthyl-1,2, 0; méthyl-2, 1; méthyl-1, 6.5; et le norbornyl-2 non-substitué, 8.5. On a attribué au cation norbornyl-2 secondaire une structure de "carbocation" et au cation tertiaire une structure d'"ion carbènium". Faisant appel à des systèmes modèles appropriés, on a fait une comparaison entre les vitesses absolues des trois processus de réarrangement commun dans les systèmes tertiaires ("carbènium") avec celles qui ont déjà été mesurées pour le cation norbornyl-2 ("carbocation"). Les énergies libres d'activation $\Delta G^{\ddagger}$ (en kcal/mol) sont: réarrangements de Wagner–Meerwein (WM): tertiaire, <4; secondaire, <4; déplacement d'hydrure 6,2-*endo*: tertiaire, 7.2; secondaire, 5.8; déplacement d'hydrure 3,2-*exo*: tertiaire, 6.6; secondaire, 11.4. Une discussion de la structure des cations norbornyl-2 tertiaires et secondaires met en évidence les points suivants: (*i*) une rationalisation du réarrangement rapide d'hydrure 6,2-*endo* observé dans les cations norbornyles n'implique pas nécessairement que l'on doive postuler l'existence d'un nortricyclène protoné ("carbocation"); (*ii*) sur la base des résultats obtenus avec des cations acycliques et ceux obtenus avec le cation diméthyl-1,2 norbornyl-2, on ne devrait pas espérer éliminer ("freeze-out") le réarrangement de WM dans la structure du cation norbornyl-2 en équilibre; (*iii*) la formation de nortricyclènes peut être reliée à la présence de lien partiel C2—C6 dans les ions; et (*iv*) la structure du cation norbornyl-2 secondaire qui peut être observée implique probablement un lien partiel C2—C6; toutefois on ne croit pas que ceci requiert une formulation statique symétrique. [Traduit par le journal]

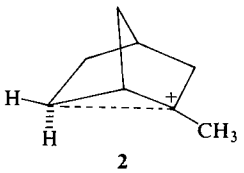
Introduction

The postulate of a symmetrical 2-norbornyl cation **1** is mainly due to Winstein (1). Following this, Saunders *et al.* (2) first reported the observable 2-norbornyl cation. This has now been studied by ^{1}H and ^{13}C n.m.r. (3, 4), Raman spectroscopy (3), and e.s.c.a. (4, 5) and these results have also been interpreted in terms of the symmetrical static structure.

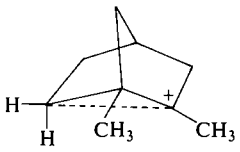
The tertiary analogs **2** and **3** are very generally regarded as having an unsymmetrical structure (5, 6). Olah has recently suggested that carboca-



1



2



3

tions be divided into "carbonium" and "carbenium" ions (7). Accordingly, the norbornyl cation **1**, specifically the C6 carbon, becomes a member of the CH_5^+ symmetrical pentacoordinate "carbonium" ion group and **2** and **3**, while regarded as having some C6—C2 bonding, are basically trivalent "carbenium" ions.

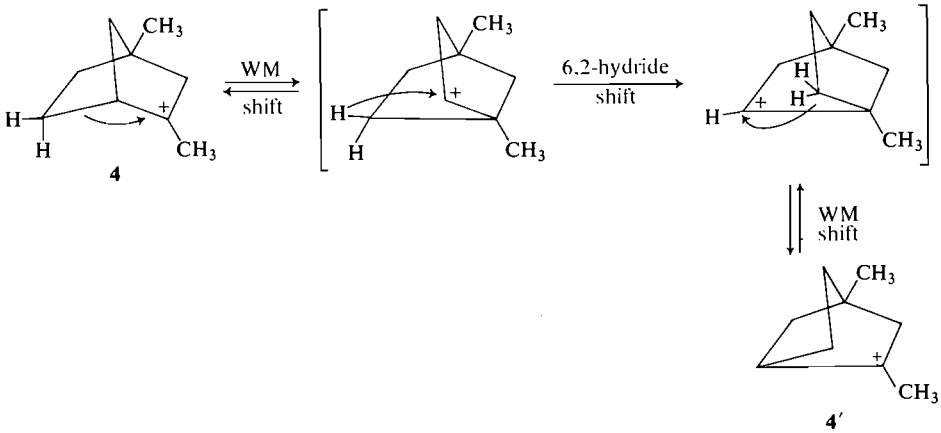
From a study of both the degenerate and irreversible rearrangements which occur in various dimethyl-2-norbornyl cations, it is now possible (this work) to estimate with some assurance the actual energy difference between **1** and **2** or **3**. It is also possible to compare the rates of the three most characteristic rearrangement processes of norbornyl cations: (*a*) the Wagner–Meerwein (WM) shift, (*b*) the *endo*-6,2-hydride shift, and (*c*) the *exo*-3,2-hydride shift, using in the case of the tertiary ions, model systems in which each of these processes (as in **1**) is degenerate. It is then of interest to see how the structural differences, **1** *vs.* **2** or **3**, affect the rates observed for each of these rearrangements.

Results and Discussion

An Estimate of the Energy Difference Between a Secondary Norbornyl Cation with a C1 Methyl vs. a C1 Hydrogen

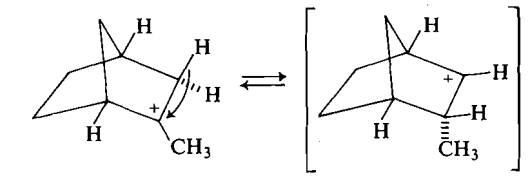
Let us start by deriving an estimate of the energy difference between a 1,2-di **H** (secondary) and a 1,2-di CH_3 (tertiary) norbornyl cation. A value of 5.5 kcal/mol has been previously derived (8) for the secondary–tertiary (methyl) energy difference using the activation energy for a degenerate rearrangement occurring in **2**. The 2,4-dimethyl-2-norbornyl cation **4**, likewise undergoes this same degenerate rearrangement[1] (eq. 1) and on analysis of this (see Experimental), one obtains the nearly identical value of 5.3 kcal/mol.

[1]

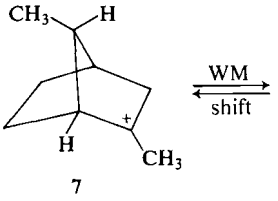


This energy difference is really the difference between a tertiary ion and a secondary ion with a C1 methyl group. The more fundamental comparison which one wants is between an ion with both C1 and C2 substituted by hydrogen, *i.e.* **1**, and a tertiary species, *i.e.* **2** or **3**. That a C1 methyl probably does increase the stability of the secondary cation was alluded to previously (9) and can be demonstrated in several ways. The following arguments are illustrative rather than comprehensive: (*a*) The activation energy barrier separating the secondary and tertiary

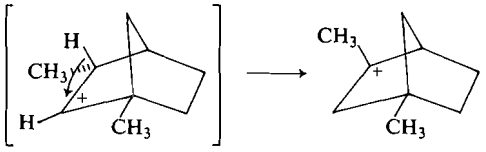
[1]A second degenerate process can also be observed which interconverts the two methyl groups but there are at least three reasonable mechanisms for this.



2 6



7



8 4

cations **2** and **6** is *ca.* 15.2 kcal/mol (8) (13.9 and 15.0 in two other structurally related cases) (9). This same barrier in the rearrangement of **7** to **4**, where one has a C1 methyl intermediate is experimentally only 12.1 kcal/mol (9). This suggests either that the C1 methyl cation **8** starts off *ca.* 2–3 kcal/mol lower in energy (than **6**) or that the activation barrier for a 3,2-hydride shift changes. We prefer the former explanation, shown schematically in Fig. 1. (*b*) The activation barrier for a 3,2-hydride shift from one secondary center to another (abbreviated previously as 2HSS) is about 11.4 kcal/mol

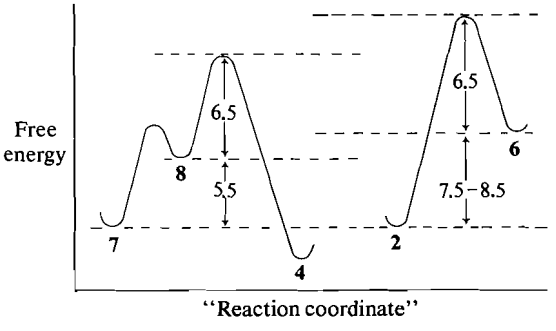


FIG. 1. Reaction coordinate diagram showing the postulated extra stability associated with cation **8** *vs.* **6**, assuming the *exo*-3,2-hydride shift barrier in both cases is 6.5 kcal/mol.

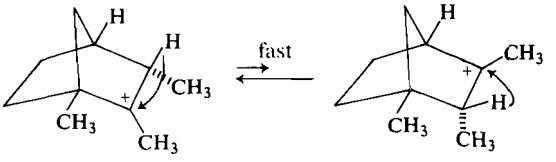
in the norbornyl cation (3). Starting from a tertiary ion, the overall barrier should be 11.4 + 5.5 = 16.9 kcal/mol. However, in the rearrangement of the 2,4-dimethyl-2-norbornyl cation **4** to the 1,2-dimethyl isomer **3**, the experimental barrier is 18.9 kcal/mol. Regardless of the actual mechanism (9), there exists a 10-step mechanism for this conversion for which one predicts, using the above value, a *ca.* 17.2 kcal/mol barrier for two rate-determining 2HSS steps. However, one of these steps involves the shift shown in eq. 2, *i.e.* a shift starting from a secondary ion having no C1 or C4 methyl group. If this were $\geq$ 2 kcal/mol less stable than a C1 methyl secondary ion, one obtains $\Delta G^{\ddagger} \geq 2 + 5.5 + 11.4 \geq 18.9$ kcal/mol, a value more in line with experiment. A barrier of this size would also be more consistent with results obtained for several other rearrangements (10).

[2] **4** —five steps→  —2HSS step→

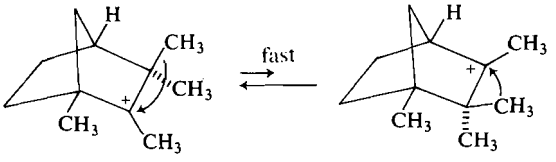
 —four steps→ **3**

The Stabilizing Influence of a C1 Methyl on Tertiary 2-Norbornyl Cations

This can be quantitatively evaluated in several ways. The most direct observation is simply that all of the dimethyl-2-norbornyl cations eventually yield the 1,2-dimethyl analog **3**. Probably the best comparison here is between the 2,4-dimethyl isomer **4** and **3**. Experimentally **3** is 1.5 kcal/mol more stable (at 25 °C) than **4** (9). Cation **3** is at least 2 kcal/mol more stable than any of the others (9) but steric interactions may play a role in this. Another approach is to look at cations such as **9** and **10**. The equilibrium here (at −80 °C for example) lies most definitely ($\Delta G \geq 1$ kcal/mol) on the side of **9** and **10**, *i.e.* the isomers with the C1 methyl (10, 11).



9



10

Overall Energy Comparison

From the foregoing, one can assign the following approximate relative energies (ΔG in kcal/mol). (In giving an energy difference for nonisomeric species one assumes, perhaps unwisely, that the extra methyl groups in "nonactive" positions are "normal" C—C and C—H bond free energies.)

The norbornyl cation energy differences are to be compared to the calculated 11–15 kcal/mol difference between the tertiary and secondary amyl cations (12). Several other estimates of the secondary–tertiary norbornyl cation energy difference have been made (4, 10, 13).

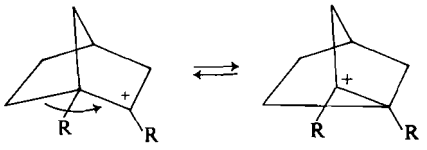
Kinetic Aspects

The WM Shift: Secondary vs. Tertiary (Methyl)

This degenerate process does not occur if the structure is symmetrical and static. However,



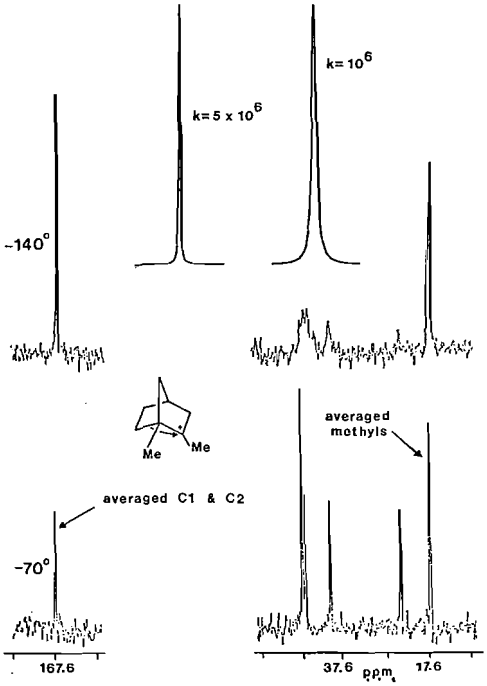


FIG. 2. ^{13}C n.m.r. spectrum of the 1,2-dimethyl-2-norbornyl cation at -70 and -140 °C in SbF_5–SO_2ClF–SO_2F_2. The feature of interest is the averaged C1 and C2 carbon signal which still remains very sharp at -140 °C. The two curves inset at the top are calculated spectra for this peak assuming the exchange rate constants shown. Both are still broader than the natural line width used in the calculations.

one can in any case put a lower limit, $\Delta G^{\ddagger} < 4$ kcal/mol, on such a hypothetical process in the secondary ion (R = H), using the recently published (4) ^{13}C n.m.r. spectrum of the 2-norbornyl cation.

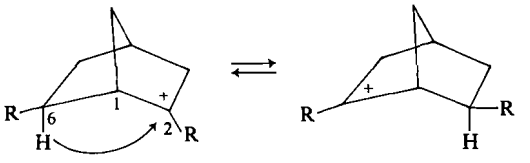
The ^{13}C n.m.r. spectrum of the tertiary equivalent, the 1,2-dimethyl cation **3** (R = CH_3), measured at -70 and -140 °C, is shown in Fig. 2. Olah and Liang have previously reported ^{13}C chemical shifts for this cation at -90 °C (14). As one goes down in temperature to -140 °C, a progressive weakening of all signals, except the coalesced methyl carbons and the coalesced C1 and C2 carbons, was observed. This apparent variability in T_1 relaxation times could be related to the WM shift and is being investigated further[2] but in any case, the existence of a sharp coalesced C1, C2 signal implies a rate constant at -140 °C of $k > 10^6\ s^{-1}$,

[2]A. J. Jones, private communication.

$\Delta G^{\ddagger} < 4$ kcal/mol. Several computed spectra assuming certain exchange rates are shown in Fig. 2 for the C1,C2 carbons of **3**, using a chemical shift separation of 4000 Hz (similar to the separation of these carbons in **2**). A broadening of the magnitude shown for $k = 10^6\ s^{-1}$ would have been detectable.

The endo-6,2-Hydride Shift: Secondary vs. Tertiary (Methyl)

The rate of this process in a secondary cation (R = H) is known, $\Delta G^{\ddagger} = 5.8$ kcal/mol (3).

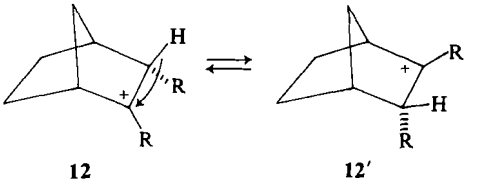


11 **11′**

Having previously prepared the 2-*exo*-6-dimethyl-2-norbornyl cation **11** (R = CH_3) (9), we were able to observe this same process in a tertiary situation. The ^1H n.m.r. spectrum of this ion is shown in Fig. 3, for various temperatures. The line broadening observed is unequivocally assigned to an *endo*-6,2-hydride shift and using the C6 and C2 methyl peaks, the computed spectra, also shown in Fig. 3, were obtained. Matching these in the usual way results in the following activation parameters, $\Delta G^{\ddagger} = 7.2$ kcal/mol at -96 °C, $\Delta H^{\ddagger} = 7.2 \pm 1$ cal/mol, $\Delta S^{\ddagger} = 0 \pm 3$ e.u.

The exo-3,2-Hydride Shift: Secondary vs. Tertiary (Methyl)

The rate for this process in the secondary cation is known, $\Delta G^{\ddagger} = 11.4$ kcal/mol (3). Using the 2-*endo*-3-dimethyl-2-norbornyl cation



12 **12′**

12 (R = CH_3), the same process in a tertiary situation can be directly observed, yielding $\Delta G^{\ddagger} = 6.6$ kcal/mol, $\Delta H^{\ddagger} = 6 \pm 1$ kcal/mol, $\Delta S^{\ddagger} = -4 \pm 7$ e.u. (15).

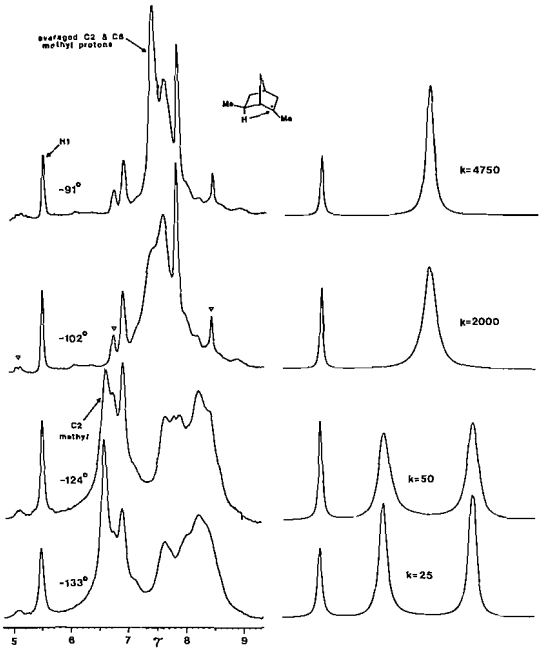


FIG. 3. ^1H n.m.r. spectrum of the 2-*exo*-6-dimethyl-2-norbornyl cation showing experimental and calculated line broadening curves. The signals designated by ▽ are peaks due to the 2,4-dimethyl-2-norbornyl cation.

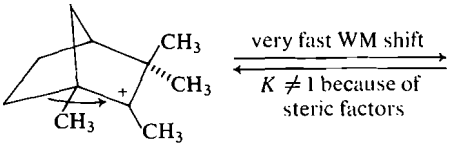
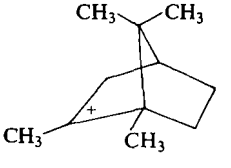
The Question of "Structure" in Tertiary (Methyl) 2-Norbornyl Cations and the Relationship if any Between this and Rearrangement Rates

Tertiary norbornyl cations such as **13** and **14** exhibit typical equilibrium behavior, *i.e.* a

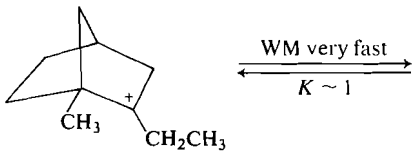


13

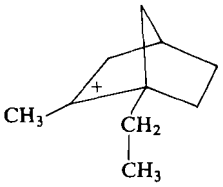


14

temperature dependent equilibrium constant (11). As in the parent 1,2-dimethyl cation **3**, one cannot "freeze out" the WM shift in the n.m.r. spectrum. Attempts to observe this same equilibrium constant behavior using the 1-ethyl-2-methyl **15** ⇄ 1-methyl-2-ethyl **16** system (this



15



16

work) were not very successful since K was very close to 1 (see Experimental for chemical shift details).

Even though the 1,2-dimethyl parent system **3** is also very probably an equilibrating pair of enantiomeric cations, this is no reason, of course, to disregard charge delocalization within each enantiomer.

We believe there is evidence, both from thermodynamics and from a comparison of n.m.r. chemical shifts, suggesting *some* bonding interaction between C6 and C2 in the tertiary cations. Olah *et al.* (6) have reached this same conclusion from e.s.c.a. experiments and ^{13}C n.m.r. shift comparisons. The thermodynamics argument is simply that a methyl is preferred at the C1 position in the cations compared to the sterically equivalent C4 position, *i.e.* the 1,2-dimethyl-2-norbornyl cation is more stable than the 2,4-dimethyl isomer. This indicates unusual charge density at C1 since in aliphatic cations there is no particular preference for a methyl *vs.* hydrogen on the carbon alpha to the cation center.

In the ^1H n.m.r. spectra, the *exo*-6-H proton in these cations is very substantially deshielded relative to the *endo*-6-H or the 7-position protons (which are in each case methylene protons at an equivalent σ bond distance from the cation center. We believe this result is reasonably interpreted as evidence that electron density has been removed from the C to *exo*-6-H bond. However, a referee suggests that some polarizing effect of the positive charge could cause this deshielding and he would dispute that there is any evidence for a weakening of this bond.

It may not be clear that either of these observations relates to a C6—C2 bond and in a sense this is true. However, one can rationalize both observations by postulating some weak overlap of the empty p orbital on C2 with the back lobe of an sp^3 orbital on C6 (6). Geometric considerations dictate that this will be the back lobe of the particular sp^3 orbital bonding to the *exo*-6 proton. If the weak bonding does occur, there can be little doubt but what the C to *exo*-6-H bond would be weakened.

The reader is also referred to a recent paper by Wolf and Farnum (16) concerning the onset of "nonclassical" delocalization in norbornyl cations.

The partial bonding from C2 to C6 is in a way similar to hyperconjugative stabilization. Thus, in hyperconjugation, one considers resonance structure contributions related to an alkene plus H^+. Similarly, the C2,C6 partial bond description has a contributing resonance structure related to a nortricyclene + H^+.

One can now ask how the structure of these tertiary (methyl) norbornyl cations is related to the three common norbornyl cation rearrangement processes? In Table 1, we contrast the absolute rearrangement rates for the secondary and tertiary 2-norbornyl cation rearrangements with the rates of analogous tertiary–tertiary processes in simple aliphatic cations (except for a 1,2-hydride shift no suitable secondary model systems are available). In observable aliphatic cations, no evidence exists for partial 1,3-bond bridging (equivalent to C6,C2 bridging in the norbornyl systems). The Table 1 comparisons suggest to us that the rapid *endo*-6,2-hydride shift in **11** is *not particularly related* to the presence of 1,3 (or C6,C2) bridging. A similar point has been made by Saunders (17). There are of course small differences in the activation energies shown in Table 1 for this shift. In a comparison of the tertiary norbornyl system with the aliphatic system, the difference is very reasonably explained on steric grounds, *i.e.* the former is conformationally rigid while in the latter the conformation for the 1,3-hydride transfer may be only one of many. The secondary–tertiary norbornyl difference is also not unreasonable since the charge density on the cation center in the former is larger.

We envisage two completely different roles for the two C6 protons. The *endo*-proton, for steric reasons, becomes the migrating proton but is not involved in charge delocalization via

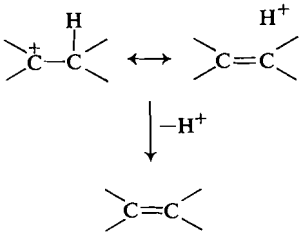
TABLE 1. Activation energies for norbornyl cation rearrangements

Rearrangement process	ΔG^* (kcal/mol) 2-Norbornyl	Tertiary 2-norbornyl	Tertiary aliphatic analog
WM shift or 1,2-dialkyl shift	<4	<4	<3.5*
endo-6,2-Hydride shift or 1,3-hydride shift	5.8	7.2	8.5†
exo-3,2-Hydride shift or 1,2-hydride shift	11.4	6.6	<4‡

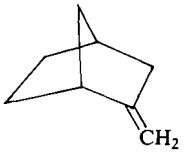
*Data for the 1,2-methyl shift in the 2,3,3-trimethyl-2-butyl cation (footnote 3 and ref. 17).
†Data for the 1,3-hydride shift in the 2,4-dimethyl-2-pentyl cation (18).
‡Data for the 1,2-hydride shift in the 2,3-dimethyl-2-butyl cation (15, 19).

C2,C6 bonding. The *exo*-proton is involved in the delocalization. The stronger the C2,C6 bonding, the weaker the C—*exo*-H-6 bonding. This is predicted to be the proton lost in forming nortricyclenes, *not the migrating proton.* In aliphatic systems where 1,3-bond bridging is unimportant in ground states, one does not normally observe cyclopropane formation although 1,3-hydride shifts readily occur (Table 1).

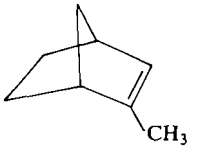
The relationship between the mode of delocalization in a carbocation and product stability of a deprotonated species is an interesting question. The proton lost in deprotonation is normally a proton for which a hyperconjugative resonance hybrid structure can be written, *i.e.*



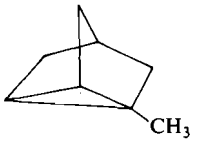
implying of course that some weakening of the bond already exists in the ion and also that some C—C double bond character is present. Assuming the deprotonation transition state occurs early in the C—H bond breaking (the Hammond postulate), then product ratios will reflect the relative ease with which various C—H bonds are broken and by implication which are the weakest. One can sometimes obtain kinetic control of products in cases involving the deprotonation of solvolytically generated carbocations but the more usual case is to obtain products of thermodynamic control under reversible protonation–deprotonation conditions. Even in this case, the observed products often appear to bear a superficial relationship to what one anticipates to be the weakest bond in the cation, *i.e.* a relationship in which breaking the weakest bond generates the thermodynamically most stable hydrocarbon. This results in the suggestion that long-lived carbocations will *tend to delocalize charge in the direction of the most stable deprotonated hydrocarbon.* Tertiary (methyl) norbornyl cations then represent an interesting group since one is assuming both significant σ-hyperconjugation (C6,C2 bonding) and π-hyperconjugation (principally the C3 protons and the C2 methyl protons). Experimentally, on the basis of the above discussion, the π-hyperconjugation is slightly dominant. In the case of 2-methyl and 1,2-dimethyl norbornyl compounds, there is experimental data relating to thermodynamic stabilities and some to kinetic control. The equilibrium percentages in the 2-methyl system have been measured at 250 °C by Maurel *et al.* (20) and are as follows.



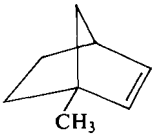
60%



21%



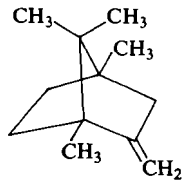
14%



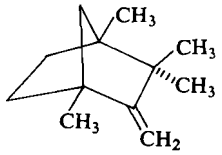
5%

For a more ambient temperature comparison, we have equilibrated (21) a pentamethyl series with the following (25 °C) results.

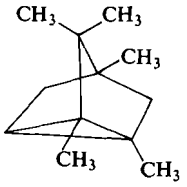
[3]M. Saunders, correspondence with H. C. Brown and circulated by Brown.



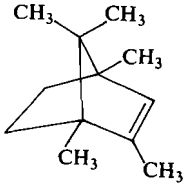
78%



14%



6.5%



1.5%

In equilibrating a single alkene isomer in the pentamethyl series, one observes that the alkenes equilibrate faster than they form the nortricyclene (initial kinetic control).

In the parent 2-norbornyl system, Schleyer (22) has shown that the equilibrium at 105°C favors nortricyclene (77%) over norbornene (23%), whereas in solvolysis (kinetic control), there is a report (23) showing that of the hydrocarbon fraction formed, 97.5% was nortricyclene and only 2.5% norbornene.

We interpret the nortricyclene formation in the tertiary ions (previously shown to be unsymmetrical even in a 1,2-dimethyl case) in terms of this σ-hyperconjugation, *i.e.* as a further piece of evidence to go with the thermodynamic and n.m.r. chemical shift arguments cited as evidence for a weak C6—C2 bond.

Coming back to the comparisons in Table 1, one notes that the tertiary WM shift and the equivalent methyl shift in an aliphatic cation are both too fast to measure. These shifts may eventually be found to be different but on the basis of our *present data*, one cannot conclude that the rapid WM shift in the 1,2-dimethyl-2-norbornyl cation has any relation to the proposed weak C6—C2 bond (nor can one exclude such a possible relationship, although admittedly one would have only 4 kcal/mol of activation energy left to differentiate these with).

Finally, the *exo*-3,2-hydride shift in the tertiary norbornyl system is considerably slower than in aliphatic systems but much faster than in the secondary ion. One anticipates that the rate of a 3,2-hydride shift would be related to the charge density of the carbocation center and on this basis one would have to conclude that the secondary center is the most delocalized, followed by the tertiary norbornyl system. However, the steric requirements for a 1,2- (or 3,2-) hydride shift appear to be extremely important (24) and in fact this factor may be the dominant one in this case. For example, in the tertiary norbornyl system, the activation free energies for the *exo*- and *endo*-3,2-hydride shifts are 6.6 and > 14 kcal/mol. Clearly this difference is unrelated to charge delocalization at the cationic center. It seems likely that the acyclic-tertiary norbornyl difference, <4 *vs.* 6.6, is also due to steric effects.

In summary, we suggest that there is evidence for weak C6—C2 bonding in tertiary 2-norbornyl cations. Paradoxically, we suggest however that this bonding has no proven connection with the three characteristic rearrangement processes found in these cations. While one cannot exclude some future structure–reactivity correlation being established, we believe a satisfactory rationalization of these rates can be made on the basis of simple acyclic models.

The Question of "Structure" in Secondary 2-Norbornyl Cations

Although this work involves secondary cations only as intermediates, we believe there are important conclusions concerning these, derivable from the tertiary cation work. Firstly, a corner-to-corner proton shift of a protonated cyclopropane (specifically a protonated nortricyclene) is now shown to be unnecessary to rationalize the rapid *endo*-6,2-hydride shift in the secondary ion. Secondly, the fact that the WM shift in this cation (assuming equilibrating enantiomers) has not been "frozen out" is not unexpected in view of the fact that neither is the WM shift in the tertiary case (known to be equilibrating enantiomers). Thirdly, the slow 3,2-hydride shift may simply reflect a poor steric alignment of the empty orbital on C2 and the C3 proton. In this connection, an unfavorable tipping of the empty p orbital may occur as a result of the weak C6,C2 bonding, the stronger this bond, the poorer the alignment.

Therefore, as in the tertiary ions, one can reasonably rationalize the rearrangements on the basis of simple aliphatic models and need not involve any C6,C2 bonding.

The observable 2-norbornyl cation has been assigned a static, symmetrically bridged struc-

ture but it now seems to us that this is a somewhat too restrictive interpretation of the excellent data obtained by Olah and co-workers. Olah has introduced (7) the terms "carbenium" and "carbonium" to refer to trivalent, and static, symmetrical pentavalent carbocations, respectively, and wants of course to have examples. However, as admitted by Olah, charge delocalization in carbocations should be a continuous function of structure and there should exist cations at each waystop on the road from "carbenium" to "carbonium" ions. We do not exclude a symmetrical structure for the 1,2-di H cation nor perversely would we exclude a package description of the 2-norbornyl cation that included equilibrating enantiomers, each enantiomer having a weakened C—*exo*-H-6 bond, a normal C—*endo*-H-6 bond, a significant C2—C6 bond, significant positive charge at C1, and considerably less charge at C2[4] than in an aliphatic secondary cation.

In this specific case, one can construct a "graph" (Fig. 4) relating C2—C6 bond strength to structure (assume bond strength one represents equal C2—C6 and C1—C6 bond strengths). At the origin, one might place the 1,2-di-*p*-anisyl structure, further along, the 1,2-dimethyl and still further somewhere the 1,2-di H structure.

Our alternative suggestion for the secondary 2-norbornyl cation structure is really a "continuum model" as opposed to the "carbonium–carbenium" dichotomy, *i.e.* both the tertiary and secondary systems are pictured as being somewhat stabilized by the C6,C2 delocalization mode.

Perhaps one is nitpicking to worry about symmetrical *vs.* partly symmetrical structures for the norbornyl cation? Nature does not usually prefer high symmetry and there is a positive entropy factor which would result from rapidly equilibrating structures. Since it would generally be conceded that carbon does not make appreciable use of 3d and higher orbitals, the issue here really involves an explicit description of the bonding at the C6 carbon atom (and hence the resulting geometry).

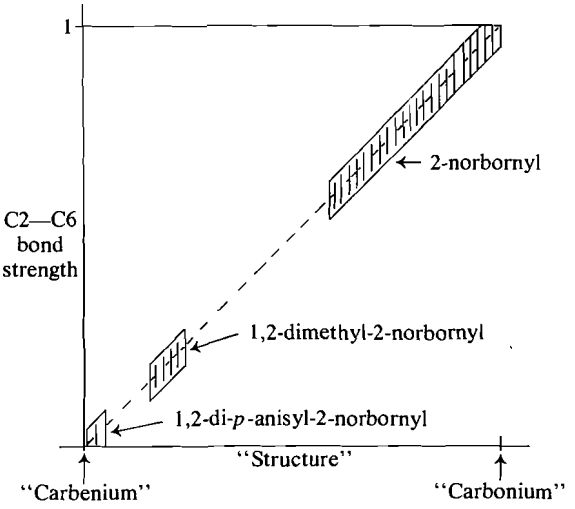


FIG. 4. Diagrammatic representation suggesting that secondary and tertiary 2-norbornyl cations should not be considered in black and white terms but as having a gradation in structure or shades of gray.

The interpretation of solvolysis results (25, 26) presents a different set of problems to those encountered in observable ion work and these have not been discussed in this paper. Solvolytically generated 2-norbornyl cation could also exist as a pair of equilibrating *R*, *S* cations with significant 6,2 bonding in each structure.

Experimental

Degenerate Rearrangement in **12**

Carbocation **12** has been reported (9). The kinetics of the degenerate *endo*-6,2-hydride shift can be best obtained using the two methyl groups. In the computed spectra, a half-width (T_2) = 8.0 Hz for C2 and for C6, a doublet, $J = 6$, was assumed with $T_2 = 4.0$ Hz. Prior to coalescence, the matching was done using the C2 methyl group. Since the upper field part of this is distorted somewhat by other absorptions, the matching was done by dividing the peak lengthwise and matching this half to computed spectra. After coalescence, a similar procedure was used, but where the peak is very broad, no matchings were attempted because of gross distortions in the line shape caused again by other peaks. Temperatures were monitored using a thermocouple directly placed in the n.m.r. tube.

Degenerate Rearrangement in **4**

Carbocation **4** has been reported (9). The kinetics of the degenerate Wagner–Meerwein shift – 6,2-hydride shift – Wagner–Meerwein shift process (line broadening) were measured in exactly the same way as described for the 2-methyl cation **2** (8).

[4]In comparing n.m.r. chemical shifts and e.s.c.a. results, Olah and co-workers have mainly been concerned with excluding structures with essentially localized charges. However, we believe the data would be equivocal if one attempted to differentiate between a symmetrical structure and, for instance, a structure where the positive charge at C1 was one-half that at C2.

Carbon-13 Nuclear Magnetic Resonance Spectrum of 3

Carbocation **3** was prepared from 3,3-dimethyl-2-*exo*-chloronorbornane (which rearranges via the 2,3-dimethyl isomer (15) eventually to **3**) dissolved in a mixture of excess SbF_5 and SO_2ClF–SO_2F_2. The concentration limit was about 10% w/v in order that precipitation did not occur at the very low temperatures. The spectrum was measured on a Bruker HFX-90 at 20° intervals from −60 to −140 °C (15). Computed ^{13}C spectra were obtained as previously described (15).

1-Methyl-exo-2-ethylbicyclo[2.2.1]heptan-2-ol

This alcohol was obtained by adding 1-methylbicyclo-[2.2.1]heptan-2-one to ethyl magnesium bromide at 0 °C, b.p. 93–96 °C/13 mm; n.m.r. (CCl_4), τ 9.02 (3H, C1 methyl), 9.115 (t, $J = 7$, 3H, C2 ethyl group).

Anal. Calcd. for $C_{10}H_{18}O$: C, 77.87; H, 11.7. Found: C, 77.98, H, 11.7.

The alcohol is probably a mixture of *exo* and *endo* hydroxyl isomers, with the latter dominant. The mixture obtained is mostly crystalline at 0 °C.

1-Methyl-2-ethyl-2-norbornyl Cation 15 and 1-Ethyl-2-methyl-2-norbornyl Cation 16

The cation mixture **15** ⇄ **16** was prepared by adding the above alcohol to FSO_3H or 1:4 FSO_3H–SO_2ClF. Relative to $TMA^+ = \tau$ 6.90, the methyl group of the rapidly equilibrating pair was located at 7.595 (−15 °C), very close to the position in the 1,2-dimethyl-2-norbornyl cation (7.58) and indicating nearly equal populations of **15** and **16**. The methyl peak moved to a lower field, 7.530 at −125 °C but this shift is too small to be significant. The CH_3 of the ethyl group, a triplet, $J = 6.75$ Hz, also moves to lower field, 8.660 at −15 °C to 8.63 at −125 °C, whereas a temperature dependent equilibrium would have suggested an upfield shift at lower temperatures if **16** really were slightly dominant.

The authors would like to thank Dr. C. J. Kim for stimulating suggestions and the National Research Council of Canada for valuable financial support.

Reaction Sequences Involving the Mutual Interconversion of All 10 Tertiary Dimethyl-2-norbornyl Cations. A Comparison of Predicted Products and Rates with Experiment

R. HASELTINE, K. RANGANAYAKULU, N. WONG, AND T. S. SORENSEN

The Department of Chemistry, University of Calgary, Calgary, Alberta T2N 1N4

Received October 31, 1974

R. HASELTINE, K. RANGANAYAKULU, N. WONG, and T. S. SORENSEN. Can. J. Chem. **53**, 1901 (1975).

All 10 tertiary dimethyl-2-norbornyl cations have been prepared. There are sequences of individual steps which will in theory interconvert any given two of these cations, a total of 45 permutations. All of the possible sequences (within a defined limit on the allowable total number of steps) for performing these interconversions were determined using a digital computer. Each step used in the computer generated sequence had previously been assigned a trial activation free energy value and a comparison is made in this paper between the actual experimental rearrangement results (in terms of both the kinetics of disappearance for the cation and what product is in fact formed) and the predicted results.

R. HASELTINE, K. RANGANAYAKULU, N. WONG et T. S. SORENSEN. Can. J. Chem. **53**, 1901 (1975).

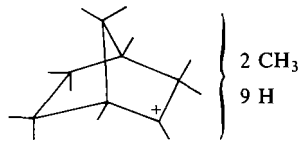
On a préparé les dix cations tertiaires diméthylnorbornyl-2. Il y a des séquences d'étapes individuelles qui transformeront en théorie n'importe quelle paire de ces cations et il y a en tout 45 permutations possibles. Toutes les séquences possibles, (à l'intérieur de limites définies pour un nombre total permissible d'étapes) pour effectuer ces transformations ont été déterminées en faisant appel à un ordinateur digital. Pour chaque étape utilisée dans la séquence générée par l'ordinateur, on avait auparavant assigné une valeur d'essai pour l'énergie d'activation et une comparaison est faite dans cet article entre les valeurs expérimentales trouvées pour ces réarrangements (en terme de cinétique de disparition de ces cations et en terme de quel produit est de fait formé) et les résultats qui sont prédits. [Traduit par le journal]

Introduction

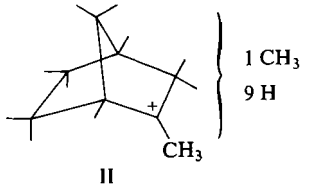
In a previous paper (1), a trial set of activation free energy parameters were deduced for all of the low energy rearrangement processes which occur in 2-norbornyl cations, using data from the rearrangements experimentally observed in the parent 2-norbornyl cation, the 2-methyl-2-norbornyl cation, and in several trimethyl and higher methylated analogs. It is now the intention to test the predictive value of these parameters using the rearrangements involved in interconversions among the complete set of tertiary dimethyl-2-norbornyl cations.

Results

There exist 55 (isomeric) dimethyl-2-norbornyl cations, **I**, if one does not differentiate *R* and *S* enantiomers. Of this total, only 10 are tertiary, **II**, *i.e.* one methyl group always at C2.



I



II

However, in constructing a diagram showing the rearrangements possible between any 2 of the 10 tertiary cations, the 45 secondary cation intermediates would have to be shown. Since this becomes extremely messy to depict, we have used an alternative approach, which is a modification

For personal use only.

of the procedure described recently by Johnson and co-workers (2) and which simply consists of a computer print-out listing the combination of single steps which would bring about any given rearrangement.

Let us say one wishes to find the routes between two tertiary dimethyl-2-norbornyl cations **A** and **D** using a number of individual steps (which each result in certain permutations of the atoms). The first problem consists in delineating the various possible individual rearrangement steps; this was reported in a previous paper (1) and is historically based, of course, on the experimental results of many previous workers. The second problem consists in deciding how many steps one will allow since with 55 nodal points, it is perhaps possible that one could find a loop-free route of 50 steps or more connecting **A** and **D**. Johnson and co-workers (2) have used a weighting factor for each individual step in deciding sequence length but since we have introduced an activation energy for each step, we have simply made an arbitrary cut-off, based largely on the cost of computing time, on the number of steps considered. Any routes which regenerate starting material or in fact any other loops, are redundant and were not printed by the computer. Furthermore, certain rearrangement categories have been excluded in the computerized treatment for reasons discussed previously (1). These include process *4* steps where the two substituents on C1 and C2 are the same and also most of the *endo*-3,2-substituent shifts (process *5*). Besides printing out all the possible sequences, the computer prints out the highest activation energy for each sequence using the set of activation free energy parameters previously deduced (1).

In practice, there turn out to be thousands of predicted routes interconnecting any given tertiary dimethyl-2-norbornyl cation with any other one. When one comes to consider which route may be the one experimentally followed, one finds that one has done the absolute minimum amount of labelling, *i.e.* no isotopic substitution or enantiomeric labelling. The computerized treatment is ideally suited for telling one how many specific labels would be required to yield an unique answer regarding any particular interconversion. As an example, simply using as starting ion a single enantiomer of known absolute configuration and determining the absolute configuration of the product ion (assuming no symmetrical intermediates) would rule out approximately one-half of the computer predicted routes since it can be shown that an even number of steps keeps the same absolute configuration for the cation and an odd number reverses it (2). In solvolysis work, this sort of approach has been elegantly used by Berson *et al.* (3) in studying the much faster and much shorter overall routes involving secondary cation (intermediates) rearrangements.

Our intention is not necessarily to unequivocally decide which particular route experimentally interconnects any given pair of cations (clearly not possible nor could the required work be justified). By assigning activation energies to each step, one will find that the barrier for some routes is much smaller than for others. Therefore, one wishes to see whether the computed route showing the lowest activation energy *correlates* with the *experimentally determined* activation energy for the process.

The overall kinetic equation for multistep reactions is only simplified where one barrier is much larger than any other (a rate-determining step). Where several highest barriers of equal height are predicted, one can readily take this into account in comparing theory and experiment. In the worst cases, where nearly equal barriers might exist, it may be impossible to obtain a meaningful comparison. Such problems will be discussed in each specific case but turn out in practice not to be as bad as one might anticipate.

The activation energy parameters used in the computer print-out are listed in Table 1. Two sets of computations were carried out: (*a*) calculations using only processes *1*, *2*, and *3* (13 steps maximum) and (*b*) calculations using processes *1*, *2*, *3*, and *4* (10 steps maximum). The process 5TT can only be degenerate (corresponding to a loop) in a dimethyl-2-norbornyl cation and therefore never appears in a sequence. The two sets were computed because it is possible to bring about any overall transformation using only the first three processes (2). From this computation, one can see what the shortest sequences excluding a *4* step will be. For each set, one needs a total of 45 separate calculations to obtain all possible interconversions. Fortunately, all of these interconversions are not experimentally measurable since this might have resulted in carbocation solutions containing in the end up to ten different cations. The success of this study,

TABLE 1. Activation energies assigned to the major rearrangement categories

Major rearrangement	Abbreviated symbol used for this operator	Subdivisions considered	Assigned activation energy parameter $\Delta G^{\ddagger}$ (kcal/mol)
Wagner–Meerwein shift	1	1TT	<4
		1TS	<9.5
		1ST	<4 (<9.5)[a]

[a]The bracketed values refer to the barrier starting from a tertiary cation energy base and these were used in the computer treatment.

in this regard, was by no means assured at the start and we were extremely lucky in that there were never more than three different observable ions present at any one time in a particular reaction sequence (at least within the limits of experimental detection).

The Thermodynamic Stability of Tertiary Dimethyl-2-norbornyl Cations

The reason that one does not eventually see all 10 cations after all possible interconversions have occurred is that two in particular represent distinct energy minima. The end product of starting with any of the other nine tertiary dimethyl-2-norbornyl cations is the eventual formation of the 1,2-dimethyl isomer. The 2,4-dimethyl isomer however represents a distinct secondary minimum. It appears to be much more stable than any of the other eight remaining cations and indeed at higher temperatures can just be detected in equilibrium with the 1,2-dimethyl isomer, although the latter is considerably more stable. Furthermore, the barrier connecting the 1,2- and 2,4-dimethyl cations is predicted, and is found experimentally (see following), to be higher than any other observed process, *i.e.* the 2,4-dimethyl isomer is in part a minimum because of its thermodynamic stability relative to the eight other cations and partly because it is walled off from the actual true minimum by the highest barrier. The fortuitous end result of this is that if any of the other eight cations can rearrange to the 1,2- or 2,4-dimethyl isomers more easily than to any other in this group, the rearrangement sequence is essentially quenched at that stage (the billiard ball drops). Even so, it is remarkable that the observed sequences never involve more than three cations.

The Overall Rearrangement Sequences

The observed behavior of all 10 tertiary dimethyl-2-norbornyl cations is shown in Fig. 1, where only those interconversions with connecting lines shown could be experimentally measured (or verified). There are two ways in which the trial parameters used in the computed sequences can be checked against experiment: (*a*) One can directly compare the rates of the experimentally observed processes against the computed rate for this process and (*b*) one can verify in a qualitative sense whether the observed product is in fact the one expected, *i.e.* connected by the lowest barrier to the reactant ion. For example, if one experimentally observes the transformation of the 2-*endo*-6-dimethyl isomer into the 1,2-dimethyl isomer, one can compare this rate with

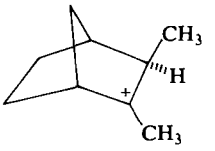
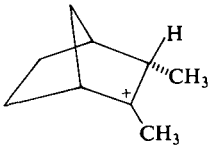
the lowest computed rate for this process. Then one can check the computer outputs to see whether there are predicted to be any still lower energy pathways leading from the 2-*endo*-6-dimethyl isomer to any of the other eight.

2-exo-3-Dimethyl-2-norbornyl Cation 1 and 2-endo-3-Dimethyl-2-norbornyl Cation 2

The preparation of these cations has been reported in a previous publication (4). One predicts the 2-*exo*-3-dimethyl **1** and 2-*endo*-3-dimethyl isomer **2** to be interconnected by a three-step sequence 1TS,3SS,1ST with a predicted barrier of 11.3 kcal/mol. The experimentally



1



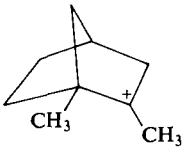
2

observed value, obtained both by n.m.r. line-broadening studies and probably by direct observation, was $\Delta G^{\ddagger} = 11.9$ kcal/mol (for **2** → **1**). The 2-*endo*-3-dimethyl cation **2** undergoes a degenerate *exo*-3,2-hydride shift (2HTT) for which $\Delta G^{\ddagger} = 6.6$ kcal/mol at -117 °C, in good agreement with the trial value for this parameter. The equilibrium constant for **2**/**1** was *ca.* 35 at -44 °C.

What else may be formed from either of these ions? Since they are interconverted by the low energy barrier of only 11.9 kcal/mol, both can be treated together, *i.e.* if another path of say $\Delta G^{\ddagger} = 15$ kcal/mol is somehow predicted for only one of the two, the other will have the same route open but the total sequence will be preceded by the three-step sequence 1TS,3SS,1ST. Unless excluded because of sequence length, this route will show up on the computer output anyhow. Equilibrium energy differences can be added to the kinetic $\Delta G^{\ddagger}$ value. It is obviously impractical to reproduce here the large number of routes interconnecting the cations **1** and **2** with all the others. It is even impractical to reproduce, in most cases, all the "lowest energy" routes. With 3 processes and 13 steps, the highest activation energy barrier mostly involves the 2HSS step (16.9 kcal/mol) or occasionally the 2HTS (or 2HST) step (15.2 kcal/mol). With the addition of process *4*, the only different routes will automatically involve the 18.0 kcal/mol barrier assigned to this. Simply for illustrative purposes, we show just one example of the fact that any one tertiary dimethyl-2-norbornyl cation, in this case **2**, can be rearranged into any one of the other nine. This is depicted in Table 2. Using only the first three processes, the shortest sequence is arbitrarily shown. If there is a still shorter sequence using process *4*, this is also shown. The highest barriers are listed together with the number of times they occur. An overall kinetic equation is very complex if two or more steps are competitive in rate. However, the higher barriers, *i.e.*, 18.0, 16.9, and 15.2 kcal/mol, are reasonably spread out and multiple steps with the same rate simply increase $\Delta G^{\ddagger}$ by the factor $RT \ln 2^{n-1}$, where n = number of like barriers. At the temperatures involved here, this will involve multiples of *ca.* 0.3 kcal/mol.

The sequences listed in Table 2 are illustrative only, since the shortest path need not involve the lowest barrier(s). However, an overall perusal of the computer output shows that one cannot do any better than shown in Table 2 except for the 2-*anti*-7-, 2-*exo*-6-, and 2,4-dimethyl isomers, where one can find single 16.9 barrier routes. If one looks at routes from the 2-*exo*-3-dimethyl isomer **1**, one finds, as expected, that the number and kind of high barriers is the same.

The actual "predicted product" results in the case of **1** and **2** are only marginally interpretable. The experimental result is the formation of the 1,2-dimethyl-2-norbornyl cation **3** with a rate constant, $k = 3 \times 10^{-4}$ s^{-1} at -39 °C, $\Delta G^{\ddagger} = 17.4$ kcal/mol. This is marginally higher than the predicted barrier for **2** → **3** of 16.9 kcal/mol.



3

Of the routes with this barrier, we prefer the shortest route shown in Table 2. That one should have formed **3** is not so obvious since the predicted barrier to any of the other cations also need involve no more than a single 2HSS step (16.9 kcal/mol). However, the 2-*endo*-6-dimethyl sequences all have **3** formed in the sequence and this route would be excluded. It may be significant in the other cases that all transformations involving a single 2HSS step also require the doubtful 2MSS step *except* for the transformation to **3**. Although the 2MSS barrier (from a tertiary base) is assigned a minimum 13.1 kcal/mol value, one can rationalize an upper

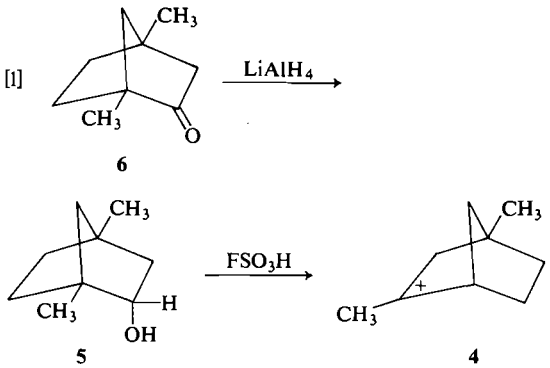
1,2-Dimethyl **3**	1TS,2HSS,1SS,2HST	—	16.9

[a]The symbol ↶↷ implies that the operations can be carried out in either order (commute).
[b]The symbol ↙R↘ implies that the operations can be carried out in either order but that a secondary–tertiary designation has to be changed.

value of perhaps 20 kcal/mol. For example, the 2MSS barrier is 11.4 kcal/mol. The 2HTT and 2MTT barriers are 7.2 and 8.9, respectively. Therefore, the 2MSS barrier could be as high as $11.4 \times 8.9/7.2 = 14$ and from a tertiary base $14 + 5.5 = 19.5$ kcal/mol. The lower limit value (13.1) will rarely be even rate determining while the upper limit value would rule out any sequences containing the 2MSS step. We will therefore keep this in mind in the subsequent discussion.

2,4-Dimethyl-2-norbornyl Cation 4

The title cation was prepared from the alcohol **5**, which was in turn obtained by hydride reduction of the ketone **6** (eq. 1). On adding **5** to the



acid, one first obtains the protonated alcohol which solvolyzes at -45 °C to give **4** ($k = ca.\ 1.5 \times 10^{-4}$ s^{-1}). The chemical shifts observed for **4** are reported in Table 3. Two degenerate rearrangement processes can be observed in **4**; the faster is a 1TS,3SS,1ST sequence and the slower is an unknown sequence which interconverts the two methyl groups. The 1TS,3SS,1ST sequence is quantitatively evaluated in another paper (5) and has also been briefly communicated previously (6).

Since the ion **4** is thermodynamically more stable than all others except the 1,2-dimethyl isomer **3**, one can only observe the transformation **4** → **3**. This process is experimentally observed, $k = 1.2 \pm 0.2 \times 10^{-4}$ s^{-1} at -19 °C, $\Delta G^{\ddagger} = 18.9$ kcal/mol. A measurable equilibrium exists at 25 °C between **4** and **3**, $K = \mathbf{3}/\mathbf{4} = 13 \pm 3$, $\Delta G = 1.5 \pm 0.2$ kcal/mol. The lowest calculated barrier for **4** → **3** is $16.9 + 0.3 = 17.2$ kcal/mol (two 2HSS steps) which occurs in numerous routes. However, all are long and the shortest is 3TS,2HSS,3SS,2MSS,3SS,2HSS,3ST. If one avoids the questionable 2MSS step, the best is ten steps, one of two possibilities is

TABLE 3. Summary of observed and calculated activation energy ($\Delta G^{\ddagger}$) barriers for all of the measurable rearrangements

Rearrangement	Observed barrier (kcal/mol)	Calculated barrier (kcal/mol)
2 → **1**	11.9	11.3
2 → **3**	17.4	16.9
4 → **3**	18.9	16.9 + 0.3
7 ⇄ **8**	≤11.0	11.3
7,8 → **4**	12.1	15.2
11 ⇄ **12**	≤11.9	11.3
11,12 → **4**	13.9	15.2 + 0.3
15 → **4**	15.3	15.2 + 0.3 × 4
17 → **3**	≲11.2	11.3

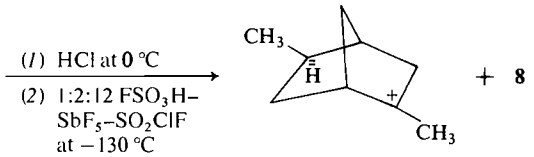
3TS,2HSS,3SS,1ST,3TS,2HSS,1SS,2HST,1TS,3ST. Using a *4* process, there is a shorter path involving 2HTS,4SS,2HSS,1SS,2HST. Looking at the observed rate, we would not rule out the process *4* sequence nor can one really rule out the 10 step sequence involving two 2HSS barriers. In any case, since the barrier is nearly 2 kcal/mol higher than predicted for the two 2HSS barriers we would tentatively conclude that our trial parameter for the 2HSS process may be too low.

2-exo-5-Dimethyl-2-norbornyl Cation 7 and 2-anti-7-Dimethyl-2-norbornyl Cation 8

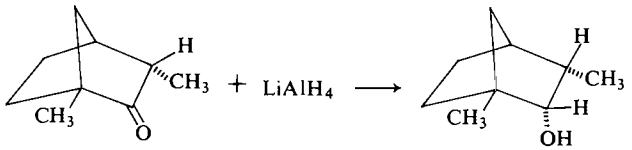
There is predicted to be a low energy barrier, 1TS,3SS,1ST, $\Delta G^{\ddagger} = 11.3$ kcal/mol, separating **7** and **8**. Experimentally, this is found to be the case. Cation solutions prepared from the chloride(s) of alcohol **9**, which should yield **7**, or from chlorides of the alcohol **10**, which should yield **8**, have identical n.m.r. spectra. The synthetic sequences start from known ketones and are shown in eq. 2. There are slight differences in the proton chemical shifts observed for **7** and **8** (listed in Table 3) so that one can clearly establish that two ions are present; however, it is not possible to assign which peaks are due to which particular ion. The equilibrium (close to unity) is established within 0.5 h at -120 °C (the Cl protons in **7** and **8** are separated enough so that one can clearly see both **7** and **8** at this temperature). One can estimate that the interconversion **7** ⇄ **8** must have a rate constant of greater than *ca.* 1×10^{-3} s^{-1} at -120 °C, $\Delta G^{\ddagger} \lesssim 11.0$ kcal/mol, in agreement with the predicted barrier. Since all other barriers for **7** and **8** to rearrange to anything else involve energies of 15.2 or 16.9 kcal/mol, one can treat the two

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

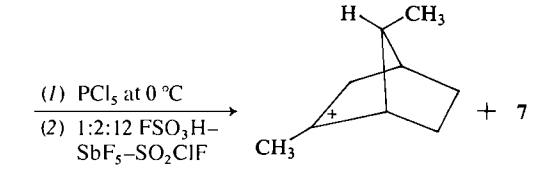
[2] 
9



7



10



8

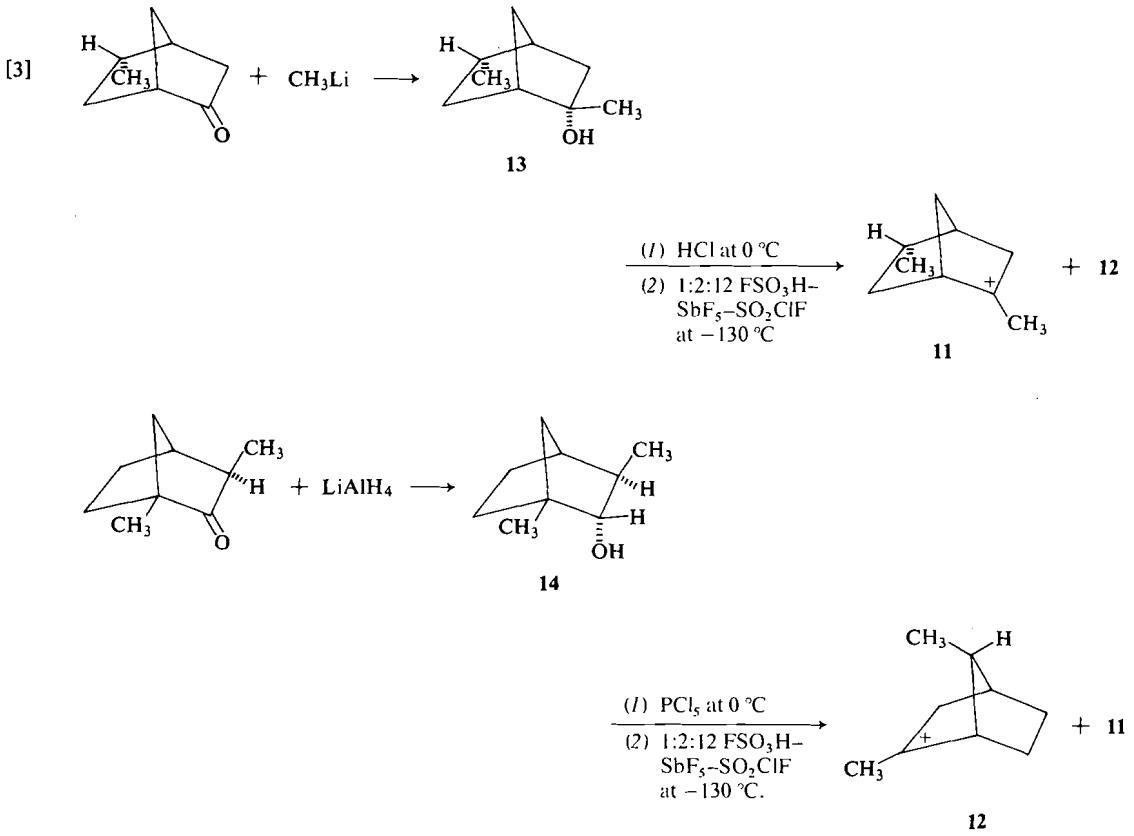
together (as was done with the two 3-methyl isomers).

Experimentally, **7** and **8** rearrange to the 2,4-dimethyl-2-norbornyl cation very rapidly, $k_{combined} = 1.35 \pm 0.5 \times 10^{-4}$ s^{-1} at -111 °C, $\Delta G^{\ddagger} = 12.1 \pm 0.1$ kcal/mol. Rather than looking at all possible interconversions, we will simply compare the barriers for these ions giving either the 1,2- or 2,4-dimethyl isomers. The shortest path to the 2,4-dimethyl isomer is from **8**, a two-step 1TS,2HST sequence involving a calculated 15.2 kcal/mol barrier. The shortest path to the 1,2-dimethyl isomer is again from **8** and involves the sequence 4TT,1TS,2HSS,1SS, 2HST, with a calculated high barrier of 18.0 kcal/mol. One can avoid this process *4* barrier by a number of much longer routes, the shortest being eight steps from **7**, 2HTS,3ST,1TS,3SS, 2MSS,3SS,2HSS,3ST, and a 16.9 kcal/mol barrier. Whichever one considers, the route to the 2,4-dimethyl isomer is clearly predicted but the predicted barrier is over 3 kcal/mol too high.

2-endo-5-Dimethyl-2-norbornyl Cation 11 and 2-syn-7-Dimethyl-2-norbornyl Cation 12

This pair are also predicted to be separated by the 11.3 kcal/mol barrier for the 1TS,3SS,1ST sequence and experimentally this is found to be the case. Cation solutions prepared from the chloride(s) of alcohol **13**, which should yield **11** or from chloride(s) of the alcohol **14**, which should yield **12**, have identical spectra. The synthetic sequences start from known ketones and are shown in eq. 3. The n.m.r. peaks of **11** and **12** overlap more than in the case of **7** and **8** and one has to warm the solution to -110 °C before the resolution is sufficiently good to be able to see two sets of  peaks. At still higher temperatures, the ratio of these does not change and therefore an equilibrium concentration of **11** and **12** has been established. It is not possible to assign the observed n.m.r. peaks to a given isomer, **11** or **12**, but in any case, the equilibrium

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.



constant is near unity. The chemical shifts are listed in Table 3. One can estimate that the interconversion rate must be larger than 5×10^{-4} s^{-1} at -110 °C, $\Delta G^{\ddagger} \gtrsim 11.9$ kcal/mol, in agreement with the calculated 11.3 kcal/mol. Since all other barriers involve values of 16.9 or 15.2 kcal/mol, one can again treat the two ions together.

Experimentally, cations **11** and **12** rearrange to the 2,4-dimethyl isomers **4** with a combined rate of $4.8 \pm 0.15 \times 10^{-4}$ s^{-1} at -83 °C, $\Delta G^{\ddagger} = 13.9$ kcal/mol. Once again, we will simply look at the barriers for these ions giving either **4** or the 1,2-dimethyl isomer **3**. The shortest sequence for giving **4** starts from **11** and involves 1TS,2HSS,3ST and a barrier of 16.9 kcal/mol. The shortest sequence giving the 1,2-dimethyl isomer **3** is five steps from **12**, 1TS, 2MSS,3SS,2HSS,3ST, and once again a barrier of 16.9 kcal/mol. There are four 15.2 kcal/mol barrier routes to **3** but all involve the questionable 2MSS step.

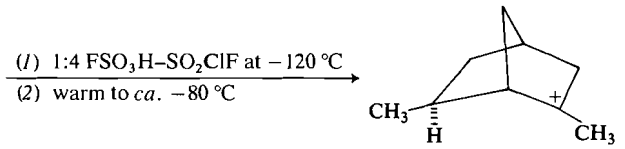
The actual route to the 2,4-dimethyl isomer **4** is predicted to *not* be the shortest sequence in this case but to involve, starting from **11**, the sequence 3TS,2HST,1TS,3SS,2HST, with two barriers of 15.2 kcal/mol. This sequence yields the 2-*exo*-5-dimethyl cation **7** after only two steps and then follows the same route to **4** as does **7**. Experimentally, the overall barrier is about 1 kcal/mol smaller than predicted. The rate-determining step must be the first 2HST step since experimentally the 2-*exo*-5-dimethyl cation **7** rearranges to **4** even faster than **11**–**12**.

2-exo-6-Dimethyl-2-norbornyl Cation 15

Carbocation **15** was prepared according to the sequence shown in eq. 4, starting from a known ketone. On addition of the alcohol **16** to the acid, one initially obtains the protonated alcohol and on warming, this gradually solvolyzes to **15**. Cation **15** undergoes a rapid, degenerate *endo*-6,2-hydride shift (see following paper) (5) which is not of interest here except that it gives one

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

[4] 
16



15

a definite value for the 3TT process, $\Delta G^{\ddagger} = 7.2$ kcal/mol. This had been only estimated previously as <11.3 kcal/mol.

Experimentally, cation **15** is found to rearrange to the 2,4-dimethyl isomer **4**, $k = 1.3 \pm 0.05 \times 10^{-4}$ s^{-1} at -57 °C, $\Delta G^{\ddagger} = 15.3$ kcal/mol.[1] As before, we will check to see what the predicted product would be by looking at the calculated barrier for **15** giving either the 2,4-dimethyl isomer **4** or the 1,2-dimethyl isomer **3**. The shortest sequence giving the 1,2-dimethyl isomer is three steps involving 4TT,1TS,3ST. There is, however, a sequence bypassing process *4* involving only four steps, 1TS,2HSS,3SS, 2HST, with a calculated 16.9 kcal/mol barrier. There are in fact four sequences for **15** → **3** which involve the 15.2 kcal/mol barrier (three of these barriers) but all require the doubtful 2MSS step. The shortest sequence from **15** to **4** and involving the lowest calculated barrier is the seven-step sequence 2HTS,3SS,2MSS,1SS, 3ST,1TS,2HST with two 15.2 kcal/mol barriers. Avoiding the questionable 2MSS step, one finds that there are only two sequences involving 15.2 kcal/mol barriers, both 12 steps. They actually differ only in the fifth, sixth, and seventh steps, involving 3TS,1SS,2HST in one case and 1TS,3SS,1ST in the other. The preferred sequence is (2HTS,1SS,3SS,2HST)(1TS,3SS,1ST) (3TS,2HST)(1TS,3SS,2HST). (For convenience, parentheses have been added to enclose sequences leading from one tertiary ion to another.) The sequence converts the 2-*exo*-6-dimethyl ion **15** first to the 2-*syn*-7-dimethyl isomer **12**, then to the 2-*endo*-5-dimethyl **11**, to the 2-*exo*-5-dimethyl isomer **7**, and finally to **4**. There is excellent experimental support for this sequence since we already know that the rate from the 2-*syn*-7-dimethyl isomer **12** to **4** is faster than the experimental barrier from **15**, *i.e.* the barrier involves the first five-step sequence. This involves two 2HTS steps, 15.2 + 0.3 = 15.5 kcal/mol, in good agreement with the observed 15.3 kcal/mol.

This case neatly points out the tremendous advantages of having activation energy parameters assigned to the individual steps. Without these, one might have been tempted incorrectly to predict as product the 1,2-dimethyl isomer with the short, five-step, 16.9 kcal/mol barrier. The activation energies are also indispensible in sorting out the large number of predicted routes for a given interconversion. What we believe to be the correct sequence (above) for **15** → **4** is actually well "buried" in the computer output, *i.e.* without considering barriers and using only the "three process" routes, there are 2 7-step sequences, 4 of 8 steps, 2 of 9 steps, 5 of 10 steps, 5 of 11 steps, 13 of 12 steps, and 17 of 13 steps.

2-endo-6-Dimethyl-2-norbornyl Cation 17

Carbocation **17** was not directly observed, as in fact expected. The sequence which should have generated cation **17** is shown in eq. 5, starting from a known ketone. Addition of the alcohol **18** to FSO_3H–SO_2ClF (1:4) at -130 °C yields predominantly the protonated alcohol and some **3**. The protonated alcohol solvolyzes fairly rapidly and has disappeared within 0.5 h at -90 °C. Carbocation **3** is the only observed product. Addition of the chloride at -129 °C to SbF_5–FSO_3H–SO_2ClF and running the n.m.r. spectrum at -120 °C shows only the cation **3**. The rate constant for **17** → **3** can be conservatively estimated as $> 5 \times 10^{-4}$ s^{-1} at -120 °C,

[1] At -60 °C, there appears to be an equilibrium, where $K = ca.$ 65 for **4**/**15**.

$\Delta G^{\neq} \lesssim 11.2$ kcal/mol. The predicted lowest barrier for **17** to rearrange to anything else is the 1TS,3ST sequence leading to **3**, with a predicted barrier of 11.3 kcal/mol.

Discussion

The use of a computer to enable one to look at all of the allowed paths (up to at least a predetermined number of steps) in a sense shows one too much. It would be gratifying to have one clearcut path which could be safely separated from the less likely ones. In fact, this probably occurs in pencil and paper type elucidations of the overall transformations since the writer may have a bias toward certain steps and will almost certainly be biased toward the shorter sequences. It is completely unmanageable to work out many of the numerous multistep sequences by hand.

In looking at the success of the trial parameters, which is the real point of this work, the critical ones are the highest barriers. Numerical errors in the low barriers will not affect the calculated overall rate of a process involving at some point a much higher barrier. In practice, the three critical values for the "three process" sequences are for 2HST (or 2HTS), 2HSS, and 2MSS. A comparison of calculated and observed behavior for all of the rearrangements are summarized in Table 3 and a perusal of this shows that some sizeable $\Delta G^{\neq}$ deviations exist. We believe at this time that the major error factor is probably a thermodynamic one, due to a neglect of the "special" effect of a C1 methyl group, *i.e.* just as we have clearly separated the secondary C2 H and tertiary C2 CH_3 cations, we should probably take into account the increased stability of a secondary *or* tertiary cation resulting from a C1 methyl *vs.* hydrogen substitution. To make this distinction in the computerized treatment of activation energies seems too restrictive; there is already enough subdivision of steps for a general treatment. Such subtle thermodynamic factors are relevant to questions about the molecular structure of 2-norbornyl cations and this point is explored in an accompanying paper (5). Basically, the results of this analysis suggest that the 2HSS value used in this work (16.9) is appropriate only to a C1 methyl-substituted secondary ion and that the 2HTS value of 15.2 is only appropriate to a C1 hydrogen-substituted secondary ion. Consideration of this brings both the **4** → **3** and **7,8** → **4** barriers closer to the experimental values. Furthermore, we can better rationalize our overall observations by assuming a 2MSS value near our previously derived upper limit so that sequences involving this barrier are discounted.

We have been rather surprised in this work to note the large thermodynamic ground state energy differences between some of the dimethyl cations, *i.e.* **1** and **2** or **4** and **15**. This complicates the use of trial activation energy parameters and suggests that one should be cautious about trying to make too fine a comparison between calculated and experimental rates. We implicitly recognize this in the transformations of **7** and **8** to **4**, or **11** and **12** to **4**, where we have not evaluated the few tenths of a kcal/mol associated with the fact that the concentration of the reactive member of the pair has less than unit concentration. Similar small effects were

[a]Relative to tetramethylammonium cation (TMA^+) = τ 6.90.
[b]These values have been obtained at extremely low temperatures and are poorly resolved. There is also some evidence that chemical shifts change slightly with temperature.
[c]The assignments for **1** are somewhat tentative. Complete assignments were not made because the higher field region is obscured by cation **2** peaks.
[d]Values in parentheses represent averaged chemical shifts caused by a particular rearrangement (see text for these).
[e]Obtained by interpolation, knowing an averaged value and one of the "frozen out" peak values (see, however, [b]).
[f]A doublet, $J_{average} = 11$.
[g]An AB quartet, $J = 11$.
[h]The spectrum of **3** has been published (14) but several small peaks have been chopped off. Above 25 °C, this cation undergoes a second degenerate rearrangement shown from DISST experiments to be identical to the second degenerate rearrangement occurring in the 2-methyl-2-norbornyl cation (1).
[j]A 2(AB) quartet, $J = 15$.
[k]Triplet, $J = 6$.
[l]Poorly resolved triplet, $J = 6$.
[m]Doublet, $J = 6.5$.
[n]This assignment may be reversed.
[p]Doublet, $J = 5$.
[q]Partially obscured by HI of **4**.
[r]Assignments for **7** ⇄ **8** and **11** ⇄ **12** are incomplete because with two ions present, one has a very complex spectrum in the 7.5–8.5 region.
[s]Doublet, $J = 7$.
[t]Doublet, $J = 6.5$.
[u]Curiously shaped with two humps on the ends and nearly flat between these.
[v]The two peaks are not equal and are somewhat broad, possibly part of an AB quartet.
[w]This peak is broad and the assignment is somewhat uncertain.

For personal use only.

also ignored, in general, in deriving the trial activation energy parameters.

In closing, perhaps the most valuable aspect of this study is to show how incredibly fast are many of these long rearrangement sequences. We have recently studied a pentamethyl-2-norbornyl cation rearrangement occuring at −40 °C where 15 steps (three processes) were needed to produce a single predicted sequence.

Experimental

Product purity was determined in each case by i.r., g.l.c., and n.m.r. Cation n.m.r. chemical shifts are reported relative to $TMA^+ = \tau$ 6.90 and were obtained on a Varian Associates HA-100.

1,4-Dimethylbicyclo[2.2.1]heptan-endo-2-ol **5**

Small quantities of the g.l.c. pure ketone, 1,4-dimethylbicyclo[2.2.1]heptan-2-one (**6**) were available from the ozonolysis of a 2-exomethylene hydrocarbon related to **6** (1). Reduction of this with lithium aluminum hydride gave the corresponding alcohol, which almost certainly has mainly the *endo* configuration; n.m.r. (CCl_4), 8.935 and 8.950 (both 3H, the C1 and C4 methyl groups), 6.155 and 6.250, (d, J = 10.5, each peak is further split into a doublet of doublets, J = 3.5 and 1.5, the C2 proton). Addition of the alcohol to FSO_3H or 1:4 FSO_3H–SO_2ClF at −80 °C yields only the protonated alcohol, peaks at 8.84 and 8.72 (3H each, the C1 and C4 methyl groups), 4.87 (d, J = 9, the C2 proton). Solvolysis becomes fairly rapid about −45 °C to yield the pure cation **4**. Secondary 2-norbornyl alcohols with an *exo* configuration cleave much more readily (7).

2-exo-5-Dimethylbicyclo[2.2.1]heptan-2-ol **9**

A commercial mixture of *exo*-5- and *endo*-5-methylbicyclo[2.2.1]hept-2-ene was converted to a mixture of the *exo*-5-, *endo*-5-, *exo*-6-, and *endo*-6-methylbicyclo-[2.2.1]heptan-2-ones using a literature procedure (8). Using a 20 ft × 3/8 in. column of 30% Carbowax 20M, it was possible to separate preparatively, without difficulty, the *endo*-6- and *endo*-5-methyl ketones, the shortest and longest retention peaks, respectively. Just the opposite g.l.c. behavior is reported (8) and the assignments in this paper may be in error. The *exo*-6- and the *exo*-5-methyl ketones have very similar retention times, the former marginally shorter. By cutting the longer retention side of the combined peak twice it was possible to obtain a sample of the *exo*-5-methyl ketone which was pure enough for our purposes (the same cations, **7** and **8**, in a pure form, are obtained from alcohol **10** and the *exo*-6-methyl cation impurity also produced from the impure **9** does not interfere with either our characterization of cations **7** and **8**, nor with the measurement of their rate of rearrangement). The split methyl peak in all four ketones is at a different chemical shift, in CCl_4, *endo*-6-methyl, τ 9.02; *exo*-5-methyl, 8.91; *exo*-6-methyl, 8.92; *endo*-5-methyl, 8.96; and based on this, the ketone fraction was about 75% *exo*-5-methyl and 25% *exo*-6-methyl. The pure *exo*-6-methyl ketone can be obtained by another route. The *exo*-5-methyl ketone (75.6 mg, 0.61 mmol) was treated with 1.2 mmol of methyl lithium in ether to yield 47.9 mg of alcohol. This was stirred with 1 ml of concentrated HCl at 0 °C for 30 min, the cold solution extracted with pentane, and the pentane dried and neutralized with anhydrous K_2CO_3. After pentane removal, the chloride residue (no —OH in i.r.) was used directly. From Berson's results (3), the alcohol–chloride transformation should proceed without appreciable rearrangement involving 6,2-hydride shifts.

1-exo-3-Dimethylbicyclo[2.2.1]heptan-2-ol **10**

The ketone, 1-*exo*-3-dimethylbicyclo[2.2.1]heptan-2-one, was prepared as previously described. The ketone (186.3 mg, 1.35 mmol) in 2 ml of ether was added dropwise to a solution of lithium aluminum hydride (102 mg) in 10 ml of ether. On work-up, 172.5 mg of alcohol **10** was obtained as a liquid at 25 °C; n.m.r. (CCl_4), τ 9.18 (d, J = 6.5, 3H, the C3 methyl), 8.945 (3H, the Cl methyl), 6.43 (d, J = 10, 1H, each peak is further split into a doublet, J = 1.5, the C2 proton). Judging from the n.m.r. spectrum, the alcohol is essentially a single isomer at C2, almost certainly the *endo*-2 alcohol. Using the phosphorus pentachloride – pentane procedure of Brown *et al.* (9), the alcohol was converted to the chloride, which is likely a mixture of the secondary and tertiary chlorides (*cf.* α-fenchol result (10) indicating that no 6,2-hydride shift is expected under these conditions).

2-endo-5-Dimethylbicyclo[2.2.1]heptan-2-ol **13**

The alcohol **13** was prepared as described for **9**. From 210 mg, 1.5 mmol, of ketone there was obtained 193 mg of **13** as a solid, m.p. 28–30 °C; n.m.r. (CCl_4), 9.02 (d, J = 6.5, 3H, the *endo*-5 methyl group), 8.78 (3H, the C2 methyl group).

Anal. Calcd. for $C_9H_{16}O$: C, 77.08; H, 11.5. Found: C, 77.02; H, 11.4.

Judging from the n.m.r. spectrum, the alcohol is mainly a single isomer at C2, almost certainly the *endo* alcohol. The alcohol was converted to the chloride (i.r.) by the same procedure described for **9**.

1-endo-3-Dimethylbicyclo[2.2.1]heptan-2-ol **14**

This alcohol was prepared by the same procedure used to prepare alcohol **10**, starting with the *endo*-3-methyl ketone (1). The alcohol has been reported (11). From g.l.c. and n.m.r., the alcohol is a mixture of the *exo*-2 and *endo*-2 alcohols. The major isomer (a solid) can be isolated by preparative g.l.c. The alcohol was converted to the chlorides by the same procedure described for **10**.

2-exo-6-Dimethylbicyclo[2.2.1]heptan-2-ol **16**

The ketone, *exo*-6-methylbicyclo[2.2.1]heptan-2-one was obtained using a procedure partially described by Beckmann *et al.* (12), starting with *exo*-2-methylbicyclo-[2.2.1]heptan-2-ol, converting this to the *endo*-2-methyl alcohol, heating this with formic acid and then saponifying. At this stage, the crude alcohol was oxidized with Jones' reagent to give a crude ketone mixture consisting mainly, as expected, of the 1-methyl ketone together with about 15% of the *exo*-6-methyl ketone and small amounts of others. Spinning band distillation (Nestor Faust Autoannular 30 in. column) at 14 mm effected the separation of most of the 1-methyl ketone, b.p. 57–58 °C. From the residue, a fraction consisting mainly of the *exo*-6-methyl ketone was separated by preparative g.l.c. (see **9**). This was further purified through the crystalline semicarbazone and hydrolysis of this in aqueous oxalic acid. The alcohol **14** was prepared as for **9** and after sublimation had

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

m.p. 38–41 °C; n.m.r. (CCl_4), τ 9.13 (d, J = 7, 3H, the *exo*-6-methyl peak), 8.79 (3H, the C2 methyl peak). The alcohol appears to be, from n.m.r. and g.l.c., a single isomer at C2, in all probability, the *endo* alcohol.

Anal. Calcd. for $C_9H_{16}O$: C, 77.08; H, 11.5. Found: C, 76.85; H, 11.98.

2-endo-6-Dimethylbicyclo[2.2.1]heptan-2-ol ***18***

The alcohol **18** was prepared as described for **9**. From 270 mg, 1.93 mmol, of the ketone, there was obtained 260 mg of alcohol, which after sublimation had a m.p. of 56–59 °C; n.m.r. (CCl_4), τ 8.77 (d, J *ca.* 6.5, 3H, the *endo*-6 methyl), 8.79 (3H, the C2 methyl). Judging from the g.l.c. and n.m.r. evidence, the alcohol is a single isomer at C2, in all probability the *endo* alcohol.

Anal. Calcd. for $C_9H_{16}O$: C, 77.08; H, 11.5. Found: C, 76.07; H, 11.2.

The alcohol was converted to the chloride (i.r.) by the same procedure described for **9**.

Rate Measurements

The preparation of the cations followed previously described procedures (13). The particular solvent system used is given under Results. Chemical shifts are given in Table 4. Plots involved a standard first-order kinetic treatment and were subject to standard least-squares analysis. The error limits represent the 90% confidence level. A given rate was run from two to five times. In the case of the lower temperatures, it was not possible to duplicate the exact temperature each time. In these cases, the best fit line is reported and the corresponding $\Delta G^{\ddagger}$ values for all runs are averaged and the deviation reported. A thermocouple was inserted directly into the n.m.r. tube and a temperature reading accompanied each time reading. The temperatures over a complete run were averaged. The specific procedures followed in each case were as follows.

Cation ***4*** → *Cation* ***3:*** (peak height of coalesced C1—C2 methyls of **3**)/2 (*a*) + C4 methyl peak height of **4** (*b*) = constant peak height (*c*). Plotted increase of (*a*)/(*c*) with time. The half-widths of (*a*) and (*b*) are nearly identical at the temperatures involved here.

Cation ***2*** → *Cation* ***3:*** followed increased peak height of coalesced C1—C2 methyls of **3** with time. The peak was standardized against a reference TMA^+ peak height.

Cations ***7*** ⇄ ***8*** → ***4:*** at the low temperatures involved, the H1 proton region shows two broad multiplet peaks. The lower field belongs to either **7** or **8** and **4**. The higher field one belongs to only one ion, either **8** or **7**. The total area of H1 protons was determined by tracing, cutting, and weighing and taken as constant. The rate was determined by plotting the decrease in the higher field H1 peak area (standardized) with time.

Cations ***11*** ⇄ ***12*** → *Cation* ***4:*** followed increased peak area of C4 methyl of **4** with time. The peak area was standardized against a reference TMA^+ peak area.

Cation ***15*** → *Cation* ***4:*** peak area of coalesced (C2—C6 methyl of **15**)/2 (*d*) + area of C4 methyl of **4** (*e*) = constant peak area (*f*). Plotted increase of (*e*)/(*f*) with time using the appropriate form of a first-order rate expression.

Program Transform

The purpose of the program is to find all possible pathways of getting from one norbornyl cation to another in N steps or less and with K different processes. A reaction sequence is represented by an integer with N digits with each digit representing a certain process and the arrangement of the digits representing the order in which they are performed. An integer is generated and the transformations are carried out, checking after each transformation to see if the product was formed. If it has been formed, then further checks are made to eliminate sequences which contain internal cycles and if the overall transformation requires less than N steps, a check is performed to eliminate identical sequences which were found previously. Finally, the sequence is printed along with complementary information concerning the nature of the intermediates, *i.e.* tertiary or secondary ions, and the energy barriers which the sequence must hurdle. The integer is incremented by one unit and the process starts over. The principle advantage of this over the elegant procedure of Johnson and co-worker (2) is that only a very limited amount of central memory is required, although our program does not execute as fast and never generates or contains the information necessary to construct a complete graph.

The authors thank the National Research Council of Canada for generous financial support and Drs. C. Collins and C. Johnson for preprints of their papers.

The Role of Excess Kinetic Energy in the Reactions of $O(^1D)$ Atoms [1,2]

RALPH OVEREND, GEORGE PARASKEVOPOULOS[3], JANICE R. CRAWFORD,[4] AND H. ALAN WIEBE[5]

Division of Chemistry, National Research Council of Canada, Ottawa, Canada K1A 0R9

Received February 10, 1975

RALPH OVEREND, GEORGE PARASKEVOPOULOS, JANICE R. CRAWFORD, and H. ALAN WIEBE. Can. J. Chem. **53**, 1915 (1975).

The effect of the excess kinetic energy of $O(^1D)$ atoms on their reactions with some gaseous compounds was investigated using two different experimental methods. $O(^1D)$ atoms with maximum excess kinetic energies of 41 ± 5 and 31 kcal/mol respectively, were produced by flash photolysis of N_2O (1800–2300 Å) and by photolysis of N_2O at 2139 Å, in the presence and absence of He which is a deactivator of kinetic energy. In the first method the competition between N_2O and one of CO_2, Xe, CO, and N_2 for $O(^1D)$ atoms was measured and it was found that the relative rate constants k_{CO_2}/k_{N_2O}, k_{Xe}/k_{N_2O}, k_{CO}/k_{N_2O}, and k_{N_2}/k_{N_2O} are not affected by the excess kinetic energy of the $O(^1D)$ atoms.

In the second method the competition between neopentane and one of CO_2, Xe, CO, and N_2 for $O(^1D)$ atoms was measured. The results of the second study were not entirely conclusive. However, they also indicate no effect or at best only a very small effect of excess kinetic energy.

RALPH OVEREND, GEORGE PARASKEVOPOULOS, JANICE R. CRAWFORD et H. ALAN WIEBE. Can. J. Chem. **53**, 1915 (1975).

Nous avons évalué l'effet de l'excès d'énergie cinétique des atomes $O(^1D)$ sur quelques-unes de leurs réactions en phase gazeuse en utilisant deux méthodes. Nous avons produit les atomes $O(^1D)$ avec un excès d'énergie cinétique de 41 ± 5 kcal/mol et de 31 kcal/mol, par une photolyse-éclair de N_2O (1800–2300 Å) et par une photolyse de N_2O à 2139 Å respectivement. Ceci a été fait en présence et absence de He qui agissait comme un désactivateur d'énergie cinétique.

Suivant la première méthode nous avons mesuré la compétition entre N_2O et CO_2, Xe, CO ou N_2 pour les atomes $O(^1D)$, et nous avons trouvé que les constantes relatives k_{CO_2}/k_{N_2O}, k_{Xe}/k_{N_2O}, k_{CO}/k_{N_2O} et k_{N_2}/k_{N_2O} ne sont pas influencées par l'excès d'énergie cinétique des atomes $O(^1D)$.

Suivant la deuxième méthode nous avons mesuré la compétition entre le néopentane et CO_2, Xe, CO ou N_2 pour les atomes $O(^1D)$. Les résultats de la deuxième étude n'ont pas été entièrement définitifs. Néanmoins, eux aussi n'indiquent guère d'effet ou, tout au plus un effet très faible.

Introduction

The photolysis of N_2O in the wavelength region 1800–2300 Å gives electronically excited oxygen atoms mainly in the $O(^1D_2)$ state (1, 2). The photon energy in this wavelength region is in excess of the N_2—O bond dissociation energy. The factors affecting the partition of the excess energy between the translational and internal modes of excitation of the photofragments are not well understood. The available evidence from the photodissociation of NO_2 and NOCl (3) shows that 60–70% of the excess energy appears as translational excitation of the fragments. In the light of this we assume that all the excess energy goes into translational excitation of the $O(^1D)$ and N_2 fragments and calculation on the basis of conservation of momentum yields an upper limit for the kinetic energy of the $O(^1D)$ atoms, in the range 25–47 kcal/mol for the wavelength region 2300–1800 Å. It is possible that the excess kinetic energy of the $O(^1D)$ atoms could have an effect on their reactivity, and indeed, Heicklen and co-workers (4–7) have suggested such an effect on the relative rates k_{2a}/k_{2b}, k_{CH_4}/k_{N_2O}, and k_{O_3}/k_{N_2O} of the reactions of $O(^1D)$ with N_2O, CH_4, and O_3.

[4] $O(^1D) + O_3 \rightarrow$ Products

On the other hand Preston and co-workers (8) found no evidence of a kinetic energy effect on the ratio k_{2a}/k_{2b}. More recently the ratio was redetermined in this laboratory by Wiebe and Paraskevopoulos (9); the value obtained agrees with that of Preston and co-workers and again it was found to be independent of the excess kinetic energy.

It should be pointed out however, that there is an inherent difficulty in all studies that attempt to detect the effect of kinetic energy on the relative rates of $O(^1D)$ atoms. Such studies involve comparisons of small differences in relative rates, measured with $O(^1D)$ atoms possessing various amounts of excess kinetic energy. This is usually accomplished by measuring the relative rates in the absence and presence of He, or other deactivators of kinetic energy. Since most of the reactions of $O(^1D)$ atoms are very fast, approaching collision efficiencies (10–13), any effect of the excess kinetic energy is likely to be small; therefore the resulting differences in relative rates due to the removal of 30–40% of it would be still smaller and difficult to distinguish from the experimental uncertainty.

The reactions of $O(^1D)$ atoms are of current interest to the chemistry of the stratosphere (14) and the present study is an attempt to further clarify the role of kinetic energy in these reactions. We have used two different methods to study the rates of deactivation of $O(^1D)$ to $O(^3P)$ by CO_2, Xe, CO, and N_2, relative to the rates of its reaction with N_2O and neopentane; the experiments were made in the absence and presence of He which is a deactivator of translational energy but does not interact in any other way with $O(^1D)$ atoms (2, 10). The deactivation reactions were chosen in this study, because in addition to their interest as a distinct class of reactions, they are generally somewhat slower than the reactions with N_2O and neopentane, and it was hoped that any effect of the kinetic energy would result in large differences in the reactivities and would be thus easier to detect. We have also discussed the present and previous results in terms of some approximate calculations of the collisional removal of kinetic energy from $O(^1D)$ by helium.

Methods

Method A

$O(^1D)$ atoms with a maximum excess kinetic energy of 41 ± 5 kcal/mol were produced by flash photolysis (1800–2300 Å) of mixtures of N_2O with CO_2, Xe, CO, and N_2, in the absence and presence of He which is a deactivator of excess kinetic energy but does not interact with $O(^1D)$ to any significant extent (2, 10). The following reactions take place:

[1] $N_2O + h\nu \rightarrow N_2 + O(^1D)$

[2a] $O(^1D) + N_2O \rightarrow N_2 + O_2$

[2b] $\rightarrow 2NO$

[5] $O(^1D) + Q \rightarrow O(^3P) + Q$

where Q = CO_2, Xe, CO, and N_2. For constant flash energy and pressures of N_2O and Q the NO or N_2 produced in the absence and presence of He should give a measure of the effect of the excess kinetic energy on the rates of the deactivation of $O(^1D)$ by Q, relative to its rate of reaction with N_2O, *i.e.*, on the ratio k_Q/k_{N_2O}.

Method B

$O(^1D)$ atoms with a maximum excess kinetic energy of 31.0 kcal/mol were produced by photolysis of N_2O at 2139 Å, and reacted subsequently with neopentane and CO_2, Xe, CO, and N_2 in the absence and presence of He. The following reactions take place:

[1] $N_2O + h\nu \rightarrow N_2 + O(^1D)$

[5] $O(^1D) + Q \rightarrow O(^3P) + Q$

[6] $O(^1D) + RH \rightarrow \alpha ROH + (1 - \alpha)(R + OH)$

[7] $O(^3P)$ + 1-butene → Products

where RH = neopentane, ROH = neopentanol, Q = CO_2, Xe, CO, and N_2, and Products are the characteristic products of the addition of $O(^3P)$ to 1-butene, *i.e.* 1,2-butene oxide, *n*-butyraldehyde, and methyl ethyl ketone (15). When the ratios (neopentane + Q)/N_2O and (neopentane + Q)/1-butene are sufficiently high, virtually all the $O(^1D)$ will react with neopentane and Q and not with N_2O or 1-butene (2, 16). The vibrationally excited neopentanol formed initially is completely stabilized and its yield becomes constant at a pressure of about 150 Torr (17). If a small amount of a scavenger of $O(^3P)$ such as 1-butene is also added, most of the $O(^3P)$ atoms formed

in the system will add to 1-butene, and the yields of the characteristic products of the addition (1,2-butene oxide, *n*-butyraldehyde, and methyl ethyl ketone) should give a measure of the deactivation of $O(^1D)$ to $O(^3P)$ by Q. This technique has been used successfully in this laboratory to identify and measure the $O(^3P)$ formed by deactivation of $O(^1D)$ and is described in detail in ref. 2. The values of the ratio $\sum O(^3P)$Products/neopentanol determined under constant conditions in the absence and presence of He should give a measure of the effect of the excess kinetic energy on the rate of deactivation of $O(^1D)$ by Q relative to its rate of reaction with neopentane.

Experimental

Method A

The flash photolysis apparatus consisted of a flash lamp reaction vessel assembly connected to a mercury free vacuum system. A 75 μF capacitor was charged to 8 kV (2400 J) and discharged in low pressure air producing a light pulse of about 20 μs duration to half-peak height. The apparatus and experimental arrangement were the same as those used in a similar study of the effect of the excess kinetic energy of the $O(^1D)$ atoms on their reaction with N_2O and have been described in ref. 9.

The NO was measured spectrophotometrically in absorption by the attenuation of the $\gamma(0, 0)$ band of NO (2267 Å line emitted by a cadmium lamp and monitored by a photomultiplier mounted at the exit slit of a 1 m scanning spectrophotometer). In order that the absorption varied linearly with NO pressure the NO γ-band was pressure broadened before measurement by addition of He to a total pressure of 1 atm. The He was added before or after the flash depending on whether the reactions took place in the absence or presence of He. The analytical arrangement and the calibration for NO have been described in detail previously (9). In a few experiments with CO_2 and Xe nitrogen was also measured as described previously (9). The N_2O and He used were the same grade and were purified in the same manner described in ref. 9. The CO_2, Xe, CO, and N_2 were Matheson research grade and were used without further purification.

Method B

The 2139 Å light was provided by two Philips 93106 E zinc lamps and were focused by Ultrasil lenses. The cylindrical photolysis cell had a volume of 195.6 ml and Suprasil quartz windows 5 cm in diameter. After photolysis the noncondensable gases were pumped off slowly through three liquid nitrogen traps; neopentanol and the other oxygenated compounds were collected, separated from the excess reactants, and measured on a 300 ft, 0.015 in. i.d. capillary column coated with β,β′-thiodipropionitrile and equipped with a flame ionization detector. The experimental and analytical techniques have been described in detail in ref. 2. The neopentane and N_2O were purified as described previously (2). The CO_2, Xe, CO, and N_2 were the same as those used in Method *A*.

Results

Method A

In the experiments with CO and N_2 as reactants only NO was determined while with CO_2 and Xe, nitrogen was also measured in some runs. The reactivity of $O(^1D)$ toward N_2O was estimated mainly from the yields of NO, assuming that the amount of $O(^1D)$ produced per flash or the light intensity delivered per flash is constant. The validity of this assumption was tested in separate experiments (9), in which 12.0 Torr of H_2O flashed at 8 kV in the presence of an excess of CO gave 16.0 mTorr ± 10% of OH per flash, as determined from the amount of CO_2 formed. Furthermore, for constant N_2O pressure and flash energy, the yields of NO and N_2 produced were reproducible to within better than 10% as may be seen in Table 1 of ref. 9. The assumption then is valid to within 10%.

The photons in our system will have energy corresponding to a wavelength of about 1900 ± 100 Å. This was estimated from the assumed blackbody intensity distribution with wavelength of the flash light, the known transmission of the quartz walls of the reaction vessel, and the absorption of N_2O in the wavelength region 2300–1700 Å (18). If we assume, as discussed in the Introduction, that all the excess energy goes into the translation of the $O(^1D)$ and N_2 fragments of the photolysis of N_2O we estimate that the $O(^1D)$ in our system will have a maximum excess kinetic energy of about 41 ± 5 kcal/mol.

The experiments were done at room temperature (25 ± 2 °C). The sequence was one experiment in the absence of He followed by one with He present. The results for CO_2 and Xe are given in Table 1 and those for CO and N_2 in Table 2. The errors in the average values reported in Tables 1 and 2, about ±15% at 1σ, were estimated from an assessment of the uncertainties in all the measurements involved (pressure, absorbance) and taking into account the propagation of errors in the calculation of the final results (19). The results show that within this error the average values of N_2 and NO, produced in the experiments with CO_2 and Xe, and of NO produced in the experiments with CO and N_2, do not change by addition of He.

*n.d. = not determined.

Method B

The experiments were done at 27 ± 2 °C. The $O(^1D)$ atoms in the system have a maximum excess kinetic energy of 31.0 kcal/mol, estimated as described above. The approximate composition of the mixtures of reactants as well as the measured values of the ratio $\sum O(^3P)$Products/neopentanol in the absence and presence of He are given in Table 3. The errors in the average values of the ratio were estimated as described above and were found to be about ±20% at 1σ.

The average values of the ratio for CO_2, CO, and N_2 appear to increase slightly in the presence of He by 17, 23, and 12% respectively, while for Xe they are the same within the experimental error. The observed differences were tested by Student's t test (19) and were only significant to the $P = 0.2$ level *i.e.*, there is 80% certainty that there is a difference.

Discussion

In our previous study (9) it was found that the ratio k_{2a}/k_{2b} is independent of the excess kinetic energy of the $O(^1D)$ atoms. This finding combined with the present results of the flash photolysis of N_2O (Method *A*) indicates that k_Q/k_{N_2O} (Q = CO_2, Xe, CO, and N_2) is also independent of the excess kinetic energy of the $O(^1D)$ atoms.

The results of the second method show that addition of He produces a definite increase of the ratio k_Q/k_{neop} for CO_2, CO, and N_2, while for Xe the ratio is not affected. The results could imply that kinetically "hot" $O(^1D)$ atoms react slightly faster with neopentane or slightly slower with CO_2, CO, and N_2, than thermalized $O(^1D)$ atoms. However, they could imply, equally well, that the $O(^3P)$ atoms formed are kinetically "hot" and are responsible for the small changes in the ratio k_Q/k_{neop}. This could come about as follows. As mentioned in the section on methods, it is assumed that most of the $O(^3P)$ atoms formed will add to 1-butene to give the characteristic addition products. This assumption is valid for thermalized $O(^3P)$ which add to 1-butene about 300 times faster than they

*The experimental conditions were: approximate composition of the photolysis mixture, 1-butene 0.5 Torr, N_2O 5 Torr, neopentane 20 Torr, (CO_2, Xe, CO, N_2) 170 Torr, pressure ≈ 195 Torr, temperature 27 ± 2 °C, reaction time ≈ 900 min.

†$\Sigma O(^3P)$ products is the total yield of products formed from addition of O(³P) to 1-butene, *i.e.*, 1,2-butene oxide, *n*-butyraldehyde, and methyl ethyl ketone.

abstract hydrogen from neopentane (2), and at the ratio of neopentane/1-butene ≈ 40 used, about 90% of the thermalized O(³P) would add to 1-butene. It is possible however, that the O(³P) atoms in our experiments may possess an appreciable amount of the kinetic energy of the O(¹D) atoms and thus be preferentially scavenged by neopentane in the absence of He. There is evidence[6] that kinetically "hot" O(³P) atoms do abstract hydrogen from some paraffins substantially faster than thermalized O(³P) atoms. It is quite likely then that the observed small increase in the ratio, $\Sigma O(^3P)$Products/neopentanol, may be due to kinetically "hot" O(³P) atoms. Since it is not possible to distinguish experimentally between the two alternatives in our system, the results for k_Q/k_{neop} are inconclusive. In view of the more definite finding that k_Q/k_{N_2O} is independent of the excess kinetic energy of the O(¹D) atoms, it seems to us more probable that k_Q/k_{neop} is also independent of such energy.

However, if we attribute variation in the ratio to a "hot" atom effect, what would be the quantitative significance of the observation?

The available theoretical treatments of "hot" atom effects range from the case discussed by Wolfgang (20) for very high energy atoms generated by nuclear reactions to the case of photolytically generated "hot" hydrogen atoms treated for example by Oldershaw and Porter (ref. 21 and references therein). In these treatments the "hot" atom has a velocity much greater than the thermal velocities of the target and moderator species. This enables a simplification in the computation of the collision density function, in that the velocity distribution of the "hot" atom is the only consideration in calculating the rate of encounter of the "hot" atom with what are considered to be stationary target and moderator molecules. In nearly all of the earlier investigations of "hot" atom reactions the velocity consideration is maintained because the reactions studied have a considerable threshold to reaction such that $E > E_0 \gg kT$, where E is the translational energy of the "hot" atom and E_0 is the threshold to reaction.

The available data for O(¹D) atom reactions have been summarized, and recommended values for the rate constants have been given by Cvetanović (14). The recommended values together with calculated values of the hard-sphere collision frequencies are given in Table 4. These indicate that both presumed "hot" and thermalized O(¹D) atoms react with close to collisional rates. This, combined with the evidence that hydrocarbon reactions with O(¹D) occur to an appreciable extent at liquid argon temperatures (22), indicates that they have negligible or very

TABLE 4. Recommended values of rate constants k, and hard-sphere collision frequencies Z, of O(¹D) reactions

For personal use only.

small activation energies. Thus theories of "hot" atom reactions are not easy to apply since $O(^1D)$ atoms react over the entire range of energies from E to kT. This complication causes the collision density function to change possibly over a factor of 2 in going from $E = 50$ kcal/mol to thermalized conditions. As an illustration of this consider a competition for $O(^1D)$ between two molecules A and B of similar collision cross sections, which react at each encounter with $O(^1D)$ though A and B have molecular weights of 16 and 50 respectively. At high translational excess energies of $O(^1D)$ the molecules A and B can be considered as stationary and the relative rate measured from the products of A and B will be

$$\frac{k_{(O(^1D)+A)}}{k_{(O(^1D)+B)}} = \frac{s^2_{(O(^1D)-A)}}{s^2_{(O(^1D)-B)}} \approx 1.0$$

(s^2 = collision cross sections) which is the ratio of collision probabilities. At thermal energies the normal collison equation will apply taking into account the Maxwell distribution of velocities of the colliding species, *i.e.*

$$\frac{k_{(O(^1D)+A)}}{k_{(O(^1D)+B)}} = 1.0\left(\frac{m_B(m_{O(^1D)} + m_A)}{m_A(m_{O(^1D)} + m_B)}\right)^{1/2} \approx 1.23$$

Thus a purely physical effect could alter the apparent rate coefficient ratio.

Notwithstanding this objection a further dilemma is in quantifying the extent of moderation in experiments where the range of moderator addition would not thermalize all the "hot" atoms. This is unfortunately the case in both our experiments and those of Heicklen and coworkers (5, 6). They compute the extent of moderation by the argument

$$\langle E \rangle = \left(\frac{E'}{E}\right)^{\alpha}$$

where, $\langle E \rangle$ is the average excess translational energy of the reacting $O(^1D)$ atoms and E'/E, the fraction of kinetic energy left to the $O(^1D)$ atom after a moderating collision is calculated from the hard-sphere, stationary target model and is equal to $(m_1^2 + m_2^2)/(m_1 + m_2)^2$, and α is the relative likelihood of collision with a moderator or reactant molecule *i.e.* $\alpha = s^2_{(mod)}/\sum s^2_{(react)}$.

We suggest that the way of determining the average energy of reaction would be developed not from the average number of collisions with moderator before meeting the reactant as above, but rather from the average energy of all the reactive encounters. This method is given in detail in the Appendix.

The objection to both models is that neither takes into account nonreactive collisions between the "hot" atom and the reactant molecule. This would reduce the mean energy of reaction.

Conclusion

On the basis of our results and the comments given above we conclude that the excess kinetic energy of the $O(^1D)$ atoms does not affect the relative rates of their reaction to any measurable extent. A possible small effect in most instances borders the experimental error when it is assessed rigorously. The interpretation of the effects of additions of moderator in any quantitative fashion is almost impossible. We suggest that studies of systems in which the reactive species reacts over the entire range of energy from E to kT be studied by means of variation in the photon energy and not by moderator addition except in the cases where moderator can be added in such an excess as to thermalize the "hot" population completely.

The authors are grateful to Dr. R. J. Cvetanović for his interest in this work, his advice, and encouragement.

Appendix

Given a gas mixture containing $O(^1D)$ atoms with excess kinetic energy E, He, and reactants A_i, the $O(^1D)$ atoms may collide with A_i and react or they may collide with He and lose some of their kinetic energy. The partially cooled $O(^1D)$ atoms may then react with A_i or be cooled further by collision with He. We are interested in calculating approximately the average kinetic energy $\langle E \rangle$ with which the $O(^1D)$ atoms will react with A_i. The "hot" $O(^1D)$ atoms have a much larger velocity than the He atoms and A_i molecules (which have a Maxwell distribution of velocities), hence, we assume the latter as stationary. Let E and E' be the kinetic energy of $O(^1D)$ before and after collision with a He atom. From the hard-sphere collision model (23) the fraction of kinetic energy transferred per collision is

$$\frac{\Delta E}{E} = \frac{E - E'}{E} = \frac{2m_1m_2}{(m_1 + m_2)^2}$$

where m_1 and m_2 are the masses of $O(^1D)$ and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

He. The fraction f_e of kinetic energy left to O(¹D) after a collision is

$$f_e = \frac{E'}{E} = 1 - \frac{\Delta E}{E} = \frac{m_1^2 + m_2^2}{(m_1 + m_2)^2}$$

Let f_c be the fraction of collisions between O(¹D) and reactants A_i, $1 - f_c$ is the fraction of collisions between O(¹D) and He

$$f_c = \frac{\sum s_{A_i}^2 P_{A_i}}{s_{He}^2 P_{He} + \sum s_{A_i}^2 P_{A_i}}$$

where s_{He}^2, $s_{A_i}^2$, are the collisional cross sections of O(¹D) with He and A_i ($s_{He} = (\sigma_{O(^1D)} + \sigma_{He})/2$, σ = collision diameters) and P_{He} and P_{A_i} are the pressures of He and A_i in the gas mixture. f_c and $1 - f_c$ are the respective probabilities that O(¹D) will collide and react with A_i with kinetic energy E or that it will collide with He and be cooled to kinetic energy $f_e E$.

We have then that: f_c O(¹D) atoms react with kinetic energy E, $1 - f_c$ atoms will be cooled to $f_e E$, from these $(1 - f_c) \cdot f_c$ will react with energy $f_e E$ and $(1 - f_c - (1 - f_c)f_c) = (1 - f_c)^2$ will be cooled to $f_e^2 E$, etc. The average kinetic energy with which all the O(¹D) atoms will react is

$$\langle E \rangle = E[f_c + f_c(1 - f_c)f_e + f_c(1 - f_c)^2 f_e^2 + \ldots f_c(1 - f_c)^n f_e^n]$$

which can be rearranged by substituting the limit of the power series to

$$\langle E \rangle = f_c \cdot E[1 - f_e(1 - f_c)]^{-1}$$

For the present experiments we estimate that $\langle E \rangle$ is about 60% of E (it is 70% of E for N_2, Method A). For the experiments of ref. 6, $\langle E \rangle$ is about 77% and 61% of E at 330 and 760 Torr of He respectively. The atomic and molecular collision diameters used in these estimates were taken from the work of Rabinovitch and co-workers (24) which appear to provide a self-consistent set. The collision diameter of O(¹D), $\sigma = 2.7$ Å was taken to be between that of He and Ne. That of N_2O, $\sigma = 4.54$ Å was taken from ref. 25.

Organoselenium Chemistry. Addition of Toueneselenenyl Chloride to Ethylene: Concerning the Reported Isolation of a Stable Episelenurane

HANS J. REICH AND JOHN E. TREND
Department of Chemistry, University of Wisconsin, Madison, Wisconsin 53706

Received December 10, 1974

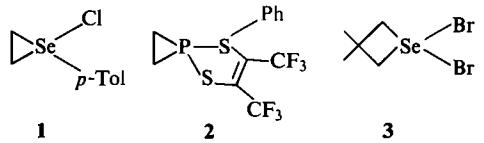
HANS J. REICH and JOHN E. TREND. Can. J. Chem. **53**, 1922 (1975).

The addition of ethylene to solutions of 4-toueneselenenyl chloride (ArSeCl) gives initially the selenide dichloride **5**. Only after more than 20% of the theoretical amount of ethylene has been added does the normal adduct appear. This anomaly is caused by the reversible reaction of the normal adduct **4** with ArSeCl, giving diselenide and **5**. The episelenurane **1** reported as a product of the reaction of ArSeCl with ethylene appears to be actually the dichloride **5**. Even at low temperature no evidence for the formation of a stable episelenurane was obtained. The ^{13}C n.m.r. spectra of several organoselenium compounds are reported, including a number of selenium-77 carbon-13 coupling constants.

HANS J. REICH et JOHN E. TREND. Can. J. Chem. **53**, 1922 (1975).

L'addition d'éthylène à des solutions de chlorure de *p*-toluènesélénenyle (ArSeCl) conduit tout d'abord à la formation du dichlorure de sélémine (**5**). Le produit d'addition normal ne commence à apparaitre que lorsque plus de 20% de la quantité théorique d'éthylène a été additionnée. Cette anomalie est dû à une réaction reversible entre le produit d'addition normal **4** et ArSeCl conduisant au disélémine et à **5**. Il a été rapporté que la réaction de ArSeCl sur l'éthylène conduit à l'épisélénuranne **1**; il semble toutefois que ce composé est le dichlorure **5**. On n'a pas pu mettre en évidence la formation d'un épisélénuranne stable, même à basse température. On rapporte les spectres r.m.n. du ^{13}C de plusieurs dérivés organosélénium; ces résultats comprennent un certain nombre de constantes de couplage sélénium-77 carbone-13.
[Traduit par le journal]

Garratt and Schmid (1) recently reported the isolation of the stable episelenurane **1**. Our interest in the stereochemistry of selenuranes (2) and in the addition of electrophilic selenium reagents to olefins (3) has led us to prepare a number of compounds related to **1**. The stability and



1 **2** **3**

spectral properties of **1** appear to be inconsistent with our observations and those reported by others.

Although phosphoranes in general show greater stability than sulfuranes and selenuranes, an attempted preparation of the epiphosphorane **2** resulted in rapid fragmentation to give ethylene even at low temperature (4).[1] Furthermore, the four-membered cyclic selenurane **3** (7) undergoes ring opening[2] below $-20°$, even though there are a number of isolable four-membered cyclic phosphoranes (8).

These and other related considerations prompted us to reexamine the preparation and characterization of **1**. In our hands the reaction of 4-toueneselenenyl chloride (ArSeCl) with excess ethylene gives the normal adduct **4** (3*a*, 9) with no indication of the formation of **1**. However, if ethylene is added to a solution of the selenenyl chloride and the reaction is monitored by n.m.r., a compound which we have identified as **5** initially appears as the major product of the reaction (Fig. 1). Signals which can be assigned to 4,4'-ditolyl diselenide (**6**) also appear in the n.m.r. spectrum. When about 25% of the theoretical quantity of ethylene has reacted, **4** begins to appear, and increases steadily at the expense of **5** and **6** as more ethylene is added. Addition of pentane when the concentration of **5** is at a maximum results in its crystallization in 23% yield (85% based on ethylene added). The material prepared in this way is identical in physical and chemical properties to **5** prepared by chlorination of **4** or by reaction of ethylene with 4-tolylselenium trichloride.

[1]It should be noted that episelenides (5) appear to be substantially less stable than epiphosphines (6).

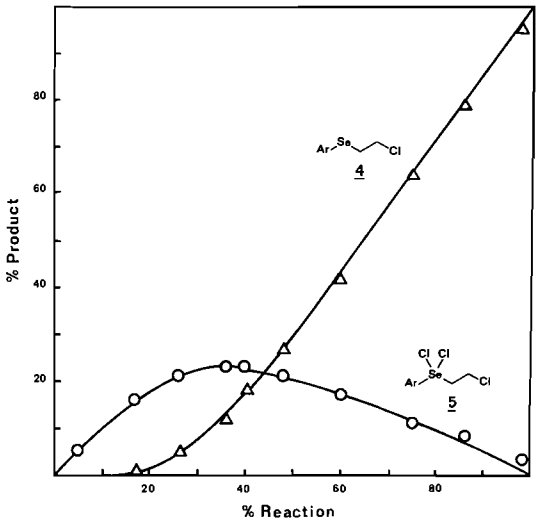

FIG. 1. Variation in product composition during the addition of ethylene to a solution of 4-tolueneselenenyl chloride (1 *M* in $CDCl_3$) at 33°; Compound **4**, △; Compound **5**, ○. The points are experimental numbers determinded by n.m.r. integration. The solid lines are calculated curves assuming the stoichiometry and mechanism of eqs. 1 and 2 with $K = k_2/k_{-2} = 13$ l mol^{-1}.

The product data summarized in Fig. 1 are rationalized by the following reactions:

[1] ArSeCl + CH_2=CH_2 $\xrightarrow{k_1}$ Ar–Se–CH$_2$CH$_2$Cl

4

[2] Ar–Se–CH$_2$CH$_2$Cl + 2 ArSeCl $\underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}}$ **4**

Ar–Se(Cl)(Cl)–CH$_2$CH$_2$Cl + ArSeSeAr

5 **6**

The equilibrium constant ($K = k_2/k_{-2}$) is approximately 13 l mol^{-1}. Thus only **5** is detected initially. As more ethylene is added, the small equilibrium concentration of ArSeCl is maintained by the chlorination of **6**, with **5** as the chlorinating agent. Solutions of appropriate mixtures of **4** and ArSeCl, or **5** and **6** prepared from the pure compounds behave the same as equivalent solutions prepared by reaction of ethylene and ArSeCl.

At low temperature (−60°) ethylene still reacts rapidly with ArSeCl (low temperature n.m.r.) giving mixtures of **4** and **5** in variable ratio (30–60% of **4**) depending on reaction conditions, but this ratio does not change when excess ethylene is present. Apparently at this temperature k_{-2} is sufficiently small that equilibration forming more ArSeCl does not occur.

Pyrolysis of **5** neat or in solution (pentachloroethane, tetrachloroethylene) gives a mixture of products, mainly 1,2-dichloroethane and **7**. Compound **7** could not be purified since it decomposed during chromatography on silica gel or during g.l.c. It was characterized spectrally by comparison with the addition products of ArSeCl to vinyl chloride.

Ar–Se(Cl)(Cl)–CH$_2$CH$_2$Cl $\xrightarrow[115°]{\Delta}$ ClCH$_2$CH$_2$Cl + ArSeCl + CH_2=$CHCl$ ⟶ **7** +

5

7

8

Reaction mixtures containing **5**, prepared by the reaction of ArSeCl with a deficiency of ethylene as described above, also give **7** and 1,2-dichloroethane on pyrolysis. *No additional **4** is formed during this pyrolysis.*

We have thus been unable to detect the presence of **1** during the reaction of ethylene with ArSeCl. Even at −60°, **4** is formed as a product, clearly incompatible with Schmid and Garratt's observation that **1** is stable above room temperature. Furthermore, **5** is formed in these reactions under appropriate conditions, and the detailed proton and carbon n.m.r. data reported for **1** (on which the structure assignment for **1** was largely based) are identical in every respect with the data we have obtained for **5** (Table 1). Table 2 lists the carbon-13 n.m.r. parameters for ArSeCl, **6**, **7**, **8**, and the model systems 4-tolyl propyl selenide and 4-tolyl propyl selenide dichloride. The c.m.r. parameters (chemical shifts, J_{C-H}, J_{C-Se}) of these compounds when compared with the data for **5** in Table 1 provide further verifica-

[e]AA′BB′ pattern with J_{AB} = 8.6 Hz (9.0 Hz).

tion for the structure assignment of **5**. We conclude that the compound identified by Schmid and Garratt as the episelenurane **1** is, in fact, the selenide dichloride **5**.

Apart from the identity of all available spectral parameters with those of **5**, there are features in the n.m.r. spectrum reported for "**1**" which are inconsistent with the episelenurane structure. The p.m.r. spectrum was reported as an AA′BB′ pattern for the ethylene fragment. Since the c.m.r. spectrum shows different carbons, the AA′ protons must be geminal. Any reasonable structure for the covalent episelenurane should have an ABCD pattern. Consideration of possible Berry pseudorotational pathways for this compound leads to the conclusion that no process exists which could average the ABCD pattern to give the proper AA′BB′ pattern while maintaining nonequivalent carbons. An episelenonium salt would have an AA′BB′ pattern but AA′ would be *cis*-vicinal rather than geminal. The pattern is, of course, exactly as expected for **5**. The unusual hybridization in three-membered rings usually results in characteristic C–C and C–H couplings.[3] The observed couplings for "**1**" are again as expected for an acyclic compound.

[3]The C–H couplings in thiirane *S*-oxide and *S*,*S*-dioxide are between 170 and 172 Hz (10). Carbon–carbon couplings have not been reported for thiiranes but cyclopropanes have internal C–C couplings of 10–16 Hz (11), as compared to 37.25 Hz for "**1**".

Experimental

Proton magnetic resonance spectra were obtained in $CDCl_3$ on a Varian XL-100, Brueker WH-270, or Jeol MH-100 spectrometer. Carbon-13 (Fourier transform) n.m.r. spectra were measured at natural abundance in $CDCl_3$ on the XL-100 system, undecoupled or using noise modulated proton decoupling, and are reported in Tables 1 and 2. Mass spectra were obtained on an AEI MS-902 spectrometer. Melting points are uncorrected.

4,4′-Ditolyl Diselenide (6)

The diselenide was prepared by published procedures from 4-tolylmagnesium bromide, m.p. 43–45° (lit. (12) 47°); p.m.r.: δ 2.33 (s, 3H), 7.07 and 7.49 (AA′BB′, J_{AB} = 8.0 Hz, 4H).

4-Tolueneselenenyl Chloride (ArSeCl)

To a solution of 1.7 g (5.0 mmol) of **6** in 15 ml chloroform was added dropwise 0.40 ml (4.9 mmol) of freshly distilled sulfuryl chloride. The mixture was stirred 5 min and purged of the SO_2 formed with a stream of nitrogen. Distillation of the dard red-orange liquid (b.p. 62°/0.07 mm) gave 1.55 g (75%) of ArSeCl; p.m.r.: δ 2.35 (s, 3H), 7.12 and 7.62 (AA′BB′, J_{AB} = 8.0 Hz, 4H).

2-Chloroethyl 4′-Tolyl Selenide (4)

A solution of 154 mg (0.75 mmol) of ArSeCl in 5 ml of $CHCl_3$ was purged with nitrogen. Ethylene was bubbled through the solution at room temperature with a glass tube until the orange-red color had faded to a light yellow and no further lightening was observed. Evaporation of solvent in a stream of nitrogen gave 175 mg (100%) of crude product. The p.m.r. spectrum showed the presence of only the adduct **4** and no others. Despite repeated purifications (low temperature crystallization from pentane or ether and sublimation) the melting point could not be raised above room temperature; however, the n.m.r. data (both ^1H and ^{13}C) were identical to those reported (1). Mass spectrum *m/e* Calcd. for $C_9H_{11}SeCl$: 233.97137. Found: 233.97157.

2-Chloroethyl 4′-Tolyl Selenide Dichloride (5)

A solution of 595 mg (1.75 mmol) of 4,4′-ditolyl diselenide (**6**) in 10 ml of $CHCl_3$ was cooled to 0° and 750 mg (5.56 mmol) of sulfuryl chloride was added dropwise with stirring. As the reaction proceeded SO_2 was evolved and a pale yellow precipitate (4-tolylselenium trichloride) was formed. On completion of the addition, ethylene was bubbled through this slurry until the precipitate had dissolved and a nearly colorless solution was obtained. Evaporation of solvent and trituration of the residue with cold pentane followed by filtration afforded 940 mg (88%) of a faint green powder, m.p. 102–102.5° (sealed tube). Crystallization from CCl_4 and pentane gave an analytical sample, m.p. 102–102.5°.

Anal. Calcd. for $C_9H_{11}Cl_3Se$: C, 35.50; H, 3.64; Cl, 34.93; Se, 25.93. Found: C, 35.42; H, 3.72; Cl, 35.04; Se, 26.31.

The Reaction of Ethylene with 4-Tolueneselenenyl Chloride

At Room Temperature (Fig. 1)

A solution (1 *M*) of ArSeCl in $CDCl_3$ was treated at room temperature with successive aliquots of ethylene added by bubbling the gas through the solution for 10–30 s using a glass capillary. At the end of each addition the p.m.r. spectrum of the solution was measured and the relative amounts of 2-chloroethyl 4′-tolyl selenide (**4**) and its dichloride (**5**) were determined by integration of the peaks at δ 2.9–3.8 and 4.2–4.6, respectively, *vs.* the Ar–methyl peaks at δ 2.3–2.4. Initially all the ethylene was immediately consumed but as the reaction neared completion (the last 5–10% reaction) the consumption of ethylene slowed so that an ethylene resonance at δ 5.29 was observed. The integration of this resonance slowly decreased with concomitant increase in product integration.

The equilibrium constant ($K = k_2/k_{-2} = 13 \pm 3$ l mol^{-1}) was determined using the p.m.r. integration data and the following relationships.

$$[\mathbf{5}] = [\mathbf{6}]$$

$$[\mathrm{ArSeCl}] = 1 - [\mathbf{4}] - 2[\mathbf{6}] - [\mathbf{5}]$$

$$K = [\mathbf{5}][\mathbf{6}]/[\mathrm{ArSeCl}]^2[\mathbf{4}]$$

The theoretical curves in Fig. 1 were calculated by solving the following equation for X (the %**4** formed) while varying Y (the %reaction) and assuming $K = 13$. The equation is derived by assuming the stoichiometry and mechanism of eqs. 1 and 2.

$$4KX^3 + (4Ka - 1)X^2 + (Ka^2 + 2Y)X - Y^2 = 0$$

$$a = 1 - 3Y$$

$$\%\mathbf{4} = X$$

$$\%\mathbf{5} = Y - X$$

At Low Temperature

While ethylene was bubbled through 0.25 ml of $CDCl_3$ at −65° (Dry Ice – $CHCl_3$ bath) a solution of 50 mg (0.24 mmol) of ArSeCl in 0.20 ml of $CDCl_3$ was added slowly by syringe at such a rate as to allow the selenenyl chloride to react before attaining any significant concentration in the ethylene-saturated $CDCl_3$ solution (as indicated by the absence of any orange-red color). The low temperature (−60°) p.m.r. spectrum of the resulting solution showed a large excess of ethylene present and a *ca.* 5:2 ratio of **4** to **5** (selenide to selenide dichloride) by integration.

Ethylene was bubbled into a solution of 50 mg (0.24 mmol) of **6** in 0.45 ml of $CDCl_3$ at −65° until the solution decolorized. The low temperature (−65°) p.m.r. spectrum showed excess ethylene present and a *ca.* 1:1 ratio of **4** to **5**. On warming to room temperature, the excess ethylene was consumed and the product composition altered to a ratio of 5:1. By addition of more ethylene the composition of the solution was further altered so that only **4** and ethylene were observed.

Isolation of 5 and 6

Ethylene was bubbled via a glass capillary into a solution prepared from 206 mg (1 mmol) of ArSeCl and 0.40 ml of $CDCl_3$ (purified by filtration through alumina) until the p.m.r. spectrum of the solution showed the integration of the resonances attributed to 2-chloroethyl 4′-tolyl selenide dichloride (**5**) to be at a maximum (*ca.* 25% of the total ArSeX species). Resonances attributed to 2-chloroethyl 4′-tolyl selenide (**4**) were also evident to the extent of *ca.* 7% of the total ArSeX species. An equal volume of pentane was added and the solution cooled to −78° until crystals formed. The mother liquor was decanted while the remaining crystalline mass was washed with CCl_4. The crude material obtained (74 mg, 24% based on ArSeCl, 75% based on ethylene added) was recrystallized from CCl_4 to give 54 mg of nearly colorless crystals m.p. 102.5–103.5°. Further recrystallization from pentane did not improve the m.p. The n.m.r. data for this compound were identical to that of **5** (Table 1).

Anal. Calcd. for $C_9H_{11}Cl_3Se$: C, 35.50; H, 3.64. Found: C, 35.16; H, 3.40.

The combined mother liquor and washings were evaporated to dryness and the oily residue crystallized from absolute ethanol to give 65 mg of yellow crystals identified as 4,4′-ditolyl diselenide (**6**) by n.m.r. comparison and m.p. (44–46°). From the mother liquor an additional 21 mg of **6** could be obtained by thin-layer chromatography (pentane – sliica gel) to give a 51% yield based on ArSeCl, 75% based on ethylene added. From the t.l.c. a second fraction was obtained containing a small amount of **4** (identified by its p.m.r. spectrum) accompanied by other unidentified products.

The Equilibrium Behavior of Binary Mixtures of Pure Components of the ArSeCl–Ethylene Reaction

Solutions of 5 and 6

When 76 mg (0.25 mmol) of authentic **5** and 42.5 mg (0.125 mmol) of pure **6** were dissolved in 0.45 ml of $CDCl_3$, a solution was obtained which by its p.m.r. spectrum was found to contain **4** and ArSeCl in addition to **5** and **6**. By integration and by assuming the stoichiometry of eq. 2, a $K = 9$ l mol^{-1} was determined for the mixture, in good agreement with the K determined for the reaction of ArSeCl with ethylene.

Solutions of 4 and ArSeCl

When 58.4 mg (0.25 mmol) of **4** and 51.4 mg (0.25 mmol) of ArSeCl were combined in 0.45 ml of $CDCl_3$, the p.m.r. spectrum of the solution revealed the presence of **5** and **6**. The K for this mixture was found to be 14 l mol^{-1}, again in agreement with previous results.

Pyrolysis of 2-Chloroethyl 4′-Tolyl Selenide Dichloride (5)

A neat sample (305 mg, 1 mmol) of **5** was heated in a sealed tube for 30 min at 115°. The tube was cooled to −78° and the red-orange pyrolysate dissolved in 0.20 ml of $CDCl_3$. The p.m.r. spectrum of the solution showed **5** to be 45% decomposed (by integration) to a mixture of two major products: 1,2-dichloroethane and a product tentatively identified as 1,2-dichloroethyl 4′-tolyl selenide (**7**). When **5** was pyrolyzed in tetrachloroethylene or pentachloroethane solution at 115°, similar results were obtained. When samples containing **5** prepared by the addition of ArSeCl to ethylene as described above were pyrolyzed at 115° in pentachloroethane, product mixtures were obtained similar to those from the pyrolysis of authentic **5**. No additional **4** was formed. Attempts to isolate pure 7 by thin-layer chromatography and gas–liquid chromatography failed due to separation difficulties and the decomposition of **7** under these conditions. The presence of 1,2-dichloroethane was established by direct p.m.r. and c.m.r. comparison with an authentic sample. Direct n.m.r. comparison also established the presence of **6**. The identification of **7** was based on its carbon (Table 2) and p.m.r. spectra: δ 2.34 (s, 3H), 3.77, 3.87, and 5.12 (ABX, J_{AB} = 12.0 Hz, J_{AX} = 8.2 Hz, J_{BX} = 5.2 Hz, 3H), 7.16 and 7.60 (AA′BB′, J_{AB} = 8 Hz, 4H). Further evidence for the identity of **7** was provided by n.m.r. comparison with the spectra of the compound obtained as the minor adduct of the addition of ArSeCl to vinyl chloride (see below).

Addition of 4-Toluneselenenyl Chloride to Vinyl Chloride

Vinyl chloride was bubbled into a solution of 205.5 mg (1 mmol) of ArSeCl in 0.30 ml of $CDCl_3$ until the solution was completely colorless. The n.m.r. spectra (^{13}C, ^1H) of the solution showed the presence of two products identified as 1,2-dichloroethyl 4′-tolyl selenide (**7**) and 2,2-dichloroethyl 4′-tolyl selenide (**8**) in a *ca.* 2:3 ratio by integration; p.m.r. spectrum of **8**: δ 2.28 (s, 3H), 3.36 (d, J = 6.5 Hz, 2H), 5.66 (t, J = 6.5 Hz, 1H), 7.04 and 7.42 (AA′BB′, J_{AB} = 8 Hz, 4H); p.m.r. spectrum of **7**, as above.

1-Propyl 4′-Tolyl Selenide

Sodium borohydride (760 mg, 20 mmol) was added under nitrogen in small portions to a slurry of 2.55 g (7.5 mmol) of 4,4-ditolyl diselenide (**6**) in 50 ml of absolute ethanol. After the vigorous evolution of heat and hydrogen had subsided a pale orange-yellow solution was obtained and 2.46 g (20 mmol) of 1-bromopropane was added. The reaction was allowed to stir overnight and then quenched with water and a few ml of 10% HCl. The mixture was then extracted with 100 ml of pentane and 25 ml of ether, and the combined organic layers dried over sodium sulfate. Evaporation of solvent and distillation (b.p. 54°/0.1 mm) gave 2.40 g (75%) of the selenide; p.m.r.: δ 0.93 (t, J = 7.5 Hz, 3H), 1.64 (sextet, J = 7.5 Hz, 2H), 2.23 (s, 3H), 2.72 (t, J = 7.5 Hz, 2H), 6.95 and 7.35 (AA′BB′, J = 8 Hz, 4H). Mass spectrum *m/e* Calcd. for $C_{10}H_{14}Se$: 214.02598. Found: 214.02598.

1-Propyl 4′-Tolyl Selenide Dichloride

A solution of 1.07 g (50 mmol) of 1-propyl 4′-tolyl selenide in 2 ml of $CHCl_3$ was treated with 0.41 ml (51 mmol) of sulfuryl chloride. As the reagent was added the solution became bright lime green and then colorless as the addition was completed. On evaporation a quantitative yield of the crude dichloride was obtained as a faintly yellow crystalline mass. Recrystallization from CCl_4 afforded 1.20 g (85%) of colorless crystals, m.p. 79–80°; p.m.r.: δ 1.15 (t, J = 7.5 Hz, 3H), 2.26 (sextet, J = 7.5 Hz, 2H), 2.32 (s, 3H), 4.14 (t, J = 7.5 Hz, 2H), 7.21 and 7.76 (AA′BB′, J = 8.5 Hz, 4H).

Anal. Calcd. for $C_{10}H_{14}Cl_2Se$: C, 42.28; H, 4.97. Found: C, 42.28; H, 4.85.

Horseradish Peroxidase. XVIII. The Arrhenius Activation Energy for the Formation of Compound I

W. D. HEWSON AND H. B. DUNFORD

Department of Chemistry, University of Alberta, Edmonton, Alberta T6G 2E1

Received November 15, 1974

W. D. HEWSON and H. B. DUNFORD. Can. J. Chem. **53,** 1928 (1975).

The rate of formation of compound I from the reaction of native horseradish peroxidase with hydrogen peroxide was studied from 3.7–70.0 °C. The second-order rate constants were used to construct an Arrhenius plot from which the activation energy of this reaction was calculated to be 3.5 ± 1.0 kcal/mol. The irreversibility of the reaction at 25 °C was confirmed by comparing absolute absorbance changes as recorded by the stopped-flow apparatus with the known spectra of the native enzyme and compound I.

W. D. HEWSON et H. B. DUNFORD. Can. J. Chem. **53,** 1928 (1975).

On a étudié, de 3.7 à 70.0 °C, la vitesse de formation du composé I par réaction de la peroxydase du raifort naturel avec le peroxydyde d'hydrogène. On a utilisé les constantes de vitesse du deuxième ordre pour établir une courbe d'Arrhénius à partir de laquelle on a pu établir que l'énergie d'activation de la réaction est de 3.5 ± 1.0 kcal/mol. On a pu confirmer que la réaction est irréversible à 25 °C en comparant les changements d'absorbtion absolue tels que mesurés par un appareil à flux stoppé avec le spectre connu de l'enzyme at du composé I.

[Traduit par le journal]

Introduction

The stoichiometric reaction for the formation of compound I from native horseradish peroxidase (HRP) is

[1] $$HRP + H_2O_2 \rightarrow \text{Compound I}$$

and is known to be second order over a range of substrate concentrations (1). The first temperature dependence of the rate of this reaction was undertaken in 1947, at which time there appeared to be no significantly measurable increase in rate with temperature (2, 3). The reverse rate of reaction 1 has been considered to be very small, approximately seven orders of magnitude smaller than the forward rate (1). The present paper describes experiments performed to obtain the temperature dependence of the reaction from which the activation energy for the formation of compound I can be calculated. Also, changes in absorbance measurements have been used to verify the essential irreversibility of this reaction.

Experimental

Materials

Horseradish peroxidase (Lot No. 7024524) was purchased from Boehringer-Mannheim Corp. as an ammonium sulfate precipitate and was prepared for use by extensive dialysis against triply distilled water followed by Millipore filtration. Isozyme C, using the notation of Shannon *et al.* (4) and of Paul and Stigbrand (5) has been determined to be the major component of HRP obtained from Boehringer-Mannheim Corp. (6). Despite some fairly complicated kinetics, there has never been any valid kinetic evidence for a detectable amount of a second isozyme component (7). Enzyme purity and concentration were determined from absorbance measurements at 280 and 403 nm. A purity number (PN is a ratio of absorbances, 403/280 nm) of 3.54 was obtained. Published values usually lie between 2.8 and 3.2. It was found that extensive dialysis tends to increase PN values. Triply distilled water was used throughout and buffers were made from reagent grade materials.

Apparatus

Kinetic runs were carried out on a Gibson-Durrum stopped-flow spectrophotometer model D-110 in the absorbance mode at 403 nm with a 2 cm cuvette. Steady-state spectra and absorbance measurements were made on a Cary 14 spectrophotometer, p*H* was measured with an Orion 801 p*H* meter outfitted with a Fisher combination electrode calibrated with fresh standard buffers, and solution temperatures were maintained to ±0.3 °C by circulating thermostated water. The upper limit of the temperature range was 70.0 °C because at any higher temperature a significant amount of HRP denatured during the incubation period. A check for decomposition of hydrogen peroxide and/or enzyme was carried out by incubating the solutions in the drive syringes to 70.0 °C for a period of time approximately equal to the time necessary to perform a kinetic experiment. Then the solutions were quickly cooled to 25.0 °C and a kinetic experiment performed in order to compare the absorbance change accompanying the reaction after incubation with the absorbance change expected without the incubation period. Because enzyme absorption at

For personal use only.

403 nm decreases with denaturation, the lack of a significant decrease in the change of absorption indicated no destruction of either reactant.

Methods

Stopped-flow kinetics were performed under second-order conditions where the initial concentrations of HRP and hydrogen peroxide are equal. The concentration of hydrogen peroxide was determined as previously described (8). One drive syringe contained 2.0 μM HRP and the other contained 2.0 μM hydrogen peroxide, resulting in an initial reactant concentration of 1.0 μM for both reactants in the 2 cm cuvette. Both drive syringe solutions had phosphate buffer (pH 7.10 $\pm$ 0.02 and ionic strength 0.01) and 0.10 M potassium nitrate as common components for a total ionic strength of 0.11. The reaction resulted in a decrease in absorbance as a function of time because the molar absorptivity at 403 nm for compound I is less than for HRP (ε_{HRP} = $1.02 \times 10^5\ M^{-1}\ cm^{-1}$ (9) and $\varepsilon_{compound\ I} = 5.31 \times 10^4\ M^{-1}\ cm^{-1}$ (10, 11)[1].) Checks on the absorbance changes recorded by both instruments should be the same. In the experiments performed on a Cary 14 spectrophometer, initiation of the formation of compound I was accomplished using a few microliters of hydrogen peroxide (equimolar with respect to HRP) on the end of a Teflon plumper.

Steady-state spectra, initiated in the same fashion, were recorded with [HRP] = 2.0 μM, [I^-] = 10.0 μM, and [H_2O_2] = 4.0 μM. The steady state spectrum of such a reaction mixture is known to be that of compound I (11). To achieve the steady state for a sufficiently long period of time to record the spectrum (about 50 s), the enzyme must cycle many times, the period of the cycle depending on the rate constant of the compound I reaction with iodide ion and the concentration of iodide ion, which govern the rate-controlling step. Iodide ion was in excess of the hydrogen peroxide so that should the steady state end before the spectrum was scanned the enzyme would revert to the native form and no longer exist as compound I which would facilitate detection of the end of the steady state.

The integrated rate expression for the reaction of HRP with H_2O_2 where reactants are in equal initial concentration and combine in a 1:1 stoichiometry is

$$[2] \qquad 1/[HRP]_t = kt + 1/[HRP]_0$$

The concentration of HRP at time t was determined by

$$[3] \qquad [HRP]_t = [HRP]_0(V_t - V_\infty)/(V_0 - V_\infty)$$

where V is the stopped-flow apparatus photomultiplier voltage and V_0, V_t, and V_∞ are voltages at times 0, t, and ∞. V_∞ values were determined by retriggering the data collection system (12) about 8 s after the reaction data had been recorded. Rate constants were determined from linear least-squares analysis of plots of $1/[HRP]_t$ *vs.* t. These plots were linear for 3 to 5 half-lives.

A near neutral pH of 7.10 was chosen because the rate of formation of compound I has been shown to be virtually pH independent from pH 5 to 9 (13). Preparing solutions at this pH at room temperature served to minimize any change in rate that might be a consequence of the change in pH of the solution with temperature.

[1]The $\varepsilon_{compound\ I}$ is corrected to the new reference value for HRP at 403 nm.

Results and Discussion

The Arrhenius plot shown in Fig. 1 was constructed from the rate constants recorded in Table 1 and yields an activation energy of 3.5 $\pm$ 1.0 kcal/mol.[2] This value corresponds to isozyme C. The activation energy of compound I formation with hydrogen peroxide has recently been determined independently for isozymes A2 and C to be 4.0 and 2.2 kcal/mol, respectively. These values were obtained from measurements at three temperatures over the range of 10 to 40 °C (14). If the experimental error of $\pm$1 kcal/mol can also be applied to their measurements (14), then all three values are identical within experimental error. A small value for the activation energy is necessary if HRP is to be an efficient enzyme.

The transition state theory interprets the Arrhenius preexponential factor A as

$$[4] \qquad A = \frac{\kappa kT}{h} \exp(\Delta S^{\ddagger}/R)$$

where κ, k, h, and $S^{\ddagger}$ are, respectively the transmission coefficient (usually assumed to be unity), Boltzmann's constant, Planck's constant, and the entropy of activation. The entropy of activation obtained from eq. 4 is -12.8 ± 0.1 cal/mol-deg, the negative value indicating a reaction where the activated complex is more ordered (less random) than the two reactants in accord with the fact that the enzyme and hydrogen peroxide must combine to form compound I (15). This correlates with a small steric factor, according to collision theory, which would lower the reaction rate.

A bimolecular rate constant in the order of $10^7\ M^{-1}\ s^{-1}$ is somewhat below the value expected for diffusion control of rate unless there are rigid steric requirements for reaction (16, 17). The limit of the value for the bimolecular rate constant is approximately $10^{10}\ M^{-1}\ s^{-1}$ for molecules of small cross-sectional area (18).

[2]The activation energy error was estimated by raising the value of the rate constant of the highest temperature and lowering the value of the rate constant at the lowest temperature by half the experimental error in the average rate constant determination; a new slope was calculated using these two points and gave a new activation energy different by 1.0 kcal/mol.

70.0	5.6±0.6	7

*Errors are the average deviation from the mean.

The value might be expected to be lower for a relatively large, thus more slowly diffusing enzyme but the fact that it presents a bigger target for encounter with substrate compensates for its slower rate of diffusion. Note that this is only strictly applicable to molecules that are uniformly reactive over their entire surface, which may (19) or may not (20) be a good model for an enzyme with an active site. In an interesting publication by Schmitz and Schurr (21) it is pointed out that moderate angular constraints imposed on reactants that orient by rotational diffusion can lead to a rather drastic decrease in the maximum diffusion-controlled rate of values of 10^6 to 5×10^8 M^{-1} s^{-1}. They contend that it is plausible that reactions thought to be far removed from the diffusion-controlled rate might in fact be strongly viscosity dependent. The model used by these workers is a rotating sphere diffusing to a localized site on a plane. This appears to be an accurate model for the planar ferriprotoporphyrin IX prosthetic group which is the active site of HRP. When a reaction rate is strongly viscosity dependent, the activation energy can in large part be determined by the temperature variation of the diffusion coefficients of the reactants as the viscosity of the water changes and not solely determined by the fraction of reactant molecules with sufficient energy to form products. Other collisions between the enzyme's protein moiety and hydrogen peroxide may be ineffective (20).

Although indisputable proof that the reaction rate between HRP and hydrogen peroxide is diffusion-controlled is lacking, the conjecture is worth considering. Since superoxide dismutase is known to react with the oxygen radical anion ($O_2 \cdot^-$) at a rate of $(1.5 \pm 0.1) \times 10^9$ M^{-1} s^{-1} (22) it might be inferred that 10^7 M^{-1} s^{-1} does not represent a diffusion-controlled rate limit. However, no entropy of activation (or steric factor) has been measured for the superoxide dismutase reaction.

When the natural logarithm of the fluidity of water is plotted against T^{-1} (K^{-1}) over the same temperature range as the Arrhenius plot, a slope of $(-1.92 \pm 0.03) \times 10^3$ deg is obtained (23), which when multiplied by the gas constant, R, gives the activation energy for the fluidity of water as 3.89 ± 0.04 kcal/mol (fluidity is the reciprocal of viscosity). This is the theoretical minimum activation energy for reactions in aqueous solution (24) and is the same as the Arrhenius activation energy for compound I formation within experimental error.

The percentage error in the measurement of a second-order rate constant can be calculated according to the method of Benson (25). Percentage errors calculated with this method at several temperatures gave an average of 37 ± 5%.

The study conducted in 1947 (2) quotes rate constants of 8, 9, and 9, all times 10^6 M^{-1} s^{-1} at 3, 25, and 42 °C, respectively, which are

consistently lower than the rate constants in Table 1 measured at comparable temperatures. Dolman *et al.* (13) have measured the rate of compound I formation to be $1.84 \times 10^7\ M^{-1}\ s^{-1}$ at p*H* 7.07 and 25 °C. This value agrees more favorably with the present work.

It is interesting to compare briefly the combining rates of other heme systems with oxygen containing substrates. The rate of lactoperoxidase compound I formation has been measured at p*H* 7.17 and 25 °C by Maguire *et al.* (26) to be $1.2 \times 10^7\ M^{-1}\ s^{-1}$, and by Chance (27) at p*H* 7.0 to be $2 \times 10^7\ M^{-1}\ s^{-1}$. The rate of formation of compound I of HRP has been measured with methyl, ethyl (1), and hydroxymethyl (28) hydroperoxides and gave the respective rate constants 1.5, 3.6, and 0.5 all times $10^6\ M^{-1}\ s^{-1}$ which are much slower than for hydrogen peroxide. Bonnischsen *et al.* (2) have measured the rate of hydrogen peroxide and horse blood catalase combination at 25 °C to be $3.5 \times 10^7\ M^{-1}\ s^{-1}$.

Much of the work on the kinetics of the reaction of blood hemoglobin and myoglobin with oxygen has been compiled by Antonini and Brunori (29). Ilgenfritz and Schuster recently used the temperature-jump technique to measure the rate of oxygen binding to blood hemoglobin (30). At low oxygen saturations a fast binding step with a rate constant of $4 \times 10^7\ M^{-1}\ s^{-1}$ was found and at high oxygen saturation two steps were found, a fast and a slow step with the respective rate constants 4×10^7 and $5 \times 10^6\ M^{-1}\ s^{-1}$. They conclude that the first binding step occurs as fast as the last step, and the low affinity of deoxyhemoglobin for oxygen arises from the fast dissociation rate of Hb_4O_2, $10^3\ s^{-1}$. The two hemoproteins show many similarities in their kinetics. However, electric field jump measurements have shown a time constant of 10^{-7} s for blood hemoglobin but a correspondingly short time constant, could not be found for myoglobin, which, in the oxidized state, gave time constants of 10^{-6} s (31). The rate of reaction of horse blood catalase with hydrogen peroxide has been measured at two different temperatures and, assuming the validity of the Arrhenius equation, the activation energy was calculated to be 1.7 kcal/mol (2). This value is well below the minimum activation energy for the fluidity of water and is therefore of doubtful validity.

To test whether reaction 1 was going to completion in the stopped-flow apparatus, the absorbance change, ΔA, at 25 °C was determined several times with an average $\Delta A = 0.095 \pm 0.003$. The theoretical ΔA at this temperature for the same solution and cuvette specifications is 0.0978. Steady-state spectra of compound I reacting with iodide ion, where more than 99% of the enzyme should be in the form of compound I gave $\Delta A = 0.100$ within the reading precision of the recorded spectra. These absorbance measurements substantiate the claim that reaction 1 is essentially irreversible (1).

Steady-state spectra were attempted at higher temperatures; but the much accelerated spontaneous decay of compound I to compound II, which is a one electron reduction of the enzyme interfered with the steady state. For p*H* values slightly greater than 7, compound I is known to react with iodide ion approximately 1000 times faster than compound II (11, 12). This means that any spontaneously formed compound II will react much less readily with iodide ion and therefore accumulate in the system if it is formed spontaneously. Accumulation of some compound II occurred at 40 °C thereby making accurate absorbance measurements impossible for steady-state experiments. The ΔA for steady-state spectra at 40 and 55 °C agreed reasonably well with the ΔA as measured at the corresponding temperature in the stopped-flow apparatus but, because of the problem of compound I spontaneously forming compound II, these results should probably not be relied upon to confirm the irreversibility of reaction 1 at these temperatures.

The Stability and Conformation of the 1,3,6,8-Tetraazatricyclo[4.4.1.1^{3,8}]dodecane System: the Structure of the Condensation Product of 1,2-Diaminocyclohexane and Formaldehyde

P. MURRAY-RUST AND F. G. RIDDELL[1]

Department of Chemistry, University of Stirling, Stirling, Scotland

Received November 22, 1974

P. MURRAY-RUST and F. G. RIDDELL. Can. J. Chem. **53**, 1933 (1975).

The condensation of *d,l-trans*-1,2-diaminocyclohexane with formaldehyde gives a pentacyclic molecule based on the 1,3,6,8-tetraazatricyclo[4.4.1.1^{3,8}]dodecane nucleus. This was shown to have S_4 symmetry by ^{1}H n.m.r. and an X-ray analysis showed crystals to be orthorhombic, *Fddd*, $a = 12.02$, $b = 19.25$, $c = 12.90$ Å. The symmetry of the compound in the crystal was D_{2d} due to a disordered arrangement and structure analysis was carried out to $R = 0.166$. When optically active diamine was used as starting material, the analogous reaction did not occur and this was attributed to strain in the tricyclic system. The conformation of the molecule is related to those of similar compounds as found by X-ray analysis.

P. MURRAY-RUST et F. G. RIDDELL. Can. J. Chem. **53**, 1933 (1975).

La condensation du *d,l-trans*-diamino-1,2 cyclohexane avec la formaldéhyde conduit à une molécule pentacyclique comportant le noyau tétraaza-1,3,6,8-tricyclo[4.4.1.1^{3,8}] dodécane. On a établi, par r.m.n. du proton que la molécule a une symétrie S_4; la diffraction des rayons-X revèle que les cristaux sont orthorhombiques, *Fddd*, $a = 12.02$, $b = 19.25$, $c = 12.90$ Å. A cause d'un arrangement désordonné la symétrie de ce composé dans le cristal est D_{2d}. La structure a été affinée jusqu'à une valeur de R de 0.166. Si une diamine optiquement active est utilisée comme produit de départ, la réaction de condensation n'a pas lieu; ceci est attribué à une tension dans le système tricyclique. La conformation de la molécule est comparée à celles établies par diffraction des rayons-X pour des composés similaires.

Introduction

The 1,3,6,8-tetraazatricyclo[4.4.1.1^{3,8}]dodecane system (**1**) is of considerable conformational interest. The parent compound has been investigated both by n.m.r. (1) and X-ray single crystal (2) analysis but doubt remains as to whether the system has D_{2d} symmetry in the ground state or consists of rapidly interconverting species with the lower S_4 symmetry. The crystal structure had site symmetries for the molecule of D_{2d} but this could have been due to disordered molecules (S_4) or even inversion in the solid state. By making the aromatic derivative (**2**) and analyzing its crystal structure (3) it was shown that the nucleus could be forced into the D_{2d} arrangement (even if this is not the ground state geometry for **1**). The present study describes a similar attempt to force the nucleus into a conformation which possesses only S_4 symmetry, where the two-carbon bridge must adopt a *gauche* conformation. A simple way to do this is to make the bridge part of a cyclohexane ring which, if it adopts the chair conformation, will force the torsional angle in the 4,5 bond to be about 60°,

approximately the angle predicted by Dreiding models (2). This might be accomplished by reacting *trans*-1,2-diaminocyclohexane with formaldehyde when two products could be expected. Reaction of one molecule of *d-trans*-1,2-diaminocyclohexane with one molecule of its enantiomer and four molecules of formaldehyde gives a product with S_4 symmetry[2] but if optically active diamine is used this cannot be formed. The only possible tricyclic product in this case is **4** (with D_2 symmetry) which is very highly strained and it is probable that other compounds such as **5** might be more stable. (This is analogous to the formation (4) of **6** from 1,3-diaminopropane and formaldehyde, where the tricyclic system would be severely overcrowded and has not been observed.) The preparation of **3** was therefore undertaken in an attempt to verify its existence and to produce crystals whose structure could be analyzed by X-ray crystallography.

Experimental

Condensation of 1,2-Diaminocyclohexane with Formaldehyde

1,2-Diaminocyclohexane was obtained from R. Emanuel Ltd. (stated to contain 80% of the *trans* isomer, the rest being mainly *cis*). As model building suggested that this impurity was unlikely to form a stable compound of the type required, the commercial sample was used without further treatment. The diamine (0.02 mol) was reacted with the calculated amount of formaldehyde in aqueous sodium hydroxide by a similar procedure (2) to that used for the preparation of **1**. After 3 weeks the solution was reduced in volume and the gluey residue extracted with acetone, from which small transparent rhombic bipyramidal crystals were obtained on evaporation. The molecular formula of these was confirmed by mass spectrometry (M^+ 276) and by the X-ray molecular weight determination (see below). The room temperature ^{1}H n.m.r. spectrum showed a well-resolved AB quartet at 5.9 and 6.2 τ (J = *ca.* 15 Hz) and broader resonances at *ca.* 7.5, 8.25, and 8.7 τ (Perkin Elmer R32 at 90 MHz).

The diaminocyclohexane was resolved via its hydrogen *d*-tartrate salt, treatment with base, and redistillation. This was then condensed with formaldehyde in an identical manner to that employed for the racemic diamine but no crystalline product could be isolated. The ^{1}H n.m.r. spectrum of the resulting syrup was clearly due to a mixture of products but showed no trace whatsoever of the AB quartet observed for the previous compound.

X-Ray Structure Analysis of the Crystalline Product

A rhombic bipyramid of *ca.* 0.3 × 0.2 × 0.2 mm was photographed by Weissenberg and precession techniques with MoKα radiation. The cell dimensions were found to be $a = 12.02$, $b = 19.25$, and $c = 12.90$ Å (all ±0.02 Å) and the space group was uniquely determined from systematic absences as *Fddd* (No. 70). The observed density of 1.25 g cm^{-3} (flotation) indicated eight molecules per unit cell for which the density is calculated to be 1.23 g cm^{-3}. The photographs showed considerable thermal diffuse reflection reminiscent (2) of that found for **1**. Reflection intensities were measured on a Hilger-Watts linear diffractometer with MoKα radiation for layers 0*kl* to 10*kl* (366 data) and *hk*0 to *hk*7 (277 data). Interlayer scalefactors were found by comparison of common reflections and the two sets were merged to give a unique set of 404 reflection data, all of which had $I > 2.5\sigma(I)$. Lorentz and polarization corrections (but none for extinction or absorption) were applied and the data put on an absolute scale by a Wilson plot, after which a Patterson synthesis was calculated.

The only eightfold positions in *Fddd* have D_2 (= 222) symmetry which is incompatible with the assumed molecular symmetry ($S_4 = \bar{4}$) of **3**. As the n.m.r. spectra and experiments with resolved diamine rule out the possibility of discrete molecules of D_2 symmetry, the crystal structure must consist of either a disordered arrangement of S_4 molecules or an infinite three-dimensional network quite different from the solution species. The former was strongly suggested by the similarity of the diffraction pattern to that of **1**, particularly the thermal diffuse reflection (common with highly symmetrical molecules of this type, especially when disorder may be present). Moreover, the cell dimensions were compatible with long cylindrical molecules lying on the points of D_2 symmetry in *Fddd*. Structure analysis therefore proceeded on the assumption of molecules of *average* crystallographic D_2 symmetry (but molecular symmetry S_4) lying on the Wyckoff points (*a*). (Throughout the calculations, the first setting (5) with the origin at *a* has been used.) The combination of the crystallographic and molecular symmetries will result in a structure with local D_{2d} (= $\bar{4}2m$) symmetry at these points. It is not surprising that the structure should be disordered as the molecules are highly symmetrical and have few directional intermolecular forces.

The Patterson function within 4.0 Å of the origin showed a close resemblance to that calculated for I (where the molecule has exact D_{2d} symmetry). On this basis the *average* positions of the atoms in the tricyclic nucleus were located and a subsequent Fourier synthesis revealed the *average* positions of the other atoms in the cyclohexane rings. A second Fourier synthesis showed that the molecule was wrongly orientated and after this correction three cycles of full-matrix least-squares refinement of the positional parameters (with the B_{iso} fixed at 4.0 Å^2) led to a structure with $R = 0.213$. (Scattering factors (6) were taken from International Tables for X-Ray Crystallography and the programs (7) used were our version of the CRYSTAL 69 suite. Unit weights were used throughout the least-squares analysis.) At this stage a difference synthesis was calculated but gave no clear indication of the precise position of the disordered molecules, except that there were large negative values at most atomic positions. Anisotropic temperature factors were introduced to simulate the disorder and three further cycles of refinement reduced the R value to 0.166. (No model with disordered molecules was

[2]The reader may find it helpful to build models of these compounds.

TABLE 1. The atomic parameters ($\times 10^4$) (with e.s.d.s. in parentheses) obtained for the average structure

	x/a	*y/b*	*z/c*	β_{11}	β_{22}	β_{33}	β_{12}	β_{13}	β_{23}
N	823(6)	524(4)	593(7)	45(7)	17(2)	82(7)	10(3)	6(6)	6(3)

NOTE: The carbon atoms in the methylene bridges are CM. The origin was taken at *a* (= 222) in the first setting for *Fddd*. The expression used for the anisotropic temperature factor was: $\exp(-(\beta_{11}H^2 + \beta_{22}k^2 + \beta_{33}l^2 + 2\beta_{12}hk + 2\beta_{13}hl + 2\beta_{23}kl))$.
*Atoms on special positions.

refined as there was no indication of their accurate geometry.) Final positional and thermal parameters are given in Table 1, where they describe the *average* positions of the disordered molecules. Bond lengths and angles for **3** cannot be accurately determined.[3]

Discussion

The ^{1}H n.m.r. spectrum of the crystalline product shows the expected AB quartet for the methylene bridge hydrogens, indicating that there is no molecular symmetry element relating these atoms. The molecular weight and crystal structure analysis then help to confirm its formulation as **3**. Although the crystallographic results do not give an accurate geometry because of the disorder the connectivity of the atoms is established with certainty. The structure (**3**) containing two diamine units of opposite absolute configuration cannot be made from optically active starting materials. Since the reaction mixture from the resolved diamine shows neither a crystalline product nor any trace of the diagnostic AB quartet, the structure (**3**) as the product from the racemic diamine is strongly supported. In any case, had the crystal consisted of equal amounts of enantiomers of D_2 symmetry (**4**) this would have become obvious from the refinement and difference syntheses.

The conformation of **3** cannot be very different from the rigid geometry produced by Dreiding models. Firstly, it is not possible for the cyclohexane rings to invert into another chair form. Secondly, any attempt to decrease the NC(1)C(2)N torsion angle from its value of *ca.* 60° leads to a similar increase in the C(6)C(1)C(2)C(3) system and causes severe angle strain in the cyclohexane ring. We can conclude from the present work that a molecule with the connectivity **1** can exist in an S_4 conformation. The present study does not allow however any estimate to be made of the magnitude of the distortion away from D_{2d} symmetry giving S_4 symmetry for **1** nor if S_4 is the ground state of **1**, can we say exactly where the minimum lies.

Carbon-13 Nuclear Magnetic Resonance Studies of Some *Lycopodium* Alkaloids

THOMAS T. NAKASHIMA, PETER P. SINGER, LOIS M. BROWNE, AND WILLIAM A. AYER

Department of Chemistry, University of Alberta, Edmonton, Alberta T6G 2E1

Received December 6, 1974

THOMAS T. NAKASHIMA, PETER P. SINGER, LOIS M. BROWNE, and WILLIAM A. AYER. Can. J. Chem. **53**, 1936 (1975).

The natural abundance ^{13}C magnetic resonance spectra of some *Lycopodium* alkaloids have been determined at both 25.15 and 22.63 MHz. By using standard techniques it has been possible to make self-consistent assignments of almost all of the resonances. The results suggest some interesting conclusions regarding the stereochemistry of some of the alkaloids and have been used to confirm the stereochemical assignment at C-12 in sauroxine and to assign the preferred conformation (axial) of the *N*-methyl group in the obscurines and *N*-methyllycodine.

THOMAS T. NAKASHIMA, PETER P. SINGER, LOIS M. BROWNE et WILLIAM A. AYER. Can. J. Chem. **53**, 1936 (1975).

On a déterminé, à 25.15 et 22.63 MHz, les spectres de résonance magnétique nucléaire du ^{13}C en abondance naturelle de quelques alkaloides *Lycopodium*. Utilisant les techniques habituelles, on a pu faire des attributions cohérentes de pratiquement toutes les résonances. Les résultats obtenus suggèrent quelques conclusions intéressantes concernant la stéréochimie de quelqu'uns des alkaloides et ces résultats ont été utilisés pour confirmer l'attribution stéréochimique en C-12 dans la sauroxine et pour attribuer la conformation privilégiée (axiale) du groupe *N*-méthyle des obscurines et de la *N*-méthyllycodine. [Traduit par le journal]

Introduction

A large amount of effort has been expended in the determination of the structures of the *Lycopodium* alkaloids.[1] Modern instrumental techniques such as mass spectrometry, optical rotatory dispersion and circular dichroism, X-ray crystallography, and proton magnetic resonance (p.m.r.) spectroscopy have all played a part (1, 2). Since, however, the majority of these alkaloids possess rather few functional groups and most of the protons reside on sp^3 hybridized carbons, the p.m.r. spectra are often of limited value due to the small chemical shifts and extensive spin–spin coupling involved. The majority of the signals appear as overlapping multiplets in the δ 1.0–2.5 region. Carbon-13 magnetic resonance (c.m.r.) is now emerging as a most attractive complimentary technique for structural elucidation (3, 4) of the alkaloids because of the sensitivity of the ^{13}C shielding parameter to slight geometric alterations.

We report here the ^{13}C chemical shifts for a series of *Lycopodium* alkaloids whose structures are shown below, along with the carbon numbering scheme for the parent alkaloid, lycopodine (**1**). The structures of each of these compounds have been determined previously (1, 2) utilizing many of the techniques mentioned above. This particular series of compounds offers the opportunity to examine substituent and geometric effects on the ^{13}C chemical shift parameter in a rather rigid system. Also the presence of the nitrogen atom allows the investigation of the effects of protonation on the ^{13}C chemical shielding and whether these protonation shifts are dependent upon the orientation of the nitrogen lone pair. With these general interests in mind we undertook a ^{13}C investigation of lycopodine (**1**), dihydrolycopodine (**2**), epidihydrolycopodine (**3**), flabelliformine (**4**), clavolonine (**5**), lycodoline (**6**), alkaloid L-23 (**7**), and α-lofoline (**8**).

[1]For recent reviews see refs. 1 and 2.

Results and Discussion

The ^{13}C chemical shifts of compounds **1**–**8** are listed in Table 1 and are summarized for convenience in graphical form in Fig. 1, which depicts changes in the carbon shielding with structural alterations within this set of related compounds. Table 2 summarizes the effects of *N*-protonation on the ^{13}C chemical shifts. Carbon-13 titration curves were determined on **1**, **4**, **5**, **6**, and **7**. Known amounts of CD_3CO_2D were added to the free base and the changes in the ^{13}C

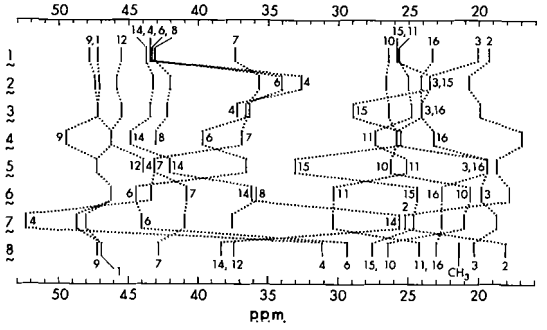

FIG. 1. Correlation of ^{13}C chemical shifts for compounds **1–8** in the 17–53 p.p.m. region.

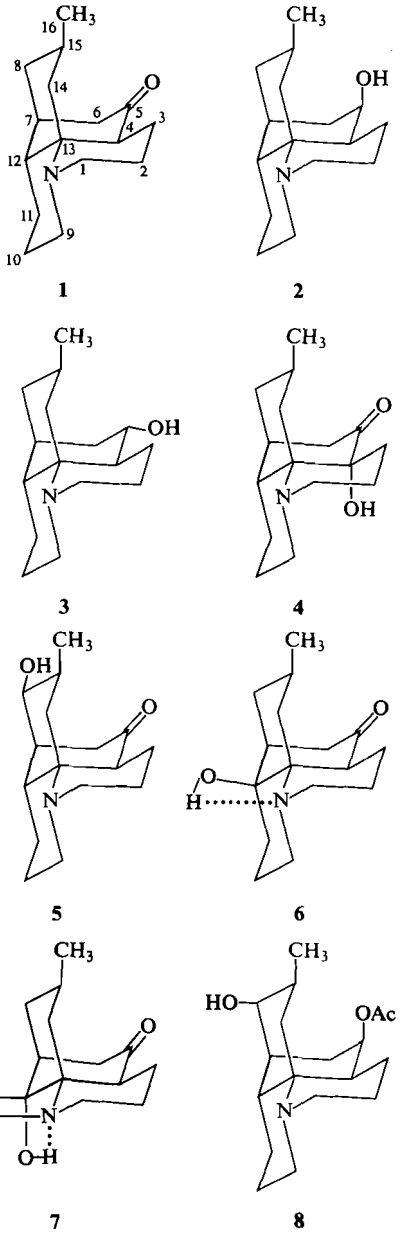
shieldings were plotted *vs.* equivalents of acid. Such plots are shown in Fig. 2 for **7**, **1**, and **6**.

For **1**, excluding C-5 and C-13, whose resonances can be readily assigned using chemical shift theory (*5*), the carbon shieldings are grouped roughly into two regions: one occurring from 16 to 27 p.p.m. and the other from 36 to 48 p.p.m., relative to TMS. Using a simple additivity approach (5–11), one may group into the first region those ^{13}C resonances due to carbons 2, 3, 10, 11, 15, and 16, and carbons 1, 4, 6, 7, 8, 9, 12, and 14 into the second. Deuteration at C-9 and at C-4 and C-6 in **1** and **2** (coupled with the ^{1}H off-resonance spectrum in the nondeuterated compounds) allowed the unambiguous assignments for the resonances of these carbons. Carbon-16 was assigned unambiguously via ^{1}H off-resonance and selective decoupling. The similarity of the chemical environments of C-1 with respect to that of C-9 led to the assignment of C-1. Carbons 12, 14, 8, and 7 were assigned on the basis of additivity considerations, multiplicities obtained from the ^{1}H off-resonance experiments and from the expected responses of these shieldings to *N*-protonation (12). Substitution of a hydroxyl group at C-12 (**6**) in **1** is expected to decrease the shielding of C-11, C-7, and C-13 via a β-axial hydroxyl effect (13), increase the shielding of C-8, C-10, and C-14 via a γ-axial hydroxyl effect (13) and have little effect on the shieldings of the remaining carbons. On this basis C-10 and C-11, and C-2 and C-3 were assigned, though there is no unambiguous means of distinguishing between the first two carbons with the present data. A slight β deuterium isotope effect (14, 15) was noted in lycopodine-*4,6,6-d*$_3$ which led to the assignment of C-3. For lycopodine-*9,9-d*$_2$ no correlation between chemical shift change *vs.* carbon position could be observed. The assignments for



the carbons for the remainder of the compounds within this series were based on arguments similar to those just presented for the lycopodine case. While several of the assignments remain tentative, as indicated in Table 1, they all seem to be internally consistent.

There are several interesting features that emerge from the ^{13}C results for this particular series of compounds. The shielding at C-15 should reflect the steric influences generated at

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

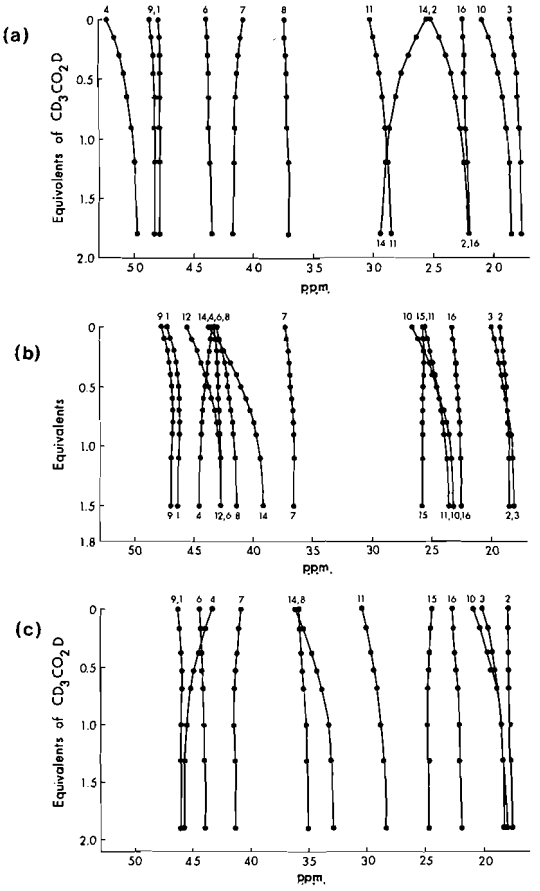


FIG. 2. Carbon-13 titration curves for (*a*) **7** (*b*) **1**, and (*c*) **6** in the 17–53 p.p.m. region.

this position via substituents attached to C-5. The shieldings found for C-15 in **1**, **2**, and **3** indicate that the steric influence of a carbonyl or an axial acetoxyl group is intermediate to that exerted by an axial hydroxyl group on one hand (shielding) and an equatorial hydroxyl group on the other (deshielding). The ε steric effect noted here may be a consequence of the proximity of C-5 to C-15 in the bicyclo[3.3.1]nonane system involved. Earlier p.m.r. studies (16) have indicated that this bicyclo[3.3.1]nonane system may be somewhat distorted from the ideal two chair form.

The shieldings of C-1 and C-9 are very similar throughout most of the series except in **4** in which there is a *syn*-axial orientation of the C-4 hydroxyl group with respect to both C-9 and C-11, which should produce a decrease in shielding for the latter two carbons. Thus, in the case of **4**, C-9 is less shielded than C-1 and C-11 deshielded with respect to C-10. The latter pair of assignments must, however, be regarded as tentative at this time. Such deshielding effects for similar geometric configurations have previously been shown to occur (17). The γ-axial effect of the hydroxyl at C-4 on C-2 in **4** is smaller than expected. This may be due to ring distortion caused by the intramolecular hydrogen bonding between the hydroxyl group and the carbonyl (18).

The most dramatic change in carbon shieldings within this set of related compounds occurs between **6** and **7** where there is a configurational change about C-12 and the nitrogen. The most notable change in shielding occurs for C-4 and C-14. The γ_{HH} and γ_{2HH} interactions (the nomenclature is that introduced by Dalling and Grant (10)) felt by C-14 in **6** from the protons of C-1 and C-3 are augmented in **7** by an additional γ_{HH} and γ_{2HH} perturbation arising from the protons of C-9 and C-11, consequently the large difference in shielding found for C-14 between the two geometrical isomers, **6** and **7**. For C-4 in **6**, a γ_{HH} and γ_{2HH} interaction is replaced in **7** by an γ-axial hydroxyl effect plus the orientational effect of the proton of the hydroxyl group in a hydrogen-bonded situation with the nitrogen lone pair. Similar changes in shielding of other carbons between the isomers may be accounted for in a like manner. These changes in shielding, especially for C-14, should prove to be a useful diagnostic tool in determining the configuration about nitrogen for compounds of related structure.

We have used these ^{13}C results to confirm the stereochemistry of sauroxine (**9**), originally assigned the configuration shown as **9***a* on the basis of a comparison of its mass spectrum and p.m.r. spectrum (19) with that of α-obscurine (**10**≡ **10***a*). The relative and absolute stereochemistry of α-obscurine, except for the configuration of the *N*-methyl group, is known through direct correlation with lycopodine (20). Since sauroxine is stereoisomeric with α-obscurine, the difference must be due to the configuration at C-12 and/or C-15. Since it is shown above that the ^{13}C shieldings are sensitive to changes in stereochemistry at C-12 (**6** *vs.* **7**), we have examined the ^{13}C spectra of these two compounds.

The ^{13}C results for **9** and **10** are summarized in Table 3 along with the results for lycodine (**11**) and *N*-methyllycodine (**12**) which were used as model compounds to aid in the chemical shift assignments. The assignments for **9**–**12** were

[h]C-7 and C-12 may be reversed.
[i]C-8 and C-14 may be reversed.
[j]C-10 and C-11 may be reversed.
[k]C-8 and C-9 may be reversed.

based on additivity (21–23) (using **1**–**8** as model compounds for certain carbons), multiplicities obtained in the ^{1}H off-resonance spectra and from the expected responses of these shieldings to *N*-protonation (12). Initially the assumption was made that the *N*-methyl group would adopt an equatorial conformation. Comparison of the ^{13}C data of **11** and **12** clearly reveals that this is not the case. The increase in shielding of both C-10 (26.4 → 19.8 p.p.m.) and C-12 (44.9 → 34.7 p.p.m.) between **11** and **12**, together with the high-field position of the *N*-methyl signal (36.4 p.p.m.) (24) may only be explained if the *N*-methyl group adopts the axial configuration in **12**. It appears that the nonbonded interaction between the *N*-methyl group and the C-3 hydrogen is sufficient to cause a reversal of the normal conformational preference. The ^{13}C data for **9** and **10** indicate that in these compounds the *N*-methyl group is axially oriented as well.

Although several of the assignments in these compounds remain tentative because of the small shielding differences in several cases, it is clear that the change in shielding for C-14 between **9** and **10** (35.2 → 43.0 p.p.m.) is of the same order as that between **7** and **6** (25.6 → 36.1 p.p.m.) and indicates that sauroxine is indeed epimeric with α-obscurine at C-12 (and consequently also at nitrogen). Also, if the two differed in configuration at C-15 one would expect dramatic shielding differences for C-4, C-5, C-15, and C-16 between **9** and **10** and this is not observed experimentally.

Turning now to the effects of acidification on the ^{13}C chemical shift parameter in this series, we found them to be more complex than at first anticipated. Morishima *et al.* (12) have studied the effect of *N*-protonation on the ^{13}C chemical shieldings for a number of nitrogen containing compounds. For saturated nitrogen heterocycles, they found that in general methyl and methylene carbons become more shielded on *N*-protonation. More fully substituted carbons usually show a diminished effect and in some cases may be deshielded on protonation, as is observed here for C-13. Our acidification results agree well with Morishima's work with the exception of C-4 and C-14 in **7**. In all the compounds studied in this investigation, C-4 is deshielded[2] and C-14 is shielded on *N*-protonation except for **7** in which

this tendency is reversed. The reason for this reversal in the 12-*epi* compound is not clear at this time.

It is informative to examine the effect of acidification on the shift of the C-5 carbonyl in these compounds. It has been shown that β-amino ketones, in which the unshared pair of electrons of the nitrogen, the α,β σ bond and the π orbital of the carbonyl are parallel, give rise to a non-classical e.t. (electron transfer) band in the 220–260 nm region in the u.v. (25). These bands, which disappear on *N*-protonation, are attributed to the splitting in the electronic energy levels caused by the interaction between the nitrogen lone pair and the π orbitals (referred to as a σ-coupled-p interaction) through the σ bond. All of the *Lycopodium* alkaloids with a carbonyl group situated at C-5 reported here show such e.t. bands with the exception of alkaloid L-23 in which this interaction does not exist because of the improper orientation of the nitrogen lone pair with respect to the carbonyl group (26). The details of the u.v. results, taken from ref. 26, are summarized in Table 4. The strength of the σ-coupled-p interaction for a related series is reflected by both the λ_{max} and ε values; the lower the λ_{max} (or the higher ε) values indicate a stronger interaction.

TABLE 4. Ultraviolet spectra of lycopodine type alkaloids in the region 215–230 nm (25)

Compound	Solvent	λ_{max} nm (ε value)
Lycopodine (**1**)	MeOH	217(2400)[a]
	Octane	217(2400)[a]
Clavolonine (**5**)	MeOH	218(1670)[a]
Lycodoline (**6**)	MeOH	221(1500)[a]
Flabelliformine (**4**)	MeOH	228(inf)(≃ 500)[a]
L-23 (**7**)	MeOH	No maximum

[a]Disappears on acidification of solution.

If appreciable charge transfer occurs in the ground state due to this interaction, the ^{13}C chemical shift data should reflect the amount of electron transfer and should be valuable in the investigation of such interactions. Some support for this view is found in the protonation shifts of the carbonyl carbon for which an induced shift of approximately −5 p.p.m. is observed for those compounds (**1**, **5**, and **6**) exhibiting strong e.t. bands while a smaller (−3 p.p.m.) shift is noted for those compounds (**4** and **7**) exhibiting weak or no e.t. transitions. The ^{13}C results imply that there is a greater increase in the electron density about the carbonyl carbon caused by *N*-protonation for compounds with a stronger σ-coupled-p interaction. Whether or not this is generally applicable to other such systems (27) remains to be determined. Such an interpretation should be viewed with caution as carbonyl shifts are known to be quite sensitive to other electronic influences (28).

One would also have expected the shieldings of C-13 to reflect this interaction since it occurs through this carbon. However, the *N*-protonation shifts for this carbon are almost identical for **6** and **7**, the stereochemical isomers.

Experimental

The ^{13}C spectra were obtained on natural abundance samples of approximately 0.5 *M* solution in $CDCl_3$ – 5% TMS (unless otherwise noted) at a frequency of 25.15 MHz (Varian HA-100 interfaced to a Digilab FTS/NMR-3 data system and associated pulser and proton decoupler) or at 22.628 MHz (Bruker HFX-90 interfaced to a Nicolet 1085 computer) in 10 mm tubes in the pulse Fourier mode. The deuterium resonance of $CDCl_3$ served as the lock signal for field/frequency stabilization. For the ^{13}C

titration experiments, known quantities of CD_3CO_2D–$CDCl_3$ (0.64 g of CD_3CO_2D in 1 ml solution) were syringed directly into the n.m.r. sample.

Compounds **1**–**8** were available from previous work in these laboratories (2). The deuterated compounds were prepared from the appropriate nondeuterated alkaloid as described below.

Lycopodine-4,6,6-d_2,d_3

Lycopodine (0.16 g) was dissolved in D_2O (1 ml) and PCl_5 (1 g) was added cautiously. The stoppered reaction mixture was allowed to stand at room temperature for 5 days, then basified by careful addition of anhydrous sodium carbonate. The mixture was diluted with D_2O, extracted with ether, the ether extract dried (anhydrous magnesium sulfate) and concentrated to give 0.135 g of a mixture of lycopodine-*4,6-d_2* and lycopodine-*4,6,6-d_3* (1:1) as shown by low-resolution mass spectrometry (A.E.I. MS-12 mass spectrometer).

Dihydrolycopodine-4,6,6-d_2,d_3

Lycopodine-d_2–lycopodine-d_3 (0.13 g), anhydrous sodium carbonate (trace), and sodium borohydride (0.1 g) were dissolved in deuteriomethanol. The reaction mixture was allowed to stand at room temperature overnight, then diluted with aqueous hydrochloric acid. The aqueous extract was washed with ether, basified with 10% sodium hydroxide solution, then extracted with methylene chloride. The methylene chloride extract was dried (anhydrous magnesium sulfate) and concentrated to give 0.125 g dihydrolycopodine-*4,6,6-d_2,d_3* (1:1) as shown by low-resolution mass spectrometry.

Lycopodine-9,9-d_2 was prepared by the method of MacLean and co-workers (29).

The Stereochemistry of the Reformatsky Reaction of Methyl 4-Bromo-3-methylbut-2-enoate with β-Cyclocitral and Related Compounds

R. N. GEDYE, PARKASH ARORA, AND A. H. KHALIL
Department of Chemistry, Laurentian University, Sudbury, Ontario P3E 2C6

Received October 11, 1974

R. N. GEDYE, PARKASH ARORA, and A. H. KHALIL. Can. J. Chem. **53**, 1943 (1975).

Both methyl *Z*- and *E*-4-bromo-3-methylbut-2-enoate react with β-cyclocitral in the presence of zinc to give the δ-lactone of 5-hydroxy-3-methyl-5-(2,6,6-trimethyl-1-cyclohexen-1-yl)-2-pentenoic acid as the main product, indicating an *E* to *Z* inversion during the Reformatsky reaction. Similar results were obtained in the Reformatsky reactions of the *Z*- and *E*-bromoesters with benzaldehyde and cyclohexenecarboxaldehyde. Here hydrolysis of the Reformatsky product gave, in each case, the corresponding *Z*-2,*E*-4-acids as the main products, indicating the formation of the δ-lactone as an intermediate. The synthesis of *Z*- and *E*-β-ionylideneacetic acid and the corresponding ring demethyl analogs using a Wittig reaction is also described.

R. N. GEDYE, PARKASH ARORA et A. H. KHALIL. Can. J. Chem. **53**, 1943 (1975).

Les bromo-4 méthyl-3 butène-2 oates de méthyle *Z* et *E* réagissent avec le β-cyclocitral en présence de zinc pour conduire à la δ lactone de l'acide hydroxy-5 méthyl-3 (triméthyl-2,6,6 cyclohexène-1 yl-1)-5 pentène-2 oique comme produit principal; ce résultat indique qu'il y a une interconversion de *E* et *Z* au cours de la réaction de Reformatsky. On a obtenu des résultats semblables lors de la réaction de Reformatsky des bromoesters *E* et *Z* avec le benzaldéhyde et le cyclohexènecarboxaldéhyde. Dans chacun de ces cas, l'hydrolyse du produit de Reformatsky conduit aux acides 2-*Z*,4-*E* correspondants comme produits principaux; ces résultats indiquent qu'il y a formation de la δ lactone comme intermédiaire. On décrit aussi la synthèse faisant appel à la réaction de Wittig des acides β-ionylidène acétiques *Z* et *E* ainsi que des analogues desméthyles cycliques correspondants. [Traduit par le journal]

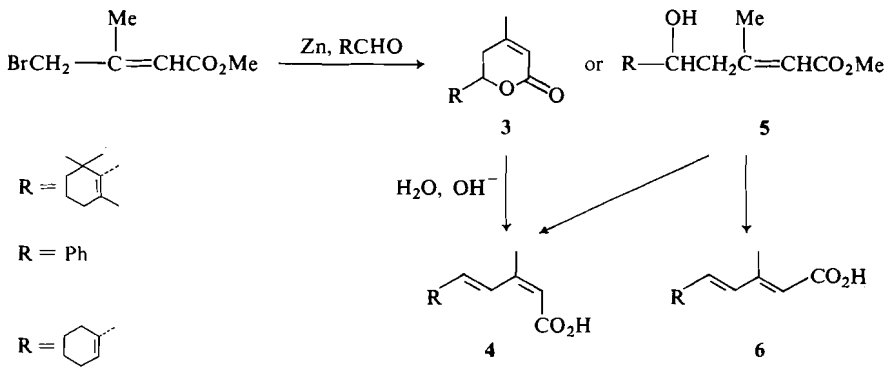
The Reformatsky reactions between benzaldehyde, β-cyclocitral, and β-ionylideneacetaldehyde with esters of 4-bromo-3-methylbut-2-enoic acid have attracted the attention of several laboratories as a possible route to the synthesis of vitamin A and related compounds (1–8). Harper and Oughton (1) and Fuson and Southwick (2) have reported that the Reformatsky reaction between benzaldehyde and methyl 4-bromo-3-methylbut-2-enoate yields a mixture of compounds in which there is a substantial amount of the δ-lactone **3***b*. The bromoester used in these Reformatsky reactions was obtained by the allylic bromination of methyl 3-methylbut-2-enoate with *N*-bromosuccinimide. The formation of the δ-lactone was ascribed either to the presence of the *Z*-bromoester **1** or to the inversion of the *E*-bromoester **2** during the Reformatsky reaction (1).

Tanabe (5), Yoshida and Tanabe (6), and Eiter *et al.* (7) have reported that the Reformatsky reaction between β-cyclocitral and the bromoester gave an isolatable δ-lactone **3** which on subsequent hydrolysis yielded *Z*-β-ionylideneacetic acid, **4***a*. Harper and Oughton (1) on the other hand, reported the formation of the hydroxy ester **5***a* but did not mention any investigation of its stereochemistry.

It is almost certain that in all the above reports, a mixture of *Z*- and *E*-bromoesters **1** and **2** has been used (9–11). It has been suggested that the use of the pure *E*-bromoester **2** might be advantageous in the synthesis of all-*trans*-vitamin A(12) but as far as we can ascertain no attempt has been made to examine the stereochemical outcome of the Reformatsky reaction using either pure *Z-1* or *E-2* to prove or disprove that the presence of the *Z*-bromoester might be responsible for the production of the δ-lactone (1).

Our present investigations have confirmed previous reports (9, 10) that the allylic bromination of methyl 3-methylbut-2-enoate gives a mixture of the two geometrical isomers **1** and **2** in the ratio 2:3. The successful separation of **1** and **2** in stereochemically pure forms enabled us to reexamine the above mentioned Reformatsky reactions using either the pure *Z*-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.



bromoester **1** or *E*-bromoester **2**. Three carbonyl substrates were used in this study: (*a*) benzaldehyde, (*b*) β-cyclocitral, and (*c*) cyclohexenecarboxaldehyde. On the basis of the identification of the products by comparison with reference compounds prepared by unequivocal procedures it was evident that the *Z*-bromoester and the *E*-bromoester afforded the same products under the same conditions. It is therefore not true that the *Z*-bromoester is solely responsible for the formation of the δ-lactone nor is there any real advantage to be gained in the use of the pure *E*-bromoester in the synthesis of vitamin A intermediates using a conventional Reformatsky reaction.

The Reformatsky reaction between benzaldehyde and the *Z*- or the *E*-bromoesters gave similar products. Although we were not successful in isolating the δ-lactone, the product showed an i.r. absorption at 1720 cm^{-1} indicative of the δ-lactone **3***b*. Alkaline hydrolysis followed by isolation of the acidic products and esterification with ethereal diazomethane gave a mixture of the *Z*-2,*E*-4 (70%) and the *E*-2,*E*-4 (30%) isomers of the methyl ester of 3-methyl-5-phenylpenta-2,4-dienoic acid. These results are in agreement with the structural assignments of the Reformatsky products made by Wiley (4), who ascribed the formation of the *Z*-2,*E*-4-isomer **4***b* to the ring opening of the δ-lactone **3***b* during the saponification process. The *E*-2,*E*-4-isomer **6***b* presumably arises, along with **4***b*, from the dehydration of the hydroxy ester **5***b*.

A similar Reformatsky reaction between cyclohexene carboxaldehyde and either the *Z*- or the *E*-bromoester showed the formation of an unsaturated δ-lactone (i.r. 1719 cm^{-1}) in all the isolated fractions. Alkaline hydrolysis of the Reformatsky product followed by isolation of the acidic product gave an acid shown to be 5-(cyclohexen-1-yl)-3-methyl-*Z*-2,*E*-4-pentadienoic acid (**4***c*). Again the acid **4***c* would be expected to arise from the ring opening of the δ-lactone **3***c* during the saponification process.

The Reformatsky reaction of β-cyclocitral and

For personal use only.

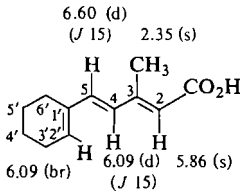
the *Z*- and *E*-bromoesters gave a product from which δ-lactone **3***a* was isolated by column chromatography on alumina. Alkaline hydrolysis of the lactone followed by acidification gave *Z*-β-ionylideneacetic acid (**4***a*).

The products in this study were determined by g.l.c. using reference compounds prepared by standard procedures, notably those of Pattenden and Weedon (13) who showed that the Wittig reaction of 4-hydroxy-3-methylbut-2-enolide (**7**) and of methyl *E*-3-formylcrotonate (**8**) with the Wittig reagent **9***b* gave a convenient method for the synthesis of the four geometrical isomers of 3-methyl-5-phenylpenta-2,4-dienoic acid (**10***b*, **4***b*, **11***b*, and **6***b*).

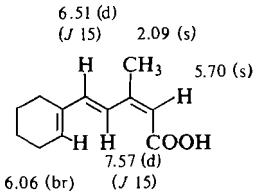
We have applied this method to the synthesis of *Z*- and *E*-β-ionylideneacetic acid. Only one isomer was formed in each reaction, probably due to steric factors, providing a convenient method for the preparation of these important vitamin A intermediates in stereochemically pure forms and in high yield.

Condensation of the Wittig reagent **9***a* (14) with the lactol **7** followed by isolation of the acidic product gave only *Z*-β-ionylideneacetic acid (**4***a*) in 87% yield. The Wittig reaction of **9***a* with methyl *E*-3-formylcrotonate (**8**) gave only the *E*-methyl ester **6***a* in 80% yield.

The *Z*-2,*E*-4 and *E*-2,*E*-4-isomers of 3-methyl-5-(cyclohexen-1-yl)penta-2,4-dienoic acid (**4***c* and **6***c*) were prepared in high yield by similar reactions using the Wittig reagent **9***c* with the lactol **7** and with methyl *E*-3-formylcrotonate, respectively. The n.m.r. properties of these previously unreported isomers **4***c* and **6***c* are shown in the accompanying formulae.



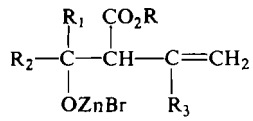
6*c*



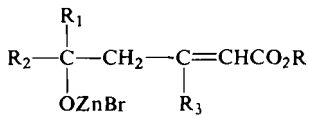
4*c*

The relative δ values for the C_3 methyl protons provides a convenient means for determining the stereochemical configuration of compounds of the β-ionylideneacetic acid series, where the absorption in the all-*trans* isomer always occurs at a lower field (11, 15).

On the basis of these experimental results the following points deserve mention. Firstly, under similar conditions in the various Reformatsky reactions the *Z*- and *E*-bromoesters afford the same products, which include the δ-lactone, and it is clear that the δ-lactone does not arise only from the *Z*-bromoester as has been suggested (1). Secondly the formation of the *Z*-2,*E*-4-isomers **4***a*, *b*, and *c*, is only explainable by the formation of δ-lactones as intermediates in the Reformatsky reactions concerned. Unsaturated lactones have been shown to open with conservation of the stereochemistry of the α,β position (16). Finally, in order to account for the formation of the δ-lactones from the *E*-bromoester the following explanations may be considered. (*i*) Excess zinc, usually used in the Reformatsky reaction, might catalyze the stereomutation of the double bond in the *E*-bromoester and result in lactonization. A similar stereomutation has been reported in the presence of iron (17). On refluxing either the pure *E*- (or pure *Z*-) bromoester in benzene with zinc for several hours, however, no stereomutation was observed using g.l.c. or n.m.r. (*ii*) Recently Coffignal and Gaudemar (18) have found that an allylic rearrangement occurs in the condensation of γ-bromocrotonates with aldehydes and ketones and suggested the reaction involved the formation of the rearranged ester **12** (R_3 = H) as the first intermediate. This undergoes equilibration with the "linear" ester **13** (R_3 = H) resulting in a mixture of the rearranged and "linear" β-hydroxy esters after hydrolysis.



12



13

Although no lactone was isolated by these workers, the formation of the δ-lactone in the present study is not inconsistent with this mechanism. The same equilibrium mixture of *Z*-

For personal use only.

and *E*-esters **13** (R_3 = Me) would be expected to result from both the *Z*- and *E*-bromoesters **1** and **2**, and the *Z* form may have lactonized during the course of the reaction.

Experimental

All boiling and melting points are uncorrected. Infrared spectra were recorded with a Beckman IR-10 double beam spectrophotometer. The n.m.r. spectra were obtained with a Varian A-60 deuteriochloroform solution unless otherwise stated, with tetramethyl silane as an internal reference. Ultraviolet spectra were recorded with a Hitachi Perkin-Elmer Model 124 double beam spectrophotometer. Gas chromatography was carried out on a Varian Aerograph Model 90-P gas chromatograph using a 160 cm × 6 mm column of 3% SE-30 silicone gum rubber on Chromosorb W with the helium as a carrier gas. Fractional distillations were carried out using a Nester-Faust annular spinning band column with 100 theoretical plates.

Methyl Z- and E-4-Bromo-3-methylbut-2-enoate (1 and 2)

A mixture of *Z*- and *E*-bromoesters was obtained from the reaction of methyl 3-methylbut-2-enoate with *N*-bromosuccinimide according to the literature procedure (9). The product, b.p. 80–88°/12 mm, n_D^{20} 1.5022, was shown by g.l.c. and n.m.r. to consist mainly of two components in the approximate ratio 2:3; the n.m.r. data for the mixture was in agreement with the literature values (9).

Fractional distillation of the isomeric mixture (40.0 g) gave (*i*) methyl *Z*-4-bromo-3-methylbut-2-enoate (**1**) (11.8 g), b.p. 63–65°/7 mm, n_D^{24} 1.4871; λ_{max} (EtOH) 215 nm (ε 11.8 × 10^3); ν_{max} (CCl_4) 1730vs, 1650s, 1440s, 1360s, 1250vs, 1160vs, 1045s, 860s, and 635 cm^{-1}; n.m.r. δ 5.80br (=CH), 4.60s (CH_2Br), 3.70s (OMe).

Anal. Calcd. for $C_6H_9BrO_2$: C, 37.3; H, 4.7; Br 41.5. Found: C, 37.1; H, 4.6; Br, 41.4.

(*ii*) Intermediate fraction (4.3 g), b.p. 65–67°/7 mm; n.m.r. and g.l.c. showed the *Z*:*E* ratio to be about 1:3. (*iii*) Methyl *E*-4-bromo-3-methylbut-2-enoate (**2**) (20.6 g), b.p. 67–8°/7 mm, n_D^{24} 1.4994; λ_{max} (EtOH) 218 nm (13.7 × 10^3); ν_{max} (CCl_4) 1730vs, 1645s, 1435s, 1355s, 1250m, 1230vs, 1210s, 1155vs, 1037s, 925w, 860w, and 620 cm^{-1}; n.m.r. 5.93br (=CH), 393s (CH_2Br), 3.70s (OMe), and 2.26d (J = 2 Hz, MeC=C).

Anal. Found: C, 37.1; H, 4.8; Br, 41.3.

Reformatsky Reaction of Benzaldehyde with Methyl Z-4-Bromo-3-methylbut-2-enoate (1)

A portion (5 ml) of a solution of the *Z*-bromoester **1** (15.0 g, 0.078 mol) and benzaldehyde (8.16 g, 0.077 mol) in dry benzene (25 ml) and dry ether (5 ml) was added dropwise to activated zinc (19) (5.23 g, 0.08 g-at.). The mixture was warmed until the reaction started. The mixture was then stirred with gentle warming and the rest of the solution added at such a rate as to maintain a slow reflux. The reaction mixture was refluxed for 30 min, cooled to 0°, and hydrolyzed with ice-cold 10% sulfuric acid (25 ml). The organic layer was separated and successively washed with water, sodium bicarbonate solution, and water and dried over anhydrous sodium sulfate. The solvent was evaporated and the residue distilled giving a pale yellow oil (8.5 g), b.p. 150–175°/3 mm. The i.r. spectrum for the fraction b.p. 169–175°/3 mm (5.9 g) showed a pronounced band at 1725 cm^{-1} indicative of the δ-lactone. Attempts to crystallize the lactone were unsuccessful. The δ-lactone band was less pronounced in the other fractions.

The fraction b.p. 169–175°/3 mm was treated with ethanolic potassium hydroxide for 12 h at 50°, diluted with water, extracted with ether, and acidified with cold 10% sulfuric acid. The white precipitate was taken up in ether, washed with water, and then dried. The ether was evaporated and the resulting crystalline material had m.p. 128–134°. A sample of this product was treated with excess ethereal diazomethane and the resulting oil was shown by g.l.c. to be a mixture of approximately 70% of the *Z*-2,*E*-4 and 30% *E*-2,*Z*-4 isomers of methyl 3-methyl-5-phenylpenta-2,4-dienoate.

Iodine-catalyzed isomerization of the isomeric mixture m.p. 128–134°, according to the directions of Pattenden and Weedon (13) gave the *E*-2,*E*-4-acid **6***b*, m.p. 156–158° (petroleum ether). The acid exhibited the spectral properties as reported (13).

Reformatsky Reaction of Benzaldehyde with Methyl E-4-Bromo-3-methylbut-2-enoate-(2)

Repetition of the preceding experiment with the *E*-bromoester **2**, gave a similar product ratio. The products from both the above reactions were identified by g.l.c. using reference compounds prepared by procedures given below (10, 13).

Reformatsky reaction of Methyl E-4-Bromo-3-methylbut-2-enoate with β-Cyclocitral

The *E*-bromoester (19.3 g, 0.1 mol) was reacted with β-cyclocitral (15.2 g, 0.1 mol) in dry benzene (85 ml) and ether (15 ml) and activated zinc (7.0 g, 0.107 g-at.) using the procedure described above for the benzaldehyde reaction. The product was distilled to give unreacted β-cyclocitral (2.5 g), b.p. 42–44°/1 mm, and a thick syrup (10.4 g), b.p. 130–153°/1 mm, which partly solidified on standing. A portion of the solid was recrystallized from 50% ethanol giving the δ-lactone **3***a*, m.p. 60–63°. Column chromatography of the syrup (2.0 g) on neutral alumina (80–200 mesh) using benzene–hexane as eluent gave the δ-lactone **3***a* (1.3 g), m.p. 60–63°. A sample obtained by recrystallization from 50% ethanol had m.p. 64–65° (lit. (5) m.p. 65–66°); λ_{max} (EtOH) 209 nm; ν_{max} ($CHCl_3$) 1716 cm^{-1} (δ-lactone). The δ-lactone (2.0 g) was hydrolyzed with ethanolic potassium hydroxide (10%, 10 ml) at room temperature, diluted with water (100 ml), extracted several times with ether, and acidified with cold 10% sulfuric acid. The precipitate was taken up in ether, washed with water, and dried over magnesium sulfate. Evaporation of the ether and recrystallization from petroleum ether (b.p. 30–60°) at 0° gave *Z*-β-ionylideneacetic acid **4***a* (0.74 g), m.p. 98–99° not depressed on admixture with an authentic sample prepared as described below. The spectral properties were also identical with those of the authentic sample.

Reformatsky Reaction of Methyl Z-4-Bromo-3-methylbut-2-enoate with β-Cyclocitral

Repetition of the preceding Reformatsky reaction using the *Z*-bromoester gave similar results. No product other than the δ-lactone was isolated.

Reformatsky Reaction of Methyl E-4-Bromo-3-methylbut-2-enoate with Cyclohexene Carboxaldehyde

The *E*-bromoester (15.0 g, 0.078 mol) was reacted with cyclohexene carboxaldehyde (20) (8.58 g, 0.077 mol) in dry benzene (25 ml) and dry ether (15 ml) and activated zinc (5.23 g, 0.08 g-at.), using the procedure described above for the benzaldehyde reaction. The product was distilled giving a pale yellow oil (7.9 g), b.p. 148–165°/6 mm. The i.r. spectrum for the fraction b.p. 150–165°/6 mm showed a pronounced band at 1719 cm^{-1} indicative of a δ-lactone. This fraction was treated with ethanolic potassium hydroxide at 50° for 12 h, diluted with water, extracted with ether, and acidified with 10% sulfuric acid. The white precipitate was evaporated and the resulting crystalline material had m.p. 158° and showed the same spectral properties as 3-methyl-5-(cyclohexen-1-yl)penta-*Z*-2,*E*-4-dienoic acid (**4***c*) prepared as described below.

Reformatsky Reaction of Methyl Z-4-Bromo-3-methylbut-2-enoate with Cyclohexene Carboxaldehyde

Repetition of the preceding Reformatsky reaction with the *Z*-bromoester gave similar results. Alkaline hydrolysis of the product gave the same *Z*-2,*E*-4-acid.

Preparation of the Reference Compounds

The 3-methyl-5-phenylpenta-2,4-dienoic acids and their methyl esters. The four isomeric acids (*Z*-2,*Z*-4, *Z*-2,*E*-4, *Z*-2,*E*-4, and *E*-2,*E*-4 isomers) were prepared using the Wittig reactions between benzyltriphenylphosphonium chloride and 4-hydroxy-3-methylbut-2-enolide and methyl *E*-3-formylcrotonate in the presence of sodium methoxide according to the method of Pattenden and Weedon (13). The methyl esters were obtained by treating the corresponding acids with ethereal diazomethane.

E-β-Ionylideneacetic Acid (6a) and its Methyl Ester

Phenyllithium (0.04 mol) in dry ether (50 ml) was added during 15 min to a well stirred suspension of triphenylcyclogeranyl bromide (14) (12 g, 0.024 mol) in dry ether (300 ml) at 10° under nitrogen. The resulting deep red solution was stirred for 20 min and methyl *E*-3-formylcrotonate (3.07 g, 0.024 mol) in dry ether (40 ml) was added during 15 min. The reaction mixture was stirred for 2 h at 10° and for 1 h at 35° and then diluted with water (300 ml). The mixture was stirred for 30 min at room temperature. The organic layer was separated, washed with water, dried, and then evaporated. The residue was diluted with petroleum ether (b.p. 30–60°), cooled to 0°, and the precipitated triphenylphosphine filtered off. The filtrate was dried over anhydrous sodium sulfate and distilled under reduced pressure giving methyl *E*-β-ionylideneacetate (5.2 g, 87%), b.p. 160–163°/5 mm (lit. (5) b.p. 110–111°/0.5 mm); g.l.c. showed only one peak; λ_{max} (EtOH) 257 and 302 nm; ν_{max} 1720vs (C=O), 1610s (C=C), 970m (CH=CH *trans*).

A sample of this ester (2.0 g) was saponified with ethanolic potassium hydroxide at room temperature and the product acidified giving *E*-β-ionylideneacetic acid (1.2 g) m.p. 125–127° (acetonitrile) (lit. (8) m.p. 126–127°), not depressed on admixture with a sample prepared according to the directions of Ishikawa (21); λ_{max} (EtOH) 258 and 290 nm.

Z-β-Ionylideneacetic Acid (4a)

Phenyllithium (0.05 mol) in dry ether (60 ml) was added during 20 min to a cooled (0°) and well stirred suspension of triphenyl-β-cyclogeranylphosphonium bromide (12.2 g, 0.026 mol) in dry ether (300 ml) under nitrogen. The resulting deep red solution was stirred for 20 min and 4-hydroxy-3-methylbut-2-enolide (3.0 g, 0.026 mol) added during 15 min. The reaction mixture was stirred for 2 h at 0° and for an additional 2 h at room temperature. It was then diluted with water (300 ml) and stirred for 30 min. The aqueous layer was separated, extracted with ether, acidified with cold 20% sulfuric acid, and the acidic product extracted several times with ether. The combined ether extracts were washed with water, dried, and evaporated leaving *Z*-β-ionylideneacetic acid (**4***a*) (5.2 g, 85%), m.p. 98–99° (petroleum ether) (lit. (8) m.p. 98.5–99.5°); λ_{max} (EtOH) 256 and 305 nm; λ_{max} 1680(s) (C=O), 1620 (C=C), and 850 cm^{-1}. The n.m.r. spectra of the *Z*- and *E*-acids were the same as reported (11). Iodine-catalyzed isomerization of *Z*-β-ionylideneacetic acid according to the procedure of Robeson *et al.* (8) gave the *E* isomer (g.l.c.). A sample of the *Z*-acid was treated with ethereal diazomethane giving the methyl ester, g.l.c. one peak; λ_{max} 257, 310 nm.

3-Methyl-5-(cyclohexen-1-yl)penta-E-2,E-4-dienoic Acid (6c) and its Methyl Ester

The reaction was carried out according to the procedure used for *E*-β-ionylideneacetic acid and its methyl ester. Methyl *E*-3-formylcrotonate (5.9 g, 0.046 mol) in dry ether (50 ml) was allowed to react with a mixture of phenyllithium (0.064 mol) in dry ether (50 ml) and triphenyl(1-cyclohexen-1-yl-methyl)phosphonium bromide (22) (20.0 g, 0.046 mol) in dry ether (300 ml). After a similar work-up procedure the product was distilled giving methyl 3-methyl-5-(cyclohexen-1-yl)-penta-*E*-2,*E*-4-dienoate (8.5 g, 89%) as a pale yellow oil, b.p. 155–158°/7 mm, n_D^{24} 1.5341; g.l.c. one peak; λ_{max} (EtOH) 207 and 318 nm; ν_{max} ($CHCl_3$) 1720vs (C=O), 1615s (C=C), 962s (CH=CH *trans*), and 880w cm^{-1}.

Anal. Calcd. for $C_{13}H_{18}O_2$: C, 75.73; H, 8.74. Found: C, 75.64; H, 8.56.

A sample of the ester (2.0 g) was saponified as described above for the preparation of **6***a* giving the *E*-2,*E*-4 acid (1.1 g), m.p. 172–175° (dec.) (benzene – petroleum ether). The acid is very sensitive to either air or light.

3-Methyl-5-(cyclohexen-1-yl)penta-Z-2,E-4-dienoic Acid (4c)

The reaction was carried out according to the procedure for *Z*-β-ionylideneacetic acid (above): 4-hydroxy-3-methylbut-2-enolide (3.4 g, 0.03 mol) in dry ether (25 ml) was reacted with a mixture of the above phosphonium salt (13.0 g, 0.03 mol) in dry ether (250 ml) and phenyllithium (0.05 mol) in dry ether (40 ml). After a similar work-up procedure the *Z*-2,*E*-4 acid **4***c* (5.2 g, 90%), m.p. 161–162° (benzene – petroleum ether) was obtained.

Anal. Calcd. for $C_{12}H_{16}O_2$: C, 75.00; H, 8.33. Found: C, 74.31; H, 7.95.

A sample of the acid was treated with excess ethereal diazomethane giving the methyl ester; g.l.c. one peak; λ_{max} (EtOH) 206 and 316 nm; ν_{max} ($CHCl_3$) 1740vs (C=O), 975s (CH=CH *trans*).

The n.m.r. spectra of these isomers (**4***c* and **6***c*) are shown in the formulae above.

Perchlorato, Nitrato, and Acetylacetonato Complexes of Copper(I). The Crystal and Molecular Structure of Perchloratobis(tricyclohexylphosphine)Copper(I)

RODERIC J. RESTIVO, ABRAHAM COSTIN, AND GEORGE FERGUSON[1]

Guelph-Waterloo Centre for Graduate Work in Chemistry, University of Guelph, Guelph, Ontario N1G 2W1

AND

ARTHUR J. CARTY

Guelph-Waterloo Centre for Graduate Work in Chemistry, University of Waterloo, Waterloo, Ontario

Received January 6, 1975

RODERIC J. RESTIVO, ABRAHAM COSTIN, GEORGE FERGUSON, and ARTHUR J. CARTY. Can. J. Chem. **53**, 1949 (1975).

Copper(I) perchlorate, nitrate, and acetylacetonate complexes of the types Cu(triphos)ClO_4 (triphos = $CH_3C(CH_2PPh_2)_3$), Cu$(Cy_3P)_2ClO_4$ (Cy_3P = $P(C_6H_{11})_3$), Cu(triphos)NO_3, Cu$(Cy_3P)_2$(HFac) (HFac = hexafluoroacetylacetonate), and Cu$(Cy_3P)_2$(TtFac) (TtFac = thienyltrifluoroacetylacetonate) have been synthesized by reduction of the corresponding perchlorate, nitrate, and acetylacetonates with tertiary phosphines. Infrared spectra indicate the presence of monodentate perchlorate groups in Cu(triphos)ClO_4 and in Cu$(Cy_3P)_2ClO_4$ and the crystal structure of the latter has been determined by a three-dimensional X-ray analysis using diffractometer data. The crystals are monoclinic, space group $C2/c$, with cell dimensions a = 18.159(6), b = 9.493(2), c = 22.182(3) Å, and β = 95.41(2)° and four molecules per unit cell. The structure was refined by block-diagonal least squares methods to a final R of 0.051 for 2617 reflections using anisotropic thermal parameters for the nonhydrogen atoms. The structure consists of discrete Cu$(Cy_3P)_2ClO_4$ molecules with symmetry C_2 separated by normal van der Waals distances. The copper atom is three-coordinate and the perchlorate anion is monodentate but disordered over two sites. Principal dimensions include: Cu—P 2.262(1) Å, Cu—O 2.220(7) Å, ∠P—Cu—P 144.46(6)°, ∠P—Cu—O 114.1(2)° and 99.8(2)°, and ∠Cu—O—Cl 122.4(6)°.

RODERIC J. RESTIVO, ABRAHAM COSTIN, GEORGE FERGUSON et ARTHUR J. CARTY. Can. J. Chem. **53**, 1949 (1975).

On a synthétisé les complexes du perchlorate, du nitrate et de l'acétylacétonate de cuivre(I) du type Cu(triphos)ClO_4 (triphos = $CH_3C(CH_2PPh_2)_3$), Cu$(Cy_3P)_2ClO_4$ (Cy_3P = $P(C_6H_{11})_3$), Cu(triphos)NO_3, Cu$(Cy_3P)_2$(HFac) (HFac = hexafluoroacétylacétonate) et Cu$(Cy_3P)_2$(TtFac) (TtFac = thiényltrifluoroacétylacétonate) en réduisant les perchlorates, les nitrates et les acétylacétonates correspondants par des phosphines tertiaires. Les spectres infrarouges suggèrent la présence de groupes perchlorates monodentates dans Cu(triphos)ClO_4 et dans Cu$(Cy_3P)_2ClO_4$; la structure cristalline de ce dernier composé a été établie à l'aide d'une analyse tridimentionnelle par rayons-X en faisant appel à des données diffractométriques. Les cristaux sont monocliniques appartiennent au groupe d'espace $C2/c$, et possèdent les dimensions a = 18.159(6), b = 9.493(2), c = 22.182(3) Å et β = 95.41(2)° et contiennent quatre molécules par maille. La structure a été affinée par la méthode des moindres carrés jusqu'à une valeur finale de R de 0.051 pour 2617 réflexions utilisant des paramètres thermiques anisotropes pour les atomes différents de l'hydrogène. La structure comprend des molécules discrètes de Cu$(Cy_3P)_2ClO_4$ possédant une symétrie C_2 qui sont séparés par des distances de van der Waals normales. L'atome de cuivre est tricoordonnée et l'anion perchlorate est monodentate mais désordonnée sur deux sites. Les dimensions principales sont Cu—P 2.262(1) Å, Cu—O 2.220(7) Å, ∠P—Cu—P 144.46(6)°, ∠P—Cu—O 114.1(2)° et 99.8(2)°, et ∠Cu—O—Cl 122.4(6)°.

[Traduit par le journal]

Introduction

Structural studies of several tertiary phosphine derivatives of copper(I) are in progress in our laboratories in an attempt to relate steric and electronic properties of the ligands to molecular stereochemistry. Considerable impetus for structural work in this area derives from the burgeoning interest in the chemistry of zerovalent nickel, palladium, and platinum phosphine compounds as a result of their synthetic and catalytic

utility (1). In the presence of a noncomplexing anion, the stereochemistry of copper(I) might be expected to show a close resemblance to that of an isoelectronic nickel(0) species. However, whereas nickel(0)–phosphine complexes are often highly sensitive and difficult to handle, the corresponding copper(I) compounds can be synthesized with ease and are generally air-stable. X-Ray studies of several copper(I) complexes of tertiary phosphines have been summarized (2). Of interest to the present work are the results of the analysis of nitratobis(triphenylphosphine)copper(I) (3) and nitratobis(tricyclohexylphosphine)copper(I) (4), (which both contain a bidentate nitrate group giving the copper atoms a pseudotetrahedral configuration), and of the tris complex, $Cu(MePh_2P)_3NO_3$, in which the nitrate group is unidentate (5). Also of relevance to this work are the structures of $Cu(Ph_3P)_2(HFac)$, $Cu(Ph_3P)_2(TFac)$, and $Cu(Ph_3P)_2(TtFac)$ (HFac = hexafluoroacetylacetonate anion, TFac = trifluoroacetylacetonate anion, and TtFac = thienyltrifluoroacetylacetonate anion) which contain pseudotetrahedrally coordinated copper atoms (6).

A synthetic route utilizing the reduction of an appropriate copper(II) compound with a tertiary phosphine ligand has led to the preparation of several new copper(I) perchlorate, nitrate, and acetylacetonate complexes of the very bulky ligand tricyclohexylphosphine (Cy_3P) and the potentially tridentate ligand 1,1,1-tris(diphenylphosphinomethyl)ethane (triphos) (7). The single crystal X-ray structural analysis of perchloratobis(tricyclohexylphosphine)copper(I) is reported herein. This molecule is of interest because the bulky tricyclohexyl groups should exert a large steric influence on the structure. Moreover, the perchlorate ion is weakly coordinating and relatively few complexes containing coordinated ClO_4^- have been structurally characterized (8) although there are many known structures with uncomplexed ClO_4^-. (A few examples are cited in ref. 9.)

Experimental

Infrared spectra were measured on Perkin–Elmer 457 and Perkin–Elmer 180 infrared spectrometers using Nujol mulls on CsI plates.

Preparations

Perchloratobis(tricyclohexylphosphine)copper(I), $Cu(Cy_3P)_2ClO_4$

Cupric perchlorate, $Cu(ClO_4)_2.nH_2O$, was first prepared by dissolving anhydrous cupric carbonate in 66% perchloric acid, followed by careful evaporation of the filtered neutral solution to low volume until crystallization occurred. The product was dried over anhydrous $Mg(ClO_4)_2$ in a vacuum desiccator.

Cupric perchlorate (1.0 g) was dissolved in absolute ethanol (25 ml) and the solution warmed to 60°. A hot solution (50 ml) (1:1 ethanol, cyclohexane) containing sufficient tricyclohexylphosphine to give a 4:1 molar ratio of copper to phosphine, was filtered into the perchlorate solution and the mixture cooled. Colorless crystals, m.p. 180–182°, of the product which could be recrystallized from absolute ethanol, were obtained.

The same complex was obtained when 8:1 molar ratios of phosphine to copper were used.

Anal. Calcd. for $Cu(Cy_3P)_2ClO_4$: C, 59.10; H, 9.33; Cl, 4.96. Found: C, 59.82; H, 9.10; Cl, 4.42.

Perchlorato[1,1,1-tris(diphenylphosphinomethyl)-ethane]copper(I), Cu(triphos)ClO_4

Sufficient triphos to give a 1.3:1 molar ratio of phosphine to copper was added to a warm solution of cupric perchlorate dissolved in absolute ethanol. The colorless product which crystallized on cooling was washed with benzene and recrystallized (m.p. 200° (dec.) from absolute ethanol and chloroform (5:1)).

Anal. Calcd. for Cu(triphos)ClO_4: C, 62.4; H, 5.0. Found: C, 61.76; H, 5.08.

Nitrato[1,1,1-tris(diphenylphosphinomethyl)ethane]-copper(I), Cu(triphos)NO_3

The product, m.p. 255° (dec.) was prepared via the method used for Cu(triphos)ClO_4 by addition of the phosphine to cupric nitrate.

Anal. Calcd. for Cu(triphos)NO_3: C, 65.50; H, 5.25. Found: C, 65.72; H, 5.30.

Hexafluoroacetylacetonatobis(tricyclohexylphosphine)-copper(I), $Cu(Cy_3P)_2HFac$, and Thienyltrifluoro-acetylacetonatobis(tricyclohexylphosphine)copper(I), $Cu(Cy_3P)_2TtFac$

The bis chelates $Cu(HFac)_2$ and $Cu(TtFac)_2$ were prepared by published procedures (10). The Cy_3P complexes were prepared under a nitrogen atmosphere by addition of the copper(II) chelate to a solution of the phosphine, in a 3:1 molar ratio of phosphine to copper, in 1:1 absolute ethanol and degassed cyclohexane. The $Cu(HFac)_2$ and triphos reacted immediately while the $Cu(TtFac)_2$ and triphos were refluxed under nitrogen for an hour and then left to cool in a refrigerator. The yellow products were recrystallized from *n*-pentane; m.p. 140° (sub.) ($Cu(Cy_3P)_2(HFac)$) and 150° (sub.) ($Cu(Cy_3P)_2(TtFac)$).

Anal. Calcd. for $Cu(Cy_3P)_2(HFac)$: C, 59.10; H, 8.1. Found: C, 59.34; H, 8.14.

Anal. Calcd. for $Cu(Cy_3P)_2(TtFac)$: C, 62.1; H, 8.5. Found: C, 62.06; H, 8.52.

For personal use only.

absorption coefficient for X-rays ($\lambda = 0.71069$ Å), $\mu = 7.86$ cm^{-1}, symmetry C_2 required.

Unit-cell and space group data were obtained from preliminary precession and Weissenberg photographs which indicated monoclinic symmetry with systematic absences: *hkl* when $h + k$ is odd and *h0l* when both *h* and *l* are odd, allowing the space group to be *Cc* or *C2/c*. The latter was chosen (but see below). The cell dimensions were obtained from a least squares treatment of the setting angles of 12 general reflections measured on a diffractometer. The crystal chosen for the data collection was a small rectangular plate with approximate dimensions 0.16 × 0.17 × 0.19 mm. Intensity data were collected to a maximum Bragg angle θ of 27° on a PDP8-I controlled Hilger and Watts Y290 four-circle diffractometer equipped with a graphite monochromator. The θ–2θ scan technique was used with a scan through 60 steps of 0.01° with 1 s counts at each step. Background counts of 15 s were made at the beginning and end of each scan. The maximum variation in intensity of the standard reflections was 1%. Lorentz and polarization corrections were applied but no absorption correction was made. Reflections which had a net count of less than 3σ above background, where $\sigma(I)$ is defined by $\sigma(I) = \sqrt{[S + 4(B_1 + B_2)]}$ and S, B_1, and B_2 are the scan, first background, and second background respectively, were taken as "unobserved". Of the 4159 independent reflections measured, 2617 were classified as "observed" and used in the solution and refinement of the structure.

Structure Analysis

The coordinates of the copper and phosphorus atoms were found from inspection of the three-dimensional Patterson function. The remaining atoms were located by application of the heavy atom method. The perchlorate group appeared to be disordered in such a way that the chlorine atom lay off the twofold axis slightly, and one of the two independent oxygen atoms was distributed equally over two sites; allowance was made for this disorder by giving the Cl, O(21), and O(22) atoms an occupancy factor of 0.5 while O(1) was given an occupancy factor of unity. The structure was first refined by full-matrix least square calculations using isotropic thermal parameters and finally by block-diagonal least squares allowing the Cu, P, Cl, and C atoms to vibrate anisotropically. Only the observed reflections were included in the least squares calculations, and the function minimized was $\Sigma\omega(|F_o| - |F_c|)^2$ with absolute weights based on $\sigma(F_o)$ being used. In all F_c calculations, atomic scattering factors were obtained from ref. 11.[2] Corrections for the anomalous dispersion (12) for Cu, P, and Cl were included in the final stages of the refinement. A difference map calculated when R was 0.079 revealed peaks (~0.7 e/Å^3) in positions corresponding to all 33 independent hydrogen atoms. These were then included in the structure factor calculations with fixed isotropic thermal parameters, but were not refined. The refinement converged with $R = \Sigma(|F_o| - |F_c|)/\Sigma|F_o| = 0.051$, and $R' = [\Sigma\omega(|F_o| - |F_c|)^2/\Sigma\omega(|F_o|)^2]^{1/2} = 0.059$ for the 2617 observed reflections. The final error in an observation of unit weight was 1.02. A table of final values of the structure amplitudes and $\sigma(F_o)$ is placed with the Depository of Unpublished Data.[3] The final positional parameters are listed in Table 1, the thermal parameters in Table 2, and interatomic distances and angles in Table 3.

On conclusion of the *C2/c* refinement, it was apparent that the disorder of the perchlorate group might be an artifact brought about by choosing *C2/c* instead of *Cc* as the space group. To check this point, we took the final coordinates (Table 1), generated a complete molecule with only one (nondisordered) perchlorate group, and proceeded to a *Cc* refinement. The result was that the *R*-factor rose slightly (to 0.059), the thermal parameters of the perchlorate atoms became anomalously large, and the Cl atom tended to move from $x \sim 0, z = 0.23$ back to $x = 0, z = \frac{1}{4}$ which would be the 2-fold axis location in *C2/c*. We accordingly abandoned this refinement and feel that we have indeed confirmed that the structure is best described in terms of a *C2/c* system with a disordered perchlorate group.

Discussion

The X-ray analysis shows that the crystal structure consists of discrete molecules of $Cu(Cy_3P)_2ClO_4$ separated by normal van der Waals contacts (Fig. 1). A view of a single molecule along with the labelling scheme is seen in Fig. 2 which shows that the coordination geometry of the copper atom is distorted trigonal (see also Fig. 3). The coordination number of 3 for copper is rather uncommon and only a few 3-coordinate complexes have now been characterized structurally. These include $[Cu(Me_3PS)_3]ClO_4$ (13), $Cu[(Me_3PS)Cl]_3$ (13), $Cu(Ph_3P)_2Br\cdot 0.5C_6H_6$ (14), $(Ph_3P)_3Cu_2Cl_2$ (15), and $[Cu(etu)_3]_2SO_4$ (etu = ethylenethiourea) (16).

The P—Cu—P angle (144.46(6)°) observed here for $Cu(Cy_3P)ClO_4$ is the largest P—Cu—P angle reported to date and it would appear that the bulkiness of the Cy_3P groups is responsible for this distortion. The corresponding P—Cu—P angle in $Cu(Cy_3P)_2NO_3$ (4) is 140(1)°. These angles are significantly greater than those typically reported for systems with the less bulky Ph_3P groups (*e.g.* 131.2(1)° in $Cu(Ph_3P)_2NO_3$ (3) and 123.26(6)° in $Cu(Ph_3P)_2BH_4$ (17)).

The Cu—P bond length 2.262(1) Å can be compared with the distance (2.29(1) Å) found in $Cu(Cy_3P)_2NO_3$ (4) (but that analysis is of low accuracy and the e.s.d.'s may be under-

[2]Atomic scattering functions were obtained from Cromer and Mann; the hydrogen scattering function was obtained from Stewart *et al.* (11).

estimated). A wide range of Cu—P bond lengths has been reported for three-coordinate copper(I) complexes (*e.g.* 2.262(2) and 2.282(2) in $Cu(Ph_3P)_2Br$ (14) and 2.183(4) Å for the three-coordinate copper atom in $(Ph_3P)_3Cu_2Cl_2$ (15)).

The perchlorate group, which is disordered about the twofold crystallograhic axis, is monodentate with a bonded Cu—O(21) length of 2.220(7) Å and a nonbonded intramolecular contact, Cu···O(22), of 3.203(10) Å. Although a number of coordination complexes purportedly containing monodentate perchlorate groups have been characterized (18), relatively few of these have been subjected to single crystal X-ray analysis. The bonded Cu—O length is considerably shorter than the Cu—O(perchlorate)

distances (2.546(3) Å) in $Cu\{[(CH_3)_2N]_2P(O)OP(O)[N(CH_3)_2]_2\}_2(ClO_4)_2$ (8*c*) and 2.61 Å observed in $Cu(en)_2(ClO_4)_2$ (en = ethylenediamine) (8*d*) where a monodentate perchlorate is present. However, in the latter complexes the copper is hexacoordinated and data are lacking for perchlorato complexes of low coordination number. The coordinated perchlorate group affords a Cu—O length which agrees favorably with the values obtained for $Cu(Cy_3P)_2NO_3$ (2.34(2) Å) (4) and $Cu(Ph_3P)_2NO_3$ (2.22(1) Å) (3) which contain symmetrically-bidentate nitrato groups. Thus, the apparent similarity of Cu—O distances in $Cu(Cy_3P)_2ClO_4$, $Cu(Ph_3P)_2NO_3$ (3), and $Cu(Cy_3P)_2NO_3$ (4) indicates that the Cu—O(perchlorate) interaction is stronger than might be predicted from a knowledge of the poor coordinating tendencies of ClO_4^-. The Cl—O distances in the disordered ClO_4 group are in the range 1.38–1.50 Å but the disorder precludes any meaningful discussion of these. There are two independent P—Cu—O(perchlorate) angles, 114.1(2) and 99.8(2)°, which together with the P—Cu—P angle of 144.46(6)° imply that the coordination at the copper atom is not planar; it lies 0.08 Å from the OPP′ plane.

Structures containing uncomplexed perchlorate groups have shown the same poor refinement characteristics (disorder or large thermal motion for the perchlorate) as observed in this crystal structure analysis. As Einstein and Rodley (9*c*) have pointed out, the disorder of perchlorate ions can be related to the spherical shape of the

*The coordinates of atoms marked with a prime are obtained from those of Table 1 by applying the twofold symmetry axis transformation $-x, y, \frac{1}{2} - z$.

(*9a*) which has one ordered and one disordered perchlorate group.

All of the intermolecular distances less than 3.5 Å were calculated. Most of the intermolecular contacts involve the hydrogen atoms of the bulky Cy_3P groups; however, no short intramolecular contacts were found.

The infrared spectrum of $Cu(Cy_3P)_2ClO_4$ shows the following bands due to the perchlorate group when compared to the spectrum of the free ligand Cy_3P: 1120 vs br, 1020 vs br, 910 m, 618 m, and 610 m. In the ionic, T_d ClO_4^- ion, the infrared active modes appear at 1119 s br cm^{-1} (ν_3) and 625 m cm^{-1} (ν_4) (19). Thus the splitting of the ν_3 band of ionic ClO_4^- into two strong broad bands at 1120 and 1020 cm^{-1} in $Cu(Cy_3P)_2ClO_4$, together with the appearance of ν_1, of ClO_4^- (i.r. inactive in the T_d ClO_4^- ion)

at 910 cm^{-1}, and the splitting of ν_4 into two bands at 618 and 610 cm^{-1} is indicative of coordination of the perchlorate ion to copper(I). The spectrum appears characteristic of C_{3v} monodentate perchlorate. Moers and Op Het Veld (20) have described the same compound. However, they have either misinterpreted their i.r. spectra or have not compared their spectra with the spectrum of the free Cy_3P ligand, for they propose that the perchlorate is uncomplexed and that the copper is two-coordinate and presumably linear. The possibility of their complex being structurally different from the complex described herein seems remote since the two compounds appear to have identical melting points.

The triphosphine complex, Cu(triphos)ClO_4 exhibits an infrared spectrum typical of coordinated perchlorate and very similar to that of $Cu(Cy_3P)_2ClO_4$. Thus ν_3 of ClO_4^- is resolved into two bands at 1130 and 1025 cm^{-1} while ν_1 of ClO_4^- appears at 905 cm^{-1} and ν_4 appears as a doublet at 615 and 610 cm^{-1}. These observations suggest that the complex may be structurally similar to that of $Cu(Cy_3P)_2ClO_4$, with a monodentate perchlorate and bidentate triphosphine or alternatively that all three phosphorus atoms are coordinated to a tetrahedral copper atom. Both bidentate and tridentate behavior have been established for the tritertiary phosphine $CH_3C(CH_2PPh_2)_3$ (7).

The infrared spectra of Cu(triphos)NO_3 and $Cu(Cy_3P)_2NO_3$ (4) in the NO_3^- region of the spectra are virtually identical. Cu(triphos)NO_3 has the following nitrate bands (derived from ν_3 of NO_3^-), 1437 s and 1291 m. These compare with 1452 cm^{-1} (ν_1) and 1288 cm^{-1} (ν_4) in $Cu(Cy_3P)_2NO_3$ (4). Hence, the triphos and nitrate ligands should be bidentate coordinated in Cu(triphos)NO_3 with a structure analogous to $Cu(Cy_3P)_2NO_3$ and not analogous to $Cu(MePh_2P)_3NO_3$ where the nitrate is unidentate (5).

In the ν(C=O) and ν(C=C) region of the infrared spectrum of $Cu(Cy_3P)_2$(HFac) strong bands appear at 1658, 1650, and 1513 cm^{-1}. These frequencies can be compared with the spectrum of $Cu(HFac)_2$ (21) (1644, 1614, 1565, and 1540 cm^{-1}) in the same spectral region. If the diketonate is bidentate in this complex, then considerable steric interaction between bulky tricyclohexyl groups and the acetylacetonate ligand may be expected to result from a large P—Cu—P bond angle (*vide infra*). Alternatively, a more ionic or monodentate form (22) of the diketonate may be indicated by the infrared spectrum.

For $Cu(Cy_3P)_2$(TtFac), a strong ν(C=O) + ν(C=C) band of the acetylacetonate appears at 1612 cm^{-1} with the weaker bands at 1547, 1529, and 1510 cm^{-1}. The parent complex $Cu(TtFac)_2$ exhibits bands at 1595 m, 1574 s, 1540 m, and 1508 cm^{-1}. These spectral changes favor bidentate diketonato bonding with somewhat weaker Cu—O bonds than in $Cu(TtFac)_2$.

We have recently prepared complexes with the extremely bulky phosphines (23) P(—*o*-$CH_3C_6H_4)_3$ and PBu^t_3. Structural studies of these compounds are underway in order to investigate the effect of ligand size on P—Cu—P bond angles and anion coordinating tendencies.

We are grateful to the National Research Council of Canada for operating grants (to G.F. and A.J.C.). All the calculations were performed on the University of Guelph IBM 370/155 computer system.

The ^{13}C n.m.r. spectra of anthracene and 11 methylated anthracenes have been examined. Analysis of the ^{1}H spectra allowed unequivocal assignments for most of the protonated carbons by selective proton decoupling. Parameters describing the methyl substituent effects on the aryl carbon shieldings were defined and refined by regression analysis so that the ^{13}C shieldings were predicted for 67 independent aryl positions in anthracenes without *peri*-methyls with a standard deviation of 0.12 p.p.m. *Peri* methyl–methyl interactions cause considerable deviations from the predicted substituent effects. The relationships of the ^{13}C shieldings to charge densities calculated by the CNDO/2 method were briefly examined. Syntheses of 2,7,9-trimethyl-, 1,4,5,8- and 1,4,5,9-tetramethyl-, and 1,4,5,8,9-pentamethylanthracene are described.

MYRON L. CASPAR, J. B. STOTHERS et NANCY K. WILSON. Can. J. Chem. **53,** 1958 (1975).

On a examiné les spectres de résonance magnétique nucléaire du ^{13}C de l'anthracène et de 11 dérivés méthylés de l'anthracène. L'analyse des spectres ^{1}H permet d'attribuer d'une façon non-équivoque la résonance de la plupart des carbones protonés en faisant appel au découplage sélectif du proton. On a défini des paramètres décrivant les effets d'un substituant méthyle sur le blindage des carbones aromatiques. Ces paramètres ont été affinés par une analyse de régression d'une façon telle que les blindages du ^{13}C ont pu être prédits (avec une déviation standard de 0.12 p.p.m.) pour 67 positions aromatiques indépendantes dans des anthracènes sans groupement méthyle en *péri*. Les interactions *péri* méthyle–méthyle causent des déviations considérables par rapport aux effets de substituants qui sont prédits. On a examiné brièvement les relations entre les blindages des ^{13}C par rapport aux densités de charges calculées par la méthode CNDO/2. On décrit la synthèse du triméthyl-2,7,9, des tétraméthyl-1,4,5,8 et 1,4,5,9 et du pentaméthyl-1,4,5,8,9 anthracène. [Traduit par le journal]

Introduction

Since the pioneering studies of ^{13}C spectra by Lauterbur and Burke and Lauterbur (1) in the early sixties, the utility of ^{13}C shieldings for identification of hydrocarbons (2–4) and assessment of electronic structure (5–6) has been firmly established. There is great interest in the relationships of the chemical reactivities and electronic structures to carcinogenicities of several polynuclear aromatic hydrocarbons (7–9). Thus the potential of ^{13}C n.m.r. studies to elicit information about the local electronic environments of these compounds has considerable practical as well as theoretical significance.

Detailed interpretation of the ^{13}C n.m.r. parameters of a group of compounds such as the methylated polycyclic aromatic carcinogens (10) depends to a large extent on an understanding of the influences governing ^{13}C shieldings in simpler methyl-substituted aryl systems. Methylbenzenes were carefully examined some time ago (3) and recently series of methylnaphthalenes have been examined in two separate studies (11, 12), one of which also included an investigation of the relationships of the ^{13}C shieldings to calculated charge densities (11).

To aid the further understanding of ^{13}C shieldings in aryl systems, in this study the ^{13}C spectra of anthracene and 11 methylated anthra-

cenes were examined. Analyses of the proton n.m.r. spectra allowed unequivocal assignments of the resonances of the proton-bearing carbons by selective proton decoupling. From the measured effects of the methyl substituents on the ^{13}C shieldings, a set of parameters describing the effect of methyl substitution at the 1-, 2-, and 9-positions was derived. Deviations from the expected substituent effects due to steric interactions of *peri*-methyl groups were found. Charge densities at the carbons calculated by the CNDO/2 method were found to correlate roughly with the ^{13}C shieldings. Two of the compounds studied, 1,4,5,9-tetramethylanthracene and 1,4,5,8,9-pentamethylanthracene, have not previously been reported in the literature. Their syntheses are described below.

Results and Discussion

Syntheses of Substrates

Polysubstituted anthracenes are commonly prepared by cyclodehydration of *o*-benzylacetophenones (13) and *o*-methylbenzophenones (14) or by reduction of the corresponding anthraquinones which are obtained by the cyclodehydration of *o*-benzoylbenzoic acids (15). These cyclodehydrations, which are carried out under vigorous pyrolytic or acid-catalyzed conditions, are subject to phenonium ion rearrangements (16), alkyl group migrations (17), and dealkylations (18). As a result of these and other unspecified side reactions, anthracenes prepared by these cyclodehydration processes are often obtained in low yields as difficult to purify mixtures (19).

In contrast to cyclodehydration leading to anthracenes and anthraquinones, anthrones can be prepared by the cyclodehydration of *o*-benzylbenzoic acids under mild conditions (80% sulfuric acid, 0 °C) and in high yields (> 90%) without rearrangement (20). Anthrones **are** particularly useful synthetic intermediates for the present study since they can be reduced by complex metal hydrides to 9,10-dihydro-9-anthranols which can then be converted to the corresponding anthracenes by mild acid-catalyzed dehydration. This route, summarized in Scheme 1, was used for the synthesis of 1,4,5,8-tetramethylanthracene (**4**).

Anthrones may also be converted conveniently to 9- or 10-alkylated anthracenes by base-catalyzed alkylation at the 10-methylene group followed by reduction and dehydration, or by Grignard addition to the carbonyl group followed by dehydration. The former route, outlined in Schemes 2 and 3, was used for the syntheses of 1,4,5,8,9-pentamethylanthracene (**6**) and 1,4,5,9-tetramethylanthracene (**12**). The latter route, shown in Scheme 4, was followed for the synthesis of 2,7,9-trimethylanthracene (**16**).

Syntheses of **4** and **16** through the anthrones confirm the structures of these anthracenes, which previously had been prepared via the anthraquinone for **4** (19) and via a modified Bradsher route for **16** (21).

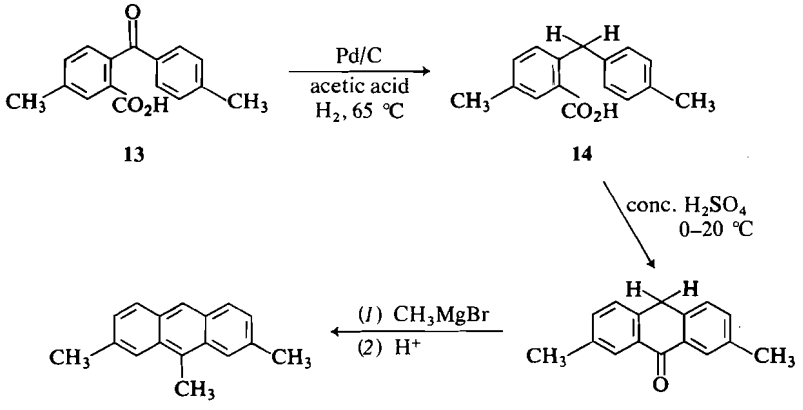

SCHEME 4. Preparation of 2,7,9-trimethylanthracene (**16**).

Nuclear Magnetic Resonance Parameters

The proton n.m.r. parameters for anthracene and 11 methylated anthracenes are given in Table 1. The deshielding effect of substitution at the 1-, 4-, 5-, 8-, 9-, or 10-positions on the *peri*-proton resonances is well established (22); thus unambiguous assignments were possible for all the proton resonances, including those giving AA′BB′ patterns, with the exception of 2-methylanthracene for which there was extensive overlap of the subspectral patterns and which also had nearly equivalent chemical shifts. Using these proton assignments, selective decoupling experiments allowed assignments of the ^{13}C resonances to specific proton-bearing carbons for all the compounds except 2-methylanthracene. Quaternary carbon signals were assigned on the basis of their relative intensities, with the assumption of approximately equal effective rotational correlation times. The nuclear Overhauser

*Observed − calculated (by additivity) values in p.p.m.

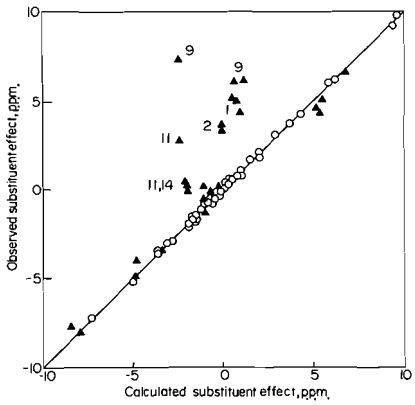

FIG. 1. Observed *vs.* calculated methyl substituent effects on aryl ^{13}C shieldings in several methylated anthracenes. ○, anthracenes without *peri*-methyl groups; ▲, anthracenes with *peri*-methyl groups. The line drawn is that for a perfect correlation with slope +1. The numbers beside groups of data points lying far off the line indicate the positions of those carbons in the anthracene molecule. Some closely clustered points have been omitted for clarity.

enhancements depend on dipolar relaxation by protons, which decreases with increases in the C–H separation, as the inverse sixth power of this separation. Thus the closer the neighboring protons, the more intense the carbon resonances, up to the maximum enhancement, which is obtained for entirely dipolar relaxation (23). The remaining resonances were assigned in a mutually consistent manner, assuming additivity of methyl group effects. The ^{13}C shieldings are collected in Table 2.

Using the results for 1-methyl-, 1,4-dimethyl-, 1,8-dimethyl-, and 1,4,5,8-tetramethylanthracene, a set of additive parameters describing the effects of a 1-methyl group on the ^{13}C shielding at all aryl positions was derived. Similarly, from the data for 9-methyl- and 9,10-dimethylanthracene, parameters for a 9-methyl substituent were obtained and from these and the data for 2-methyl- and 2,7,9-trimethylanthracene, the corresponding parameters for a 2-methyl substituent were found. After refinement of the parameters to provide the best overall fit for the set of all methylated anthracenes lacking *peri* substituents, the methyl substituent parameters given in Table 3 were obtained. These parameters predict the ^{13}C shieldings at all 67 independent aryl positions in the methylanthracenes lacking *peri*-methyl substitution with a standard error of 0.12 p.p.m. This is illustrated in Fig. 1, which compares the predicted to the observed methyl substituent effects, where the open circles correspond to data points for non-*peri*-substituted methylanthracenes. The substituent effects of a 1-methyl group on the anthracene ^{13}C shieldings are similar to those previously observed for 1-methylnaphthalenes (11). For positions which are nearly equivalent in the two systems, these agree within 0.2 p.p.m., except for the deshielding effects of the 1-methyl at C-1 and C-2, which are smaller by −0.4 and −0.5 p.p.m. in anthracene. The 2-methyl substituent effects in anthracene differ from those in naphthalene by −0.5, 0.0, 0.6, and 0.6 p.p.m., for C-1, C-2, C-3, and C-4, respectively. Although these effects are more pronounced at positions near the substituent in anthracene, at the methyl-substituted carbon C-2, they are identical, 9.6 p.p.m. in both naphthalene and anthracene.

A different picture emerges for the anthracenes with *peri* methyl–methyl interactions, 1,4,9-trimethyl-, 1,4,5,9-tetramethyl-, and 1,4,5,8,9-pentamethylanthracene. These compounds have ^{13}C shieldings which differ markedly from those predicted on the basis of the derived substituent parameters and the assumption of additivity. These differences are illustrated by the shaded triangles in Fig. 1 and are listed in Table 4.

In contrast to the increased shielding generally associated with crowded carbons separated by three bonds (24, 25) and observed for the methyl carbons with *ortho*-dimethyl substitution in naphthalenes (11), steric crowding of carbons separated by four bonds leads to deshielding of the carbons involved. This δ effect, only recently clearly recognized (26), is evident in the deshielding of the 1-methyl and 9-methyl carbons, 7.4 and 6.6 p.p.m., respectively, relative to their ^{13}C shieldings in their nonhindered counterparts. Other carbons in the sterically crowded part of the molecule likewise evince this deshielding. Thus at the methyl-substituted carbons, a single *peri*-methyl interaction results in average deshieldings of 4.9 p.p.m. at C-1 and C-9. In 1,8-dimethylnaphthalene (11) this effect was 5.1 p.p.m. at C-1. At positions *ortho* to the *peri*-methyl groups, C-2, C-11, and C-14, these effects average 3.6, 2.2, and 2.1 p.p.m., respectively. These, too, are similar to those observed in 1,8-dimethylnaphthalene, 3.0 p.p.m. at C-2 and 1.2 p.p.m. at C-9. Interestingly, the deshielding δ effects appear to be approximately additive, as is shown by comparison of the differences between

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

predicted and observed shieldings (Table 4) for C-9 of 1,4,5,8,9-pentamethylanthracene, which has two *peri*-methyl interactions, with those differences at the same carbon in 1,4,9-trimethyl- and 1,4,5,9-tetramethylanthracene, each of which has only one *peri*-methyl interaction. The 9-methyl carbon shieldings in these three compounds exhibit similar behavior, with two *peri*-methyl interactions giving rise to a deshielding of 13.1 p.p.m. and one a deshielding of 6.6 p.p.m. This 6.6 p.p.m. methyl carbon deshielding resulting from one *peri*-methyl interaction is exactly that observed in 1,8-dimethylnaphthalene (11). It seems likely that the deviations in Table 4 resulting from steric crowding of the methyl groups arise partially from alterations in the aryl carbon –carbon bond orders in the parts of the molecule close to the methyl groups. Other factors cannot, however, be discounted.

One contribution to the shielding of a given ^{13}C nucleus results from the electronic charge density at that nucleus (24). Several studies have indicated that charge distributions calculated by the CNDO/2 method (27) correlate reasonably well with experimental trends in ^{13}C n.m.r. data (28). To test for such correlations between the observed aryl shieldings and calculated charge densities for the methylated anthracenes, CNDO/2 calculations (29) for anthracene and its 1-methyl, 2-methyl, 9-methyl, 1,4-dimethyl, 1,8-dimethyl, 9,10-dimethyl, 2,7,9-trimethyl, and 1,4,5,8-tetramethyl derivatives were carried out. The results of these calculations are plotted in Fig. 2 *vs.* the experimental ^{13}C shieldings. The points shown are for the total charge density; the π charge density gave a similar plot but the correlation was slightly poorer. It was anticipated from the previous work on methylated naphthalenes (11), that aryl carbons in the β positions (C-2, C-3, C-6, C-7) of unsubstituted rings and these carbons when two bonds removed from the substituted carbon in substituted rings would be more shielded than the general trend for the other carbons, illustrated by the straight line in Fig. 2, would indicate. Data points for these β carbons were clustered tightly about one point, showing no trend in shielding with charge density. The *peri* effects of 1-methyl groups on the C-9 shieldings are sufficiently large that no discernible correlation of these shieldings with total charge density was found. For all carbons at ring junctions, C-11, -12, -13, and -14, the trends in both π and total charge densities successfully predicted the ordering of the ^{13}C resonances, but extension of these predictions to include all quaternary aryl carbons was unsuccessful, suggesting that the prediction of the ordering of the condensed carbon shieldings was somewhat fortuitous. The observed ^{13}C shieldings in the methylated anthracenes are related to the electronic charge distributions, but crudely, and other contributions to these shieldings, including bond orders and possibly as yet ill-defined steric effects, must be considered.

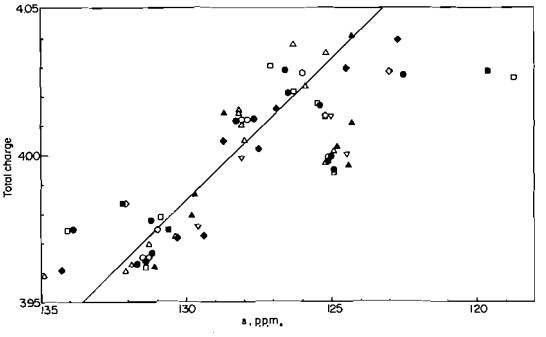

FIG. 2. Total charge densities *vs.* ^{13}C shieldings of aryl carbons in methylated anthracenes. ○, anthracene; ●, 1-methylanthracene; △, 2-methylanthracene; ▲, 9-methylanthracene; ◇, 1,4-dimethylanthracene; ◆, 2,7,9-trimethylanthracene; □, 1,8-dimethylanthracene; ■, 1,4,5,8-tetramethylanthracene; ▽, 9,10-dimethylanthracene. The total charge is given in units of *e*, the charge on the electron.

Experimental

Materials

Anthracene and 2-methyl-, 9-methyl-, and 9,10-dimethylanthracene of reagent quality were commercially obtained and used without further purification. Literature methods were followed for the syntheses of 1-methylanthracene (30), 1,4-dimethylanthracene (31), 1,8-dimethylanthracene (20), and 1,4,9-trimethylanthracene (31).

*1,4,5,8,9-Pentamethylanthracene (**6**)*

*(a) 2-(2,5-Dimethylbenzyl)-3,6-dimethylbenzoic Acid (**2**)*

To a well-stirred solution of 14.1 g (0.05 mol) of 2-(2,5-dimethylbenzoyl)-3,6-dimethylbenzoic acid (**1**) in 1500 ml of 10% sodium hydroxide heated at reflux, 50 g of zinc dust was added over a period of 48 h (19). The mixture was refluxed for an additional 24 h and then filtered. The filter cake was washed with 10% sodium hydroxide and with boiling water. The combined filtrates were strongly acidified with hydrochloric acid and extracted with benzene. The benzene extracts were dried, treated with charcoal, concentrated and then diluted with hexane. Crystallization gave 9.5 g (71%) of **2**.

(b) 1,4,5,8-Tetramethylanthrone (3)

A mixture of 2.68 g (0.01 mol) of finely powdered 2-(2,5-dimethylbenzyl)-3,6-dimethylbenzoic acid (**2**) and 20 ml of ice-cold concentrated sulfuric acid was stirred for *ca.* 15 min until all the solid had dissolved to give a clear lemon-yellow solution. This solution was allowed to warm to room temperature over 30 min, then poured onto ice and the resultant colorless solid was filtered and washed with hot water. The crude solid was dissolved in benzene, treated with anhydrous potassium carbonate and charcoal, and recrystallized from benzene–hexane to give 2.26 g (90%) of **3**, m.p. 198.5–199 °C.

Anal. Calcd. for $C_{18}H_{18}O$: C, 86.36; H, 7.25. Found: C, 86.35; H, 7.25.

The ^1H n.m.r. spectrum of **3** in $CDCl_3$ showed singlets for the 1- and 8-methyl (δ 2.48, 6H), the 4- and 5-methyl (δ 2.73, 6H), and the methylene (δ 3.82, 2H) protons; and an AB quartet (centered at δ 7.185, J = 8 Hz, 4H) for the aromatic protons.

(c) 1,4,5,8,10-Pentamethylanthrone (5)

To a refluxing, vigorously stirred suspension of 1.50 g (5.99 mmol) of 1,4,5,8-tetramethylanthrone (**3**) in 75 ml of 95% ethanol and 25 ml of methyl iodide, 9 g (0.15 mol) of potassium hydroxide was added over a period of 1 h. The cooled reaction mixture was poured into 1 l of water, filtered, and dried to give 1.61 g of a crude heterogeneous yellow and red solid.

This solid was dissolved in chloroform, treated with anhydrous sodium sulfate and charcoal and crystallized from chloroform – carbon tetrachloride to give 1.43 g (91%) of **5**.

Anal. Calcd. for $C_{19}H_{20}O$: C, 86.35; H, 7.63. Found: C, 86.28; H, 7.71.

The ^1H n.m.r. spectrum of **5** in $CDCl_3$ showed singlets for the 1- and 8-methyls (δ 2.44, 6H) and the 4- and 5-methyls (δ 2.65, 6H); a doublet for the 10-methyl (δ 1.33, 3H, J = 7 Hz); a quartet for the 10-methine proton (δ 4.40, 1H, J = 7 Hz); and an AB quartet (centered at δ 7.12, 4H, J = 8 Hz) for the aromatic protons. A carbonyl absorption at 1665 cm^{-1} was observed in the i.r. spectrum of **5** in a KBr pellet.

(d) 1,4,5,8,9-Pentamethylanthracene (6)

To a stirred solution of 1.0 g (26 mmol) of lithium aluminum hydride in 100 ml of absolute ether at 0 °C was added 100 mg (0.38 mmol) of 1,4,5,8,10-pentamethylanthrone (**5**). The solid dissolved rapidly to give a pale yellow-green solution which turned colorless over 15 min. The reaction was allowed to continue for 1 h at 0 °C. Stirring and cooling was continued while ice was added over a period of 1 h and while anhydrous magnesium sulfate was added over a second 1 h interval. The mixture was filtered and the filtrate evaporated to dryness under a stream of nitrogen to give 104 mg of a colorless mixture of *cis*- and *trans*-1,4,5,8,10-pentamethyl-9-anthranol (>90% *cis*).

The ^1H n.m.r. spectrum of this alcohol, 100 mg in 0.5 ml dimethyl sulfoxide-d_6, exhibited singlets for the 1- and 8-methyls (δ 2.38, 6H), the 4- and 5-methyls (δ 2.48, 6H), and the aromatic protons (δ 6.99, 4H); doublets for the 10-methyl (δ 1.42, 3H, J = 7 Hz), the carbinol proton (δ 5.97, 1H, J = 4 Hz) and the hydroxyl proton (δ 5.14, 1H, J = 4 Hz); and a quartet for the 10-methine proton (δ 4.25, 1H, J = 7 Hz).

Dehydration of the alcohol was carried out in the n.m.r. tube by the addition of 0.05 ml of acetic acid-d_4 and heating to 130 °C. After heating for 10 min the spectrum of the alcohol was completely replaced by the spectrum of 1,4,5,8,9-pentamethylanthracene (**6**), which showed singlet resonances for all protons; the 1- and 8-methyls (δ 2.82, 6H), 4- and 5-methyls (δ 2.70, 6H), and 9-methyl (δ 3.03, 3H); the 2-, 3-, 6-, and 7-aromatic protons (δ 7.16, 4H) and the 10- aromatic proton (δ 8.36, 1H).

1,4,5,8,9-Pentamethylanthracene (**6**) was isolated by dilution with water and extraction with chloroform as a slightly yellow, blue-green fluorescent solid (81 mg, 87%). Aged samples lost their fluorescence and turned yellow. Due to rapid oxygen incorporation, with formation of a photo-oxide of formula $C_{19}H_{20}O_2$, probably by oxygen addition across the 9,10 or 1,4 positions (32), satisfactory elemental analyses could not be obtained.

Vacuum sublimation of **6** at *ca.* 115 °C and 20 mm Hg gave a yellow crystalline solid, m.p. 140–148 °C. This solid was sublimed at 0.35 mm Hg and the fraction which sublimed between 110 and 150 °C was passed through a silica gel column (Woelm activity grade 1) with 5% benzene–hexane. The first-eluting component was concentrated and pumped at room temperature for 45 min at 0.15 mm Hg. The resulting very pale yellow crystalline solid had m.p. 154–157 °C. Its mass spectrum had the anticipated molecular ion at *m/e* 248 and the expected mass fragments for a pentamethylanthracene of formula $C_{19}H_{20}$. No significant impurities were observed.

1,4,5,8-Tetramethylanthracene (4)

This preparation was similar to the preparation of **6** above, but 1,4,5,8-tetramethylanthrone (**3**) was the starting material. The 1,4,5,8-tetramethylanthracene, in 87% yield from **3**, recrystallized from benzene–hexane and sublimed had m.p. 221–221.5 °C (lit. (19) m.p. 220–221 °C).

Anal. Calcd. for $C_{18}H_{18}$: C, 92.26; H, 7.74. Found: C, 92.34; H, 7.60.

1,4,5,9-Tetramethylanthracene (12)

(a) 2-(2,5-Dimethylbenzyl)-6-methylbenzoic Acid (9)

To a cooled, stirred solution of 50 g (0.31 mol) of 3-methylphthalic anhydride (33) in 400 ml of *p*-xylene was added 190 g of anhydrous aluminum chloride. The reaction mixture was heated at 60–65 °C for 4 h, poured onto ice, acidified with hydrochloric acid, and extracted with benzene. The benzene extracts were extracted with 5% sodium hydroxide. This basic solution was treated with charcoal, filtered, and acidified to give, upon filtration and washing with hot water, 56 g (68%) of a mixture of 2-(2,5-dimethylbenzoyl)-3- and 6-methylbenzoic acids (**7**). This mixture of isomeric acids was dissolved in 3 l of 10% sodium hydroxide and heated at reflux for 72 h with 250 g of zinc dust, which was added in portions over the course of the reduction. The hot mixture was filtered and the residue washed with hot 10% sodium hydroxide and hot water. The filtrates were strongly acidified with hydrochloric acid and extracted with benzene. The benzene extract was treated with charcoal, then fractionally recrystallized from benzene–hexane. From the more soluble fractions there was isolated 2.4 g of 2-(2,5-dimethylbenzyl)-6-methylbenzoic acid (**9**), m.p. 103–104.5 °C.

Anal. Calcd. for $C_{17}H_{18}O_2$: C, 80.28; H, 7.13. Found: C, 80.22; H, 7.26.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

From the less soluble fractions there was obtained 15.6 g of 2-(2,5-dimethylbenzyl)-3-methylbenzoic acid (**8**), m.p. 184–185 °C.

Anal. Calcd. for $C_{17}H_{18}O_2$: C, 80.28; H, 7.13. Found: C, 80.20; H, 7.30.

The structures of the isomeric acids **8** and **9** were determined from the ^1H n.m.r. spectra. The proton *ortho* to the carboxyl group in **8** appeared as a multiplet at δ 7.8, with the remainder of the aromatic protons absorbing at δ 6.8–7.5. With a methyl group *ortho* to the carboxyl group in **9**, all of the aromatic proton resonances were at δ 6.8–7.5.

(b) 1,4,8-Trimethylanthrone (10)

A mixture of 1.5 g (5.9 mmol) of 2-(2,5-dimethylbenzyl)-6-methylbenzoic acid (**9**) and 10 ml of concentrated sulfuric acid was stirred at 0 °C for *ca.* 10 min until a clear yellow solution was obtained. This solution was allowed to stand at room temperature for 30 min, then poured onto ice. Filtration and washing with water followed by recrystallization from benzene–hexane gave 1.15 g (83%) of **10**.

Anal. Calcd. for $C_{17}H_{16}O$: C, 86.40; H, 6.83. Found: C, 86.22; H, 6.92.

The ^1H n.m.r. spectrum of **10** in $CDCl_3$ exhibited singlet absorptions for the 4-methyl (δ 2.36, 3H), the 1- and 8-methyls (δ 2.72 and 2.77, 6H), and the methylene (δ 4.06, 2H); and a multiplet for the aromatic protons (centered at δ 7.25, 5H).

(c) 1,4,8,10-Tetramethylanthrone (11)

To a refluxing solution of 500 mg (2.16 mmol) of 1,4,5-trimethylanthrone (**10**) in 75 ml of ethanol under a nitrogen atmosphere, was added 1.0 g (17 mmol) of potassium hydroxide followed by the slow addition of 14 g (0.1 mol) of methyl iodide. The reaction was heated at reflux for 30 min, cooled to room temperature, diluted with 50 ml of water, and concentrated with a rotary evaporator. Filtering and drying gave 519 mg (98%) of pale yellow 1,4,8,10-tetramethylanthrone (**11**).

The ^1H n.m.r. spectrum of **11** in $CDCl_3$ showed singlets for the 4-methyl (δ 2.41, 3H) and the 5- and 8-methyls (δ 2.67 and 2.70, 6H); a doublet for the 10-methyl (δ 1.38, 3H, $J = 7$ Hz); a quartet for the methine proton (δ 4.22, 1H, $J = 7$ Hz); and a multiplet for the aromatic protons (centered at δ 7.2, 5H).

Attempts to recrystallize this anthrone **11** from chloroform–pentane caused the formation of a colorless high melting, sparingly soluble product. The same product appeared in aged samples of the anthrone.

(d) 1,4,5,9-Tetramethylanthracene (12)

A fresh sample of 1,4,8,10-tetramethylanthrone (**11**) was prepared by the above procedure from 100 mg of 1,4,8-trimethylanthrone (**10**) and without purification was directly subjected to reduction and dehydration. The crude dried **11** was dissolved in 100 ml of ether, to which, at the boiling point, 1.0 g (26 mmol) of lithium aluminum hydride was added. The reaction was stirred at room temperature for 45 min, then poured into a vigorously stirred mixture of 250 ml of ether and 10 ml of water. After 15 min of stirring, the mixture was dried with anhydrous magnesium sulfate. The filtrate was concentrated to 100 ml and then heated at the boiling point with several crystals of *p*-toluenesulfonic acid and 1 ml of water for 10 min. The solution was cooled, dried over anhydrous potassium carbonate, and evaporated to dryness with a stream of nitrogen to give 81 mg (82%) of pale yellow crystalline 1,4,5,9-tetramethylanthracene (**12**).

The mass spectrum of **12** gave the expected molecular ion at *m/e* 234 and fragments consistent with a tetramethylanthracene $C_{18}H_{18}$. About 7% of the sample was an oxygenated impurity, $C_{18}H_{18}O_2$, probably the transannular peroxide (32). Since this oxygen adduct formed rapidly in solution, n.m.r. analyses were obtained on the directly prepared product above.

Vacuum sublimation of 2 mg of **12** recovered from the n.m.r. analyses at 115 °C and *ca.* 20 mm Hg gave pale yellow crystals, m.p. 131–135 °C.

2,7,9-Trimethylanthracene (16) (34)

(a) 2-(4-Methylbenzoyl)-5-methylbenzoic Acid (13)

To 15 ml of 100% sulfuric acid was added 16.3 g (64.2 mmol) of a mixture of 2-(4-methylbenzoyl)-4- and 5-methylbenzoic acids (35). The bright orange mixture was heated at 50 °C for 49 h.

The resulting deep brown solution was poured with rapid stirring onto a slurry of crushed ice and water. The precipitate was extracted into ether and the ether solution extracted with a saturated solution of sodium bicarbonate. The basic solution was treated with charcoal, acidified with concentrated hydrochloric acid and the precipitated keto acid was extracted into ether. The ether solution was washed with water and a saturated solution of sodium chloride. After the ether solution was dried over magnesium sulfate and evaporated to dryness, 10.6 g of product was recovered, m.p. 127–144 °C. Fractional crystallization from benzene–heptane and chloroform–heptane as alternating solvent systems yielded 1.73 g (16.3%) of 2-(4-methylbenzoyl)-5-methylbenzoic acid (**13**), m.p. 162–163 °C. The i.r. spectrum showed absorption maxima at 760, 830, and 940 cm^{-1} characteristic of **13**, with no bands at 778, 842, 858, and 963 cm^{-1} characteristic of 2-(4-methylbenzoyl)-4-methylbenzoic acid.

Anal. Calcd. for $C_{16}H_{14}O_3$: C, 75.57; H, 5.55. Found: C, 75.69; H, 5.49.

The structure of keto acid **13** was proven by decarboxylation (36) to 4,4′-dimethylbenzophenone. To 19 mg of basic cupric carbonate in a short path distillation apparatus was added 500 mg (1.97 mmol) of keto acid **13**. The mixture was heated gently with a free flame until the acid melted and neutralization was complete. Water was removed on a steam bath under reduced pressure. Decarboxylation was accomplished by heating the mixture in a sand bath at 265 °C until evolution of carbon dioxide ceased. Distillation of the residue (0.5 mm) gave 205 mg (49.7%) of a yellow oil. Pale yellow needles, m.p. 91–93 °C, were obtained after a solution of the yellow oil in 95% ethanol was allowed to cool slowly. A mixture melting point of 91–93 °C was obtained for the crystallized product and an authentic sample of 4,4′-dimethylbenzophenone, m.p. 92.5–93.5 °C (lit. (37) 95 °C). The i.r. spectra of the two samples were superimposable.

(b) 2-(4-Methylbenzyl)-5-methylbenzoic Acid (14)

To 50 ml of glacial acetic acid in a Parr bottle was added 4.65 g (18.3 mmol) of keto acid **13** and 0.6 g of 5% palladium-on-carbon. The mixture was hydrogenated on a Parr apparatus under 40 psi of hydrogen at 65 °C for 6 h. The catalyst was filtered off and the acetic acid filtrate diluted with water to give 3.95 g (90%) of 2-(4-methyl-

For personal use only.

benzyl)-5-methylbenzoic acid (**14**), m.p. 113–115 °C. An analytical sample was prepared by recrystallization from chloroform–benzene, m.p. 116 °C.

Anal. Calcd. for $C_{16}H_{16}O_2$: C, 79.97; H, 6.71. Found: C, 79.69; H, 7.00.

(c) 2,7-Dimethylanthrone (15)

To 5 ml of 98% sulfuric acid at 0 °C was added 500 mg (2.1 mmol) of 2-(4-methylbenzyl)-5-methylbenzoic acid (**14**). The orange solution was allowed to warm to room temperature over 30 min, poured onto ice, and filtered. The dried product was recrystallized from chloroform–hexane to give 403 mg (87%) of pale yellow needles, m.p. 153–154 °C.

Anal. Calcd. for $C_{16}H_{14}O$: C, 86.45; H, 6.35. Found: C, 86.60; H, 6.25.

(d) 2,7,9-Trimethylanthracene (16)

To a chilled solution of methylmagnesium bromide (9 mmol) in 15 ml of ether was added 400 mg (1.8 mmol) of 2,7-dimethylanthrone **15**. The reaction mixture was vigorously stirred for 2 h while cooled in an ice-water bath. The mixture was then poured into dilute hydrochloric acid and extracted with ether. The ether solution was washed with water, 5% sodium bicarbonate, and saturated sodium chloride and dried over anhydrous magnesium sulfate. The dried ether solution was treated heavily with charcoal and evaporated to dryness. Recrystallization from ethanol gave 286 mg (72%) of 2,7,9-trimethylanthracene **16**, m.p. 124–126 °C (lit. 126 °C (21)).

Spectra

The ^1H n.m.r. spectra were obtained by pulsed Fourier transform operation on a Varian XL-100 spectrometer with internal deuterium lock, using 5% (w/v) solutions in chloroform-*d* containing 0.5% tetramethylsilane (TMS) at 28 °C. These spectra were examined with methyl protons and other protons decoupled as appropriate to obtain more accurate line positions by removal of line broadening due to small long-range couplings. Additional spectra in other solvents, *e.g.*, benzene-d_6 and acetone-d_6, were used to aid the interpretation of the overlapping patterns observed for some of the compounds. Analysis of the spectra was done with the aid of the iterative spectral fitting program LAOCN3 (38). Natural abundance ^{13}C spectra were obtained similarly, using 10–15% (w/v) solutions in chloroform-*d* containing a few drops of TMS at 40 °C. The individual aryl carbon shieldings were measured from noise-decoupled spectra. Definitive assignments of the protonated carbon resonances were then made by single frequency proton decoupling at relatively low decoupler power, with the decoupler frequency set at the proper value for each individual proton resonance in turn. The 500 Hz sweep widths used for the ^{13}C spectra gave precisions of ± 0.03 p.p.m., however, dilution effects are anticipated to be significant in these systems (11), although probably small at the concentrations employed (10), and the shieldings are therefore reported to ± 0.1 p.p.m., except for very closely lying signals.

Mass spectra were obtained by gas–liquid chromatography coupled with methane chemical ionization and 70 eV electron impact mass spectrometry on a Finnigan Model 1015C mass spectrometer interfaced with a Finnigan model 9500 gas chromatograph and on a Hewlett-Packard 5930 70 eV electron impact mass spectrometer interfaced with a Hewlett-Packard 5700 gas chromatograph. Single components and the expected mass fragments were observed for 1-methyl-, 1,4-dimethyl-, 1,8-dimethyl-, and 1,4,5,8-tetramethylanthracene. The 1,4,5,9 compound ($C_{18}H_{18}$) contained less than 7% of an oxygenated impurity ($C_{18}H_{18}O_2$) and the 1,4,5,8,9 compound contained approximately 4% of a similar impurity ($C_{19}H_{20}O_2$). Attempts to prepare acetate derivatives of the concentrated impurities were unsuccessful. These impurities are probably photooxides (32) formed by oxygen addition. To prevent formation of photooxides, the solid methylated anthracenes were stored in the dark in the freezer and solutions for n.m.r. analysis were made up immediately prior to the acquisition of spectra.

CNDO/2 Calculations

Standard bond lengths and bond angles as given by Pople and Beveridge (27) and planar ring systems were assumed. The CNINDO program from QCPE (29) was used without modification. Calculations were done on the IBM 370/165 computer of the Triangle Universities Computation Center.

We thank Dr. E. O. Oswald and Dr. G. W. Sovocool for obtaining and interpreting the mass spectra, Dr. R. D. Zehr and Miss Ināra Grikis for technical assistance, and the National Research Council of Canada for partial financial support of this research.

A Facile Route to 1 → 6 Linked Disaccharides: Syntheses of 6-*O*-β-D-Glucopyranosyl-D-glucose (Gentiobiose) and of 2-Acetamido-6-*O*-(2-acetamido-2-deoxy-β-D-galactopyranosyl)-2-deoxy-D-galactose[1]

RUSSELL R. KING[2] AND CLAUDE T. BISHOP

Division of Biological Sciences, National Research Council of Canada, Ottawa, Canada K1A 0R6

Received February 4, 1975

RUSSELL R. KING and CLAUDE T. BISHOP. Can. J. Chem. **53,** 1970 (1975).

The condensation of acetohalogeno sugars with unblocked benzyl hexopyranosides gave the 1 → 6 linked disaccharides exclusively and in good yield. The utility of this "open" synthesis was demonstrated by preparation of 6-*O*-β-D-glucopyranosyl-D-glucose (gentiobiose) and of a new disaccharide, 2-acetamido-6-*O*-(2-acetamido-2-deoxy-β-D-galactopyranosyl)-2-deoxy-D-galactose.

RUSSELL R. KING et CLAUDE T. BISHOP. Can. J. Chem. **53,** 1970 (1975).

La condensation des saccharides acétohalogénés avec les glycosides benzyliques des hexoses conduit exclusivement aux disaccharides à liaison 1 → 6 en bon rendement. On a démontré l'utilité de cette synthèse "ouverte" en préparant le 6-*O*-β-D-glucopyranosyl-D-glucose (gentiobiose) et un nouveau disaccharide, le 2-acétamido-6-*O*-(2-acétamido-2-deoxy-β-D-galactopyranosyl)-2-deoxy-D-galactose.

Previous studies (1, 2) have shown that condensation of unblocked glycosides with glycosyl halides offers an attractive synthetic route to disaccharides, particularly those for which a suitably protected aglycone would be difficult to obtain. Those studies were done with a 6-deoxyhexopyranoside (benzyl α-L-rhamnopyranoside) as the aglycone, thus eliminating the possibility of reaction at the C-6 position. It was noted (2) that the greater reactivity of primary hydroxyl groups would undoubtedly lead to a predominance of 1 → 6 linked disaccharides when this method was used with hexopyranoside aglycones.

The present report confirms the utility of this "open" synthesis for β 1 → 6 linked disaccharides by describing the preparation of a known compound, 6-*O*-β-D-glucopyranosyl-D-glucose (gentiobiose), and of a new disaccharide required for structural and serological studies, 2-acetamido-6-*O*-(2-acetamido-2-deoxy-β-D-galactopyranosyl)-2-deoxy-D-galactose.

Thus, condensation of 2,3,4,6-tetra-*O*-acetyl-α-D-glucopyranosyl bromide (**1**) with benzyl β-D-glucopyranoside (**2**) in nitromethane at 24 °C in presence of silver carbonate gave a single disaccharide product in 56% yield. The p.m.r. spectrum of this compound showed the presence of one benzyl and four acetyl groups, consistent with the expected compound (**3**). Deacetylation and hydrogenolysis of the condensation product (**3**) yielded 6-*O*-β-D-glucopyranosyl-D-glucose (**4**) (gentiobiose), characterized as its crystalline octaacetate.

The formation of a 1 → 6 linked disaccharide from 2-acetamido-3,4,6-tri-*O*-acetyl-2-deoxy-α-D-galactopyranosyl chloride (**5**) and benzyl 2-acetamido-2-deoxy-β-D-galactopyranoside (**6**) required more rigorous conditions than those used with the neutral sugar derivatives. However, condensation was effected successfully by heating the two compounds under reflux in benzene–nitromethane in the presence of cadmium carbonate. The single new compound that was formed in 13% yield gave analytical values and a p.m.r. spectrum that were appropriate for the expected disaccharide derivative (**7**). The crystalline condensation product (**7**) was readily oxidized by periodate thus confirming the anticipated 1 → 6 linkage. Deacetylation of **7** yielded a crystalline benzyl glycoside (**8**), hydrogenolysis of which furnished the new disaccharide, 2-acetamido-6-*O*-(2-acetamido-2-deoxy-β-D-galactopyranosyl)-2-deoxy-D-galactose (**9**). The p.m.r. spectrum of this disaccharide showed a doublet for the internal anomeric proton with $J_{1',2'} = 7.0$ Hz, consistent with a β-linkage (3). The yield of initial condensation product (13%) in this "open" synthesis is comparable with

those obtained (15–20%) from the reaction of acetohalogeno amino sugars with specifically blocked neutral sugars (4) and better than the 5.3% yield reported for the initial condensation step in the synthesis of 2-acetamido-6-*O*-(2-acetamido-2-deoxy-β-D-glucopyranosyl)-2-deoxy-D-glucose (5). The results show that this "open" synthesis (*i.e.* no specific blocking of the aglycone), is a practical route to β 1→6 linked disaccharides of hexopyranoses.

Experimental

Melting points were determined on a Kofler hot stage microscope and are uncorrected. Optical rotations were measured with a Perkin-Elmer 141 polarimeter and are equilibrium values unless stated otherwise. Proton magnetic resonance spectra were recorded on a Varian Anaspect EM 360 NMR spectrometer with tetramethylsilane as an internal standard except as noted. Thin-layer chromatograms were run on glass plates coated with silica gel F-254. Solvent mixtures used were (v/v): (*A*) chloroform–methanol, 5:1 and (*B*) chloroform–methanol, 7:3. Components were detected on thin-layer chromatograms by examination under u.v. light (for all benzyl glycosides) or by charring after a spray of 5% sulfuric acid in ethanol. Reducing sugars were detected by *p*-anisidine spray (6).

Benzyl 6-O-(2,3,4,6-Tetra-O-acetyl-β-D-glucopyranosyl)-β-D-glucopyranoside (3)

Benzyl β-D-glucopyranoside (**2**) (7) (0.5 g) was dissolved in nitromethane (25 ml) and the solution was stirred for 18 h with silver carbonate (1.0 g) and Drierite (2.0 g). 2,3,4,6-Tetra-*O*-acetyl-α-D-glucopyranosyl bromide (**1**) (8) (1.2 g) was added to the stirred mixture over a period of 1 h and stirring was continued for a further 18 h. The inorganic salts were removed by filtration, washed with methanol (2 × 15 ml), and the combined filtrate and washings were evaporated to dryness under diminished pressure. The condensation product was separated from unreacted monomers by preparative thin-layer chromatography (solvent *A*) which furnished pure benzyl 6-*O*-(2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranosyl)-β-D-glucopyranoside (**3**), 623 mg (56% based on **2**), crystallized from acetone, m.p. 114–116 °C, $[\alpha]_D^{24}$ −38.8° (*c*, 1.0 in ethanol); p.m.r. ($CDCl_3$) τ 2.66 (5 H singlet, aromatic protons), 7.94 (12 H quartet, 4 × OAc).

Anal. Calcd. for $C_{27}H_{36}O_{15}$: C, 53.99; H, 6.04. Found: C, 53.82; H, 6.12.

6-O-β-D-Glucopyranosyl-D-glucose (4, Gentiobiose)

The tetraacetate (**3**) (450 mg) was deacetylated in methanol (10 ml) by sodium methoxide (0.1 *N*, 10 ml). The solution was deionized (Amberlite IR-120), evaporated, and the resultant benzyl glycoside was shaken overnight with palladium black (40 mg) in 95% ethanol (25 ml) under hydrogen at atmospheric pressure. The catalyst was removed by filtration and evaporation of the filtrate gave 6-*O*-β-D-glucopyranosyl-D-glucose (142 mg), $[\alpha]_D^{24}$ +9.8° (*c*, 2.0 in water), characterized as its β-octaacetate, identical with an authentic sample, m.p. and mixture m.p. 193–194 °C.

Benzyl 2-Acetamido-6-O-(2-acetamido-2-deoxy-3,4,6-tri-O-acetyl-β-D-galactopyranosyl)-2-deoxy-β-D-galactopyranoside (7)

A mixture of 2-acetamido-3,4,6-tri-*O*-acetyl-2-deoxy-α-D-galactopyranosyl chloride (**5**) (9) (2.0 g), benzyl 2-acetamido-2-deoxy-β-D-galactopyranoside (**6**, for preparation see below) (750 mg), cadmium carbonate (1 g), and Drierite (3 g), in benzene–nitromethane (30:70, 75 ml), was heated under reflux, with stirring, until complete reaction of **6** was indicated by t.l.c. (solvent *B*), 20 min. The inorganic residue was removed by filtration, washed with acetone (2 × 75 ml) and the combined filtrate and washings were evaporated to dryness under diminished pressure. Preparative t.l.c. (solvent *B*) of the residual sirup yielded benzyl 2-acetamido-6-*O*-(2-acetamido-2-deoxy-3,4,6-tri-*O*-acetyl-β-D-galactopyranosyl)-2-deoxy-β-D-galactopyranoside (**7**) (207 mg, 13.4% based on **6**) which crystallized from ethanol, m.p. 230–232 °C, $[\alpha]_D^{24}$ −34.8° (*c*, 1.0 in water); p.m.r. (D_2O, external standard) τ 2.53 (5 H singlet, aromatic protons), 7.76 (3 H singlet, OAc), 7.90 (3 H singlet, OAc), 7.98 (3 H singlet, OAc), 8.03 (3 H singlet, NAc), and 8.09 (3 H singlet, NAc).

Anal. Calcd. for $C_{29}H_{40}N_2O_{14}$: C, 54.38; H, 6.25; N, 4.37. Found: C, 54.07; H, 6.32; N, 4.06.

This compound was sensitive to oxidation by aqueous sodium metaperiodate (reaction monitored by t.l.c., solvent *B*).

Benzyl 2-Acetamido-6-O-(2-acetamido-2-deoxy-β-D-galactopyranosyl)-2-deoxy-β-D-galactopyranoside (8)

Deacetylation of compound 7 (175 mg), as described for compound **3**, yielded the benzyl glycoside (**8**) (118 mg) which crystallized from methanol, m.p. 244–246 °C, $[\alpha]_D^{24}$ −26.5° (*c*, 1.0 in water).

Anal. Calcd. for $C_{23}H_{34}N_2O_{11}$: C, 53.67; H, 6.61; N, 5.44. Found: C, 53.22; H, 6.42; N, 5.02.

2-Acetamido-6-O-(2-acetamido-2-deoxy-β-D-galactopyranosyl)-2-deoxy-D-galactose (9)

Hydrogenolysis of compound **8** (105 mg), as described for the preparation of compound **4**, yielded the disaccharide **9** (66 mg) as a sirup, $[\alpha]_D^{24}$ +42.5° (*c*, 1.0 in H_2O); p.m.r. (D_2O, external standard) τ 4.27 (½ H doublet, $J_{1,2}$ = 3.5 Hz, H-1 of α-D-form), 4.62 (½ H doublet, $J_{1,2}$ = 7.0 Hz, H-1 of β-D-form), 5.49 (1 H doublet, $J_{1',2'}$ = 7.0 Hz, H^1-1), 7.97 (6 H singlet, 2 × NAc).

Benzyl 2-Acetamido-2-deoxy-β-D-galactopyranoside (6)

A mixture of benzyl alcohol (5 ml), 2-acetamido-2-deoxy-3,4,6-tri-*O*-acetyl-α-D-galactopyranosyl chloride (**5**) (9) (4.2 g), cadmium carbonate (2.5 g), and Drierite (8.0 g) in benzene–nitromethane (30:70, 125 ml) was heated under reflux with stirring for 2 h. The inorganic residue was removed by filtration, washed with chloroform (2 × 100 ml), and the combined filtrate and washings were evaporated to dryness under reduced pressure.

The sirupy residue was redissolved in chloroform (150 ml), the solution was washed with 10% aqueous sodium chloride (150 ml) and dried over anhydrous sodium sulfate. Evaporation of the solution gave a sirup that crystallized from ether furnishing benzyl 2-acetamido-2-deoxy-3,4,6-tri-*O*-acetyl-β-D-galactopyranoside

(1.6 g), m.p. 185–186 °C, $[\alpha]_D^{24}$ −42.6° (*c*, 1.0 in methanol) (lit. (10), m.p. 180–182 °C, $[\alpha]_D^{23}$ −55° (*c*, 1.0 in chloroform).

Anal. Calcd. for $C_{21}H_{27}NO_9$: C, 57.66; H, 6.18; N, 3.20. Found: C, 57.78; H, 6.15; N, 2.96.

The foregoing triacetate was deacetylated as described for compound **3** to yield benzyl 2-acetamido-2-deoxy-β-D-galactopyranoside (**6**) (810 mg) which crystallized from methanol, m.p. 232–234 °C, $[\alpha]_D^{24}$ −22.5° (*c*, 1.0 in methanol) (lit. (10) values for the hemihydrate, m.p. 210–212 °C, $[\alpha]_D^{23}$ −3.4° (*c*, 0.5 in water).

Anal. Calcd. for $C_{15}H_{21}NO_6$: C, 57.86; H, 6.75; N, 4.50. Found: C, 57.56; H, 6.47; N, 4.03.

We are grateful to F. P. Cooper for the p.m.r. spectra and H. Seguin for the microanalyses.

Isomerization of Bicyclic Hydrazine Monoesters to *N*-Amino-2-pyridone Esters, Precursors to Bicyclic "Isosydnones"

DONALD MACKAY AND LICHIN L. WONG

Department of Chemistry, University of Waterloo, Waterloo, Ontario N2L 3G1

Received December 23, 1974

DONALD MACKAY and LICHIN L. WONG. Can. J. Chem. **53**, 1973 (1975).

Selective aqueous alkaline hydrolysis of the diazetidine diesters **4** gives the basic monoesters **1** which isomerize quantitatively in trifluoroacetic acid or by refluxing with sodium methoxide in dioxane to the *N*-aminopyridone esters **2**. The bridged pyridazine ester **5***a* can also be selectively hydrolyzed to the presumed intermediate **10**, hydrolysis being accompanied by immediate isomerization to **2***a*. A common mechanistic pattern is proposed for these isomerizations.

Heating of **2** causes loss of alcohol to give the mesoionic "isosydnone" **3**, a fairly stable ring system slowly opened by ethanol to **2***b* and by concentrated alkali to the *N*-aminopyridone **16***a*. Oxidation of **16***a* with lead tetraacetate gives the pyridone **18***a*.

DONALD MACKAY et LICHIN L. WONG. Can. J. Chem. **53**, 1973 (1975).

L'hydrolyse alkaline aqueuse sélective des diesters de diazétidine **4** conduit au monoester basique **1** qui s'isomérise quantitativement en ester de *N*-aminopyridone **2** lorsqu'on le traite par de l'acide trifluoroacétique ou par reflux en présence de méthylate de sodium dans le dioxanne. L'ester cyclisé de pyridazine **5***a* peut aussi être hydrolysé sélectivement pour conduire à l'intermédiaire présumé **10**; l'hydrolyse est accompagnée par une isomérisation immédiate en **2***a*. On suggère que ces isomérisations procèdent par un mécanisme commun.

Le chauffage de **2** conduit à une perte d'alcool fournissant "l'isosydnone" mésoionique **3**, un système cyclique relativement stable, ouvert lentement par l'éthanol pour conduire à **2***b* et par les bases concentrées pour conduire à la *N*-aminopyridone **16***a*. L'oxydation de **16***a* par le tétraacétate de plomb conduit à la pyridone **18***a*. [Traduit par le journal]

We have recently reported that an excess of trifluoroacetic acid (TFA) isomerizes the basic diazetidine ester **1***a* to the aminopyridone ester **2***a* which cyclizes with loss of methanol to the mesoionic structure **3** (1).

We now wish to describe some aspects of the chemistry of these ring systems and in particular to show that the esters **2** can be obtained under other quite different reaction conditions, again involving deep seated skeletal rearrangements.

The diesters **4**, the precursors to **1**, were readily available in quantity as the end products of the thermal isomerization of the adducts **5** of azo esters with 2,5-dimethyl-3,4-diphenylcyclopentadienone (2). Though they are very stable to heat we have already shown that **4***a* is labile to acid, TFA causing demethylation and rearrangement to **6** (3). We were interested in trying to prepare the parent nitrogen unsubstituted 1,2-diazetidine **7**, since examples of such diazetidines are unknown.

Under varying conditions of alkaline hydrolysis it was found that one ester group in **4***a* was always easily removed. The product **1***a* was unstable to prolonged exposure to the hydrolysis conditions especially at high temperature or with high alkali concentration but when it was allowed to react completely the major end product was not the expected **7**, but the dimer of the cyclone 2,5-dimethyl-3,6-diphenylcyclopentadie-

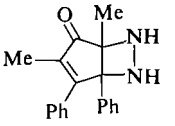
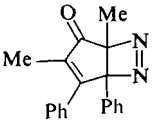
6



7

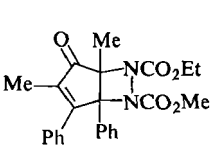


8

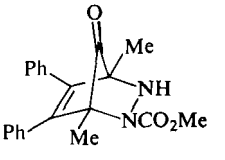
none. It seems likely that **7** is formed but is highly unstable and decomposes to the cyclone by direct loss of diimide or by prior hydrogen transfer[1] to give the diazetine **8** which would be expected to lose nitrogen readily.

The amino ester **1***a* was a faintly yellow solid, m.p. 159–160°. The optimum conditions for its preparation (90%) from **4***a* required the use of 1 *N* sodium hydroxide in aqueous ethanol for 12 h at room temperature or a 0.1 *N* solution for 6 h at reflux. The survival of the diazetidine ring followed from its conversion back into **4***a* with methyl chloroformate in refluxing pyridine; similarly it gave the mixed ester **9**, m.p. 189.5–190°, by treatment with ethyl chloroformate. The i.r. bands at 3250, 1726, and 1695 cm^{-1} (Nujol) for the NH, ester, and keto stretching frequencies and the β-phenyl-α-methyl enone chromophore at 281 nm (4) supported the bicyclic urethane structure but gave no information on the position of the ester group. The compelling evidence for our assignment is found in the n.m.r. spectrum. The parent diester has methoxy absorptions at 6.22 and 7.05 $\tau(CDCl_3)$, the latter being at unusually high field. The X-ray analysis of the *p,p'*-dibromo analog (5) showed clearly that the ester group on N-6 was very close to the face of the C-4 phenyl ring and it is reasonable that a powerful shielding effect would persist in solution. The ester absorption at 6.87 τ in the hydrolysis product thus completely identifies its structure as **1***a*; the greater resistance of this ester group to hydrolysis may be attributed to steric protection.

Hydrolysis of **4***b* under the same conditions gave a 75% yield of **1***b*, m.p. 129.5–130°. The n.m.r. absorptions of the methylene protons in its remaining ester group were widely separated, one at 5.96 and the other, highly shielded, at 6.55 τ, an effect observed for the corresponding ester group in **4***b* as previously noted (2).



9



10

Isomerization of **1***a* was complete in the time (~30 s) taken to dissolve a sample in TFA in an n.m.r. tube and run the spectrum: the reaction was quantitative. An excess of acid was necessary, however, amounts less than 1 equiv. giving a complex mixture, which contained the isomer and some of the dienone dimer but which was not analyzed further.

Isolation of the isomer involved evaporation of the TFA solution and addition of a few drops of methanol to the residue. *N*-Carbomethoxy-1-amino-3,6-dimethyl-4,5-diphenyl-2-pyridone (**2***a*), m.p. 232–233° (with loss of methanol), had n.m.r. absorptions at 6.16, 7.80, and 8.06 τ assignable to the methoxy, C_6, and C_3-methyl groups, i.r. bands at 3140(NH), 1756, and 1640cm^{-1} (ester and ring CO) and strong chromophores at 245 and 317 nm (*cf.* i.r. and u.v. spectra of ring substituted 1-amino-2-pyridones (6,7)). The structure was finally confirmed by X-ray analysis.[2]

The preparation of the ethyl ester **2***b*, m.p. 218–218.5° was carried out in the same way. Its spectra were completely analogous to those of **2***a*.

Our results with the selective hydrolysis of the diester **4***a* prompted us to examine the behavior of the parent isomeric compound **5***a* with alkali. The use of 1 *N* sodium hydroxide in methanol or, as for **4***a*, aqueous methanol at room temperature caused considerable decomposition but the major product (50–60%) was again **2***a*. The pyridone ester is evidently a stable end product of both the [2.2.1] and the [3.2.0]diazabicyclo systems. This reaction which also involves monohydrolysis and decarboxylation, presumably went through the basic ester **10**, an isomer of **1***a*, but it did not involve the sequential rearrangements **10** → **1***a* → **2***a*, since **1***a* was found to be stable to the solvolysis conditions. The conversion of **10** to **2***a* thus probably occurred directly. The isomerization of **1***a* to **2***a* (70% yield) with basic catalysis could, however, be

[1]Since **7** would be sensitive to air oxidation the hydrolysis was repeated under nitrogen but without affecting the result.

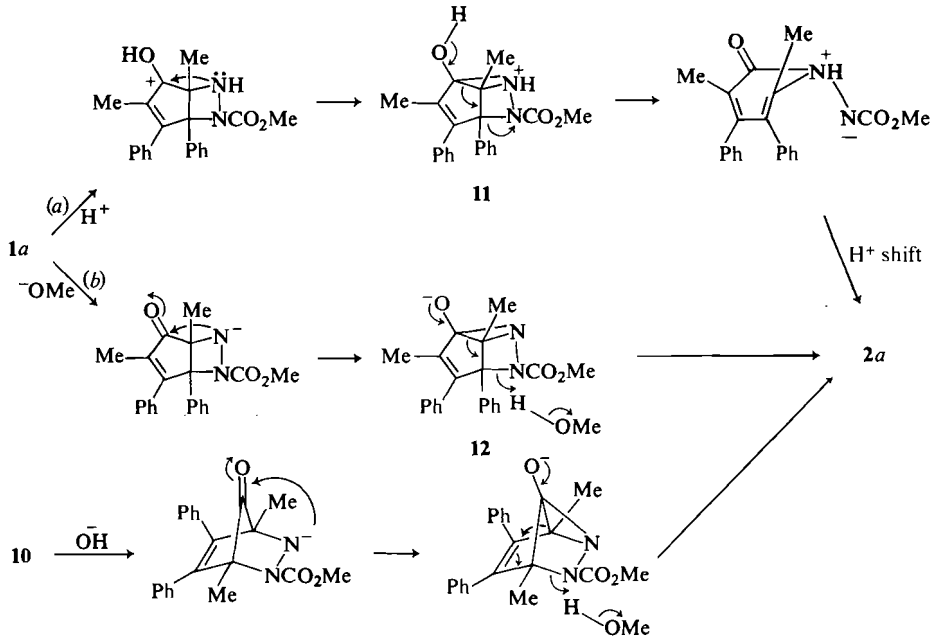

SCHEME 1

achieved with a suspension of sodium methoxide in refluxing dioxane.

These isomerizations to **2***a* involve in effect the transposition of the *tert*-methyl and the adjacent basic nitrogen. We have suggested (1) that the acid catalyzed route from **1***a* involves the tricyclic azirdinium ion **11** (Scheme 1, route *a*). In the methoxide catalyzed reaction (Scheme 1, route *b*) of **1***a* the intermediate by analogy would be **12**, the anion equivalent of **11**; similarly the alkaline isomerization of **10** would go through the tricyclic anion **13**. The acidity of the NH in **1***a* and **10** would be promoted by the adjacent electron withdrawing urethane group.

Treatment of **2***a* in dimethoxyethane with sodium hydride followed by methyl chloroformate gave the diester **14**, m.p. 217.5–219°. Its methoxy groups gave the sharp singlet in the n.m.r. spectrum expected from the symmetry of the molecule and rapid N—N rotation.

Hydrolysis of the ester group in **2***a* was slow in dilute alkali and only 65% complete after refluxing for 24 h in 4 *N* sodium hydroxide in aqueous dioxane. The product *N*-aminopyridone was more efficiently made from the bicyclic compound **3**.

Loss of alcohol from **2***a* or *b* was rapid at the m.p., the product immediately solidifying and remelting at 300–301°.[3] On a preparative scale it was conveniently made by heating a sample of **2***a* at 270° for 15 min. The n.m.r. absorptions at 7.50 and 7.77 τ showed that the methyl groups were still located on unsaturated centers but the profound changes in the u.v. spectrum, with λ_{max} at 278 with a shoulder at 305 nm, clearly originated from a quite different π bond arrangement. There was one intense carbonyl singlet at 1780 cm^{-1} in Nujol, shifted to 1755 cm^{-1} in chloroform. The high m.p., the spectra, the method of formation, and the ensuing chemical reactions are consistent only with the mesoionic ("isosydnone") structure 5,8-dimethyl-6,7-diphenyl-1,3,4,-oxadiazolo[3,2-*a*] pyridin-2(*3H*)-one (**3**).

Monocyclic analogs of this ring system have been examined (8), as well as the bicyclic parent compound **15** (9), the latter being evidently the more stable type towards nucleophilic opening of the oxadiazolone ring (10). This is presumably due to the contribution of resonance forms **15***a* and *b* involving a formal pyridinium cation, a

[3]The quantitative nature of the isomerization is emphasized by the observation that a mixture of **2***a* and *b* heated in a capillary tube gave **3** which melted sharply at 300–301°.

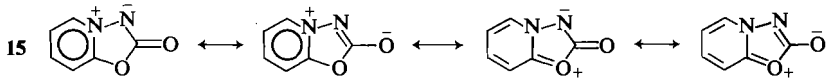
14

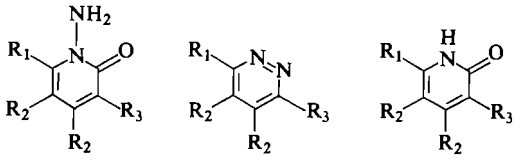


15

a b c d

source of stabilization which is unavailable to the monocyclic species and which makes the oxadiazolone ring relatively unattractive to nucleophiles. In keeping with this **3** was very slowly (17 days) cleaved by refluxing ethanol to give **2***b* and required refluxing for 3 h with 4 *N* sodium hydroxide for complete hydrolysis to 1-amino-3,6-dimethyl-4,5-diphenyl-2-pyridone (**16***a*), m.p. 217–219°, which gave a yellow benzylidene derivative, m.p. 233–233.5°.

Rees and Yelland (11, 7) found that oxidation of a series of ring substituted *N*-aminopyridones **16** with lead tetraacetate in methylene chloride proceeded with loss of carbon monoxide to give the pyridazines **17** and by deamination to give the pyridones **18** as major products, the proportions depending on the substitution pattern. Thus the tetraphenyl derivative **16***b* gave **17***b* and no **18***b*,



16 17 18

a $R_1 = R_3 = Me$; $R_2 = Ph$
b $R_1 = R_2 = R_3 = Ph$
c $R_1 = R_2 = Ph$; $R_3 = H$
d $R_1 = Me$; $R_2 = R_3 = Ph$

the triphenyl derivative **16***c* gave a little **17***c* and mostly **18***c*, whereas the triphenyl monomethyl derivative **16***d* gave only **18***d*. Predictably from these results the similar oxidation of **16***a* gave a mixture whose n.m.r. spectrum showed the main product to be the pyridone **18***a* (48%) but no low field methyl absorption which could be attributed to the pyridazine **17***a*.[4] Work-up gave **18***a* of m.p. 309.5–310.5°. Its identity followed from comparison of its properties with those published (13) for the pyridone synthesized by ring closure.

[4]All absorptions occurred above 7.5 τ. The methyl absorption in **17***a* would be expected at lower field than in 3,4,6-trimethylpyridazine in which both the C_3- and the C_6-methyl groups absorb at 7.40 τ in $CDCl_3$ (12).

Experimental

The following spectrometers were used: for i.r. a Beckman IR 10; for u.v. a Coleman EPS-3T Hitachi; for n.m.r. a Varian T-60, absorptions being given in τ values against tetramethylsilane; for m.s. an AEI MS-30.

Magnesium sulfate was used as drying agent for solutions in organic solvents; melting points are uncorrected.

1,3-Dimethyl-4,5-diphenyl-6-carbomethoxy-6,7-diazabicyclo[3.2.0]hept-3-en-2-one (1a)

A solution of the diazetidine **4***a* (2) (600 mg, 1.48 mmol) in 0.1 *N* sodium hydroxide in aqueous methanol (1:9, 30 ml) was refluxed for 6 h, neutralized with acetic acid, and evaporated to near dryness to give a solid residue (470 mg, 91%) which was washed thoroughly with water.

Alternatively **4***a* (200 mg) was allowed to stand for 12 h at room temperature in 1 *N* sodium hydroxide in aqueous methanol (1:1, 10 ml) and the solution neutralized and worked-up as above. The yield was about the same.

Crystallization from methanol and then benzene–isooctane gave faintly yellow prisms of the basic ester **1***a*, m.p. 159–160°; ν(Nujol) 3250 (NH), 1726, 1695 cm^{-1} (ester, keto C=O); λ_{max} (EtOH) 281 nm (ε 12 800); τ($CDCl_3$) 2.5–3.0 (10 phenyl H), 4.77 (s, 1 NH), 6.97 (s, 3H, OMe), 7.90 (s, 3H, vinyl Me), 8.92 p.p.m. (s, 3H *tert*-Me); *m/e* 348(P^+, 9%), 260 ($C_{19}H_{16}O^+$, 100%).

Anal. Calcd. for $C_{21}H_{20}N_2O_3$: C, 72.39; H, 5.79; N, 8.04. Found: C, 72.28; H, 5.80; N, 8.22.

Hydrolysis of 4a under Vigorous Conditions

A sample of **4***a* (100 mg, 0.25 mmol) was refluxed for 1 h in 1 *N* sodium hydroxide in aqueous ethanol (5:1, 10 ml). Neutralization, evaporation, and addition of water to the residue gave mainly the dimer of 2,5-dimethyl-3,4-diphenylcyclopentadienone, identified by i.r. and n.m.r. spectra and by its mixture m.p. of 185–186° after crystallization from aqueous ethanol. The same result was obtained when the hydrolysis was carried out under nitrogen.

Reconversion of 1a to 4a

The basic ester **1***a* (100 mg, 0.29 mmol) and methyl chloroformate (0.2 ml) were refluxed in pyridine (3 ml) for 1.5 h. The solution was evaporated, water was added,

For personal use only.

and the solid residue (90 mg, 76%) twice crystallized from aqueous methanol to give **4***a*, m.p. 198–200°, mixture m.p. 200–201° with an authentic sample.

*Conversion of **1***a* to 1,3-Dimethyl-4,5-diphenyl-6-carbomethoxy-7-carbethoxy-6,7-diazabicyclo[3.2.0]-hept-3-en-2-one (**9**)*

A solution of **1***a* (100 mg, 0.29 mmol) in pyridine (1 ml) containing ethyl chloroformate (50 mg 0.046 mmol) was kept at room temperature for 3 days and then evaporated to dryness. Addition of water gave the mixed ester **9** (87 mg, 72%), which when twice crystallized from aqueous ethanol had m.p. 189.5–190°; ν(Nujol) 1755, 1726, 1710 cm^{-1} (ester, keto C=O); τ($CDCl_3$) 2.2–3.4 (10 phenyl H), 5.75 (q, 2 ethoxy CH_2, J = 7.0 Hz), 7.06 (s, 3 OMe H), 7.91 (s, 3H, vinyl Me), 8.71 (t, 3H, ethoxy Me), 8.82 p.p.m. (s, 3H, *tert*-Me).

Anal. Calcd. for $C_{24}H_{24}N_2O_5$: C, 68.56; H, 5.75; N, 6.66. Found: C, 68.63; H, 5.88; N, 6.93.

*1,3-Dimethyl-4,5-diphenyl-6-carbethoxy-6,7-diazabicyclo[3.2.0]hept-3-en-2-one (**1b**)*

A solution of the diazetidine **4***b* (500 mg, 1.15 mmol) in 1 *N* sodium hydroxide in aqueous ethanol (1:4, 50 ml) was kept at room temperature for 12 h and then neutralized with acetic acid and evaporated to a small volume. The residual gum crystallized on addition of water. The product (340 mg, 82%) was twice crystallized from cyclohexane giving almost colorless prisms, m.p. 129.5–130°; ν(Nujol) 3180(NH) 1704, 1682 cm^{-1} (ester, keto C=O); λ_{max} (EtOH) 282 nm (ε 13 000); τ($CDCl_3$) 2.4–3.3 (10 phenyl H), 4.7 (broad, 1 NH), 5.96 (octet, 1H, methylene A portion of ester AMX_3, J_{AM} = 10.2, J_{AX} = J_{MX} = 7.0 Hz), 6.55 (octet, 1H, broadened, M portion of AMX_3, 3H), 7.82 (s, 3H, vinyl Me), 8.84 (s, 3H, *tert*-Me), 9.11 p.p.m. (t, 3H, X_3 portion of AMX_3).

Anal. Calcd. for $C_{22}H_{22}N_2O_3$: C, 72.91; H, 6.12; N, 7.73. Found: C, 72.84; H, 6.37; N, 7.95.

*N-Carbomethoxy-1-amino-3,6-dimethyl-4,5-diphenyl-2-pyridone (**2a**)*

A solution of **1***a* (300 mg, 0.86 mmol) in TFA (3.0 ml) was kept at room temperature for 4 h and then evaporated in a stream of nitrogen. Trituration of the residue with methanol caused crystallization and the product (282 mg, 94%) was collected and washed with aqueous sodium bicarbonate. Its spectra were identical with those obtained after recrystallization from methanol as colorless prisms, m.p. 232–233°, followed by loss of methanol, solidification, and remelting at 300–301° (the m.p. of **3**); ν(Nujol) 3140(NH), 1756, 1640 cm^{-1} (ester, ring C=O); λ_{max}(EtOH) 245, 317 nm (ε 13 000, 7500); τ($CDCl_3$) 1.15 (s, 1 NH) 2.6–3.4 (10 phenyl H), 6.16 (s, 3H, OMe), 7.80 (s, 3H, C_3–Me), 8.06 p.p.m. (s, 3H, C_6-Me).

Anal. Calcd. for $C_{21}H_{20}N_2O_3$: C, 72.39; H, 5.79; N, 8.04. Found: C, 72.19; H, 5.83; N, 7.97.

When a sample of **1***a* (50 mg) was added to TFA (0.5 ml) in an n.m.r. sample tube it rapidly dissolved. The spectrum was scanned within 30 s but showed absorptions only for the product **2***a*; τ(TFA) 2.3–3.3 (10 phenyl H), 5.93 (s, 3H, OMe), 7.53 (s, 3H, C_3-Me), 7.76 p.p.m. (s, 3H, C_6-Me).

*Reaction of **1***a* with Limited Amounts of TFA*

A solution of **1***a* (200 mg, 0.58 mmol) in methylene chloride (2 ml) was treated with TFA (10 μl, 0.13 mmol) and a portion monitored by n.m.r. analysis. The spectrum slowly became very complex but showed no further change after 7 h; the amount of **2***a* was rather less than 50%. Work-up with methanol of the residue from the whole reaction gave a small amount of the sparingly soluble dimer of 2,5-dimethyl-3,4-diphenylcyclopentadienone, identified by comparison with a synthetic sample.

*N,N-Dicarbomethoxy-1-amino-3,6-dimethyl-4,5-diphenyl-2-pyridone (**14**)*

To a solution of **2***a* (348 mg, 1 mmol) in dry dimethoxyethane (10 ml) was added first a sodium hydride – paraffin oil dispersion (1:1, 72 mg, 1.5 mmol) which caused evolution of hydrogen and the formation of a yellow solution and then, immediately, methyl chloroformate (75 μl, 1 mmol). The solution rapidly became cloudy and sodium chloride precipitated. The mixture was left for 12 h and worked-up with ether and water, the organic layer being thoroughly washed with water and dried. It gave on evaporation almost pure diester **14** (326 mg, 81%), which crystallized from aqueous methanol as rods, m.p. 217.5–219°; ν(Nujol) 1821, 1668 cm^{-1} (2 ester, ring C=O); λ_{max} (EtOH) 247, 319 nm (ε 15 000, 7900); τ($CDCl_3$) 2.6–3.3 (10 phenyl H), 6.04 (sharp s, 6H, OMe), 7.98 (s, 3H, C_3-Me), 8.04 p.p.m. (s, 3H, C_6-Me).

Anal. Calcd. for $C_{23}H_{22}N_2O_5$: C, 67.97; H, 5.46; N, 6.89. Found: C, 68.06; H, 5.35; N, 7.16.

*N-Carbethoxy-1-amino-3,6-dimethyl-4,5-diphenyl-2-pyridone (**2b**)*

The basic ester **1***b* was treated with an excess of TFA exactly as described for **1***a*. The yield was nearly quantitative. Crystallization from aqueous methanol gave prisms, m.p. 218–218.5°, followed by loss of ethanol, solidification, and remelting at 299–300°; ν(Nujol) 3150 (NH), 1754, 1638 cm^{-1} (ester, ring C=O); λ_{max} (EtOH) 245, 317 nm (ε 13 000, 7300); τ($CDCl_3$) 1.25 (s, 1NH), 2.6–3.4 (10 phenyl H), 5.71 (q, 2H, ester methylene, J = 7.1 Hz), 7.82 (s, 3H, C_3-Me), 8.07 (s, 3H, C_6-Me), 8.71 p.p.m. (t, 3H, ester Me).

Anal. Calcd. for $C_{22}H_{22}N_2O_3$: C, 72.91; H, 6.12; N, 7.73. Found: C, 73.01; H, 6.30; N. 7.97.

*Reaction of 1,4-Dimethyl-5,6-diphenyl-2,3-dicarbomethoxy-2,3-diazabicyclo[2.2.1]hept-5-en-7-one (**5a**) with Sodium Hydroxide*

(a) Aqueous methanol

A solution of **5***a* (100 mg, 0.25 mmol) in 1 *N* sodium hydroxide in aqueous methanol (1:1, 5 ml) was allowed to stand at room temperature for 12 h. Most of the methanol was removed by evaporation at room temperature and the milky solution was thoroughly extracted with methylene chloride. The n.m.r. of the residue (60 mg) contained about 70% of **2***a* (overall yield 50%), determined by integration. It was identified as described in *b*.

(b) Methanol

A solution of **5***a* (200 mg) in 1 *N* sodium hydroxide in methanol (20 ml) was allowed to react at room temperature over 24 h and then reduced in volume and neutral-

For personal use only.

ized with acetic acid. Evaporation to near dryness and addition of water gave product (103 mg) which was nearly pure **2***a* (60%). Recrystallization from carbon tetrachloride – cyclohexane gave material of m.p. 231–232°, identified by spectra and mixture m.p. The end result was the same if the alkaline solution was not neutralized.

Control Reaction: Stability of 1a to Methanolic Sodium Hydroxide

When **1***a* (50 mg) was treated under the exact conditions of reaction *b* above it was quantitatively recovered.

Sodium Methoxide Catalyzed Isomerization of 1a to 2a

A suspension of sodium methoxide (54 mg, 1 mmol) in dry dioxane (10 ml) containing **1***a* (100 mg, 0.29 mmol) was refluxed for 24 h. The mixture was evaporated to dryness and treated with methylene chloride and an excess of dilute acetic acid. The organic layer on drying afforded solid (83 mg) whose n.m.r. spectrum showed the presence of **2***a* in an overall yield of 70%. Crystallization from carbon tetrachloride – cyclohexane gave pyridone of m.p. and mixture m.p. 230–231°.

5,8-Dimethyl-6,-7-diphenyl-1,3,4-oxadiazolo[3,2-a]-pyridine-2(3H)-one (3)

The pyridone **2***a* (300 mg, 0.86 mmol) was heated at 270° for 15 min during which it melted, lost methanol, and then solidified. The product (276 mg, 100%) was twice crystallized from ethanol as long needles, m.p. 300–301°; ν(Nujol) 1780 cm^{-1} (C=O); ν($CHCl_3$) 1755 cm^{-1} (C=O); λ_{max} (EtOH) 278, sh 305 nm (ε 15 200, 8800); τ($CDCl_3$) 2.5–3.2 (10 phenyl H), 7.50 (3H, C_8-Me), 7.77 p.p.m. (3H, C_5-Me); *m/e* 316 (P^+, 100%), 288 (13%), 274 (15%), 246 (14%), 205 (14%), 115 (15%), 77(11%).

Anal. Calcd. for $C_{20}H_{16}N_2O_2$: C, 75.93; H, 5.10; N, 8.86. Found: C, 75.66; H, 5.25; N, 8.55.

Compound **3** could be similarly made in quantitative yield by elimination of ethanol from the pyridone **2***b* at 270°.

1-Amino-3,6-dimethyl-4,5-diphenyl-2-pyridone (16a)

(a) Hydrolysis of 2a

To a solution of **2***a* (100 mg, 0.29 mmol) in dioxane (1 ml) was added aqueous 4 *N* sodium hydroxide (2 ml). The two-phase system was refluxed for 24 h, the dioxane was evaporated off, and the residue, which slowly crystallized, was collected by filtration. Its n.m.r. spectrum showed it to contain 35% of starting material and 65% of the product **16***a*. Its i.r. spectrum likewise showed only bands for these two compounds. No effort was made to isolate **16***a*, a more efficient synthesis being available as described in *b*.

(b) Hydrolysis of 3

A two-phase mixture of aqueous 4 *N* sodium hydroxide (3 ml) and dioxane (1 ml) containing **3** (100 mg, 0.32 mmol) was refluxed for 3 h. Evaporation of the dioxane layer produced the crystalline hydrazine **16***a* (89 mg, 97%) whose spectra were indistinguishable from those of material obtained by recrystallization from aqueous methanol, m.p. 217–219° (dec.); ν(Nujol) 3256, 3156 (NH_2), 1630 cm^{-1} (C=O); λ_{max} (EtOH) 318, sh 245 nm (ε 7500, 13 000); τ($CDCl_3$) 2.7–3.4 (10 phenyl H), 4.55 (s, 2NH), 7.72 (3H, C_3-Me), 8.02 p.p.m. (3H, C_6-Me).

Anal. Calcd. for $C_{19}H_{18}N_2O$: C, 78.59; H, 6.25; N, 9.65. Found: C, 77.91; H, 6.34; N, 9.55.

The benzylidene derivative was prepared by refluxing **16***a* (72 mg, 0.25 mmol) and benzaldehyde (40 mg, 0.38 mmol) for 3.5 h in ethanol (3 ml) containing 3 drops of acetic acid. Evaporation and addition of water gave the product (60 mg, 63%) which was recrystallized from aqueous ethanol as yellow needles, m.p. 233–233.5°; ν(Nujol) 1637, 1610 cm^{-1} (C=O, C=N); λ_{max} (EtOH) 349 nm.

Anal. Calcd. for $C_{26}H_{22}N_2O$: C, 82.51; H, 5.86; N, 7.40. Found: C, 82.42; H, 5.95; N, 7.43.

Ethanolysis of 3

A solution of **3** (100 mg) was refluxed in ethanol (5 ml) and the progress of the reaction followed by evaporation and n.m.r. analysis of the residue. Solvolysis had occurred to the extent of 60% in 7 days and was complete in 17 days. The reaction was quantitative, and one crystallization from aqueous ethanol gave **2***b*, m.p. 216–216.5°, undepressed on admixture with authentic ester.

Oxidation of 16a with Lead Tetraacetate (7)

A solution of **16***a* (100 mg, 0.35 mmol) in dry methylene chloride (5 ml) was treated with lead tetraacetate (200 mg, 0.45 mmol) in portions. There was vigorous effervescence and the development of a yellow color. Unraacted oxidizing agent was destroyed by adding a few drops of 2-propanol and the filtered solution was washed out with water and aqueous potassium carbonate. The n.m.r. spectrum of the residue (100 mg) was complex in the methyl region, which occurred above 7.5 τ, but the major product was 3,6-dimethyl-4,5-diphenyl-2-pyridone, **18***a* (48%, determined by area measurement of its two methyl peaks as a fraction of the total). Two crystallizations from methanol gave the pale yellow pyridone **18***a*, m.p. 309.5–310.5° (lit. (13) m.p. 305–307°); ν(Nujol) 3415 (NH), 1640 cm^{-1} (C=O); λ_{max} (EtOH) 243.5, 317 nm (lit. (13) 242, 314 nm); τ($CDCl_3$) 2.5–3.3 (10 phenyl H and 1 NH, exchangeable with D_2O), 7.78 (3H, C_3-Me), 8.04 p.p.m. (3H, C_6-Me).

Anal. Calcd. for $C_{19}H_{17}NO$: C, 82.88; H, 6.22; N, 5.09. Found: C, 83.16; H, 6.18; N, 5.11.

High Resolution ^{13}C Spectrum and Long-range $^{13}C,H$ Couplings in 2-Pyrone

A. A. CHALMERS AND K. G. R. PACHLER

Chemical Physics Group, National Chemical Research Laboratory, Council for Scientific and Industrial Research, P.O. Box 395, Pretoria 0001, Republic of South Africa

Received January 21, 1975

A. A. CHALMERS and K. G. R. PACHLER. Can. J. Chem. **53**, 1980 (1975).

The natural abundance ^{13}C n.m.r. spectrum of 2-pyrone has been analyzed by the ^{13}C–$\{^1H\}$ SPI technique. The magnitudes and signs of all long-range $^{13}C,H$ couplings have been obtained and are compared with those of related compounds.

A. A. CHALMERS et K. G. R. PACHLER. Can. J. Chem. **53**, 1980 (1975).

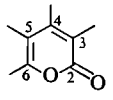
On a analysé, par la technique SPI ^{13}C–$\{^1H\}$, les spectres r.m.n. du ^{13}C en abondance naturelle de la pyrone-2. On a obtenu les amplitudes et les signes de tous les couplages $^{13}C,H$ à longue distance et on a comparé ces valeurs avec celles de composés apparentés.

[Traduit par le journal]

Introduction

Determination of long-range $^{13}C,H$ coupling constants from natural abundance ^{13}C spectra is becoming increasingly more feasible as modern FT spectrometers make available high resolution, high sensitivity spectra. Second-order analysis of the ^{13}C spectra can give the assignment and signs of such couplings (1–3) but ^{13}C spectra commonly show only slight second-order features so that ambiguities can arise (4). Since the ^1H part of the spectrum cannot usually be observed the $J(C,H)$ assignments will depend on either ^{13}C–$\{^1H\}$ double resonance or knowledge of the magnitudes of couplings in related structures. Present knowledge is still sparse but it appears that similar values for ^2J, ^3J, and ^4J are possible (5). More data are, therefore, required if these couplings are to become of use in structural studies.

The double-resonance method used here, ^{13}C–$\{^1H\}$ SPI (6), has been employed previously in studies on three-spin systems (7, 8) and so the five-spin systems of 2-pyrone (**1**) provide a more exacting test of the method.



1

In **1** five differing carbons are all coupled to four nonequivalent protons and consequently 16 long-range $^{13}C,H$ couplings exist. Analysis of the $^{13}C,H$ long-range couplings requires first analysis of the usual ^1H spectrum for chemical shifts $\delta(H)$ and coupling constants $J(H,H)$. Although the ^1H spectrum of 2-pyrone has already been analyzed (9), data obtained under identical conditions (solvent, concentration, and temperature) as for the ^{13}C spectra are required. The appropriate data are given in the experimental section. In dilute solution (3 mol%) in C_6D_6 the ^1H spectrum of **1** is close to first order and a ^1H–$\{^1H\}$ INDOR study of this spectrum showed that all $J(H,H)$ have the same sign which is presumed to be positive. Assignments of the ^{13}C chemical shifts were obtained unambiguously from the ^{13}C–$\{^1H\}$ SPI experiments and agree with the assignments already reported (10).

Spectra and Method

Figure 1 shows the complete ^{13}C spectrum of **1** with expanded high-field halves of C_4, C_5, and C_6. The low-field halves are mirror images

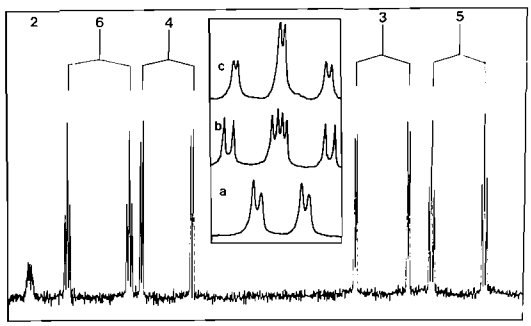


FIG. 1. Single-resonance ^{13}C spectrum of **1**. Insert expanded high-field halves of (*a*) C_4, (*b*) C_5, and (*c*) C_6.

of those shown and it is clear that the spectra are close to first order, as is the spectrum of C_3 which is displayed in Fig. 3*a*. The spectrum of C_2 is shown in Fig. 2.

In the following analysis the method is divided into making assignment experiments and sign determination experiments. An SPI irradiation in the region of a proton resonance $\delta(H_i)$ will usually cause sufficient perturbation of the ^{13}C lines for assignment of all long-range $J(C,H_i)$ provided there is no serious overlap of the H_i lines with those of other protons. This convenient procedure has been demonstrated in a previous communication (7). Irradiations at the other $\delta(H)$ regions will enable all the $J(C,H)$ to be assigned and hence theoretical ^1H spectra for every ^{13}C isotopomer can be constructed. Selective irradiations at specific ^1H lines will then give the sign information.

Figure 4*a* shows the calculated ^1H spectrum for the C_3 isotopomer and serves to illustrate the two examples of selective experiments, the results of which are displayed in Fig. 3. In Fig. 4*a* the $J(C,H)$ couplings are indicated as an aid to the understanding of the splitting pattern. Irradiation at line 2 of Fig. 4*a* gives the DSPI spectrum (7) Fig. 3*c* and can be viewed as an assignment experiment since it shows that the second smallest coupling to C_3 is $^4J(C_3,H_6)$. Another irradiation at either an H_5 or an H_4 line then allows complete assignment of the couplings to C_3. Figure 4*c* represents the lower field half of the C_3 resonance, that is the left hand part of Fig. 3*a*, and shows the assignment of the couplings as determined above. The combination of spin states shown in Fig. 4*c* comes from the sign determination experiment in which line 1 of Fig. 4*a* was irradiated. The known spin states ($^1J(C,H)$ and all $J(H,H)$ positive) give the representation of the H_3 lower field outer satellites shown in Fig. 4*b*. Thus, the DSPI spectrum Fig. 3*b* for irradiation at line 1 shows that all the long-range $J(C_3,H)$ are positive except for $^4J(C_3,H_6)$. Analogous experiments at other lines give the complete data given in Table 1.

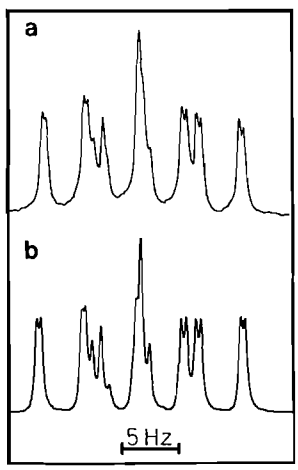

FIG. 2. (*a*) Observed and (*b*) calculated spectra of C_2.

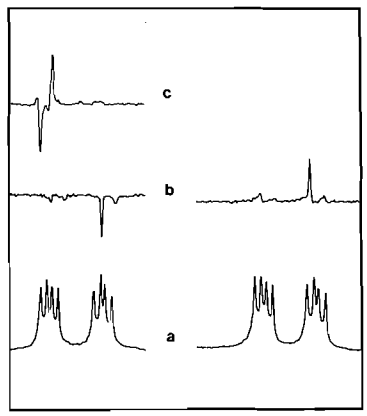

FIG. 3. (*a*) Single-resonance ^{13}C spectrum of C_3, (*b*) and (*c*) $^{13}C_3$-{^1H} DSPI spectra.

The spectrum of the C_2 isotopomer Fig. 2*a* deserves some extra comment since it shows definite second-order features which are essentially confined to the low-field half of the

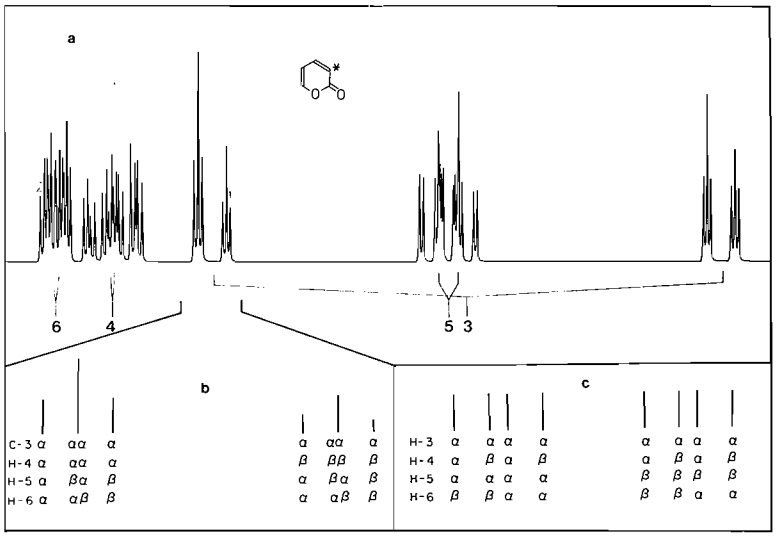

FIG. 4. (*a*) Calculated ^1H spectrum of C_3 isotopomer. (*b*) Expanded portions of *a* with spin states. (*c*) Low-field half of C_3 resonance with spin states.

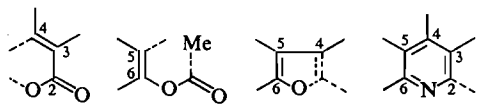
spectrum. The SPI spectra are straightforward when the ^1H irradiation is located so as to perturb the high-field half of this resonance. The calculated spectrum Fig. 2*b* reproduces moderately well the second-order features although no adjustment was made for isotope effects on the ^1H chemical shifts and the J(C,H) used came directly from the SPI results. Further calculations show that the second-order features are due to interaction between the H_4 and H_6 parts of the spin system.

Discussion

The only unresolved coupling is $^2J(C_4,H_3)$ and from the overall resolution of the spectrum its absolute value must be less than 0.3 Hz. The signs of the couplings are in agreement with previous work (3, 11) on six-membered ring molecules; ^4J(C,H) negative, and ^3J(C,H) and ^2J(C,H) positive. In Table 1 the couplings are compared with literature values (1–3) of some molecules which contain structural moieties similar to **1** *viz.* acrylic acid (**2**), vinyl acetate (**3**), furan (**4**), and pyridine (**5**). The structures of these molecules are drawn below, numbered artificially for ease of comparison with **1**.



2 **3** **4** **5**

The data for **2** and **1** agree remarkably well. For **3** the couplings to the carbonyl are unfortunately not available but the couplings shown are both large as in **1**. Comparison of **1** and **5** shows that although all couplings to C_2 are very different in the two molecules and for C_6 there is a large difference between the $^2J(C_6,H_5)$ the other couplings show rather close agreement and especially so for C_3. The couplings in **4**, however, show little similarity to those of **1** reflecting the structure differences between the furan and 2-pyrone rings.

Experimental

Compound **1** was prepared from coumalic acid and purified by vacuum distillation (12); 2.5 ml of **1** containing 10% hexadeuterioacetone for internal lock was used for ^{13}C spectra. The ^1H spectrum of this solution gave the chemical shifts (δ) $H_3 = 6.40$, $H_4 = 7.58$, $H_5 = 6.45$, $H_6 = 7.77$ and J(H,H), $J(3,4) = 9.45$, $J(3,5) = 1.15$, $J(3,6) = 1.20$, $J(4,5) = 6.32$, $J(4,6) = 2.24$, $J(5,6) = 5.20$. The 25.2 MHz ^{13}C spectra were recorded in the FT mode on a Varian XL-100-15 spectrometer equipped with gated gyrocode. DSPI spectra (7) were produced using Varian Program No. 994100-D modified by Dr P. L. Wessels. The computer size was 16 K.

Reversible Inhibition of Carboxypeptidase A. III.[1] Inhibition of Specific Esterase Activity by Substituted Benzoate and Related Anions

JOHN W. BUNTING AND CHESTER D. MYERS
Department of Chemistry, University of Toronto, Toronto, Ontario M5S 1A1
Received December 16, 1974

JOHN W. BUNTING and CHESTER D. MYERS. Can. J. Chem. **53**, 1984 (1975).

The reversible inhibition of the hydrolysis of *O*-hippuryl-L-3-phenyllactic acid by bovine carboxypeptidase A, has been studied for a series of *para*-substituted benzoate ions (p-$XC_6H_4CO_2^-$) at p*H* 7.5, 25°, ionic strength 0.2. For X = H, F, CN, NH_2, CH_3 competitive inhibition occurs, whereas non-competitive inhibition occurs for X = CF_3, NO_2, Cl, Br, $(CH_3)_2N$, CH_3O, $(CH_3)_2CH$, $(CH_3)_3C$. For X = C_2H_5 mixed inhibition is observed and this can be separated into individual competitive and noncompetitive components. Uncompetitive inhibition occurs with X = I. The distinction between competitive and noncompetitive inhibition appears to depend on the size of X rather than on its chemical properties. The p-tolylacetate and 3-(p-tolyl)propanoate ions display partially competitive inhibition consistent with the formation of $E.I_2$ species. The inhibition by the 3-(p-iodophenyl)propanoate ion is complex and depends on the binding of at least two inhibitor ions per enzyme molecule.

JOHN W. BUNTING et CHESTER D. MYERS. Can. J. Chem. **53**, 1984 (1975).

On a étudié à un p*H* de 7.5, une température de 25° et une force ionique de 0.2, l'inhibition réversible, par une série d'ions benzoates substitués en *para* (p-$XC_6H_4COO^-$), de l'hydrolyse de l'acide *O*-hippuryl L-phényl-3 lactique par la carboxypeptidase A du bœuf. Une inhibition compétitive se produit avec X = H, F, CN, NH_2 et CH_3; par ailleurs, il y a une inhibition non-compétitive lorsque X = CF_3, NO_2, Cl, Br, $(CH_3)_2N$, CH_3O, $(CH_3)_2CH$, $(CH_3)_3C$. Lorsque X = C_2H_5, on observe une inhibition mélangée qui peut être séparée en composantes individuelles compétitives et non-compétitives. Une inhibition non-compétitive se produit lorsque X = I. Il semble que la distinction entre inhibition compétitive et incompétitive dépend de la grosseur plutôt que des propriétés chimiques du groupe X. Les ions p-tolylacétate et (p-tolyl)-3 propanoate sont des inhibiteurs partiellement compétitifs formant des espèces $E.I_2$. L'inhibition par l'ion (p-iodophényl)-3 propanoate est complexe et dépend de l'association d'au moins deux ions inhibiteurs par molécule d'enzyme. [Traduit par le journal]

As a part of our continuing investigation (1, 2) of the influence of the structure of the inhibiting ion on the form and extent of the reversible inhibition of bovine carboxypeptidase A, we now wish to report a study of the effect of modifications in the benzoate anion on its reversible inhibition of the enzymic hydrolysis of the specific ester substrate, *O*-hippuryl-L-3-phenyllactic acid. Benzoate ion, itself, is a competitive inhibitor for this ester substrate (1) but we have found that the introduction of certain simple substituents into the aromatic ring in a position *para* to the carboxylate group can cause the form of inhibition to become noncompetitive. On the other hand, there are other *para*-substituted benzoate anions that are competitive inhibitors of this same ester substrate, although these are usually poorer inhibitors than the unsubstituted benzoate ion. This discrimination between competitive and noncompetitive modes of inhibition by different *para* substituents in the benzoate ion appears to be related mainly to the size of the *para* substituent rather than to its chemical nature.

We have also investigated the reversible inhibition of the enzymic hydrolysis of this ester by a few higher homologs of some of these *para*-substituted benzoate ions and in these cases have observed a variety of forms of reversible inhibition.

Experimental

All carboxylic acids except 3-(p-iodophenyl)propanoic acid were obtained commercially. This latter acid was prepared by the method of Plati *et al.* (3). All acids were recrystallized to constant melting point in agreement with literature values and their identities were checked by p.m.r. spectroscopy. Stock solutions of the carboxylate inhibitors were then prepared by titration of aqueous suspensions of the acids to p*H* 7.5 with aqueous potassium hydroxide.

O-Hippuryl-L-3-phenyllactic acid was purchased from Fox Chemical Co., Los Angeles, California. Stock solutions of bovine carboxypeptidase A (Worthington Biochemical Corporation (Code COA)) were prepared from a toluene-preserved suspension of the crystalline enzyme as previously described (1).

The enzymic hydrolysis of *O*-hippuryl-L-3-phenyllactic acid was followed on the p*H*-stat at p*H* 7.5, 25°, ionic strength 0.2 (adjusted with sodium chloride). All experimental techniques and data treatment were as previously described (1, 2). For the uninhibited reaction under these conditions $K_m = 7.2 \times 10^{-5}$ *M* and $k_{cat} = 2.50 \times 10^4$ min^{-1} (1). All substrate concentrations were $< 4 \times 10^{-4}$ *M*, so that substrate inhibition which intervenes at higher concentrations of this substrate could be neglected. In all cases linear Lineweaver–Burk plots were observed which is a clear indication that the Michaelis–Menten equation is a suitable description of the reaction under the present conditions.

Results

Lineweaver–Burk plots (E/v *vs.* $1/S$) for the hydrolysis of *O*-hippuryl-L-3-phenyllactic acid by carboxypeptidase A in the presence of the *para*-substituted benzoate anions **1**: X = F, NH_2, CH_3, CN are shown in Fig. 1 and indicate that these anions are competitive inhibitors for this substrate. Dixon plots (E/v *vs.* *I*) for these same anion inhibitors are linear (Fig. 2). Inhibition constants, K_i, calculated from Figs. 1 and 2, are in good agreement for each of these competitive inhibitors (Table 1).

On the other hand, for the benzoate anions **1**: X = NO_2, OCH_3, CF_3, $(CH_3)_2CH$,

1

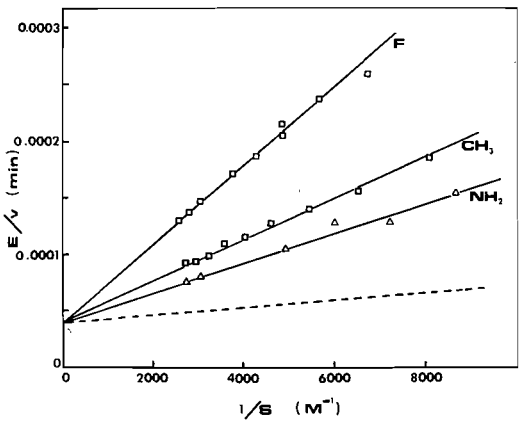

FIG. 1. Lineweaver–Burk plots for the inhibition of the hydrolysis of *O*-hippuryl-L-3-phenyllactic acid by carboxypeptidase A (p*H* 7.5, 25°, ionic strength 0.2) by *para*-substituted benzoate anions (**1**): X = F (62.6 m*M*); CH_3 (45.5 m*M*); NH_2 (143 m*M*). Data for X = CN (118 m*M*) (not shown) are almost exactly superimposable on data for X = F. Broken line indicates the uninhibited reaction.

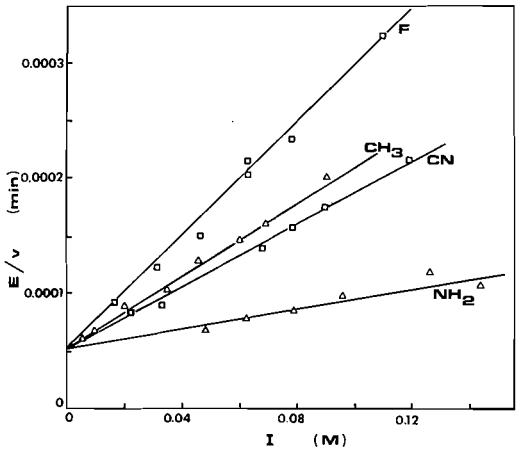

FIG. 2. Dixon plots for the inhibition of the hydrolysis of *O*-hippuryl-L-3-phenyllactic acid ($S = 0.20$ m*M*) by carboxypeptidase A (p*H* 7.5, 25°, ionic strength 0.2) by *para*-substituted benzoate anions (**1**).

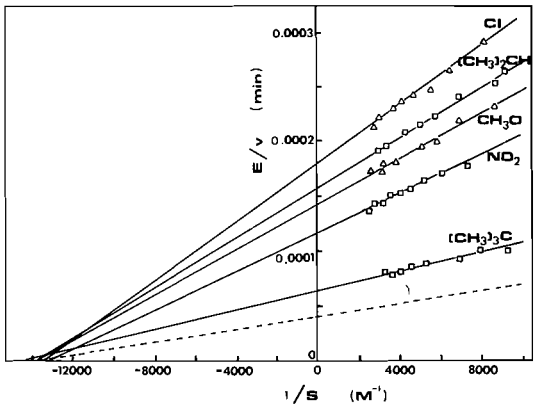

FIG. 3. Lineweaver–Burk plots for the inhibition of the hydrolysis of *O*-hippuryl-L-3-phenyllactic acid by carboxypeptidase A (p*H* 7.5, 25°, ionic strength 0.2) by *para*-substituted benzoate anions (**1**): X = Cl (52.1 m*M*); $(CH_3)_2CH$ (19.3 m*M*); CH_3O (126 m*M*); NO_2 (42.1 m*M*); $(CH_3)_3C$ (3.49 m*M*). Data not shown for other noncompetitive inhibitors: X = CF_3 (32.4 m*M*, $k_{cat}^{app} = 4.76 \times 10^3$ min^{-1}, $K_m^{app} = 6.76 \times 10^{-5}$ *M*); Br (39.9 m*M*, $k_{cat}^{app} = 4.90 \times 10^3$ min^{-1}, $K_m^{app} = 6.54 \times 10^{-5}$ *M*); $(CH_3)_2$ N (37.3 m*M*, $k_{cat}^{app} = 6.47 \times 10^3$ min^{-1}, $K_m^{app} = 7.70 \times 10^{-5}$ *M*). Broken line indicates the uninhibited reaction.

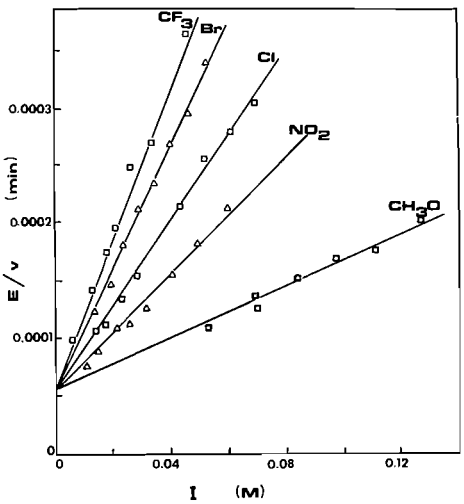

FIG. 4. Dixon plots for the inhibition of the hydrolysis of *O*-hippuryl-L-3-phenyllactic acid (*S* = 0.20 m*M*) by carboxypeptidase A (p*H* 7.5, 25°, ionic strength 0.2) by *para*-substituted benzoate anions (**1**). Linear plots were also observed for X = $(CH_3)_2N$, $(CH_3)_2CH$, $(CH_3)_3C$ (not shown).

$(CH_3)_3C$, $N(CH_3)_2$, Cl, Br, the Lineweaver–Burk plots are typical of noncompetitive inhibition (Fig. 3). Dixon plots for each of these latter anions are again linear (Fig. 4) and

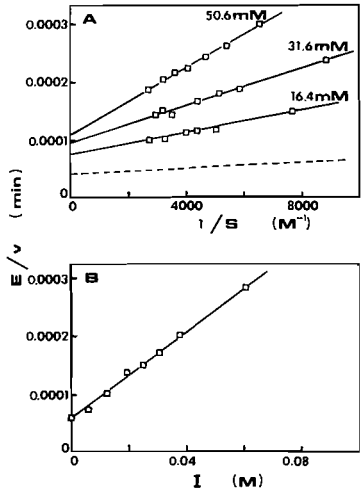

FIG. 5. Inhibition of the hydrolysis of *O*-hippuryl-L-3-phenyllactic acid by carboxypeptidase A (p*H* 7.5, 25°, ionic strength 0.2) by the *p*-ethylbenzoate anion: *A*, Lineweaver–Burk plots at indicated inhibitor concentrations; *B*, Dixon plot at *S* = 0.20 m*M*. Broken line indicates the uninhibited reaction.

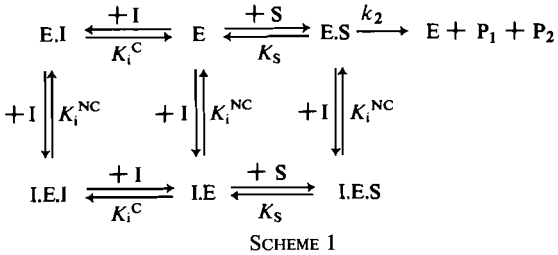
inhibition constants calculated from these latter plots, assuming noncompetitive inhibition, are in close agreement with the K_i values, calculated from the Lineweaver–Burk plots for these anions (Table 1).

Unlike the above purely competitive and noncompetitive inhibitor anions, the anion **1**: X = C_2H_5 displayed mixed inhibition kinetics (Fig. 5*A*) although the Dixon plot was linear in *I* (Fig. 5*B*). Since the lower (**1**: X = CH_3) and higher (**1**: X = $(CH_3)_2CH$) homologs of this ion are competitive and noncompetitive inhibitors respectively, it seemed reasonable to assume that for **1**: X = C_2H_5, the observed mixed inhibition probably arises from a mixture of competitive and noncompetitive inhibitory modes. Such a reaction scheme is indicated in Scheme 1. Analysis of this scheme, assuming all equilibria are attained rapidly relative to k_2,



SCHEME 1

gives the dependence of initial velocity on substrate and inhibitor concentrations (for S, $I \gg E$) in eq. 1.

$$[1] \qquad \frac{v}{E} = \frac{k_2/(1 + I/K_i^{NC})}{1 + \frac{K_s}{S}(1 + I/K_i^{C})}$$

At constant inhibitor concentration, this equation has the form of the Michaelis equation having

$$K_m^{app} = K_s(1 + I/K_i^{C})$$

and

$$k_{cat}^{app} = \frac{k_2}{1 + I/K_i^{NC}}$$

Thus K_i^{C} and K_i^{NC} may be individually calculated from a Lineweaver–Burk plot at constant inhibitor concentration.

Competitive (K_i^{C}) and noncompetitive (K_i^{NC}) inhibition constants calculated in this way for the *p*-ethylbenzoate ion, using the K_m^{app} and k_{cat}^{app} values defined by the data in Fig. 5*A* are collected in Table 2. These values of K_i^{C} and K_i^{NC} are apparently independent of inhibitor concentration and so suggest that Scheme 1 is probably a reasonable representation of the mixed inhibition which is observed for this inhibitor.

Attempts to study the inhibitor **1**: X = OH were frustrated by the buffering effect of the phenolic moiety of this inhibitor on the p*H*-stat studies at the relatively high concentrations of this inhibitor that were found necessary to produce significant amounts of inhibition. It is clear, however, that this species is a much poorer inhibitor than the unsubstituted benzoate anion and we have estimated that at $I = 80$ mM this inhibitor produces 50% inhibition for $S = 2.0 \times 10^{-4}$ M. In the light of the other substituent effects observed (see later discussion), it seems likely that this species would be a competitive inhibitor, and making this assumption, we have estimated $K_i = 21$ mM from the observed 50% inhibition at $I = 80$ mM.

The *p*-iodobenzoate ion (**1**: X = I) differs from all the other substituted benzoate ions examined in displaying neither competitive nor noncompetitive inhibition. Rather, Lineweaver–Burk plots at various concentrations of this inhibitor are parallel to the uninhibited line (Fig. 6*A*); the Dixon plot is linear in I (Fig. 6*B*).

Parallel Lineweaver–Burk plots are typical of what has variously been denoted as "uncompetitive" or "coupling" inhibition (4, 5). The simplest form of such inhibition arises when an inhibitor binds to E.S to form E.S.I but will not bind (or binds only very poorly with respect to S) to the free enzyme to form E.I (Scheme 2).

$$E + S \underset{}{\overset{K_s}{\rightleftarrows}} E.S \overset{k_2}{\rightarrow} E + P_1 + P_2$$

$$E.S + I \overset{K_{si}}{\rightleftarrows} E.S.I$$

SCHEME 2

Assuming that the equilibria are established rapidly relative to k_2, this scheme generates equation (2) for the dependence of initial velocity on substrate and inhibitor concentrations. This equation is of

$$[2] \qquad \frac{v}{E} = \frac{k_2/(1 + I/K_{si})}{1 + \frac{K_s}{S(1 + I/K_{si})}}$$

the classical Michaelis form at constant I, with $k_{cat}^{app} = k_2/(1 + I/K_{si})$ and $K_m^{app} = K_s/(1 + I/K_{si})$ and hence K_{si} may be calculated from either k_{cat}^{app} or K_m^{app}. Values for K_{si} calculated in this way from the data for the *p*-iodobenzoate ion are given in Table 3 and appear to be indepen-

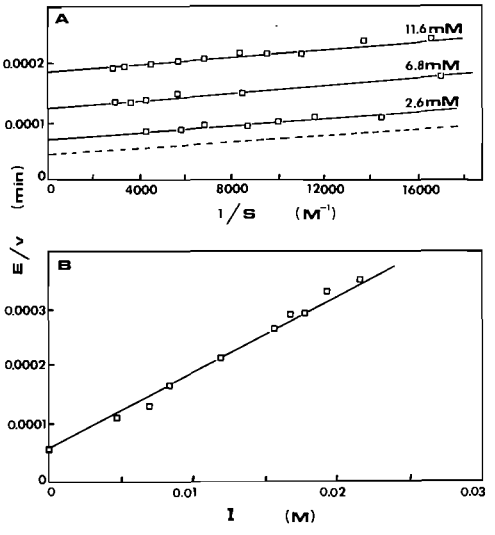

FIG. 6. Inhibition of the hydrolysis of *O*-hippuryl-L-3-phenyllactic acid by carboxypeptidase A (p*H* 7.5, 25°, ionic strength 0.2) by the *p*-iodobenzoate anion: *A*, Lineweaver–Burk plots at indicated inhibitor concentrations; *B*, Dixon plot at $S = 0.20$ mM. Broken line indicates the uninhibited reaction.

dent of inhibitor concentration. Thus, Scheme 2 seems to be a reasonable representation of the reversible inhibition by the *p*-iodobenzoate ion of the hydrolysis of *O*-hippuryl-L-3-phenyllactic acid by this enzyme.

In addition to the above substituted benzoate ions, we have also investigated inhibition of ester hydrolysis by a few higher homologs of **1**. Thus, *p*-fluorophenylacetate ion (**2**: X = F) is also a competitive inhibitor ($K_i = 1.5$ m*M* from

2

both Lineweaver–Burk and Dixon plots; *cf.* $K_i = 0.52$ m*M* for the phenylacetate ion (**2**: X = H) (1)). The *p*-tolylacetate (**2**: X = CH_3) and 3-(*p*-tolyl)propanoate (**3**: X = CH_3) ions

3

both appear to be competitive inhibitors in Lineweaver–Burk plots at several inhibitor concentrations (Fig. 7). However, in both these cases the calculated competitive K_i values are dependent on inhibitor concentration (Table 4) and, furthermore, the Dixon plots are nonlinear in *I*, although linear in I^2 (Fig. 8). We have previously observed similar partially competitive inhibition with other carboxylate inhibitors of the esterase activity of this enzyme (1, 2, 6) and have shown (2, 6) that such inhibition is consistent with Scheme 3. This scheme predicts that plots of $1/K_i^{app}$ *vs. I* should be linear, and such appears to be the case for **3**: X = CH_3 (Fig. 9) with values of the product $K_i' K_{ii}'$ calculated (6) from Figs. 8 and 9 independently for this inhibitor being in reasonable agreement (Table 4).

Inhibition by 3-(*p*-iodophenyl)propanoate (**3**: X = I) was of particular interest in view of the X-ray crystallographic investigations that have been made of the binding of this species to crystalline bovine carboxypeptidase A (7). Lineweaver–Burk plots for this inhibitor are displayed in Fig. 10*A* and it seems that such plots

become parallel at high inhibitor concentrations. Dixon plots for this inhibitor are linear in I^2 (Fig. 10*B*) and so indicate that the binding of two of these inhibitor ions per enzyme molecule occurs. As discussed above, parallel Lineweaver–Burk plots are typical of uncompetitive inhibition. In view of the observed dependence of E/v on I^2 in this case (Fig. 10*B*), it appears that uncompetitive inhibition with **3**: X = I must be superimposed on some simpler form of reversible inhibition by this same species;

Broken line indicates the uninhibited reaction.

e.g. the binding of a second inhibitor anion to E.S.I to form E.S.I_2 much more readily than the binding of I to E.I to give E.I_2. It should be noted, that there is X-ray crystallographic evidence for multisite binding of the 3-(*p*-iodophenyl)propanoate ion to this enzyme (7).

Discussion

It is clear from the data in Table 1 that the distinction between competitive and noncompetitive modes of inhibition by *para*-substituted benzoate anions is not related to the chemical nature of the *para* substituent X. Thus, for X = F competitive inhibition is observed, whereas, for X = Cl[2] or Br the inhibition is noncompetitive.

[2]A dramatic effect from a *p*-chloro substituent also is apparent in a comparison of the hydrolysis of *O*-hippuryl-L-mandelic acid and *O*-hippuryl-L-*p*-chloromandelic acid by this enzyme. Thus K_m for the latter ester substrate is estimated to be approximately 1000 times greater than for the former (8).

Similarly, X = NH_2 leads to competitive inhibition but X = $N(CH_3)_2$ displays noncompetitive inhibition and purely hydrocarbon X moieties may produce either competitive (X = CH_3, C_2H_5) or noncompetitive inhibition (X = C_2H_5, $(CH_3)_2CH$, $(CH_3)_3C$). In each of these comparisons it is clear that the larger X substituents are associated with noncompetitive inhibition and the smaller X substituents with competitive inhibition, and perusal of all substituents in Table 1 confirms that small substituents lead to competitive inhibition, whereas noncompetitive inhibition is observed for large X.

We have previously shown (1) that for a series of carboxylate anion (RCO_2^-) competitive inhibitors for the present substrate, log K_i is linearly related to Hansch's π-parameter for the hydrophobicity of R provided that R does not become too large. When R contains a phenyl ring, the benzoate (K_i = 6 m*M* (1)), phenylacetate (K_i = 0.52 m*M* (1)) and 3-phenylpropanoate (K_i = 0.17 m*M* (1)) ions are increasingly effective competitive inhibitors. One might therefore have predicted that since **1**: X = CH_3 and **1**: X = C_2H_5 have the same π values as phenylacetate and 3-phenylpropanoate, respectively, these two substituted benzoate ions would both be stronger inhibitors than the benzoate ion itself. In fact, **1**: X = CH_3 (K_i = 8.3 m*M*) is a slightly poorer inhibitor than benzoate (K_i = 6 m*M*) and **1**: X = C_2H_5 (K_i = 23 m*M*) is an even poorer inhibitor. So it is clear that in these two cases it is not hydrophobic character alone that determines the interaction of R with the enzyme. This effect is even more magnified for X = $(CH_3)_2CH$ and $(CH_3)_3C$ such that competitive modes of inhibition are no longer observed with these inhibitors. The most obvious explanation for these observations is that these alkyl groups are too large to penetrate to that region of the hydrophobic pocket where the *para* substituent of a *para*-substituted benzoate ion would be located. The fact that this effect is apparent even for X = CH_3 suggests that the interior of the hydrophobic pocket is restricted in such a way that it is able to accept an aromatic ring but not the methyl group of **1**: X = CH_3 without some unfavorable interactions with the wall of the pocket. In support of this idea it should be noted (1) that the largest straight-chain alkanoate

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

For personal use only.

ion competitive inhibitor that is acceptable in its energetically most favorable conformation is the pentanoate ion which is somewhat shorter than the 3-phenylpropanoate ion in its most extended conformation.

In light of the above suggestion that the size of the alkyl group is important in determining the binding of these *p*-substituted benzoate ions, it would be expected that other *para* substituents of the same size as, or larger than, a methyl group would also encounter accommodation problems in the hydrophobic pocket. This expectation seems to be borne out by the data in Table 1. The only substituent larger than methyl to display competitive inhibition is the ethyl group. While ethyl is larger than methyl, it is also more hydrophobic which would be expected to favor binding; even so, **1**: X = C_2H_5 is approximately a three-fold poorer inhibitor than **1**: X = CH_3.

It is quite unexpected of course, that those anions that are very poor competitive inhibitors according to the above concepts, should instead be reasonably good noncompetitive inhibitors. The observation of noncompetitive inhibition implies, of course, the existence of a second binding site for carboxylate anion inhibitors, which is quite distinct from the binding sites for the substrate and carboxylate anion competitive inhibitors. The analysis of the apparent mixed inhibition observed with the *p*-ethylbenzoate ion in terms of distinct competitive and noncompetitive inhibition modes is quite consistent with this idea.

For noncompetitive inhibition, as for competitive inhibition, there seems to be little dependence of K_i on the chemical nature of X (Table 1). The most strongly bound noncompetitive inhibitor is **1**: X = $(CH_3)_3C$ and the order $K_i(C_2H_5) > K_i((CH_3)_2CH) > K_i((CH_3)_3C)$ suggests a preference for a hydrophobic X substituent at the noncompetitive site. On the other hand, $K_i(NO_2) \approx K_i(C_2H_5)$ is not consistent with such a hypothesis. Of course, it is quite possible that there is more than one binding site which leads to noncompetitive inhibition by these benzoate anions. The observed specificity for X in noncompetitive inhibitors is probably best accommodated by postulating two noncompetitive binding sites, one of which shows a preference for hydrophobic X substituents and the other being relatively nonspecific and able to accept a variety of X substituents containing various electronegative atoms.

The details of the partially competitive inhibition that is observed for the *p*-tolylacetate and 3-(*p*-tolyl)propanoate ions are consistent with the formation of an $E.I_2$ species (Scheme 2) and are typical of the form of partially competitive inhibition that has been previously observed (1, 6) for a range of other carboxylate anions having large hydrophobic moieties. Thus, the heptanoate, octanoate, cyclohexanecarboxylate, cyclohexylacetate, 3-cyclohexylpropanoate, and 4-phenylpentanoate ions all display similar partially competitive inhibition characteristics (1, 6). This requirement for a large hydrophobic moiety for the formation of an $E.I_2$ species indicates the presence of a hydrophobic region in the enzyme that is capable of accepting such a unit.

The complicated mixed inhibition that is observed for 3-(*p*-iodophenyl)propanoate is similar to that previously observed for some carboxylate anions having very large hydrophobic moieties, *e.g.* nonanoate, 4-cyclohexylbutanoate and 6-phenylhexanoate ions (1). In each of these cases K_m^{app} seems to pass through a maximum value with increasing inhibitor concentration as in Fig. 10*A*. These data are indicative of complex mixed modes of reversible inhibition which we have not attempted to analyze further.

The examples of noncompetitive inhibition in Table 1 represent the first cases as far as we are aware of noncompetitive inhibition of the *esterase* activity of bovine carboxypeptidase A. The continuing elucidation of the reversible inhibition of this enzyme by carboxylate ions continues to provide evidence for a number of possible binding sites for carboxylate anions to this enzyme in such a way as to influence the catalytic activity of the enzyme towards ester hydrolysis. Unfortunately it is not possible at the present time to even speculate on the relationship of these various sites to one another and to the general active site region of the enzyme. The possibility that one or more of these inhibitor binding sites may be remote from the active site region and may influence catalytic activity via an important enzyme conformational change is also a distinct possibility. The totally unexpected distinction between

competitive and noncompetitive inhibitors as observed in Table 1, stresses the need for *systematic* studies of inhibitor and substrate structural effects in this and other enzymic reactions. In particular, the totally unexpected difference between the *p*-fluorobenzoate (competitive), p-chloro- and p-bromobenzoate (noncompetitive), and *p*-iodobenzoate (uncompetitive) ions as reversible inhibitors indicates that the utmost caution is required in extrapolating data for one inhibitor (or substrate) for this enzyme to even closely related species.

We appreciate the continued support of this work by the National Research Council of Canada and the award of a Walter C. Sumner Memorial Fellowship to C.D.M.

Reversible Inhibition of Carboxypeptidase A. IV.[1] Inhibition of Specific Esterase Activity by Hippuric Acid and Related Species and other Amino Acid Derivatives and a Comparison with Substrate Inhibition

JOHN W. BUNTING AND CHESTER D. MYERS

Department of Chemistry, University of Toronto, Toronto, Ontario M5S 1A1

Received December 16, 1974

JOHN W. BUNTING and CHESTER D. MYERS. Can. J. Chem. **53**, 1993 (1975).

The anions of each of the following carboxylic acids exhibit uncompetitive inhibition of the hydrolysis of *O*-hippuryl-L-3-phenyllactic acid by bovine carboxypeptidase A at p*H* 7.5, 25°, ionic strength 0.2: hippuric acid, *p*-chloro- and *p*-nitrohippuric acids, hippurylglycine, carbobenzoxyglycine, phenaceturic acid, *N*-(3-phenylpropanoyl)glycine, benzoxyacetic acid, 3-benzoylpropanoic acid, and *O*-hippuryl-D-mandelic acid. In each case, this uncompetitive inhibition is consistent with the ordered binding of substrate and inhibitor to the enzyme; *i.e.* the inhibitor binds to E.S but not to the free enzyme. Evidence is presented for the binding site for uncompetitive inhibitors being the same as for inhibitory ester substrate molecules. Comparison of the specificities of uncompetitive inhibitors and esters which display substrate inhibition provides evidence for a critical conformational change which controls the binding of uncompetitive inhibitors and inhibitory substrate molecules.

D-Phenylalanine, D-leucine, D-*p*-nitrophenylalanine, glycyl-L-tyrosine, glycyl-L-phenylalanine, and glycyl-L-leucine are competitive inhibitors of the enzymic hydrolysis of *O*-hippuryl-L-3-phenyllactic acid, whereas the *N*-chloroacetyl derivatives of L-tyrosine, L-phenylalanine, and L-leucine are noncompetitive inhibitors. For the above D-amino acids, glycyl dipeptides, and *N*-chloroacetyl amino acids, the phenylalanine derivative in each case is a considerably stronger inhibitor than the corresponding leucine derivative. This preference is similar to that observed for the binding of peptide substrates but the reverse of that observed for ester substrates and simple mono- and dicarboxylate ion inhibitors.

The peptide substrates carbobenzoxyglycylglycyl-L-phenylalanine and *N*-chloroacetyl-L-phenylalanine are noncompetitive inhibitors of the enzymic hydrolysis of *O*-hippuryl-L-3-phenyllactic acid. This clearly demonstrates the presence of different ester and peptide binding sites in this enzyme, which is consistent with conclusions from recent studies in other laboratories.

JOHN W. BUNTING et CHESTER D. MYERS. Can. J. Chem. **53**, 1993 (1975).

A un p*H* de 7.5, une température de 25° et une force ionique de 0.2, les anions de chacun des acides carboxyliques suivants agissent comme inhibiteurs incompétitifs pour l'hydrolyse de l'acide *O*-hippuryl L-phényl-3 lactique par la carboxypeptidase A du boeuf: l'acide hippurique, les acides *p*-chloro- et *p*-nitrohippuriques, la hippurylglycine, la carbobenzoxyglycine, l'acide phénacéturique, la *N*-(phényl-3 propanoyl) glycine, l'acide benzoxyacétique, l'acide benzoyl-3 propanoïque et l'acide *O*-hippuryl D-mandélique. Dans chaque cas, cette inhibition incompétitive est en accord avec une association ordonnée du substrat et de l'inhibiteur à l'enzyme; *i.e.* l'inhibiteur s'associe au E.S mais non à l'enzyme libre. On présente des résultats suggérant que le site d'association des inhibiteurs incompétitifs est le même que le site pour les molécules d'esters agissant comme substrats inhibiteurs. Une comparaison des spécificités des inhibiteurs incompétitifs et des esters agissant comme substrats inhibiteurs indique qu'il y a des changements conformationnels critiques qui controlent l'association des inhibiteurs incompétitifs et des molécules de substrats inhibiteurs.

La D-phénylalanine, la D-leucine, la D-*p*-nitrophénylalanine, la glycyl L-tyrosine, la glycyl L-phénylalanine et la glycyl L-leucine sont des inhibiteurs compétitifs de l'hydrolyse enzymatique de l'acide *O*-hippuryl L-phényl-3 lactique; toutefois les dérivés *N*-chloroacétylés de la L-tyrosine, de la L-phénylalanine et de la L-leucine sont des inhibiteurs non-compétitifs. Dans le cas des acides aminés de la série D, des dipeptides contenant de la glycine et des acides aminés *N*-chloroacétylés, on remarque dans chaque cas que le dérivé de la phénylalanine est un inhibiteur beaucoup plus fort que le dérivé correspondant de la leucine. Cette préférence est semblable à celle observée pour l'association de substrats peptidiques; cet ordre est toutefois l'inverse de celui observé pour des substrats de type ester de même que pour les inhibiteurs ioniques dérivés d'acides mono- et dicarboxyliques simples.

[1]For Part III see ref. 3.

Les substrats peptidiques carbobenzoxyglycylglycyl L-phénylalanine et *N*-chloroacétyl L-phénylalanine sont des inhibiteurs non-compétitifs de l'hydrolyse enzymatique de l'acide *O*-hippuryl L-phényl-3 lactique. Ceci démontre sans ambiguité la présence, dans l'enzyme, dessites d'association différents pour les esters et les peptides; cette conclusion est en accord avec d'autres dérivées d'études récentes émanant d'autres laboratoires.

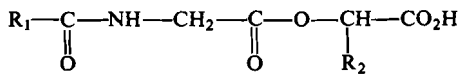
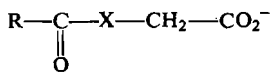
Recent studies (1–3) in our laboratory of the reversible inhibition of the hydrolysis of *O*-hippuryl-L-3-phenyllactic acid by bovine carboxypeptidase A have revealed a variety of competitive, partially competitive, and noncompetitive modes of inhibition by carboxylate anions. The form of inhibition appears to be very dependent on the size and structure of the hydrophobic unit of the inhibiting anion. In a parallel investigation (4, 5), we have also been exploring the phenomenon of substrate inhibition which is displayed by some ester substrates in their hydrolysis by this enzyme and have deduced some structural features that are common to those ester substrates which exhibit this phenomenon.

Substrate inhibition of the esterase activity of this enzyme is consistent with the binding of a second substrate molecule to the catalytically productive E.S complex to give an $E.S_2$ species which is considerably less reactive ($E.S_2$ is 25-fold less reactive than E.S for hippuric acid esters) (5). Our studies on the dependence of substrate inhibition on the structure of ester substrates of general formula **1** indicate that: (*i*) the dissociation



1

constant K_{ss} for $E.S_2 \rightleftarrows E.S + S$ is independent of R_2 for hydrocarbon R_2 units at least as large as isobutyl and benzyl (5); (*ii*) R_1 should be phenyl or other hydrophobic group of similar size for most effective substrate inhibition (4); and (*iii*) the integrity of the amide CONH group is essential for the formation of $E.S_2$: replacement of NH in **1** by NCH_3, O, or CH_2 results in the complete disappearance of substrate inhibition effects (4). In general, the formation and hydrolysis of E.S are much less sensitive to these same structural modifications in **1**. The fact that K_{ss} is independent of both the R_2 substituent and also of the configuration of the α-carbon atom of the terminal α-hydroxy acid unit of **1** (5) suggests that the formation of $E.S_2$ involves the interaction of only the acid unit ($R_1CONHCH_2CO_2H$) of the substrate with the enzyme at the binding site responsible for substrate inhibition. To explore this conclusion further we have now investigated the reversible inhibition of the enzymic hydrolysis of *O*-hippuryl-L-3-phenyllactic acid by a series of carboxylate anions **2** related to the acid units



2

of the esters which we have previously surveyed for substrate inhibition. The majority of these species proved to be uncompetitive inhibitors of the hydrolysis of this ester, thus establishing that they bind at a site that does not overlap with the productive binding site for this ester substrate. Furthermore, the structural dependence of the binding of the inhibitors **2** proved to be quite different to the influence of similar structural variations in the esters **1** on the formation of an $E.S_2$ species. This leads to a modified interpretation of the dependence of substrate inhibition on the structure of the acid unit of the ester substrate.

We also report in this paper some studies of the reversible inhibition of the enzymic hydrolysis of *O*-hippuryl-L-3-phenyllactic acid by some derivatives of phenylalanine and leucine in an attempt to further explore the previously noted discrimination by the enzyme between aliphatic and aromatic hydrophobic groups in the binding of ester substrates and simple mono- and dicarboxylate anion inhibitors but not in the binding of peptide substrates (5).

Experimental

All *N*-acyl glycines and related species and *O*-hippuryl-D-mandelic acid were available from previous studies (4–6) and were recrystallized to constant melting point. Derivatives of phenylalanine, tyrosine, and leucine were purchased from Sigma Chemical Co., St. Louis, Missouri. The preparation of D-*p*-nitrophenylalanine followed the method of Houghten and Rapoport (7). The identities of all inhibitors were checked by p.m.r. spectroscopy. Stock solutions of the carboxylate inhibitors were prepared by titration of aqueous suspensions of the carboxylic acids to p*H* 7.5 with aqueous potassium

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

hydroxide. The stock solution of *O*-hippuryl-D-mandelic acid was prepared by the acetone solution procedure previously described for related substrates (4).

O-Hippuryl-L-3-phenyllactic acid was purchased from Fox Chemical Co., Los Angeles, California. Stock solutions of bovine carboxypeptidase A (Worthington Biochemical Corporation (Code COA)) were prepared from a toluene-preserved suspension of the crystalline enzyme as previously described (1).

The enzymic hydrolysis of *O*-hippuryl-L-3-phenyllactic acid was followed on the p*H*-stat at p*H* 7.5, 25°, ionic strength 0.2 (adjusted with sodium chloride). All experimental techniques and data treatment were as previously described (1, 2). For the uninhibited reaction under these conditions $K_m = 7.2 \times 10^{-5}$ *M* and $k_{cat} = 2.50 \times 10^4$ min^{-1} (1). All substrate concentrations were $< 4 \times 10^{-4}$ *M*, so that substrate inhibition which intervenes at higher concentrations of this substrate could be neglected. In all cases linear Lineweaver–Burk plots were observed which is a clear indication that the Michaelis–Menten equation is a suitable description of the reaction under the present conditions.

Results

Reciprocal plots (E/v *vs.* $1/S$) for the dependence of the initial velocity (v/E) on substrate concentration (S) for the hydrolysis of *O*-hippuryl-L-3-phenyllactic acid by carboxypeptidase A in the presence of various concentrations of hippuric acid anion (**2**: R = C_6H_5; X = NH) are given in Fig. 1. These data at each constant inhibitor concentration appear to describe parallel lines which are also approximately parallel to the Lineweaver–Burk plot in the absence of inhibitor. Such parallel plots are typical of a form of inhibition that has been variously referred to as "uncompetitive" or "coupling" inhibition (8, 9). The simplest reaction scheme that gives rise to this form of inhibition involves the ordered binding of substrate and inhibitor molecules as indicated in Scheme 1. Assuming that the equilibria are established rapidly relative to k_2, Scheme 1 generates eq. 1

$$\begin{array}{c} \overset{K_s}{\rightleftarrows} \quad \overset{k_2}{\rightarrow} \\ E + S \rightleftarrows E.S \rightarrow E + P_1 + P_2 \\ \\ \overset{K_i}{\rightleftarrows} \\ E.S + I \rightleftarrows E.S.I \end{array}$$

SCHEME 1

$$[1] \qquad \frac{v}{E} = \frac{k_2/(1 + I/K_i)}{1 + K_s/S(1 + I/K_i)}$$

for the dependence of initial velocity on substrate and inhibitor concentrations. Such an equation has the form of the Michaelis equation with $K_m^{app} = K_s/(1 + I/K_i)$ and $k_{cat}^{app} = k_2/(1 + I/K_i)$ and thus $k_{cat}^{app}/K_m^{app} = k_2/K_s$ independent of I. The value of K_i may be calculated from either k_{cat}^{app} or K_m^{app} at each inhibitor concentration. Since k_{cat}^{app} is determined much more accurately than K_m^{app}, we have used k_{cat}^{app} to calculate K_i from the data in Fig. 1 at each inhibitor concentration. Values for K_i are collected in Table 1 and lie in the range 10 ± 3 m*M*.

Rearrangement of eq. 1 gives eq. 2 which indicates that at constant substrate concentra-

$$[2] \qquad \frac{E}{v} = \frac{1 + K_s/S}{k_2} + \frac{I}{k_2 K_i}$$

tion plots of E/v *vs.* I (Dixon plots) should be linear and of slope $1/k_2K_i$. Such a plot for inhibition by hippurate anion is shown at $S = 0.20$ m*M* in Fig. 2 and the value of K_i calculated from the slope of this line is 8.1 m*M* which lies in the range of values obtained from the data in Fig. 1.

Lineweaver–Burk plots which were approximately parallel to the data for the uninhibited reaction were also observed (*e.g.* Fig. 3) for a number of other anions related to the hippurate anion. For each of these inhibitors, K_i values were calculated from both the Lineweaver–Burk plots and Dixon plots assuming uncompetitive inhibition as in Scheme 1. Values of K_i calculated in this way are included in Table 1. In general, there is reasonable agreement between the K_i values for any given inhibitor as evaluated from both Lineweaver–Burk and Dixon plots and this suggests that the assumption of Scheme 1 for each of these inhibitors is quite reasonable.

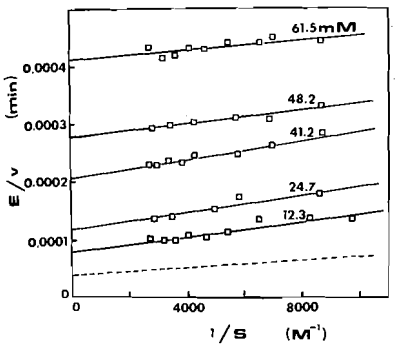


FIG. 1. Lineweaver–Burk plots for the inhibition of the hydrolysis of *O*-hippuryl-L-3-phenyllactic acid by carboxypeptidase A (p*H* 7.5, 25°, ionic strength 0.2) by the hippurate anion at indicated inhibitor concentrations. Broken line indicates the uninhibited reaction.

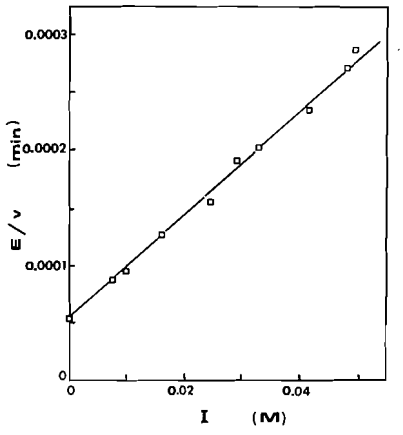

FIG. 2. Dixon plot for the inhibition of the hydrolysis of O-hippuryl-L-3-phenyllactic acid ($S = 0.20$ mM) by carboxypeptidase A (pH 7.5, 25°, ionic strength 0.2) by the hippurate anion.

For several of the inhibitors in Table 1 deviations from parallel Lineweaver–Burk plots are observed at high inhibitor concentrations; *e.g.* phenaceturate ion (**2**: R = $C_6H_5CH_2$; X = NH) in Fig. 4. The Dixon plots for these inhibitors show deviations from linearity at similar inhibitor concentrations and suggest that the binding of a second inhibitor ion per enzyme molecule is becoming important at these inhibitor concentrations. This effect appears to be particularly pronounced with hexahydrohippuric acid (**2**: R = cyclo-C_6H_{11}; X = NH) for which E/v is linear in I^2 rather than I up to greater than 80% inhibition (Fig. 5). We have, therefore, been unable to evaluate this latter species as an uncompetitive inhibitor.

The N-methylhippurate anion also displays a linear dependence of E/v on I^2 at constant substrate concentration (Fig. 5). Unlike the related inhibitors in Table 1, the Lineweaver–Burk plots in this case seem to indicate noncompetitive inhibition (Fig. 6). However, calculation of an inhibition constant from the data in Fig. 6 assuming noncompetitive inhibition gives a K_i value which appears to decrease with increasing inhibitor concentration (Table 2). A similar phenomenon of K_i decreasing with increasing inhibitor concentration has also been observed for a number of carboxylate anions which are

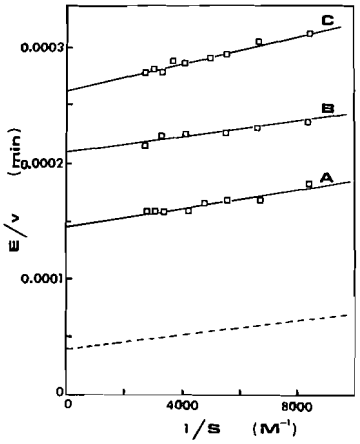

FIG. 3. Lineweaver–Burk plots for the inhibition of the hydrolysis of *O*-hippuryl-L-3-phenyllactic acid by carboxypeptidase A (p*H* 7.5, 25°, ionic strength 0.2): *A* and *C*, 3-benzoylpropanoate ion at 6.64 and 15.5 m*M*, respectively; *B*, *O*-hippuryl-D-mandelic acid at 18.8 m*M*. Broken line indicates the uninhibited reaction.

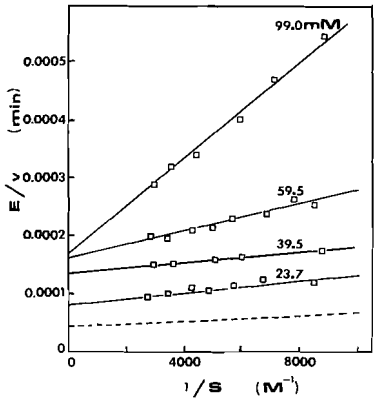

FIG. 4. Lineweaver–Burk plots for the inhibition of the hydrolysis of *O*-hippuryl-L-3-phenyllactic acid by carboxypeptidase A (p*H* 7.5, 25°, ionic strength 0.2) by the phenaceturate anion (**2**: R = $C_6H_5CH_2$; X = NH) at the indicated inhibitor concentrations. Broken line indicates the uninhibited reaction.

nominally competitive inhibitors but which also show a linear dependence of E/v on I^2 (2, 3, 10). This partially competitive inhibition has been shown to be consistent with the formation of both E.I and E.I_2 species. By analogy, the inhibition observed for the *N*-methylhippurate anion should presumably be referred to as partially noncompetitive inhibition and can be most simply described by Scheme 2. It should be noted that Scheme 2 is not the same as the most commonly postulated form of partially

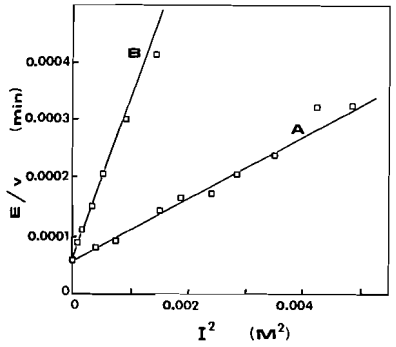

FIG. 5. Dependence of E/v on I^2 for the inhibition of the hydrolysis of *O*-hippuryl-L-3-phenyllactic acid (S = 0.20 m*M*) by carboxypeptidase A (p*H* 7.5, 25°, ionic strength 0.2): *A*, *N*-methylhippurate ion (**2**: R = C_6H_5; X = NCH_3); *B*, hexahydrohippurate ion (**2**: R = cyclo-C_6H_{11}; X = NH).

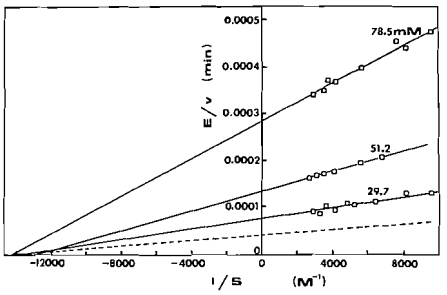

FIG. 6. Lineweaver–Burk plots for the inhibition of the hydrolysis of *O*-hippuryl-L-3-phenyllactic acid by carboxypeptidase A (p*H* 7.5, 25°, ionic strength 0.2) by the *N*-methylhippurate ion at the indicated inhibitor concentrations. Broken line indicates the uninhibited reaction.

noncompetitive inhibition (11). The presence of E.I_2 and E.I_2.S species in the present case is demanded by the dependence of E/v on I^2 rather than on I.

Amide hydrolysis results in no significant net uptake or release of protons at p*H* 7.5. While this fact makes it impossible to study amide hydrolysis on the p*H*-stat at p*H* 7.5, it may be taken advantage of to study the reversible inhibition of ester hydrolysis by amide substrates. Thus, we have investigated the inhibition of the enzymic hydrolysis of *O*-hippuryl-L-3-phenyllactic acid by carbobenzoxyglycylglycyl-L-phenylalanine which is a much studied peptide substrate of carboxypeptidase A (12–15). Reciprocal plots for the dependence of initial velocity on substrate concentration at two concentrations of cbz-gly-gly-L-phe are displayed

TABLE 2. Noncompetitive inhibition of the esterase activity of carboxypeptidase A [a]

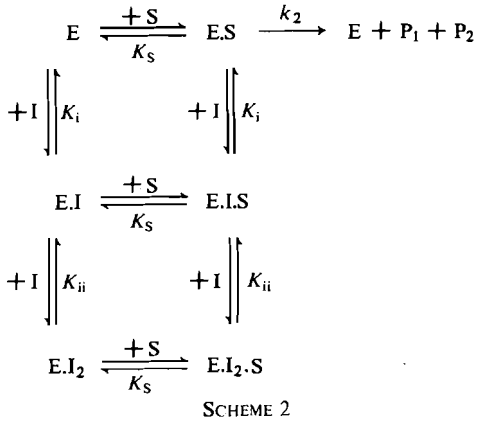

SCHEME 2

in Fig. 7*A*. Although this figure appears to indicate mixed inhibition, it is clear that the predominant contribution is from noncompetitive inhibition. Calculation of K_i values from k_{cat}^{app} at each inhibitor concentration assuming noncompetitive inhibition gives values which agree with one another (Table 2) and also with the K_i value calculated from the Dixon plot (Fig. 7*B*) for this inhibitor assuming noncompetitive inhibition.

In addition to cbz-gly-gly-L-phe, we have also studied the inhibition of ester hydrolyses by some small amide substrates for this enzyme. Thus the *N*-chloroacetyl derivatives of each of L-phenylalanine, L-tyrosine, and L-leucine proved to be noncompetitive inhibitors of specific ester hydrolysis (Fig. 8); the Dixon plots for each of these inhibitors are linear in I and there is close agreement between the K_i values calculated by both methods (Table 2). On the other hand, glycyl-L-tyrosine and glycyl-L-phenylalanine are competitive inhibitors for the same ester substrate (Fig. 9). The K_i values calculated from Fig. 9 and from linear Dixon plots for those inhibitors are in agreement (Table 3). The study of inhibition by glycyl-L-leucine was complicated by buffering effects from the free amino group of this inhibitor at the relatively high inhibitor concentrations found necessary to produce reasonable amounts of inhibition. The K_i value in Table 3 for glycyl-L-leucine is therefore estimated, assuming competitive inhibition,

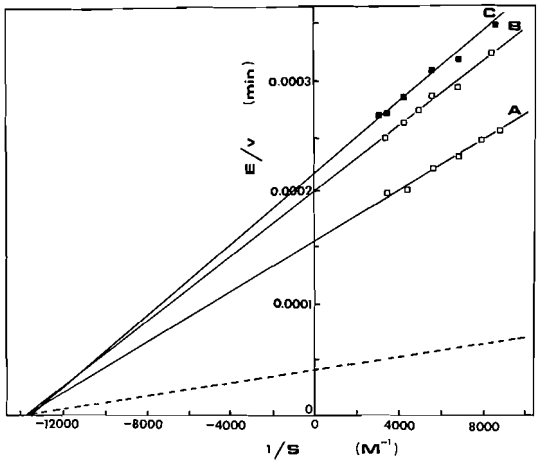

FIG. 8. Lineweaver–Burk plots for the inhibition of the hydrolysis of O-hippuryl-L-3-phenyllactic acid by carboxypeptidase A (pH 7.5, 25°, ionic strength 0.2): A, N-chloroacetyl-L-phenylalanine (1.47 mM); B, N-chloroacetyl-L-tyrosine (1.90 mM); C, N-chloroacetyl-L-leucine (10.5 mM). Broken line indicates the uninhibited reaction.

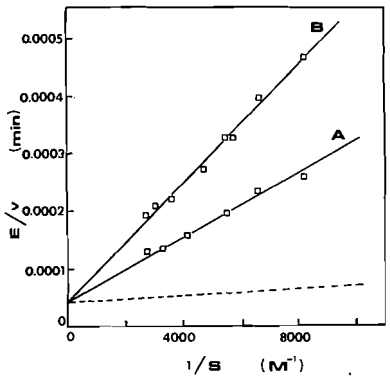

FIG. 9. Lineweaver–Burk plots for the inhibition of the hydrolysis of O-hippuryl-L-3-phenyllactic acid by carboxypeptidase A (pH 7.5, 25°, ionic strength 0.2): A, glycyl-L-phenylalanine (1.78 mM); B, glycyl-L-tyrosine (1.72 mM). Broken line indicates the uninhibited reaction.

from the observation that approximately 50% inhibition is produced by 13 mM solutions of this dipeptide at $S = 0.20$ mM.

In the light of observations (16–18) that the D-amino acids are much stronger inhibitors of the peptidase activity of this enzyme at pH 7.5 than their L-analogs, we have also examined the inhibition of the hydrolysis of O-hippuryl-L-3-phenyllactic acid by some of these species. The D-isomers of each of phenylalanine, leucine, and p-nitrophenylalanine proved to be competitive inhibitors for the hydrolysis of this ester (Fig. 10); K_i values are collected in Table 3. The corresponding L-isomers of these three amino acids proved to be at least three to five times poorer competitive inhibitors in each case.

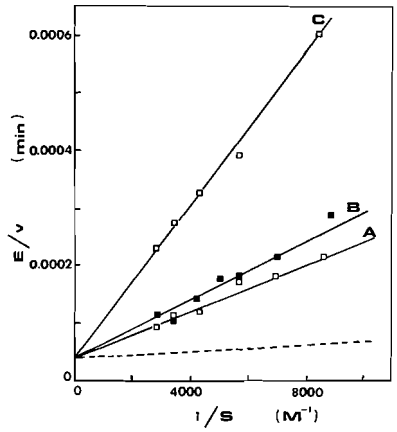

FIG. 10. Lineweaver–Burk plots for the inhibition of the hydrolysis of O-hippuryl-L-3-phenyllactic acid by carboxypeptidase A (pH 7.5, 25°, ionic strength 0.2): A, D-leucine (18.1 mM); B, D-p-nitrophenylalanine (5.40 mM); C, D-phenylalanine (2.94 mM). Broken line indicates the uninhibited reaction.

Finally, aceturic acid (**2**: R = CH_3; X = NH) also proved to be a weak competitive inhibitor (Table 3).

Discussion

The uncompetitive inhibition of the hydrolysis of *O*-hippuryl-L-3-phenyllactic acid that is observed for the inhibitors in Table 1 seems to be consistent with the ordered binding of substrate and inhibitor molecules to the enzyme which is outlined in Scheme 1. The close agreement between K_i values calculated independently from Lineweaver–Burk plots and Dixon plots for each of these inhibitors (Table 1) indicates that Scheme 1 is a reasonable expression of the inhibition observed in these cases.

We have previously shown that substrate inhibition of the hydrolysis of hippuric acid esters by carboxypeptidase A is the result of the formation of a relatively unreactive $E.S_2$ species and moreover, that the binding of substrate molecules at the catalytically productive and inhibitory sites in $E.S_2$ is either truly ordered or else closely approximates ordered binding (5). Furthermore, substrate binding at the inhibitory site depends only on the acyl unit of the ester and is independent of the alcohol moiety of these substrates (4, 5). In this light, uncompetitive inhibition by hippurate anion of the enzymic hydrolysis of *O*-hippuryl-L-3-phenyllactic acid involving ordered binding of substrate and inhibitor molecules exactly parallels the ordered binding of two substrate molecules at the catalytically productive and inhibitory sites, and strongly suggests that the hippurate anion is binding at the same site as the inhibitory substrate molecule. As further confirmation of this conclusion, it should be noted that *O*-hippuryl-D-mandelic acid, which is known (5) to be able to replace its L-isomer at the inhibitory substrate site, is an uncompetitive inhibitor of *O*-hippuryl-L-3-phenyllactic acid in the present study (Table 1). The value of K_i = 4.4 m*M* (ionic strength 0.2) found for *O*-hippuryl-D-mandelic acid in the present study is in reasonable agreement with the dissociation constant of 2.6 m*M* (ionic strength 0.5) previously found (5) for dissociation of this ester from the inhibitory site of the $E.S_2$ complex.

In recent work in our laboratory (6), it has been shown that *p*-chloro- and *p*-nitrohippuric acid esters also display marked substrate inhibition of their hydrolyses by carboxypeptidase A. Analyses of the kinetic data for these esters indicate that the presence of the chlorine substituent slightly promotes binding at the inhibitory substrate site, whereas the *p*-nitro group diminishes binding at this site approximately threefold. Phenaceturate esters are also known (4) to be bound less strongly at the inhibitory site than are hippurate esters. Comparison of the K_i values in Table 1 for *p*-chlorohippurate ion, *p*-nitrohippurate ion, and phenaceturate ion with that for hippurate ion are in qualitative agreement with the above observations of substrate affinity for the inhibitory site, and this fact further supports identical binding sites for these uncompetitive inhibitors and inhibitory substrate molecules.

In view of this satisfying relationship between uncompetitive inhibition and substrate inhibition, it comes as a surprise to find that, whereas esters of 3-benzoylpropanoic acid, benzoxyacetic acid, and hippurylglycine do not display substrate inhibition, the anions of these three acids do nevertheless act as uncompetitive inhibitors of the enzymic hydrolysis of *O*-hippuryl-L-3-phenyllactic acid (see Table 4). At first sight, this observation may seem to contradict the above postulated identical binding sites for uncompetitive inhibitors and inhibitory substrate molecules. However, it should be remembered that both uncompetitive inhibition and substrate inhibition appear to involve ordered binding, and that in each case the inhibitory effects arise from either inhibitor or substrate binding to the E.S complex. Now, 3-benzoylpropanoic acid anion is able to bind to the E.S complex when the substrate is *O*-hippuryl-L-3-phenyllactic acid (Table 1) but an ester of this same acid cannot bind to the E.S complex when the substrate is 2-(3-benzoylpropanoxy)butanoic acid (4). One might therefore conclude that the enzymic site that accepts the 3-benzoylpropanoyl unit is available in the E.S complex of the former substrate but not in the E.S complex of the latter substrate; *i.e.* the E.S complexes that these two substrates form with carboxypeptidase A are not equivalent. Since substrate inhibition is equally apparent in both *O*-hippuryl-L-3-phenyllactic acid and 2-hippuroxybutanoic acid (5), this nonequivalence cannot be related to the presence of different alcohol units in the above two substrates. Furthermore, hippuric acid and 3-benzoylpropanoic acid are isosteric so that *if* these two

substrates bind to the enzyme at the same site, the lack of substrate inhibition for the 3-benzoylpropanoate ester cannot be due to the substrate inhibitory site being physically blocked in the E.S complex by the presence of the substrate molecule that is bound at the catalytically productive site.

We must then conclude that one of the following situations exists: (*i*) in the E.S complexes of the two substrates presently under consideration, the substrate molecules are bound at either partially or wholly different sites and in the case of the 3-benzoylpropanoate ester the first-bound substrate molecule blocks the binding of a second substrate molecule; or (*ii*) the two substrate molecules are bound in either identical or different sites to the enzyme, but one of the E.S complexes can undergo an important conformational change which is not available to the other. This latter condition actually encompasses two separate possibilities; (*iia*) the binding of hippurate esters may cause a conformational change which makes the inhibitory site accessible to a second substrate molecule, or alternatively, (*iib*) the binding of the 3-benzoylpropanoate ester may produce a conformational change which makes the inhibitory site inaccessible. The conformational mobility of carboxypeptidase A in its interaction with substrates and inhibitors is well established on the basis of X-ray crystallographic, chemical modification, spectroscopic, and temperature-jump studies (19–24).

The observation of ordered binding by both uncompetitive inhibitors and inhibitory substrate molecules to the E.S complex for hippurate ester substrates would seem to be most readily accommodated by case *iia*. In both cases *i* and *iib*, if both binding sites preexist in the enzyme molecule, it is difficult to understand why binding should be ordered rather than random, when the enzyme is confronted with both an inhibitor ion and a hippurate ester substrate molecule. The requirement for a conformational change in the E.S complex of a hippurate ester substrate (case *iia*), which makes the binding site accessible to the uncompetitive inhibitor or inhibitory substrate molecule (or which creates such a binding site), is the situation that is most satisfactorily reconciled with the experimental observations of ordered binding.

It should be noted that K_m for the hippurate ester is a factor of 10 smaller than K_m for any of the other esters in Table 4 (4). There is evidence for other carboxypeptidase substrates (both esters and peptides) (25, 26) that K_m is a true measure of the dissociation constant (K_s) of the E.S complex provided that nonproductive binding modes are absent. Thus, the especially small K_m for the hippuric acid esters appears to reflect the importance of the NH unit of these esters in their interaction with the enzyme. Replacement of this NH by either NCH_3 or O drastically increases K_m by a factor of at least 200 and strongly suggests a role for the NH unit as a hydrogen bond donor in the interaction of hippuric acid esters with this enzyme. Since this same structural feature also appears to be essential to the display of substrate inhibition (4),

we tentatively suggest that the formation of this hydrogen bond is also related to the enzymic conformational change which is envisioned in *iia* above.
